A form of chain reaction is the autoxidation of sulphites[189-193], which can conveniently be investigated by a polarographic method, since the reaction is studied by measuring the concentration of oxygen in the solution. The Reviewer has been the first to use polarography to investigate this reaction. Coumarins exert a considerable inhibiting effect[194] (Fig. 10), which consists in significant retardation of the rate of autoxidation by interaction of the added coumarin molecules with radicals appearing during the reaction. The inhibiting effect becomes stronger with increase in the molecular mass of the coumarin, in the degree of branching of the molecule, and in the number of phenolic groups.

The mechanism of this reaction, involving ion–radical processes, models redox processes occurring in the living organism. Therefore the useful pharmacological action of many medicinal and biologically active compounds, including coumarin derivatives, is accompanied by a harmful inhibiting effect on redox processes in healthy cells of the organism. In the case of pathological processes (cancer) the inhibiting effect may be of positive value: indeed several coumarins are used for the treatment of malignant diseases[195]. Detailed investigation of the mechanism of the inhibiting effect of coumarins (based on mathematical equations and models) will help to reveal the biological functions of coumarins in plant and animal organisms at a higher level, and thereby establish a more exact model of the dependence of pharmacological action on chemical structure.

The formation of hydrogen peroxide during the autoxidation of sulphites has also been shown by a polarographic method—from the increase in height of the second oxygen wave—which has permitted a more thorough investigation of the mechanism of this reaction. On this basis it is possible to study the mechanism of the aging of coumarins, and also to develop methods for their accelerated aging, enabling the useful life of coumarin preparations to be predicted.

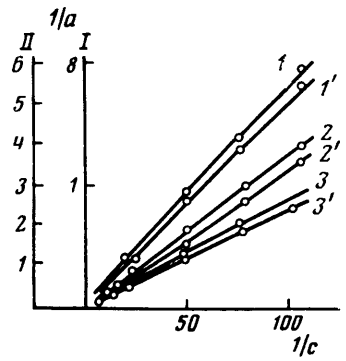

**Figure 11.** Adsorption isotherms for xanthotoxin on silica gel with: I) column chromatography; II) thin-layer chromatography (primed numerals) and different mobile phases: 1) chloroform; 2) acetone; 3) methanol.

## 4. Adsorption Phenomena

The investigation of adsorption phenomena at the mercury–solution interface is one of the most important fields in the electrochemistry and the physical chemistry of surface phenomena, permitting a more profound and detailed interpretation of polarographic investigations. The occurrence of adsorption phenomena in solutions of coumarins has been established[17,32] from the character of the electrocapillary curves and the Gibbs adsorption isotherms[118,119] plotted from data obtained by means of a dropping mercury electrode. Coumarin is desorbed on the negative branch of the electrocapillary curve. Adsorption phenomena supplement certain information on electrochemical reactivity, and also model exchange processes at biological membranes. In combination with column chromatography, furthermore, the polarographic method enables adsorption isotherms (Fig. 11) to be obtained for coumarins[196,197].

A new method of plotting the adsorption isotherms of organic compounds[53], based on thin-layer chromatography, involves measurement of the difference between the distances advanced by the solvent front and by the substance $\Delta lf$.

## 5. Solubility of Coumarins

The great sensitivity of the polarographic method and the possibility of electrochemical reduction in the most diverse media enable it to be widely used to determine the solubility of coumarins by polarographing saturated solutions after dilution with the appropriate solvent.

**Table 8.** Solubility of coumarin in various solvents at 20°C ($c$ is the content of the substance in grams per 100 ml solution).

| Solvent | $c$ | Solvent | $c$ |
|---|---|---|---|
| Methanol | 15.10 | Butanol | 6.35 |
| Ethanol | 8.30 | Pentanol | 4.10 |
| Propan-1-ol | 5.80 | Dioxan | 39.40 |
| Propan-2-ol | 7.20 | Acetone | 44.40 |

At the same time the solubility was determined refractometrically[41,198]. Table 7 shows that the solubility increases with the number of carbon atoms in the alcohol molecule.

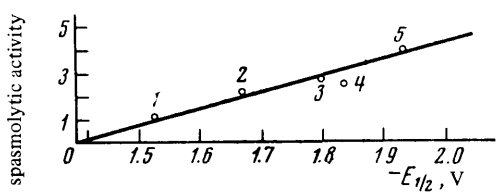

**Figure 12.** Dependence of spasmolytic action of coumarins (according to results obtained in the Pharmacology Laboratory of the Kharkov Chemical and Pharmaceutical Scientific Research Institute) on the half-wave potential: 1) coumarin; 2) umbelliferone; 3) 4-methylumbelliferone; 5) aesculin; 6) aesculetin.

## 6. Half-wave Potential and Biological Activity

The biological activity of organic molecules can be assessed from a combination of pharmacological, biochemical, and physicochemical investigations. Considerable progress can be made in this field by the application of polarography according to the following scheme: (i) comparative estimation, based on the half-wave potentials,

of oxidation and reduction, ionisation potentials, and electron affinities, parametrising the principal physicochemical and biological properties of organic molecules; (ii) comparative assessment of the quantum-chemical parameters and the degrees of homolysation of organic molecules by comparing the polarographic half-wave potentials with quantities—energy of longer-wavelength absorption band, refraction, dipole moments—obtained by other physicochemical methods; (iii) experimental determination of inhibiting effect on chemical models and enzyme systems from the duration of inhibition found from the fall in wave height; (iv) determination of metabolic products; (v) comparative study of chemical and electrochemical stability of pharmacologically important units in the molecules; and (vi) determination of resorptive adsorption capacity.

We have compared the half-wave potentials with the spasmolytic activities of naturally occurring coumarins (Fig. 12) from Khadzhai's results[199]. The greater the electron density of the 2-pyrone ring in the coumarin system the greater the spasmolytic activity (e.g. the activity of simple coumarins is far lower than that of furocoumarins, which applies also to the half-wave potentials).

A polarographic method has been used also to study the photo-oxidation of furocoumarins[200] in the living organism from the consumption of oxygen.

# Thermochemistry of Organic Compounds of Transition Metals

V.I.Tel'noi and I.B.Rabinovich

Experimental enthalpies of formation of carbonyl, cyclopentadienyl, arene, and alkoxyl compounds of transition metals are discussed with methods for their determination. Mean dissociation energies calculated therefrom for the bonds formed by the metals in these compounds vary regularly with the nature of the ligand and the position of the metal in the Periodic System. All the thermochemical quantities cited have been recalculated on the basis of current values of the initial data. A list of 112 references is included.

## I. INTRODUCTION

Organic compounds of transition metals have acquired applied importance e.g. in the industrial production of several pure metals from their carbonyls, the manufacture of metal oxide films from alkoxy-compounds of the metals, as catalysts and antiknock additives, and for other purposes. On the other hand, the great interest taken in these compounds by research workers is due to their structural features and their reactions, as well as the specific nature of the $\pi$ bond formed by transition metals with organic ligands.

Although the systematic study of the properties of organic compounds of transition metals began comparatively recently—after the discovery of ferrocene in 1951—very many experimental and theoretical investigations have now been made on the molecular structure of and the nature of the chemical bonds in these compounds, on developing methods for the preparation of novel classes of such compounds, and on elucidating the mechanism of their reactions. Far less work has been done on the thermodynamic parameters of these compounds. Nevertheless, significant information is already available even on these aspects, but it has been published in diverse scientific periodicals, and has not been summarised. Yet such data are necessary for technical calculations of processes involving these compounds, and are important also for the theory of the chemical bond and of heterogeneous catalysis. In particular, the calculation of reaction enthalpies requires knowledge of the enthalpies of formation of the reactants. The same data are necessary in order to compute the energies of dissociation of chemical bonds. For these reasons the present Review will survey published information on the enthalpies of formation of organic transition-metal compounds.

The enthalpy of formation $\Delta H_f^\circ$ of an organic compound Org (from the elements in phase states that are stable under the given conditions) is usually calculated from its enthalpy of combustion $\Delta H_c^\circ$:

$$\Delta H_f^0(\text{Org}) = \sum \nu_i \Delta H_f^0(i) - \Delta H_c^\circ(\text{Org}),$$

where $\Delta H_f^\circ(i)$ is the enthalpy of formation of the $i$th combustion product (from tables), and $\nu_i$ is its stoichiometric coefficient in the equation for the combustion of the organic compound. The enthalpy of formation of the test compound can similarly be calculated from the measured enthalpy of any other reaction involving it and known values of $\Delta H_f^\circ$ for all the other reactants.

Many published enthalpies of formation of organic transition-metal compounds have been calculated from their experimental enthalpies of combustion. Several difficulties of technique are usually encountered during the determination of the latter in a bomb calorimeter—(*a*) complicated purification of test compounds, (*b*) their rapid oxidisability (sometimes spontaneous combustion) in air, (*c*) the explosive character of combustion in the bomb, (*d*) possibility of formation of products of incomplete combustion, (*e*) possibility of reactions between combustion products, and (*f*) complexity of analysis of combustion products—which complicate the extraction of reliable results.

With easily oxidisable crystalline organometallic compounds serious difficulties arise in preventing premature oxidation before ignition. The use of glass or polymer ampoules, which are widely employed in the study of liquids, is rarely successful because of the dispersal of crystals inside the bomb by the extremely rapid combustion. Sometimes, therefore, the weighed portion of the compressed or powdered test substance is placed in molten paraffin wax, the latter is allowed to solidify, and the two are burned together. Not only does this protect the test substance from oxidation in the preliminary stage of the experiment but it also promotes more complete combustion. A disadvantage of this method is the fairly large correction needed for the enthalpy of combustion of the paraffin wax.

Good et al.[1] determined the enthalpy of formation of decacarbonyl dimanganese by combustion in a rotating bomb. This method entailed dissolution of the combustion products in the bomb in order to establish a definite final state of the reaction system. The necessity of selecting an appropriate solvent in each specific case, the appearance of new sources of errors, and the laborious character of the series of operations prevent widespread adoption of this method.

Both thermal decomposition (into metal and carbon monoxide) and high-temperature iodination have been recommended[2] for the calorimetric investigation of carbonyls.

In the subsequent discussion of published results the method of determination will be indicated and attention will be paid to the surmounting of experimental difficulties. The observed heats of combustion from which heats of formation have been calculated are given and discussed. Values in the Review for the mean energy of dissociation $\overline{D}$ of metal–ligand bonds in compounds $ML_n$ have been calculated as one-$n$th of the enthalpy of atomisation $\Delta H_{at}^\circ$ of the compound in the gaseous state, which is given by the equation

$$\Delta H_{at}^0(ML_n,(g)) = \Delta H_f^0(M,(g)) + n\Delta H_f^0(L,(g)) - \Delta H_f^0(ML_n,(g)).$$

Methods for calculating values of $\overline{D}$ in compounds RML are described in connection with specific compounds.

In the present Review values of enthalpies of combustion or of other reactions $\Delta H_r^\circ$ are accompanied by the accuracy indicated in the original papers. Values of enthalpies of formation and of mean bond dissociation energies have been recalculated by the Reviewers on the basis of current values for the enthalpies of formation of atoms and substances. Calculation of dissociation energies of metal–ligand bonds in cyclopentadienyl compounds is complicated by the absence of a reliably established value for the enthalpy of formation of the cyclopentadienyl radical: thus this function has been given as 45.4 ± 10,[3] ~50,[4,5] 63,[6] 53 ± 12,[7] and 47 ± 4 [8] kcal mole$^{-1}$; the Reviewers have adopted the arbitrary value $\Delta H_f^\circ(C_5H_5,g)$ = 50 kcal mole$^{-1}$. Values of the enthalpies of formation of other substances used by Reviewers in thermochemical calculations are listed in Table 1. Values in the Review are expressed in thermochemical calories (1 cal = 4.184 J) and relate to a standard pressure (always denoted by a ° sign) and the standard temperature of 298.15 K. The letters in parentheses accompanying chemical formulae (c, l, g, and s) denote respectively the crystalline, liquid, and gaseous states and a solution.

Table 1. Enthalpies of formation used in the calculations.

*Here and subsequently: g = gaseous state; l = liquid state; c = crystalline state; and s = solution.

## II. CARBONYL COMPOUNDS

### 1. Tetracarbonylnickel

Among determinations of the enthalpy of combustion of tetracarbonylnickel[21-23] the most soundly based[23] paid special attention to analysis of the products, including carbon and nickel monoxides. The solid products contained together with the latter a considerable quantity (9–21%) of metallic nickel. After correction for the incomplete oxidation of nickel, the enthalpy obtained for the process

$$Ni(CO)_4(l) + 2.5O_2(g) \rightarrow NiO(c) + 4CO_2(g)$$

was $\Delta H_c^\circ = -282.2 \pm 0.5$ kcal mole$^{-1}$, whence $\Delta H_f^\circ[Ni.(CO)_4, l] = -151.3 \pm 0.5$ kcal mole$^{-1}$.

The enthalpy of formation has been calculated also from equilibrium data on formation of the tetracarbonyl from metallic nickel and gaseous carbon monoxide[24-26], and these results have been critically examined[23,27,28]. The value $-149 \pm 2$ kcal mole$^{-1}$ was suggested[28] for the enthalpy of formation of tetracarbonylnickel in the liquid state. From the above results[23-28] Skinner[29] recommended the value $\Delta H_f^\circ[Ni(CO)_4, l] = -150.4 \pm 1.5$ kcal mole$^{-1}$. Together with the enthalpy of vaporisation $\Delta H_v^\circ[Ni(CO)_4] = 6.6 \pm 0.3$ kcal mole$^{-1}$ this gives $\Delta H_f^\circ[Ni.(CO)_4, g] = -143.8 \pm 1.5$ kcal mole$^{-1}$ and $\bar{D}(Ni-CO) = 35.2 \pm 0.4$ kcal mole$^{-1}$. Many carbonyls are partly associated in the gas phase[30]. In view of the comparative instability of these aggregates, however, disregard of association does not significantly distort the results calculated for $\bar{D}(M-CO)$.

The mean dissociation energy of the nickel–carbonyl bond has been determined also by electron bombardment[31,32]. The difference between the appearance potential of the $Ni^+$ ion in the process $Ni(CO)_4 + e \rightarrow Ni^+ + 4CO + 2e$ and the first ionisation potential of nickel gave values of $\bar{D}$ of $39.3 \pm 1.0$ and $43 \pm 1$ kcal mole$^{-1}$ respectively[31,32]. These overestimates in relation to the calorimetric results were attributed[31,32] to the presence of excess energy in the mass-spectrometric breakdown products of the initial compound.

### 2. Pentacarbonyliron

Early results for the enthalpy of combustion[33,34] cannot be accepted because of the absence of a detailed description of the experiments[33,34]. In later work[35] each enthalpy measurement was followed by careful analysis of the gaseous combustion products for carbon dioxide and of the solid products for the presence of metallic iron and the oxides FeO, $Fe_2O_3$, and $Fe_3O_4$. Most of the iron (72 to 96%) had been oxidised to the sesquioxide. After correction for incomplete oxidation of carbon and iron the enthalpy of the reaction

$$Fe(CO)_5(l) + 3.25O_2(g) \rightarrow 0.5Fe_2O_3(c) + 5CO_2(g)$$

became $\Delta H_c^\circ = -385.9 \pm 1.7$ kcal mole$^{-1}$, which correspond to $\Delta H_f^\circ[Fe(CO)_5, l] = -182.6 \pm 1.8$ kcal mole$^{-1}$. Using the published value[36] $\Delta H_v^\circ = 9.6 \pm 0.3$ kcal mole$^{-1}$, we obtain $\Delta H_f^\circ[Fe(CO)_5, g] = -173.0 \pm 1.8$ kcal mole$^{-1}$ and $\bar{D}(Fe-CO) = 28.1 \pm 0.4$ kcal mole$^{-1}$. Electron bombardment gives[31] for this dissociation energy the value 33 kcal mole$^{-1}$. It is interesting that considerably less energy is required for detachment of the first carbonyl group from the pentacarbonyl: thus mass spectrometry yields[37] $D[Fe(CO)_4-CO] \simeq 16$ kcal mole$^{-1}$.

### 3. Nonacarbonyldi-iron and Dodecacarbonyltri-iron

Skinner et al.[38] have studied the thermal decomposition of the nonacarbonyl at 553–573 K and its ionisation at 524–573 K. The results indicate that the enthalpy of the process $Fe_2(CO)_9(c) \rightarrow 2Fe(c) + 9CO(g)$ occurring at the standard temperature is $99 \pm 3$ kcal mole$^{-1}$, which corresponds to $\Delta H_f^\circ[Fe_2(CO)_9, c] = -337 \pm 3$ kcal mole$^{-1}$. Thermal decomposition and iodination of the dodecacarbonyl have been studied[38] over the range 494–544 K. Conversion of the results to 298.15 K gave for $Fe_3(CO)_{12}.(c) \rightarrow 3Fe(c) + 12CO(g)$ the value $\Delta H_r^\circ = 125 \pm 4$ kcal mole$^{-1}$, corresponding to $\Delta H_f^\circ[Fe_3(CO)_{12}, c] = -442 \pm 4$ kcal mole$^{-1}$.

The enthalpies of sublimation were estimated[38] as $18 \pm 5$ and $23 \pm 5$ kcal mole$^{-1}$ for the nonacarbonyl and dodecacarbonyl respectively. From these results we obtain for $\Delta H_f^\circ(g)$ the corresponding values $-319 \pm 6$ and $-419 \pm 7$ kcal mole$^{-1}$.

### 4. Decacarbonyldimanganese and Decacarbonyldirhenium

Good et al.[1] determined the enthalpy of formation of the manganese carbonyl by combustion in a rotating bomb, the products being dissolved in aqueous nitric acid and hydrogen peroxide. For the reaction

$$Mn_2(CO)_{10}(c) + 4HNO_3(16H_2O, s) + 6O_2(g) \rightarrow 2Mn(NO_3)_2(10.3H_2O, s) + 10CO_2(g) + 2H_2O(l)$$

they obtained $\Delta H_c^\circ = -777.0 \pm 0.8$ kcal mole$^{-1}$, and hence $\Delta H_f^\circ[Mn_2(CO)_{10}, c] = -400.5 \pm 1.0$ kcal mole$^{-1}$. Recent measurements[2] of the enthalpy of iodination in a Calvet microcalorimeter have given for the process

$$Mn_2(CO)_{10}(c) + 2I_2(g) \rightarrow 2MnI_2(c) + 10CO(g)$$

the value $\Delta H_r^\circ = -12.6 \pm 1.5$ kcal mole$^{-1}$, which corresponds to $\Delta H_f^\circ[Mn_2(CO)_{10}, c] = -408.6 \pm 1.5$ kcal mole$^{-1}$.

Determination of the enthalpy of combustion of the rhenium carbonyl in a stationary calorimetric bomb has given[39] for the reaction

$$Re_2(CO)_{10}(c) + H_2O(l) + 8.5O_2(g) \rightarrow 2HReO_4(20H_2O, s) + 10CO_2(g)$$

the value $\Delta H_c^\circ = -857.9 \pm 0.6$ kcal mole$^{-1}$, whence $\Delta H_f^\circ[Re_2(CO)_{10}, c] = -396.3 \pm 2.1$ kcal mole$^{-1}$. Other workers[38] have measured the enthalpies of thermal decomposition and of high-temperature iodination of the same compound. For the process $Re_2(CO)_{10}(c) \rightarrow 2Re(c) + 10CO(g)$ under standard conditions they find that $\Delta H_r^\circ = 131 \pm 5$ kcal mole$^{-1}$, which yields $-395 \pm 5$ kcal mole$^{-1}$ for the heat of formation.

Table 2. Thermochemical parameters (in kcal mole$^{-1}$) of dimanganese and dirhenium decacarbonyls.

| Carbonyl | $\Delta H_f^0$ (c) | $\Delta H_s^0$ | $\Delta H_f^0$ (g) | $\bar{D}$ (M–CO) |
|---|---|---|---|---|
| $Mn_2(CO)_{10}$ | $-404.6 \pm 2.0$ | $19.2 \pm 0.5$ | $-385.4 \pm 2.0$ | $23.6 \pm 0.4$ |
| $Re_2(CO)_{10}$ | $-395.6 \pm 2.0$ | $22.3 \pm 0.1$ | $-373.3 \pm 2.0$ | $43.5 \pm 0.5$ |

Thus the use of different methods to determine enthalpy of formation has given mutually consistent results for both manganese and rhenium carbonyls. We have therefore used their average values in the thermochemical calculations (Table 2). The enthalpies of sublimation $\Delta H^{\circ}_{s}$ have been discussed in detail[40]. Mass-spectrometric data have been used to calculate mean bond dissociation energies: $D[(CO)_5Mn-Mn(CO)_5] = 21 \pm 3$ [41] and $D[(CO)_5Re-Re(CO)_5] = 44.7$ [42] kcal mole$^{-1}$. It is noteworthy that $\bar{D}(Re-CO)$ is almost double $\bar{D}(Mn-CO)$.

## 5. Manganese and Rhenium Pentacarbonyls

Skinner et al.[40] have measured the enthalpies of the high-temperature iodination of several methylated and halogenated manganese and rhenium pentacarbonyls, which gives the calculated enthalpies of formation in Table 3. The enthalpies of sublimation of methylmanganese and methylrhenium pentacarbonyls have been calculated from the experimental[43,44] temperature dependence of their vapour pressure.

Table 3. Thermochemical parameters (kcal mole$^{-1}$) of manganese and rhenium pentacarbonyls.

| Carbonyl | $-\Delta H^{0}_{f}$(c) | $\Delta H^{0}_{s}$ | $-\Delta H^{0}_{f}$(g) | $\bar{D}$ (M—$CH_3$) |
|---|---|---|---|---|
| $CH_3Mn(CO)_5$ | 189.8±2.2 | 15.0±0.5 | 174.8±2.3 | 26.7±3.2 |
| $ClMn(CO)_5$ | 241.2±3 | — | — | — |
| $BrMn(CO)_5$ | 231.8±2 | — | — | — |
| $CH_3Re(CO)_5$ | 198.8±2.2 | 16.0±0.5 | 182.8±2.3 | 53.1±3.8 |

Values of $\bar{D}(M-CH_3)$ have been calculated by means of the formula

$$\bar{D}(M-CH_3) = \Delta H^{0}_{f}(M,g) + \Delta H^{0}_{f}(CH_3,g) + 5\Delta H^{0}_{f}(CO,g) - \Delta H^{0}_{f}[CH_3M(CO)_5,g] - 5\bar{D}(M-CO)$$

on the assumption that $\bar{D}(M-CO)$ is the same in these compounds and in the corresponding decacarbonyls $M_2(CO)_{10}$. Table 3 shows that $\bar{D}(Re-CH_3)$ is twice $\bar{D}(Mn-CH_3)$: i.e. the same ratio is found between the metal–methyl bond dissociation energies as for the metal–carbonyl bonds in the rhenium and manganese decacarbonyls.

## 6. Tricarbonylcyclopentadienylmanganese

Determination of the enthalpy of combustion

$$C_5H_5Mn(CO)_3(c) + 8.7O_2(g) \rightarrow MnO_2(c) + 8CO_2(g) + 2.5H_2O(l)$$

as $\Delta H^{\circ}_{c} = -918 \pm 2$ kcal mole$^{-1}$ was recognised[45] to involve the possible formation of products of incomplete oxidation. Other workers[46] checked the completeness of combustion by determining manganese and carbon dioxides in the products; they found complete oxidation to manganese dioxide and obtained the value $-922 \pm 2$ kcal mole$^{-1}$. We recommend the mean of these results[45,46]: $\Delta H^{\circ}_{c} = -920 \pm 2$ kcal mole$^{-1}$, from which we calculate[30] $\Delta H^{\circ}_{f}[Mn(CO)_3.C_5H_5,c] = -127.8 \pm 2$ kcal mole$^{-1}$. Using $\Delta H^{\circ}_{s} = 12.5 \pm 0.8$ kcal mole$^{-1}$, we have $\Delta H^{\circ}_{f}[Mn(CO)_3C_5H_5,g] = -115.3 \pm 2.1$ kcal mole$^{-1}$.

## 7. Chromium, Molybdenum, and Tungsten Hexacarbonyls

The results of the first investigation[47] of the thermochemical properties of the three hexacarbonyls, involving measurement of their enthalpies of combustion in a stationary calorimetric bomb, were discussed in detail by workers[48] who redetermined these enthalpies. Analysis of the solid products revealed[48] that the oxides were accompanied by a certain quantity of unoxidised metal, which entailed appropriate corrections to the enthalpies of formation. The above results[47,48] have recently been carefully checked by Skinner et al.[49–51], using not only combustion in a stationary bomb but also their calorimetric methods of thermal decomposition and high-temperature iodination.

Table 4. Enthalpies of formation (kcal mole$^{-1}$) of chromium, molybdenum, and tungsten hexacarbonyls.

| Carbonyl | $-\Delta H^{0}_{f}$(c) | Method of determination | Ref. |
|---|---|---|---|
| $Cr(CO)_6$ | 249.3±0.5 | combustion, $\Delta H^{0}_{c} = -451.3 \pm 0.5$ | 47 |
| | 257.5±0.5 | combustion, $\Delta H^{0}_{c} = -443.1 \pm 0.5$ | 48 |
| | 234.3±1.8 | iodination, $\Delta H^{0}_{r} = 23.4 \pm 1.0$ | 2 |
| | 234.7±0.6 | combustion, $\Delta H^{0}_{c} = -465.9 \pm 0.5$ | 52 |
| | 238.9±4.5 | combustion, $\Delta H^{0}_{c} = -461.8 \pm 4.0$ | 51 |
| | 233.8±0.5 | decomposition, $\Delta H^{0}_{r} = 75.3 \pm 0.2$ | 51 |
| $Mo(CO)_6$ | 235.8±0.5 | combustion, $\Delta H^{0}_{c} = -506.7 \pm 0.5$ | 47 |
| | 235.0±0.3 | combustion, $\Delta H^{0}_{c} = -507.5 \pm 0.3$ | 48 |
| | 229.5±1.0 | decomposition, $\Delta H^{0}_{r} = 71.0 \pm 1.0$ | 2 |
| | 236.8±1.0 | combustion, $\Delta H^{0}_{c} = -505.7 \pm 0.9$ | 49 |
| | 236.4±0.4 | decomposition, $\Delta H^{0}_{r} = 77.9 \pm 0.4$ | 49 |
| $W(CO)_6$ | 226.0±0.5 | combustion, $\Delta H^{0}_{c} = -539.7 \pm 0.5$ | 47 |
| | 227.9±0.3 | combustion, $\Delta H^{0}_{c} = -537.8 \pm 0.3$ | 48 |
| | 229.7±1.2 | combustion, $\Delta H^{0}_{c} = -536.0 \pm 1.0$ | 50 |
| | 229.3±0.5 | decomposition, $\Delta H^{0}_{r} = 70.8 \pm 0.4$ | 50 |

All published experimental values of the enthalpies of formation of chromium, molybdenum, and tungsten hexacarbonyls are listed in Table 4. The enthalpies of combustion in the third column are based on the reactions

$$Cr(CO_6)(c) + 3.75O_2(g) \rightarrow 0.5Cr_2O_3(c) + 6CO_2(g)$$
$$M(CO)_6(c) + 4.5O_2(g) \rightarrow MO_3(c) + 6CO_2(g)$$
M – Mo or W.

The enthalpy of iodination of chromium hexacarbonyl relates to the process

$$Cr(CO)_6(c) + I_2(g) \rightarrow CrI_2(c) + 6CO(g).$$

The enthalpies of thermal decomposition correspond to the reactions

$$M(CO)_6(c) \rightarrow M(c) + 6CO(g)$$
M – Cr, Mo or W.

Table 4 shows good mutual agreement among values obtained for the enthalpy of formation of chromium hexacarbonyl on the basis of its iodination[2], combustion[52], and decomposition[51]. Hence we have used the average value

for our thermochemical calculations. The earlier results[47,48] for chromium hexacarbonyl must be regarded as incorrect. The most accurate values for the enthalpies of formation of molybdenum and tungsten hexacarbonyls are those of Skinner et al.[49,50], since for each substance they obtained results in good agreement by two different methods.

Table 5 gives recommended[53] enthalpies of sublimation. Values of $\bar{D}$(M–CO) in the last column have been calculated by the Reviewers from selected values of $\Delta H_f^\circ$.[M(CO)$_6$, g]. As for Group VII transition metals (Table 2), this bond dissociation energy increases considerably with the atomic number of the metal.

Table 5. Recommended thermochemical parameters (kcal mole$^{-1}$) of chromium, molybdenum, and tungsten hexacarbonyls.

| Carbonyl | $-\Delta H_f^0$ (c) | $\Delta H_s^0$ | $-\Delta H_f^0$ (g) | $\bar{D}$ (M–CO) |
|---|---|---|---|---|
| $Cr(CO)_6$ | 234.3±0.4 | 17.1±0.1 | 217.2±0.4 | 25.6±0.1 |
| $Mo(CO)_6$ | 236.6±0.2 | 17.6±0.2 | 219.0±0.3 | 36.2±0.1 |
| $W(CO)_6$ | 229.5±0.7 | 18.3±0.3 | 211.2±0.8 | 42.9±0.2 |

Table 6. Thermochemical parameters (kcal mole$^{-1}$) of arenechromium tricarbonyls.

| Carbonyl | $-\Delta H_f^0$ (c) | $\Delta H_s^0$ | $-\Delta H_f^0$ (g) | $\Delta H_r^{0*}$ |
|---|---|---|---|---|
| $(C_6H_6)Cr(CO)_3$ | 106±2 | 21.8±1 | 84.2±2.2 | 120±3 |
| $(C_6H_5CH_3)Cr(CO)_3$ | 114±2 | 22.6±1 | 91.4±2.2 | 119±3 |
| $[1,3,5\text{-}C_6H_3(CH_3)_3]Cr(CO)_3$ | 136.5±2 | 25.9±1 | 110.6±2.2 | 122,5±3 |
| $[C_6(CH_3)_6]Cr(CO)_3$ | 166.5±3 | 29.5±1 | 137.0±3.2 | 132±4 |
| $(C_6H_5Cl)Cr(CO)_3$ | 111±5 | 24.5±1 | 86.5±5.1 | 115±5 |
| (cyclo-$C_7H_8$)$Cr(CO)_3$ | 74±3 | 22.5±1 | 51.5±3.2 | 111±4 |

*The enthalpies of decomposition of the compounds into chromium and the ligands.

## 8. Arenechromium Tricarbonyls

Skinner et al.[54,55] have used high-temperature calorimetry to study the thermal decomposition and the iodination of several compounds of type $Cr(CO)_3$Arene. Standard enthalpies of formation calculated from the results are given in Table 6 together with the measured[55] enthalpies of sublimation.

The last column in Table 6 indicates the enthalpies of decomposition

$$(\text{Arene})Cr(CO)_3(g) \rightarrow Cr(g) + \text{Arene}(g) + 3CO(g).$$

It was assumed[55] that the energy of dissociation of the chromium–carbonyl bond is the same in all these chromium compounds, 25.6 kcal mole$^{-1}$ as in chromium hexacarbonyl. To this approximation they found that the ligands formed the sequence

$$\text{cyclo-}C_7H_8 \simeq C_6H_5Cl < C_6H_6 \simeq C_6H_5CH_3 \simeq \simeq C_6H_3(CH_3)_3 < C(CH_3)_6$$

according to the mean energy of dissociation of the bonds formed with chromium. However, the hypothesis that $\bar{D}$(Cr–CO) has the same value in these carbonyl derivatives requires experimental confirmation.

## 9. Mesitylenemolybdenum Tricarbonyl

The Reviewers have measured the enthalpy of combustion by the method of Ref. 46. Determinations of molybdenum trioxide and carbon dioxide established the absence of products of incomplete combustion. They found for the reaction

$$[C_6H_3(CH_3)_3]Mo(CO)_3(c) + 15O_2(g) \rightarrow MoO_3(c) + 12CO_2(g) + 6H_2O(l)$$

the value $\Delta H_c^\circ = -1598 \pm 1$ kcal mole$^{-1}$, which corresponds to $\Delta H_f^\circ[Mo(CO)_3C_6H_3(CH_3)_3, c] = -119 \pm 1$ kcal mole$^{-1}$.

## 10. Carbonyl Compounds of Cobalt

Calorimetric determinations[56,57] have yielded for the enthalpies $\Delta H_r^\circ$ of the reactions

$$Co_2(CO)_8(c) + 2Br_2(n\text{-}CCl_4, s) \rightarrow 2CoBr_2(c) + 8CO(g);$$
$$Co_3(CCl)(CO)_9(c) + 4.5Cl_2(n\text{-}CCl_4, s) \rightarrow 3CoCl_2(c) + 9CO(g) + CCl_4(l);$$
$$Co_3(CBr)(CO)_9(c) + 4.5Br_2(n\text{-}CCl_4, s) \rightarrow 3CoBr_2(c) + 9CO(g) + CBr_4(n\text{-}CCl_4, s).$$

the respective values $-19.5 \pm 0.5$, $-107.5 \pm 1.6$, and $-191.4 \pm 1.0$ kcal mole$^{-1}$. Skinner et al.[38], using thermal decomposition and high-temperature iodination, found that the enthalpies of the processes

$$Co_2(CO)_8(c) \rightarrow 2Co(c) + 8CO(g)$$
$$Co_4(CO)_{12}(c) \rightarrow 4CO(c) + 12CO(g)$$

occurring under standard conditions were respectively $87 \pm 1$ and $124 \pm 4$ kcal mole$^{-1}$.

Table 7. Thermochemical parameters (kcal mole$^{-1}$) of cobalt carbonyls.

| Carbonyl | $-\Delta H_f^0$ (c) | $\Delta H_s^0$ | $-\Delta H_f^0$ (g) |
|---|---|---|---|
| $Co_2(CO)_8$ | 297.1±1.0 | 15.6±0.8 | 281.5±1.3 |
| $Co_4(CO)_{12}$ | 441±4 | (23±5) | 418±7 |
| $Co_3(CCl)(CO)_9$ | 280.5±2.2 | 23.8±0.4 | 256.7±2.2 |
| $Co_3(CBr)(CO)_9$ | 280.3±2.4 | 28.1±0.6 | 252.2±2.5 |

The enthalpies of formation of cobalt carbonyls calculated from the above data[38,56,57] are given in Table 7. The value found in Refs. 56 and 57 for the enthalpy of formation of octacarbonyldicobalt agrees with the calculated[38] value ($-296.3 \pm 1.2$ and $-298 \pm 2$ kcal mole$^{-1}$). The average of these results is therefore given in Table 7. The enthalpy of sublimation of the dodecacarbonyl has been estimated[38]. Those of the remaining compounds have been calculated[57] from the temperature dependence of their vapour pressure studied by Knudsen's effusion method over the range 288–318 K.

From the mass-spectrometric value of $D[(CO)_4Co–Co(CO)_4] = 14.5 \pm 2.0$ kcal mole$^{-1}$ and $\Delta H_f^\circ[Co_2(CO)_8, g] = -281.5 \pm 1.3$ kcal mole$^{-1}$, we calculate that $\bar{D}$(Co–CO) = $32.6 \pm 0.4$ kcal mole$^{-1}$.

## 11. Carbonyl Compounds of Ruthenium, Rhodium, Osmium, and Iridium

Skinner et al.[38,58] have used thermal decomposition and high-temperature iodination to determine the enthalpies of formation of polynuclear carbonyls of these platinum

metals. Table 8 lists the results together with the estimated enthalpies of sublimation.

The molecule of a polynuclear carbonyl in general contains three types of chemical bonds—terminal and bridging metal–carbonyl bonds and metal–metal bonds—whose energies of rupture are denoted [38] by the respective symbols $\overline{T}$, $\overline{B}$, and $\overline{M}$. Table 8A gives the enthalpies of the dissociation processes

$$M_m(CO)_n(g) \rightarrow m\,M(g) + n\,CO(g)$$

with the types and numbers of bonds undergoing rupture.

Table 8. Thermochemical parameters (kcal mole$^{-1}$) of ruthenium, rhodium, osmium, and iridium carbonyls.

| Carbonyl | $-\Delta H_f^0$ (c) | $\Delta H_s^0$ | $-\Delta H_f^0$ (g) |
|---|---|---|---|
| $Ru_3(CO)_{12}$ | 459±5 | (24±5) | 435±7 |
| $Rh_4(CO)_{12}$ | 435±3 | (24±5) | 411±6 |
| $Rh_6(CO)_{16}$ | 578±4 | (28±5) | 550±6 |
| $Os_3(CO)_{12}$ | 418±5 | (25±5) | 393±7 |
| $Ir_4(CO)_{12}$ | 435±4 | (25±5) | 410±7 |

Table 8A.

| Carbonyl | Enthalpy of dissociation, kcal mole$^{-1}$ | No. of bonds broken on dissociation |
|---|---|---|
| $Fe_2(CO)_9$ | 281±6 | $6\overline{T}+6\overline{B}+\overline{M}$ |
| $Fe_3(CO)_{12}$ | 401±7 | $10\overline{T}+4\overline{B}+3\overline{M}$ |
| $Co_2(CO)_8$ | 275±2 | $6\overline{T}+4\overline{B}+\overline{M}$ |
| $Co_4(CO)_{12}$ | 511±7 | $9\overline{T}+6\overline{B}+6\overline{M}$ |
| $Ru_3(CO)_{12}$ | 589±7 | $12\overline{T}+3\overline{M}$ |
| $Rh_4(CO)_{12}$ | 626±6 | $9\overline{T}+6\overline{B}+6\overline{M}$ |
| $Rh_6(CO)_{16}$ | 925±7 | $12\overline{T}+8\overline{B}+11\overline{M}$ |
| $Os_3(CO)_{12}$ | 643±7 | $12\overline{T}+3\overline{M}$ |
| $Ir_4(CO)_{12}$ | 733±7 | $12\overline{T}+6\overline{M}$ |

Table 8B.

| Carbonyl | $\overline{T}$, kcal mole$^{-1}$ | $\overline{M}$, kcal mole |
|---|---|---|
| $Ru_3(CO)_{12}$ | 42 | 29 |
| $Rh_4(CO)_{12}$ | 40 | 27 |
| $Rh_6(CO)_{16}$ | 40 | 27 |
| $Os_3(CO)_{12}$ | 46 | 31 |
| $Ir_4(CO)_{12}$ | 46 | 31 |

The energies of rupture of these bonds were calculated [38,58] on the assumption that $\overline{T}$, $\overline{B}$, and $\overline{M}$ each have the same value in $Fe(CO)_5$, $Fe_2(CO)_9$, and $Fe_3(CO)_{12}$, when we obtain for $\overline{B}$ and $\overline{M}$ the values 15.5 and 19.3 kcal mole$^{-1}$ respectively. The further assumption that corresponding bond dissociation energies are equal in $Co_2(CO)_8$ and $Co_4(CO)_{12}$ gives corresponding values of 15.0 and 22.0 kcal mole$^{-1}$. Hence for the iron and cobalt carbonyls we have $\overline{M} \simeq 0.68\overline{T}$ and $\overline{B} \simeq 0.5\overline{T}$. On the assumption of the same energy distribution among bonds also in polynuclear carbonyls of ruthenium, rhodium, osmium, and iridium, the values in Table 8B were calculated [38] for $\overline{T}$ and $\overline{M}$ in these compounds. This calculation is tentative in character, because of the use of estimates of enthalpies of sublimation, and also the hypothesis of constant ratios between $\overline{T}$, $\overline{B}$, and $\overline{M}$ in carbonyls differing significantly in composition and structure.

## III. CYCLOPENTADIENYL COMPOUNDS

### 1. Dicyclopentadienyls of 3*d* elements

Cotton and Wilkinson [4] calculated the enthalpy of formation of crystalline ferrocene from its enthalpy of combustion measured in a stationary calorimetric bomb. Chemical analysis showed that the solid product was a mixture of $Fe_2O_3$ and $Fe_3O_4$, which was allowed for in the calculations. (The quantity of iron oxidised to the sesquioxide did not exceed 18%.) They obtained the value $\Delta H_f^\circ$. $[(C_5H_5)_2Fe, c] = 33.8 \pm 1.3$ kcal mole$^{-1}$. These workers also measured the enthalpy of combustion of dicyclopentadienylnickel [59], found by chemical analysis that the solid products comprised a mixture of unoxidised nickel and the monoxide, and established that the quantity of nickel oxidised did not exceed 50%. They calculated that $\Delta H_f^\circ[(C_5H_5)_2Ni, c] = 63.0 \pm 0.6$ kcal mole$^{-1}$.

More recent measurements have been made [60–62] of the enthalpies of combustion both these compounds and of the dicyclopentadienyl derivatives of vanadium, chromium, manganese, and cobalt. These yielded the values [61,62] $40.3 \pm 0.4$ and $68.2 \pm 0.4$ kcal mole$^{-1}$ for the enthalpies of formation of crystalline ferrocene and dicylcopentadienylnickel respectively. In view of the experimental difficulties in the thermochemical study of this class of compound, the agreement between the results [4,59,61,62] for the two derivatives must be regarded as satisfactory. Average values are therefore given for them in Table 9.

Table 9. Thermochemical parameters (kcal mole$^{-1}$) of dicyclopentadienyls of 3*d* metals.

| Compound | $-\Delta H_c^0$ (c) | $\Delta H_f^0$ (c) | $\Delta H_s^0$ | $-\Delta H_f^0$ (g) | $\overline{D}$ (M–$C_5H_5$) |
|---|---|---|---|---|---|

| Bond | V–$C_5H_5$ | Cr–$C_5H_5$ | Mn–$C_5H_5$ | Fe–$C_5H_5$ | Co–$C_5H_5$ | Ni–$C_5H_5$ |
|---|---|---|---|---|---|---|
| $\overline{D}$, kcal mole$^{-1}$ | 90; 91 | 90; 69 | 72 | 75; 72 | 78 | 69; 69 |

In order to prevent premature oxidation and to achieve complete combustion the test substances were placed [60-62] under vacuum conditions in a known mass of molten paraffin wax, which was allowed to solidify, after which the experiments were made on the composite specimens. Because of its stability, ferrocene was ignited in several experiments in polyethylene ampoules. The mass of the organometallic compound taken for an experiment was established by determining the quantity of carbon dioxide among the combustion products. The solid products were subjected to quantitative X-ray examination and chemical analysis, which gave the compositions listed in Table 9A.

The enthalpies of combustion in Table 9 were based on the processes

$$\left.\begin{array}{l}(C_5H_5)_2V(c) + 55/4O_2(g) \rightarrow 1/2V_2O_5(c)\\ (C_5H_5)_2Cr(c) + 53/4O_2(g) \rightarrow 1/2Cr_2O_3(c)\\ (C_5H_5)_2Mn(c) + 79/6O_2(g) \rightarrow 1/3Mn_3O_4(c)\\ (C_5H_5)_2Fe(c) + 79/6O_2(g) \rightarrow 1/3Fe_3O_4(c)\\ (C_5H_5)_2Co(c) + 13O_2(g) \rightarrow CoO(c)\\ (C_5H_5)_2Ni(c) + 13O_2(g) \rightarrow NiO(c)\end{array}\right\} + 10CO_2(g) + 5H_2O(l)\ .$$

Enthalpies of sublimation were calculated from the temperature dependence [60-65] of vapour pressure. The mean $M-C_5H_5$ bond dissociation energies in Table 9 (where M = V, Cr, Mn, Fe, Co, Ni) were found by means of the equation

$$\bar{D}(M-C_5H_5) = 1/2\,\{\Delta H_f^0(M, g) + 2\Delta H_f^0(C_5H_5, g) - \Delta H_f^0[(C_5H_5)_2M, g]\}\ .$$

Mass-spectrometric study of these compounds yielded the values in Table 9B. [66,67]

Thus values of $\bar{D}(M-C_5H_5)$ obtained mass-spectrometrically in all cases exceed the corresponding thermochemical values. This is attributed to excess energy in the mass-spectrometric breakdown products of the initial compounds, which is difficult to allow for.

## 2. Cyclopentadienyl Compounds of Titanium, Zirconium, and Hafnium

The Reviewers [60,68-70] have measured the enthalpies of combustion of cyclopentadienyltitanium trichloride and of a series of compounds of general formula $(C_5H_5)_2MR_2$, where M = Ti, Zr, Hf and R = Cl, $CH_3$, $C_6H_5$, $C_6H_5CH_2$, $C_6H_5OCO$. A stationary calorimetric bomb made of a special chromium–nickel steel was used for experiments on the combustion of chlorinated compounds, in order to avoid reaction of the combustion products with the material of the bomb. Conversion into hydrogen chloride of all the chlorine present in a chlorinated compound, which was necessary to obtain a quite definite thermochemical equation, was accomplished by introducing an appropriate quantity of hydrazine hydrochloride into the bomb, in aqueous solution on the glass cloth covering its internal surface. The mass of substance taken for combustion was determined from the quantity of carbon dioxide formed. X-Ray diffraction revealed the crystalline dioxides of the metals among the products. Chemical analysis of the solid products indicated the absence of unoxidised or incompletely oxidised metals.

Table 10. Thermochemical parameters (kcal mole$^{-1}$) of cyclopentadienyl compounds of titanium, zirconium, and hafnium.

| Compound | $-\Delta H_c^0$ (c) | $\Delta H_f^0$ (c) | $\Delta H_s^0$ | $\Delta H_f^0$ (g) | $\bar{D}$ (M–$C_5H_5$) | $\bar{D}$ (M–R) |
|---|---|---|---|---|---|---|
| $(C_5H_5)TiCl_3$ | 737.8±1.6 | −145.5±1.6 | (25±2) | −120.5±3 | 62±3 | — |
| $(C_5H_5)_2TiCl_2$ | 1427.2±1.8 | −91.6±1.8 | 28.4±0.5 | −63.2±1.8 | 64.3±1.0 | — |
| $(C_5H_5)_2Ti(CH_3)_2$ | 1914±2* | 13±2 | (19±1) | 32±2 | — | 60±2 |
| $(C_5H_5)_2Ti(CH_2C_6H_5)_2$ | 3349.3±1.2 | 46.8±1.2 | (20±2) | 66.8±2 | — | 54±2 |
| $(C_5H_5)_2Ti(OCOC_6H_5)_2$ | 2935±3 | −231±3 | — | — | — | — |
| $(C_5H_5)_2ZrCl_2$ | 1427.5±0.7 | −128.6±0.7 | 25.1±0.5 | −103.5±0.9 | 85.7±1.0 | — |
| $(C_5H_5)_2Zr(CH_3)_2$ | 1927.6±0.5 | −10.6±0.5 | 19.4±0.5 | 8.8±0.7 | — | 65.6±1.1 |
| $(C_5H_5)_2Zr(C_6H_5)_2$ | 3081.2±2.6 | 65.9±2.6 | (22±1) | 87.9±3 | — | 69.8±2.0 |
| $(C_5H_5)_2HfCl_2$ | 1432.0±0.6 | −128.1±0.6 | 25.5±0.5 | −102.8±0.8 | 85.8±0.6 | — |

*Value corrected by the authors [68].

Values of $\Delta H_c^\circ$ in Table 10 for alkylated or arylated compounds relate to their oxidation to the crystalline metal dioxide, gaseous carbon dioxide, and liquid water. Combustion of the chlorinated compounds is represented by the equations

$$(C_5H_5)TiCl_3(c) + 6.5O_2(g) \rightarrow TiO_2(c) + 5CO_2(g) + H_2O(l) + 3HCl(400H_2O, s)$$
$$(C_5H_5)_2MCl_2(c) + 13O_2(g) \rightarrow MO_2(c) + 10CO_2(g) + 4H_2O + 2HCl(200H_2O, s)$$
M–Ti, Zr or Hf.

Values of the enthalpy of sublimation in parentheses (Table 10) have been estimated from values of this function for compounds of similar composition and structure. Values of $\Delta H_s^\circ$ in the remaining cases have been calculated from the temperature dependence of vapour pressure measured by the Knudsen effusion method. We regard as incorrect the values of −1366 ± 5 and −1398 ± 5 kcal mole$^{-1}$ obtained [71] for the enthalpies of combustion of dicyclopentadienyl-titanium and -zirconium dichlorides, because of inaccurate determination [71] of the composition of the products.

The bond dissociation energies in the last two columns in Table 10 have been calculated by means of the equations

$$\bar{D}(M-C_5H_5) = 1/2\,\{\Delta H_f^0(M, g) + 2\Delta H_f^0(C_5H_5, g) + 2\Delta H_f^0(Cl, g) - \Delta H_f^0[(C_5H_5)_2MCl_2, g] - 2\bar{D}(M-Cl)\};$$
$$\bar{D}(M-R) = 1/2\,\{\Delta H_f^0(M, g) + 2\Delta H_f^0(C_5H_5, g) + 2\Delta H_f^0(R, g) - \Delta H_f^0[(C_5H_5)_2MR_2, g] - 2\bar{D}(M-C_5H_5)\}.$$

The values of $\bar{D}(M-C_5H_5)$ have been obtained on the assumption that metal–chlorine bond dissociation energies are approximately the same in the dicyclopentadienylmetal dichlorides as in the corresponding tetrachlorides. Thus within the limits of experimental error the Ti–Cl bonds have the same length in $(C_5H_5)_2TiCl_2$ as in $TiCl_4$ (2.24 ± 0.01 [72] and 2.21 ± 0.03 Å [73]); and this applies also to the Zr–Cl bonds in $(C_5H_5)_2ZrCl_2$ and $ZrCl_4$ (2.31 ± 0.01 [74] and 2.33 ± 0.05 Å [73]). The bond dissociation energies in the tetrachlorides have been calculated from the data in Table 1 as respectively 102.9 ± 0.3, 116.8 ± 0.4, and 118.6 ± 0.3 kcal mole$^{-1}$ for $\bar{D}(Ti-Cl)$, $\bar{D}(Zr-Cl)$, and $\bar{D}(Hf-Cl)$. It is significant that such calculation gives closely similar bond dissociation energies $\bar{D}(Ti-C_5H_5)$ in $C_5H_5TiCl_3$ and $(C_5H_5)_2TiCl_2$ (Table 10). This is consistent with structural measurements indicating that all the carbon atoms in these compounds are equidistant from the

titanium atom [75]. Since the error in the value adopted $\Delta H_f^\circ(C_5H_5, g) = 50$ kcal mole$^{-1}$ is unknown (Section I), it is not included in the error in the determination of $\overline{D}(M-C_5H_5)$ given in Table 10.

Study of the thermochemistry of a compound having the empirical formula $(C_5H_5)_2Ti$ was based [60] on the assumption of a monomeric ferrocene-like structure. However, it has been established [76] that this compound has a more complicated structure. Therefore the Reviewers' earlier value [60,77] of $\overline{D}(Ti-C_5H_5) = 108$ kcal mole$^{-1}$ is not the mean dissociation energy of the titanium–cyclopentadienyl bond, but represents the total enthalpy of several processes.

In the calculation of $\overline{D}(M-R)$ it has been assumed that the metal–cyclopentadienyl bond dissociation energy is the same in corresponding compounds $(C_5H_5)_2MCl_2$ and $(C_5H_5)_2MR_2$. It must be noted that the unreliability of the value of $\Delta H_f^\circ(C_5H_5, g)$ does not affect the accuracy of the calculated $\overline{D}(M-R)$ values.

The above results show clearly that $\overline{D}(Zr-C_5H_5)$ and $\overline{D}(Hf-C_5H_5)$ are closely similar and exceed $\overline{D}(Ti-C_5H_5)$ by 21 kcal mole$^{-1}$. Like the above relations among values of $\overline{D}(M-CO)$ for transition metals (Table 2–5) this corresponds to the rule [78] that the dissociation energy of the bonds formed with a given ligand (atom) increases with the atomic mass of the transition metal down a particular subgroup.

The mean dissociation energy of the zirconium–phenyl bond exceeds that of the zirconium–methyl bond by 4.2 kcal mole$^{-1}$. It is interesting that a difference of the same order is always found for non-transition metals [79]. The enthalpy of combustion $\Delta H_c^\circ = -2995 \pm 3$ kcal mole$^{-1}$ measured [68] for $(C_5H_5)_2Ti(C_6H_5)_2(c)$ led to an abnormally high dissociation energy calculated for the titanium–phenyl bond. For this reason the value given [68] for the enthalpy of combustion must be regarded as tentative.

### 3. Cyclopentadienyl Compounds of Molybdenum and Tungsten

The Reviewers have used a calorimeter with a stationary bomb to measure [69,80] the enthalpies of combustion of compounds $(C_5H_5)_2MX_2$, where M = Mo, W and X = H, Cl, I. For the combustion of chlorinated compounds reaction between the walls of the bomb and the products of combustion was prevented by the insertion of a tightly fitting tantalum pot, whose inner surface was covered with glass cloth impregnated with 10 ml of water containing 0.05 mass % of hydrogen peroxide (to ensure completely conversion of chlorine into hydrogen chloride). In all experiments the mass of hydrochloric acid found among the combustion products coincided, within the limits of experimental error, with that calculated from the mass of the initial compound. The quantity of substance taken for combustion was determined from the amount of carbon dioxide among the products. X-Ray determinatin indicated that the solid products were the crystalline trioxides of the metals. No unoxidised or incompletely oxidised metal was detected. The enthalpies of combustion [69,80] listed in Table 11 are based on the reactions

$$(C_5H_5)_2MH_2(c) + 14.5O_2(g) \rightarrow MO_3(c) + 10CO_2(g) + 6H_2O(l)$$
$$(C_5H_5)_2MCl_2(c) + 13.5O_2(g) \rightarrow MO_3(c) + 10CO_2(g) + 4H_2O(l) + 2HCl(200H_2O, s)$$
$$(C_5H_5)_2MI_2(c) + 14O_2(g) \rightarrow MO_3(c) + 10CO_2(g) + 5H_2O(l) + I_2(c).$$

The enthalpies of sublimation of the "hydrides" were calculated from the temperature dependence of vapour pressure measured [80] by the Knudsen effusion method. Those for the remaining compounds were estimated on the basis of their monomeric character is the gas phase.

Table 11. Thermochemical parameters (kcal mole$^{-1}$) of cyclopentadienyl compounds of molybdenum and tungsten.

| Compound | $-\Delta H_c^0$(c) | $\Delta H_f^0$(c) | $\Delta H_s^0$ | $\Delta H_f^0$(g) |
|---|---|---|---|---|
| $(C_5H_5)_2MoH_2$ | 1575.1±0.6 | 46.6±0.6 | 22.1±0.5 | 68.7±0.8 |
| $(C_5H_5)_2MoCl_2$ | 1448.2±0.6 | −22.9±0.6 | (24±1) | 1.1±1.2 |
| $(C_5H_5)_2MoI_2$ | 1467.4±0.5 | 7.2±0.5 | (24±1) | 31.2±1.1 |
| $(C_5H_5)_2WH_2$ | 1611.7±0.6 | 59.9±0.6 | 23.0±0.5 | 82.9±0.8 |
| $(C_5H_5)_2WCl_2$ | 1477.4±0.6 | −17.0±0.6 | (25±1) | 8.0±1.2 |
| $(C_5H_5)_2WI_2$ | 1511.5±0.7 | 28.0±0.7 | (25±1) | 53.0±1.2 |

The calculation of $\overline{D}(M-C_5H_5)$ and $\overline{D}(M-X)$ for these compounds was similar to the above calculation of bond dissociation energies for titanium, zirconium, and hafnium compounds $(C_5H_5)_2MR_2$. It was assumed that here $\overline{D}(Mo-Cl)$ and $\overline{D}(W-Cl)$ are approximately equal to those in the hexachlorides (72.6 ± 1.7 and 83.0 ± 0.2 kcal mole$^{-1}$) calculated from the data in Table 1. This postulate should correspond to approximate equality of metal–chlorine internuclear distances between the molybdenum and tungsten test compounds and their respective hexachlorides. Unfortunately, the structural data required for comparison are lacking. However, the molybdenum–chlorine bond length is known to be 2.47 Å [81] in $(C_5H_5)_2$.$MoCl_2$, but 2.27 ± 0.02 Å [73] in molybdenum pentachloride. Since a decrease in the energy of rupture of a bond corresponds to an increase in its length, and $\overline{D}(Mo-Cl)$ is 9.1 kcal mole$^{-1}$ smaller in molybdenum hexachloride than in the pentachloride (calculated from standard data [9]), the bond is probably longer in the hexachloride, and the postulated approximate equality of $\overline{D}(Mo-Cl)$ in $(C_5H_5)_2MoCl_2$ and $MoCl_6$ is likely to be correct. The calculated results in Table 12 show that both $\overline{D}(M-C_5H_5)$ and $\overline{D}(M-X)$ are larger for tungsten than for molybdenum.

### 4. Cyclopentadienyl Compounds of Platinum

A massive microcalorimeter has been used [82] to measure the enthalpies of combustion of crystalline cyclopentadienyltrimethylplatinum and dicyclopentadienyldimethylplatinum as respectively −1270.8 ± 0.5 and −1706.3 ± 1.7 kcal mole$^{-1}$, the products being gaseous carbon dioxide, liquid water, and crystalline platinum. These values were used to calculate the corresponding heats of formation $\Delta H_f^\circ(c)$ are 40.3 ± 0.5 and 31.2 ± 1.7 kcal mole$^{-1}$.

The enthalpy of sublimation of the trimethyl derivative was calculated from the temperature dependence of the vapour pressure studied by the Knudsen effusion method, which gave $\Delta H_s^\circ = 18.6 \pm 0.5$ kcal mole$^{-1}$ for the range 290–305 K. The enthalpy of sublimation of the dicyclopentadienyl compound was taken to be 20 ± 1 kcal mole$^{-1}$. We then have for the heats of formation in the gaseous state $\Delta H_f^\circ(g)$ the respective values 58.9 ± 0.7 and 51.2 ± 1.9 kcal mole$^{-1}$.

On the assumption that bond dissociation energies are constant in these compounds, comparison of the heats of formation in the gaseous state yields $\overline{D}(Pt-C_5H_5) = 75 \pm 3$ and $\overline{D}(Pt-CH_3) = 51 \pm 1$ kcal mole$^{-1}$.

Table 12. Mean dissociation energies (kcal mole$^{-1}$) in cyclopentadienyl compounds of molybdenum and tungsten.

| Compound | $\overline{D}$ (M–$C_5H_5$) | $\overline{D}$ (M–H) | $\overline{D}$ (M–I) |
|---|---|---|---|
| $(C_5H_5)_2MoCl_2$ | 84.3±1.8 | — | — |
| $(C_5H_5)_2MoI_2$ | 84.3±1.8 | — | 54.1±2.0 |
| $(C_5H_5)_2MoH_2$ | 84.3±1.8 | 61.9±1.9 | — |
| $(C_5H_5)_2WCl_2$ | 94.4±0.8 | — | — |
| $(C_5H_5)_2WI_2$ | 94.4±0.8 | — | 57.0±1.1 |
| $(C_5H_5)_2WH_2$ | 94.4±0.8 | 68.6±1.0 | — |

### 5. Tricyclopentadienyl Derivatives of Rare-earth Metals

Enthalpies of combustion have been measured[83] for the tricyclopentadienyl compounds of scandium, yttrium, lanthanum, praseodymium, thulium, and ytterbium. X-ray diffraction has established formation of the crystalline oxide $Pr_6O_{11}$ but the crystalline sesquioxides of the other five rare-earth metals. Neither unoxidised metals nor oxides of other compositions were detected among the products of combustion. Table 13 lists the standard enthalpies of combustion to gaseous carbon dioxide, liquid water, and the metal oxide. It includes the standard enthalpies of formation in crystalline and gaseous states together with the mean $M-C_5H_5$ bond dissociation energies.

Table 13. Thermochemical parameters (kcal mole$^{-1}$) of tricyclopentadienyls of rare-earth metals.

| Compound | $-\Delta H_c^0$ (c) | $\Delta H_f^0$ (c) | $\Delta H_s^0$ | $\Delta H_f^0$ (g) | $\overline{D}$ (M–$C_5H_5$) |
|---|---|---|---|---|---|
| $(C_5H_5)_3Se$ | 2148±1 | −3.2±1 | 26.2±1 | 23.0±1.5 | 72.7±0.5 |
| $(C_5H_5)_3Y$ | 2140±1 | −10.8±1 | 26.7±1 | 15.9±1.5 | 78.5±0.5 |
| $(C_5H_5)_3La$ * | 2146±1 | −6.4±1 | 27.4±1 | 21.0±1.5 | 77.3±0.5 |
| $(C_5H_5)_3Pr$ | 2144±2 | −6.7±2 | 30.0±1 | 23.3±2.0 | 71.9±1.0 |
| $(C_5H_5)_3Tm$ | 2137±1 | −11.8±1 | 26.6±1 | 14.8±1.5 | 64.8±0.5 |
| $(C_5H_5)_3Yb$ | 2147±1 | 7.0±1 | 26.0±1 | 33.0±1.5 | 51.1±0.5 |

*We have used the value $\Delta H_f^\circ(La_2O_3, c) = -458$ kcal mole$^{-1}$ taken from tables[15] in calculating $\Delta H_f^\circ[(C_5H_5)_3La, c]$. In Ref. 84 the enthalpy of formation of lanthanum sesquioxide was given as −428.6 kcal mole$^{-1}$, which is significantly lower than the values for scandium and yttrium sesquioxides (−456.4 and −455.4 kcal mole$^{-1}$). This casts doubt on the accuracy of the latter results[84], since the enthalpies of formation of the same type of oxides of other transition metals increase with the atomic number of the metal (Table 1).

Heats of formation of the gaseous cyclopentadienyls have been calculated from enthalpies of sublimation found from the temperature dependence of vapour pressure[85,86] over the range 473–673 K. We assumed that the enthalpies of sublimation of these compounds at 298.15 K exceed by 3 ± 1 kcal mole$^{-1}$ the experimental values for the above temperature range. Mass-spectrometric results were used[87] to calculate the enthalpy of the process

$$(C_5H_5)_3Yb(g) \rightarrow (C_5H_5)_2Yb(g) + C_5H_5(g),$$

as 58 ± 5 kcal mole$^{-1}$. Together with data in Table 13 this yields $\Delta H_f^\circ[(C_5H_5)_2Yb, g] = 41 \pm 5$ and $\overline{D}(Yb-C_5H_5) = 48 \pm 3$ kcal mole$^{-1}$. Hence the energies of dissociation of the ytterbium–cyclopentadienyl bond in tri- and di-cyclopentadienylytterbium are closely similar, which indicates a low energy of transition of ytterbium from the bivalent to the tervalent state.

## IV. ARENE COMPOUNDS

### 1. Dibenzenevanadium

The enthalpy of combustion of dibenzenevanadium

$$(C_6H_6)_2V(c) + 16.25O_2(g) \rightarrow 0.5V_2O_5(c) + 12CO_2(g) + 6H_2O(l)$$

was determined[88] as $\Delta H_c^\circ = -1732.7 \pm 1.8$ kcal mole$^{-1}$, which corresponds to $\Delta H_f^\circ[(C_6H_6)_2V, c] = 8.7 \pm 2.4$ kcal mole$^{-1}$. Premature oxidation was prevented by placing the compound in glass ampoules. However, the combustion products were not analysed[88], so that the above value for the enthalpy of combustion cannot be accepted as reliable, in view of the tendency of vanadium to exist in various states of oxidation (VO, $V_2O_3$, $VO_2$, and $V_2O_5$).

For the enthalpy of sublimation Fischer et al.[88,89] give the value 8.9 kcal mole$^{-1}$. However, this has been shown[90] to be incorrect, for $\Delta H_s^\circ \simeq 18$ kcal mole$^{-1}$. From this we find that $\Delta H_f^\circ[(C_6H_6)_2V, g] = 26.7 \pm 2.6$ kcal mole$^{-1}$, whence we obtain also $\overline{D}(V-C_6H_6) = 77.0 \pm 1.4$ kcal mole$^{-1}$.

### 2. Dibenzenechromium

The enthalpy of combustion in a stationary calorimetric bomb was given[91] as $\Delta H_c^\circ = -1696 \pm 8$ kcal mole$^{-1}$. The dibenzenechromium was placed in molten thymol to eliminate premature oxidation. More accurate determination was regarded[91] as impossible because of the large heat of combustion, the need to use auxiliary materials, and the difficulties in calculating several corrections. However, this is unconvincing, since the work[91] involved defects of method. The quantity of heat produced by the combustion of thymol amounted to 50–70% of the total quantity evolved in the bomb during the experiment. The heat of combustion, which was required to calculate the appropriate correction, was found with an error of ~0.2%. It can easily be reckoned that this will lead to an error of 3–6 kcal mole$^{-1}$ in $\Delta H_c^\circ[(C_6H_6)_2Cr, c]$.

Furthermore, determination of carbon dioxide and analysis of the solid products showed[91] that a high degree of combustion was not achieved: the quantity of the former was considerably smaller than expected, and the solid products contained elementary chromium. Since neither free nor combined carbon was detected in the solid phase, it was concluded[91] that the gaseous products included carbon monoxide, whose quantity was calculated.

Appropriate corrections for incomplete oxidation of carbon and chromium (respectively 5–49 and 3–21 kcal mole$^{-1}$) were made in processing the experimental results. However, such a procedure for determining the quantity of carbon monoxide among the combustion products is not exact, since carbon-containing products of thermal decomposition of the initial compound may be formed in the absence of a high degree of combustion.

A subsequent determination[92] of the enthalpy of combustion of dibenzenechromium gave $\Delta H_c^\circ = -1725.4 \pm 2.0$ kcal mole$^{-1}$. It is impossible to assess the reliability of this value because of the absence of any detailed description of the experiment[92].

Because of the sharp divergence between these results[91,92] the Reviewers redetermined the enthalpy of combustion of dibenzenechromium[93]. The compound was purified by repeated vacuum sublimation, and placed in polyethylene ampoules in the bomb. The mass taken for combustion was established by determining carbon dioxide in the products. Analysis of the solid products showed that neither unoxidised chromium nor unoxidised carbon was present, and a qualitative test for carbon monoxide in the gaseous products (which were passed through aqueous palladium dichloride) gave a negative result. The values obtained were $\Delta H_c^\circ = -1710 \pm 2$ and $\Delta H_f^\circ[(C_6H_6)_2Cr, c] = 35 \pm 2$ kcal mole$^{-1}$. Other workers[54] studied the high-temperature iodination of dibenzenechromium and obtained for the heat of formation 34 ± 2 kcal mole$^{-1}$, which agrees with the Reviewers' value[93] within the limits of experimental error.

Taking the average of these results[54,93] and using the heat of sublimation[94] $\Delta H_s^\circ = 19.6 \pm 0.5$ kcal mole$^{-1}$, we have $\Delta H_f^\circ[(C_6H_6)_2Cr, c] = 35.4 \pm 1.0$ and $\Delta H_f^\circ[(C_6H_6)_2Cr, g] = 54.1 \pm 1.1$ kcal mole$^{-1}$, and find from the latter that $\bar{D}(Cr-C_6H_6) = 40.2 \pm 0.7$ kcal mole$^{-1}$. This result agrees well with the mass-spectrometric values[95,96] of 40.5 and 39 kcal mole$^{-1}$, but is lower than the mass-spectrometric value[97] of 46 kcal mole$^{-1}$. It is interesting that considerably less energy is required to detach the first benzene ring than to detach the second: thus[96] $D_1(C_6H_6-CrC_6H_6) = 23$ and $D_2(Cr-C_6H_6) = 55$ kcal mole$^{-1}$.

### 3. Compounds of Chromium with Alkylated Benzenes

A stationary calorimetric bomb was used[92] to measure the enthalpies of combustion of compounds formed by chromium with methylated benzenes, and the Reviewers have studied[98] ethyl and isopropyl derivatives of dibenzenechromium by the same method. The enthalpies obtained for combustion of these compounds to crystalline chromium(III) oxide, gaseous carbon dioxide, and liquid water, together with the calculated standard enthalpies of formation and the mean chromium–ligand bond dissociation energies, are given in Table 14. Analytical data were absent[92] for solid and gaseous combustion products from compounds (I) and (II). In view of the closely similar results obtained for them (as was to be expected for compounds having the same composition and similar structures), however, the values given for the enthalpies of combustion are probably feasible: the formation of products of the incomplete combustion of (I) and (II) of the same nature and mass is improbable because of the non-standard conduct of the experiments. The solid combustion products from compounds (III)–(VI) were subjected[98] to X-ray examination and chemical analysis, when products of the incomplete oxidation of chromium were not detected.

Table 14 contains for compound (VI) the chromium–isopropylbenzene bond dissociation energy, calculated by means of the equation

$$\bar{D}(Cr-C_6H_5C_3H_7) = \Delta H_f^\circ(Cr, g) + \Delta H_f^\circ[C_6H_4(C_3H_7)_2, g] + \\ + \Delta H_f^\circ(C_6H_5C_3H_7, g) - \Delta H_f^\circ[(VI), g] - \bar{D}[Cr-C_6H_4(C_3H_7)_2]$$

on the assumption that $\bar{D}[Cr-C_6H_4(C_3H_7)_2]$ has the same value in (V) and (VI).

The enthalpies of sublimation of (I) and (II) were calculated[92] from the measured temperature dependence of vapour pressure as respectively 15.4 and 8.0 kcal mole$^{-1}$. The marked difference between these values casts doubt on their accuracy. In order to calculate $\Delta H_f^\circ(g)$ the Reviewers have assumed that the enthalpies of sublimation of these compounds differ little from the value for dibenzenechromium and are ~20 kcal mole$^{-1}$. The enthalpies of vaporisation of compounds (III)–(VI) have been taken from the literature[90,94,99–101].

Table 14 shows that the chromium–ligand bond dissociation energy in compounds (I)–(VI) is the same within the limits of experimental error. Mass spectrometry gave[97] for $\bar{D}[Cr-C_6H_3(CH_3)_3]$ in compound (I) the value 61 kcal mole$^{-1}$, which is considerably larger than the corresponding thermochemical value. The discrepancies often met between published thermochemical and mass-spectrometric results are due mainly to the absence of a reliably established mechanism of the breakdown of an organometallic compound on electron bombardment and also to the presence of excess energy in the breakdown products.

### 4. Diarenechromium Halides

Enthalpies of combustion have been measured and standard enthalpies of formation calculated[93] for dibenzenechromium chloride and bromide, and ditoluene, di-*m*-xylene, dimesitylene-, and dibiphenyl-chromium iodides

**Table 14.** Thermochemical parameters (kcal mole$^{-1}$) of compounds of chromium with alkylated benzenes.

| No. | Compound | $-\Delta H_c^0$ | $\Delta H_f^0$ | $\Delta H_s^0$ | $\Delta H_v^0$ | $\Delta H_f^0$ (g) | $\bar{D}$ (Cr – Ligand) |

(Table 15). A tightly fitting tantalum pot prevented interaction between the walls of the bomb and the halides. In the determination of the enthalpy of combustion of dibenzenechromium chloride complete conversion of chlorine into hydrogen chloride was ensured by covering the inside surface of the bomb also with glass cloth impregnated with aqueous hydrazine dihydrochloride. Absence of unoxidised or incompletely oxidised chromium and carbon was shown in every experiment by analysis of the combustion products. Furthermore, hydrogen bromide was absent from the products of the combustion of dibenzenechromium bromide, and hydrogen chloride from those of the chloride.

Skinner et al.[54] obtained for the thermal decomposition

$$(C_6H_6)_2CrI(c) \rightarrow Cr(c) + 2C_6H_6(g) + 0.5I_2(g)$$

the enthalpy $\Delta H_r^\circ = 35 \pm 1$ kcal mole$^{-1}$, which corresponds to $\Delta H_f^\circ[(C_6H_6)_2CrI, c] = 12 \pm 1$ kcal mole$^{-1}$. In determining the enthalpy of combustion the Reviewers[102] paid especial attention to purifying the compound, and obtained for the process

$$(C_6H_6)_2CrI(c) + 15.75O_2(g) \rightarrow 0.5Cr_2O_3(c) + 12CO_2(g) + 6H_2O(l) + 0.5I_2(c)$$

the value† $\Delta H_c^\circ = -1684.8 \pm 0.5$ kcal mole$^{-1}$, corresponding to $\Delta H_f^\circ[(C_6H_6)_2CrI, c] = 10.0 \pm 0.5$ kcal mole$^{-1}$, close to Skinner's result[54].

### 5. Dibenzenemolybdenum

The enthalpy of combustion was found[88] to be $\Delta H_c^\circ$. $[(C_6H_6)_2Mo, c] = -1789.8 \pm 2.2$ kcal mole$^{-1}$, but no analysis of the combustion products was reported[88]. The assumed equation

$$(C_6H_6)_2Mo(c) + 16.5O_2(g) \rightarrow MoO_3(c) + 12CO_2(g) + 6H_2O(l).$$

yielded $\Delta H_f^\circ[(C_6H_6)_2Mo, c] = 73.2 \pm 2.2$ kcal mole$^{-1}$. Using[88,101] $\Delta H_S^\circ = 22 \pm 1$ kcal mole$^{-1}$, we find that $\Delta H_f^\circ[(C_6H_6)_2Mo, g] = 95.2 \pm 2.4$ kcal mole$^{-1}$. Mass spectrometry gives[104] $\bar{D}(Mo-C_6H_6) = 59$ kcal mole$^{-1}$.

## V. ALKOXY-COMPOUNDS

### 1. Alkoxy-compounds of Titanium

Determinations[105] of the enthalpies of the processes

$$TiCl_4(l) + 4C_2H_5OH(l) \rightarrow (C_2H_5O)_4Ti(l) + 4HCl(g)$$
$$TiCl_4(l) + 4C_2H_5OH(l) \rightarrow (C_2H_5O)_4Ti(l) + 4HCl(51.3H_2O, s)$$

gave respectively 19.5 ± 0.4 and −49.1 ± 0.6 kcal mole$^{-1}$, from which calculation gave for the enthalpy of formation of liquid tetraethoxytitanium the values −349.7 ± 1.8 and −348.4 ± 2.0 kcal mole$^{-1}$ in good agreement.

The enthalpy of formation of solid tetraethoxytitanium was calculated[106] from the enthalpy of combustion determined in a stationary calorimetric bomb: for the process

$$(C_2H_5O)_4Ti(c) + 12O_2(g) \rightarrow TiO_2(c) + 8CO_2(g) + 10H_2O(l)$$

the value $\Delta H_c^\circ = -1308.6 \pm 1.2$ was obtained, whence it was found that $\Delta H_f^\circ[(C_2H_5O)_4Ti, c] = -352.6 \pm 1.2$ kcal mole$^{-1}$. The enthalpy of fusion of this compound was estimated[106] as 3–6 kcal mole$^{-1}$. Good agreement is evident between these results[105,106].

Averaging the results[105] gave $\Delta H_f^\circ[(C_2H_5O_4)_4Ti, l] = -349.0 \pm 1.4$ kcal mole$^{-1}$, which was used to find[107] enthalpies of formation of several other alkoxytitanium compounds. For this purpose calorimetric determinations were made[107] of the enthalpies of the reactions

$$(C_2H_5O)_4Ti(l) + 4ROH(l) \rightarrow (RO)_4Ti(l) + 4C_2H_5OH(l),$$

where R = n-$C_3H_7$, iso-$C_3H_7$, n-$C_4H_9$, iso-$C_4H_9$, s-$C_4H_9$, t-$C_4H_9$, n-$C_5H_{11}$, and t-$C_5H_{11}$. The results of these measurements ($\Delta H_r^\circ$) and those of the corresponding calculations are given in Table 16.

The heats of formation of tetra-n-butoxy- and tetra-t-pentyloxy-titanium were checked[107] by studying the thermochemistry of the processes

$$[(C_2H_5)_2N]_4Ti(l) + 4n\text{-}C_4H_9OH(l) \rightarrow n\text{-}C_4H_9O)_4Ti(l) + 4(C_2H_5)_2NH(l),$$

$$[(C_2H_5)_2N]_4Ti(l) + 4t\text{-}C_5H_{11}OH(l) \rightarrow (t\text{-}C_5H_{11}O)_4Ti(l) + 4(C_2H_5)_2NH(l),$$

for which $\Delta H_r^\circ$ was respectively −69.4 ± 0.6 and −55.4 ± 0.4 kcal mole$^{-1}$. From the value found[107] for the heat of formation of tetrakisdiethylaminetitanium $\Delta H_f^\circ(l) = -116.8$ kcal mole$^{-1}$ and the known values for the alcohols and diethylamine it was calculated[107] that $\Delta H_f^\circ[(n\text{-}C_4H_9O)_4Ti, l] = -399$ and $\Delta H_f^\circ[(t\text{-}C_5H_{11}O)_4Ti, l] = -457$ kcal mole$^{-1}$, in good agreement with the values in Table 16.

Enthalpies of vaporisation (Table 16) were estimated[107] from the experimental values for tetra-t-butoxy- and tetra-t-pentyloxy-titanium, with allowance for depolymerisation of the compounds on evaporation. Table 16 shows that values of $\bar{D}$(RO—Ti) are little affected by the nature of the radical, and the mean must be taken as 105 ± 2 kcal mole$^{-1}$.

† In an earlier determination[103] we had obtained the low value $\Delta H_c^\circ = -1664$ kcal mole$^{-1}$, probably owing to inadequate purification of the specimen of dibenzenechromium iodide.

Shaulov et al.[108] used combustion in a stationary calorimetric bomb, and obtained for the enthalpies of formation of tetraisopropoxytitanium and tetra-n-butoxytitanium the respective values $-372.3 \pm 1.2$ and $-392.7 \pm 4.2$ kcal mole$^{-1}$, which differed by a few kilocalories per mole from those in Ref. 107 (Table 16).

Lappert et al.[109] determined the enthalpy of the process

$$TiCl_4(l) + 4iso\text{-}C_3H_7OH(l) \rightarrow (iso\text{-}C_3H_7O)_4Ti(l) + 5HCl(g)$$

and obtained $\Delta H_r^\circ = 19.3 \pm 1.2$ kcal mole$^{-1}$, which corresponds to $\Delta H_f^\circ[(iso\text{-}C_3H_7O)_4Ti, l] = -389 \pm 2$ kcal mole$^{-1}$. This value exceeds by 10 and 17 kcal mole$^{-1}$ respectively those obtained by the above workers[107,108]. The reasons for the discrepancy in these results[107-109] are obscure. Nevertheless, the detailed discussion[107] of the experimental conditions and the necessary corrections lead to acceptance of the results in Ref. 107 as the most soundly based.

## 2. Alkoxy-compounds of Vanadium and Chromium

Bradley and Hillyer[110] determined the enthalpies of the reactions of vanadium tetrachloride and of tetra-t-butoxyvanadium with aqueous hydrochloric acid, and found the enthalpy of the overall process

$$VCl_4(l) + 4t\text{-}C_4H_9OH(l) \rightarrow (t\text{-}C_4H_9O)_4V(l) + 4HCl(51.3H_2O, s)$$

to be $-22.7 \pm 0.9$ kcal mole$^{-1}$. Table 17 gives the enthalpy of formation of tetrabutoxyvanadium calculated from this result together with that of tetra-t-butoxychromium calculated[110] from its enthalpy of hydrolysis in aqueous sulphuric acid, allowing for the possibility of disproportionation of quadrivalent chromium to the tervalent and sexivalent states.

Table 17. Thermochemical parameters (kcal mole$^{-1}$) of alkoxy-derivatives of vanadium and chromium.

| Compound | $-\Delta H_f^0$ (l) | $\Delta H_v^0$ | $-\Delta H_f^0$ (g) | $\bar{D}$(t-C$_4$H$_9$O-M) |
|---|---|---|---|---|
| (t-C$_4$H$_9$O)$_4$V | 344±1 | (15.8±1) | 328.2±1.4 | 90±2 |
| (t-C$_4$H$_9$O)$_4$Cr | 321±1 | (15.8±1) | 305.2±1.4 | 77±2 |

The enthalpies of vaporisation of these complexes were equated[110] to the experimental value for tetra-t-butoxytitanium (Table 16).

## 3. Alkoxy-compounds of Zirconium and Hafnium

Lappert et al.[109] found that the enthalpy $\Delta H_r^\circ$ of the process

$$MCl_4(l) + 4iso\text{-}C_3H_7OH(l) \rightarrow (iso\text{-}C_3H_7O)_4M(c) + 4HCl(g)$$

was respectively $21.4 \pm 1.8$ and $10.4 \pm 1.8$ kcal mole$^{-1}$ when M = Zr and Hf. Enthalpies of formation of the alkoxy-compounds of zirconium and hafnium calculated from the results are given in Table 18. Enthalpies of sublimation were estimated[109] from the enthalpy of vaporisation of tetraisopropoxytitanium (Table 16) and their assumed value of 3 kcal mole$^{-1}$ for the enthalpy of fusion.

Comparison of the values in Table 18 with that in Table 16 for $\bar{D}$(RO–Ti) indicates that

$$\bar{D}(iso\text{-}C_3H_7\text{–}Ti) < \bar{D}(iso\text{-}C_3H_7O\text{–}Zr) < \bar{D}(iso\text{-}C_3H_7O\text{–}Hf)$$

i.e. $\bar{D}$(RO–M) increases with increase in the atomic number of the metal as Group IV of the Periodic System is descended.

Table 18. Thermochemical parameters (kcal mole$^{-1}$) of alkoyx-derivatives of zirconium and hafnium.

| Compound | $-\Delta H_f^0$ (c) | $\Delta H_s^0$ | $-\Delta H_f^0$(g) | $\bar{D}$(iso-C$_3$H$_7$O-M) |
|---|---|---|---|---|
| (iso-C$_3$H$_7$O)$_4$Zr | 429±1.8 | (20±5) | 409±5 | 126±2 |
| (iso-C$_3$H$_7$O)$_4$Hf | 443±1.8 | (20±5) | 423±5 | 130±2 |

## 4. Alkoxy-compounds of Niobium and Tantalum

The Reviewers[111] have determined the enthalpies of combustion of the penta-alkoxy-compounds $(RO)_5M$, in which M = Nb, Ta and R = $CH_3$, $C_2H_5$, n-$C_3H_7$. X-Ray phase analysis showed that the solid combustion products were niobium and tantalum pentoxides respectively. No products of incomplete oxidation of the metals were detected. Combustion of the test compounds was represented by the equation

$$(C_nH_{2n+1}O)_5M(l, c) + 7.5O_2(g) \rightarrow 0.5M_2O_5(c) + 5nCO_2(g) + (5n + 2.5)H_2O(l).$$

The values obtained for the enthalpies of combustion and the standard enthalpies of formation calculated from them are given in Table 19 together with the mean RO–M bond dissociation energies. Enthalpies of vaporisation were calculated from the temperature dependence of vapour pressure measured by the Knudsen effusion method. The enthalpies of fusion of crystalline niobium and tantalum methoxides were estimated as $3 \pm 1$ kcal mole$^{-1}$.

Table 19. Thermochemical parameters (kcal mole$^{-1}$) of alkoxy-compounds of niobium and tantalum.

| Compound | $-\Delta H_c^0$ | $-\Delta H_f^0$ | $\Delta H_s^0$ | $\Delta H_v^0$ | $-\Delta H_f^0$(g) | $\bar{D}$ (RO–M) |
|---|---|---|---|---|---|---|
| (CH$_3$O)$_5$Nb(c) | 871.5±0.4 | 337.9±0.6 | 19.2±2.5 | — | 318.7±2.6 | 100.3±2.0 |
| (C$_2$H$_5$O)$_5$Nb(l) | 1642.6±0.4 | 378.6±0.6 | — | 18.9±2.0 | 359.7±2.1 | 99.8±1.0 |
| (n-C$_3$H$_7$O)$_5$Nb(l) | 2426.4±0.8 | 406.7±1.0 | — | 24.4±1.6 | 382.3±1.8 | 99.8±2.0 |
| (CH$_3$O)$_5$Ta(c) | 878.3±0.4 | 349.0±0.6 | 21.1±3.2 | — | 327.9±3.3 | 105.2±2.0 |
| (C$_2$H$_5$O)$_5$Ta(l) | 1647.3±0.5 | 391.8±0.7 | — | 18.9±2.0 | 273.9±2.1 | 105.5±1.0 |
| (n-C$_3$H$_7$O)$_5$Ta(l) | 2430.2±0.8 | 420.7±1.0 | — | 26.6±2.1 | 394.1±2.3 | 105.2±2.0 |

Comparison of the RO–M bond dissociation energies in Table 19 with the RO–V value in Table 17 indicates that

$$\bar{D}(RO\text{–}V) < \bar{D}(RO\text{–}Nb) < \bar{D}(RO\text{–}Ta).$$

Thus, as in other cases, the RO–M bond dissociation energy increases with atomic number of the metal.

## VI. CONCLUSION

The most reliable values for the enthalpies of formation $\Delta H_f^\circ$ of organic compounds of transition metals and the mean bond dissociation energies $\bar{D}$ calculated from them are assembled in Tables 20–23. The experimental results collected in them and illustrated by Figs. 1–4 reveal corresponding rules for the mean energy of dissociation of the chemical bonds formed by transition metals in their organic compounds.

Table 20. Thermochemical parameters (kcal mole$^{-1}$) of carbonyl compounds of transition metals.

*This column gives either $\Delta H_f^\circ$(c) or $\Delta H_f^\circ$(l), the appropriate symbol—(c) or (l)—being placed immediately after the formula of the compound.

1. For a given ligand the mean dissociation energy of its bond with a transition metal increases with the atomic number of the metal in a given group of the Periodic System. This energy is considerably smaller for transition metals of the first series than for those of the second series, whereas metals of the second and third series usually have closely similar values. The interest of this rule established by the Reviewers [61,70,77,78,80,111] is enhanced by the fact that non-transition elements exhibit the opposite relationship: the mean energy of dissociation of the bonds formed by an element with a given radical diminishes with increase in the atomic number of the element down a group in the Periodic System [79].

2. For a given transition metal M we find in all cases that

$$\bar{D}(M-OR) > \bar{D}(M-C_5H_5) > \bar{D}(M-C_6H_6) > \bar{D}(M-CO).$$

3. Any effect of alkyl substituents in the benzene ring in diarenechromium compounds on the mean chromium–ligand bond dissociation energy lies within the experimental error of its determination [77,98].

4. In the series—vanadium, chromium, manganese, and iron—the mean methyl–cyclopentadienyl bond dissociation energy depends on the atomic number of the element qualitatively in the same way as does the enthalpy of atomisation of the metal (Fig. 5). This evidently means that the specific electronic structure of atoms of 3*d* elements has a qualitatively similar influence on $\pi$-bond formation in sandwich compounds and on that of a metallic bond in the elements. Despite the closely similar enthalpies of atomisation of iron, cobalt, and nickel (Table 1), however, the energy of dissociation of the Fe–$C_5H_5$ bond exceeds by 8 kcal mole$^{-1}$ the value of $\bar{D}$(Co–$C_5H_5$), which in turn is 5 kcal mole$^{-1}$ larger than $\bar{D}$(Ni–$C_5H_5$). A correlation between $\bar{D}$(M–$C_5H_5$) and the enthalpy of atomisation of the metal is observed also in a series of tricyclopentadienyl compounds of rare-earth metals—lanthanum, praseodymium, thulium, and ytterbium (Tables 1 and 13).

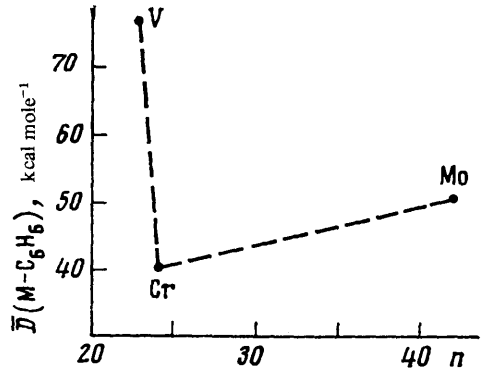

Figure 3. Variation of mean M–$C_6H_6$ bond dissociation energy with atomic number of metal.

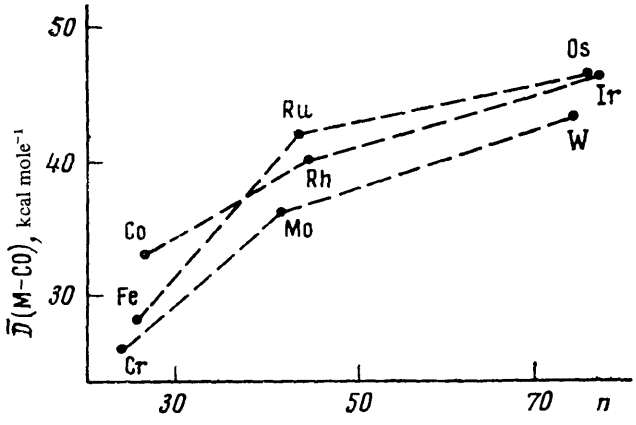

Figure 1. Variation of mean M–CO bond dissociation energy with atomic number of metal.

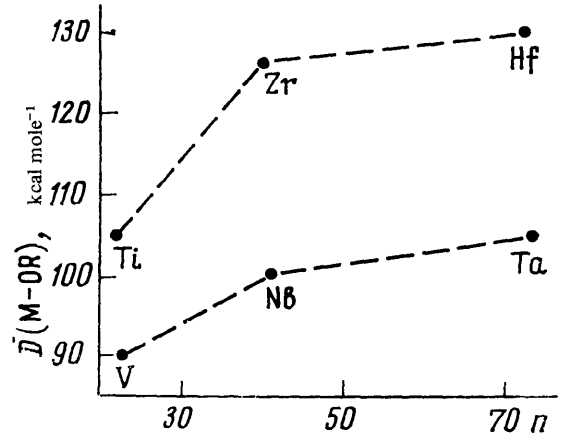

Figure 4. Variation of mean M–OR bond dissociation energy with atomic number of metal.

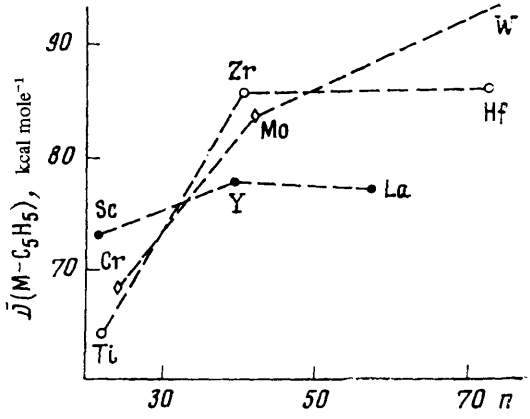

Figure 2. Variation of mean M–$C_5H_5$ bond dissociation energy with atomic number of metal.

Armstrong and his coauthors[112] have recently used the CNDO–MO method to describe the electronic properties of unsubstituted metallocenes of transition metals of the 3*d* series. They have calculated the charges on the metal atoms and the degree of completion of their orbitals; they have also computed the metal–carbon bond orders, which they assume[112] to be a quantitative measure of the interaction between metal and ring. According to the negative charges on the metal atoms in these compounds in the ground state the metals form the sequence

Fe>Cr>Co>Ni>V>Mn;

and according to the bond orders the sequence

Fe>Cr>Mn>V>Co>Ni,

whereas the experimental values of $\bar{D}$(M–$C_5H_5$) yield

V>Fe>Cr>Co>Ni>Mn.

Hence it is only for the series

$(C_5H_5)_2Fe$, $(C_5H_5)_2Cr$, $(C_5H_5)_2Co$, $(C_5H_5)_2Ni$

that a qualitative correspondence exists between the trend of variation in the experimental mean M–$C_5H_5$ bond dissociation energy and the bond order calculated from the

electronic structure of the metallocene. No analogous calculations have yet been made for other series of organic compounds of transition metals[112]. It must be supposed that further extension of experimental thermochemical investigations of these compounds, together with the development of quantum-mechanical calculations of the electronic characteristics of their molecules, will provide a deeper insight into the laws governing the energy parameters of organic compounds of metals.

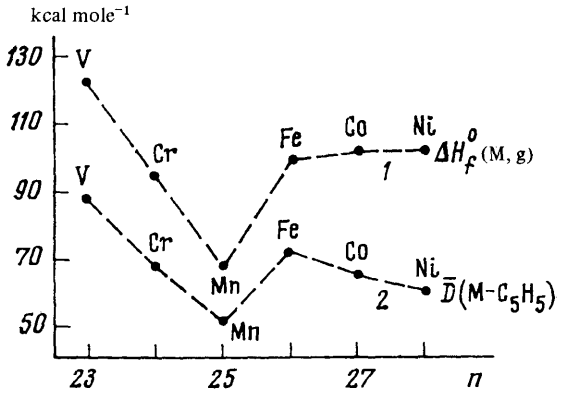

Figure 5. Influence of atomic number of metal in the 3*d* series of the Periodic System on: 1) enthalpy of atomisation of metal; 2) mean M–$C_5H_5$ bond dissociation energy.

# Structural Aspects of Solid-phase Polymerisation

V.E.Shklover, N.G.Bokii, and Yu.T.Struchkov

The two main mechanisms of this new method—polymerisation in non-crystalline, armorphous zones and topochemical polymerisation—are closely connected with the morphology of the products. Especially detailed attention is paid to examples of topochemical polymerisation, by means of which it is possible in several cases to obtain single crystals of polymers. A list of 94 references is included.

III. Polymerisation of monomers with multiple bonds 712

## I. INTRODUCTION

Whereas the polymerisation of monomers in the liquid phase has been well studied, solid-phase polymerisation has attracted the attention of research workers comparatively recently. Such reactions should differ significantly from the corresponding reactions in the liquid, since their course is largely determined by the environment and by the orientation of the monomer molecules in the crystal. Some of the most complete surveys of various aspects of the extremely complicated process of solid-phase polymerisation are listed here[1-6]. The present Reviewers have not attempted complete coverage of all the published information on solid-phase polymerisation, but have confined their attention to structural and crystal-chemical aspects of the possibilities and extent of polymerisation in solid organic (and organometallic) compounds. For example, the Review does not consider channel polymerisation, a review of which[2] does not, unfortunately, pay due regard to the work of Soviet researchers.

The two main types of mechanism—topochemical polymerisation and polymerisation in non-crystalline zones—were first distinguished in a review[1]. Topochemical polymerisation consists in a direct transition from monomer molecules to polymer chains without disruption of the crystal lattice of the monomer and without formation of non-crystalline intermediates[1,7,8]. The opposite type of solid-phase polymerisation takes place in non-crystalline zones, formed at the monomer–polymer interface and resembling a melt or a gas phase in character. This yields an amorphous polymer, which may then crystallise. The concept of a topotactic process—i.e. one in which a solid phase is formed with its crystallographic directions related to those of the crystal of the initial substance—is used to describe reactions in the solid state irrespective of the mechanism of polymerisation: in other words, topotactic reactions involve an unambiguous correspondence between the lattices of the initial (monomer) phase and the resulting (polymer) phase.

A necessary condition for the occurrence of topochemical solid-phase reactions consists in maximum displacements of the equilibrium positions of atoms in the interacting molecules with sufficiently intense thermal motion (vibration). This is the fundamental principle of lattice-controlled reactions formulated by Schmidt[9,10], and by Kargin and Kabanov[1] in its application to solid-phase polymerisation. The molecules in a crystal of a monomer are separated by van der Waals distances, and are usually too far apart for direct formation of chemical bonds between them. Therefore the reactivity of a solid is determined in principle by the mobility of individual units of the crystal lattice, i.e. molecules. In order that polymerisation should take place by a topochemical mechanism the distances between active (reactive) atoms in neighbouring molecules firstly should not exceed a certain value, respectively[11] 4.0 Å for C...C and C...N, 3.95 Å for P...N, and 3.7 Å for C...O interactions. Monomers in whose crystals active carbon atoms of neighbouring molecules are 4.3–4.7 Å apart are unable to polymerise in the solid phase. From these results the maximum distance $R$ between atoms A and B in neighbouring molecules at which polymerisation in the crystal is still possible can be estimated as $R = R_A + R_B + 0.5$ Å, where $R_A$ and $R_B$ are the van der Waals radii of atoms A and B. Secondly, solid-phase polymerisation is more probable, under otherwise similar conditions, with shorter than with longer distances between the reactant atoms in the crystal[12]. We must mention that this work[11,12] was concerned with the dimerisation of molecules, which in some cases can be regarded as a first step in polymerisation.

In the solid phase the actual polymerisation may be followed by relaxation processes, which change the morphology of the polymer formed initially[6,8]. This complicates the correlation between the mechanism of polymerisation and the morphology of the polymer obtained.

In order to make the account of solid-phase polymerisation more systematic, we shall discuss separately the solid-phase polymerisation of cyclic monomers and of unsaturated monomers containing multiple bonds. Both topochemical and non-topochemical polymerisation can take place in either group of monomers. The same division has been used previously[4].

## II. POLYMERISATION OF CYCLIC MONOMERS

A mechanism based on the arrangement of the molecules in a crystal of the monomer was suggested[8] for the solid-phase polymerisation of such cyclic monomers as e.g. trioxan and hexamethylcyclotrisiloxane. These molecules form stacks (Fig. 1) with the number of contacts between atoms of adjacent molecules in a stack larger, and the corresponding intermolecular distances shorter, than those between molecules in different stacks. Therefore polymerisation takes place in a stack with ring cleavage to form extended polymeric helices.

Another limiting case is the polymerisation of monomers in layers of molecules. This should yield planar zigzag molecules.

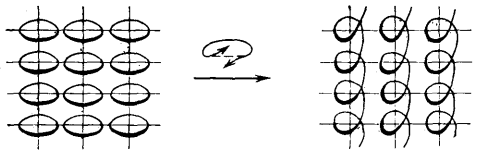

Figure 1. Polymerisation of cyclic molecules, present as stacks in the monomer crystal, to form helical polymer chains.

## 1. Oligomers of Formaldehyde

The action of $\gamma$-rays on single crystals of cyclic oligomers of formaldehyde—1,3,5-trioxan (TOX), 1,3,5,7-tetroxocan (TEX), 1,3,5,7,9-pentoxecan (POX), and 1,3,5,7,9,11-hexoxodan (HOX)—leads to polymerisation with cleavage of the ring and formation of a crystalline polyoxymethylene (POM)† (Table 1).[13-15] In all cases the polyoxymethylene chain grows in certain crystallographic directions of the monomer crystal: i.e. a quite definite mutual orientation is exhibited by the crystallographic directions of monomer and polymer crystals. Thus the polymerisation of these monomers is a topotactic process.

† Only the trigonal modification of polyoxymethylene is formed in all cases other than in the polymerisation of the hexoxodan (see later).

The possibility of obtaining macrocrystals of polyoxymethylene by the polymerisation of crystals of the trioxan has been known for a long time[16-18]. Morphological investigations have shown that, except with gaseous surface initiation, the polyoxymethylene consists of crystalline fibres well oriented both mutually and with respect

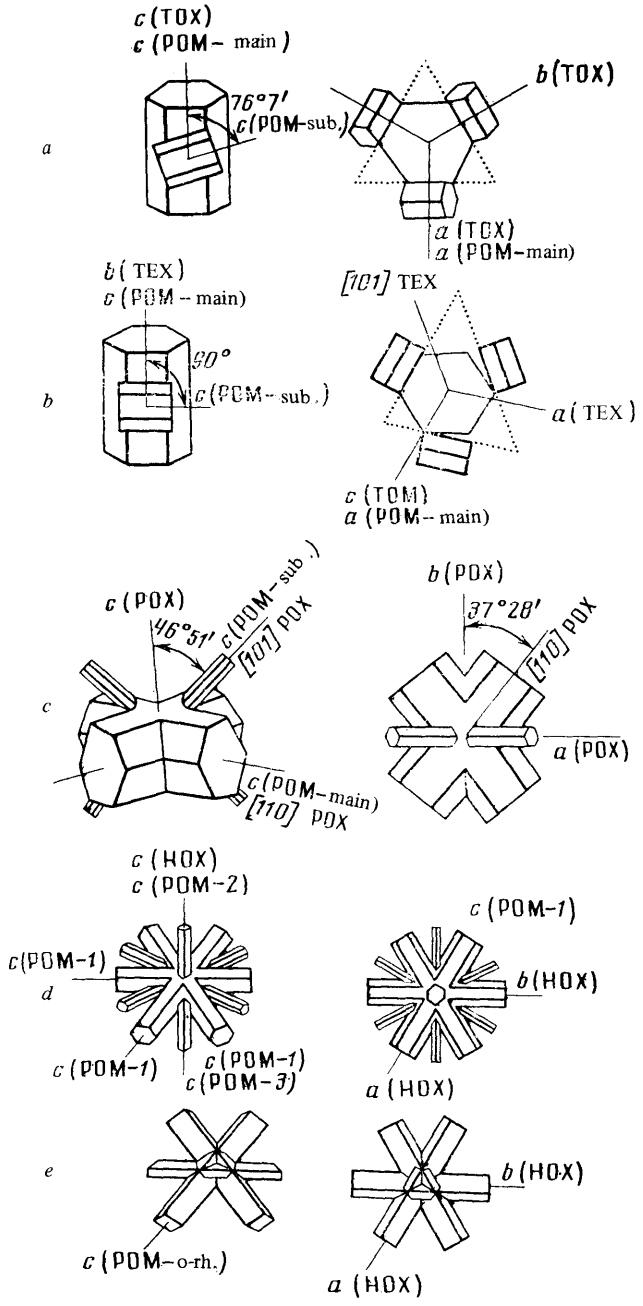

Figure 2. Diagram showing orientations of crystals of trigonal polyoxymethylene relative to crystals of: *a*) trioxan; *b*) tetroxocan; *c*) pentoxecan; *d*) hexoxodan; *e*) orthorhombic polyoxymethylene relative to a hexoxodan crystal. The dotted lines (*a* and *b*) show the relative orientations of the subcrystals.

to the crystallographic directions of the single crystal of the monomer[6,18]. Polyoxymethylene crystals obtained by solid-phase polymerisation possess unusual physical properties in comparison with crystals obtained from solutions or melts[6,19]. It was suggested[20,21] that those obtained by the solid-phase polymerisation of trioxan consist of elongated chains. A serious difficulty in studying the relation between the orientation of the growing fibres and the mechanism of the formation of polymer chains in a crystal matrix has been twinning of the polyoxymethylene: i.e. formation of a crystal having the predominant orientation (henceforward termed the "main crystal") is accompanied by that of crystals growing in other preferred directions[13,22]. The volume of such "subcrystals" becomes negligible when the temperature of polymerisation is raised. The subcrystals disappear also when the polymer is heat-treated at 170°C.[23]

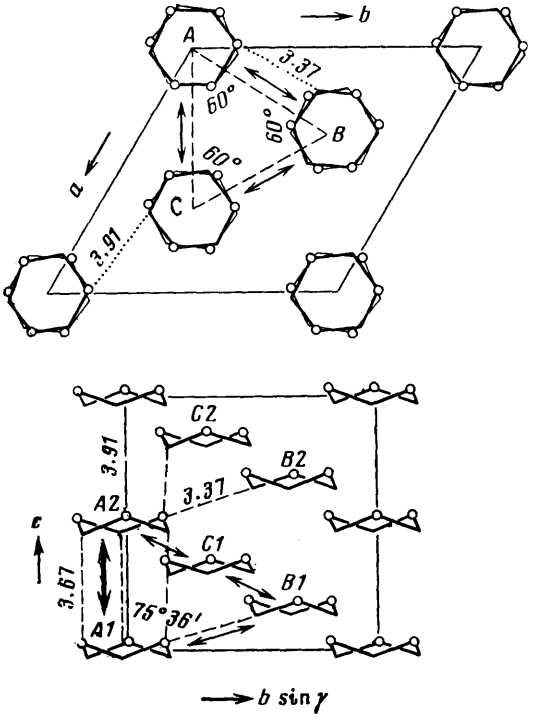

Figure 3. Packing of molecules in a crystal of trioxan. The thick and thin double arrows show the directions of the polymer chains in the main polyoxymethylene crystal and its subcrystals respectively. As also in Figs. 4, 6, and 7, the open circles indicate oxygen atoms.

The *c* axis of the main crystal of polyoxymethylene (the axis of the polymer chain) coincides with that of the initial trioxan crystal, but the (100) plane of the polymer is perpendicular to the *a* axis of the monomer (Fig. 2*a*). The *c* axes of the subcrystals are inclined to that of the main crystal at an angle of 76°7′, and their (100) planes are parallel to the (100) plane of the latter; the relative arrangement of the subcrystals corresponds to threefold axial symmetry. The tetroxocan can be polymerised[13] by precisely the same methods as with trioxan, but the morphology of the resulting polyoxymethylene is somewhat different: the *c* axis of the polymer (the axis of the chain) is parallel to the *b* axis of the monomer; and the *a* axis of the polyoxymethylene is parallel to the *c* axis of the tetroxocan (Fig. 2*b*). As in the polymerisation of trioxan, the X-ray diffraction patterns of the polyoxymethylene obtained from tetroxocan have additional, weaker reflections, indicating the formation of twin subcrystals in addition to the main crystal, but their orientation relative to the latter is different: the *c* axes of the subcrystals are perpendicular to that of the main crystal, and their (100) planes are parallel to the *c* axis of the main crystal. The directions of the *c* axes of the subcrystals are exactly parallel to the [100] (*a* axis), [001] (*c* axis), and [101] directions of the tetroxocan crystal. The twinned structure of the crystalline polyoxymethylene fibres is lost if polymerisation is conducted at temperatures above 80°C (and also when the polymer is annealed). In spite of this, however, density fluctuations are preserved in directions perpendicular to the axes of the polyoxymethylene macromolecules.

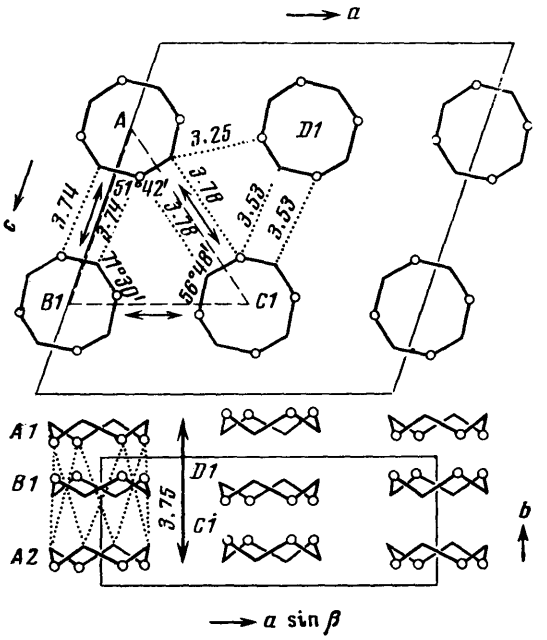

Figure 4. Packing of molecules in a crystal of tetroxocan. The thick arrow (below) and the thin double arrows (above) show the directions of the polymer chains of the main crystal and the subcrystals respectively.

Trioxan and tetroxocan molecules are stacked in the direction of growth of the polymer chain of the main crystals in such a way that the carbon atoms of one molecule are relatively close to the oxygen atoms of the neighbouring molecule (Figs. 3 and 4). The trioxan crystal includes three equivalent C...O distances of 3.67 Å in this direction (the *c* axis), and the tetroxocan crystal eight C...O distances of 3.75 Å (in the direction of the *b* axis).

**Table 2.** Parameters of the molecular packing of trioxan, tetroxocan, and pentoxecan in certain crystallographic directions (see Figs. 3, 4, and 6).

*Two notations—directions between centres of gravity of molecules and crystallographic—are used. Where they coincide, both are given.

**Direction of polymer chain of main crystal.

***Direction of polymer chain of subcrystal.

****These lengths may differ somewhat from the repeat distances in the corresponding crystallographic directions. For example, the distance between the centres of gravity of the tetroxocan molecules $A1$ and $A2$ is 4.18 Å, but the repeat distance in the [010] direction (along the $b$ axis) is 4.16 Å.

*****Distance per monomer unit if polymerisation occurs in the given direction.

******Area per molecule perpendicular to the given direction.

Table 2 shows that the distances between the centres of gravity of the molecules are shorter in these directions ($A1...A2$ and $A...B$ respectively, both of 4.18 Å) than in others. This should result in maximum probability of interaction between molecules in these directions of the monomer crystals.

Trioxan crystals belong to the polar class $C_{3v}$, so that the vectors of the dipole moments have the same orientation relative to the $c$ axis. Such a structure, involving strong dipole interaction, tends to favour polymerisation[24]. Tetroxocan crystals belong to the non-polar class $C_2$, but molecules arranged along the $b$ axis, the preferential direction of polymer growth, form the same stacks as in trioxan. It is interesting that X-ray examination indicates that thermal motion in the tetroxocan crystal is most intense precisely in the direction of the $b$ axis[14]. The shortest C...O distance (3.37 Å) in trioxan is found between molecules $A1$ and $B1$ (Fig. 3). Subcrystals are formed in this direction and also in the equivalent $B1...C1$ and $C1...A2$ directions. Analysis of the reflection intensities on the X-ray patterns showed that the proportion of each of the subcrystals was ~15%, giving a total of ~45% for all subcrystals[14]. In the tetroxocan crystal the closest intermolecular contacts occur in the directions of the $a$ and $c$ axes, but such contacts are few. Thus the growth of polymer chains in this direction is explained by the larger number of C...O collisions during thermal motion and by the dipole interaction in the same direction.

The distance between monomer units along the axis of the polyoxymethylene helix is 1.93 Å, whereas in a "monomeric" crystal of tetroxocan, for example, four monomer units fit into the repeat distance of 4.18 Å along the $b$ axis, so that one monomer unit occupies only 1.05 Å. This discrepancy is smaller in the trioxan crystal, 1.39 Å per monomer unit in the direction of the $c$ axis. However, the form of the "monomeric" crystals of trioxan and tetroxocan remains unchanged on polymerisation. Resolution of this contradiction depends on elucidating the role of the subcrystals in polymerisation. The distance of 1.87 Å per monomer unit of trioxan in the $A1...B1$ direction‡ (the direction in which subcrystals are formed) is closely similar to the 1.93 Å between monomer units along the axis of the polyoxymethylene helix; furthermore, the cross-section of a molecule perpendicular to the $A1...B1$ direction is similar to that of the helix perpendicular to its axis (19.0 and 17.3 $Å^2$). Therefore the development of polymerisation in $A1...B1$ direction causes only slight stress in the trioxan crystal and seems adequate for relieving the stresses produced by growth of the main crystal[21]. At high temperatures the latter stresses can be removed by the strong thermal motion[25], with decrease in the number of subscrystals.

A relation has been discovered between the direction of dislocations in trioxan crystals and the direction of growth of polyoxymethylene[26]. If dislocations in trioxan favour polymerisation, as in many other crystalline monomers[27], a mechanism is possible in which a short polyoxymethylene chain formed initially is oriented along a dislocation, whose space it uses for its growth[6]. The formation of dislocations may well depend on a volume deficiency arising on polymerisation in the direction of the $c$ axis in the trioxan crystal[28]. The growth of polymerisation may lead to further development of dislocations, so that these two structure-dependent processes develop in parallel.

Two alternative molecular models of the structure of crystalline polyoxymethylene fibres have been suggested[6] in connection with the molecular mechanism of the solid-phase polymerisation of trioxan and the dampening effect of subcrystals. In the first model the difference in orientation between individual segments of the polymer chain (Fig. 5$a$) leads to the appearance of differently oriented

‡ Polymerisation does not occur in the $A1-C1$ direction, which would appear suitable with terms of the distance per monomer unit and the cross-section of the molecules, because of the large C...O distances (Table 2).

crystallites, which form the main crystal and the subcrystals[29,30]. On the other hand, microfilaments may consist entirely of segments having elongated chains and segments having "folded" chains (Fig. 5*b*).[31] The former model (Fig. 5*a*) is to be preferred, and provides a better explanation of the behaviour of polyoxymethylene when annealed.

As along the *c* axis in trioxan, the packing of tetroxocan molecules along the *b* axis is too dense for a uniform polyoxymethylene helix to be formed in this direction without additional displacement of molecules. Furthermore, the cross-section of the tetroxocan molecule is considerably larger than that of the polymer helix (Table 2). About 50% of the molecules in the series of polymerising along the *b* axis are forced to move from their lattice positions during polymerisation[26,32].

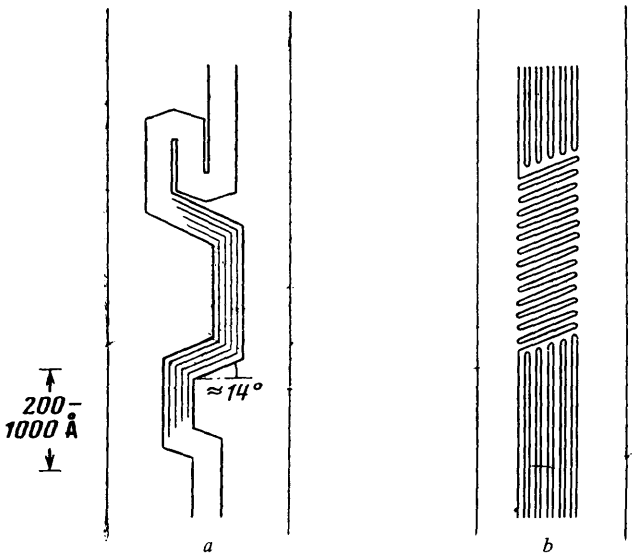

Figure 5. Alternative models (*a* and *b*) of the structure of crystalline polyoxymethylene fibres obtained by the solid-phase polymerisation of trioxan.

In the polymerisation of pentoxecan[14,33] the axis of the polymer chain (the *c* axis) lies in the [110] direction of the monomer, while the *a* axis of the polyoxymethylene is perpendicular to the *c* axis of the monomer (Fig. 2*c*). Since pentoxecan crystals belong to the orthorhombic system (Table 1), and the [110] and [$\bar{1}$10] directions are equivalent, polymer chains grow in both directions, and a twinned crystal is formed. High exposures lead to the appearance of new, considerably weaker and diffuse polyoxymethylene reflections on the X-ray diffraction patterns, which indicates other directions of growth of the polymer crystals (main crystal and subcrystals). The *c* axes of the subcrystals lie in the equivalent directions [101] and [$\bar{1}$01], while the *a* axes are located in the *ac* plane of pentoxecan, forming angles of 46°51′ with its *a* axis. Columns of molecules can formally be distinguished along the *c* axis in the pentoxecan crystal (Fig. 6), but the shortest C...O distance between these molecules (6.79 Å) is too large for chemical bonding. The C...O distances in the directions of the *a* and *b* axes are also large (4.76 and 6.43 Å respectively—Table 2). Interaction of monomer molecules with the formation of chemical bonds between them can therefore be expected only in the diagonal directions [110], [101], and [011]. In the [011] direction, however, there are two kinds of distances between centres of gravity of molecules: $A...C = 5.74$ Å and $B...D = 7.48$ Å, giving an average of 6.61 Å (Fig. 6). Only between the molecules *B* and *D* are the C...O distances sufficiently short; such close contacts are absent between molecules *A* and *C*, so that polymerisation in the [011] direction is impossible. Growth of main crystal and subcrystals in the [110] and [101] directions respectively is probably explained by the smaller difference between the distances per monomer unit in polyoxymethylene (1.93 Å) and in these directions in pentoxecan (1.35 and 1.12 Å—Table 2).

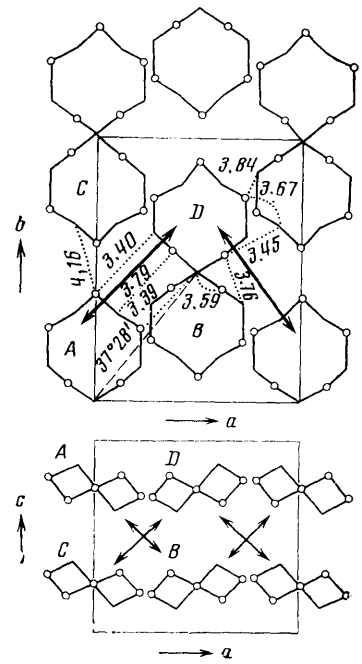

Figure 6. Packing of molecules in a crystal of pentoxecan. Thick and thin double arrows show the directions of the polymer chains in the main crystal and the subcrystals respectively.

X-Ray diffraction has revealed three orientations of the trigonal polyoxymethylene crystals formed by the polymerisation of hexoxodan. These crystals are denoted POM-1, POM-2, and POM-3 in order of their diminishing content in the specimen determined by X-ray diffraction[15]. The POM-1 crystals are elongated (the *c* axis) in the equivalent directions [100], [010], and [1$\bar{1}$0] of the trigonal hexoxodan crystal (Fig. 2*d*). The POM-3 crystals are elongated in the three equivalent directions [210], [$\bar{3}$20], and [1$\bar{3}$0]. The axis of the chain in the POM-2 crystal is parallel to the *c* axis of the monomer, so that POM-2 grows only in one direction. The powdery character of the polyoxymethylene obtained from hexoxodan is a consequence of the variety of its growth orientations. It must be pointed out that Fig. 2 shows only the directions of the crystallographic axes, and bears no relation to the actual

morphology of polyoxymethylene crystals observed e.g. by electron microscopy. In addition, an orthorhombic modification of polyoxymethylene (POM-orh.) is also formed in the polymerisation of hexoxodan. This is the first observed case of an oriented orthorhombic modification of polyoxymethylene. The axis of the chain (the *c* axis) is parallel to that of POM-1 (Fig. 2*e*). The polyoxymethylene chain forms a 9/5 helix in a trigonal crystal and a 2/1 helix in an orthorhombic crystal: i.e. the helices differ little in structure and especially in their radii. The [110] direction of POM-orh. is parallel to the *a* axis of POM-1, with very similar arrangements of the molecules in the two modifications. The reasons why two different modifications of polyoxymethylene grow in the same crystallographic direction in hexoxodan are obscure.

Table 3. Intermolecular distances *d* in the structure of hexoxodan*.

| C(4) I...O(1) III | 3.94 | | |

*Contacts I...II and I...III correspond to the [211] and [100] directions respectively (see Fig. 7).

The normal amplitudes of the thermal vibrations of atoms in a partly polymerised specimen of hexoxodan at room temperature, when polymerisation is fairly rapid, show that polymerisation is not accompanied by disorientation of monomer molecules that have not reacted. The twelve-membered rings that open and then combine into polymer chains should be in direct contact, at least in the initial stages of polymerisation.

It is significant that in many cases such characteristics of polymerisation as the limiting conversion, activation energy, etc. are not reproducible. Furthermore, reflections due to polyoxymethylene crystals are observed on X-ray diffraction patterns even below 5% conversion. This suggests that polymerisation is not a microscopically homogeneous process, but occurs at a multitude of individual foci, which may be for instance crystal defects.

With respect to intermolecular distances the [211] and [100] directions appear to be the most advantageous for the polymerisation of hexoxodan (Fig. 7 and Table 3). However, the initial molecule contains six oxymethylene groups, although the distance between the centres of molecules in the [211] direction is only 5.93 Å. The molecules are obviously arranged too close together in this direction for unstressed polymerisation. The formation of polymer chains not only in the [100] but also in the [210] and [001] directions, in which close C...O contacts are absent, may well be possible for monomers that polymerise by a non-topochemical mechanism, although no other such examples are known. Fig. 8, illustrating the mutual orientation of monomer and polymer molecules, shows that the arrangement of centres of gravity of each of the polymers—POM-1, POM-2, and POM-3—mimics quite well the initial lattice, which has not always been observed in trioxan and tetroxocan crystals. Perhaps study of the role of dislocations will produce clearer ideas on the mechanism of the polymerisation of hexoxodan.

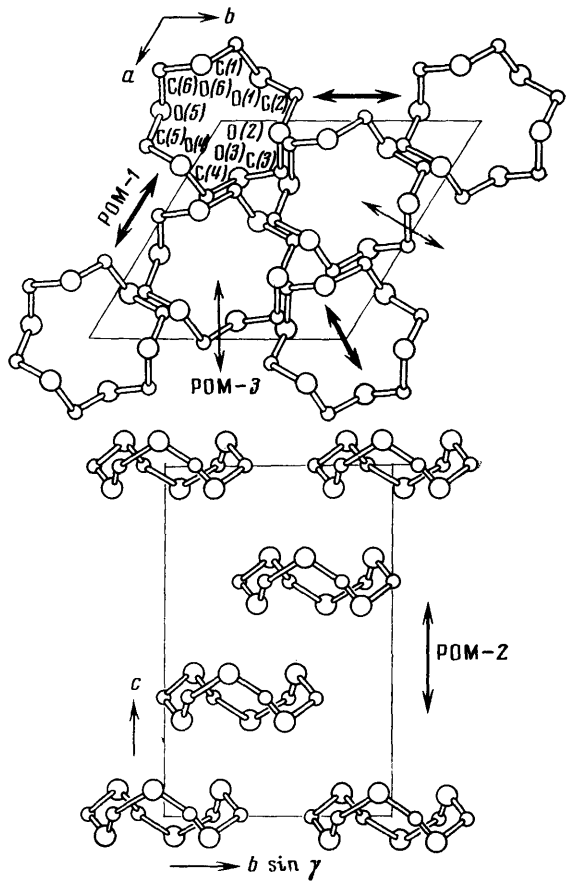

Figure 7. Two projections of the packing of molecules in a crystal of hexoxodan. The arrows show possible directions of the polymer chains.

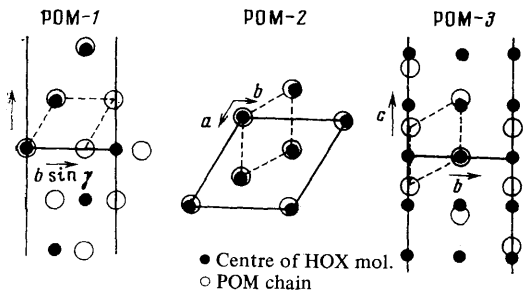

Figure 8. Diagram of distribution of HOX, POM-1, POM-2, and POM-3 molecules in projections along the axes of the polymer chains. Full and broken lines show the unit cells of hexoxodan and polyoxymethylene respectively.

In conclusion we note that the orientation and the structure of polymer crystals is determined by many factors, that transition from the initial monomer crystal to the polymer crystal involves many stages, and that it is quite difficult to establish precisely the role of the structure of the initial crystal in each stage, even if the overall process is topotactic [15].

## 2. Other Cyclic Monomers

Introduction of an initiator—potassium trimethylsilanoxide—enables hexamethylcyclotrisiloxane, as well as the *cis*- and *trans*-isomers of trimethyltriphenylcyclotrisiloxane, to be polymerised in the solid phase at room temperature or above [34]. Recent X-ray structural studies on hexaphenylcyclotrisiloxane [35], the above *cis*- and *trans*-isomers [36,37], and hexamethylcyclotrisiloxane [38] have led to several interesting conclusions on the possibilities and the mechanism of the solid-phase polymerisation of cyclotrisiloxanes. The organic derivatives have a characteristic layer structure (Fig. 9), with large interlayer spacings in trimethyltriphenylcyclotrisiloxane (9.48 and 9.52 Å in the *cis*- and *trans*-isomers). This completely eliminates the possibility of initiation of polymerisation between the layers, so that the polymer chain must develop in the plane of a layer, in which intermolecular Si...O contacts are sufficiently close (e.g. 4.28 and 4.51 Å in the *trans*-isomer). Thus the above "stacking" scheme of the polymerisation of cyclic monomers (suggested in particular even for hexamethylcyclotrisiloxane), according to which monomer molecules are arranged in piles in the crystal and polymerisation leads to the formation of elongated polymer helices, cannot be applied to these trisiloxanes [8].

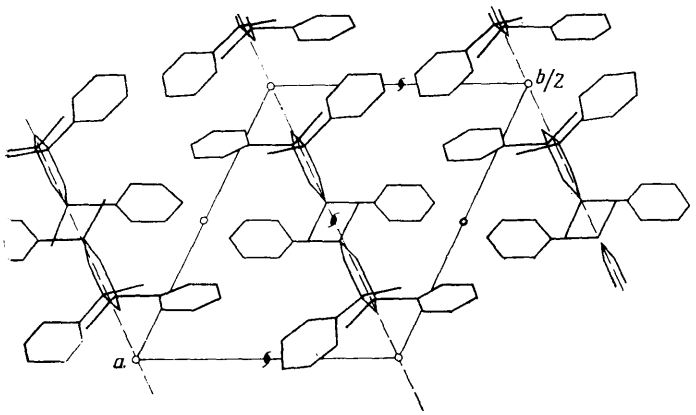

Figure 9. Packing of molecules in a crystal of *trans*-trimethyltriphenylcyclotrisiloxane. The broken lines show the direction of the layers of molecules.

Topochemical polymerisation by a single crystal of cyclic bithiazyl $S_2N_2$ has recently yielded an analytically pure single crystal of polythiazyl $(SN)_x$ (Fig. 10), which acts as a unidimensional metallic conductor [39-42]. The macromolecules have a completely planar structure, which with a topochemical mechanism can be achieved only by polymerisation in the layer. This evidently provides experimental confirmation of solid-phase polymerisation with ring cleavage occurring in layers of molecules.

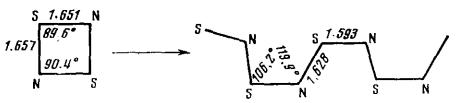

Figure 10. Polymerisation of bithiazyl. Bond lengths and angles obtained from X-ray examination of monomer and polymer crystals.

A thorough study has been made also of the polymerisation of 3,3-bischloromethyloxetan

and its analogues. It was suggested that this polymerisation is rigidly controlled by the lattice, since a highly crystalline and oriented polymer is formed [43,44]. But the formation of polymers when oxetans are exposed to X-rays leads neither to shifts in the reflections from the monomer crystals nor to the appearance of additional reflections, in contrast to for example the polymerisation of solid oligomers of formaldehyde [45] (above). X-Ray examination of the structures of bisiodomethyloxetan [46,47] and also of polybischloromethyloxetan [48] has shown that polymerisation should entail considerable displacement of the halogenomethyl groups. Such a transition must involve intermediate formation of amorphous zones. Hence the morphology and the orientation of products of the solid-phase polymerisation of oxetans are governed not by the actual mechanism of polymerisation but by secondary processes.

## III. POLYMERISATION OF MONOMERS WITH MULTIPLE BONDS

The solid-phase polymerisation of molecules containing double and triple bonds differs in many respect from that of heterocyclic monomers. Transition from a cyclic molecule to a linear unit in a polymer chain involves no change in the valency configuration of the atoms, whereas the polymerisation of unsaturated compounds is accompanied by rehybridisation of the interacting atoms of the initial molecules. The mechanics of growth of the polymer chain is also fundamentally different in the solid-phase polymerisation of cyclic and of unsaturated monomers: in the former case the gap between adjacent molecules in the crystal, joining together to form the polymer chain, is filled as a result of cleavage of the cyclic molecules and straightening-out of the monomer unit in the direction of chain growth; in the case of unsaturated monomers the distance between adjacent monomer molecules forming the polymer chain should contract by ~2 Å (the difference between the intermolecular distance and the interatomic bond length in the macromolecule [4]). The "lever" mechanism of the polymerisation of rigid rodlike molecules suggested by

Wegner[5] (Fig. 11) can be applied in the latter case. The molecules, in the form of small sticks with reactive functional groups at their ends, are stacked in the crystal in such a way that two reactive groups in adjacent molecules are ~3 Å apart. Polymerisation takes place without displacement of the centres of gravity of the molecules in the lattice, either by their gradual rotation proceeding from molecule to molecule or by simultaneous rotation throughout a stack. Reactions occurring in this way are termed *topochemical* in the narrow sense.

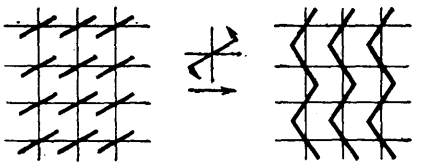

Figure 11. Simplified scheme of topochemical solid-phase polymerisation by the lever mechanism.

The solid-phase polymerisation of dienes (termed "four-centre polymerisation"), monomers containing triple bonds, and also certain other linear monomers with multiple bonds takes place by such a "lever" mechanism.

## 1. Four-centre Polymerisation

Molecules such as distyrylpyrazine (DSP) and derivatives of *p*-phenylenediacrylic acid§, packed "head to tail" in the crystal, yield polymers containing cyclobutane rings in the main chain and a completely ordered arrangement of substituents[49-54] (Fig. 12). Solid-phase polymerisation gives a product of exceptionally high crystallinity[55], but in solution an amorphous polymer is obtained.

Distyrylpyrazine molecules are arranged in the crystal in such a way that the relative positions and mutual orientation of the reactive double bonds are favourable for the formation of a cyclobutane ring; but crystals of another polymorphic modification (of undetermined structure) do not polymerise in the solid phase. Fig. 13*a* shows that the approximately planar distyrylpyrazine molecules are stacked along the *c* axis, which favours polymerisation in this direction. The shortest distance between the centres of double bonds in adjacent molecules is 3.94 Å (I*a*...II*b*, II*a*...III*b*, etc.). The next shortest distance, between double bonds of molecules in different stacks (5.42 Å), is too large for interaction[11]. It is therefore most probable that double bonds related by centres of symmetry react on irradiation (with the formation of cyclobutane rings), so that the polymer chains should grow in the direction of the *c* axis.

During polymerisation the X-ray diffraction pattern of distyrylpyrazine gradually changes into that of the polymer[51]. The mutual orientation of crystals of monomer and polymer has been established from the rotation photographs and the Weissenberg patterns of a partly polymerised crystal: the *a*, *b*, and *c* axes of the polymer are parallel to the corresponding axes of the monomer, but the characteristic elongation of spots on the X-ray patterns indicates some disordering of the polymer in the (001) plane. Since a single crystal of the monomer is converted by polymerisation into a polycrystal consisting of slightly disoriented fine blocks (crystallites), no X-ray structural analysis of the polymer has yet been made. Electron-microscopic study of polydistyrylpyrazine crystals has shown[56] that they consist of rodlike crystallites of square cross-sections about 1 μm thick, elongated in the direction of the *c* axis.

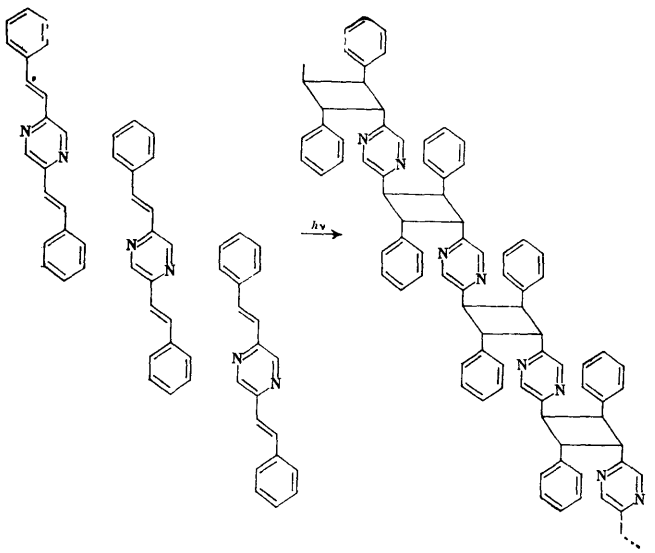

Figure 12. Four-centre photopolymerisation of dienes exemplified by that of distyrylpyrazine.

When crystals of distyrylpyrazine are exposed to light of wavelength exceeding 400 nm, polymerisation ceases at an intermediate stage: an oligomer having a mean degree of polymerisation of 5 is formed[57]. Comparison of the X-ray patterns of monomer and oligomer indicates that the latter, like the polymer, is well oriented, with its axes parallel to the corresponding axes of the monomer. The oligomer can be converted into the polymer by exposure to light of shorter wavelength. The degree of orientation of the polymer obtained from the oligomer is almost the same as that of the polymer obtained from the monomer. On conversion of the monomer into the polymer the *a* axis contracts by 11%, the *b* axis becomes 13% longer, and the *c* axis decreases by <2%. Thus the centre of gravity of the unit cell of the monomer is only slightly displaced in the direction of chain growth (the *c* axis), which is important for obtaining polymers in good yield.

The source of lattice deformations is the change in the distance between the double bonds I*a* and II*b* from the van der Waals value to the length of the σ bond in cyclobutane (1.56 Å).[58] Since the repeat distance along the *c* axis remains almost unchanged on polymerisation, the interaction of these double bonds leads to close contact of the

§ Dienes that polymerise by this mechanism are listed in Refs. 5 and 49.

second double bond II*a* with the double bond III*b*, as a result of which the excited molecule III reacts more readily with a double bond in II than in the next molecule IV. Fig. 13*b* shows how the polymer chain is superposed on the (010) projection of the monomer crystal; despite rotation of the central segment, displacement of the phenyl side-chains is insignificant.

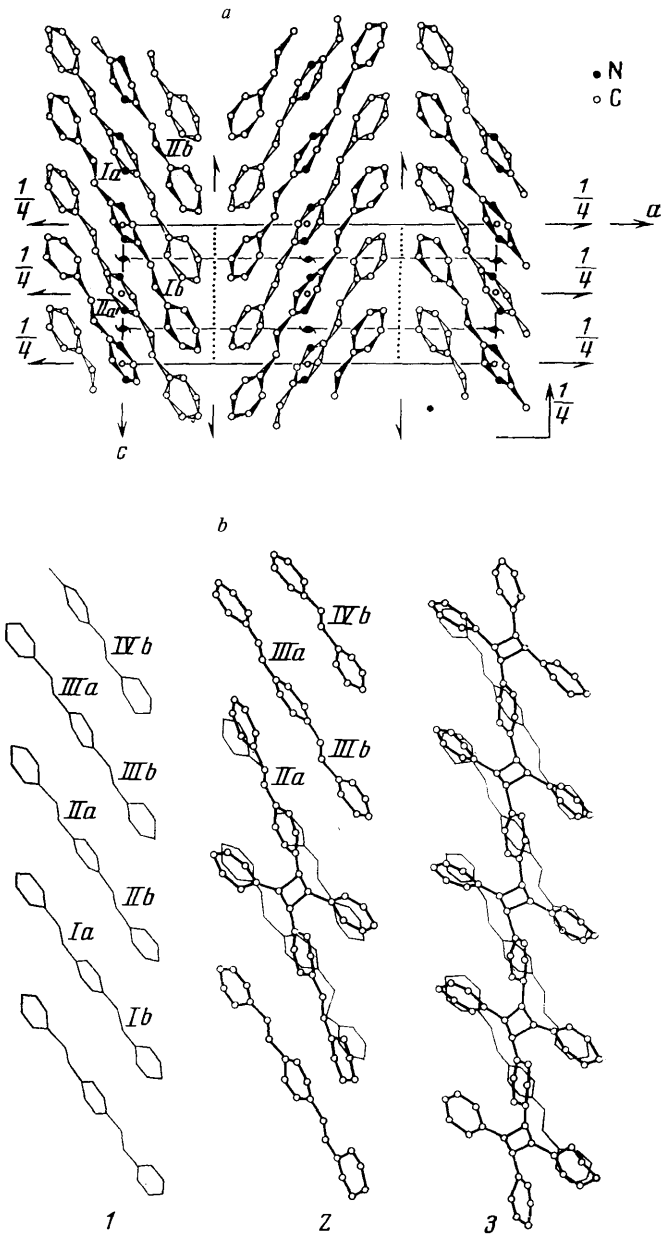

Figure 13. (*a*) Packing of molecules in a crystal of distyrylpyrazine. (*b*) Scheme of polymerisation of distyrylpyrazine shown by projections of the monomer: 1) alone; 2) combined with molecular model of dimer; 3) combined with molecular model of polymer.

Important results are obtained from a study of the behaviour of polydistyrylpyrazine on recrystallisation. The difference between the X-ray patterns of recrystallised and initial polymers[59] shows that the latter is formed under the control of the crystal lattice of the monomer and is not in the thermodynamically most stable form. It is extremely interesting that polydistyrylpyrazine undergoes thermal depolymerisation in high yield[53]. The scheme in Fig. 14 for the reversible interconversion of monomer and polymer is based[7] on thermodynamic and spectral investigations of the polymerisation–depolymerisation and a comparison of X-ray patterns obtained at various stages in these processes. Crystalline polydistyrylpyrazine is thermally more stable than the amorphous polymer, probably because the crystal lattice of the polymer protects the cyclobutane groups from thermal degradation by restricting local movement of the polymer chain.

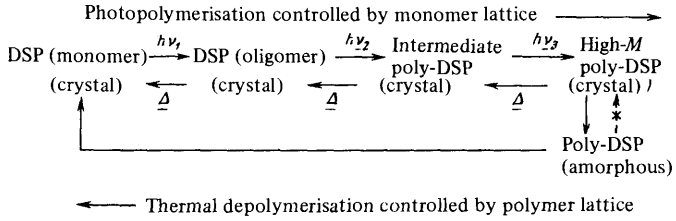

Figure 14. Scheme of reversible polymerisation of distyrylpyrazine (DSP).

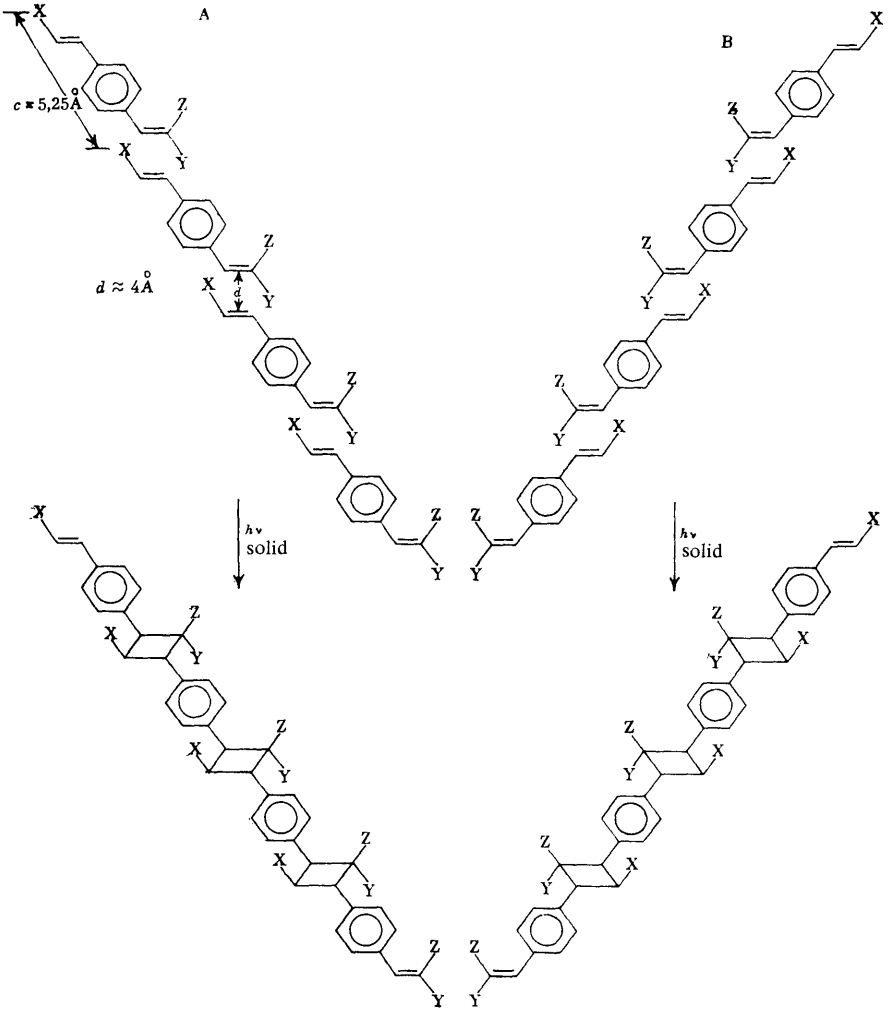
In connection with the growing interest in asymmetric synthesis by topochemically controlled reactions in a chiral crystal[5,60–64] a series of 1,4-photodimerising monomers has been obtained containing as substituents "chiral handles" promoting crystallisation of these monomers into asymmetric structures[65,66]. Dimers and polymers obtained from the monomers (Fig. 15) are in fact chiral, with optical rotation of opposite sign to that of the monomer. A racemic crystal of structure similar to that of one of the enantiomers A or B (Fig. 15)¶, but containing (in equal quantities) substituents X of opposite chirality, also yields an optically active polymer on exposure. On the other hand, replacement of the chiral groups in an optically active monomer by methyl groups enhances the optical activity of the polymer. Thus optical induction accompanying polymerisation is caused by the chiral influence of the environment of the reaction centre in the crystal, not by the chiral influence of the "chiral handles".

## 2. Polymerisation of Monomers with Conjugated Triple Bonds

The solid-phase polymerisation of monomers containing conjugated triple bonds, discovered by Wegner in 1968, is a classic example of topochemical polymerisation by a

¶ The optically active monomer (Fig. 15) and its racemate crystallise in the $P1$ space group with closely similar cell parameters.



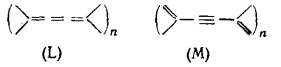


Figure 15. Structure and polymerisation in enantiomorphous crystals A and B. The suggested structure of the monomer is based on the parameters of the unit cell (molecular plane in the *ab* plane), and that of the polymer from n.m.r. data for the dimer and data for polydistyrylpyrazine.

lever mechanism [6,67-69]. The process is shown diagrammatically in Fig. 16. Equation (1) represents the formation of a polymer whose main chain, according to X-ray examination [70,71], is a planar conjugated system with a *trans*-arrangement of the substituents:

$$n\mathrm{R{-}C{\equiv}C{-}C{\equiv}R{-}R \rightarrow {-}\underset{\mathrm{R}}{\mathrm{C}}\left[=\underset{\mathrm{R}}{\mathrm{C}}{-}\mathrm{C}{\equiv}\mathrm{C}{-}\mathrm{C}\right]_n=\underset{\mathrm{R}}{\mathrm{C}}{-} \quad (1)$$

The distribution of bond lengths in the main chain (Fig. 17) is described better by M of the two possible structures

(L) (M)

for 1,4-addition products. The same distribution of bond lengths is suggested also by spectral investigation [72].

The polymerisation of diynes yields a completely ordered three-dimensional macroscopic single crystal of the polymer, in many cases of the same size as the single crystal of the monomer. For example, a polymeric single crystal weighing >1 g can easily be obtained from hexa-2,4-diynylene ditoluene-*p*-sulphonate [5]†. The polymerisation of colourless single crystals of diynes is usually accomplished by ultraviolet irradiation or by heating below the melting point, although other methods of initiation are possible, and is accompanied by a marked change in colour. Polymerisation does not take place in the melt or in solution [67].

Only imperfect microcrystalline aggregates of the polymers, often possessing a fibrous structure, are

† A list of diynes that polymerise in the solid phase will be found in Ref. 5.

obtained in the previous cases of the solid-phase polymerisation of trioxan and tetroxocan [13,14,16-18] and in four-centre photopolymerisation [55,56]. In these cases polymerisation is accompanied by breakdown of the initial monomer single crystal. This is due to the mechanism of polymerisation, which may be described as a phase transition characterised by stages of nucleation and growth of nuclei of the new (polymer) phase in a matrix of the initial crystal. This is known as heterogeneous solid-phase polymerisation. In homogeneous solid-phase polymerisation the polymer chains are "dissolved" in the matrix of the monomer crystal, and phase separation does not occur. The polymerisation of monomers containing conjugated triple bonds is such a homogeneous process [73].

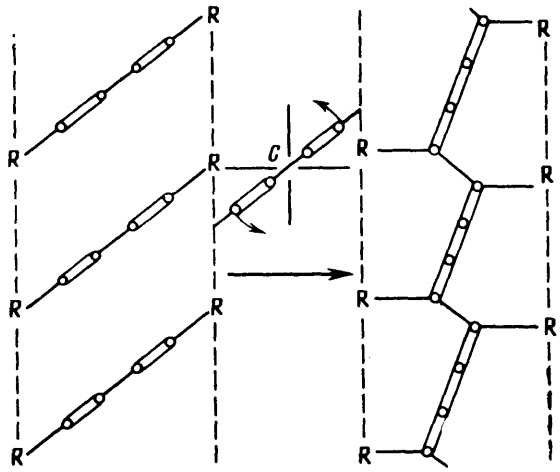

Figure 16. Polymerisation of conjugated diynes. Reaction involves rotation of monomer molecules about the centres of gravity *C*.

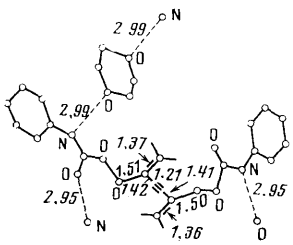

Figure 17. Structure of polymer obtained from hexa-2,4-diynylene bisphenylcarbamate. The broken lines show hydrogen bonds with neighbouring polymer chains and with molecules of dioxan of crystallisation.

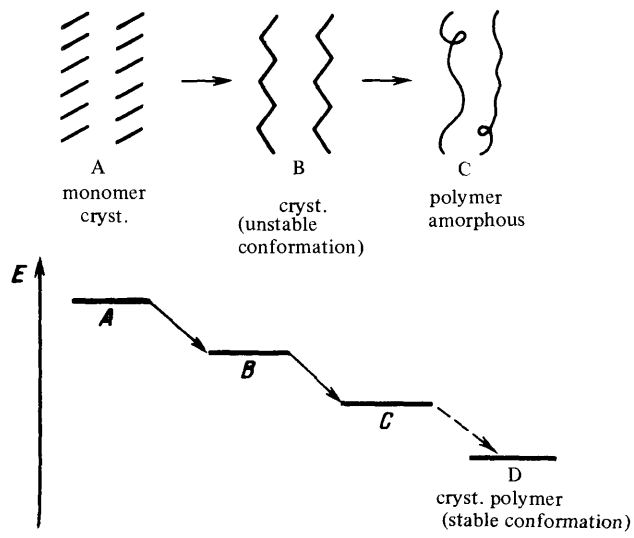
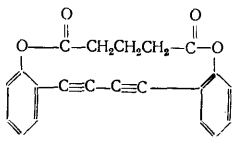
In the polymerisation of certain diynes no change in density takes place, and no appreciable quantity of amorphous polymer is formed, but monomer and polymer are completely isomorphous. Such isomorphism has been noted e.g. with hexa-2,4-diynylene ditoluene-*p*-sulphonate [74]. However, other diynes, e.g. hexa-2,4-diynylene bis-stearoylcarbamate, give polymers possessing only two-dimensional orientation. These phenomena can be related and explained by means of the simple scheme [8] shown in Fig. 18. We suppose that a monomer passes into a polymer topochemically, by lever polymerisation, the solid product being in a modification that is not in general the energetically most advantageous, since the molecules are in an unfavourable stressed conformation. This is the transition $A \rightarrow B$. State *D* is thermodynamically stable for the polymer. If the monomer lattice is disturbed sufficiently, e.g. because of the difference between its density and that of the polymer, or if unchanged monomer is removed, the macromolecules relax and pass into state *D*. This state is not usually achieved, for the mobility of molecules is limited at the usual temperatures of polymerisation or extraction. The polymer therefore passes into a vitreous state *C*. Clearly, lowering the temperature of polymerisation may result in fixation of state *B*. This may explain the observations that, when diethynyl *p*-phenylenediacrylate undergoes polymerisation below 5°C, the polymer modification corresponding to state *B* is "frozen in", whereas at about 30°C relaxation ensues with the appearance of an amorphous structure corresponding to state *C*. In the polymerisation of hexa-2,4-diynylene bisphenylcarbamate and ditoluene-*p*-sulphonate, however, the polymer formed topochemically corresponds to the thermodynamically stable modification. Polymerisation of the bis-stearoylcarbamate follows a different course, with the resulting polymer modification stable only in the presence of the monomer lattice. This involves "forced" isomorphism of monomer and polymer, in which the monomer structure is kinetically (but not thermodynamically) preferable, for the resulting polymer, to the polymer structure possessing minimum free energy. Therefore the lattice changes accompanying polymerisation are minimal.





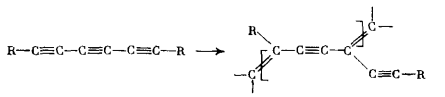


Figure 18. Relative stability of polymer chains in crystalline and amorphous polymer.

The possible isomerism of polymers obtained from cyclic diynes has been discussed[5]. If the monomer molecules are linked in the crystal only by translations, they should yield the chiral polymer shown diagrammatically in Fig. 19*a*. If, however, neighbouring molecules are linked in the direction of polymerisation by a reflecting glide plane, the achiral polymer of Fig. 19*b* should be formed, in which the side loops (rings) are alternately above and below the plane defined by the conjugated main chain. Crystals of the cyclic diyne

readily undergo photopolymerisation, but thermal polymerisation is very slow. X-Ray examination has shown that the polymer has the structure indicated in Fig. 19*b*. Unfortunately, it has not yet proved possible to select a crystalline modification of a cyclic diyne having translational symmetry only in the direction of polymerisation, although a fairly large number of reactive modifications of cyclic diynes have been described[5,75].

The solid-phase polymerisation of triynes is well known, and is easily detected from the spontaneous coloration of the monomer crystals[5,69]:

As with diynes, polymerisation is a consequence of 1,4-addition, with an acetylenic side-chain present in the monomer unit.

However, not all diynes and triynes undergo solid-phase polymerisation. The reactivity of monomers is largely determined by their packing, not by e.g. mesomeric or inductive effects. If a monomer can be obtained in different modifications, the latter usually exhibit different tendencies to undergo solid-phase polymerisation. Frequently only one modification polymerises in the solid phase, and the others do not. It is significant, for example, that crystals of hexa-2,4-diynylene bisphenylcarbamate polymerise only if they contain dioxan of crystallisation, which probably ensures that the packing of the molecules in a crystal is favourable for polymerisation[71]. Hexa-2,4-diynylene dibenzoate crystallises in two forms, one of which (S) can polymerise under the influence of high pressures, but the other (T) cannot[76]. Molecules are located at centres of symmetry and have the same conformation in both forms of crystals. However, whereas the C...C distances between triply-bonded atoms in adjacent molecules in the S form of crystal (4.02 Å) can be shortened by high pressures to the critical value at which covalent bonds are formed, the corresponding shortest C...C distance in the T form of crystal is 5.37 Å, which could not be shortened by pressure to the critical value.

Solid-phase polymerisation is possible when adjacent molecules in a crystal are arranged as shown in Fig. 20. The angle $\alpha$ between the translation relating the centres of gravity of adjacent reactant molecules and the direction of their conjugated bond system should be ~40°. The distance between the centres of gravity of neighbouring molecules is 4.7–5.2 Å, with an optimum of 4.9 Å for polymerisation: i.e. polymerisation is accompanied by minimal changes in the parameters of the unit cell.

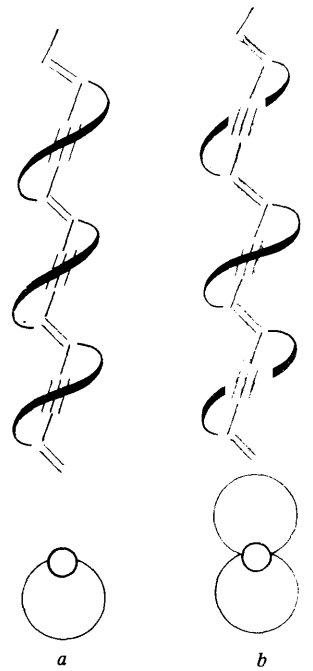

**Figure 19.** Structure of polymers obtained by the solid-phase polymerisation of cyclic diynes: *a*) chiral; *b*) achiral. Projections along the axes of the macromolecules shown at foot of diagrams.

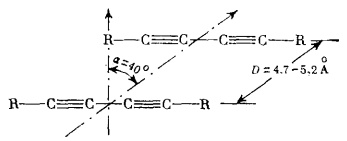

**Figure 20.** Arrangement of adjacent molecules in a stack in a diyne crstal undergoing solid-phase polymerisation, where $D$ is the distance between the centres of gravity of the molecules and $\alpha$ the angle between the axis of the molecule and the direction of translation relating neighbouring molecules in a stack.

In this connection it is very interesting to study the difference in reactivity between two substituted diacetylenes[77]: hexa-2,4-diynediol polymerises slowly in the solid phase, but diphenylbutadiyne hardly polymerises at all. Reactant molecules in a crystal of the former are related by the diagonal translation *ac*. The molecules are joined by hydrogen bonding in the direction of the *c* axis, but no hydrogen bonds are formed in the *ac* direction. The geometrical parameters $\alpha$ and $D$ (Fig. 20) are 5.34 Å and 41.4° in hexa-2,4-diynediol, and 6.04 Å and 50.9° in diphenylbutadiyne. Polymerisation of the first monomer should involve a contraction of 0.44 Å in the distance between the centres of adjacent reactant molecules, while the axes of the molecules should turn through 28°. The relative inactivity of the second monomer in the solid phase is attributed to the considerable displacement and

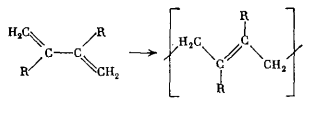
rotation of molecules necessary for polymerisation by 1,4-addition (respectively 1.14 Å and 37.5°). The distances between the terminal atoms of the reactive butadiyne groups are also different: 3.54 Å in the first monomer, and 4.69 Å in the second.

The relative arrangement of diyne molecules is dictated by the packing of lateral substituents. Reactive modifications should obviously be formed by diynes substituted by polar groups—hydroxyl, carboxyl, amide, and urethane—able to promote suitable orientation of the molecules in the crystal by dipole–dipole interaction or hydrogen bonding. A system of hydrogen bonds interconnecting neighbouring monomer units has been found[71] in a crystal of polymeric hexa-2,4-diynylene bisphenylcarbamate.

The parallel packing of adjacent benzene rings in the direction of the polymer chain in the crystal of poly-1,2-di(toluene-*p*-sulphonyloxymethyl)but-1-en-3-ynylene[70], which fixes the relative arrangement of neighbouring monomer units, is probably also a consequence of the dipole–dipole interaction of polar side-groups. Nevertheless, the presence of such groups is neither a necessary nor a sufficient condition for the solid-phase polymerisation of diynes. For example, octacosadiyne containing purely aliphatic substituents has a low-temperature modification which undergoes photopolymerisation exceptionally readily, whereas its high-temperature modification is inactive from 15°C up to the melting point[5]. Thus the orientation of adjacent molecules necessary for polymerisation can be ensured also by the packing of non-polar groups. On the other hand, among diphenylbutadiyne derivatives disubstituted with polar groups only the *ortho* and *meta* isomers are active in the solid phase, whereas the corresponding *para*-disubstituted compounds do not polymerise[57].

The best test of the above ideas of Wegner[5], of course, would have been a structural investigation both ot the monomer and of the polymer formed from it, but this has not yet been done. With many diynes, e.g. bisphenylcarbamates, X-ray examination is difficult because of the extreme rapidity of polymerisation on exposure. With diynes that polymerise slowly in the solid phase (hexa-2,4-diynediol, etc.) the crystalline structure of the monomers is known[74,78], but the structure of the polymer has not been investigated. On the application of large radiation doses with the aim of achieving high degrees of conversion the polymeric hexadiynediol becomes amorphous[78]. The structure of diphenylbutadiyne is known[79], but it is almost inactive in the solid phase.

Successive determination of the Raman spectra during the polymerisation of diynes[72] revealed spectral bands due to states intermediate between the initial monomer and the final polymer. The intensity of the bands due to the intermediate states increased initially, and then diminished. However, the vibration frequencies of the intermediate states were independent of the degree of polymerisation. Investigation of the ultraviolet spectra during the polymerisation of hexa-2,4-diyne-1,6-ylene revealed two intermediate spectral states differing both from the monomer, from the polymer, and from combinations thereof. However, lower intermediate products could not be identified by thin-layer chromatography[67]. The infrared spectra of partly polymerised hexa-2,4-diyne-1,6-diol show that the intermediates, present in considerable quantities, are completely hydrogen-bonded both in the monomer crystal and in the extracted polymer[72].

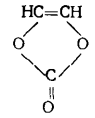


Thus spectral methods clearly establish the stepwise character of the solid-phase polymerisation of diynes, but the nature of the intermediates is obscure and requires further investigation.

## 3. Polymerisation of Monoethylenic Monomers

The above lever mechanism is impossible for the polymerisation of alkenes‡, and growth of the polymer chain requires considerable displacement of the molecules. Therefore topochemical polymerisation is not usually observed with these compounds[5]. The solid-phase polymerisation of vinyl monomers generally yields amorphous polymers, and the actual process takes place in "amorphous zones" or "local melts" arising from the absence of geometrical correspondence between monomer and polymer lattices.

Only the polymerisation of vinyl stearate and other quasi-crystalline long-chain vinyl and acrylic monomers takes place under definite structural control[81–83], occurring preferentially in monolayers, apart from the channel polymerisation of dienes in the form of inclusion compounds[84,85]. Polymerisation of ethylenic monomers in a quasi-crystalline state is possible if their molecules contain suitable substituents capable of being densely packed, while the ethylenic groups are situated in quasi-liquid regions and hence are highly mobile. This phenomenon is termed the "crystallinity of side-chains"[86,87]. A typical case is the polymerisation of *N*-*p*-vinylphenylbenzamide[88] or vinyl stearate, when the packing of the side-chains is largely preserved during polymerisation, but the linking of the double bonds is not specific and an atactic polymer is formed. The solid-phase polymerisation of long-chain unsaturated compounds has recently aroused especial interest, since it may occur in monolayers or in multilayer structures formed from them[82,83].



In channel inclusion compounds the "host" molecules, e.g. urea or thiourea, form an open structure, in the channels in which the molecules of a suitable monomer may be distributed. The polymerisation of alkenes in the form of inclusion compounds in urea or thiourea has been known for a long time[34,89]. Direct X-ray structural investigation of butadiene and its 2,3-disubstituted derivatives in the lattice of perhydrotriphenylene or urea as host has recently shown[62,85,90] that such derivatives are tightly packed "head to tail" in the channels. Powerful irradiation yields *trans*-1,4-polybutadiene by 1,4-addition:

The host lattice does not disintegrate during polymerisation, and an isolated stressed macromolecule is formed in each channel. After the host lattice has been cautiously dissolved, a highly crystalline fibrous product remains, comprising stressed chains[85]. The specific character of these reactions consists in the mutual isolation of the channels and the greatly restricted mobility of the monomer molecules. In a channel a monomer molecule is unable to rotate about its long axis, its mobility being reduced to the possibility of translational diffusion, which creates the necessary conditions for the formation of an ordered polymer.

‡ Because no rotation of such molecules is able to bring the ends of the double bonds within the distance necessary for polymerisation.

Crystals of vinylene carbonate

which polymerise on exposure to $\gamma$-rays, comprise layers perpendicular to the [$\bar{2}$01] direction[91]. The shortest intermolecular C...C distance between vinyl groups lies in the plane of the ($\bar{2}$01) layer (Fig. 21). But the formation of chemical bonds in this plane would have required large molecular rotations both in and perpendicular to the plane, which would have results in local stresses in the lattice. Polymerisation develops preferentially along surfaces parallel to the axes of the polymer to form a heterogeneous phase[92]. Weissenberg diagrams obtained after irradiation for 48 h established that the *a* and *b* axes of the polymer were parallel to those of the monomer. Thus polymerisation proceeds in the (110) plane. The polymer chain is a 3/1 helix extending along the *b* axis of the monomer crystal. At 10% conversion a signal due to the amorphous polymer appears on the diffractograms, at 35% only two peaks corresponding to a crystalline substance remain, and at 67% conversion the polymer is completely amorphous. The initially formed polymer probably has a thermodynamically unstable conformation and is able to exist only when a considerable crystalline environment is preserved by the monomer[92].

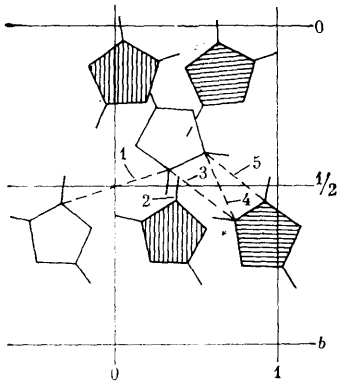


Figure 21. Packing of molecules in a crystal of vinylene carbonate projected on the ($\bar{2}$01) face (plane of layer). Molecules lying above and below this plane are shown by vertical and horizontal hatching respectively. Intermolecular vinyl–vinyl distances < 4 Å are indicated (Å): 1) 3.776; 2) 3.778; 3) 3.902; 4) 3.864; 5) 3.902.

The initial stage in the polymerisation of crystalline acenaphthylene is also a topotactic process[93,94], which, like that of vinylene carbonate, takes place not in the plane of the separating layers but in planes having $z = 0.25$ and 0.75. The polyacenaphthylene chains are oriented along the *a* and *b* axes of the monomer crystal. From the size of the identity period along the chain axis a *threo*-diisotactic structure was suggested for the polymer chain.

---o0o---

The above survey has shown that solid-phase polymerisation is not necessarily controlled by the lattice and does not necessarily give a stereoregular crystalline polymer. The crystal structure of the monomer may be destroyed by the growing polymer chains, so that only the initial stages of oligomerisation take place under the control of the lattice. This yields an amorphous polymer, which in some cases (oxetans) is able to crystallise. On the other hand, the product of solid-phase polymerisation frequently does not possess the expected morphological properties, because relaxation processes, which are so characteristic of other polymer reactions, may occur in structures obtained topochemically.

Two general types of lattice-controlled solid-phase polymerisations can be distinguished. (i) Polymerisation with ring cleavage is characteristic of cyclic monomers whose molecules are arranged in stacks or layers in the crystal. Polymerisation in stacks involves the opening of rings with formation of helical polymer molecules (trioxan, tetroxocan, etc.). Monomers having a stressed-ring structure (cyclotrisiloxanes and probably bithiazyl), in contrast, undergo polymerisation in layers. (ii) Lever polymerisation is accomplished by the concerted displacement and rotation of rigid rodlike molecules. A clear example of the lever mechanism is provided by monomers having conjugated triple bonds, which on polymerisation give units with alternating double, triple, and single bonds. The polymerisation of these monomers completely satisfies Schmidt's conditions[9,10] and is topochemical in the narrow sense.

The next important step in the study of solid-phase polymerisation should be to obtain quantitative structural–chemical criteria of the process, in particular to investigate potential barriers to motion, the geometry, and the dynamics of molecular groups during the process by the method of interatomic potentials.

# The Applications of Lewis Acids in Carbohydrate Chemistry

R.I.Sarybaeva, V.A.Afanas'ev, G.E.Zaikov, and L.S.Shchelokhova

The review gives a systematic account of the results of studies on the use of Lewis acids as catalysts of the chemical reactions of carbohydrates including polysaccharides. The data concerning the effect of Lewis acids have been grouped. in terms of the types of chemical reactions characteristic of the given class. The scope and certain limitations of their practical applications are indicated.
The bibliography includes 167 references.

## I. INTRODUCTION

Catalysis by acids and bases of the Brønsted type is widely used in carbohydrate chemistry[1-3]. Systematic studies on the kinetics of reactions under the conditions of homogeneous acid–base catalysis established many qualitative and quantitative rules governing the influence of the acidity of the medium on the kinetic and activation parameters, the equilibrium, and the mechanisms of many reactions of simple sugars (see, for example, Refs. 4–10). The study of the mechanisms of these reactions promoted in its turn the determination of the fundamental rules of acid–base catalysis and the development of physical organic chemistry[11-14].

The situation is somewhat different as regards the applications of Lewis acids (LA) in carbohydrate chemistry. One cannot say that agents of this type have been altogether disregarded by chemists specialising in the field of carbohydrates. Thus, as early as 1892 Stockhausen and Gatterman[15,16], and then in 1926 Kunz and Hudson[17], drew attention to the formation of the disaccharide chloroderivative when lactose octa-acetate is treated with a solution of aluminium chloride in chloroform. It was shown that the acetyl group at the glycosidic centre ($C_{(1)}$) had been substituted by chlorine. The crystalline product isolated from the reaction mixture was called neolactose. In subsequent years, research workers frequently used Lewis acids in order to elucidate the scope of their applications in preparative sugar chemistry. In many instances, these studies led to a significant development of the methods in carbohydrate chemistry. As regards the theoretical aspect of catalysis by Lewis acids, the problem has not been the subject of any kind of systematic investigation. It is useful to survey the available literature data and to outline the principal trends of the development of Lewis acid catalysis as a method in carbohydrate chemistry.

In the vast majority of studies, compounds of the type $MX_n$, where X is a halogen and M the central atom functioning as an acceptor of electron pairs, have been used as Lewis acids. Attempts have been frequently made to arrange systematically compounds of this type in terms of their acid and catalytic functions[18-20], but they did not lead to the development of a universal acidity scale. The relative acidity scale of $MX_n$, obtained on the basis of the valence interactions of the Lewis acid with a base in terms of measurements of the equilibrium constants for these reactions[19], is the most successful:

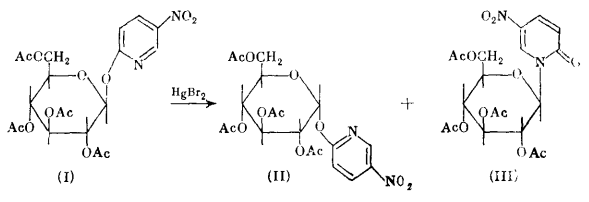
$$MX_n + yB \rightleftarrows MX_nB_y \quad .$$

This scale in general agrees well with experimental data (for example with the chemical shifts of the $\alpha$-protons in the $^1$H NMR spectra of a series of oxygen compounds coordinated to Lewis acids)[20]. By analogy with the Hammett function $H_0$, Moiseev[21] proposed for variable-valence metal ions an aprotic acidity function $\theta M$, which may be used to interpret processes involving the $\pi$-complexes of ions and unsaturated compounds.

Quantum-chemical calculations have shown that, in estimating the Lewis acidity, one must take into account not only the electronic structure of the central atom but also the steric configuration of the Lewis acid complex with the base[22,23]. On the whole, the problem of the acidity spectrum of Lewis acids is still far from being fully solved, which is a serious obstacle to the development of a quantitative theory.

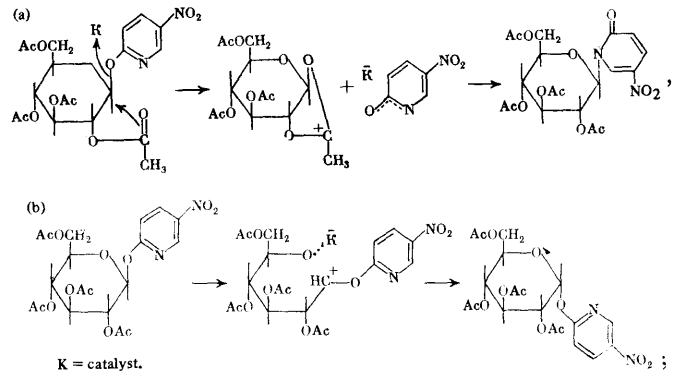
As in protic catalysis, the mechanisms of the Lewis catalysis of reactions can be represented by schemes providing for the interaction of the central atom of the Lewis acid with the heteroatoms of the carbohydrate molecule, involving the formation of a coordinate of covalent bond. However, with the exception of isolated individual studies[24-28], the experimental research devoted to problems of the formation of complexes by carbohydrates with Lewis acids is still insufficient to infer with any certainty the role of coordination compounds in the catalysis of the reactions of sugars. The problem of the possible activation of molecules by the protic acid produced at the stage in which the Lewis acid is coordinated to the heteroatom (for example $HB + MX_4 \rightarrow HB.MX_4 \rightarrow B - MX_3 + HX$) has not been considered in the literature at all. Nevertheless such a possibility must be taken into account in the analysis of the mechanisms of Lewis catalysis, particularly when the reactions are carried out in the presence of traces of water. In the present review, the literature data have been grouped in terms of their relevance to the characteristic reactions of simple sugars and polysaccharides.

## II. ISOMERIC TRANSFORMATIONS OF *O*-GLYCOSIDES



In contrast to monosaccharides and *N*-glycosides, *O*-glycosides are known[1] not to undergo anomerisation in moderately acidic aqueous solutions. Within the framework of general ideas on catalysis by Brønsted acids[6,13], the stability of the *O*-glycoside system can be accounted for by the low basicity of the proton acceptors—the ring and glycosidic oxygen atoms—responsible for the acid activation of the molecule. Appreciable protonation of these centres can be observed only in concentrated acid solutions, but in this case the anomerisation phenomenon is masked by the rapid acid hydrolysis of the *O*-glycosidic linkage. Anomerisation uncomplicated by the hydrolysis of the *O*-glycoside system can be observed in non-aqueous media, for example, in an acid methanolic solution of methyl β-D-glucopyranoside[29] or in inert organic solvents containing added Lewis acids.

This phenomenon was first observed by Pacsu[30-32] on refluxing briefly methyl tetra-*O*-acetyl-β-glucoside, cyclohexyl tetra-*O*-acetyl-β-glucoside, and methyl hepta-*O*-acetyl-β-cellobioside in the presence of $TiCl_4$ or $SnCl_4$ in dry chloroform. Fully acetylated and benzoylated sugars are also anomerised under the influence of $BF_3$ in chloroform, $HgBr_2$ in benzene, and many other Lewis acids in non-aqueous media[33-39]. In contrast to alkyl derivatives, glycosides with aromatic *O*-aglycones do not anomerise appreciably under analogous conditions[40]. The introduction of an electron-accepting aglycone suppresses to a large extent the anomerisation and at the same time increases the probability of the dissociation of the glycosidic linkage and the halogenation of the glycosidic atom. Anomerisation under the influence of non-aqueous $TiCl_4$ solutions is used nowadays in the preparative chemistry of carbohydrates in order to obtain anomeric forms of *O*-glycosides, which are otherwise difficult to synthesise (see, for example, Refs. 39 and 41).

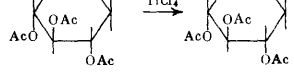


There exist contradictory views concerning the anomerisation mechanism which, incidentally, may be said also of other reactions of the glycosidic centre[5]. The problem of the detailed mechanisms of the catalysis of carbohydrate reactions is one of the most obscure in sugar chemistry. This does not involve the kinetic description of the reaction systems but is concerned with the selection of the most probable scheme for the coordination of the catalytic agent to the active centres and the mechanism of the subsequent reaction of the activated molecules.

According to Lindberg[34], anomerisation involves the opening of the carbohydrate ring with formation and subsequent cyclisation of an intermediate. The scheme of Lemieux and Shyluk[40] provides for the coordination of the catalyst to both ring and glycosidic oxygen atoms and for the possibility of reaction with heterolysis of the glycosidic or inner hemiacetal linkage, but without the formation of kinetically detectable ions.

The anomerisation of the *O*-glycoside (I) in the presence of $HgBr_2$ is accompanied by an intramolecular rearrangement (*ON*-transglycosylation), which results in the formation of the β-anomer of the *N*-glycoside (III)[42]:

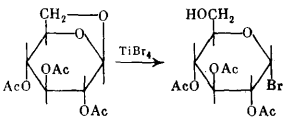
The above rearrangement under the influence of Lewis acids has been studied in a number of investigations[38,42-44]. The proposed mechanisms of the catalysis presuppose two possible types of coordination of the Lewis acid—with the glycosidic (a) or ring (b) oxygen atoms, the first of which leads to intramolecular *ON*-trans glycosylation and the second to the anomerisation of the initial *O*-glycoside:



The activities of Lewis acids in the anomerisation reaction (b) increase in the following sequence: $TiCl_4 < SbCl_5 < SnCl_4 < CdCl_2 < ZnBr_2 < HgBr_2$.[38]

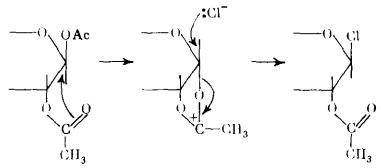
Lewis acids are apparently capable of inducing the epimerisation reaction in carbohydrates. For example, D-mannose-6-phosphate epimerises in an acetate buffer at pH 6 and 50°C in the presence of $Fe^{3+}$, $Cr^{3+}$, $Al^{3+}$, etc. to D-fructose-6-phosphate and D-glucose-6-phosphate[45]. The authors suggest that the ability of metal ions to catalyse the isomerisation reaction is determined by their properties as Lewis acids; the selectivity of the reaction does not in essence depend on the catalyst: D-fructose-6-phosphate is formed in all cases.

Another type of isomerisation occurring under the influence of Lewis acids is the Amadori reaction, the kinetics of which have been investigated in the presence of $ZnCl_2$ in anhydrous dioxan[46].

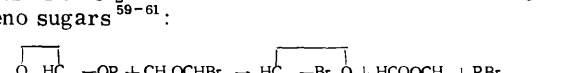


## III. THE FORMATION OF GLYCOSYL HALIDES

The halides of Group IV elements behave in relation to carbohydrates not only as catalysts but also as effective halogenating agents—a factor which must be always borne in mind in the analysis of the mechanisms of Lewis catalysis. When fully or partly acetylated sugars are introduced into the reaction in non-polar or weakly polar media, mainly the substituent at $C_{(1)}$ is replaced by the halogen[15-17]. A method for the synthesis of glycosyl halides, whereby one can obtain unstable anomeric forms of glycosyl halides, has been developed on this basis[47,48]. For example, tetra-*O*-acetyl-β-D-glucopyranosyl chloride can be obtained in a satisfactory yield after a brief treatment of β-D-glucose with a benzene solution of $TiCl_4$:



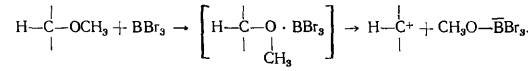
On further treatment of the β-anomer with $TiCl_4$, the former undergoes anomerisation with formation of the α-anomer, which is thermodynamically more stable under the conditions of Lewis catalysis. Anhydrous $AlCl_3$ in



chloroform has a similar effect[47,49-51]. Treatment of tri-*O*-acetyl-laevoglucosan with a $TiBr_4$ solution causes the formation of **2,3,4**-tri-*O*-acetyl-α-glucosyl bromide[52]:

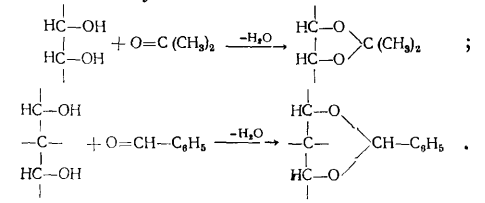
$TiCl_4$ has a similar effect on the hexa-*O*-acetyl derivatives of 1,6-anhydrocellobiose[53] and 1,6-anhydromaltose[54]. When hydrogen halides are used as the halogenating agents, the reaction is completed by the formation of a mixture of anomeric forms of the glycosyl halides in which the more stable α-anomer predominates. In contrast to this, the halogenation reaction involving the halides of Group III and IV elements is controlled by kinetic factors and may be arrested at the stage involving the formation of the β-anomers. The mechanism of the substitution of the aglycone for a halogen in acetyl derivatives of sugars may be represented by a scheme involving the participation of the neighbouring acetyl group[55,56]:

The effect of neighbouring group participation plays an important role in the stereochemical pathways of the reactions of the glycosidic centre[1] and its investigation is essential for the development of methods of stereospecific synthesis of sugar derivatives. For example, it has been established that, in the mercaptanolysis of the penta-*O*-acetyl derivatives of glucose and mannose in the presence of $ZnCl_2$, the reactivity of the β-anomers is much greater than that of the α-anomeric forms[57]. Measurements of the rates of exchange of the acetoxy-group at $C_{(1)}$ in the penta-*O*-acetyl derivatives of glucose and mannose with tin trichloride acetate in the presence of $SnCl_4$ in chloroform showed that the 1,2-*trans*-anomeric forms react much faster than the 1,2-*cis*-anomers[58]. These observations permit the conclusion that there is an intramolecular nucleophilic attack by the acetyl group at $C_{(2)}$ on the glycosidic centre, which weakens the glycosidic linkage (intramolecular nucleophilic catalysis). Acetylated derivatives of pentoses, hexoses, and disaccharides as well as partly acetylated sugars with a free glycosidic hydroxyl readily react with α-halogenoethers in the presence of catalytic amounts of $ZnCl_2$ in chloroform with formation of acetohalogeno sugars[59-61]:



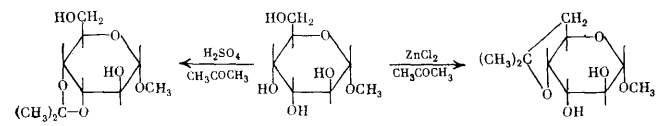
The yields of α-bromo-derivatives of tetra- and penta-*O*-acetylmonosaccharides vary in the range 50–60%.[59]

## IV. THE DISSOCIATION AND FORMATION OF CARBON–OXYGEN BONDS



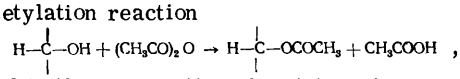
### 1. Chemical Reactions involving the Hydroxy-Groups

An effective low-temperature method for the demethylation of sugar derivatives under the influence of boron halides has been developed[62-66]. The same catalysts may also be used for deacetylation and the removal of the acetal group. For example, for the exhaustive demethylation of 2,3,4,6-tetra-*O*-methylglucopyranose, it is sufficient to keep the ether in methylene chloride in the presence of $BBr_3$ for 30 min at −80°C.[49] The use of $BCl_3$ under the same conditions leads to only partial demethylation (while hydrogen chloride dissociates only the glycosidic linkage and does not affect the ether linkages[65]) and the elimination of the methyl group may be accompanied by epimerisation at the carbon atom undergoing *O*-demethylation[67]. Monosaccharides are fully resistant to the action of $BCl_3$, with the exception of D-fructose and L-sorbose, the demethylation of which is accompanied by the formation of appreciable amounts of 5-hydroxymethylfurfural[66]. It has been noted that, in contrast to $BBr_3$, $BCl_3$ does not cleave the glycosidic linkages in disaccharides. Polycondensation with formation of di- and oligo-saccharides is also possible in the demethylation process[63]. There is no information in the literature about the mechanism of the demethylation reactions. It is suggested that the first stage involves the heterolysis of the carbon–oxygen bond in accordance with the scheme[64]



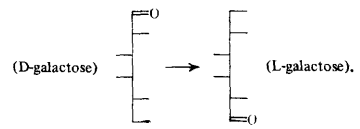
Lewis acids are widely used in the chemistry of carbohydrates, including polysaccharides, in order to synthesise ethers, including the selective protection of hydroxy-groups. $CH_2N_2 + BF_3$ (or $BF_3$ etherate) is a convenient methylating system for the synthesis of methyl ethers of sugars[68-72]. For example, a method has been developed on this basis for the synthesis of 2-*O*-methyl-D-galactose, involving the treatment of 4,6-*O*-benzylidene-3-*O*-benzoyl-β-benzyl-D-galactopyranoside with an excess of $CH_2N_2$ in solution in methylene chloride in the presence of $BF_3$ etherate, followed by debenzoylation under the influence of lithium tetrahydro-aluminate and hydrogenolysis over palladised charcoal[69].

Much attention has been devoted in carbohydrate chemistry to anhydrous zinc chloride as the catalyst of the selective protection of glycol OH groups by the formation of isopropylidene and benzylidene derivatives[73-75]:



Both strong inorganic acids and $ZnCl_2$ can be used in the synthesis of the isopropylidene derivatives (1)[75-77]. On the other hand, in order to obtain benzylidene derivatives (2), mainly $ZnCl_2$ is used[74,78-82]. When the isopropylidene protecting group is introduced in the presence of $ZnCl_2$, the six-membered *m*-dioxan ring is formed preferentially. It is less stable than the five-membered dioxolan ring formed in the reaction catalysed by protic acids[83]:

A similar tendency has been observed also in catalysis by zinc chloride of the reaction involving the formation of benzylidene derivatives[74,78,84]. Incidentally, this rule is

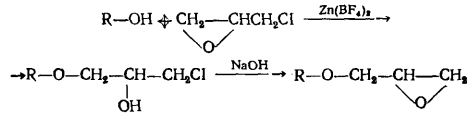


not entirely rigorous. The structure of the cyclic protecting group depends not only on the nature of the catalyst, but also on the form in which the initial monosaccharide participates in the reaction—open-chain or cyclic. In particular, when *O*-glycosides with the cyclic structure are substituted by acetone, the isopropylidene protecting group gives rise to *m*-dioxan and dioxolan rings. On the other hand, the isopropylidene protecting group enters into the open-chain forms of monosaccharides mainly as the dioxolan fragment.

The acetylation reaction

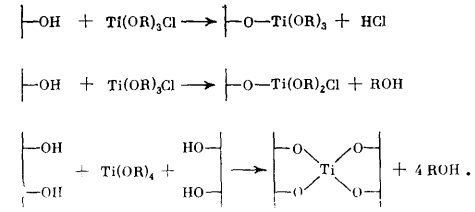
widely used in the preparative chemistry of sugars, is catalysed by both acid and basic catalysts. Among the Lewis acids used in this reaction, $ZnCl_2$ is most common. Fructose[85,86], salts of aldonic acids[87], cellulose[88], and other derivatives have been successfully acetylated in the presence of $ZnCl_2$. The addition of $BF_3$ accelerates the acetylation of uronic acids by acetic anhydride[51,89]. As in other reactions of sugars, the anomerisation of partly or fully acetylated forms is a complicating factor. In the presence of acid catalysts, the equilibrium shifts towards the preferential accumulation of the $\alpha$-anomer as the temperature is raised. $ZnCl_2$ can therefore be used to obtain the $\alpha$-anomer directly during acetylation with a mixture of acetic anhydride and acetic acid. For example, in order to obtain the $\alpha$-anomer of penta-*O*-acetylgalactopyranose, it is sufficient to treat the $\beta$-anomer with the acetylating mixture in the presence of $ZnCl_2$.[90,91]

We may note that the D–L isomerisation of a galactose derivative has been achieved by Micheel and coworkers[92,93] on the basis of the acetylation reaction in the presence of $ZnCl_2$ via the mechanism



i.e. by converting the 6-hydroxy-group into a formyl group and the glycosidic centre into a primary alcohol fragment. They showed that treatment of 2,3,4,5-tetra-*O*-acetyl-6-tosyl-*al*-D-galactose with zinc chloride in acetic anhydride leads to the formation of a racemic mixture of the D- and L-forms of hepta-*O*-acetylgalactose. After 30 years, Micheel returned to the study of this reaction and confirmed with the aid of $C_{(1)}$-labelled galactose the validity of the fundamental isomerisation mechanism[94].

It has been shown that $BF_3$ in anhydrous dioxan catalyses the formation of methyl 4,6-*O*-methylene-D-glycopyranosides on reaction of methyl glycopyranosides with formaldehyde[95]. Furthermore, $BF_3$ and $SbCl_5$ in methylene chloride catalyse the addition of glycosidic fragments to the free OH groups of acetylcellulose when the latter reacts with *O*-protected thio-, *O*-, and *N*-glycosides[96]. The degree of substitution varies in the range 0.1–0.47 depending on the nature of the glycosylating agent. Compared with $BF_3$ and $SbCl_5$, Lewis acids such as $AlCl_3$, $AlBr_3$, $TiCl_4$, and $ZnCl_2$ proved to be less effective agents in the substitution reaction.



Lewis acids are also used in the chemistry of polysaccharides, particularly cellulose, in order to synthesise its alkyl and acyl derivatives. Comparative studies have shown that the Lewis acids can be arranged in the following sequence in terms of their catalytic activity in the formation of cellulose ethers and esters[97]: $FeCl_3 > SbCl_5 > AlCl_3 > TiCl_4 > SnCl_4 > ZnCl_2 > BF_3.O(C_2H_5)_2 > HgCl_2$.

The influence of Lewis acids on the reactions of cellulose, acetylcellulose cellulosedialdehyde, and carboxymethylcellulose with the epoxy-derivative of butadiene has been studied[98]. It has been shown that the reaction of cellulose with chloromethyloxiran in the presence of zinc tetrafluoroborate followed by treatment of the product with a dilute solution of NaOH leads to the formation of a cellulose ether containing a free epoxy-group[99]:

However, comparative studies of the influence of the addition of acids and bases on the interaction of cellulose with various aromatic mono- and bi-functional epoxy-derivatives have shown that Lewis acids are nevertheless less suitable than alkaline agents for the preparation of cellulose ethers, since they initiate many side reactions arising owing to the degradation of the macromolecules[100].

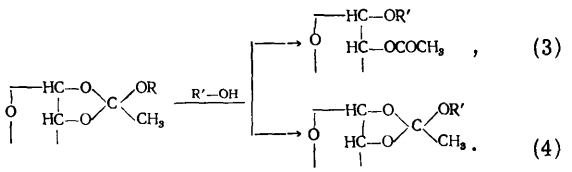
The interaction of $TiCl_4$, alkoxytitanates, and titanate orthoesters with polyols, unsubstituted sugars, and cellulose leads to the partial or complete substitution of the chlorine atoms and alkoxy-groups and the formation of Ti–O–C linkages as a result of the exchange interaction with the free OH groups of the carbohydrate chains[101,102] for example:

Ammonia, pyridine, formamide, or dimethylformamide are used as the hydrogen chloride acceptors. In contrast to $TiCl_4$ complexes with acetylated sugars, titanium-containing sugar and cellulose ethers [and esters?] are resistant to hydrolysis in weakly alkaline and neutral media.

Lewis acids exhibit a catalytic effect in the transesterification of cellulose nitrates by carboxylic acid chlorides[103–106]. The nitrogen content in the substitution product varies approximately exponentially with catalyst concentration at a fixed instant. For example, in the reaction of cellulose nitrate and acetyl chloride at 20°C, the dependence of the nitrogen content on the $AlCl_3$ concentration is of the following form 60 min after the start of the reaction[106]:

$$\ln [N],\ (\%) = 2.50 - 0.25\,[AlCl_3],\quad r = 0.98.$$

The possible mechanisms of this reaction have been analysed[103].



## 2. The Formation and Dissociation of Glycosidic Linkages

The synthesis of *N*-glycosides with strongly and moderately basic aglycones does not as a rule present special difficulties[107]. The problem of finding effective (particularly stereoselective) methods for the synthesis of glycosides with weakly basic aglycones (in particular *O*-glycosides[1]) constitutes a more urgent problem. In the search for these methods, the influence of Lewis acids has been frequently studied. Thus it has been suggested[108] that $ZnCl_2$ be used to synthesise thioglycosides, while in another

study[109] anhydrous $AlCl_3$ was proposed for the synthesis of O-arylglycosides by the Helferich method. However, the greatest success has been achieved in the employment of mercury salts as initiators of the formation of glycosidic linkages[50,56,110-112].

The Zemplen–Helferich version[113,114] of the Koenigs–Knorr O-glycosylation method, according to which mercury acetate or cyanide is added to the organic solvent (benzene, chloroform, nitromethane, acetonitrile) in order to obtain O-alkyl glycosides, has been widely used in laboratory practice. These additives are believed to play the role of acceptors of hydrogen chloride, which is eliminated from the initial acyl halides, although one cannot rule out the possibility that they also exhibit the catalytic functions characteristic of Lewis acids. Among individual reports, one may mention the catalysis by mercury chloride of the formation of O-glycosidic linkages in 2-deoxysugar derivatives[115-117].

Kochetkov and coworkers[118,119] proposed and subsequently developed significantly[120,124] a method for the synthesis of O-glycosides as a result of the interaction of catalytic amounts of $HgBr_2$:

(3)

(4)

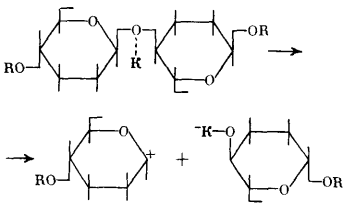
The mode of reaction depends significantly on the nature of the solvent and the amount of catalyst. Thus, the transesterification [reaction (4)] takes place preferentially in dichloroethane with formation of a new orthoester. On the other hand, when nitromethane is used and at $HgBr_2$ concentrations not exceeding $8 \times 10^{-3}$ mole per mole of the initial orthoester, the reaction is directed towards glycosylation [reaction (3)].[125] Certain disaccharides and polysaccharides have been obtained by this method[126-128].

One of the highly promising trends in carbohydrate chemistry involves studies on the development of specific methods for the synthesis of polysaccharides[1,129]. The vigorous development of research on this problem is associated with the task of finding new biopolymers—blood plasma substitutes, anticoagulants, etc. As a rule the acid-catalysed polycondensation of simple sugars with unsubstituted OH groups leads to the formation of oligo- and poly-saccharides with different sets of hemiacetal and ether linkages between the monosaccharide units and a disordered branched structure. Lewis acids have been used to accelerate the synthesis of polysaccharides only in very few investigations. One may mention the polymerisation of 1,6-anhydroglucose in the presence of boron, aluminium, and iron halides[130], the polymerisation of 1,4-anhydro-2,3,6-tri-O-benzylglucopyranoside in the presence of boron trifluoride etherate and antimony and phosphorous pentafluorides[131], and the copolymerisation of O-substituted derivatives of 1,6-anhydroglucose and 1,6-anhydromaltose under the influence of $PF_5$ in methylene chloride at low temperatures[132]. Tetra-O-acetyl-β-D-mannopyranoside polymerises under the influence of $ZnCl_2$ with formation of oligomers[133]. An approximately 10% yield of a linear polymer with a regular structure has been obtained by treating 2,3,4,2′,3′,4′-hexa-O-acetyl-6-t-butylmelibiosyl chloride with mercury cyanide in boiling nitromethane and subsequent Zemplen deacetylation[134].

The orthoester method of forming O-glycosidic linkages is promising for the specific synthesis of oligo- and polysaccharides[126,127]. Prolonged treatment of partly substituted sugar orthoesters (having one free OH group) with small amounts of $HgBr_2$ in boiling nitromethane leads to the formation of regular polysaccharides. In particular, a galactoglucan—a heteropolysaccharide consisting of alternating α-galactopyranose and α-glucopyranose units linked by 1,6-bonds (molecular weight approximately 1500)—and an arabinan—a polysaccharide made up of α-L-arabinofuranose with α-glycosidic linkages (molecular weight approximately 8000)—have been obtained in this way[126].

There is comparatively little information about the catalytic activity of Lewis acids in reactions involving the dissociation of O-glycosidic linkages. Kinetic studies[135-137] demonstrated a pronounced destructive action of $AlCl_3$, $TiCl_4$, and $SnCl_4$ in non-polar solvents in relation to the acetal linkages of cellulose. During the first 5–10 min from the start of the reaction, the average degree of polymerisation ($DP_{av}$) already reaches its lowest value (150–200) and remains constant virtually without change even after 10 days of treatment with the degrading agent. Under these conditions, temperature does not have a significant influence on the process kinetics. Thus, when cotton cellulose is kept in 0.1% $AlCl_3$ solution in dry carbon tetrachloride for 5 min, $DP_{av}$ falls from 2200 to 200 and in the resulting specimen there are no macromolecules with $DP > 200$ whatsoever. X-Ray diffraction analysis of the degraded specimens showed that the positions and relative intensities of the diffraction reflections remain the same as in the initial cellulose. This result can be explained by the fact that mainly the glycosidic linkages in the structurally disordered regions, which do not give rise to an intrinsic diffraction pattern, are degraded. On the other hand, the ordered part of the cellulose fibre retains its supermolecular structure during treatment with the degrading agent. There is virtually no decomposition from the ends of the chains.

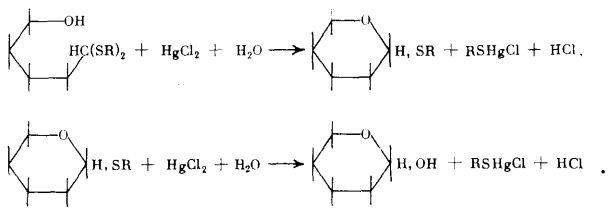
The solvent in which the process is carried out has a marked influence on the degradation kinetics[138]. It has been shown that the degree of degradation of cellulose with 0.1 and 1% solutions of Lewis acids at 20°C diminishes regularly over a period of 5–60 min with increase of the dielectric constant $\epsilon$ of the non-aqueous solvent. The nature of the change of the average degree of polymerisation as a function of $\epsilon$ shows that the subsequent electrostatic interaction plays a significant role together with the donor–acceptor interaction via the lone electron pair of the solvent molecule and the vacant orbital of the central atom of the Lewis acid. For example, the influence of organic solvents with low dielectric constants ($\epsilon < 12$) on the degree of degradation of cellulose specimens by 1% $TiCl_4$ solutions in 60 min can be represented by a relation of the type



$$DP_{av} = 259.05\varepsilon - 432, \quad r = 0.995.$$

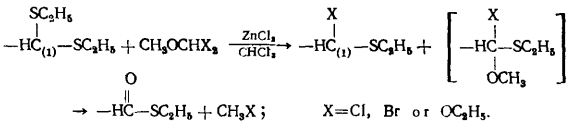
The shape of the curve relating the content of carbonyl groups in the degraded specimens to the dielectric constant, the number of carbonyl groups being determined by the Szabolcs method, makes it possible to reiterate with a greater degree of certainty the conclusion reached above: the degree of degradation of cellulose decreases monotonically with increase of $\epsilon$, which is described quantitatively by the equation

$$[CO] = \frac{1.345}{\varepsilon} + 0.043, \quad r = 0.940.$$



The differential molecular weight distribution curves for the specimens subjected to brief treatment with Lewis acid solutions in dry organic solvents in most cases have a shape close to that of the Gaussian distribution and indicate the formation of specimens homogeneous as regards the degree of polymerisation[139-141], in which the water-soluble fraction does not exceed 2% and there are no macromolecules with a degree of polymerisation exceeding 1000.

The mechanism of the decomposition of the cellulose chain may be represented by a scheme providing for the coordination of the Lewis acid molecule to the ring or glycosidic oxygen atoms and for subsequent heterolysis of the $C_{(1)}$–O bond with formation of a $C_{(1)}$ carbonium ion:



## V. REACTIONS OF SUGAR THIOACETALS

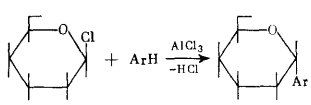
The formation of thioglycosides in the decomposition of dithioacetals in the presence of mercury(II) chloride, established by Schneider and Sepp[142-144] and then by Pacsu and coworkers[145,146] is of great importance for the development of the chemistry of sugar thio-derivatives. The composition of the products of the decomposition of the dithioacetals depends on the reaction conditions and the $HgCl_2$ concentration. In the presence of an excess of $HgCl_2$, stable and readily separated complexes of the dithioacetals with $HgCl_2$, which have been proposed for the identification of sugars[147,148], are formed. The degree of decomposition of the dithioacetals depends on the ratios of the rate constants for the successive stages of the formation of the thioglycoside and its decomposition to the monosaccharide:

The highest yield has been observed for glucose and ribose thioacetals; the rate of the second stage for mannose and xylose thioacetals is higher than that of the first and it is in practice impossible to isolate the thioglycoside from the reaction mixture[149,150]. It is important to note that thioglycosides in the furanose form may be synthesised by this method. This is favoured by carrying out the reaction at low temperatures and by adding mercury(II) oxide in order to bind hydrogen chloride[151]. The corresponding thioglycopyranosides are produced together with the furanose forms[152].

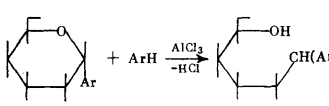
The cleavage of the monosaccharide mercaptals in the presence of catalytic amounts of $ZnCl_2$ and $\alpha$-halogenoethers is accompanied by the formation of products of the substitution of one of the mercapto-groups by a halogen atom and an alkoxy-residue[59]:

In absolute alcohol in the presence of $HgCl_2$, the decomposition of dithioacetals leads to the formation of the corresponding *O*-alkyl glycoside in the furanose or pyranose form[147,151]:

At room temperature in the presence of added mercury(II) oxide, glycofuranosides are formed in high yields[149,153,154]; on the other hand, the formation of glycopyranosides is promoted by an increase of temperature and an acidic pH of the medium[155]. According to Pacsu[156], the formation of *O*-alkyl glycosides under the conditions of the alcoholysis of dithioacetals is preceded by the formation of a mixed acetal:



The latter is an intermediate in the *O*-glycosylation reaction. The formation of acetal forms of this kind has been confirmed experimentally[157,158].



A change in the reaction conditions can lead to the formation of dialkyl acetals, as shown[159] for the diethyl dithioacetal of L-rhamnose. The highest yield of the acetal is observed on low-temperature treatment of the diethyl dithioacetal of fructose in methanol with mercury(II) chloride in the presence of an excess of mercury(II) oxide[156]. When the reaction is carried out in aqueous solution in the presence of $HgCl_2$, the thioacetal protecting groups are fully removed[160,161]. This method is used widely in carbohydrate chemistry, particularly in the synthesis of acetylated *al*-forms of monosaccharides[160] sugars with nitrogen atoms in the carbohydrate ring[162,163], and oligosaccharides[164].

## VI. THE FORMATION OF CARBON–CARBON BONDS

The formation of *C*-glycosides as a result of arylation at $C_{(1)}$ of acetylglucosyl chloride in the presence of anhydrous aluminium chloride, observed by Hurd and Bonner[165,166], may serve as an analogue of the Friedel–Crafts reaction in carbohydrate chemistry:

With increase of $AlCl_3$ concentration, an acyclic disubstituted arylation product is formed:

This reaction is complicated by a number of side processes and for this reason has not found applications in the synthesis of *C*-glycosides[167].

---o0o---

Summarising the data described, we may note that, although Lewis acids have found fairly extensive applications in the synthesis of various derivatives of simple sugars, nevertheless their possibilities have been by no means fully exhausted. It is already clear that the range of their activity is much wider than that of Brønsted acids, which are extensively used in carbohydrate chemistry. The interaction of Lewis acids with polysaccharides has been investigated to a much lesser extent and the studies have been concerned only with cellulose, without involving other polysaccharides. With rare exceptions, this has been basically applied research. The results which have already been obtained urgently require a further profound development of research in this field.

# Oxidative Dehydrogenation of Hydrocarbons

V.K.Skarchenko

Experimental data are examined and the present state of the theory of the oxidative dehydrogenation reactions of hydrocarbons is discussed. Fundamental varieties of oxidative dehydrogenation have been considered as a function of dehydrogenating agent and the involvement of the solid surface in the process. Attention is concentrated on the elucidation of the process characteristics, the reaction mechanisms, and the nature of the active surface.
The bibliography includes 196 references.

I. Introduction 738
II. Dehydrogenation of paraffinic hydrocarbons in the gas phase 739
III. Dehydrogenation reactions in the presence of solid catalysts 743
IV. Dehydrogenation in the presence of solid acceptors of hydrogen iodide 749

## I. INTRODUCTION

The abstraction of a hydrogen atom from the dehydrogenated molecule in the oxidative dehydrogenation reaction proceeds under the influence of an oxidant which binds hydrogen into a chemical compound. The most thoroughly investigated dehydrogenating agents (oxidants) are oxygen and iodine, under the influence of which hydrogen is removed from the hydrocarbon molecule with formation of water and hydrogen iodide respectively. Hydrocarbons belonging to different homologous series, namely paraffins, naphthenes, aromatic alkyl-substituted compounds, etc., undergo oxidative dehydrogenation. This process arises from a comparatively recently established and successfully developing series of studies. It makes it possible to synthesise very effectively olefins and diene monomers from more saturated hydrocarbons. The study of the oxidative dehydrogenation reactions as a new and unusual variety of partial oxidation of organic compounds is also of independent theoretical interest.

Various data concerning the oxidative dehydrogenation have been published in a number of reviews [1-8]. Oxidative dehydrogenation reactions are exothermic. The equilibrium yields of lower olefins are higher compared with the usual dehydrogenation of the same hydrocarbons. The dehydrogenation of olefins and aromatic alkyl-substituted hydrocarbons is achieved with high yields of products and selectivity in the presence of oxygen and solid catalysts, while the dehydrogenation of paraffins can be carried out similarly in the presence of iodine and oxygen or solid acceptors of hydrogen iodide.

The oxidative dehydrogenation of butenes to butadiene (or the similar dehydrogenation of isopentenes to isoprenes),

$$C_nH_{2n} + {}^1/_2O_2 \rightarrow C_nH_{2n-2} + H_2O\,, \qquad (1)$$

is a heterogeneous-catalytic reaction. Paraffinic hydrocarbons are oxidised by oxygen in the gas phase by a radical-chain mechanism with low yields of olefins in accordance with the overall equation

$$C_nH_{2n+2} + {}^1/_2O_2 \rightarrow C_nH_{2n} + H_2O\,. \qquad (2)$$

The use of iodine-containing substances makes it possible to achieve fairly readily the dehydrogenation of $C_4$–$C_5$ paraffins to diolefins. Iodine, reduced via the reaction

$$C_nH_{2n+2} + I_2 \rightarrow C_nH_{2n} + 2HI \qquad (3)$$

or

$$C_nH_{2n+2} + 2I_2 \rightarrow C_nH_{2n-2} + 4HI \quad (n \geqslant 4)\,, \qquad (4)$$

can be regenerated by oxidising with oxygen the hydrogen iodide formed:

$$2HI + {}^1/_2O_2 \rightarrow I_2 + H_2O\,, \qquad (5)$$

or by binding it to solid acceptors, for example constant-valence metal oxides:

$$MeO + 2HI \rightarrow H_2O + MeI_2\,, \qquad (6)$$

or variable-valence oxides:

$$Me_2O_3 + 6HI \rightarrow 2MeI_3 + 3H_2O + I_2\,. \qquad (7)$$

In the last case the oxide is partly reduced with liberation of iodine. The iodine sorbed by the acceptor can be regenerated by atmospheric oxygen via the reaction

$$MeI_3 + {}^1/_2O_2 \rightarrow MeO + I_2\,. \qquad (8)$$

Solid catalysts which are not HI acceptors but which are capable of greatly accelerating the oxidative dehydrogenation reactions of paraffins in the presence of iodine and oxygen are also known. The nature of the activity of these catalysts differs significantly from that of the usual heterogeneous catalysts.

Industiral processes for the synthesis of butadiene by the oxidative dehydrogenation of butenes in the presence of oxygen and solid catalysts and of n-butane in the presence of iodine, oxygen, and solid HI acceptors are being developed at the present time. A number of other unsaturated hydrocarbons can also be obtained in high yields with the aid of oxidative dehydrogenation.

## II. DEHYDROGENATION OF PARAFFINIC HYDROCARBONS IN THE GAS PHASE

### 1. THE REACTIONS OF HYDROCARBONS IN THE PRESENCE OF INDIVIDUAL RADICAL-FORMING SUBSTANCES

#### (a) The Nature of the Additive and the Selectivity of the Decomposition Reaction

The reactions of hydrocarbons are influenced significantly by the addition of substances which decompose into radicals or facilitate the formation of free radicals in the reaction system. The acceleration of the decomposition of paraffins by the addition of oxygen, iodine, epoxyethane, nitrogen oxides, hydrogen sulphide, bromine, azomethane, tetramethylethylene, metal alkyls, peroxides, etc.[9-22] and the retardation of the decomposition following the addition of nitric oxide, olefins, oxygen, hydrogen sulphide, hydrogen bromide, amides, hydrides, alkali metal hydroborates, and certain other substances[12,14,17,23-31] have been noted in the literature.

According to modern ideas, the addition of substances promoting the formation of free radicals has a dual effect (accelerating and retarding) on the reaction. The acceleration of the reaction is attributed to the replacement of the step involving chain generation or propagation by faster steps involving a molecule of the additive or the radicals (atoms) formed on its decomposition, while the retardation of the reaction is attributed to the replacement of the more active radical by a less active one or by the involvement of the additive in the chain termination stages[17,32-34]. Depending on the nature of the radical-forming additives and the experimental conditions, the mode of decomposition of hydrocarbons can vary significantly. The change in selectivity may be attributed to the acceleration or retardation of the individual stages of the overall process, leading to the formation of a particular product. In the presence of certain substances (iodine, bromine, chlorine, hydrogen sulphide, oxygen, and nitrous oxide), the ratio of the dehydrogenation and cracking products increases† [10,15,21,35-37].

The influence of the addition of iodine, oxygen, nitric acid, and epoxyethane on the reactions of butane has been investigated[13] under the conditions usually employed in oxidative dehydrogenation: 530°C and dilution with an inert gas at an overall pressure of 1 atm. Under these conditions, the addition of oxygen, iodine, epoxyethane, and nitric acid accelerates the decomposition of n-butane: in the absence of these substances, there is no change in n-butane. Cracking is the principal mode of reaction in the presence of all the above radical-forming additives in amounts up to approximately 8%.

The available information about the additives investigated suggests that the reaction of n-butane is initiated via the following process:

$$C_4H_{10} + R \rightarrow \dot{C}_4H_9 + RH\,, \qquad (9)$$

where $R = \dot{I}$, $O_2$, $\dot{N}O_2$ or $\dot{C}H_3$, and the activation energies $\epsilon$ are respectively ~25, 40, 23, and 10 kcal mole$^{-1}$.[17,19,38,39]

The mechanism of the decomposition of the butyl radical with formation of cracking products in the presence of small amounts of additives is apparently the same as in the absence of additives, as shown by the similarity of the composition of the decomposition products. The cracking products are formed via the unimolecular decomposition of the butyl radical and the interaction of lower alkyl radicals with the initial molecule:

$$\dot{C}_4H_9 \rightarrow \dot{C}H_3 + C_3H_6 \quad \varepsilon = 23\text{—}27 \text{ kcal mole}^{-1}, \qquad (10)$$

$$\dot{C}_4H_9 \rightarrow \dot{C}_2H_5 + C_2H_4\,, \qquad (11)$$

$$C_4H_{10} + \dot{C}H_3 \rightarrow \dot{C}_4H_9 + CH_4 \quad \varepsilon \simeq 9 \text{ kcal mole}^{-1}, \qquad (12)$$

$$C_4H_{10} + \dot{C}_2H_5 \rightarrow \dot{C}_4H_9 + C_2H_6\,. \qquad (13)$$

When much greater amounts of the additives are introduced (up to 15–30%), differences are observed in the mode of reaction depending on the nature of the radical-forming substance, which indicates the interaction of the butyl radical with the additive. In the presence of iodine, dehydrogenation takes place and in the presence of the same amount of the other compounds cracking products are formed.

The activation energies quoted for reaction (9) in which hydrogen atoms are abstracted show that the dehydrogenating action of the additives is not related to their activity with respect to the abstraction of hydrogen atoms. Evidently the formation of large amounts of olefins does not involve the abstraction of hydrogen atoms by the active species from the alkyl radical, i.e.

$$\dot{C}_4H_9 + R \rightarrow C_4H_8 + HR\,,$$

and takes place via addition reactions between them.

Thus the dehydrogenating action of iodine is associated with the properties of the intermediates formed during the interaction between the alkyl radical and the additive. The interaction of the butyl radical with iodine

$$\dot{C}_4H_9 + \dot{I} \rightarrow C_4H_9I$$

or

$$\dot{C}_4H_9 + I_2 \rightarrow C_4H_9I + \dot{I}$$

leads to the formation of alkyl iodides, which readily decompose at temperatures below 300° with formation of an olefin and HI or an olefin, a paraffin, and iodine[40,41].

One principle of the action of effective dehydrogenating agents (radical-forming substances), which is apparently general, follows from the data presented: the dehydrogenating effect of radical-forming substances is due to their inability to form compounds with alkyl radicals, which readily decompose into olefins.

#### (b) Dehydrogenation in the Presence of Iodine.

The conversion of paraffinic hydrocarbons into olefins by reaction (3) at approximately 300°C proceeds according to Benson's data via the interaction of the alkyl radical with an iodine molecule and the decomposition of the iodide thus produced. For example, the following equations may be formulated for the dehydrogenation of propane to propene[38]:

$$\begin{gathered} I_2 + M \rightleftarrows 2\dot{I} + M \quad \varepsilon = 35{,}5 \text{ kcal mole}, \\ C_3H_8 + \dot{I} \rightleftarrows \text{iso-}\dot{C}_3C_7 + HI \quad \varepsilon \simeq 25 \text{ kcal mole}^{-1}, \\ \text{iso-}\dot{C}_3H_7 + I_2 \rightleftarrows \text{iso-}C_3H_7I + \dot{I}\,, \\ \text{iso-}C_3H_7I \rightleftarrows C_3H_6 + HI\,. \end{gathered} \qquad (I)$$

The mechanism of the dehydrogenation of paraffins having a long chain with $C \geqslant 4$ [reaction (4)] has been examined by Raley et al.[15] According to their data,

†Cracking is understood in the present review as the decomposition of the hydrocarbon with rupture of the C–C bond.

paraffins are dehydrogenated to mono-olefins at approximately 300°C via the formation and decomposition of intermediate iodine compounds, as in Benson's mechanism. At higher temperaturss (500°C), the concentration of atomic iodine increases markedly and, according to the authors [15], the preferred pathway involves the formation of olefins via the direct abstraction of a second hydrogen atom by an iodine atom:

$$\dot{C}_nH_{2n+1} + \dot{I} \rightarrow C_nH_{2n} + HI .$$

According to Raley et al. [15], the dehydrogenation of a mono-olefin to a di-olefin proceeds similarly to the dehydrogenation of a paraffin to a mono-olefin. The reaction mechanism for n-butane is as follows:

$$\begin{gathered} I_2 + M \rightleftarrows 2\dot{I} + M , \\ C_4H_{10} + \dot{I} \rightarrow \dot{C}_4H_9 + HI, \varepsilon = 25 - 27 \text{ kcal mole}^{-1} , \\ \dot{C}_4H_9 + \dot{I} \rightarrow C_4H_8 + HI , \\ C_4H_8 + \dot{I} \rightarrow \dot{C}_4H_7 + HI, \varepsilon \simeq 10 \text{ kcal mole}^{-1} , \\ \dot{C}_4H_7 + \dot{I} \rightarrow C_4H_6 + HI . \end{gathered} \qquad (II)$$

However, comparison of the above data for the reaction of n-butane in the presence of iodine and other radical-forming substances is inconsistent with the hypothesis that olefins are formed without an intermediate iodide. The intermediate formation of iodides has also been confirmed by experiments on the decomposition of the latter under dehydrogenation conditions [41].

A more complete mechanism of the dehydrogenation of n-butane has been proposed by Chekhov et al. [42]:

$$\begin{gathered} I_2 + M \rightleftarrows 2\dot{I} + M , \\ C_4H_{10} + I \rightleftarrows \dot{C}_4H_9 + HI , \\ \dot{C}_4H_9 + I_2 \rightleftarrows C_4H_9I + \dot{I} , \\ C_4H_9I + \dot{I} \rightleftarrows C_4H_9 + HI + \dot{I} , \\ C_4H_9I \rightleftarrows C_4H_8 + HI , \\ C_4H_8\text{-}1 + \dot{I} \rightleftarrows \dot{C}_4H_7 + HI , \\ C_4H_8\text{-}2 + \dot{I} \rightleftarrows \dot{C}_4H_7 + HI , \\ \dot{C}_4H_7 + I_2 \rightleftarrows C_4H_7I + \dot{I} , \\ C_4H_7I + \dot{I} \rightleftarrows C_4H_6 + HI + \dot{I} , \\ C_4H_7I \rightleftarrows C_4H_6 + HI , \end{gathered} \qquad (III)$$

which involves, in conformity with scheme (I), stages in which iodides are formed and, in conformity with scheme (II), stages in which intermediate butenes are formed. Scheme (III) leads to the following equation for the rate of consumption of b-butane, which is close to the experimental equation:

$$w = k\,[C_4H_{10}]\,[I_2]^{1/2}/(1 + \beta),$$

where $\beta$ characterises the reversibility of the reaction. The activation energy for the reaction at 380–535°C is 43 kcal mole$^{-1}$. [43]

The dominant products of the reactions of higher paraffins with iodine are aromatic hydrocarbons:

$$C_nH_{2n+2} + 4I_2 \rightleftarrows C_nH_{2n-6} + 8\,HI \;(n \geqslant 6) .$$

By analogy with catalytic dehydrocyclisation and oxidative dehydrogenation of lower paraffins to diolefins, the aromatisation of $C \geqslant 6$ paraffins presumably proceeds via the following consecutive stages: paraffin → mono-olefin → diene → triene → cyclohexadiene → aromatic hydrocarbon [44].

(c) Reactions of Paraffinic Hydrocarbons in the Presence of Oxygen

One of the products of the high-temperature oxidation of paraffins by oxygen is an olefin with the same number of carbon atoms. However, the yields of dehydrogenation products are small. The main reaction pathway is cracking and, in the presence of high oxygen concentrations, also complete oxidation.

Most workers have adopted nowadays the mechanism of the formation of olefins by reaction (2) involving the successive abstraction of two hydrogen atoms from the paraffin molecule [45-51]:

$$C_nH_{2n+2} + O_2 \rightarrow \dot{C}_nH_{2n+1} + H\dot{O}_2 \; \varepsilon \simeq 40 \text{ kcal mole}^{-1} .$$
$$\dot{C}_nH_{2n+1} + O_2 \rightarrow C_nH_{2n} + H\dot{O}_2 .$$

Appleby et al. [10] proposed a mechanism for the conversion of n-butane in the presence of oxygen, according to which cracking products are formed via the unimolecular decomposition of the butyl radical [reactions (10)–(13)]. The mechanism involves stages in which butene is formed and also chain propagation and termination stages with participation of the $H\dot{O}_2$ radical:

$$\begin{gathered} C_4H_{10} + O_2 \rightarrow \dot{C}_4H_9 + H\dot{O}_2 , \\ \dot{C}_4H_9 + O_2 \rightarrow C_4H_8 + H\dot{O}_2 , \\ H\dot{O}_2 + C_4H_{10} \rightarrow H_2O_2 + \dot{C}_4H_9 , \\ 2\,H\dot{O}_2 \rightarrow H_2O_2 + O_2 , \\ H_2O_2 \xrightarrow{\text{wall}} H_2O + {}^1/_2O_2 , \\ 2\,H\dot{O}_2 \xrightarrow{\text{wall}} H_2O + 1{,}5\,O_2 , \\ \dot{C}_4H_9 \rightarrow \dot{C}H_3 + C_3H_6 , \\ \dot{C}H_3 + C_4H_{10} \rightarrow CH_4 + \dot{C}_4H_9 , \\ \dot{C}_4H_9 \rightarrow \dot{C}_2H_5 + C_2H_4 , \\ \dot{C}_2H_5 + C_4H_{10} \rightarrow C_2H_6 + \dot{C}_4H_9 . \end{gathered} \qquad (IV)$$

Scheme (IV) leads to a kinetic equation whose order is 1.5 with respect to butane and 0.5 with respect to oxygen, in agreement with experimental data in the presence of small amounts of added oxygen. However, this scheme does not agree with the kinetic equations for oxygen : butane ratios greater than 0.08–0.1, which involve higher orders with respect to butane and oxygen under these conditions [51]. Furthermore, scheme (IV) does not include reactions with participation of reactive $\dot{O}H$ radicals present in the hydrocarbon–oxygen reaction system (the activation energy for the abstraction of a hydrogen atom by the $\dot{O}H$ radical from the n-butane molecule should be not more than 8 kcal mole$^{-1}$) nor does it include reactions involving the formation of extensive oxidation products. With increase of the concentration of oxygen, its interaction with butyl radicals becomes more significant. We have proposed [51] a mechanism for the formation of cracking and far-reaching oxidation products of n-butane, which includes, in contrast to scheme (IV), reactions involving the formation, isomerisation, and decomposition of peroxy-radicals, a chain propagation stage with participation of the $\dot{O}H$ radical and unimolecular $\dot{O}H$ termination, as well as the overall formaldehyde oxidation reaction:

$$\begin{gathered} C_4H_{10} + O_2 \rightarrow \dot{C}_4H_9 + H\dot{O}_2 , \\ \dot{C}_4H_9 + O_2 \rightarrow C_4H_8 + H\dot{O}_2 , \\ C_4H_{10} + H\dot{O}_2 \rightarrow \dot{C}_4H_9 + H_2O_2 , \\ H_2O_2 \xrightarrow{\text{wall}} H_2O + {}^1/_2O_2 , \\ \dot{C}_4H_9 \rightarrow \dot{C}H_3 + C_3H_6 , \\ \dot{C}_4H_9 \rightarrow \dot{C}_2H_5 + C_2H_4 , \\ C_4H_{10} + \dot{C}H_3 \rightarrow \dot{C}_4H_9 + CH_4 , \end{gathered}$$

$$
\begin{gathered}
C_4H_{10} + \dot{C}_2H_5 \rightarrow \dot{C}_4H_9 + C_2H_6 , \\
\dot{C}_4H_9 + O_2 \rightarrow C_4H_9\dot{O}_2 , \\
n\text{-}C_4H_9\dot{O}_2 \rightarrow \dot{C}_4H_8O_2H , \\
\dot{C}_4H_8O_2H \rightarrow C_3H_6 + CH_2O + \dot{O}H , \\
C_4H_{10} + \dot{O}H \rightarrow \dot{C}_4H_9 + H_2O , \\
CH_2O + O_2 \rightarrow CO_2 + H_2O , \\
iso\text{-}C_4H_9\dot{O}_2 \rightarrow \dot{C}_3H_4CH(O_2H)CH_3 , \\
\dot{C}_3H_4CH(O_2H)CH_3 \rightarrow C_3H_4 + CO + \dot{O}H + CH_4 , \\
\dot{O}H \xrightarrow{wall} \text{termination} .
\end{gathered}
\qquad (V)
$$

Scheme (V) leads to kinetic equations for cracking and extensive oxidation, which are of second order with respect to butane and of third order with respect to oxygen, in agreement with experimental data.

## 2. DEHYDROGENATION OF PARAFFINIC HYDROCARBONS IN THE PRESENCE OF IODINE AND OXYGEN

The dehydrogenation of paraffins in the joint presence of iodine and oxygen was first investigated by Raley et al.[15], who concluded that the role of oxygen consists in regenerating iodine via reaction (5). They proposed a reaction mechanism for 500°C:

$$
\begin{gathered}
I_2 + M \rightleftarrows 2\dot{I} + M , \\
C_4H_{10} + \dot{I} \rightarrow \dot{C}_4H_9 + HI , \\
\dot{C}_4H_9 + \dot{I} \rightarrow C_4H_8 + HI , \\
C_4H_8 + \dot{I} \rightarrow \dot{C}_4H_7 + HI , \\
\dot{C}_4H_7 + \dot{I} \rightarrow C_4H_6 + HI , \\
2HI + {}^1/_2O_2 \rightarrow I_2 + H_2O , \\
\dot{C}_4H_9 + O_2 \rightarrow C_4H_9\dot{O}_2 ,
\end{gathered}
\qquad (VI)
$$

$C_4H_9\dot{O}_2$ – cracking and extensive oxidation products.

However, further investigations showed that the role of oxygen is not limited to its participation in the oxidation of hydrogen iodide [reaction 5].[1,52,53] The role of oxygen and iodine depends on the reactant concentration ratios. At concentrations close to those employed by Raley et al. (equimolar iodine/hydrocarbon ratio, amount of oxygen much less than that of iodine), oxygen reacts mainly with hydrogen iodide, since the dissociation energy of the H–I bond (71.3 kcal mole$^{-1}$) is much smaller than that of the C–H bond in the paraffin (89–95 kcal mole$^{-1}$).

With decrease of the amount of iodine in the system and increase of the concentration of oxygen, one of the functions of the latter becomes the generation of the active radicals $\dot{O}H$, $\dot{C}H_3$, etc., as happens in the reaction of n-butane in the absence of iodine (see above). Calculation based on the kinetic equation of the collision theory assuming that the pre-exponential factors are the same showed that the rates of abstraction of a hydrogen atom by an oxygen molecule,

$$C_4H_{10} + O_2 \rightarrow \dot{C}_4H_9 + H\dot{O}_2 , \qquad (O)$$

and an iodine atom,

$$C_4H_{10} + \dot{I} \rightarrow \dot{C}_4H_9 + HI , \qquad (i)$$

are comparable at approximately 500°C, provided that the concentration of atomic iodine is approximately $10^4$ times smaller than that of molecular oxygen:

$$\frac{w_0}{w_i} = \frac{a_0\, e^{-40/RT}\,[C_4H_{10}]\,[O_2]}{a_i\, e^{-25/RT}\,[C_4H_{10}]\,[\dot{I}]} \simeq 10^{-4}\,\frac{[O_2]}{[\dot{I}]} .$$

This ratio of $w_0$ and $w_i$ can obtain in the presence of an excess of oxygen by one or two orders of magnitude relative to molecular iodine, since the equilibrium degree of dissociation of iodine molecules into atoms is approximately $10^{-2}$ at 530°C, while under the conditions of the reacting system the equilibrium is apparently not attained.

The fact that $w_0$ and $w_i$ are comparable implies the dominant role of oxygen in the formation of alkyl radicals, since the reactions of oxygen with a hydrocarbon involve the formation of considerable amounts of species more active than iodine and oxygen ($\dot{O}H$, $H\dot{O}_2$, $\dot{C}H_3$, etc.). This conclusion is confirmed by kinetic data for the conversion of n-butane in the presence of equimolar amounts of oxygen and small amounts of iodine[52-54].

The role of iodine introduced in small amounts consists mainly in its participation in the stages determining the selectivity of the reaction, i.e. in the stages of further transformation of butyl radicals and not their generation. This is indicated, in particular, by the fact that the addition of iodine up to approximately 7% relative to butane increases the fraction of dehydration products, but has little influence on the degree of conversion of the hydrocarbon[53,55]. Apart from its participation in the formation of dehydrogenation products, the role of iodine consists in inhibiting cracking, which may occur in consequence of the replacement of active radicals by less active species, for example as a result of the replacement of alkyl or hydroxy-radicals by iodine atoms[18]. When larger amounts of iodine are introduced into the system, the reaction of atomic iodine with the initial butane begins to play an increasing role:

$$C_4H_{10} + \dot{I} \rightarrow \dot{C}_4H_9 + HI ,$$

as a result of which the rate of conversion of butane increases.

The above considerations may be applicable also to the subsequent two hydrogen abstraction stages: its abstraction from the butene molecule and from the butenyl radical. Butene is known to be oxidised in the presence of oxygen at high temperatures with high degrees of conversion, the first stage of the reaction consisting of the formation of the butenyl radical[9], and in the absence of iodine or special catalysts, for example bismuth molybdate (see below), appreciable amounts of butadiene are not formed.

Until recently, there have been few data on the mechanism of the regeneration of iodine by oxygen [reaction (5)]. In the development of the mechanism of the dehydrogenation of butane in the presence of iodine and oxygen (see below), the present author proposed a radical HI oxidation stage:

$$HI + O_2 \rightarrow \dot{I} + H\dot{O}_2 , \qquad (14)$$

the activation energy of which was estimated as approximately equal to the heat of reaction (approximately 20 kcal mole$^{-1}$).

The following mechanism has been proposed recently for the oxidation of hydrogen iodide at temperatures in the range 100–200°C[56]:

$$
\begin{gathered}
HI + O_2 \rightleftarrows \dot{I} + H\dot{O}_2 , \\
HI + H\dot{O}_2 \rightleftarrows \dot{I} + H_2O_2 , \\
2\dot{I} + M \rightleftarrows I_2 + M .
\end{gathered}
$$

The activation energy was found to be close to 20 kcal mole$^{-1}$. The reaction is inhibited by the product (iodine).

On the basis of the conclusions reached concerning the role of the individual reactants and about the intermediate formation of iodides and butenes[13,41], the present author

proposed a mechanism for the dehydrogenation of n-butane to butadiene in the presence of oxygen and iodine for small iodine/oxygen ratios [52,53]:

$$
\begin{aligned}
&I_2 + M \rightarrow 2\dot{I} + M\,,\\
&C_4H_{10} + O_2 \rightarrow \dot{C}_4H_9 + H\dot{O}_2\,,\\
&C_4H_{10} + H\dot{O}_2 \rightarrow \dot{C}_4H_9 + H_2O_2\,,\\
&C_4H_{10} + \dot{O}H \rightarrow \dot{C}_4H_9 + H_2O\,,\\
&C_4H_{10} + \dot{C}H_3 \rightarrow \dot{C}_4H_9 + CH_4\,,\\
&C_4H_{10} + \dot{C}_2H_5 \rightarrow \dot{C}_4H_9 + C_2H_6\,,\\
&\dot{C}_4H_9 + \dot{I} \rightarrow C_4H_9I\,,\\
&\dot{C}_4H_9 + O_2 \rightarrow C_4H_9\dot{O}_2\,,\\
&\dot{C}_4H_9 \rightarrow \dot{C}H_3 + C_3H_6\,,\\
&\dot{C}_4H_9 \rightarrow \dot{C}_2H_5 + C_2H_4\,,\\
&C_4H_9I \rightarrow C_4H_8 + HI\,,\\
&C_4H_9\dot{O}_2 \rightarrow \dot{O}H + \text{cracking and extensive oxidation products,}\\
&C_4H_8 + H\dot{O}_2 \rightarrow \dot{C}_4H_7 + H_2O_2\,,\\
&C_4H_8 + \dot{O}H \rightarrow \dot{C}_4H_7 + H_2O\,,\\
&C_4H_8 + \dot{C}H_3 \rightarrow \dot{C}_4H_7 + CH_4\,,\\
&C_4H_8 + \dot{C}_2H_5 \rightarrow \dot{C}_4H_7 + C_2H_6\,,\\
&\dot{C}_4H_7 + \dot{I} \rightarrow C_4H_7I\,,\\
&C_4H_7I \rightarrow C_4H_8 + HI\,,\\
&HI + O_2 \rightarrow \dot{I} + H\dot{O}_2\,,\\
&2\dot{I} + M \rightarrow I_2 + M\,,\\
&2\dot{C}_4H_7 \rightarrow \text{termination,}\\
&H_2O_2 \rightarrow H_2O + {}^1/_2O_2\,.
\end{aligned}
\qquad \text{(VII)}
$$

On the assumption of a steady state, scheme (VII) leads to an equation for the rate of dehydrogenation of n-butane to butadiene which is close to that obtained experimentally for low degrees of conversion:

$$w = k\,[C_4H_{10}]^{0.4}\,[I_2]^{0.6}\,[O_2]^{0.4}$$

and to an activation energy which is close to the experimental value (approximately 35 kcal mole$^{-1}$).

A mechanism for the dehydrogenation of n-butane in the presence of iodine and oxygen was also proposed[42,57] by Chekhov and coworkers. It includes, apart from the stages comprised in scheme (III) in the absence of oxygen, also a stage with its participation:

$$
\begin{aligned}
&I_2 + M \rightleftarrows 2\dot{I} + M\\
&C_4H_{10} + \dot{I} \rightleftarrows \dot{C}_4H_9 + HI\,,\\
&\dot{C}_4H_9 + I_2 \rightleftarrows C_4H_9I + \dot{I}\,,\\
&C_4H_9I + \dot{I} \rightleftarrows C_4H_8 + HI + \dot{I}\,,\\
&C_4H_9I \rightleftarrows C_4H_8 + HI\,,\\
&C_4H_8\text{-}1 + \dot{I} \rightleftarrows \dot{C}_4H_7 + HI\,,\\
&C_4H_8\text{-}2 + \dot{I} \rightleftarrows \dot{C}_4H_7 + HI\,,\\
&\dot{C}_4H_7 + I_2 \rightleftarrows C_4H_7I + \dot{I}\,,\\
&C_4H_7I + \dot{I} \rightleftarrows C_4H_6 + HI + \dot{I}\,,\\
&C_4H_7I \rightleftarrows C_4H_6 + HI\,,\\
&2\,HI + {}^1/_2O_2 \rightarrow I_2 + H_2O\,, \qquad (a)\\
&\dot{C}_4H_9 + O_2 \rightarrow C_4H_8 + H\dot{O}_2\,, \qquad (b)\\
&\dot{C}_4H_9 + O_2 \rightarrow C_4H_9\dot{O}_2\,, \qquad (c)\\
&C_4H_9\dot{O}_2 \rightarrow \text{cracking and extensive oxidation products}\,. \qquad (d)
\end{aligned}
\qquad \text{(VIII)}
$$

According to scheme (VIII), the role of oxygen consists, apart from stages (*b*), (*c*), and (*d*) in scheme (VI), in abstracting a hydrogen atom from the butyl radical [reaction (*b*)].

Adel'son et al.[58] proposed the following mechanism for the conversion of isopentane in the presence of iodine and oxygen:

$$
\begin{aligned}
&I_2 + M \rightleftarrows 2\dot{I} + M\,, && (a)\\
&\text{iso-}C_5H_{12} + \dot{I} \rightleftarrows \text{iso-}\dot{C}_5H_{11} + HI\,, && (b)\\
&\text{iso-}\dot{C}_5H_{11} + I_2 \rightleftarrows \text{iso-}C_5H_{11}I + \dot{I}\,, && (c)\\
&\text{iso-}C_5H_{11}I \rightleftarrows \text{iso-}C_5H_{10} + HI\,, && (d)\\
&\text{iso-}C_5H_{10} + \dot{I} \rightleftarrows \text{iso-}\dot{C}_5H_9 + HI\,, && (e)\\
&\text{iso-}\dot{C}_5H_9 + I_2 \rightleftarrows \text{iso-}C_5H_9I + \dot{I}\,, && (f)\\
&\text{iso-}C_5H_9I \rightleftarrows \text{iso-}C_5H_8 + HI\,, && (g)\\
&\text{iso-}C_5H_{12} + H\dot{O}_2 \rightarrow \text{iso-}\dot{C}_5H_{11} + H_2O_2\,, && (h)\ (\text{IX})\\
&\text{iso-}\dot{C}_5H_{11} \rightarrow \dot{C}H_3 + C_4H_8\,,\\
&\text{iso-}\dot{C}_5H_{11} \rightarrow \dot{C}_2H_5 + C_3H_6\,,\\
&2\,H\dot{O}_2 \rightarrow H_2O_2 + O_2\,,\\
&2\,HI + {}^1/_2O_2 \rightarrow I_2 + H_2O\,, && (p)\\
&\text{iso-}\dot{C}_5H_{11} + O_2 \rightarrow \text{iso-}C_5H_{10} + H\dot{O}_2\,, && (r)\\
&\text{iso-}\dot{C}_5H_{11} + O_2 \rightarrow \text{iso-}C_5H_{11}\dot{O}_2\,, && (s)\\
&\text{iso-}C_5H_{11}\dot{O}_2 \rightarrow CO + H_2O + \text{decomposition products.} && (t)
\end{aligned}
$$

The stages in which isopentane is dehydrogenated to isopentenes [reactions (*a*)–(*d*)] are analogous to those in the dehydrogenation of propane via Benson's mechanism (I), while the stages involving the dehydrogenation of isopentenes to isoprene [reactions (*e*)–(*g*)] are analogous to those in the dehydrogenation of isopentane to isopentene. Apart from the reactions included in the previous scheme or processes analogous to them [reactions (*p*)–(*t*)], the role of oxygen consists in the participation of the oxygen-containing radical $H\dot{O}_2$ in the formation of butyl radicals [reaction (*h*)].

Each of the last three mechanisms of the oxidative dehydrogenation of $C_4$–$C_5$ paraffins in the presence of iodine and oxygen [mechanisms (VII)–(IX)] can give a satisfactory quantitative agreement with experimental reaction rates for a reasonable choice of constants for the fundamental stages[54,57,58]. Nevertheless, none of them can claim to be complete. Thus the only reaction of oxygen in scheme (VIII), apart from the regeneration of iodine and the formation of side products, is abstraction of a hydrogen atom from the butyl radical. However, in the presence of iodine, which is much more selective in relation to dehydrogenation than oxygen, this stage hardly plays a significant role. On the other hand, the reactions of the most active radicals ($\dot{O}H$, $\dot{C}H_3$, $\dot{C}_2H_5$, and $H\dot{O}_2$) were not taken into account in this mechanism. For this reason, the applicability of scheme (VIII) to the reaction in the presence of large amounts of oxygen is unlikely. In scheme (IX) for the dehydrogenation of isopentane, the involvement of oxygen is represented by a large number of reactions. However, this scheme also does not include chain propagation reactions with participation of lower alkyl or hydroxy-radicals. In the present author's mechanism (VII) published previously, the reactions of butane in the presence of oxygen and comparatively small amounts of added iodine are represented by the reactions of oxygen-containing lower alkyl radicals with hydrocarbon molecules. However, it does not include certain reactions with participation of iodine, which are present in other schemes: the interaction of atomic iodine with hydrocarbon molecules and of hydrocarbon radicals with molecular iodine.

In later studies, Adel'son and coworkers[59,60] introduced a further series of reactions into scheme (IX), in particular the interaction of hydrocarbon molecules with the methyl radical:

$$\dot{C}H_3 + \text{iso-}C_5H_{12} \rightarrow CH_4 + \text{t-}\dot{C}_5H_{11},$$

$$\dot{C}H_3 + \text{iso-}C_5H_{10} \rightarrow CH_4 + \text{iso-}\dot{C}_5H_9,$$

and of isopentane with the hydroxy-radical:

$$\dot{O}H + \text{iso-}C_5H_{12} \rightarrow H_2O + \text{t-}\dot{C}_5H_{11}.$$

However, in order to devise a sufficiently complete detailed mechanism for the reaction in this extremely complex system, which is subject in addition to the influence of the surface (this will be discussed below), further studies are necessary and it is first essential to revise the kinetic data for the fundamental stages of the dehydrogenation process and concomitant reactions.

## III. DEHYDROGENATION REACTIONS IN THE PRESENCE OF SOLID CATALYSTS

### 1. DEHYDROGENATION OF OLEFINS IN THE PRESENCE OF OXYGEN

#### (a) Certain Experimental Data

The available information about the chemical compositions of the catalysts of the oxidative dehydrogenation of olefins in the presence of oxygen [reaction (1)] and the yields of products is given in the reviews published previously[1,8,61]. High yields of butadiene and isoprene were obtained in the presence of many catalysts having different compositions. Most of them (bismuth–molybdenum, antimony–tin, etc.) were known previously as catalysts of incomplete oxidation. However, certain catalysts of the oxidative dehydrogenation of olefins are similar in composition to the catalysts of ordinary dehydrogenation (for example, the mixed nickel, calcium, and chromium phosphate).

Aromatic alkyl-substituted hydrocarbons also undergo heterogeneous-catalytic oxidative dehydrogenation in the presence of oxygen; however, the optimum catalysts for these substances have a composition different from that of the catalysts for the dehydrogenation of olefins. The high yields of styrene in the dehydrogenation of ethylbenzene in the presence of aluminium oxide are striking[62].

Among binary systems of the type $MoO_3$–oxide of a Group V element (bismuth, arsenic, phosphorus, and antimony) deposited on $\alpha$-$Al_2O_3$, the molybdenum–bismuth catalyst is the most active[63]. Its optimum composition without a carrier or on carriers for the dehydrogenation of $C_4$–$C_5$ olefins lies within the limits of the ratio Bi : Mo = 0.5–2.[64-69]. Among catalysts having the composition $M_mO_n$–$Sb_2O_4$ (where M = Fe, Sn, Mn, V, Cr, Ni, Co, or Cu), the $Fe_2O_3$–$Sb_2O_4$ catalyst (atomic ratio in the range $1/16 \leq Fe/Sb \leq 1/4$) has the best parameters for the dehydrogenation of butene[70] and is followed in this respect by $SnO_2$–$Sb_2O_4$ (optimum composition $1/4 \leq Sn/Sb \leq 4/1$).[71-73] In the presence of the bismuth–molybdenum catalyst, the rate of dehydrogenation of but-1-ene is higher than that of but-2-ene [74,75] and the rate of dehydrogenation of 3-methylbut-1-ene is higher than those of the dehydrogenation of the remaining two isopentene isomers[76,77]. The rates of dehydrogenation of 3-methylbut-1-ene, 2-methylbut-2-ene, and 2-methylbut-1-ene at 386° in the presence of the catalyst with the atomic ratio Mo : Bi = 1 are in the proportions 4.3 : 1.2 : 1.[77]

The dependence of the reactivity of olefins on their molecular structure in the presence of other catalysts has been investigated comparatively little, but it is clear that it can differ significantly from that in the presence of the bismuth–molybdenum catalyst. Thus the yields of isoprene in the presence of the iron–zinc–chromium catalyst in the dehydrogenation of isopentenes decrease in the sequence 2-methylbut-2-ene > 2-methylbut-1-ene > 3-methylbut-1-ene.[78] The reactivities of the isopentene isomers decrease in the same sequence in the presence of phosphoric acid deposited on silica gel[79].

In the presence of the bismuth–molybdenum catalyst, a zero reaction order with respect to oxygen and a nearly first order with respect to mono-olefins is observed over a fairly wide range of concentrations and experimental conditions[80-82]. A zero order with respect to oxygen obtains also with increase of oxygen concentration above a limiting value, which is usually much lower than the concentration of the hydrocarbon. A zero reaction order with respect to oxygen has likewise been observed in the presence of the iron–chromium–zinc and phosphoric acid catalysts[83,84], but has not been found in the presence of the iron–antimony and antimony–tin catalysts even at oxygen concentrations exceeding by several factors of ten the concentration of the olefin. In the presence of low product concentrations, reaction orders close to 1/2 with respect to mono-olefins and oxygen have been found for these catalysts[85].

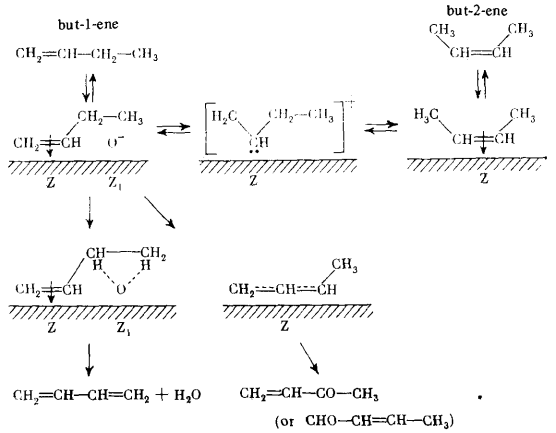
With decrease of temperature from 420° to 350°C, the apparent activation energy for the dehydrogenation of but-1-ene in the presence of the bismuth–molybdenum catalyst in a stirred reactor increases from 11 to 36 kcal mole$^{-1}$,[86] which has attributed to the inhibition of the reaction by butadiene[87]. Dehydrogenation in the presence of these catalysts may be inhibited by added water and unsaturated carbonyl compounds[88,89], which can be attributed, like the poisoning by butadienes, to the blocking of active centres.

#### (b) The Dehydrogenation Mechanism

Oxidative dehydrogenation of mono-olefins has nowadays come to be regarded as a reaction analogous to allylic oxidation: the oxidation of propene to acrolein and oxidative ammonolysis[66,87,90-92]. According to the mechanism of Adams and Jennings[93], the oxidative dehydrogenation in the presence of the bismuth–molybdenum catalyst proceeds via an intermediate allyl complex, for example:

$$CH_2=CH-CH_2-CH_3 \quad \text{or} \quad CH_3-CH=CH-CH_3 \xrightarrow{(a)} \rightarrow \underbrace{H_2C=CH=CH-CH_3}_{Z} \xrightarrow[+Z_1-O]{(b)} \underbrace{H_2C=CH=CH-CH_2}_{Z} \rightarrow$$

$$\xrightarrow{(c)} Z\,(H_2C=CH-CH=CH_2) \xrightarrow{(d)} H_2C=CH-CH=CH_2. \qquad (X)$$



The rate limiting stage is believed to be the dissociative adsorption of the initial olefin.

According to the data of Margolis and Krylov[92,94], who also treat oxidative dehydrogenation as a reaction analogous to allylic oxidation, the stage involving the interaction between the surface hydrocarbon radical and the adsorbed oxygen [reaction (*b*)] is more complex than shown in scheme (X) and includes the formation of an intermediate positively charged hydrocarbon–oxygen complex containing an excess of carbon atoms relative to

oxygen atoms. The rate-limiting stage of the dehydrogenation process is believed to be the formation of the hydrocarbon–oxygen complex.

However, the analogy between the oxidation of propene to acrolein and the oxidative dehydrogenation of butenes is not observed in all cases. This is shown by a number of facts. There are catalysts in the presence of which the oxidation of propene to acrolein and oxidative ammonolysis proceed satisfactorily, while oxidative dehydrogenation takes place to only a slight extent [for example copper (I) oxide[95] and the vanadium–molybdenum catalyst[96]]. On the other hand, other catalysts are more or less active in oxidative dehydrogenation, but allylic oxidation does not take place in their presence [the iron–zinc–chromium, antimony–chromium[97], copper (II) oxide, manganese–molybdenum, vanadium–bismuth, and other[96] catalysts]. However, only partial specificity of catalytic activity to oxidative dehydrogenation reactions and reactions involving oxidation to acrolein is observed even in the presence of bismuth–molybdenum catalysts. Thus the $\beta$-phase is most active in the former reactions while the $\alpha$- and $\gamma$-phases are most active in the latter[99]. In the oxidative dehydrogenation of butenes, the products contain small amounts of methyl vinyl ketone and crotonaldehyde, which must be regarded as very close analogues of acrolein formed via the allylic mechanism. However, the relative yields of butadiene and unsaturated carbonyl products in the presence of the same catalyst differ appreciably for different butene isomers[100]. In the oxidation of isopentene isomers, the reactivity series with respect to unsaturated carbonyl compounds and isoprene do not agree. For example, the rate of partial oxidation in the presence of $Cu_2O$ decreases in the sequence 2-methylbut-1-ene > 2-methylbut-2-ene ≥ 3-methylbut-1-ene, while the rate of oxidative dehydrogenation in the presence of the same catalyst decreases in the sequence 3-methylbut-1-ene > 2-methylbut-1-ene > 2-methylbut-2-ene.[95]

Alkhazov et al.[101] proposed a mechanism for the oxidative dehydrogenation of butenes with the intermediate formation of the surface butene $\pi$-complex; the allyl complex is regarded as an intermediate in the formation of products containing the carbonyl group:

(XI)

According to scheme (XI), the dehydrogenation of but-2-ene can occur only after its preliminary isomerisation to but-1-ene. Scheme (XI) is therefore difficult to apply to the catalysts (iron–antimony[102] and uranium–antimony[103]) in the presence of which but-2-ene is dehydrogenated, but butenes are not isomerised.

The available data suggest that the oxidative dehydrogenation of mono-olefins can proceed via different mechanisms. One of the manifestations of these features is probably the dependence of the relative reactivity of isopentene isomers on the chemical composition of the catalyst. The differences in the mechanisms can consist in the formation of different surface intermediates. Thus in the presence of CuO the rate of oxidative dehydrogenation of 2-methylbut-1-ene and 2-methylbut-2-ene is almost independent of the addition of other mono-olefins (pent-1-ene or 3-methylbut-1-ene), i.e. there is no competition between the hydrocarbons as regards adsorption[98]. This shows that the dehydrogenation reaction on CuO bypasses the isopentene chemisorption stage. The pre-catalytic effect involving an enhancement of the adsorption of butenes under the influence of the adsorption of oxygen has not been observed in the presence of the iron–zinc–chromium catalyst. This effect, indicating the formation of an oxygen–hydrocarbon complex, has been observed in the presence of other catalysts of the oxidative dehydrogenation of butenes (molybdenum–bismuth, antimony–tin, and antimony–chromium). The above findings imply, according to the authors[97], that, in contrast to other catalysts, oxygen does not react with the butene molecule in the presence of the iron–zinc–chromium catalyst and its role consists in oxidising the hydrogen split off from the butene. This may also be the mechanism of the oxidative dehydrogenation of butenes on palladium[104].

During the oxidative dehydrogenation reaction in the presence of the bismuth–molybdenum catalyst, oxygen in the catalyst lattice is consumed. This involves partial reduction of the higher oxides of bismuth and molybdenum to lower oxides. The active oxidised form of the catalyst is maintained by the supply of oxygen from the gas phase. The catalyst dehydrogenation and reduction reactions proceed at comparable rates[105]. Thus the rate of the overall oxidative dehydrogenation process is determined within certain concentration limits by the rate of reduction, which is of first order with respect to butene and of zero order with respect to oxygen. Analogous results, indicating the oxidative dehydrogenation of but-1-ene via alternate oxidation and reduction, have been obtained in the presence of the antimony–tin[106] and iron–antimony[107] catalysts. With increase of the degree of reduction, its rate decreases rapidly, while the rate of oxidation rises. The steady state in the process corresponds to the surface of the iron–antimony catalyst being reduced approximately to the extent of 55%.[107]

The oxidation-reduction mechanism for the reactions of butenes, including side and secondary reactions, can be represented schematically as follows (Boreskov et al.[102]):

$$
\begin{gathered}
K(O) + C_4H_8 \rightleftarrows K(OC_4H_8)\,, \\
K(OC_4H_8) \rightarrow K(C_4H_8) + H_2O \xrightarrow[\text{fast}]{} C_4H_8 + K(r)\,, \\
K(OC_4H_8) \xrightarrow{+x_1K(O)} \nu_1CO_2 + \nu_1H_2O + (x_1+1)K(r)\,, \\
K(O) + C_4H_8 \rightleftarrows K(OC_4H_8)\,, \\
K(OC_4H_8) \xrightarrow{+x_2K(O)} \nu_2CO_2 + 3/4\nu_2H_2O + (x_2+1)K(r)\,, \\
K(r) + O_2 \rightarrow K(O_2^-) \xrightarrow[\text{fast}]{+K(r)} 2K(O)\,,
\end{gathered}
\qquad \text{(XII)}
$$

where K(O) and K($r$) are respectively the oxidation and reduction sites on the catalyst surface, $x_1$ and $x_2$ are coefficients, and $\nu_1$ and $\nu_2$ are stoichiometric coefficients. An interaction of the hydrocarbon molecule with the catalyst surface more extensive than the formation of the intermediate surface butene is not taken into account in scheme (XII). On the assumption that the surface is homogeneous and that there is no mutual influence of the

adsorbed species, but without the postulate that adsorption equilibrium is reached and that a rate-limiting stage is present, scheme (XII) leads to a kinetic equation for the overall conversion of butene with a reaction order of 1/2 with respect to butene and oxygen, in agreement with experimental results. The oxidation-reduction mechanism with alternate oxidation and reduction evidently cannot occur in the presence of catalysts such as $Al_2O_3$ by virtue of the very nature of this catalyst.

In the presence of the spinel zinc–chromium ferrite catalyst, oxidative dehydrogenation also occurs without the involvement of lattice oxygen. The catalyst is not reduced during the reaction. This is suggested by the finding that, in the absence of oxygen, the yield of butadiene is very low. It amounts to not more than several per cent of the yield in the presence of oxygen and falls to zero after the consumption of 1–2 oxygen monolayers [108]. According to the mechanism proposed by the authors [108] for the converson of butene in the presence of the zinc–chromium ferrite catalyst, the first hydrogen atom is abstracted at an active centre consisting of an iron(III) cation with participation of adsorbed oxygen:

$$[A] + C_4H_8 + Fe^{3+} + O_a^- \rightarrow (C_4H_7Fe)^{3+} + OH^- ,$$

while lattice oxygen is involved in the abstraction of the next hydrogen atom:

$$(C_4H_7Fe)^{3+} + O_L^{2-} \rightarrow C_4H_6 + Fe^{2+} + OH .$$

Here [A] is an anionic vacancy associated with $Fe^{3+}$, $O_a^-$ is an adsorbed oxygen radical, and $O_L^{2-}$ is the lattice oxygen. The oxygen involved in the reaction is regenerated by the following processs:

$$2OH^- \rightarrow H_2O + O_L^{2-} + [A] ,$$

$$Fe^{2+} + 1/2O_2 \rightarrow Fe^{3+} + O_a^- .$$

Boreskov et al. [109] observed in the presence of the same specimens of the iron(III) oxide catalyst the occurrence of the dehydrogenation reaction via different mechanisms, one of which was the oxidation-reduction mechanism. Depending on the oxygen content in the reaction mixture, the catalyst operating in the steady state consists of magnetite on which the oxidation-reduction reaction takes place or $\alpha$-$Fe_2O_3$ on which the hydrogenation mechanism is different from the oxidation-reduction mechanism.

### (c) The Nature of the Active Surface of the Catalyst

In many cases, the catalytic activities in the oxidation of propene to acrolein, oxidative ammonolysis, and oxidative dehydrogenation of olefins are found to vary in parallel. For example, all three reactions proceed satisfactorily in the presence of bismuth–molybdenum or antimony–tin catalysts. The optimum compositions of the bismuth–molybdenum catalyst for these reactions are similar. However, as noted above, the specificities of the catalysts in relation to the above reactions are frequently not the same.

Data concerning the influence of chemical composition on catalytic properties agree with the hypothesis that the oxidative dehydrogenation of olefins can proceed via different mechanisms, one of which is analogous to allylic oxidation. In this case, the oxidative dehydrogenation reactions can probably proceed both on active centres for partial oxidation and on other centres.

A correlation is observed between the catalytic properties and the physicochemical characteristics associated with the mobility of the lattice oxygen and the strength with which the hydrocarbon adsorbed on the surface is retained. In order to characterise the mobility of oxygen, parameters such as the susceptibility of the catalysts to reduction [105,110], the diffusion of the bulk-phase lattice oxygen to the catalyst surface [111], the activation energy for the isotope exchange of the lattice oxygen with labelled molecular oxygen [66], and finally the energies of the bonds between oxygen and the catalyst surface, calculated from the heats of oxidation and reduction of the catalyst [112] or from data for the thermal desorption of oxygen from the catalyst surface [113], have been used. The most important conclusion reached in these studies is that the mobility of oxygen must have a definite optimum value for selective oxidation. When the mobility of oxygen is low, the catalyst is inactive, while an excessively high mobility entails the formation of products of the complete oxidation of the hydrocarbon.

The oxygen on the catalyst surface is as a rule inhomogeneous as regards the strength of its binding to the surface; the activity and selectivity of the catalytic action depend on the strength of this binding [112,114]. Thus the removal of 10–12% of the oxygen monolayer from the surface of the calcium-nickel phosphate catalyst leads to a decrease of the degree of conversion of butene and an increase in the selectivity with respect to butadiene [115].

According to Marshneva's data [113], weakly bound oxygen, involved in the complete oxidation reaction, has binding energies of 4–9 kcal $mole^{-1}$ on different catalysts. On the other hand, the energy spectrum of the surface oxygen on the bismuth–molybdenum and iron–antimony catalysts for oxidative dehydrogenation lies in the region above 61 kcal $mole^{-1}$.

The relation between the catalytic properties and the strength of binding of the hydrocarbon to the surface is manifested by the correlations between the reactivity and ionisation potentials [77,78]. Since the adsorbed hydrocarbon species are charged, the ionisation potentials can be regarded as a measure of the capacity of the hydrocarbons for adsorption on the catalyst surface. On the bismuth–molybdenum and antimony–tin catalysis, the reactivity increases, while on the catalysts with iron oxides it diminishes with increase of the ionisation potential [78].

The catalytic properties of individual oxides in mixed catalysts based on them have been compared [101]. Systems comprising mixtures of oxides, one of which is moderately active in relation to extensive oxidation (bismuth, tin, manganese, and indium oxides) and the other is active with respect to the isomerisation of but-1-ene to but-2-ene (molybdenum, tungsten, antimony, and phosphorus oxides), are active in the oxidative dehydrogenation of butenes. The ability of the catalysts to promote isomerisation apparently reflects in a definite manner the optimum energy of binding of the olefin to the catalyst.

There are still few data concerning the nature of the active centres responsible for chemisorption and catalysis in oxidative hydrogenation reactions. The most active incomplete oxidation catalysts are mixed oxides with a definite ratio of the cations (for example Bi : Mo = 2 : 1–1 : 2). Hence follows the hypothesis that allylic oxidation requires the obligatory presence in the catalyst of a doublet consisting of two ions of different kinds on which the hydrocarbon and oxygen are adsorbed respectively [95,116–118]. The presence of paired centres in oxidation catalysts is indicated by the finding that, at high dilutions of the transition metal oxide by a non-transition metal oxide (down to transition metal concentrations of the order

of 1% and less), the catalytic activity diminishes, in contrast, for example, to the catalyst of the usual dehydrogenation, whose activity increases under the conditions of such dilution[94].

Various hypotheses have been put forward concerning the site of adsorption and the nature of the bond between the hydrocarbon and the surface of the catalyst of allylic oxidation. According to Sachtler and de Boer[110,119], the allyl group is retained on the surface as a result of the formation of a carbon–oxygen σ bond between one of the carbon atoms and a surface oxygen ion. Other workers[105] believe it to be more likely that the allyl group is bound to a transition metal ion as a result of the formation of a π-complex, while the hydrogen atom is linked to an oxygen atom. If the hydrocarbon is adsorbed on metal ions, the cations retaining the hydrocarbon in bismuth–molybdenum catalysts may be $Mo^{6+}$ [94,105] or $Bi^{3+}$.[116,120]

In the general case, the presence of cations of different kinds is not an obligatory condition for the oxidative dehydrogenation of olefins. This is demonstrated by the occurrence of dehydrogenation in the presence of catalysts such as silica gel or phosphoric acid on carriers[79,121] and also by the possible occurrence of reactions via an impact mechanism between the adsorbed oxygen and gas-phase olefin molecules (CuO, see above).

The optimum strength of the binding of oxygen to the surface is attained for a definite lattice structure. It is suggested that such a structure may be formed by oxygen ions bound to cations by double bonds[122–125]. This hypothesis is supported by the correlation between the selectivity and the number or strength of the Mo=O double bonds in molybdate catalysts[126,127]. The strength of binding of the complexes to the surface, the degree of deformation of the C–H bonds, and the mobility of oxygen depend on the nature of the positive lattice ions, which is probably the cause of the differences between the reaction mechanisms on catalysts of different chemical compositions. For example, in the presence of the iron–zinc–chromium catalyst, on which there is no interaction between the adsorbed hydrocarbon and oxygen according to Krylova et al.[97], dissociative adsorption apparently takes place on the catalyst cations, similar to the behaviour in the usual catalytic dehydrogenation.

In the presence of catalysts such as phosphoric acid or alumina, the yields of oxidative dehydrogenation products are correlated with their acidic properties[128,129], which probably play a significant role in the nature of their acidity. The phosphoric acid catalyst contains protic and aprotic centres and is poisoned by butylamine. Alumina is a strong aprotic acid. The acid centres of the catalysts can serve as the adsorption sites for the reactant and for the formation of intermediate surface compounds[128,130].

## 2. DEHYDROGENATION OF PARAFFINIC HYDROCARBONS IN THE PRESENCE OF OXYGEN, HALOGENS, AND SULPHUR COMPOUNDS

### (a) Reaction in the Presence of Oxygen

Table 1 presents certain typical data for the formation of the dehydrogenation products of paraffinic hydrocarbons in the presence of oxygen and solid catalysts. Compared with the reaction under similar conditions but in the absence of catalysts (see, for example, Skarchenko[1]), there is a sharp increase of the yields of diolefins.

The overall conversion into dehydrogenation products increases to a lesser extent, although in some cases (n-butane) it may exceed severalfold the yields of these products in the empty reactor. The difference between the reaction in the presence and absence of the catalyst is nevertheless not large enough to rule out the occurrence in the presence of the catalyst of gas-phase reactions, which apparently make a significant contribution to the overall conversion of the hydrocarbon.

Table 1. The formation of dehydrogenation products from paraffinic hydrocarbons in the presence of oxygen and solid catalysts.

| Initial hydrocarbon | Catalyst | Molar ratio $C_nH_{2n+2}$:$O_2$:$N_2$(or $H_2O$) | Temp., °C | Yields of products*, mole % | | Selectivity w.r.t. dehydrogenation products, mole % | Refs. |
|---|---|---|---|---|---|---|---|
| | | | | monoolefins | diolefins | | |
| Ethane | mixed Zn, Pb, and Na oxides | 1:0.4:0 | 770 | 30 | — | 85 | 131 |
| Propane | mixed Na, V, and Al oxides | 1:0.3:1.2 | 490 | 17 | — | 79 | 132 |
| n-Butane | Na phosphomolybdate | 1:1:0 | 600 | 5 | 17 | 78 | 133 |
| n-Butane | nickel–molybdenum | 1:1:8 | 560 | 4 | 11 | 66 | 134 |
| n-Butane | mixed Ni, Mg, and P oxides | 1:1:14 | 593 | 4 | 14 | 44 | 135 |
| n-Butane | mixed Ni, Sn, P, and K oxides | 1:1:10 | 595 | 7 | 20 | 65 | 136 |
| Isopentane | mixed Fe, Ni, and Sb oxides | 1:1:20 | 538 | 1 | 7 | 44 | 137 |

*The yields of products are expressed in mole % relative to the initial hydrocarbon.

The surface of the reactor walls has a significant influence on the oxidation of paraffinic hydrocarbons regardless of whether complete or incomplete oxidation, dehydrogenation, or cracking predominates[1,11,12,41,138–141]. The influence of the solid surface on radical-chain reactions is usually attributed to its involvement in chain initiation and termination processes[11,12,17]. The termination of oxidation chains on the surface may involve the capture of $\dot{O}H$, $\dot{H}O_2$, $\dot{C}H_3$ etc. radicals. The conversion may be initiated on an active surface centre via the reaction[11]

$$C_nH_{2n+2} \xrightarrow{+(O_2)_{ads}} \dot{C}_nH_{2n+1}\,. \qquad (15)$$

However, the initiation and termination of chains on the surface is apparently only the simplest instance of the influence of the surface on the rate of radical-chain reactions. The influence of the surface may be attributed also to its involvement in chain branching of propagation. For example, according to Norikov et al.[139], in the oxidation of n-butane the surface of quartz catalyses the isomerisation of an unstable intermediate (s-butylperoxy-radical), which leads to the formation of one of the products of incomplete oxidation–acetaldehyde.

One of the functions of the catalyst in the oxidative dehydrogenation of paraffins is evidently the inhibition of oxidative cracking and of far-reaching oxidation, which has been observed on the surface of quartz[12,41]. All this does not of course rule out the possibility of the simultaneous occurrence in the system of definite heterogeneous-catalytic oxidative and other reactions with formation of dehydrogenation products. One of the possible mechanisms of the heterogeneous-catalytic oxidative

dehydrogenation of n-butane (in the presence of cobalt molybdate) has been proposed by Boutry et al.[142] The dehydrogenation of paraffins cannot proceed via a mechanism analogous to the dehydrogenation of olefins in the presence of bismuth molybdate, since the latter does not catalyse the dehydrogenation of paraffins[74]. Dieolefins may be formed from the intermediate mono-olefins via the usual heterogeneous-catalytic mechanism. Indeed substances such as phosphates or molybdates dehydrogenate mono-olefins with high yields of dienes. This probably explains the finding that the yields of butadiene in the presence of catalysts become higher than the yields of butenes (Table 1).

Mono-olefins may be formed to some extent via the usual dehydrogenation mechanism: mixed oxides containing substances such as chromium, vanadium, nickel, zinc, etc. are dehydrogenation catalysts[143]. Jouy and Balaceanu[144] indicate the possible role of the interaction of oxygen with the hydrogen removed from the hydrocarbon molecule. Thus all the catalysts which they tested (platinum, aluminium–chromium, etc.) readily oxidised hydrogen and there was no dehydrogenation of paraffin in the absence of oxygen under these conditions.

(b) Dehydrogenation in the Presence of Iodine and Oxygen

The characteristics of the dehydrogenation of n-butane in the presence of solid catalysts were investigated by the present author[1,145,146]. The experiments were performed mainly at 530°C in the presence of small (up to 3–4% relative to the hydrocarbon and oxygen) amounts of iodine. The dehydrogenation reaction is accelerated by the reactor walls, broken quartz, and to a particularly large extent in the presence of certain metal oxides and halides and other compounds on a porous carrier. An analogy is observed between the occurrence of dehydrogenation in the presence of solid catalysts and in the empty reactor. Changes in process parameters such as temperature, contact time, and reactant ratio had approximately the same influence on the conversion of n-butane in the presence of solid catalysts as in the empty reactor. A marked influence, comparable to that of the chemical composition of the catalyst, is shown by factors which determine the surface/volume ratio and the distribution of the surface in the reaction zone.

These studies led to the conclusion[1,146] that oxidative dehydrogenation in the presence of oxygen and iodine is not a heterogeneous-catalytic reaction. The increase of the yield of dehydrogenation products under the influence of solid catalysts cannot be accounted for by the inhibition of a side or secondary reaction, since the catalytic effect of the surface is not necessarily accompanied by a significant change in the distribution of products and the rate of conversion of butadiene in the presence of catalysts is actually higher than in the empty reactor. The characteristics of the action of a solid surface can be explained in terms of the hypothesis that the active surface accelerates a slow stage occurring in the bulk-phase reaction without altering significantly its mechanism. The oxidation of hydrogen iodide and the activation of oxygen and iodine by the surface have been considered to be stages of this kind.

The oxidation of hydrogen iodide [reaction (5)] is accelerated by oxidative dehydrogenation catalysts, but this cannot explain the increase of the yield of butadiene, since the rate of reaction (5) under the experimental conditions greatly exceeded the rate of dehydrogenation[1,147]. To test the possibility of heterogeneous initiation via the reaction of the hydrocarbons with oxygen [reaction (15)], a study was made[41] of the influence of broken quartz packing on the conversion of n-butane in the presence of oxygen. It was found that, under conditions close to those in the dehydrogenation reaction (but without iodine), the quartz surface strongly inhibits the conversion of butane and this is incompatible with the hypothesis of heterogeneous initiation [reaction (15)] with participation of oxygen. The data obtained can be explained if it is assumed that iodine may be activated on the catalyst surface, for example as a result of an increase of the concentration of atomic iodine in the system (analogously to the assumption made by Semenov for the chlorination reaction[18]):

$$I_2 + L \rightarrow L - I + \dot{I}$$

or by the formation of a reactive chemisorbed iodine molecule.

The role of the catalyst consists in accelerating the reactions of hydrocarbon molecules and radicals with iodine. At the same time the solid catalyst may also have a negative influence on the process, accelerating the secondary reactions of the dehydrogenation products.

Oxidative dehydrogenation in the presence of oxygen, iodine, and solid catalysts has also been investigated by Adel'son and coworkers. In the majority of experiments isopentane (and in addition also isopentenes and isobutane) were dehydrogenated and iodine was taken in an amount of 10% relative to carbon and oxygen. The observed characteristics proved to be in many respects analogous to those described above for the dehydrogenation of n-butane. Thus the dehydrogenation of those catalysts is accelerated by the addition of broken quartz[148–150]. The catalytic effect of the surface has been explained by the acceleration of a slow stage of the process[150,151]. The role of the catalyst does not consist in activating oxygen, since the quartz surface inhibits the conversion of hydrocarbons in the absence of iodine[152,153]. However, in contrast to the results quoted above for the dehydrogenation of n-butane, the authors[150,151] concluded that, under the conditions of their experiments, the slowest reaction stage is the oxidation of hydrogen iodide [reaction (5)] and that the role of the catalyst is to accelerate it. It is noteworthy that unduly high activation energies for reaction (14), involving the abstraction of the hydrogen atom from the hydrogen iodide molecule (29 kcal mole$^{-1}$ [150] and 25 kcal mole$^{-1}$ [151]) were used in a comparative estimate of the rates of oxidation of hydrogen iodide and dehydrogenation[150,151] instead of the more reliable value of 20 kcal mole$^{-1}$ (see above). This must have led to unduly low rates of oxidation of HI.

The ratio of the rate of oxidation of HI and dehydrogenation depends in general on the reactivity of the hydrocarbons and the reactant concentration ratios. With increase in the reactivity of the hydrocarbon and the concentration of iodine, which accelerates dehydrogenation and inhibits the oxidation of hydrogen iodide (see Section II), the above rate ratio can change significantly towards a reduced rate of reaction (5) and the acceleration of this reaction by the catalyst then becomes one of the causes of the increase of the yields of dehydrogenation products.

The dehydrogenation of n-hexane in the presence of iodine and oxygen is also accelerated by broken quartz and other active solid catalysts[145]. The main product of the iodine-induced dehydrogenation of n-hexane is benzene regardless of the presence of oxygen or solid catalysts. The preferential formation of the aromatic product takes place not only for appreciable degrees of conversion (above 30–40%) into dehydrocyclisation

products, as in the usual heterogeneous-catalytic processes [143], but also for low degrees of conversion (less than 10%). [145] If the aromatisation of paraffins in the presence of iodine proceeds via intermediate olefins (see above), the implication is that the difference between the reactivity of hexenes and hexane in iodine-induced dehydrogenation is very large.

(c) Dehydrogenation in the Presence of Chlorine- and Bromine-Containing Substances

Considerable advances have been made in recent years in the dehydrogenation of paraffins under the influence of chlorine, bromine, their compounds, and oxygen (Table 2). For the same halogen/hydrocarbon ratio, the yields of dehydrogenation products decrease in the sequence iodine > bromine > chlorine compounds. Mixtures of halogens are extremely effective. Juding from the available data[162,163], more effective dehydrogenation parameters are achieved in the presence of a mixture of iodine, bromine, and chlorine than when only one of the halogens is used. It follows from other patents [164-167] that higher yields of dienes and styrene were achieved in the dehydrogenation of olefins and ethylbenzene respectively than in the dehydrogenation of paraffins in the presence of the same amounts of the halogen. The main products of the dehydrogenation of n-hexane in the presence of HCl and oxygen for degrees of conversion up to 30% were hexenes (Table 2).

Table 2. The yields of products in the presence of HCl or bromine compounds, oxygen, and solid catalysts.

| Initial hydrocarbon | Catalyst | Halogen-containing substance (X) | Molar ratio $C_nH_{2n+2}:X:O_2$ | Temp., °C | Yields of products, mole %: mono-olefins | diolefins | benzene | Selectivity w.r.t. dehydrogenation products, mole % | Refs. |
|---|---|---|---|---|---|---|---|---|---|
| Ethane | Fe, Li, Ln chlorides-$Al_2O_3$ | HCl | 1:1:1 | 575 | 79 | — | — | 87 | 154 |
| n-Butane | $CeCl_3$-$SiO_3$ | HCl | 1:2:1,5 | 560 | 30 | 32 | — | 80 | 155 |
| n-Butane | $Fe_2O_3$-RbCl-$SiO_2$ | HCl | 1:2.3:1.3 | 585 | 28 | 33 | — | 76 | 156 |
| n-Pentane | $Fe_2O_3$-KCl-$SiO_2$ | HCl | 1:1.7:1 | 525 | 32 | 11 | — | 87 | 157 |
| Isopentane | mixed oxides and chlorides | HCl | 1:1.4:1 | 500 | 27 | 20 | — | 79 | 158 |
| n-Hexane | $Fe_2O_3$-CsCl-$SiO_2$ gel | HCl | 1:0.6:0.7 | 521 | 23 | 4 | 2 | 50 | 159 |
| n-Butane | Mg ferrite | HBr | 1:0.16:1.2 | 525 | 3 | 51 | — | 80 | 160 |
| Isopentane | $CoCl_2$-LiCl-$MgCl_2$-pumice | $Br_2$ | 1:0.1:1.9 | 500 | 21 | 17 | — | 71 | 161 |

In the presence of HCl and oxygen but without a catalyst, there is virtually no dehydrogenation. Thus at 550°C and for the butane : HCl : $O_2$ = 1 : 0.8 : 1 ratios, 38% of butenes and butadiene is formed in the presence of the $FeCl_3$–KCl–$SiO_2$ catalyst; in the absence of the catalyst, dehydrogenation products were not detected [168]. Dehydrogenation in the presence of HCl and $O_2$ apparently proceeds via a mechanism different than in the presence of chlorine, which is capable, in contrast to HCl, of interacting directly under the dehydrogenation conditions with the hydrocarbon in the gas phase via a radical-chain mechanism [169]. The role of the catalyst in the dehydrogenation of paraffins in the presence of chlorine may be to generate chlorine atoms by the cleavage of molecular chlorine, as has been assumed for the chlorination of hydrocarbons [18,169]. On the other hand, dehydrogenation in the presence of HCl and oxygen should probably be regarded as a heterogeneous-catalytic reaction.

Both in the presence of chlorine and in the presence of HCl and oxygen, hydrocarbons are probably dehydrogenated via intermediate organic chlorides. These products are formed on direct interaction of the hydrocarbons with chlorine [169]. In the presence of HCl, oxygen, and metal chloride as catalysts, methane and ethane undergo oxidative chlorination with formation of alkyl chlorides in accordance with the overall equation [170]

$$HCl + 1/2O_2 + RH \rightarrow RCl + H_2O .$$

It is also known that $C_3$–$C_4$ alkyl chlorides readily decompose above 300–400°C into olefins and HCl. [169]

There is a correlation between the activity of catalysts in relation to oxidative dehydrogenation and oxidation of HCl:

$$4HCl + O_2 \rightarrow 2Cl_2 + 2H_2O . \qquad (16)$$

The activity increases for both reactions in the following series of metal compounds: Nb < Ce < Bi < (Mn, Fe, Co, Ni, Pd) < V < Cu. [171]

Ioffe and Kikot' [155] proposed a multistage mechanism for the dehydrogenation of n-butane to butadiene via the intermediate formation of alkyl and alkenyl chlorides, chlorine, and butenes:

$$\begin{aligned} &4HCl + O_2 \rightarrow 2Cl_2 + 2H_2O , \\ &C_4H_{10} + Cl_2 \rightarrow C_4H_9Cl + HCl , \\ &C_4H_9Cl \rightarrow C_4H_8 + HCl , \\ &C_4H_8 + Cl_2 \rightarrow C_4H_7Cl + HCl , \\ &C_4H_7Cl \rightarrow C_4H_6 + HCl , \end{aligned} \qquad (XIII)$$

where the rate-limiting stage is the oxidation of HCl [reaction (16)]. According to scheme (XIII), the hydrocarbon reacts with chlorine alone and the role of oxygen is limited to its involvement in the formation of chlorine [reaction (16)]. According to scheme (XIII), chlorine should be a much more active dehydrogenation agent than HCl, which has not been confirmed experimentally [168].

Tarasova and Solomatina [168] proposed mechanisms for the dehydrogenation of butane to butenes:

$$C_4H_{10} + 1/2O_2 + HCl \rightarrow [C_4H_9Cl] + H_2O \qquad (XIV)$$
$$\downarrow$$
$$C_4H_8 + HCl$$

and to butadiene:

$$C_4H_{10} + 2HCl + O_2 \rightarrow [C_4H_8Cl_2] + 2H_2O \qquad (XV)$$
$$\downarrow$$
$$C_4H_6 + 2HCl ,$$

According to these mechanisms, the reaction proceeds without the formation of intermediate chlorine. These mechanisms reflect to a greater extent the specific features of the process than mechanism (XIII). However, when butadiene is formed [mechanism (XV)], the absence of intermediate butene is doubtful. There are few experimental data concerning the conversion of paraffins into mono- and di-olefins in the absence of chlorine compounds. However, it is known that the dehydrogenation of butane in the presence of HCl and oxygen involves the formation of an appreciable amount of butenes, whose capacity for conversion into butadiene in the presence of the same catalyst is greater than that of butane [172]. At least a significant fraction of butadiene should therefore be formed via butenes.

Bromine compounds behave more like iodine compounds in oxidative dehydrogenation reactions than like chlorine compounds. In the presence of oxygen and HBr (in contrast to HCl and similarly to HI), dehydrogenation occurs also in the empty reactor [147,173]. Thus at 500°C and for the isopentane : oxygen : HBr = 1 : 1 : 2.1 ratios, 13% of isoprene is formed in the absence of the catalyst [173].

When the catalyst ($CoCl_2$, LiCl, and $MgCl_2$ on pumice) was introduced, the yield of isoprene rose to 26%.

In the joint presence of iodine and chlorine or bromine, the dehydrogenation of hydrocarbons apparently proceeds via a radical-chain mechanism. The acceleration of the reaction under the influence of the addition of the second halogen may be associated with the interaction between the halogens, which leads to the replacement of the slow reaction stages by faster stages. For example, when chlorine is added to the paraffin–iodine system, the comparatively slow formation of the alkyl radical on interaction with iodine

$$C_4H_{10} + \dot{I} \rightarrow \dot{C}_4H_9 + HI, \quad \varepsilon \simeq 25 \text{ kcal mole}^{-1}$$

is replaced by the rapid reaction [39]

$$C_4H_{10} + \dot{Cl} \rightarrow \dot{C}_4H_9 + HCl, \quad \varepsilon \simeq 1 \text{ kcal mole}^{-1}.$$

On the other hand, the formation of atomic chlorine in the presence of iodine is facilitated by the fact that it may not involve the dissociation of a chlorine molecule:

$$Cl_2 + M \rightarrow 2\dot{Cl} + M, \quad \varepsilon \simeq 57 \text{ kcal mole}^{-1}$$

but may proceed, for example, via the reaction

$$Cl_2 + \dot{I} \rightarrow ClI + \dot{Cl},$$

whose rate should be much higher.

### (d) The Reaction of Hydrocarbons in the Presence of Sulphur Compounds

Appreciable yields of dehydrogenation products are reached in the presence of sulphur or sulphur compounds ($H_2S$, $SO_2$, COS, etc.) and solid catalysts [174–178]. In the dehydrogenation of ethane in the presence of $H_2S$ and oxygen (with $C_2H_6 : H_2S : O_2 = 1 : 1.5 : 0.75$) and cadmium oxide on $Al_2O_3$ with a specific surface less than 1 $m^2\ g^{-1}$, the yield of ethylene was 77% for a selectivity of about 90%. [174] In the dehydrogenation of butane in a mixture with $SO_2$ on a bismuth–iron phosphate catalyst, the sum of butenes and butadiene formed was 38% for a selectivity of 38%, while in the dehydrogenation of isobutane on molybdenum sulphide the yield of isobutenes was 30% for a selectivity of 61%. [175]

Olefins with long $C_4$–$C_5$ chains are dehydrogenated with higher yields of products than the corresponding paraffins [175]. In the presence of sulphur (0.5 mole) and oxygen (1 mole per mole of hydrocarbon), ethylbenzene is converted into styrene with a yield exceeding 80% for a selectivity above 90%. [178,179] The degree of conversion of n-hexane in the presence of various catalysts and $SO_2$ reached 44–93%. [175] The dominant product for highest degrees of conversion was benzene (in a yield up to 54%). For moderate degrees of conversion, a considerable proportion of the products consisted of olefins, whose yields (up to 23–24%) exceeded those which are reached in the usual catalytic dehydrogenation [143,180]. Thus higher yields are reached in many instances in the dehydrogenation of hydrocarbons in the presence of sulphur compounds than in oxidation by oxygen or in the usual catalytic dehydrogenation.

There are reasons why dehydrogenation in the presence of sulphur compounds should be regarded as a process involving heterogeneous-catalytic reactions [178,185]. In the absence of the catalyst, the reaction proceeds to only a slight extent. Thus the dehydrogenation of n-hexane and cyclohexane (500°C, space velocity 0.5 $h^{-1}$) in a 1 : 1 mixture with $SO_2$ on alumina leads to the formation of up to 15 and 35% of benzene respectively. When alumina is replaced by quartz, the reaction hardly occurs. In the absence of sulphur dioxide, there is also no dehydrogenation on $Al_2O_3$. [182] During the reaction, $SO_2$ interacts directly with the hydrocarbon but not with the hydrogen evolved, since dehydrogenation ceases immediately after the removal of $SO_2$. Here $SO_2$ behaves as a hydrogen acceptor, being converted in the dehydrogenation reaction into hydrogen sulphide, for example:

$$C_4H_{10} + 1/3SO_2 \rightarrow C_4H_8 + 1/3H_2S + 2/3H_2O.$$

By accepting hydrogen, sulphur is similarly converted into hydrogen sulphide, for example via the reaction

$$C_4H_{10} + 1/2S_2 \rightarrow C_4H_8 + H_2S.$$

According to Pasternak and Vadekar [183], mixtures of $H_2S$ and oxygen are more effective. During the oxidation of $H_2S$, which occurs simultaneously with the dehydrogenation reaction, the $S_2$ biradical as well as other active species ($H\dot{S}$, $S_2^+$) are formed and are probably involved in the intermediate dehydrogenation stages.

## IV. DEHYDROGENATION IN THE PRESENCE OF SOLID ACCEPTORS OF HYDROGEN IODIDE

### 1. THE INFLUENCE OF THE CHEMICAL COMPOSITION OF THE HYDROGEN IODIDE ACCEPTOR

The influence of the chemical composition of the acceptor on the yield of n-butane, propane, and isopentane dehydrogenation products in the presence of iodine (but without oxygen) has been investigated [145]. The specimens were prepared by mixing ground oxide powders with a binder. In terms of the yields of the n-butane dehydrogenation products, the constant-valence metal oxides investigated can be arranged in the following sequence:

$$SrO \simeq CaO > ZnO > MgO. \qquad (17)$$

In the presence of variable-valence metal oxides, which are reduced on interaction with HI, the yields of butadiene decrease in the sequence

$$Mn_3O_4 \simeq Fe_2O_3 > Co_3O_4 > Ni_2O_3 > CuO > Cu_2O. \qquad (18)$$

Fairly high yields of butadiene were obtained only in the presence of $Mn_3O_4$ and $Fe_2O_3$. In the presence of the remaining variable-valence metal oxides, the main process is oxidation by the oxygen evolved from the lattices of the oxides as a result of their partial reduction by the hydrocarbon. In the dehydrogenation of propane and isopentane, the oxide acceptors investigated can be arranged, with slight deviations, in the same sequences in terms of the yields of products as in the dehydrogenation of n-butane.

The influence of the chemical composition of HI acceptors on the dehydrogenation of paraffinic hydrocarbons by oxygen supplied to the system has been investigated in a number of studies. The highest yields of isoprene in the presence of calcium, barium, strontium, zinc, nickel, iron, cobalt, copper, and manganese oxides have been obtained when alkaline earth metal and manganese oxides were used [184]. Alkali metal hydroxides deposited on carriers are extremely effective acceptors. In the dehydrogenation of isopentane in the presence of iodine and oxygen, the yield of isoprene decreases in the sequence [185]

$$NaOH > KOH > BaO > CaO > CuO \qquad (19)$$

(the oxides and hydroxides were deposited on $Al_2O_3$).

NaOH, KOH, and $MnO_2$ acceptors deposited on $Al_2O_3$ were investigated[186]. On sodium acceptors, it is possible to achieve higher yields of butadiene and a much smaller loss of iodine from the reactor than in the presence of the manganese acceptor[186]. However, a disadvantage of the sodium acceptor is the appreciable corrosion of the reaction apparatus. In the presence of the potassium acceptor, the loss of iodine from the reactor is smaller, but the yields of butadiene for the same amount of iodine are lower than in the presence of the sodium acceptor[187].

The influence of the chemical composition of HI acceptors in the dehydrocyclisation of n-hexane has been investigated[188]. The metal oxides were prepared by pressing their powders with added binder and potassium iodide. Tor the ratios $C_6H_{14}:I_2:O_2 = 1:{\sim}0.9:1$, the yields of benzene decreased in the sequence

$$Fe_2O_3 > Mn_2O_3 > CaO > ZnO > CuO > Co_3O_4 > Ni_2O_3 \qquad (20)$$

and in the presence of the last four oxides they were lower than in the reaction in the empty reactor.

Under optimum conditions, yields of benzene exceeding 60% were achieved in the dehydrocyclisation of n-hexane in the presence of an acceptor[189], but they do not exceed the yield of this product in the usual catalytic aromatisation. The yields of hexene in the presence of HI acceptors are even lower than in the empty reactor or in the presence of non-accepting solid catalysts. Considerable amounts of coke-like and tarry side products are formed.

The distribution of acceptors in sequences (17)–(20) apparently depends to a definite extent on the method of preparation of the specimens, the additives present, and the experimental conditions. For low amounts of iodine supplied (iodine/hydrocarbon = 0.1) and an equimolar amount of oxygen, the yields of butadiene obtained in the presence of active HI acceptors such as sodium hydroxide on $Al_2O_3$ are lower than in the presence of ground quartz[190] and only a mixture of the acceptor and quartz makes it possible to obtain higher yields of butadiene than on quartz. A similar effect has been observed in the dehydrogenation of isopentane. The fact that the replacement of quartz by an active HI acceptor for low amounts of iodine supplied leads to a decreased yield of diolefins can be accounted for, on the one hand, by the catalytic influence of quartz and, on the other hand, by the fact that the acceptor binds HI and removes a definite proportion of the iodine from the reaction sphere. The study of the time variation of the yield of diolefins showed that, after complete iodination, the acceptor has approximately the same influence on the reaction as the quartz packing.

## 2. THE BINDING OF HYDROGEN IODIDE BY SOLID ACCEPTORS

Reactions involving the absorption of HI [reactions (6) and (7)] belong to the class of exchange topochemical reactions:

$$\text{solid}_{(1)} + \text{gas}_{(1)} \rightarrow \text{solid}_{(2)} + \text{gas}_{(2)}$$

and exhibit properties characteristic of reactions of this type.

The comparative reactivities of a number of metal oxides in relation to HI have been investigated[191,192]. The oxides were prepared in two ways: by deposition in a thin layer on quartz plates and by the granulation of commercial preparations. The oxide grains (approximately 2 mm in size) were the same as those employed in experiments on oxidative dehydrogenation in the presence of iodine (see above). The average thickness of the layer of oxide deposited on plates was approximately 1–2 μm. The specific surfaces of the finished specimens did not exceed several $m^2\ g^{-1}$ and their pore volumes were in the range 0.1–0.3 $cm^3\ g^{-1}$. The experimental data for the oxides investigated are described by the kinetic equation

$$\alpha = kt^n \qquad (21)$$

or

$$1 - \sqrt[3]{1-\alpha} = kt^m\,, \qquad (22)$$

where $\alpha$ is the degree of conversion and $n$ and $m$ are constants. The reactions of the metal oxides with HI are retarded up to a complete arrest for degrees of conversion departing widely from equilibrium. The granulated constant-valence metal oxides can be arranged in the following sequence in terms of their reactivity for low (up to 1–2%) degrees of conversion:

$$SrO > BaO > CaO > ZnO > MgO\,, \qquad (23)$$

while variable-valence metal oxides can be arranged in the following sequence:

$$Mn_3O_4 > Co_3O_4 > CuO > Fe_2O_3 > Ni_2O_3\,. \qquad (24)$$

The rate of reaction of the granulated metal oxides with HI is much lower than that of the oxides deposited on plates. For all the oxides in the grains, except zinc oxide, the reaction virtually ceases under the conditions investigated when the degree of conversion is less than 5%. The degree of conversion reached for the same oxide on plates is between 10 and 95%. Thus the dependence of the reactivity of the oxides on their particle size is so great that it is manifested even more markedly than its dependence on the chemical nature of the oxide. The arrest of the reaction of the oxide with hydrogen iodide under conditions remote from equilibrium has been explained[192] in terms of the theory of impedance in topochemical reactions[193]. The ionic radius of $I^-$ (2.2 Å) greatly exceeds that of $O^{2-}$ (1.4 Å). The molar volume of the iodide formed is therefore much greater than that of the initial oxide, i.e. the volume of the reaction system greatly increases during the reaction. The molar volumes of the iodides of the metals investigated (calcium, magnesium, strontium, barium, manganese, nickel, and copper) are greater by a factor of 2.7–5.8 than those of the corresponding metal oxides. As a consequence of the increased volume of the system, the conversion of the oxide into the iodide entails an increase in the compactness of the outer layer of the specimen, which inhibits the diffusion of HI into the bulk of the oxide and the removal of water vapour, and, in the case of variable-valence oxides, also the removal of iodine from the reaction zone.

In the majority of experiments with oxides deposited on plates and with granulated oxides in all cases, the observed values of $n$ and $m$ in Eqns. (21) and (22) were smaller than unity and the apparent activation energies above 400°C did not exceed 10–11 kcal $mole^{-1}$,[194] which is characteristic of reactions occurring under conditions with diffusion-induced inhibition. The only exception (with respect to the values of $m$ and activation energies) is ZnO on plates. The product of the reaction of ZnO with HI (zinc iodide) sublimes under the experimental conditions. The removal of the iodide from catalyst sites containing ZnO which has not reacted should lead to an increase with time

of the proportion of defects in the surface layer of the oxide and to the formation of transport pores, which is probably the cause of the pronounced S-shape of the kinetic curves for reactions involving the absorption of HI by zinc oxide and also the comparatively small extent of the diffusion-induced inhibition of this reaction [192]. The impedance phenomenon has a significant influence on the dehydrogenation process in the presence of oxides which are HI acceptors. The acceptor is rapidly exhausted, so that its large excess relative to the hydrocarbon is required.

### 3. FACTORS DETERMINING THE EFFICIENCY OF HYDROGEN IODIDE ACCEPTORS IN THE OXIDATIVE DEHYDROGENATION PROCESS

In order to elucidate the factors which determine the efficiency of HI acceptors, the yields of dehydrogenation products were compared with the rates and equilibria of the reactions of metal oxides with hydrogen iodide [41,145]. At temperatures in the range 300–530°C, the equilibrium degree of conversion of all the oxides investigated (BaO, SrO, CaO, ZnO, $Cu_2O$, etc.), except magnesium oxide, into the iodides is close to 100%, while for MgO it is not more than 10%. [145,194] The yields of diolefins in the oxidative dehydrogenation of n-butane and isopentane in the presence of magnesium oxide are also lower than on the remaining constant-valence metal oxides. However, no relation is observed for the latter oxides between the degree of approach to equilibrium in the reaction with HI and the yields of dehydrogenation products, since the equilibrium in the reaction involving the absorption of HI is almost completely displaced towards the formation of the iodide on virtually all the oxides‡.

Under the conditions of the dehydrogenation experiments, the acceptor : hydrocarbon weight ratio was 140 to 150. For low degrees of conversion (up to 1–2%), the rate of sorption of HI by the granulated metal oxides decreases in sequences (23) and (24) and the yield of butadiene decreases as a function of the chemical composition of the acceptor in sequences (17) and (18). Thus, for constant-valence metal oxides, there is a correlation between the reactivity in relation to HI and the yields of butadiene in the dehydrogenation of n-butane [sequences (17) and (23)]. In the presence of $Mn_3O_4$, the highest yields of butadiene are observed and the rates of binding of HI by this oxide are a maximum. However, for the remaining variable-valence metal oxides, no correspondence is observed between sequences (18) and (24). This can probably be accounted for by the catalytic influence of some of the above oxides, promoting the dehydrogenation and complete oxidation of the hydrocarbons [41].

The correspondence between the yields of dehydrogenation products and the reactivities of the acceptor in relation to HI is associated with the fact that the reaction involving the absorption of HI is not sufficiently fast under the dehydrogenation conditions to influence the rate and equilibrium of the dehydrogenation reaction, and the efficiency of the acceptor is determined by the rate of its reaction with HI. The observed impedance phenomenon and other experimental findings, in which a pronounced diffusion-induced inhibition of the reaction of the oxides with HI is manifested, demonstrates the particular importance of ensuring a sufficient degree of dispersion of the acceptor in order to improve its efficiency. Indeed, under the conditions usually employed in oxidative dehydrogenation (in the presence of a large excess of the acceptor relative to HI), the yield of dehydrogenation products begins to fall for degrees of conversion of the oxides into the iodides not exceeding several per cent [194,195].

When dehydrogenation with an HI acceptor proceeds in the presence of oxygen, the binding of HI is accompanied by the oxidation of the metal iodide by oxygen—reaction (8), involving the regeneration of iodine and the acceptor, takes place. The rate of dehydrogenation is therefore also important for the yields of the products of this reaction. According to Kolobikhin [187], the yields of butadiene on the potassium acceptor (KOH deposited on $Al_2O_3$) are much lower than on the sodium acceptor for the same content of iodine. At the same time, the rate of binding of hydrogen iodide on the potassium acceptor is apparently higher than on the sodium acceptor, as can be inferred from the loss of HI from the reactor. However, the rate of regeneration of the potassium acceptor is much lower than that of the sodium acceptor: under the conditions tested, the sodium acceptor is regenerated to the extent of 52% after 20 min, while the potassium acceptor is regenerated to the extent of only 8.7%. Thus the yields of the dehydrogenation products decrease with increase of the rate of regeneration of the acceptor.

In the study of granulated HI acceptors, a dependence of either the rate of absorption of HI or of the rate of dehydrogenation on their porous structure was not observed (although one must bear in mind that the pore volumes and the specific surfaces of the acceptors were small [192,194]). This can be explained by the fact that the increased compactness of the outer layer of the grain as a result of impedance is so great that the inner surface is blocked and hardly participates in the reaction. However, the dependence on the porous structure of the acceptor is manifested when a granulated acceptor is compared with one deposited on a carrier with a well developed porous structure (for example CaO on the KSK silica gel with a specific surface of about 100 $m^2 g^{-1}$). [1,196]

The influence of the inner surface of the acceptor on the conversion of the hydrocarbon is caused, on the one hand, by the increased rate of binding of HI and of the regeneration of the acceptor and, on the other, by the increased extent of the secondary reactions of the dehydrogenation products. In the presence of porous catalysts, isoprene undergoes a particularly extensive conversion. The yields of isoprene in the dehydrogenation of isopentane in the presence of porous acceptors as well as in the presence of porous non-accepting catalysts are therefore low.

o0o

Studies in the field of the oxidative dehydrogenation of hydrocarbons have been carried out during the last decade mainly on the following lines.

1. The development of the theory and technology of industrial processes (iodine dehydrogenation of butane, oxygen dehydrogenation of butenes). The technological aspects of the problem were not considered in the present review.

‡For this reason, it is difficult to justify theoretically the hypothesis [184] of a relation between the yields of isoprene and the decrease of the free energy of binding of HI for the oxides of metals such as barium, strontium, zinc, manganese, etc.

2. The accumulation of data (mainly empirical data) on the yields of products and the selection of catalysts and process conditions for other oxidative dehydrogenation procedures, which are of clear practical interest and are likely to be applied on an industrial scale in the near future (dehydrogenation in the presence of chlorine and sulphur compounds, dehydrogenation of paraffinic hydrocarbons in the presence of oxygen and solid catalysts).

3. The search for new, previously unknown dehydrogenating agents and the associated development of ideas about the general principles of the action of dehydrogenating agents.

There is an extremely large variety of types of oxidative dehydrogenation processes. Those which have been most thoroughly investigated can be subdivided into two types to a first approximation: heterogeneous-catalytic reactions and radical-chain reactions catalysed by the surface. The dehydrogenation of olefins in the presence of oxygen belongs to the first variety, which may also include the dehydrogenation of paraffins in the presence of HCl or sulphur compounds and oxygen. Iodine dehydrogenation (in the presence or absence of oxygen) belongs to the second variety.

The accumulated experimental data show that, in dehydrogenation involving halogen compounds, there are analogies between the reactions of hydrocarbons belonging to different homologous series, the reactivity increasing with increased degree of unsaturation of the hydrocarbon. The influence of unsaturation in iodine dehydrogenation is so great that the dehydrogenation of $C_4$–$C_5$ paraffins leads to the almost exclusive formation of diolefins, while the dehydrogenation of $C_6$ paraffins yields aromatic products. The dehydrocyclisation of higher paraffins in the presence of chlorine and sulphur compounds and oxygen as well lead, like ordinary catalytic dehydrocyclisation, to the formation of a considerable amount of mono-olefins. In dehydration in the presence of oxygen, there is as a rule no similarity in the behaviour of paraffins and olefins.

Iodine dehydrogenation is employed in practice in an extremely complex system with gaseous and solid regenerators (acceptors); solid acceptors also exhibit a catalytic activity. The mechanism of iodine dehydrogenation in the presence of oxygen and an HI acceptor has been elucidated mainly by the separate investigation of the reaction in simplified and model systems (dehydrogenation in the presence of individual radical-forming substances, the influence of non-accepting catalysts, the reactions of acceptors with HI, etc.). The results can be regarded as a first approximation to the reaction mechanism involving the simultaneous occurrence of these processes in a real system.

Iodine dehydrogenation can be regarded merely as a first advance in the field of oxidative dehydrogenation of paraffins. Further development of methods for oxidative dehydrogenation should probably lead to the development of additional processes with more readily available and cheaper dehydrogenating agents, particularly agents based on chlorine or sulphur compounds. There already exists a definite theoretical basis, which makes it possible to direct the search for new systems of dehydrogenating agents (mixtures of radical-forming substances) along a rational pathway.

# Chemical Transformations of Aminoglycoside Antibiotics

B.N.Strunin

Aminoglycoside antibiotics belong to the class of pseudo-oligosaccharides, which is a chemotherapeutically important group of antibiotics with a broad spectrum of antimicrobial activity. The review surveys and gives a systematic account of the literature data relevant to the chemical properties of aminoglycosides. Particular attention has been devoted to the chemical transformations of natural antibiotics.
The bibliography includes 323 references.

## I. INTRODUCTION

Aminoglycoside antibiotics have changed in recent years from a very narrow and specific group of preparations into a large family with many members, including antibiotics such as streptomycin, neomycin, kanamycins, gentamicins, etc. This class of antibiotics has aroused interest of representatives of a wide variety of disciplines—experts in therapy, selection [of drugs ?], chemical synthesis, and biochemists: the broad search for Actinomycite strains producing aminoglycosides and the vigorous development of biosynthesis is due to the chemotherapeutic properties of the aminoglycoside antibiotics used to fight the most dangerous types of infection.

At the same time the appearance of new antibiotics is accompanied by an increase of the number of bacterial strains with multiple resistance to therapeutic agents. One of the main forms of bacterial resistance to aminoglycosides consists in their inactivation by enzymes produced by micro-organisms. Chemists were faced with the acute problem of specific modification of aminoglycosides in order to create preparations active in relation to multiply resistant forms of bacteria. The determination of the mechanisms of the enzymatic inactivation of aminoglycoside antibiotics, the study of the mechanisms of their action, and the elucidation of the dependence of the biological activity of a compound on its structure made it possible to establish promising trends in chemical transformations. Progress in the study of chemical properties was achieved with the aid of the latest techniques in physicochemical methods of research such as NMR, infrared spectroscopy, mass spectrometry, X-ray diffraction analysis, gas–liquid chromatography, high-pressure liquid chromatography, and electrophoresis.

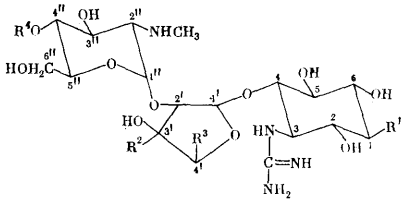
Natural aminoglycoside antibiotics have become the richest source of a wide variety of monosaccharides, have enriched carbohydrate chemistry in unusual previously unknown aminosugars, and have exerted a significant influence on its development.

The present review surveys and gives a systematic account of the literature data relevant solely to the chemical properties of aminoglycosides, since examination of important problems such as biosynthetic pathways, methods for the determination of structures, the mechanism of action, the dependence of biological properties on structure, etc., would have greatly increased the size of the review. Particular attention is devoted to methods for the specific chemical transformations of natural antibiotics.

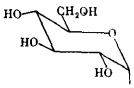
The stereochemistry of aminoglycosides has been examined in detail in Umezawa[1,2] and Daniels'[3] reviews. The methods for the determination of the structures of the products of the enzymatic inactivation of aminoglycoside antibiotics have been discussed in Umezawa's reviews[4,5]. †

## II. CLASSIFICATION OF AMINOGLYCOSIDE ANTIBIOTICS

Chemically, aminoglycoside antibiotics are pseudo-oligosaccharides. Their molecules consist of two fundamentally different components. One component is a carbohydrate containing at least one amino-group, and the other is the aglycone. The aminosugar is linked to the aglycone by the glycosidic $C_{(1)}$–O bond. The number of carbohydrate rings in the molecule varies from one to four and at least two carbohydrate substituents are linked to the aglycone. The aglycone is a cyclitol or an aminocyclitol. Antibiotics with the most valuable antibacterial properties contain aminocyclitols, mainly streptidine or deoxystreptamine. Thus, aminoglycoside antibiotics belong to the class of aminoglycosidic aminocyclitols.



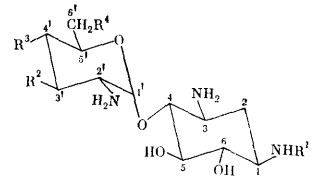
Since aminoglycoside antibiotics are pharmaceutical preparations, it is quite natural that their classification should be based on molecular properties which have the greatest influence on their biological activity. Analysis of the literature data has shown that the biological activity of aminoglycosides depends significantly on their structure (the number, nature, and relative positions of the carbohydrate rings linked to the aglycone and the nature of the



† The problems of biosynthesis have been analysed by Rhinehart and Stroshane[310].

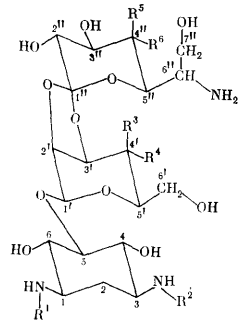
aglycone), functional groups, and molecular configuration and conformation. It is most useful to base the classification on the structural properties of aminoglycoside molecules.

Depending on the nature of the aglycone, aminoglycosides are divided into two important subclasses: one of them includes antibiotics containing streptidine and the other includes those containing deoxystreptamine. The subclass of aminoglycosides containing streptamine has very few members, but includes therapeutically important antibiotics—streptomycin, dihydrostreptomycin, and mannosidostreptomycin. Bleunsomycin, differing from the other streptomycin antibiotics by the structure of the aglycone, has come to be included in the same subclass.



Aminoglycosides containing deoxystreptamine are distinguished by their wide variety, and their characteristic feature is the large number of members of each antibiotic family. Thus two neomycins, four hybrimycins, two lividomycins, four butirosins, the isomeric ribostamycin and xylostasin, seven kanamycins, at least fifteen gentamicins, and several antibiotics of the type of sisomicin are known at the present time. The deoxystreptamine antibiotics can be subdivided into several groups depending on the nature and number of carbohydrate substituents in the molecule and their distribution relative to the carbon atoms of the deoxystreptamine ring.

| | $R^1$ | $R^2$ | $R^3$ | $R^4$ |
|---|---|---|---|---|
| Streptomycin | $-NHC(=NH)NH_2$ | CHO | $CH_3$ | H |
| Dihydrostreptomycin | $-NHC(=NH)NH_2$ | $CH_2OH$ | $CH_3$ | H |
| Mannosidostreptomycin | $-NHC(=NH)NH_2$ | CHO | $CH_3$ |  |
| Oxystreptomycin | $-NHC(=NH)NH_2$ | CHO | $CH_2OH$ | H |
| Bluensomycin | $-OCONH_2$ | CHO | $CH_3$ | H |

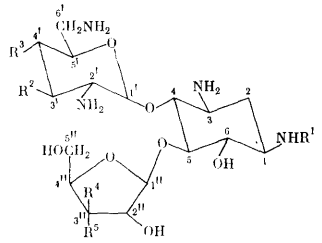


Depending on the number of substituents in the aglycone, aminoglycoside antibiotics containing deoxystreptamine can be divided into two types. The first includes antibiotics in which deoxystreptamine has one carbohydrate substituent, and the second includes those which have two carbohydrate substituents in the deoxystreptamine ring. In aminoglycosides which are monosubstituted 2-deoxystreptamines, the pyranosyl substituent is attached to the carbon atom either in the 4- or 5-position.

Neamine[6], paromamine[9,11], and their semisynthetic derivatives such as 4′-deoxyneamine[12], 3′,4′-dideoxyneamine[13,14], 3′,4′,5,6-tetradeoxyneamine[15], 1-*N*-[(*s*)-4-amino-2-hydroxybutyryl]neamine[16,17], 1-*N*-[(*s*)-4-amino-2-hydroxybutyryl]-4′-deoxyneamine[12], and 1-*N*-[(*s*)-4-amino-2-hydroxybutyryl]-3′,4′-dideoxyneamine[18–21] form a group of antibiotics which are pseudodisaccharides, in which the 2-deoxystreptamine ring has a pyranosyl substituent at the carbon atom in the 4-position:

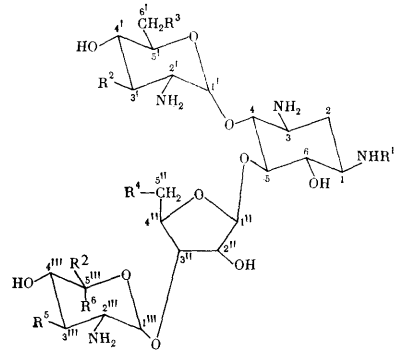
| | $R^1$ | $R^2$ | $R^3$ | $R^4$ |
|---|---|---|---|---|
| Neamin | H | OH | OH | $NH_2$ |
| Paromamine | H | OH | OH | OH |
| 3′,4′-Dideoxyneamine | H | H | H | $NH_2$ |
| 1-*N*-[(*s*)-4-Amino-2-hydroxybutyryl]neamine | $-CO-\underset{OH}{CH}-CH_2-\underset{NH_2}{CH_2}$ | | OH | OH | $NH_2$ |
| 1-*N*-[(*s*)-4-Amino-2-hydroxybutyryl]-3′,4′-dideoxyneamine | $-CO-\underset{OH}{CH}-CH_2-\underset{NH_2}{CH_2}$ | | H | H | $NH_2$ |

The antibiotics characterised by the presence of only one substituent in the aglycone also include antibiotics of the destomycin series. In contrast to neamine and paromamine, the carbohydrate substituent in the molecules of these antibiotics is at the $C_{(5)}$ carbon atoms of the deoxystreptamine ring and the pyranose ring also has a substituent—destomic acid. This group includes hygromycin B,[22–25] the antibiotic A-396-1 (SS-56-D),[26,27] destomycins A, B, and C,[28–33] and the antibiotics SS-56-C,[27] and A-16316-C.[34]

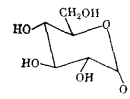


| | $R^1$ | $R^2$ | $R^3$ | $R^4$ | $R^5$ | $R^6$ |
|---|---|---|---|---|---|---|
| Destomycin A | $CH_3$ | H | $CH_3$ | H | OH | H |
| Destomycin B | $CH_3$ | $CH_3$ | H | OH | H | OH |
| Destomycin C | $CH_3$ | $CH_3$ | OH | H | OH | H |
| Hygromycin B | H | $CH_3$ | OH | H | OH | H |
| A-396-1 | H | H | OH | H | OH | H |
| A-16316-C‡ | $CH_3$ | $CH_3$ | H | OH | OH | H |

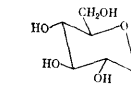
A characteristic feature of the aminoglycosides belonging to the group of disubstituted 2-deoxystreptamines is the presence of a pyranosyl substituent at $C_{(4)}$. The second substituent is either at $C_{(5)}$ or $C_{(6)}$. A pyranosyl substituent is located at $C_{(6)}$, while only the furanosyl substituent is at $C_{(5)}$ in all known instances. Accordingly, aminoglycoside antibiotics of this type can be subdivided into two varieties. The first includes aminoglycosides whose deoxystreptamine ring has pyranosyl and furanosyl substituents at the carbon atoms in the 4- and 5-positions respectively, while the second variety combines antibiotics having paranosyl substituents at $C_{(4)}$ and $C_{(6)}$.

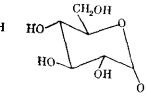


‡ The structure of this antibiotic has not been established exactly.

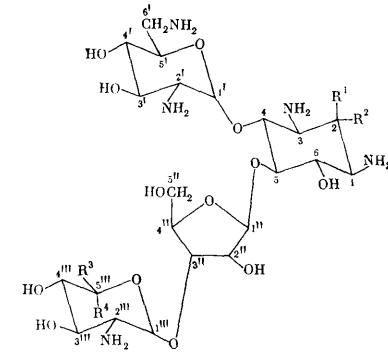


Aminoglycosides containing a furanosyl substituent (D-ribose or D-xylose) can be divided in their turn into two groups. The first includes antibiotics containing unsubstituted D-ribose or D-xylose. Its representatives are ribostamycin[16,35-38], xylostasin[16,37,39], butirosins A and B[16,37,40-47], and the antibiotics Bu-1709 $E_1$ and $E_2$ [46] as well as their semisynthetic derivatives 3′-deoxyribostamycin[48], 4′-deoxyxylostasin[12], 3′,4′-dideoxyribostamycin[20,49], 3′,4′,5″-trideoxyribostamycin[20,49], 1-*N*-methylribostamycin[50], 4′-deoxybutirosins A and B,[12,37] 3′,4′-dideoxybutirosin B,[51] and 5″-amino-5″-deoxybutirosin[52].





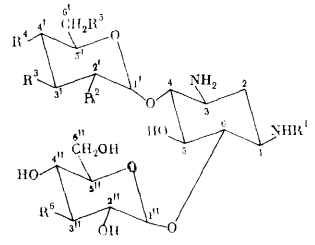
| | $R^1$ | $R^3$ | $R^4$ | $R^5$ | $R^6$ |
|---|---|---|---|---|---|
| Ribostamycin | H | OH | OH | H | OH |
| Xylostasin | H | OH | OH | OH | H |
| Butirosin A | —CO—CH(OH)—$CH_2$—$CH_2$—$NH_2$ | OH | OH | OH | H |
| Butirosin B | —CO—CH(OH)—$CH_2$—$CH_2$—$NH_2$ | OH | OH | H | OH |
| 3′,4′-dideoxyribostamycin | H | H | H | H | OH |
| 3′,4′-dideoxybutirosin B | —CO—CH(OH)—$CH_2$—$CH_2$—$NH_2$ | H | H | H | OH |



The second group includes antibiotics having an additional pyranosyl substituent at the $C_{(3'')}$ atom of the D-ribose ring: neomycins B and C,[6,53] paromomycins I and II,[54-56], and lividomycin B.[57] Lividomycin A[58-62] and mannosylparomomycin[63], which are 4″-*C*-mannosyl derivatives of lividomycin B and paromomycin respectively, can be usefully combined into a separate subgroup together with 5″-deoxylividomycin A[64] and 1-*N*-[(*s*)-4-amino-2-hydroxybutyryl]-lividomycin A.[65] A characteristic feature of these antibiotics is the presence of four carbohydrate rings in the molecule.

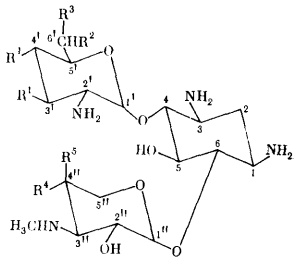
| | $R^1$ | $R^2$ | $R^3$ | $R^4$ | $R^5$ | $R^6$ | $R^7$ |
|---|---|---|---|---|---|---|---|
| Neomycin B | H | OH | $NH_2$ | OH | OH | $CH_2NH_2$ | H |
| Neomycin C | H | OH | $NH_2$ | OH | OH | H | $CH_2NH_2$ |
| Paromomycin I | H | OH | OH | OH | OH | $CH_2NH_2$ | H |
| Paromomycin II | H | OH | OH | OH | OH | H | $CH_2NH_2$ |
| Lividomycin B | H | H | OH | OH | OH | $CH_2NH_2$ | H |
| Lividomycin A | H | H | OH | OH |  | $CH_2NH_2$ | H |

| | $R^1$ | $R^2$ | $R^3$ | $R^4$ | $R^5$ | $R^6$ | $R^7$ |
|---|---|---|---|---|---|---|---|
| 5″-Deoxylividomycin A | H | H | OH | H |  | $CH_2NH_2$ | H |
| 1-*N*-[(*s*)-4-amino-2-hydroxybutyryl]-lividomycin A | —CO—CH(OH)—$CH_2$—$CH_2$—$NH_2$ | H | OH | OH |  | $CH_2NH_2$ | H |



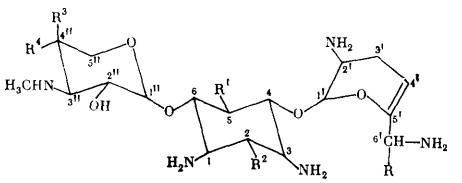
The neomycin group of antibiotics also includes hybrimycins A1, A2, B1, and B2,[66,67] in which the aglycones are streptamine (hybrimycins A) and epistreptamine (hybrimycins B).

| | $R^1$ | $R^2$ | $R^3$ | $R^4$ |
|---|---|---|---|---|
| Hybrimycin A1 | H | OH | H | $CH_2NH_2$ |
| Hybrimycin A2 | H | OH | $CH_2NH_2$ | H |
| Hybrimycin B1 | OH | H | H | $CH_2NH_2$ |
| Hybrimycin B2 | OH | H | $CH_2NH_2$ | H |



The aminoglycoside antibiotics whose deoxystreptamine ring has two pyranosyl substituents at the $C_{(4)}$ and $C_{(6)}$ atoms are the most important chemotherapeutically. Depending on the nature of the carbohydrate substituent at the $C_{(6)}$ atoms, they can be divided into two groups with numerous members. The first comprises the family of kanamycin antibiotics, a characteristic feature of which is the presence of 3-amino-3-deoxy-$\alpha$-D-glucose at the $C_{(6)}$ atom of the deoxystreptamine ring. The second group consists of the gentamicin antibiotics, whose deoxystreptamine ring has either garosamine[68] or 3-methyl-amino-3-deoxypentapyranose at the $C_{(6)}$ atom.

The family of kanamycin antibiotics includes kanamycins A, B, and C,[69-74] the antibiotics NK-1001, NK-1012-1, NK-1013-1, and NK-1013-2,[75] tobramycin (nebramycin, factor 6),[76-82] nebramycins, and factors 2,4,5, and 5′,[76,80-83] as well as their semisynthetic derivatives 3′-deoxykanamycin A,[84] 4′-deoxykanamycin A,[85] 6″-deoxykanamycin A,[86-88] 6′-*N*-methylkanamycin B,[89] 3′,4′-dideoxykanamycin B,[90-91] 3′,4′-dideoxy-6′-*N*-methylkanamycin B,[89] amikacin (BB-K8),[92-94] 1-*N*-[(*s*)-4-amino-2-hydroxybutyryl]kanamycin B,[95] 1-*N*-[(*s*)-4-amino-2-hydroxybutyryl]-3′,4′-dideoxykanamycin B,[95] etc.



| | R¹ | R² | R³ | R⁴ | R⁵ | R⁶ |
|---|---|---|---|---|---|---|
| Kanamycin A | H | OH | OH | OH | $NH_2$ | $NH_2$ |

The family of gentamicin antibiotics includes the gentamicin complex C [3,68] (the gentamicins $C_1$, $C_2$, and $C_{1a}$ [96-110]), the gentamicins, A, [111-113] $A_1$, [113] $A_2$, [113] $X_2$, [113-118], B (the antibiotic Sch 14 342), [113-118] and $B_1$, [113] the antibiotics JI-20 A and JI-20 B, [113] G-418, [113,119-121], and sagamicin [122-125].

| Gentamicin A | OH | H | OH | OH | H |
| Sagamicin | H | $NHCH_3$ | H | $CH_3$ | OH |

The gentamicin antibiotics also comprise sisomicin [126-134], mutamicins [135], verdamicin [113,136], and the antibiotics 66-40B and 66-40D. [113,137] A characteristic feature of these antibiotics is the presence of an unsaturated carbohydrate substituent (dehydropurpurosamine) at the $C_{(4)}$ carbon atom of the deoxystreptamine ring §.

The following principles have been adopted in the numbering of the carbon atoms of different fragments of the molecules of aminoglycoside antibiotics.

1. Each cyclic fragment of the molecule (carbohydrate, aminocyclitol) has its own independent numbering of the carbon atoms.
2. The numbering in aminocyclitol begins with the carbon atom linked to the amino-group; the numbering proceeds in the direction such that the second amino-group is attached to the carbon atom with the smallest number.
3. The numbering of the carbon atoms in the carbohydrate substituents corresponds to the numbering adopted in carbohydrate chemistry: it begins with the carbon atom linked to the hemiacetal hydroxyl.
4. The carbon atoms of the carbohydrate substituent at the $C_{(4)}$ atom of the aminocyclitol are designated by primed numbers.
5. The carbon atoms of the carbohydrate substituent at the $C_{(5)}$ or $C_{(6)}$ carbon atom of the aminocyclitol are designated by doubly primed numbers.
6. The carbon atoms in the carbohydrate rings attached to the carbohydrate substituents of the aminocyclitol are designated by triply primed numbers.

## III. THE MAIN PHYSICOCHEMICAL PROPERTIES OF AMINOGLYCOSIDES

Since aminoglycoside antibiotics are pseudo-oligosaccharides, it follows naturally that they possess many physicochemical properties and undergo many of the reactions characteristic of oligosaccharides. For example, aminoglycosides do not absorb between 220 and 360 nm in the ultraviolet. In most cases, their infrared spectra have no characteristic absorption bands and resemble those of oligosaccharides.

It has been shown for kanamycin monosulphate [73,74] and streptomycin [138] that the wavelengths corresponding to the bonds in the aminoglycoside antibiotics have values characteristic of ordinary covalent bonds. The interatomic distances in kanamycin are as follows: 1.48 Å for S = O (four bonds), 1.55 Å for C–C (sixteen bonds), 1.45 Å for C–N (four bonds), and 1.45 Å for C–O (fifteen bonds). The lengths of the intramolecular hydrogen bonds in the kanamycin molecule show that the oxygen of the hydroxy-groups at the $C_{(5)}$ atom of the deoxystreptamine ring is linked by a strong hydrogen bond to the hydroxy-group at the $C_{(2)}$ atom of the 6-amino-6-deoxy-$\alpha$-D-glucose ring, i.e. the stereochemical structure of the 4-O-[6'-amino-6'-deoxy-$\alpha$-D-glucopyranosyl]-2-deoxystreptamine molecule is rigid and determines the stability of the compound even in aqueous solutions.

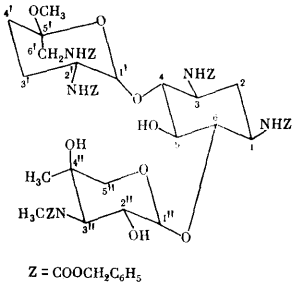
The $^1$H NMR spectra of aminoglycoside antibiotics are extremely complex and require the use of model compounds for their interpretation [313]. The $^{13}$C NMR spectroscopy has come to be widely used in the study of the stereochemistry of aminoglycosides in recent years [23,38,314-317]. The employment of $^{13}$C NMR spectroscopy made it possible to elucidate the nature of $\alpha$- and $\beta$-streptomycins [318]. $^{13}$N NMR spectroscopy has been used in the study of nebramycin antibiotics [319].

Crystalline aminoglycosides strongly retain water and carbon dioxide [103]. The gentamicin antibiotics retain water so tenaciously that it cannot be removed completely even on heating the specimens *in vacuo* for seven days at 50°C. [109]

Aminoglycoside antibiotics are readily adsorbed by cellulose, celite, and other filter materials [139], and the total initial amount of the antibiotic cannot be recovered even on acidification.

Aminoglycosides are extremely stable on prolonged storage in both powdered and crystalline state as well as in

§ Reports of the isolation of new antibiotics of the sisomicin series have appeared recently [311,312].



aqueous solutions[140,141,301]. There is no change in the activity of aqueous kanamycin solutions when they are heated in an autoclave for 30 min at 120°C in the pH range 2–9.[141] The gentamicin complex C also withstands heating in an autoclave for 20 min.[142]

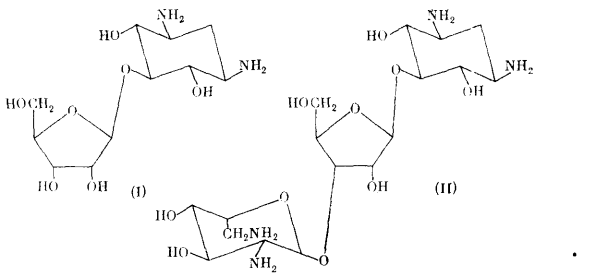
## IV. REACTIONS INVOLVING GLYCOSIDIC LINKAGES. HYDROLYSIS OF AMINOGLYCOSIDES

Aminoglycoside antibiotics are as a rule stable in solution at pH ≥ 7.0, but are relatively readily hydrolysed in acidic media. An exception is streptomycin, which is unstable in alkaline solutions; at pH 8.5, rapid inactivation takes place[143,144]. Kanamycin is more stable in the pH range 6–8 than at pH 2.0.[71,145] The gentamicin complex C is stable in the pH range between 2.0 and 14.[142]

Hydrolysis of aminoglycoside antibiotics by hydrochloric acid solutions under various conditions leads to the rupture of the glycosidic linkages and the formation of compounds which correspond to fragments of the aminoglycoside molecules in different combinations[146]. It has been shown for kanamycin that hydrolysis involves initially the glycosidic linkage between 6-amino-6-deoxy-α-D-glucose and 2-deoxystreptamine[147–149]. The acid hydrolysis of antibiotics of the gentamicin and sisomicin series does not entail the rupture of the glycosidic linkage between the purpurosamine rings and garamine, which is evidently due to the presence of the 2′-*C*-$NH_2$ group[302]. The main hydrolysis product is gentamine. On the other hand, *N*-substituted sisomicins are extremely sensitive to hydrolysis [they can be hydrolysed by treatment with the Amberlite IR-120 ($H^+$) resin]. The main hydrolysis product is garamine[303] and further hydrolysis of the latter is not observed.

It should also be noted that the methanolysis of pentakis-*N*-benzyloxycarbonyl-sisomicin results in the formation, together with garamine, of a methanol adduct having the following structure:

Z = $COOCH_2C_6H_5$



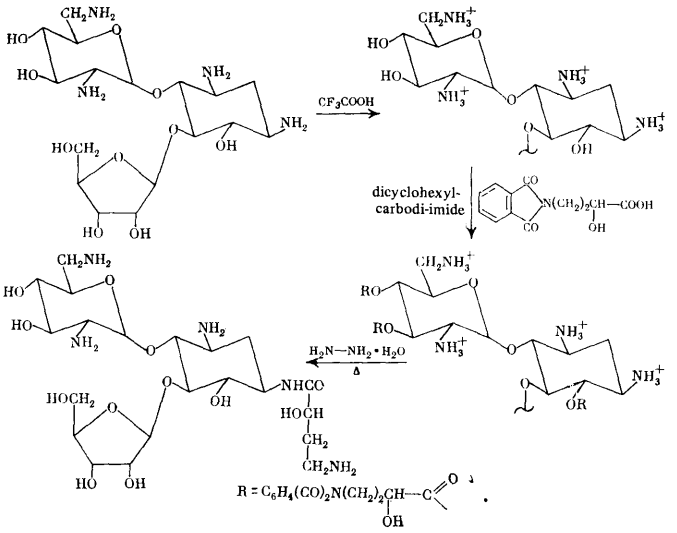
Acid hydrolysis of aminoglycoside antibiotics combined with the periodate oxidation of the *N*-acylated hydrolysis products is the basis of studies designed to determine their structure. For example, the method has been used successfully for kanamycins A,[150–155] B[156] and C,[7,10] lividomycin A,[58,60] and the antibiotic G-418. Analysis of the products of the mild acid hydrolysis of destomycin A and hygromycin B showed that these antibiotics differ in the structure of the main glycoside, but also have a component in common—destomic acid[23,28–31].

However, it is better to use acid methanolysis in the determination of the structures of antibiotics. The combination of acid methanolysis with the periodate oxidation of the hydrolysis products and the simultaneous acid hydrolysis of per-*N*-acetyl-per-*O*-methyl derivatives makes it possible to determine the detailed structure of the aminoglycoside. The method has been used in the determination of the structures of kanamycin[157–164], gentamicin[180,112,165,166], sisomicin[167], ribostamycin[36], Bu-1975 $C_1$ and $C_2$,[12] and many other aminoglycoside antibiotics. Methanolysis of the gentamicin complex C yields gentamicin and an anomeric mixture of methylgarosamides. The degradation of purpurosamine under these conditions is not observed, since the rupture of the glycosidic linkage is apparently prevented by the protonation of the 2′-*C*-amino group.

The rupture of the glycosidic linkage in acid hydrolysis has been used successfully not only for the determination of the structures of new antibiotics, but also for synthetic purposes. For example, in the synthesis of 1-*N*-[(*S*)-4-amino-2-hydroxybutyryl]neamine, the furanosyl linkage in butirosins A and B is hydrolysed by a solution of hydrochloric acid in methanol[16,19,20]. It is noteworthy that the amide bond between the aminoacyl group and the 1-*C*-amino-group in the deoxystreptamine ring is retained on acid hydrolysis. The rupture of the amide bond is observed during moderate alkaline hydrolysis. Ribostamycin is then formed from butirosin B,[16] while the alkaline hydrolysis of 4′-deoxybutirosin yields the corresponding 4′-deoxyribostamycin[19].

The selective cleavage of the glycosidic linkage in the elimination of the mannose component in the synthesis of lividomycin B from the lividomycin A is achieved by Barry's method (treatment with sodium periodate in the dark with subsequent removal of iodate, hydrolysis, and treatment with phenylhydrazine)[61,168].

The periodate oxidation of per-*N*-benzyloxycarbonyl derivatives of paromomycin and neomycin leads to the elimination of one or two diaminosugar rings, depending on the reaction conditions. After the removal of protecting groups, either a pseudodisaccharide (I) or a pseudotrisaccharide (II) is obtained[169]:



In conclusion one should note the possibility of the acid hydrolysis of paromomycin (I), neomycin, and kanamycin with the aid of ion-exchange resins[170].

## V. REACTIONS INVOLVING AMINO-GROUPS

Aminoglycoside antibiotics readily form salts with inorganic acids. The ability of aminoglycosides to form salts has been used for the selective protection of the amino-groups in an elegant synthesis of butirosin B from ribostamycin[171]. The amino-groups of ribostamycin were

protected by preliminary treatment with trifluoroacetic acid. The scheme of the synthesis is presented below.

Aminoglycoside antibiotics readily form Schiff bases with aldehydes in aqueous alcoholic media[69,172-175]. Streptomycin, which contains the formyl group, forms Schiff bases on reaction with amines[176]. In contrast to other aminoglycosides, when gentamicin antibiotics give rise to Schiff bases, a cyclic oxazolidine is formed via the $NH_2$ group at the $C_{(3'')}$ atom and the OH group at the $C_{(4'')}$ atom in the garosamine component of the molecule[175,177].

Salicylidene derivatives of aminoglycosides are used in mass-spectrometric studies[178-180] and in the investigation of the dispersion of the optical rotation of aminoglycoside aminocyclitols[181].

The reduction of the Schiff bases with sodium tetrahydroborate leads to the formation of *N*-alkyl- and *N*-aryl-kanamycins and other basic antibiotics[174,176,182-184]. It is interesting to note that the possibility of obtaining monoalkylate products has been demonstrated for neomycins and paromomycin[182]. *N*-Alkyl derivatives of aminoglycosides can be obtained also without the preliminary synthesis of the corresponding Schiff bases—by reductive alkylation[174]. The ability of 1-fluoro-2,4-dinitrobenzene to partially dinitrophenylate kanamycin, neomycin, and paromomycin constitutes a method for the determination of the number of free amino-groups and the molecular weights of basic antibiotics[185].

The antibiotics react with formaldehyde to form products corresponding to different degrees of substitution, depending on the reaction conditions[183,186]. It has been shown that the hydrogenolysis of kanamycin in water in the presence of formaldehyde leads to the formation of *N*-octamethylkanamycin. On the other hand, when the reaction is carried out in an acidic medium (acetic acid), the formation of *N*-tetramethylkanamycin is promoted[187]. Various methods for the synthesis of *N*-methanesulphonate and *N*-methanesulphinate derivatives of aminoglycoside antibiotics have been developed[188]. The corresponding "Mannich bases" have been obtained from kanamycin and tetracycline[189-191].

The kanamycin Schiff bases react with carbon disulphide in an alkaline alcoholic medium, forming compounds having the general formula $KM(CSSA)_n$, where KM is kanamycin and A is an alkali metal atom[192]. In an aqueous alkaline solution, kanamycin reacts with trichloromethanesulphenyl chloride, forming *N*-trichloromethylthiokanamycin. Other basic antibiotics behave similarly[193,194]. Derivatives of basic antibiotics having antibacterial properties can be obtained by the reaction of the aminoglycoside bases with trichloromethanesulphenyl chloride and 2-amino-1-(*p*-nitrophenyl)propane-1,3-diol[193].

The aminoacid derivatives of aminoglycosides formed via the $NH_2$ group at the $C_{(1)}$ atom of the deoxystreptamine ring have continuously attracted the attention of chemists, biochemists, and specialists in chemotherapy in recent years. This interest was aroused by the antibacterial properties of the derivatives, particularly by their high activity against species of micro-organisms exhibiting multiple drug resistance. The problem of the synthesis of aminoacid derivatives reduces intrinsically to the problem of the selective protection of the amino-groups exhibiting a higher reactivity than the 1-*C*-amino-group.

The amino-groups of aminoglycoside antibiotics are known to be located in molecular fragments of different types and have different environments; nevertheless, in most cases they are hardly distinguishable as regards their reactivity, and the chemical reaction involves all the groups simultaneously. For example, the amino-groups are readily acetylated by acetic anhydride in methanol at room temperature[111,142,148,172,195-197] and react with ethyl[198] and benzyl[88,199] chlorocarbonate esters and dimedone[200]. Differences between the reactivities of the amino-groups can be detected in reactions of aminoglycosides with mild acylating agents such as *N*-benzyloxycarbonylhydroxysuccinimide or benzyl *p*-nitrophenyl carbonate and t-butoxycarbonyl azide.

In a series of studies devoted to the synthesis of amikacin (BB-K8) and its positional isomers and analogues, *N*-benzyloxycarbonylhydroxysuccinimide was used successfully for the selective protection of the amino-groups[92,93,201]. Aminoacid derivatives of tobramycin were obtained using a similar scheme[202]. The sequence in which the positional isomers of amikacin are synthesised and their structures make it possible to arrange the kanamycin amino-groups in order of their decreasing activity in the acylation reaction (sequence based on the positions in the molecule):

$$C(6') > C(1) > C(3) > C(3'').$$

It is interesting to note that, in the series of gentamicin antibiotics, the selectivity in the mode of acylation depends on the pH of the medium and the mode of reaction changes almost completely if the amino-groups of the antibiotics are protonated. Under these conditions, the 1-*C*-$NH_2$ group is the most reactive in relation to acylating agents, while the primary $-CH_2NH_2$ group exhibits the lowest reactivity. This phenomenon, noticed for the first time by Wright[304], has been used to obtain 1-*N*-acyl derivatives of gentamicin $C_{1a}$, sisomicin, and verdamicin[305]. The acylation of kanamycin is usually carried out with *N*-substituted aminoacids subjected to preliminary activation with *N*-hydroxysuccinimide[16,93,203].

It has been shown in relation to the synthesis of amikacin and 1-*N*-[(*S*)-4-amino-2-hydroxybutyryl]kamamycin B that benzyloxycarbonyl chloride can also be recommended for the selective blocking of the $NH_2$ group at $C_{(6)}$.[204] Evidently, t-butoxycarbonyl azide[205] is the most suitable agent for the selective protection of the $NH_2$ group at the $C_{(2')}$ atom in the synthesis of aminoacid derivatives of kanamycin B and 3′,4′-dideoxykanamycin B.[95,206,207] The t-butoxycarbonyl protecting group has valuable advantages over

other types of protecting groups—it can be removed selectively in the presence of *N*-benzyloxycarbonyl groups by means of trifluoroacetic acid, which permits the subsequent modification of only one amino-group. 6′-*N*-Alkyl derivatives of amikacin have been obtained by this method[184].

The $NH_2$ groups at the $C_{(2')}$ and $C_{(3)}$ atoms have been successfully protected with the trifluoroacetyl group in the synthesis of 1-*N*-[(*S*)-4-amino-2-hydroxybutyryl]- and 1-*N*-[(*S*)-3-amino-2-hydroxypropionyl]-gentamicins $C_1$ by treating the gentamicin with an equivalent amount of ethyl trifluorothioacetate in methanol solution[208,209]. The sequence in which the trifluoroacetyl protecting group is introduced makes it possible to arrange the amino-groups of gentamicin $C_1$ in the following sequence in terms of their activity with respect to this reagent (sequence based on the positions in the molecule):

$$C(2') > C(3) > C(1) > C(6') > C(3').$$

It is noteworthy that the selective acylation of the $NH_2$ group at the $C_{(1)}$ atom of gentamicin $C_{(1)}$ by γ-amino-α-hydroxybutyric acid can be carried out also without the preliminary blocking of the 2′-*C*- and 3-*C*- amino groups[210].

In the synthesis of the isomers of the aminoacid derivatives of butirosin from natural butirosin, it was necessary to select for the protection of the free amino-group a substituent having extremely specific properties: its bond with the amino-group must be stable in an alkaline medium and must be readily ruptured under conditions ensuring the retention of the amide linkage. It was shown that the most suitable protecting group is produced by forming a conjugated enamine in the reaction with dimedone[200]. The advantages of the products thus obtained are their high solubility, intense absorption in the ultraviolet, and ready purification by ion-exchange chromatography. The dimedone groups are removed with the aid of gaseous chlorine.

A new approach to the selective protection of the amino-groups, based on the formation of a cyclic carbamate or oxazolidone via the $NH_2$ group at the $C_{(1)}$ atom and the OH group at the $C_{(6)}$ atom of the deoxystreptamine ring, was introduced into the chemistry of aminosugars and aminocyclitols by Umezawa and coworkers[211]. This approach has been employed successfully in synthesis of butirosin B,[47,212] 3′-deoxybutirosin B,[213] and the aminoacid derivatives of 3′,4′-dideoxyneamine[18,21], 3′,4′-dideoxyribostamycin[212], lividomycin A,[65,214] and 6′-amino-6′-deoxylividomycin A.[215]

Carbamates or oxazolidinones are usually obtained by treating *N*-per(benzyloxycarbonyl)aminoglycosides with sodium hydride in dimethylformamide at room temperature. The formation of the cyclic carbamate can be explained by the initial attack by sodium hydride on the OH group at $C_{(6)}$ with subsequent anchimeric attack by the resulting alkoxide ion on the urethane carbonyl at $C_{(1)}$. The use of cyclic carbamates for the protection of groups in the *trans*-positions has been described for the first time in connection with the synthesis of *D*-glucopyranosido[2,3 : 4,5]-2′-oxazolidinones[216] with the aid of *NN*′-carbonyldi-imidazole. When the resulting carbamate is heated with barium hydroxide in aqueous dioxan, selective hydrolysis with liberation of the $NH_2$ group at $C_{(1)}$ and the OH group at $C_{(6)}$ takes place. Subsequent acylation at the amino-group and elimination of all the protecting groups lead to the aminoacid derivatives of aminoglycosides formed via the $NH_2$ group at $C_{(1)}$.

Weinstein and coworkers[177] showed in relation to the gentamicin complex C that simultaneous selective protection of the amino- and hydroxy-groups of the garosamine ring can be achieved as a result of the formation of oxazolidine when the gentamicin complex reacts with aldehydes in ethanol.

It has been shown for the synthesis of butirosin that the aminoacid derivatives of aminoglycoside antibiotics having a free hydroxy-group at the $C_{(6)}$ atom of the deoxystreptamine ring can be obtained by the elegant reaction involving the O→N acyl migration of the aminoacid group from the $C_{(6)}$ atom to the amino group at $C_{(1)}$[171] (see the reaction scheme at the beginning of this Section).

*N*-Benzyloxycarbonyl derivatives of aminoglycoside antibiotics are reduced to the corresponding *N*-methylaminoglycosides on heating with lithium tetrahydroaluminate in tetrahydrofuran. The reaction has been used in the preparative synthesis of 6′-*N*-methylkanamycin and 3′,4′-dideoxy-6′-*N*-methylkanamycin B.[89] The selective 6′-*N*-benzyloxycarbonylation of aminoglycosides has been carried out successfully with the aid of benzyl *p*-nitrophenyl carbonate[217] in aqueous dioxan at 0–5°C.

*N*-Glycoside derivatives of aminoglycoside antibiotics, exhibiting antibacterial activity, are obtained by Pan's enzymatic transglycosylation reaction[218–221].

## VI. REACTION INVOLVING HYDROXY-GROUPS

The most characteristic reactions of the hydroxy-groups of aminoglycoside antibiotics are those involving the formation of esters[222–225] and ethers[14,88,155,198,226]. They are used widely in the protection of hydroxy-groups in the synthesis of various derivatives of antibiotics.

Like the amino-groups, the hydroxy-groups of aminoglycosides have different reactivities. The primary alcoholic OH groups at $C_{(6'')}$ and $C_{(6')}$ are chemically the most reactive, the hydroxy-groups and $C_{(2')}$ and $C_{(2'')}$ are somewhat less reactive, and the hydroxy-group at the $C_{(5)}$ atom of the deoxystreptamine ring is least reactive. The reactivities of the remaining hydroxy-groups are virtually the same. The only known instance of reaction involving the hydroxy-group at $C_{(5)}$ is the synthesis of esters of gentamicin $C_{1a}$.[227]

The interaction of kanamycin with concentrated sulphuric acid at a reduced temperature leads to the formation of kanamycin sulphonate esters, the number of ester groups corresponding to the number of hydroxy-groups in the molecule of the antibiotic. This property of basic antibiotics has been used to develop a method for the determination of the number of free hydroxy-groups in biological preparations[222]. Kanamycin Schiff bases are readily *O*-acylated by benzoyl chloride, benzoic acid anhydride, and benzoate esters with formation of the corresponding *O*-benzoate esters after acid hydrolysis[223]. Kanamycin esters having the general formula $(RCO_2)_nC_{18}H_{21}O_4(OH)_{7-n}(NH_2)_4$, where R is an alkyl group, an alkoxy-group, a *p*-substituted phenyl group, an aryl group, etc, are formed by the reaction of sodium alkoxides derived from the kanamycin Schiff bases with acid chlorides[224].

On reaction with alkane- and arene-sulphonyl chlorides, aminoglycosides readily form sulphonates, which are used to introduce various functional groups into the molecule of the antibiotic (halogen, H, $N_3$, COOH, $NH_2$, etc,) via an exchange reaction of the sulphonyloxy-groups with a particular nucleophile. Trifluorophenyl derivatives of aminoglycosides can also be used for such purposes instead of the sulphonate derivatives[88,198].

*O*-Methyl derivatives are usually obtained by treating aminoglycosides with dimethyl sulphate in the presence of alkali by the method of West and Holden[228] modified by Umezawa et al.[155] This reaction has been used in the synthesis of 3′- and 4′-*O*-methylneamines[14,226]. Diazomethane has been used a methylating agent in the synthesis of 4′,6′-*O*-methyl-lividomycin A;[215] the reaction was catalysed by boron trifluoride etherate.

The differences between the reactivities of the hydroxy-groups have been used in the synthesis of many derivatives of aminoglycosides formed via the most reactive OH group at the $C_{(6'')}$ or $C_{(6')}$ atom; the syntheses are based on the exchange reactions of aminoglycos-6″-*O*-ylalkane(arene)-sulphonates with nucleophiles. 6″-Deoxykanamycin[86-88,229], kanamycin-6″-uronic acid, its methyl ester and amide[198], 6″-hydrazinokanamycin[230,231], 6″-halogenokanamycins[88,231], kanamycin-6″-phosphate[232,233], and 6′-amino-6′-deoxygentamicin A[234] have been obtained in accordance with this scheme. Among aminoglycoside antibiotics containing a furanosyl substituent, the most reactive hydroxy-group is at the $C_{(5'')}$ atom. The following derivatives of these antibiotics have been obtained: ribostamycin-5″-uronic acid, its methyl ester and hydrazide[235], lividomycin A-5″-phosphate and 5″-deoxylividomycins B[236,237] and A,[64] 6′-amino-5″,6′-dideoxylividomycin A,[64] 5″-amino-5″-deoxybutirosin[52], and 5″-amino-3′,4′,5″-trideoxybutirosin[238]. Apart from the OH groups at the $C_{(5'')}$ atom, lividomycins A and B have a further hydroxy-group with a high reactivity—the groups at the $C_{(6')}$ atom. A number of derivatives have also been obtained via this hydroxy-group: 6′-amino-6′-deoxylividomycins A[215] and B[239] and 6′-deoxy-6′-methylamino- and 6′-deoxy-6′-(2-hydroxyethylamino)lividomycins B.[239]

Derivatives of aminoglycoside antibiotics readily epimerise at the 2″-*C*-hydroxy-group in solutions in the presence of bases or simply on heating in dimethylformamide. Thus, such treatment of kanamycin derivatives leads to the formation of the corresponding mannosyl derivatives[240-243]. It has been shown for gentamicin $C_1$ that epimerisation is also observed on solvolysis of the 2″-C-methanesulphonate in 10% aqueous dimethylformamide[244]. The epimerisation of paromamine in the 3′-*C*-position has been achieved by reduction with sodium tetrahydroborate of the corresponding glycos-3′-yl derivative obtained by oxidising tri-*N*-(benzyloxycarbonyl)-di-4′,6′-*O*-isopropylideneparomamine in the methyl sulphoxide–acetic anhydride system in the dark at room temperature for three days[245]. The epimerisation at the 2′-*C*-hydroxy-group has been observed in the synthesis of 3′-amino-3′-deoxykanamycin via a mechanism which is based on the cyclisation of the dialdehyde obtained by the periodate oxidation of tetra-*N*-acetylkanamycin with nitromethane followed by the reduction and hydrazinolysis[242]. Direct treatment of the intermediate 3′-deoxy-3′-nitro-derivative with hydrazine leads to the decomposition of the nitrosugar component of the compound.

In contrast to the modification of amonoglycosides via the chemically most reactive hydroxy-group at $C_{(6'')}$, the problem of transformations via the 3′-*C*- and 4′-*C*-hydroxy-groups is much more complex, since such reactions necessitate the blocking of all the hydroxy-groups of the antibiotics except those at $C_{(3')}$ and $C_{(4')}$. This is very difficult to achieve in view of the virtually identical reactivities of the hydroxy-groups (except those at $C_{(6'')}$ or $C_{(5'')}$). On the other hand, the synthesis of 3′- and 4′-deoxy and 3′,4′-dideoxy-derivatives of aminoglycosides in one of the tasks of primary importance, since these semisynthetic antibiotics are in fact highly active in relation to bacterial strains inactivating aminoglycosides via the commonest mechanism of enzymatic inactivation—*O*-phosphorylation at $C_{(3')}$. This task can be carried out readily only when there exists a simple method for the selective protection of the functional groups of the antibiotic. At the present time such a method has not been developed yet, and, for example, 3′-deoxykanamycin A has not so far been obtained from the natural antibiotic. The situation is simpler in the case of aminoglycosides incorporating a non-amino-fragment. Nevertheless, the synthesis of 3′- and 4′-deoxy-derivatives of these antibiotics are extremely complex multistage processes, with very low yields of the required product.

Antibiotics containing a non-amino-component give rise to a 3′-deoxy derivative as a result of the selective tosylation of the OH group at $C_{(3')}$ with subsequent exchange for the halogen atom and reduction. A typical scheme for the synthesis of 3′-deoxykanamycin B[79] is as follows. After protecting the amino-groups, the hydroxy-groups at $C_{(3')}$, $C_{(4')}$, $C_{(4'')}$, and $C_{(6'')}$ are blocked with the aid of the isopropylidene or cyclohexylidene groups and the 2″-*C*-hydroxy-group is benzolated; the protecting groups are removed from the 3′- and 4′-*C* positions under mild conditions, the toluenesulphonate group is introduced selectively at $C_{(3')}$ and is exchanged for the halogen atom, and 3′-deoxykanamycin B is obtained after reduction and elimination of protecting groups. A virtually similar scheme constitutes the basis of the synthesis of 3′-deoxy-derivatives of ribostamycin[48] and butirosin B.[213] It has been shown for the synthesis of 3′-deoxybutirosin B that the 2-nitrobenzene-1-sulphonate group is exchanged for a halogen atom more readily than the tosyl group[213].

In the synthesis of 3′,4′-dideoxy-derivatives of aminoglycosides, after the methanesulphonation of the hydroxy-groups at $C_{(3')}$ and $C_{(4')}$ a double bond is introduced by the Tipson–Cohen method[246,247] and hydrogenated, and, after the removal of the blocking groups, the required compound is obtained. This scheme is the basis of the synthesis of aminoglycoside derivatives such as 3′,4′-dideoxykanamycin B,[51,90,91,248] 3′,4′-dideoxy- and 3′,4′,5″-trideoxy-ribostamycin[20], 3′,4′-dideoxybutirosins B[51,212] and A,[249] 5″-amino-3′,4′,5″-trideoxybutirosin A,[238,250] 3′,4′-dideoxyneamine[13], and 1-*N*-[(*s*)-4-amino-2-hydroxybutyryl]-3′,4′-dideoxyneamine[19].

An unexpected synthesis of 4′-deoxykanamycin A of kanamycin A has been discovered. It has been shown that the hydrogenolysis of nona-*NO*-acetyl-6′-*N*-benzyloxycarbonylkanamycin A over palladium on charcoal at room temperature results in the migration of the *O*-acetyl group from the 4′-*C*-position to the 6′-*C*-amino-group. Thus a simple method has been found for protecting all the amino- and hydroxy-groups except the hydroxy-group at $C_{(4')}$.[251] In this synthesis, the 4′-*C*-hydroxy-group is removed by exchanging the methanesulphonyl group for the thioloacetate group with subsequent reduction over Raney nickel at atmospheric pressure.

A second method for the synthesis of 4′-deoxykanamycin, based on the formation of a 4′,6′-cyclic carbamate by the reaction of the tri-*N*-ethoxycarbonyl derivative of kanamycin with phenyl chloroformate[211], was described at the same time[251]. However, this method is complex, it is sufficient to say that it consists of thirteen stages.

The synthesis of deoxy-derivatives of gentamicin is complicated by a series of cyclisations and rearrangements in the garosamine ring[244]. The attempt to obtain 2″-deoxygentamicin $C_1$ was unsuccessful owing to epimerisation. The 2″-*C*-hydroxy-group was removed from gentamicin $C_2$. Methanesulphonation of the pentabenzylidene derivative of gentamicin $C_2$ led to the formation of the 2″-*O*-methanesulphonyl derivative, which cyclises to an epimine after the removal of the benzylidene groups. The

epimine was acetylated with acetic anhydride in methanol and the acetyl derivative was reduced over Raney nickel at 140°C and 176 atm in 30 h. After the removal of the protecting groups, two products were obtained—2″-deoxygentamicin $C_2$ and its rearrangement product—2″-deoxy-3″-desmethylamino-2″-methylaminogentamicin $C_2$, the second substance being the main reaction product.

The reduction of penta-*N*-benzyloxycarbonylper-*O*-acetylgentamicin $C_1$ with sodium in liquid ammonia leads to 4″-deoxygentamicin $C_1$.[252] It has been shown for garamine that the reaction cannot be extended to the synthesis of 2″-deoxyderivatives by reducing the 2″-acetyl- or 2″-thiobenzoyl-garamine[252].

## VII. COMPLEXES OF AMINOGLYCOSIDES

Owing to the large number of their hydroxy- and amino-groups, aminoglycoside antibiotics readily form complexes with heavy metal salts. The formation of aminoglycoside complexes with water-soluble inorganic copper, nickel, cobalt, zinc, magnesium, and iron salts has been described[253-258]. The metal content in the complex varies in the range 0.5–3.0 atoms per mole of the antibiotic[320].

The study of the infrared spectra of chelates of kanamycin, deoxystreptamine, and ethylenediamine with copper(I) chloride, led Yamabe[255] to the conclusion that kanamycin forms a chelate with $Cu^{2+}$ via the propylidenediamine component of deoxystreptamycin. On the other hand, comparison of the polarograms of the chelates of kanamycin and deoxystreptamine shows that these complexes are of different types[255] Thus the problem of the particular amino-groups of kanamycin involved in the formation of chelates with heavy metal ions remains open. The structure of the chelates must undoubtedly depend on the nature of the amino-groups participating in the formation of the complex and on their reactivity.

It has been shown that $Ca^{2+}$ and $Mg^{2+}$ salts decrease the degree of binding of gentamicin and other deoxystreptamine-containing antibiotics to bacterial and blood serum proteins. The maximum binding (70%) is observed in the absence of metal cations, the degree of binding decreasing with increase of the metal ion concentration[259]. There is no doubt that this phenomenon is based on the ability of the aminoglycoside antibiotics to form complexes with metal salts. Under conditions involving competition between the binding of aminoglycosides by metal salts or proteins, the preferred process is apparently the formation of complexes of metal ions.

The capacity of aminoglycoside antibiotics for complex formation is used in the analysis of drugs[260,261]. Kanamycin forms anisotropic monoaxial crystals with the Reinecke salt[262]. The reaction makes it possible to determine kanamycin in solutions at the minimum concentration of 1 : 100 000.

The most important application of the ability of aminoglycosides to form complexes of the Reeves cuprammonium method for the determination of structures[263]. The method has been used to determine the structures of virtually all aminoglycoside antibiotics[54,264-268].

Aminoglycoside antibiotics are known to form carbonates readily by reaction with carbon dioxide. However, the study of the $^{13}C$ NMR spectra of the products resulting from the absorption of carbon dioxide by gentamicins $C_1$, $C_2$, and $C_{1a}$ showed that carbon dioxide is bound by these substances without the formation of carbonates. The structure of the resulting complexes is unknown[103].

## VIII. THE FORMATION OF *O*-GLYCOSIDIC LINKAGES. DIRECT SYNTHESIS OF AMINOGLYCOSIDES

The so called "total" synthesis of aminoglycosides, involving the condensation of mono- and pseudodi-saccharides by the Koenigs–Knorr reaction, is very important in the chemistry of aminoglycoside antibiotics. Despite its complexity, the method retains its importance, because it makes it possible to decide finally the validity of the determination of the structure of the aminoglycoside antibiotic and also to obtain derivatives of aminoglycosides which cannot so far be synthesised by the transformation of existing antibiotics.

After the preliminary synthesis of the initial monosaccharides and aminocyclitols[269-281], the method has been used to synthesise streptomycin[282], dihydrostreptomycin[283,321], kanamycins A,[284-287] B,[288,289] and C,[290-292] ribostamycin[293,294,322], xylostasin[39], 3′-*O*-methylkanamycin A,[295] 3-amino-2,3-dideoxy-$\alpha$-arabinohexapyranosylgentamine $C_1$,[296] the isomeric di-*O*-($\alpha$-D-glucopyranosyl)-2-deoxystreptamines[297], as well as a number of glycosides containing 6′-amino-6′-deoxy-$\alpha$-D-glucopyranosyl-2-deoxystreptamine[271], etc.,[323].

It is noteworthy that the classical method of glycoside synthesis (the Koenigs–Knorr reaction) is unsuitable on an industrial scale not only because of the low yields of the final product, but also because of the formation of large amounts of the $\beta$-isomer. A new method of synthesis of $\alpha$-D-glucopyranosyldeoxystreptamines, developed by the Lemieux–Nagabhushan group and based on the reaction of dimeric tri-*O*-acetyl-2-deoxy-2-nitroso-$\alpha$-D-glucopyranosyl chloride with alcohols[298-306], is therefore of definite interest. The Lemieux–Nagabhushan reaction has been used successfully to obtain various derivatives of gentamicin $X_2$,[307] gentamicin B,[308] and pentosyl derivatives of garamine[309].

In conclusion one should note that, in the absence of a suitable method for the selective protection of hydroxy-groups, the method of "total" synthesis is so far the only available procedure for obtaining 3′-deoxykanamycin[84,299,300]. The method is also important for the synthesis of various isomers of aminoglycosides required for the elucidation of the role of the structural components of the aminoglycoside molecules in their antibacterial activity.

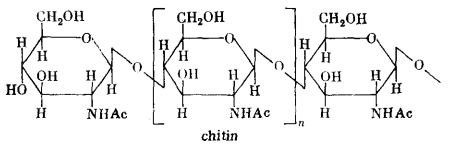
## I. INTRODUCTION

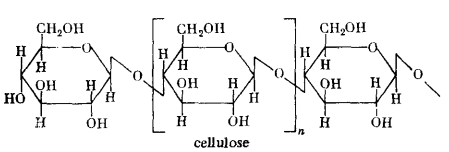
Despite the fact that chitin has been known for a long time[1,2] and occurs widely in nature, it has still been little investigated. There has been an increase of interest in chitin owing to the general development of the chemistry of polysaccharides and synthetic polymers. A number of studies have been published recently on chitin derivatives which are of practical value. There has been a considerable expansion of research also on the properties of deacetylated chitin (chitosan). A survey of the literature data is therefore of definite value, particularly since the available reviews[3-7] do not reflect fully the advances achieved in this field.

## II. THE STRUCTURE AND PROPERTIES OF CHITIN

Chitin occurs in nature in the organisms of certain lower animals and plants, predominantly in crustacea[8-11], insects[12], and fungi[11-15]. It is always present in combination with other substances[16], such as proteins, inorganic salts, or polysaccharides. During its isolation in a pure form, the chitin-containing material is therefore treated with appropriate reagents[13,17-19], which decompose the secondary substances but do not affect the chitin macromolecule. Plant and animal chitins are identical, which has been confirmed by their chemical composition[20], specific gravity[21], specific optical rotation[22], and the repeat period obtained by X-ray diffraction[23].



Chitin is one of the commonest polysaccharides in nature; marine crustacea alone yield thousands of millions of tons of chitin annually[24]. However, the industrial utilisation of chitin is difficult owing to its even distribution in nature.



### 1. The Hydrolysis of Chitin

The complete acid hydrolysis of chitin leads to the formation of glucosamine and an equimolar amount of acetic acid[25]. After the hydrolysis of chitin with 70–72% sulphuric acid at room temperature for 2–3 days, monoacetylglucosamine was isolated[26]. This important discovery made it possible to determine the position of the acetyl group in monoacetylglucosamine. By hydrolysing chitin with highly concentrated hydrochloric acid, Zechmeister and coworkers[27,28] obtained not only the final chitin hydrolysis product (acetylglucosamine) but also a number of intermediate fractions, the acetylation of which gave a biose octa-acetate and chitotriose acetate[29]. They noted that the biose octa-acetate is identical with the chitobiose octa-acetate isolated in other investigations[30,31] by the acetolysis of chitin. Partial hydrolysis of chitin by concentrated hydrochloric acid in later studies[32-36] gave *N*-acetylchito-oligosaccharides. The chito-oligosaccharides were separated by thin-layer[37-39] and ion-exchange chromatography[40] as well as other methods[41-43]. Acetolysis of plant and animal chitins yielded chitobiose octa-acetate and chitotriose undeca-acetate, which are identical regardless of whether they are obtained from plant or animal chitin[35,36,44,45].

Chitin is very resistant to the action of bacteria[46], but micro-organisms decomposing it do exist[47-49]. It has been shown[50,51] that chitin is hydrolysed by the enzyme chitinase with formation of up to 80% of acetylglucosamine. A similar yield of acetylglucosamine has been obtained on cleavage of plant chitin with chitinase[52]. The above data suggests that chitin is a homogeneous linear polymer.

Comparison of the activation energies for the hydrolysis of chitin by nitric acid[53] and of cellulose by sulphuric acid[54] and of their repeat periods obtained by X-ray diffraction[23,55-57] as well as the formation of chitobiose octa-acetate by the acetolysis of chitin and the specificity of the action of chitinase show that the *N*-acetylglucosamine residues are joined via oxygen with the $\beta$-glucosidic 1,4-linkage and are alternately rotated by 180°, i.e. the chitin macromolecule has a structure similar to that of cellulose, but differs from it by the fact that there is an acetamide group at $C_{(2)}$ instead of a hydroxyl:

The oxidation of chitin by periodate also confirmed the above structure[58].

## 2. The Supermolecular Structure of Chitin

Many studies on the structure of chitin [59-71] led to the conclusion that chitin has a highly ordered stereoregular structure. Its X-ray diffraction pattern reveals a well-defined orthorhombic lattice [66]. The macromolecular chains of chitin are involved in strong hydrogen bonds both via the NH and CO group and via hydroxy-groups [68, 69, 72]. The crystal structure proposed by Carlström [68] has been confirmed by data obtained in a study [72] of the infrared spectrum of chitin. Detailed analysis of this spectrum confirmed the presence of the intermolecular C=O...N–H hydrogen bond along the fibre axis and the absence from the chitin crystals of free OH, NH, and C=O groups not involved in the hydrogen bond. The authors believe that the OH group at $C_{(6)}$, which exhibits free rotation, may be linked by an intramolecular hydrogen bond to the bridge oxygen and the nitrogen atom in a neighbouring glucosamine unit.

Recent X-ray diffraction studies [4,69,73] indicate the existence of chitin in three crystalline forms ($\alpha$, $\beta$, and $\gamma$), differing in the size of the crystal lattice. It has been shown [74] that $\alpha$-chitin is orthorhombic and its unit cell contains fragments of two chains only, arranged in opposite directions. All the forms are stable in boiling 5% KOH or NaOH solution [75], but their treatment with 6 *N* HCl leads to the conversion of the $\beta$- and $\gamma$-forms into the $\alpha$-form [75]. Similar conversions have been observed also by other workers [11,73].

## 3. The Properties of Chitin

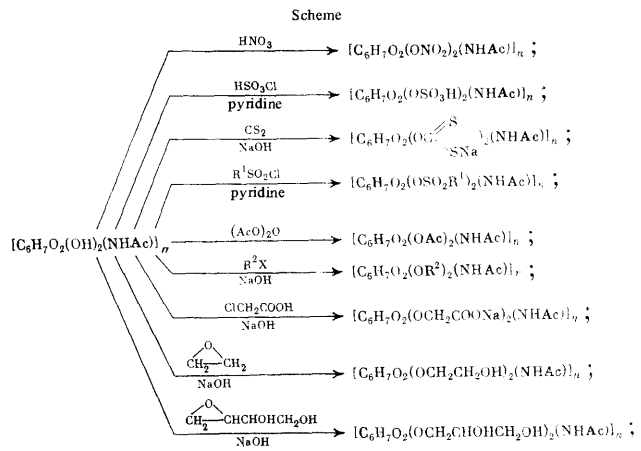
Despite the similarities of the structures of chitin and cellulose, they differ significantly. In contrast to cellulose, chitin swells only slightly in solutions of alkalis and does not dissolve in the solvents used for cellulose (solutions of the amminecopper complex, the iron–tartrate–sodium complex, benzyltriethylammonium hydroxide, and the cadmium–ethylenediamine complex), probably due to the absence from chitin of two adjacent hydroxyls, which in the case of cellulose are responsible for the formation of molecular compounds [76,77].

At the same time, chitin dissolves comparatively readily in concentrated hydrochloric and sulphuric acids [78,79], from which it can be isolated almost unaltered [80]. Nitric and phosphoric acids also dissolve chitin [81,82]. When chitin is dissolved in acids, gradual hydrolysis takes place, as a result of which a glucosamine salt is formed. Chitin solutions are laevorotatory; in hydrochloric acid with a specific gravity of 1.16, the initial specific rotation is $-14.7°$ and the final rotation is $+56°$ (which corresponds to the rotation of the glucosamine hydrochloride formed [22]). In view of this, chitin solutions in acids are unstable, their viscosity varying with time, so that it is impossible to determine the true molecular weight by viscometric, osmometric, light scattering, or sedimentation methods. An attempt has been made to estimate the molecular weight of chitin by measuring its viscosity in 50% nitric acid [81] and by extrapolating the viscosity to zero dissolution time. By comparing the values obtained with the analogous viscosities of wood cellulose in amminecopper solution, the authors [81] concluded that chitin and wood cellulose have similar molecular weights; this method is only approximate.

The method of copper numbers (determination of the content of terminal aldehyde groups) was used by Iterson [83] to estimate the degree of polymerisation (DP) of chitin. According to his data, the degree of polymerisation of chitin corresponds to 103 units. However, in another study [84] this method gave DP = 66. The method is comparatively rapid and can be used to characterise the variation of the degree of polymerisation of chitin. However, it does not yield unambiguous results owing to the polydispersity of the specimen and the possible oxidation of the terminal aldehyde groups to carboxy-groups. According to the data of other investigators [85-87], the degree of polymerisation of chitin varies from several hundreds to thousands of *N*-acetylglucosamine residues.

Chitin dissolves on heating in concentrated solutions of certain salts [87,88] and the latter can be arranged in the following sequence in terms of their dispersing capacity [38]:

$$LiSCN > Ca(SCN)_2 > CaI_2 > CaBr_2 > CaCl_2.$$



Partial dissolution of chitin has been observed in mixtures of dimethylformamide and nitrogen dioxide [89].

## III. REACTIONS IN THE CHAINS OF THE CHITIN MACROMOLECULE

Chitin is less reactive than cellulose when an attempt is made to modify it chemically, because of the characteristics of its supermolecular structure—the presence in chitin of stronger hydrogen bonds and a small active surface area, which follows from the determination of the amount of non-freezing water [90] and the measurements of the heats of swelling of chitin and cellulose [90].

In contrast to cellulose, there are only two hydroxy-groups in chitin, which can be involved in chemical reactions and can form disubstituted chitin derivatives. However, owing to their low reactivity, complete substitution is not usually achieved. The known reactions of chitin modifications are indicated schematically below:

Scheme

$R^1 = CH_3$ or $CH_3C_6H_4$; $R^2 = CH_3$ or $C_2H_5$.

### 1. The Synthesis of Esters

Chitin acetates cannot be obtained by the method [91] involving the use of perchloric acid as the catalyst. Chitin has been acetylated [92] with acetic anhydride and dry hydrogen chloride in the course of 120 h at room temperature; an overall degree of substitution of 2.99 (taking into account the acetyls group in the initial chitin) was

achieved. Chitin acetate substituted to this extent dissolves in formic acid and in 50% aqueous resorcinol solution. When water is added to the solution, acetylchitin is precipitated. Concentrated inorganic acids (sulphuric and hydrochloric) slowly dissolve acetylchitin, but it cannot be isolated from the solutions, since hydrolysis takes place. Concentrated nitric acid (specific gravity 1.50) dissolves acetylchitin very rapidly and the latter can be isolated from the solution by the addition of water, nitroacetylchitin, containing 2.14% of nitro-nitrogen, being precipitated.

Chitin has been acetylated[53] for three months with a mixture of acetic acid and acetic anhydride in the presence of zinc chloride; this yielded chitin acetate containing 2.5 acetyl groups per residue. The preparation was highly destructured.

Chitin dissolved in phosphoric acid has been acetylated[93] both in the presence and absence of perchloric acid as the catalyst. In the presence of 1% $HClO_4$, 27.5% of acetyl groups were introduced in 4 h at 75°C, which corresponded to a degree of substitution of 1.80; in the absence of the catalyst, a maximum degree of substitution of 1.70 was attained at 80°C. It is seen from these data that the limiting degree of substitution is not reached under homogeneous conditions. The esters obtained dissolved in 50% aqueous resorcinol solution and phenol and partially in *m*-cresol.

Chitin nitrates were obtained for the first time[94] by nitrating chitin with fuming nitric acid. Schorigin and Hait[95] investigated this process in detail and established that, during nitration with nitric acid alone (specific gravity 1.50), the maximum yield of chitin nitrate containing 7.51% of nitro-nitrogen, which corresponds to the substitution of 1.5 hydroxy-groups, is attained. The chitin nitrate obtained ignites at 163°C and is denitrated by sodium hydrogen sulphide in 3 h at 16°C. Its X-ray diffraction pattern indicates a fibrous structure with the same repeat period as that of chitin[81].

Among organic solvents, nitrochitin dissolves partly only in formic acid and can be isolated from solution by the addition of water. It also dissolves in sulphuric and hydrochloric acids but is not reprecipitated by the addition of water.

Chitin xanthate was described for the first time by Thor and Henderson[96-98], who impregnated chitin with a 43% solution of NaOH at 25°C for 2 h and then mixed it with crushed ice and added carbon disulphide; this resulted in the conversion of chitin into a gel and then its dissolution. The solution is unstable, chitin is deacetylated at room temperature, and chitosan xanthate is precipitated from solution. To avoid coagulation, the solution must be stored below 0°C. Chitin xanthate solutions are suitable for the formation of filaments and films[98].

Chitin sulphate esters have been described[99,100] and the authors obtained them by treating chitin with chlorosulphonic acid in different media. In pyridine[99] the sulphate formation reaction was carried out over a period of 7 h during which 14.4% of sulphur was introduced. When the reaction was carried out in dichloroethane[100] for 2 h, a sulphate ester containing 13–15% of sulphur, depending on temperature, was obtained. Chitin with this sulphur content dissolves in water. The molecular weights of all the esters were determined by the osmometric method and were found to be 14 000–17 000, depending on the conditions of synthesis[100]. In order to avoid the possible degradation of the chitin macromolecule, it has been suggested that formamide be used as a solvent for chlorosulphonic acid[101].

Methanesulphonate and toluene-*p*-sulphonate esters[102] have been obtained by treating with methanesulphonyl and toluene-*p*-sulphonyl chlorides chitin which had been subjected to preliminary activation by reprecipitation from solution in phosphoric acid in the presence of dry pyridine. The optimum conditions under which the maximum sulphur content is achieved (10.22%) during tosylation obtain in the presence of the chitin : tosyl chloride : pyridine = 1 : 10 : 50 ratios and when the reaction is carried out at room temperature for 10 days. The mono(toluene-*p*-sulphonate) ester[102] contains 8.98% of sulphur. In the preparation of the monomethanesulphonyl derivative of chitin, the optimum conditions obtain in the presence of the chitin : methanesulphonyl chloride : pyridine = 1 : 10 : 40 ratios at room temperature and when the synthesis is carried out over a period of 7 days[102], whereupon up to 12.57% of sulphur can be introduced (the monomethanesulphonate chitin ester should contain 11.4% of sulphur).

## 2. The Synthesis of Ethers

Methyl ethers containing 9.34% of $OCH_3$ group have been obtained[103] after 45 methylations of alkali-treated chitin with dimethyl sulphate. Preliminary activation of chitin with hydrochloric acid and subsequent 15 methylations in the presence of alkali made it possible to increase the content of methoxy-groups to 16.07%, which corresponds to monomethylchitin. Monomethylchitin dissolves in formic acid, swells strongly, and partly dissolves in glacial acetic acid.

Ethyl ethers containing 33.83% of $OC_2H_5$ groups, which correspond to a degree of substitution of 1.59, were obtained for the first time[104] by treating alkylchitin with ethyl chloride for 10 h with stepwise heating of the reaction mixture to 130°C. During the synthesis of the ether, the acetyl groups of chitin are hydrolysed. The ether contained 2.04% of free amino-groups, 2.75% of hydroxy-groups, and 4.53% of acetyl groups, which corresponds to the composition $[C_6H_7O_2(OH)_{0.34}(NH_2)_{0.70}(NHCOCH_3)_{0.21}.(OC_2H_5)_{1.59}]_n$. The molecular weight of the ether thus obtained[103], determined in ethyl methyl ketone by the method of sedimentation in an ultracentrifuge, was 66 000. Ethylated chitin forms films with a strength of 6.8–7.3 kgf mm$^2$ and an elongation of 15–23%.

Hydroxyethyl ethers are obtained by treating alkali-treated chitin with epoxyethane under heterogeneous[104] or homogeneous conditions[16,105]. More severe heterogeneous conditions are required for the reaction than in the case where homogeneous conditions are employed. In both cases the formation of water-soluble ethers requires a considerable excess of epoxyethane. A nitroxyethyl ether of chitin[104], containing 5.71% of nitro-nitrogen, has been obtained from the hydroxyethyl ether.

Glyceryl ethers[106] have been synthesised by treating alkali-treated chitin with glycerol monochlorohydrin or with glycidol. Treatment of chitin with glycerol monochlorohydrin did not give rise to a water-soluble ether, despite the high content of glycerol residues (up to 49%). In contrast to the initial chitin, the ether obtained

did not dissolve even in hydrochloric or phosphoric acids, which indicated the cross-linking of the ether with traces of the glycerol dichlorohydrin present in the monochlorohydrin. When glycidol was used to alkylate chitin, ethers soluble in 4 and 8% sodium hydroxide were obtained.

Carboxymethyl ethers in the form of sodium salts (Na-CMC) have been described[107-110]. The kinetics of the carboxymethylation of chitin dissolved in solutions of alkali have been investigated[108] and it has been shown that, with increase of the concentration of sodium hydrodide to 15–20% and of temperature to 20° to 30°C, the rate of reaction increases sharply. However, an increase of the reaction temperature entails the formation of a precipitate from the alkaline solution owing to the elimination of the acetyl groups and the formation of chitosan. For this reason, at the end of the carboxymethylation reaction the reaction mixture is sometimes subjected to additional acetylation with acetic anhydride at pH 10 for 2 h at room temperature[116]. In order to determine the structure of Na-CMC, it was subjected to periodate oxidation and acid hydrolysis[111]. Chromatographic analysis of the hydrolysis product showed that substitution takes place mainly at $C_{(6)}$, which is indicated also by the susceptibility of Na-CMC to periodate oxidation. During carboxymethylation[108] under heterogeneous conditions, the acetyl groups are not hydrolysed. At room temperature, the reaction proceeds most completely and a degree of substitution of 0.8–1.0 is attained. An increase of reaction temperature to 40–60°C accelerates the hydrolysis of monochloroacetic acid, so that the main reaction requires a smaller amount of the alkylating agent.

A new method has been described[110] for the preparation of carboxymethylchitin involving the preliminary activation of chitin with dimethyl sulphoxide. Carboxymethylchitin with a degree of substitution of 0.99, which is readily soluble in water, has been synthesised in this way. Acidification of Na-CMC with a dilute hydrochloric acid solution[109] yielded a chitino-glycolic acid, which swells strongly and partly dissolves in water, in contrast to celluloso-glycolic acid[112]. Na-CMC containing 6% Na and more readily dissolves in water. Aqueous solutions of Na-CMC and H-CMC exhibit polyelectrolytic properties, i.e. the intrinsic viscosity increases on diluting the solution[113].

## IV. THE PREPARATION OF CHITOSAN AND ITS PROPERTIES

The preparation of chitosan from chitin has been described in numerous articles[34,84,114-117] and patents[118,119]. Gilson[114] was the first to obtain chitosan by fusing chitin with potassium hydroxide at 180–190°C; this treatment results in the hydrolysis of the *N*-acetyl groups. A patent[118] proposes milder conditions for the preparation of chitosan, involving the heating of chitin with a 40% solution of sodium hydroxide at 110°C for 4 h. The methods of preparation of chitosan have been studied in detail[116]. The author notes that the deacetylation of chitin in 40% sodium hydroxide at 135–140°C is slow; 60% of the acetyl groups are hydrolysed after 24 h. The deacetylation of chitin at 120°C in an anhydrous medium consisting of potassium hydroxide (50%), ethanol (25%), and monoethylene glycol (25%) has been described[115]. In order to achieve the required degree of deacetylation and the corresponding viscosity, the reaction is carried out for a specified time, which yields satisfactorily reproducible data[115]. The deacetylation of chitin with a mixture of potassium hydroxide and hydroxylamine is more difficult[120]. At 100°C and pH 13 approximately 70% of the acetyl groups are removed in the course of 10–20 h.

Darmon and Rudall[67] followed the changes in the infrared spectra during the deacetylation of chitin. The intensity of the carbonyl (1625 $cm^{-1}$) and amide (3265 and 3100 $cm^{-1}$) bands diminishes during the formation of chitosan, while that of the 3365 and 3445 $cm^{-1}$ bands increases, which indicates the appearance of the $NH_2$ group. X-Ray diffraction studies on chitosan have shown that it has the same crystal lattice as chitin, but the degree of order in its macromolecules is smaller[64,67]. Chitosan, regenerated in the form of a film in a salt or basic form[121], gives rise to X-ray diffraction patterns characteristic of amorphous substances.

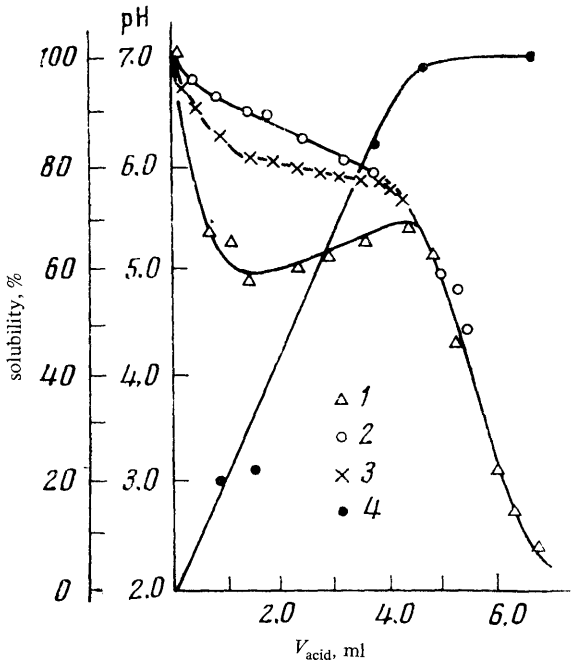


Figure 1. Potentiometric titration curves for chitosan: 1) direct titration of the initial chitosan; 2) back titration; 3) direct titration of reprecipitated chitosan; 4) solubility.

We established that the changes in the supermolecular structure during the dissolution of chitosan may be followed by its potentiometric titration. Direct potentiometric titration of the initial chitosan with acid by the individual sample method (Fig. 1, curve *1*) yields a titration curve with two extrema. The minimum at pH 4.9 corresponds to the neutralisation of the accessible amino-groups, after which further addition of acid leads to a gradual increase of pH to 5.5 (the maximum on the curve) as a result of the liberation of the amino-groups which had been previously involved in hydrogen bonding. The maximum corresponds to the complete dissolution of chitosan (Fig. 1, curve *4*); under these conditions, the supermolecular structure has been disrupted and all the

amino-groups become accessible to titration. The back-titration curve (Fig. 1, curve 2) forms a hysteresis loop with curve 1, from the area of which it is possible to estimate the energy consumed in the disruption of the structure [when $pH - \lg\alpha/(1-\alpha)$ is plotted against $\alpha$, where $\alpha$ is the degree of dissociation]. This energy, amounting to 2.8 kcal mole$^{-1}$, corresponds to the dissociation energy of the hydrogen bonds. In the direct titration of reprecipitated chitosan (Fig. 1, curve 3), the area of the hysteresis loop is much smaller, which indicates the incomplete restoration of the intermolecular hydrogen bonds on reprecipitation.

The viscosity and hence the molecular weight of chitosan are greatly influenced by the conditions used in the deacetylation of chitin: in an atmosphere of an inert gas (nitrogen, argon), chitosan with a higher molecular weight is obtained[122,123]. In contrast to chitin, chitosan dissolves in dilute acid solutions from which it can be isolated without alteration. Chitosan can be therefore readily characterised on the basis of its viscosity and polydispersity. A study of the flow of aqueous solutions of chitosan hydrochloride in a capillary showed[124] that its solutions do not exhibit structural viscosity.

The amino-group imparts polyelectrolytic properties to chitosan, as shown by a study of the viscosity of chitosan hydrochloride [solutions][124,125]. It was found that, at a fairly high ionic strength, the intrinsic viscosity becomes a linear function of concentration. In order to suppress completely the polyelectrolytic effect of chitosan solutions in acetic acid, it is necessary to add sodium chloride to a concentration of 0.5 M; in hydrochloric acid, this is achieved at an acid concentration of 0.3 M.

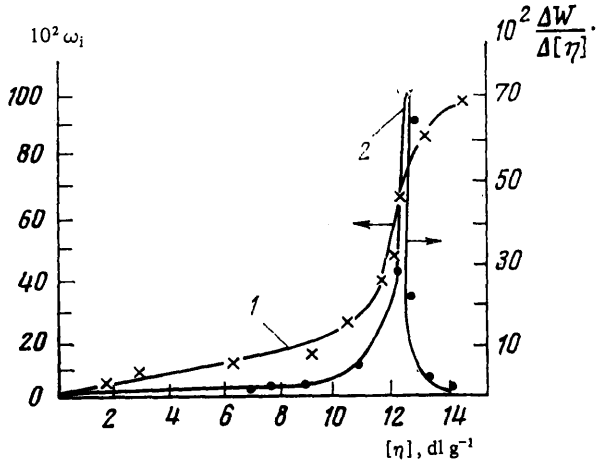

Figure 2. The integral (curve 1) and differential (curve 2) curves for the distribution of chitosan with respect to molecular weight; $w_i$ is the proportion by weight of the given fraction, $W$ the overall proportion by weight, and $[\eta]$ the intrinsic viscosity.

The polydispersity of chitosan has been demonstrated qualitatively in the extraction of chitosan lyophilised with alcohol[122], which resulted in a decrease of the relative viscosity. The molecular weight distribution has been studied by the fractional precipitation of chitosan from solution in 2% acetic acid[123] with acetone. The integral and differential distribution curves with respect to molecular weight (Fig. 2) indicate a comparative homogeneity of chitosan.

## V. REACTIONS IN THE CHITOSAN CHAINS

The presence of two hydroxyls and of a primary amino-group in chitosan extends the scope of its possible modification. In the synthesis of chitosan derivatives, the preparation of specifically substituted compounds (the synthesis of *O*- or *N*-derivatives) is of special interest. The method developed previously for the specific synthesis of chitosan esters (*O*- and *N*-sulphochitosans)[126] has been recently supplemented by a method for the specific synthesis of ethers (*O*-sulphoethyl- and *O*-carboxymethyl-chitosans)[127]. The synthesis of selectively substituted chitosan derivatives ensures the formation of compounds with specified properties, required in various applications.

### 1. The Synthesis of Esters

The sulphonation of chitosan was achieved for the first time[128] by treatment with a mixture of sulphur trioxide and dioxide at the boiling point of the mixture. The resulting ester contained 14.8% of sulphur and exhibited anticoagulation activity *in vivo* and *in vitro*. Subsequently chlorosulphonic acid in pyridine[129], the sulphur trioxide–pyridine complex[130], and sulphuric acid[131,132] were used to sulphonate chitosan. In the last case, the formation of fully *N*-sulphonated chitosan was noted[132].

A method has been developed for the selective sulphonation of chitosan by altering the reagent and media[126]. Using the pyridine–sulphur trioxide complex as the sulphonating agent in an aqueous alkaline medium at pH 9–10, the authors obtained *N*-sulphochitosan containing one sulphamate group per glucosamine unit. Subsequent treatment of *N*-sulphochitosan with a mixture of sulphur dioxide and trioxide in the cold yielded the *O*-sulphonated derivative (75% of the hydroxy-groups were substituted). The authors note the absence of anticoagulation activity of the *N*-derivative and the high activity of this kind of the *ON*-derivative of chitosan.

The phosphorylation of chitosan has been carried out by treatment with phosphoryl chloride at 40°C for 5 h.[99] The authors do not state either the degree or site of phosphorylation.

The acetylation of chitosan with acetic anhydride at 100–135°C in a sealed tube yields a highly destructured preparation, whose properties resemble those of chitin[133,134].

The acylation of chitosan by treatment with formic acid and propionic and butyric anhydrides at 110° to 125°C leads to the formation of the corresponding *N*-derivatives of chitosan[135]. A similar type of reaction occurs when alkali-treated chitosan is treated with benzoic anhydride, as shown by the insolubility of the specimens in dilute hydrochloric acid.

The arenesulphonation of chitosan has been achieved by the reaction of benzene- and naphthalene-sulphonyl chloride with alkali-treated chitosan[135]. The derivatives contained approximately one substituent per

glucosamine unit. Benzenesulphonylchitosan is partly soluble in dilute hydrochloric acid and readily soluble in solutions of alkali in contrast to naphthalenesulphonylchitosan, which is sparingly soluble in alkali.

### 2. The Synthesis of Ethers

The synthesis of chitin ethers in an alkaline medium in the absence of special precautions entails a smaller or greater degree of deacetylation. For this reason, the final products are sometimes the corresponding chitosan ethers. Thus, in the synthesis of ethyl[103], carboxymethyl[107], and glyceryl[108] ethers of chitin, the degree of deacetylation is 60% and more, as a result of which the final product was called in one instance[107] carboxymethylchitosan. In view of the simultaneous occurrence of the deacetylation and alkylation processes, the resulting compound cannot be regarded as solely an *O*-derivative.

The formation of chitosan ethers with substituents located in specified positions requires the introduction of *N*-protecting groups.

The sulphoethylation of chitosan[136] has been carried out by treatment with sodium β-chloroethanesulphonate in the presence of alkali in isopropyl alcohol and in mixtures of *o*-xylene with propyl and isopropyl alcohols. The highest degree of substitution reached 0.35. Determination of the position of the substituent by the analysis of the amino-nitrogen and conductimetric titration showed that both *O*- and *N*-sulphoethylation take place.

For specific *O*-alkylation of chitosan, the amino-group was protected by reaction with an aromatic aldehyde, which results in the formation of a Schiff base[127,137]:

$$[C_6H_7O_2(OH)_2NH_2]_n + nR^1C_6H_4CHO \rightarrow [C_6H_7O_2(OH)_2N=CHC_6H_4R^1]_n ;$$
(I) (II) (III)

$$(III) \xrightarrow{ClR^2ONa} [C_6H_7O_2(OH)_{2-x}(OR^2ONa)_xN=CHC_6H_4R^1]_n ;$$
(IV)

$$(IV) \xrightarrow{CH_3COOH} [C_6H_7O_2(OH)_{2-x}(OR^2OH)_xNH_2 \cdot CH_3COOH]_n + R^1C_6H_4CHO ;$$
(V)

$$(V) \xrightarrow{NaOH} [C_6H_7O_2(OH)_{2-x}(OR^2ONa)_xNH_2]_n ;$$
(VI)

$R^1 = H, OH, OCH_3$ or $NO_2$; $R^2 = C_2H_4SO_2$ or $CH_2CO$;

$x$ is the degree of substitution. Chitosan was treated in a neutral medium with the corresponding aromatic aldehyde at room temperature for 3 h. In contrast to benzaldehyde, anisaldehyde, and *o*-nitrobenzaldehyde, salicylaldehyde reacts fully with the amino-groups of chitosan. Salicylidenechitosan is stable in an alkaline medium but decomposes in an acidic medium into the initial components. The sulphoethylation of salicylidenechitosan has been carried out under the conditions used for the sulphoethylation of chitosan[136]. The resulting sulphoethylsalicylidenechitosan was decomposed with 50% acetic acid and then treated with a 2% solution of sodium hydroxide in order to convert it into the basic form. The final product was *O*-sulphoethylchitosan, which was confirmed by the Van Slyke analysis of the amino-nitrogen and conductimetric titration; the highest degree of substitution was 0.31. Such sulphoethylchitosan is soluble in water and in 2% acetic acid solution; when the degree of substitution is lower, the product is soluble only in dilute acids.

*O*-Carboxylation of chitosan has also been achieved via salicylidenechitosan[127] by treating the latter with sodium monochloroacetate; using 9 moles of the reagent per mole of the chitosan, a monosubstituted carboxymethylchitosan with free amino-groups was obtained.

Cyanoethylchitosan was obtained by the reaction of alkali-treated chitosan with acrylonitrile at different temperatures[138]. It was shown that it is desirable to carry out the reaction at 20°C for 24 h, since this entails the complete substitution of both hydroxy-groups without the hydrolysis of the cyanoethyl groups. An increase of temperature causes the hydrolysis of the cyanoethyl groups, so that one obtains derivatives with a lower degree of substitution. Cyanoethylation does not take place in a neutral medium, while in an acidic medium 0.31 of a cyanoethyl group per glucosamine unit is introduced at 20°C over a period of 24 h.

### 3. *N*-Alkylation of Chitosan

The *N*-methylation of chitosan has been carried out[135] by heating powdered chitosan with a tenfold excess of methyl iodide at 100°C for 6 h. A single treatment yielded mono-*N*-methylchitosan and subsequent treatment did not increase the degree of *N*-methylation. The hydriodide of mono-*N*-methylchitosan has been obtained by treating the doubly methylated chitosan with methyl iodide at 50°C for 3 h.

*N*-Methoxyethylchitosan has been obtained by the reaction of hydroxyethylchitosan with methyl iodide[139].

*NNN*-Trimethyl- and *NNN*-triethylchitosans have been synthesised by heating chitosan up to the boiling point of the corresponding alkyl iodide in absolute ethanol in the presence of organic bases[140]. Treatment with an organic base under these conditions is more effective the higher its p$K_a$. In the presence of triethylamine, almost fully *NNN*-trimethylated chitosan was obtained in a single treatment, which was confirmed by NMR.[140] The NMR spectrum of the resulting *NNN*-trimethylchitosan contains a signal at 6.80 p.p.m., confirming the presence of nitrogen in the tetra-substituted state. Signals corresponding to protons attached to secondary and tertiary nitrogen are absent.

*NNN*-Trimethyl- and *NNN*-triethyl-chitosans in salt-forms are readily soluble in water, while in the basic forms they are soluble in benzyltriethylammonium hydroxide solutions. The iodides of the quaternary bases are unstable, evolving iodine on storage. *N*-derivatives of chitosan are polyelectrolytes and their basicity increases with the degree of substitution.

## VI. THE APPLICATIONS OF CHITIN, CHITOSAN, AND THEIR DERIVATIVES

There are numerous data concerning the attempts to use chitin, chitosan, and their derivatives in various branches of industry and medicine. A wide variety of the properties of the above compounds are used: their ability to form fibres and films, their capacity for ion exchange and complex formation, and their physiological activity in the absence of toxicity. The above wide

variety of properties of the chitin and chitosan compounds make it useful to synthesis new derivatives and to employ them in practice.

## 1. Films and Fibres Based on Chitin and Chitosan

The possibility of forming films and fibres from chitin dispersions was demonstrated as early as 1926.[10,141] However, a more thorough development of this process was achieved later in a study[97] whose authors obtained films by depositing dispersions of chitin xanthate onto a glass support with subsequent regeneration of chitin in a coagulation bath containing 40% of ammonium sulphate and 5% of sulphuric acid in water. The resulting film has a tensile strength of 9.49 kgf $mm^{-2}$ in the dry state and 1.75 kgf $mm^{-2}$ in the moist state. The films did not swell in water, dilute acids and alkalis, and organic solvents. This method constitutes the basis of the formation of mixed chitin-cellulose fibres via chitin and cellulose xanthates[142]. The fibres exhibit increased dyeability and have ramielike properties. The fibre obtained from partly hydrolysed chitin by the method of Thor and Henderson[97] exhibits ion-exchange properties and can be used to regenerate and purify antibiotics, aminoacids, and other organic acids[116].

Films made of chitosan and its salts are obtained from solutions in acids or water[143-145]. The films are distinguished by a high strength, resistance to alkalis, and possess effective electrotechnical properties[121,146]. When such films were acetylated by treatment with acetic acid and dicyclohexylcarbodi-imide in solutions of alkali or in water containing an organic base, chitin films were obtained with a high mechanical strength, rigidity, and transparency[147]. The regenerated chitin films retain their properties for 30 years[148].

In order to obtain chitosan fibres, Chi-Ming Pao used a solution of chitosan in acetic acid with added lead acetate, glycerol, and alcohol and a precipitation bath containing alkali, glycerol, and sodium sulphate[116,149]. The strength of this fibre corresponds to 9–10.8 dissociative km [? (Ed. of Translation)] and the elongation on rupture is 30%. A method is also available for the preparation of fibres from a mixture of aqueous solutions of chitosan and poly(vinyl alcohol)[150]. The resulting fibres can be dyed with direct acid dyes and show a low capacity for the acquisition of an electrical charge. The use of chitosan in textile industry as a finishing[151], sizing[152], and anti-shrinking agent[153], which improves at the same time the capacity of fabrics for being dyed[154], is based on its film-forming properties. Chitosan can also be used as a thickening agent in pastes for pigment printing on fabrics[155-157]. In the paper industry, chitosan is used as an adhesive[158-160]. The graft-copolymer of chitosan with 2-acrylamido-2-methylpropanesulphonic acid, acrylamide, or acrylic acid is added to paper pulp in order to improve the printing and mechanical properties of the paper[161,162]. When a chitosan coating is applied to the surface of lithographic paper[163] and photographic paper[164,165], the sensitivity of the paper to the formation of an image and the stability of the latter are improved. When chitosan is added to paper pulp and when paper is subjected to a surface treatment with chitosan solutions, many of its properties are improved: the tensile strength, breaking strength, the resistance to breaking and puncturing, and also wet strength[166]. The same effect is achieved when cyanoethylchitosan is introduced into paper or when paper is subjected to a surface treatment with cyanoethylchitosan solutions; papers of this kind also exhibit improved dielectric properties[167].

## 2. Anion Exchangers Based on Chitosan

The anion-exchange properties of chitosan due to the presence of the primary amino-group have aroused interest in this substance as a basis for the preparation of anion-exchange resins. Such resins have been obtained by treating chitosan with formaldehyde[168] and epichlorohydrin[169,170] or by treating chitin with epichlorohydrin and subsequent deacetylation[171,172]. The resins based on chitosan are resistant to alkalis and have an exchange capacity of approximately $4 \times 10^{-3}$ mole $g^{-1}$ (with respect to a neutral salt). These resins have been used to separate DL-mandelic acid into its optical isomers[171]. Cellulose impregnated with chitosan formate[173] and paper impregnated with chitosan[174] are used in the ion-exchange chromatography of nucleic acids. The separation on ion-exchangers of this kind is more effective than on paper impregnated with diethylaminoethylcellulose.

## 3. Analytical Applications of Chitin and Chitosan

Chitin and chitosan have been recently used in various types of chromatography for the separation of nucleic acid derivatives[175,176], for the isolation of egg albumen lysozyme[177,178], and for the separation of the tobacco mosaic virus[179]. Using chitin or chitosan, agar has been fractionated with respect to the degree of sulphonation[180] as a result of the formation of a complex with the highly sulphonated component of agar.

Colloidal titration of chitosan[139] and glycol-chitosan[181] has been used to determine pectin and pectic acid and colloidal titration of hydroxyethyl- and methoxyethyl-chitosan has been used to determine lignosulphonic acid[182].

The use of chitosan for the determination of heavy metals in sewage, sea water, and aqueous brines, is based on its capacity to form polymeric complexes with such metals[183-195]. Chitosan has been used as a chromatographic solid carrier for the selective extraction and accumulation of mercury, cobalt, gold, antimony, silver, chromium, iron, zinc, iridium, palladium, copper, cadmium, nickel, and lead ions[183,184,187-189,192]. The resistance of chitosan to radiation with retention of chelating properties suggested its use for the concentration of waste from nuclear fuel[185,190,191]. These studies have been reviewed in detail in a monograph[7].

## 4. The Applications of Chitosan and Its Derivatives in Medicine

There are numerous data concerning the usefulness of chitosan for the treatment and diagnosis of various diseases. This is promoted by the low toxicity of chitosan and its derivatives even in large doses[196].

Studies on these lines were begun by the investigation of the use of sulphochitin and sulphochitosan as blood anticoagulants. In terms of their activity, the above compounds are comparable to the natural anticoagulent heparin[197-200]. The study of the influence of the structure of sulphochitosan (*O*- and *N*-sulpho-derivatives) on its anticoagulation activity revealed that it is manifested only when all the amino-groups are sulphonated and increases rapidly with increase of the degree of *O*-sulphonation[201]. The introduction of carboxy-groups by oxidising chitosan sulphate increases its activity. In the intravenous administration of chitosan, its molecular weight is important: a decrease of the latter increases the toxicity of the

preparation[129]. By sulphonating chitosan films, antithrombogenic surfaces, retarding the coagulation of blood, have been obtained[202]. Complexes of chitosan with heparin and dextran sulphate also exhibit anticoagulation activity[203,204].

Studies of another type involve the use of chitosan for the treatment of the gastric ulcer based on its antacid activity[205] and the ability to suppress the activity of pepsin[206]. A composition containing chitosan has been proposed and has been recommended under conditions of increased acidity[207]. Chitin-based compositions accelerate the healing of wounds when applied to the affected surface[208,209]. In one study[210], the antisclerocic activity of chitosan due to the activation of lipoprotein lipase[211], was noted. The influence of chitosan on the activities of certain enzymes has been observed in a number of studies: inhibition of deoxyribonuclease[212], activation of hyaluronidase[213], and $\beta$-glucuronidase[214]. The complex salt of chitosan with the 1,4-lactone of D-glucaric acid also exhibits physiological activity[215].

Reports have appeared recently on studies of the use of chitosan for the inhibition of cell growth[212] and the decomposition of cells[216] in certain types of malignant tumours. The complex of chitosan with iododeoxycytidylic acid penetrates cancer cells selectively, which facilitates the diagnosis of cancer[217]. Chitosan causes the selective aggregation of the cells of L 1210 leukaemia *in vitro*[218].

## 5. Other Applications of Chitin and Chitosan

Individual reports indicate the usefulness of chitin, chitosan, and their derivatives in a wide variety of branches of the national economy. In the mining industry, chitin sulphate, carboxymethylchitin, and carboxyethylchitin are used for the preparation of drilling compositions[219] and the water-soluble salts of these derivatives are suitable for the formation of cementing materials[220]. Partly deacetylated chitin is used in the dye industry for the improvement of the susceptibility of glass[221] and synthetic[222] fibres to dyeing. Finely ground chitin is added in the cosmetic industry as an additive to creams, gels, and other cosmetic agents[223]. In the food industry, chitosan is used to clarify plant juices and extracts[224]. Chitosan has also been proposed for the coagulation of turbidity in various aqueous media[225].

# The Chemistry of the Surfaces of the Acid Forms of Natural Layer Silicates

N.G.Vasil'ev and F.D.Ovcharenko

Modern ideas about the nature of the exchangeable acidity of a group of layer silicates (clay minerals) are described and the results obtained during the last decade with the aid of physical and physicochemical techniques are surveyed. The dependence of the surface acidity on non-stoichiometric substitutions in the structure of the minerals, the influence of a number of factors on the spontaneous conversion of the H-forms of the silicates into Al-Fe-Mg-forms, the mechanism of this phenomenon, the ion-exchange properties and the thermal stabilities of the H- and Al-Fe-Mg-forms, and other problems are examined.
The bibliography includes 80 references.

CONTENTS

I. Introduction 775
II. Non-stoichiometric substitutions in the structure and the nature of the exchangeable acidity 775

VI. The influence of temperature on the state of the exchangeable acid ions 784
VII. The exchangeable acidity of silicates activated by inorganic acids and of electrodialysed silicates 786

## I. INTRODUCTION

Natural silicates (clay minerals) have acquired considerable importance recently in scientific research and in practice[1-11]. The amounts of these minerals available in the USSR are enormous and many of their physicochemical properties permit their successful use as substitutes for expensive and scarce synthetic materials. For a more effective and purposeful utilisation of layer minerals in industry, it is necessary to have at ones disposal reliable information both about the chemistry of their surfaces and about methods for their modification. The present review deals with modern ideas about the nature of the exchangeable acidities† of the acid forms of clay minerals. The solution of this problem opens considerable prospects for the application of the above forms as catalysts, stationary phases in gas-adsorption chromatography, fillers of polymeric media, etc. The elucidation of the nature of the exchangeable acidity of clay minerals is important for geochemistry and soil science, since it promotes a correct understanding of the processes involved in the genesis of minerals and soils and also for the development and justification of practical measures undertaken to improve the fertility of acid soils.

## II. NON-STOICHIOMETRIC SUBSTITUTIONS IN THE STRUCTURE AND THE NATURE OF THE EXCHANGEABLE ACIDITY

In the study of the nature of clay minerals and of the chemical stability of their hydrogen-forms, one must take into account the crystal structures of these aluminosilicates and the causes, associated with the latter, which are responsible for the cation exchange in which such substances are involved. For this purpose, it is necessary to develop new, more accurate methods for the determination of the non-stoichiometric isomorphous substitutions or other defects in the lattices of the minerals, which cause them to behave as ion exchangers.

Table 1. The influence of the heat treatment of the Li-forms of layer silicates on their capacity ($\mu$equiv.g$^{-1}$) (duration of heat treatment of specimens 1.5 h).

| Mineral | 25° C | 100° C | 200° C | 300° C | 400° C | 500° C | Isomorphism, % | |
|---|---|---|---|---|---|---|---|---|
| | | | | | | | in octahedra | in tetrahedra |
| Pyzhevskii [Pyzhev?] montmorillonite | 1130 | 1050 | 40 | 34 | 10 | 0 | 97.0 | 0.0 |
| Gorbskii [Gorbi?] beidellite | 410 | 410 | 410 | 408 | 400 | 395 | 0.0 | 100.0 |
| Kovdorskii [Kovd?] vermiculite | 1420 | 1420 | 1420 | 1420 | 1420 | 1420 | 0.0 | 100.0 |
| Bug region nontronite | 980 | 965 | 202 | 202 | 202 | 190 | 79.0 | 21.0 |
| Glukhov kaolinite | 250 | 242 | 34 | 34 | 46 | 48 | 86.0 | 12.0 |
| Cherkassy palygorskite | 150 | 150 | 120 | 80 | 208 | 210 | 47.0 | 53.0 |

A method based on the different types of behaviour of the exchangeable $Li^+$ ions on heating layer minerals at 200 to 300°C for 1-1.5 h has been proposed[12] (Table 1). It follows from the data in the Table that, when the non-stoichiometric isomorphous substitutions in minerals with a dioctahedral structure are located in the octahedral network, then $Li^+$ ions migrate under the influence of temperature to the vacant sites of the silicate[13] or into the interstices[14]. The excess negative charge of the layer is neutralised and the mineral loses its capacity for ion exchange. When the non-stoichiometric substitutions are located in the tetrahedral network, the Li-form fully retains its ion-exchange properties after heating. The above observation holds also in the presence of isomorphous substitutions in both tetrahedral and octahedral networks.

†This implies $H^+$, $Al^{3+}$, and $Fe^{3+}$ ions capable of being exchanged for other cations.

The influence of the positions of the non-stoichiometric substitutions in the structures of layer silicates on the nature of their exchangeable acidity was examined on the basis of the above results [15]. Pyzhevskii [Pyzhev?] montmorillonite, the Bug region nontronite, Kovdorskii [Kovd?] vermiculite (particle size $< 40$ μm), Gorbskii [Gorbi?] beidellite, Cherkassy palygorskite, and Glukhov kaolinite were chosen for investigation. The acid forms of the above aluminosilicates were prepared from the Na-forms by the ion-exchange method under static conditions [16]. The content and nature of the exchangeable acid ions on the surface were determined electrochemically[17,18] and also by analysing the equilibrium solution after treating the acid forms of the minerals with 0.5 *N* $BaCl_2$ solution. A detailed analysis of other methods for the investigation of the surface acidity of solids has been described by Ovcharenko and Vasil'ev [18].

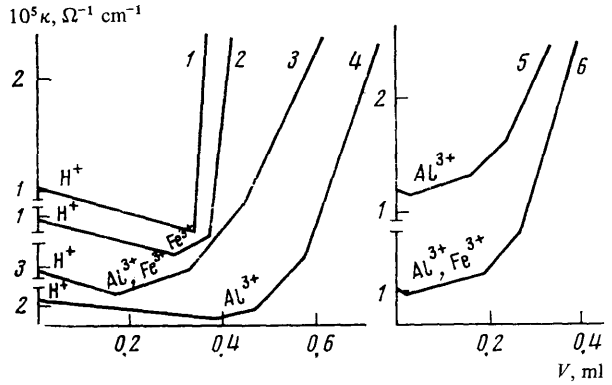

**Figure 1.** Curves for the conductimetric titration of acid forms of layer silicates with 0.095 *N* NaOH solution: 1) montmorillonite (0.027 g); 2) nontronite (0.037 g); 3) palygorskite (0.22 g); 4) kaolinite (0.19 g); 5) beidellite (0.041 g); 6) vermiculite (0.014 g).

Fig. 1 presents conductimetric titration curves for aqueous suspensions of freshly prepared acid forms of layer silicates. It follows from the data in the Figure that, after the complete or partial distribution of non-stoichiometric substitutions in the octahedral network (montmorillonite, nontronite, palygorskite, and kaolinite, see Table 1), the H-form of this type of mineral acquires strongly acid properties and contains on its surface freely mobile exchangeable hydrogen ions (Fig. 1, curves *1–4*). A completely different behaviour is observed in the titration of the acid forms of both vermiculite and beidellite in which non-stoichiometric isomorphous substitutions are almost completely distributed in the tetrahedral network. Their titration curves are analogous to the titration curves of a weak acid by a sodium hydroxide solution (Fig. 1, curves *5* and *6*). Analysis of a salt extract (0.5 *N* $BaCl_2$) showed that $Al^{3+}$ ions are present on the surface of beidellite, while the vermiculite surface contains $Al^{3+}$ and $Fe^{3+}$ ions in approximately equal amounts. These results lead to the conclusion that, after the substitution of the exchangeable $Na^+$ ions of the mineral by the $H^+$ ions of the resin [15], the exchangeable protons immediately interact with the tetrahedra where silicon has been substituted by aluminium or tervalent iron.

According to the proposed model [15] (Fig. 2), three exchangeable protons compensate the ruptured bonds (i.e. there is a conversion of $\equiv SiO^-$ into $\equiv SiOH$ groups) and the $Al^{3+}$ (or $Fe^{3+}$) ion liberated from the tetrahedron neutralises the charges of two neighbouring intact tetrahedra and one charge formed at the apex of the disrupted tetrahedron. $Al^{3+}$ (or $Fe^{3+}$) ions can also compensate the charges of the intact tetrahedra located in neighbouring basal planes. The simultaneous disruption of all the defective tetrahedra is impossible owing to the deficiency of the exchangeable $H^+$ ions, since three protons are required to transfer $Al^{3+}$ or $Fe^{3+}$ ions to a site where exchange is possible.

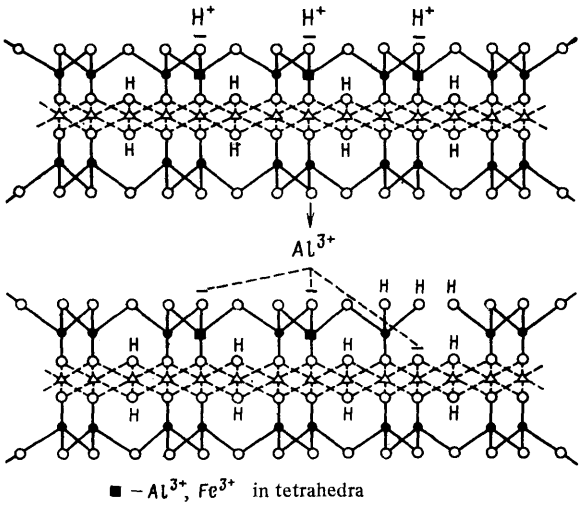

**Figure 2.** The disruption by exchangeable protons of the tetrahedra in which silicon has been substituted by aluminium or tervalent iron.

The transfer of the charge of the mineral from the tetrahedral to the octahedral network is confirmed by the constancy of the exchange capacities of the silicates before and after treatment with the KU-2 resin in the H-form [15,19]. Furthermore, it follows from Fig. 2 that, after the complete substitution of the exchangeable $Na^+$ ions of the silicate by the $H^+$ ions of the resin and rapid conversion of the H-form into the Al-Fe-form, one-third of the surface charge of the mineral is transferred from the tetrahedral to the octahedral network. After the conversion of Al-Fe-vermiculite into the Na-form and after the regeneration of the acid mineral, one-third of the exchange capacity should be due to the exchangeable $H^+$ ions. The results of these experiments are presented in Table 2, which shows that approximately one-third of the exchange capacity of vermiculite after the above operations have been carried out is indeed due to the exchangeable hydrogen ions. The H-Al-Fe-form of vermiculite obtained proved to be chemically unstable and was converted after 6 h (at 25°C) into the Al-Fe-Mg-form. The homoionic H-forms of vermiculite and beidellite could not be obtained after several (>2) treatments with the resin, since their structure was disrupted by protons [15,19].

The above considerations concerning the decomposition of defective tetrahedra by hydrogen ions have been confirmed by ESR studies [19]. The ESR spectra of the specimens were recorded in the X-range. The ESR spectrum of Kovdorskii [Kovd?] Na-vermiculite (Fig. 3, curves *1* and *2*) contains a very broad and intense band of complex shape with the absorption centre at $g \simeq 4.3$ and a relatively weak band at $g \simeq 2$. The low-field signals ($g = 4$–$6$) are usually assigned [20,21] to ions in the S-state ($Mn^{2+}$, $Fe^{3+}$) in a strong crystal field of low symmetry, for example in glasses. In vermiculite, the majority of $Fe^{3+}$ ions exist in the form of isomorphous substitutions in the tetrahedral network [22].

**Table 2.** The exchangeable acidity of Na-vermiculite after two cycles of treatment of the mineral with the KU-2 resin in the H-form ($c_{susp}$ = 0.6 wt.%; $V_{susp}$ = 200 ml; $V_{resin}$ = 200 ml).

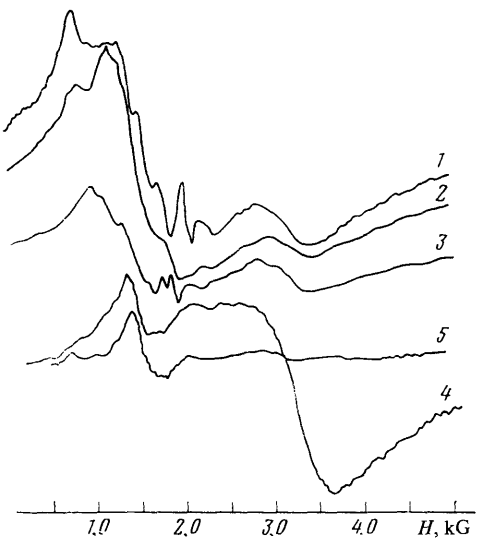

**Figure 3.** ESR spectra of Kovdorskii [Kovd?] Na-vermiculite: 1) air-dry; 2) dried at 105°C; 3) treated with 2 *N* HCl for 1 h; 4) treated with the KU-2 resin in the H-form for 6 h; 5) treated with the resin for 8 h.

The exchangeable cations, located directly at the iron–oxygen tetrahexra, greatly reduce the symmetry of the crystalline environment about the $Fe^{3+}$ ions (to orthorhombic and below). In terms of the approximation of the crystal field to orthorhombic or similar symmetry, the solution of the Hamiltonian [19] yields the ESR absorption in the region [23] of $g \simeq 4.3$. Consequently the intense band in the ESR spectrum of vermiculite must be assigned mainly to $Fe^{3+}$ ions in the tetrahedral network. The $Fe^{3+}$ ions in the octahedral layer of vermiculite involved in the exchangeable complex may contribute to this band. It follows from a comparison of spectra *1* and *2* in Fig. 3 that adsorbed water is present in the immediate environment in the $Fe^{3+}$ ions and has a significant influence on the form of the ESR spectrum. When vermiculite is treated with an acid (Fig. 3, curve *3*), the main change in the ESR spectrum consists in a decrease of the intensity of the band at $g \simeq 4.3$. This is associated with the removal of part of the tetrahedral and ion-exchange iron.

**Table 3.** The exchangeable acidity of vermiculite after its Na-form has been in contact with the KU-2 resin in the H-form ($c_{susp}$ = 0.9 wt.%; $V_{susp}$ = 200 ml; $V_{resin}$ = 200 ml).

| Time of contact with resin, h | Amount of exchangeable ions on surface, μequiv. $g^{-1}$ | | Total exchange capacity, w.r.t. $Ba^{2+}$, μequiv. $g^{-1}$ | Time of contact with resin, h | Amount of exchangeable ions on surface, μequiv. $g^{-1}$ | | Total exchange capacity, w.r.t. $Ba^{2+}$, μequiv. $g^{-1}$ |
|---|---|---|---|---|---|---|---|
| | $Al^{3+}+Fe^{3+}$ | $Mg^{2+}$ | | | $Al^{3+}+Fe^{3+}$ | $Mg^{2+}$ | |
| 0.33 | 490 | — | 1420 | 5.0 | 1200 | 180 | 1410 |
| 0.50 | 680 | — | 1420 | 6.0 | 1260 | 200 | 1410 |
| 1.0 | 850 | — | 1420 | 8.0 | 1030 | 260 | 1400 |
| 2.0 | 890 | 180 | 1410 | 9.0 | 950 | 350 | 1380 |
| 3.0 | 1120 | 280 | 1410 | 11.0 | 840 | 420 | 1260 |
| 4.0 | 1160 | 240 | 1410 | 14.0 | 480 | 740 | 1240 |

Table 3 shows that the interaction of Na-vermiculite with the KU-2 resin in the H-form leads to the complete substitution, even in the first few hours, of $Na^+$ by $Al^{3+}$ and $Fe^{3+}$ ions, which appear as a result of the disruption of the tetrahedral network of the mineral. For example, the complex band at $g \simeq 4.3$ disappears almost completely from the ESR spectrum of vermiculite treated with the cation-exchange resin for 6 h (Fig. 3, curve *4*). In this part of the spectrum, a narrow signal remains, while the broad band at $g \simeq 2$ hardly changes but diminishes appreciably on further contact with the resin (Fig. 3, curve *5*), but the narrow signals with $g \simeq 4.3$ remain unaltered. Spectra *4* and *5* (Fig. 3) are characteristic of montmorillonite [24,25]. Analysis of the infrared spectra [19] also shows that, when Na-vermiculite is treated with the ion-exchange resin for 8 h, a montmorillonite structure with the absorption bands characteristic of this mineral is formed. X-Ray diffraction analysis indicates the appearance on the diffractometer trace of the resin-treated vermiculite of distinct reflections characteristic of montmorillonite [19].

Thus, when Na-vermiculite comes into contact with the cation exchanger in the H-form, the substitution of $Na^+$ ions by $H^+$ ions is followed by the dissociation of the oxygen bridges joining the defective tetrahedra to neighbouring tetrahedra and octahedra, as a result of which structural $Al^{3+}$ and $Fe^{3+}$ ions pass to exchange sites and then to the resin. This is manifested in the ESR spectrum to the disappearance of the broad band at $g \simeq 4.3$ due to the $Fe^{3+}$ ion located initially in the tetrahedral network.

It follows from the above data that, when the non-stoichiometric isomorphous substitutions are fully or completely distributed in the octahedral network, it is possible to obtain under certain conditions [17,18] the hydrogen- or mixed H-Al-Fe-form of the layer aluminosilicate with strongly acid properties. When the non-stoichiometric substitutions are located in the tetrahedral network, the exchangeable protons rapidly decompose the defective tetrahedra, as a result of which exchangeable $Al^{3+}$ or $Fe^{3+}$ ions appear on the aluminosilicate surface.

## III. CHEMICAL STABILITY OF THE H-FORMS OF LAYER SILICATES AND THE MECHANISM OF THEIR AGEING

It was established as early as 1934 [26] that the H-forms of argillaceous minerals are chemically unstable and are converted spontaneously into the Al-Fe-Mg-forms (age). The authors of one of the earliest investigations of this problem found [27] that, after storage for one month, the exchange capacity of air-dry H-montmorillonite is virtually determined solely by hydrogen ions. In the specimen of the same mineral which had been repeatedly saturated with water and dried, a large proportion of the total exchange capacity was due to the fraction of aluminium ions. Similar data were obtained in other investigations [28-31]. In some of these, the influence of various factors on the ageing of H-clays was studied [30,31]. Our investigations showed that, with increase of temperature, the rate of ageing of the H-forms of natural aluminosilicates investigated‡ increases sharply [17,18,32-34]. Fig. 4 illustrates the temperature dependence of the ageing process of H-montmorillonite§. [33] A study of the rate of ageing of H-days in methyl, ethyl, and n-propyl alcohols and dioxan showed [17,18,32-35] that ageing is not observed in pure organic solvents, while in their mixtures with water the rate of this process depends on the content of the organic component in the mixture (Fig. 5). Fig. 5 shows that, compared with alcohols, dioxan has a stronger influence. The influence of the content of the disperse phase in the suspensions on the ageing of H-minerals was also studied. The experiments showed that, with increase of the content of the solid phase, particularly when it exists in the form of a dense deposit, the rate of ageing falls. Continuous stirring of the suspension accelerated the ageing of the specimen somewhat [17,18,36].

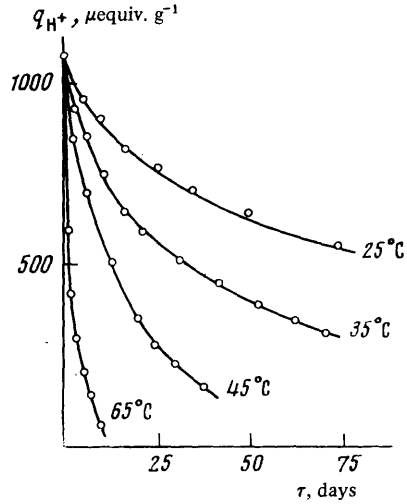

**Figure 4.** The influence of temperature on the rate of ageing of a 0.3% suspension of H-montmorillonite.

‡The kinetic experiments were performed on dilute suspensions of the H-forms with constant stirring.

§Here and henceforth data are presented only for H-montmorillonite. Similar results were obtained for other minerals.

Only a few studies have been devoted to the elucidation of the mechanism of the ageing of the hydrogen-forms of natural aluminosilicates. Miesserov believes [37,38] that the ageing of the H-form of montmorillonite involves the octahedral layer and is a result of the interaction of the hydrogen in the hydroxy-groups in the tetrahedral layer with the hydroxy-groups located at the aluminium atoms. Mitra and Singh [30] concluded that H-montmorillonite ages owing to the exchange of the hydrogen ions located in the basal planes of the clay particles for the aluminium ions on the crystal faces. As a result of the Brownian movement of the particles, the double layers formed by $H^+$ and $Al^{3+}$ ions overlap, which leads to exchange. However, if this mechanism is adopted, one cannot understand why the process ceases completely in a polar solvent such as methyl alcohol.

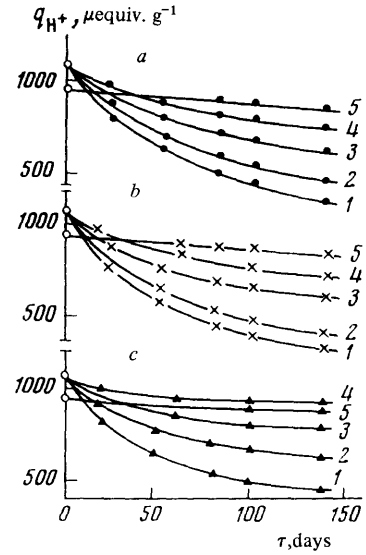

**Figure 5.** The influence of the content of organic solvent in the intermicellar medium on the rate of ageing of a 0.3% suspension of H-montmorillonite; content of solvent in the mixture (wt.%): 1) 10; 2) 30; 3) 60; 4) 60; 5) 100; *a*) ethanol; *b*) propanol; *c*) dioxan.

Eeckman and Loudelaut [31] established by a series of experiments that the rate of ageing of montmorillonite in the hydrogen-form is described empirically by the equation of a parabola. They suggested that the ageing mechanism involves the mutual diffusion of $H^+$ and $Al^{3+}$ ions. Aluminium ions diffuse along the surface of the particles from the crystal faces to the centre and there is a flux of hydrogen ions in the opposite direction. As soon as the hydrogen ions reach the crystal faces, they interact with the lattice, as a result of which a constant concentration of $Al^{3+}$ ions is maintained on the lateral surface. According to the authors, the rate of ageing is determined solely by the diffusion of $H^+$ and $Al^{3+}$ ions. To test the diffusion mechanism of ageing which they proposed, Eeckman and Loudelaut [31] used the following procedure. Assuming that the empirical parabolic equation which they derived is equivalent to Fick's Second Law, they obtained, after a

series of mathematical transformations, an expression susceptible to an experimental test. The test showed that the mutual diffusion coefficient of $H^+$ and $Al^{3+}$ ions is extremely small during the ageing of H-montomorillonite ($10^{-20}$ $cm^2$ $s^{-1}$), which is inconsistent with the observed rate of ageing and its temperature dependence [17,18]. By comparing the principal results of the application of the diffusion mechanism to the description of the ageing of H-montmorillonite, it can be easily shown that these ideas suffer from significant disadvantages [17]. In particular, the use of Fick's Second Law to characterise the mutual diffusion of $H^+$ and $Al^{3+}$ ions during ageing is completely unjustified. It is well known that Fick's Laws do not describe satisfactorily the diffusion of charged species, because in the given instance the occurrence of the process depends on many specific factors, primarily on the electric field arising during the migration of ions (the diffusional potential jump) [39,40]. The mutual diffusion coefficient calculated by the authors [31] is therefore doubtful. We may also recall that the theoretical calculations performed by Eeckman and Loudelaut are in poor agreement with their own experimental data.

Another attempt to interpret the mechanism of the ageing of the hydrogen-form of montomorillonite was undertaken recently [41,42]. To describe the ageing of the H-forms of this mineral, the authors used hyperbolic functions. This empirical approach to the process, without a definite physical basis, appears to be unjustified. The conclusion reached [41,42] about the kinetics of the ageing process (reaction order $n = 1$) is therefore unconvincing.

On the basis of the analysis of the entire set of the available literature data and our own experiments [18,33], we suggest that the ageing of the H-forms of clay minerals is a heterogeneous chemical reaction involving hydronium ions and not free protons. The involvement of water molecules in the given reaction is indicated by the results presented in Fig. 5, from which it follows that, when an organic solvent is added to the intermicellar medium, the rate of ageing of the H-form of the layer silicate falls. This is because in a water–organic solvent mixture some of the $H^+$ ions of the clay are solvated with formation of lyonium (and not hydronium) ions, for example $C_2H_5OH_2^+$, which are produced to a greater extent the higher the content of the organic component in the mixture. In non-aqueous media, where hydronium ions are altogether absent, ageing ceases completely. Together with the above factors, the rate of ageing of H-clays in water–organic solvent mixtures may be influenced by the association of the organic solvents with water, which results in a decrease of the activity of water molecules [43]. The validity of the above ideas concerning the decisive role of water in this reaction is confirmed very convincingly by the results [33] presented in Fig. 6. They show that the air-dry specimens of the H-forms of aluminosilicates, which still contained a certain amount of water, aged gradually. On the other hand, the specimens subjected to additional dehydration *in vacuo*, with simultaneous freezing out of water by liquid nitrogen, and then stored in sealed bulbs showed no signs of ageing whatever.

As shown above (Fig. 4), the rate of ageing of the H-forms of silicates increases sharply with increasing temperature, like the rate of any chemical reaction. This finding proves the chemical nature of the phenomenon investigated. We used a general kinetic equation for the mathematical description of this reaction. It was assumed [18,33] that the rate of ageing of H-minerals is determined mainly by the content of exchangeable $H^+$ ions, since the concentrations of other reactants—aluminium, iron, and magnesium present in the solid phase and the water present in the system in excess—may be regarded as constant. Therefore

$$-dq_{H^+}/d\tau = kq_{H^+}^n, \quad (1)$$

where $q_{H^+}$ is the content of exchangeable $H^+$ ions in $\mu$equiv. $g^{-1}$, $\tau$ the time in days, $k$ the reaction rate constant, and $n$ the power exponent corresponding to the order of the chemical reaction. Having plotted the dependence of the reaction rate on the concentration of exchangeable $H^+$ ions in terms of logarithmic coordinates, it is easy to determine from the slopes of the straight lines the orders of the chemical reactions [17,18,32–34]. Calculations showed that at the beginning of the ageing process is of third order, after which there is a decrease of the order to second and below. The activation energies were calculated separately for the second- and third-order reactions by plotting lg $k$ against the reciprocal of temperature. The results fit on parallel straight lines corresponding to the following activation energies: 20 kcal g-ion$^{-1}$ for the ageing of H-montmorillonite and H-nontronite; 17 kcal g-ion$^{-1}$ for the ageing of H-palygorskite; 25 kcal g-ion$^{-1}$ for the ageing of H-kaolinite. [18] Fig. 7 presents examples of the above determinations for the ageing of H-montmorillonite. These results show that the ageing of the hydrogen-forms of layer silicates is indeed a heterogeneous chemical reaction.

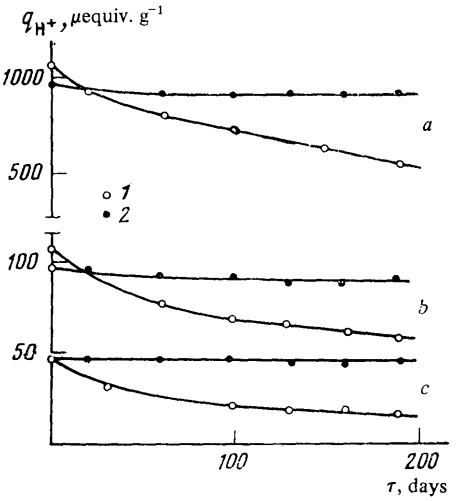

Figure 6. Kinetics of the ageing of air-dry (1) and fully dried specimens (2) of the H-forms of montmorillonite (*a*), palygorskite (*b*), and kaolinite (*c*) at 25°C.

Fig. 8 illustrates the model proposed [44] for the disruption by the exchangeable protons and water molecules of the crystal structure of montmorillonite. Evidently, three exchangeable $H^+$ ions are involved in the fundamental reaction step. One proton (Fig. 8*a*) reacts with a basic OH group (=Al–OH) and forms a water molecule. Simultaneously, two other protons attack via an electrophilic mechanism the ≡Si–O–Al= bonds, as a result of which the latter are broken with formation of two silanol groups and the liberation of an $Al^{3+}$ ion. The loss of the aluminium

ion from the octahedral network reduces the stability of the silicon–oxygen tetrahedra. The presence of a water molecule in the system and the catalytic effect of the exchangeable $H^+$ and $Al^{3+}$ ions [45,46] lead to the dissociation of the ≡Si–O–Si≡ bonds, as a result of which two molecules of silicic acid are released into the equilibrium solution¶:

$$2\left[\begin{array}{l}\equiv Si-O\\ \equiv Si-O\end{array}\!\!>Si(OH)_2\right] + 4H_2O \rightarrow 4[\equiv SiOH] + 2Si(OH)_4 . \quad (2)$$

When the next three exchangeable protons interact, the same products are obtained (Fig. 8*b*). In this case, the siloxane linkages are ruptured in accordance with the equation

$$2[\equiv Si-O-Si(OH)_3] + 2H_2O \rightarrow 2[\equiv SiOH] + 2Si(OH)_4 . \quad (3)$$

In contrast to the first reaction step (Fig. 8*a*), in this instance two exchangeable $H^+$ ions apparently rupture initially the ≡Si–O–Al≡ bond, after which one proton reacts with a hydroxy-group at an aluminium atom.

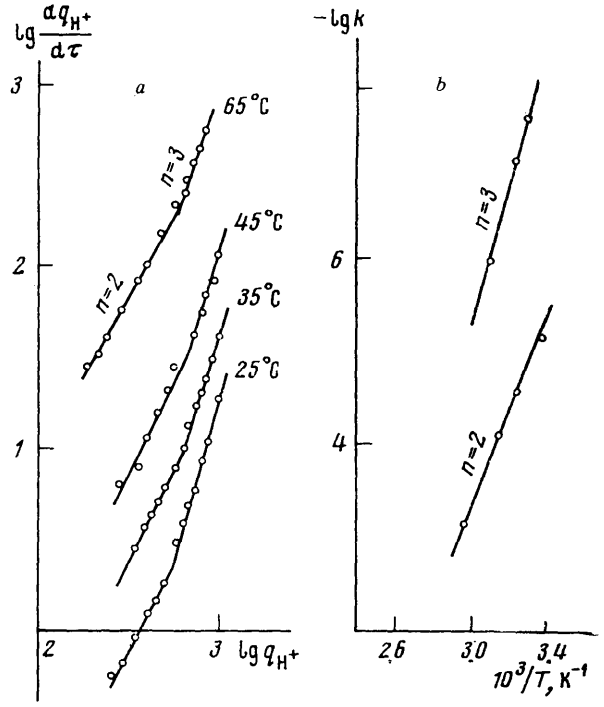

Figure 7. Dependence of the ageing of a 0.3% suspension of H-montmorillonite in water on its content of exchangeable $H^+$ ions at different temperatures (*a*) and of the logarithms of the rate constants for the second- and third-order reactions on the reciprocal of temperature (*b*).

It follows from Eqns. (2) and (3) that water is one of the reactants in the ageing of H-silicates. In is now understandable why ageing of the H-forms is not observed in non-aqueous media [17,18,33–35].

¶Silicic acid was determined in terms of $SiO_2$ by a standard method [47,48].

Subsequently the reaction under consideration proceeds analogously to those illustrated in schemes *a* and *b* in Fig. 8. After the complete conversion of the hydrogen-form of the aluminosilicate into the Al-form (the ageing cycle), its exchange capacity falls [31], because during the ageing of the H-forms of the minerals some of the $Mg^{2+}$ ions emerge from the octahedral layer (Fig. 8*c*), i.e. the number of non-stoichiometric isomorphous substitutions in this structure diminishes. The decrease of the number of isomorphous substitutions leads in its turn to a decrease of the exchange capacity of the aluminosilicate. Studies have shown [44] that the exchange capacity decreases by 130–140 mequiv. $g^{-1}$ in each ageing cycle of H-montmorillonite (five cycles in all were carried out).

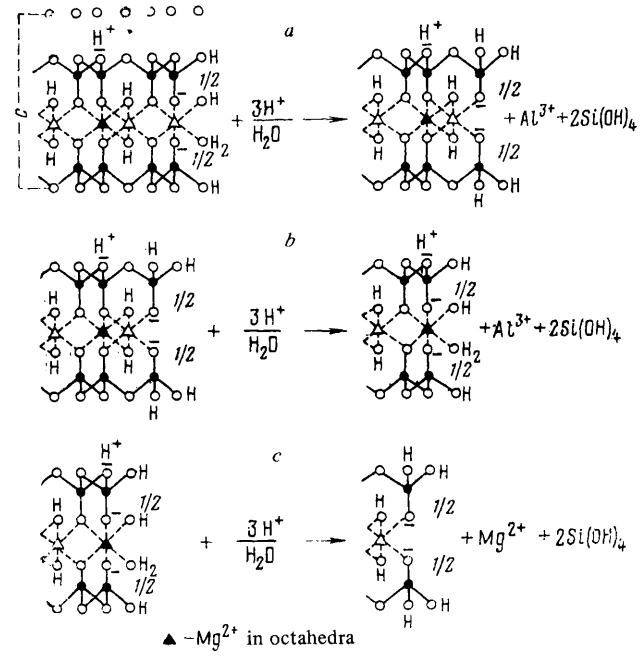

Figure 8. The disruption of the crystal structure of montmorillonite by protons.

It follows from the structure of layer silicates that the exchangeable protons, which neutralise the ruptured bonds at the crystal faces, are the first to enter into the reaction investigated. Since the exchangeable $H^+$ ions located on the basal planes are highly mobile [5,17,18,49,50], they reach the faces of the mineral and interact with the latter, liberating aluminium (iron, magnesium) ions from the lattice. The latter diffuse onto the basal plane and compensate its excess negative charge, generated after the removal of $H^+$ ions. At the same time, ions may migrate also in a different way. As a result of the Brownian movement or stirring of the suspension, the silicate particles can be oriented in such a way that the basal plane of one approaches closely to that of another. During the ion exchange between two solid phases in an aqueous medium, protons are adsorbed on the crystal faces and aluminium ions are adsorbed on the basal plane of a neighbouring particle [30]. However, it must be emphasised that neither

the mutual diffusion of $H^+$ and $Al^{3+}$ (or $Fe^{3+}$, $Mg^{2+}$) ions nor ion exchange between the aluminosilicate particles [30,31] determines the rate of reaction.

It has been shown [17,18,32-34] that the dependence of the logarithms of the rate constants for the ageing of H-silicates on the reciprocal of temperature is linear. These data as well as the high activation energies show that the process under consideration proceeds only under kinetic conditions [51]. Consequently the kinetics of the ageing of dilute suspensions of the H-forms are determined mainly by the rate of reaction of the exchangeable protons with the face of the mineral, i.e. by the rate of dissociation of the ≡Si–O–Al= and ≡Si–O–Si≡ bonds, while ion transport is of secondary importance. Basic hydroxy-groups play an important role in this process [52]. Only in the ageing of paste-like and air-dry specimens of the H-forms can the mutual diffusion of ions exert some influence on the rate of the process.

As already mentioned, the calculated activation energies for the ageing of H-silicates are the same for the second- and third-order reactions. This equality and also the observed stoichiometric amounts of $Al^{3+}$, $Fe^{3+}$, and $Mg^{2+}$ ions released from the mineral lattices suggest that the order of the reaction is in our case three, in conformity with the proposed model (Fig. 8). The observed decrease of the reaction order is caused mainly by the decrease of the concentration of the exchangeable $H^+$ ions during ageing. Only at the beginning of the process, where the surface concentration of $H^+$ ions is high, are the necessary conditions created for the occurrence of the third-order reaction. With decrease of their content, the rate of dissociation of the aluminosiloxane linkages falls. At the same time, the substitution of hydronium ions of the exchangeable $Al^{3+}$ ions located on the lateral faces of the silicates becomes more difficult. The validity of this interpretation is confirmed by a number of data [17,53]. It follows from the latter that, with decrease of the exchange capacity of montmorillonite and kaolinite†, the orders of the ageing reactions of the H-forms decreased by unity. Together with the causes described above, one cannot exclude the influence of other factors, such as the imperfection of the crystal structure of the aluminosilicate, the accumulation of silicic acid in the equilibrium solutions and its polymerisation on the surface of the particles with formation of secondary particles [54], etc.

Apart from their direct involvement in the dissolution of the aluminosilicate, water molecules play a number of additional functions. For example, owing to the considerable hydration energies of the $Al^{3+}$, $Fe^{3+}$, and $Mg^{2+}$ ions, water promotes their liberation from the octahedral layer. As a consequence of the formation of hydronium ions, it ensures a high mobility of the exchangeable protons. The addition of alcohols of dioxan to the intermicellar medium leads, as already stated above, to the appearance of lyonium ions, which are formed to a greater extent the higher the content of the organic solvent in the mixture. As a result of this, the mobility of the exchangeable protons falls with a consequent decrease of the rate of the ageing process.

It has been shown [44] that a similar pattern in the disruption of the aluminosilicate structure is observed when the aluminosilicate comes into contact with an inorganic acid. Table 4 shows that, in the interaction of the Ba-form of montmorillonite with a 0.01 *N* hydrochloric acid solution (with constant stirring of the suspension), aluminium ions and silicic acid are released into the equilibrium solution‡. As for exchangeable $H^+$ ions, the rate of reaction of the silicates with protons from the solution increases with increase of temperature. We therefore also used a general kinetic equation for the mathematical description of this process [18,33,44]. It was assumed that the rate is determined by the number of $H^+$ ions reacting, since the concentrations of the other reactants — aluminium and silicic acid present in the solid phase and the excess water in the system — can be regarded as constant. Fig. 9 shows that the dependence of the rate of reaction on the concentration of $H^+$ ions which have reacted, plotted in terms of logarithmic coordinates, consists of two linear sections. The orders of the corresponding reactions were determined from the slopes of these sections and were found to be 2 and 1. The decrease of the order of the reaction by unity compared with the ageing of the H-forms of layer silicates can be explained as follows. In contrast to the ageing reaction when Ba-montmorillonite interacts with HCl, a considerable amount of $Al^{3+}$ ions accumulates in the equilibrium solution. Since silicic acid molecules also pass to the solution, this leads to the formation of the strong aluminosilicic acid and the interaction of each aluminium ion with $Si(OH)_4$ yields one $H^+$ ion [55]. Three protons are involved in the fundamental reaction step (Fig. 8). However, after the liberation of the $Al^{3+}$ ion and two silicic acid molecules from the lattice, aluminosilicic acid is formed and one proton returns to the equilibrium solution.

Notation: $[H^+]_a$ is the amount of sorbed $H^+$ ions, $[Al^{3+}]_s$ and $[Al^{3+}]_{soln}$ are the amounts of $Al^{3+}$ liberated from the mineral onto its surface and into the equilibrium solution respectively, and $c_{SiO_2}$ is the amount of silicic acid, in terms of $SiO_2$ evolved from the mineral.

†The H-forms were prepared from specimens of these minerals subjected to preliminary activation with an inorganic acid.

‡The amount of amorphous silicic acid was determined by a standard method [48].

This is confirmed by Table 4, which shows that the amount of aluminium ions evolved from the mineral lattice is approximately one-third greater than the amount of absorbed hydrogen ions. Furthermore, the decrease of the concentration of $H^+$ ions as a result of their interaction with the montmorillonite crystals faces leads to an increase of the order of the reaction.

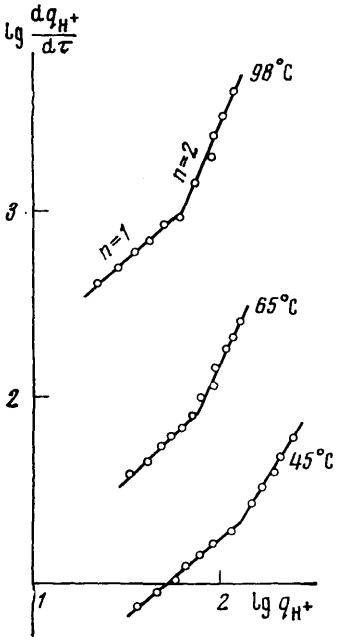

Figure 9. Dependence of the rate of interaction of $H^+$ ions with montmorillonite on the number of such ions reacting at different temperatures.

In order to calculate the activation energy for the dissolution of the mineral in an acid, we plotted[44] the logarithm of the reaction rate constant against the reciprocal of temperature. The data found for the first- and second-order reactions fit on parallel straight lines, which correspond to an activation energy of 24 kcal g-ion$^{-1}$. This value is close to that obtained earlier for the decomposition of the montmorillonite structure by exchangeable protons.

The mechanism proposed for the decomposition of natural aluminosilicates by $H^+$ ions is valid for all minerals in which non-stoichiometric substitutions or other defects, responsible for their ion-exchange capacity, are located in the octahedral network. A difference may be observed only in the quantitative release of silicic acid into the equilibrium solution (depending on the crystal-chemical type of the mineral). When layer silicates interact with inorganic acids one must bear in mind that aluminium ions exist in the intermicellar solution as cations derived from aluminosilicic acid. These cations may be adsorbed on the surface of the natural aluminosilicate instead of $Al^{3+}$ ions[56]. One should also note that, when clay minerals interacted with concentrated hydrochloric acid solutions (0.05 and 0.1 *N*), the absorption of protons was not observed[44]. This is apparently associated with the formation under certain conditions of aluminosilicic acids of different composition and the liberation of $H^+$ ions into the equilibrium solution.

## IV. THE ION-EXCHANGE PROPERTIES OF THE ACID FORMS OF NATURAL SILICATES

Extremely valuable information about the strength of binding of acid ions to the surfaces of clay minerals can be obtained from the analysis of the ion-exchange properties of the latter. At room temperature, H-silicates do not undergo appreciable changes during the first hours of ageing, which makes it possible to rule out the influence of this process when adsorption experiments are performed. The Langmuir equation has been used[17,18,57-59] to describe the ion-exchange interaction of the hydrogen- and electrodialysed (Al- and Fe-)forms of silicates with solutions of alkali and alkaline earth metal salts. The constant $b$ (adsorbability) of this equation serves as a quantitative characteristic:

$$a = a_\infty \frac{bc_e}{1+bc_e}, \qquad (4)$$

where $a$ is the degree of adsorption of the ions in $\mu$equiv. g$^{-1}$, $a_\infty$ the maximum degree of adsorption of the ions corresponding to complete coverage of the mineral surface by the latter in $\mu$equiv. g$^{-1}$, and $c_e$ the equilibrium concentration of the ions in solution in $\mu$equiv. ml$^{-1}$.

Table 5. The constants of the Langmuir equation ($a_\infty$, $\mu$equiv. g$^{-1}$; $b$, ml $\mu$equiv.$^{-1}$) characterising the adsorption of cations on the hydrogen- and aluminium-forms of the minerals.

The sorption isotherms obtained for the cations on both acid forms of clay minerals are described satisfactorily by the Langmuir equation[17,18]. The experimental points fitted satisfactorily on the straight line obtained in terms of the coordinates of Eqn. (4), from which the constants $a_\infty$ and $b$ were found by a graphical method[60]; the constants are listed in Table 5. Evidently $a_\infty$ remains invariant, within the limits of experimental error, and equal to the content in the initial specimen of hydrogen

and aluminium ions§ which are exchanged for the salt cations. This indicates the independence of the exchange capacity (due to isomorphism) of clay minerals of the nature of the adsorbed cation. The constant $b$, characterising the adsorbability of the cations investigated, varies as a function of both the properties of the salt cation and the nature of the exchangeable ion in the acid form of the aluminosilicate. The latter is manifested by the fact that the adsorbability of alkali and alkaline earth metal cations on the H-forms of minerals is an order of magnitude greater than on the aluminium-forms. Consequently the bonds between the exchangeable hydrogen ions and the silicate surface of the particle are much weaker than those linking the exchangeable $Al^{3+}$ ions.

Aluminium ions are strongly hydrated in solution and their mobility is low[61], while the acid proton is not even permanently attached to a particular water molecule with which it forms a hydronium ion, migrating continuously from one water molecule to another[62]. Presumably $H^+$ and $Al^{3+}$ ions retain their properties also in the adsorbed state. This explains our observation of the greater adsorbability of cations on the hydrogen-forms of clay minerals than on the aluminium-forms. Thus it follows from the literature[57-59] that exchangeable $H^+$ ions exhibit a high mobility and behave similarly to univalent cations. The anomalous behaviour of hydrogen ions[63] can be explained by the fact that aluminium-forms of clay minerals and not hydrogen-forms were in fact investigated.

The differences in the properties of exchangeable hydrogen and aluminium ions influence also the positions of alkali and alkaline earth metal cations in the series based on their adsorbability on the acid forms of layer silicates. Whereas the cations considered can be arranged in the sequence

$$Ba^{2+} = Ca^{2+} > Cs^{+} = Rb^{+} > K^{+} > Na^{+},$$

in terms of their capacity to enter into the exchangeable complex of H-minerals, another series holds for the aluminium-forms:

$$Cs^{+} > Rb^{+} > Ba^{2+} > Ca^{2+} > K^{+} > Na^{+}.$$

The change in the cation adsorbability series as a function of the nature of the exchangeable cation of the acid form can be accounted for from the standpoint of modern ideas about the behaviour of electrolytes in solution. According to these ideas, hydrogen ions as well as alkaii and alkaline earth metal cations migrate in solution without a hydration shell[64]. Such data are lacking for aluminium ions, but, by analogy with the behaviour of beryllium ions, $Al^{3+}$ ions presumably migrate together with water molecules. In ion-exchange processes, the fundamental step in the substitution of one type of ion by another may occur, depending on the properties of the cations, both with and without the involvement of the hydration shell. This apparently leads to the fundamental difference between the ion-exchange processes on the H- and Al-forms of minerals. Whereas in the former case unhydrated cations are exchanged, in the latter the process is determined by the fact that $Al^{3+}$ ions can be displaced only together with their hydration shells. When the fundamental exchange step on the surface of a layer silicate is not complicated by the hydration of cations, their adsorption from solutions should occur more effectively the stronger their attraction to the surface of the particle. This attraction is greater the higher the charge of the ion and, for the same charge, the greater its polarisability. In the exchange of hydrogen ions for alkali and alkaline earth metal cations, doubly charged ions are therefore adsorbed more strongly than singly charged ions and, in individual groups of cations, the adsorbability increases with increasing radius of the unhydrated ion.

In the exchange processes on the aluminium-forms of clay minerals, $Al^{3+}$ ions are probably involved together with their hydration shells. Their substitution might be facilitated if their shell were disrupted in some way. This apparently actually occurs in the exchange of $Al^{3+}$ ions for $Rb^+$ and $Cs^+$ ions, which are characterised by negative hydration, consisting in the fact that, under the influence of these ions, water molecules, as it were, become more mobile than in the pure solvent[64]. This is why the adsorbability of $Rb^+$ and $Cs^+$ ions on the Al-forms of the minerals is greater than that of the remaining cations investigated, including bivalent cations. Thus the results presented show that the exchangeable $H^+$ ions of clay minerals do not exhibit any anomalous properties and retain the features characterising them in aqueous electrolyte solutions.

## V. THE INFLUENCE OF THE MOBILITY OF THE EXCHANGEABLE $H^+$ IONS ON THE NATURE OF $^1H$ NMR SPECTRA

Apart from their strongly acid properties the exchangeable $H^+$ ions manifest yet another interesting property—they influence proton magnetic resonance spectra. The $^1H$ NMR spectra of the water present in oriented preparations of the H-, Li-, and H-Li-forms of montmorillonite have been analysed[65]. The investigation showed that the shape of the $^1H$ NMR spectrum of the protons in the water molecules adsorbed by the Li-form of montmorillonite depends on the disposition of the film of the partly oriented mineral in the magnetic field. Together with a narrow line in the centre of the spectrum (Fig. 10, curve *2*), there is a distinct doublet, the distance between the peaks of which is described satisfactorily by the relation $3\cos\theta - 1$ [sic], where $\theta$ is the angle between the normal to the plane of the aluminosilicate packets and the external magnetic field $H_0$. These data indicate the anisotropic movement of $H_2O$ molecules in the interlayer space of the Li-montmorillonite obtained previously in a study of powdered specimens[66]. It is noteworthy that the maximum splitting of the doublet for the oriented preparation, when the magnetic field is applied at right angles to the plane of the film ($\theta = 0$, Fig. 10, curve *2*), amounts to approximately 4 G, which exceeds by a factor >2 the corresponding value for powdered specimens with the same moisture content[66]. The angle $\gamma_{iR}$ between the interproton vector and the normal to the plane of the packet was determined from the calculated second moment of the doublet (6 $G^2$) and was found to be ~38°. This value agrees satisfactorily with the results from a number of studies[67,68]. The $^1H$ NMR spectrum of the water in the H-form of montmorillonite shows a single narrow line, regardless of the orientation of the films in the magnetic field (Fig. 10, curve *1*). The absence of the doublet from the spectrum can be accounted for both by the different state of the water molecules in the interlayer space of H-montmorillonite and by the specific influence of the mobile exchangeable $H^+$ ions on the form of the $^1H$ NMR spectra. The nature of the mobility of the water in the Li- and H-forms should not differ significantly.

§The decrease of the content of exchangeable $Al^{3+}$ ions relative to hydrogen ions is due to the decomposition of the silicates during electrodialysis.

Studies have shown[65] that the introduction of even an insignificant amount (1–2% of the exchange capacity of the mineral) of exchangeable hydrogen ions leads to the disappearance of the doublet from the spectrum of the Li-form of the aluminosilicate. The change in the state of water under these conditions must be slight. One can therefore postulate that the introduction of small amounts of hydrogen ions into the mineral accelerates significantly only the proton exchange in the system. The role of this factor in the disappearance of the doublet structure of the $^1H$ NMR spectrum of water in the montmorillonite gels had been noted earlier[69,70] in a comparison of pulsed proton and deuteron magnetic resonance signals. It also follows from the results presented that the mechanism of "relay" proton exchange is more probable, since the formation of short-lived $H_3O^+$ ions requires a rearrangement of the electronic configuration of water molecules. Furthermore, it is difficult to suppose that all the water molecules participated in the formation of $H_3O^+$ ions in the proton exchange process in the presence of such a low concentration of $H^+$ ions on the surface of Li-montmorillonite.

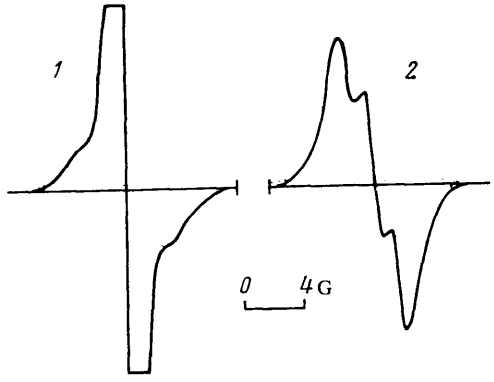

**Figure 10.** The $^1H$ NMR spectra of the oriented specimens: 1) air-dry H-montmorillonite; 2) air-dry Li-montmorillonite.

The narrow line in the centre of the $^1H$ NMR doublet spectrum of the Li-form of montmorillonite (Fig. 10, curve *2*) was assigned to the state of water whose mobility is close to that of isotropic water[66]. However, the appearance of the narrow line can also be accounted for by the influence of proton exchange, which occurs when montmorillonite is hydrated[71]. The protolytic dissociation of water molecules which takes place in this case owing to the polarising action of the cations and the surface may influence the proton exchange in the system. This effect should become more pronounced with increase of the ionic strength due to the cations. This may explain the difficulty of observing the doublet structure of the NMR spectra of the water protons when the exchangeable complex contains certain bivalent metal cations[72].

## VI. THE INFLUENCE OF TEMPERATURE ON THE STATE OF THE EXCHANGEABLE ACID IONS

The catalytic activity of natural aluminosilicates is related mainly to their surface acidity. As already stated, the hydrogen forms of layer silicates are chemically unstable and undergo the ageing process. In order to elucidate the mechanism of the chemical reactions, it is therefore necessary to take into account, under certain conditions in the catalytic process, both the composition and the state of the acid aluminosilicate ions on the surface.

Table 6. The influence of the temperature and duration ($\tau$) of heat treatment on the content of exchangeable $Al^{3+}$ and $Fe^{3+}$ ions ($\mu$equiv.g$^{-1}$) on the surface of layer silicates.

| $\tau$, h | 25–400° C | 500° C | 600° C |
|---|---|---|---|
| Al-montmorillonite | | | |
| 1.0 | 1100 | 750 | 100 |
| 2.0 | 1100 | 680 | 90 |
| 3.0–4.0 | 1100 | 600 | 90 |
| Al, Fe-palygorskite | | | |
| 1.0 | 145 | 140 | 70 |
| 2.0–4.0 | 145 | 140 | 60 |
| Al-kaolinite (Prosyanovskii [Prosyanaya?] deposit) | | | |
| 1.0–4.0 | 55 | 55 | 53 |

Tables 6 and 7 present data for the influence of the temperature and duration of the heat treatment on the content of exchangeable $Al^{3+}$, $Fe^{3+}$ and $H^+$ ions on the surface of air-dry specimens of minerals. They show that the Al-forms are chemically stable at fairly high temperatures, while the H-forms of the minerals are chemically unstable and the mechanism of their ageing changes significantly as a function of temperature.

Below 200°C, the ageing of air-dry specimens of H-clays proceeds only as far as a definite content of hydrogen ions on the surface of the aluminosilicate and then becomes sharply retarded. Such inhibition can be accounted for by the fact that the ageing process under the given conditions is determined by the rate of the spontaneous conversion of the H-form of the mineral into the Al-form and by the evaporation of water from the surface of the silicate particles[18,36]. After the removal of water, this process ceases. The proposed explanation is confirmed by the results of a study of the ageing of a completely dried H-specimens¶—even at 200°C it is hardly converted into the aluminium-form (Table 7). A completely different behaviour was observed in the ageing of the H-forms above 200°C (Table 7). In contrast to the ageing mechanism already known, the exchangeable $H^+$ ions disappear completely from the surface without the removal from the mineral structure of a stoichiometric amount of $Al^{3+}$ ions. After the heat treatment of the H-forms of clay minerals for 1 h at 300–400°C, the

¶The dry specimen of the H-mineral was prepared from the air-dry specimen by prolonged evacuation accompanied by the freezing out of moisture by liquid nitrogen, after which it was stored in a sealed bulb.

exchange capacity of the mineral decreases irreversibly by an amount equal to the number of exchangeable hydrogen ions.

The observed phenomenon is probably similar to the migration of $Li^+$ ions in the octahedral layer of the clay mineral noted earlier. The small $Li^+$ cations may be located either at vacant octahedral sites [13] or in the interstices between them [14].

*In vacuo.

In order to elucidate the causes of the loss of exchange capacity by H-montmorillonite on heating to 300–400°C, a study was made of the NMR spectra of both acid forms [78]. It was observed that the NMR spectra of the initial air-dry specimens of the H- and Al-forms show an intense narrow band due to the adsorbed water molecules and hydrogen ions. The difference between the NMR spectra of the H- and Al-forms is manifested only after the removal of sorbed $H_2O$ molecules. For example, the NMR spectrum of the Al-form heated for 1 h at 200°C (Fig. 11, 1*a*) contains a broad band due to hydroxy-groups. The calculated second moment, which is approximately 4 G$^2$, agrees well with data for OH groups obtained for other cation-substituted forms of montmorillonite [14].

In contrast to the Al-form, the NMR spectrum of H-montmorillonite heated to 200°C shows a distinct narrow line with $\Delta H \simeq 0.5$ G (Fig. 11, 2*a*), against the background of the band due to hydroxy-groups, which we assigned to mobile exchangeable hydrogen ions. Quantitative study of the form of the NMR signal obtained reveals a downfield shift of the band due to $H^+$ ions relative to the signal of hydroxy-groups. Owing to the considerable width of the bands observed in the spectrum, it is difficult to estimate the shift quantitatively. If it is assumed that, on raising the temperature to 300°C, hydrogen ions become located at the ion-exchange centres on the aluminosilicate, then the NMR spectrum should exhibit a broadening of the band due to hydroxy-groups as a result of the increase in proton density. In fact, a narrow proton line is observed even at a heat treatment temperature of 500°C and the content of protons decreases (only) above this temperature, where the loss of the structural hydroxy-groups of the mineral already takes place (Fig. 11, *b*). Since at 300°C and above there are no exchangeable protons on the surfacd of montmorillonite (Table 7), it is reasonable to suppose that they migrate into its crystal structure. It also follows from the results presented that the protons captured by the lattice are not located at definite electron-donating centres, but diffuse throughout the crystal structure.

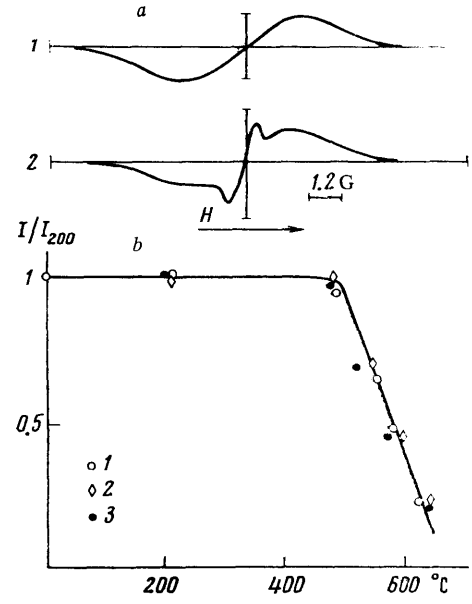

**Figure 11.** *a*) NMR spectra of the protons of the specimens of the Al-form (*1*) and the H-form (*2*) of montmorillonite dehydrated at 200°C; *b*) variation of the integral intensities in the NMR spectra of the hydroxyl protons and $H^+$ ions in the acid form of montmorillonite as a function of the temperature of the heat treatment of the specimens; 1) OH groups in the Al-form; 2) OH groups in the H-form; 3) $H^+$ ions.

X-Ray diffraction studies on the H-form of montmorillonite heated at different temperatures (25–450°C) showed that its crystal lattice does not undergo appreciable changes during the ageing processes. The non-basal reflections (4.39, 3.12, 2.48, 1.66, 1.48, and 1.27 Å, etc.) for both acid forms of the mineral are characteristic in the experimental temperature range also of other cation-substituted forms of montmorillonite [74].

Thus the available data show that the nature of the surface of the acid forms of layer silicates depends to a large extent on their heat treatment temperature. In the study of chemical transformations, it is therefore necessary to take into account the change in the chemical nature of the surface under certain conditions of catalysis. Thus, in the investigation of the catalytic process on the aluminium-form, one must bear in mind the decrease of the content of exchangeable $Al^{3+}$ ions of silicates above 500°C. The study of the mechanism of catalytic reactions on the minerals in the hydrogen-forms must be approached with

even greater caution. The elucidation of the true mechanism of the catalytic reaction is complicated in this case by the ageing processes of the H-form. Under conditions where there is no water in the system, the H-form is a chemically stable complex up to 200°C. Above this temperature exchangeable protons migrate spontaneously in the crystal structure of the mineral, which is reflected in its catalytic activity. A slight activity may be manifested under these conditions owing to the thermal dissociation of the surface hydroxy-groups [75] or other active centres in the crystals.

## VII. THE EXCHANGEABLE ACIDITY OF SILICATES ACTIVATED BY INORGANIC ACIDS AND OF ELECTRODIALYSED SILICATES

Considerable advances have been made in the study of the adsorption-structural and physicochemical properties of acid-activated minerals [1,7,76]. These investigations have established that the sorbents and catalysts obtained in this way exhibit enhanced adsorption, bleaching, and catalytic properties. The studies performed have shown[53] that both the composition of the exchangeable cations and the exchange capacity of montmorillonite depend on the activation time (Table 8). With increase of activation time, the content of hydrogen ions on the surface of the mineral falls and that of the aluminium ions increase. When the sorbent is treated with a 20% hot solution of $H_2SO_4$ for 6 h, its virtually homoionic Al-form is produced.

**Table 8.** The influence of the activation time on the amount of exchangeable $H^+$ and $Al^{3+}$ ions of montmorillonite ($\mu$equiv.$g^{-1}$) and on the concentration of $Al^{3+}$ ions in the mother liquor $[Al^{3+}]_{soln}$ (activation temperature 98°C).

| Treatment time, h | Exchange capacity, $\mu$equiv. $g^{-1}$ | Washing without cooling | | Washing after cooling | | $\frac{[Al^{3+}]_{soln}}{N}$ |
|---|---|---|---|---|---|---|
| | | $H^+$ | $Al^{3+}$ | $H^+$ | $Al^{3+}$ | |
| 1 | 960 | 350 | 615 | 500 | 465 | 0.06 |
| 2 | 880 | 300 | 580 | 390 | 490 | 0.07 |
| 3 | 790 | 190 | 605 | 310 | 485 | 0.10 |
| 4 | 780 | 80 | 710 | 180 | 610 | 0.13 |
| 5 | 700 | 50 | 655 | 100 | 605 | 0.17 |
| 6 | 650 | 40 | 660 | 40 | 660 | 0.21 |
| 8 | 630 | 30 | 640 | 30 | 640 | 0.22 |

The decrease of the number of exchangeable $H^+$ ions during the activation process can be explained as follows. When a hot solution of sulphuric acid comes into contact with the clay mineral, the mineral faces dissolve, as a result of which aluminium ions and polysilicic acid gradually accumulate in the mother liquor. On washing the specimen, the selective adsorption of tervalent aluminium (or aluminosilicate [56]) ions results in the partial or complete substitution by the latter of the hydrogen ions in the equilibrium solution depending on the concentration of the tervalent ions. At the same time, one cannot rule out also the possibility of the ageing of the H-form of the aluminosilicate during activation and particularly during the washing of the hot specimens. This is indicated by the dependence of the composition of the exchangeable cations of the activated mineral on the washing conditions: samples which were washed free of the excess electrolyte without cooling contain fewer exchangeable hydrogen ions compared with samples which had been subjected to preliminary cooling for 24 h (Table 8). This is because on cooling a suspension of the mineral in an acid solution, the $Al^{3+}$ ions cannot be distributed on the surface, since they are readily displaced by protons owing to the high concentration of the latter. During the washing of the hot specimen, the H-mineral ages after the first portion of the mother liquor has been decanted, with migration of exchangeable aluminium ions onto the surface.

The hydrogen-aluminium-form of the activated montmorillonite thus obtained is chemically unstable and is converted after a time into the homoionic Al-form. As for the homoionic H-forms of clay minerals, this process depends on the content of the disperse phase in the system, the composition of the intermicellar medium, and temperature. With increase of the concentration of the suspension and following the introduction of methanol into the dispersion medium, the rate of ageing of the activated specimens falls. In dehydrated methanol and in the dried state, the specimens investigated do not show any signs of ageing. With increase of temperature, the rate of ageing of the specimens in the aqueous suspension increases sharply. These results show that the ageing process of the activated mineral is similar to the ageing of the homoionic H-forms of layer silicates described above and is a heterogeneous chemical reaction of the exchangeable protons on the aluminosilicate faces. A necessary condition for this reaction is the presence of water molecules in the system. The calculated activation energy for the ageing of the H–Al-form (21 kcal g-ion$^{-1}$) proved to be equal to the value for the ageing of the homoionic H-form of the mineral.

Table 8 shows that the exchange capacity of the silicate after activation for 6 h changes insignificantly. This is because a large amount of aluminium ions and silicic acid accumulates in the mother liquor, as a result of which a chemical equilibrium is established in the system. At the same time, the inhibition of the dissolution of minerals may be influenced by the polymerisation processes of the above compounds. Amorphous polyaluminosilicic and polysilicic acids may be deposited on the lateral faces of silicates and prevent the interaction of hydronium ions with the latter.

It follows from the analysis of the extensive literature on the acid activation of minerals that solutions of concentrated acids (up to 20%) are used as a rule for this process [1,7,76,77]. However, in these solutions the degree of dissociation of the acid is greatly reduced and the activity of $H^+$ ions is insignificant. In order to intensify the above treatment, it is therefore desirable to use more dilute solutions of inorganic acids. One must also take into account the fact that, when unpurified minerals are used, part of the acid is consumed in the dissolution of impurities such as oxides, carbonates, organic substances, etc., which are always present in natural specimens.

Electrodialysis of aqueous suspensions of minerals is a very convenient method of obtaining their acid forms [17]. Its advantage is due to the fact that, in contrast to acid activation, it does not require additional operations involved in the removal of electrolytes from the dispersed silicate by washing, particularly since both methods frequently lead to minerals in the Al-(Fe-, Mg-)forms [17]. It has been shown in a number of studies [1,78,79] that electrodialysis of suspensions of aluminosilicates causes

the disruption of their lattices. The mechanism of the dissolution process is apparently similar to that described above and consists of the following steps. When a constant electric field is applied, the exchangeable cations in the suspension† migrate to the cathode and accumulate in the cathodic compartment. The negatively charged silicate species diffuse to the anode, becoming concentrated near the cellophane partition. During electrodialysis, water molecules are known to decompose:

$$6H_2O \rightarrow 2H_2 + O_2 + 4H^+ + 4OH^-, \quad (5)$$

$OH^-$ ions accumulating at the cathode and $H^+$ ions at the anode. When the cathodic compartment is washed with distilled water, the exchangeable cations are removed in the form of metal hydroxides. The excess negative charge of the individual mineral particles is compensated by hydrogen ions. As shown above, the H-form of the natural aluminosilicate is chemially unstable and is converted into the Al-Fe-Mg-form. Since electrodialysis is almost always accompanied by an increase of temperature, the ageing reaction proceeds under these conditions at a high rate. As a result, the mineral faces break down (Fig. 8) with liberation of silicic acid, which is always observed in the anodic compartment [17,80].

One should also note that the intensity of the given process depends both on the nature of the exchangeable cation and on the potential difference applied to the electrodes. The stronger the binding of the exchangeable cation to the surface, the greater the potential gradient required for the transfer of the exchangeable cation to the cathodic compartment. If a potential difference capable of causing the desorption of the exchangeable $Al^{3+}$ ($Fe^{3+}$) ions from the surface and of transferring them to the cathodic compartment is applied to the system, a continuous dissolution of the mineral is observed. In order to obtain the acid form of the aluminosilicate by the electrodialysis of aqueous suspensions, it is therefore necessary to monitor the process carefully. The monitoring consists in analysing the electrolyte in the cathodic and anodic chambers. As soon as the flow of exchangeable cations into the cathodic compartment ceases and silicic acid appears in the anodic compartment (in the form of $SiO_3^{2-}$ ions), electrodialysis is stopped. The composition and amount of exchangeable acid ions on the surface of the silicate are determined at the same time.

In order to obtain reliable data on the nature of the exchangeable acidity of powdered specimens, one must bear in mind the fact that the drying of their pastes must be carried out at room temperature or below. Such drying conditions inhibit the ageing of the H-forms of the minerals.

# The Photoelectron Spectroscopy of Organophosphorus Compounds

V.V.Zverev and Yu.T.Kitaev

The applications of the method of photoelectron spectroscopy in the study of the electronic and steric structures of organophosphorus compounds is examined. The spectra of two-, three-, and four-coordinated phosphorus are interpreted in terms of the approximation of Koopmans' theorem. Attention is concentrated on the elucidation of the composition of the upper occupied orbitals. The manifestations of the $n-\pi$ and $n-n$ interactions in the photo-electron spectra of these compounds are investigated.
The bibliography includes 104 references.

## I. INTRODUCTION

The ultraviolet photoelectron spectroscopy (PES) is a unique method whereby it is possible to establish the sequence of the ionisation potentials of molecules. The first reports showing that the photoelectron spectrum contains information about the set of ionisation potentials were published by Vilesov et al.[1] and Turner and Al-Joboury[2] more than ten years ago, but the period of the most intense development of the method covers the last five years. The method of X-ray (photo)electron spectroscopy, which permits the determination of the electron binding energies in the inner non-valence levels, was developed somewhat earlier[3], but the survey of the available information about the applications of this method in the study of organophosphorus molecules is outside the scope of the present review.

This review deals with the applications of the PES method in the study of the compositions of the upper occupied molecular orbitals and of the steric structures of organophosphorus compounds. The photoelectron spectra of phosphorus compounds have been obtained by many groups of investigators and the number of compounds which have been investigated is fairly large.

The method of ultraviolet PES, described in a number of reviews and monographs (see, for example, Refs. 4–9), has become firmly established in organic chemistry. The most important results have been obtained by the PES method in the study of the $\pi-\pi$ interaction in conjugated and non-conjugated molecules with $\pi$ bonds[10,11], the $\pi-\sigma$ mixing of orbitals in non-planar molecules[12,13], the problem of the $\pi-\sigma$ separation in planar conjugated systems[14,15], the $n-n$ interaction of lone electron pairs (LEP)[16], and the $n-\pi$ interaction of LEP with an unsaturated fragment of the molecule[17-20]. The possibility of investigating by the PES method the steric structures of conjugated molecules[16-21], the steric hindrance to conjugation[17-20], and conformational equilibria[16,21] is of considerable interest. The PES method has been used in a number of studies to investigate reactivity[22-25].

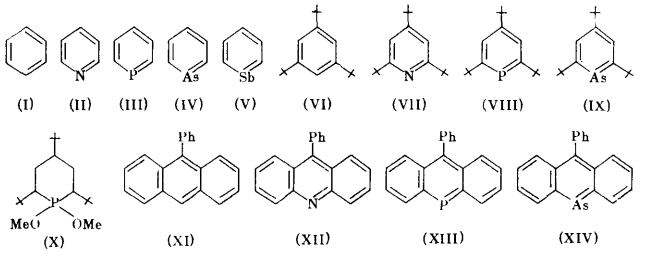
The information obtained by the PES method is extensive and varied. The threshold value of the ionisation current yields the adiabatic potential $IP_m^a$, which is defined as the difference between the energies of the molecules and the ion in the zero-point vibrational state. The vertical ionisation potentials $IP_m^v$ may be determined from the maximum change in the ionisation current, which corresponds to the most probable ionisation transition.

The interpretation of the experimental data obtained by the PES method is simplest and most convenient in terms of the approximation of Koopmans' theorem[26,30], according to which the values of $IP_m^v$ are equal to the energies (with the opposite sign) of the corresponding molecular orbital:

$$IP_m^v = -\varepsilon_m. \quad (1)$$

In terms of the approximation of Koopmans' theorem, the ionisation potential $IP(\psi_m)$ may be regarded as the energy of the ionisation of an electron from the occupied orbital $(\psi_m)$. In comparing the experimental values of $IP_m^v$ with the calculated orbital energies $(-\epsilon_m)$, one also uses relations of the type

$$IP_m^v = a + b(-\varepsilon_m), \qquad (2)$$



which have come to be referred to as the weakened form of Koopmans' theorem [31,32].

However, the empirical methods for the interpretation of PES data, based on the definite characteristic nature of the properties of the bands in the spectrum, are no less valuable. Thus the LEP of oxygen, sulphur, and halogen atoms contribute specific narrow bands to the photoelectronic spectra, while the delocalisation of the LEP, particularly their involvement in the $n-\pi$ interaction, leads to a broadening of the bands and a change in their shape [5]. When the LEP electrons of nitrogen [33] and phosphorus [34] are dislodged, broad bands are obtained (the difference between $IP_1^v$ and $IP_1^a$ amounts in this case to approximately 0.5 eV), which is associated both with the involvement of the LEP of these atoms in bonding and with the change in the geometry of the ion on ionisation. The upper $\pi$ orbitals of conjugated systems give rise to narrow bands with a resolved vibrational structure [5]. The intensity of the bands depends both on the nature of the atom where the corresponding orbital is predominantly localised and on the contribution to the latter by $s$ and $p$ electrons [35].

In the interpretation of PES data, relations governing series of related compounds are used, the spectra of the test compound and its perfluoro-analogue are compared [36], and account is taken of the spin–orbital and Jahn–Teller band splitting [37,39] as well as the dependence of the band intensity on the degree of degeneracy of the orbitals [37] and the energy of the ionising radiation [38]. The above procedures make it possible in many instances to interpret fairly unambiguously the photoelectron spectrum and to determine the energy of the orbitals and the nature of their interaction.

## II. $\lambda^3$-PHOSPHORINS

The photoelectron spectra of $\lambda^3$-phosphorin and its derivatives

have been obtained and interpreted by Schäfer's [40–45] and Heilbronner's [46] groups. The disposition of the molecular orbitals in $\lambda^3$-phosphorin was established by comparison with *ab initio* calculations [46] and with calculations by the method of complete neglect of differential overlapping (CNDO/2) [40,41] and was confirmed by ionisation potential data for series of related compounds [43–45] (Fig. 1 and Table 1).

**Table 1.** The vertical ionisation potentials of $\lambda^3$-phosphorins and their interpretation.

| Compound | $IP^v$, eV | | | | | Refs. |
|---|---|---|---|---|---|---|
| $\lambda^3$-Phosphorin | 9.2<br>$3b_1(\pi)$ | 9.8<br>$1a_2(\pi)$ | 10.0<br>$13a_1(\sigma, n)$ | 11.5<br>$8b_1(\sigma)$ | 12.1<br>$2b_1(\pi)$ | 46 |

| 1,1-Dibenzyl-2-phenyl-1-phosphanaphthalene | 6.0<br>$\pi_1$ | 7.90<br>$\pi_2$ | 8.8<br>Ph, $B_Z$, $\pi_3$ | 9.4 | | 44 |

When a heteroatom is introduced into the benzene molecule, the upper degenerate benzene orbital $1e_{1g}(\pi)$ splits into two orbitals of the type $b_1(\pi)$ and $a_2(\pi)$, in conformity with the $C_{2v}$ symmetry group of the substituted molecule. Since the atomic coefficient of the $a_2(\pi)$ orbital is zero at the site of substitution, the orbital should be little affected by the influence of the substituent (Fig. 2). In contrast to $a_2(\pi)$, the $b_1(\pi)$ orbital has no node at the site of substitution and its energy must depend significantly on the nature of the substituent. In terms of the approximation of the Hückel method, the change in the energy of the $b_1(\pi)$ orbital is determined by the product of the square of the atomic coefficient at the site of substitution and the Coulomb integral for the heteroatom $\Delta\alpha_X$:

$$\Delta\varepsilon(b_1(\pi)) = [C_{b_1(\pi),x}]^2 \Delta\alpha_x. \qquad (3)$$

The absence of a charge on the phosphorus atom in the $a_2(\pi)$ orbital also follows from the electron density map for the $b_1(\pi)$ and $a_2(\pi)$ orbitals of the $\lambda^3$-phosphorin molecule [47].

In the pyridine molecule, the energy of the $a_2(\pi)$ orbital is higher than that of the $b_1(\pi)$ orbital, because the nitrogen atom is more electronegative than carbon and stabilises the $b_1(\pi)$ orbital. In contrast to the pyridine molecule, in $\lambda^3$-phosphorin and in heterocyclic arsenic(IV) and antimony(V) compounds, the $b_1(\pi)$ orbital lies above the $a_2(\pi)$ orbital (Fig. 1). The reversal of the sequence of $\pi$ orbitals in $\lambda^3$-phosphorin in relation to pyridine constitutes the main problem in the interpretation of the photoelectron spectra of these compounds [40–46]. The reversal of the orbitals has been comprehensively investigated and demonstrated in several ways. The reversal of the sequence of $\pi$ orbitals can be demonstrated by quantum-chemical calculations of $\lambda^3$-phosphorin [46]. We shall also examine empirical methods for the elucidation of the reversal of levels and the conclusions concerning the electronic structure of the

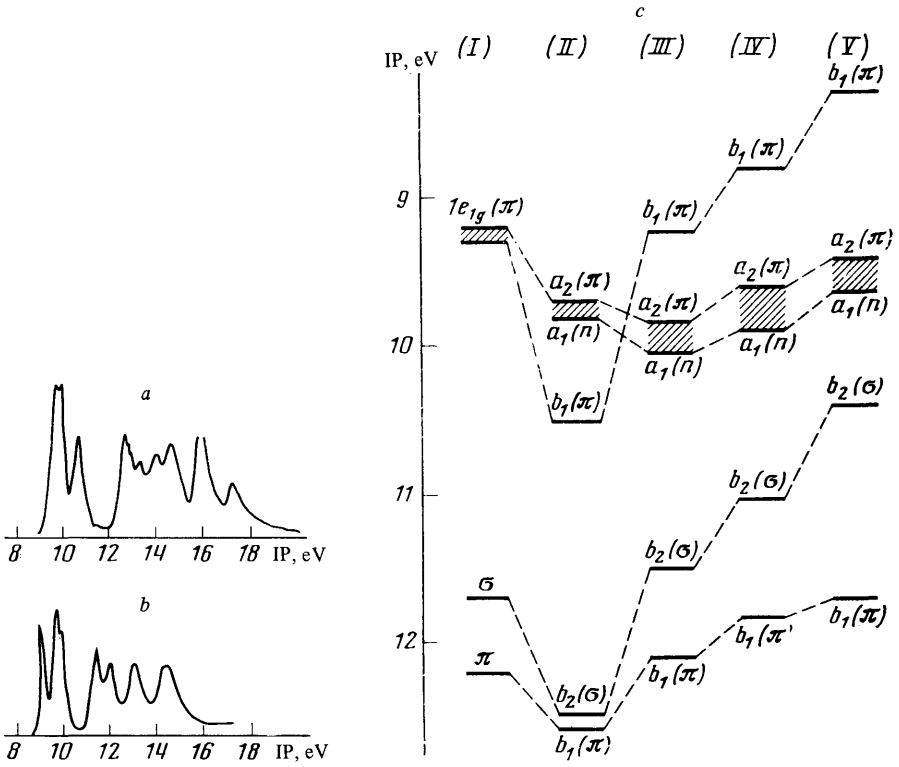

**Figure 1.** Photoelectron spectra: *a*) pyridine (II); *b*) $\lambda^3$-phosphorin (III); *c*) correlation energy level diagram for compounds (I)–(V).[46]

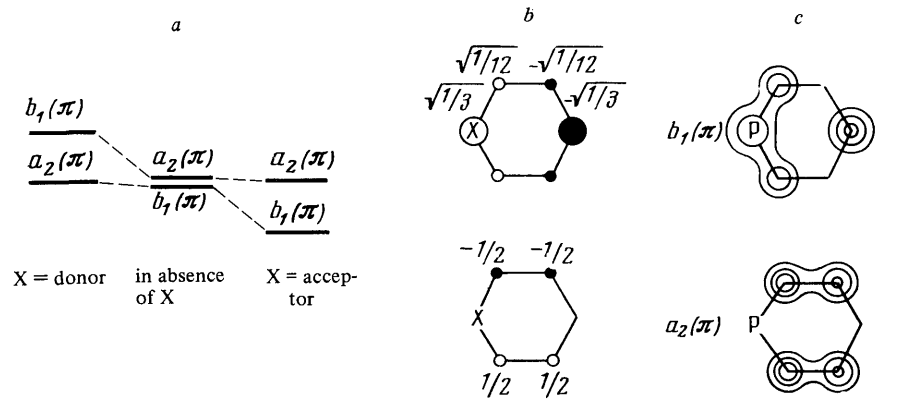

**Figure 2.** The influence of the substituents X on the relative positions of the $a_2(\pi)$ and $b_1(\pi)$ orbitals (*a*), a schematic representation of the atomic coefficients of these orbitals (*b*), and electron density maps for the $a_2(\pi)$ and $b_1(\pi)$ orbitals of $\lambda^3$-phosphorin (*c*).[47]

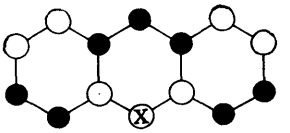
$\lambda^3$-phosphorin molecule which follow from this reversal. In the series of compounds (I)–(V), the ionisation potentials of the $b_1(\pi)$ orbitals are correlated with the ionisation potentials IP(X) of the atoms X:

| X | N | C | P | As | Sb |
|---|---|---|---|---|---|
| IP(X), eV | 14.53 | 11.26 | 11.0 | 9.81 | 8.64 |

when the reversal of orbitals is postulated[46]. In the derivation of the relation

$$IP^v[b, (\pi)] = 5.24 \text{ eV} + 0.362 \text{ IP(X)}, r = 0.9998 \quad (4)$$

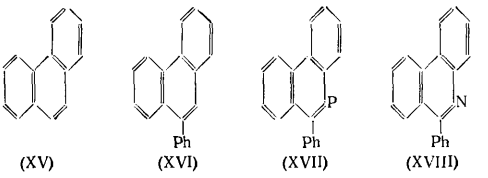


$IP_3^V[b_1(\pi)]$ was used for pyridine and $IP_1^V[b_1(\pi)]$ was used for the remaining compounds. The ionisation energy of the second occupied $\pi$ orbital of the $b_1(\pi)$ type is also correlated with IP(X):

$$IP^v[b, (\pi)] = 10.25 \text{ eV} + 0.163 \text{ IP(X)}. \quad (5)$$

In compounds (I)–(V), the potentials $IP[b_1(\pi)]$ vary less than IP(X), because the atomic coefficient $C_{b_1,X}$ of this orbital is significantly less than unity at the site of substitution. $(C_{m,x})^2 = 1/3$ is obtained for the upper $b_1(\pi)$ orbital and $(C_{m,x})^2 = 1/6$ is obtained for the second orbital of the $b_1(\pi)$ type[46]. In conformity with Eqn. (3), these squares of the atomic coefficients should determine the slopes of the linear relations between $IP[b_1(\pi)]$ and IP(X); the empirical slopes of the straight lines, described by Eqns. (4) and (5), are indeed very close to 1/3 and 1/6.

The nitrogen atom, which exhibits electron-accepting properties, stabilises the $b_1(\pi)$ orbital in pyridine [IP(N) = 14.53 eV, IP(C) = 11.26 eV]. In contrast to this, the phosphorus, arsenic, and antimony atoms destabilise the $b_1(\pi)$ component of the $1e_{1g}$ orbital of the benzene molecule, showing at the same time electron-donating properties. However, whereas the $b_1(\pi)$ orbitals in $\lambda^3$-phosphorin are destabilised compared with the corresponding benzene orbitals, the $a_2(\pi)$ orbital is additionally stabilised. It has been noted[46] that, according to *ab initio* calculations, a shift of electron density away from the phosphorus atom is observed in $\lambda_3$-phosphorin.



The inversion of the sequence of orbitals in compounds (I)–(V) and (VI)–(VIII) was also observed when the $IP^V[b_1(\pi)]$ of these compounds were compared with the $IP_1$ of the anthracene hetero-derivatives[42]. The problem of the degeneracy of the orbitals and of their disposition after the removal of degeneracy, which is crucial for benzene derivatives, is altogether absent for anthracene and its derivatives. In anthracene, the upper occupied $b_{2g}(\pi)$ orbital is not degenerate, its energy is much higher than that of the subsequent orbitals, and it has no node at any of the atoms:

$b_{2g}(\pi)$

Like the orbital of the $b_1(\pi)$ type, this orbital should be subject to the inductive influence of the heteroatom X (Fig. 3).

The photoelectron spectra of compounds (XI)–(XIV) show a separate band of the $\pi$ type, which unambiguously determines the value of $IP_1^V$. The inversion of the orbital sequence follows from the fact that the $IP_1^V$ of compounds (XI)–(XIV) are correlated with the values of $IP^V[b_1(\pi)]$ of compounds (I)–(V) and (VI)–(IX), selected taking into account the inversion. Since the atomic coefficient of the $b_{2g}(\pi)$ orbital at the site of substitution is smaller than the corresponding coefficient of the $b_1(\pi)$ orbital in benzene, the range of variation of $IP_1^V$ in compounds (XI)–(XIV) is also significantly narrower than in compounds (I)–(V) and (VI)–(IX) (Fig. 3). Like the correlation equations (4) and (5), these data also indicate the applicability of Eqn. (3) to the description of the dependence of the energy of the orbital without a node at the site of substitution on the electronegativity of the heterosubstituent.

(XV) (XVI) (XVII) (XVIII)

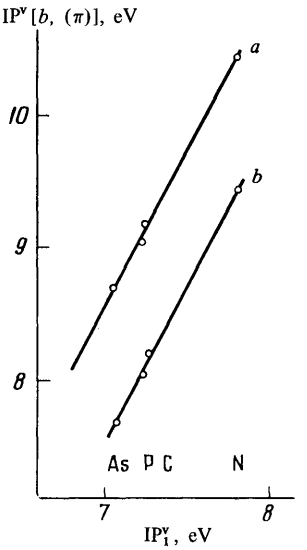


**Figure 3.** Relation between $IP^V[b_1(\pi)]$ and $IP_1^V$ of compounds (I)–(IV) and (XI)–(XIV) (*a*) and compounds (VI)–(IX) and (XI)–(XIV) (*b*).[42]

In their discussion of the photoelectron spectra of compounds (XV)–(XVIII), Schäfer et al.[45] concluded that the electronic influences of the phosphorus atom and the $sp^2$-hybridised carbon atom are identical, because, in contrast to the nitrogen-containing hetero-derivative (XVIII), the upper ionisation potentials of 9-phenyl-$\lambda^3$-phosphaphenanthrene (XVII) and 9-phenylphenanthrene (XVI) are extremely close (Fig. 4). The changes in the ionisation potentials of 2-phenylnaphthalene are just as small when the carbon atom in the 1-position is substituted by phosphorus[4] (Table 1). However the initial compounds (benzene and $\lambda^3$-phosphorin) have different photoelectron spectra; the substitution of a carbon atom by phosphorus removes the degeneracy and shifts the ionisation potentials of some of the orbitals, although to a much smaller extent than does substitution by a nitrogen atom (Fig. 4). The very significant changes in the ionisation potentials for the $\pi$ orbitals of 9-phenylphenanthrene and 2-phenylnaphthalene

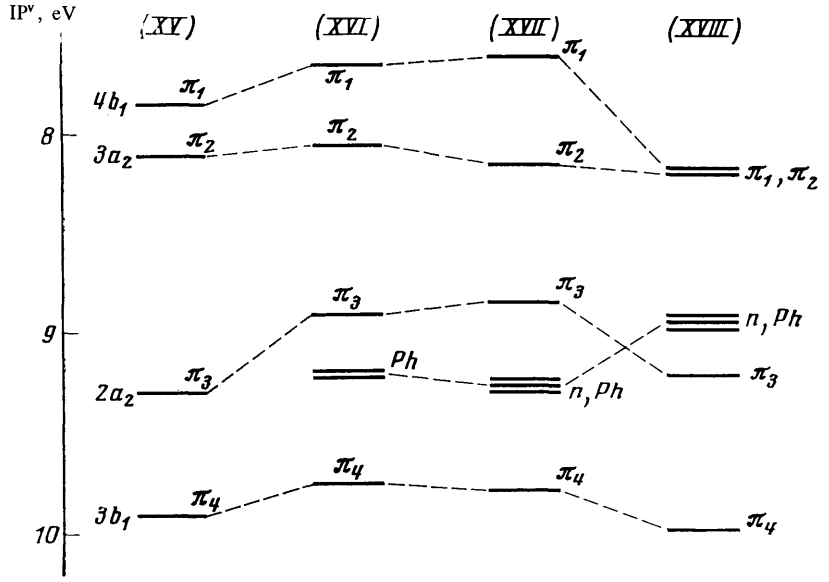

Figure 4. Correlation diagram for the ionisation potentials of compounds (XV)–(XVIII).[45]

on substitution of a carbon atom by phosphorus can be readily understood: the $\pi$ orbitals in the 9-phenylphenanthrene molecule are significantly delocalised, the atomic coefficients of the individual orbitals at the site of substitution are small and, according to Eqn. (3), the corresponding changes in the orbital energies and ionisation potentials should be insignificant.

In the discussion of the photoelectron spectrum of $\lambda^3$-phosphorin, the problem of the role of *d* orbitals was raised. On the basis of the populations of the *d* orbitals calculated by the CNDO/2 method, Schäfer and coworkers[40,41] postulated that the additional stabilisation of the $a_2(\pi)$ level as a result of the interaction with the vacant $a_2(d_{xy})$ orbital, plays a definite role in the inversion of the $b_1(\pi)$ and $a_2(\pi)$ levels. However, the excellent correlation between IP$^V[b_1(\pi)]$ and the ionisation potentials IP(X) of the heteroatoms shows that the changes in IP$^V[b_1(\pi)]$ of $\lambda^3$-phosphorin are determined solely by the electron-donating properties of phosphorus. Furthermore, *ab initio* calculations have shown[45] that the calculated sequence of $b_1(\pi)$ and $a_2(\pi)$ orbitals in $\lambda^3$-phosphorin is independent of the inclusion of *d* orbitals in the treatment. Nevertheless, if one considers only the inductive influence of the phosphorus atom, leading to the destabilisation of the $b_1(\pi)$ orbital, it is very difficult to understand the cause of the appreciable stabilisation of the $a_2(\pi)$ orbital.

We shall consider the ionisation potentials IP(n) of the LEP of phosphorus in the photoelectron spectrum of $\lambda^3$-phosphorin and its derivatives. In the range 9.5–10 eV, the spectrum of $\lambda^3$-phosphorin has two overlapping bands (Fig. 1). Since the first has a sharper peak than the second, the authors[46] suggest that $IP_2^V = 9.8$ eV corresponds to the $a_2(\pi)$ orbital and $IP_3^V(n) = 10.0$ eV corresponds to the $a_1(\sigma,n)$ orbital of the lone pair. IP$^V(n)$ is 9.25 eV for 9-phenyl-$\lambda^3$-phosphaphenanthrene[45], while IP$^V(n)$ of 1,3,5-tri-t-butyl-$\lambda^3$-phosphorin is reduced to 8.6 eV.[43] It is of interest that the ionisation potentials of the $a_2(\pi)$ and $a_1(\sigma,n)$ orbitals of all the compounds in the series (II)–(VI) (Fig. 1) are similar and vary in parallel, while in the photoelectron spectra the corresponding bands are poorly resolved.

In contrast to $\lambda^3$-phosphorin, the electronic structures of $\lambda^5$-phosphorins have been investigated by the PES method to a lesser extent. The first ionisation potential of 2,4,6-tri-t-butyl-1,1-dimethoxy-$\lambda^5$-phosphorin is reduced to 6.7 eV,[43] while that of 1,1-dibenzyl-2-phenylphosphanaphthalene is only 6.0 eV.[44] The cause of such considerable destabilisation has still not been explained. It has been noted[44] that the phosphorus atom is involved in conjugation in $\lambda^5$-phosphorins.

## III. COMPOUNDS OF THREE-COORDINATED PHOSPHORUS

The photoelectron spectra of compounds of three-coordinated phosphorus have been obtained by various groups of investigators[34,48-69]. In many cases, the first ionisation potential is attributed to the removal of an electron from the LEP of phosphorus. In a series of compounds investigated, this quantity varies over a wide range—from 12.29 eV for $PF_3$ to 7.88 eV for $Ph_3P$.[52,61] The dependence of the ionisation energy of the LEP on the charge of the phosphorus atom[7] and on the sum of the constants $\sigma_I^{ph}$[64] has been noted; the empirical ionisation potentials have been compared with the calculated orbital energies[61,70-72]. The adiabatic ionisation potentials IP$^a$ have been published for a much smaller number of compounds than have the vertical potentials IP$^V$. We may note that the adiabatic potential has been used[70,71] in a comparison with the results of *ab initio* calculations for $PH_3$ and the vertical potential has been used for other compounds. The same error has been made also in a review[7]. A handbook[73] also quotes the adiabatic potentials for some compounds and the vertical potentials for others.

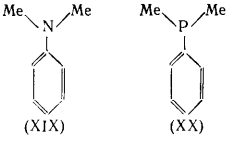
The difference between the values of $IP_1^V$ and $IP_1^a$ characterises the change in the geometry of the ion compared with the isolated molecule[34,49]. The differences $IP_1^V - IP_1^a$ for phosphine, methylphosphine, trimethylphosphine, and phosphorus trifluoride molecules are 0.64, 0.58, 0.59,

and 0.70 eV respectively[34,52,62]. In the case of chloroalkylchlorophosphines, the differences are 0.47 eV for $PCl(CH_2Cl)_2$ and 0.59 eV for $PCl_2(CH_2Cl)$.[58]

The PES method has been used[34,49] to estimate quantitatively the geometrical parameters of the ions derived from the $PH_3$ and $PF_3$ molecules. The irregularity of the vibrational levels and the appreciable broadening of the first peak indicate a somewhat pyramidal structure of the $PH_3^+$ ion. The $PF_3^+$ ion has a planar structure, because the distances between its vibrational peaks are equal. Analysis of the vibrational structures of the photoelectron spectra enabled Maier and Turner[34] and Potts and Price[49] to determine the angle between the X–H bond and the axis of rotation for a number of hydrides. In the $PH_3^+$ ion, the angle is approximately 87°[40] and the barrier to inversion amounts to 0.07 eV.[34]

The reciprocal relation between the photoelectron spectra and the steric structures of the trimethyl compounds ($Me_3X$) of Group V elements has been examined[63]. The atomic ionisation potentials of the central atom X decrease on passing from nitrogen to antimony, varying in exactly the same way as the ionisation potentials of the corresponding heterocyclic compounds (I)–(VI). In contrast to these quantities, the first ionisation potentials of the compounds $Me_3X$ do not vary in parallel with the ionisation potentials of the atoms X. The same may be said also of the hydrides $H_3X$. When the heteroatom X is altered, a decrease of $IP_1^V$ is not observed in these series of compounds (Table 2).

The anomalous constancy of the $IP_1^V$ is associated with the decrease of the C–X–C valence angle in the series of compounds $Me_3X$. The C–X–C angle is 180° in trimethylamine, 99° in trimethylphosphine, and 96° in trimethylstibine. The decrease of the valence angle leads to an increase of the amount of *s* character of the LEP of the atom X on passing from nitrogen to antimony, which increases its ionisation potential. Thus the decrease of the intrinsic ionisation potential of the *p* orbital of the atom X is prevented by the increase of the amount of *s* character of the LEP, which leads to an almost constant value of the first ionisation potential.



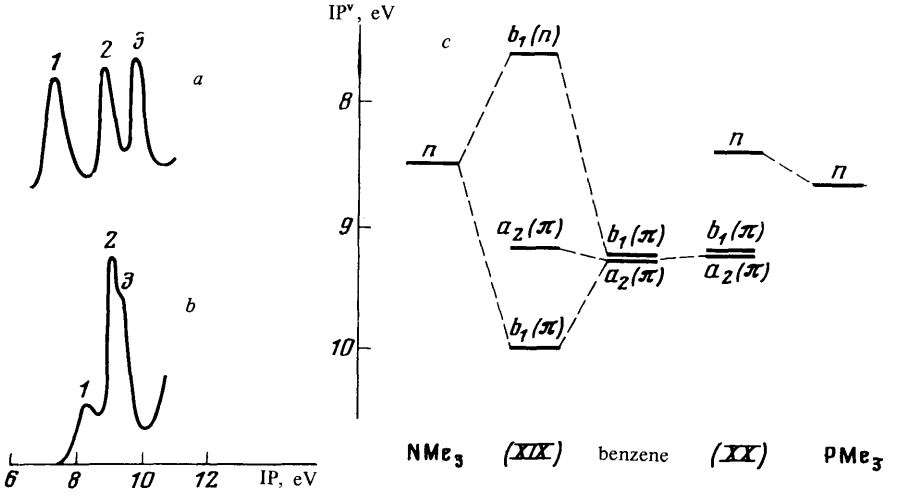
We may note that the next band in the photoelectron spectra of compounds of the type $Me_3X$ is associated with ionisation from a degenerate orbital of the *e* type, which in contrast to LEP is largely localised at the methyl groups, and should therefore be insensitive to changes in the valence angle. The ionisation potential of this orbital $IP^V(e)$ decreases correspondingly on passing from $Me_3N$ to $Me_3Sb$ (Table 2), in parallel with the ionisation potential of the atom X.

**Table 2.** The ionisation potentials (eV) of Group V elements and their trimethyl[63] and triphenyl[61] derivatives.

| $Me_3X$ | IP(X) | $IP_1^V$ (LEP) | $IP_2^V$ | $IP_3^V$ | $Ph_3X$ | $IP_1^V$ (LEP) |
|---|---|---|---|---|---|---|
| $Me_3N$ | 14.53 | 8.50 ($a_1$) | 12.3 ($a_2$) | 12.75 ($e$) | $Ph_3N$ | 10.27* |
| $Me_3P$ | 11.0 | 8.60 ($a_1$) | 11.34 ($e$) | (13.7)** | $Ph_3P$ | 7.88 |
| $Me_3As$ | 9.81 | 8.65 ($a_1$) | 10.70 ($e$) | (13.6) | $Ph_3As$ | 7.95 |
| $Me_3Sb$ | 8.64 | 8.48 ($a_1$) | 10.3 ($e$) | (13.3) | $Ph_3Sb$ | 8.18 |

*$IP_1^V(\pi) = 6.99$ eV; $IP^V(LEP) = 10.27$ eV.
**The values in brackets have been determined approximately.

We shall now examine the manifestation in the photoelectron spectra of the interaction of the LEP of phosphorus with a conjugated system. The spectra of phenylphosphines have been published by several groups of investigators[53,59–61,64], the authors conclusions about the electronic structures of phenylphosphines differing somewhat.



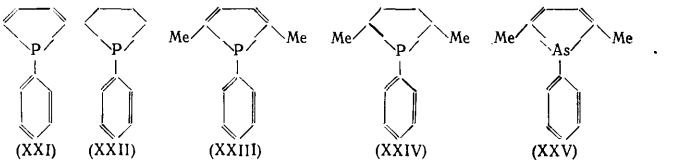


**Figure 5.** Photoelectron spectra and their interpretation[59]: *a*) *NN*-dimethylaniline (**XIX**); *b*) dimethylphosphine (**XX**).

Whereas the spectrum of *NN*-dimethylaniline has three bands of equal intensity in the region of low potentials at 7.6, 9.2, and 10.0 eV, the spectrum of dimethylphenylphosphine shows not three but two bands of different intensities, at 8.45 and 9.2 eV (Fig. 5). The second, more intense band with a maximum at 9.2 eV is not resolved into two components. The spectra of the two related molecules have been interpreted[59] in terms of the $n-\pi$ approximation, i.e. the upper occupied orbitals are represented as a combination of $n$ and $\pi$ orbitals of the heteroatom and the benzene ring. The vertical ionisation potential of the LEP of the $Me_3N$ molecule is 8.5 eV, while the ionisation potential of the degenerate $1e_{1g}$ $\pi$ orbital of benzene is 9.24 eV. As a result of the interaction with the LEP of the nitrogen atom, the degenerate $1e_{1g}$ level of benzene in dimethylaniline is split into two. The orbital of type $a_2(\pi)$, having a node at the site of substitution, does not interact with the LEP of nitrogen and its energy does not change. In contrast to it, the $b_1(\pi)$ orbital, which does not have a node at the site of substitution, interacts vigorously with the $n$ orbital of nitrogen, forming two orbitals with $b_1$ symmetry. The upper occupied $b_1(n-\pi)$ orbital receives a preferential contribution from the LEP of the nitrogen atom, while the $b_1(\pi + n)$ orbital is mainly of the $\pi$ type. The significant change in the energies of the resultant orbitals indicates an appreciable $n-\pi$ interaction in the dimethylaniline molecule (Fig. 5).

In contrast to *NN*-dimethylaniline, the energy of the highest occupied orbital in dimethylphenylphosphine is higher by only 0.15 eV compared with $Me_3P$, while the band corresponding to the degenerate benzene orbital is not split into two (Fig. 5). Hence the authors[59] conclude that there are two virtually unconnected fragments in dimethylphenylphosphine: the system of the benzene ring and the LEP of phosphorus. Accordingly $IP_1$ was assigned to the ionisation of the LEP of phosphorus and $IP_2$ to the unsplit $a_2(\pi)$ and $b_1(\pi)$ orbitals of the phenyl substituent.

We may note that the photoelectron spectra of substituted benzenes PhX, where X is a substituent containing nitrogen[17,19], sulphur[67], oxygen[17,74,75], halogens[4,75], a double bond[20], or the phenyl group[76], have been fairly well investigated. It has been shown that the splitting of the $1e_{1g}$ level depends both on the nature of the heteroatom and on the dihedral angle between the interacting fragments—the $\pi$-electron system of the benzene ring, and the $n$ or $\pi$ orbital of the substituent. Later data were obtained demonstrating the orthogonality of the plane of the benzene ring and the LEP of phosphorus[77], but no stereochemical conclusions were reached in the study by Schäfer and Schweig[59].

The next communication by the same workers[60] contains, in their view, direct proof of the non-aromatic nature of phospholes and arsoles.

(XXI) (XXII) (XXIII) (XXIV) (XXV)

The spectrum of compound (XXI) has two bands (Fig. 6), each of which refers to ionisation from two orbitals of similar energies. The appearance of the first band is interpreted as a result of ionisation from the $a_2(\pi)$ orbital of the cyclopentadiene system and the LEP of phosphorus and the second has been assigned to the $\pi$ orbitals of the phenyl substituent. Owing to hyperconjugation, the methyl substituent in the phosphole fragment increases the energy of the $a_2(\pi)$ cyclopentadiene orbital, because the energies of this orbital and the LEP of phosphorus become different. In the spectrum of the hydrogenated derivative (XXII), the component of the first band corresponding to the ionisation from the $a_2(\pi)$ cyclopentadiene orbital is absent, since the

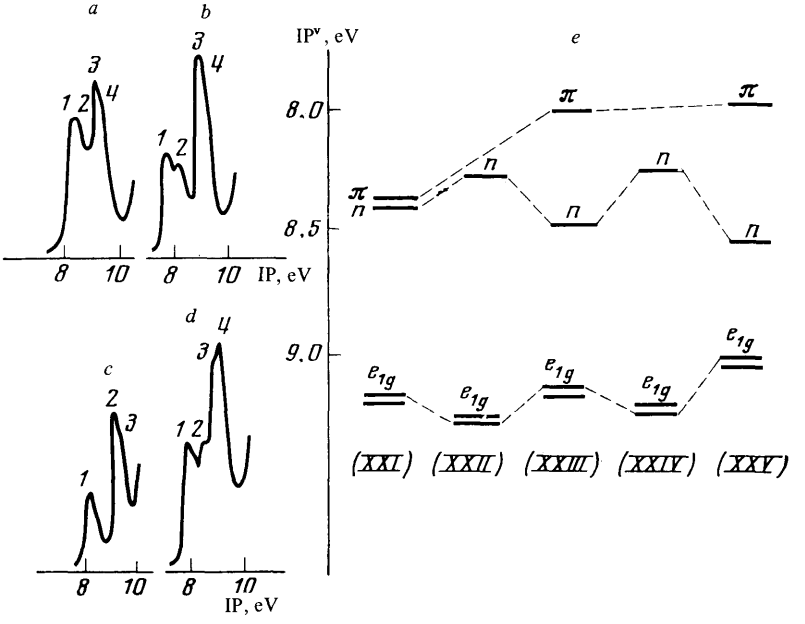

**Figure 6.** Photoelectron spectra of heterocyclic compounds: *a*) (XXI); *b*) (XXIII); *c*) (XXII); *d*) (XXV); *e*) correlation diagram for the ionisation potentials in the (XXI)–(XXV) series[60].

first band of this compound has reduced intensity and refers solely to the LEP of phosphorus. The above facts show that in the ground state the molecule of phosphole (XXI) has three non-conjugated fragments—the $\pi$-electron system of the phenyl substituent, the LEP of the phosphorus atom, and the localised diene system. The authors[59] speak of the non-aromatic nature of phosphole precisely in this sense. According to a calculation by the CNDO/2 method[72], the $C_4H_4NH$ molecule is planar, while the angle between the plane of the cyclopentadiene fragment and the P–H bond in the $C_4H_4PH$ molecule is approximately 90°.

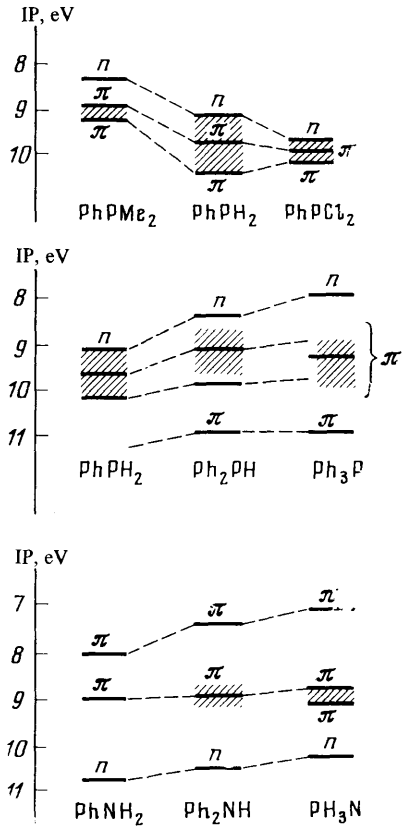

**Figure 7.** Vertical ionisation potentials and band widths (shaded regions) in the photoelectron spectra of phenyl derivatives of Group V elements[61].

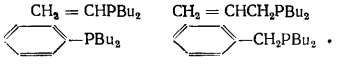
Betteridge et al.[53] note the absence of the splitting of the $\pi$ level of the phenyl substituent in dichlorophenylphosphine. They suggest that the first band, with a maximum at 9.7 eV, corresponds to ionisation from three orbitals—two orbitals of the $\pi$ level of the phenyl group and the LEP of phosphorus. However, they do not indicate the absence of interaction between the LEP and the $\pi$-electron system of the phenyl substituent. They postulate that, firstly, the $PCl_2$ substituent is an electron acceptor compared with hydrogen and, secondly, that a substituent of this kind does not lead to the splitting of the upper level of benzene in other instances either. However, the authors do not quote an example confirming this conclusion, while it is known that electron-accepting substituents such as Cl,[4] F,[75] $NO_2$,[78] and CN [79] cause a very significant splitting of this level. Quantitative analysis of the spectra of $PhPCl_2$ on benzene enabled Betteridge et al. to conclude that the first band in the photoelectron spectrum of $PhPCl_2$ is compound. They also quote[53] the photoelectron spectrum of triphenylphosphine, but do not discuss this spectrum or the corresponding band assignments.

Debies and Rabalais[61] quote the photoelectron spectra of a large series of phenyl derivatives of Group V elements (Fig. 7). Thus the first ionisation potentials of phenylphosphines have been interpreted[53,59,60] as the energy required to dislodge an electron from the LEP of phosphorus. This result has been additionally confirmed by comparing the spectra of phenylphosphine and aniline obtained using two radiation sources. Compared with the experiments involving the use of the He(I) line, the use of the radiation of the He(II) line reduces the intensity of the signals due to the electrons dislodged from the 3*s* and 3*p* orbitals of phosphorus to a greater extent than the signal of the electrons dislodged from the 2*s* and 2*p* orbitals of carbon[36]. The employment of He(II) radiation in the case of phenylphosphine reduces the intensity of the shoulder on the band in the region of low energies relative to the central part of the band, which confirms the validity of the assignment of the shoulder to ionisation from the phosphorus *n* orbital and of the central band to the ionisation of the phenyl $\pi$ electrons. The fact that the intensity of the shoulder does not diminish quite as much as in other phosphorus compounds[61] shows that this orbital is delocalised to an even greater extent.



On successive substitution of the hydrogen atoms in phosphine (as well as in arsine and stibine), the intensity of the band corresponding to the phosphorus *n* orbital remains unchanged, while the intensities of the subsequent bands, corresponding to ionisation from the $\pi$ orbitals, increase owing to the increase of the number of $\pi$ electrons. This finding shows that, as in phenylphosphine, in diphenyl- and triphenyl-phosphines the first ionisation potential refers to the phosphorus *n* orbital. On the other hand, in phenylamines there is a change in intensity not in this first band but in one of the subsequent bands in the region of higher ionisation energies.

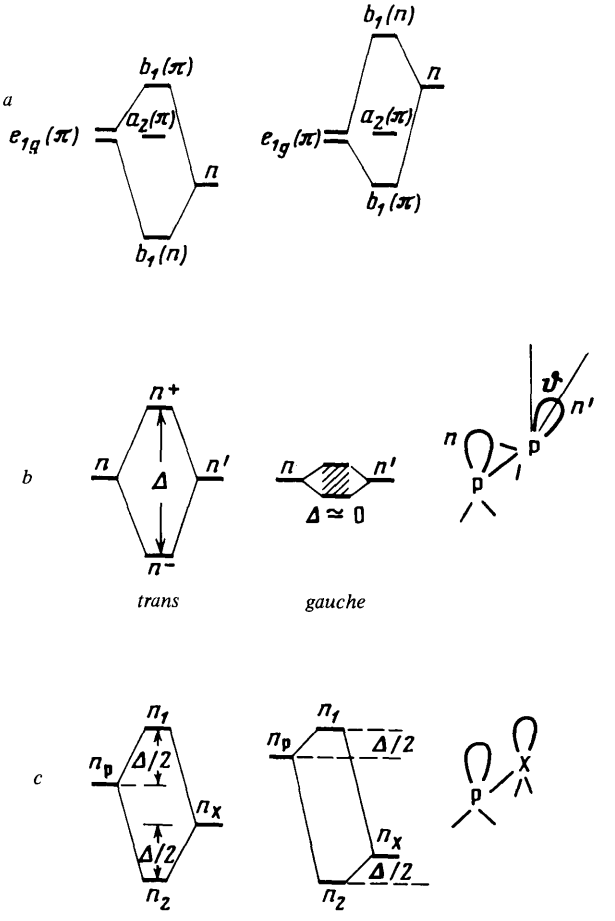
In contrast to studies[53,59,60] where it was concluded that there is no splitting of the $a_2(\pi)$ and $b_1(\pi)$ components of the $1e_{1g}$ level of benzene in phenylphosphines, the large combined bands were resolved by Debies and Rabalais[61] into their components and the $IP_V$ corresponding to the individual $a_2(\pi)$ and $b_1(\pi)$ orbitals were thus determined (Fig. 7). The splitting obtained in this way is small (0.66 eV in phenylphosphine, while the value in aniline is 1.1 eV) and can probably be partly caused by the inductive influence of the $PH_2$ group. Debies and Rabalais suggest that, in contrast to the stabilisation of the *n* orbital in phenylamines, the destabilisation of the *n* orbital in phenyl-substituted phosphorus, arsenic, and antimony compounds is a consequence of the shift of electron density from the phenyl substituent to the phosphorus, arsenic, or antimony atom via the $d_\pi$–$p_\pi$ mechanism. However, not only in phenylphosphine but also in *NN*-dimethylaniline[59], in phenylhydrazones[74], and in iodobenzene[4], i.e. in all cases where the energy of the initial *n* orbital is higher than that of the $\pi$ orbital, the upper destabilised orbital is predominantly of the *n* type when the orbitals interact (Fig. 8). In contrast to *NN*-dimethylaniline, in aniline itself the energy of

the ground $n$ orbital is below the energy of the $b_1(\pi)$ orbital and the upper orbital is predominantly of the $\pi$ type.

According to Debies and Rabalais[61], the anomalous sequence of the $IP_1^V$ of the compounds $Ph_3X$ (Sb > As > P) compared with the electronegativity series and the atomic ionisation potentials (Sb < As < P) is also a consequence of the involvement of $d$ orbitals in the interaction. It is suggested that the inversion of the sequence of ionisation potentials is caused by the reduced involvement of $d$ orbitals in the interaction when the size of the central atom increases, this being accompanied by a decrease of charge transfer to the central atom and an increase of the ionisation potential of the molecule. However, in the series of trimethyl compounds $Me_3X$ (Table 2), the same anomalous sequence of potentials, caused by the increase of the contribution of the $s$ orbital to the upper occupied $n$ orbital with increased size of the heteroatom and decreased the C–X–C valence angle, is observed.

Additional evidence showing that the interaction between the LEP of phosphorus and the $\pi$-electron system is weak was provided by a study of compounds with the methylene group[64]:

According to calculation by the CNDO/2 method, the most favoured conformation of the above compounds is one where the LEP of phosphorus lies in the plane of the $\pi$-electron system and does not interact with it[64]. The photoelectron spectra of the compounds indicate an appreciable interaction between the $\pi$ orbitals and the P–C bond.



The interaction of the LEP of the phosphorus atom and that of the neighbouring atom X linked to it was also investigated by the PES method. Analysis of the $n$–$n$ interaction is one of the most important achievements of the PES method. The dependence of the $n$–$n$ interaction on stereochemical factors has been investigated in a series of compounds with N–N, O–O, and S–S bonds[16,80,82]. The two equivalent LEP $n$ and $n'$ orbitals interact through space or via a bond and form two semi-localised orbitals (Fig. 8):

$$n^+ = \frac{1}{\sqrt{2}}(n + n') \text{ and } n^- = \frac{1}{\sqrt{2}}(n - n').$$

The difference between $IP(n^+)$ and $IP(n^-)$ characterises the efficiency of the interaction and depends on the disposition of the LEP in space[18,80–82].

The photoelectron spectrum of the compound $F_2PPF_2$ has been obtained[52]. The first ionisation potential of 9.64 eV was assigned to a symmetrical combination ($n^+$) of the LEP of the phosphorus atoms, while the second ionisation potential (12.45 eV) was assigned to their antisymmetrical combination ($n^-$). The observed difference between ionisation potentials $IP_2^V - IP_1^V = 2.81$ eV indicates an extremely effective interaction between the LEP. The energy of the individual LEP in the $F_2PPF_2$ molecule, given by $\frac{1}{2}(IP_1^V + IP_2^V) = 11.04$ eV, proved to be close to the first ionisation potential of $F_2PH$ (11.0 eV), which confirms the above interpretation of the first two ionisation potentials of $F_2PPF_2$.

A lower degree of $n$–$n$ interaction of the LEP of phosphorus in the compounds $Me_2PPMe_2$ and $(CF_3)_2PP(CF_3)_2$ was later reported[56,57]; the manifestation of conformational isomerism was observed in the photoelectron spectra. In the region of low ionisation energies, the photoelectron spectra of these compounds contain three peaks. Two of these, $IP_1^V$ and $IP_3^V$, correspond to the $n^+$ and $n^-$ combinations of the LEP of the *trans*-conformer. The third low-intensity $IP_2^V$ peak indicates the presence of a certain amount of the *gauche*-conformer, for which there is no $n$–$n$ splitting (Table 3). According to the authors, the fact that the average $IP^V$ (LEP) of the *trans*-conformer is somewhat smaller than the corresponding value for the *gauche*-conformer is associated with the slight destabilisation arising when the *trans*-oriented LEP interact. However, we may note that contradictory results, obtained in a study of the conformational isomerism by the PES method[21], have also been published.

*trans* *gauche*

Figure 8. Dependence of the $n$–$\pi$ (*a*) and $n$–$n$ interactions on the relative energies of the initial orbitals: b) for equivalent $n$ orbitals; c) for non-equivalent $n$ orbitals.

For a number of molecules such as those of $(CF_3P)_m$, containing different numbers of phosphorus atoms, the average potentials are correlated with the induction constant (as a consequence of the interaction of the LEP of the phosphorus atoms). This finding indicates an insignificant role of the $d_\pi$–$p_\pi$ interaction in the above molecules[57].

The study of the $n$–$n$ interaction of non-equivalent LEP by the PES method is much more complicated. In this case, the difference between ionisation potentials $IP(n^+) - IP(n^-)$, referring to the $n$ orbitals, does not in any way

characterise the extent of the $n-n$ interaction (Fig. 8). The difference $IP(n^+) - IP(n^-)$ is determined by the difference between the LEP energies before interaction and by the $n-n$ splitting, both quantities being unknown. However, in the $Me_2PCl$ molecule one of the chlorine LEP (of the $a''$ type) is not involved in the interaction with the phosphorus LEP and thus plays the role of an internal standard, which makes it possible to estimate the extent of the $n-n$ interaction between the chlorine LEP ($a'$ type) and the phosphorus LEP.[65] The possibility of the interaction between the LEP of the phosphorus and chlorine atoms in the $PF_2Cl$ molecule was also assumed by Bassett and Lloyd[52], but they postulated that the LEP of the individual atoms in the $F_2POPF_2$ molecule do not interact with one another.

Table 3. The vertical ionisation potentials (eV) and the percentage contents of the conformers[57].

| Compound | Content of conformers, % | $IP^V$(LEP) | $IP^V$(P-P or As-As) | $IP^V$(P-P or As-C) |
|---|---|---|---|---|
| *gauche*-$Me_4P_2$ | 16 | 8.79 | 10.33 | 11.22; 11.83 |
| *trans*-$Me_4P_2$ | 84 | 7.88; 9.54 | 10.33 | 11.22; 11.83 |
| *gauche*-$Me_4As_2$ | 12 | 8.85 | 9.82 | 10.60; 11.21 |
| *trans*-$Me_4As_2$ | 88 | 7.91; 9.50 | 9.82 | 10.60; 11.21 |
| *gauche*-$(CF_3)_4P_2$ | 10 | 11.57 | 13.09 | 13.49 |
| *trans*-$(CF_3)_4P$ | 90 | 10.71; 12.11 | 13.09 | 13.49 |
| *trans*-$(CF_3)_4As_2$ | 100 | 10.39; 11.94 | 12.07 | 12.58 |

Dewar and coworkers[56] compared the photoelectron spectra of a number of compounds with the P–N bond: $(Me_2N)_mPF_{5-m}$ and $(Me_2N)_mPF_{3-m}$. The spectra were interpreted in terms of the $n$ approximation. In all cases, $IP_1$ was assigned to ionisation from the LEP of nitrogen (Table 4). If the interpretation of $IP^V$ given below is adopted, it is found that the substitution of the ethyl group at the nitrogen atom by a methyl group has a considerable influence on the phosphorus LEP[65]:

| Compound | LEP, N | LEP, P |
|---|---|---|
| $Et_2NPF_2$ | 9.45 | 10.25 |
| $Me_2NPF_2$ | 9.60 | 10.50 |

It is suggested that this is caused by a change in the valence and torsional angles. The hypothesis of the $n-n$ interaction, described by the difference $IP(n,P)-IP(n,N)$, has been used to explain the change in the torsional energy barrier to rotation about the P–N bond, which is anomalous in relation to the degree of steric hindrance[66].

Compounds of three-coordinated phosphorus $PX_3$, containing equivalent groups X = halogen, OR, $NR_2$, etc., are convenient for the investigation of the relation between PES data and the stereochemistry of the molecule. If the molecular symmetry is $C_2$ or $C_{3v}$, then the upper occupied orbitals should include degenerate orbitals of the $e$ type. The bands corresponding to these orbitals in the photoelectron spectrum should have approximately doubled intensities or should undergo spin-orbital or Jahn–Teller splitting[55,77]. When the molecule has a lower symmetry, the $e$ levels are absent under these conditions.

$P(Hal)_3$ molecules have the $C_{3v}$ symmetry and their photoelectron spectra have been interpreted in terms of ideas of this group of workers[53,55]. The first ionisation potentials are associated with ionisation from the non-bonded $a_1$, $a_2$, and $e$ orbitals. The $a_1$ orbital is preferentially localised at the phosphorus atom, while the $a_2$ and $e$ orbitals arise as a result of the interaction of the three equivalent LEP of the halogens. The band corresponding to the $e$ orbital in the spectra of $PBr_3$ and $PI_3$ undergoes spin–orbital splitting[54].

Table 4. The vertical ionisation potentials (eV) of the LEP of nitrogen [N(2$p$)] and phosphorus [P(3$p$)].

| Compound | N (2$p$) | P (3$p$) |
|---|---|---|
| $Me_2NPF_4$ | 10.35 | — |
| $(Me_2N)_2PF_3$ | 8.84; 9.95 | — |
| $(Me_2N)_3PF_2$ | 8.04; 9.03; 9.31 | — |
| $(Me_2N)PF_2$ | 9.58 | 10.48 |
| $(Me_2N)_2PF$ | 8.18; 9.14 | 10.40 |
| $(Me_2N)_3P$ | 7.61; 7.89; 8.86 | 9.98 |

Table 5. The ionisation potentials of $P(OMe)_3$, the band intensities $I$ (arbitrary units), and band assignments[53].

| $IP^V_m$, eV | $I$ | Orbital symmetry | Localisation region |
|---|---|---|---|
| 9.0 | 1 | $a$ | LEP, P |
| 10.6 | 2 | $e$ | LEP, O |
| 11.1 | 4 | $a+e+a$ | LEP, O + C–O, $\sigma$ |
| 12.4 | 2 | $e$ | P—O, $\sigma$ |
| 13.0 | 1 | $a$ | P—O, $\sigma$ |

In their interpretation of the photoelectron spectrum of $P(OMe)_3$, Betteridge et al. used data for the ionisation potentials of methanol[53]: 11.0 eV (LEP, O); 12.7 eV (C–O, $\sigma$); 15.0 eV ($CH_3$). The $C_{3v}$ symmetry was adopted for the $P(OMe)_3$ molecule and the molecular orbitals were represented by a combination of the LEP of phosphorus, the three equivalent LEP of oxygen, the C–O $\sigma$ bonds, etc. Accordingly a band corresponding to the ionisation of the LEP of phosphorus, two bands with the 1 : 2 intensity ratio associated with the $a$ and $e$ orbitals produced as a result of the $n-n$ interaction of the three LEP of the oxygen atoms ($n_O$), two bands with an intensity ratio of 1 : 2 associated with the $a$ and $e$ orbitals of the three C–O $\sigma$ bonds, etc. should accordingly be expected in the $P(OMe)_3$ spectrum. The interpretation of the photoelectron spectrum of $P(OMe)_3$ obtained in this way is illustrated in Table 5. We believe that the interpretation of this spectrum (Fig. 9) corresponds to the $C_3$ and not the $C_{3v}$ symmetry type. For the $C_3$ symmetry, where the LEP of oxygen does not undergo $\pi$-type overlapping, the degenerate $e(n_O)$ orbital should in fact be the second from above.

The mechanisms of the $n-n$ interactions of the LEP of phosphorus ($n_P$), oxygen ($n_O$), and nitrogen ($n_N$) atoms are examined in Figs. 9 and 10. In the case of $\sigma$-type overlapping[83], where the LEP ($n_X$) axes of the $X_3$ atoms are located in the $X_3$ plane, the energy of the semilocalised $e(n_X)$ orbital is also smaller than that of the $a(n_X)$ orbital. For the $\pi$-type overlapping of the LEP ($n_X$), the opposite relative positions of the $a(n_X)$ and $e(n_X)$ levels are obtained. In contrast to the $\pi$ approximation, the $n$ approximation, i.e. consideration of $n$ electrons independently of the $\sigma$ framework, is less justified[13]. The overlap integrals of the $n_X$ orbitals in the compounds $PX_3$ are small and $n-\sigma$ mixing can therefore exceed the degree of the $n-n$ interaction, leading to a different sequence of orbitals in the molecule.

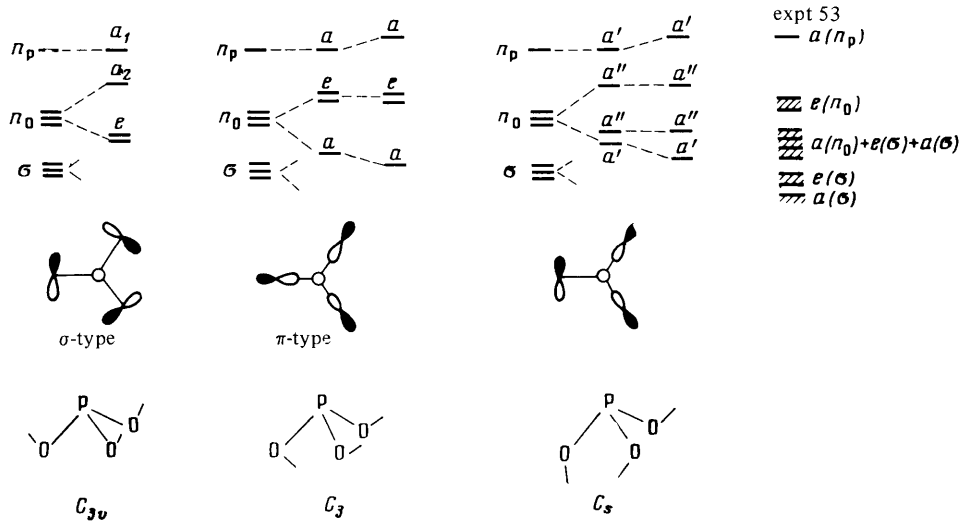


Figure 9. Schematic illustration of the $n$–$n$ interaction of the LEP of the oxygen ($n_O$) and phosphorus ($n_P$) atoms.

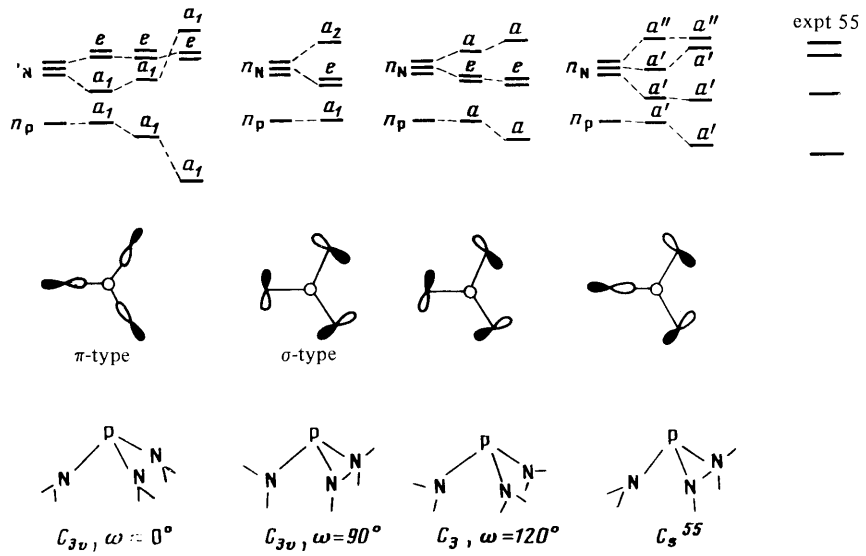

Figure 10. Schematic illustration of the $n$–$n$ interaction of the LEP of the nitrogen ($n_N$) and phosphorus ($n_P$) atoms.

Fig. 11 illustrates a correlation diagram for the $P(OH)_3$ and $P(OMe)_3$ orbital energies calculated by the CNDO/2 method[84]; the geometrical parameters were taken from Naumov and coworkers[85]. The orbital sequence obtained differs from the sequence which may be predicted in terms of the $n$ approximation (Fig. 9). The energies of the orbitals of the model compound $P(OH)_3$ reproduce in the same way the photoelectron spectrum of $P(OMe)_3$ for structures with $C_3$ and $C_S$ symmetries (Fig. 11). The intense bands with maxima at 10.6 and 11.1 eV are extremely broad and may be due to a superposition of close overlapping bands. We believe that calculations on $P(OMe)_3$ assuming the $C_S$ symmetry gives the best agreement with experiment. In the case of the $C_3$ symmetry, the two neighbouring $e$-type orbitals might have given rise to individual bands. The total energies of the structures with the $C_3$ and $C_S$ symmetries of the model compound $P(OH)_3$ proved to be similar, but the $P(OMe)_3$ structure with the $C_S$ symmetry is energetically more satisfactory. Naumov and coworkers[85] also quote qualitative evidence in support of the $C_S$ symmetry in $P(OMe)_3$ based on electron diffraction.

According to Cowley et al.,[55] the $C_S$ symmetry of the $P(NMe_2)_3$ molecule obtained by Vilkov[86] conflicts with the photoelectron spectrum of the molecule. Experimental data show that the upper occupied orbitals have similar energies, while in the case of the $C_3$ symmetry the degenerate orbital is the second highest (Fig. 10). Cowley et al.[55] proposed the $C_S$ symmetry for $P(NMe_2)_3$. In this

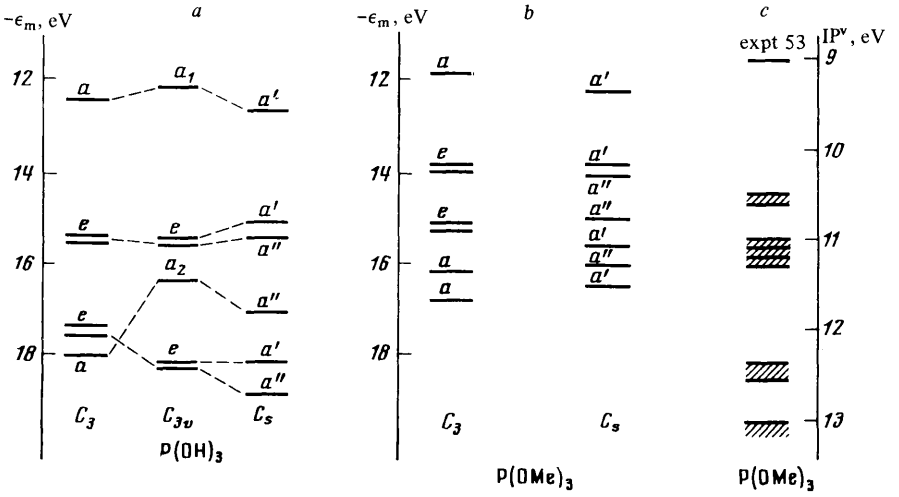

**Figure 11.** Theoretical dependence of the energies of P(OH)$_3$ (*a*) and P(OMe)$_3$ (*b*) on the steric structure of the molecules (CNDO/2 method) together with experimental data[53] (*c*).

case $IP_1$ and $IP_3$ correspond to the $n^+$ and $n^-$ combinations of the nitrogen LEP involved in σ-type overlapping, while $IP_2$ and $IP_4$ correspond to the same combinations of the phosphorus and nitrogen LEP (Fig. 10). It is suggested that the structure with the $C_S$ symmetry is stabilised owing to the smaller degree of the Coulombic repulsion of the LEP.

The compound B(NMe$_2$)$_3$, which has a similar structure, had been investigated previously by Bock and Fuss[87]. In conformity with the π-type overlapping, the second band corresponds to an *e*-type orbital ($C_3$ symmetry). The smaller difference $IP_2^V - IP_1^V$ for B(NMe$_2$)$_3$ (1.62 eV) compared with its cyclic analogue (2.2 eV) was explained by the propeller rotation of the amino-group about the B–N bond ($\omega = 33°$). In contrast to aminoborines, the $n-\sigma$ mixing and the Jahn–Teller splitting of the *e* orbital were resorted to in order to explain the photoelectron spectra of cyclohexane hetero-derivatives on the basis of $C_3$ symmetry[82].

## IV. COMPOUNDS OF FOUR-COORDINATED PHOSPHORUS

The most systematic studies on the photoelectron spectra of compounds in the series WPXYZ for W = O or S have been carried out by Vovna, Vilesov, and coworkers[58, 88–93]. The spectra of individual compounds were also obtained by other workers[37,53,71] and Bock's group studied the interaction between $X_3P$ and $BH_3$ as well as the photoelectron spectra of ylids[68,94]. The PES[58] method has been used to analyse the intramolecular interactions in compounds of four-coordinated phosphorus. Calculation by the CNDO/2 method[95] reproduces satisfactorily the changes in the ionisation potentials of the compounds WPXYZ. Thus the values of $IP_1^V$ for the compounds OPF$_3$ and OPMe$_3$ are 13.52 and 9.76 eV,[68] while the calculated values ($-\epsilon_1$) are 18.84 and 14.18 eV respectively.

The form of the photoelectron spectra of the compounds WPXYZ resembles that of the spectra of the corresponding tervalent phosphorus compounds PXYZ, but there are also significant differences (Fig. 12). The formation of the WP bonds leads to the disappearance of the band due to the ionisation of the phosphorus LEP ($n_P$) orbital. The band corresponding to the ionisation of the four $p_\pi$ electrons of W as well as a band (in the region of high ionisation energies) corresponding to the $\sigma_{PW}$ orbital of the newly formed W–P bond appear in the WPXYZ spectra. The remainder of the spectrum, characterising the ionisation of electrons from orbitals localised preferentially at the X, Y, and Z atoms, remains unchanged, being displaced towards higher ionisation energies in conformity with the electronegativity of the WP group. The first ionisation potential characterises the energy of the binding of the $p_\pi$ electrons of the W atom and the series of subsequent potentials is related to the ionisation of the LEP of the substituents. Thus, according to Zverev et al.,[58] the formation of the $\dot{O}PCl(OEt)_2$, $OPCl(\dot{O}Et)_2$, and $OP\dot{C}l(OEt)_2$ radical-cations from the OPCl(OEt)$_2$ molecule requires energies of 10.96, 11.50, and 12.28 eV respectively. In certain compounds with a P–N bond, the nitrogen atom exhibits the greatest electron-donating capacity and the first ionisation potential is determined by the nitrogen LEP. Comparison of the energies of the $n_P$, $p_{\pi,W}$, and $\sigma_{PW}$ orbitals characterises the degree of charge transfer and the amount of double-bond character of the WP linkage. The stabilisation of the $\sigma_{PW}$ orbital compared with the $n_P$ orbital indicates charge transfer from the P atom to W, while the energy of the $p_{\pi,W}$ orbital may be a measure of the reverse transfer and the amount of double bond character[68].

The band appearing on formation of the W=P bond in the region of low ionisation energies and determining the values of $IP_1$ of a large number of compounds (Table 6) is fairly characteristic of this class of compounds. In the spectra of the compounds $WPX_3$, belonging to the $C_{3v}$ or $C_3$ symmetry group, this band arises on ionisation from a degenerate *e*-type orbital localised preferentially on the $p_\pi(p_x, p_y)$ orbitals of the W atom. The broad shape of the band contour indicates the involvement of the $p_{\pi,W}$ orbital in the bonding between W and P atoms. It has been suggested on the basis of a comparison with calculations[37, 52,71,96] that this orbital is involved in $p_{\pi,W} - p_{\pi,P}$ and $p_{\pi,W} - d_{\pi,P}$ interactions. The fact that in the spectra of molecules of the type WPXYZ the band is not split into two

components is regarded as evidence for the insignificant delocalisation of the orbital over the XYZ group of atoms.

Following Zverev et al.,[58] we shall examine a series of additional factors characterising the $e(p_\pi)$ orbital of the W=P bond. In the compounds $WPX_3$ (X = Cl, Br, or OEt), the LEP of the substituents $X_3$ give rise to two semilocalised orbitals $a_2(n_X)$ and $e(n_X)$. A change in the inductive influence of the W atom should cause the same shifts of the energies of these orbitals, while conjugation, leading to mixing of the $e(n_X)$ orbital with other $e$-type orbitals, can alter the difference between the energies of the $a_2(n_X)$ and $e(n_X)$ orbitals. Experimental data (Table 7) show that in the $PCl_3$ molecule this difference is smaller (0.3 eV) than in the $OPCl_3$ (0.63 eV) and $SPCl_3$ (0.59 eV) molecules, i.e. in these molecules the $e(n_X)$ orbital interacts more effectively with $e$-type orbitals: the occupied $e(p_\pi)$ orbital or the vacant $e(d_\pi)$ orbital. However the interaction between the $e(n_X)$ and $e(p_\pi)$ orbitals cannot be significant, because the difference between the energies of the $a_2(n_X)$ and $e(n_X)$ orbitals remains constant for the compounds $OPX_3$ and $SPX_3$, despite the significant difference between the energies of the $e(p_\pi,S)$ and $e(p_\pi,O)$ orbitals[58].

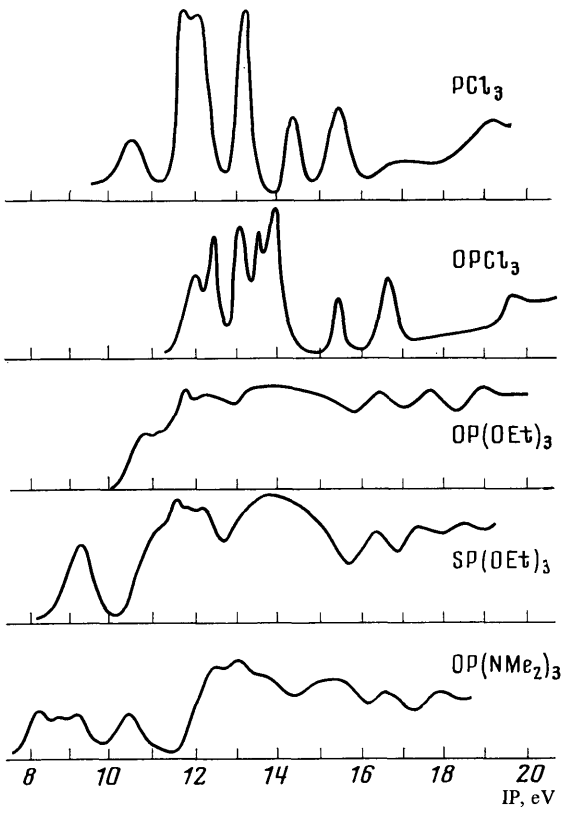

**Figure 12.** Photoelectron spectra of certain compounds of the type WPXYZ[58,90,91].

In contrast to the $WPX_3$ molecules under consideration, a number of data for the compound $OP(NMe_2)_3$ indicate the mixing of the $p_\pi,O$ orbital with the nitrogen $n$ orbitals. This mixing of the orbitals greatly reduces the ionisation potentials of the $n$ orbitals and increases the ionisation energy of the $p_\pi,O$ orbital. The dependence of the ionisation potentials corresponding to ionisation from the $p_\pi,W$ orbital on the constants $\sigma^*$ and $\sigma^{ph}$ has been examined[58]. The nitrogen-containing molecules of the phosphoryl series constitute a special group; owing to mixing with the nitrogen $n$ orbitals, the ionisation potentials corresponding to ionisation from the $p_\pi,O$ orbital in such compounds are larger than in the case where account is taken of the inductive influence alone.

**Table 6.** The vertical ionisation potentials of the compounds SPXYZ and OPXYZ referring to the $p_\pi$ orbital of the W=P bond[37,58,68,89-91].

| XYZ | $IP_1^V$ | XYZ | $IP_m^V$ |

Direct experimental evidence for the delocalisation of the $p_\pi,O$ orbital in the direction of the atoms of the substituents is provided by the photoelectron spectrum of $OPBr_3$.[37] In this compound, spin–orbital splitting of the highest occupied $e$ orbital by the atoms of the substituents is observed, which indicates its delocalisation over the $Br_3$ atoms.

Comparison of the values of $-\Delta G^\circ$ for the formation of the complexes XYZPO...$I_2$ [97] with the ionisation potentials of the compounds XYZPO confirms the interpretation of the $OP(NMe_2)_3$ spectrum and the scheme describing the mixing of the $p_\pi,O$ and $n_N$ orbitals (Fig. 13). $-\Delta G^\circ$ for the compound $OP(NMe_2)_3$ is correlated with a potential intermediate between $IP_4^V$ and $IP_3^V$. $IP_4^V$ refers to the $p_\pi,O$ orbital, but is increased owing to the $p_\pi - n_N$ interaction. A similar effect is manifested also for $OPCl(NMe_2)_2$. In contrast to a series of compounds of the type XYZPO, in

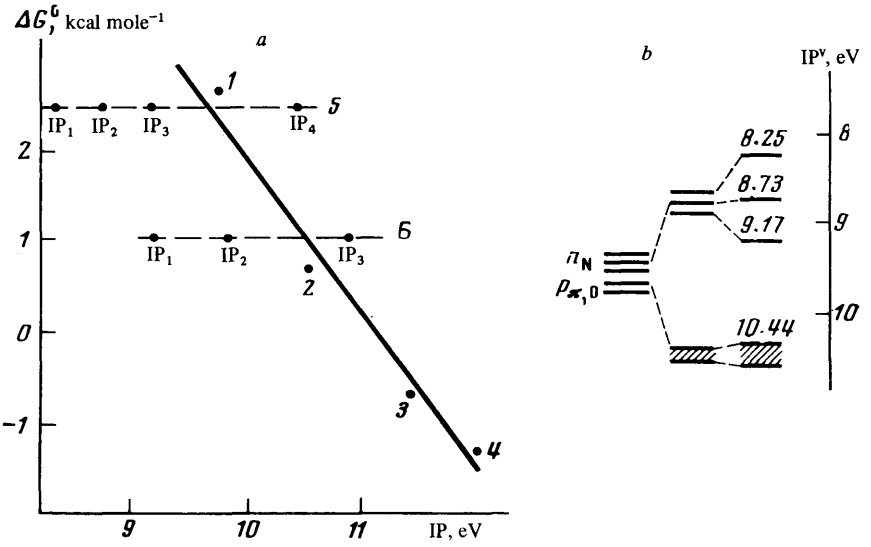

**Figure 13.** Dependence of $-\Delta G^\circ$ for the formation of complexes of the compounds XYZPO with $I_2$ (Paetzold and Niendorf[97]) on $IP_I^V$ for different compounds (*a*) [1) $Me_3PO$; 2) $(EtO)_3PO$; 3) $(EtO)Cl_2PO$; 4) $Cl_3PO$; 5) $(Me_2N)_3PO$; 6) $(Me_2N)_2ClPO$ (the values of several $IP_m^V$ are indicated for compounds *5* and *6*)] and schematic illustration of the interaction between the orbitals of compound *5* (*b*).

the compounds SPXYZ investigated, the energy of the $p\pi$,S orbitals is characterised in all cases by the potential $IP_I^V$. Hence the following relation has been found to hold[92]:

$$-\Delta G^0 = -2.7\ IP_I^V + 25.7.$$

We may note that in the series of dihexylphenylphosphines[69] a linear relation has been observed, as in the compounds WPXYZ, between $pK_a$ characterising the basicity in solution and IP(LEP) of phosphorus:

$$pK_a = -4.8\ IP_n^V + 42.2.$$

**Table 8.** The ionisation potentials of the LEP of the XYZ ligands in the compounds OPXYZ and SPXYZ and their assignments.

| XYZ | IP(LEP), eV | | Assignment |
|---|---|---|---|
| OPXYZ | | SPXYZ | |
| $Cl(OEt)_2$ | 12.28 | 12.00 | LEP, Cl |
| $Cl(CH_2Cl)_2$ | 12.69 | 12.33 | LEP, Cl |
| $Cl_m(OEt)_{3-m}$ | 12.13 | 11.83 | $LEP_{av}$, XYZ |
| $Br_3$ | 11.70 | 11.18 | $LEP_{av}$, $Br_3$ |
| $Cl_2(OEt)$ | 11.89 | 11.59 | LEP, O |
| $Cl_2(NMe_2)$ | 9.87 | 9.92 | LEP, N |

Comparison of the ionisation potentials for the LEP of the substituents X, Y, and Z (both the individual values of $IP_m^V$ and the values averaged with respect to the *n* orbitals) makes it possible to consider the problem of the effective electronegativity of the WP groups. The ionisation potentials $IP_{n_X}$ of the LEP (X = Cl, Br, or OEt) form the sequence $IP_{n_X}(OP) > IP_{n_X}(SP) > IP_{n_X}(P)$, i.e. the effective electronegativity increases in the sequence OP > SP > P. The OP group thus exhibits the greatest electron-accepting influence (Table 8).

**Table 9.** Certain ionisation potentials and NQR frequencies[99] of the compounds OPXYZ and SPXYZ.

| XYZ | OPXYZ | SPXYZ | Assignment of potential |
|---|---|---|---|
| | $IP^V$, eV | | |
| $Cl_2OEt$ | 11.89 | 11.59 | LEP, O |
| $Cl(OEt)_2$ | 11.65 | 11.37 | LEP, O |
| $(OEt)_3$ | 11.36 | 11.20 | $LEP_{av}$, O |
| $Cl_2N(Me)_2$ | 9.87 | 9.92 | LEP, N |
| $Cl(NMe_2)_2$ | 9.31 | 9.62 | LEP, N |
| $(NMe_2)_3$ | 8.72 | 9.13 | $LEP_{av}$, N |
| | $\nu_{P-Cl}$, MHz | | |
| $Cl_3$ | 28.950 | 29.735 | |
| $Cl_2Ph$ | 26.635 | 27.840 | |

The above sequence is infringed by the ionisation potentials of the orbitals localised preferentially at the LEP of nitrogen, which form the sequence SP > OP > P (Tables 8 and 9). For example, in the compounds $WP(NMe_2)_3$ the average ionisation potentials of the nitrogen LEP form the sequence 9.13 (SP) > 8.72 (OP) > 8.12 (P). The additional decrease (compared with the inductive influence of the OP group) of the potentials of the nitrogen LEP is due to the resonance interaction of the $p\pi$,O orbitals and the nitrogen *n* orbitals. It is of interest that comparison of both $^{35}Cl$ and $^{14}N$ NQR frequencies yields the same sequence of the effective electronegativities of the groups: SP > OP > P.[98]

Comparison of the ionisation potentials of the LEP of the substituents also makes it possible to examine the role of the W atom in the transmission of the electronic effect of substituents via the WP group (Tables 8 and 9). In the

compounds OPXYZ, the range of variation of the ionisation potentials of the LEP of the OEt or $NMe_2$ group is greater after substitution by chlorine atoms than in the SPXYZ series. In view of its more pronounced electron-accepting properties and greater amount of double bond character, the OP group is apparently a better transmitter of the influence of the X atom in the X–PO–$Y_2$ molecule on the ionisation potentials of the LEP of the $Y_2$ group. The corresponding effects are also shown when the NQR frequencies are compared (Table 9) and in kinetic measurements[100].

We shall next consider the photoelectron spectra and the structures of individual compounds. The compound $SPCl_2Ph$ gives rise to a well resolved spectrum, which makes it possible to determine 14 ionisation potentials[89]. The first ionisation potential (9.47 eV) is due to the $3p_\pi$ electrons of sulphur and the next (9.93 eV) was assigned to the unsplit ($a_2 + b_1$) $\pi$ orbitals of the phenyl group. Thus the addition of the phenyl group to a four-coordinated phosphorus atom, like the addition to a three-coordinated phosphorus atom, does not split the upper $\pi$ level of benzene. According to Vovna et al.,[89] the absence of splitting shows that the $SPCl_2$ substituent exhibits only an inductive influence. Vilkov's electron diffraction data[101] showed that the benzene ring in the compound $OPCl_2Ph$ lies in the plane of the OPC atoms. The mutual orthogonality of the two $\pi$-electron systems (Ph and SP) is apparently the cause of the absence of splitting.

The $OP(OMe)_3$ and $OP(OEt)_3$ spectra obtained by Vovna et al.[91] were interpreted on the assumption that the molecules have $C_{3v}$ symmetry. The three equivalent LEP of the oxygen atom give rise to two semilocalised orbitals of the $a_2$ and $e$ types. Although the photoelectron spectra of these compounds, like that of $SP(OEt)_3$,[90] are poorly resolved, it is possible to establish that the $e$-type orbital lies below the $a_2$ orbital. In terms of the $n$ approximation, this implies $\sigma$-type overlapping of the oxygen LEP (Fig. 9).

However, according to electron diffraction data[102], the compound $OP(OMe)_3$ exists as a mixture of two conformers with $C_3$ symmetry. The calculated energies of the upper levels in the compounds $WP(OR)_3$, like those in $P(OMe)_3$ (Fig. 11), change little when the steric orientation of the methyl groups is varied. Furthermore, the inversion of the relative positions of the $a_2$- and $e$-type levels formed by the oxygen LEP in the compounds $P(OMe)_3$ and $OP(OMe)_3$ is striking: the $e$-type orbital in $P(OMe)_3$ lie above the $a$ orbital[53], while the opposite situation obtains in $OP(OMe)_3$. It is difficult to say whether this is due to experimental error or is a consequence of molecular structure. There is no inversion in the compounds $PHal_3$ and $WPHal_3$.

The spectra of $P(NMe_2)_3$ and $OP(NMe_2)_3$ in the region of the ionisation of the nitrogen LEP contain three peaks of approximately equal intensities (Fig. 12). If the molecules had a threefold symmetry axis, one would expect the presence in the spectrum of two peaks and not three, with an intensity ratio of 1 : 2. The cause of the absence of the spectroscopic manifestation of the $e$ level was not discussed by Vovna and coworkers[89,91], but Betteridge et al., who also obtained the photoelectron spectrum of $OP(NMe_2)_3$, put forward three hypotheses[53]. Firstly, the observed photoelectron spectrum may be a result of a superposition of several spectra, secondly the P–N $\sigma$ orbitals may also have low ionisation potentials, and finally, the molecule does not have the $C_{3v}$ symmetry. The authors themselves are inclined to accept the last hypothesis.

The compound $OP(NH_2)_3$ was investigated by X-ray diffraction[103] and it was shown that the positions of the nitrogen atoms deviate appreciably from the $C_{3v}$ symmetry. The O–P–N valence angles differ by 10°. Such appreciable infringement of the $C_{3v}$ symmetry may, however, be a consequence of the formation of intermolecular hydrogen bonds in the crystalline state, while in the gas phase the molecule may have a different structure. Fig. 14 presents a diagram of the $OP(NH_2)_3$ levels, calculated by the CNDO/2 method taking into account $d$ orbitals. In all the versions, the positions of the nitrogen atoms are the same and correspond to the $C_{3v}$ symmetry. Fig. 14 shows that even a change in the positions of two hydrogen atoms causes a significant alteration in the relative positions of the levels. The $e$-type orbital, localised preferentially at the nitrogen atoms should be split on reduction of symmetry to $C_s$ into widely separated $a'$ and $a''$ orbitals, in agreement with experiment. Such a marked dependence of the energies of the orbitals on the configuration of the atoms (in contrast to the data in Fig. 11) is apparently a consequence of the greater delocalisation of the nitrogen LEP compared with the oxygen LEP.

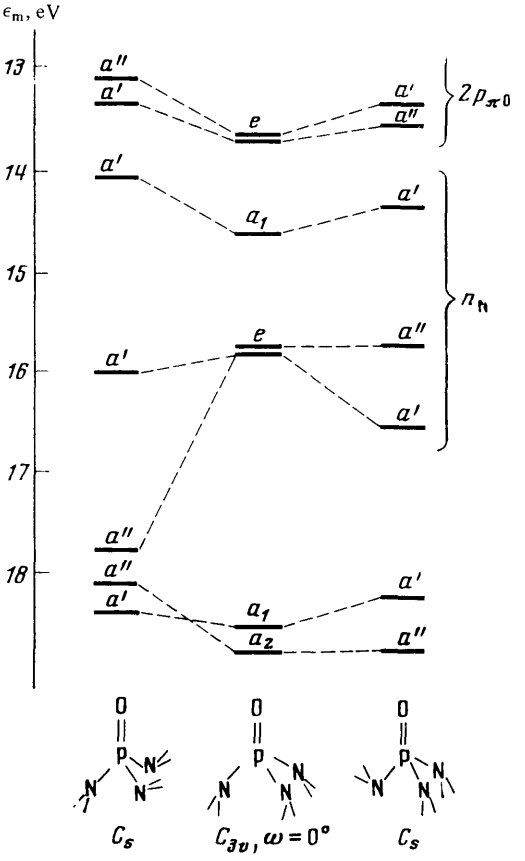

**Figure 14.** Theoretical dependence of the energy of the $OP(NH_2)_3$ orbitals on structure (calculation by the CNDO/2 method).

Like other phosphorus ylids, the compound $Me_3P{=}CH_2$ has a low ionisation potential, which indicates the accumulation of a large negative charge on the carbon atom of the $CH_2$ group, which has been confirmed by CNDO/2 calculations. The only band in the region of low ionisation energies, determining the first ionisation potential, arises in

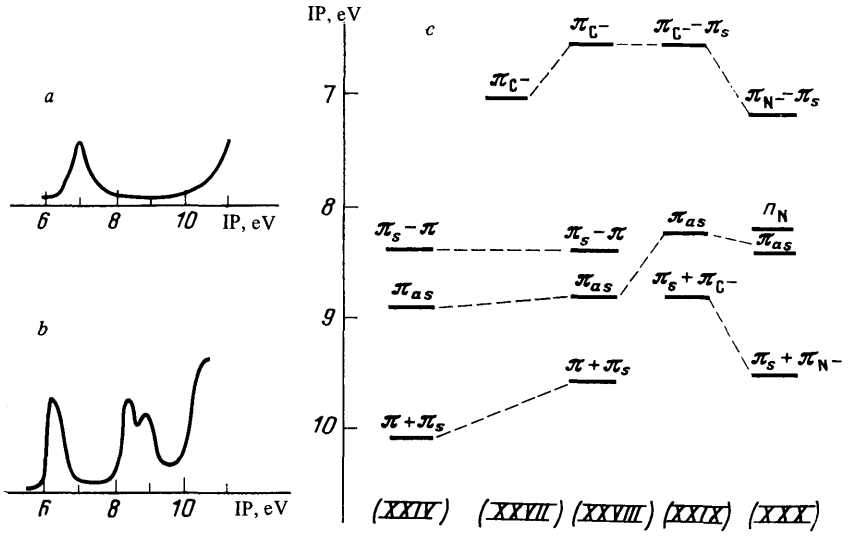

**Figure 15.** Photoelectron spectra: *a*) compound (XXVII); *b*) compound (XXIX); *c*) $IP_m^v$ correlation diagram for compounds (XXVI)–(XXX).[94]

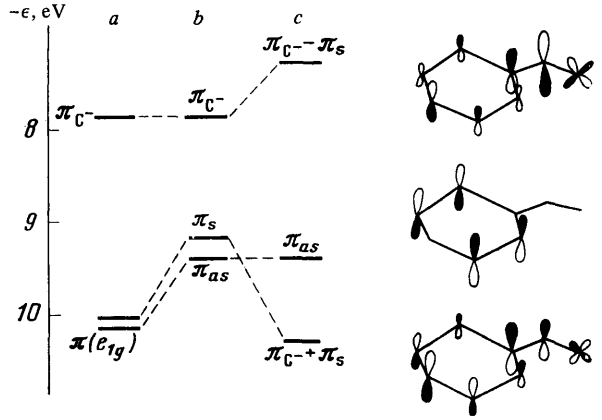

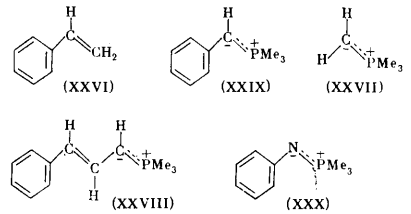

**Figure 16.** Analysis by the CNDO/2 method of the electronic structure of compound (XXIX); orbital energies of compounds (XXVII) and benzene (*a*) and compound (XXIX) allowing for Coulombic interaction but not for the conjugation of the ylid and phenyl fragments (*b*) and taking into account both forms of interaction (*c*).[94,104]

the $Me_3P{=}CH_2$ spectrum following ionisation from the "carbanionic" $\pi_{C^-}$ orbital, which is localised preferentially at the carbon atom of the $CH_2$ group[94] (Fig. 15).

Two additional bands, due to ionisation from orbitals localised preferentially in the phenyl substituent, appear in the $Me_3P{=}CHPh$ spectrum. The first is the $\pi_{as}(a_2)$ benzene orbital, which does not interact with the "carbanionic" $\pi_{C^-}$ orbital by virtue of symmetry, and the second characterises the energy of the mixed $\pi_S + \pi_{C^-}$ orbital, where $\pi_S$ is the symmetrical $\pi(b_1)$ orbital. The first ionisation potential is determined by the energy of the $\pi_{C^-} - \pi_S$ orbital (Fig. 15). The experimentally observed splitting of the energies of the $\pi_{as}$ and $\pi_S + \pi_{C^-}$ orbitals, which is particularly pronounced in $Me_3P{=}NPh$, indicates the conjugation of the "carbanionic" centre with the phenyl substituent.

It is remarkable that the energy of ionisation from the $\pi_{as}$ orbital as well as from the $\pi_S + \pi_{C^-}$ orbital is smaller than the ionisation potential of benzene, which shows that not only $IP_1$ but also the ionisation energies corresponding to the removal of electrons from orbitals localised preferentially in the phenyl substituent decrease under the influence of the field of the negative charge of the "carbanionic" centre. CNDO/2 calculations (Fig. 16), carried out by Ostoja Starzewski et al.,[104] reveal clearly the successive influence of the field and conjugation on the energies of the upper occupied orbitals.

---o0o---

The photoelectron spectra of compounds of two-, three-, and four-coordinated phosphorus were examined above. The information obtained about the electronic structures of these molecules in the gas phase is extensive and has been interpreted fairly unambiguously; it demonstrates the fruitfulness of the application of the PES method to the chemistry of organophosphorus compounds, the centenary of the birthday of one of the founders of which, Academician A. E. Arbuzov, has been celebrated by the scientific community of the USSR.

# The Kerr Effect and the Structure of Organophosphorus Compounds

R.P.Arshinova

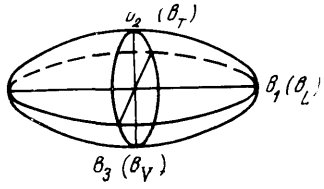
The results of research on the steric and electronic structures of organophosphorus compounds with the aid of the Kerr effect and the combined employment of the Kerr effect and other physical methods (dipole moments, depolarisation of Rayleigh light scattering, spectroscopic methods) are surveyed. The additive refractions, polarities and polarisabilities of phosphorus bonds are analysed and data are presented on the conformational analysis of acyclic phosphorus-containing molecules and four-, five-, and six-membered phosphorus-containing heterocycles.
The bibliography includes 130 references.

CONTENTS

I. Introduction 809
II. The Kerr constants of phosphorus compounds. The additive polarities and polarisabilities of phosphorus bonds 810
III. The steric and electronic effects in phosphorus(III) compounds 814
IV. The structures of four-coordinated phosphorus compounds 820

## I. INTRODUCTION

The distribution of electron density in the molecule (polarity) and the ability of the electron clouds to shift under the influence of an electric field (polarisability) are fundamental properties of matter, which in many respects determine its structure and reactivity. There are only a few experimental methods for the direct investigation of the electrical and electro-optical characteristics of molecules. Among these, the dipole moment method (DM), which yields information about the polarity of molecules, occupies an important place. The less widely used methods of double refraction in an electric field (the Kerr effect) and of the depolarisation of Rayleigh light scattering are the only ones available for the study of polarisability.



The polarisability $\alpha$ is defined as the dipole moment $\mu_{ind}$ induced by a unit electric field: $\alpha = \mu_{ind}/E$. For an isotropic species, the resultant vector of the induced moment is parallel to the applied field vector **E**. The polarisabilities of anisotropic species parallel and at right angles to the vector **E** are not equal ($\alpha_{\parallel} \neq \alpha_{\perp}$) and the induced dipole forms an angle with the vector **E**.

The anisotropic nature of a substance leads to the phenomenon of double refraction following the application of an electric field, i.e. at a given wavelength $\lambda$ the refractive index $n$ assumes different values in the directions parallel and at right angles to the applied field and we have $\Delta n = n_{\parallel} - n_{\perp} = B\lambda E^2$, where $B$ is the Kerr constant, determined by the properties of the substance itself. The molar Kerr constant ${}_mK$, which is defined as the difference between the molecular refractions $R$ for light polarised parallel and at right angles to **E**, is used in chemistry: ${}_mK = (R_{\parallel} - R_{\perp})/E^2$. For mixtures, ${}_mK$ is additive, so that the Kerr constant for a mixture of $n$ isomers is

$$ {}_mK_{exp} = \sum_{i=1}^{n} {}_mK_i N_i $$

where $N_i$ are the mole fractions of the isomers in the mixture and $\sum N_i = 1$.

In a theoretical treatment, the polarisabilities in different directions are described with the aid of the ellipsoid of polarisability

with three principal axes $b_1$, $b_2$, and $b_3$ for a molecule or $b_L$, $b_T$ and $b_V$ for an individual bond, where $b_L$ is the longitudinal polarisability and $b_T$ and $b_V$ are the transverse and vertical polarisabilities respectively (the letter $b$ denotes optical polarisability, i.e. the electron shift in the electromagnetic field of the light wave). It is assumed that $b_L$ has the same direction as the bond. For axially symmetrical bonds, $b_L \neq b_T = b_V$.

In the general case, polarisability must be regarded as a function of the orientation of the species relative to the direction of the polarising field **E**. In a cartesian coordinate system, each component of the induced moment ($m_x$, $m_y$, and $m_z$) is a function of three components of **E** ($E_x$, $E_y$, and $E_z$). In terms of matrix notation, one can write $\mu_{ind} = \Phi E$, where $\Phi$ is the polarisability tensor:

$$ (\Phi) = \begin{vmatrix} b_{xx} & b_{xy} & b_{xz} \\ b_{yx} & b_{yy} & b_{yz} \\ b_{zx} & b_{zy} & b_{zz} \end{vmatrix} . $$

The components of this tensor are the induced moments arising in the direction of the $i$ axis when the field acts along the $j$ axis. The polarisability tensor is a symmetrical tensor of the second rank. The invariants of the tensor are its trace and anisotropy, equal to the difference between the principal axes of the polarisability ellipsoid: $\gamma = b_L - b_T$. The trace of the tensor $b$ determines the molecular refraction of the substance. The components of the molecular polarisability tensor are closely related to the following three experimentally determined characteristics of the molecule:

1) The refraction $R_\infty$ extrapolated to the infinite wavelength:

$$P_E = R_\infty = \frac{4\pi N}{9}(b_{xx} + b_{yy} + b_{zz}), \quad (2)$$

where $P_E$ is the electronic polarisation. The polarisability determined from molecular refraction is the average optical polarisability:

$$\bar{b} = (b_1 + b_2 + b_3)/3 . \quad (3)$$

2) The coefficient of the depolarisation of the scattered light ${}_2\delta^2_\infty$:

$${}_2\delta^2_\infty = \frac{(b_{xx} - b_{yy})^2 + (b_{xx} - b_{zz})^2 + (b_{yy} - b_{zz})^2 + 6(b^2_{xy} + b^2_{xz} + b^2_{yz})}{(b_{xx} + b_{yy} + b_{zz})^2} . \quad (4)$$

3) The molar Kerr constant of the substance containing anisotropic ($K_1$) and dipole ($K_2$) components:

$${}_mK = K_1 + K_2 , \quad (5)$$

$$K_1 = \frac{2\pi N}{9kT} \cdot \frac{P_D}{45P_E}[(b_{xx} - b_{yy})^2 + (b_{xx} - b_{zz})^2 + (b_{yy} - b_{zz})^2 + 6(b^2_{xy} + b^2_{xz} + b^2_{yz})] , \quad (6)$$

$$K_2 = \frac{2\pi N}{9kT} \cdot \frac{1}{45kT}[m^2_x(2b_{xx} - b_{yy} - b_{zz}) + m^2_y(2b_{yy} - b_{xx} - b_{zz}) + m^2_z(2b_{zz} - b_{xx} - b_{yy}) + 6(m_x m_y b_{xy} + m_x m_z b_{xz} + m_y m_z b_{yz})] , \quad (7)$$

where $P_D$ is the deformation polarisation.

Eqn. (7) includes the components of the dipole moment along the coordinate axes, so that the magnitude and direction of the molecular dipole moment must be known in order to find ${}_mK$.

The majority of studies carried out previously involved the measurement of the Kerr effect and the refraction [1,2]. Investigation of the depolarisation of Rayleigh light scattering gives rise to new possibilities both for applied structural research and in the study of detailed intramolecular interactions and electron redistributions [3].

This review is devoted to the principal results and possibilities which are available to investigators of organophosphorus compounds using the Kerr effect method in conjunction with Rayleigh light scattering data in many instances. Much attention has also been devoted to the methodological aspect of the application of the dipole moment method, since dipole moments in many respects determine the validity of the calculation of ${}_mK$.

## II. THE KERR CONSTANTS OF PHOSPHORUS COMPOUNDS. THE ADDITIVE POLARITIES AND POLARISABILITIES OF PHOSPHORUS BONDS

### 1. The Kerr Constants of Phosphorus Compounds

The major advances achieved in the application of electro-optical methods to the study of the steric and electronic structures of organic compounds belonging to a wide variety of glasses (see the relevant reviews [1-3]) gave rise to the hope that these methods will be useful in the investigation of organophosphorus componnds, which are characterised by a wide variety of intramolecular electronic interactions: involving the lone electron pair (LEP), the multiple bond of phosphorus, etc.

Table 1 lists the phosphorus compounds investigated with the aid of the Kerr effect up to 1977 [4-32] (the numbering of the compounds in Table 1 is used henceforth in the text and in the other Tables). The first studies in this field, starting from 1961, were carried out by Le Fevre and coworkers [4,7,11,17,20,23,32] for twenty identically substituted compounds of three- and four-coordinated phosphorus. Certain difficulties, which will be noted below, limited further structural research.

Research involving the determination of the Kerr constants and of the degrees of depolarisation of Rayleigh light scattering in organophosphorus compounds was begun in Kazan in 1970 under the general supervision of Academician B. A. Arbuzov.

**Table 1.** The experimental Kerr constants for phosphorus compounds.

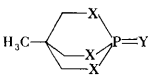
*Solvents: d = dioxan; b = benzene; c.t. = carbon tetrachloride; c = cyclohexane.

**Here and henceforth in the text the constants ${}_mK$ are understood to be multiplied by $10^{-12}$. The exceptions are compounds (XXXI)–(XXXV) and (XLIV)–(XLVI) for which the values of ${}_mK$ were determined to within $10^{-11}$.



***The degrees of depolarisation of Rayleigh light scattering $2\delta^2_\infty \times 10^3$ were determined for these compounds and the following values were obtained: 8.3 for (IV); 11.4 for (LII); 17.4 for (LXX); 3.4 for (XCII); 4.6 for (CIII).

## 2. The Additive Computational Scheme for Phosphorus Compounds

The theoretical treatment of the electrical and electro-optical properties of molecules is based on the hypothesis that they are additive. A characteristic dipole moment vector and polarisability tensor can be ascribed to each chemical bond or group of atoms. This is usually done on the basis of experimental data for a limited number of molecules, called the model compounds. The bond parameters obtained in this way make it possible to calculate the physical constants of a large set of molecules. The additive values of the bond parameters are effective and express not only the properties of the bonds themselves but also the influence on the latter of neighbouring substituents in the model compounds. The mutual influence may change on passing to systems with another environment; in this case, the deviations from additivity serve as a measure of the intramolecular interaction.

The validity of the valence-optical additive scheme can be regarded as firmly established to a zeroth approximation [33]. This scheme can be extended not only to the dipole moments and the anisotropic bond polarisabilities but also to the derivatives of these quantities with respect to changes in bond length, serving thus as the basis of the modern theory of intensities in infrared and Raman spectra, which is in good agreement with experiment [33].

The simplest identically substituted molecules, known *a priori* not to exhibit conformational isomerism, are chosen for phosphorus derivatives as model compounds. These substances are of the type $PX_3$ and $Y{=}PX_3$, in which the threefold symmetry axis coincides with the direction of the resultant dipole moment of the P–X and P=Y bonds and with the direction of the longitudinal $b_1$ axis of the molecular polarisability ellipsoid. For non-regular groups P–X–R, where X = O, S, NR, etc., the model compounds used [32,34] are rigidly fixed bicyclic systems of the type

Y = LEP, O, S,

where internal rotation is impossible. The corresponding additive parameters of the phosphorus bonds may be calculated from the experimental dipole moments and Kerr constants ${}_mK$ by a vector or tensor expansion with the subtraction of certain parameters of the carbon bonds. As mentioned above, refraction data are also necessary in order to find the axes of the polarisability ellipsoids.

The numerical values of the phosphorus bond refractions have been analysed most fully by Tolkmith [35]. On the basis of extensive experimental data (for 500 phosphorus compounds), he concluded that the refraction of the given bond depends both on the environment of the phosphorus atom itself and on the nature of the substituent in the P–X–R chain. The phosphorus bond refractions most frequently employed are listed in Table 2.

Table 2. The refractions of the phosphorus bonds for the D line of Na. [35]

| Bond | $R_D$ | Bond | $R_D$ | Bond | $R_D$ |
|---|---|---|---|---|---|
| $P^{III}$ LEP | 5.4 | P—$NC_2$ | 1.3 | P—Cl | 6.95 |
| P—OH, P—OP | 1.45 | P—N=C | 1.9 | P—Br | 10.2 |
| P—OC, P—OSi | 1.35 | P—$C_{sp^3}$ | 1.85 | P—Si | 3.4 |
| P—SH | 6.25 | P—$C_{arom}$ | 2.75 | P—P | 3.5 |
| P—SC, P—SSi | 5.65 | P—C≡N | 2.55 | P=O | 4.15 |
| P—SP | 5.3 | P—$CCl_3$ | 2.7 | P=S | 11.9 |
| P—SeP | 7.3 | P—C=O | 2.05 | P=Se | 15.6 |
| P—$NH_2$ | 1.7 | P—H | 2.2 | P=N | 5.8 |
| P—NHC, P—NP | 1.5 | P—F | 1.5 | | |

It follows from the above that the creation of an additive computational scheme is based on a comparison of data for compounds of three- and four-coordinated phosphorus. The former ($PX_3$) serve as a basis for the determination of the P–X bond parameters. The P=Y bond parameters are determined as the vector or tensor differences between the corresponding experimental values for $PX_3$ and $YPX_3$. A weak aspect of such calculation is the hypothesis that the parameters of the $P^{III}$–X and $P^{IV}$–X bonds remain unchanged. Evidently, in most cases the inaccuracy of the result should be compensated implicitly by a distortion

of the values for P=Y. However, the difference is caused not only by the different states of hybridisation of the central atom, but also by the uncertainty of the contribution of the phosphorus(III) LEP to the required parameters in the initial $PX_3$ molecules.

### 3. The Influence of the Dipole Moment of the Lone Electron Pair on the Results of Calculations

The problem of the degree of displacement of the centre of gravity of the LEP electron cloud relative to the positively charged atomic nucleus ($\bar{x}$), which determines the LEP dipole moment ($m_{LEP} = 2e\bar{x}$) is widely discussed in the literature. However, the direct experimental determination of $\bar{x}$ is extremely difficult. The proposed methods [36,37] are laborious and not very reliable, since the experimental error is close to the postulated displacement of the charge. For a phosphorus atom with a valence angle of 93.4°, analysis of the intensities of the absorption bands in infrared spectra [36] yielded 0.2 D. Comparison of the experimental dipole moments of triarylphosphines and the valence angles led the authors [38] to the conclusion that the maximum phosphorus(III) LEP dipole moment is 2.93 D. Smaller values follow from quantum-mechanical calculations: 1.35 D [27] (valence angle 100°) and 1.15 D in phosphine. [39]

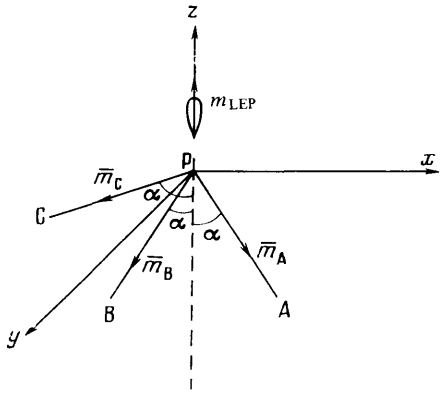


**Figure 1.** The configuration of the P(ABC) molecule in the cartesian coordinate system.

According to Mauret and Fayet [40], the dipole moment of trialkylphosphines (1.6 D) is equal to $m_{LEP}$ as a consequence of the similarity of the electronegativities of the carbon and phosphorus atoms. The unknown parameter may be determined on the basis of the vector additive scheme for the dipole moments of several compounds, specifying $m_{LEP}$ as an independent vector together with the bond dipole moments, as has been done in a number of studies [41-43]; $m_{LEP} = 0.92$ D [41] and $m_{LEP} = 1.49$ D [43] was obtained. Calculations of this kind are sensitive to the chosen angular parameters. When the latter are equal, the relation between the molecular and the required dipole moments is in most cases linear, deviations from linearity being caused not only by the contribution of the LEP moment but also by non-additivity factors, appearing as a result of the mutual influence of the atoms and the differences between the valence angles. In such cases, a small (in absolute magnitude) change in the non-additivity factor can ultimately lead to a wide variation in the parameters being determined. This in fact explains the fairly large difference (approximately 0.6 D) between the values found by Matrosov et al. [41] and Chernokal'skii et al. [43]

Thus the problems of the absolute value of the LEP moment of the phosphorus atom can be regarded as still open. However, in the light of the problems solved with the aid of the dipole moments and Kerr effect methods, it is important to determine the influence of the dipole moment of the lone electron pair $m_{LEP}$ on the magnitude and direction of the resultant dipole moment. We shall consider this problem for non-identically substituted molecules of the type P(ABC), since in the case of molecules with symmetrical substitution $m_{LEP}$ enters implicitly into the bond moments of the given atom obtained by the vector resolution of the experimental dipole moments of model compounds. Three symetrically substituted compounds $PA_3$, $PB_3$, and $PC_3$ with the molecular dipole moments $\mu A$, $\mu B$, and $\mu C$ serve as the model compounds for the determination of the P–A, P–B, and P–C bond moments designated by $m_A$, $m_B$, and $m_C$. Each bond moment $m_i$, where $i$ = A, B, or C, is calculated as follows:

$$m_i = \frac{\mu_i - m_{LEP}}{3\cos\alpha}, \qquad (8)$$

where $\alpha$ is the angle formed by the bond with the three-fold symmetry axis (Fig. 1).

The dipole moment $\mu$ of the compound P(ABC) is then expressed by the following sum:

$$\mu^2 = [m_{LEP} + \cos\alpha\,(m_A + m_B + m_C)]_z^2 + \left[m_A \sin\alpha - \right.$$
$$\left. - \frac{1}{2}(m_B + m_C)\sin\alpha\right]_x^2 + [2(m_B - m_C)\sin\alpha]_y^2 . \qquad (9)$$

The substitution in this expression of the bond moments determined for symmetrical compounds by Eqn. (8) (for identical angles) leads to the final expression

$$\mu^2 = \left[\frac{(\mu_A + \mu_B + \mu_C)}{3}\right]_z^2 + \left[\frac{(2\mu_A + \mu_B + \mu_C)}{6}\tan\alpha\right]_x^2 +$$
$$+ \left[\frac{2(\mu_B - \mu_C)}{3}\tan\alpha\right]_y^2, \qquad (10)$$

in which $m_{LEP}$ cancels out fully.

Eqn. (10) shows that, for the determination of the magnitude and direction of the resultant molecular moments of asymmetrically substituted compounds, in most cases [with the exception of substances of the type $PH_n(CH_3)_{3-n}$ with $n$ = 1–3, where the valence angles at the phosphorus atom are appreciably less than 100°C] there is no need for the introduction of the vector of the LEP moment as an independent parameter. Since the compounds considered [$PA_3$, $PB_3$, $PC_3$, and P(ABC)] can differ by their intramolecular interactions, the contributions of the interaction moment, called above the non-additivity factor, must be introduced into Eqns. (9) and (10).

### 4. The Dipole Moments of Phosphorus Bonds

The disposition of the bonds at the phosphorus atoms may be regarded as nearly tetrahedral, if the fourth bond is represented by the lone electron pair.

Mathematically this is analogous to the tetrahedral orientation of bonds at a carbon atom; consequently the

vector of the LEP moment is analogous to the vector of the C–H bond dipole moment, which serves as a basis for the determination of the dipole moments of all the remaining bonds of organic compounds. It follows from Eqn. (10) that the absolute value of $m_{LEP}$ has no influence on the results of calculations, but is closely related to the intermediate values of $m_i$, i.e. to the bond moments. This fact can explain the existence of several sets of bond moments differing by the initial data. The principal requirement for a correct calculation of dipole moments is therefore a unique set of initial parameters. For phosphorus compounds, the number of such systems of parameters is increased owing to the different absolute values of $m_{LEP}$ adopted by different investigators.

Table 3. The dipole moments of phosphorus bonds.

*Despite the identical values of $m_{P-O}$, the calculations in Refs. 6 and 50 were based on different initial data: $m_{C-O}$ = 1.12 D, found from the dipole moments of tetrahydropyran and 1,3-dioxan ($m_{H-C}$ = 0.28 D and $m_{LEP}$ = 0) was used in Ref. 6, while $m_{P-O}$ was calculated from the dipole moment of the bicyclic phosphite (C); in Ref. 50, the moment $m_{Alk-O}$ = 0.87 D was determined from the measured dipole moments of dialkyl esters after eliminating the contribution of the rotational vibrations of the molecule to the polarisation, while $m_{P-O}$ was calculated on the basis of a compound whose bonds are fixed in space—triethyl phosphite, for which the *cis*, *cis*, *cis*-conformation was adopted, but was not subsequently confirmed by an electron diffraction study of trimethyl phosphite[70].

**In the calculation of $m_{P-S}$ and $m_{P-N}$ in Refs. 52 and 58, the P=S bond moment was treated as a constant value equal to 2.62 D.

***The interaction moments in different conjugated systems were calculated in Refs. 48 and 63–65.

****The high sensitivity of $m_{P=O}$ to the electronegativities of the substituents was demonstrated in Refs. 50, 60, and 68: $m_{P-O} = 4.80 - 0.353\,\Sigma X$, where $X$ is the Thomas–Chattenden "shift constant".

*****According to Refs. 60 and 69, $m_{P=S} = 9.75 - 0.924\,\Sigma X$.

One of the first studies on the analysis of the dipole moments of organophosphorus compounds was performed in Kazan by Arbuzov and Rakov[44]. The bond dipole moments were examined most fully and systematically for the first time by Arbuzov and Shavsha[45–47]. It is nowadays postulated that the bond moments depend to a large extent on the environment at the phosphorus atom. Table 3 presents some of the bond dipole moments most widely used in calculations. If $m_{LEP} \neq 0$ and if the bond moments have been determined from the dipole moments of compounds asymmetrically substituted relative to the phosphorus atom, then Table 3 indicates in brackets, after the dipole moment, the value of $m_{LEP}$ adopted by the authors and the intermediate environment at the phosphorus atom. The dipole moments calculated taking into account $m_{LEP}$ appear to be more reliable in the light of the existing theoretical ideas. However, as shown above, in the additive calculation of dipole moments this is not important and identical results are obtained.

It follows from the data in Table 3 that the phosphorus bond dipole moments are extremely sensitive to the environment and in the analysis of the dipole moments of phosphorus compounds it is therefore desirable to examine the entire set of bonds. The method of isoelectric maps[6], whereby it is possible to find simultaneously bond and structural parameters, is extremely promising in this respect. It is described in detail in Section IV for 1,3,2-dioxaphosphorinane derivatives as an example.

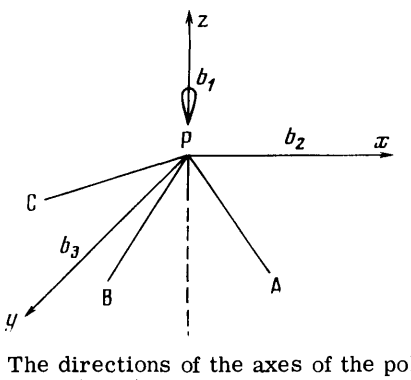

Figure 2. The directions of the axes of the polarisability ellipsoid of the P(ABC) molecule.

## 5. The Anisotropy of the Polarisability of Phosphorus Bonds

In the calculation of the additive parameters of the polarisability ellipsoids of phosphorus bonds, the problem of the allowance for the LEP contribution remains obscure, as for dipole moments. We shall place a symmetrically substituted molecule $PA_3$, $PB_3$, or $PC_3$ in a cartesian coordinate system, as shown in Fig. 2 for the P(ABC) molecule. Denoting the molecular anisotropy of polarisability by $\Gamma_i = b_1 - b_2$, it is possible to calculate the anisotropy of the polarisability of the $i$th bond:

$$\gamma_i = \frac{\Gamma_i - \gamma_{LEP}}{4.5\cos^2\alpha - 1}. \qquad (11)$$

The differences between the diagonal elements and the non-diagonal components of the molecular polarisability

tensor matrix of the P(ABC) molecule, which are necessary for the calculation of ${}_{m}K$, can be calculated in conformity with Eqns. (6) and (7):

$$
\begin{aligned}
b_{xx} - b_{yy} &= -\gamma_A(1-\cos^2\alpha) - \sum_{i=B,C} 0.5\gamma_i(1-\cos^2\alpha);\\
b_{xx} - b_{zz} &= \gamma_A(1-2\cos^2\alpha) + \sum_{i=B,C} \gamma_i(0.25-1.25\cos^2\alpha) - \text{LEP};\\
b_{yy} - b_{zz} &= -\gamma_A\cos^2\alpha + \sum_{i=B,C} \gamma_i(0.75-1.75\cos^2\alpha) - \text{LEP};\\
b_{xy} &= \sum_{i=B,C} (\mp\gamma_i \sin^2\alpha\cdot\cos 60^\circ\cdot\sin 60^\circ);\\
b_{xz} &= -\gamma_A\cos\alpha\cdot\sin\alpha + \sum_{i=B,C} (\gamma_i\cos\alpha\cdot\sin\alpha\cdot\cos 60^\circ);\\
b_{yz} &= \sum_{i=B,C} (\mp\gamma_i\cos\alpha\cdot\sin\alpha\cdot\cos 60^\circ).
\end{aligned}
\qquad (12)
$$

*Calculated from the molecular refraction and the empirical equation relating $b_L$ and the bond length[1].
**Calculated by the author of the review.
***See Section III.

Substitution of $\gamma_i$ from Eqn. (11) in Eqn. (12) leads to expressions where the contribution of the LEP vanishes after appropriate mathematical operations, and only the experimental quantities $\Gamma_A$, $\Gamma_B$, and $\Gamma_C$ remain, i.e. there is no need to take into account in an explicit form the LEP polarisability ellipsoid. Taking into account the absolute value of the LEP polarisability $b = 6.3$ Å$^3$ found by Tolkmith[35], it is possible to calculate the required parameters of the four-coordinated phosphorus bonds: they are equated to the differences between the axes of the polarisability ellipsoids of the bonds and the isotropic lone pair of the tervalent atom. Table 4 presents the parameters of the polarisability ellipsoid of bonds and groups of atoms obtained in this way.

We may note the wide variation of the bond polarisability parameters, particularly on passing from symmetrically substituted to asymmetrically substituted compounds. This invalidates the usually employed method of calculation for such systems (see above) and requires a non-trivial approach. For this reason, compounds of three- and four-coordinated phosphorus will be henceforth considered separately.

### 6. The Solvent Effect

In the practical application of the values quoted in Table 1, particular attention must be paid to the possible interaction of the given compounds with the solvent. Thus Le Fevre's attempt to use the parameters found for the polarisability ellipsoids of the phosphite and phosphate groups in the analysis of the structures of the trialkyl phosphites (V)–(VIII) and the trialkyl phosphates (X) to (XVI) was unsuccessful[7]. It was subsequently observed that the experimental values of ${}_{m}K$ in benzene differ considerably from those determined in other solvents [see the data for compounds (IX), (XIX), (XX), and (XXVI) in Table 1]. This can be explained by the formation of complexes by phosphorus compounds with benzene[11], so that the conclusions reached by Le Fevre and coworkers[7,17,20] are incorrect. The use of the bond polarisability ellipsoids found for compounds (I), (II), (XXX), (XXVI), and (XLVII), whose ${}_{m}K$ values were determined in benzene, also requires particular caution.

## III. THE STERIC AND ELECTRONIC EFFECTS IN PHOSPHORUS(III) COMPOUNDS

The use of the Kerr effect in conformational analysis and in the study of intramolecular electronic effects requires the knowledge of the polarisability ellipsoids of bonds or groups of atoms. Comparison of the experimental constants ${}_{m}K$ and the values calculated for various rotational isomers permits conclusions about the steric structure, while comparison of the true values and those obtained on the basis of the additive resolution of the polarisability ellipsoids gives rise to the possibility of analysing the electron redistribution in the molecules being compared. The dipole moments and the constants ${}_{m}K$ are calculated from the bond lengths and valence angles (see the relevant reviews for phosphorus compounds[74-76]) by the method of Corey and Sneen[77].

The data in Table 1 show that the values of ${}_{m}K$ for 2-X-1,3,2-dioxaphosphorinane molecules have been most fully investigated. These compounds have been used traditionally in the Kazan School of Chemistry. As early as the beginning of the 1950s, A. E. Arbuzov and coworkers developed methods for the synthesis of various saturated phosphorus-containing heterocycles[71-73] and began the first studies of their physical and chemical properties.

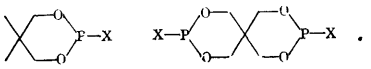
It is noteworthy that phosphorus(III) compounds are characterised by a wide variety of effects due to the mutual influence of atoms; this is shown particularly by the wide scale of changes in the chemical shifts due to the phosphorus atomic nucleus in $^{31}P^{III}$ NMR (from −230 to +450 p.p.m.) compared with four- (from −130 to +115 p.p.m.) and five-coordinated phosphorus (from −30 to +100 p.p.m.)

The problem therefore arises of the validity of employing the usual additive parameters for the calculation, since incorrect results may be obtained when no account is taken of the high sensitivity of the electrical and electro-optical bond characteristics to electronic interactions.

This hypothesis was confirmed in a study of the structure of one of the simplest 1,3,2-dioxaphosphorinanes – 2-chloro-1,3,2-dioxaphosphorinane (LXIX), which exists solely as the chair conformer. The calculation of dipole moment and the constant $_mK$ for compound (LXIX) from the parameters found from the corresponding values for symmetrically substituted derivatives leads to the conclusion that the P–Cl bond is equatorial[27]:

$\mu_A = 2.94$ D; $_mK = -101$ $\mu_e = 3.37$ D; $_mK = 144$

$\mu_{exp.} = 3.47$ D; $_mK_{exp.} = 164$



This conclusion conflicted with electron diffraction data[78] and the analysis of $^1$H NMR spectra[79–82] and chemical reactions[82], but agreed with the calculation of the band contours in vibrational spectra[83]. It may be that the inaccuracies of the additive phosphorus bond parameters led to erroneous results in the application of the dipole moment and Kerr effect methods.

The ideal solution to the problem of the selection of the additive parameters for solving conformational problems was one in which both bond and structural parameters are determined simultaneously. Bearing in mind that the exact calculation of $_mK$ is impossible without knowledge of the exact values of the dipole moments, we shall consider initially how correct are the bond dipole moments employed.

## 1. The Nature of the Electron Density Distribution in 2-X-1,3,2-Dioxaphosphorinanes

The simultaneous determination of the phosphorus bond dipole moments ($m_{P-O}$ and $m_{P-X}$) and of the orientation (axial or equatorial) of the exocyclic substituent X, i.e. three unknown parameters, is possible by extending the range of compounds investigated which are known *a priori* to have identical structures (the so called isoconformational compounds) but different directions of the molecular dipole moment.

It is useful to compare 2-X-1,3,2-dioxaphosphorinanes with their 5-spiro-analogues, which have been indeed shown to have identical structures by the study of steric interactions[84] and by the analysis of $^1$H NMR spectra[85]:

The symmetry of spiro-compounds is such that the dipole moments of the ring P–O bonds have little effect on the final results as a consequence of the mutual cancellation of the $m_{P-O}$ values. The dipole moment of compound (LXIX), calculated with the usual parameters for the equatorial conformation (3.37 D), is closer to the experimental value (3.47 D) than the moment for the axial conformation (2.94 D), whereas there is no doubt that the P–Cl bond in the spiro-analogue (LXXII) has the axial orientation [$\mu_{aa} = 2.01$; $\mu_{ee} = 3.53$; $\mu_{exp} = 2.10$ D (Arbuzov et al.[6])].

A method for the simultaneous determination of the structure and phosphorus bond dipole moments has been proposed[6] on the basis of data for the two types of compounds considered. The bond polarities $m_{P-O}$ and $m_{P-X}$ were treated as the unknown quantities. Vector summation of the bond dipole moments makes it possible to express the experimental dipole moments of the compounds as functions of the unknown quantities $m_{P-O}$ and $m_{P-X}$ for the axial and equatorial conformations. Each of the three equations described a three-dimensional surface in the space defined by the coordinates $m_{P-O}$, $m_{P-X}$, and the resultant moment $\mu$. Their intersection by the $\mu^2_{exp}$ plane yields constant-property lines whose projections on to the $m_{P-O}$ and $m_{P-X}$ planes are illustrated graphically in Fig. 3 (for X = Cl). The method may be referred to as the method of isoelectric maps. An analytical solution of the systems of equations is also possible, but the graphical procedure is simpler and clearer. The solution, consisting of a compatible set of bond moments for both types of compounds, are given by the points of intersection of the straight lines representing $\mu^2_{exp}$ for compound (LXXII) with the curves corresponding to $\mu^2_{exp}$ for compound (LXIX). The requirement that the values obtained are physically significant, i.e. that the parameters thus found do not differ greatly from the values obtained for the dipole moments of symmetrically substituted compounds, serves as a criterion of the validity of the particular solution. Fig. 3 shows that, for the equatorial conformation of the P–Cl bond, the phosphorus bond moments satisfying simultaneously the experimental dipole moments have improbable values; for the axial orientation of the chlorine atom, the unique solution $m_{P-O} = -0.72$ D and $m_{P-Cl} = 0.92$ D [6] is acceptable. The higher polarity of P–Cl bond in 2-chloro-1,3,2-dioxaphosphorinane compared with $PCl_3$ is consistent with the lower $^{35}$Cl NQR frequency and the greater length of the P–Cl bond[86].

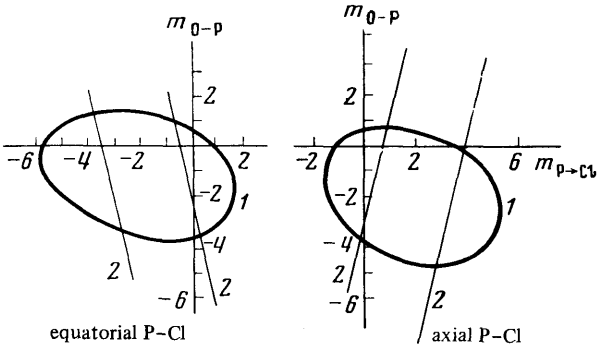


**Figure 3.** Dependence of the squares of the dipole moments of compounds (LXX) (curve *1*) and (LXXII) (curve *2*) on the dipole moments of the P–O ($m_{O \to P}$) and P–Cl ($m_{P \to Cl}$) bonds.

Of the eight possible solutions for X = $NEt_2$ (Fig. 4), only one is realistic—with $m_{P-O} = 0.65$ and $m_{P-N} = 1.37$ D; it corresponds to the equatorial position of the P–N bond[87]. In 2-phenyl-1,3,2-dioxaphosphorinanes (Fig. 5), two solutions are most probable: $m_{Ph-P} = -0.95$ and $m_{O-P} = 0.06$ D for the axially oriented phenyl group and

$m_{Ph-P}$ = 0.96 and $m_{O-P}$ = 0.43 D for its equatorial position. By resorting to the dipole moment of a third isoconformational compound, namely 5-methyl-5-nitro-2-phenyl-1,3,2-dioxaphosphorinane ($\mu_{exp}$ = 6.23 D),[88] a choice between these two possible solutions still cannot be made. Since comparison of the experimental dipole moments of triphenylphosphine and its tri-*p*-substituted derivatives shows that the moment of the Ph–P group is directed towards the benzene ring, we give preference to the first solution.

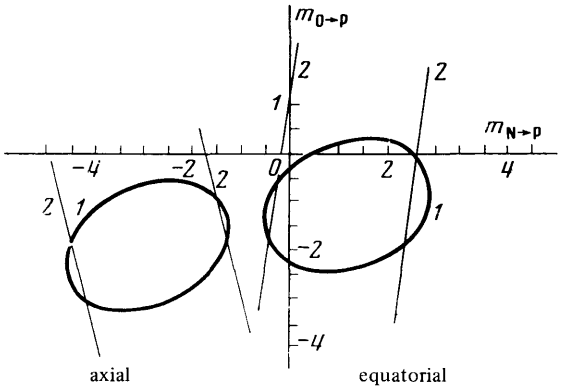

**Figure 4.** Dependence of the squares of the dipole moments of 2-diethylamino-1,3,2-dioxaphosphorinane (curve *1*) and its 5-spiro-analogue (curve *2*) on the dipole moments of the P–O ($m_{O\to P}$) and P–N ($m_{N\to P}$) bonds.

The symmetry of the substitution of phosphorus atoms in 2-alkoxy-1,3,2-dioxaphosphorinanes (X = O-Alk) eliminates the necessity for the determination of the P–O bond dipole moment and one can therefore assume that the calculation of the dipole moments of these compounds using $m_{P-O}$ = 0,[6] found from the dipole moment of the bicyclic phosphite (C), is valid. Determination of the structure of compounds of this type is a more difficult problem, since, apart from the position of the exocyclic bond, it is necessary to determine the orientation of the P–O–Alk fragment relative to the phosphorus LEP (*cis*-, *trans*-, or *gauche*-, Fig. 6). Graphical comparison of the values of $\mu^2$ for two isoconformational compounds—2-ethoxy-1,3,2-dioxaphosphorinane and the 5-spiro-analogue (Fig. 7*a*)—makes it possible to determine two unknown structural parameters: the axial position of the exocyclic P–O bond and the *gauche*-orientation of the ethoxy-group[84]. The application of an analogous method to 2-phenoxy-1,3,2-dioxaphosphorinanes (Fig. 7*b*)[84,129] on the assumption that the values of $m_{P-O}$ for the ring and exocyclic bonds are equal leads to the conclusion that the phenoxy-group has the *cis*-orientation. However, in the compounds examined the environment at the phosphorus atom is not rigorously symmetrical, since the exocyclic P–O bond adjoins the benzene ring and not the alkyl group.

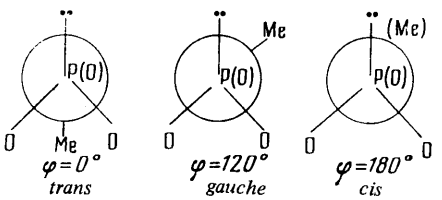

**Figure 6.** Internal rotation relative to the exocyclic P–O bond determined by the dihedral angle $\varphi$.

A change in the dipole moments of the P–O bonds should not lead to a sharp alteration of the principal structural conclusions—they can change only to give the *gauche*-conformation. If one disregards structural parameters, then there are only two unknown quantities—the dipole moments of the exocyclic and ring P–O bonds; it is therefore quite sufficient to examine two isoconformational compounds whose dipole moments are not linearly related: compound (LXXXIX) and its 5-spiro-analogue ($\mu_{exp}$ = 2.89 D). In setting up systems of equations for $m_{Ph-O(PIII)}$ corresponding to the *cis*- and *gauche*-forms, 1.10 D was used[8]. Simultaneous solution of each system of equations yielded the following parameters:

$m_{O-P(acyclic)}$ = 0.22 and $m_{O-P(cyclic)}$ = +0.8 D for the *cis*-form;

$m_{O-P(acyclic)}$ = −0.8 and $m_{O-P(cyclic)}$ = +0.42 D for the *gauche*-form.

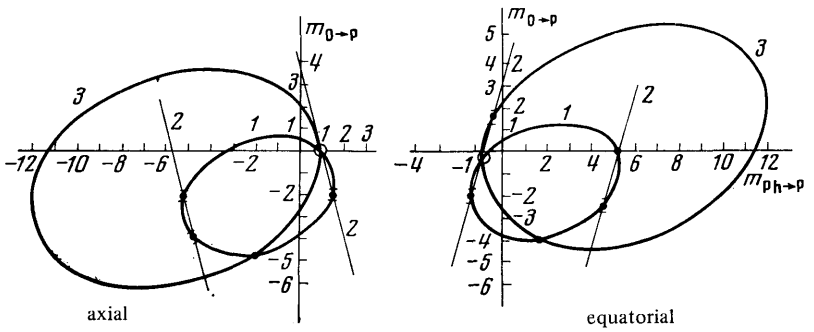

**Figure 5.** Dependence of the squares of the dipole moments of 2-phenyl-1,3,2-dioxaphosphorinane (curve *1*), its 5-spiro-analogue (curve *2*), and the 5-methyl-5-nitro-derivative (curve *3*) on the dipole moments of the P–O ($m_{O\to P}$) and Ph–P ($m_{Ph\to P}$) bonds.

A choice can be made between these two sets, i.e. the third structural parameter can be found, only when additional dipole moment data for other isoconformational compounds are resorted to: the *p*-bromo derivative of compound (XC) and the *p*-nitro-derivative of compound (XCI). The results of the calculations show that the agreement with experiment is reached only for the *cis*-form. The bond polarity data obtained made it possible to estimate the angle of rotation of the benzene ring in the *o*-substituted (*o*-bromo- and *o*-nitro-) derivatives. The experimental data ageee with the calculated results for the structure where the benzene ring is perpendicular to the plane of the P–O–$C_{aryl}$ bonds.

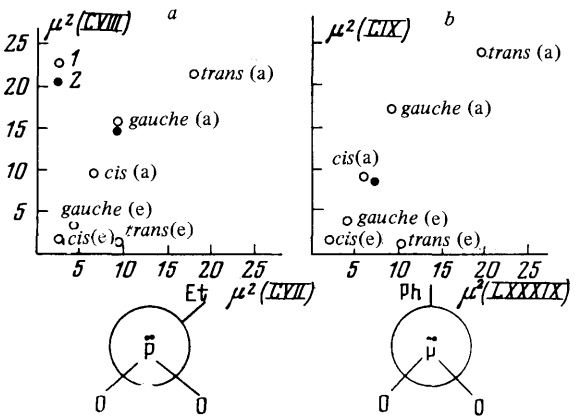

**Figure 7.** Graphical relations between the squares of the dipole moments of 2-ethoxy-1,3,2-dioxaphosphorinane (CVII) and its 5-spiro-analogue (CVIII) (*a*) and between the squares of the dipole moments of 2-phenoxy-1,3,2-dioxaphosphorinane (LXXXIX) and its 5-spiro-analogue (CIX) (*b*): 1) calculated values; 2) experimental values.

Table 5. The dipole moments of phosphorus bonds in 2-X-1,3,2-dioxaphosphorinanes $O_2PX$ according to data obtained by the isoelectric map method.

| Environment at P | Dipole moment | Substituent X | | | | |
|---|---|---|---|---|---|---|
| | | O(Ph) | Cl | O(Et) | Ph | $N(Et_2)$ |
| $O_2PX$: | $m_{P-O}$ | −0.8 | −0.72 | −0.32 | 0.06 | 0.65 |
| | $m_{P-X}$ | 0.22 | 0.92 | 0.14 | 0.95 | 0.37 |
| $PX_3^*$: | $m_{P-X}$ | 0 | 0.56 | 0 | 1.18 | 0.31 |

*See corresponding footnotes to Table 3.

The phosphorus bond dipole moments presented in Table 5 demonstrate the extreme electronic lability of phosphorus(III) compounds as a function of the environment at the phosphorus atom.

We emphasise yet again that the bond dipole moments obtained are effective values and thus reflect the nature of the redistribution of electron density. When a comparison is made with the bond polarities of symmetrically substituted phosphorus compounds, a deviation from these values is observed for exocyclic bonds. The greatest deviation $\Delta m_{P-Cl} = 0.36$ D is directed towards the chlorine atom and indicates its electron-accepting properties. The P–O ring bonds undergo much greater changes: whereas in the compound with $X = NEt_2$ there is a redistribution of electron density to the extent of approximately $0.4e$ from the phosphorus atom to the neighbouring oxygen atoms with an almost unchanged $m_{P-N}$, in the compound with X = Cl or OPh virtually the same electron density ($0.44e$) is transmitted from the ring oxygen atoms to the phosphorus atom. The nature of the electron redistribution for X = OEt and Ph is approximately the same. Consequently a strong geminal interaction, which depends on the nature of the atom X and is strongly reflected in the properties of the O–P bonds, is observed in the $O_2P$–X series. A possible mechanism for this interaction is examined below.

2. The Intramolecular Interactions and the Anisotropy of the Polarisability of the $P^{III}$– Cl Bond

The problem of the simultaneous determination of the bond polarisability ellipsoids and molecular conformations is mathematically more complex than the determination of dipole moments. We shall consider this problem for the $O_2PCl$ group in compound (LXX), since there are no grounds for doubting the validity of the electro-optical parameters of the carbon bonds. The group has a plane of symmetry and one must therefore determine four independent parameters: three polarisability axes and their orientations defined by the angle $\varphi$ (Fig. 8). A necessary condition for the solution of this problem is an increase in the number of experimental parameters either by extending the range of isoconformational compounds or by increasing the number of methods used. As in the previous section, compound (LXX) and its spiro-analogue (LXXII) were examined and their $_mK$ constants were determined. Determinations of the depolarisation of scattered light for compound (LXX) served as an additional method.

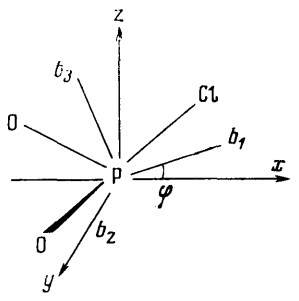

**Figure 8.** The directions of the axes of the polarisability ellipsoid of the $O_2PCl$ group.

The experimental values of $_mK$ for compounds (LXX) and (LXXII) and of $_2\delta^2_\infty$ for compound (LXX) were expressed as functions of the unknown quantities $\gamma_{P-O}$ and $\gamma_{P-Cl}$ for the axial and equatorial conformations. The equations obtained are presented in Fig. 9 in a graphical form. The limits of the rectangle denote the region outside which the bond polarisabilities have no physical significance.

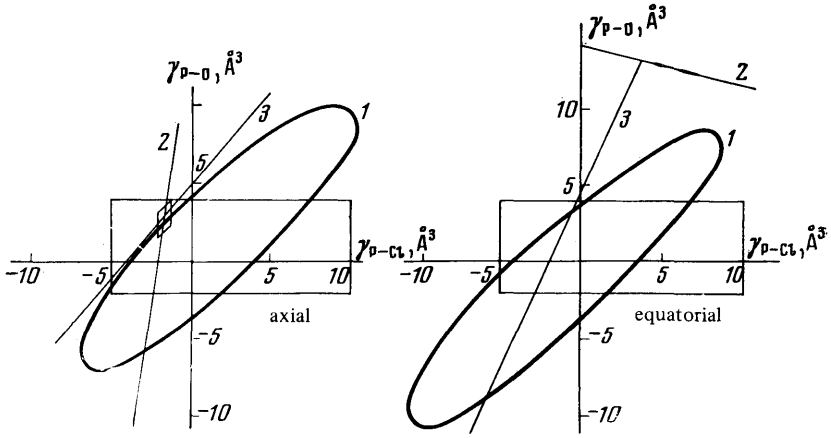

**Figure 9.** Dependence of $\gamma^2$ (curve *1*) and $K_2$ (curve *2*) for compound (LXX) and of ${}_mK$ (curve *3*) for compound (LXXII) on the anisotropy of the P–O and P–Cl bond polarisabilities; $|\gamma^2| = {}_2\delta^2_\infty (b_{xx} + b_{yy} + b_{zz})^2$.

Analysis of the graphical relation shows that a full set of values of $\gamma_{P-O}$ and $\gamma_{P-Cl}$ (the points of intersection of the straight lines and the ellipse) is possible only for the axial disposition of the P–Cl bond, since in this case three lines converge in one region. The tensor summation of the values $\gamma_{P-O} = 2.7$ and $\gamma_{P-Cl} = -1.7$ obtained yields the polarisability ellipsoid for the $PO_2Cl$ group with $b_1 = 6.8$, $b_2 = 7.8$, and $b_3 = 3.0$ Å$^3$ and the angle $\varphi = -7$ between $b_1$ and the plane of the $PO_2$ fragment (Fig. 8). The principal axes of the polarisability ellipsoid for the $PO_2Cl$ group may be determined more accurately without considering each bond separately and hence without introducing the hypothesis of their axial symmetry ($b_T \neq b_V$). The solution of three equations with three experimental values using the total group polarisability (17.56 Å$^3$) for the four unknown parameters yields two sets of polarisability ellipsoids: $b_1 = 6.437$, $b_2 = 3.369$, $b_3 = 7.537$, and $\varphi = -13°$; $b_1 = 6.783$, $b_2 = 7.871$, $b_3 = 3.135$, and $\varphi = -10°$. The second set almost coincides with the values obtained in terms of the approximation of axial symmetry, which proves the validity of the approach employed. The values obtained describe satisfactorily the structure of the 4-methyl derivative (LXIX) and of compound (LXXI).[6]

The axes of the bond polarisability ellipsoids may be determined by the joint examination of data derived by two related methods—double refraction and the depolarisation of Rayleigh light scattering—for the same compound. Thus the graphical representation of experimental values of ${}_mK$ and $10^{-3}\ {}_2\delta^2_\infty$ for 2-chloro-1,3,2-dioxaphospholane as a function of the unknown $\gamma_{P-O}$ and $\gamma_{P-Cl}$ showed[6] that the only possible solution, where the ellipse and the straight line intersect, corresponds to the axial position of the chlorine atom with $\gamma_{P-O} = 1.93$ and $\gamma_{P-Cl} = 0.37$ Å$^3$.[6]

The successive application of the methods considered above for the determination of the anisotropy of bond polarisabilities can also lead to satisfactory results. For example, the analytical solution of the system of two equations for the axial and equatorial conformations of 2-chloro-1,3,2-dithiaphosphorinane (CIII), the experimental values ${}_mK = 78$ and ${}_2\delta^2_\infty = 4.6 \times 10^{-3}$ for which were expressed as functions of the unknown $\gamma_{P-S}$ and $\gamma_{P-Cl}$, led to four possible versions: (1) 0.65 and −1.33 and (2) −3.04 and −0.76 Å$^3$ for the axial conformation and (3) 2.97 and 2.18 and (4) −3.97 and −1.84 Å$^3$ respectively for the equatorial conformation. The latter solution is unlikely owing to the high negative values of $\gamma$. The choice from the three remaining solutions (i.e. the determination of the third structural parameter) was made by examining the values of ${}_mK$ for 2-phenyl-1,3,2-dithiaphosphorinane (CIV): the high negative value ${}_mK = -344$ may be obtained in only one case—when the P–Ph bond is axial, $\gamma_{P-S} = 0.65$ Å$^3$, and the plane of the benzene ring is perpendicular to the plane of symmetry of the molecule. Using the average bond polarisabilities (Table 2), it is possible to calculate the components of the polarisability tensor of the P–S bond: $b_L = 3.24$ and $b_T = b_V = 2.59$ Å$^3$; the corresponding values for the P–Cl bond are $b_L = 2.46$ and $b_T = b_V = 3.79$ Å$^3$.

The anisotropies of phosphorus bond polarisabilities in methyl phosphorodichloridite (IV) were calculated for the observed electron-diffraction structure[89] (angle of deviation of the methoxy-group from the *cis*-position $\varphi = 17°$): $\gamma_{P-O} = 1.54$ and $\gamma_{P-Cl} = 1.78$ Å$^3$.[36] The latter value is intermediate between the corresponding parameters for phosphorus trichloride and cyclic phosphoromonochloridites. The P–Cl bond length also varies in parallel with $\gamma_{P-Cl}$.[6] The observed parallel variation may be useful in the determination of the values of $\gamma_{P-Cl}$ for the substituted phosphites $PCl_n(OR)_{3-n}$.[6]

All the facts presented above show that the environment of the phosphorus(III) atom has a marked influence on the system of mobile electrons. This precludes the use of homogeneous electro-optical characteristics even for compounds of the same class but conformationally inhomogeneous. A change in the anisotropy of the phosphorus bond polarisabilities has been observed[6] in 2-chloro-1,3,2-dioxaphospholane and its 4,4,5,5-tetramethyl analogue (LXI). The cause of this is associated with the difference between the conformations: the first compound has the form of an envelope with an axial P–Cl bond and the second has the form of a half-chair; as a result of this, the P–Cl bond length[90,91] and the shielding of the phosphorus nucleus[6] are altered. Thus, phosphorus(III) compounds require a special non-trivial approach, where all the unknown structural and bond parameters are found simultaneously for a series of isoconformational compounds.

The cause of such unusual mobility of the electron cloud of phosphorus(III) has not so far been elucidated, but it is apparently associated with intramolecular interactions. Analogous deviations from the additivity of polarisability for an asymmetric environment have been observed in $\alpha$-chloromethyl ether[92] and methanesulphonyl chloride[3]. The anomalous behaviour of $\alpha$-chloroethers[93] and compounds of Group IV elements with $\alpha$-carbofunctional groups[94] is manifested also in other properties and can be explained by intramolecular coordination of the type of a three-centre bond formed by $\sigma$ electrons (the so called $\alpha$-effect[93]). The involvement of the oxygen LEP creates an excess of $\pi$ electrons at the chlorine atom and the $^{35}Cl$ NQR frequency falls compared with alkyl chlorides. An analogous decrease of frequencies has been observed[86] also for the asymmetric phosphorochloridites $ROPCl_2$ and $(RO)_2PCl$ compared with phosphorus trichloride. The variation of the frequencies and of the P–Cl bond length cannot be explained by the involvement of the vacant *d* orbitals of the phosphorus atom, since this should have led to a deficiency of electrons at the chlorine atom[86].

Other, alternative mechanisms of the observed effect have also been proposed: direct interaction of the geminal atoms in the direction of the field[95] and hyperconjugation of the LEP of the oxygen atom with the C–Cl bond[96]. The possibility of the $\sigma$, $\pi$ conjugation for the phosphorus atom has been discussed recently[97]; it was noted that hyperconjugation with $\sigma$-bonds formed by the elements in the Third Period should be observed. By analogy with pyranoid derivatives, for the axial position of the P–Cl bond the oxygen *p* orbital is disposed in a manner "convenient" for overlapping with the antibonding $\sigma^*$ orbital of the P–Cl bond. This type of delocalisation strengthens the P–O bond and weakens the P–Cl bond. In fact, the P–Cl bond length in 2-chloro-1,3,2-dioxaphosphorinane (2.128 Å) is much greater than in phosphorus trichloride (2.043 Å).[86] The formation of many-centre bonds is also stereospecific and is possible only for the axial conformation. Whatever the mechanism of the observed interaction, it should lead to an increase of the perpendicular component of the polarisability ($b_T = b_V$) of the bond with the chlorine atom: this was observed in phosphorochlorodites, 2-chloro-1,3,2-dithiaphosphorinanes, chloro- and bromoarsenites[99,100], and $\alpha$-chloroethers[92]. The concept of the delocalisation of the LEP of the oxygen atom to the antibonding orbital of the exocyclic bond explains, within the framework of the general theory of molecular orbitals, the anomeric effect[98,101] and the *gauche*-effect[101,102], i.e. the stabilisation of the conformations which were established above for phosphorus(III)-containing heterocycles; the present author therefore believes that this concept is preferable, although it does leave many problems unsolved.

### 3. The Anisotropy of the Polarisability of $P^{III}$–O Bonds.

The above analysis of the bond dipole moments in 2-X-1,3,2-dioxaphosphorinanes showed that the P–O bonds within the ring undergo the greatest changes. The redistribution of electron density should lead to an alteration of the anisotropy of the polarisability. The value $\gamma_{P-O} = -0.59$ Å$^3$, most widely used in the literature, was obtained by Le Fevre[1] on the basis of $_mK$ for the bicyclic phosphite (C), determined in dioxan, but it is inconsistent with the values of $_mK$ for compounds of the 1,3,2-dioxaphosphorinane series. Thus the value of $\gamma_{P-O}$ for 2-chloro-1,3,2-dioxaphosphorinane (2.7 Å$^3$), 2-chloro-1,3,2-dioxaphospholane (1.93 Å$^3$), and methyl phosphorodichloridite (1.54 Å$^3$) were presented in the previous section. The determination of the steric structures (see Section I) of the 2-alkoxy-[84] and 2-phenoxy-derivatives[129] of compound (LXXXIX) and of 2-phenyl-1,3,2-dioxaphosphorinanes (XCIX) makes it possible to calculate the phosphorus bond polarisability eliipsoids. For the axial *gauche*-conformation of the methoxy-group[84], $\gamma_{P-O} = -0.25$ Å$^3$ in compound (LXXXV).[129] The phenoxy-group in compound (XCII) has the axial *cis*-orientation and its benzene ring is arranged at right angles to the plane of symmetry of the molecule[129]; the anisotropies of the exocyclic and ring P–O bond polarisabilities, calculated for this structure, are respectively 2.35 and 3.11 Å$^3$.[129]

The axial orientation of the phenyl group in 5,5-dimethyl-2-phenyl-1,3,2-dioxaphosphorinane (XCIX) was demonstrated in Section III. Such a bulky substituent can occupy the axial position only when the plane of the benzene ring is perpendicular to the plane of symmetry of the molecule (as was found for 2-phenyl-1,3,2-dithiaphosphorinane in Section III, by Martin and Robert[103], and from the analysis of $^1H$ NMR spectra[104] and X-ray diffraction data[105]). When $_mK_{exp} = -298$ is expressed as a function of two unknown parameters, the following relation is obtained:

$$13.43\gamma_{P-O} + 0.78\gamma_{P-C(Ph)} = 26.43,$$

the analysis of which shows that reasonable solutions are possible only for positive values of $\gamma$, $\gamma_{P-O}$ being capable of variation over the very narrow range 1.8–2.0 Å$^3$, whereas the range of the corresponding solutions for $\gamma_{P-C(Ph)}$ is somewhat wider—from 0.6 to 2.9 Å$^3$. A positive value of $\gamma_{P-C_{sp^2}(Ph)}$ is also obtained on the hypothesis that the anisotropies of the $P-C_{sp^3}$ and $P-C_{sp^2}$ bond polarisabilities are close, differing by the exaltation of the total polarisability. The latter is expressed in terms of the difference between the refractions (Table 2). Then $b_L = 3.28$ and $b_T = 0.79$ Å$^3$. The value $\gamma = 2.49$ Å$^3$ obtained appears more reliable than the value calculated by Le Fevre[1] on the basis of the empirical relation between $b_L$ and the bond length ($\gamma = -0.3$ Å$^3$, Table 4).

The data presented show that $\gamma_{P-O}$ is positive in most cases. We may note the similarity of $\gamma_{P-O}$ and $m_{P-O}$ for phenoxy-derivatives and 2-chloro-1,3,2-dioxaphosphorinane, which shows that the electronic interactions are related.

The determination of the anisotropy of the P–O bond polarisability permits the solution of complex conformational problems associated with the determination of several structural parameters, one or two of which vary continuously. In such cases, the combined and successive application of related methods to a series of isoconformational compounds is most effective. This procedure has been partly demonstrated above in the analysis of molecular and bond dipole moments and of the anisotropies of the P–O bond polarisabilities in 2-phenoxy-1,3,2-dioxaphosphorinanes. The last stage in the structural study of such molecules involves the determination of the angle of rotation of the benzene ring, which may be found from the $_mK$ data for compounds (LXXXIX)–(XCI). The calculations were made for the *cis*-axial orientation of the phenoxy-group found above, with the parallel and perpendicular arrangements of the plane of the benzene ring relative to the plane of the $P-O-C_{aryl}$ bonds. The following values were used for the $O-C_6H_4-Br-p$ and $O-C_6H_4-NO_2-p$ fragments: $b_1 = 18.23$, $b_2 = 13.47$, and $b_3 = 9.38$ Å$^3$, calculated from Le Fevre's data[1], and $b_1 = 18.99$, $b_2 = 12.62$, and $b_3 = 7.62$ Å$^3$.[106] The smallest calculated values were obtained for the perpendicular conformation and agree best with experiment.

In phenyl *o*-phenylene phosphites, the structural problem reduces to the determination of the following unknowns: the angle of the non-planarity of the five-membered ring $\Psi$, the position of the exocyclic bond, the angle of rotation relative to the P–O bond $\varphi$, and the angle of rotation of the benzene ring of the phenoxy-group $\theta$, the first and last parameters varying continuously (Fig. 10).

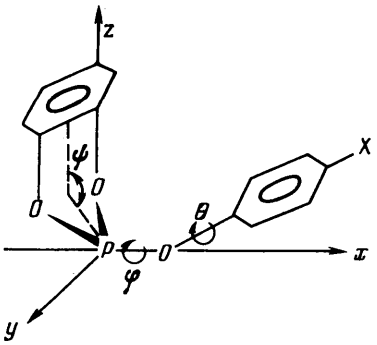

**Figure 10.** Determination of the steric structure of *o*-phenylene phenyl phosphites.

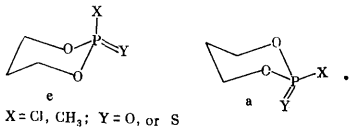

The joint examination of the dipole moment of phenyl *o*-phenylene phosphite (LXVII) itself and of its *p*-bromo- and *p*-methoxy-derivatives permits the determination of the dihedral angle of the bending of the five-membered ring (155°) corresponding to the axial position of the exocyclic bond, and the *gauche*-orientation of the phenoxy-group may be demonstrated[8]. The angle of rotation of the benzene ring was calculated from the Kerr effect data for the observed conformation[8]. The angle was varied from 0° (when the plane of the benzene ring and the plane formed by the P–O–C bonds coincide) to 180° in 30° steps. The positive direction of rotation was assumed to be that in which the position of the aryl group closest to the phosphorus moves away from the oxygen atom. A 35° angle corresponds to the experimental value of ${}_{m}K$. The strong steric interactions in the *oop*-tri-t-butyl derivative (LXVIII) induce a reorientation of the benzene ring: the experimental value of ${}_{m}K$ changes sign [157 for compound (LXVII) and −35.5 for compound (LXVIII)], which corresponds to an additional displacement of the benzene ring from the initial plane: the angle increases to 90°.[8]

## IV. THE STRUCTURES OF FOUR-COORDINATED PHOSPHORUS COMPOUNDS

Since four-coordinated phosphorus forms highly polar and anisotropic bonds (Tables 3 and 4), the dipole moments and the values of ${}_{m}K$ are very sensitive to conformational changes. In view of the necessity to test the validity of and to refine the additive values for phosphorus(IV) bonds, studies were begun on systems which are simple as regards conformation and where the probable number of rotational isomers does not exceed two. 1,3,2-Dioxaphosphorinanes, investigated by a wide variety of physical methods, may be included among them. Comparison of the results of several investigations may serve as a criterion of the validity of the methods of calculation employed. Conformational analysis of heterocyclic molecules is a problem of independent interest—the study of the influence of the nature of the substitutent at the phosphorus atom on the structure of the molecule as a whole.

### 1. Conformational Analysis of Heterocyclic Molecules

Owing to the absence† of rotational isomerism in the exocyclic part of the molecule, the set of the probable conformations of the acid chlorides and methyl derivatives of 1,3,2-dioxaphosphorinanes is reduced to a minimum: there are two chair forms with the axial (a) or equatorial (e) orientations of the P=Y bond:

The existence of conformations other than the chair conformations has not been confirmed by NMR data[107,108]

Table 6 presents the experimental and calculated values (the standard parameters found from the constants ${}_{m}K$ for symmetrically substituted compounds were used for the phosphorus bonds: $\gamma_{P-O} = -0.59$; $\gamma_{P-C} = 1.49$; $\gamma_{P-Cl} = 2.66$ Å$^3$, subject to the conditions that $\gamma_{C-C} = 0.71$ and $\gamma_{C-O} = 0.43$ Å$^3$.[1] We shall compare initially data for the thiono-derivatives (LXXVI) and (LXXVII), on the one hand, and (LXXXI) and (LXXXII), on the other. While the polarities of the acid chlorides (LXXVI) and (LXXVII) are similar, the dipole moments of compounds (LXXXI) and (LXXXII) differ markedly, which indicates a difference between their conformations. The dipole moments and the constants ${}_{m}K$ found for compounds (LXXXII) and (LXXVII) are closest to the values calculated for the chair form with an equatorial thiophosphoryl group (Table 6). The stabilisation of one conformer is possible for the *cis*-configuration of the 4-methyl group and the P=Y bond. The constant ${}_{m}K$ for this structure agrees with the experimental value for compound (LXXXII). The satisfactory agreement confirms the applicability of the additive P–O, P=S, and P–C bond polarisabilities and makes it possible to determine the structure of compound (LXXXI), which exists in the form of an equilibrium mixture of two chair forms, where the conformation with the thiophosphoryl group in the axial position predominates (mole fraction 0.8).

The phosphorochlorothioate (LXXVI) is conformationally homogeneous[111] and, according to dipole moment measurements, has the chair form with an equatorial thiophosphoryl group[30]. However, all the calculated values of ${}_{m}K$ proved to be much lower than the experimental results[30]; for this reason, the effective anisotropy of the P–Cl bond polarisability, determined from the experimental ${}_{m}K$ for this compound ($\gamma_{P-Cl} = -1.31$ Å$^3$), was considered. The value obtained led to the identification of the equatorial conformation (for the P=Y bond) of the 4-methyl analogue (LXXVII) [30] and the phosphorochloridate (LXXV).[29]

In connection with the study of the problem of internal rotation about the O–P bond, it was of greatest interest to investigate compounds symmetrically substituted relative to the phosphorus atom—2-alkoxy-derivatives of

†The rotation of the methyl group does not affect the calculated dipole moment and the constant ${}_{m}K$.

Table 6. The calculated and experimental parameters for 1,3,2-dioxaphosphorinanes with phosphorus(IV).

*(a) represents the axial position of the methyl group at $C_{(4)}$ and (e) represents the corresponding equatorial position.
**In conformity with the analysis of $^1$H NMR spectra [31,109,110], only the equatorial orientation of the methyl group at $C_{(4)}$ was considered for these compounds; (*c*), (*t*), and (*g*) represent calculations for the *cis*-, *trans*-, and *gauche*-conformations of the $OCH_3$ group.

1,3,2-dioxaphosphorinanes. The probability of conformational equilibrium between two chair forms (which would greatly complicate the solution of the conformational problem) was ruled out by the introduction of the 4-methyl group into the ring. Oxidation and addition of sulphur to the *cis*- and *trans*-isomers of 2-methoxy-4-methyl-1,3,2-dioxaphosphorinane yielded two pairs of geometrical isomers of the corresponding phosphates and phosphorothioates, for which the dipole moments and the constants $_mK$ were determined and calculated (Table 6). Joint analysis of the results obtained by spectroscopic methods ($^1$H NMR, infrared, and Raman spectroscopy) and of the dipole moments and the constants $_mK$ made it possible tp identify the structures produced [the multiple bond is in the equatorial and axial positions respectively in the *cis*- and *trans*-isomers of compounds (LXXXV) and (LXXXVII)] and to reach a conclusion about the stereospecificity of the chemical reactions investigated [31].

Earlier studies [29,30] of the Kerr effect in 1,3,2-dioxaphosphorinanes containing phosphorus(IV) were based on a preliminary analysis of the initial bond parameters and, where necessary, effective quantities were considered. The determination of the fundamental characteristics of the steric structures of compounds of this class (the greater tendency towards equilibrium between two chair forms compared with tervalent phosphorus analogues, the dependence of the conformation of the heterocycle on the nature of the exocyclic substituent, and the general nature of the conformational behaviour of compounds with phosphoryl and thiophosphoryl groups) makes it possible to analyse in greater detail the electrical and the electro-optical parameters of the phosphorus bonds. It was noted above that it is necessary to compare for this purpose the corresponding compounds with three- and four-coordinated phosphorus.

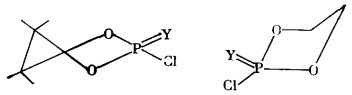
Section III presented the necessary data for 2-X-1,3,2-dioxaphosphorinanes with X = Cl, OAlk, $NR_2$, etc.

On the basis of the polarities of the *cis*- and *trans*-isomers of *cis*-4,6-dimethyl-2-dimethylamino-1,3,2-dioxaphosphorinane and their known steric structures [112], it is possible to determine the polarity of the phosphoryl group: 3.33 and 3.60 D were obtained for its equatorial and axial positions respectively [113].

μ = 5.80 D μ = 4.05 D

The difference between the dipole moments indicates the stereospecificity of the intramolecular interactions: the lower dipole moment of the equatorial phosphoryl group is apparently associated with the more pronounced conjugation between this group and the lone electron pairs of the ring oxygen atoms. Indeed, according to quantum-mechanical calculations, the multiplicity of the equatorial P=Y bond is greater than that of the axial bond [113]. The non-equivalence of the bond dipole moments in the two chair conformations was also noted for 2-methyl-2-thiono-1,3,2-dioxaphosphorinane. [30]

The identification of the conformations of two stereoisomeric 2-hydro-4-methyl-2-oxo-1,3,2-dioxaphosphorinanes (XCIV) and (XCV) [109,110] made it possible to revise the parameters of the polarity and polarisability of the phosphorus bonds [130] and to calculate the previously unknown anisotropy of the P–H bond polarisability, namely $\gamma_{P-H} = -1.1$ Å$^3$. [130]



(XCIV): μ = 5.77 D; $_mK$ = 541; $m_{P=O}$ = 2.95 D, $\gamma_{P=O}$ = 0.81 Å$^3$;
(XCV): μ = 4.19 D; $_mK$ = 160; $m_{P=O}$ = 3.48 D, $\gamma_{P=O}$ = 0.3 Å$^3$.

The values obtained proved useful for the investigation of the steric structures of compounds (XCVI)–(XCVIII), which are involved in a complex conformational equilibrium[127].

Spectroscopic study of the phosphorochloridate (LXXV)[114] and the phosphorochlorothioate (LXXVI) [111], demonstrated their conformational homogeneity; the dipole moments and analysis of the $^1$H NMR spectra indicate a chair conformation with the equatorial position of the double bond. The parameters determined for this structure have the following values: $m_{P=O}$ = 2.40 D, $\gamma_{P=O}$ = 1.34 Å$^3$, $m_{P=S}$ = 2.10 D, and $\gamma_{P=S}$ = 3.06 Å$^3$ (Arshinova et al.[126]) (they differ somewhat from the values quoted by Arbuzov and Arshinova[5], who carried out the calculation on the basis of $\gamma_{P=O}$ and $\gamma_{P-Cl}$ calculated for $_mK$ in dioxan solutions).

The dipole moments and the constants $_mK$ for 2-chloro-2-oxo- and 2-chloro-2-thiono-1,3,2-dioxaphospholanes (LVII)–(LXVI) [126] were analysed on the basis of the results. According to Arshinova et al.[126], the 4,4,5,5-tetramethyl derivatives have the half-chair conformation; for the remaining compounds investigated, the envelope ring conformation, with the carbon atom displaced from the plane of the ring, is believed to be the most probable. The multiple bond is oriented preferentially pseudoaxially:

(LXI), (LXVI) (LVII), (LXII)

Four-membered rings constitute a more complex case for the conformational analysis of heterocycles, since one of the structural parameters (the angle of ring nonplanarity) varies continuously. The dipole moment and the constant $_mK$ for 3-chloro-3-thiono-1,3-thiaphosphetan (XLIX) were calculated as functions of the dihedral ring bending angle $\theta$, which was varied from 120°, when the P=Y bond is arranged pseudoequatorially, to 180°, when the ring is planar, and further to 240°, when the P=Y bond becomes pseudoaxial[24]. Electron diffraction data for the geometry of 3-chloro-3-oxo-1,3-thiaphosphetan were used in the calculation[115] and the parameters found for thietan were used for the C–S bond: 0.86 D; $b_L$ = 2.05; $b_T$ = 1.61 Å$^3$.[116] The experimental dipole moment of compound (XLIX), which is 2.18 D, agrees with the calculated minimum value (2.17–2.20 D) for $\theta$ = 130 to 150°. Joint examination of the dipole moment and the constant $_mK$ shows that the angle is 135°.[24] In the 3-oxo-derivative, the oxygen atom, whose bulk is smaller, may also occupy the pseudoaxial position, which leads to the coexistence of a whole set of conformers. Calculation of the energies of the conformations by Hoffmann's method confirmed this hypothesis[24].

In the corresponding 3-methoxy-1,3-thiaphosphetans (L) and (LI), the conformational problem is complicated owing to the rotational isomerism of the methyl group relative to the P–O bond. The number of possible conformations increases by a factor of three and simple comparison of the calculated and experimental parameters does not allow an unambiguous choice[25]. The procedure involving the joint application of two related methods, proposed by Vereshchagin et al.[116], in which one plots the calculated $_mK$ against the square of the dipole moment, is particularly useful in such situations. The point corresponding to the experimental values defines the required parameters. Fig. 11 illustrates the graphical relations obtained. The positions of the experimental points identify unambiguously the conformations of compound (L) and (LI). Both substances have the same dihedral ring bending angle (135–140°) as the value found for the acid chloride (XLIX) and the pseudoaxial methoxy-groups have the *gauche*-orientation. An analogous structure was found also for the phenoxy-derivatives[25].

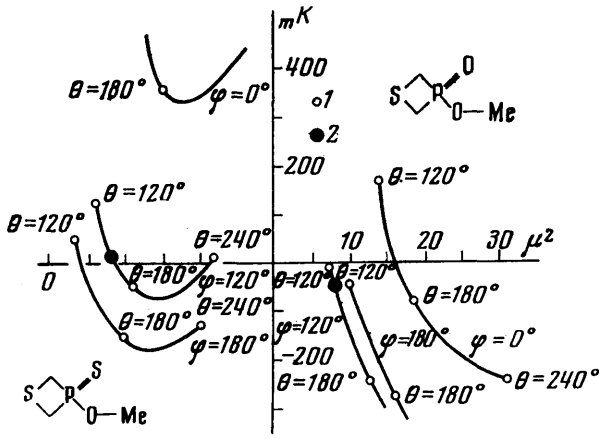


**Figure 11.** Graphical relation between the Kerr constants and the squares of the dipole moments of 3-methoxy-1,3-thiaphosphetans; $\theta$ is the dihedral angle of the nonplanarity of the four-membered ring and $\varphi$ the angle determining the rotation relative to the P–O bond: 1) calculated values; 2) experimental values.

The examples examined show how effective is the joint graphical interpretation of data derived by two related methods. Problems which are insoluble by each method separately can be solved unambiguously by means of a graphical comparison. Other examples If the combined application of physical methods, which lead to new possibilities in the conformational analysis of complex systems, are given below.

## 2. Internal Rotation in Acyclic Compounds

The main difficulty in the employment of the Kerr effect in structural studies on acyclic molecules is due to the uncertainty of the bond parameters. The problem of their selection for compounds which are asymmetrically substituted relative to the phosphorus atom has been analysed[6] in relation to dichloromethylphosphine oxide (XXVI) and sulphide (XXVIII) as examples. In the former case, the dipole moment and the constant $_mK$ can be expressed in terms of the parameters determined for phosphoryl chloride. In the latter case [compound (XXVIII)], there is no additivity and the determination of the bond characteristics requires the use of an additional compound having the same environment at the phosphorus atom but a different direction of the dipole moment. Dichloro-(trichloromethyl)phosphinesulphide (XXIX) has such properties. Joint examination of the constants $_mK$ for both compounds leads to the following values: $\gamma_{P-Cl}$ = 3.12 and $\gamma_{P=S}$ = 4.39 Å$^3$; these differ appreciably from the

values found for symmetrically substituted compounds. We shall therefore consider henceforth substances where the four-coordinated phosphorus atom has the same immediate environment.

The infrared spectra, dipole moments, and the constants $_mK$ of chloromethyldiphenylphosphine (XXII) indicate the existence of two conformers in proportions of 0.9 : 1.[13] Comparison of the dipole moments and the constants $_mK$ with the calculated values makes it possible to identify these structures: *trans*-, *gauche*- ($_mK$ = 55 for the *trans*-disposition relative to the P=O bond and −58 for the *gauche*-disposition, the experimental value being 44). The agreement between the conclusions obtained by the three methods confirms the validity of the chosen model and makes it possible to investigate more complex systems, where one considers the rotation of two irregular groups of the type $CH_3P(O)(CH_2X)_2$ in compounds (XXIII) and (XXIV). These substances are interesting from the standpoint of the observation of the mutual influence of the rotating groups. They have a large number of possible conformations, of which there are six for the *gauche*- and *trans*-dispositions of the bonds. Analysis of the infrared bands in the spectra of crystalline compounds (XXIII) and (XXIV) and their solutions with different dielectric constants of the medium led to the conclusion that two conformers are in thermodynamic equilibrium. On the plot of the square of the dipole moment against $_mK$, the experimental point for compound (XXIII) ($_mK$ = 33.6) corresponds best to equilibrium between the *trans*,*trans*- ($_mK$ = 7.9) and *trans*,*gauche*-forms (the calculated value for the latter is 101 and 122 respectively for the clockwise or anticlockwise 60° rotation of the C–C bond relative to the eclipsed position) (Fig. 12)[14]. The replacement of chlorine atoms by bromine in the halogenomethyl groups led to an appreciable alteration of the preferred conformations: the conformer with the *trans*-orientation of the C–Br bond was displaced from the equilibrium. The *trans*,*gauche*-form ($_mK$ = 1.67), which exists in equilibrium with the *gauche*,*gauche*-form ($_mK$ = −240) is the most stable; the experimental values is 74.[15]

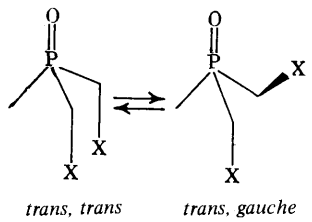

**Figure 12.** The preferred conformations of acyclic molecules.

The much more complex case of the rotation of three irregular halogenomethyl groups was investigated in relation to the trihalogenomethylphosphine oxides (XXI) and (XXV). When the eclipsed forms are excluded, the number of conformers is seven. The combined application of the data obtained by several physical methods (infrared spectroscopy, dipole moment measurements, and the Kerr effect) for dihalogenomethyl derivatives showed[12,15] that the replacement of the halogen also alters the composition of the conformational equilibrium mixture. Whereas the proportions of the *trans*, *trans*, *trans*- and *gauche*, *gauche*, *gauche*-forms are 0.8 : 0.2 for X = Cl,[12] in the case of the bromo-derivative the first of these forms is displaced from equilibrium and the *trans*, *trans*, *gauche*-conformer predominates[15].

The problem of the internal rotation about the P-heteroatom bonds is of interest as regards conformations. The greatest number of studies have been concerned with the P–O bond, despite the fact that the nature of the potential energy curve for this bond has still not been finally established. As mentioned above, the study of the structures of the methyl phosphinate esters (L) and (LI) and of their structural analogues with the phenyl group led to the conclusion that only the *gauche*-conformer in relation to the phosphoryl or thiophosphoryl linkage exists. The *gauche*-orientation of the methoxy-group has been established for the *cis*-isomers of 1,3-butylene phosphates (LXXXIII) and phosphorothioates (LXXXV)[31] (Table 6). In all the cases quoted, the alkoxy-group occupies the axial position, where the steric interaction with hydrogen atoms may constitute a significant obstacle to the realisation of the conformation which is more stable from the standpoint of the electronic properties. Indeed, for the equatorial orientation of the P–OR group in the corresponding *trans*-isomers of compounds (LXXXIV) and (LXXXVI), conformational equilibrium between the *trans*- and *gauche*-forms was observed (Table 6). The equilibrium was confirmed by infrared and Raman spectra[31]. In five-membered rings, the steric interactions of the exocyclic P–OR bond with the remainder of the molecule may be greatly reduced owing to the planar structure of the 1,3,2-dioxaphospholen[117,118] or phospholen[49] ring or, in the case of the envelope conformation, of the 1,3,2-dioxaphospholan ring with the carbon atom at the apex[119]. This also leads to the *trans*-orientation being greatly preferred.

Among acyclic molecules, the trialkyl phosphates (X), (XV), and (XVII), whose dipole moment spectra and, for the last two compounds, also the constants $_mK$ have been investigated[9,10], are closest to the systems investigated. Graphical comparison of the squares of the dipole moments and the constants $_mK$ for compound (XVII), taking into account the populations of the conformations known from the infrared spectra, showed that the *gauche*, *gauche*, *cis*-form predominates in the conformational equilibrium[9]. This conclusion is disputed by Egorov et al.[50], whose analysis of the dipole moments led to the detection of the equilibrium between the *trans*, *trans*, *gauche*- and *trans*, *trans*, *trans*-conformers, the dipole moments being calculated from the bond dipole moments, which have been criticised[10]. The conclusion reached by Raevskii et al.[9] also appears unlikely. It is didficult to imagine an equilibrium mixture of *cis*, and *gauche*-forms, between which there is no energy barrier according to quantum-mechanical calculations[120–122]. It is more correct to consider intermediate forms with a torsional angle ranging from 120° (*gauche*) to 180° (*cis*) and further to 240° (*gauche*) in the "cisoid" conformations. Instead of the formal sixteen structures, one can then postulate six. After revising the structure of trialkyl phosphorothioates from these standpoints, the authors[10] concluded that the conformer with the cisoid or *gauche*-disposition of all the OR groups predominates in the thermodynamic equilibrium between the conformers of compound (XVII). The *gauche*,*gauche*, *gauche*-conformer of compound (XV) is fully stabilised.

3. The Conjugation Effects

Measurements of Kerr constants and light scattering constitute a unique procedure for the investigation of the rotation of the plane of the benzene ring relative to the element–phenyl bond. On the basis of data derived by these two methods, it is possible to determine reliably the conformations of aromatic compounds in solutions, since the anisotropy of the polarisability of the phenyl group is very large [1–3]. At the phosphorus atom, the conjugations with the lone electron pair, the multiple bond, or the vacant *d* orbitals have different stereospecificities so that the solution of this type of conformational problem yields directly information about the strength and nature of the possible conjugation effects, which are determined by the orientation of the aryl groups.

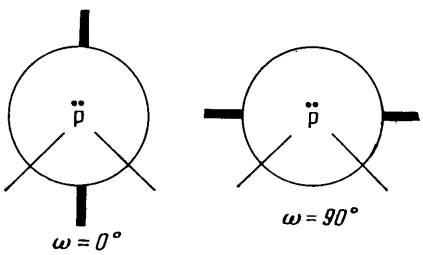

**Figure 13.** The rotation of the benzene ring relative to the Ph–P bond.

In this sense, monoaryl derivatives are of greatest interest, since additional aromatic groups at the phosphorus atom can lead to the steric repulsion of the substituents in the *o*-positions of the aryl groups. It was shown above for 2-phenyl-1,3,2-dioxaphosphorinane (XCIX) and 2-phenyl-1,3,2-dithiaphosphorinane (CIV) that the most preferred conformation is one where the plane of the benzene ring is perpendicular to the plane of symmetry of the molecule ($\omega = 90°$ in Fig. 13), but the *syn*-axial interactions [the 2-phenyl groups in compounds (XCIX) and (CIV) are arranged axially] prevents the realisation of the alternative conformation, so that it is desirable to examine less sterically overloaded molecules of the type $PX_2Ph$ and their oxides. Such phosphines [compounds (XXXI)–(XXXV) and (XLIV)–(XLVI)] have been investigated [18,19]. In the calculation for the $C_{sp^2}$–P bond, the value $\gamma = -0.3$ Å$^3$, obtained by a semiempirical method, was used. For the two conformations with $\omega = 0$ and 90°, the authors [18,19] obtained the following values of the Kerr constant (the values of $10^{11}{}_mK_{0°}$, $10^{11}{}_mK_{90°}$, $10^{11}{}_mK_{exp}$ are quoted): 3, −4, and 1 for (XXI); 4, −3, and 5 ± 2 for (XXXII); 96, 90, and 132 for (XXXIII); 6, −8, and 2 for (XXXIV); 7, −17, and 10 ± 3 for (XXXV); 33.4, −73.8, and 30 for the oxide (XLIV); 24.2, −85.9, and 24.9 for the oxide (XLV); 35.3, −46.7, and 44.4 for the oxide (XLVI). In all cases the plane of the benzene ring coincides, according to these data, with bisector of the RPR angle ($\omega = 0°$) and the LEP of phosphorus(III) or the phosphoryl group in the case of phosphine oxides is thus coplanar with the benzene ring, which rules out the possibility of the $p-\pi$ interaction with the LEP. We may note that the conformation with $\omega = 0°$ differs in principal from the conformation of dimethylaniline [123] and its derivatives, where the molecule is a flattened pyramid and $\omega = 90°$. *p*-Aminobenzoic acid has a similar structure [124]. The change in the conjugation of the aromatic system with the LEP of phosphorus(III) and nitrogen(III) may play a definite role in the alteration of the conformations of the phenyl derivatives of these elements. According to Raevskii et al.[18], the energy of the $p-\pi$ conjugation in phosphorus(III) compounds is insignificant owing to the considerable amount of *s* character of the phosphorus(III) LEP orbital and cannot compete with the energy of the steric interactions between the hydrogen atoms of the phenyl group and the substituents at the phosphorus atom.

When two aryl groups are present, the *o*-hydrogen atoms in the observed bisector conformation, located within the pyramid, approach one another and suffer steric repulsion, so that there is a possibility of the displacement of the two aromatic rings from the plane. Having adopted an initial situation in which the plane of each aryl group is perpendicular to the $C_{sp^2}$–P–$C_{sp^2}$ plane and having analysed the graphical relation between ${}_mK$ and the angles of rotation of the phenyl groups, the authors [22] concluded that the conformation of the molecules of compounds (XLI)–(XLIII) is close to that where each aromatic ring is perpendicular to the $C_{sp^2}$–P–$C_{sp^2}$ plane, with a possible deivation up to 15° in the direction leading to the eclipsing of the phosphoryl group. The occurrence of the bisector conformation ($\omega = 32°$) is hindered by the strong steric interaction between the inner *o*-hydrogen atoms.

The steric repulsion of the *o*-hydrogen atoms within the pyramid increases by a factor of three on passing to the triaryl derivatives, so that one may expect an even greater twisting of the molecules. The symmetrically substituted triphenylphosphine (XXX), its oxide (XXXVI), and its sulphide (XLII) were investigated for the first time by Le Fevre [17,20], but the constants ${}_mK$ were determined in benzene. Since the subsequent measurement of ${}_mK$ for compound (XXXVI) in carbon tetrachloride [21] led to significantly different results, we shall consider only the latter study. Comparison of the experimental ${}_mK$ and the values calculated assuming $C_3$ symmetry for compounds (XXXVI)–(XL) yielded the following angles of rotation of the benzene ring: 55°, 65°, 49°, 60°, and 52° respectively. According to the authors [21], the introduction of substituents such as the chlorine atom of the methyl group causes flattening, which may be accounted for by the conjugation of the aromatic rings with the phosphorus *d* orbitals; the influence of the direct polar conjugation with the phosphoryl group is significant in *p*-chloro-derivatives.

The Kerr effect method may be useful in the study of the steric and electronic structures of organophosphorus compounds. The joint application of the Kerr effect and other physical methods is particularly promising, gives rise to wide possibilities, and makes it possible to investigate complex conformational problems associated with the determination of several unknown parameters. The combined use of several methods permitted systematic and specific investigations of the influence of the nature of substituents at the phosphorus atom on the conformation of the molecule and of the nature of the hindered rotation relative to the P–O, P–C, P–Ph, etc. bonds in compounds of three- and four-coordinated phosphorus.

Organophosphorus compounds, which are distinguished by a wide variety of intramolecular interactions, are excellent objects for the investigation of such interactions by electro-optical methods. The graphical isoelectric and isoanisotropic map methods make it possible to

estimate quantitatively the electron redistributions occurring in the molecules being compared and hence provide a justification for conclusions concerning the nature, magnitude, and direction of the electronic effects. The conclusion concerning the extreme electronic lability of phosphorus(III) compounds, which makes it virtually impossible to employ the usual additive scheme in calculations on asymmetrically substituted compounds, is of interest in this sense.

The determination of the additive bond characteristics and the development of methods for their determination permit the study of systems where the phosphorus atom has a different coordination. Compounds of five-coordinated phosphorus and heteroaromatic systems are of special interest for the investigation of steric and electronic structures. The different coordination causes a radical alteration of the nature of the intramolecular interactions [with the phosphorus(III) lone electron pair, with the multiple bonds involving phosphorus(II) and phosphorus(IV), and with the *d* orbitals of phosphurus(V)], so that comparison of the conformations and internal rotations for identical phosphorus bonds in the $P^{III}$–$P^{IV}$–$P^{V}$ series (and in certain cases also for $P^{II}$ and $P^{VI}$) leads to the prospect of the direct investigation of the influence of intramolecular interactions on molecular conformation.

Simultaneous examination of the electrical and electro-optical properties of conjugated and heteroaromatic phosphorus compounds permits the determination of the nature of the distribution of electron density and of the direction of the exaltation of polarisability induced by the introduction of the phosphorus atom. Such studies have been carried out for pyridine and its derivatives[125]. Comparison with phosphorus-containing analogues will make it possible to investigate the conjugation problem in detail.

Further development of research on the application of the Kerr effect to organophosphorus compounds will involve the formulation in greater detail and extension of the additive system of bond and group polarities and polarisabilities. The lack of rigorously tested parameters for many phosphorus bonds is a serious obstacle. The creation of new methods and the development of earlier non-trivial methods for the simultaneous determination of bond and structural characteristics should be of great assistance.

# Kinetics of the Hydrolysis of Phosphate Esters

V.E.Bel'skii

The available information about the kinetics of the hydrolysis of phosphate esters in neutral, alkaline, and acidic media is considered and the mechanisms of the hydrolysis of various reactive forms of mono-, di-, and tri-esters are discussed. A systematic account is given of the rate constants, taking into account the type of ester and its reactive form.
The bibliography includes 106 references.

I. Introduction 828
II. Fundamental data on the mechanisms of the hydrolysis of P-O-C ester linkages 828
III. Kinetics of the hydrolysis of phosphate esters 828

## I. INTRODUCTION

Quantitative data on the reactivities of the labile P-O-C ester linkages, which are frequently encountered in various organophosphorus compounds, are of intersst for a number of scientific disciplines. The hydrolytic reactions of phosphate esters have been the subject of vigorous kinetic studies in view of their extensive practical applications in engineering, agriculture, and medicine, and the growing interest of investigators in the mechanisms of biochemical processes in which individual phosphate esters play an important role.

The reactivity of ester linkages involving the phosphorus atom can vary within very wide limits (by a factor greater than $10^{10}$) and it is therefore often necessary to estimate it *a priori*. Theoretical methods for the estimation of the reaction rate constants have not has yet been adequately developed and one therefore usually employs empirical correlations based on the principle of linear relations between the free energies of various chemical processes. It is important to arrange systematically the results accumulated and to express them in a form convenient for analytical research.

## II. FUNDAMENTAL DATA ON THE MECHANISMS OF THE HYDROLYSIS OF P-O-C ESTER LINKAGES

The mechanisms of reactions involving nucleophilic substitution at the phosphorus atom, including the hydrolysis of ester linkages, have been frequently discussed[1-8]. Under certain conditions, there is a possibility of monomolecular heterolytic cleavage of the bond between phosphorus and the group to be eliminated ($S_N1P$ mechanism) and of bimolecular substitution with attack by the nucleophile on phosphorus in the rate-determining stage of the reaction ($S_N2P$ mechanism). Nucleophilic substitution reactions involving phosphorus acid esters can also take place at the carbon atom of the ester linkage.

The anionic forms of phosphate monoesters[9-11] and monoacyl phosphates[12,13] are hydrolysed via the $S_N1P$ mechanism. The metaphosphate ion, formed in the hydrolysis of such compounds, is unstable owing to its coordination unsaturation and is rapidly hydrated. The $S_N2P$ mechanism is more common. Studies of the hydrolysis of certain cyclic esters of phosphorus acids have shown that it proceeds as described by Westheimer[6]. The formation of a bond between phosphorus and the attacking nucleophile leads to five-coordinated phosphorus in the transition state, the structure of which may be represented by a trigonal bipyramid with the axial disposition of the eliminated and introduced groups. This geometry is supported by data for the molecular structures of five-coordinated phosphorus compounds, in which the axial bonds are longer and weaker than the equatorial bonds[14,15].

Westheimer[6,16] discussed the possibility of the existence of a relatively unstable intermediate compound with five-coordinated phosphorus in the hydrolysis of cyclic phosphates. Rapid exchange of ligands between the axial and equatorial positions in the intermediate via the pseudorotation of the bipyramid could ensure the simultaneous cleavage of the endo- and exo-cyclic ester linkages, which has been observed experimentally.

Bimolecular substitution of the $S_N2P$ type is also characteristic of the alkaline hydrolysis of many phosphorus acid esters. In neutral and acidic media, the POAlk linkages are frequently hydrolysed with the cleavage of the C-O bond (via the $S_N2$ or $S_N1$ mechanism) at the carbon atom of the alkoxy-group[7,8,17-19].

The hydrolysis of partly esterified phosphoric acid may be complicated by the involvement in the mechanism of various ionic forms of the substrate. At different pH, the monoesters exist in the form of the dianions $ROPO_3^{2-}$, the monoanions $ROPO_3H^-$, the neutral molecules $ROP(O).(OH)_2$, and the protonated form $ROP(OH)_3^+$. The considerable differences between the successive dissociation constants of these species are responsible for the preferential existence of only one or two of them at a fixed pH of the medium. Because of this, only some of the many possible reaction pathways actually occur under specific conditions. The displacement of the ionisation equilibria as the pH is altered changes the reactive species and frequently the reaction mechanism.

## III. KINETICS OF THE HYDROLYSIS OF PHOSPHATE ESTERS

The kinetics and mechanisms of the hydrolysis of phosphate esters, higher polyphosphates, and mixed anhydrides, such as acetyl phosphate, have been examined in a review[7] devoted mainly to the hydrolysis of polyphosphates; earlier results are described in other communications[5,8]. The existence of three series of phosphate esters—the monoesters $ROPO_3H_2$, the diesters $(RO)_2PO_2H$, and triesters $(RO)_3PO$—as well as their

different ionic species differing in the degree of protonation necessitated a systematic arrangement in groups of the available kinetic data in terms of the type of ester and its reactive form. Each group may include data for esters reccting via different mechanisms. In some cases, the observed rate constant may be a compound quantity reflecting the overall rate of reaction proceeding via two or more parallel mechanisms.

## 1. Hydrolysis of Phosphate Monoesters

Phosphate monoesters are dibasic acids with $pK_{a1} = 1$ to 2 and $pK_{a2} = 6-7$.[3,9] As mentioned above, the monoesters can exist in four forms differing in the charge and degree of protonation. For each of them, it is possible to postulate hydrolytic mechanisms involving nucleophilic attack by a water molecule on the phosphorus atom or the carbon of the ester linkage and monomolecular heterolysis with the cleavage of the bond at the phosphorus or carbon atom. The site of cleavage of the bond during the reaction can be reliably determined by an isotope method and a conclusion may be reached concerning the mechanism on the basis of kinetic data. The variation of the observed rate constant with the acidity of the medium is due to the influence of the latter on the relative contents of the different monoester species; for this reason, the involvement of the individual species in the reaction mechanisms is elucidated by analysing the dependence of the effective rate constant on pH. According to the data in Ingold's book[20], studies on the influence of the pH of the medium on the rate of hydrolysis of monoalkyl phosphates began at the end of the past century.

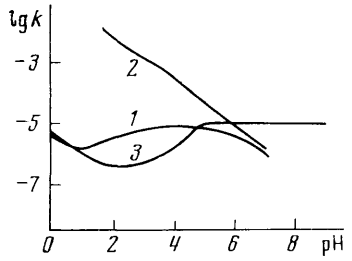

Figure 1. Dependence of lg $k$ on the pH of the medium in the hydrolysis of monoesters: 1) $C_2H_5OP(O)(OH)_2$ at 100°C [21]; 2) t-$C_4H_9OP(O)(OH)_2$ at 74°C [29]; 3) 2,4-$(NO_2)_2$. .$C_6H_3OP(O)(OH)_2$ at 25°C.[10]

The type of dependence of the rate constant for the hydrolysis of monoesters on pH encountered most frequently is described by curve *1* in Fig. 1. The rate of reaction $dc/dt$ depends only on the concentration of the monoanions over a wide range of pH:

$$\frac{dc}{dt} = k[ROPO_3H^-] = kc\frac{K_1[H^+]}{[H^+]^2 + K_1[H^+] + K_1K_2},$$

where $c$ is the overall concentration of the monoester in solution:

$$c = [ROPO_3^{2-}] + [ROPO_3H^-] + [ROP(O)(OH)_2];$$

$K_1$ and $K_2$ are the first and second ionisation constants of the monoester. The rate constant passes through a maximum at $pH = (pK_1 + pK_2)/2$, where the relative content of the monoanion is a maximum, which indicates a much higher reactivity of the monoanion compared with the dianion and the neutral molecule. Plots of the rate of hydrolysis against pH have been investigated for a series of monoalkyl and monoaryl phosphates[9,10,21-27,31-36]. The rate maximum in the pH range 3–5 has been observed for many monoesters, but such behaviour is not general. On the other hand, when the neutral molecule is more reactive than the monoanion, the rate constant increases monotonically with decrease of pH (curve *2*). Relations of this kind are characteristic of the monoesters which hydrolyse with the cleavage of the C–O bond via the $S_N1$ mechanism with formation of a carbonium ion[28-30], and also of certain monoacyl phosphates[12,13]. The dependence of the rate of hydrolysis of highly reactive monoaryl and acyl phosphates on pH is described by curve *3* in Fig. 1. A higher reactivity of the dianion compared with that of the monoanion corresponds to this type of dependence. For all three types of relation, the rate constants increase on passing to highly acidic media as a result of acid hydrolysis. The protonated form of the monoester is involved in the latter.

Detailed information is now available about the site of the dissociation of the bond in the hydrolysis of phosphate monoesters with participation of different reactive species. The cleavage of the bonds at the phosphorus atom has been demonstrated on many examples for monoaryl phosphates reacting as the monoanions[25], the dianions[11,39,40], the neutral molecules[25], and the protonated forms[25]. The bond at the phosphorus atom is also dissociated in the monoanions of alkyl phosphates[23,29,32,34,41], except for the t-butyl ester in which the C–O bond is partly cleaved[28].

The hydrolysis of neutral monoalkyl phosphate molecules proceeds with the rupture of the C–O bond, as shown for methyl phosphate[23] and t-butyl phosphate[28]. In the acid hydrolysis of monomethyl and monoethyl phosphates, simultaneous cleavage of the bonds at the phosphorus and carbon atoms takes place[23,32], while in the hydrolysis of the isopropyl and t-butyl esters, the C–O bonds are ruptured exclusively[28,32].

The rate of hydrolysis of many phosphate monoesters is very low at the usual temperatures and in many studies the kinetics have been investigated at 100°C. We adjusted some of the constants in Table 1 to these conditions on the basis of the temperature relations. The rate constants for the monoanions of many monoalkyl phosphates increase after the introduction of electron-accepting substituents in the alkyl group. A similar effect has been observed also for the monoanions of monoaryl phosphates. An exception is provided by the data quoted in the paper of Mhala et al.[38] The rate constants for the hydrolysis of the monoanions of aryl and acyl phosphates are higher by 1.5–2 orders of magnitude than the corresponding values for the monoanions of alkyl phosphates. This is probably due to the favourable role of the resonance interaction of the ester oxygen with the benzene ring or the carbonyl group, which may compete with the effect of the $p\pi - d\pi$ conjugation between oxygen and phosphorus, which weakens the P–O bond ruptured in the reaction.

The inductive effect of the electron-accepting groups and the resonance delocalisation of the lone electron pairs of the ester oxygen atom must have an unfavourable influence on the proton transfer to the group being eliminated, which is believed[5,9,11] to facilitate the rupture of the P–O bond in the monoanions. Since the rate constants actually increase as the basic properties of the ester oxygen are reduced, the variation of another factor, which more than compensates for the decrease of the basicity of the oxygen,

is probably responsible for the increase of the reactivity. This factor may be the decrease of the energy of the ruptured bond. Owing to the opposed effects of these factors, whose influences on the reactivity are not comparable in magnitude, the dependence of the rate constants on the nature of the groups eliminated is weakened, which is confirmed when the slopes of the lg $k$–p$K_a$ relations are compared for the monoanions and dianions[9,11]. In the dianions, there is no proton transfer to the eliminated group and the reactivity is determined solely by the bond energy. For the monoanions of aryl and alkyl phosphates, the dependence of lg $k$ on the p$K_a$ of the eliminated group is characterised by a slope several times smaller than the slopes of the corresponding relation for the dianions of aryl and acyl phosphates[11].

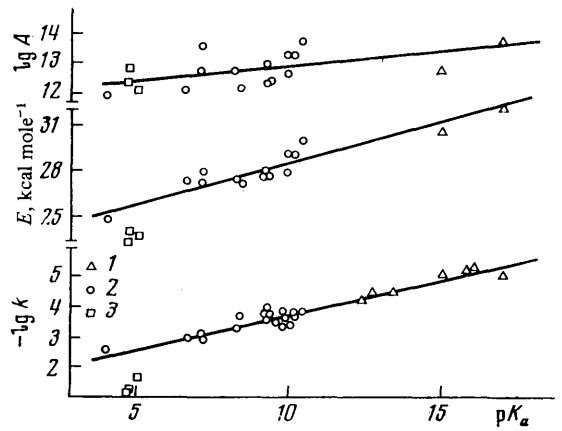

Figure 2. Dependence of the parameters lg $k$, $E$, and lg $A$ for the hydrolysis of the monoester monoanions at 100°C on the p$K_a$ of the eliminated group. The p$K_a$ values were taken from Refs. 9 and 11, the sources indicated therein, and from Refs. 46–49: 1) alkyl phosphates; 2) aryl phosphates; 3) acyl phosphates.

Fig. 2 illustrates the variation of lg $k$ with p$K_a$ for monoanions, expressed by the equation†

$$\lg k = -0.23pK_a - 1.38 \quad (n = 25;\ r = 0.97;\ s = 0.2),$$

which differs only slightly from that quoted by Kirby and Varvoglis[11]. With decrease of the p$K_a$ of the eliminated group, the rate constant for the hydrolysis of monoanions increases and the activation energy $E$ and the pre-exponential factor diminish (Fig. 2). Hence it follows that the reactivity increases owing to the decrease of $E$. The very low values of $E$ and lg $A$ quoted by Mhala et al.[38] for the monoanions of 4-bromophenyl and 2-methoxyphenyl phosphates do not fit on the plots of $E$ and lg $A$ against p$K_a$ in Fig. 2, in contrast to the remaining data. The markedly higher reactivity of the monoanions of acyl phosphates is due to the additional decrease of $E$ compared with the value expected from the plot of $E$ against p$K_a$.

†Here and henceforth $n$ is the number of compounds, $r$ the correlation coefficient, and $s$ the standard deviation.

The higher reactivity of the monoanions of acyl phosphates is probably associated with the unusual mechanism of their hydrolysis. A proton may be transferred to the oxygen of the carbonyl group and not to the anhydride oxygen[12]. The mechanism established for the monoanions of certain carbamoyl phosphates, which are hydrolysed with the cleavage of the C–O bonds, is more significantly different[50].

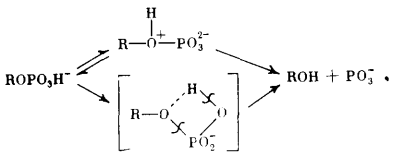

Table 1. The rate constants for the hydrolysis of phosphate monoester monoanions $ROPO_3H^-$ at 100°C and the parameters of the equation $k = A\exp(-E/RT)$.

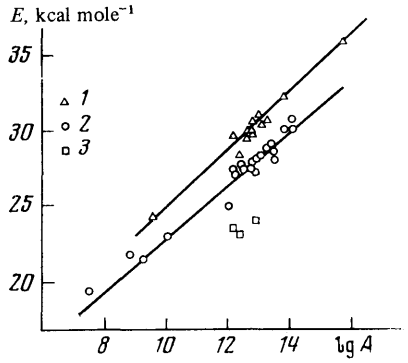
[a]These values were calculated by the author of the review from data in the studies quoted.
[b]According to Bunton et al.[9], $k = 302 \times 10^6$ $s^{-1}$ at 100°C.

High activation energies are characteristic of almost all the monoanions investigated. Estimates of the activation entropies from the pre-exponential factors listed in Table 1 yield in most cases $\Delta S^{\neq} \simeq 0 \pm 5$ cal mole$^{-1}$ k$^{-1}$,

in agreement with the monomolecular $S_N1P$ mechanism of the rate-limiting stage of the hydrolytic reaction. A proton may be transferred to the eliminated group either in the rapid pre-equilibrium process or synchronously with the dissociation of the bond at the phosphorus atom[11]:

Nor can one exclude the possibility of the involvement of a water molecule in the proton transfer[41]. The six-membered ring formed in the reaction with participation of water may be less strained than the four-membered ring without water.

The small kinetic isotope effect in the hydrolysis of the monoanion of methyl phosphate ($k_{H_2O}/k_{D_2O} = 0.87$)[23] shows that in alkyl esters the proton transfer occurs in the pre-equilibrium stage and not in the rate-limiting stage. However, for highly reactive monoanions, the situation may change in favour of the mechanism with the synchronous proton transfer. In particular, this is indicated by the much greater isotope effect in the hydrolysis of the monoanion of 2,4-dinitrophenyl phosphate ($k_{H_2O}/k_{D_2O} = 1.45$).[11]



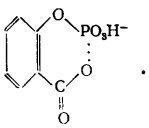


Figure 3. Relation between $E$ and $\lg A$ for the hydrolysis of monoester monoanions: 1) alkyl phosphates; 2) aryl phosphates; 3) acyl phosphates.

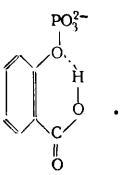

The parameters of the Arrhenius equation $E$ and $\lg A$ for the monoanions of alkyl phosphates tend to cancel out, which has also been noted for aryl phosphates (Fig. 3). There is no general relation between $E$ and $\lg A$ for alkyl and aryl phosphates, although they fit on a single straight line in the plot of $\lg k$ against $pK_a$. Possibly a unique line is obtained only approximately owing to the similarity of the influence of the conjugation effect on the ionisation of phenols and the reaction under consideration.

The metaphosphate ion formed on cleavage of the bond in the monoanions is rapidly hydrated, which hinders the demonstration of its formation. At low water concentrations in the reaction medium, the hydration is accompanied by the polymerisation of the metaphosphate ions; the formation of trimetaphosphate has been demonstrated in the hydrolysis of a concentrated solution of potassium monophenyl phosphate[51]. Attempts have been made at an indirect confirmation of the formation of the metaphosphate ion by studying the composition of the solvolysis products of monoesters in aqueous alcoholic media[5,8]. It was assumed that the metaphosphate ion reacts non-selectively with water and alcohol, giving a product ratio corresponding to the composition of the aqueous alcoholic medium. However, the metaphosphate ion formed on hydrolysis in many cases reacted preferentially with alcohol, which may be due to the selective solvation by one of the components of the solvent of the substrate and of the metaphosphate ions formed[5,11].

In the hydrolysis of certain monoanions, intramolecular catalysis was observed in some cases. The monoanions of *o*-carboxyphenyl and *o*-carboxynaphthyl phosphates are particularly reactive[26,52]. For example, $E = 24.1$ and $\lg A = 12.97$ for the monoanion of salicyl phosphate[52], so that the rate constant at 100°C is $7.1 \times 10^{-2}$ s$^{-1}$. This value is approximately 200 times greater than the *m*- and *p*-carboxyphenyl phosphates and higher than all the constants quoted in Table 1. To explain the exceptionally high rate of hydrolysis of the monoanions of salicyl phosphate and similar esters, the authors suggested[26,52] intramolecular nucleophilic catalysis by the carboxylate group with the possible formation of an acyl phosphate as an intermediate:

Bender and Lawlor later showed[53] that the acyl phosphate cannot be an intermediate owing to the relatively low rate of hydrolysis and pointed out the possibility of intramolecular acid catalysis in the hydrolysis of salicyl phosphate and similar esters:

The intramolecular catalysis by the hydroxy-group, demonstrated for the monoanions of 8-hydroxy-1-naphthyl phosphate[53] and 3-hydroxy-2-pyridylmethyl phosphate[54], involves a similar mechanism. Catalysis by the $N^+$–H group has been demonstrated for 2-pyridylmethyl and 2-pyridylethyl phosphates[55].

At high pH values, phosphate monoesters exist as doubly charged anions. The reactivity of the dianions of monoalkyl phosphates is extremely low and for this reason there are virtually no kinetic data for such species. The dianions of aryl phosphates are more reactive than their alkyl analogues. As for the monoanions, the rate of reaction increases in the presence of electron-accepting substituents in the eliminated group. Comparison of the data in Tables 1 and 2 shows that the activation energy as well as the pre-exponential factor for the hydrolysis of the dianions are as a rule higher than for the monoanions.

The estimation of the values of $\Delta S^{\neq}$ from the data presented in Table 2 shows that they are positive in all cases. In this connection, a monomolecular mechanism has been proposed[10-12] for the rate-limiting stage of the hydrolysis of the dianions:

$$ROPO_3^{2-} \rightarrow PO_3^- + RO^- .$$

The alternative hypothesis, according to which the mechanism can be regarded as involving a bimolecular reaction between the hydroxide ion and the monoanion of the monoester, was disproved[10,11], because it would necessitate the assumption of an unrealistically high rate constant for the latter process. The rate-limiting stage does not include proton transfer from the solvent, as shown by the absence of a kinetic isotope effect in the hydrolysis of the dianion of 2,4-dinitrophenyl phosphate[11]. The high slope of the relation between lg $k$ and the p$K_a$ for the eliminated group is consistent with an $S_N1P$ reaction mechanism[9,11]. According to the data in Table 2, this relation (at 100°C) is described by the following equation for the dianions of aryl phosphates:

$$\lg k = -1{,}01\ pK_a + 3.15 \quad (n = 10,\ r = 0{,}991,\ s = 0{,}3)$$

bThe rate constants in 1 $N$ NaOH solution are quoted.

A similar slope (−1.23) has been found (at 39°C) for the dianions of aryl and acyl phosphates[11]. Comparison with the analogous relation for the monoanions shows that, for p$K_a$ < 5.8, the dianions are more reactive than the monoanions, as mentioned previously[11].

The dianion of salicyl phosphate 2-$(CO_2^-)C_6H_4OPO_3^{2-}$ hydrolyses approximately 500 times faster than the dianions of $m$- and $p$-carboxyphenyl phosphates[35]. This is probably due to the intramolecular nucleophilic catalysis by the carboxylate anion, postulated initially for the hydrolysis of the monoanion of salicyl phosphate[26,52]. Intramolecular catalysis by the hydroxyl has been observed in the hydrolysis of the dianion of 3-hydroxy-2-pyridylmethyl phosphate[54]. The hydrolysis of the dianion of glucose-6-phosphate[37] can apparently also be accelerated as a result of the intramolecular catalysis by the OH group.

At pH < 1, the ionisation of the acid groups of the monoesters is suppressed and they exist predominantly in the neutral form $ROP(O)(OH)_2$, which is usually unreactive. For monoalkyl phosphates, which are incapable of undergoing the cleavage of the C–O bond via the formation of a carbonium or a hydroxycarbonium ion, the dependence of the reaction rate constant on pH has a minimum in the pH range 0–1.[22-24] Owing to the low reactivity of the neutral form compared with the monoanion and the protonated form, the hydrolysis in this region is frequently represented by the sum of the reactions involving the monoanions and the neutral and protonated forms, which complicates the estimation of the reactivity of the neutral monoester molecules. The simplest example is provided by the hydrolysis of phenyl and $p$-cresyl phosphates, for which the absence of acid catalysts has been suggested because of the insignificant change in the reaction rate constant in $HClO_4$ solutions. The rate constant was attributed (after subtracting the contribution due to the monoanion) to the reaction proceeding via the neutral form[25]. For many substituted aryl phosphates, acid catalysts begins to be manifested in the region where the monoanion makes a large contribution to the overall reaction and a reliable estimate of the reactivity of the neutral molecules becomes impossible[9,10].

aSee footnote to Table 1.

Table 3 lists the rate constants for the hydrolysis of the neutral molecules of certain monoesters. It is noteworthy that the neutral molecules of monoalkyl and monoaryl phosphates react via different mechanisms. Alkyl phosphates are involved in reactions of the $S_N2$ and $S_N1$ type at the carbon atom[5,23,28-30,32], while in aryl phosphates substitution at the phosphorus atom takes place[25].

By considering jointly data for the hydrolysis of the dianions, monoanions, and neutral molecules of monoesters, one may note a definite similarity of the mechanisms of the reactions involving the dianions and monoanions and the clear difficulty of a similar mechanism for the neutral molecule. The $S_N1P$ mechanism is manifested in the purest form in the hydrolysis of the dianions. The latter shows that the capacity for the elimination of the metaphosphate ions depends strongly on the p$K_a$ of the eliminated group and diminishes as the p$K_a$ increases. In the series of monoanions, the elimination of the metaphosphate ion is complicated by the proton transfer to the eliminated group. The role of the proton transfer should probably be small in the case of aryl phosphates with readily removed groups and the sequence of rate constants observed for such compounds (dianion > monoanion) reflects the reactivity in the processes proceeding via an $S_N1P$ mechanism. The significant role of the additional factor (proton transfer) in the hydrolysis of monoanions in which the p$K_a$ values of the eliminated groups are high leads to an alteration of this sequence (the monoanion

becomes more reactive). The reactivity via an $S_N1P$ mechanism decreases further on passing to the neutral molecule. The absence of the cleavage of the C–O bond in the hydrolysis of the neutral molecules of monoalkyl phosphates is consistent with this observation. The hydrolysis of the neutral molecules of monoaryl phosphates probably proceeds via an $S_N2P$ mechanism[9].

The acid catalysed hydrolysis of phosphate monoesters has been studied in a number of investigations[9,10,25,28,29,32,33,38,56]. The acid hydrolysis of the phenyl and alkyl esters proceeds via different mechanisms. Two parallel reactions, leading to the dissociation of the P–O and C–O bonds at comparable rates, have been demonstrated for the alkyl esters[23,32], but in the esters eliminating a carbonium ion there is exclusive dissociation of the C–O bond[28,29,32]. The dependence of the rate constant on the stoichiometric acid concentration over a wide range of compositions and at a constant ionic strength has been found for the acid hydrolysis of methyl and ethyl phosphates[23,32]. On this basis, a bimolecular mechanism was proposed for each of the parallel processes. It is suggested that the rate-limiting stage involves nucleophilic attack by an $H_2O$ molecule on the phosphorus or carbon atom in the ester linkage of the protonated form of the ester[23]. In the acid hydrolysis of the t-butyl and isopropyl esters, only the C–O bond is cleaved. The linear dependence (with a slope of unity) of lg $k$ on the acidity function $H_0$ indicates the unimolecular cleavage of the protonated form. The assessment of the reaction mechanism with the aid of Bunnett's criterion also confirms the unimolecularity of the rate-limiting stage[32]. Fig. 4 shows that the hydrolysis of isopropyl phosphate, which proceeds via unimolecular heterolysis (curve *2*), is most sensitive to changes in the acidity of the medium. The behaviour of acyl phosphates in acid hydrolysis shows a definite analogy with that of methyl and ethyl phosphates, although the dissociation of the C–O bond is preferred for acyl phosphates[56]. An increase of the hydrolysis rate constant in proportion to the stoichiometric acidity of the solution at a constant ionic strength has been established for certain acyl phosphates (Table 4) and a bimolecular reaction mechanism is therefore proposed[56].

phenyl phosphates with electron-donating groups in the benzene ring has been postulated[9,10,25] in view of the insignificant change in the rate constant in concentrated solutions of strong acids. In this connection, one should note that the involvement of the protonated form of the ester is probable in acid hydrolysis. If the rate constant for the reaction proceeding via the protonated form ($k_{SH^+}$) is greater than the rate constant for the reaction involving the neutral molecule ($k_S$), then the observed rate constant $k = k_S + k_{SH^+}$ should increase on conversion of the ester into the protonated form. On the other hand, when $k_S > k_{SH^+}$, the observed rate constant should decrease with increase of the acid concentration. One may assume, with some approximation, that the invariance of the rate constant as the acid concentration is altered over a fairly wide range indicates the similarity of the rate constants $k_S$ and $k_{SH^+}$.

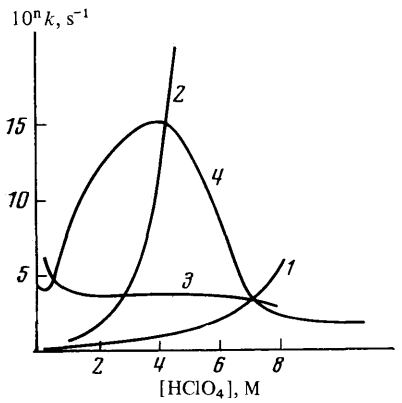

Figure 4. Dependence of the rate constants for the hydrolysis of monoesters on the acid concentration: 1) $C_2H_5OP(O)(OH)_2$, $n = 6$, 100°C [32]; 2) iso-$C_3H_7OP(O)(OH)_2$, $n = 5$, 100°C [32]; 3) $C_6H_5OP(O)(OH)_2$, $n = 5$, 100°C [25]; 4) 4-$NO_2C_6H_4OP(O)(OH)_2$, $n = 5$, 73°C.

[a]See footnote to Table 1.

Acid hydrolysis of monoaryl phosphates includes a reaction at the phosphorus atom[25]. The absence of an acid-catalysed reaction of phenyl phosphate and substituted

The slope of the plot of lg $k$ against p$K_a$ for acid hydrolysis, amounting to −0.5,[9,10] is smaller than for the reactions of dianions, but larger than for monoanions. Judging from the data in Table 4, the activation entropies for the acid hydrolysis of aryl phosphates are significantly lower than for reactions of mono- and di-anions, which suggests a bimolecular mechanism of the acid hydrolysis of monoaryl phosphates.

In a rigorous consideration of acid hydrolysis, account must be taken of the effects due to changes in the ionic strength and the activity of water with increase of the concentration of acid. It has been shown[10,25] that the rate of the acid-catalysed hydrolysis of aryl phosphates passes through a maximum in concentrated solutions of acids. However, the maximum disappears if the rate of reaction is measured in solutions at a constant ionic strength. Since the influence of salts and acids on the activity of water is similar, the maintenance of a constant ionic strength in solution smooths out the changes in the activity of water. Hence it follows that the maximum on the curves relating the rate constant to the concentration of acid may be attributed to a change in the activity of water. The rate

of hydrolysis of 2-methoxy-, 4-methoxy-, and 4-ethoxyphenyl phosphates in perchloric acid solutions at a constant ionic strength was independent of the acidity of the medium[38]. It was noted above that such behaviour probably indicates similar values of the rate constants for the reactions involving the neutral and protonated forms.

## 2. Hydrolysis of Phosphate Diesters

Phosphate diesters contain a single acid group at the phosphorus atom with $pK_a = 1-2$ (Kirby and Warren[3]) and can participate in reactions as anionic, neutral, and protonated species. The reactivity of the diester anions is very low, the anions of five-membered cyclic esters being an exception. The difficulty of the unimolecular heterolysis of the P=O bond in the diester anions also shows that the relatively high reactivity of the monoester monoanions is due to the special role of the P–O–H fragment in the reaction mechanism. Proton transfer to the eliminated group in the hydrolysis of monoester monoanions constitutes in essence a variety of the intramolecular catalysis by the acidic hydroxyl. In bimolecular nucleophilic substitution reactons, conditions for nucleophilic attack on the diester anion are unfavourable for two reasons. The first is the displacement of electron density from the oxygen atom to phosphorus, which makes the latter less electrophilic. The second factor, which is important in reactions with negatively charged nucleophiles, is the electrostatic repulsion of the two anionic species involved in the reaction.

The reactivity of neutral diester molecules is much higher than that of the anions. Analysis of the dependence of the rate constants for the hydrolysis of diesters on pH [25,57-64] reveals an increase of reactivity in the sequence

$$(RO)_2PO_2^- < (RO)_2P(O)OH < (RO)_2P(O)(OH)_2^+.$$

Typical relations between the rate constants and pH are illustrated in Fig. 5.

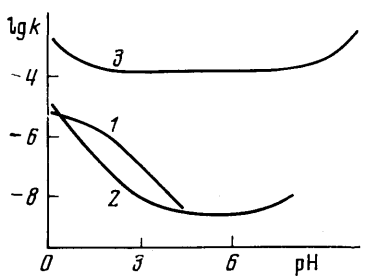

Figure 5. Dependence of lg $k$ on pH for the hydrolysis of diesters at 100°C: 1) $(CH_3O)_2P(O)OH$ [57]; 2) $(C_6H_5O)_2$. $.P(O)OH$ [25]; 3) $[2,4-(NO_2)_2C_6H_3O]_2P(O)OH$.[58]

The kinetics and mechanism of the hydrolysis of dimethyl phosphate have been investigated in detail[57]; a similar behaviour should probably be expected also for many other dialkyl phosphates which do not show a tendency towards the elimination of alkyl groups in the form of carbonium ions. In the pH range 0–5, the dependence of the rate constant for the hydrolysis of dimethyl phosphate on pH differs sharply from the corresponding dependence for monomethyl phosphate, the hydrolysis rate constant of which has a maximum at pH 4.[23] Dimethyl phosphate hydrolyses extremely slowly at pH > 4 even at high temperatures, which precludes the determination of the rate constant for the reaction of its anion with water; when the pH is reduced, there is a monotonic increase of the reaction rate, which continues also in strongly acidic media. In the pH range 1–4, the increase of the rate constant is proportional to the relative content of neutral dimethyl phosphate molecules in equilibrium with the anions[57].

Experiments with $H_2^{18}O$ have shown that hydrolysis of the neutral dimethyl phosphate molecule proceeds via two parallel mechanisms with the cleavage of the P–O and C–O bonds. In the acid and alkaline hydrolysis, the dissociation of these bonds also takes place at comparable rates[57,65]. A bimolecular nucleophilic substitution mechanism has been adopted for reactions involving the neutral molecule and dimethyl phosphate species protonated at both reaction centres[57], in agreement with the mechanisms of the analogous processes for monomethyl and trimethyl phosphates. Data for the reactivity of various forms of dimethyl phosphate are presented in Table 5. Near pH ~ 1, mainly the neutral forms of dialkyl phosphates are present and the contribution of acid hydrolysis to the overall rate is insignificant judging from the data for dimethyl phosphate. Comparison of the rate constants at pH 1.25 [57,61] therefore yields the correct idea about the variation of the reactivities of neutral dialkyl phosphate molecules in the following sequence [the values of $10^6k$ ($s^{-1}$) at 100°C and pH 1.24 are quoted]:

$$\underset{4,56}{(\text{iso-}C_3H_7O)_2P(O)OH} > \underset{3,13}{(CH_3O)_2P(O)OH} > \underset{0,8}{(p\text{-}C_3H_7O)_2P(O)OH}.$$

Table 5. The rate constants for the hydrolysis of various reactive forms of dimethyl phosphate[57] at 100°C in aqueous solutions.

| Ruptured bond | $10k$, $s^{-1}$ | | $10^6k$, litre $mole^{-1}$ $s^{-1}$ |
|---|---|---|---|
| | $(CH_3O)_2PO_2^-$ | $(CH_3O)_2P(O)OH$ | $(CH_3O)_2P(OH)_2^+$ |
| P–O | $<10^{-3}$ | 0.9 | 0.11 |
| C–O | $<10^{-3}$ | 3.3 | 0.91 |

The high reactivity of the di-isopropyl ester can be due to the $S_N1$ mechanism of the reaction with elimination of a carbonium ion, as in the case of tri-isopropyl phosphate[66].

The dimethyl phosphate anion is extremely stable and the kinetics of its alkaline hydrolysis have been investigated at 115° and 125°C.[67] Extrapolation of these data to 25°C yields the approximate rate constant listed in Table 6. Under the conditions of alkaline hydrolysis, dimethyl phosphate reacts mainly via the carbon atom, which results in the cleavage of the C–O bond to the extent of 90%.[65]

In neutral, acidic, and alkaline media, aromatic diesters hydrolyse with the dissociation of the P–O bond[25,58,59]. Some contribution by the dissociation of the C–O bond was noted only for bis-(2,4-dinitrophenyl) phosphate[62], the benzene ring of which is activated (in relation to aromatic nucleophilic substitution) by two strong electron-accepting groups. Diaryl phosphates have low $pK_a$ values, the determination of which is difficult. Probably owing to the lack of $pK_a$ values, the dependence of the rates of hydrolysis of diaryl phosphates on pH in

order to estimate the rate constants for the hydrolysis of the neutral molecules was not analysed[58] and only the rate constants for the hydrolysis of the anions were obtained. The anions of diaryl phosphates are much more reactive than those of dialkyl phosphates and certain kinetic data for their interaction with water (spontaneous hydrolysis) and hydroxide ions are available (Tables 6 and 7). The low activation entropy for the spontaneous hydrolysis of the anion of bis-(2,4-dinitrophenyl) phosphate ($\Delta S^{\neq}$ = −26 cal mole$^{-1}$ K$^{-1}$) indicates a bimolecular mechanism of their reaction with water[58,59]. The kinetic isotope effect $k_{H_2O}/k_{D_2O}$ = 1.5 observed for this reaction suggests the occurrence of general base catalysis by a second water molecule[58]. The bimolecular $S_N2P$ mechanism was also adopted for the alkaline hydrolysis of the diester anions[59]. The negative charge on the oxygen atom, capable of being delocalised to the reaction centre via a $p_\pi$–$d_\pi$ interaction, inhibits significantly the nucleophilic attack by the hydroxide ion. This increases the activation energy, which is higher by several kcal mole$^{-1}$ for the diester anions than for the full esters of phosphoric acid.

*According to Kirby and Younas[58], $E$ = 19.6 kcal mole$^{-1}$ and lg $A$ = 7.77. The value of lg $A$ (s$^{-1}$) was estimated by the present author.

The influence of the structure of diaryl phosphate anions on the rate of their reaction with water has been investigated[58]. The dependence of lg $k$ on the p$K_a$ for the phenols formed in the reaction at 100°C is expressed by the equation[58]

$$\lg k = -0.97pK_a - 0.20.$$

The authors[58] noted that the sensitivity of the reaction to the nature of the eliminated group in diarl phosphate anions is much greater than in the monoester monoanions. However, one must bear in mind that, in the reaction series under consideration, the coefficient of p$K_a$ reflects not only the influence of the eliminated group but also of the remaining group and the latter is not constant either. If it is assumed that both groups have the same effect on the rate of reaction, the slope of the relation between lg $k$ and p$K_a$ calculated per eliminated group is lower by a factor of 2 (0.5). An analogous relation between lg $k$ and the p$K_a$ of the eliminated group (or the remaining group, since both are varied) exists in the alkaline hydrolysis of phosphate diester anions (Fig. 6). For the hydrolysis at 25°C, it corresponds to the equation

$$\lg k = -0.80\,pK_a + 0.76 \quad (n = 4,\ r = 0.996,\ s = 0.27).$$

The rate constant for the alkaline hydrolysis of dimethyl phosphate as well as the rate constants for the hydrolysis of diaryl phosphates are described by this equation when account is taken of the reaction of dissociated P–O bonds in the reaction (10%).

Five-membered cyclic phosphate esters exhibit an unusually high reactivity, the rate of their hydrolysis being higher by a factor of $10^7$–$10^8$ than that of acyclic diesters[57,68-70]. According to Westheimer[6], the much

higher reactivity of five-membered cyclic phosphates is partly due to the steric strain in the five-membered rings. Neutral and alkaline hydrolysis of the ethylene phosphate anion includes the cleavage of the P–O bond[65]. In the acid-catalysed hydrolysis, there is oxygen exchange between the phosphoryl group of ethylene phosphate and $H_2^{18}O$, the rate of which is comparable to the rate of cleavage of the ester bond. Since the oxygen exchange does not require the opening of the ring, it was assumed that the ring strain is reduced on formation of the intermediate containing the five-coordinated phosphorus atom[65]. The enthalpy of hydrolysis of the ethylene phosphate anion quoted by Westheimer and coworkers[68] is higher by 4.5 kcal mole$^{-1}$ than for the diethyl phosphate anion, which confirms the strain in the cyclic ester.

Penta-alkoxyphosphoranes with five-membered rings are known to be formed more readily than the acyclic analogues[72] and this confirms indirectly the possibility of the involvement of such structures in the mechanism of the hydrolysis. The favourable effect of the stereochemistry of the transition state on the reaction is indicated by the activation entropy $\Delta S^{\neq} = -15$ cal mole$^{-1}$ K$^{-1}$ found for the alkaline hydrolysis of the dimethylvinylene phosphate anion[70]. The mechanism of the hydrolysis of cyclic phosphates has been discussed in detail in a review[6].

The acceleration of the hydrolysis of certain phosphate diesters owing to intramolecular catalysis has been observed. Intramolecular catalysis in the hydrolysis of β-hydroxyalkyl phosphate anions is important for the understanding of the mechanisms of certain biochemical reactions[73,74]. It has been established that the alkaline hydrolysis of anions containing the β-hydroxyalkyl group proceeds via two competing mechanisms, one of which involves the formation of an oxiran ring on elimination of the β-hydroxyalkyl group and the other is associated with the intermediate formation of a five-membered cyclic phosphate:

The oxiran ring and the five-membered cyclic phosphate are then rapidly converted into a glycol and a glycol phosphate. The ratio of these products depends on the second alcoholic moiety of the ester if the latter is an alkoxyalkyl group. However, the exclusive elimination of phenoxides in the reaction was observed for aryl β-hydroxyalkyl phosphates. The rate of reaction depended on the p$K_a$ of the eliminated phenols or alcohols if the fraction of the observed rate constant referring to hydrolysis via a five-membered cyclic phosphate was considered for the latter[73].

Another example of intramolecular catalysis in the hydrolysis of phosphate diesters is the nucleophilic catalysis by the carboxylate group in the *o*-position relative to the ester linkage in aryl 2-carboxyphenyl phosphates[63]. The alkaline hydrolysis of the anions of these esters is $10^7$–$10^8$ faster than that of the analogous compounds without a $CO_2^-$ group in the *o*-position. The intermediate formation of a cyclic acyl phosphate during this reaction was demonstrated[63].

### 3. Hydrolysis of Phosphate Triesters

The hydrolysis of triesters is a potentially multistage process whose final product is phosphoric acid. The first stage, involving a change in the structure of the substrate, is considered in this section. Owing to the tribasic nature of phosphoric acid, there is a considerable scope for the alteration of the structures of triesters by the synthesis of mixed compounds with different alcoholic groups. The study of the kinetics of the hydrolysis of trialkyl phosphates began in the past century[76,77]; nevertheless, the number of triesters investigated hitherto is small (Table 8–10).

[a]See footnote to Table 1.

In reactions involving neutral triester molecules, the attack by the nucleophile may be directed to the phosphorus or carbon atom of the ester linkage. Water and the hydroxide ion react with trialkyl phosphates in conformity with Pearson's concept of the interaction of hard and soft acids and bases. In alkaline hydrolysis, the reaction centre is the phosphorus atom, while in the reaction with water or in spontaneous hydrolysis the reaction centre is the α-carbon atom of the alkoxy group of the ester. Using $H_2^{18}O$, it was possible to establish that the dissociation of the P–O bond occurs in the alkaline hydrolysis of alkyl[78,79] and aromatic[79,80] esters, but in the reaction with water these two types of ester linkages, POAr and POAlk, are cleaved via different mechanisms. Aromatic nucleophilic substitution is known to proceed readily only when the benzene ring contains strongly electron-accepting groups[20],

[a]See footnote to Table 1.
[b]The rate constant for the cleavage of the P–$OCH_3$ bond.

so that the spontaneous hydrolysis of aromatic esters, like the alkaline hydrolysis, usually takes place at the phosphorus atom [79,80]; the same type of cleavage of P–OAr bonds is characteristic of the acid hydrolysis [80]. The spontaneous and acid hydrolysis of alkyl esters takes place with rupture of the C–O bond [66,79,81,82]. As a rule the POAr ester linkages are less resistant to hydrolysis than the POAlk linkages and in the alkaline hydrolysis of mixed compounds the P–OAr bonds are cleaved preferentially. It has been shown for dibenzyl *p*-nitrobenzoyl phosphate that the anhydride linkage is the most reactive [83], being hydrolysed at the carbonyl carbon atom. Fig. 7 shows that plots of the hydrolysis rate constants for certain triesters against pH have a plateau in the region of weakly acid pH values. The extent of the plateau on the side of high pH values is determined by the ratio of the rate constants for the alkaline and spontaneous hydrolysis and on the side of low pH values by the ratio of the rate constants for the acid and spontaneous hydrolysis and the p$K_a$ for the protonated form of the ester. In the region of the plateau, the reaction between the neutral trialkyl phosphate molecule and water may proceed via an $S_N2$ or $S_N1$ mechanism at the carbon atom of the ester linkage. A mechanism of the $S_N1$ type, involving the cleavage of a carbonium ion, has been demonstrated for esters of secondary and tertiary alcohols [66].

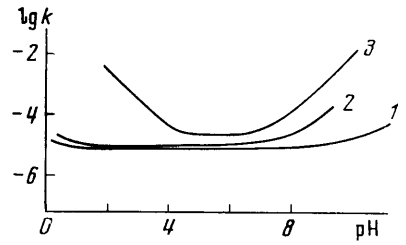

**Figure 7.** Dependence of the rate constants for the hydrolysis of triesters on the pH of the medium: 1) $(C_2H_5O)_3PO$ at 101°C [84]; 2) $4\text{-}NO_2C_6H_4OP(O)(OC_2H_5)_2$ at 70°C [85]; 3) ethylene methyl phosphate at 25°C. [86]

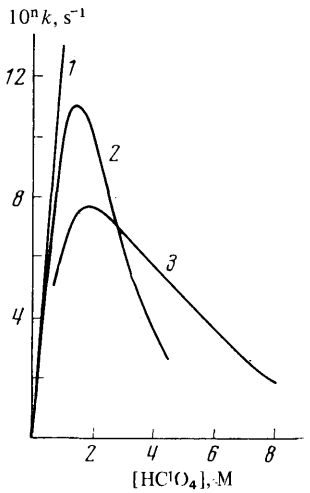
The kinetic isotope effect for trimethyl and triethyl phosphates ($k_{H_2O}/k_{D_2O}$ = 1.25) agrees with the hypothesis of an $S_N2$ mechanism of the spontaneous hydrolysis of these esters [81,87]. The low values of $\Delta S^{\neq}$ for the esters (−18 and −20 cal mole$^{-1}$ K$^{-1}$ respectively) are consistent with a bimolecular rate-limiting stage. A significantly greater isotope effect for the solvent ($k_{H_2O}/k_{D_2O} \simeq 2$) was noted in the cleavage of the P–OAr bond in the spontaneous hydrolysis of 2-aryloxy-2-oxo-1,3,2-dioxaphosphorinanes, which enabled the authors [80] to postulate the occurrence of general base catalysis by a second water molecule in the reaction via an $S_N2P$ mechanism involving the phosphorus atom.

Unsubstituted trialkyl phosphates are insensitive to acid catalysis. In the hydrolysis of trimethyl phosphate, the replacement of water by a 3 M $HClO_4$ solution increases the rate of reaction by [only] 20%. [79] Appreciable catalysis by 0.5 M $H_2SO_4$ of the hydrolysis of triethyl phosphate was not observed either [81]. The appearance of an acid-catalytic effect is promoted by carrying out the reaction in aqueous organic media, where the rate of spontaneous hydrolysis is sharply reduced owing to the decrease of the activity of water [81,87]. The low sensitivity of trialkyl phosphates to acid catalysis may be attributed to the long distance between the site of addition of the proton (the phosphoryl group) and the reaction centre. The high negative activation entropy for the acid hydrolysis of triethyl phosphate and the low isotope effect ($k_{H_2O}/k_{D_2O}$ = 0.6 in 0.56 M $HClO_4$) served as a basis for the adoption of a bimolecular reaction mechanism, including proton transfer in the equilibrium stage [81].

An isokinetic relation of the compensation type and covering the $\Delta S^{\neq}$ range from 0 to −50 kcal mole$^{-1}$ K$^{-1}$ has been established between the activation parameters in the acid hydrolysis of triesters [88]. It probably due to the gradual transition from an $S_N2$ to an $S_N1$ mechanism as the structure of the trialkyl phosphate is altered.

In contrast to trimethyl and triethyl phosphates, the rate constants for the hydrolysis of which increase monotonically with increase of the concentration of acid in aqueous organic media (Fig. 8), the rate constants for the acid hydrolysis of aromatic esters passes through a

maximum, whose position depends on the nature of the ester and the acid employed, as for mono- and di-aryl phosphates[25,80].



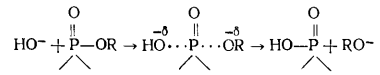


**Figure 8.** Dependence of the rate constants for the hydrolysis of triesters on the $HClO_4$ concentrations: 1) $(C_2H_5O)_3PO$, $n = 6$, in water–dioxan (35%) at 101°C [81]; 2) $(C_6H_5O)_3PO$, $n = 5$, in water–dioxan (60%) at 100°C [25]; 3) $4\text{-}NO_2C_6H_4OP(O)(OC_6H_5)_2$, $n = 4$, in water–dioxan (5%) at 100°C. [89]

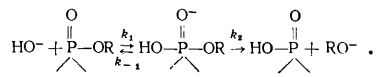
The acid hydrolysis of *p*-nitrophenyl diphenyl has been studied in detail[89]. In this case, the maximum is due to the strong negative salt effect in concentrated solutions of inorganic acids. At a constant ionic strength, the hydrolysis rate cojstant therefore increases in proportion to the stoichiometric acidity and has no maximum. The use of Bunnett's improved method makes it possible to characterise the reaction mechanism in terms of the slope of the relation

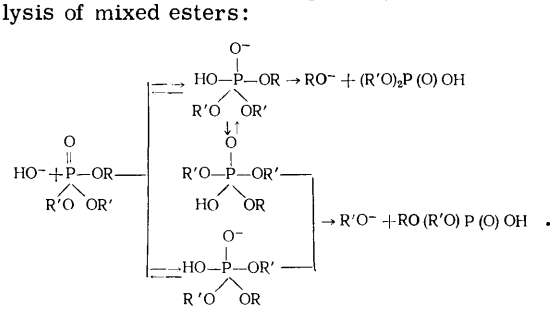


$$\lg k + H_0 = f(\lg c_{H^+} + H_0),$$

where $H_0$ is the acidity function and $c_{H^+}$ the stoichiometric concentration of $H_3O^+$. In $H_2OS_4$, HCl, and $HClO_4$ solutions, these relations had slopes of 1.5, 1.1, and 1.25 respectively, which is characteristic of reactions with a slow proton transfer in the rate-limiting stage. Similar slopes (1–1.4) were obtained for the corresponding relations in the acid hydrolysis of monoaryl phosphates[89]. In HCl solution, the maximum corresponds to an acid concentration of 6 M; the parameters of the Arrhenius equation under these conditions are $E = 14.8$ kcal mole$^{-1}$ and $\lg A = 5.4$, whence $\Delta S^{\neq} = -39$ cal mole$^{-1}$ K$^{-1}$.[89] The value $\Delta S^{\neq}$ obtained indicates the vigorous solvation of the transition state, in the formation of which the activity of water plays an important role. In conformity with these findings, the rate of acid hydrolysis is reduced by a factor of approximately 2 when the reaction is carried out in a 60% aqueous solution of dioxan. According to Bunton[5], the attack by a water molecule on the phosphorus atoms in the acid hydrolysis of the P–O–Ar linkages may proceed in unison with proton transfer to the ester molecule, complete proton transfer not being obligatory for the attainment of the transition state.

The alkaline hydrolysis of phosphate triesters, which is as a rule described by a kinetic equation for second-order reactions and has an $S_N2P$ mechanism, has been investigated in greatert detail[1–8]. Two types of $S_N2P$ mechanisms are possible for the alkaline hydrolysis. In one of them, the synchronous formation and cleavage of bonds in the transition state is postulated:

In the other version, the successive addition of the nucleophile and removal of the eliminated group with participation of a metastable intermediate compound in the reaction is postulated:



According to the method of steady-state concentrations, the observed rate constant is a compound quantity. The rate of this reaction $dc/dt$ is expressed by the equation

$$\frac{dc}{dt} = k_1 k_2 c\,[HO^-]/(k_{-1} + k_2),$$

where $c$ and $[HO^-]$ are the concentrations of the ester and the hydroxide ions respectively. It follows from the last equation that, for comparable values of $k_{-1}$ and $k_2$, oxygen should be exchanged during the reaction between the phosphoryl group of the ester and water. It has been shown for triphenyl phosphate that in reality there is no exchange between $H_2^{18}O$ and phosphate triesters during alkaline hydrolysis[79]. This is probably due to the low stability of the negatively charged phosphorans[97]. In the absence of oxygen exchange, one may assume that $k_2 \gg k_{-1}$ and the expression for the reaction rate simplifies to

$$dc/dt = k_1 c\,[HO^-].$$

In the alkaline hydrolysis of diethyl *p*-nitrophenyl phosphate and *p*-nitrophenyl diphenyl phosphate, $k_{H_2O}/k_{D_2O} \simeq 1$ (more precisely 0.87 and 1.10 respectively), which agrees with the hypothesis of the nucleophilic attack by the hydroxide ion on the phosphorus atom in the rate-limiting stage[100]. The activation entropies $\Delta S^{\neq} < -20$ cal mole$^{-1}$ K$^{-1}$, which can be found from the data in Table 10, are also consistent with this hypothesis. The increase in the complexity of the $S_N2P$ mechanism may be due to the rapid ligand exchange between non-equivalent positions in the intermediate compound[99], for which a bipyramidal structure is postulated. According to Westheimer[6], as a result of the pseudorotation of the bipyramid the hydrolysis of cyclic phosphates may involve the formation of various reaction products. The hypothesis of pseudorotation in the intermediate is difficult to prove, as can be seen from the general scheme for the possible pathways in the alkaline hydrolysis of mixed esters:

When the influence of the structure on the rate of spontaneous, acid, and alkaline hydrolysis of triesters is considered, one may note a definite analogy in the influence of the nature of the alcoholic ester moieties on the rate of hydrolysis of phosphate mono-, di-, and tri-esters. Electron-accepting substituents in alkyl and aryl groups usually favour the dissociation of ester linkages, which is confirmed for triesters by the data in Tables 8–10.

The esters of secondary and tertiary alcohols exhibit a higher reactivity during spontaneous hydrolysis than those of primary alcohols owing to the ease of the cleavage of the C–O bonds via an $S_N1$ mechanism[66], which is analogous to the behaviour of the corresponding phosphate mono- and di-esters. An unusually high reactivity has been observed for five-membered cyclic esters, which hydrolyse in neutral, acid, and alkaline media $10^6$–$10^8$ faster than their six- or seven-membered cyclic analogues and cyclic esters[86,97]. Among five-membered cyclic phosphates, derivatives of vinylene phosphate are particularly unstable[92].

The influence of the structure of triesters on the rate of spontaneous and acid hydrolysis cannot be considered in greater detail owing to the scarcity of the available data. It has been shown for the alkaline hydrolysis[101] that the dependence of lg $k$ on the p$K_a$ of the eliminated group is close to linearity when the nature of the eliminated group is altered in the sequence OAlk, OAr, OP(O)$R_2$, F. However, using detailed data for the kinetics of the alkaline hydrolysis of substituted aryl diethyl phosphates[98], one may note that a more rigorous linear relation between lg $K$ and the p$K_a$ of the eliminated groups is observed when the nature of such groups is altered only slightly. For example, Fig. 9 shows that the relation between lg $k$ and the p$K_a$ of the eliminated group of aryl diethyl phosphates is described (at 25°C) by the equation

$$\lg k = -0.57\mathrm{p}K_a + 2.48 \quad (n = 27,\ r = 0.976,\ s = 0.1),$$

which differs from the general relation

$$\lg k = -0.42\mathrm{p}K_a + 0.86 \quad (n = 29,\ r = 0.974,\ s = 0.2),$$

where the rate constants for the hydrolysis of triethyl phosphate and tetraethyl pyrophosphate are included. One should note, however, that the relation (at 39°C)

$$\lg k = -0.41\mathrm{p}K_a + 2.79,$$

whose slope is close to that of the general relation, has been obtained for the alkaline hydrolysis of 2-aryloxy-2-oxo-1,3,2-dioxaphosphorinanes[80], whose structures are very similar to those of aryl diethyl phosphates.

The intramolecular catalysis of the hydrolysis of phosphate triesters has been investigated in a number of studies[95,102–106]. In the hydrolysis of aryl 2-carboxyphenyl phosphates intramolecular nucleophilic catalysis by the ionised carboxy-group led to the preferential cleavage of the P–OAr bond[63], which was explained by the inhibition of pseudorotation in the five-coordinated intermediate compounds containing two negatively charged oxygen atoms in the equatorial positions of the bipyramidal structure. In triesters of similar structure [but without a carboxylate group], there is only one negatively charged ligand in the equatorial position and pseudorotation is not hindered. The ready transfer of the salicylate oxygen to the axial position of the bipyramid ensures the possibility of the formation of two reaction products. Salicylic acid is the main product (96%) of the hydrolysis of 2-carboxyphenyl diphenyl phosphate in alkaline media, but in the region of acid pH the elimination of phenol predominates (90%).[104] The intermediate formation of an acyl phosphate in an alkaline medium has been established for the reaction with hydroxylamine; it was shown that the rate of formation of the acyl phosphate is close to the rate of hydrolysis of the substrate. The ratio of the two reaction products (salicylic acid and phenol) depended on the p$K_a$ of the phenol when the latter contained substituents, a decrease of p$K_a$ favouring the elimination of the phenol[104].

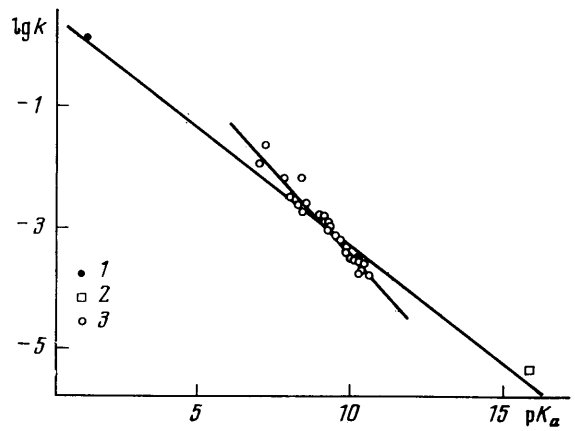


Figure 9. Dependence of lg $k$ on the p$K_a$ of the eliminated group in the alkaline hydrolysis of triesters at 25°C: 1) tetraethyl pyrophosphate (lg $k$ – lg 2); 2) triethyl phosphate (lg $k$ – lg 3); 3) aryl diethyl phosphates.

In the hydrolysis of dialkyl 2-carboxyphenyl phosphates, intramolecular catalysis, accelerating the hydrolysis of such esters by a factor of approximately $10^7$ relative to the corresponding compounds without a carboxy-group, was also observed[103]. Other examples of intramolecular catalysis in the hydrolysis of phosphate triesters have been described[102,105,106].

In conclusion, we may note that the data presented in this review characterise the kinetics of the hydrolysis of an extremely small proportion (approximately 140 compounds) of the many thousands of phosphate mono-, di-, and tri-esters available at the present time. The need for further studies of the kinetics of the hydrolysis of phosphate esters is therefore evident. The author believes that the data, a systematic account of which has been given in this review, will be useful in the consideration of various problems concerning the determination of the relation between the structure and reactivity of phosphates.

# Phosphorus Nitrides

E.V.Borisov and E.E.Nifant'ev

The literature data on the methods of preparation, structures, and properties of phosphorus nitrides PN, poly(phosphorus nitrides) (PN), ($P_3N_5$), etc., poly(phosphorus oxynitride) (NPO), and its thio-analogue (NPS) are surveyed and their practical applications, in particular as unique starting materials, formed as a result of the direct binding of molecular nitrogen, in the manufacture of phosphorus-nitrogen fertilisers are examined.
The bibliography includes 169 references.

## I. INTRODUCTION

More than 100 years have elapsed since the first synthesis of phosphorus nitrides[1], but fairly complete and reliable data on their structures and properties have been obtained only recently. This can be explained by the specific features of the high-temperature synthesis of such systems, the wide variety of their polymeric forms, and the difficulty of studying them. Nevertheless the possibility of extensive practical applications of phosphorus nitrides continues to attract the attention of specialists in various branches of chemistry, physics, engineering, and agriculture. Systematic research in this field was carried out at the beginning of the century in Germany, in the 1930's in France, and after the war in the USA.[1] Studies on poly(phosphorus nitrides) have developed recently to a considerable degree in the Soviet Union.

Unfortunately the review literature on phosphorus nitrides[1-4] does not describe adequately the advances in the study of their structures, properties, and reactivities. In Allcock's book[5], wholly devoted to phosphorus–nitrogen systems, there are no data whatever on these compounds. All these factors make it useful to publish the present review, which covers the classical research and the entire modern literature published up to January 1976 known to the authors.

## II. THE SYNTHESIS, PROPERTIES, AND ELECTRONIC STRUCTURE OF THE PN MOLECULE

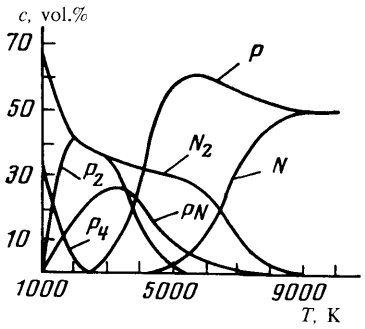
### 1. Synthesis

Monomolecular phosphorus nitride, detected spectroscopically for the first time by Curry and Herzberg[6], is stable in the vapour state at temperatures between approximately 450° and approximately 800°C. At lower temperatures, PN is deposited on the walls of the vessels in the form of an amorphous polymer, while at higher temperatures it decomposes into the elements[7-10].

The free energies of the gas-phase formation of PN molecules via the reactions

$$P_2 + N_2 = 2PN\ , \quad (1)$$
$$2P + N_2 = 2PN\ , \quad (2)$$
$$P_4 + 2N_2 = 4PN \quad (3)$$

are respectively 12, −97, and 68 kcal mole$^{-1}$ at 298 K and 3, −53, and −3 kcal mole$^{-1}$ at 2000 K according to calculations[11]. Thus phosphorus nitride is formed comparatively readily only when nitrogen interacts with atomic phosphorus [reaction (2)]. Low temperatures are optimum for the occurrence of this reaction, but $P_2$ molecules dissociate above 2500–3000 K†. The synthesis of PN from $P_2$ and $N_2$ requires a large expenditure of energy. The formation of phosphorus nitride via reaction (3) is even less likely, particularly since $P_4$ dissociates into diatomic phosphorus about 1500°C.[12,13]



The equilibrium composition of the homogeneous phase incorporating P, $P_2$, $P_4$, N, $N_2$, and PN (see Figure) was calculated by Krasnokutskii and coworkers[13,14] (see also Vil'k et al.[12]). It was shown that, in the temperature range 1000–10 000 K and pressures in the range 0.1–1000 atm and for $N_2 : P_2$ ratios of 1–4, there is a possibility of direct synthesis of PN from $P_2$ and $N_2$. The concentration of PN at 1000 atm and 5000 K reaches 33.8%. The optimum conditions for the synthesis are as follows: temperature 2500–3000 K, pressure 1–10 atm, and a nitrogen : phosphorus ratio of 2. Under these conditions, the PN concentration is 20.5% and the energy consumed is 0.177 kW h mole$^{-1}$.[13,14] A further increase of temperature leads to the decomposition of phosphorus nitride. According to calculations, the temperature of the greatest thermal stability of phosphorus nitride is related to pressure in the system by the expression

$$T_{stab} = 3{,}236p^{0{,}06295} \cdot 10^3 \pm 20\ \text{K}\ . \quad (4)$$

†The temperature range 3200–3250 K corresponds to the maximum proportion of phosphorus nitride formed by reaction (2).[12]

An increase of pressure in the system to 1000 atm leads to an increase of the PN concentration in the gas only by a factor of 1.4, so that it is pointless to employ such a pressure in the synthesis of phosphorus nitrides[13,14].

Ginderich[15] carried out a careful experimental study on the thermodynamics of the formation of PN molecules. He investigated the equilibrium in the vapour phase over the UP–BN system. The enthalpies of reactions (1) and (2) were determined mass-spectrometrically. The values of $\Delta H^{\circ}_{298}$ obtained are respectively 47.6 and −65.3 kcal mole$^{-1}$.

The calculated equilibrium composition of the P–N system at a pressure of 1 atm and for nitrogen : phosphorus = 1.

The kinetics and equilibria in the reactions involving the synthesis and decomposition of PN molecules below 905°C were investigated by Huffman et al.[9] The equilibrium constant in the synthesis of PN from diatomic molecules [reaction (1)] was found to be 0.01 at 900°C and 0.2 at 2000°C. The heat of formation of PN via reaction (1) is −14 kcal mole$^{-1}$. The activation energy for reaction (1) was calculated as approximately 31 kcal mole$^{-1}$ from the above value and from the observed activation energy for the decomposition of the PN molecule into $P_2$ and $N_2$. Having compared this value with the dissociation energies of $N_2$ and $P_2$, the authors[9] concluded that N and P atoms are not involved in the formation of the activated complex in the synthesis of phosphorus nitride. However, the activation energy, corrected using Ginderich's data[15] (approximately 47 kcal mole$^{-1}$), shows that this conclusion is not adequately justified. The hypothesis that the rate of formation of PN is not the factor responsible for the low yield of phosphorus nitride also appears to be premature.

Fedorov and coworkers[13,16] investigated the kinetics of the synthesis of PN in the temperature range 3000–7000 K. By numerical integration on a computer of the system of differential equations corresponding to chain, molecular, atomic, and overall mechanisms, they showed that a satisfactory agreement between calculated and experimental parameters is obtained only for the interaction between atoms:

$$P + N + M \rightarrow PN + M \qquad (5)$$

where M is a third body—an atom or molecule (or the reactor wall). The reaction

$$P_2 + M \rightarrow P + P + M \qquad (6)$$

does not affect the yield of PN, which can be explained by the high rate of decomposition of the molecules of the initial phosphorus. Thus the nitrogen content in the product and the rate of formation of the latter are determined solely by reaction (5), whose rate constant is $1.25 \times 10^9$ litre$^2$ mole$^{-2}$ s$^{-1}$ under these conditions.

The efficiency of the synthesis of PN molecules from the elements may be increased by using an electric discharge or catalysts to initiate the dissociation of the parent molecule. The interaction of the nitrogen atoms, obtained by exposing the $N_2$ molecule to a microwave discharge, with $P_4$ molecules in the temperature range 100–400° has been investigated by Khanna et al.[17] According to these authors, the upper limit to the rate constant for the second-order reaction

$$P_4 + N \xrightarrow{k} [P_4N] \begin{cases} \rightarrow (P_xN_y) + P \\ \xrightarrow{[N]} P_4 + N_2 \end{cases} \qquad (7)$$

is approximately $5 \times 10^{12}$ cm$^3$ mole$^{-1}$ s$^{-1}$.

The mechanism of the formation of phosphorus nitride molecules in a low-temperature plasma has been analysed by Mel'nik et al.,[18] who showed that the synthesis of PN should proceed via a complex mechanism involving a series of competing stages. This chain process is initiated by the formation of phosphorus atoms from $P_4$ and $P_2$ molecules and also by the formation of $P_3$ radicals.

The dependence of the rate of synthesis of PN molecules from the elements in a glow discharge on the potential $u$, the discharge current $i$, and the pressure $p$ in a closed reactor was studied by Millers and coworkers[19]. Mathematical treatment of experimental data showed that there are maxima in the rate of absorption of nitrogen as a function of pressure, the optimum values of which are 0.08–0.1 and 0.03–0.06 mmHg. There is a linear relation between the rate of reaction and the discharge current. The change in the mass of nitrogen in the reactor, characterising the reaction dynamics, is described by the equation

$$dm = -miK(p, i, u)dt, \qquad (8)$$

where $K(p) = ce^{\alpha/p}$ and $c$ and $\alpha$ are constants for the given $i$ and $u$. The same workers investigated the interaction of phosphorus and nitrogen in a glow discharge for different methods of supplying nitrogen to the reactor[19] (see also the Addendum to this review).

## 2. Physical Constants, Electronic Structures, and Properties

The upper limit to the dissociation energy of the PN molecule (7.8 eV) has been determined by the Birge–Sponer linear extrapolation of the observed energies of the vibrational levels in the ground state[6,7]. A detailed study of the electronic spectra of this molecule led to $D^0_0$ = 6.3 eV (obtained by extrapolation of the energy of the vibrational levels of the lowest excited state $A^1\Pi$). It has been noted[7] that the relatively small number of the identified vibrational levels (10 out of the 95 possible levels in the ground state and 9 out of the 76 possible levels in the excited state) may be the cause of the possible error in the determination of the dissociation energy from spectroscopic data. The study of the equilibrium in an equiatomic mixture of nitrogen and phosphorus at temperatures in the range 895–905°C led to $D^0_0$ = 7.1 eV.[9] A somewhat higher value (7.57 eV) was obtained by Vu and Karlson[20]

in a study of the evaporation of $P_3N_5$, but their investigation has been criticised[15,21]. The value of $D_0^0$ obtained from the analysis of the thermodynamics of the evaporation of phosphorus nitride is 7.0 eV.[21] However, the most reliable dissociation energy has been found by Ginderich[15]. The dissociation energies of the $P_2$ and PN molecules which he calculated are listed in Table 1.

Table 1. Comparative characteristics of the $N_2$, PN, and $P_2$ molecules.

| Parameter | $N_2$ | PN | $P_2$ | References |
|---|---|---|---|---|
| $E_{dis}$ (exp.), eV | 9.90 | 6.43 | 5.08 | 15, 31 |
| Interatomic distance, Å | 1.094 | 1.49085 | 1.894 | 7, 22, 48 |
| Vibration frequency, $cm^{-1}$ | 2359.61 | 1337.24 | 780.43 | 7, 48 |
| Ionisation potential, eV | 15.8 | 11.85 | 10.2* | 20, 31, 40 |
| Energy of corresponding single bond, kcal | 38 | 70 | 50 | 51 |

*Value obtained by the LCAO-MO SCF method[37].
**The decrease of the total energy following the inclusion of 3*d* orbitals in the calculation.
***$E^b$ are the dissociation energies of the molecules obtained by quantum-chemical calculations.

The rotational spectrum of the PN molecule in the microwave range was studied recently[22]. Measurements were made of the frequencies of five lines of the quadrupolar hyperfine structure corresponding to the rotational transitions in the ground and first excited states; using literature data, the effective rotational, centrifugal distortion, and vibrational-rotational interaction constants were calculated from them. The calculated interatomic distance agrees well with the value found earlier from the analysis of the vibrational spectrum (Table 1). The millimeter and submillimeter regions of the rotational spectrum of phosphorus nitride have been studied[23].

The potential curves for the ground and first excited states of phosphorus nitrides were calculated using Lippincot's three-parameter function[24]. The dissociation energies obtained for the above two states are 6.3 and 4.0 eV (the dissociation energies of the $P_2$ molecule in the corresponding $X^1\Sigma_g^+$ and $B^1\Sigma_u^+$ states are 5.1 and 2.2 eV). Witchel[25] calculated the internuclear distance in the $A^1\Pi$ state of the PN molecule (1.5466 Å). Szoke[26] used a semiempirical method for the derivation of the potential energy function for the PN molecule as well as $P_2$ and $N_2$. It was shown that the Rydberg–Klein–Rees potential, obtained from the known spectroscopic constants and extrapolated with the aid of the Rydberg and Lippincot potentials, agrees with the experimental data over a wide range of internuclear distances.

Sankaraharayanan[27,28] calculated the Frank–Condon factors for certain bands of the $A^1\Pi - X^1\Sigma^+$ system, the electron transition moment for interatomic distances in the range 1.426–1.630 Å, and the relative probabilities of the transitions, which made it possible to explain the characteristic features of the vibronic spectrum of the PN molecule. Silver and Moller[29] showed that the values of the Frank–Condon factors obtained from the relative band intensities in the resonance fluorescence spectrum agree well with the theoretical values. The same workers used the Hanle effect to determine the lifetime of the $A^1\Pi$ state of the PN molecule as 230 ± 70 ms.[29]

The thermodynamic functions of the PN molecule in the temperature range 273–15 000 K have been calibrated by Potter and Di Stefano[30] (see also Ref. 31). The results of two non-empirical calculations for the ground ($^1\Sigma^+$) state of the PN molecule by the LCAO-MO SCF method have been published[32,34]. A calculation similar to the calculation by the Hartree–Fock method has been carried out by McLean and Yoshimine[32]. The basis set included 25 σ and 13 π Slater-type functions proportional to $e^{-\zeta r}$, where ζ is a parameter usually referred to as the exponent in quantum-chemical literature. Boyd and Lipscomb[34] used the minimum basis set of Slater-type functions and, in the case of the phosphorus atom, took into account the 3*d* functions, whose exponents were varied. The electronic configuration of the PN molecule obtained by *ab initio* calculations, namely ... $5\sigma^2 6\sigma^2 7\sigma^2 2\pi^4$, is analogous to that calculated for the $^1\Sigma_g^+$ states of the $N_2$ and $P_2$ molecules[35–37]‡. The contribution of the atomic orbitals of phosphorus to the upper occupied molecular orbitals of PN is fairly large, which is the reason for the smaller ionisation potential of the PN molecule compared with that of $N_2$ (Table 1).[32,39]§

Table 1 presents the dissociation energies of the $N_2$, PN, and $P_2$ molecules obtained from the most accurate of the published non-empirical calculations. These values differ from the experimental energies by the additional molecular correlation energy, equal to the difference between the correlation energies for the above molecules and for their constituent atoms[41]. The additional molecular correlation energies found in this way are virtually identical for the $N_2$ and PN molecules and differ slightly from the value for the $P_2$ molecule, which is probably too high. This may be caused, on the one hand, by the similarity of the correlation energies of the electrons in the inner shells of the molecules and their constituent atoms and, on the other, by the similarity of the bonds in these diatomic molecules.

A clear idea about the characteristics of the distribution of electron density in PN, $P_2$, and $N_2$ is provided by the full and difference maps of charge density. The formation of the above diatomic orbitals leads to an increase of electron density in the region between the nuclei along the molecular axis and to a decrease in density at the nuclei and in the direction away from the molecular axis[34,42,43]. The concentration of electronic charge in the internuclear region together with the overlapping of the atomic orbitals is known to play an important role in bond formation. The relative decrease in the density of the electron cloud in the internuclear region is responsible for the decreased stability of the above diatomic orbitals in the sequence $N_2 > PN > P_2$. This is caused by the presence in the phosphorus atoms of additional inner filled shells and by the lower capacity of the phosphorus valence orbitals for *sp* hybridisation compared with the corresponding valence orbitals of the nitrogen atom[37,39]. Analysis of the difference maps characterising the distribution of the π and σ

‡The agreement between the calculated and experimental molecular orbital energies for the $N_2$ and PN molecules has been analysed[38,39].

§According to Wu and Fehlner's data[40], the photoelectron spectrum of PN has two distinct maxima at 11.85 and 12.52 eV, which may be attributed to the σ and π levels.

electron densities, shows that the contribution of $\pi$ electrons towards bonding diminishes in the sequence $N_2 > PN > P_2$. Analysis of the overlap populations leads to an analogous conclusion[36,39,42,44].

The inclusion in the calculation of 3*d* orbitals, which play the role of polarising terms in the above three molecules, leads to an increase of electron density in the bonding region[42,45]. The population of the 3*d* orbitals increases when nitrogen atoms are replaced by phosphorus atoms. The changes in the total energies, occurring when the 3*d* orbitals are included in the calculations for the $P_2$ and $N_2$ molecules, are in their turn virtually identical (Table 1). According to Boyd's data[42], the change in the exponent of the 3*d* atomic orbitals from 1.0 to 1.5 (the optimum values for non-empirical calculations with an unbalanced basis set) leads to an increase of the overall overlap population, which diminishes somewhat on further contraction of the 3*d* orbitals. The optimum value of the $\sigma$-bonding component of the overlap population also corresponds to the optimum value of the exponent, since the $\pi$-bonding component diminishes monotonically with decrease in the size of the 3*d* orbitals. The overlap population of the $d^{\sigma}$ phosphorus orbitals with the corresponding nitrogen orbitals increases monotonically under these conditions, the overlap population of the phosphorus $d^{\pi}$ orbitals diminishes, and the kinetic energy of the electrons and the sum of the molecular orbital energies increase[42].

The heteroatomic PN molecule has a dipole moment, which has been measured (2.75 D) by Raymonda and Klemperer[46] from the electrical resonance spectrum in a molecular beam. They also described the dependence of the dipole moment and the quadrupole interaction constant on the vibrational state of the molecule. The dipole moment is due to a redistribution of electron density in the PN molecule compared with the "non-interacting" atoms. Using his method for subdividing space into regions corresponding to atoms and the results of a non-empirical calculation[32], Politzer[47] calculated the effective charges $\Delta q$ of the P and N atoms (0.25 and −0.25 a.u. respectively) and the distances from the centres of the positive and negative charges to the centre of the interatomic distance (0.715 and 0.768 Å). The centre of the negative atomic charge is beyond the nuclei, owing to the presence of the lone electron pair at the nitrogen atom. Politzer's calculated effective atomic charges are somewhat smaller than the values obtained by the LCAO-MO SCF method in terms of the CNDO/2 valence approximation[49] with and without allowance for the 3*d* functions of the phosphorus atom¶ ($|\Delta q| = 0.35$ and 0.45 a.u. respectively[39,45]).

As already mentioned, the phosphorus nitride molecule is stable over a narrow temperature range. The simplest derivatives of PN, the great structural variety of which has frequently led to some confusion in the interpretation of experimental data[1], are also extremely labile. In this situation, it is necessary to employ, together with physicochemical data, the results of quantum-chemical calculations of various characteristics of such systems, and also to calculate the potential surfaces for the chemical reactions. A logical investigation of the relation between the electronic structure and properties of phosphorus nitride and its derivatives is being carried out by one of the authors of the review[39,45,52,53].

¶The exponents of the 3*d* orbitals were assumed to be 1.6, in agreement with the value optimised by Boyd[42].

A fragment of the potential surface for the protonation of the PN molecule has been calculated[45] by the CNDO/2 method. It was found that the minimum total energy corresponds to a nearly linear geometry of the cation with the proton attached to the nitrogen atom. In the $(HNP)^+$ cation, the polarity of the H–N bond is low as a result of the acceptance by the proton of electrons from the *s* orbital of the nitrogen atom and the $p^{\pi}$ orbital of the phosphorus atom. The overall population of the 3*d* orbitals in the cation, calculated by the CNDO/2 method, hardly changes relative to the PN molecule and there is only a redistribution of electron density between the $d^{\pi}$ and $d^{\sigma}$ orbitals.

The characteristic features of the electronic structures of the $H_2NP$ and $H_4NP$ isomers have been analysed[52] and the relation between the electronic structure and properties of aminophosphine $H_2NPH_2$ has been examined theoretically in detail[53–56].

## III. METHODS OF PREPARATION AND PROPERTIES OF POLY(PHOSPHORUS NITRIDES) (PN), $(P_3N_5)$, ETC.

A common feature of the PN and $P_2$ molecules is the formation of polymers with different structures, which is not characteristic of nitrogen. Aggregation leads to the formation of new $\sigma$ bonds (two additional bonds per diatomic molecule), the sums of the energies of which for PN and $P_2$ are greater than the dissociation energies of the diatomic molecules by approximately 62 and 33 kcal respectively, while in the case of $N_2$ the sum is smaller by 114 kcal (Table 1). Thus the ability of phosphorus nitride to form stable polymeric systems should be more pronounced than that of phosphorus.

Polymeric compounds of nitrogen and phosphorus, whose composition corresponds to the formulae $(P_3N_5)$, $(P_4N_6)$, and (PN), have been described. Variable-composition compounds with nitrogen : phosphorus ratios in the range 0.9–1.7 are also possible[1].

### 1. The Synthesis and Properties of (PN)

Poly(phosphorus nitride) (PN) was obtained for the first time[57] by exposing a mixture of nitrogen and white phosphorus vapours under a pressure of 200 mmHg to a silent electric discharge at a potential of 4000–15 000 V. It was noted that at pressures less than 200 mmHg, red phosphorus, which limits the reaction, is formed simultaneously with (PN). The action of a silent electric discharge on a mixture of nitrogen and phosphorus vapour has also been investigated in other studies[58,59]. Mourey and Wetroff[10] obtained (PN) by passing nitrogen and phosphorus vapours (at an overall pressure of 1 atm) through an electric arc maintained between tungsten electrodes by a potential of several thousands of volts. Poly(phosphorus nitride) is also formed when nitrogen atoms interact with phosphine,

$$N + PH_3 = PH_2 + HN,$$
$$PH_2 + N = PN + H_2,$$

in the temperature range 80–290°C,[60] when a high-frequency discharge is passed through a mixture of nitrogen and phosphorus trichloride[29], when phosphorus trichloride interacts with ammonia at −78°C,[61] in the reaction of triphosphonitrile chloride with sodium[62,63], etc.

At room temperature, (PN) is a stable yellow (possibly owing to contamination with phosphorus) amorphous powder, which is insoluble in water, liquid ammonia, and the

usual organic solvents[64,65]. The polymer sublimes without leaving a residue[9,62] and condenses below 500°C. It dissolves readily, but more slowly than $(P_3N_5)$ in hot sulphuric acid with formation of phosphoric acid, ammonium sulphate, and sulphur dioxide[65]. It is readily oxidised by peroxides and sodium nitrate[62]. Above 500°C, it reacts with chlorine to form the trimeric phosphonitrile chloride contaminated with phosphorus pentachloride[66-68] and it also reacts with atomic nitrogen[69] and ammonia[9] to form $(P_3N_5)$.

## 2. The Synthesis of $(P_3N_5)$

A solid substance with a composition $(P_3N_5)$ was obtained for the first time by Briegleb and Genther[70] in 1862 by the reaction of magnesium nitride with phosphorus pentachloride:

$$5Mg_3N_2 + 6PCl_5 = 2P_3N_5 + 15MgCl_2 .$$

Both Briegleb and Genther[70] and later investigators (Schneider[71] and Stock and Grunberg[72]) were unable to isolate in a pure form the phosphorus nitride obtained in this way; the product was also contaminated with a small amount of magnesium and chlorine. Nor could a pure product be obtained by the reaction of $NH_3$ with $(NPCl_2)_3$.[73] A fairly effective method for the preparation of pure $(P_3N_5)$, based on the reaction of phosphorus pentasulphide with ammonia, was developed at the beginning of the present century by Stock and Hoffman[74]:

$$40NH_3 + 3P_2S_5 = 2P_3N_5 + 15(NH_4)_2S .$$

The phosphorus nitride produced in this reaction consists of an extremely porous mass[59].

The method of synthesising phosphorus nitrides by heating phospham ($PN_2H$) at 400–700°C has become very common. This reaction was discovered by Besson[75] in 1892. Phospham is usually obtained by the prolonged heating of the products of the reaction of ammonia with phosphorus pentachloride and by heating to 800°C tri- and tetra-phosphonitrile chlorides[4], diamidotetrachlorophosphorus nitride[76], and hexa-aminophosphonitrile chloride[4].

Thermodynamic calculation of the equilibrium composition of the P–N system in the temperature range 1000–10 000 K, in the pressure range 0.1–1000 atm, and for N : P ratios of 1–4, 12, and 24 showed[13,14] that the synthesis of the poly(phosphorus nitride) $(P_3N_5)$ via the reaction

$$3PN(gas) + N_2 = (P_3N_5) \qquad (9)$$

at high temperatures can be extremely effective. At atmospheric pressure below 1100 K, virtually the entire PN is converted into $(P_3N_5)$. An increase of pressure makes it possible to condense the nitride at higher temperatures. It has been noted that the highest yield is obtained when nitrogen interacts with phosphorus in the high-temperature homogeneous region with subsequent quenching of the reaction products at a temperature below 1100 K. On quenching to room temperature, the maximum yield of $(P_3N_5)$ corresponds to the maximum concentration of PN obtained in the homogeneous region (2500–3500 K). The minimum energy expenditure (3.26 kW h $kg^{-1}$ at 2500 K, 1 atm, and N : P = 2) corresponds to the same conditions. By increasing the pressure, it is possible to increase the content of the nitride in the product to 48 wt.% (for N : P = 1), but this entails an increase of the energy expenditure to 4–5 kW h $kg^{-1}$. On raising the N : P ratio, one can obtain a $(P_3N_5)$ concentration in the product up to 61 wt.%, but the energy expenditure then increases to 4.3 kW h $kg^{-1}$.[13,14]

A study of the synthesis of $(P_3N_5)$ in a flow-type arc reactor showed that the maximum yield of the product is reached at temperatures greatly exceeding that of the maximum thermal stability of PN, whence it was concluded that the process proceeds under non-equilibrium conditions[14].

The synthesis of $(P_3N_5)$ in the presence of an incandescent tungsten wire is also a non-equilibrium process. The rate-limiting stage in the formation of solid phosphorus nitride from $P_2$ and $N_2$ molecules at temperatures in the range 1720–2127 K is the catalytic dissociation of $P_2$ into atoms[9]. This follows from the similarity of the activation energy for this reaction (approximately 59 kcal at approximately 1800 K) to the dissociation energy of $P_2$ and also from the observed relation between the rate constant for the formation of phosphorus nitride $k$ and the concentration of $P_2$:

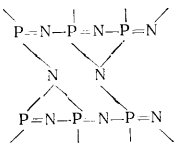
$$d c_{P_2}/d t = k c_{P_2}^{1/2} .$$

The process probably includes a stage in which $P_2$ is adsorbed on the surface of the tungsten wire, phosphorus atoms are removed from the surface, and then react with nitrogen in the gas phase†. It is apparently possible to explain in this way the deviation of the composition of the solid product formed under experimental conditions (N : P = 1.03–1.19) from the equimolecular composition of the initial gaseous mixture.

According to the authors[9], the reaction of a phosphorus atom with an $N_2$ molecule leads to the formation of the complex PNN, which may react with another phosphorus atom. The resulting groups probably combine to form the polymer (PN) or continue to grow, colliding alternately with nitrogen and phosphorus molecules until the molecular N : P ratio reaches the highest possible value (as in $P_3N_5$).

## 3. The Structure and Properties of Poly(phosphorus nitrides)

The synthesis usually yields the amorphous phosphorus nitride $(P_3N_5)$, which may be converted into a crystalline form by heating in a stream of nitrogen or ammonia above 800°C.[69] The study of the crystal structures of phosphorus nitrides is of considerable interest because of their potential wide variety and structural similarity to the corresponding modifications of phosphorus, from which the structures of phosphorus nitrides may be formally derived by a regular (or stochastic) replacement of phosphorus atom by nitrogen atoms[2]. However, bearing in mind the high thermal stability of phosphorus nitrides with a regular structure and also the sequence of the energies of the single and multiple NN, NP, and PP bonds (Table 1), one may assume *a priori* that such compounds cannot contain fragments with single and multiple NN bonds as well as the –P=P– and –P=N– linkages. Thus the principal structural element in phosphorus nitrides must be the single P–N bond and the multiple $\rangle$P=N– bond. We may note that the average bond energy (68.3 kcal) calculated from the energy of formation of the amorphous (PN)[77] is virtually identical with the energy of the P–N bond in $(Me_2N)_3P$[50] (Table 1). Crystalline phosphorus nitrides



† Tungsten nitrides and phosphides are not formed at these temperatures[1].

are obtained in the form of powders, which are stable up to 700°C; on subsequent heating to the melting point or sintering, the powders may decompose or their structure may change[78-80].

X-Ray diffraction analysis showed[81] that ($P_3N_5$) crystallises in the hexagonal system with formation of spherulites 2–5 μm in size. A tetragonal modification, formed when phosphorus oxynitride is acted upon by ammonia, has also been detected[82,83]. The crystals of this modification have dimensions of approximately 30 μm. By treating the tetragonal modification with ammonia, it is possible to obtain the hexagonal modification. The converse transition cannot be achieved[84]:

$$(P_3N_5)\ \text{(tetragon.)} \xrightarrow[850^\circ C]{NH_3} (P_3N_5)\ \text{(hexagon.)} \xrightleftharpoons{NH_3+O_2}$$
$$\rightleftarrows (NPO) \xrightleftharpoons[O_2+NH_3]{NH_3\ \text{slow}} (P_3N_5)\ \text{(tetragon.)}$$

On the basis of the analysis of the infrared spectra, Steger[85] suggested that amorphous ($P_3N_5$) has a three-dimensional structure:

Judging from infrared spectroscopic data, the hexagonal modification of ($P_3N_5$) has an analogous but more ordered structure in which the phosphorus atom forms four σ bonds and one π ($pd$) bond with the neighbouring nitrogen atoms[84]. The infrared spectrum of the tetragonal modification has no band with $\nu_{max} = 1260\ cm^{-1}$, which may be attributed to the antisymmetric vibrations of the $\geq P=N-$ linkages[5]; this is regarded[84] as evidence for the presence in such systems of five P–N bonds. This band is also absent from the infrared spectrum of the crystalline modification of ($P_3N_5$) obtained from the hexagonal modification on treatment with ammonia at 500°C and approximately 40 atm.[86] The X-ray diffraction pattern of this modification differs from that of the tetragonal modification identified by Millers and coworkers[82].

Under the usual conditions, the phosphorus nitrides ($P_3N_5$) are white or yellowish highly stable substances, which are insoluble in water and organic solvents and are resistant to the action of dilute nitric and hydrochloric acids and alkalis[59,65]. ($P_3N_5$) can be dried in air at 120°C without risk of decomposition, which begins above 700°C at the normal pressure.

The evaporation of ($P_3N_5$) at 690–950°C has been investigated[20]. A combination of mass-spectrometric measurements with a study of the overall rate of diffusion of the preparation was employed. Under the conditions of congruent evaporation and for equal ionisation cross-sections of the PN and $P_2$ molecules, the partial pressures of $N_2$, PN, and $P_2$, corresponding to the overall reaction (8) at 970–1270 K, were determined. Owing to a number of methodological inadequacies and the lack of identification of the test substance, the thermodynamic characteristics for the evaporation process obtained in the above study involve large systematic errors. Thus the calculated dissociation energy of PN is appreciably higher than the value in Table 1. In order to determine the ratios of the partial pressures of PN, $P_2$, and $N_2$, Gordienko et al.[21] used a thermodynamic method of calculation. They analysed the temperature variation of the equilibrium constants for the reactions expressed in terms of the mass-spectrometric currents corresponding to the vapour components. Analysis of the mass spectra obtained at 950–1100 K and for an ionisation energy of approximately 30 eV showed that the evaporation of the hexagonal and tetragonal modifications of ($P_3N_5$) corresponds to the consecutive occurrence of reaction (9) and the reverse reaction (1). The mechanism of the evaporation of the two modifications is the same. However, the strength of the chemical bonds in the tetragonal modification is greater than in the hexagonal modification, which is confirmed by the higher heats of evaporation (111.0 and 105.1 kcal $mole^{-1}$ respectively) and the higher heats of formation (352.4 and 339.5 kcal $mole^{-1}$ respectively).

On heating in a stream of nitrogen, phosphorus nitride ($P_3N_5$) decomposes into elemental nitrogen and phosphorus; in a stream of hydrogen, phosphorus and ammonia are formed[59,64,65] and in a stream of air one obtains a residue consisting of $P_2O_5$.[59] Like (PN), phosphorus nitrides of the type ($P_3N_5$) can be chlorinated at 700°C with formation of triphosphonitrile chlorides[68]; on interaction with fluorine or nitrogen trifluoride, they give rise to the trimers and tetramers of phosphonitrile fluorides[87]. On heating in a sealed tube, nitric acid decomposes ($P_3N_5$) quantitatively. The ease of decomposition of phosphorus nitride by hot concentrated sulphuric acid has been used by Postnikov and Kuz'min[59] in chemical analyses. Phosphorus nitrides are also decomposed on fusion with alkalis and alkali metal salts. Heating of phosphorus nitride with lead, arsenic, antimony, etc. oxides leads to the liberation of the corresponding elements in a free state[59]. When ($P_3N_5$) interacts with fused magnesium, the phosphonitrile amide $PN(NMg)_2$ is formed; the analogous reaction with calcium begins at 200°C.[88]

The action of water on phosphorus nitrides has been studied in detail[1,59,89,90]. When ($P_3N_5$) is heated with water it does not dissolve at all and does not decompose. On treatment with steam at 150°C, the period during which amorphous phosphorus nitrides are 50% hydrolysed is about 55 h. Subsequent heating increases the rate of decomposition. Above 250°C under pressure, quantitative hydrolysis takes place in 2–3 h in accordance with the equations

$$PN + 3H_2O = (NH_4)H_2PO_4,$$
$$P_3N_5 + 12H_2O = 2(NH_4)_2HPO_4 + (NH_4)H_2PO_4,$$

amorphous phosphorus nitride (PN) hydrolysing more slowly at the same temperatures than ($P_3N_5$). The activation energy for the hydrolysis of ($P_3N_5$) is about 30 kcal $mole^{-1}$.[1]

The poly(phosphorus nitride) ($P_4N_6$) is an intermediate in the reaction of phosphorus trichloride with ammonia:

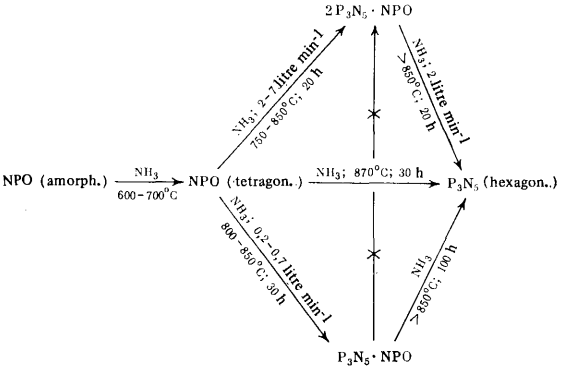
$$PCl_3 \xrightarrow{+NH_3} P(NH_2)_3 \xrightarrow[500-600^\circ]{-NH_3,H_2} (P_4N_6) \xrightarrow[750^\circ]{-N_2} (PN).$$

It is a yellowish substance which ignites spontaneously in air and is hydrolysed by water more readily than (PN).[89,91] Analysis of the hydrolysis products showed that the ratio of phosphorus(V) and phosphorus(III) in this compound is three and that ($P_4N_6$) is not a simple mixture of the phosphorus nitrides ($P_3N_5$) and (PN).[3] By allowing phosphorus trichloride to react with sodium azide, Grudmann and Ratz[92] obtained a coloured substance, which is hexa-azidophosphonitrile $[PN(N_3)_2]_3$. Phosphorus azides $P(N_3)_3$ as well as $OP(N_3)_3$ are exceptionally unstable and explosive[4].

## IV. METHODS OF PREPARATION AND PROPERTIES OF POLY(PHOSPHORUS OXYNITRIDE) (NPO) AND ITS THIO-ANALOGUE (NPS)

The NPO and NPS molecules have not been identified, but, bearing in mind the somewhat greater affinity of phosphorus for oxygen and sulphur[50], the results of the studies of the infrared spectra of the corresponding monomeric forms, as well as data on the structure and properties of poly(phosphonitrile halides) ($Hal_2PN$) (Allcock[5]) and nitrous oxide, these molecules presumably have a linear geometry with a two-coordinated phosphorus atom. These structures are preferred owing to the greater capacity for involvement in bonding of the 3*d* orbitals of the atoms of elements in the Third Period compared to the corresponding elements in the Second Period[93].

Poly(phosphorus oxynitride) (NPO), obtained for the first time by Gerhardt in 1846[1], exists in amorphous and crystalline forms, like the phosphorus nitride ($P_3N_5$). Amorphous (NPO) is obtained by heating phosphoric acid triamide $OP(NH_2)_3$ *in vacuo*[94] or by the reaction of phosphonitrile chlorides with metal oxides[95].‡ A detailed study of the first reaction has been carried out recently[96, 97]. Analysis of the infrared spectra of the condensation products showed that the P=N–P group is apparently formed as a result of the elimination of an $NH_3$ molecule with formation of the P–NH–P group and its subsequent rearrangement to P=N–P. Thus the formation of (NPO) from $OP(NH_2)_3$ can be represented by the following scheme:



$$OP(NH_2)_3 \xrightarrow[\sim 100^\circ]{-NH_3} (NH_2)_2P(O)—NH—P(O)(NH_2)_2 \xrightarrow[\sim 300^\circ]{-NH_3}$$
$$\rightarrow H_2N—[NP(O)—NH]_n—N \xrightarrow{450-500^\circ} (NPO)\,.$$

The white poly(phosphorus oxynitride) formed has a coarsely porous structure and a relatively small specific surface[98]. This white substance melts above 1000° with formation of black vitreous bodies, which exist in three and more forms. Under normal conditions, (NPO) is insoluble in water and the usual solvents[98]. On heating, atmospheric water causes the dissociation of the PN bond with subsequent substitution of the $NH_2$ groups by OH via a tautomeric rearrangement[96,97]. The final product of the hydrolysis of (NPO) at 175°C is $(NH_4)H_2PO_4$. Poly(phosphorus oxynitride) is resistant to the action of dilute acids and alkalis, but readily decomposes on fusion with alkalis, forming ammonia and alkali metal phosphates. It reacts with concentrated sulphuric acid to form ammonium phosphate[98]: at 800°C, it reacts with chlorine and gives rise to $POCl_3$ and traces of phosphonitrile chlorides[68]. Above 550°C, it is appreciably volatile, losing approximately 55% of its weight in 4 h.[96]

When it is pressed under a pressure of 140 atm at 800°C, (NPO) is converted into a ceramic, which is not very resistant to hydrolysis[99]. The preparation of crystalline (NPO) has been described[100]. Poly(phosphorus oxynitride) crystallises in the tetragonal system[83].

The results of mass-spectrometric studies on the composition of the vapour of crystalline (NPO), formed on evaporation *in vacuo* (0.2 mmHg) at 905–1225 K, have been published[101]. A method analogous to that employed in the study[21] of the evaporation of ($P_3N_5$) was used and it was found that (NPO) vaporises without change in the composition of the solid phase. The $N^+$, $N_2^+$, $PN^+$, $P_2^+$, $P_4^+$, and $P_4O_{6-10}^+$ ions were detected in the spectra, the principal vapour components being $N_2$, PN, $P_2$, and $P_4O_{10}$.

The conversion of poly(phosphorus oxynitride) into ($P_3N_5$) on treatment with ammonia has been investigated in detail[102,103]. When X-ray-amorphous (NPO) interacts with ammonia, different products are obtained depending on the temperature, the ammonia flow rate, and the duration of heating: crystalline (NPO); a crystalline phase with the empirical formula ($P_3N_5$.NPO); the crystalline phase ($2P_3N_5$.NPO), which was not described previously. The overall interaction of amorphous (NPO) can be represented by the following scheme:

Phosphorus thionitride (NPS) is obtained by the ammonolysis of phosphorus pentasulphide[74,104,105]:

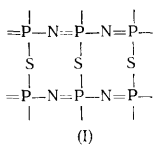
$$P_4S_{10} + 4NH_4Cl \rightarrow 4(NPS) + 6H_2S + 4HCl\,.$$

The yield of product after heating for 2 h at approximately 300°C reaches 85%. (NPS) is a grey insoluble diamagnetic substance, which decomposes at approximately 600°C. It reacts with hydrogen at 450°C to form ammonia, hydrogen sulphide, and phosphine. The reaction with chlorine proceeds in accordance with the equation

$$2(NPS) + 3Cl_2 \rightarrow 2(Cl_2PN) + S_2Cl_2\,,$$

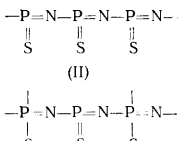
the product being phosphonitrile chlorides having different molecular weights[105]. The reaction with dry hydrogen chloride at 350°C involves the mechanism

$$(NPS) + 4HCl \rightarrow NH_4Cl + SPCl_3\,.$$



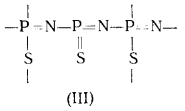
The adduct ($AlCl_3$.NPS), which is stable up to approximately 700°C, is formed when phosphorus thionitride reacts with aluminium chloride at 350°C.[105]

The sulphur in (NPS) may be substituted by oxygen under comparatively mild conditions, for example on boiling with water for a short time.[1]



On the basis of infrared spectroscopic data, Steger[85] suggested that the most probable structure of phosphorus oxynitride is one containing phosphonitrile and phosphate chains. This type of structure is preferred also in view of the considerable difference (approximately 80 kcal) between the sum of the energies of two P–O bonds and the energy of the P=O bond. On the other hand, the difference between the energies of two P–S bonds and the P=S bond is only 12 kcal.[50] Thus, together with structure (I) analogous to that proposed for (NPO), non-cross-linked or

‡ There is also an indication that (NPO) may be formed during the simultaneous oxidation of nitrogen and phosphorus in a low-temperature plasma[18].



partly cross-linked structures (II) and (III) are possible for phosphorus thionitride:

## V. ELECTROPHYSICAL PROPERTIES OF PHOSPHORUS NITRIDES

As already mentioned, it is quite appropriate to attempt to draw analogies when one considers the characteristic features of the structures and properties of various modifications of phosphorus, phosphorus nitrides, and their derivatives.

Orthorhombic black phosphorus is known to be a semiconductor[106]; the electrical conductivity of polycrystalline black phosphorus is a maximum at 40 K.[107] At very high pressures and low temperatures, phosphorus acquires the properties of a superconductor[108,109].

The presence of a large number of electrons capable of being delocalised in phosphorus nitrides is apparently the reason why the specific conductances of phosphorus oxynitride and nitride show an exponential temperature dependence, which is characteristic of semiconducting materials[79]§. In the temperature range 286–800 K, the specific conductances of the substances investigated decrease in the sequence

$$(P_3N_5)^{cr} > (NPO)^{cr} > (NPO)^{am} .$$

The electrical d.c. resistances of phosphorus thionitride have been investigated[111] in the range 20–120°C. At 20°C, the specific conductance of (NPS) is $1.5 \times 10^{-9}$ $\Omega^{-1}$ $cm^{-1}$, exceeding by several orders of magnitude the specific conductances of the cyclic phosphazenes $(X_2PN)_3$, which are $10^{-11}$–$10^{-13}$ $\Omega^{-1}$ $cm^{-1}$. According to the authors[111], the greater number of conjugated bonds and $\pi$ electrons in phosphorus thionitrides [see Structures (I)–(III)] compared with phosphazenes should be responsible for the mainly electronic nature of the conduction, which is ohmic at an electric field strength of 500–1000 V $cm^{-1}$. It was noted, that in the temperature range employed, the energy gap $E\sigma$ is virtually constant at 0.82 eV. The conductivity of (NPS) and $E\sigma$ are appreciably influenced by the applied pressure. For pressures of 100, 300, 500, and 1000 atm at 20°C, the resistivities are $9.3 \times 10^9$, $1.4 \times 10^9$, $6.9 \times 10^8$, and $4.7 \times 10^8$ $\Omega$ cm respectively and the values of $E\sigma$ vary in the range 0.04–1.80 eV.[111]

The extension of the temperature range in the measurement of the conductivities of phosphorus nitrides towards lower values is of considerable interest. We may recall here the metallic conduction in the (NS) polymer at liquid helium temperatures and its superconducting properties at 0.3 K.[112–115]

Poly(phosphorus selenonitride) (NPSe), which has not so far been synthesised, may possess interesting electrophysical properties.

§ Powders pressed into discs, clamped in an evacuated cell, were investigated. The excess of $p$ electrons is apparently responsible also for the weak photoluminescence of (NPO).[110]

## VI. PRACTICAL APPLICATIONS AND INDUSTRIAL SYNTHESIS OF PHOSPHORUS NITRIDES

### 1. Applications of Phosphorus Nitrides

Phosphorus nitrides are already used in engineering. It has been shown that $(P_3N_5)$ is an active diffusant when a silicon surface is saturated with phosphorus[116]. The possibility of employing $(P_3N_5)$ in the manufacture of semiconductors is also indicated in a patent[117]. Like (NPO), poly(phosphorus nitride) is a more convenient gas absorber than red phosphorus in the manufacture of incandescent lamps and similar apparatus[118,119]. Cellulose articles containing 10% $(P_3N_5)$ or 12% (NPO) are resistant to spontaneous inflammation and combustion and the addition of phosphorus nitride does not impair the mechanical properties of articles[120].

Further study of the binding (by reaction with phosphorus) of molecular nitrogen in the poly(phosphorus nitrides) $(P_3N_5)$ and (PN), which constitute an extremely attractive ballast-free starting material for the preparation of phosphorus–nitrogen fertilisers[59]¶, is of undoubted interest. The need for such research has become particularly urgent recently owing to a number of economic and technological causes. Among these, mention should be made of the increasing requirement for fertilisers† due to the growing world population, the reduced yield of grain crops per unit weight of fertilisers[127,129], the increasing price of fertilisers, and also the increasing cost of agricultural production (per unit weight of fertilisers)[130–134], the disproportion in the manufacture and consumption of individual components of fertilisers in developed and under-developed countries[127], etc.

The hydrolysis of phosphorus nitrides results in the formation of ammonium phosphates, which are widely used in the manufacture of fertilisers (including complex, solid, and liquid fertilisers), animal feed‡, and for technical purposes[126,134–136]. Ammonium phosphates are obtained by the reaction of ammonia with phosphoric acids or phosphorus pentoxide, formed when elemental phosphorus is combusted[126,137–139]. The desirability of employing phosphorus itself in the manufacture of phosphorus-containing compounds increases from year to year in view of the increasing development of the electrothermal manufacture of phosphorus. This is due to the gradual exhaustion of phosphate ores with a high $(P_2O_5)$ content, the increasingly stringent requirements for the purity of

¶ The direct employment of $(P_3N_5)$ as a fertiliser in a pure form is hardly possible in view of its resistance to different reagents under the usual conditions. Allison[121] introduced $(P_3N_5)$ into soil under the required conditions in order to convert nitrogen into a nitrate form. Since this conversion was not observed, he concluded that $(P_3N_5)$ as such cannot serve as a satisfactory fertiliser. Other workers[122,123], who investigated the decomposition of $(P_3N_5)$ in heated soil, later arrived at a similar conclusion. A systematic study of the possible employment of different compounds with PN bonds as fertilisers has been carried out[124,125] (see also Mattinghley and Taligudden[126]).

† During the last 15 years, the world requirement for combined nitrogen increased by 400% and for phosphorus by 150%[127] (see also Kodama[130]).

‡ The production of chemical additives to animal feed in the USSR will reach 5 million tonnes in 1980.[128]

the products§, and the possibility, in principle, of a fairly complete extraction of secondary components from slags in electrothermal manufacturing processes: fluorine, lanthanides[140,141], etc. The preparation of ammonium phosphates by the hydrolysis of phosphorus nitrides, which are formed directly from nitrogen and phosphorus, will reduce the cost of phosphoric¶, sulphuric, and nitric acids, which are used in the manufacture of phosphorus-containing fertilisers[138,142], and also of ammonia†.

An undoubted advantage of this method of synthesis is the absence of waste, which is important for the protection of the environment, the transportability of phosphorus nitrides, and also the possibility of preparing from them various compositions with nutrient substances.

The use of phosphorus nitrides as the starting materials for the preparation of phosphonitrile halides[66-68] and their derivatives, which have recently found extensive practical applications[5,145-147] in catalysis, etc., is no less promising.

## 2. Industrial Synthesis

The methods of obtaining phosphorus nitrides on an industrial scale were already outlined before the war. Miner[148] patented a method for the large-scale synthesis of (PN) based on the reaction of phosphorus halides with metal nitrides. However, the direct synthesis from the elements is more promising. It is recommended that ($P_3N_5$) be obtained by the direct reaction of nitrogen and phosphorus at a pressure of 1000 atm at 850 K.[149,150] An approximately analogous method has been proposed in a patent[151]. Quite recently Krasnokutskii and coworkers[13,152] investigated the interaction of nitrogen with gaseous phosphorus in a flow-type electric arc reactor. Nitrogen was passed to the electric arc chamber of the reactor where it was heated to a temperature of approximately 6500–7000 K, emerging from the anode-nozzle in the form of a jet, into which phosphorus vapour heated to 600°C was introduced. It was found that the content of bound nitrogen increases with the space velocity of the gases and the enthalpy of nitrogen, reaching approximately 25% by weight for the optimum volume of the reaction chamber, contact time (approximately $10^{-3}$ s), and temperature (3000–4500 K). The experimentally obtainable maximum contents of bound nitrogen are close to the amount in the P–N system found by thermodynamic calculation for the experimental conditions[14,152]. Kinetic studies are essential for a more complete description of the specific features of the given process.

The efficiency of the high-temperature method of manufacture of phosphorus nitrides follows from a comparison of the energy expenditures characterising various thermal processes in which molecular nitrogen is combined (Table 2).[152]

Table 2. Energy expenditure in manufacturing processes[138].

| Method of binding atmospheric nitrogen | Maximum product concentration, vol.% | Minimum energy expenditure per tonne of bound nitrogen, $10^3$ kW h |
|---|---|---|
| Formation of nitrogen oxides | 8 | 27.9 |
| Formation of dicyanogen | 59 | 17.2 |
| Simultaneous formation of hydrogen cyanide and acetylene | 11 | 10.6 |
| Formation of phosphorus nitride | 50* | 7.6 |

*Weight percentages.

Methods involving the combined initiation of this reaction (high temperature, discharge, irradiation) as well as catalytic processes are no less promising. Urbain[153,154] suggested that nitrogen and phosphorus vapours be compressed over a catalyst consisting of aluminium, titanium, magnesium, and bauxite in the presence of traces of cobalt, aluminium, and potassium oxides above 900°C. A scheme for an industrial apparatus, in which phosphorus nitride is manufactured on a scale consistent with the synthesis of fertilisers, has been proposed in a patent[155]. The recommended process includes the thermal generation of phosphorus vapour, the reaction of which with molecular nitrogen is initiated by an electric discharge.

The importance of plasmas has recently greatly increased in chemical engineering[156,157]. In the synthesis of phosphorus nitrides, plasmas may be used not only to initiate the reaction between nitrogen and phosphorus molecules but also to obtain elemental phosphorus from phosphorus-containing ores[157,158].

A decrease of the intrinsic cost of the manufacture of phosphorus nitride would be possible if the gases from phosphorus furnaces containing 14% of phosphorus and 86% of carbon monoxide were used instead of pure phosphorus[158]. This would permit the elimination of the stages involving the condensation of phosphorus and its consequent evaporation. The corresponding thermodynamic analysis showed that the quasi-equilibrium composition of the $N_2$–P–CO system hardly differs from the composition of the $N_2$–P system presented in Fig. 1. In the temperature range 1000–4000 K, only P, $P_2$, $N_2$, CO, and PN are present in the system in large amounts. The maximum concentration of PN in the mixture reaches approximately 7 vol.%. It was noted that the concentrations of polyatomic phosphorus and nitrogen oxides may be neglected in the above temperature range[158].

Vinokurov et al.[159] made a thermodynamic analysis[158] of the possibility of obtaining phosphorus nitrides (as well as phosphorus and iron) from ferrophosphorus, which is a waste product in high-temperature electrothermal manufacture. The highest yield of phosphorus nitride (22 wt.%) in the nitrogen plasma is ensured at a temperature of 3300 K and for the ratio nitrogen : ferrophosphorus = 1 : 1. The highest concentration of PN in the gas phase (26%) should be reached for the ratio ferrophosphorus : nitrogen = 8 : 1 at 3300 K.

§In the course of the current 5-year plan in the USSR, it is planned to obtain mineral fertilisers containing not less than 40% of nutrient substances[128].

¶According to Greek's data[143], 80% of the phosphoric acid obtained in industry is used to synthesise phosphorus fertilisers.

†Synthetic ammonia serves at the present time as the starting material for the synthesis of the majority of products containing bound nitrogen. The manufacture of ammonia has reached a high degree of technical sophistication. However, its manufacture may require a large capital expenditure and expensive materials, and, furthermore is based on a hydrocarbon starting material[144], the availability of which is limited.

Presumably further experimental and theoretical research will lead to the development of an effective industrial method for the synthesis of phosphorus nitrides and will give rise to further prospects for their employment in various branches of science and engineering. On the other hand, the study of phosphorus nitrides and their derivatives will permit a deeper understanding of their general properties and will make it possible to discover differences between the structures, properties, and reactivities of compounds with single and multiple NN, NP, and PP bonds.

## ADDENDUM

Mention should be made of the following data published during the preparation of the review for printing. One of the principal disadvantages of the high-temperature methods of synthesis of phosphorus nitrides is the use of the readily inflammable and toxic white phosphorus, some of which remains in the reaction product. The application of ion bombardment for the evaporation of phosphorus makes it possible to avoid the heating of the apparatus under laboratory conditions[160]. The resulting amorphous nitride contains no white phosphorus, which makes it possible to open the reactor and carry out experiments with the product in air.

Table 3. The effective charge on the phosphorus atoms in poly(phosphorus nitride) $(P_3N_5)$*.

| $\Delta q^P$, e.u. | | | |
|---|---|---|---|
| *A* | *B* | *C* | *D* |
| 1.65 | 0.63 | 1.08 | 1.1 |

*Method of calculation: *A*) from the estimate of the total number of electrons removed from the orbitals of the phosphorus atom[166]; *B*) from the change in the effective charge in a sphere with a radius equal to the covalent radius of phosphorus[167]; *C*) from the empirical relation[168]

$$\Delta q = 0.813\sqrt[4]{E_b^{2p} - 130.1};$$

*D*) by a method based on the combination of the Boron–Haber cycle with Kapustinskii's lattice equation[168].

A simple method was proposed recently for the preparation of (NPO).[161,162] The one-stage synthesis includes the interaction of concentrated phosphoric acid, pyrophosphoric acid, $P_4O_{10}$, and ammonium phosphates or urea with melamine, guanamines, and trialkyl($C_{1-3}$)-1,3,5-triazines at 500–750°C.

A convenient method for the synthesis of $P(N_3)_3$, $PO(N_3)_3$, and $P(N_3)_5$ as well as a detailed study of the structures of these compounds by vibrational and NMR spectroscopy were published by Volgnandt and Schmidt[163]. According to Pelavin et al.,[164] the interaction of phosphorus pentafluoride with an excess of sodium azide in acetonitrile at −20°C can be represented schematically as follows:

$$PCl_5 + 10NaN_3 \begin{cases} \nearrow P(N_3)_5 + 5NaCl + 5NaN_3 \\ \searrow NaP(N_3)_6 + 5NaCl + 4NaN_3 \end{cases}.$$

The hexa-azidophosphate anion hydrolyses in accordance with the equation

$$P(N_3)_6^- + 2H_2O \rightarrow PO_2(N_3)_2^- + 4HN_3 .$$

A number of attempts have been made to determine the effective charge of phosphorus $\Delta q$ in $(P_3N_5)$ from the binding energies, obtained from X-ray photo electron spectra, of the 2*p* electrons of phosphorus ($E_b^{2p}$) in $(P_3N_5)$ and red phosphorus (133.2 and 130.1 eV respectively—Table 3). Naturally the employment of different models in calculations gives rise to a different significance and different values of the calculated effective charges.

Veprek and Koos[169] showed that a dielectric constant of $(P_3N_5)$ varies linearly with temperature in the range 77–525 K. Phase transformations were not observed in the temperature range 300–765 K, but the structure of $(P_3N_5)$ synthesised from the elements in an ultrahigh frequency discharge depends on the precipitation temperature. At a precipitation temperature of 265°C, it is amorphous, while at higher temperatures a crystalline product is obtained. The dielectric strength of $(P_3N_5)$ is $0.9 \times 10^7$ W $cm^{-1}$.

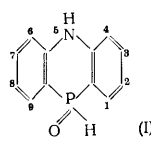
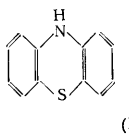
# Chemistry of Dihydrophenophosphazines

A.I.Bokanov and B.I.Stepanov



Work during recent years on the synthesis and investigation of 5,10-dihydrophenophosphazines is summarised. It is suggested that these compounds containing tervalent phosphorus may be of interest as pharmacological preparations. A complete list of 5,10-dihydrophenophosphazines synthesised by 1976 is given, together with 40 references.

CONTENTS

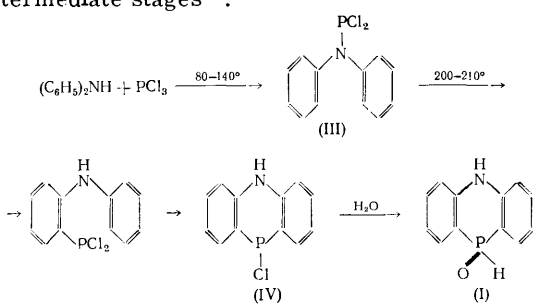


I. Introduction 855
II. Methods of synthesis 855
III. Reactions of dihydrophenophosphazines 856
IV. Physicochemical properties 857

## I. INTRODUCTION

Almost all our knowledge of 5,10-dihydrophenophosphazines has been obtained during the past 16 years, for only 5 papers had been published on them before 1960.[1] In 1890 Michaelis and Schenk reported[2,3] that diphenylamine reacts with phosphorus trichloride at 250°C; elementary analysis of the substance obtained by hydrolysing the reaction mass suggested three possible structures. In 1938 Sergeev and Kudryashov[4] improved the method of preparation, and proved by chemical methods that it had a dihydrophenophosphazine structure. In 1960 the structure of the product obtained by Michaelis et al.[2-5] was finally established: Häring[6] identified it as 5,10-dihydro-10-oxophenophosphazine (I).

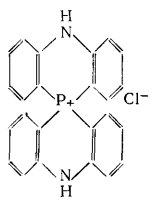
(I)



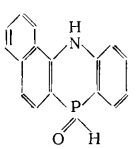
(II)

5,10-Dihydrophenophosphazines are phosphorus analogues of phenothiazines. Derivatives of phenothiazine (II) are used as antioxidants and therapeutic preparations[7,8]. A few patents have claimed that dihydrophenophosphazines may also find application in analogous fields of technology and medicine[9-11].

## II. METHODS OF SYNTHESIS



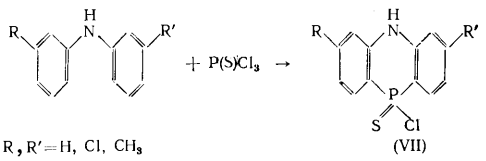
The preparation of dihydrophenophosphazines by the action of phosphorus trichloride on diphenylamine or its homologues has been described in the greatest detail[6,12]. The process is conducted at normal pressure in the absence of a catalyst, by gradually raising the temperature to 200–210°C. The reaction passes through a series of intermediate stages[12]:



(1)

In agreement with the suggested mechanism, the dihydrophenophosphazine (I) has been synthesised[12] by the thermolysis of the previously prepared chloro-amide (III). Intermediate formation of (III) is supported also by the fact that *N*-methyldiphenylamine[13] and *N*-methylditolylamine[12] do not react with phosphorus trichloride under the above conditions. The suggestion that reaction terminates at the formation of 10-chloro-5,10-dihydrophenophosphazine (IV) is less strongly based, since the reaction mass is treated with water in the procedure adopted[4,6,12], and the acid chloride (IV) has not once been isolated. It is possible that the main component of the reaction mixture before hydrolysis is a polymer containing phosphorus–nitrogen bonds, not the acid chloride (IV).

Reaction between diphenylamine and phosphorus trichloride yields a mixture of substances. The chief side-product is 5,5′-dihydro-10,10′-spirobiphenophosphazinium chloride (V).[12,14]



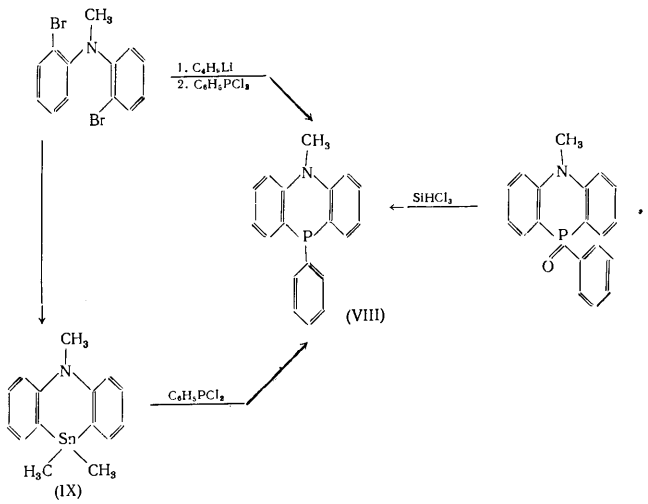
(V)

(VI)

The limits of applicability of reaction (1) have not yet been determined, but naphthylphenylamine is known to react with phosphorus trichloride similarly to diphenylamine, the products being 7,12-dihydro-7-oxobenzo[*c*]-phenophosphazine (VI) and the corresponding spiro-compound[12].

The use of thiophosphoryl chloride has also been suggested for converting diarylamines into 5,10-dihydrophenophosphazines[9]:

(2)



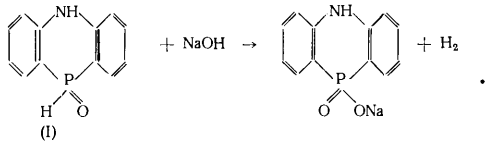
R, R′ = H, Cl, $CH_3$ (VII)

In contrast to the reaction with phosphorus trichloride, the acid chlorides, 10-chloro-5,10-dihydro-10-thionophenophosphazines (VII), have been isolated and identified. The patent description[9] does not indicate the yields of these compounds (VII), but from other information[1] it appears that, of the two procedures—in the absence of a

solvent under pressure at 200°C or in boiling *o*-dichlorobenzene at normal pressure—the former gives the higher yields.

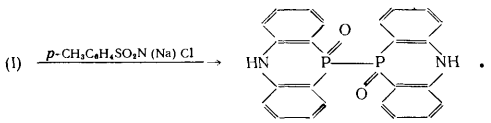
Derivatives of phenothiazine (II) have found widespread therapeutic use, e.g. as antihistamines [8,15]. Synthetic work on 5,10-dihydrophenophosphazines [6,9,16-18] has been stimulated by the efforts to find new medicinals like phenothiazines. Hitherto these attempts have not achieved real success, which can be explained formally by the fact that only phenothiazines containing bivalent sulphur possess biological activity, whereas the 10-oxo- and 10-thiono-5,10-dihydrophenophosphazines tested [6,9,16-18] are analogues of phenothiazine *S*-oxides. It is more likely that medicinals will be found among phenophosphazines containing a tervalent phosphorus atom.

These latter compounds may be synthesised by analogy with 5,10-dihydro-5-methyl-10-phenylphenophosphazine (VIII): [19-21]



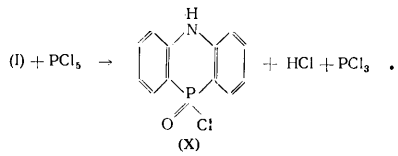
*N*-Alkyl-*oo'*-dibromodiphenylamines are difficultly accessible, which restricts the possibilities of their use for the synthesis of 5,10-dihydrophenophosphazines [13,19]. The latter can be obtained by replacing the tin atom in heterocycles of the type (IX), [20] which demonstrates the greater thermodynamic stability of phosphorus–carbon than of tin–carbon bonds, but this method is of no synthetic value, since the initial 5,10-dihydrophenazastannines are obtained from the same *oo'*-dibromodiphenylamines. In many cases the most rational method for obtaining dihydrophenophosphazines containing tervalent phosphorus atoms may be reduction [21] of the corresponding *P*-oxides or *P*-sulphides.

## III. REACTIONS OF DIHYDROPHENOPHOSPHAZINES



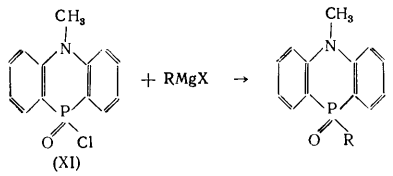
### 1. Reactions of the Heteroatoms

Derivatives of 5,10-dihydrophenophosphazine are usually obtained from the 10-oxo-compound (I) as starting material. The latter undergoes the reactions characteristic of oxides of secondary phosphines [22]: it adds at an activated multiple bond, and can be alkylated and oxidised at the phosphorus atom. Several methods have been prepared for oxidising (I) to phenophosphazinic acid—with air in boiling tetralin [4,6], or with hydrogen peroxide in acetic acid [6] or in aqueous alkali [12]—but in the last case the use of hydrogen peroxide is not necessary, since boiling aqueous alkali converts the phenophosphazine (I) smoothly into a salt of phenophosphazinic acid [23]:

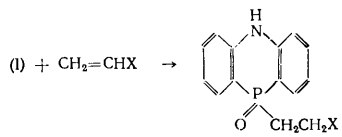


(The mechanism of the oxidation of oxides of secondary phosphines in alkaline media has been discussed in Ref. 24.)

Elementary iodine and chloramine T effect a different course of oxidation, converting (I) into 5,5'-dihydro-10,10'-dioxo-10,10'-diphenophosphazinyl [6]:



If the final aim is to prepare derivatives of phenophosphazinic acid, it is most rational to use phosphorus pentachloride as oxidant [25]:

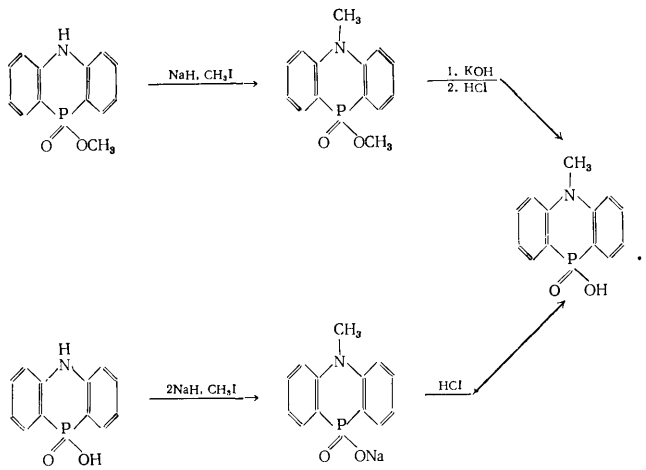


Phenophosphazinic esters and amides can be obtained by replacing the chlorine atom in the acid chloride (X). [6,11,17,25,26] The thio-acid chlorides (VII) undergo analogous reactions with alcohols and amines [1,6,11,17,18], but in this case the products of esterification must be further investigated to differentiate between thionic and thiolic isomers $\diagdown$PS.OR and $\diagdown$PO.SR. [6,18]

The acid chloride (XI) reacts with organomagnesium compounds with the formation of phosphorus–carbon bonds [21]:

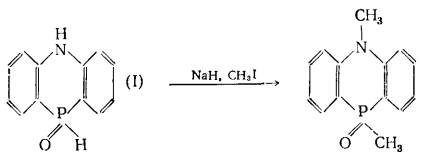
R=CH$_3$, C$_6$H$_5$; X=I, Br .

However, most of the phenophosphazines containing exocyclic phosphorus–carbon bonds have been obtained directly from the phenophosphazine (I) by addition to alkenes and azomethines [16,27]. The reaction conditions depend on the structure of the alkene. With acrylic acid and its derivatives, for example, the process is conducted without a solvent and without a catalyst at 140–170°C: [27]



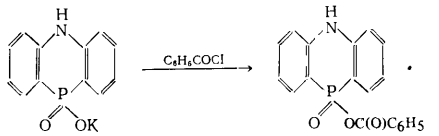
X=COOH, COOCH$_3$, CN .

1-Phenylprop-2-en-1-one adds to (I) in the presence of sodium ethoxide in alcoholic solution at 20°C. [16] At the



present time no kinetic data are available for a correlation to be sought between the reactivity and the structure of the reactants; moreover, not all the facts can be explained even qualitatively. Thus it has been established[16] that the phenophosphazine (I) does not add to azodicarboxylic ester, but it reacts with the dimorpholide of the acid in boiling ethanol in the absence of catalysts.

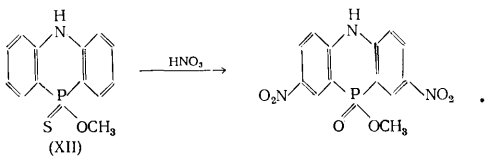
Examination of published results[16,27] leads to the preliminary conclusion that the reactivity of multiple bonds towards (I) increases in the sequence N:N < C:C < C:N. Addition takes place at the phosphorus atom independently of the nature of the multiple bond[16,27]. In view of these facts, Häring's conclusion[6] that phenyl isocyanate adds at the nitrogen atom in the phenophosphazine (I) cannot be accepted without proof.



The nitrogen atom can be alkylated[21,23] when its nucleophilic character has been enhanced by ionisation of the imino-group $\rangle NH \rightarrow \rangle N^-$:

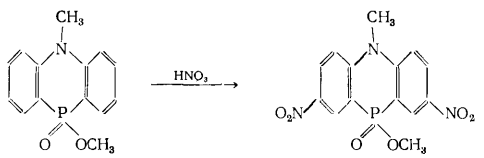
Under the corresponding conditions the phenophosphazine (I) yields a dimethylated product[21]:

When protolysis of the nitrogen–hydrogen bond is excluded, the nucleophilicity of the imino-group is extremely low. Thus a phenophosphazinate salt undergoes benzoylation at the oxygen atom, not at the nitrogen atom[6]:



Thus the activity of the nucleophilic centres in dihydrophenophosphazines diminishes in the sequence $\rangle N^- > \rangle PO.O^- > \rangle NH$.

2. Electrophilic Aromatic Substitution



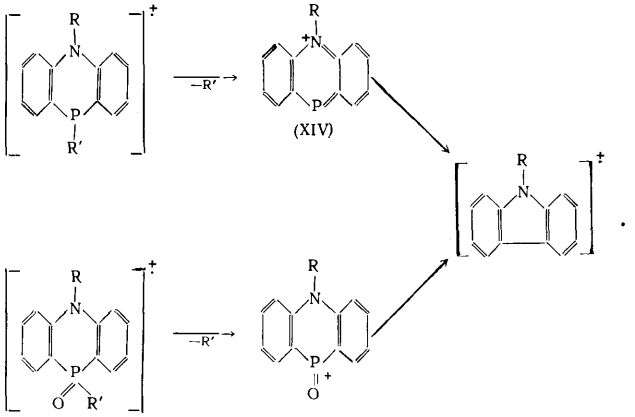
At 5°C molecular bromine in formic acid oxidises 5,10-dihydro-10-oxophenophosphazine (I) and simultaneously brominates its benzene rings[6], forming a mixture of products of different degrees of bromination, among which a dibromo-5,10-dihydro-10-hydroxy-10-oxophenophosphazine (dibromophenophosphazinic acid) predominates in which the positions of the bromine atoms have not been established. It is not known whether phenophosphazinic acid is brominated under the same conditions, and therefore the sequence of oxidation and substitution is obscure.

According to McHattie[1] the 10-thionophenophosphazine (XII) does not react with the *p*-nitrobenzenediazonium ion, whereas in boiling nitric acid it undergoes simultaneous nitration and oxidation:

(XII)

Nitration of 5,10-dihydro-10-methoxy-5-methyl-10-oxophenophosphazine in acetic acid yields the dinitro-product (XIII), whose structure has been proved unambiguously by proton magnetic resonance[23]:

(XIII)



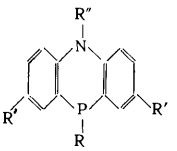
## IV. PHYSICOCHEMICAL PROPERTIES

Since 1960 the infrared spectra have been used to identify dihydrophenophosphazines. In no case have the vibrations been calculated, and the frequencies representing vibrations of the heterocycle have not been identified. Investigators working with 5,10-dihydro-10-oxophenophosphazines usually mention the frequency of the P=O bond[6,12,18,21,23]. The frequency of stretching vibrations of this bond is lower in dihydrophenophosphazines containing imino-groups, perhaps owing to formation of intermolecular hydrogen bonds, and appears in the range 1150 to 1195 $cm^{-1}$.[12,18] Alkylation of the nitrogen raises the frequency to 1180–1240 $cm^{-1}$.[21,23] Thus the original assignment[6] of bands at 1340–1350 $cm^{-1}$ to vibrations of the P:O bond is incorrect.

Among nuclear magnetic resonance methods only proton resonance has been used to investigate 5,10-dihydrophenophosphazines, mainly to identify alkyl groups attached to the nitrogen and phosphorus atoms[12,20,21]. In the $^1H$ n.m.r. spectrum of the dinitro-compound (XIII), however, the chemical shifts of non-equivalent aromatic protons differ so considerably that the spectrum in this region could be completely deciphered[23]. The spin–spin interaction constants in the (XIII) molecule, $^3J(PH) = 14.0$ and especially $^4J(PH) = 7.2$ Hz, are considerably larger than those in triphenylphosphine oxide and its substituted derivatives, where the corresponding values are 11.2–12.4 and 1.8–2.7 Hz.[28,29]

Data have been published on the mass spectra of individual dihydrophenophosphazines[12,21,23,30]. The main

routes by which these compounds break down can be represented by the scheme



The ion (XIV) is the chief product in the mass spectra of the tervalent phosphorus derivatives, even with ionising radiation of energy 30 eV.[21] Oxidation of the phosphorus atom enhances the stability of the molecular ion, which is usually the main product in the spectra of 5,10-dihydro-10-oxophenophosphazines.

Table 1. Electronic spectra of 10-substituted (R) 5,10-dihydro-5-methyl-10-oxophenophosphazines[21].

In the opinion of Freedman and Styles[31] the ultraviolet spectra of phenophosphazinic acids indicate conjugation of a quinquevalent phosphorus atom with the π-electron system of aromatic rings. Table 1 shows that the character of the spectrum, and hence of conjugation in phenophosphazines, is little affected by the nature of substituents attached to the phosphorus atom.

The adiabatic ionisation potentials of four dihydrophenophosphazines have been determined[32] by photoionisation mass spectroscopy. The values of 6.90 ± 0.05 eV obtained for 5,10-dihydro-5-methyl-10-phenylphenophosphazine (VIII) lies within the range given for *N*-methylphenothiazine (6.60—6.96 eV [33,34]). Since the pharmacological activity of phenothiazines is attributed to their low ionisation potentials[34,35], it is very likely that pharmacological products can be based also on 5,10-dihydrophenophosphazines.

Tables 2—5 contain a complete list of all the 5,10-dihydrophenophosphazines reported in periodicals, patents,

Table 2 lists dihydrophenophosphazines containing a tervalent phosphorus atom; Tables 3 and 4 give dihydrophenophosphazines derived from quinquevalent phosphorus, with both the nitrogen atom and the benzene rings unsubstituted; and Table 5 contains the remaining dihydrophenophosphazines with a quinquevalent phosphorus atom. Within each table the compounds are arranged in order of increasing number of carbon atoms in the molecule. The columns headed "identification" list the simple derivatives (salts, hydrochlorides, methiodides) and spectral methods by which the compounds have been characterised.

† McHattie's results are quoted in the book by Mann [1].

*7,10-Dihydro-7-oxobenzo[*c*]phenophosphazine (VI).

## ADDENDUM

Four more papers on dihydrophenophosphazines appeared [37-40] while the manuscript was being prepared for press. The Reviewers have collaborated with Bychkov [37] in developing a simple and effective method for synthesising phenophosphazinic acid. The proton magnetic resonance spectrum of the dinitro-compound (XIII), described in a deposited paper [23], has now been published in a more accessible source [38]. X-Ray examination of 5,10-dihydro-5-methyl-10-phenylphenophosphazine (VIII) shows that the molecule is not planar, the angle between the planes of the phenylene rings being 145° [39].

Petrov et al. [40] have improved the method of isolating the phenophosphazine (I) from the mixture of products of reaction (1). 5,10-Dihydro-10-oxophenophosphazines containing hydroxymethyl and aminomethyl groups attached to the phosphorus atom have been obtained from this compound (I), and the infrared spectra have been discussed in detail [40].

# Structure and Reactivity of Esters of Thio-acids of Three-coordinated Phosphorus

E.A.Krasil'nikova

The structure and the chemical behaviour of thio-esters of three-coordinated phosphorus $R_nP(SR')_{3-n}$ ($n = 0-2$) are examined, and their reactions are discussed with electrophilic reagents differing both in the number and in the nature of the electrophilic centres. The peculiar character of such reactions is due primarily to the presence of two competing nucleophilic centres to the ambidenticity of the phosphorus(III)-sulphur(II) group, and to the high reactivity of two-coordinated sulphur (thionic and thiolic) in esters of three- and four-coordinated phosphorus. A list of 170 references is included.

## I. INTRODUCTION

The chemistry of derivatives of three-coordinated phosphorus is now a well studied field. Structural features and regularities in the chemical behaviour of these compounds have been quite widely discussed in several review papers [1-4] and in monographs published during recent years [5-8].

The structure and the reactivity of compounds of three-coordinated phosphorus containing a phosphorus–sulphur bond have either not been discussed at all in these works [5] or have been only incompletely considered [4,7,8]. However, esters of thio-acids of phosphorus have extremely characteristic properties, distinguishing them strongly from the well studied oxygen analogues. The few papers and their contradictions prevented until recently a comprehensive view of the reactivity of these compounds. Only a series of investigations on the interaction between these esters and several electrophilic reagents, published during recent years, have made it possible to note several general rules controlling these processes.

Esters of thio-acids of three-coordinated phosphorus possess two nucleophilic reaction centres—phosphorus and sulphur—the main feature of the bond between these atoms being that both elements belong to the third period and have electron shells of closely similar structure. Hence considerable competition may be expected between the two atoms in intramolecular donor–acceptor interaction, as well as in reactions with electrophilic and nucleophilic reagents.

The literature shows no abatement of the controversy on the bond structure and intramolecular donor–acceptor interactions in compounds of elements in the third period—silicon, phosphorus, sulphur, and chlorine—especially on the capacity of the lone pairs of electrons on phosphorus(III) and sulphur(II) atoms for $p,\pi$ and $p,d$ interaction. Some workers [6,9-24] have attempted not only to detect but also in several cases to estimate a $+M$ effect in phosphorus(III), whereas others [3,7,25] give results that they regard as evidence of the absence of such an effect. It has been assumed that the $p,\pi$ effect of sulphur(II) is slight [16, 26-28], but larger than that of phosphorus [3].

The legitimacy of using ideas on the participation of $d$ orbitals in forming chemical bonds of both $\sigma$ and $\pi$ types has also been discussed. Several workers consider [26,29-35] that even with phosphorus(III) and sulphur(II) the possibility of the participation of $3d$ orbitals in hybridisation cannot be completely excluded. The involvement of $d$ orbitals in $\pi$ bonding explains several peculiarities of compounds of elements in the third period in comparison with the corresponding compounds of elements in the second period [3,36-43]. In the view of other authors [44-46] the role of $d$ orbitals cannot be significant because of their high energy. Attempts have recently been made to explain the peculiarity of compounds of elements in the third period without regard to the main structural feature—the presence of vacant $d$ orbitals in the valency layer—of the electron shells of their atoms [47-51]. The opinion has been expressed [51] that the $d$-orbital concept cannot be correctly used in describing structural features of compounds of elements in the third period.

Within the scope of the method of molecular orbitals the concept of the participation of $d$ orbitals need not in general be introduced into the description of bond formation in molecules containing phosphorus with coordination numbers 3–6. In the valence bond method, which retains the classical structural formula with its two-centre, two-electron bond, $d$ orbitals are enlisted both for describing bonds and in the theory of electron displacements ($p,d$ and $\pi,d$ effects). In the discussion of the acceptor properties of phosphorus an attempt has been made to replace the $d$-orbital concept ($-M$ effect of the phosphorus atom) by that of a negative hyperconjugation effect [51]. At the present time, however, such substitution of one effect by another hardly changes the situation with respect to qualitative ideas on electron displacements in organic molecules.

Data on intramolecular donor–acceptor effects in compounds containing phosphorus–phosphorus and sulphur–sulphur bonds are of especial interest in connection with this problem. The ultraviolet spectra of cyclopolyphosphines have been interpreted [52-57] as supporting a $+M$ effect, which is justified also by quantum-mechanical calculations [54]. Similarly in diphosphines, also on the basis of ultraviolet spectra, the possibility of combined $p,d$ effects has been suggested [58], as a consequence of which both phosphorus atoms are simultaneously donors and acceptors of lone pairs of electrons, which is apparent

in the chemical properties of diphosphines[59]. Similar effects are assumed in natural sulphur, in dihydrogen disulphide, and in dialkyl disulphides[26], and are confirmed also by the abnormally high energy of dissociation of the sulphur–sulphur bond[26,60].

Similarly, the group $>\ddot{P}-\ddot{S}-$ is an ambident system, in which two types of mesomeric displacements

may theoretically occur, the first representing a $+M$ effect and the second a $-M$ effect of the phosphorus atom. In terms of the theory of resonance the ambident system is a resonance hybrid of three structures:

$$>\ddot{P}-\ddot{S}- \leftrightarrow >\overline{P}..=\overset{+}{S} \leftrightarrow >\overset{+}{P}=\overline{S}: .$$

A qualitative estimate has been made of the donor–acceptor interactions in the phosphorus–sulphur bond[61], which are obviously determined primarily by the energies of the highest occupied orbitals and the lowest vacant orbitals of both atoms. Comparison of data[62] on ionisation potentials, electron affinities, and electronegativities of phosphorus and sulphur atoms (Table 1) indicates that sulphur possesses more clearly defined electron-accepting properties ($-I$ and $-M$ effects) than does the phosphorus atom.

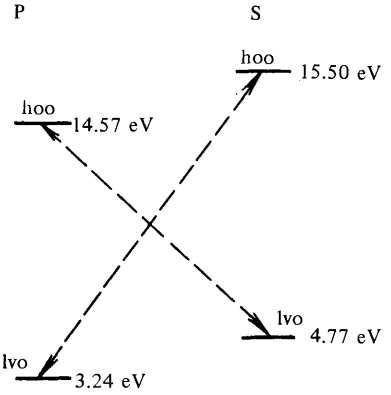

**Figure 1.** Relative arrangement of highest occupied orbitals (hoo) and lowest vacant orbitals (lvo) of phosphorus and sulphur atoms†.

The energy difference between the highest occupied level of phosphorus and the lowest vacant level of sulphur is actually smaller than the corresponding energy difference between sulphur and phosphorus (9.8 and 12.26 eV—Fig. 1)†. Hence electron displacements towards the sulphur atom are energetically more probable. However, the opposite interaction cannot be completely excluded[63]. This is made still more probable by the negative inductive and mesomeric effects of sulphur conferring a considerable positive charge on the phosphorus, which may be partly balanced by reverse $\pi$ bonding. Quite a high degree of delocalisation of electron shells may be expected in such a system from the close proximity of the energy states of phosphorus and sulphur atoms.

† Broken lines are drawn in Fig. 1 to indicate probable electron displacements, not the transfer of an electron from one energy level to another.

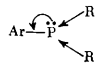
## II. ELECTRONIC EFFECTS IN ESTERS OF THIO-ACIDS OF THREE-COORDINATED PHOSPHORUS

The question of electron displacements in compounds $R_nP(SR')_{3-n}$ is probably part of the more general problem, already discussed in a review[3] and in several papers[15,64], of the nature of the interaction of a three-coordinated phosphorus atom with substituents containing a $\pi$-electron system. Among the latter are e.g. the phenyl, vinyl, and ethynyl radicals, the carbonyl group, and obviously groups containing a two-coordinated sulphur atom. It may be supposed that the phosphorus atom in such systems is able to develop both donor and acceptor properties. No generally accepted opinion has yet been reached on which of these effects is inherent in a three-coordinated phosphorus atom in a static (non-reacting) molecule[15,64,65].

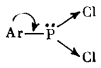
Probably no definite conclusions on the direction of electron displacements can at present be drawn from data on dipole moments. The contradictoriness of published values[66–75] is not surprising, since the dipole moment of a molecule is a function of several factors acting simultaneously, whose combined effect is extremely difficult to assess[76,77]. In molecules containing atoms having lone pairs of electrons the dipole moment depends not only on the dimensions, the electronegativities of the atoms, and the bond angles, but mainly on the type of hybridisation of the orbital of the lone pair. Several authors[69,72] made calculations having equated the dipole moment of the lone pair to that of the phosphorus–carbon bond, which can hardly be accepted as correct[77]. The type of hybridisation has been taken into account in calculating dipole moments for several phosphorus(III) compounds[73–75]. However, a method of calculation[78] that had been criticised[31] was used to determine the character of the hybridisation. Nor do the ultraviolet spectra provide an unambiguous indication of the nature of the conjugation in aromatic phosphines[3,6,7,58,79–84].



Electronic effects in compounds containing three-coordinated phosphorus have been discussed in terms of proton and phosphorus-31 nuclear magnetic resonance[35,72,85–91]. Attempts were made[87–91] to relate the phosphorus-31 chemical shifts wich such parameters as the electronegativities of substituents, bond angles, degree of $\pi$ bonding, type of hybridisation, character of the lone pair, etc. However, it has not yet proved possible to develop a general theory relating the chemical shift of the phosphorus atom with the structure of the molecules. The most comprehensive investigation[35] also is evidently not free from defects, and has been criticised by several workers[90,92,93].

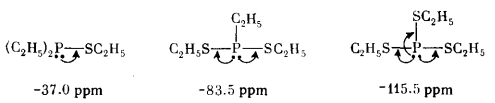
Nevertheless, certain considerations pertaining to the character of possible interactions of a three-coordinated

phosphorus atom with the $\pi$-electron system of an aromatic ring can be expressed on the basis of published $^{31}P$ n.m.r. data [72,94,95]. Table 2 lists a series of compounds (Nos. 1–9) in which replacement of an alkyl by a phenyl group leads to a down-field shift in the phosphorus-31 resonance signal, e.g.



$$\underset{+20.4\ \text{ppm}}{(C_2H_5)_3P} > \underset{+16.0\ \text{ppm}}{(C_2H_5)_2P{-}C_6H_5} > \underset{+8.0\ \text{ppm}}{(C_6H_5)_3P}\ .$$

A low-field displacement of a signal can be attributed to an inductive effect. However, the ethyl and phenyl groups have closely similar electronegativities (2.6 and 2.8), [96,97] differing little from that of the phosphorus atom itself (2.79 for tetrahedral hybridisation [62]). This donor effect may perhaps be regarded as a consequence of $p,\pi$ conjugation of the lone pair of the phosphorus with the aromatic ring, which is favoured by $+I$ effects of the alkyl groups:



The alkoxycarbonyl group in compounds of the type $R_2PCOOR'$ has a strong electron-accepting action [98], as is indicated by the down-field shift in the resonance signal of the phosphorus nucleus (compounds No. 21–23 compared with No. 1 in Table 2), the infrared absorption by the carbonyl group at 1695–1685 $cm^{-1}$, and certain chemical properties of such compounds. Acetyl phosphides exhibit [100,101] opposite electron displacements, perhaps promoted by the $+I$ effect of the alkyl groups.

On the other hand, the presence of strongly electron-accepting groups (e.g. halogen atoms) attached to the phosphorus atom produces a high-field shift in the resonance signals when ethyl is replaced by phenyl (compounds No. 10–20 in Table 2), which can probably be explained by a $\pi,d$ effect:

Comparison of values of $\delta(^{31}P)$ in several series—(I) Nos. 24 and 25, (II) 26 and 27, and (III) 28 and 29 in Table 2—shows that, relative to propenyl, an alkyl group displaces the resonance signal up-field in the presence of such electron-accepting groups as chloro, alkoxyl, and dialkylamino attached to the phosphorus [99]. Unfortunately, the correlation between $\delta(^{31}P)$ and the structure of substituents bound to the phosphorus atom is satisfactory only for a limited number of compounds of similar structure, and available data are insufficient for final conclusions to be reached.

Comparison of the chemical shifts of phosphorus nuclei in a series of tervalent thio-esters (Table 3) permits an analogous discussion of the electron displacements (in terms of inductive and mesomeric effects) in the ground state of molecules [19,61] in conformity with the above structure of the phosphorus–sulphur bond. Experimental values of $\delta(^{31}P)$ suggest that one or other type of electron displacement will develop (predominate) depending on the nature of the groups R and R', as well as on the number of sulphur atoms combined with the phosphorus (Table 3). In all the series investigated [19,61] the successive replacement of alkyl or phenyl by alkylthio (phenylthio) results in a down-field shift in the resonance signal—Table 3, series (I), compounds No. 1, 5, and 15); (II) Nos. 3, 4, and 15; and (III) Nos. 2, 9, and 13—so that the donor effect of the phosphorus increases with the number of alkylthio-groups because of the strong electron-accepting properties of the sulphur atom, e.g.

Similarly, the replacement of alkylthio by phenylthio produces a low-field shift of the resonance signal in all the cases examined, which is obviously due to the more strongly developed electron-accepting properties of the phenylthio-group—series (I), Nos. 1 and 2, (II) Nos. 4 and 7, (III) Nos. 5 and 9, (IV) Nos. 11 and 12, and (V) Nos. 13 and 15—but in several cases—(I) Nos. 1, 3, and 16; (II) Nos. 4 and 5, and (III) Nos. 7 and 9—a high-field shift of the phosphorus-31 resonance signal is observed.

Strengthened shielding of the phosphorus nucleus can evidently be attributed to displacement of electrons as in the $\pi,d$ effect, e.g. in the sequence

$$\underset{-37\ \text{ppm}}{(C_2H_5)_2PSC_2H_5} < \underset{-32.5\ \text{ppm}}{(C_2H_5)(C_6H_5)PSC_2H_5} < \underset{-26.5\ \text{ppm}}{(C_6H_5)_2PSC_2H_5}$$

| 8 | $C_3H_7$ | $SC_2H_5$ | $SC_2H_5$ | −81.0 | 16 | $C_2H_5$ | $C_6H_5$ | $SC_2H_5$ | −32.5 |

Thus in this series of compounds phosphorus exhibits acceptor properties towards the phenyl radical.

Hence the $^{31}P$ n.m.r. data listed in Tables 2 and 3 indicate that three-coordinated phosphorus may develop either a donor or an acceptor character depending on the nature of the substituents.

Alkyl groups (ethyl, propyl, butyl) make almost the same contribution to the resonance signal, as is indicated by closely similar values of $\delta(^{31}P)$ for compounds Nos. 5, 8, and 10 in Table 3. An exception is the methyl group, which causes a larger up-field shift of the resonance signal than does phenyl—series (I) Nos. 11 and 4, and (II) Nos. 12 and 7. Similarly strong shielding of the phosphorus nucleus by a methyl group has been explained[71] by hyperconjugation:

$$H_3CP(SR')_2 \leftrightarrow H^+CH_2^-P(SR')_2 .$$

Several workers have shown[102-117] that the phosphorus atom is able to exhibit both a definite acceptor and a donor character even in a dynamic state. This is especially apparent in reactions in which the phosphorus, while not acting as a reaction centre, helps to stabilise the transition state. In some cases[112,113,118] phosphorus exerts an acceptor effect, and the carbanions formed in the reaction are stabilised by *d*-orbital resonance. A similar *d*-orbital effect is observed with silicon and sulphur atoms in the reactions of vinylsilanes[119] and vinyl sulphides[26,120]. In other cases[17,109,110], however, the low energy barrier to pyramidal inversion in certain three-coordinated phosphorus derivatives has been attributed to considerable strengthening in the transition state of the donor effect of phosphorus(III) in the static molecule. According to modern ideas in theoretical chemistry, dynamic electronic effects do not necessarily operate in the same direction as electron displacements in the static molecule[121].

## III. DUAL REACTIVITY (AMBIDENTICITY) OF PHOSPHORUS(III) THIO-ACIDS TOWARDS ALKYL HALIDES

Compounds containing a $\rangle\ddot{P}-\ddot{S}-$ group occupy a special place among ambident derivatives of three-coordinated phosphorus such as esters, amides, and thioesters. Two types of reactions—electrophilic addition $A_E$ at the lone pair and nucleophilic substitution $S_N$—characterise derivatives of three-coordinated phosphorus in conformity with the special structure of its electron shell and depending on the structure of its nearest neighbours and the nature of the reagent[4-6,102]. The same types of reactions occur readily also with compounds containing two-coordinated sulphur[26]. Because of the close similarity in the electron configurations of phosphorus and sulphur atoms, the mechanisms of their reactions should have much in common. This must obviously be borne in mind when considering the interaction of the esters $R_nP(SR')_{3-n}$ with electrophilic reagents.

### 1. Ability of Esters $R_nP(SR')_{3-n}$ to form Onium Derivatives

An element possessing a lone pair of electrons is able to form onium—oxonium, ammonium, phosphonium, sulphonium, etc.—compounds on reaction with electrophilic reagents. Esters of type $R_nP(SR')_{3-n}$ can therefore reasonably be expected to form onium derivatives of two types—quasi-phosphonium and quasi-sulphonium[122-124]:

$$\rangle\ddot{P}-\ddot{S}-R' + R''X \rightarrow \left[\rangle P\langle^{R''}_{\ddot{S}R'}\right]^+X^- ,$$

(I)

$$\rangle\ddot{P}-\ddot{S}-R' + R''X \rightarrow \left[\rangle\ddot{P}-\overset{R''}{\overset{|}{\ddot{S}}}-R'\right]^+X^- .$$

(II)

The quasi-sulphonium structure ascribed[124] to products of the alkylation of trialkyl (triaryl) phosphorotrithioites has since been confirmed[22] by their proton magnetic resonance spectra. Several workers have isolated quasi-phosphonium compounds by treating alkyl dialkylphosphinothioites with alkyl halides[22,123,125] and with other electrophilic reagents[126].

Interesting results have been obtained from the alkylation of dialkyl alkylphosphonodithioites, which form[22,61] mixtures of onium derivatives of both types, the quantitative relations between which vary with the structure of R and R′. To interpret the reactivities of compounds containing P−S, S−P−S, and $S-P\langle^{S}_{S}$ groups use has been made[61,127] of Pearson's concept of hard and soft acids and bases[128,129]. In the ambident system sulphur is a "hard", and phosphorus a "soft", basic centre (sulphur is more electronegative and less polarisable than phosphorus). In esters of type $R_2P.S.R'$, therefore, phosphorus undergoes electrophilic attack by a "soft" electrophilic centre (an $sp^3$-hybrid carbon atom in an alkyl halide), with formation of quasi-phosphonium derivatives of type (I).

The esters $RP(SR')_2$ contain three nucleophilic centres—one "soft" (the phosphorus atom) and two "hard" (the sulphur atoms)—and the displacement of electron density towards the latter weakens the nucleophilic character of the phosphorus atom and increases the probability of attack by an electrophilic species on the "hard" sulphur atom, even if such species is a "soft" acid. As a consequence, a mixture of quasi-phosphonium (I) and quasi-sulphonium

(II) derivatives is formed. In trialkyl phosphorotrithioites four donor centres are competing. The three sulphur atoms greatly deplete the electronic environment of the phosphorus atom, and hence weaken its nucleophilic character. Furthermore, the probability factor favouring attack on the sulphur increases. All this leads to the formation of quasi-sulphonium derivatives (II). The steric factor may play some part, but no information has been published on the role of steric hindrance in these reactions.

Thus the ability to form quasi-sulphonium compounds [61] falls in the sequence

$$(RS)_3P > (RS)_2PR' > RSPR_2'.$$

## 2. Thio-esters of Three-coordinated Phosphorus in the Arbuzov Reaction

The mechanism of the action of alkyl halides on oxygen-containing esters of three-coordinated phosphorus has been studied quite well, although few quantitative data on this reaction are yet available [4-6]. The number of investigations on the behaviour of $R_nP(SR')_{3-n}$ esters ($n = 0-2$) in the Arbuzov reaction is at present quite insignificant.

The peculiar behaviour of diphenylphosphinothious esters with alkyl halides was first investigated by Arbuzov, whose results were reported at the Twelfth Congress of Russian Naturalists and Physicians in 1910. [122] He found that "esters of general type $(C_6H_5)_2P.SR$, as derivatives of tervalent phosphorus and like the corresponding oxygen compounds, isomerise under the influence of alkyl iodides into sulphides containing quinquevalent phosphorus, of general type $(C_6H_5)_2PS.R$. However, the isomerisation of sulphur-containing esters is complicated by secondary reactions, viz. the formation of small quantities of tetra-substituted phosphonium iodides and probably esters of formula $(C_6H_5)_2PSSR$". [123]

Dialkyl- and alkylaryl-phosphinothious esters undergo similar reactions [125,131]. Arbuzov suggested the scheme [122]

$$R_2P(SR') + R''X \rightarrow R_2P(S)R'' + R'X\ , \quad (1)$$

$$2R_2P(SR') \rightarrow R_2PR' + R_2P(S)(SR')\ , \quad (2)$$

$$R_2PR' + R''X \rightarrow [R_2PR'R'']^+X^-\ . \quad (3)$$

Equation (1) represents the main reaction, while (2) and (3) are secondary processes.

Kabachnik et al. [124] showed that trialkyl phosphorotrithioites react unusually with preservation of the coordination number of the phosphorus atom:

$$(RS)_3P + R'X \rightarrow \underset{(II)}{\left[(RS)_2P{-}\overset{R'}{\overset{|}{S}}{-}R\right]^+}X^- \rightarrow (RS)_2PX + R'{-}S{-}R\ .$$

They isolated the acid chlorides $(RS)_2PX$ and the dialkyl sulphides, thus showing for the first time that the reaction may take place at the sulphur atom, not at phosphorus. Decomposition of the quasi-sulphonium salt (II) can evidently be regarded as nucleophilic substitution at three-coordinated phosphorus, the electrophilic character of which is enhanced by the positively charged sulphur.

Mixed *O*- and *S*-esters of phosphorous acid [130] react with alkyl halides to form both the normal Arbuzov products and several secondary products. The appearance of the latter was attributed to the involvement of a second nucleophilic centre—a sulphur atom—as well as the phosphorus.

The reactions of dialkyl alkyl(or aryl)phosphonodithioites are most complicated [132,133]. The researchers [61,127,132,134] suggested a scheme involving several parallel and consecutive processes, each of which could be reproduced in separate experiments:

$$\underset{(III)}{RP(SR')_2} + \underset{(IV)}{R''X} \rightarrow \underset{(V)}{R''R'P(S)SR'} + \underset{(VI)}{R'X} + \underset{(VII)}{RP(SR')X} + \underset{(VIII)}{R'{-}S{-}R''}$$

$$\underset{(IX)}{RP(S)(SR')_2} + \underset{(X)}{RR''P(SR')} \qquad \underset{(XI)}{RR''\ddot{P}(S)X} + \underset{(XII)}{R'{-}S{-}R'}$$

$$(X) + (IV) \rightarrow \underset{(XIII)}{RR''_2P(S)} + (VI)$$

$$(IX) + (VI) \rightarrow \underset{(XIV)}{RP(S)(SR')X} + (XII)\ .$$

Compounds (V) and (VI) are products of an Arbuzov reaction, and are obviously formed by the breakdown of a quasi-phosphonium (I) type of intermediate. The products (VII) and (VIII) result from reaction at a sulphur atom, with intermediate formation of quasi-sulphonium derivatives of type (II). Compounds (IX)–(XIV) are formed by secondary processes occurring in the reaction mixture [61, 134]. The above scheme shows that the complexity is due not only to the dual reactivity (ambidenticity) of these compounds but also to the ease of occurrence of secondary reactions among starting materials and products [61,127,134].

It is by no means always possible to isolate and identify all the products indicated in the above scheme [61,127]. Their reasons for this are the highly reactive character of compounds containing a phosphorus–sulphur bond and the complexity of their isolation consequent on the formation of difficultly separable azeotropic mixtures. In most cases successful separation can be achieved only by means of column, gas–liquid, and thin-layer chromatography [135,136]. Formation of certain products—(XI) (VII), (XIV)—was detected when the course of the process was monitored by $^{31}P$ n.m.r. spectroscopy [61,127,142].

The extremely complicated problem of the relative proportions of the first and second types of reaction (at phosphorus and at sulphur respectively) has been only partly solved [61,127,142]. This work has shown that the structure of the alkyl halide has a significant influence firstly on the extent of reaction at phosphorus and sulphur atoms, and secondly on the reaction velocity. Table 4 gives data on the main reaction products containing phosphorus—(V), (IX), and (X)—obtained from the ratio of the integral intensities of the resonance peaks of the phosphorus nucleus, together with quantitative data, obtained by gas–liquid chromatography, on the contents of the dialkyl sulphides (VIII) and (XII). [127,137] The considerable quantities of the normal Arbuzov reaction product (V) and the low contents (0.5–11.0%) of the dialkyl sulphide (VIII) in the reaction mixture obtained from n-alkyl bromides and the esters (III) indicate that the proportion of reaction at the sulphur is insignificant. The dialkyl sulphide (VIII) was not isolated from the reaction with benzyl bromide, so that in this case reaction at the sulphur probably does not take place at all. In the reactions with secondary and tertiary alkyl bromides the yield of the normal Arbuzov reaction product (V) falls (24–30%), while the yield of the dialkyl sulphide (VIII) increases (9.0–31.4%).

On the basis of the results all the alkyl bromides investigated can be arranged in the sequence

$$t\text{-}C_4H_9 > iso\text{-}C_4H_9 > s\text{-}C_4H_9 \simeq iso\text{-}C_3H_7 > n\text{-}C_4H_9 > n\text{-}C_3H_7 > C_2H_5 > CH_3 > C_3H_5 > C_6H_5CH_2$$

according to their tendency to react with the sulphur [61]. This experimental rule can be stated in terms of the concept of soft and hard acids and bases [61]: the hardness of the $sp^3$ carbon atom in alkyl halides increases in a homologous series and also on passing from primary to secondary and to tertiary compounds [129].

Table 4. Yields (%) of product of the reaction $RP(SR')_2 + R''X$.

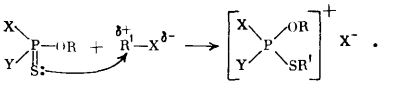
The rate curves in Fig. 2 have been plotted from the variation in the concentration of the initial ester $C_6H_5P.(SC_3H_7)_2$ during its reaction with several alkyl bromides determined from the $^{31}P$ n.m.r. spectra [61,127,142]. In order of decreasing rate of reaction with $RP(SR')_2$ the alkyl bromides examined form the sequence



$$CH_3 > C_2H_5 > n\text{-}C_3H_7 > n\text{-}C_4H_9 > t\text{-}C_4H_9 \simeq iso\text{-}C_4H_9 > iso\text{-}C_3H_7 > s\text{-}C_4H_9.$$

The principal secondary processes complicating the reaction are [61,127,134] firstly the exchange of sulphur atoms—reductive desulphurisation—and secondly interaction of esters of four-coordinated phosphorus like (V) and (IX) with the alkyl halides [137]. These reactions are due to the ability of both thionic and thiolic sulphur atoms (like phosphorus) to react both with electrophilic and with nucleophilic reagents, because of the presence of lone pairs of electrons and vacant *d* orbitals. Thus a two-coordinated sulphur atom reacts with several nucleophilic reagents, including the three-coordinated phosphorus atom [138–140]. Reactions of several phosphorus(III) compounds with a thiophosphoryl group have been reported [61, 127,134,140,141,143–145]:

$$X_3\ddot{P} + S{=}P\!\lessdot \rightarrow X_3P{=}S + \ddot{P}\!\lessdot \ .$$

The tendency to react with thionic sulphur is not simply related to the nucleophilic character of the reagent, so that the use by certain authors of the terms "thiophilicity" [26,138] or "S-nucleophilicity" [26,139] seems entirely justified.

On the other hand, sulphur(II) is able to react with electrophilic reagents [26]. The high donor power of sulphur in the thiophosphoryl group $>\!P{=}S$ has been investigated by several workers [146–149]. The substituents X and Y favour reaction if they enhance the nucleophilic character of sulphur [148]:

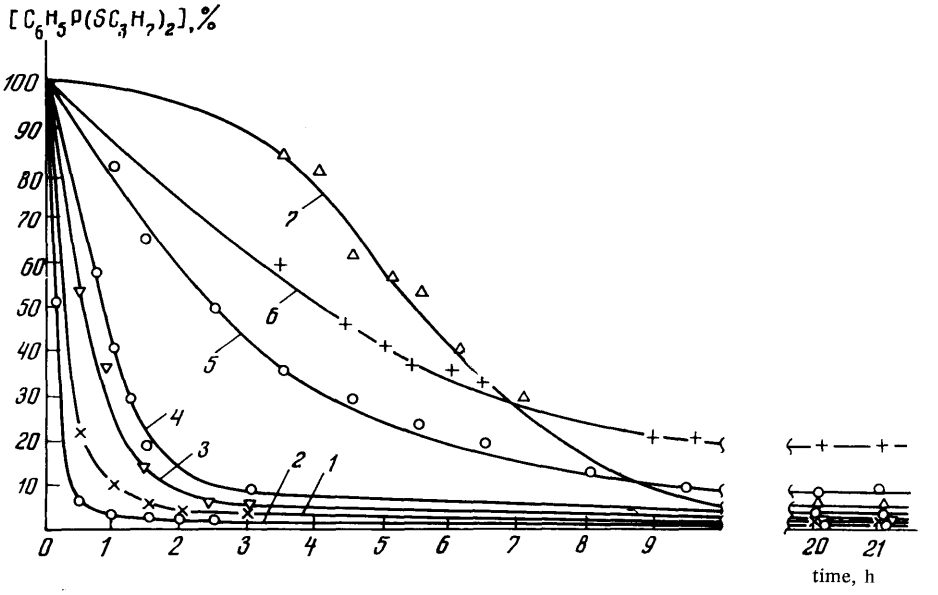


Figure 2. Variation of concentration of $C_6H_5P(SC_3H_7)_2$ with time during reaction with alkyl bromides: 1) $CH_3Br$; 2) $C_2H_5Br$; 3) n-$C_3H_7Br$; 4) n-$C_4H_9Br$; 5) t-$C_4H_9Br$; 6) iso-$C_3H_7Br$; 7) s-$C_4H_9Br$.

Examination of a series of compounds revealed [148] that the infrared absorption frequencies of the thiophosphoryl group can serve as a criterion of reactivity towards electrophilic reagents. Contradictory information has been published on the behaviour of thiolic sulphur towards such reagents: some authors assume [147,148] that thiolic sulphur in the group PO.SR does not react; other publications [137, 150,151] report that reaction does occur. The two sulphur atoms in the group PS.SR may compete, for under mild conditions the thionic sulphur reacts, but on heating the thiolic sulphur may also be involved [137]:

$$RR'P(S)SR'' + R'''Br \begin{cases} \longrightarrow RR'P(S)SR''' + R''Br \\ \xrightarrow[\text{heat}]{} RR'P(S)Br + R''-S-R''' \end{cases}.$$

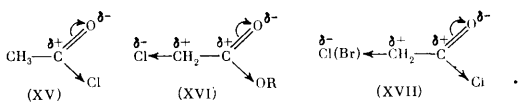
## IV. REACTIONS WITH HALOGENOCARBONYL REAGENTS

Descriptions have appeared of the reactions of sulphur-containing esters $R_nP(SR')_{3-n}$ with several types of halogenocarbonyl compounds—acetyl chloride [124,152-154], chloral [155-157], chloroacetic and chloroformic esters [61,127, 142,158-162], and chlorinated and brominated acetyl chlorides [61,127,163].

Reactions with chloral are complicated, and the reaction mechanism has not been elucidated. In several cases the multicomponent mixture contains vinyl ethers [157], whose presence suggests that the reaction proceeds partly in conformity with Perkov's scheme.

Acetyl chloride acts on trialkyl phosphorotrithioites, phosphorothious chlorides [124], alkyl(or aryl)phosphonodithious [152] and dialkylphosphinothious [125] esters, and also mixed *O*,*S*-phosphites [153] at a sulphur atom:

$$\rangle P-S-R + CH_3COCl \rightarrow \rangle P-Cl + CH_3COSR$$



Acyl chlorides act on phospho(i)namidothious esters initially at the nitrogen atom [154]:

$$\begin{matrix} R'S \\ R \end{matrix}\!\!\rangle P-NR''_2 + CH_3COCl \rightarrow \begin{matrix} R'S \\ R \end{matrix}\!\!\rangle P-Cl + CH_3CONR''_2 .$$

The sulphur atom is then attacked:

$$\begin{matrix} R'S \\ R \end{matrix}\!\!\rangle P-Cl + ClCOCH_3 \rightarrow \begin{matrix} Cl \\ Cl \end{matrix}\!\!\rangle P-R + CH_3COSR' .$$

Esters and chlorides of chloro(or bromo)acetic acid differ from acetyl chloride in the nature and number of electrophilic centres:

(XV) (XVI) (XVII)

In chloroacetic esters (XVI) the methylene carbon atom in the $sp^3$-hybrid state is a soft electrophilic centre, whereas the carbonyl carbon atom in the $sp^2$-hybrid state is a hard Lewis acid. It would appear that dual reactivity—reaction of the soft electrophilic centre with phosphorus and of the hard electrophilic centre with sulphur—might be expected in chloroacetic esters. In all the reported cases, however, only one type of reaction—of $R_2PSR'$ and $RP(SR')_2$ esters according to the usual Arbuzov scheme—has been observed [158,159], obviously with intermediate formation of a quasi-phosphonium product:

$$\rangle P-S-R' + (XVI) \rightarrow \left[\rangle P\begin{matrix} SR' \\ CH_2COOR \end{matrix}\right]^+ Cl^- \rightarrow \rangle P(S)CH_2COOR + R'Cl .$$

The reaction is complicated by secondary processes [159], such as nucleophilic attack by phosphorus(III) on thionic sulphur

$$R_2P\begin{matrix} S \\ CH_2COOR'' \end{matrix} + :P\begin{matrix} R \\ SR' \end{matrix} \rightarrow R_2\ddot{P}CH_2COOR'' + R_2P(S)SR'$$

with subsequent formation of a phosphonium salt

$$R_2PCH_2COOR'' + ClCH_2COOR'' \rightarrow [R_2P(CH_2COOR'')_2]^+ Cl^- .$$

In the case of esters of the $RP(SR')_2$ type the quasi-phosphonium salt then breaks down:

$$\left[\begin{matrix} SR' \\ | \\ R-P-CH_2COOR'' \\ | \\ CH_2COOR'' \end{matrix}\right]^+ Cl^- \rightarrow RP(S)(CH_2COOR'')_2 + R'Cl .$$

The probable reason for the complete absence of the second type of reaction—involving sulphur—is that the carbonyl carbon is a considerably less active electrophilic centre in these compounds than is the $sp^3$ carbon atom of the methylene group ($C_{sp^3} > C_{sp^2}$).

Replacement of the alkoxy-group by halogens produces a sharp increase in activity of the $sp^2$-hybrid carbon atom, and chloroacetyl and bromoacetyl chlorides (XVII) react with ethyl(and phenyl)phosphonodithious esters in two ways—at the phosphorus and sulphur atoms—also accompanied by secondary processes [61,127,169]:

$$RP(SR')_2 + Cl(Br)CH_2COCl \rightarrow RP(Cl)SR' + Cl(Br)CH_2COSR' , \quad (4)$$
$$RP(Cl)SR' + Cl(Br)CH_2COCl \rightarrow RPCl_2 + Cl(Br)CH_2COSR' , \quad (5)$$
$$RP(SR')_2 + Cl(Br)CH_2COCl \rightarrow RP(S)(SR')(CH_2COCl) + R'Cl(Br) , \quad (6)$$
$$RP(S)(SR')(CH_2COCl) + RP(Cl)(SR') \rightarrow RP(SR')(CH_2COCl) + RP(S)Cl(SR') , \quad (7)$$
$$RP(S)(SR')(CH_2COCl) + RP(SR')_2 \rightarrow RP(SR')(CH_2COCl) + RP(S)(SR')_2 . \quad (8)$$

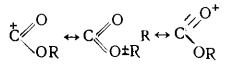
Chloroacetyl chloride reacts initially only with the sulphur (Eqns. 4 and 5) by means of the carbonyl electrophilic centre. Under more severe conditions the Arbuzov reaction (6) also takes place. Bromoacetyl chloride reacts with a thioester $RP(SR')_2$ simultaneously at the two nucleophilic centres (4)–(6), with the phosphorus attacking the methylene carbon, and the sulphur attacking the carbonyl carbon. Such behaviour can conveniently be explained in terms of soft and hard acids and bases: phosphorus and methylenic carbon atoms are soft reaction centres, whereas sulphur and carbonyl atoms are hard centres.

Chloroformic esters ClCOOR″ react with phosphonodithious and phosphinothious esters only at the phosphorus atom [160,162]. Reaction with esters of the latter type can be represented by two consecutive processes [162]:

$$R_2PSR' + ClCOOR'' \rightarrow R_2P(S)COOR'' + R'Cl ,$$
$$R_2P(S)COOR'' + R_2PSR' \rightarrow R_2P(S)SR' + R_2PCOOR'' .$$

This appears somewhat unexpected, since there are data [164] indicating that chloroformic ester is a stronger acylating agent than is acetyl chloride, which acts only on the sulphur atom in all types of esters $R_nP(SR')_{3-n}$, as noted above. The electrophilic centre in chloroformic ester is surrounded by three strongly electronegative groups, and therefore carries a high positive charge:

$$Cl-\overset{\overset{O}{\|}}{C}-OR'' .$$



Chloroformic esters should be hard acids. However, the sequence of diminishing hardness [129]

$$CH_3COCl > ClCH_2COCl > ClCOOC_2H_5$$

indicates that chloroformic ester is a less active hard reagent, at least in certain reactions.

Furthermore [164], sodium salts of keto–enols are attacked by chloroformic ester at oxygen (a hard centre), but copper salts at carbon (a soft centre). This can be explained by Nesmeyanov and Kabachnik's concept of dual reactivity [165]. In the case of the copper salt of acetoacetic ester the reaction involves migration of the reaction centre. This is considered [164,165] to occur when the active reagent is strongly electrophilic (i.e. is a hard acid according to Pearson), and the carbon–metal bond is unionised.

With regard to the reactivity of chloroformic ester in the above reaction, the observed features of its chemical behaviour are most consistent with Kornblum's rule [166]. An electrophilic reagent may change its reactivity not only according to the nature of the nucleophile, for even in the same reaction its tendency to react with the softer centre of an ambident system increases on passing from an $S_N1$ to an $S_N2$ mechanism [121,166]. Hence chloroformic ester will interact preferentially with a hard centre (sulphur) only if the reaction conditions favour an $S_N1$ process. If, however, the reaction mechanism is closer to the $S_N2$ type, reaction must be expected at a soft centre, i.e. at phosphorus. This ester is obviously little able to form a stable intermediate carbocation and hence react by an $S_N1$ mechanism: the negative inductive effects of the carbonyl oxygen and of the alkoxy-group, which impair the stability of the carbocation, are stronger than stabilising resonance effects of the type

The slowness of $S_N1$ reaction with $\alpha$-halogenated ketones is explained similarly [167].

On the other hand, steric hindrance to formation of the transition state in $S_N2$ processes is absent from the chloroformic ester molecule owing to the planar structure of the $sp^2$-hybrid carbon atom. Further stabilisation of the transition state may result from overlap of the electron shell of the nucleophilic species with the $\pi$-electron system of the carbonyl group. As a consequence of these factors chloroformic ester shows a greater tendency to react by an $S_N2$ mechanism and therefore to attack the soft centre of the system—the phosphorus atom.

It is clear from the literature also that chloromethyl ether, like chloroformic ester, reacts with the sodium salts of keto–enols at the oxygen atom [168], and with the copper salts at a carbon atom [164]. The tendency of halogenated ethers to react by an $S_N2$ mechanism can probably be explained also by their ability to interact with the soft centre—the phosphorus atom [170]:

$$R_2PSR' + ClCH_2OR' \rightarrow R_2P(S)CH_2OR' + R'Cl, \quad (9)$$

$$R_2P(S)CH_2OR' + R_2PSR' \rightarrow R_2\overset{+}{P}CH_2OR' + R_2P(S)SR', \quad (10)$$

$$R_2\overset{+}{P}CH_2OR' + ClCH_2OR' \rightarrow [R_2P(CH_2OR')_2]^+Cl^-. \quad (11)$$

Thus the results for the reactivities of halogenocarbonyl compounds (and of chloromethyl ethers and esters) towards thio-esters of three-coordinated phosphorus $R_nP(SR')_{3-n}$ ($n = 0-2$) enable them to be arranged in the sequence

$$ClCOOR \approx ClCH_2OR \approx ClCH_2COOR > BrCH_2COCl > ClCH_2COCl > RCOCl$$

of diminishing softness towards the phosphorus atom [61,127]. The tendency of the electrophilic reagent to attack a hard centre in the ambident system—a sulphur atom—increases in the same sequence.

# Chemistry of α-Nitrohetero-organic Compounds

S.L.Ioffe, L.M.Leont'eva, and V.A.Tartakovskii

Methods of preparation, problems of the establishment of structure and elementotropism, and chemical reactions are surveyed on the basis of 177 references.

## I. INTRODUCTION

During recent years we have witnessed vigorous development of the chemistry of organoelementary compounds and of nitro-compounds. The results of these investigations have been summarised in a considerable number of monographs and review papers. Hitherto, however, no attempt has been made to examine from a uniform viewpoint the chemistry of compounds in which both a nitro-group and a heteroatom are attached to the same atom of the molecular framework, i.e. the chemistry of α-nitrohetero-organic compounds.

Yet an analysis of the reactions of this class of compounds is of undoubted interest, both theoretical and applied. Indeed, several methods of preparation involve interaction of an ambident nitro-anion with an electrophile in which the positive charge is concentrated mainly on the heteroatom, which may prove interesting in the study of dual reactivity. Furthermore, these compounds are able to develop elementotropism, a phenomenon well known with carbonyl compounds, which can now be considered on new models. On the other hand, the preparation of these α-nitro-compounds and the investigation of their properties will broaden the opportunities for using both hetero-organic compounds and the nitro-derivatives in organic synthesis. There are indications that α-nitrohetero-organic compounds may be used directly in herbicidal and insecticidal compositions, and also as intermediates for the production of surface-active agents, biologically active products, explosives, and finishing agents in the textile industry. The present review summarises results on methods for the preparation of α-nitrohetero-organic compounds, examines the chief principles on which their structure is established, and describes several chemical reactions. It covers the literature to 1974. It does not include data on α-halogeno-α-nitro-compounds, nor certain earlier results, whose reliability is open to doubt.

## II. METHODS OF PREPARATION

### 1. Reaction of Salts of Nitro-compounds with Halogenated Hetero-Organic Compounds

The chief examples of this reaction that have been studied are sulphenylation, silylation, and diethylborylation. Salts of mononitro-compounds react with sulphenyl halides and thiocyanates to form α-nitroalkyl sulphides[1,2]:

$$RSX + [R'R''C(NO_2)]Na \rightarrow RSCR'R''(NO_2) + NaX \quad (1)$$

R = *p*-$MeC_6H_4$, *m*-$NO_2C_6H_4$, 2,4-$(NO_2)_2C_6H_3$; R' = H, Me, Et, n-Pr; R'' = H, Me; X = Cl, Br, SCN.

Furthermore, corresponding disulphides are also formed†. Anions of polynitro-compounds have been successfully sulphenylated by means of sulphenyl halides and sulphenium salts[4-7]:

$$RC(NO_2)_2^-Z^+ + R'SX \rightarrow RC(NO_2)_2SR' \quad \text{or} \quad RC(NO_2)=N\begin{matrix}\nearrow O\\ \searrow OSR'\end{matrix}$$

R = H, Me, $NO_2$; R' = Me, Ph, *p*-$MeOC_6H_4$, *p*-$NO_2C_6H_4$, 2,4-$(NO_2)_2C_6H_3$; Z = K, Ag, $(CH_2)_5NH_2$; X = Cl, Br, $SbF_6$, $BF_4$.

The synthesis of nitromethyl trichloromethyl sulphide[8,9]

$$MeNO_2 + CCl_3SCl \xrightarrow[EtOH]{NaOH} (NO_2)CH_2SCCl_3$$

is clearly also a reaction of this type. The preparation of bis-1-nitroalkyl disulphides from the sodium salts of nitroalkanes and sulphur monochloride has been patented[10,11]:

$$RCH(NO_2)^-Na^+ \xrightarrow[ether]{S_2Cl_2} [RCH(NO_2)S]_2$$

R = Alk $C_1$—$C_6$, Ar $C_6$—$C_{15}$.

Nitro-derivatives containing oxidised sulphur are obtained by the action of sulphonyl chlorides on salts of nitro-compounds. In particular, a convenient method has been proposed[12] for synthesising 1-nitroalkyl *p*-tolyl sulphones:

$$RR'C(NO_2)^-K^+ + p\text{-}MeC_6H_4SO_2X \rightarrow p\text{-}MeC_6H_4SO_2CRR'NO_2$$

R = H, Me; R' = H, Me, Et, Ph‡; *p*-$ClC_6H_4$, *p*-$MeOC_6H_4$; RR' = $(CH_2)_5$; X = Br, I.

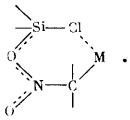
This reaction takes place by a radical-anion mechanism[12]:

$$Tos\,I + Me_2C(NO_2)^- \rightarrow Tos^- + ICMe_2NO_2$$
$$ICMe_2NO_2 \rightleftarrows I^\cdot + Me_2CNO_2^\cdot$$
$$Tos^- + Me_2CNO_2^\cdot \rightleftarrows Tos\,C(NO_2)Me_2^{\cdot-}$$
$$Tos\,C(NO_2)Me_2^{\cdot-} + ICMe_2NO_2 \rightleftarrows Tos\,C(NO_2)Me_2 + ICMe_2NO_2^{\cdot-}$$
$$ICMe_2NO_2^{\cdot-} \rightarrow I^- + Me_2CNO_2^\cdot \text{ etc.}$$

†Reaction (1) will be discussed in detail in Section IV, 1*a*. The products $CH_3CH(NO_2)SR'''$ (where R''' = $Cl[CH_2]_2$ or *m*-$NO_2C_6H_4$) were oxidised to the corresponding sulphones without being isolated[3].

‡The salt of this nitroalkane was treated also with benzenesulphonyl chloride.

where Tos = $p$-$CH_3C_6H_4SO_2$. $N$-Nitrosulphonamides can be obtained from salts of nitramines and sulphonyl chlorides: e.g.[13]



$$Me_3C{-}\underset{\underset{CH_2}{\|}}{C}{-}\underset{\underset{NO_2}{|}}{N}Na + PhSO_2Cl \rightarrow Me_3C{-}\underset{\underset{CH_2}{\|}}{C}{-}\underset{\underset{NO_2}{|}}{N}{-}SO_2Ph \ .$$

Nitro-silyl derivatives are also obtained from salts of nitro-compounds. In contrast to $\alpha$-sulphur-substituted nitro-compounds, however, the only final products are $O$-esters of nitronic acids:

$$M^+[C(NO_2)RR']^- + R''_3SiCl \rightarrow RR'C{=}N{-}O{-}SiR''_3$$

R = R' = $CO_2Me$[14], $NO_2$[15,16]; R = $NO_2$, R' = CN[17]; R'' everywhere Me or Ph.

The potassium salt of trinitromethane and the sodium salt of dimethyl nitromalonate do not react with trimethylchlorosilane§. From this it is concluded[14,16] that the silylation of salts of nitro-compounds by trimethylchlorosilane requires electrophilic assistance in abstracting the leaving group, perhaps in a cyclic transition complex of the type

The silver salts of methylnitramine, $N$-nitrotoluene-$p$-sulphonamide, and ethyl $N$-nitrocarbamate are also silylated by trialkylhalogenosilanes:

$$[RN(NO_2)]Ag + Me_2SiClR' \rightarrow [RN(NO_2)]SiMe_2R'$$

R = Me, R' = H, Me, iso-Pr[20];
R = EtOCO[21], $p$-$MeC_6H_4SO_2$[22], R' = Me.

Diethylboryl derivatives of nitroalkanes have been isolated or detected when diethylboryl chloride acts on salts of the nitroalkanes and functionally substituted nitro-compounds in inert aprotic solvents:

$$[RR'C(NO_2)]M \xrightarrow[-MCl]{Et_2BCl} RR'C{=}N{-}O{-}BEt_2$$

R = Me, R' = Me, CHMeEt, M = Na[23];
R = H, R' = Me, n-Pr, $CO_2Me$, $CONH_2$;
R' = Ph, $CO_2Me$, $CONH_2$; R = R' = $CO_2Me$, M = Na, K[24].

Similarly, diethylboryl derivatives of $N$-nitro-compounds have been obtained by the action of diethylboron chloride on silver salts of several nitramines and $N$-nitroamides[25,26]:

$$[RN(NO_2)]Ag + Et_2BCl \xrightarrow[-AgCl]{} [RN(NO_2)]BEt_2 \ .$$

Reaction between silver salts of nitramines and trialkyltin halides yields organotin derivatives of the nitramines[27]:

$$[R'N(NO_2)]Ag + R_3SnX \xrightarrow[-AgX]{} R'N(NO_2)SnR_3$$

R = Me, Et, Ph; R' = Me, Et, iso-Pr, t-Bu, Ph; X = Cl, Br.

Mercuric chloride reacts with the sodium salt of nitromethane to give the mercury salt of the latter[28-30]:

$$2CH_2NO_2Na + HgCl_2 \rightarrow Hg[CH_2NO_2]_2 \ .$$

§There has been a report[18] (without any experimental data) that $\alpha$-nitroalkyl-trimethylsilyl derivatives are formed by the interaction of sodium salts of primary and secondary nitroalkanes "under specific conditions". Also without experimental support Manzur and Zamudio[19] postulate the intermediate formation of trimethylsilyl methanenitronate in the reaction of trimethylchlorosilane with nitromethane in pyridine.

## 2. Nitration of Hetero-organic Compounds

This method is used only to obtain compounds that are resistant to hydrolysis and do not undergo any great oxidative degradation under the influence of nitrating agents. Mainly the nitration of organosulphur compounds has been reported, with the use of acidic nitrating agents and also alkyl nitrates in the presence of bases.

Many $N$-nitrosulphonamides have been obtained by the nitration of arenesulphonamides with nitric acid or a mixture of sulphuric and nitric acids:

$$ArSO_2NHR \rightarrow ArSO_2NRNO_2$$

Ar = Ph, R = Me, Et[31]; Ar = Ph, $p$-$BrC_6H_4$, $m$-$NO_2C_6H_4$, R = Alk $C_3$—$C_7$,
$(CH_2)_9N(NO_2)SO_2Ph$[32,33]; Ar = Ph, $p$-$MeC_6H_4$, 4-Me-3-$NO_2C_6H_3$, R = H, Me, Et[34-36]; Ar = 4-Me-3-$NO_2C_6H_3$,
R = $CH_2CH_2Br$, $CH_2CHBrMe$, $MeCHCH_2Br$[37] .

Nitrogen pentoxide has been used to nitrate the sodium salts of $N$-alkylsulphonamides[38]:

$$[RSO_2NR']Na + N_2O_5 \rightarrow RSO_2N(NO_2)R' + NaNO_3$$

R = Me, Ph, $p$-$MeC_6H_4$; R' = Me, n-Bu, s-Bu, Allyl .

Trismethylsulphonylmethane on treatment with a mixture of nitric and sulphuric acids gives the nitro-derivative in 68% yield[39]:

$$CH(SO_2Me)_3 \xrightarrow{HNO_3+H_2SO_4} NO_2C(SO_2Me)_3 \ .$$

$\alpha$-Nitro-sulphones are obtained in good yield by nitrating alkyl and aryl sulphones with alkyl nitrates in the presence of bases[40,41]:

$$RCH_2SO_2R' \xrightarrow[Nu]{R''ONO_2} RCH(NO_2)SO_2R'$$

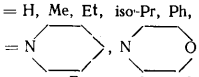
R = H, Et, n-Pr, Ph, $p$-$MeOC_6H_4$, $p$-$ClC_6H_4$;
R' = Alk $C_1$—$C_4$, Ph, $PhCH_2$, $p$-$MeC_6H_4$;
R'' = Et, $C_6H_{11}$; Nu = t-BuOK, $KNH_2/NH_3$.

The nitration of sulphonates with alkyl nitrates in the presence of bases has been studied in detail[42,43]. In the suggested reaction scheme

$$RCH_2SO_3CH_2\overset{|}{C}H \xrightarrow[Nu]{R'ONO_2} \left[H_A{-}\overset{|}{C}RSO_3CH_2\overset{|}{C}H_B\right] \rightleftarrows \underset{\underset{O_2NOR'}{\vdots}}{\phantom{x}} \quad (I)$$

$$\rightleftarrows \left[H_ACR(NO_2)SO_3CH_2\overset{|}{C}H_B + R'O^-\right] \quad (II)$$

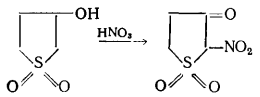
$$\left[H_B\overset{|}{C}CH_2OSO_2C(NO_2)R\right]^- \quad (III) \qquad RCH_A(NO_2)SO_3^- \quad (IV) + CH_2{=}C\!\!< \quad (V) \qquad (2)$$



either the normal nitration product (III) or a mixture of compounds (IV) and (V) is formed depending on which proton ($H_A$ or $H_B$) is attacked by the nucleophile $Nu^-$. The composition of the reaction mixture is, of course, determined by the structure of the radical $CH_2CH_B$. In agreement with this, neopentyl sulphonates not containing $H_B$ are smoothly converted into the corresponding nitro-derivatives, whereas the nitration of ethyl and octyl butane-1-sulphonates yields secondary products (potassium 1-nitrobutane-1-sulphonate and oct-1-ene). In full agreement with scheme (2) the nitration of ethyl butane-2-sulphonate does not give the expected ethyl 2-nitrobutane-2-sulphonate but a >50% yield of potassium 2-nitrobutane-2-sulphonate, together with ethyl 3-methylpentane-3-sulphonate[43]:

$$EtCHMeSO_3Et \xrightarrow[2.NH_4Cl]{1.KNH_2/NH_3/EtONO_2} EtC(Me)(NO_2)SO_3K + Et_2CMeSO_3Et \ .$$

Alkyl nitrates can be used also to obtain *NN*-dialkylated α-nitro-sulphonamides¶:



$$RR'CHSO_2NR''_2 + B \xrightarrow[0^\circ]{\text{oxolan}} RR'C^-SO_2NR''_2 \xrightarrow{EtONO_2} \rightarrow RR'C(NO_2)SO_2NR''_2 + EtO^-$$

R = Ph, R′ = H, R″ = Me, B = KH[44];
R = H, Me, Et, iso-Pr, Ph, R′ = H, Me,

$NR''_2$ =  ,

B = t-BuOK, n-BuLi[45].

Nitration is sometimes accompanied by partial oxidation or degradation of the initial organosulphur compound. Thus when acyclic or cyclic 3-hydroxy-sulphones are treated with nitric acid (at 60–90°C), the corresponding 3-keto-2-nitro-sulphones are obtained: e.g. [46]

Several β-keto-sulphides are converted by ethyl nitrate followed by oxidation into the corresponding nitromethyl sulphones [47,48]:

$$RSCH_2COMe + EtONO_2 \xrightarrow{EtONa} RSCH{=}NO_2Na \xrightarrow[AcOH]{H_2O_2} RSO_2CH_2NO_2$$

R = Me, *p*-MeC$_6$H$_4$.

α-Nitroalkylphosphonates have been obtained by nitrating phosphorylated aldehydes, ketones, and β-alkoxy-vinylphosphonates with acetyl nitrate in acetic anhydride[49]:

$$(RO)_2P(O)CH_2COX + AcONO_2 \longrightarrow (RO)_2P(O)CH_2NO_2$$
$$(RO)_2P(O)CH{=}CHOEt + AcONO_2 \longrightarrow \uparrow$$

R = Alk $C_1$—$C_4$; X = H, Me.

### 3. Action of Nitro-compounds on Hetero-organic Derivatives

α-Nitro-derivatives of hetero-organic compounds of many elements—silicon, mercury, thallium, indium, tin, lead, boron, etc.—have been obtained by this method.

Free nitro-compounds and nitramines can be silylated by means of many silylating agents. In particular, functionally substituted mono- and poly-nitro-compounds are silylated in inert aprotic solvents by *NN′*-diphenyl-*N*-trimethylsilylurea:

$$RR'CHNO_2 + PhNHCON(SiMe_3)Ph \rightarrow RR'C{=}N{-}OSiMe_3 + (PhNH)_2CO$$

R=R′=$CO_2Me$[14]; R=$CO_2Me$, R′=H, $NO_2$[50];
R=R′=$NO_2$[16]; R=Me, R′=$NO_2$[17].

This agent was unsuitable for silylating nitroalkanes, for which purpose the stronger donor of a trimethylsilyl group, *NO*-bistrimethylsilylacetamide, was used [17,52]†:

$$RR'CHNO_2 + MeC(OSiMe_3){=}NSiMe_3 \rightarrow RR'C{=}N{-}OSiMe_3 + AcNHSiMe_3$$

R = H, Me, Et, Ph; R′ = H, Me.

Trimethylsilyl derivatives of methylnitramine and *N*-nitro-toluene-*p*-sulphonamide are formed by silylation of the free *N*-nitro-derivatives:

$$RNHNO_2 + Me_3SiX \rightarrow [RN(NO_2)]SiMe_3$$

R = Me[20]; *p*-MeC$_6$H$_4$SO$_2$[22]; X = MeNH, PhNHCONPh, AcNSiMe$_3$.

Lovett [53] patented a method for preparing salts of light metals with trinitromethane, of general formula $MR_n[C(NO_2)_3]_x$ (where M = Li, Be, Mg, B, or Al and R = Alk, $C_6H_5$, aralkyl, or cycloalkyl), to several of which he assigned a covalent structure. These compounds are formed by the action of the metal alkyls on trinitro-methane or halogenotrinitromethanes. However, the absence of experimental data or evidence of the structure of the products casts doubt on the correctness of these results.

Much attention has been paid to the preparation of organomercury nitro-derivatives. Aryl and alkyl derivatives of nitromethylmercury are obviously extremely unstable. Their formation was postulated [54] by the action of nitromethane on phenylmercury hydroxide or bismethyl-mercury oxide, and also by the action of mercury dialkyls on the product of the reaction between mercuric oxide and nitromethane‡. Nevertheless, alkylmercury deriva-tives of polynitroalkanes proved to be comparatively stable compounds [54,55]:

$$R_2Hg + HC(NO_2)_3 \rightarrow RHgC(NO_2)_3$$

R = n-Bu, Ph.

Mercury and silver oxides are convenient starting materials for the preparation of bistrinitromethylmer-cury [56–58], bisfluorodinitromethylmercury [59], and silver derivatives of trinitromethane [60–62]:

$$M_mO + p\text{-}X(NO_2)_2CH \rightarrow M[C(NO_2)_2X]_n$$

M = Hg, X = $NO_2$, F, *m* = 1, *n* = 2;
M = Ag, X = $NO_2$, *m* = 2, *n* = 1.

Intermediate formation of α-nitroalkylplatinates is assumed in the reaction of tetrakistriphenylphosphine-platinum with nitroalkanes [63,64]:

$$Pt(PPh_3)_4 \rightleftarrows Pt(PPh_3)_2 + 2PPh_3$$
$$Pt(PPh_3)_2 \xrightarrow{RR'CHNO_2} \left[ PPh_3,\ C(RR'),\ H{-}Pt,\ O,\ N{=}O,\ PPh_3 \right]$$

R = H, Me; R′ = H, Me.

The preparation has been described of α-mono- and α-poly-nitroalkyl derivatives of thallium [65–67], and also that of α-mononitroalkyl derivatives of indium [68]:

$$R_3M + HC(NO_2)R'_2 \rightarrow R_2MC(NO_2)R'_2 + RH$$

M = Tl, In, R = Me, Et, R′ = H, Me;
M = Tl, R = Et, R′ = $NO_2$, Cl, F.

Good yields of organotin derivatives of nitramines are obtained by the action of a tetra-alkylstannane or bis-trialkylstannyl oxide on primary nitramines [27]:

$$2R'NHNO_2 + (R_3Sn)_2O \rightarrow 2R'N(NO_2)SnR_3 + H_2O$$

R = iso-Pr, R′ = Me, t-Bu;

$$R'NHNO_2 + R_4Sn \rightarrow R'N(NO_2)SnR_3 + RH$$

R = Et, R′ = Me, iso-Pr.

¶ Yet *NN*-dialkyl-α-nitroalkanesulphonamides could not be obtained by nitrating alkanesulphonamides with nitric acid or ethylenesulphonamides with nitrogen sesquioxide [44].

†On silylating nitromethane with *NN′*-diphenyl-*N*-tri-methylsilylurea, Klebe [51] isolated bistrimethylsilyl methazonate. He assumed that trimethylsilyl methane-nitronate was an intermediate in this reaction.

‡ The nitromethyl-phenylmercury described by Petukhov [30] was actually phenylmercury fulminate [54]:

$$PhHgOH + MeNO_2 \rightarrow [PhHgCH_2NO_2] \rightarrow PhHgONC + H_2O.$$

Several hetero-organic derivatives of amines react with nitro-compounds[69-71]§:

$$L_mM(NR_2)_n + nR'R''CHNO_2 \rightarrow L_mM(O{-}N{=}CR'R'')_n + nR_2NH$$
$$\downarrow O$$

R = Me, Et, $SiMe_3$; R′ = H, Me; R″ = H, Me; L = Me, Et; M = Sn, Pb ($n = 1$, $m = 3$), Hg ($n = m = 1$).

Triethylboron reacts with α-nitroalkenes to form diethylboryl alkanenitronates[73]:

$$2R'CH{=}C(NO_2)R + 2BEt_3 \rightarrow \left[R'CH(Et)CR{=}N\begin{matrix}O\\ \diagdown\\ OBEt_2\end{matrix}\right]_2$$

R=R′=Me; R=Me, R′=Et; R= iso-Pr, R′=Me.

## 4. Replacement of Halogen in Halogenated Nitro-compounds

The first synthesis of an α-nitrohetero-organic compound from a halogenonitro-compound was accomplished in 1872, when nitromethanedisulphonic acid $NO_2CH(SO_3H)_2$ was obtained[74] from picryl chloride and potassium sulphite. The formation of this product was probably due to development of the properties of a "positive" halogen by one of the chlorine atoms. Reaction between chloronitro-compounds and sodium or ammonium sulphite has been successfully used also to obtain salts of other sulphonic acids[44,75]:

$$RR'C(NO_2)Cl + M_2SO_3 \rightarrow RR'C(NO_2)SO_3M \xrightarrow{HCl} RR'C(NO_2)SO_3H$$

where M = K or $NH_4$ and R, R′ = H, Alk, cycloalkyl, $C_6H_5$, or a heterocyclic radical.

Studies have been made on the reactions of picryl chloride and bromide with mercapto-derivatives of thiazole and thiadiazole[76,77], aliphatic and aromatic thiols[78], and also alkali-metal sulphides and sodium hydrogen sulphide[79]. It was assumed that derivatives of nitrotrithio-orthoformic esters $(RS)_3CNO_2$ or mercapto-derivatives of the type $(HS)_3CNO_2$ were formed as intermediates. Mono- and di-bromonitro-methane and also -ethane react similarly with arenethiols in alkaline medium[80]. However, intermediate sulphur-containing α-nitro-derivatives were neither isolated nor identified[76-80].

Halogenonitroalkanes have been successfully used to obtain α-nitro-sulphones[1,81-84]:

$$RR'C(NO_2)X + R''SO_2Na \rightarrow R''SO_2CRR'(NO_2) \quad (3)$$

R and R′=H, Alk $C_1$–$C_3$, $(CH_2)_4$, $(CH_2)_5$, $(CH_2)_6$; R″ = Ph, p-$MeC_6H_4$, p-$BrC_6H_4$, $C_{10}H_7$; X=Cl, Br, I.

It is interesting that one of the nitro-groups in a polynitro-compound may play the part of a halogen[84]:

$$Me_2C(NO_2)_2 + PhSO_2Na \rightarrow Me_2C(NO_2)SO_2Ph \quad . \quad (4)$$

Kornblum et al. have shown[84] that reactions (3) and (4) have a radical-anion mechanism:

$$Me_2CI(NO_2) + PhSO_2^- \rightarrow Me_2CI(NO_2)^{\cdot-} + PhSO_2^{\cdot}$$
$$Me_2CI(NO_2)^{\cdot-} \rightarrow Me_2C(NO_2)^{\cdot} + I^-$$
$$Me_2C(NO_2)^{\cdot} + PhSO_2^- \rightarrow [Me_2C(NO_2)SO_2Ph]^{\cdot-}$$
$$[Me_2C(NO_2)SO_2Ph]^{\cdot-} + Me_2C(NO_2)I \rightarrow Me_2C(NO_2)SO_2Ph + Me_2CI(NO_2)^{\cdot-} \quad .$$

§Products of undetermined structure had earlier been isolated[72] from the reaction of a dialkylaminotrialkyltin with nitromethane.

The one-electron oxidation of diphenylmercury by tetranitromethane or a halogenotrinitromethane in solvents of various polarities—acetonitrile, sulpholan, chloroform—yields phenyltrinitromethylmercury[85]:

$$Ph_2Hg + C(NO_2)_4 \rightarrow [Ph_2Hg^+C(NO_2)_4^{\cdot-}] \rightarrow Ph^{\cdot} + NO_2^{\cdot}$$
$$\downarrow \qquad\qquad\qquad\qquad \downarrow RH \quad \downarrow$$
$$PhHgC(NO_2)_3 \qquad\qquad C_6H_6 \quad N_2O_4 \quad .$$

Reaction of triphenylphosphine with a bromonitroalkane involves intermediate formation of an α-nitroalkylphosphonium bromide, but different workers interpret differently the further changes undergone by these products[80,86-89].

Trialkyl phosphites and dialkyl phosphorohalidites obviously form with halogenonitroalkanes unstable products of the type $>P(:O).O.N(\rightarrow O):CCR'$,[90] but no evidence has been given[80,89,90] for the structure of the unstable nitro-derivatives.

## 5. Other Methods of Preparation

Other reactions are known that result in the formation of α-nitrohetero-organic compounds. Thus nitromethane and nitrocyclohexane are sulphonated by the dichloroethane, pyridine, and dioxan complexes of sulphur trioxide[91] to give insignificant yields of sulphonated products.

α-Nitroalkanesulphonyl chlorides were obtained[92] by the photochemical chlorosulphonation of $C_{1-10}$ aliphatic nitro-compounds:

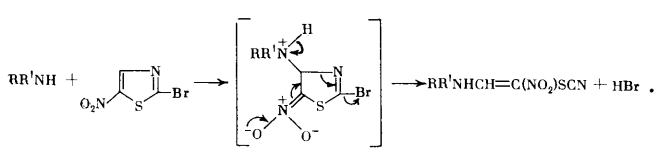
$$RCH_2NO_2 + SO_2 + Cl_2 \xrightarrow{h\nu} NO_2CHR(SO_2Cl) \quad .$$

However, no physical constants of the products isolated were given, and attempts to repeat this reaction have been unsuccessful[44].

Acyl esters of dinitromethanenitronic acid are converted by treatment with 2,4-dinitrobenzenesulphenyl chloride into 2,4-dinitrophenyl trinitromethyl sulphide[93]:

$$(NO_2)_2C{=}N\begin{matrix}O\\ \diagdown\\ OCOR\end{matrix} + (NO_2)_2C_6H_3SCl \rightarrow (NO_2)_2C_6H_3SC(NO_2)_3 \quad .$$

Reaction of sodium toluene-*p*-sulphinate with the potassium salts of nitroalkanes and iodine in dimethylformamide yields α-nitro-sulphones[12]:



$$p\text{-}MeC_6H_4SO_2Na + RR'C{=}NO_2K + I_2 \rightarrow p\text{-}MeC_6H_4SO_2C(NO_2)RR'$$
R=H, Me, R′=H, Me, Et; RR′=$(CH_2)_5$ .

A simple method for obtaining α-nitroisoalkylphosphonates is to oxidise the α-aminoisoalkylphosphonates[49]:

$$(RO)_2P(O)CRMeNH_2 \xrightarrow{KMnO_4} (RO)_2P(O)CRMeNO_2 \quad .$$
R=Me, Et

Silver salts of polynitroalkanes are obtained from other salts of these compounds by the action of silver nitrate[60,94-97].

Sterically hindered secondary aliphatic amines open the ring of a substituted nitrothiazole to give 2-dialkylamino-1-nitrovinyl thiocyanates[98]:

Several workers have postulated the formation of unstable α-nitrohetero-organic compounds. This has

been assumed in particular in the reaction between nitromethane and aluminium tribromide [99]:

$$AlBr_3 \cdot MeNO_2 + MeNO_2 \rightleftarrows \left\{ CH_2{=}N\overset{O}{\diagup\diagdown}OAlBr_2 \cdot MeNO_2 + HBr \right\}.$$

A mixture of products $(NO_2CH_2)_nSnCl_{4-n}$ ($n = 1-3$) is supposed to be formed when nitromethane acts on tin tetrachloride in a primary amine [100]. Formation of the radical-anions

$$O_3SCH_2NO_2^{\cdot-}, SCH_2NC_2^{\cdot-}$$

$$O_3PCH_2NO_2^{\cdot-}, O_2P(H)CH_2NO_2^{\cdot-}, O_2AsCH_2NO_2^{\cdot-}.$$

has been recorded [101] when certain radicals add to the anion of aci-nitromethane.

### 6. Synthesis of α-Nitro-ylides

α-Nitro-ylides of triphenylarsenic have been obtained by the reactions [102,103]

$$\begin{aligned} &Ph_3AsCl_2 + PhCH_2NO_2 \xrightarrow[C_6H_6]{Et_3N} Ph_3As{=}C(NO_2)Ph \\ &Ph_3AsO + MeNO_2 \longrightarrow \begin{cases} \xrightarrow{Ac_2O} Ph_3As{=}C(NO_2)Ac \\ \xrightarrow[P_2O_5]{Et_3N} Ph_3As{=}CH(NO_2) \end{cases} \end{aligned} \qquad (5)$$

for which the mechanism

$$Ph_3AsO + Ac_2O \rightarrow [Ph_3As^+OAc] \xrightarrow{CH_2NO_2^-} [Ph_3As^+CH_2NO_2] + OAc^- \xrightarrow{-H^+} Ph_3As^+{-}\bar{C}HNO_2 \leftrightarrow Ph_3As{=}CHNO_2$$

has been suggested. The corresponding α-nitro-ylides of phosphorus were unstable compounds [102]. The product of the decomposition of trimethylsilyl dinitromethanenitronate $[C(NO)NO_2]$ has been detected as the ylide with triphenylphosphine [16]:

$$Ph_3P + [C(NO)NO_2] \rightarrow Ph_3P^+[C(NO_2)NO]^-.$$

When dimethyl sulphoxide was treated with dinitromethane in the presence of acetic anhydride, the corresponding αα-dinitro-ylide of sulphur $(CH_3)_2S^+{-}C^-(NO_2)_2$ was obtained [104].

## III. ESTABLISHMENT OF STRUCTURE

Elementotropism is now known in many classes of organic compounds. Therefore any α-nitrohetero-organic compound can in principle exist as an equilibrium tautomeric mixture:

$$\underset{\text{"O-form"}}{\diagup C{=}N\overset{O}{\diagdown}OElR_n} \text{ or } \underset{\text{"O-form"}}{-N{=}N\overset{O}{\diagdown}OElR_n} \rightleftarrows \underset{\text{"C" or "N-form"}}{\diagup C(NO_2)ElR_n} \text{ or } \underset{\text{"C" or "N-form"}}{-N(NO_2)ElR_n} \qquad (6)$$

$$\diagup C(NO_2)^- ElR_n^+ \text{ or } [-N(NO_2)]^- ElR_n^+$$

The presence of a particular form and the position of the equilibrium (6) are, of course, determined both by the nature of the element and by the structure of the nitro-containing group. Furthermore, it must be borne in mind that the compound isolated may be either kinetically or thermodynamically preferred. In most cases the nature of the product has not been firmly established¶.

¶Products of the sulphenylation of mono- and polynitro-compounds are kinetically preferred, since their structure depends on the nature of the sulphenylating reagents as well as on the process conditions [2,7].

In view of the above considerations neither the chemical reactions nor the method of preparation can be a criterion in establishing the structure of α-nitrohetero-organic compounds, but at best merely enable one form to be identified. Therefore only a combined study by physicochemical methods will establish the structure. Confirmation of a structure is obtained by comparing spectroscopic characteristics with corresponding properties of model compounds. However, such correspondence must be approached extremely cautiously, since the introduction of an element in the α position with respect to a nitro-group may itself distort appreciably the properties of the model. The choice of method for proving the structure is, of course, determined by the nature of the element adjacent to the nitro-group. Much published information on this question appears to be incorrect, and requires critical review.

### 1. Physicochemical Methods

Papers have appeared during recent years on the use of ultraviolet, infrared, and nuclear magnetic resonance spectroscopy to investigate the structure of α-nitrohetero-organic compounds. Reports of the use of Mössbauer spectroscopy, mass spectrometry, or nuclear quadrupole resonance are considerably less frequent.

*(a)* Electronic absorption spectra

Polynitro-compounds and functionally α-substituted nitro-compounds exhibit marked differences in the ultraviolet spectra of anions, *O*-derivatives (alkyl esters of the corresponding nitronic acids), and true nitro-compounds [105,106], which may be used to determine the structure of α-nitrohetero-organic compounds derived from them. Nevertheless, the differences between the ultraviolet spectra of anions and *O*-derivatives have largely levelled off with mononitroalkanes and nitramines, so that it is difficult to use ultraviolet spectroscopy to determine the structure of α-nitrohetero-organic compounds obtained from them.

Kharasch and Cameron [3] regarded 2-chloroethyl and *p*-tolyl 1-nitroethyl sulphones as true nitro-compounds, having shown that their far ultraviolet spectra were similar to the ultraviolet spectrum of nitroethane. The intense absorption maximum in the range 290–320 nm, characteristic of alkyl esters of substituted nitromethanenitronic acids, is absent from the ultraviolet spectra of sulphides of general formula $RC(NO_2)_2SR'$ (R = H, $CH_3$, $NO_2$ and R' = H, $CH_3$, 2,4-$(NO_2)_2C_6H_3$, *p*-$CH_3OC_6H_4$, *p*-$NO_2C_6H_4$) [6,7], which indicates that the above polynitroalkyl sulphides are *C*-nitro-derivatives. When the sulphenylating agent was changed, however, other products were isolated, regarded as *O*-derivatives on the basis of their ultraviolet spectra [7].

Electronic absorption spectra have been used to investigate trialkylsilyl derivatives of aliphatic nitro-compounds. These products can be regarded as nitronic esters, since the ultraviolet spectra of $RR'C{:}NO.OSi(CH_3)_3$ contain a characteristic absorption maximum ($\lambda_{max}$ = 240 nm for R, R' = H, Alk [17,52] and 265–315 nm for R, R' = $COOCH_3$, $NO_2$, CN [14-16,50], with lg $\epsilon$ = 3.7–4.0), coinciding with a maximum in the corresponding standard alkyl nitronates [107-109].

The ultraviolet spectra of diethylboryl derivatives of nitroalkanes contain a maximum at $\lambda$ = 228–235 nm ($\epsilon$ = 10200–10700), [23,73] which is consistent with their suggested structure as dialkylboron nitronates.

Degrees of ionisation in solution have been determined for several α-nitrohetero-organic compounds from their molar extinction coefficients. It has been shown in particular that bistrinitromethylmercury has a covalent structure in solvents of low polarity[110,111]. Its complexes may be either *C*-derivatives or ionic compounds depending on the nature of the ligand[112,113]. Bisfluorodinitromethylmercury is almost completely unionised in solvents of various polarities (dimethylformamide, acetonitrile, acetone, alcohol).[111] Silver salts of polynitroalkanes are assumed[60,114,115] also to be covalent in several aprotic solvents†

Trinitromethyl derivatives of diethylthallium are completely ionised both in protic and in aprotic solvents. However, equilibrium between ionic and covalent forms is assumed[67] for diethylthallium derivatives of *gem*-dinitroalkanes in weakly ionising solvents:

$$Et_2Tl^+A^- \rightleftarrows Et_2Tl{-}A$$
$$A{=}CH(NO_2)_2,\quad C(NO_2)_2Me.$$

Ultraviolet spectra have been determined[103] for α-nitro-ylides of triphenylarsenic. The ultraviolet spectrum of $(C_6H_5)_3As:CHNO_2$ contains three maxima—at 223 nm (lg ε = 4.39), 265 nm (3.76), and 298 nm (3.81)—and that of $(C_6H_5)_3As:C(NO_2).COCH_3$ has two maxima—at 222 nm (4.40) and 315 nm (4.06).

(*b*) Infrared and Raman spectra

The method of infrared and Raman spectroscopy enables the structure of an α-nitrohetero-organic compound to be established not only in solution but also in the crystalline state. A rigorous choice between true nitro-compounds and anions or nitronic esters can be based on the infrared spectra of derivatives of nitroalkanes[109,117-119]. In true nitroalkanes the $\nu_{as}$ band of the nitro-groups lies in the range 1530–1560 $cm^{-1}$, whereas the C=N stretching vibration lies between 1585 and 1620 $cm^{-1}$‡. In the Raman spectra of nitroalkanes the $\nu_{as}$ vibration of the nitro-group is usually apparent as a weak depolarised line, whereas $\nu_{C:N}$ is seen as a strong polarised band. From this it may be concluded that infrared spectroscopy permits *C*-derivatives of α-nitrohetero-organic compounds to be distinguished from nitronic esters or ionic compounds§. Nevertheless, it is difficult on the basis of the infrared spectra to choose between hetero-organic *O*-derivatives of nitroalkanes and ionic structures.

Introduction of an electronegative functional substituent (including a nitro-group) in an α position with respect to the nitro-group in a nitroalkane shifts the $\nu_{as}$ band of the latter group to higher frequencies[119,120], while the C:N stretching vibration in an *O*-alkyl derivative may move to lower frequencies[14]. As a result the $\nu_{as,NO_2}$ and $\nu_{C:N}$ ranges overlap, and sharp demarcations can no longer be made from the infrared spectra between *C*- and *O*-derivatives of such nitro-compounds (including α-nitro-hetero-organic compounds). It may be supposed that the Raman spectra preserve the difference between these structures, but this question has not yet been examined experimentally. With functionally substituted α-nitro-hetero-organic compounds, on the other hand, infrared spectroscopy enables a clear choice to be made between ionic and covalent structures, since very significant differences are evident in the infrared and Raman spectra of corresponding nitro-compounds and their salts[117].

In the infrared spectra of silyl alkanenitronates the $\nu_{C:N}$ band is located in the range 1617–1622 $cm^{-1}$, which differs by 40–60 $cm^{-1}$ from $\nu_{as}$ for the nitro-group in the corresponding nitroalkanes. The $\nu_{C:N}$ band is strongly developed also in the Raman spectra of the products[17,52]. The introduction of electronegative substituents into methanenitronic acid shifts the $\nu_{C:N}$ band to shorter wavelengths (1595–1605 $cm^{-1}$), where it almost coincides with $\nu_{as,NO_2}$ in the corresponding nitro-compounds. Several silyl derivatives of functionally substituted nitro-compounds exhibit an intense $\nu_{C:N}$ band in the Raman spectra[14,15,17,50].

The infrared and Raman spectra of trialkylmetal nitronates of general formula $R'R''C:NO.OMR_3$ (where $R = CH_3$, $C_2H_5$, n-$C_4H_9$; $R' = R'' = H$, $CH_3$; $R' = H$, $R'' = CH_3$; and M = Sn, Pb) are almost identical with those of salts of the corresponding nitro-compounds[121], so that the structure of *C*-derivatives was rejected for these products. Analysis of the spectra of compounds in which $R = CH_3$ established[121] that the $MC_3$ group has $D_{3h}$ symmetry.

In the infrared spectra of diethylboron dialkylated methanenitronates the C:N stretching band appears at 1630–1645 $cm^{-1}$.[23,73] The infrared spectrum of the diethylboron derivative of methyl α-nitropropionate indicates that the boron atom is attached to the carbonyl oxygen atom by a donor–acceptor bond[24], which moves $\nu_{C:O}$ by more than 150 $cm^{-1}$ to lower frequencies. Yet coordination of boron with the carbonyl group is probably absent from diethylboron derivatives of amides of α-nitro-acids, the boron being coordinated with the amide nitrogen atom[24].

Bands characteristic of anions of nitro-compounds are absent from the infrared spectra of the mercury salts of nitromethane[122] and trinitromethane[110,123,124] and from those of many complexes of the mercury salt of trinitromethane[112]; all these products are regarded as *C*-derivatives. Yet the infrared spectra of crystalline polynitromethyl derivatives of thallium[66,67] and silver[60,114,115] are almost identical with those of the potassium salts, which indicates that the products have an ionic structure. However, infrared spectroscopic data suggest that the silver salts of polynitroalkanes are not ionised in certain solvents[60].

Bands characteristic of covalent true nitro-compounds are present in the infrared spectra of α-nitroalkyl sulphones[40,43,84,125] and poly-α-nitroalkyl sulphides[6]. Bands due to the nitro-group and to carbonyl have shifted to lower frequencies in the infrared spectra of nitro-ylides of arsenic having the general formula $(C_6H_5)_3As:CR.NO_2$ (where $R = H$, $COCH_3$): $\nu_{s,NO_2}$, $\nu_{as,NO_2}$, and $\nu_{C:O}$ are respectively 1208, 1395, and 1595 $cm^{-1}$.[103] Spectral data are available also for trichloromercapto-derivatives of arylhydrazones of nitroformaldehyde[8] and for thiocyanates of general formula $R'RNCH:C(NO_2)SCN$ in which R, R' = n-$C_3H_7$, iso-$C_3H_7$, $C_6H_5CH_2$, $[CH_2]_5$, $[CH_2]_7$, etc.[98].

For alkylnitramine derivatives infrared spectroscopy in principle enables a choice to be made between *O*-forms, *N*-forms, and ionic compounds. The infrared spectra of primary and secondary nitramines contain $\nu_{s,NO_2}$ bands at

---

†Nielsen[116] cites several references to the preparation of covalent salts of heavy metals, but these results cannot be regarded as entirely reliable.

‡This conclusion cannot be extended to derivatives of nitromethane[117].

§It may be assumed that, under the influence of electropositive elements—boron, silicon, tin, etc.—the $\nu_{as}$ vibration of the nitro-group will undergo further displacement to lower frequencies, which should facilitate identification of the α-nitrohetero-organic compound.

1310–1340 $cm^{-1}$ and $\nu_{as,NO_2}$ bands at 1570–1590 and 1510–1550 $cm^{-1}$ respectively[117,126,127]. Furthermore, those of *O*-alkyl derivatives of alkylnitramines are characterised by two intense bands at 1240–1260 $cm^{-1}$ and 1545–1570 $cm^{-1}$.[128] The presence of two stereoisomers splits the shorter-wavelength band, whose shorter-wavelength shoulder corresponds to the *cis*-isomer of the *O*-derivative[129]. Anions of alkylnitramines are characterised by the $\nu_{s,NNO_2}$ band in the range 1400–1500 $cm^{-1}$.[127] It is thus obvious that ionic structures of derivatives of nitramines are easily distinguished by means of the infrared spectra from covalent structures, and a choice between *O*- and *N*-forms can be based on the $\nu_s$ band of the nitro-group. It must be remembered, however, that the positions of characteristic bands in the infrared spectra of nitramine derivatives depend significantly on the conditions under which the spectra are determined¶, so that special attention must be paid to comparing the spectra of specimens recorded under closely similar conditions.

It may be expected from general considerations that the characteristic bands of the *O*-forms and ionic structures of α-nitrohetero-organic compounds will not differ significantly from the corresponding bands in the analogous alkyl derivatives, whereas the introduction of a heteroatom α to the nitro-group in the *N*-form may produce considerable shifts in the $\nu_s$ and $\nu_{as}$ bands of the nitro-group.

In conformity with this the *O*-trialkylsilyl derivatives of methylnitramine exhibit intense bands at 1250–1270 and 1550–1560 $cm^{-1}$.[20,130] In the *N*-trialkylsilyl derivatives, however, the $\nu_{as,NO_2}$ band appears in the range 1500–1510 $cm^{-1}$: i.e. it has undergone a low-frequency shift of $>70$ $cm^{-1}$ in comparison with methylnitramine†. The low-frequency shift of $\nu_{s,NO_2}$ in these compounds is considerably smaller: in trialkylsilyl derivatives of methylnitramine this band appears around 1300 $cm^{-1}$.[20,130] Similarly, in the pyridine complex of diethylborylmethylnitramine the $\nu_{as}$ band of the nitro-group has been displaced to lower frequencies than in methylnitramine by about 100 $cm^{-1}$.[25]

Organotin derivatives of alkylnitramines of general formula $R'N(NO_2)SnR_3$ (R = Alk, $C_6H_5$, and R′ = Alk) are assumed[27] to have the structure of *N*-derivatives with the tin atom coordinated with an oxygen atom of the nitro-group. The infrared spectra of these compounds do not contain in the region of 1550 $cm^{-1}$ bands due to N=N(→O).O–vibrations, nor bands typical of alkali-metal salts of primary nitramines‡.

The structure of an *O*-derivative has been assigned to the trimethylsilyl derivative of *N*-nitrotoluene-*p*-sulphonamide, since its infrared spectrum does not contain the $\nu_{s,NO_2}$ band (1280–1290 $cm^{-1}$) characteristic of *N*-alkyl-*N*-nitrosulphonamides, while bands found with the standard *O*-isopropyl derivative of *N*-nitrotoluene-*p*-sulphonamide are present[22].

¶In solvents $\nu_{as,NO_2}$ shifts to higher frequencies, but $\nu_{s,NNO_2}$ to lower frequencies.

†The spectra of the trialkylsilyl derivatives of methylnitramine were determined in dichloromethane.

‡According to the infrared spectra data, however, an ionic structure cannot be completely excluded for these products.

(*c*) Nuclear magnetic resonance spectroscopy

This method is probably the most informative with respect to the structure of α-nitrohetero-organic compounds, but hitherto has not been sufficiently widely used, and then mainly as proton magnetic resonance. Analysis of hetero-organic derivatives of aliphatic nitro-compounds is usually based on the chemical shifts of protons $\delta_H$ attached to α- and β-carbon atoms (relative to the nitro-group), the $J_{El-H}$ constants in the El–$CH(NO_2)$– group, and also the shifts $\delta_H$ of protons attached to the heteroatom. The principal $^1H$ n.m.r. spectroscopic data for the hetero-organic derivatives of aliphatic nitro-compounds are listed in Table 1, which includes corresponding values for model nitro-compounds. The signals from protons attached to α- and β-carbon atoms in nitronic esters and nitroalkane salts exhibit down-field shifts relative to the analogous signals in the corresponding *C*-nitro-derivatives.

It may be assumed that the introduction, at an α position with respect to the nitro-group in the *C*-form, of an element of electronegativity less than that of hydrogen–lead, tin, mercury, thallium, silicon, boron—will produce an up-field shift in the signals of corresponding protons[131], whereas the introduction of such groups into the *O*-form or especially into an ionic structure should not significantly change the $\delta_H$ of the protons in comparison with the model compounds. Hence it should be easy by means of $^1H$ n.m.r. data to distinguish covalent *C*-derivatives of α-nitrohetero-organic compounds from the corresponding *O*-derivatives, provided that they contain one of the above six elements, as is confirmed by Table 1. Compounds No. 1–24 are *O*-derivatives, and therefore in most of them the signals due to protons attached to α- and β-carbon atoms are displaced down-field relative to those of the corresponding nitro-compounds§. Compound No. 4 was regarded[65] as a *C*-derivative, but the methylene proton chemical shifts and certain other criteria indicate that it is undoubtedly an *O*-derivative.

The introduction of hetero-organic groups of electronegativity exceeding that of hydrogen into an α position relative to the nitro-group should shift the signals of α or β protons down-field[131]. In agreement with this the signals of these protons in α-nitroalkyl sulphones[40,44,45,84,125] and α-nitroalkanesulphonates[43] are considerably displaced down-field relative to those of analogous protons in nitro-compounds, and almost coincide in the value of $\delta_H$ with the signals of α and β protons in *O*-alkyl derivatives of closely related nitronic acids. In the spectra of *C*-derivatives of α-nitrohetero-organic compounds containing thallium, mercury, and certain other elements a spin–spin interaction should be evident between the element and the α or β proton[138]. The absence of such an interaction for compounds No. 2, 4, 6, 11, and 13 in Table 1 finally eliminates the *C*-derivative structure for them.

Study of the dependence of $\delta_H$ for trimethylstannyl on the nature of the element with which this group is combined reveals[71] that the shift in compounds No. 2, 6, and 11 corresponds exactly with $\delta_H$ for $(CH_3)_3Sn$–O– and differs considerably from that for $(CH_3)_3Sn$–C. However, a cautious approach must be adopted towards such analogies, since the introduction of the very electronegative and anisotropic nitro-groups may distort the picture.

§The abnormally low value of $\delta_{CH_3}$ for compound No. 9 was noted by the authors themselves[71].

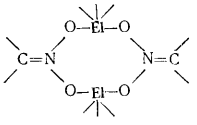
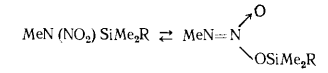
*Solution in tetrachloromethane at 20 or 35°C.



**Here and subsequently chemical shifts are given on the δ scale in all n.m.r. spectra. The standards adopted were tetramethylsilane for $\delta_H$, $\delta_{13C}$, and $\delta_{29Si}$; nitromethane for $\delta_{14N}$ and $\delta_{15N}$; and boron trifluoride–diethyl ether for $\delta_{11B}$.

***Solution in acetonitrile; structure according to Ref. 65.

****Solution in dichloromethane at −20°C; the product has a dimeric structure.



*****The product has a dimeric structure.

It is interesting that the α-nitrohetero-organic compounds listed in Table 1 do not exhibit non-equivalence of protons in α and β positions relative to the C=N(→O).O group, although such non-equivalence is very strongly developed in the corresponding *O*-alkyl derivatives. The averaging of the signals of α and β protons is attributed in trialkylsilyl derivatives to rapid exchange of the trialkylsilyl group between the two oxygen atoms of the O–N → O group[132,139], but in trialkyl-tin and -lead nitronates[71] it is due to the formation of symmetrical dimeric structures.

(see further in this subsection and also under *d*). In diethylboryl derivatives of nitroalkanes the averaging of the signals is also due to the formation of stable dimers[23,73], but in dialkylboryl methoxycarbonyl- and carbamoylmethanenitronates only the *cis*-isomer of the nitronic ester is present in the reaction mixture, owing to coordination of the boron atom with the functional group[24]. In diethylboryl dimethoxycarbonylmethanenitronate rapid intramolecular transfer of the diethylboryl radical from one methoxycarbonyl group to the other has been established by proton magnetic resonance, and several kinetic parameters of the process have been determined[24].

The proton magnetic resonance spectra of α-nitrohetero-organic derivatives of nitramines do not permit a choice between *O*- and *N*-forms, since the $\delta_H$ ranges in the corresponding model compounds overlap[37]. However, use of this method to study dynamic processes in such compounds has established the presence of tautomerism in trialkylsilyl derivatives of methylnitramine[20,130]:

Appreciable displacement of this equilibrium in favour of the *O*-form is produced by rise in temperature and by the substituents R in the sequence t-$C_4H_9$ ≫ iso-$C_3H_7$ > $CH_3$ > H.

Heteronuclear magnetic resonance has hitherto been used mainly to analyse organosilyl and diethylboryl derivatives of nitro-compounds and nitramines. Table 2 shows that the α-carbon-13 signals are located in higher fields in aliphatic mononitro-compounds than in corresponding salts and *O*-alkyl derivatives. Published data suggest that, as in the $^1H$ n.m.r. spectra, replacement of a proton α to a nitro-group by an element of lower electronegativity should produce a diamagnetic shift in the α-carbon-13 signal[142], whereas the replacement of alkyl in an *O*-derivative by a hetero-organic group should not affect significantly the chemical shift $\delta_\alpha$-$^{13}C$. The signal from the α-carbon atom will then distinguish covalent *O*- and *C*-derivatives of α-nitrohetero-organic compounds (it is more difficult to distinguish *O*-derivatives from ionic structures). It is evident that this holds for compounds 1–9 in Table 2. However, the α-carbon-13 signal from compound No. 10, which according to ultraviolet spectral data is a *C*-derivative[112,113], is located considerably down-field from the signals for trinitromethane and trinitroethane. This suggests that the proposed criterion cannot be used to interpret the structures of α-nitrohetero-organic derivatives of polynitro-compounds.

Among other peculiarities of the $^{13}C$ n.m.r. spectra of α-nitrohetero-organic compounds is firstly their temperature dependence determined e.g. for compound No. 4, which indicates rapid exchange of the trimethylsilyl group

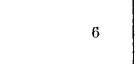
*At −80°C the carbonyl carbon atom gives two signals differing in δ values by 1.45 ppm, and the methoxy-carbon atom two signals differing by 0.73 ppm.
**In dichloromethane at −60°C.

between the two oxygen atoms of the O–N → O group. Secondly, analysis of the spectra of diethylboryl derivatives of nitro-compounds shows that in compounds 5–7 the boron atom is coordinated with the carbonyl oxygen atom. This produces a paramagnetic shift in the $^{13}C{=}O$ signal exceeding 10 ppm. In compounds 8 and 9, in which boron is coordinated with an amino-nitrogen atom, the paramagnetic shift is considerably smaller.

The $^{13}C$ n.m.r. spectra for silyl and diethylboron derivatives of methylnitramine show a sharp difference between the $^{13}CH_3{-}N$ signals for *N*- and *O*-derivatives[25,130]. The $^{14}N$ n.m.r. spectra of α-nitrohetero-organic derivatives of nitroalkanes and functionally substituted nitro-compounds usually permit reliable differentiation between covalent *C*- and *O*-products: firstly the signals from the O–N → O group in *O*-derivatives are considerably broader than the signals from the nitro-group in *C*-products, and secondly they are appreciably displaced up-field. However, comparison of the nitrogen-14 and nitrogen-15 chemical shifts in $Hg[C(NO_2)_3]_2$ (a *C*-product) and in $(^{15}NO_2)_2C{=}^{15}N(\rightarrow O).O.COCH_3$ shows that the accumulation of nitro-groups tends to level off this difference in chemical shifts[93]. It must be noted that, in the case of α-nitrohetero-organic derivatives of nitroalkanes, it is difficult to distinguish *O*-derivatives from ionic structures by means of the nitrogen-14 spectra without additional investigations.

Table 3 shows appreciable differences between nitrogen-14 chemical shifts for the nitro-group and for O–N → O in *O*- and *N*-hetero-organic derivatives of methylnitramine, without any significant influence of the nature of the heteroatom on the chemical shifts. The half-width of the line due to the nitro-group is considerably smaller than that for the O–N → O group. It is advisable to use $^{15}N$ n.m.r. at a low temperature in order to analyse labile compounds. Trimethylsilyl and diethylboron derivatives of *N*-nitrotoluene-*p*-sulphonamide are assumed to be *O*-products because the nitrogen-14 signal from the O–N → O group is very broad in their spectra.



Analysis of n.m.r. spectra on nuclei of the heteroatoms may prove extremely fruitful in elucidating the structure of α-nitrohetero-organic compounds. Such studies have hitherto been made on trialkylsilyl and diethylboron derivatives of nitro-compounds and nitramines. Comparison of the silicon-29 n.m.r. spectra of silyl nitronates (compounds 2 and 3 in Table 4) with those of trialkylsilyl derivatives of the corresponding oximes confirms that silicon is not five-coordinated in nitronic esters. Compounds 5 and 6 show that the ranges of $\delta^{29}Si$ values for *N*- and *O*-forms are sharply delimited in the case of trialkylsilyl derivatives of nitramines. The boron-11 n.m.r. spectra for a series of α-nitrohetero-organic compounds (Table 5) indicate that the boron atom in them is hybridised. Fluorine-19 n.m.r. spectral data have been published[145] for several complexes of bisfluorodinitromethylmercury.

### (*d*) Mass spectrometry

The mass spectra of α-nitro-sulphones of general formula $p\text{-}CH_3C_6H_4SO_2C(NO_2)RR'$ have been investigated with R = H, $CH_3$ and R′ = H, $CH_3$, $C_2H_5$, $C_6H_5$, $p\text{-}ClC_6H_4$, $p\text{-}CH_3OC_6H_4$.[12,84] If R or R′ = H, the mass spectrum contains an intense peak having *m/e* 172 ($C_7H_8SO_3^{+}\cdot$). The fragmentation of nitromethyl *p*-tolyl sulphone is given as example:

$$\left(p\text{-}MeC_6H_4SO_2CH_2N\begin{matrix}O\\O\end{matrix}\right)^{+} \xrightarrow{-HCNO} \underset{m/e\ 172}{(p\text{-}MeC_6H_4SO_3H)^{+}} \begin{cases} \xrightarrow{-SO_2} C_7H_8O^{+} \ m/e\ 108 \\ \xrightarrow{-HSO_3} C_7H_7^{+} \ m/e\ 91 \end{cases}$$

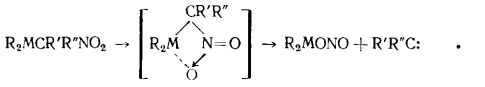
The tropylium cation has been identified in the mass spectrum of benzyl $\alpha$-nitrobenzyl sulphone [12].

In the opinion of Lorberth and Lange [71] the mass spectra of trialkyltin, trialkyl-lead, and alkylmercury derivatives of nitroalkanes confirm the suggested nitronic ester structure, since the $NO_2$ and NO peaks are absent. The mass spectra of trialkyl-lead, trialkyltin [71], and diethylboryl [23,73] derivatives of nitroalkanes indicate that these compounds are dimeric, which eliminates the possibility of salt structures.

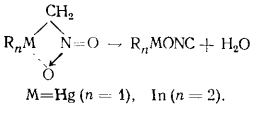
$\alpha$-Nitro-ylides of arsenic on electron bombardment undergo the fragmentation [103]

(*e*) Nuclear $\gamma$-ray and quadrupole resonance spectroscopy



Mössbauer spectroscopy enables the structure of solid specimens containing tin to be elucidated. Lorberth et al. [121] have shown that trialkylstannyl alkanenitronates have a trigonal bipyramidal structure with five-coordinated tin. *N*-Trialkylstannyl derivatives of alkylnitramines also contain tin coordinated to the nitro-group [27].

Chlorine-35 and indium-115 nuclear quadrupole resonance data for the diethylthallium derivative of chloronitromethane and for dialkylindium derivatives of nitroalkanes respectively were regarded [66,68] as showing that these compounds are *C*-derivatives, with intramolecular coordination of the metal to oxygen of the nitro-group. However, this conclusion is not supported by the investigation of organothallium derivatives of certain nitro-compounds by other physicochemical methods—see (*c*) above.



2. Establishment of Structure by Chemical Reactions

Several chemical reactions of α-nitrohetero-organic compounds may give information on their structure. Firstly mention must be made of 1,3-dipolar cycloaddition, by means of which several alkyl nitronates had earlier been detected[146]. However, *O*-acyl nitronates do not undergo this reaction[93], so that it cannot be regarded as common to all *O*-derivatives of nitro-compounds. Only trialkylsilyl nitronates have yet been subjected to such addition with alkenes, and therefore the possibility of detecting in this way *O*-derivatives of α-nitrohetero-organic compounds has so far been examined very roughly. (This reaction will be considered in detail in Section IV.)

The possibility of intramolecular coordination has been suggested[65,66,68] for *C*-derivatives of α-nitrohetero-organic compounds in which the heteroatoms have vacant *d* orbitals, leading to elimination of the corresponding carbene and formation of a nitrite:

However, the formation of carbenes in this process has not been rigorously confirmed, and the structure of the initial nitro-derivatives (especially the diethylthallium derivative of nitromethane) arouses great doubt. Therefore the isolation of nitrites of the type $R_2MONO$ cannot serve as a strict proof of the existence of the corresponding α-nitrohetero-organic compounds in the *C*-form. All the above considerations apply also to the formation of fulminates from hetero-organic derivatives of nitromethane. This reaction has been assumed[54,68] to be characteristic of *C*-derivatives of nitro-compounds and to involve intramolecular coordination of a mercury or an indium atom:

M=Hg ($n = 1$), In ($n = 2$).

Yet Lorberth and Lange[71] observed that methylmercury fulminate is readily formed also by the methylmercury derivative of nitromethane, which is a nitronic ester¶.

It is assumed[2] that the reaction of salts of primary nitroalkanes with 2,4-dinitrobenzenesulphenyl chloride forms *O*-derivatives, which then rearrange into *C*-products or else undergo a series of chemical reactions. The following tests have been suggested[1] for distinguishing α-nitro-sulphides from the corresponding *O*-derivatives — (i) treatment with alkali followed by oxidation, when α-nitro-sulphides undergo no changes, whereas the corresponding nitronic esters should decompose, and (ii) oxidation, which converts α-nitro-sulphides into the corresponding sulphones, whereas *O*-derivatives should be cleaved at the sulphur–oxygen bond (more detailed information on the reactions of *O*- and *C*-derivatives will be found in Section IV, 3 and 6*c*).

¶Theoretically the above hetero-organic derivatives of nitro-compounds may exist as an equilibrium tautomeric mixture, with one form present in such minute quantity that it cannot be reliably detected by physicochemical methods. In the equilibrium mixture, however, this particular form may well be responsible for conversion into nitrite or fulminate.

Chemical reactions enabling the *N*-form to be distinguished from *O*-derivatives are unknown for α-nitrohetero-organic compounds derived from nitramines. Among possible reactions of this type, mention may be made of the Franchimont test[147], which has been successfully used for the qualitative detection of various nitramines. Furthermore, the action of 40% sulphuric acid on certain *O*-alkyl derivatives of nitramines results in rapid evolution of nitrous oxide[148]. However, it is not clear how effective and specific this reaction is for the *O*-forms of α-nitrohetero-organic compounds.

In the identification of α-nitrohetero-organic compounds by means of chemical reactions it must be borne in mind that many of them are hydrolytically extremely unstable (Section IV, 2), so that reagents having a mobile hydrogen atom cannot be used for their analysis.

Several general conclusions on the structure of α-nitrohetero-organic compounds derived from aliphatic nitro-compounds and nitramines can be drawn from the above discussion. The structure depends on the nature of the element and the residue containing the nitro-group. Derivatives of mercury, phosphorus, and sulphur are usually true nitro-compounds, whereas those of boron and especially silicon are often nitronic esters. Contrary to published views[65-68] thallium and indium derivatives of nitroalkanes are also nitronic esters. The overwhelming majority of α-hetero-organic derivatives of mononitro-compounds exist in the *O*-form. The contribution of ionic structures is increased by the attachment of electronegative substituents to the carbon atom bearing the nitro-group.

Since the majority of α-nitrohetero-organic compounds are most probably not kinetically favoured products, their structure cannot be related to the direction of attack by the heteroatomic group on the ambident nitro-anion. Information on the structure of hetero-organic derivatives of nitramines and nitroamides is insufficient for any significant generalisations to be made, but even in these cases the compounds isolated are thermodynamically favoured products.

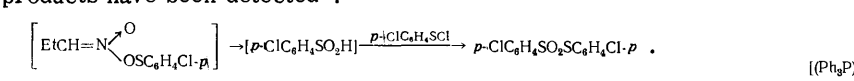
It is interesting that trialkylsilyl and diethylboron derivatives of alkylnitramines[20,25,130] are tautomeric mixtures of *N*- and *O*-forms containing the two structural isomers in comparable quantities. However, the pyridine complex of the diethylboryl derivative of methylnitramine is the pure *N*-form[25].

## IV. CHEMICAL PROPERTIES

We shall first discuss the properties common to most α-nitrohetero-organic compounds.

1. Thermal Decomposition

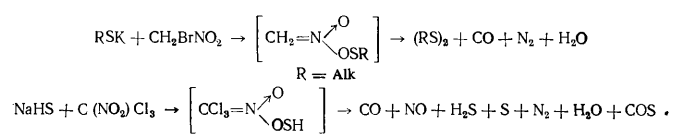
On the whole these compounds are less thermostable than the corresponding nitro-compounds or their salts; *O*-derivatives are usually thermally less stable than their *C*- or *N*-analogues.



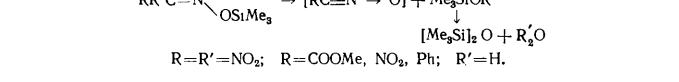
(*a*) Thermal decomposition of *O*-derivatives

The modes of decomposition of the *O*-forms of α-nitrohetero-organic compounds differ from the rearrangements of alkyl nitronates[108]. The character of the former process and the final products depend on the nature of the nitro-component and the heteroatom. The way in which nitronic esters of the type RCH : N(→O).O.SAr

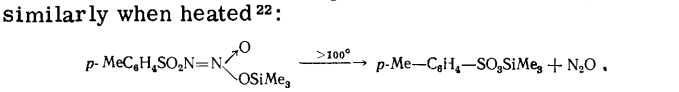
breakdown is supposed[2] to be determined by the structure of the aryl radical. Thus if Ar = 2,4-$(NO_2)_2C_6H_3$ or $m$-$NO_2C_6H_4$, the $O$-derivatives rearrange into aryl nitroalkyl sulphides and decompose into bisnitroaryl disulphides: e.g.



If, however, Ar = $p$-$ClC_6H_4$, quite different decomposition products have been detected[2]:

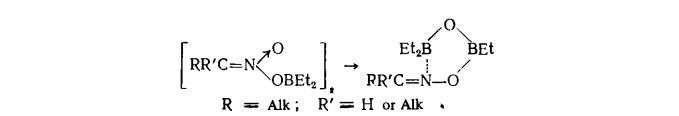


$O$-Thienyl derivatives of polynitroalkanes are also thermally unstable[7].



In the reactions of potassium and sodium salts of thols or of sodium hydrogen sulphide with halogenonitromethanes[76-80] unstable $O$-alkylthio- or $O$-mercapto-derivatives of alkanenitronic acids are obviously formed, which decompose to give mixtures of products:

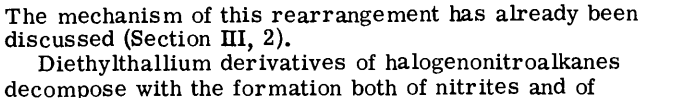
Trialkylsilyl nitronates break down in a different way[15-17,50]:



If R′ = H, parallel hydrolysis of the nitronic esters by trimethylsilanol takes place. The $O$-trimethylsilyl derivative of $N$-nitrotoluene-$p$-sulphonamide decomposes similarly when heated[22]:

Trialkylsilyl derivatives of methylnitramine are unstable at room temperature, but the way in which they decompose has not been studied[20].

Diethylboron derivatives of alkanenitronic acids, whether in solid form or in solution, undergo rearrangement into a new heterocyclic system, a 4-alkylidene-2,5,5-triethyl-1,3-triethyl-1,3-dioxa-4-aza-2,5-diborolidine[23,24]:



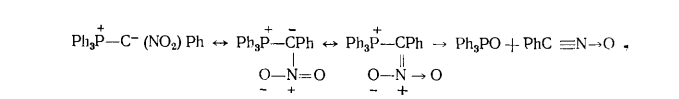
### (*b*) Conversion into nitrites or fulminates

Certain $\alpha$-nitrohetero-organic compounds are converted into the corresponding nitrites[65,68]:

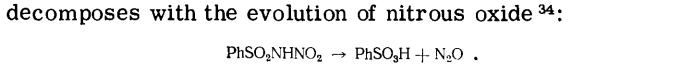
The mechanism of this rearrangement has already been discussed (Section III, 2).

Diethylthallium derivatives of halogenonitroalkanes decompose with the formation both of nitrites and of diethylthallium halides[66]. In particular, chloro (and fluoro)nitromethyldiethylthallium pass rapidly into diethylthallium nitrite, whereas difluoronitromethyldiethylthallium forms diethylthallium fluoride[66]. Alkylmercury and dialkylindium derivatives of nitromethane are similarly converted into the corresponding fulminates†:

Beck and Schorpp[63,64] assume that in the reaction



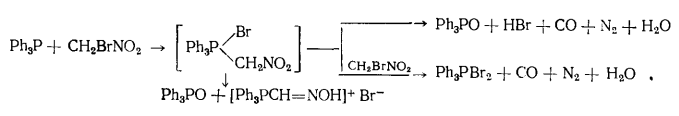
platinum derivatives of nitromethane and of nitroalkanes are formed, and then pass rapidly into the corresponding fulminates or nitrites.



### (*c*) Decomposition of hetero-organic *C*-derivatives of nitro-compounds and *N*-derivatives of nitramines

Compounds whose structure as $C$-derivatives has been firmly established are usually stable at ordinary temperatures.

Thermal changes undergone by $\alpha$-nitro-ylides of phosphorus closely resemble the Wittig reaction[102]:

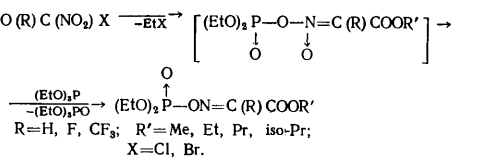


The thermal decomposition of hetero-organic $N$-derivatives of nitramines remains almost uninvestigated. Organotin derivatives of nitramines are stable below 150°C.[27] $N$-Nitrobenzenesulphonamide when heated decomposes with the evolution of nitrous oxide[34]:

### (*d*) Decomposition of hypothetical $\alpha$-nitrohetero-organic compounds

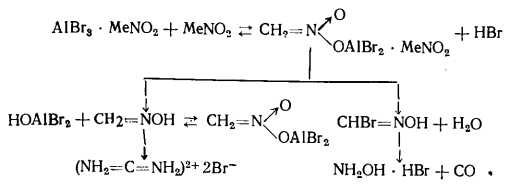
Here we consider reactions of $\alpha$-nitrohetero-organic compounds whose formation has been postulated in studies of the chemical changes undergone by nitroproducts.

The oxidation of triphenylphosphine by bromonitromethane is assumed to involve formation of an unstable triphenylnitromethylphosphonium bromide[80,86-89]‡:



Dibromonitromethane reacts similarly with triphenylphosphine[80]. Nevertheless, the action of trialkyl

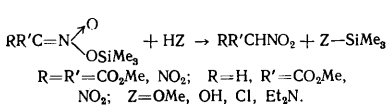
---



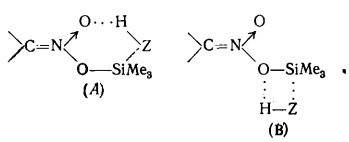
†A review on nitronic acids and esters[116] gives two references[149,150] reporting decomposition of the mercury salt of nitromethane into mercury fulminate. However, it has been shown more recently[122] that the former salt is stable up to 180°C.

‡The corresponding alkanonitriles have been detected in reactions of $\alpha$-halogenonitroalkanes with triphenylphosphine, and are obviously formed by reduction of the nitrile oxides by the triphenylphosphine[87].

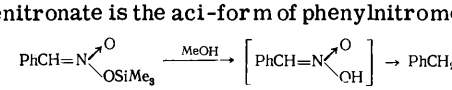
phosphites on α-halogenonitro-compounds gives[90] unstable nitronic esters, which rapidly oxidise the phosphite:



The reaction of nitromethane with aluminium bromide can be represented by the scheme[99]



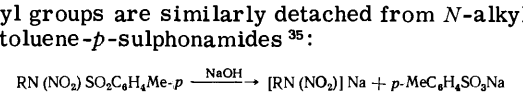
## 2. Reaction with Compounds containing a Mobile Hydrogen Atom



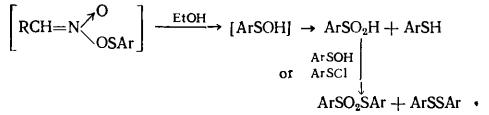
The resistance of α-nitrohetero-organic compounds to hydrolysis or solvolysis is governed by the nature of the heteroelement, the structure of the nitro-group, and in several cases also the form of the hetero-organic compound. Among the relatively thermostable α-nitrohetero-organic compounds the most sensitive to hydrolysis and solvolysis are α-organosilicon derivatives of nitro-compounds, which react readily with water, alcohols, acids, and primary and secondary amines[14,16,17,50,52]:

The reaction probably involves a multicentre transition state of type (*A*) or (*B*)[14]

In agreement with this it has been shown that the primary product of the methanolysis of trimethylsilyl phenylmethanenitronate is the aci-form of phenylnitromethane



Trimethylsilyl derivatives of methylnitramine[20] and *N*-nitrotoluene-*p*-sulphonamide[22] also react with water and alcohols:

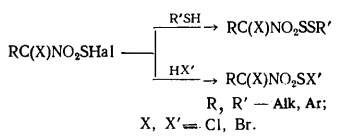


However, the rate of alcoholysis of hetero-organic compounds of this type is significantly retarded by the presence of a t-butyl radical in the trialkylsilyl group[20].

Diethylboryl derivatives of alkanenitronic acids[23,24,73] (including functionally substituted compounds), as well as diethylboryl derivatives of methylnitramine[25] and *N*-nitrotoluene-*p*-sulphonamide[22] are very readily hydrolysed by water, and they react with alcohols. Organotin derivatives of alkylnitramines are perfectly stable in air, but break down fairly slowly on treatment with water[27].

Diethylthallium derivatives of α-nitroalkanes readily undergo solvolysis in protic solvents, but on the addition of hydrochloric acid or a salt thereof the nitroalkyl group is replaced by the halogen:

*O*-Alkylthio-derivatives of nitro-compounds are extremely unstable in alcohols[2]:

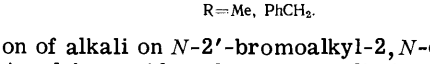


Nevertheless, α-nitroalkyl[1] and αα-dinitroalkyl[6,7] sulphides are unaffected by proton-containing solvents. In trinitromethyl sulphides, on the other hand, the sulphur–carbon bond is labile towards protic solvents[6]:

α-Nitro-sulphones and *N*-nitrosulphonamides are inert towards water and alcohols[1,2,34].

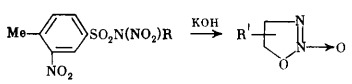
α-Nitroalkylphosphonates of general formula $NO_2CR'(CH_3).PO(OR)_2$ (where R, R′ = $CH_3$, $C_2H_5$) give the corresponding acids $NO_2CR'(CH_3).PO(OH)_2$ on treatment with an acid§[49]. With dialkyl nitromethylphosphonates the course of this reaction is complicated and involves the nitro-group.

α-Halogeno-α-nitroalkanesulphenyl chlorides react with acids and thiols at the sulphur–halogen bond[11,151]:



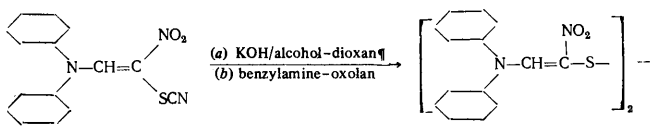
## 3. Reaction with Nucleophilic Reagents

The action of alkalis or alkali-methyl alkoxides on certain α-nitrohetero-organic compounds results in the formation of salts of the corresponding nitro-compounds[17,24,73] or nitramines[20,22,25]. With α-organosulphur derivatives of nitro-compounds[1,6,40,45,47,48,82] and with *N*-nitrosulphonamides[34,35], in particular, these alkaline reagents yield the nitronate salts. If an α-nitrohetero-organic compound of this type does not contain a mobile hydrogen atom, other reactions may occur. Thus, under the influence of alkali, trismethylsulphonylnitromethane loses one of its methylsulphonyl groups[39]:



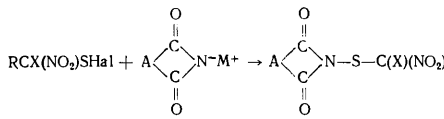
Sulphonyl groups are similarly detached from *N*-alkyl-*N*-nitrotoluene-*p*-sulphonamides[35]:

The action of alkali on *N*-2′-bromoalkyl-2,*N*-dinitrotoluene-4-sulphonamides also causes elimination of the sulphonyl group, with intramolecular alkylation of anions



§Nitroalkylphosphonic chlorides are formed by the action of phosphorus pentachloride.

of the nitramines with formation of the 2-oxides of 4,5-dihydro-1,2,3-oxadiazoles [37]:



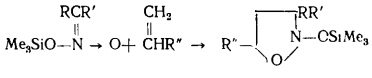
R=$CH_2CH_2Br$, CH(Me)$CH_2Br$, $CH_2CHBrMe$; R′=Me.

Certain α-nitro-organosulphur compounds undergo greater breakdown under the influence of alkalis [98]:

α-Nitroalkane-sulphenyl and -sulphonyl chlorides react with nucleophilic reagents at the sulphur–halogen bond:

Hal and X = Br, Cl; M=Na, K;

R= Alk ($C_1$—$C_6$); R′=H, Alk ($C_1$—$C_6$);



R″=H, Alk [10];

$R_2NH + R'R''C(NO_2)SO_2Cl \rightarrow R'R''C(NO_2)SO_2NR_2$

R=H, Me; R′ and R″=H, Alk, cyclo Alk, or N, O, or S heterocycle [44,75].

## 4. 1,3-Dipolar Cycloaddition

Among all the α-nitrohetero-organic compounds that exist as the *O*-esters only the silyl nitronates have been studied in this reaction. Styrene and methyl acrylate have been used as model compounds, and in isolated cases ethylene. Silyl nitronates undergo cycloaddition to selected alkenes to give good yields of the corresponding cycloadducts:

for R″=$CO_2$Me: R=H, Me, Et, R′=H, Me [52];

R=R′=$CO_2$Me; R=H, $CO_2$Me, R′=H, $NO_2$ [14,50];

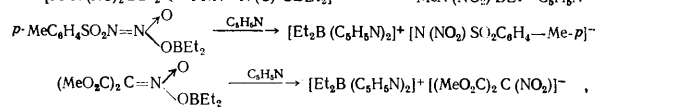
for R″=Ph: R=H, Me, Et, R′=H, Me [52];

R=R′=$CO_2$Me [14], $NO_2$ [15,16,152], R=$CO_2$Me, H,

R′=H, $NO_2$ [50];

for R″=H: R=$CO_2$Me, R′=H [50,153];

R=R′=$NO_2$ [16].



This reaction exhibits strict structural and in most cases also steric regiospecificity.

Silyl nitronates are rather less reactive than their alkyl analogues, but their enhanced thermal stability extends significantly the possibility of using nitro-compounds in the synthesis of heterocyclic structures by 1,3-dipolar cycloaddition. It is noteworthy that silyl dinitromethanenitronates $(NO_2)_2C:NOOSi(CH_3)_n(C_6H_5)_{3-n}$ ($n$ = 0, 1, 3) with methyl acrylate undergo direct silylation, not 1,3-cycloaddition [15,16].

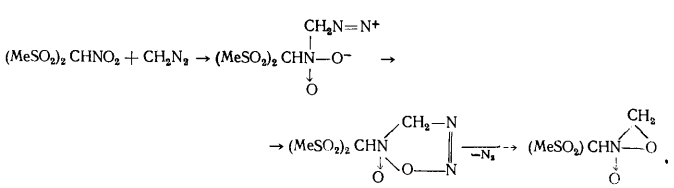
¶Alcoholic hydrogen chloride acts on the starting material of this reaction to give dicyclohexylamine hydrochloride.

## 5. Complexes of α-Nitrohetero-organic Compounds

Bistrinitromethylmercury [112] and bisfluorodinitromethylmercury [145] readily form complexes with many organic ligands (ethers, dioxan, dimethyl sulphoxide, etc.). Both neutral complexes [25] and boronium salts [22,24,26] have been isolated from the action of pyridine on diethylboryl derivatives of nitro-compounds and nitramines: e.g.

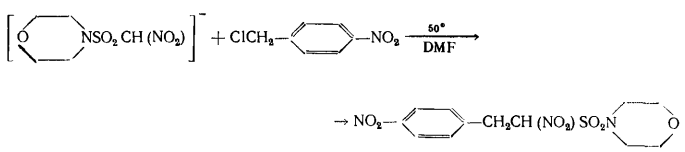
Below we shall discuss reactions undergone only by individual types of α-nitrohetero-organic compounds. The most detailed studies have been made, of course, on the most stable compounds, which include organosulphur and organomercury derivatives of mononitro- and polynitro-compounds.

## 6. Reactions of α-Organosulphur Derivatives of Nitro-compounds



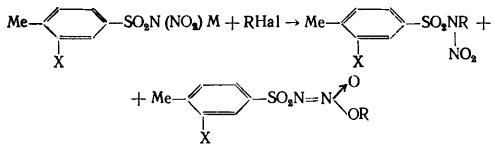
Many reactions well known in the chemistry of aliphatic nitro-compounds have been reported for α-nitroalkyl and α-nitramine derivatives of organosulphur compounds.

### (*a*) Alkylation



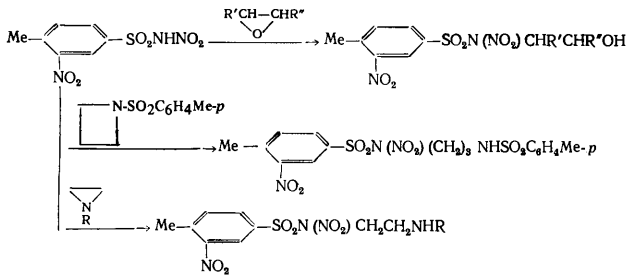
The direction of alkylation depends on the nature of the nitro-component, the alkylating reagent, and the solvent. Thus nitromethyl *p*-tolyl sulphone is alkylated by diazomethane at an oxygen atom in the nitro-group [47]:

The alkylation of dimethylsulphonylnitromethane by diazomethane follows a completely different course [154]:



Anions of α-nitroalkanesulphonamides do not react with benzyl chloride, but with *p*-nitrobenzyl chloride they give *C*-alkylated products [45]:

This reaction was regarded as having a radical-anion mechanism. The alkylation of salts of αα-dinitroalkyl sulphides by methyl iodide gives *C*-substituted products [6]:



The alkylation of salts of *N*-nitroarenesulphonamides by alkyl halides gives a mixture of *N*- and *O*-alkylated products:

X=H, R=$C_6H_5CH_2$; M=Ag, Hal=Cl[35];
X=H, $NO_2$, R=Alk, $C_1$—$C_3$, adamantyl,
M=Ag, Na, Hal=Br, I[155].

The accumulation of alkyl groups in the alkylating reagent increases the proportion of the *O*-product, while the quantity of the *N*-alkylated product increases in the sequence of solvents—hexane < ether < ethyl acetate < diglyme < acetonitrile < dimethylformamide < acetone < methanol.

Silver and potassium salts of 2,*N*-dinitrotoluene-4-sulphonamide give with methyl iodide only the *N*-alkylated product[35,156]. Diazomethane, adamantyldiazoketone, and triethyloxonium tetrafluoroborate also alkylate nitrosulphonamides at the amino-nitrogen atom[155]. 2,*N*-Dinitrotoluene-4-sulphonamide reacts with oxirans and with aziridines and azetidine containing electronegative *N*-substituents to form *N*-2-hydroxyalkylated and *N*-2-amidoalkylated *N*-nitrosulphonamides[157]†:

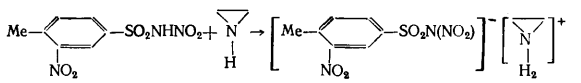
R=$COC_6H_4NO_2$-*p*, $SO_2C_6H_4Me$-*p*; R′, R″=H or Alk.

(*b*) Halogenation

Nitro-derivatives of sulphones, sulphonamides, and sulphides in which the nitro-group is accompanied by a mobile hydrogen atom are readily halogenated either in the presence or in the absence of a base. In particular, dimethylsulphonylnitromethane and its sodium salt react in aqueous solution with bromine and chlorine[39]:

$$O_2NCR(SO_2Me)_2 + X_2 \rightarrow O_2NC(X)$$

X=Cl, Br; R=H, Na.



The bromination of α-nitro-sulphones may lead to isolation of the corresponding monobrominated[40,82] or dibrominated[40] derivatives:

$$RCH(NO_2)SO_2R' \xrightarrow[2.\ Br_2]{1.\ R''O^-} RCBr(NO_2)SO_2R'$$

$$CH_2(NO_2)SO_2Me \xrightarrow[2.\ Br_2/CCl_4]{1.\ R''O^-} MeSO_2C(NO_2)Br_2$$

R=Bu, Ph; R′=Ph, $CH_2Ph$, $CH_2CH_2Me$;
R=H, R′=*p*-$MeC_6H_4$; R″=Alk.

†Reaction of 2,*N*-dinitrotoluene-4-sulphonamide with aziridine itself results merely in the formation of an aziridinium salt[157]:

The bromination of primary α-nitro-sulphonamides has been described[45]:

Bis-1-nitroalkyl disulphides are converted by halogens into 1-halogeno-1-nitroalkanesulphenyl halides[10,11]:

$$RCH(NO_2)S—SC(NO_2)RH \xrightarrow{X_2} 2RCX(NO_2)SX$$

R=Alk, Ar; X=Cl, Br.

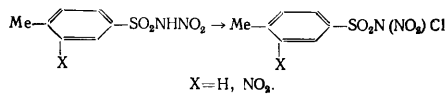
Salts of dinitromethyl sulphides give 70–95% yields of chloro-derivatives[6]:

$$[RSC(NO_2)_2]^-M^+ + Cl_2 \rightarrow RSC(NO_2)_2Cl + MCl$$

R=Me, 2,4-$(NO_2)_2C_6H_3$; M=K, 

Alkyl 1-nitroalkanesulphonates have been identified by conversion into the corresponding brominated products[43]:

$$RCH(NO_2)SO_2R' \xrightarrow[2.\ Br_2,CCl_4]{1.\ KOH—EtOH} RC(NO_2)BrSO_2R'$$



R,R′ = — Alk.

In some cases the halogenation of sulphonyl derivatives is hindered by the presence of a nitro-group. Thus the conversion of α-nitro-sulphonate salts into the acid chlorides requires more severe conditions than does preparation of the unsubstituted sulphonyl chlorides[44,75]:

$$RCH(NO_2)SO_2Na \xrightarrow{PCl_5,POCl_3} RCH(NO_2)SO_2Cl$$

R=H, Alk, cycloAlk, Ar.

*N*-Chloro-*N*-nitroarenesulphonamides are obtained by the action of t-butyl hypochlorite on the corresponding *N*-nitrosulphonamides[158]:

X=H, $NO_2$.

(*c*) Oxidation and reduction

Oxidation of the sulphur atom in α-mono- and αα-di-nitroalkyl sulphides has been reported:

$$RSC(NO_2)R'R'' \xrightarrow[AcOH]{H_2O_2} RSO_2CR'R''(NO_2)$$

R=Me, R′=R″=H[48]; R=*p*-$MeC_6H_4$,
R′=R″=H[47]; R=$ClCH_2CH_2$, 3-$NO_2C_6H_4$,
R′=H, R″=Me[3]; R=Me, Ar, R′=$NO_2$,
R″=H, Me[7].

The corresponding oximes can be isolated from the reduction of certain α-nitro-sulphides by lithium tetrahydroaluminate[3]:

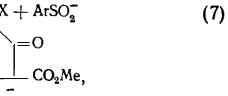
$$p\text{-}MeC_6H_4SCH(NO_2)Me \rightarrow p\text{-}MeC_6H_4SC(Me)=NOH.$$

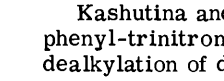
Yet the action of this reductant on a sulphone of similar structure is accompanied by cleavage of the carbon–sulphur bond and formation of toluene-*p*-sulphinic acid (in 80% yield)[3]. Reduction of the same sulphone by hydrogen over Raney nickel gives a mixture of products[3]:

$$p\text{-}MeC_6H_4SO_2CH(NO_2)Me \xrightarrow[Ni/Re]{H_2} p\text{-}MeC_6H_4SO_2C(Me)=NOH + p\text{-}MeC_6H_4SO_2NH_4 + p\text{-}MeC_6H_4SO_2H.$$

Dimethylsulphonylnitromethane is reduced by lithium tetrahydroaluminate with the evolution of ammonia[39]:

$$NO_2CH(SO_2Me)_2 \xrightarrow{LiAlH_4} CH_2(SO_2Me)_2 + NH_3.$$





In the catalytic or electrolytic hydrogenation of certain α-nitro-organosulphur compounds the nitro-group may be reduced to amino[75]:

$$RR'C(NO_2)SO_2NR''R''' \rightarrow RR'C(NH_2)SO_2NR''R'''$$
R, R', R'', R'''=H, Alk, cycloAlk, etc.

(*d*) Other reactions

Several anions act on α-nitroalkyl sulphones with elimination of the sulphonyl group[125,159]:

$$RR'C(NO_2)SO_2Ar + X^- \rightarrow RR'C(NO_2)X + ArSO_2^- \quad (7)$$

$X^- = [Me_2C(NO_2)]^-$,  ,  ,

$MeC^-(CO_2Me)_2$, $p$-$MeC_6H_4SO_2^-$,
$p$-$ClC_6H_4S^-$.
R, R' = Alk, cycloAlk.

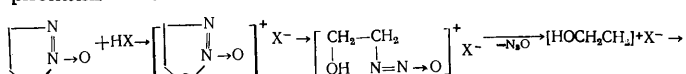
The reaction is accomplished under mild conditions at room temperature. It takes place by a radical-anion mechanism:

$$TosCMe_2(NO_2) + [Me_2C(NO_2)]^- \rightarrow [TosCMe_2(NO_2)]^{\cdot-} + Me_2C(NO_2)^{\cdot}$$
$$[TosCMe_2(NO_2)]^{\cdot-} \rightarrow Tos^- + Me_2C(NO_2)^{\cdot}$$
$$Me_2C(NO_2)^{\cdot} + [Me_2C(NO_2)]^- \rightarrow [Me_2C(NO_2)-C(NO_2)Me_2]^{\cdot-}$$
$$[Me_2C(NO_2)-C(NO_2)Me_2]^{\cdot-} + TosCMe_2(NO_2) \rightarrow [Me_2C(NO_2)]_2 + [TosCMe_2(NO_2)]^{\cdot-},$$

In addition to the products indicated in Eqn. (7) potassium salts of α-nitroalkyl sulphones and iodine are isolated from the reaction of the potassium salt of 2-nitropropane with α-iodo-α-nitroalkyl sulphones[125].

Sodium nitrite acts on α-nitroalkyl sulphones under mild conditions[41]:

$$RSO_2CH(NO_2)R' + NaNO_2 \rightarrow RSO_2C(NO_2)(NO)R' \xrightarrow{B^-} \rightarrow [RSO_2\bar{C}(NO)R' \leftrightarrow RSO_2CR'(=N\bar{O})] \xrightarrow{-H_2O} RSO_2CR'(=NOH)$$
R=$p$-$MeC_6H_4$, $C_6H_5CH_2$; R'=H, Me, Et, Ph,
$p$-$MeOC_6H_4$, $p$-$ClC_6H_4$.



An α-bromo-α-nitroalkyl sulphone reacts with potassamide[40]:

$$PrC(NO_2)(Br)SO_2CH_2Pr \xrightarrow[NH_3]{KNH_2} PrCH=C(SO_2NH_2)Pr.$$

With benzenediazonium salts α-nitro-sulphones of general formula $RSO_2CH_2NO_2$ (R = $C_6H_5$, $p$-$BrC_6H_4$) form hydrazones $RSO_2C(NO_2):NHC_6H_5$. Analogous hydrazones can be obtained also by the interaction of an arenediazonium chloride and nitromethyl trichloromethyl sulphide[8,9]:

$$[RC_6H_4N\equiv N]^+Cl^- + CH_2NO_2(SCCl_3) \xrightarrow{AcONa} RC_6H_4NH-N=C(NO_2)SCCl_3$$
R=H, $p$-Me, $p$-MeO, $m$- and $p$-$NO_2$, $p$-Cl, etc.

An interesting reaction takes place between 4,5-dihydro-1,2,3-oxadiazole 2-oxide and 2,*N*-dinitrotoluene-4-sulphonamide[37]:

$\rightarrow HOCH_2CH_2X$ or $AcH + HX$
X=$Me(NO_2)C_6H_3SO_2N(NO_2)$.

The addition of *N*-chloro-*N*-nitrosulphonamides to unsaturated compounds gives mixtures of *O*- and *N*-halogenoalkylated products[159]:

$$p\text{-}MeC_6H_4SO_2N(Cl)NO_2 + RCH=CHR' \rightarrow p\text{-}MeC_6H_4SO_2N(NO_2)CHRCHR'(Cl) +$$
$$+ p\text{-}MeC_6H_4SO_2N=N(O)OCHRCHR'Cl$$
R=H, Me, Ph; R'=H; R and R'=$(CH_2)_4$.

With butadiene *N*-chloro-*N*-nitrotoluene-$p$-sulphonamide forms the 1,4(*N*)-adduct $p$-$CH_3C_6H_4SO_2N(NO_2)CH_2CH:CHCH_2Cl$, and from its reaction with diphenylacetylene $p$-$CH_3C_6H_4SO_2N(NO_2)C(C_6H_5):CCl.C_6H_5$ is isolated in low yield[159].

## 7. Reactions of Polynitroalkylmercury Derivatives

The main chemical reactions of trinitromethylmercury derivatives and of bisfluorodinitromethylmercury have been reviewed in detail[112,146,160,161], and only a few additional results will be given here.

Kashutina and Okhlobystin[54] have shown that butyl- and phenyl-trinitromethylmercury can be obtained by the dealkylation of dibutyl- and diphenyl-mercury respectively:

$$Hg[C(NO_2)_3]_2 + R_2Hg \rightarrow 2RHgC(NO_2)_3$$
R=Bu, Ph.

Reaction of bitrinitromethylmercury with vinyltrimethylsilane in solvents varying polarity—water, alcohol, benzene, tetrachloromethane—yields bis-3,3,3-trinitro-1-trimethylsilylpropylmercury[162]:

$$2Me_3SiCH=CH_2 + Hg[C(NO_2)_3]_2 \rightarrow Hg[Me_3SiCHCH_2C(NO_2)_3]_2.$$

A similar reaction occurs with but-3-enyltrimethylsilane[162]. A product of the reaction of bistrinitromethylmercury with allyltrimethylsilane is 2,2-bistrinitromethyl-1,3-bistrinitromethylmercurypropane (VI)[162]:

$$Me_3SiCH_2CH=CH_2 + Hg[C(NO_2)_3]_2 \rightarrow Me_3SiCH_2CH[C(NO_2)_3]CH_2Hg[C(NO_2)_3] \xrightarrow{-Me_3SiH} \rightarrow CH_2=C[C(NO_2)_3]CH_2HgC(NO_2)_3 \xrightarrow{Hg[C(NO_2)_3]_2} [(NO_2)_3CHgCH_2]_2C[C(NO_2)_3]_2$$
(VI)

The reactions of (VI) with halogens and with hydrogen chloride can be represented by the scheme

$$(VI) \begin{cases} \xrightarrow{Br_2} (BrHgCH_2)_2C[C(NO_2)_3]_2 \xrightarrow[(PhCO_2)_2]{Br_2} (BrCH_2)_2C[C(NO_2)_3]_2 \\ \xrightarrow{HCl} [ClHgCH_2]_2C[C(NO_2)_3]_2 + 2HC(NO_2)_3 \end{cases}$$

## 8. Other Reactions of α-Nitrohetero-organic Compounds

Nitrotriphenylarsenylmethylide reacts with aromatic aldehydes to form the corresponding alkenes—*trans*-β,4-dinitrostyrene with $p$-nitrobenzaldehyde, and ω-nitrostyrene with benzaldehyde[103]:

$$Ph_3As=CH(NO_2) + RCHO \rightarrow RCH=CH(NO_2) + Ph_3AsO$$
R=Ph, $p$-$NO_2C_6H_4$.

While the Review was being prepared for press, communications have appeared on the preparation and properties of organosulphur derivatives of nitro-compounds[163,164,176], various nitro-ylides[165-167,172], organophosphorus derivatives of aliphatic nitro-compounds[173-175], and also the mechanism of silatropic rearrangements in trialkylsilyl derivatives of nitramines[168-170] and *N*-nitrourethanes[171], as well as the problem of the structure of various hetero-organic derivatives of nitromethane[177].

# New Data on the Chloromethylation of Aromatic and Heteroaromatic Compounds

L.I.Belen'kii, Yu.B.Vol'kenshtein, and I.B.Karmanova

The fundamental methods and applications of the chloromethylation of aromatic and hetero-aromatic compounds as well as ideas concerning the reaction mechanism are considered on the basis of data published mainly during the last ten-fifteen years. The bibliography includes 285 references.

CONTENTS

I. Chloromethylation methods and applications of the reaction 891
II. Chloromethylation by treatment with formaldehyde and hydrogen chloride 891
III. Chloromethylation by treatment with chloromethyl ethers 895

## I. CHLOROMETHYLATION METHODS AND APPLICATIONS OF THE REACTION

Chloromethylation is a specific and most important instance of halogenoalkylation. It consists of the direct substitution of a hydrogen atom by the chloromethyl group. Hydrogen atoms linked not only to carbon but also to heteroatoms may be substituted (see, for example, Refs. 1–5), but chloromethylation at a carbon atom in an aromatic or heteroaromatic ring is of greatest importance, and this in fact will be considered below.

Chloromethylation of aromatic compounds was achieved for the first time in 1898 by Grassi and Maselli[6], who succeeded in obtaining benzyl chloride by the reaction of benzene with trioxymethylene and hydrogen chloride in the presence of zinc chloride. Nowadays chloromethylation is one of the important synthetic methods in organic chemistry.

The studies of the last ten–fifteen years will be mainly considered below, since the fundamental achievements in this field approximately up to 1962 have already been described in a number of reviews[7-9]. As regards the use of chloromethylation methods which have already become classical, we shall as a rule confine ourselves merely to references to the corresponding papers and patents published after 1962. The treatment of studies in which the reaction mechanism is considered as well as certain specific examples of chloromethylation methods which have developed recently will be relatively detailed. These are the chloromethylation of deactivated aromatic and heteroaromatic compounds, particularly the reactions using chloromethyl ethers.

Judging from the data presented in reviews[7-9], the result of the reaction under consideration depends greatly on the nature of the chloromethylating agent, the catalyst, and the process conditions. Effective chloromethylating agents are formaldehyde, paraformaldehyde or trioxymethylene with hydrogen chloride, and monochloromethyl and $\alpha\alpha'$-bischloromethyl ethers. The reaction is carried out in the presence of $ZnCl_2$, $SnCl_4$, $AlCl_3$, $BF_3$, $FeCl_3$, $TiCl_4$, as well as protic acids—HCl (taken in excess and behaving simultaneously as a reactant), $H_2SO_4$, $H_3PO_4$, $ClSO_3H$, and $CH_3COOH$. Zinc chloride is used most frequently. To increase its activity, it is often used with a small amount of aluminium chloride. However, the employment of $AlCl_3$ as a catalyst can entail the formation of a side product—a diarylmethane derivative—so that aluminium chloride is used mainly for compounds with deactivating substituents for which zinc chloride may be insufficiently effective. The water evolved in chloromethylation in the presence of metal halides hydrolyses the catalyst. In order to remove the water, the chlorides of inorganic acids are sometimes added to the reaction mixture, for example thionyl chloride[10,11]. Chloromethylation may be carried out under both heterogeneous and homogeneous conditions. $CH_3COOH$, $CCl_4$, $CHCl_3$, $CH_2Cl_2$, $CS_2$, as well as an excess of the chloromethyl ether are widely used as solvents.

The chloromethyl group, which has a mobile chlorine atom, can be converted into a methyl, hydroxymethyl, cyanomethyl, formyl, dialkylaminomethyl, and other functional groups. It is possible to obtain in this way many compounds otherwise difficult to synthesise, particularly biologically active compounds and substances used as intermediates in various syntheses, for example benzene[12-15], biphenyl[16], thiophen[17-24], furan[25], benzofuran[26], isoxazole[27], oxazine[28], benzoxazine[29], benzopyrimidine[30], and xanthotoxin[31] derivatives, as well as chromones[32] and flavones[33,34]. The interaction of bischloromethyl derivatives with various nucleophiles can lead not only to bifunctional compounds but also to complex bicyclic and polycyclic systems (see, for example, Refs. 35–41). Certain chloromethylated aromatic compounds have found industrial applications. Isothiuronium and pyridinium salts of anthraquinone-acridones[42], obtained from chloromethylderivatives, are used as dyes. Technical syntheses of pyromellitic dianhydride, trimellitic anhydride[43], terephthalic acid[44], phthalic and benzenepolycarboxylic acids[45], surfactants[46], etc. have been developed on the basis of mono- and bis-chloromethyl derivatives of aromatic hydrocarbons. The use of the chloromethylation reaction in the manufacture of ion-exchange resins has assumed significant importance recently[47-49].

## II. CHLOROMETHYLATION BY TREATMENT WITH FORMALDEHYDE AND HYDROGEN CHLORIDE

Chloromethylation is usually carried out with the aid of formaldehyde (normally in the form of formalin or paraformaldehyde) and hydrogen chloride in aqueous or non-aqueous media. Chloromethylation with formaldehyde in HCl was extensively redeveloped at one time by Blanc[50],

which led to his name being given to this reaction [7,51], although the process conditions do not differ from those described by Grassi and Maselli [6]. Zinc chloride is usually employed as the catalyst [52-58], more rarely tin(IV) chloride [59] or aluminium chloride [57]. However, when the $CH_2Cl$ group is introduced into aromatic compounds containing activating substituents, hydrogen chloride may serve as the catalyst [44,60-69]; in certain cases the reaction is carried out under pressure [43]. Other protic acids are also used successfully as catalysts—sulphuric [70], phosphoric [56,57], and perchloric [58]. The chloromethylation method considered here is applicable also to the compounds containing simultaneously activating and deactivating substituents, for example to hydroxybenzoate esters [71-74] and dimethoxybenzaldehydes [75]. Studies on the chloromethylation of the benzene rings of the condensed and partly hydrogenated 2-benzofuranone and 3,4-dihydrocoumarin [76,77] as well as phenoxathiin [78] systems are related to the above investigations. The reactions of pyromucic acid esters [79], 2,5-dimethylthiophen [80], 2-phenylbenzofuran [81], 1,2,5-thiadiazole [82], substituted $\alpha$-pyridone [83], and a derivative of tetrahydrocorrin [84] may be quoted as examples of the chloromethylation of heterocycles by treatment with formaldehyde and HCl.

The chloromethylation of deactivated aromatic compounds by treatment with formaldehyde and HCl is frequently carried out in concentrated sulphuric acid [85-88]. In some cases, the reaction is performed in the absence of HCl; the chloromethylating mixture is then prepared from paraformaldehyde, chlorosulphonic acid, and concentrated sulphuric acid [89,90].

Specific difficulties arise in the chloromethylation of alkyl aryl ketones. In the absence of activating substituents in the benzene ring, as in the case of dialkyl ketones (see, for example Dermer and Newcombe [91]), the $\alpha$-position in the side chain is substituted. For example the chloromethylation of acetophenone in the side chain is carried out by treatment with paraformaldehyde and HCl in glacial acetic acid at 100°C in the presence of phosphoric or sulphuric acid [92-95]. The use of paraformaldehyde and concentrated hydrochloric acid in acetic acid, in the presence of 70% $HClO_4$, makes it possible to introduce two $CH_2Cl$ groups into the methyl group of acetophenone [96].

It is quite likely that chloromethylation of the side chain proceeds via the mechanism of the Prins reaction [97-99]—the condensation of formaldehyde with olefins in the presence of acid catalysts. As a result of the interaction of formaldehyde with the catalyst, the hydroxymethyl cation is produced in this reaction and then attacks the double bond of the olefin. The chloromethyl derivative may be formed in the presence of HCl—for example, on treatment with paraformaldehyde and HCl in acetic acid, 1,1-diphenylethylene is converted into 3-chloro-1,1-diphenylprop-1-ene [100].

We believe that, in the reaction involving alkyl aryl ketones, the $(CH_2OH)^+$ cation attacks the enolic form of the ketone, after which the newly formed cation is stabilised by the elimination of a proton, this being followed by the substitution of the hydroxy-group by chlorine. This process may be represented schematically as follows:

$$CH_2O + HX \rightleftarrows HO\overset{+}{C}H_2 + X^- ,$$

$$RC(=O)-CH_3 \rightleftarrows R-C(OH)=CH_2 ,$$

$$R-C(OH)=CH_2 + \overset{+}{C}H_2OH \rightarrow R-\overset{+}{C}(OH)-CH_2CH_2OH ,$$

$$R-C(OH)(\overset{+}{C})-CH_2CH_2OH \xrightarrow{-H^+} R-C(OH)=CHCH_2OH ,$$

$$R-C(OH)=CHCH_2OH + HCl \rightarrow R-C(=O)-CH_2CH_2Cl .$$

It is important to note that the introduction of electron-donating substituents into the benzene ring of an alkyl aryl ketone alters the mode of chloromethylation—the $CH_2Cl$ group enters the aromatic ring and not the side chain [92,101-106]. It therefore becomes understandable why acyl derivatives of activated heteroaromatic systems (furan [107], thiophen [108-114], and selenophen [115]) are also chloromethylated in the ring.

Chloromethylation is a typical electrophilic substitution reaction. Nazarov and Semenovskii [116] have shown that the amount of the *meta*-chloromethyl derivative increases in the following sequence in chloromethylation, as in other electrophilic substitution reactions (nitration and halogenation):

$$C_6H_5CH_3 < C_6H_5CH_2COOC_2H_5 < C_6H_5CH_2Cl .$$

In the chloromethylation of halogenobenzenes, a gradual increase of the amount of *o*-isomers is observed on passing from fluorobenzene to iodobenzene [116]. A similar variation of the proportions of the isomers occurs, for example, in the nitration of halogenobenzenes [117]. The study of the proportions of the isomers obtained in the chloromethylation of alkylbenzenes [116,118,119] has shown that they fully obey the rules established for other electrophilic substitution reactions. The chloromethyl group enters mainly the *para*- and *ortho*-positions. Substitution in the *meta*-position is observed to only a slight extent and the fraction of the *meta*-isomer increases for alkylbenzenes with increase in the bulk of the alkyl group in the sequence $CH_3 < C_2H_5 <$ iso-$C_3H_7 <$ t-$C_4H_9$. For example, the chloromethylation of toluene results in the formation of only traces of the *meta*-chloromethyl derivative, while t-butylbenzene gives rise to 6.1% of *meta*-t-butylbenzyl chloride [119].

Comparison of the results of the chloromethylation [116,120] of toluene, ethylbenzene, cumene, and other hydrocarbons differing in the bulk of the alkyl substituent established that the amount of *o*-isomer decreases from 51.7% to 0% in the series of $C_6H_5Alk$ derivatives, where Alk = $CH_3$, $C_2H_5$, n-$C_3H_7$, n-$C_4H_9$, iso-$C_4H_9$, cyclo-$C_6H_{11}$, iso-$C_3H_7$, or t-$C_4H_9$†. This phenomenon is due to the increasing steric hindrance in the *o*-position on passing from toluene to t-butylbenzene. The same type of regular decrease of the amount of *o*-isomer is characteristic of other electrophilic substitution reactions [121].

It is noteworthy that the available quantitative literature data for the relative rates of chloromethylation of aromatic hydrocarbons are extremely contradictory at first sight. Thus the observed ratio of the rates of chloromethylation of toluene and benzene ($k_t/k_b$) varies within very wide limits—from 3 [122,123] to 30 [124] and even to 112. [125] Incidentally, one should note that in the above studies [122-125] the reactions were carried out under different conditions and different chloromethylating agents were used. Furthermore, we believe that some of the workers [122,123] employed an inadequate analytical method and it is quite likely that errors might have been made in the determination of the concentration of chloride ions.

† Traces of *o*-t-butylbenzyl chloride have been detected [119].

Vavon et al.[122] used for chloromethylation a monochloromethyl ether in glacial acetic acid at 100°C and measured the rate of reaction on the basis of the amount of HCl evolved on hydrolysis of the ether which failed to react. Szmant and Dudek[123] carried out the reaction by treatment with paraformaldehyde and HCl in glacial acetic acid at 85°C. The kinetics were followed from the change in the concentration of chloride ions during the reaction. Brown and Nelson[125] were unable to reproduce the results of Vavon et al.[122] and Szmant and Dudek[123] and carried out the reaction under other conditions, namely they used trioxymethylene and gaseous HCl in the presence of zinc chloride as the catalyst in solution in glacial acetic acid at 60°C. The ratio $k_t/k_b$ was found by the method of competition kinetics, by a quantitative determination of the corresponding hydrocarbons, isolated after the reduction of the chloromethyl derivatives with lithium tetrahydroaluminate‡. For the chloromethylation rate constant ratio $k_t/k_b = 112$ obtained by Brown and Nelson[125], a linear relation is observed between the logarithms of the partial rate factors for substitution in the *p*-position ($\lg f_p$) and the selectivity factors $F_S = \lg(f_p/f_m)$, where $f_m$ is the partial rate factor for substitution in the *m*-position, as for other electrophilic substitution reactions.

The fact that chloromethylation is an electrophilic substitution reaction is consistent also with the reaction constant $\rho$, which has been determined[124,126] and found to be of the order of $-5$. In the above studies, paraformaldehyde with hydrochloric acids were used as the chloromethylating agent. The reaction mixture was analysed for hydrochloric acid and formaldehyde at specified time intervals. The isomeric composition of the chloromethylated derivatives was determined after their catalytic reduction to the corresponding polymethylbenzenes. The experimental relative rates agree satisfactorily with data calculated by Condon's method[127] from the partial rate factors for substitution in the *o*-, *m*-, and *p*-positions in toluene.

Attempts to elucidate the mechanism of chloromethylation by treatment with formaldehyde and HCl have been made frequently. Darzens[128] believed that chloromethyl acetate $ClCH_2OOCCH_3$ is the chloromethylating agent when the reaction is carried out in acetic acid:

$$CH_2O + CH_3COOH + HCl \rightarrow ClCH_2OOCCH_3 + H_2O\,,$$
$$ArH + ClCH_2OOCCH_3 \rightarrow ArCH_2Cl + CH_3COOH\,.$$

However, Brown and Nelson[125] showed that the reaction of benzene with this ester at 75–80°C for 16 h without catalysts and for 4 h in the presence of zinc chloride does not give rise to benzyl chloride. Chloromethyl acetate can be used for the chloromethylation of benzene if the mixture is allowed to stand for 100 h.

The reaction of $CH_2O$ and HCl may lead to the formation of $CH_2Cl_2$, but the latter is not a chloromethylating agent: the attempt to chloromethylate benzene by methylene chloride in the presence of zinc chloride was unsuccessful[129]. It was believed[130] that the chloromethylating agent is $\alpha\alpha'$-bischloromethyl ether formed in the reaction between $CH_2O$ and HCl. In fact, as will be shown in the next section, the formation of the bischloromethyl ether is most likely in the chloromethylation of relatively inactive compounds under severe conditions. On the other hand, in chloromethylation under mild conditions, particularly in aqueous solutions, other possibilities must be considered.

Together with the mechanism presented above, two ionic mechanisms have also been put forward for the chloromethylation reaction. The first[131] presupposes that the attacking species is $[CH_2Cl]^+$, which may be formed in the first stage in conformity with the following reaction scheme:

$$CH_2O + HCl + H^+ \overset{K_1}{\rightleftarrows} CH_2OHCl + H^+ \overset{K_2}{\rightleftarrows} \overset{+}{C}H_2Cl + H_2O\,,$$
$$ArH + \overset{+}{C}H_2Cl \overset{k}{\rightarrow} ArCH_2Cl + H^+\,.$$

According to this scheme, the rate of reaction should be described by the equation

$$\frac{dx}{dt} = k\,[ArH][\overset{+}{C}H_2Cl] = kK_1K_2\frac{[ArH][CH_2O][HCl][H^+]}{[H_2O]}\,,$$

where $K_1$ and $K_2$ are the equilibrium constants and $k$ is the rate constant.

However, the above mechanism conflicts with experimental data[132]: when the reaction is carried out in $H_2SO_4$ in the absence or presence of chloride ion (LiCl), the rate constant is virtually the same, i.e. the chloride ion does not affect the rate and yet if the reaction involves the mechanism under consideration such an effect should have been observed, because the rate equation includes the concentration of HCl. On the basis of this mechanism, the rate of the chloromethylation reaction should be described by the equation for third-order kinetics, which also conflicts with experimental data[133].

Another mechanism which postulates the formation of the hydroxymethyl cation $[CH_2OH]^+$ and subsequent attack by the latter on the aromatic compound appears to be most justified at the present time; in the next stage, the hydroxy-group is substituted by a chlorine atom, which leads to the formation of the final compound[132,134,135]. The conclusion that the attacking species is the hydroxymethyl cation was reached[124] particularly on the basis of the finding that the formation of *o*- and *p*-isomers in identical proportions is observed in the bromomethylation and chloromethylation of toluene, ethylbenzene, and cumene. This shows that in both cases the same attacking species is active, consisting of the protonated form of formaldehyde, namely $[CH_2OH]^+$§. If the reaction involved the halogenomethyl ion, then bromomethylation should have produced a greater amount of the *p*-isomer than chloromethylation, since the bulk of the bromomethyl group is significantly greater than that of the chloromethyl group. Furthermore, it has been shown[134] that, under the chloromethylation conditions, the hydroxy-group in the benzyl alcohol is fully substituted by chlorine.

This conclusion has been confirmed by the kinetic studies of Ogata and Okano[132] on the chloromethylation of mesitylene by treatment with formaldehyde and HCl in 90% aqueous acetic acid and by Farberov and coworkers[135] on the chloromethylation of xylenes and pseudocumene by

‡ According to recently published data[284], the analytical method employed by Brown and Nelson[125] leads to an unduly high value of $k_t/k_b$. It is possible to infer from the results obtained by gas–liquid chromatography directly for mixtures of the chloromethyl derivatives formed under the conditions of competing reactions[284] that this quantity is about 30 (cf. Mironov et al.[124]).

§ In this connection, it is interesting to note that at equilibrium in acid media (pH < 2.6) formaldehyde is present in the form of the hydroxymethyl cation[136].

treatment with formaldehyde and hydrochloric acid. The following chloromethylation mechanism was proposed[135]:

$$CH_2O + H^+ \underset{K}{\overset{\text{fast}}{\rightleftharpoons}} \overset{+}{C}H_2OH ,$$

$$ArH + \overset{+}{C}H_2OH \xrightarrow{\text{slow}} [\overset{+}{Ar}HCH_2OH] ,$$

$$[\overset{+}{Ar}HCH_2OH] \rightarrow ArCH_2OH + H^+ ,$$

$$ArCH_2OH + HCl \xrightarrow{\text{fast}} ArCH_2Cl + H_2O .$$

If it is postulated that the rate-limiting stage is the addition of the protonated form of formaldehyde to the molecule of the aromatic hydrocarbon, then kinetic analysis leads to the following expression for the rate of reaction:

$$\frac{dx}{dt} = k[ArH][\overset{+}{C}H_2OH] = kK[ArH][CH_2O][H^+] = K_F[ArH][CH_2O] ,$$

where $k$ is the rate constant, $K$ the equilibrium constant, and $K_F = kK[H]^+$.

After taking logarithms in this equation, we obtain the relation

$$\lg K_F = -H_0 + \text{const} ,$$

where $H_0$ is the Hammett acidity function.

Experimental data confirm the proposed mechanism, since it has been observed that the rate of reaction is directly proportional to the product $[ArH][CH_2O]$. A linear relation has been obtained[135] between the logarithm of the rate constant and the Hammett acidity function for the monochloromethylation of *m*-xylene and pseudocumene by treatment with formaldehyde and hydrochloric acid. The concentration of hydrochloric acid and the molar ratios of hydrochloric acid, the hydrocarbon, and formaldehyde have a considerable influence on the rate of chloromethylation, which confirms the acid-catalysed reaction mechanism.

Detailed studies have shown that the monochloromethylation of *m*-xylene and pseudocumene by treatment with $(CH_2O)_n$ and HCl for a constant acidity function $H_0$ is described by a second-order kinetic equation, which confirms the last mechanism[135]. When the reaction was carried out in different solvents—formic, acetic, and propionic, and butyric acids and dioxan—it was observed that the rate of chloromethylation in the presence of aliphatic acids is much higher than in dioxan and water[137]. According to the authors, this phenomenon can be accounted for by the formation of the protonated form of the aliphatic acid, which exhibits a high proton-donating capacity. This results in an increase of the concentration of $[CH_2OH]^+$ and of the rate of the rate-limiting stage of reaction (2). If the reaction is performed in acetic acid in the presence of zinc chloride, the latter forms with acetic acid the complex acid $H_2[ZnCl_2(OCOCH_3)_2]$, which is just as strong as inorganic acids[138]. The acceleration of the process can be explained by the increase of acidity of the medium, leading to an increase of the concentration of $[CH_2OH]^+$ ions[139].

The mechanism of chloromethylation by treatment with $CH_2O$ and HCl in the presence of zinc chloride in the absence of a catalyst can be represented as follows[8]:

$$CH_2O + HCl + ZnCl_2 \rightleftharpoons [CH_2OH]^+ ZnCl_3^- ,$$

$$ArH + [CH_2OH]^+ ZnCl_3^- \rightleftharpoons \text{(arenium ion, R, } CH_2OH\text{)} \quad ZnCl_3^- \xrightarrow{HCl} ArCH_2Cl + ZnCl_2 + H_2O ,$$

or

$$\overset{\delta+}{CH_2O} \rightarrow \overset{\delta-}{ZnCl_2} + \text{(C}_6\text{H}_6\text{)} \rightleftharpoons Cl_2Zn{-}O{-}C(H)(H){-}\text{(arenium ion)} \xrightarrow[-H^+]{HCl} \text{(C}_6\text{H}_5\text{)}{-}CH_2Cl + H_2O + ZnCl_2 .$$

Together with the formation of monochloromethyl derivatives, bischloromethyl derivatives are produced as an admixture. By carrying out the reaction with a specific reactant ratio, it is possible to drive it towards the formation of bischloromethyl derivatives. For example, the bischloromethylation of xylene and pseudocumene[135] at 95° requires a considerable excess of hydrochloric acid, (8–10 moles) and paraformaldehyde (4–6 moles) relative to the stoichiometric amount. Very few studies have been made on the kinetics and mechanism of the formation of bischloromethyl derivatives. According to Ishii and Yamashita[140], the chloromethylation of monochloromethylxylene is not described by the equation for zero-order kinetics. However, on the basis of a study of the kinetics of the formation of the products of the bischloromethylation of *m*- and *p*-xylenes, Mironov et al.[141] proposed for this reaction the same mechanism as for monochloromethylation; the observed kinetic relations were interpreted in terms of the second-order equation for acid-catalysed reactions.

The most important side reaction in the chloromethylation process is the formation of diarylmethanes as a result of the further condensation of the initial compounds and the chloromethyl derivative obtained. It has been reported that the formation of diarylmethane may be inhibited by employing arsenic(III) chloride or arsenic(III) oxide as the catalyst[142]. In some cases, this reaction may be of independent interest, since it gives rise to polymethylbenzenes (as a result of the hydrocracking of the corresponding diarylmethanes[143]), benzophenonepolycarboxylic acid, and their anhydrides[144]. It has been shown by studying the kinetics of the chloromethylation of pseudocumene and *m*-xylene and the subsequent synthesis of diarylmethanes in the presence of toluene-*p*-sulphonic acid that the condensation reaction is described by the equation for second-order kinetics[133] (first order with respect to $CH_2O$ and first order with respect to HCl). The slowest stage, determining the overall rate of reaction, is the addition of the hydroxymethyl cation to the aromatic hydrocarbon molecule, as in chloromethylation[133].

It has been suggested recently[145] that the active chloromethylating species is the protonated form of the hypothetical chloromethanol ($ClCH_2\overset{+}{O}H_2$). The overall mechanism may be represented by a scheme[145] similar to that proposed previously[146]:

$$CH_2O + 2HCl + ZnCl_2 \rightleftharpoons ClCH_2\overset{+}{O}H_2ZnCl_3^- ,$$

$$H_2\overset{+}{O}CH_2Cl + \text{(C}_6\text{H}_5\text{)}{-}R \rightleftharpoons \text{(arenium ion, R, } ClH_2C,\ H\text{)} \xrightarrow{-H^+} \text{(C}_6\text{H}_4\text{)}(R)(CH_2Cl) .$$

This mechanism does not conflict with the kinetic data discussed above (first order with respect to $CH_2O$ and ArH), but it gives rise to a number of objections. In the first place, the authors who proposed it[145] established themselves that the $ClCH_2\overset{+}{O}H_2$ species exists only below −65 °C even in a very acid medium. Chloromethylation is possible in principle at such temperatures (see, for example, Ref. 147), but the reaction is usually carried out at a higher temperature. On the other hand, the above mechanism presupposes the direct introduction of the $CH_2Cl$ group, and not $CH_2OH$, into the aromatic ring. A number of arguments against this view were examined above. Furthermore, there is direct experimental evidence in support of the primary formation of hydroxymethyl derivatives, which are converted into chloromethylation products only in later stages[106,148].

## III. CHLOROMETHYLATION BY TREATMENT WITH CHLOROMETHYL ETHERS

### 1. Conditions and Characteristic Features of the Use of the Reaction

Another important group of chloromethylating agents are chloromethyl ethers, mainly monochloromethyl (MCME) and $\alpha\alpha'$-bischloromethyl (BCME) ethers. Chloromethylation by alkyl chloromethyl ethers was described for the first time by Sommelet[149]. By treating benzene with $\alpha$-monohalogenoalkyl ethers in the presence of $AlCl_3$ in $CS_2$, he obtained a mixture of the benzyl ether and benzyl chloride. He believed[149] that the primary product is an ether which is readily converted into the chloromethyl derivatives under the influence of the HCl liberated during the reaction:

$$ArH + ClCH_2OR \xrightarrow[CS_2]{AlCl_3} ArCH_2OR,$$
$$ArCH_2OR \xrightarrow{HCl} ArCH_2Cl.$$

Apart from $AlCl_3$, the catalysts used for this reaction were $ZnCl_2$, $SbCl_5$, and $SnCl_4$; the author believed that $SnCl_4$ was the most suitable catalyst. Aluminium chloride usually gives rise to further condensation reactions with formation of diphenylmethane and high-molecular-weight products.

Vavon and Bolle[150] suggested that aromatic hydrocarbons be chloromethylated under homogeneous conditions, namely by treatment with MCME in acetic acid without a catalyst. However, under these conditions the reaction is much slower than in the presence of a catalyst. Presumably, on treatment with MCME in acetic acid, chloromethylation may be accompanied by acetoxymethylation, since solutions of MCME in acetic acid contain methoxymethyl acetate[151]. However, the product of the acetoxymethylation of mesitylene was not isolated. As stated above, the substituted benzyl acetate formed is readily cleaved by the HCl evolved or MCME.[151] Lock[129] showed that the optimum conditions for chloromethylation by treatment with MCME are the use of zinc chloride as the catalyst in a heterogeneous medium with an excess of the aromatic compound as the solvent.

The chloromethylation with $\alpha\alpha'$-bischloromethyl ether was also carried out for the first time in the synthesis of benzyl chloride and related compounds[130]. The chloromethylating agent was the unpurified product obtained by treating paraformaldehyde or an aqueous formaldehyde solution with hydrogen chloride; Tishchenko[152] showed that it contains mainly BCME¶. A certain amount of MCME is also present in this mixture, because formaldehyde usually contains an admixture of methanol[156,157] and the interaction of $CH_3OH$, $CH_2O$, and HCl is known to be a preparative method for synthesising MCME.[158-160]

It has been shown[161] that the mixture obtained when HCl is passed into formalin contains, apart from MCME, and BCME, the bischloromethyl acetal of formaldehyde $CH_3(OCH_2Cl)_2$, which can also serve as a chloromethylating agent. This conclusion was reached in a study of the chloromethylation of selenophen and its homologues. It is of interest to note that, according to Yur'ev et al.[161] treatment in acetic acid with BCME, specially prepared and purified by a standard method[162], failed to yield chloromethylselophens. We believe that this finding can be explained by the fact that the reaction mixture does not contain HCl, which usually plays the role of the catalyst. Furthermore, BCME obtained by the standard method[162] contains paraformaldehyde and, according to Pesin and D'yachenko[163], bases and pseudobases (urotropine, dimethylformamide and paraformaldehyde) inhibit chloromethylation with BCME. It must be emphasised that the mixture of MCME and BCME usually used for chloromethylation always contains an admixture of HCl, since it is obtained by passing HCl into formalin and is used in the reaction without preliminary purification.

The data presented permit the conclusion that the chloromethylation by treatment with $CH_2O$ and HCl may result in the formation of BCME and MCME. It may be that, in the chloromethylation of comparatively reactive aromatic compounds in an aqueous medium, the rate of formation of the ethers is low. On the other hand, the chloromethylation of deactivated aromatic compounds with paraformaldehyde and hydrogen chloride in the presence of $H_2SO_4$, oleum, or $HSO_3Cl$ actually proceeds under conditions in which BCME is formed on a preparative scale[162]. The chloromethylation of deactivated aromatic compounds takes place fairly slowly and the rate of reaction may therefore be comparable to the rate of formation of BCME in the reaction medium. Evidently, under such conditions the reaction mechanism must reflect the involvement of the chloromethyl ethers. The problem of the mechanism of chloromethylation by BCME and MCME is discussed below. Examples of the employment of chloromethyl ethers for the synthesis of the corresponding substituted aromatic and heteroaromatic derivatives are also given.

Chloromethyl ethers are used as chloromethylating agents for a wide variety of compounds differing greatly in their reactivities. The reactivity of BCME is higher than that of MCME;[130] furthermore, it depends significantly on the catalysts employed and also on different impurities and additives. The chloromethylation of reactive aromatic compounds (hydrocarbons with *ortho–para* directing substituents and heterocycles) is usually carried out by treatment with MCME in acetic acid[164-166] or in carbon disulphide in the presence of tin(IV) chloride at 0°C.[167,168] Compounds containing simultaneously activating and deactivating substituents, for example nitrophenols, are chloromethylated by treatment with MCME or BCME when heated in the presence of catalysts—usually zinc chloride[169,170]. Under the same conditions, it is possible to chloromethylate also fairly stable aromatic compounds[171]. Deactivated compounds are normally acted upon by chloromethyl ethers in sulphuric acid or oleum, sometimes in the presence of chlorosulphonic acid[172-174].

Chloromethylation with chloromethyl ethers has come to be widely used in the manufacture of ion-exchange resins. Polystyrene[175-183]†, the copolymers of styrene with divinylbenzene[185-193], *NN'*-arylenedimethacrylamides[194,195], 9-alkyl-3-vinylcarbazoles[196], divinylbenzene, acrylonitrile[48], and ethylene terephthalate[197], polyphenylisoprene[198], poly-(*p*-phenylene-ethylene)[199], and other polymers have been chloromethylated for this purpose. The chloromethyl group usually enters the *p*-position and to a small extent the *o*-position in the aromatic ring. The reaction is frequently accompanied by side processes—the polymer chains are cross-linked by methylene bridges[185,187]. The nature of the catalyst

¶ It has been found that, when formaldehyde and HCl interact in the gas phase, BCME is also formed[153-155].

† Chloromethylated polystyrene can also be obtained by the polymerisation of *p*-chloromethylstyrene[184].

has a significant influence on the rate of reaction and the degree of conversion of the copolymer, i.e. the average number of chloromethyl groups per benzene ring in the polymer molecule. Comparison of the degrees of conversion of the copolymer over a specified period, the effective rate constants, and the activation energies made it possible to arrange the catalysts investigated in the following sequence in terms of their activities [200]:

$$SnCl_4 > ZnCl_2 > AlCl_3 > SnCl_2 > FeCl_3 .$$

The introduction of various additivites into the reaction mixture ($SiCl_4$ [201] and $ZrCl_4$ [202]) increases significantly the degree of conversion of the copolymer. These additives apparently regenerate the catalyst during the reaction.

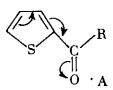
The use of chloromethyl ethers instead of formaldehyde and HCl in the examples considered here is due to the fact that the diffusion of the reactants into the polymer is of decisive importance for these reactions, which take place in a heterogeneous medium. At the same time the fact that under comparable conditions the chloromethyl ethers are apparently more reactive chloromethylating agents than formaldehyde and HCl may also play a role in other instances. For example, when an unpurified mixture of MCME and BCME in acetic acid was used, the chloromethylation of 2-pyrones was achieved for the first time [203,204]. On the other hand, chloromethylpyrones could not be obtained by treatment with paraformaldehyde in the presence of HCl or zinc chloride.

Substituents influence the rate of reaction of chloromethyl ethers in the same way as that of formaldehyde and HCl. In particular, substituents with the $+I$ effect accelerate the reaction; for example, the rate of chloromethylation of mesitylene with MCME is much higher than that of benzene [149]. As shown for isoxazole derivatives [205,206], the reaction is facilitated by the presence in the ring of substituents such as methyl or phenyl and in all cases the chloromethyl group is directed to the 4-position of the isoxazole ring, similarly to other electrophilic substitution reactions, for example, nitration and halogenation [207].

Similar results were obtained also in the chloromethylation of 2,1,3-thia- and selena-diazoles and their homologues [208-211]. The chloromethyl group enters the 4-position, as in chlorination [212,213]; the reaction is facilitated by the introduction of electron-donating groups and is hindered in the presence of electron-accepting substituents. The activating influence of the alkyl substituent has also been observed for a series of *N*-aryl-*N*-methylsulphonylanilides [214-217].

Phenols and alkylphenols are chloromethylated readily, but immediately undergo further condensation reactions [218, 219]. For this reason, it has so far been impossible to isolate chloromethylphenols. Romadane and coworkers [220,221] chloromethylated *p*-alkoxybenzenes by various methods and showed that the main reaction product is 2-alkoxy-5-alkylbenzyl chloride (96–99%), while a second isomer, 5-alkoxy-2-alkylbenzyl chloride, is formed in a yield of 1–4%.

When 4-alkylphenyl methyl carbonates are chloromethylated by MCME in the presence of $SbCl_5$ as the catalyst, a mixture of isomers with the chloromethyl group in the 2- and 3-positions is formed, with the former isomer predominating [222,223]. It was possible to obtain bischloromethyl derivatives of these compounds only by treatment with BCME and in the presence of $SbCl_5$ as the catalyst [224]. The introduction into the ring of substituents with the $-I$ effect and even more so the introduction of substituents with the $-I$ and $-M$ effects (for example, using $CH_2O$ + HCl) [150] hinders further chloromethylation. Thus dichlorobenzenes are chloromethylated with much greater difficulty than monosubstituted derivatives [225-229]. The attempts to introduce the chloromethyl group into 5-nitrosalicylaldehyde by the usual methods were unsuccessful. The reaction proceeds only when an excess of $AlCl_3$ and MCME is used [230].



The chloromethylation of nitrobenzenes is carried out under severe conditions—by treatment with strong chloromethylating agents such as BCME and MCME and in the presence of strong inorganic acids. For example, when nitrobenzene is treated with BCME in 96% sulphuric acid (at 45–50°C for a week!), a 35% yield of *m*-nitrobenzyl chloride is obtained [231]. Berezovskii et al. [232] investigated the interaction of *p*-nitrotoluene with BCME and showed that, when the reaction is carried out in chlorosulphonic acid, or 5% oleum at a temperature not exceeding 10°C, the monochloromethyl derivative is obtained in an almost quantitative yield. An increase of temperature to 40–50°C and the use of 20–40% oleum or an excess of chlorosulphonic acid make it possible to introduce two chloromethyl groups into the *p*-nitrotoluene molecule. *p*-Ethylnitrobenzene gives 43% of 2-chloromethyl-1-ethyl-4-nitrobenzene and 10% of the corresponding 2,6-bischloromethyl derivative; *p*-isopropylnitrobenzene gives rise to monosubstituted products only, while *p*-t-butylnitrobenzene does not react at all [233]. The chloromethylation of phenols having deactivating substituents (the nitro-group or halogens) has been described in patents [234,235]. The reaction was carried out under different conditions: by treatment with bischloromethylether in sulphuric acid [234] and by treatment with mixture of 55% oleum and BCME. [235] The corresponding monochloromethyl derivatives were obtained in all instances. In the course of development of the synthesis of disubstituted tetrahydroisoquinolines, Beeby and Mann [236] obtained 2-(2-chloroethyl)-5-nitrobenzyl chloride as an intermediate, having treated 2-(*p*-nitrophenyl)ethyl chloride with BCME in the presence of 20% oleum. Under the influence of BCME in sulphuric acid, benzoic acid is converted into a mixture of *o*-, *m*-, and *p*-chloromethyl derivatives, with the *m*-isomer predominating [237] (see also Ref. 238). Under these conditions, alkylbenzoic acids give rise to bischloromethyl derivatives [239]. Chloromethyl derivatives of *N*-arylphthalimides have been obtained by treatment with BCME in concentrated sulphuric acid [240]; a patent [241] showed that indigo dyes can be mono- and di-chloromethylated. There have been a number of patents by the same investigators devoted to the chloromethylation of condensed systems deactivated by the carbonyl group [242-251]. The products of these reactions are of interest for the synthesis of dyes [244-247].

As in chloromethylation with formaldehyde and HCl (see above), on treatment with MCME the $CH_2Cl$ group can be directed to the side chains of alkyl aryl ketones; the reaction is carried out in the presence of boron trifluoride etherate as the catalyst [252,253]. However, on treatment with MCME using an excess (2.5 moles) of aluminium chloride without a solvent [254] or under the influence of BCME in the presence of 1.4 moles of $AlCl_3$ in chloroform [255], the chloromethyl group enters the *m*-position of the benzene ring. Under these conditions, acetophenone exists in the form of a complex with $AlCl_3$, [256] which is the cause of the change in the mode of substitution. In the reaction involving complexes of 2-acylthiophens with $AlCl_3$, a change in the site where the $CH_2Cl$ group is introduced into the thiophen ring is also observed. The chloromethylation of 2-acylthiophens by paraformaldehyde and HCl leads to the formation of a mixture of

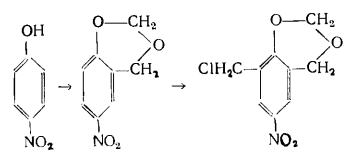
4- and 5-chloromethyl derivatives in nearly equimolecular proportions [109-111]. The chloromethylation of thiophen-2-aldehyde and 2-acetothienone by MCME in the presence of 2.2 moles of $AlCl_3$ without a solvent or in chloroform yields 4-chloromethyl derivatives containing 7% and 2% of the 5-isomers respectively [110,257].

By carrying out the reaction in a solvent, it is possible to discover the essential features of the processes occurring, since there is the possibility of varying the amount of $AlCl_3$ (in experiments without a solvent, one must use more than 2 moles of $AlCl_3$ per moles of the carbonyl compound, since solid complexes are formed with small amounts of $AlCl_3$). In chloromethylation by treatment with MCME in the presence of comparatively small amounts of $AlCl_3$ in chloroform, the main reaction products are 5-substituted derivatives (70%, 90%, and up to 95% yields when 1.8, 1.3, and 0.9 moles of $AlCl_3$ are used respectively) [257]. This is undoubtedly caused by the dissociation of the complex of the carbonyl compound with $AlCl_3$ under the influence of MCME. The use of a weaker base (BCME) as the chloromethylating agent makes it possible to obtain 4-chloromethyl derivatives virtually without the 5-isomers even when the chloromethylation is carried out in the presence of 1.3 moles of $AlCl_3$. [257]

Thus, as in other electrophilic substitution reactions [258,259], the change in the mode of chloromethylation is a consequence of the formation of a 1 : 1 complex with $AlCl_3$ via the carbonyl group. By enhancing the electron-accepting capacity of the substituent, complex formation leads to such appreciable deactivation of the 5-position that the 4-position in the thiophen ring becomes the most reactive. This is confirmed by $^1H$ and $^{13}C$ NMR data for complexes of carbonyl derivatives of thiophen with $AlCl_3$. [256,260] The same effect, involving a change in the mode of electrophilic substitution, particularly in chloromethylation by chloromethyl ethers, is observed also when the carbonyl group is modified by protonation or complex formation with a strong protic acid [261,262]:

$A = AlCl_3$ or $H^+$.

One should note that the formation of a complex with aluminium chloride may influence the mode of substitution also in compounds with electron-donating substituents. Thus treatment of thioanisole with MCME in the presence of an excess of $AlCl_3$ leads to a high degree of selectivity with respect to the *p*-chloromethyl derivative. Nevertheless, in the presence of a deficiency of aluminium chloride, or when the reaction with MCME is carried out in acetic acid, or on chloromethylation by treatment with formalin and HCl, the product contains considerable amounts of the *o*-isomer (up to the equimolar ratio) together with the *p*-isomer [263].



## 2. The Problem of the Mechanism of Chloromethylation by Treatment with Chloromethyl Ethers

In contrast to chloromethylation by treatment with formaldehyde and HCl, there are few kinetic data for the reactions of aromatic compounds with chloromethyl ethers in the literature. With the exception of the study [264] when the kinetics of the reaction of MCME with *p*-dichlorobenzene were investigated (however, unfortunately a detailed analysis of the mechanism in relation to the authors' kinetic data had not been carried out), the remaining investigations were devoted mainly to the study of the kinetics of the chloromethylation of polystyrene [265] or its copolymers [194,200]. The results thus obtained can be used only with important reservations, because, apart from the brief initial stage of the process, the rate of reaction is limited by the diffusion of the MCME–catalyst complex into the polymer

Two versions of the mechanism of the chloromethylation reaction involving chloromethyl ethers are possible. In the first, chloromethylation is preceded by the cleavage of the chloromethyl ether $ROCH_2Cl$ at the C–O bond under the influence of the protic or aprotic acid used as the condensing agent; the chloromethylating species is then the cation $\overset{+}{C}H_2Cl$. [261,264] In the second version the chloromethyl ether behaves as the alkylating agent, forming the cation $\overset{+}{C}H_2OR$ in the limiting case [187,257,262]. The alkoxymethyl derivatives formed are cleaved under the influence of the hydrogen chloride evolved and the aprotic acid (Verley [266]):

$$ArH \rightarrow ArCH_2OR \rightarrow ArCH_2Cl\ .$$

The reaction can proceed in principle simultaneously via two pathways or either pathway can predominate, depending on the conditions; however, the second pathway appears to be preferable. Indeed the alkylation of aromatic compounds by dialkyl ethers in the presence of Lewis acids takes place at elevated temperatures (of the order of 150–170°C), [267] i.e. under much more severe conditions than chloromethylation. Furthermore, MCME is known to be difficult to cleave by $AlCl_3$ (approximately to the extent of 3% after 100 h at 55°C), while BCME is still more stable [268]. On the other hand, chloromethyl ethers contain an exceptionally mobile halogen atom, capable of being exchanged via an $S_N1$ mechanism [269], which is probably associated with the stabilising effect of the oxygen atom on the cationic centre [270]. The formation of alkoxymethyl compounds noted above (see also Refs. 257, 263, 271, and 272) agrees with the second hypothesis. Since the alkoxymethyl derivatives are ethers of the benzyl type, they should be cleaved comparatively readily under the influence of $AlCl_3$ and HCl. [273,274] Indeed, additional treatment with hydrogen chloride and $AlCl_3$ of the reaction mixture obtained as a result of the interaction of 2-acetothienone with MCME in the presence of 1.3 moles of $AlCl_3$ lowers the content of 5-methoxymethyl-2-acetothienone approximately by a factor of two [257] (see also Belen'kii et al. [255]). When the reaction of 2-acetothienone with MCME is carried out in the presence of aluminium chloride etherate, i.e. under conditions promoting the cleavage of methoxymethyl derivatives by $AlCl_3$, the main product is a mixture of 4- and 5-methoxymethyl-2-acetothienones [257]. Topchiev and Stavrovskaya [275,276] showed that treatment of *p*-nitrophenol with BCME in the presence of $ZnCl_2$ entails initial alkylation and subsequent intramolecular ring closure and the formation of the methylene ether of 5-nitrosaligenin, which is then converted into the methylene ether of 3-chloromethyl-5-nitrosaligenin:

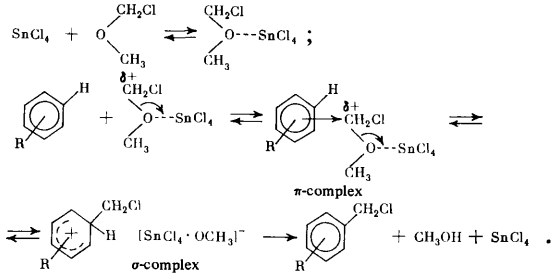
Thus the formation of chloromethyl derivatives when aromatic compounds are treated with chloromethyl ethers in the presence of $AlCl_3$ is the result of a multistage process, which may be represented by the following scheme:

$$ROCH_2Cl + AlCl_3 \rightleftarrows (ROCH_2)^+\ AlCl_4^-\ , \quad (1)$$

$$ArH + (ROCH_2)^+\ AlCl_4^- \rightleftarrows (ArHCH_2OR)^+\ AlCl_4^-\ , \quad (2)$$

$$(ArHCH_2OR)^+ AlCl_4^- \rightarrow ArCH_2OR + HCl + AlCl_3 , \quad (3)$$
$$ArCH_2OR + AlCl_3 \rightarrow ArCH_2Cl + RCl + AlOCl , \quad (4)$$
$$ArCH_2OR + HCl \rightarrow ArCH_2Cl + ROH . \quad (5)$$

In the reactions with MCME and BCME, R = $CH_3$ and R = $CH_2Cl$ or $CH_2Ar$ respectively.



The process under consideration includes the formation of an electrophilic species [stage (1)], which is converted via a σ-complex [stage (2)] into a benzyl ether analogue $ArCH_2OR$ [stage (3)]; the latter gives rise to a chloromethyl derivative on cleavage under the influence of $AlCl_3$ [stage (4)] or HCl [stage (5)]. Nor can one rule out the possibility of the joint action of HCl and $AlCl_3$ on the ether with the intermediate formation of the protonated form $ArCH_2OHR^+.AlCl_4^-$.

The substances formed in stages (4) and (5) are the "normal" products of the cleavage of ethers by $AlCl_3$ [277] and HCl [273] (the cleavage of benzyl ethers by Lewis acids is also described by Gol'dfarb [278] and Stadnikov and Kashtanov [279]). If chloromethylation on treatment with BCME proceeds via the dibenzyl ether analogue $(ArCH_2)_2O$, then its cleavage by both an aprotic acid and by HCl should lead to the formation of two $ArCH_2Cl$ molecules [280]. The cleavage of an ether of the type $ArCH_2OCH_2Cl$ by HCl can lead to a chloromethyl derivative and the unstable chloromethanol $HOCH_2Cl$. The latter can function as a chloromethylating agent either directly or after dehydration with formation of BCME. Thus both $CH_2Cl$ groups of the initial BCME can be used in the reaction [255,257].

However, the above mechanism does not provide a complete idea about the process considered, because it does not reflect the formation of diarylmethanes and bis-chloromethyl derivatives (for further details, see Belen'kii et al. [255]). In principle, the same mechanism is also probable when the reaction is carried out in strong inorganic acids. It has been shown [145] that alkyl chloromethyl ethers are protonated at the oxygen atom in an ultra-acidic medium and the protonated forms produced are dehydrochlorinated above −60°C, being converted into alkoxy-methyl cations‡:

$$ClCH_2OR \xrightarrow[-80°]{FSO_3H-SbF_5} ClCH_2-\overset{+}{O}(H)-R \xrightarrow[-60°]{-HCl} CH_2=\overset{+}{O}R .$$

A significant argument against the mechanism under consideration, involving attack by an alkoxymethyl cation, arises from the fact that the ion may react not only via the carbon atom with formation of an alkoxymethyl derivative but can also behave as a methylating agent (with liberation of formaldehyde) [281]. One can therefore consider a chloromethylation mechanism which does not provide for the formation of alkoxymethyl or chloromethyl cations and in which the chloromethylating species is a complex of the chloromethyl ether with a protic or aprotic acid. Mechanisms of this kind have been put forward in a number of studies [282,283]. In the relevant reports, it is postulated in essence that the $CH_2Cl$ fragment from a complex of MCME and a Lewis acid enters into the aromatic ring. One of these mechanisms [283] is presented below:

If this or a similar mechanism is adopted, one cannot explain the formation of methoxymethyl derivatives discussed above. The reaction mechanism must apparently take into account both possible primary processes—chloromethylation and alkoxymethylation.

Despite the great importance of chloromethylation and its large-scale employment for preparative purposes, only partly described in this Review, many significant aspects of this reaction, associated primarily with its mechanism, have still been inadequately elucidated. This situation is apparently due to the great complexity of the process and its many pathways, as a result of which one can obtain, together with monochloromethyl derivatives, not only disubstituted derivatives but also products of another type—diarylmethanes and benzyl ethers. At the same time, the great scope of the synthesis based on chloromethyl derivatives led to the undertaking of further new investigations whose aim is both to modify the methods and to investigate the mechanism of the chloromethylation reaction.

‡ A mechanism of a similar type has also been proposed [284] for chloromethylation and bromomethylation by treatment with 1-chloro-4-[chloro(bromo)methoxy]-butanes and 1,4-bis[chloro(bromo)methoxy]butanes, which have been recently described as effective halogenomethylating agents [285]. A characteristic feature of these substances is the possibility of the intermedite formation and involvement in the reaction of chloro-(bromo) methyltetrahydrofuranonium ions, which has been confirmed by the detection [284] with the aid of $^1H$ NMR of this type of ion, formed as a result of the following reaction at −50°C in $SO_2$:

$$ClCH_2O(CH_2)_4Cl + SbCl_5 \rightarrow ClCH_2-\overset{+}{O}\!\!<\!\!\begin{matrix}CH_2-CH_2\\ |\\ CH_2-CH_2\end{matrix}\!\!> SbCl_6^- .$$

The halogenoalkylation by these reagents proceeds with high yields in the presence of $SnCl_4$ or $ZnBr_2$. An advantage of these new agents over the less active BCME is a lower volatility and hence a smaller danger to the human organism [285].

# Oxidation by Ozone of Hetero-organic Compounds of the Silicon Subgroup

Yu.A.Aleksandrov and B.I.Tarunin

The kinetics and the reaction products are surveyed, and the mechanism is discussed. The reactivity of the compounds towards ozone depends on the nature of the heteroatom, the attached substituent, and non-specific and specific solvation. A list of 68 references is included.

I. Introduction 905
II. Reaction products and mechanism 906
III. Reactivity towards ozone 907

## I. INTRODUCTION

The early publications devoted to the action of ozone on hetero-organic compounds[1-3] report only qualitative observations concerned to elucidate oxidisability. Thus Bailey et al.[1] noted that bubbling ozone through vinyltrichlorosilane in tetrachloromethane at 0°C gave a product whose hydrolysis with dilute aqueous hydrogen peroxide yielded silicon dioxide. It was suggested that an ozonide was formed as intermediate in the ozonolysis of vinyltrichlorosilane. A possible structure for the ozonide was not discussed[1]. Later Clasen[2] showed that under ordinary conditions diethylsilane is oxidised by ozone with cleavage of the alkyl–silicon bond. Barry and Beck[3] found that siloxanes are formed by the oxidation of organosilicon compounds.

More recently it has been reported that ozone is able to cleave the lead–lead bond in diplumbanes[4], which has been used to obtain triphenylplumbane hydroxide and acetate from hexaphenyldiplumbane. Enek'yanov et al.[5] utilised the high reactivity of tetraethylplumbane towards ozone in the application of this toxic organolead compound. Investigations on the ozonolysis of hetero-organic compounds of non-transition elements of Groups V and VI have been discussed in some detail[6].

Reactions of ozone with organic derivatives of transition and non-transition metals of other groups have remained almost uninvestigated. Only isolated studies have shown that ferrocene and its vinyl derivatives are readily oxidised by ozone[7,8], and that the main product of the ozonisation of phenylmagnesium bromide in an inert atmosphere at low temperatures (−78°C) is phenol[9], but products of the action of ozone on certain mercury-containing organic compounds[10,11] may be acids (if the organic group is of normal structure) or ketones and alcohols (if it is secondary or tertiary).

The ozonolysis of hetero-organic compounds of elements in the silicon subgroup has been investigated systematically since 1965 (by Spialter, Austin, Aleksandrov, et al.). The results were summarised in a review [12], but more than five years have elapsed since its publication, during which period a considerable number of

studies have been made, extending significantly our knowledge of the ozonolysis of hetero-organic compounds. This work will be surveyed in the present Review.

## II. REACTION PRODUCTS AND MECHANISM

### 1. Fully Organic Derivatives of the Elements

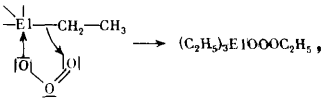
Information has now been published on the ozonolysis of tetraethylsilicon [13-19], tetraethylgermanium [18], tetramethyltin [20], tetraethyltin [16-23], tetrapropyltin [20], tetrabutyltin [20], tetraisobutyltin [20], tetrapentyltin [20], tetraethyllead [23,24], tetrapropyl-lead [24], diethyldimethylsilane [14], methyltriethylsilane [14], and phenyltrimethylsilane [14]. All completely organic derivatives of elements in the silicon subgroup whose reactions with ozone have been investigated are usually extremely stable in air at room temperature [25]. However, they are readily oxidised by ozone under these conditions.

The rate of ozonolysis of the tetra-alkyl derivatives is described by a kinetic equation of the first order with respect to ozone and the first order with respect to the initial hetero-organic compound [19,20]. The example of tetraethyltin in n-nonane and in the absence of a solvent shows [22] that ozonolysis of a hetero-organic compound does not initiate oxidation of the solvent. The proportions of ozone and tetra-alkyl compound that react are nearly equimolecular [22]. The composition of the ozonolysis products indicates [13-17,21-24] that the heteroatom–carbon bond is attacked.

The ozonolysis of tetraethylsilane (up to 50% and more conversion of the initial organosilicon compound) yields as hetero-organic products a mixture [13,14] of various polyethylsiloxanes of linear or cyclic structure (hexaethyldisiloxane, hexaethylcyclotrisiloxane, octaethylcyclotetrasiloxane, octaethyltrisiloxane). 1,1,3,3-Tetraethyl-1,3-dimethyldisiloxane has been detected as main product of the ozonolysis of methyltriethylsilane at room temperature, but under analogous conditions phenyltrimethylsilane gives hexamethyldisiloxane in theoretical yield [13]. Ozonolysis of tetraethylsilane involves formation in the early stages [15] of triethylsilyl hydroperoxide, bistriethylsilyl peroxide, hexaethyldisiloxane, hydrogen peroxide, water, acetaldehyde, and acetic acid.

A complicated mixture of products is formed by the ozonolysis of tetraethylstannane [22]: free acetaldehyde is accompanied by organotin compounds containing ethylidene, diethylstannylene, and terminal triethylstannyl groups linked by oxygen or a peroxide bond. Hydrolysis of these products gives acetaldehyde, diethyltin oxide, hydrogen peroxide, and triethylstannyl hydroxide in respective yields (hydrolysis of the reaction mixture after ozonolysis of tetraethylstannane in the absence of a solvent at 0°C) of 0.68, 0.70, 0.86, and 1.29 mole mole$^{-1}$ active oxygen. It was also established [22] that the peroxide product present in the reaction mixture is an intermediate: its rate of accumulation diminishes with rise in temperature, but at a sufficient degree of conversion of the tetraethylstannane (ozonolysis in trichlorobenzene, tetrachloromethane, and 1,1,2,2-tetrachloroethane) the rate curves for the accumulation of active oxygen are extremal in character.

It was suggested [21] that the reactions of ozone with tetraethylsilane and with tetraethylstannane have the same mechanism, but that the latter process is complicated by secondary reactions of intermediate peroxy-compounds. The oxidation of tetraethylstannane by ozone was therefore investigated in the presence of a large excess of water, i.e. under conditions of controllable secondary reactions, when triethylstannyl hydroperoxide or peroxide, if formed, would undergo hydrolysis:



$$(C_2H_5)_3SnOOH + H_2O \rightarrow (C_2H_5)_3SnOH + H_2O_2,$$
$$(C_2H_5)_3SnOOSn(C_2H_5)_3 + 2H_2O \rightarrow 2(C_2H_5)_3SnOH + H_2O_2.$$

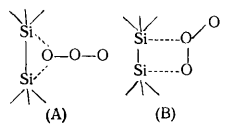
It would then be expected that equimolar quantities of acetaldehyde, hexaethyldistannoxane, and hydrogen peroxide would accumulate in the reaction mixture when tetraethylstannane undergoes ozonolysis in the presence of water. The main products were in fact hydrogen peroxide, acetaldehyde, and triethylstannyl hydroxide in nearly equimolecular quantities. It was shown further [21] that tetraethyldistannoxane dihydroxide is also formed, by ozonolysis of triethylstannyl hydroxide as intermediate.

Discussion of the mechanism of the ozonolysis of tetra-n-alkylated hetero-organic compounds [12,16,17] has led to the suggestion that reaction with ozone involves the sequence of stages—(1) coordination of ozone to the heteroatom by means of vacant *d* orbitals of the latter and the electron shell of the nucleophilic centre of ozone

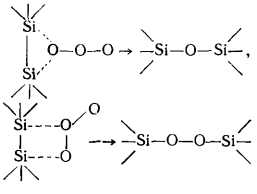
$$(C_2H_5)_4E1 + O_3 \longrightarrow (C_2H_5)_4E1 \cdot O_3, \quad (1)$$

(2) electrophilic attack by the coordinated ozone on the heteroatom–carbon bond to form an intermediate trioxide

(2)



and (3) transformation of the trioxide with migration of hydrogen from the $\alpha$-carbon atom to the middle oxygen atom of the trioxide



(3)

### 2. Bihetero-organic Compounds

Only three representatives of this class of compounds—hexamethyldisilane [14], hexaethyldistannane [26], and octa-t-butylstannetan [27]—have been examined. Spialter and Austin [14] showed that hexamethyldisilane reacts readily with ozone at room temperature, giving hexamethyldisiloxane as sole organosilicon product. Two possible mechanisms were discussed [14], involving intermediate formation of either a three-membered (A) or a four-membered (B) complex

subsequent conversion of which would give either hexamethyldisiloxane or bistriethylsilyl peroxide:

From the composition of the products of ozonolysis it was supposed[14] that the action of ozone on hexamethyldisilane involves a three-membered intermediate complex:

$$(CH_3)_3SiSi(CH_3)_3 + O_3 \rightarrow (CH_3)_3SiOSi(CH_3)_3 + O_2 . \quad (4)$$

The ratio of hexaethyldistannoxane formed to the quantities of hexaethyldistannane and ozone that have reacted at room temperature also corresponds to the stoichiometry of reaction (4).[26] When hexaethyldistannane is treated in isopropyl chloride with excess of ozone at −100°C, however, hexaethyldistannoxane is accompanied by an almost equimolecular quantity of bistriethylstannyl peroxide. This was attributed[26] to a different reaction mechanism from the above[14], at least at temperatures considerably lower than 0°C. It was assumed[26] that formation of an intermediate trioxide

$$(C_2H_5)_3SnSn(C_2H_5)_3 + O_3 \rightarrow (C_2H_5)_3SnOOOSn(C_2H_5)_3$$

was followed by the reaction

$$(C_2H_5)_3SnOOOSn(C_2H_5)_3 + (C_2H_5)_3SnSn(C_2H_5)_3 \rightarrow (C_2H_5)_3SnOOSn(C_2H_5)_3 + (C_2H_5)_3SnOSn(C_2H_5)_3.$$

Under these conditions (−100°C) the reaction of bistriethylstannyl peroxide with hexaethyldistannane, which occurs comparatively easily at room temperature[28], can play no significant part. On these views the observance of the stoichiometry of Eqn.(4) is attributed to the thermal instability of the trioxide at room temperature:

$$(C_2H_5)_3SnOOOSn(C_2H_5)_3 \rightarrow (C_2H_5)_3SnOSn(C_2H_5)_3 + O_2.$$

The action of ozone on hetero-organic compounds containing several heteroatom–heteroatom bonds also takes place predominantly at these bonds. Thus the oxidation of octa-t-butylstannetan involves[27] ~4 moles of ozone, in conformity with the equation

$$(t\text{-}C_4H_9)_8Sn_4 + 4O_3 \rightarrow 4(t\text{-}C_4H_9)_2SnO + 4O_2.$$

This result is consistent with the above mechanism for the action of ozone on the heteroatom–heteroatom bond[26].

## 3. Bihetero-oxanes, Alkoxy and Hydroxy-derivatives

Information on ozonolysis is available only for these derivatives of silicon and tin[13,14,16,17,21,29,30]. The main products of the oxidation of hexaethyldisiloxane by ozone at room temperature are acetic acid and a mixture of various polydiethylsiloxanes (hexaethylcyclotrisiloxane, octaethylcyclotetrasiloxane, octaethyltrisiloxane)[14]. The ozonolysis of triethylsilyl hydroxide or ethoxytriethylsilane at room temperature[14] yields hexaethyldisiloxane as the main product, oxidation being more rapid with the second compound.

A detailed investigation of the ozonolysis of hexaethyldistannoxane by Aleksandrov and Sheyanov[29] showed that oxidation in n-decane at 10–60°C yields a polydiethylstannoxane $(C_2H_5)_3Sn.[O.Sn(C_2H_5)_2]_6.CSn(C_2H_5)_3$ together with acetaldehyde and triethylstannyl acetate. Estimation of the quantity of ozone consumed suggested that initiated oxidation of the initial organotin oxide either does not occur or plays no significant part in the ozonolysis of hexaethyldistannoxane.

The ozonolysis of triethylstannyl hydroxide in aqueous solution[21] is accompanied by the formation of acetaldehyde and tetraethyldistannoxane dihydroxide, whereas that of diethyldimethoxystannane in n-nonane yields acetaldehyde, acetic acid, and an organotin compound $(C_2H_5)_2Sn(OCH_3).OSn(OCH_3)_2C_2H_5$.[30] This work showed also[30] that diethyldimethoxystannane readily undergoes ozonolysis in n-decane at room temperature, but rise in temperature has little effect on the reaction velocity, as with hexaethyldistannoxane[29].

The mechanism of ozonolysis suggested earlier for tetraethyl derivatives of elements of the silicon subgroup is assumed to apply to the ethyl derivatives, alkoxides, and hydroxides of bihetero-oxanes[30,31].

## 4. Hetero-organic Halides and Hydrides

Information has been published on the ozonolysis of triethyltin chloride[16,17,30,32], diethyltin dichloride[16,17,30,33], triethyl-lead chloride[16,17,30,33], and organosilicon compounds containing various numbers of unsubstituted hydrogen atoms[13,14,34–41].

Ozone reacts readily with halides of organic derivatives of Group IV elements at room temperature and in the absence of illumination[16,17]. Under such conditions these compounds are extremely stable towards oxygen. Ozonolysis of triethylstannyl chloride in n-hexane at 0°C leads to the formation[32] of acetaldehyde and a solid product presumed to be $2(C_2H_5)_3SnCl.CSn(C_2H_5)Cl.O_3$. The same workers found[30,33] that the ozonolysis of triethylplumbyl chloride under similar conditions yields acetaldehyde, acetic acid, ethanol, and ethyl-lead chloride oxide $(C_2H_5ClPbO)_n$. The yields of these products and the quantity of ozone that reacts correspond to the stoichiometric relation

$$(C_2H_5)_3PbCl + O_3 \rightarrow 0.9 \cdot C_2H_5ClPbO + 0.9 \cdot CH_3CHO + 0.24 \cdot CH_3COOH + 0.57 \cdot C_2H_5OH .$$

The oxidation of diethyldichlorostannane under the same conditions[30,33] gives acetaldehyde, acetic acid, and an organotin product $C_2H_5Sn(COH)Cl_2.(C_2H_5)_2SnCl_2$, in the respective yields 0.1, 0.33, and 0.46 mole mole$^{-1}$ initial organotin compound.

The mechanism of the ozonolysis of hetero-organic chlorides is assumed[12] to be fundamentally the same as that of the reaction of ozone with fully organic derivatives of the elements.

Organosilicon compounds containing unsubstituted hydrogen atoms undergo ozonolysis at a silicon–hydrogen bond to form the corresponding silanols[13,14,34–41]. The mechanism is assumed[34,37,38] to involve formation of an intermediate trioxide:

$$R_3ElH + O_3 \rightarrow R_3ElOOOH \rightarrow R_3ElOH + O_2.$$

# III. REACTIVITY TOWARDS OZONE

## 1. Influence of Nature of Heteroatom

The kinetics of the ozonolysis of $(C_2H_5)_4El$[18,42,43] and $(C_2H_5)_3El.El(C_2H_5)_3$[44–46] (where El represents an element of the silicon subgroup) has been investigated in tetrachloromethane over the range 0–20°C. The results (Table 1) show that the reaction is first order with respect both to ozone and to the hetero-organic compound. The temperature dependence of the ozonolysis rate constant $k$ is described satisfactorily by the Arrhenius equation for all the compounds investigated.

It is noteworthy that the ozonolysis rate constants for hexaethyldisiloxane, hexaethyldigermanoxane, and hexaethyldistannoxane (Nos. IX–XI), representing the most reactive (towards ozone) of the corresponding reaction products[16], are significantly smaller than those for

the initial compounds. For this reason the ozonolysis rate constants obtained for compounds I–VIII can be assigned quite accurately to the primary act.

Table 1. Influence of nature of heteroatom on reactivity towards ozone [27,46].

| No. | Compound | $k_{20°C}$, $M^{-1}\,s^{-1}$ | lg $k_0$ | $E$, kcal mole$^{-1}$ | $\alpha \pm 0.01$ |
|---|---|---|---|---|---|
| I | $(C_2H_5)_4Si$ | $2.4\cdot10^{-2}$ | 4.1 | 7.6 | 3.583 |
| II | $(C_2H_5)_4Ge$ | $1.2\cdot10^{-1}$ | 7.3 | 11 | 3.574 |
| III | $(C_2H_5)_4Sn$ | 96 | 6.7 | 6.3 | 3.563 |
| IV | $(C_2H_5)_4Pd$ | 1300 | 8.5 | 7,0 | 3.559 |
| V | $(C_2H_5)_6Si_2$ | 0,7 | 6.5 | 9.0 | 3.573 |
| VI | $(C_2H_5)_6Ge_2$ | 2,1 | 6.0 | 7.5 | 3.567 |
| VII | $(C_2H_5)_6Sn_2$ | 300 | 8.0 | 7,5 | 3.549 |
| VIII | $(C_2H_5)_6Pb_2$ | 1650 | — | — | 3.542 |
| IX | $[(C_2H_5)_3Si]_2O$ | $1\cdot10^{-2}$ | — | — | — |
| X | $[(C_2H_5)_3Ge]_2O$ | $4\cdot10^{-2}$ | — | — | — |
| XI | $[(C_2H_5)_3Sn]_2O$ | 40 | 7.1 | 7.5 | — |

In the series of compounds investigated—$(C_2H_5)_4El$, $(C_2H_5)_6El_2$, and $[(C_2H_5)_3El]_2O$—which are equivalent with respect to the influence of the organic groups, steric hindrance, and the presence of vacancies in the coordination capacity of the heteroatom, there is considerable variation in the electronegativity of the heteroatom. Ozonolysis rate constants for the first two series at 20°C correlate satisfactorily with the effective electronegativities of the heteroatoms in these compounds [27]. The latter were measured by the "stability ratios" $\alpha$ of the heteroatoms, calculated from the Gordy system of electronegativities [47]:

$$\text{for } (C_2H_5)_4El,\ \lg k = 709 - 198.4\cdot\alpha,$$
$$\text{for } (C_2H_5)_6El_2,\ \lg k = 389 - 109\cdot\alpha.$$

This result indicates parallel variation in the reactivity towards ozone with the nucleophilicity of the heteroatom. In view of the suggested mechanism [30,48,49] the results indicate that the bimolecular reaction of the hetero-organic compound with ozone is limited at the stage of electrophilic attack by ozone on a heteroatom–carbon or heteroatom–heteroatom bond.

## 2. Influence of Substituent attached to Heteroatom

### (*a*) Fully organic derivatives and halides

The ozonolysis of several tetra-alkylstannanes in tetrachlorom ethane has been used [20] to investigate the influence of the inductive effect of the organic substituent in alkyl derivatives of Group IV elements. The reaction of these compounds with ozone is overall of second order, and the temperature dependence satisfies the Arrhenius equation (Table 2). The values obtained for the ozonolysis rate constant can be attributed quite accurately to reaction of the tetra-alkylstannanes with ozone [27]: i.e. the kinetics of ozonolysis of the initial compounds is not complicated by secondary reactions or by the products. Comparison of the kinetic parameters (Table 2, compounds II–VI) with the sum of the Taft inductive constants of the organic groups [50] indicates that differences in the $+I$ effects of the substituents have little influence on the reactivity of the tetra-alkyl derivative towards ozone.

When ethyl groups in tetraethylstannane and tetraethylgermane are replaced by substituents possessing powerful $-I$ effects (bromo, chloro, hydroxy), the reactivity of the compound is greatly diminished (Table 3) [51,52]. The dependence of lg$k$ on $\Sigma\sigma^*$ (Table 3) had led to the suggestion [27,51] that in this case the reaction velocity is probably influenced by at least two effects: firstly the strong inductive effect of chlorine, bromine, or hydroxyl tends to diminish the electron density on the carbon atoms adjacent to the tin atom, which hinders electrophilic attack by ozone on the tin–carbon bond; secondly, $d_\pi - p_\pi$ conjugation of the $p$ electrons of chlorine with vacant $d$ orbitals of tin tends to oppose the inductive effect and to promote such electrophilic attack. It is noteworthy that the presence of $d_\pi - p_\pi$ conjugation in the corresponding silicon compounds is convincingly supported by independent physical methods [53].

Table 2. Effect of organic radical on rate of ozonolysis of organotin compounds ($\sim10^{-3}$–$10^{-5}$ M) in tetrachloromethane [20] ([$O_3$] = $10^{-4}$–$10^{-7}$ M).

| No. | Compound | $k_{0°C}$, $M^{-1}\,s^{-1}$ | lg $k_0$ | $E$, kcal mole$^{-1}$ | $\Sigma\sigma^*$ |
|---|---|---|---|---|---|
| I | $(CH_3)_4Sn$ | $2.8\cdot10^{-2}$ | 5 | 8.2 | 0 |
| II | $(C_2H_5)_4Sn$ | 46 | 6.7 | 6.3 | 0.40 |
| III | $(p\text{-}C_3H_7)_4Sn$ | 18 | 7 | 7.3 | 0.46 |
| IV | $(p\text{-}C_4H_9)_4Sn$ | 17 | 7 | 7.2 | 0.52 |
| V | $(iso\text{-}C_4H_9)_4Sn$ | 16 | 7 | 7.2 | 0.50 |
| VI | $(p\text{-}C_5H_{11})_4Sn$ | 16 | 6.3 | 6.4 | 0.65 |

Table 3. Influence of $-I$ effect of substituent on rate of ozonolysis of hetero-organic compounds ($10^{-2}$–$10^{-5}$ M) in tetrachloromethane [51] ([$O_3$] = $10^{-4}$–$10^{-7}$ M).

| No. | Compound | $k_{20°C}$, $M^{-1}\,s^{-1}$ | lg $k_0$ | $E$, kcal mole$^{-1}$ | $\Sigma\sigma^*$ [50] |
|---|---|---|---|---|---|
| I | $(C_2H_5)_4Ge$ | $1.2\cdot10^{-1}$ | 7.3 | 11 | −0.40 |
| II | $(C_2H_5)_3GeBr$ | $1.5\cdot10^{-2}$ | 3 | 6.3 | 2.6 |
| III | $(C_2H_5)_4Sn$ | 96 | 6.7 | 6.3 | −0.40 |
| IV | $(C_2H_5)_3SnCl$ | 1.34 | 5.3 | 6.6 | 2.7 |
| V | $(C_2H_5)_2SnCl_2$ | $6.5\cdot10^{-2}$ | 3.8 | 6.6 | 5.7 |
| VI | $(C_2H_5)SnCl_3$ | $2\cdot10^{-2}$ | — | — | 8.7 |
| VII | $(C_2H_5)_3SnOH$ | 3 | — | — | 1.35 |
| VIII | $(C_2H_5)_3SnBr$ | 1.6 | — | — | 2.6 |

### (*b*) Organosilanes

A fairly long series of trisubstituted organosilicon derivatives has been used [54–56] to examine the influence of substituents attached to the heteroatom on the rate of reaction with ozone. Organosilanes provided a more convenient model to solve this problem because ozone acts bimolecularly on organosilicon hydrides and only at the silicon–hydrogen bond. The products are the corresponding silanols [13,14,34–41], which, like the organic solvents (hydrocarbons, halogenated hydrocarbons, etc.), have no appreciable chemical role in the reaction.

Relative ozonolysis rate constants for a considerable group of silanes have been correlated with the silicon–hydrogen stretching frequency $\nu_{Si-H}$ [35] or with the Hammett and Taft inductive constants [34,37–39]. These correlations were obtained on the assumption that inductive effects have a decisive influence on such frequencies [57]

and on the rate constants. Resonance effects ($d_\pi - p_\pi$ and $\sigma,\sigma$ conjugation) were disregarded, which cannot be accepted as correct[53].

Table 4. Effect of $\Sigma\sigma^*$ of substituents on ozonolysis rate constants for silanes in tetrachloromethane at 20°C.[54]

| No. | Silane | $\Sigma\sigma^*$ | $k_{exp}$ | $k_{calc}$ | $\Delta \lg k$ | $E$, cal mole$^{-1}$ | $10^{-7} k_0$, $M^{-1} s^{-1}$ |
|---|---|---|---|---|---|---|---|
| I | $(C_5H_{11})_3SiH$ | −0.486 | 107 | — | — | 7 700 | 6.3 |
| II | $(C_4H_9)_3SiH$ | −0.390 | 100 | — | — | 7 600 | 5 |
| III | $(C_3H_7)_3SiH$ | −0.345 | 94.5 | — | — | 7 700 | 4 |
| IV | $(C_2H_5)_3SiH$ | −0.300 | 80 | — | — | 8 000 | 6.3 |
| V | $(C_2H_5)(C_6H_5CH_2)_2SiH$ | 0.330 | 30 | — | — | — | — |
| VI | $(C_6H_5CH_2)_3SiH$ | 0 645 | 18.5 | — | — | 9 100 | 10 |

Determination of the ozonolysis rate constants for sixteen organosilanes (Table 4) has shown[54] that they all react readily with ozone at room temperature. Variation in the initial concentration of ozone or silane by factors of 5–10 has no effect on the rate constant. The stoichiometry is almost equimolecular, which indicates a first-order reaction with respect to ozone and to the initial organosilane. The equation for the rate constant is

$$M^{-1} s^{-1} = k_0 \exp(-E/RT).$$

Values of $k_0$ and $E$ are included in Table 4.

The organosilanes investigated can be divided into three groups (Table 4). Only the inductive effect of the substituents can reasonably be expected to appear in the first group (compounds I–VI), but in the second group (VII–IX) this is supplemented by $d_\pi - p_\pi$ interaction with the heteroatom. The third group of organosilanes (X to XIV and XV, XVI) is of interest in comparison with the first and second groups respectively, since the $\sigma,\sigma$-conjugation effect of methyl exceeds considerably those of other alkyl and aralkyl radicals[50].

The dependence of the ozonolysis rate constants for the organosilanes on the sum of the inductive constants of the organic substituents is described[54] by the Hammett–Taft equation

$$(\lg k = \rho\Sigma\sigma^* + \text{const}),$$

as illustrated by Fig. 1. For organosilanes of the first group at 20°C the equation is

$$\lg k = -0.696\,\Sigma\sigma^* + 1.7114. \quad (5)$$

The sensitivity to $\Sigma\sigma^*$ of the reactivity of the organosilanes (i.e. the slope $\rho$) is almost independent of temperature (Table 5). The negative slope supports a mechanism of the primary reaction of an organic compound of a non-transition Group IV element with ozone as coordination of the latter to the heteroatom followed by electrophilic attack at a heteroatom–carbon or heteroatom–hydrogen bond (depending on the nature of the hetero-organic compound). According to these views, reactivity towards ozone in a series of such compounds differing only in the total inductive effect of the substituents should increase with decrease in $\Sigma\sigma^*$. This is quantitatively consistent with experimental results[54].

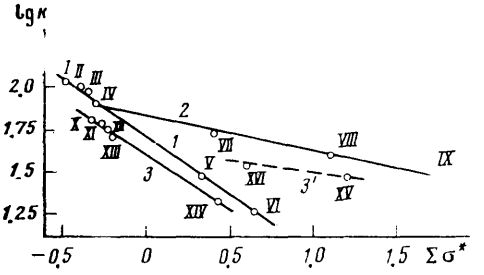

Figure 1. Dependence of $\lg k$ on $\Sigma\sigma^*$ for reaction of ozone with organosilanes in tetrachloromethane at 20°C: the numbering of the straight lines (1–3, 3′) corresponds to the groups of silanes.

Table 5. Values of $\rho$ at various temperatures of ozonolysis of the first group of organosilanes in tetrachloromethane[54].

| $t$, °C | $\rho$ | $r$ |
|---|---|---|
| 20 | −0.696 | 0 998 |
| 15 | −0.735 | 0.980 |
| 10 | −0.787 | 0.996 |
| 5 | −0.672 | 0.995 |
| 0 | −0.762 | 0.995 |

For organosilanes of the second and third groups the dependence of $\lg k$ on $\Sigma\sigma^*$ is not described by Eqn. (5), as is illustrated by Fig. 1. Rate constants $k_{calc}$ calculated by means of formula (5) from values of $\Sigma\sigma^*$ are smaller than the experimental values $k_{exp}$ for organosilanes of the second group, but larger in the third group (Table 4, compounds X–XIV). In the case of the second group this is attributed[54] to $d_\pi - p_\pi$ interaction of phenyl radicals with silicon, which opposes the negative inductive effect of this substituent and is formally equivalent to a decrease in its $-I$ effect; and for silanes of the third group to $\sigma,\sigma$ conjugation of the methyl group.

The explanation of the difference between experimental and calculated rate constants for the second group of organosilanes solely by $d_\pi - p_\pi$ interaction is supported by the linear relation (Fig. 2) between $\Delta \lg k = \lg k_{exp} - \lg k_{calc}$ for compounds VII–IX (Table 4) and values[58] of $\Delta\nu$Si–H for these compounds (where $\Delta\nu$Si–H is the contribution to the change in the silicon–hydrogen stretching frequency due solely to the $d_\pi - p_\pi$ interaction between silicon and phenyl substituents).

Quantitative comparison of the contributions by $\sigma,\sigma$ conjugation to the reactivity of the third group of organosilanes (X–XIV) could not be made[53] owing to the relatively minute differences in the values of $\Delta\nu$Si–H for these compounds. However, the "point" on Fig. 2 corresponding to the organosilanes with "unresolved" frequency differences lies satisfactorily on the general straight line.

The additivity of the effects of $d_\pi - p_\pi$ interaction and $\sigma,\sigma$ conjugation on the reactivity of the organosilanes towards ozone is confirmed by the good agreement, with the linear relation obtained between $\Delta \lg k$ and $\Delta\nu$Si–H (Fig. 2), of analogous experimental data for methyldiphenylsilane and phenyldimethylsilane (XV and XVI in Table 4), values of $\Delta\nu$ for which have been taken also from Refs. 53 and 58.

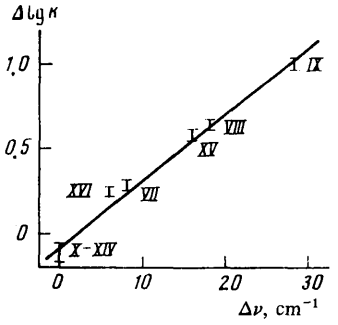

Figure 2. Relation between $\Delta \lg k$ and $\Delta\nu$ for organosilanes.

Table 6. Calculated charges and reactivity indices of reaction centre $\tau_C/\beta$ for certain organotin compounds (here and subsequently charges are given in units of the electronic charge).

| ЭОС | $q_{Sn}$ | $q_C$ | $\tau_C/\beta$ | ЭОС | $q_{Sn}$ | $q_C$ | $\tau_C/\beta$ |
|---|---|---|---|---|---|---|---|
| $(C_2H_5)SnCl_3$ | 0.78 | −0.05 | 4.05 | $(C_2H_5)_3SnCl$ | 0.68 | −0.16 | 4.16 |
| $(C_2H_5)_2SnCl_2$ | 0.73 | −0.11 | 4.11 | $(C_2H_5)_4Sn$* | 0.63 | −0.21 | 4.21 |

*The parameters $q_{Sn}$, $q_C$, and $\tau_C/\beta$ have the same values for $(n\text{-}C_3H_7)_4Sn$, $(n\text{-}C_4H_9)_4Sn$, $(n\text{-}C_5H_{11})_4Sn$, and $(iso\text{-}C_4H_9)_4Sn$ as for $(C_2H_5)_4Sn$.

Comparison of the ozonolysis rate constants with the distribution of electron density in several organotin (Table 6) and organosilicon compounds leads to extremely interesting conclusions[27,59]. The tin atom always bears the highest calculated positive charge, while the charge on the carbon atoms adjacent to the heteroatom is more negative than on the other carbon atoms, so that $\tau_C/\beta$ has its highest positive value. Comparison of the calculated charges on the reaction centre with the relative ozonolysis rate constants $k/k_0$, where $k_0$ is the rate constant for tetraethyltin (Table 3), leads to a dependence whose semilogarithmic form is almost linear (Fig. 3). The relative rate constant increases with the absolute value of the negative charge on the carbon atom of the reaction centre. These results are consistent with the above heterolytic mechanism of ozonolysis. Departure from linearity may be due to disregard of the $d_\pi - p_\pi$ interaction between chlorine and tin atoms, since such interaction tends to increase the negative charge on the carbon atom.

The analogous calculation of the distribution of electron density in a series of silanes—methyldiethyl, methyldi-n-propyl, methyldi-n-butyl, methyldi-n-pentyl, triethyl, tri-n-propyl, and tri-n-butyl—gives[27] almost the same charge density on silicon, *Si*-hydrogen, and *Si*-carbon atoms [$q$Si, $q$H(Si), and $q$C(Si) respectively +0.33, from −0.15 to −0.16, and from −0.07 to −0.09]. This result indicates that the empirical method of calculation used[27] (the Del Re method) is not sufficiently effective to "resolve" differences in the electronic structure of the silanes. However, the higher electron density on the hydrogen than on the carbon atom attached to silicon is of interest. It is consistent with the experimental observation in the ozonolysis of silanes that attack by the coordinated ozone is directed at the silicon–hydrogen bond, not at a silicon–carbon bond[13,14].

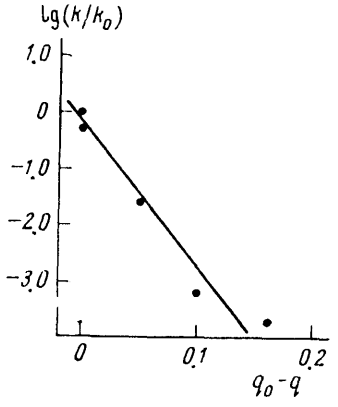

Figure 3. Dependence of logarithm of relative rate of ozonolysis of organotin compounds on variation in charge on reaction centre.

### 3. Effect of Non-specific Solvation

The influence of non-specific solvation on reactivity towards ozone has been investigated[60] on two organosilanes (tribenzyl and triethyl) and also on two biheteroorganic derivatives (hexaethyl-disilane and -digermane). Significant differences in reactivity towards ozone are present in both of these pairs of compounds (see subsection 1). In the choice of solvents preference was given to tetrachloromethane and 1,1,2,2-tetrachloroethane, which possess comparatively low dielectric constants $\epsilon$ and contain no functional groups that might have caused specific solvation of the test compounds.

The investigation has established[60] that at 25°C the dependence of the ozonolysis rate constant on the dielectric constant of the medium (for a mixed solvent the latter was calculated by means of the formula

$$\lg \varepsilon = N_1 \lg \varepsilon_1 + N_2 \lg \varepsilon_2,$$

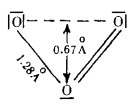
where $N_i$ and $\epsilon_i$ are the respective component mole fractions and dielectric constants) is described by Kirkwood's equation

$$\lg k = A + B(\varepsilon - 1)/(2\varepsilon + 1) \qquad (6)$$

with the coefficients listed in Table 7 ($1 > r$ (correlation coefficient) $> 0.99$, method of least squares). The results indicate that non-specific solvation of the heteroorganic compound and of ozone enhance their mutual reactivity. In each pair of compounds the sensitivity of

ozonolysis to non-specific solvation is greater the greater the reactivity towards ozone. Such a dependence is consistent with a heterolytic mechanism of ozonolysis [12,16,17].

Table 7.



| Compound | Triethylsilane | Tribenzylsilane | Hexaethyldigermane | Hexaethyldisilane |
|---|---|---|---|---|
| *A* | 1.72 | 1.24 | −0.45 | −0.63 |
| *B* | 1.15 | 1.11 | 3.87 | 2.32 |

In the activated complex the valency electrons of the heteroatom are probably in an $sp^3d$ state owing to coordination of ozone with the quadrivalent silicon (or germanium) atom. Such hybridisation seems improbable if the test compounds are solvated in the tetrachloromethane–1,1,2,2-tetrachloroethane system. In discussing the effect of the medium, therefore, we have grounds for ignoring the formation of "diffusion pairs", and interpreting the results in terms of the greater polarity of the activated complex than of the initial reactants. On this basis the slope $B$ in Eqn.(6) is related to the dipole moment $\mu^{\ddagger}$ and the effective radius $r^{\ddagger}$ of the activated complex, as well as to the corresponding parameters of the initial reactants ($\mu_1$ and $r_1$ for the hetero-organic compound, and $\mu_2$ and $r_2$ for ozone), by the well known formula [61]

$$B = -\frac{1}{2{,}3\,kT}\left(\frac{\mu_1^2}{r_1^3} + \frac{\mu_2^2}{r_2^3} - \frac{\mu^{\ddagger 2}}{r^{\ddagger 3}}\right) \qquad (7)$$

which has been used to estimate the dipole moment of the activated complex and the relative charge $q$ on the heteroatom.

For the calculations the value $\mu_2 = 0.53$ D [62] was adopted. The choice of $r_2$ and $r^{\ddagger}$ was governed by the amphiphilic nature of ozone, with its nucleophilic centre coordinated with the heteroatom, entailed in a heterolytic reaction mechanism. The latter was therefore taken to be $r^{\ddagger} = r_{Si-O} = 1.64$ Å [63] for silanes and hexaethyldisilane, and $r_{Ge-O} = 1.85$ Å [63] for hexaethyldigermane, while $r_2$ was given the values 1.28 and 0.67 Å depending on the different steric positions

For triethylsilane and tribenzylsilane $r_1 = 1.47$ Å, while $\mu_1$ has the values 1.54 and 1.31 D respectively [65]; for hexaethyldisilane and hexaethyldigermane $r_1$ was taken to be 2.34 and 2.41 Å, while $\mu_1$ was equated to zero [63]. The above data were used to calculate $\mu^{\ddagger}$ and $q$ for the activated complex in the ozonolysis. Table 8 shows satisfactory agreement between the value of $q$ with $r_2 = 1.28$ Å and the value obtained by other investigators from spectroscopic data [65], from which it can be concluded [60] that 1.28 Å is more probable than 0.67 Å for $r_2$ in the ozonolysis of the hetero-organic compounds investigated. Hence the dipolar ozone molecule entering into reaction is preferably regarded as an amphiphilic form with the nucleophilic centre localised mainly on a single oxygen atom.

An analogous investigation was made with individual solvents [66] differing essentially in nature (and dielectric constant)—tetrachloromethane (2.23), chloroform (4.72), 1,2-dichloroethane (10.16), 1,1,2,2-tetrachloroethane (8.08), propionic acid (3.2), acetic acid (6.2), and acetic anhydride (20.5)—the test compounds being methyldi-n-propylsilane, tribenzylsilane, hexaethyldisilane, and hexaethyldigermane. This established that the dependence of the ozonolysis rate constant on the dielectric constant was also described by Kirkwood's equation, which indicated non-specific solvation of the substrates in the solvents. The coefficients in the relations (6) established at 0°C are given in Table 9 [66] (method of least squares, $0.90 < r < 0.99$).

Table 8. Calculation of $\mu^{\ddagger}$ and $q$ for ozonolysis at 25°C [60] (values of $q$ in units of the electronic charge).

| Compound | $\mu^{\ddagger}$ ($r_2$=1.28 Å) | $q$ ($r_2$=1.28 Å) | $\mu^{\ddagger}$ ($r_2$=0.67 Å) | $q$ ($r_2$=0.67 Å) | $q^{obs}$ |
|---|---|---|---|---|---|
| $(C_2H_5)_3SiH$ | 2.08 | 0.26 | 2.84 | 0.36 | 0.22 |
| $(C_6H_5CH_2)_3SiH$ | 1.85 | 0.24 | 2.55 | 0.32 | 0.18 |
| $(C_2H_5)_6Ge_2$ | 1.78 | 0.20 | 2.87 | 0.32 | — |
| $(C_2H_5)_6Si_2$ | 1.25 | 0.16 | 2.26 | 0.29 | — |

Table 9.

| Compound | Methyldipropylsilane | Tribenzyl silane | Hexaethyldigermane | Hexaethyldisilane |
|---|---|---|---|---|
| *A* | 0.91 | 0.44 | −0.60 | −1.09 |
| *B* | 1.88 | 1.35 | 2.50 | 1.45 |

Table 10. Values of $\mu^{\ddagger}$ and $q$ for hetero-organic–ozone activated complex at 0°C ($r_2 = 1.28$ Å). [66]

| Compound | $\mu^{\ddagger}$ | $q$ | Compound | $\mu^{\ddagger}$ | $q$ |
|---|---|---|---|---|---|
| $(CH_3)(C_3H_7)_2SiH$ | 2.24 | 0.32 | $(C_2H_5)_6Si_2$ | 1.08 | 0.14 |
| $(C_6H_5CH_2)_3SiH$ | 2.10 | 0.30 | $(C_2H_5)_6Ge_2$ | 1.49 | 0.20 |

The type of relations established is consistent with the results obtained in binary mixtures of tetrachloromethane and 1,1,2,2-tetrachloroethane. Substitution in Eqn.(7) of the same values for $r^{\ddagger}$, $r_1$, $r_2$, $\mu_1$, and $\mu_2$ as in the preceding case yielded calculated values of $\mu^{\ddagger}$ and $q$ for the activated complex agreeing satisfactorily with those obtained with use of the binary solvents (Table 10).

## 4. Effect of Specific Solvation

The first study of the effect of specific solvation on the ozonolysis has been made [67] on triethylstannyl chloride in tetrachloromethane in the presence of dimethylformamide, which solvates the initial hetero-organic compound specifically. The phenomenology of the reaction remains almost unchanged in the presence of dimethylformamide [67]. In this case, however, the rate constant depends significantly on its concentration (Table 11).

The observed [67] kinetic effect of the medium is explained by specific solvation of triethylstannyl chloride

by dimethylformamide, by analogy with the well known complexes formed by halides of alkylstannanes with many ligands (amides, ketones, etc.[68]). Calorimetric and spectroscopic measurements were made[67] to test this hypothesis. Determination of the heat of mixing of triethyltin chloride and dimethylformamide in the proportions 1 : 2 at 20°C gave for the enthalpy of formation of the complex the value $-5 \pm 0.5$ kcal mole$^{-1}$. The infrared spectra of a 20 : 1 mixture showed a significant low-frequency shift (by 18 cm$^{-1}$) of the carbonyl-stretching frequency (for pure dimethylformamide $\nu C:O = 1680$ cm$^{-1}$), which was accepted as proof of complex formation through the lone pair on the carbonyl oxygen atom of the amide molecule. Proofs of the specific solvation of triethylstannyl chloride by dimethylformamide were obtained[67] also on analysing the infrared spectra of the former compound.

Table 11. Effect of additions of dimethylformamide ($N = [D_0]/[A_0]$) on rate of oxidation of triethylstannyl chloride (concentration $c$, M) by ozone ($2 \times 10^{-4}$ M) in tetrachloromethane.

| $N$ | $k$, M$^{-1}$ s$^{-1}$ | $N$ | $k$, M$^{-1}$ s$^{-1}$ | $N$ | $k$, M$^{-1}$ s$^{-1}$ |
|---|---|---|---|---|---|
| −17°C, $c=4.23\cdot10^{-3}$ | | 0° C, $c=2.82\cdot10^{-3}$ | | 20° C, $c=1.41\cdot10^{-3}$ | |
| 0 | 0.110 | 0 | 0.42 | 0 | 1.34 |
| 5.2 | 0.184 | 5.2 | 0.53 | 2.7 | 1.38 |
| 8.7 | 0.250 | 7.9 | 0.62 | 5.4 | 1.44 |
| 12.2 | 0.300 | 13.1 | 0.76 | 8.0 | 1.62 |
| 15.2 | 0.320 | 18.3 | 0.91 | 13.5 | 1.59 |
| 20.8 | 0.380 | 23.5 | 0.93 | 20.0 | 1.89 |
| 29.6 | 0.390 | 31.3 | 0.93 | 27.0 | 2.18 |
| | | 39.2 | 0.93 | 40.0 | 2 17 |

The degree of charge transfer in the dimethylformamide complex of the hetero-organic compound was 5–7% estimated for one donor–acceptor bond from the correlation[68] of the enthalpy of complex formation with the transfer of charge. From the results it was assumed[67] that the increase in the rate of reaction of triethylstannyl chloride with ozone in the presence of dimethylformamide was due to formation of a complex that was more reactive towards ozone than was the original hetero-organic compound. To analyse the kinetic results we denote triethylstannyl chloride, dimethylformamide, ozone, and the reaction products by A, D, C, and P respectively, when the process can be written

$$A + C \xrightarrow{k_1} P,$$

$$A + D \underset{k_{-2}^{(1)}}{\overset{k_2^{(1)}}{\rightleftarrows}} AD, \qquad (8_1)$$

$$AD + D \underset{k_{-2}^{(2)}}{\overset{k_2^{(2)}}{\rightleftarrows}} AD_2, \qquad (8_2)$$

. . . . . .

$$AD_{n-1} + D \underset{k_{-2}^{(n)}}{\overset{k_2^{(n)}}{\rightleftarrows}} AD_n. \qquad (8_n)$$

$$AD + C \xrightarrow{k_3^{(1)}} P,$$

$$AD_2 + C \xrightarrow{k_3^{(2)}} P,$$

. . . . . .

$$AD_n + C \xrightarrow{k_3^{(n)}} P.$$

The reaction velocity will then be

$$w = k_1[A] \cdot [C] + \sum_{i=1}^{n} k_3^{(i)}[AD_i][C].$$

When the extent of oxidation of triethylstannyl chloride is small,

$$[A] = [A]_0 - \sum_{i=1}^{n} [AD_i],$$

$$k_{exp} = \frac{w}{[A]_0[C]} = k_1 + \frac{\sum_{i=1}^{n} k_3^{(i)}[AD_i] - k_1 \sum_{i=1}^{n} [AD_i]}{[A]_0}. \qquad (9)$$

On the hypothesis[67] that the complexes formed by reactions $(8_1)-(8_n)$ differed significantly in reactivity, the mathematics was simplified by considering only the most reactive complex towards ozone (of arbitrary composition $AD_n$). With $[D]_0 \gg n[AD_n]$ Eqn.(9) then becomes

$$k_{exp} = k_1 + (k_3^{(n)} - k_1)\frac{N^n}{N^n + \frac{1}{K[A]_0^n}}, \qquad (10)$$

where $N = [D]_0/[A]_0$ and $K$ is the equilibrium constant of the overall process comprising stages $(8_1)-(8_n)$.

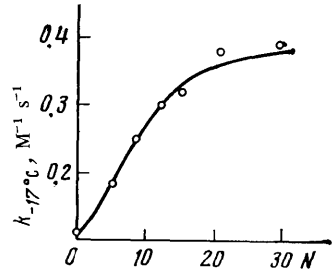


**Figure 4.** Agreement between ozonolysis rate constants $k$ obtained experimentally (points) and calculated by means of Eqn.(11) (curve).

Experimental data (Table 11) were substituted in Eqn. (10) to find the minimum standard deviation, for each temperature investigated, over the range $n = 0.5-3$ in steps of 0.5 with optimum values of $K$ estimated from the standard deviation between calculated and experimental values. The optimum value $n = 2$ was found, and the experimental results at −17°C (Table 11) were satisfactorily described by the equation

$$k_{exp} = k_1 + (k_{max} - k_1)\frac{N^2}{N^2 + 70} \qquad (11)$$

(standard deviation not exceeding 3%). Formation of a 1 : 2 complex of triethylstannyl chloride with dimethylformamide is confirmed by the good agreement between ozonolysis rate constants $k$ in the presence of dimethylformamide determined experimentally at −17°C and calculated by means of formula (11) (Fig.4).

# The Mechanism and Stereochemistry of the Oxidation of Bicyclic Hydrocarbons with a Bridge Bond

E.A.Lazurin, V.V.Voronenkov, and Yu.G.Osokin

Reactions involving the oxidation of unsaturated bicyclic hydrocarbons with a bridge bond by oxygen, hydroperoxides, peracids, and hydrogen peroxide are examined, particular attention being devoted to the mechanism and the stereochemistry of the oxidation of norbornene hydrocarbons and their derivatives.
The bibliography includes 98 references.

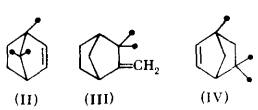
## I. INTRODUCTION

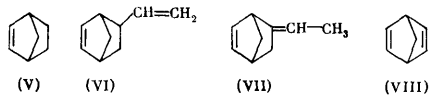
Bicyclic hydrocarbons with a bridge bond include a series of important natural compounds (terpenes). Since the beginning of the 1960s, individual representatives of hydrocarbons of this class (bicyclic olefins—mainly norbornene and its homologues) have been finding increasing practical applications as monomers[1-4] for the manufacture of high-molecular-weight compounds with valuable technical properties, obtained mainly by solution polymerisation and copolymerisation in the presence of Ziegler–Natta catalysts.

Owing to their complex steric structure, bicyclic hydrocarbons with a bridge bond are excellent objects for the study of the mechanisms and stereochemical characteristics of chemical reactions[5-7], among which the oxidation reactions are of special interest.



## II. AUTOXIDATION

Having autoxidised dicyclopentadiene (I), Hock and Depke[8] found that the primary reaction products are derivatives with hydroperoxy-groups in the 5- and 8-positions; the 1- and 4-positions (at the bridgehead of the bicyclic system) remain unaffected.



(I)

The oxidation of certain bicyclic hydrocarbons—derivatives of bicyclo[2,2,1]heptane—was described most fully for the first time by Nesmeyanov et al.,[9] who showed that bornylene (II), camphene (III), and δ-fenchene (IV), i.e.

(II) (III) (IV)

are hardly oxidised by oxygen in the presence of cobalt and manganese stearates. Similar results were also obtained when an attempt was made to oxidise norbornene (V), vinylnorbornene (VI), ethylidenenorbornene (VII), and norbornadiene (VIII)[10,11] (Fig. 1).

(V) (VI) (VII) (VIII)

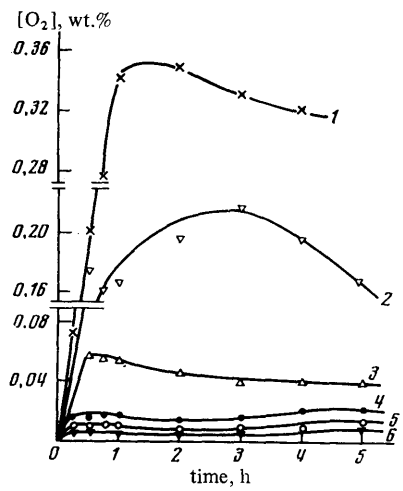


**Figure 1.** Kinetic curves for the accumulation of hydroperoxides (calculated in relation to active oxygen) at 95°C: 1) vinylcyclohexene; 2) tetrahydroindene; 3) dicyclopentadiene; 4) vinylnorbornene; 5) ethylnorbornene; 6) norbornene.

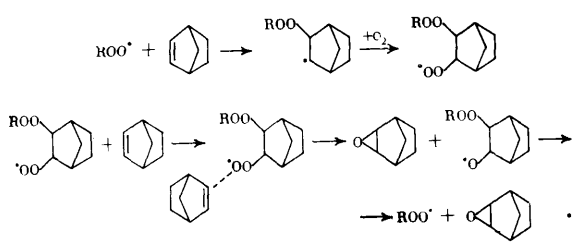
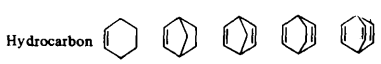
Nesmeyanov[9,12] explained the chemical passivity of the α-$C_{tert}$–H bond in the above systems as follows: the reactivity of the C–H bond in hydrocarbons depends on its strength, which diminishes in the presence of σ,π-conjugation. The latter takes place to the maximum extent only when the C–H bond and the axes of the "π-electron" clouds



are nearly parallel; on the other hand, if they are at right angles, there is no conjugation and it has no influence on the C–H bond. In the above hydrocarbons (I)–(VIII), the $\alpha$-C$_{tert}$–H bond is firmly fixed nearly at right angles to the axes of the "$\pi$-electron" clouds, which removes the $\alpha$-C$_{tert}$–H bond from the $\sigma,\pi$-conjugation and reduces its chemical reactivity. It follows from Nesmeyanov's ideas that the axial $\alpha$-C–H bond should show the greatest tendency towards oxidation in cyclic olefins, because, in contrast to the equatorial C–H bond, it exhibits the maximum degree of $\sigma,\pi$-conjugation, which has been confirmed experimentally[11,13].

A subsequent explanation of the passivity of the $\alpha$-C$_{tert}$–H bond in bicyclo[2,2,1]heptane derivatives is associated with hypotheses concerning the structure of the transition state[14]. The hydroperoxide—the primary oxidation product—is known[15] to be formed via the mechanism

$$ROO^{\cdot} + RH \rightarrow ROOH + R^{\cdot}\,.$$



The formation of the radical R$^{\cdot}$ involves the transition of the carbon atom in the C–H bond from the $sp^3$-hybrid state to the $sp^2$-hybrid state. Since the rigid structure of bicyclo[2,2,1]heptane derivatives preclude such transition, then evidently the C–H bonds in this hydrocarbon must be chemically passive in radical reactions, in agreement with experiment[10]. It is noteworthy that the idea of taking into account the ring energy in considering the structure of the transition state has been used to explain the different rates of oxidation of $C_5$–$C_{10}$ cycloparaffins[16].

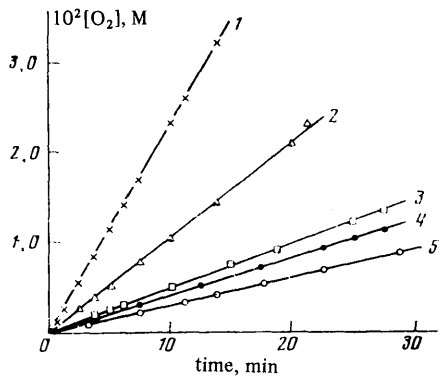
Data on the oxidation of bicyclo[2,2,1]hept-2-ene in the presence of initiators proved to be extremely interesting. Mayo[17] observed that, when bicyclo[2,2,1]hept-2-ene is oxidised by oxygen in the presence of azobisisobutyronitrile (AIBN), an epoxy-derivative is formed. It was shown subsequently[18] that the epoxide is the main product of the oxidation of bicyclo[2,2,1]hept-2-ene derivatives by oxygen in the presence of not only AIBN but also of benzoyl peroxide. The study of the mechanism of the oxidation of bicyclo[2,2,1]hept-2-ene derivatives[10,19] showed that the formation of the epoxide from norbornene is described by the following mechanism:

The mechanism agrees satisfactorily with the reaction kinetics.

The main cause of this type of oxidation of norbornene and its derivatives is the presence of a strained double bond in their ring systems. A strained double bond is understood as one involving appreciable angular distortions and therefore possessing a large potential energy. The strain of the double bond is estimated experimentally from heats of hydrogenation[20,21] (as a rule a large absolute negative heat of hydrogenation corresponds to a large strain of the double bond in the system):

| Hydrocarbon | | | | | |
|---|---|---|---|---|---|
| $-\Delta H_{hydr}$, kcal mole$^{-1}$ | 28,9 | 33,1 | 35,0 | 35,0 | 37,6 |

Comparison of the rates of initiated oxidation of cyclohexene and norbornene (Fig. 2) and also of the reaction products led to the hypothesis that the double bond of norbornene undergoes homolysis to a greater extent than that of cyclohexene[11], possibly because the $p_z$ orbitals of the norbornene double bond overlap to a lesser extent than the $p_z$ orbitals of the double bond of cyclohexene. This view has been confirmed by a comparison of the relative rates of autoxidation of hydrocarbons of different classes[22] (Table 1). Table 1 shows that olefins are oxidised much more readily than aromatic alkylhydrocarbons. The explanation is probably that the degree of conjugation in the allyl group is greater than in the benzyl group. The products of the oxidation of olefins (as well as cyclo-olefins) are hydroperoxides, unsaturated alcohols, and ketones, i.e. the products of oxidation involving C–H bonds in the $\alpha$-position relative to the double bond. High rates of autoxidation are also characteristic of norbornene hydrocarbons, but here the ring double bond is oxidised and not the $\alpha$-C–H bond.



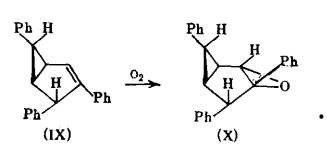


**Figure 2.** Kinetic curves for the absorption of oxygen at 50°C in the presence of AIBN (0.0304 M): 1) tetrahydroindene; 2) ethylidenenorbornene; 3) cyclohexene; 4) vinylnorbornene; 5) norbornene.

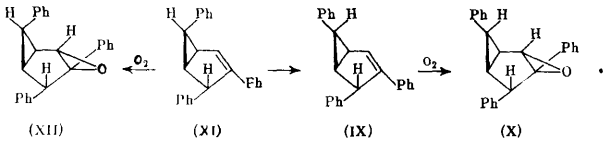
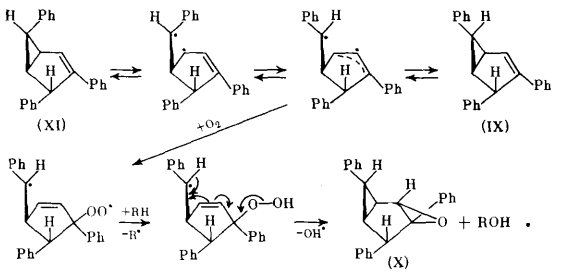
**Table 1.** The relative rates of autoxidation of hydrocarbons[22].



| Hydrocarbon | $k_{rel}$ | Hydrocarbon | $k_{rel}$ | Hydrocarbon | $k_{rel}$ |
|---|---|---|---|---|---|
| Cyclohexene | 10.15 | 2-Methylbut-1-ene | 6.54 | Isopropylbenzene | 1.00 |
| Cyclopentene | 9.34 | Indan | 4.30 | Ethylbenzene | 0.83 |
| 2-Methylbut-2-ene | 8.50 | *p*-Ethyltoluene | 1.30 | *p*-Xylene | 0.73 |
| Dicyclopentadiene | 8.21 | *p*-Isopropyltoluene | 1.27 | *m*-Xylene | 0.67 |
| Norbornene | 7.82 | *o*-Ethyltoluene | 1.05 | Toluene | 0.28 |

A study of the oxidation of the stereoisomers of 3,4,6-triphenylbicyclo[3,1,0]hex-2-ene in xylene[23] showed that the *exo*, *exo*-isomer (**IX**) gives rise to the *exo*,*exo*-epoxide (**X**):

(IX) (X)

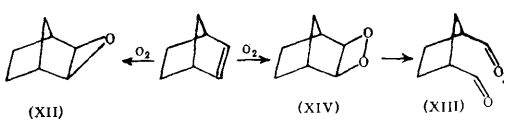


On the other hand, the oxidation of *exo,endo*-3,4,6-triphenylbicyclo[3,1,0]hex-2-ene (**XI**) results in the formation of *exo,exo*-2,4,6-triphenylbicyclo[3,1,0]hex-2-ene (**IX**) and its *exo,exo*-epoxide (**X**) together with the corresponding *exo,endo*-epoxide (**XII**):

(XII) (XI) (IX) (X)

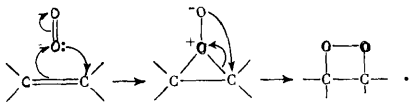
Evidently, in this case hydrocarbon (**XI**) is not only converted into the epoxide (**XII**) but also isomerises to hydrocarbon (**IX**), which is oxidised to compound (**X**). To demonstrate the occurrence of the isomerisation process, the authors[23] heated hydrocarbon (**IX**) or (**XI**) in nitrogen and obtained an equilibrium mixture of hydrocarbons (**IX**) and (**XI**) in proportions of 16 : 1.

A mechanism for the formation of products (**IX**) and (**X**) from compound (**XI**), according to which the rupture of the cyclopropane ring of the bicyclo-olefin leads to an intermediate biradical which then interacts with oxygen to form a peroxy-radical, was proposed on the basis of literature data[24,25]. The subsequent reactions of the peroxy-radical lead to products (**IX**) and (**X**):



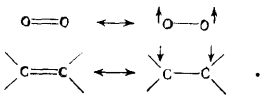
A study of the sensitised photochemical oxidation of norbornene by singlet oxygen at room temperature in different solvents showed[26] that a mixture of the *exo*-epoxide of norbornene (**XII**) and *cis*-cyclopentane-1,3-dialdehyde (**XIII**) is formed in all cases (Table 2).

**Table 2.** The composition of the products of the photochemical oxidation of norbornene by singlet oxygen in various solvents at room temperature.

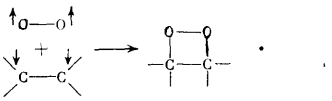


| Solvent | Composition of products, % | |
|---|---|---|
| | (XII) | XIII) |
| $CH_3CN$ | 39 | 61 |
| $CH_3COC(CH_3)_3$ | 53 | 47 |
| $CH_3COCH_3$ | 65 | 35 |

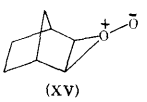
The authors[26] believe that the dialdehyde is formed via a dioxetan (**XIV**) stage,



(XII) (XIV) (XIII)

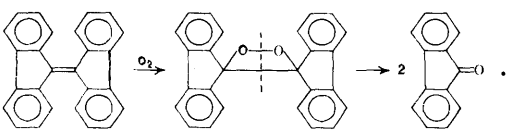


the mechanism of the formation of which can be represented as follows[27,28]:



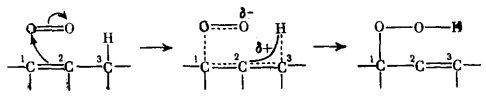
However, we believe that dioxetan can be formed in a different way. In the presence of a sensitiser, the carbon and oxygen double bond systems pass to excited triplet and singlet states[29-31]:

Since the species formed are paramagnetic, the synthesis of dioxetan can be regarded as a homolytic and not a polar interaction:



The mechanism of the formation of the norbornene *exo*-epoxide was not finally elucidated[26], but the authors suggest that dioxetan (**XIV**) or the perepoxide (**XV**) may serve as precursors of the epoxide:

(XV)



It is noteworthy that the sensitised oxidation of a strained double bond is a general reaction. If the allylic hydrogen atom is inactive and the double bond is highly strained, the dioxetan formed on oxidation may be isolated as a product[27,32,33]. For example, the photochemical oxidation of 9,9'-difluorenylidene, which has a strained double bond, proceeds with formation of fluorenone via an intermediate dioxetan stage[34] in accordance with the following mechanism:

Jefford and Boschung[35] also investigated the photochemical oxidation by singlet oxygen of 2-methylnorborn-2-ene, 2-methylenenorbornane, and their 7,7-dimethyl derivatives in the presence of a sensitiser. They showed that the primary reaction products are not epoxides but unsaturated hydroperoxides. Table 3 lists the relative rates of photochemical oxidation of certain cyclic and bicyclic olefins. The ratios of the rates of *exo*- and *endo*-attack by oxygen on the double bond were calculated for certain bicyclic hydrocarbons from the relative yields of the *exo*- and *endo*-products (Table 4).

The data presented in Tables 3 and 4 indicate a high sensitivity of the photochemical oxidation to steric hindrance: the *endo*-attack by singlet oxygen on the double bond of 2-methylnorborn-2-ene is 1000 times slower than in the reaction involving 1-methylcyclopentene, while the rate of *exo*-attack is reduced approximately by a factor of 250 following the introduction of two methyl substituents in the 7.7-position of 2-methylnorborn-2-ene.

Jefford and Boschung[35] proposed the following mechanism, taking into account the geometry of the transition state in the formation of the hydroperoxide:

(XVI)

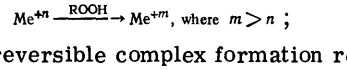
and concluded that the transition state (**XVI**) has a dipolar structure.

**Table 3.** The relative rates of photochemical oxidation and partial rates of *exo*- and *endo*-attack by singlet oxygen on the double bonds in cyclo- and bicyclo-olefins.

| Hydrocarbon | Relative rate of photochemical oxidation | Partial rates | |
|---|---|---|---|
| | | of *exo*-attack | of *endo*-attack |
|  | 2.3 | 1.15 | 1.15 |
|  | 115.0 | 57.5 | 57.5 |
|  | 9.5 | 4.5 | 4.5 |
|  | 1.0 | 0.97 | 0.03 |
|  | 3.2 | 3.15 | 0.05 |
|  | 0.262 | 0.108 | 0.154 |
|  | 0.077 | 0.012 | 0.065 |

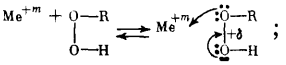
**Table 4.** The ratios of the rates of *exo*- and *endo*-attack ($v_{exo}/v_{endo}$) by singlet oxygen on the double bond in bicyclic hydrocarbons[35].

| Hydrocarbon |  |  |  |  |
|---|---|---|---|---|
| $v_{exo}/v_{endo}$ | 66.0 | 0.19 | 28.0 | 0.67 |



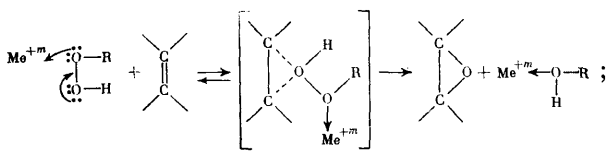
The addition of an oxygen atom to the first carbon atom of the double bond leads to the appearance on the central carbon atom of the allyl fragment of a positive charge δ+, which is delocalised via hyperconjugation with a C–H bond in the α-position relative to the C–C bond. The formation of the hydroperoxide is completed by the transfer of the conjugated γ-hydrogen atom to the $O^-$ centre and the migration of the double bond. The displacement of the double bond in hydrocarbons has been demonstrated with the aid of a deuterium label[35].

## III. INTERACTION WITH HYDROPEROXIDES



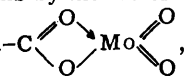
The epoxidation of olefins by reaction with hydroperoxides proceeds in the presence of catalysts. It is recommended that metals whose ions must possess the following fundamental properties be used as catalysts[36]: a high positive charge; vacant electronic orbitals (*d* orbitals) capable of accommodating pairs of electrons; a tendency towards the formation of unstable complexes with the reactants. Such metals are molybdenum, chromium, tungsten, vanadium, manganese, cobalt, niobium, tantalum, titanium, rhenium, selenium, etc.[37] Molybdenum, tungsten, vanadium, and chromium compounds, which may be used as such or with added iron, nickel, manganese, and cobalt are the most common catalysts[38]. The proposed catalysts may be homogeneous and heterogeneous. The most active homogeneous systems comprise molybdenum and vanadium carboxylates and acetylacetonates, alkyl molybdates, and $MoO_3$ and $WO_3$ complexes with organic oxygen, nitrogen, and sulphur compounds, etc.[39] Among the catalysts enumerated above, preference is given to molybdenum compounds, which ensure a high selectivity of the epoxidation process[40-42].

A mechanism for the epoxidation of olefins by hydroperoxides in the presence of variable-valence metals has been proposed by Gould et al.[36] and has been confirmed in many investigations[43-50]. On the basis of the above studies, the mechanism of the liquid-phase epoxidation of olefins by hydroperoxides can be represented as follows:

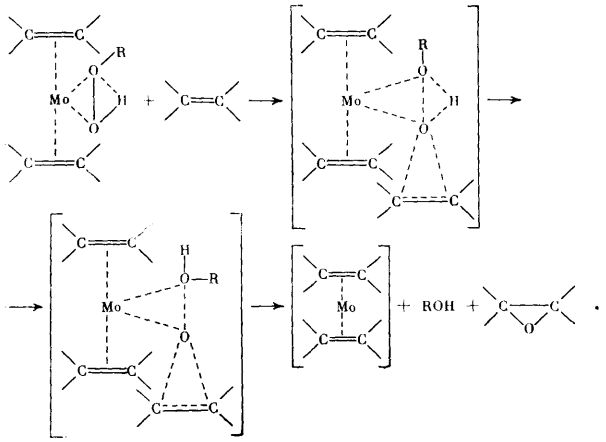


(1) rapid and irreversible activation of the catalyst:

(2) rapid and reversible complex formation reaction:



(3) reaction of the complex with the olefin (the stage limiting the rate of the entire process):



(4) rapid reversible exchange of ligands:

It has been shown[51] that, when ethylphenyl hydroperoxide is added in the oxidation of olefins by the latter in the presence of molybdenum resinate  , the valence of the metal changes: molybdenum(V) is converted into molybdenum(VI) and compounds of molybdenum in the +5 and +6 oxidation states (*n* and *m* respectively in the mechanism) exist simultaneously during the epoxidation reaction, and the proportions of the two types of compounds are influenced by the concentration of the epoxidising agent.

In a detailed study of the individual stages of the epoxidation of cyclohexene by ethylphenyl hydroperoxide in the presence of the molybdenum catalyst, it was suggested[52] that the formation of the epoxide proceeds via the reaction

of the hydroperoxide bound in a complex with a new olefin molecule:

It has been found in studies [53,54] by NMR and ESR of the epoxidation of olefins by t-butyl hydroperoxide in the presence of dioxobis(cyclohexane-1,2-diolo)molybdenum that stable paramagnetic free radicals are formed during the reaction and give rise at the beginning to a complex of the catalyst–t-butyl peroxy-radical type and, after the addition of the olefin, a catalyst–t-butylperoxy-radical–olefin complex is formed.

It was shown above that an olefin with a high negative heat of hydrogenation is oxidised at a high rate. In a study of the catalytic epoxidation of individual isomeric butenes by t-butyl hydroperoxide, Farberov and coworkers [55] found that *cis*-but-2-ene is the most reactive. This is consistent with the negative heats of hydrogenation of the relevant hydrocarbons [21] (Table 5).

**Table 5.** The negative heats of hydrogenation and the reactivities of isomeric butenes in the epoxidation reaction in the presence of molybdenum acetylacetonate (epoxidation temperature 50°C, hydrocarbon concentration 4.0 M, catalyst concentration $1.0 \times 10^{-4}$ M).

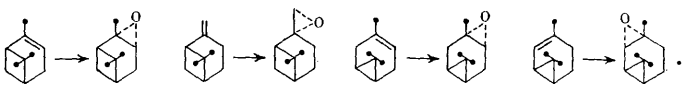
| Olefin | $-\Delta H_{hydr}$, kcal mole$^{-1}$ | Rate constant for epoxidation reaction, litre mole$^{-1}$ s$^{-1}$ | Relative rate of epoxidation |
|---|---|---|---|
| But-1-ene | 26.8 | $0.08 \cdot 10^{-3}$ | 1.0 |
| *trans*-But-2-ene | 27.6 | $1.08 \cdot 10^{-3}$ | 14.2 |
| *cis*-But-2-ene | 28.6 | $2.74 \cdot 10^{-3}$ | 36.0 |

It has been shown similarly [56,57] that in the series of cyclic olefins the carbon atom involved in the most strained bond is epoxidised most readily (Table 6). Furthermore, it has been shown by $^1$H NMR and infrared spectroscopy that, in all cases of the epoxidation of cyclic olefins having double bonds in the ring and in the side chain (vinylnorbornene and vinylcyclohexene), the products are in all cases monoepoxy-derivatives formed on the ring double bond, which indicates a high degree of strain of the latter compared with that of the double bond in the side chain.

It has been found in the oxidation of norbornene, vinylnorbornene, cyclopentene, cyclohexene, and camphene by t-butyl hydroperoxide in the presence of the molybdenum catalyst [58] that the relative rates of epoxidation of the above hydrocarbons are in the ratios 6.5 : 6.0 : 5.0 : 2.0 : 1 respectively. The opposite dependence of the rate of epoxidation of hydrocarbons on the stretching vibration frequency of the ring C–C bond in the infrared spectra was observed.

**Table 6.** Degree of conversion of t-butyl hydroperoxide in the epoxidation of cyclo-olefins in the presence of molybdenum acetylacetonate (temperature 0°C, molar ratio olefin : hydroperoxide = 3:1, catalyst concentration 0.001 mole of Mo per mole of hydroperoxide, reaction time 30 min).

| Hydrocarbon | Camphene | Vinylcyclohexene | Vinylnorbornene |
|---|---|---|---|
| Conversion of hydroperoxide, wt.% | 4.0 | 21.0 | 26.5 |



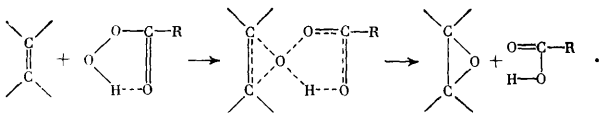
The epoxidation of olefins by hydroperoxides in the presence of catalysts has an electrophilic mechanism [59,60]. Consequently in a series of norbornene derivatives the rate of oxidation should vary as a function of the electronegativity of the substituent. This has been confirmed in a study [61] where it was found that, in the epoxidation of norbornenes by t-pentyl hydroperoxide in the presence of $MoCl_5$, compounds with electron-donating substituents are oxidised at higher initial rates than compounds containing electron-accepting substituents (Table 7).

**Table 7.** The rates of oxidation of 6-substituted norbornene derivatives by t-pentyl hydroperoxide [61]:

| R | $CO_2CH_3$ | $CH_2OCO_2CH_3$ | $OCO_2CH_3$ | OH | *exo*-CN | *endo*-CN | Cl | $CH_2OH$ | H | $CH_3$ |
|---|---|---|---|---|---|---|---|---|---|---|
| $10^7W$, mole litre$^{-1}$ s$^{-1}$ | 2 | 5 | 6 | 7 | 8 | 9 | 15 | 23 | 35 | 116 |

The stereochemistry of the catalytic epoxidation of bicyclic olefins by hydroperoxides has been investigated [60,62] and it has been established that $\alpha$- and $\beta$-pinenes as well as $\Delta^3$- and $\Delta^4$-carenes, which have a markedly hindered double bond, give rise only to the *endo*-epoxides on oxidation by t-pentyl hydroperoxide in the presence of $MoCl_5$, because in all cases there is *endo*-attack on the reactant:

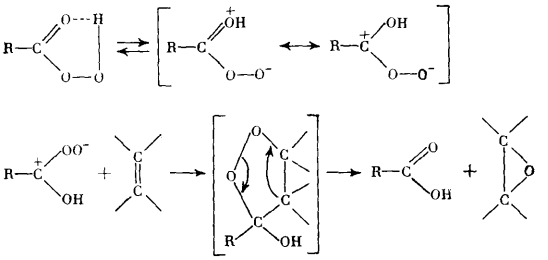
Methods for the determination of the conformations of terpene epoxides by $^1$H NMR have been developed by Arbuzov et al. [63]



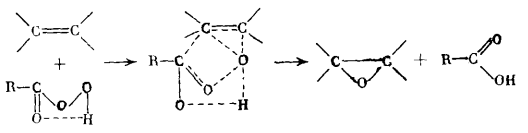
## IV. OXIDATION BY PERACIDS

The oxidation of olefins by peracids has been investigated in detail; together with reports containing data on the kinetics and mechanisms of individual reactions, a number of reviews[47,64-66] and monographs[67,68] devoted to the Prilezhaev reaction have appeared in recent literature. It was suggested previously[68,69] that the epoxidising species is the free hydroxyl cation $OH^+$, which attacks the olefin via the reaction

However, it was found that the Prilezhaev reaction does not undergo general acid catalysis.

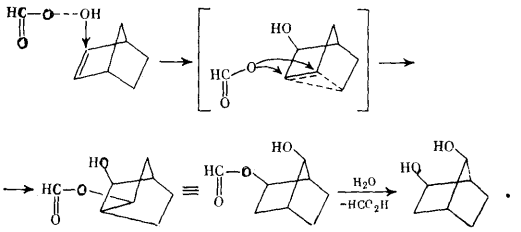


In later studies of the kinetics of the epoxidation of various olefins by peracids[70-73], it was suggested that the epoxide is formed via a $\pi$-complex:



The formation of an intramolecular hydrogen bond in peracids was noted and demonstrated for the first time by Emanuel' et al.[74]

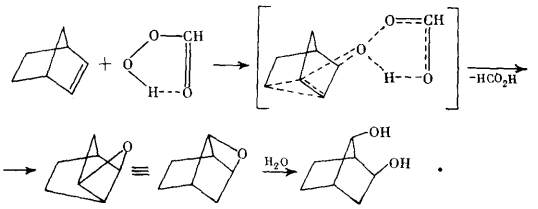
The mechanism of the epoxidation of olefins proposed by Bartlett[70] and Lynch and Pausacker[71] in general agrees satisfactorily with the fundamental process characteristics[67,75]. It explains readily the irreversibility of the reaction and the energetic process characteristics, because the formation of a complex reduces the energy required to abstract an oxygen atom from the peracid and to transfer it to the C=C bond.



In highly polar solvents, epoxidation via a mechanism involving dipolar 1,3-addition is possible[67,76]:

or

A characteristic feature of the Prilezhaev reaction is high stereospecificity leading to pure *cis*-addition of the oxygen atom with retention of the configuration of the substituents at the double bond[67]. However, the bridge structure of bicyclic olefins leads in many instances to an anomalous epoxidation reaction. Thus it was found in one of the early studies[77] that, in the oxidation of norbornene by performic acid, the only product is *cis*-norcamphane-2,7-diol. The authors suggested that the reaction proceeds with a Wagner–Meerwein rearrangement via a stage involving the formation of 2-formyl-7-hydroxynorbornane:



The proposed mechanism is based on the dissociation of performic acid into ions via the reaction

However the $HO^+$ cation should have a high energy[47] and its formation is not very likely under the given conditions. The intermediate—2-formyl-7-hydroxynorbornane—was not isolated either.

According to modern ideas[67], the oxidation of norbornene by performic acid probably involves a stage in which 2,7-epoxynorbornane is formed:

A study of the epoxidation of norbornene and *exo*-dihydrobicyclopentadiene by perbenzoic acid[78] showed that the reaction proceeds without a Wagner–Meerwein rearrangement and the consequent formation of *exo*-2,3-epoxynorbornane and *exo*-2,3-epoxy-*exo*-5,6-cyclopentanonorbornane respectively (the yield was 80% in both cases). These results were confirmed by Gassman and Pape[79], who oxidised bicyclo[2,2,1]hept-2-ene-7-one and bicyclo[2,2,1]-hept-2-*anti*-7-ol by perbenzoic acid and established that in both cases the reaction also proceeds without a Wagner–Meerwein rearrangement and the consequent formation of *exo*-products: *exo*-2,3-epoxybicyclo[2,2,1]heptan-7-one and *exo*-2,3-epoxybicyclo[2,2,1]heptan-*anti*-7-ol.

*endo*-Products are formed in the oxidation of norbornadiene by peracids[80-82]. It was shown in the studies quoted that the *endo*-2,3-epoxynorbornene formed undergoes a partial rearrangement which results in the formation of *endo*-bicyclo[3,1,0]hex-2-en-6-al[80,81] or *endo*-9-formylbicyclo[3,1,0]hex-2-ene[82]. The *endo*-pathway of the oxidation of norbornadiene and its homologue is most likely because double bond between the $C_{(5)}$ and $C_{(6)}$ carbon atoms is not shielded by hydrogen atoms[83].

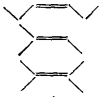
In a study of the stereochemistry of the epoxidation of norbornene and its homologues with subsequent reduction of the products by lithium in ethylenediamine, Brown et al.[84] found that a mixture of *endo*- and *exo*-hydroxy-derivatives is formed in all cases (Table 8). They also demonstrated[84] that the presence of the 7,7-dimethyl substituents in the norbornene molecule decreases the overall rate of epoxidation by a factor of 100 and the rate of *exo*-attack by a factor of 1000; in such cases, the epoxidation proceeds mainly via *endo*-attack on the reactant (Table 8).

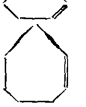
A study of the stereoselectivity of the oxidation of olefin double bonds by peracids showed[85] that peroxybenzimidic acid is the least stereoselective reagent in relation to double bonds among other peracids (for example $CH_3COOOH$). Table 9 presents the relative rates of epoxidation of olefins by peroxybenzimidic and peracetic acids (the rates of reaction of the above acids with cyclohexene were assumed to be unity).

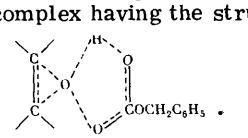
**Table 8.** The ratio of the amounts of *endo*- and *exo*-products obtained in the epoxidation of norbornene and its homologues by *m*-chloroperbenzoic acid.

| Hydrocarbon | Composition of products, % | |
|---|---|---|
| | *exo*-form | *endo*-form |
| Norbornene | 99.0 | 1.0 |
| 7,7-Dimethylnorbornene | 12.0 | 88.0 |
| 1-Methylnorbornene | 99.0 | 1.0 |
| 2-Methylnorbornene | 99.5 | 0.5 |
| 1,7,7-Trimethylnorbornene | 5.0 | 95.0 |

**Table 9.** The rates of epoxidation of olefins by peracids.



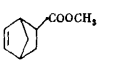




| Hydrocarbon | Relative rate of epoxidation | | Hydrocarbon | Relative rate of epoxidation | |
|---|---|---|---|---|---|
| | by peroxybenzimic acid | by peracetic acid | | by peroxubenzimic acid | by peracetic acid |
|  | 0.4 | 0.039 |  | 1.46 | — |
| | 0.9 | 1.0 | | | |
| | 1.3 | 1.0 | | | |
|  | 2.1 | 7.95 |  | 0.92 | 1.43 |
|  | 3.5 | — | | | |
|  | 1.0 | 1.0 |  | 2.03 | 1.36 |
| | | |  | 3.8 | 1.2 |

**Table 10.** The yields of *endo*-epoxides in the epoxidation of R-5-norbornenes.

| R | Yield of epoxide, % |
|---|---|
| $COOCH_3$ | 39 |
| $(CH_2)_2OCOCH_3$ | 53 |
| $(CH_2)_3OCOCH_3$ | 39 |



In a study of the oxidation of 5-substituted norbornenes by *o*-benzylmonoperoxycarbonic acid—an extremely effective epoxidising agent yielding mainly *endo*-epoxides—it was found[86] that the reaction gives rise to an intermediate olefin–peracid complex having the structure

(XVII)

This fact constitutes direct confirmation of the mechanism[70,74] of the epoxidation of olefins by perbenzoic acids described above.

**Table 11.** The oxidation of norbornene derivatives by peracetic acid at 20°C.

| Compound | Yield of epoxide, % |
|---|---|
|  | 80 |
|  | 72 |
|  | 55* |
|  | 51 |

*Under these conditions, dicyclopentadiene gives rise to 30% of the epoxide  and 25% of the epoxide 

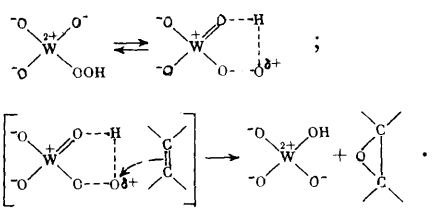


Table 10 presents the yields of the *endo*-epoxides of 5-substituted norbornenes obtained by the reaction of the corresponding hydrocarbons with *o*-benzylmonoperoxycarbonic acid.

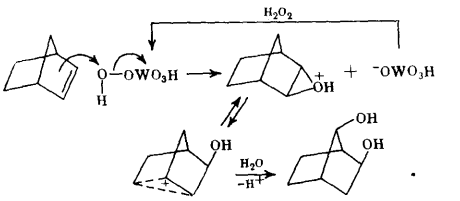
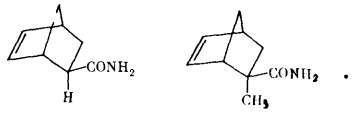
The oxidation of norbornene derivatives by peracetic acid takes place mainly via *exo*-attack on the double bond[87]. The yields of the resulting *exo*-epoxides are listed in Table 11.



## V. REACTIONS WITH HYDROGEN PEROXIDE

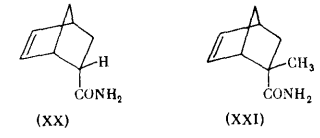
The oxidation of olefins by hydrogen peroxide has been investigated in detail[47]. The reaction is accelerated in the presence of tungstic acid and tungstates. The epoxidation mechanism can be represented as follows[88-90]:

$$HWO_4^- + H_2O_2 \rightleftarrows HWO_5^- + H_2O\ ;$$



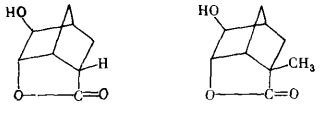
In one of the early papers[91], it is stated that the interaction of norbornene with a solution of hydrogen peroxide in t-butyl alcohol in the presence of tungstic acid yields *exo*, *syn*-norbornane-2,7-diol and not the epoxide. However, the mechanism proposed by the authors includes an epoxide-formation stage:

The occurrence of the rearrangement, caused by the structure of the epoxidised hydrocarbon, constitutes evidence for the cationic mechanism of the addition reaction catalysed by tungstic acid, since the rearrangement is not observed when the corresponding bicyclic radical is formed[92].



The epoxidation of norbornene hydrocarbons containing functional groups proceeds anomalously. It has been shown[93,94] that, when the functional groups are in the *exo*-positions, the only reaction product is an epoxide. The *endo*-configuration of the carboxy-[93,95], hydroxymethyl[94,96], and methoxycarbonyl[97] groups leads to the complete or partial formation of tricyclic structures containing a heteroatom.

The oxidation of stereoisomeric carbonamides of the norbornene series was investigated in a later study[98]. The authors showed that the oxidation of *endo*-carboxamides (XVIII) and (XIX), containing a strained double bond, proceeds readily with formation of the corresponding epoxides having the *exo*-configuration:



(XVIII) (XIX)

The epoxidation of the stereoisomeric *endo*-carboxamides (XX) and (XXI) leads to the formation of the lactones (XXII) and (XXIII), by virtue of the nucleophilic attack on the carbon atom of the carbonyl group directed towards the positively charged carbon atom in the intermediate complex, formed as a result of the electrophilic attack by the peracid on the norbornene double bond.

(XX) (XXI)

(XXII) (XXIII)

---o0o---

The review of the literature data on the oxidation of bicyclic hydrocarbons with a bridge bond shows that the oxidation reaction is of theoretical interest, particularly from the standpoint of stereochemistry. Presumably some of these reactions will be used in future in the chemical industry.

# Polarographic Study of the Reactions of Carbonyl Compounds with Ammonia and Its Derivatives and Their Application in Polarographic Analysis

Ya.I.Tur'yan

The theoretical principles and the experimental results of the application of polarography to the study of equilibria in single- and multi-stage reactions of carbonyl compounds with ammonia and its derivatives and of the acid-base properties of their products are examined. A comparison is made with data obtained by other research techniques. More than 100 reactions are analysed taking into account the nature of the carbonyl compound and the nucleophile.
The mechanism of the polarographic electrochemical reduction of the reaction products, including aminocarbinols, is considered. The analytical application of the reactions in the indirect polarographic determination of carbonyl and nitrogen compounds is discussed.
The bibliography includes 207 references.

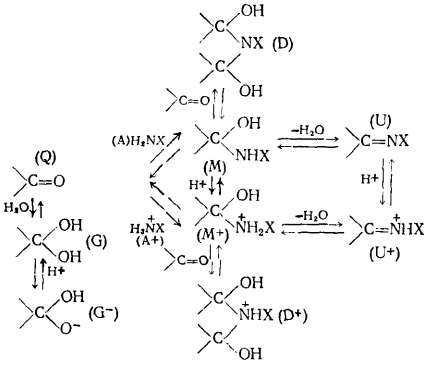
## I. INTRODUCTION



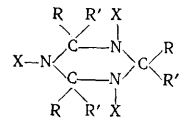
The use of the reactions of carbonyl compounds with ammonia and its derivatives in polarography makes it possible to investigate the physicochemical parameters of these reactions [1-3] and to achieve in many instances important indirect determinations of the substances involved. The latter is very important for the understanding of the mechanism of the nucleophilic interaction [4,5], which is widely used in other branches of analytical chemistry [6,7].

Among the physicochemical parameters of the reactions of carbonyl compounds with ammonia and its derivatives, the equilibrium constants and the acid–base dissociation constants of the products have been most widely investigated with the aid of polarography. These applications of the polarographic method are examined in the present review together with the mechanism of the reduction of the reaction products and the analytical applications.

## II. REACTION EQUILIBRIA AND ACID–BASE PROPERTIES OF PRODUCTS

An extensive application of polarography in the study of the reactions of carbonyl compounds with ammonia and its derivatives was achieved for the first time by Zuman [8-11] and by Zuman and Březina [12,13]. However, in the majority of the early studies [8-21] the polarographic method was used to investigate the simpler single-stage interaction and Matoušek [22] was the first to use polarography to characterise quantitatively the multistage interaction on the basis of the reactions with formaldehyde. This research was developed further [23-29] and now involved the determination of quantitative reaction parameters. The development of the theoretical and experimental principles of the application of polarography to the study of single-stage and partly multistage interactions was continued in other studies [30-35].

Among the reactions involved in the given equilibrium, it is possible to isolate the main and side reactions. The main reactions, which are observed in aqueous solution, can be described by the following general mechanism [36-38]:



(1)

where Q, G, and G′ are respectively the carbonyl compound, its hydrated form, and its anion, A and $A^+$ are ammonia or an ammonia derivative and its form protonated at the nitrogen atom, M, D, and $D^+$ are adducts—hydroxyalkyl- and bishydroxyalkylamines (there is also a possibility of trishydroxyalkylamines T and $T^+$ in the reaction between HCHO and $NH_4^+$ [28])—and the corresponding forms protonated at the nitrogen atom, and U and $U^+$ represent the dehydration products—an unsaturated compound and its form protonated at the nitrogen atom.

The reaction of secondary amines HNXX′ with formaldehyde leads to the formation, apart from M($M^+$), of the corresponding cation of the quaternary amino-derivative [39-41] $X'X\overset{+}{N}(CH_2OH)_2$. A similar reaction is also characteristic [39] of tertiary amines $XX'X''\overset{+}{N}CH_2OH$, although according to Matoušek [22] there is also a possibility of the formation of the compound $XX'X''\overset{+}{N}CH_2O^-$ under these conditions.

Together with the main reactions (1), numerous side reactions have been noted[36], among which those involving the formation of the cyclic trimer

(2)

and the diamine $\diagdown C(HNX)_2$ are the most important[38,39].

We shall use the following notation for the equilibrium constants of the main reactions:

$$L_G = [G]/[Q], \quad (3)$$
$$L_M = [M]/[A][Q], \quad (4)$$
$$L_{M^+} = [M^+]/[A^+][Q], \quad (5)$$
$$L_D = [D]/[A][Q]^2, \quad (6)$$
$$L_{D^+} = [D^+]/[A^+][Q]^2, \quad (7)$$
$$L_T = [T]/[A][Q]^3, \quad (8)$$
$$L_{T^+} = [T^+]/[A^+][Q]^3, \quad (9)$$
$$L_U = [U]/[A][Q], \quad (10)$$
$$L_{U^+} = [U^+]/[A^+][Q], \quad (11)$$

and for the acid dissociation constants:

$$K_G = [G^-][H^+]/[G], \quad (12)$$
$$K_{A^+} = [A][H^+]/[A^+], \quad (13)$$
$$K_{M^+} = [M][H^+]/[M^+], \quad (14)$$
$$K_{D^+} = [D][H^+]/[D^+], \quad (15)$$
$$K_{T^+} = [T][H^+]/[T^+], \quad (16)$$
$$K_{U^+} = [U][H^+]/[U^+]. \quad (17)$$

If the reaction involves the anion of the carbonyl compound (for example, the anion of pyruvic acid) or with the anion of the nucleophile (for example, the anion of an aminoacid), then $L_M$, $L_D$, $K_{M^+}$, $K_{D^+}$, and $K_{U^+}$ are replaced by $L_{M^-}$, $L_{D^-}$, $K_{M^\pm}$, $K_{D^\pm}$, and $K_{U^\pm}$. For the reaction of the anion of the carbonyl compound with the nucleophile anion, we have $L_M$ = and $K_{M^\pm}$. In a fairly acid pH range, Eqns.(5), (7), and (13)–(15) hold also for aminoacids. Here it is necessary to bear in mind that the constant $K_{A^+}$ has not been determined experimentally and is usually assumed[42] to be equal to the acid dissociation constant of the methyl or ethyl ester of the aminoacid. On the other hand, the acid dissociation constants of the carboxy-group in the protonated form of the aminoacid $K'_{A^+}$ as well as the acid dissociation constants $K_{A^\pm}$ of the protonated nitrogen atom in the aminoacid dipolar ion have been determined experimentally[42]. Some of the above constants are interrelated:

$$K_{M^+} = K_{A^+}L_M/L_{M^+}, \quad (18)$$
$$K_{D^+} = K_{A^+}L_D/L_{D^+}, \quad (19)$$
$$K_{T^+} = K_{A^+}L_T/L_{T^+}, \quad (20)$$
$$K_{U^+} = K_{A^+}L_U/L_{U^+}. \quad (21)$$

In view of the insignificant influence[42] of the carbonyl compound undergoing the addition reaction on the constant $K'_{A^+}$, we obtain a similar relation also for aminoacids:

$$K_{M^\pm} = K_{A^\pm}L_{M^-}/L_{M^+}. \quad (22)$$

We shall now consider equations for the determination of equilibrium constants from the average limiting polarographic current $\bar{i}_{lim}$ for the reduction of the reaction products. If $G^-$, D, and $D^+$ are neglected in mechanism (1) for $c_Q$ = const. ($c$ is the overall concentration, the subscript indicates the substance involved, and the square brackets represent the equilibrium concentration), we obtain the equation[32]:

$$L_e = \frac{[M]+[M^+]+[U]+[U^+]}{([Q]+[G])([A]+[A^+])} = (L_{M^+}+L_{U^+})\frac{K_{A^+}\{(L_M+L_U)/(L_{M^+}+L_{U^+})\}+[H^+]}{(1+L_G)(K_{A^+}+[H^+])} =$$
$$= \frac{\bar{i}_{lim}\cdot\bar{i}^0_{lim}}{(\bar{i}^0_{lim}-\bar{i}_{lim})(c_A\bar{i}^0_{lim}-c_Q\bar{i}_{lim})}. \quad (23)$$

The sums of the constants $L_M + L_U$ and $L_{M^+} + L_{U^+}$ (for the reaction between HCHO and $NH_2NH_2$)[33] were determined from the dependence of the effective equilibrium constant $L_e$ on pH and the individual equilibrium constants were found with the aid of additional investigations[33,34]. In Eqn.(23), $\bar{i}^0_{lim}$ is the limiting current in the presence of an excess of nucleophile such that a further increase of $c_A$ does not lead to an increase of $\bar{i}_{lim}$, i.e. under these conditions virtually the entire carbonyl compound is converted into products which can be polarographed; $\bar{i}_{lim}$ and $\bar{i}^0_{lim}$ can have both diffusional and kinetic origins[30,32]. The dehydration product $U^+$ is reduced[1,32,34] and, if a diffusion current obtains, the stages involving the protonation of M and U and the $M(M^+)$ dehydration stages are fairly rapid and there is insufficient time for the equilibrium in the stages involving the formation of the adduct $M(M^+)$ to be appreciably displaced at the surface of the dropping electrode. The latter condition should also be observed in the presence of a kinetic current[30–35], which is due to slow stages involving either the protonation of U or the dehydration of $M^+$ (see below).

If the study is performed with $c_A$ = const., $\bar{i}_{lim}$ is determined in the presence of an excess of the carbonyl compound and Eqn.(23) then has the same form, but $c_A$ and $c_Q$ must be interchanged.

Under the conditions such that $L_U \gg L_M$ and $L_{U^+} \gg L_{M^+}$ (M and $M^+$ may be neglected), Eqn.(23) assumes a simpler form when account is taken of Eqn.(21):[32]

$$L'_e = \frac{[U]+[U^+]}{([Q]+[G])([A])+[A^+])} = L_{U^+}\frac{K_{U^+}+[H^+]}{(1+L_G)(K_{A^+}+[H^+])} =$$
$$= \frac{\bar{i}_{lim}\cdot\bar{i}^0_{lim}}{(\bar{i}^0_{lim}-\bar{i}_{lim})(c_A\bar{i}^0_{lim}-c_Q\bar{i}_{lim})}. \quad (24)$$

The equilibrium constants for the individual stages can now be found directly from Eqn.(24) (for the reactions of various carbonyl compounds with $NH_2NH_2$, with the exception of HCHO).[31,33,35]

A further simplification of Eqn.(24) is achieved when $c_A \gg c_Q$:[12,13,17,30,34]

$$L'_e = L_{U^+}\frac{K_{U^+}+[H^+]}{(1+L_G)(K_{A^+}+[H^+])} = \frac{\bar{i}_{lim}}{(\bar{i}^0_{lim}-\bar{i}_{lim})c_A}. \quad (25)$$

When $c_Q \gg c_A$ ($c_A$ = const.), it is necessary to replace $c_A$ by $c_Q$ in Eqn.(25). Eqn.(25) has been used in a number of studies[12,13,17] but without taking into account the hydration of the carbonyl compound. Furthermore, the limiting diffusion current $\bar{i}_d$ for the carbonyl compound was used in some investigations[8,10–13] instead of $\bar{i}^0_{lim}$, which is less accurate, because the constants of the $U(U^+)$ and Q diffusion currents may differ. On the other hand, in the case of the kinetic current the replacement of $\bar{i}^0_{lim}$ by $\bar{i}_d$ is altogether inadmissible.

If $L_M \gg L_U$ and $L_{M^+} \gg L_{U^+}$ (i.e. U and $U^+$ may be neglected), then [U], $[U^+]$, $L_{U^+}$, and $K_{U^+}$ in Eqns.(24) and (25) must be replaced by [M], $[M^+]$, $L_{M^+}$, and $K_{M^+}$ respectively. $M^+$ may then be reduced at the electrode instead of $U^+$.

Retaining M, $M^+$, D, and $D^+$ in Eqn.(1), introducing T and $T^+$ (for the reaction between HCHO and $NH_4^+$),[28] and

neglecting A, $G^-$, U, and $U^+$, the present author and Cheremukhina [28] obtained the equation

$$\frac{\bar{i}_{\lim}}{\bar{i}^0_{\lim}-\bar{i}_{\lim}} = L_{M^+}\frac{K_{M^+}[H^+]}{(1+L_G)[H^+]}c_Q + L_{D^+}\frac{K_{D^+}[H^+]}{(1+L_G)^2[H^+]}c_Q^2 + L_{T^+}\frac{K_{T^+}+[H^+]}{(1+L_G)^3[H^+]}c_Q^3, \quad (26)$$

but no account was taken of the hydration of Q. In the derivation of Eqn.(26), it was assumed that $c_Q \gg c_A$ ($c_A$ = const.) and that the sum of the products $M^+ + D^+ + T^+$ is reduced. The current $\bar{i}^0_{\lim}$ was determined in the presence of a large excess of Q. If A is also involved in mechanism (1), then $[H^+]$ in the denominators of all the terms on the right-hand side of Eqn.(26) must be replaced by $K_{A^+} + [H^+]$. When $[H^+] \gg K_{A^+}(K_{M^+}, K_{D^+}, K_{T^+})$ or $[H^+] \ll K_{A^+}(K_{M^+}, K_{D^+}, K_{T^+})$, then Eqn.(26) and the corresponding equation with $K_{A^+} + [H^+]$ in the denominators can be greatly simplified [23,24,26,41]. Furthermore, the trishydroxyalkyl derivative $T(T^+)$ was not involved in the equilibrium [reactions of formaldehyde with aminoacids [24,25], $\overset{+}{N}H_3OH$, [26] and $(CH_3)_2\overset{+}{N}H_2$ [40,41]] and the third term in Eqn.(26) (with $c_Q^3$) was eliminated. The equilibrium constants were found with the aid of equations of type (26) [23-26,28,41] using a graphical method analogous to the methods of determining the equilibrium constants for stepwise complex-formation reactions based on the study of potentials [43] (potentiometry) or half-wave potentials [44] (polarography).

Eqn.(25) can be used to describe the equilibrium in the reactions involving $NH_2NHCONH_2$ [17,30] without any changes (because $U + U^+$ predominates). On the other hand, in the studies [8,10-13] of the reactions involving $NH_3$, $NH_2RCOO^-$, and $NH_2CH_2CH_2OH$ in the presence of an excess of the nucleophile, the adduct M [8,10,11] or $M + M^+$ [12,13] was the dominant species and $L_{M^+}(L_M)$ and $K_{M^+}$ were apparently determined from Eqn.(25) [8,10-13] rather than $L_{U^+}(L_U)$ and $K_{U^+}$, as believed by the authors [8,10-13]. We shall return to this problem later.

The single-stage interaction (the dominance of $M^+$ in the reactions of formaldehyde with aminoacids in an acid medium [29] and of M in the reaction of formaldehyde with $NH_2CH_2CH_2OH$ [45,46] in the presence of an excess of the latter) has been investigated polarographically using Eqns. (26), in which only the first term (the aminoacid term) was retained and (25) in which $L_{U^+}$ and $K_{U^+}$ were replaced by $L_{M^+}$ and $K_{M^+}(NH_2CH_2CH_2OH)$ respectively. The insignificant concentration of $D^+$ in the reactions involving aminoacids with a primary amino-group in an acid medium [29] is apparently due to the relatively low value of $L_{D^+}$, which has been confirmed by data obtained using kinetic [24,29] and other methods [47].

It is noteworthy that, in a polarographic study [24] of the reactions of formaldehyde with aminoacids in an alkaline medium, samples were polarographed in an acid medium in order to increase $\bar{i}_{\lim}(\bar{i}^0_{\lim})$. Under these conditions, the limiting current decreased with time $t$ and values of $\bar{i}_{\lim}(\bar{i}^0_{\lim})$ extrapolated by $t = 0$ were used in the calculations. The extrapolation was facilitated by the fact that the kinetic equation relating $\bar{i}_{\lim}(\bar{i}^0_{\lim})$ to time was of first order [24], which can be explained by the rapid and almost complete decomposition of $D^+$ to $M^+$ and the reduction of $M^+(L_{D^+}/L_{M^+} \ll L_{M^+})$. Thus, although only the $M^+$ wave was observed in the acid solution, its height corresponded to the sum of the concentrations of the adducts [M] + [D] formed in the alkaline medium.

In contrast to these reactions, the $HCHO-\overset{+}{N}H_3OH$ [26] and $HCHO-\overset{+}{N}H_4$ [28] equilibria in an acid medium, i.e.

$$Q + A^+ \underset{k_{-1}}{\overset{k_{+1}}{\rightleftarrows}} M^+ + Q \underset{k_{-2}}{\overset{k_{+2}}{\rightleftarrows}} D^+, \quad (27)$$

which were also investigated by the polarographic method, are characterised by the opposite relation: $L_{D^+}/L_{M^+} \gg L_{M^+}$, which is probably due to the much smaller influence of steric hindrance than in the reactions with aminoacids. When account is taken of the relation $k_{-1} \gg k_{+2}$, [27] which is most likely to be characteristic of aminoacids (steric effect), the decomposition reaction between $M^+$ and $D^+$ (aminoacids) involving the reformation of the initial substances via a first-order mechanism cannot be accounted for by postulating the attainment of equilibrium in the $D^+ \rightleftharpoons M^+ + Q$ stage. As stated above, here it is necessary to assume (bearing in mind the very low value of $L_{D^+}/L_{M^+}$, so that $k_{-2} \gg k_{+2}$) a rapid and almost complete decomposition of $D^+$ to $M^+$ and a slow decomposition of $M^+$ into the initial substances Q and $A^+$ in accordance with a first-order kinetic equation [24]. It is noteworthy that, when the reactions between formaldehyde and aminoacids were carried out in an alkaline medium and samples were polarographed in an acid medium [24] in the presence of an excess of formaldehyde, the currents $\bar{i}^0_{\lim}$ were readily attained. On the other hand, when the reactions were carried out in the acid medium used in the polarographic experiments [29], $\bar{i}^0_{\lim}$ could not be attained even in the presence of a very large excess of formaldehyde, because of the low value of $L_{M^+}$. The values of $\bar{i}^0_{\lim}$ obtained by carrying out the reactions in an alkaline medium [24] were therefore used to calculate $L_{M^+}$. [29]

Equilibria (1) can be investigated polarographically also on the basis of the wave of the carbonyl compound [14,16,19], but the scope of the method is then limited: (1) the use of only an excess of the nucleophile hinders the study of the equilibrium involving the formation of D($D^+$) and even more so of $T(T^+)$; (2) the wave of the carbonyl compound may be distorted by the superposition of the reduction of the reaction product [22].

Since either the reaction products or the starting material are consumed at the electrode during the polarographic experiment, there is a possibility of a shift of the equilibrium at the electrode surface. This results in exaltation of the limiting current [48] and the values of $\bar{i}_{\lim}$ are no longer suitable for a sufficiently accurate determination from the latter of the equilibrium constants for the reactions investigated. The degree of such exaltation of $\bar{i}_{\lim}$ is greater the larger are the rate constants for the first stages of reactions of type (27) under conditions corresponding to the reduction of M, D, and T ($M^+$, $D^+$, and $T^+$). It has been shown [48] that the above influence cannot introduce a major error if $k_{-1} \leq 0.1-0.2\ s^{-1}$, while in the reduction of the initial substance Q and in the presence of only the stage involving the formation of M, [14,16] we have $k_{+1}[A] \leq 0.1-0.2\ s^{-1}$. This rule holds [48] in the reduction (and also oxidation) of substances subject to both diffusional and kinetic limitations, but in the latter case the limitations should not be associated with the displacement of the equilibria in the test reactions at the electrode surface. The kinetic limitation may be caused either by the slow protonation of the adducts M (D, T) [28] or of the dehydration product [31-35] (the adducts D and T are absent and U is reduced or hydrogen is evolved catalytically under the influence of $U^+$ [30]). This conclusion can be extended to the limiting kinetic current due to the slow dehydration of the adduct M (U is reduced) [32,33].

We may note that the rate constants for the decomposition of the adducts $M^+$ into the initial substances (the reactions between formaldehyde and aminoacids), which have been investigated by the polarographic method [24], remained sufficiently low in an acid solution (Table 1) to cause the undesirable exaltation of $\bar{i}_{\lim}$ in the study of the

equilibrium [24]. Under these conditions, the constants $k_{+1}$ and $k_{-1}$ depended appreciably on the nature of the amino-acid and the observed increase of $k_{-1}$ with increase of both the $-I$ and $+I$ effects of the substituent X (Table 1) can be explained on the basis of the kinetic scheme of Cordes and Jencks [56]:

$$X\overset{+}{N}H_2CH_2OH \overset{-H^+}{\rightleftarrows} X\overset{+}{N}H_2CH_2O^- \xrightarrow[slow]{} HCHO + NH_2X \overset{H^+}{\rightleftarrows} \overset{+}{N}H_3X. \qquad (28)$$

The substituent X with a $-I$ effect accelerates the slow stage (the inductive effect facilitating the dissociation of the $C-\overset{+}{N}$ bond predominates); the acceleration of the reaction with increase of the $+I$ effect of the substituent X is due to the dominance of the steric factor, which is manifested by the displacement of the initial equilibrium stage to the right. The steric effect also predominates in glycine and, since it is smaller, the result is a relatively low value of $k_{-1}$ (Table 1). The correlation between $k_{-1}$ and $K'_{A^+}$ (Table 1) confirms the above role of the inductive and steric factors. It is also possible to follow the influence of the steric factor on $k_{+1}$ (Table 1). With the exception of glycine, this effect predominates at the equilibrium stage involving the deprotonation of the nucleophile (the increase of $k_{+1}$ with increase of the $+I$ effect). The reduced steric hindrance in glycine is apparently manifested to a greater extent in the slow stage involving interaction with formaldehyde, which in fact leads to a relatively larger value of $k_{+1}$ (Table 1). Mechanism (28) also makes it possible to understand the reason why $k_{-1}$ increases with pH [24] without the need to take into account the appreciable amount of the doubly protonated $M^{2+}$ species [24] (protonated at the nitrogen and oxygen atoms).

Table 1. The limiting current constants ($I^0_{lim}$, $\mu A\ mmole^{-1}\ mg^{-2/3}\ s^{1/2}$) for the reduction of the adduct $CH_2(OH)\overset{+}{N}H_2X$, [24] the rate constants for the formation of the adduct from formaldehyde monohydrate and an amino-acid ($k_{+1}$), [29] the rate constants for its decomposition ($k_{-1}$) [24] into the initial substances, and the dissociation constants of the carboxy-groups of the corresponding aminoacids ($K_{A^+}$) [49] (the rate constants were determined at pH ~ 1 and 25°C).

| Aminoacid | X | $I^0_{lim}$ | $10^4 k_{+1}$, litre mole$^{-1}$ s$^{-1}$ | $10^3 k_{-1}$, s$^{-1}$ | $pK'_{A^+}$ |
|---|---|---|---|---|---|
| β-Alanine | $CH_2CH_2COOH$ | 0.55 | — | 0.19 | 3.55 |
| Glycine | $CH_2COOH$ | 0.91 | 5.6 | 3.0 | 2.35 |
| α-Alanine | $CH(COOH)CH_3$ | 1.5 | 0.68 | 3.4 | 2.35 |
| Norvaline | $CH(COOH)(CH_2)_2CH_3$ | 2.7 | 1.4 | 3.8 | — |
| Norleucine | $CH(COOH)(CH_2)_3CH_3$ | 2.5 | 1.1 | 4.5 | 2.34 |
| Leucine | $CH(COOH)CH_2CH(CH_3)_2$ | 2.5 | — | 5.2 | 2.33 |
| α-Aminoadipic acid | $CH(COOH)(CH_2)_3COOH$ | 2.4 | — | 6.7 | — |
| Valine | $CH(COOH)CH(CH_3)_2$ | (3.1) | 2.9 | 8.8 | 2.29 |
| Glutamic acid | $CH(COOH)(CH_2)_2COOH$ | 2.5 | — | 12.8 | 2.30 |
| β-Phenyl-α-alanine | $CH(COOH)CH_2C_6H_5$ | 2.7 | — | 17.6 | 2.11 |
| Aspartic acid | $CH(COOH)CH_2COOH$ | 2.7 | — | 26.0 | 1.99 |

The reaction between formaldehyde and $\overset{+}{N}H_3OH$ is also fairly slow because the limiting current has a diffusional origin [51]. Only the rate constant for the decomposition of $D^+$ into $M^+$ and Q ($k_{-2} = 2 \times 10^{-4}\ s^{-1}$) has been obtained for this reaction (by the polarographic method) [26,27].

With increase of pH, the rate of formation of M (D, T) and U increases appreciably. Thus, on the basis of kinetic data (polarographic method) [10] for the reaction between $CH_3COCOO^-$ and $NH_3$ (pH 9.25), one may assume [48] that the author [10] worked under the conditions corresponding to the limit of a fairly reliable application of the method to the study of the equilibrium in this reaction on the basis of the values of $\bar{i}_{lim}$. The rate of formation of the adduct M in the reaction between pyridine-4-aldehyde and methylamine at pH 10.5 is so high that the kinetics are controlled in this case by the carbonyl dehydration step [52]. $k_{-1} = 58\ s^{-1}$ was obtained [52] for this dehydration stage (by the stopped-flow method), which implies that, during the polarographic reduction of M, there is an appreciable exaltation of $\bar{i}_{lim}$ and the polarographic method becomes unsuitable for the investigation of the equilibrium in the formation of this adduct.

The pH dependence of the rates of the reactions $Q + A(A^+) \rightarrow U(U^+)$ is more complex because these reactions proceed via the formation and dehydration of $M(M^+)$ and involve a change in pH, as shown by Jencks [37,53]; there is also a change in the rate-determining stage. However, here too the problem of the degree of the distorting influence of the reactions involving the formation of an intermediate aminocarbinol (the reduction of U [17,31-35]) at the electrode surface can be in many instants solved comparatively simply. The point is that, in the majority of reactions of this kind, the equilibrium concentrations of $M(M^+)$ may be neglected compared with the concentrations of $U(U^+)$ and in the calculations one must therefore use the overall equilibrium constant and the effective rate constant for the reaction $Q + A(A^+) \rightarrow U(U^+)$ and not the equilibrium and kinetic parameters of the individual stages. The maximum value of $k_{-1}$ is obtained [37] for the reaction between $(CH_3)_2CO$ and $NH_2OH$. .($\overset{+}{N}H_3OH$) under fairly acid conditions (the value of $L_{U^+}$ for the calculations was taken from Conant and Bartlett [54]), but this value too ($k_{-1} = 3.5 \times 10^{-3}\ s^{-1}$) is much lower than the lowest permissible limit [48]. This conclusion can probably be extended also to reactions of aliphatic carbonyl compounds with hydrazine (the formation and reduction of hydrazones) [31-35], although no direct kinetic measurements have been made. This is indicated by the invariance of the equilibrium constants over a wide range of nucleophile concentrations [31-35].

The equilibrium constants for the side reactions between nucleophiles and carbonyl compounds [the formation of a cyclic trimer (2) and a diamine], found in a number of studies [38,39,47,55,56], show that the concentrations of these products are insignificant under the conditions of the polarographic study [24,29]. Only the glycinate anion gives rise to an appreciable concentration of the trimer under the given conditions (alkaline solution) [24], but here too it does not exceed 9%.

The acid dissociation of the hydrated form of the carbonyl compound is also indicated in mechanism (1), but in the majority of studies $[H^+] \gg K_G$, so that this process may be neglected. On the other hand, polarographic data [24] for the reactions of formaldehyde with aminoacids in an alkaline medium were recently revised [25] taking into account the acid dissociation of $CH_2(OH)_2$.

It is noteworthy that, under the conditions of the polarographic study at ordinary temperatures and relatively low concentrations of the carbonyl compound, the influence of the additional (apart from hydration) deactivation of the carbonyl compound (for example owing to polycondensation [57], aldol condensation, or the Cannizzaro reaction [58]) can also be usually neglected, at any rate for the usual accuracy of the equilibrium constants (±10–30%). In the determination of $\bar{i}^0_{lim}$, the concentration of formaldehyde reached [28] a fairly high value in some cases (7.0 M), but under these conditions the side reactions of

[a] $L_U$, $L_{M^-} = 10.5$ from Ref. 37; [b] $L_{M^-} = 25.5$ from Ref. 37; [c] $L_M = 1.1$ from Ref. 37; [d] $L_M = 1.3$ from Ref. 68; [e] $L_M = 1.9 \times 10^9$ from Ref. 34.

Tables 2–7 present the equilibrium constants, including those obtained by nonpolarographic methods, for the reactions of nucleophiles with various carbonyl compounds. A fairly complete compilation of equilibrium constants (Tables 6 and 7) is available for protonated species, since the polarographic method is particularly promising, because of its high sensitivity, for the investigation of equilibria of this kind. It is noteworthy that the study of the equilibria involving the protonated forms of the nucleophile and the products, carried out for the first time in polarographic investigations [12,17,25], makes it possible to eliminate to a considerable degree the distorting influence of the cyclisation of the product [39,47]. In order to take into account the hydration of carbonyl compounds (which has been done in only a few studies; the effective equilibrium constants are more difficult to compare), the present author selected the most reliable values for $L_G$ [69] (Tables 2–7). In the calculations for carbonyl compounds those values of $L_G$ have not been determined, it was assumed that $L_G \ll 1$, although this was not apparently valid in all cases [for example, in the reactions involving $CH_2(OH)COCH_2OH$, $CH_2(OH)CH(OH)CHO$, and $CH_2(OH)CHO$ in Tables 5 and 7]. Tables 1–7 also list the acid dissociation constants of the initial nucleophiles taken from Ref. 49. Furthermore, the values of $K_{A^+}$ are indicated for certain aminoacids in an acid medium; as mentioned above, they were assumed equal to the values of $K_{A^+}$ for the methyl or ethyl esters of the corresponding aminoacids [70–72].

*Measured by the iodometric method; in the remaining cases, the polarographic method was used.
**$L_{U^+}$.
***$L_{M^+} = 2.4 \times 10^5$ from Ref. 33.

The reproducibility of the equilibrium constants in various studies using polarographic and other methods is quite satisfactory in many instances: the reactions of formaldehyde with α-alanine and glycine (Table 2), with leucine and aspartic acid (Table 3), and dimethylamine (Table 6). On the other hand, in some cases it is so far

difficult to regard the constants as reproducible within one order of magnitude, this being particularly true of the equilibrium constants $L_D$ (Tables 2 and 3). The values of $L_M$ for reactions between RR'CO and $NH_3$ taken from Ogata and Kawasaki[59] (Table 2) are probably too high owing to failure to take into account, as suggested by Gaux and Le Henaff[38], the cyclisation of the adduct. The value of $L_M$ (Table 2) found from $L_{M^+}$ and $K_{M^+}$ for the reaction between formaldehyde and ammonia also appears too high[28]. However, the stoichiometry of the reactions in an acid medium, established by the present author and Cheremukhina[28], rules out the likelihood of the cyclisation of the adduct, particularly since one of the possible cyclisation products (hexamethylenetetramine) is polarographically inactive[73]. The hypothesis of the formation in the reaction between formaldehyde and $NH_4^+$ of a similar cyclisation product with several nitrogen atoms of type (2) or of hexamethylenetetramine must be rejected also because of the observation of two titration jumps corresponding to strong and weak ($pK_{A^+} \simeq 5$ for the reaction product) acids. On the other hand, one cannot assume the similarity of the $pK_{A^+}$ for several groups in the cyclisation product, protonated at the nitrogen atom, because of the strong inductive effect (for example $pK_{A^{2+}} = 5.57$ and $pK = 9.81$ for piperazine). However, the formation of mono-, bis-, and tris-hydroxymethyl derivatives of ammonia with similar $pK_{A^+}$ values in the range 4.3 to 4.5 in the reaction between formaldehyde and $NH_4^+$ [28] fully justifies the single-stage titration of the adducts as acids whose strength is close to that of acetic acid. Another possible factor causing an unduly high value of $L_M$(HCHO + $NH_3$) [25] is the formation of the dehydration product $NH{=}CH_2$ and not the adduct $NH_2CH_2OH$. However, the existence of $NH{=}CH_2$ in solution is hardly possible in an appreciable concentration owing to the marked tendency of this compound to cyclise[36]. The formation of the fairly stable cyclic hydrate

(29)

on the basis of the adduct appears more probable, which leads to an increase of $L_M$.

Other nucleophiles (Table 2) as well as other carbonyl compounds form less stable cyclic hydrates of type (29) owing to steric hindrance, and an anomalously high value of $L_M$ is therefore characteristic of such compounds (Table 2). This can also be said of the protonated form of the adduct, including the adduct obtained in the reaction between formaldehyde and $NH_4^+$.[28] The enhanced overall hydration of both the initial protonated nucleophile and of the protonated adduct under these conditions rules out a significant influence of the formation of the cyclic hydrate on $L_{M^+}$. The values of $L_{M^+}$ for the reaction between formaldehyde and $NH_4^+$ and other analogous reactions are therefore fairly comparable (Table 6). Admittedly, the cause of the lower values of $L_{M^+}$ for the reactions of formaldehyde with $\overset{+}{N}H_3CH_2COOH$ and $CH_3CH(\overset{+}{N}H_3)COOH$, taken from the study of Zhantalai and the present author[29], compared with the data of Feraud and Le Henaff[47] is not altogether clear, particularly since the values of $L_{M^+}$ in these studies are similar for the reactions involving valine (Table 6). It is noteworthy that the reliability of the data from Ref. 29 was also confirmed by kinetic measurements (Table 1).[24,29].

The relation between the reactivity and the nature of the carbonyl compound in reactions with the same nucleophile was considered on the basis of the Hammett equation (aromatic carbonyl compounds[67]) and the Taft equation (aliphatic carbonyl compounds[33,59]). An increase of the equilibrium constants with increase of the positive charge on the carbonyl carbon was demonstrated (Tables 2–7).

In the reactions of aliphatic carbonyl compounds with ammonia, primary amines, aminoalcohols, and amino-acids, the concentrations of the dehydration products U($U^+$) can usually be neglected. When aliphatic aldehydes are considered, the main cause of the low capacity of the adducts M($M^+$) formed under these conditions for dehydration is due to the overall electron-accepting effect of the substituents at the carbonyl group[4], which hinders the protonation of the oxygen of the hydroxy-group in M and even more so in the $M^+$ species protonated at the nitrogen atom. It would appear that aliphatic ketones should have led to a shift of the equilibrium towards dehydration products, which has in fact been suggested[8-13,63]. However, here too (probably owing to the insufficient electron-donating effect) the equilibrium involves the preferential formation of the adducts M($M^+$), as shown by a comparison with other equilibrium constants (Tables 2 and 6).

The values of $L_M$ and $L_U$ have been found separately[37] for the reactions involving $NH_2OH$. The higher values of $L_M$ for $NH_2OH$, $NH_2NHCONH_2$, and $NH_2NH_2$ compared with other nucleophiles are noteworthy, which has been explained[37] by the stabilisation of the adduct in the former case owing to an intramolecular hydrogen bond. The lower values under these conditions of $L_M$ for furfural and benzaldehyde (Table 5) are caused[37] by the conjugation of the carbonyl group and the aromatic ring. The influence of the intramolecular hydrogen bond in the initial carbonyl compound on the kinetics of reactions with $NH_2CH$ was noted by Knorre and Emanuel'.[74]

There are many reactions (Tables 5 and 7) where the equilibrium between M($M^+$) and U($U^+$) is almost completely displaced towards the dehydration product U($U^+$), which is characteristic of nucleophiles containing nitrogen or oxygen next to the $NH_2$ group (the compounds $NH_2NH_2$, $NH_2NHCONH_2$, and $NH_2OH$). In these reactions, with the exception of those between formaldehyde and $NH_2NH.CONH_2$ ($NH_2NH_2$, $\overset{+}{N}H_3NH_2$, $\overset{+}{N}H_3OH$),[26,32,33,52] the relation $L_U \gg L_M$ or $L_{U^+} \gg L_{M^+}$ holds (Tables 5 and 7). Under these conditions, the thermodynamic stabilisation of the dehydration products owing to the presence of conjugated systems in the latter apparently has the main influence[5,53]. The higher values of $L_U$ for furfural and benzaldehyde (Table 5) have been explained[37] by the additional stabilisation of the dehydration product as a result of the conjugation of the azomethine group with the aromatic ring. On the other hand, in the reactions of formaldehyde with $NH_2NHCONH_2$ ($NH_2NH_2$, $\overset{+}{N}H_3NH_2$, $\overset{+}{N}H_3OH$), the electron-accepting effect of the two hydrogen atoms at the carbon atom of the $CH_2OH$ group of the aminocarbinol to a large extent prevents the protonation of the oxygen in the hydroxy-group and hence hinders the dehydration of the aminocarbinol. For example, $L_U/L_M \simeq L_{U^+}/L_{M^+} = 0.31$ for $NH_2NH_2(\overset{+}{N}H_3NH_2)$.[33] Since the values of $L_M$ and $L_U$ may be expected to be similar also for the reaction of formaldehyde with $NH_2NHCONH_2$, the observed[52] equilibrium constant, which the authors[52] believed to be $L_M$, was included in Table 5 (see $L_U$).

The problem of the relation between reactivity and the nature of the nucleophile is more complex. Apart from the effects of the intramolecular hydrogen bond and conjugation discussed above ($NH_2NH_2$, $NH_2NHCONH_2$, $NH_2OH$), attention was directed[37] to the absence of any correlation between $L_M$($L_U$) and $K_{A^+}$ (Tables 2–7). Jencks[37] and Kallen and Jencks[39] explained the latter by the similarity

of the values of σ* for the hydrogen atom and the RR'COH group substituting it, as a result of which the polar effects of the substituents in the nucleophile should not influence $L_M(L_U)$ appreciably. This is the difference [39] between the reactions under consideration and those of carbonyl compounds with nucleophiles such as CH acids [75-77]. Nevertheless the problem of the role of the polar effect of substituents in nitrogen-containing nucleophiles is apparently more complex. Thus the relations $L_M \gg L_{M^+}$ and $L_U \gg L_{U^+}$ (Tables 2 and 7), the increase of $L_M$ [38,56] in the series of aminoacids $NH_2(CH_2)nCOO^-$ with increase of $n$, and the influence of the nature of the substituents in amides on the rates of reaction with formaldehyde [78] can be explained [38,78] by the polar effect. Furthermore, a distinct correlation between $L_{M^+}$ and $K_{A^+}$ (Table 6) and between $L_{M^+}$ and σ* for the substituent X in $\overset{+}{N}H_3X$ has been observed for several nucleophiles ($\overset{+}{N}H_4$, $\overset{+}{N}H_3CH_2COOH$, $\overset{+}{N}H_3OH$) with a primary amino-group in the protonated state [79]. For reasons which are obscure, $CH_3\overset{+}{N}H_3$ deviates significantly from this correlation (Table 6). Protonated secondary amines and also aminoacids of the type $H_3\overset{+}{N}(CH_2)nCOOH$ likewise failed to show a correlation between $L_{M^+}$ and $K_{A^+}$ (Table 6).

Sander and Jencks [52] obtained a correlation (also confirmed by Hine and Redding [80]) between the reactivity and the nature of the nucleophile using a set of constants expressing the ratios of the equilibrium constants for the given series to the equilibrium constant for a standard nucleophile (methylamine). However, these data are insufficient for reactions involving aliphatic carbonyl compounds, particularly since formaldehyde exhibits an appreciable deviation from the correlation [52].

The reactivity of the nucleophile depends appreciably on steric factors [36,38,39]. This is manifested in the series of aminoacids [36], for example, on passing from glycine to α-alanine, and also in the relation $L_{M^-} > L_{D^-}/L_{M^-}$ (Tables 2 and 3). It is noteworthy that the relation $L_{M^+} < L_{D^+}/L_{M^+}$ holds for protonated forms (Table 6), which is most probably due to the dominant influence of the decrease of the degree of hydration on passing from $A^+$ to $M^+$. However, the dominance of steric factors may also be expected for aminoacids ($L_{M^+} \gg L_{D^+}/L_{M^+}$), since the formation of $D^+$ could not be observed experimentally [29,47,56]. It has been noted [38] that the steric factors of nucleophiles are manifested to a lesser extent in the reactions of acetaldehyde compared with those of formaldehyde. Apparently for this reason we have $L_M < L_D/L_M(CH_3CHO)$ (Table 2).

On the basis of Eqns. (18)-(22) and using the equilibrium constants $L_M$, $L_U$, $L_{M^+}$, and $L_{U^+}$, the acid dissociation constants of adducts protonated at the nitrogen atom (Table 8) and of the dehydration products (Table 9) were found in a number of studies. Some of the results have been revised using the average equilibrium constants (when different equilibrium constants are quoted in the literature for the same reaction). Furthermore, Tables 8 and 9 present some of the results of direct measurements of $K_{M^+}$ and $K_{U^+}$. It is necessary to consider the considerable discrepancies between the results [54,67] (see $K_{U^+}$ for $C_6H_5CH{=}\overset{+}{N}NH_2CONH_2$; Table 9) and also the considerable variation of $K_{M^+}$ for the adduct obtained in the reaction between RR'CO and $\overset{+}{N}H_4$ as a function of the nature of the carbonyl compound (Table 8). In contrast to other nucleophiles, in the latter case the formation of a cyclic hydrate of type (29) and the sensitivity of this factor to the nature of the carbonyl residue (the steric effect) show a more significant influence; the sensitivity is lowest for formaldehyde. On the other hand, a somewhat low value of $K_{M^+}$ for $\overset{+}{N}H_3C(CH_3)_2CH$ was apparently found [12] (Table 8). Nucleophiles which themselves introduce an appreciable steric hindrance (for example α-aminoacids) form adducts for which the difference between the $K_{M^+}$ as a function of the nature of the carbonyl compound are small (Table 8). The dependence of $K_{U^+}$ for the dehydration product on the nature of the carbonyl compound (reactions with $NH_2NH_2$ and $\overset{+}{N}H_3NH_2$) is described by the Taft equation [33].

[a] Adjusted for $pK_{A^+} = 3.43$; [b] adjusted for $pK_{A^+} = 5.97$; [c] in methanol; [d] $pK_{A^+} = 8.19$ was used in Refs. 31, 33, and 35; here the values of $pK_{U^+}$ have been adjusted to $pK_{A^+} = 8.1$.

The main conclusion which can be drawn from Tables 8 and 9 is the occurrence of the relations $K_{M^+} \gg K_{A^+}$ and $K_{U^+} \gg K_{A^+}$, which is very important for the acid–base titration of the reaction products [6,7]. Under these conditions, $K_{M^+}$ ($K_{M^\pm}$) is greater by 1.5–3.0 orders of magnitude than $K_{A^+}$ ($K_{A^\pm}$), while $K_{U^+}$ is greater than $K_{A^+}$ by 2.0–4.0 orders of magnitude. Whereas the higher values of $K_{U^+}$ compared with $K_{A^+}$ can be readily explained (by the polar effect of the azomethine group), the reason for the appreciably higher values of $K_{M^+}$($K_{M^\pm}$) is still insufficiently clear, because, as stated by Kallen and Jencks [39], polar effects do not change very greatly when the hydrogen atom is replaced by the C(OH)RR′ group. The above authors' hypothesis of the significant role in this case of the common hydration factor is quite justified (by analogy with amines [82]), but the formation under these conditions of a cyclic hydrate of type (29), particularly for the adduct involving HCHO and $NH_4^+$, which causes an additional enhancement of the acid function of the protonated nitrogen, is probably also important. Aminocarbinols where the amino-group is not in the 1-position apparently form less stable hydrates (with more than 6 units) and the role of this factor is reduced. Naturally, the direct electron-accepting effect of the R″C(OH)RR′ group in such aminocarbinols is less pronounced, which also reduces their acid properties.

## III. THE MECHANISM OF THE POLAROGRAPHIC REDUCTION OF REACTION PRODUCTS

The mechanism of the reduction of the dehydration products (hydrazones, oximes, etc.) has been investigated in greater detail (Lund [83,84], Kitaev and coworkers [85–87]). This mechanism was recently considered in Kitaev and Buzykin's review [88] and will be only briefly described in the present review, with the exception of the problem of the kinetics of the limiting current which has not been dealt with adequately. The possible mechanisms of the electrochemical reduction of adducts (aminocarbinols) have been considered in the literature in less detail, particularly since their reduction via the formation of the usual dehydration product U (the adduct of a nucleophile with a secondary or tertiary amino-group) is frequently ruled out.

As stated in Section II, the presence of conjugated systems [5] is characteristic of the dehydration product U having the structure RR′C=NYR″, where Y is either a nitrogen atom (hydrazones) or an oxygen atom (oximes), which, together with protonation, facilitates the dissociation of the N–Y bond during their reduction. Under these conditions, four-electron reduction is usually observed in an acid solution [83–87]:

$$\begin{aligned} RR'C{=}N{-}YR'' \xrightarrow{H^+} (RR'C{=}N{-}YR'')^+ H \xrightarrow{2\bar{e};2H^+} \\ \rightarrow R''YH + RR'C{=}\overset{+}{N}H_2 \xrightarrow{2\bar{e};2H^+} RR'CH\overset{+}{N}H_3. \end{aligned} \qquad (30)$$

It has recently been shown [34] that unsubstituted hydrazones of aliphatic carbonyl compounds also undergo a four-electron reduction reaction at pH ≤ 8. Since hydrazones of this kind are to a large extent hydrolysed, a microcoulometric study has been carried out [34] in the presence of a very large excess of hydrazine.

If Y is a carbon atom in the compounds RR′C=NYR″ (azomethines), only the double bond is reduced (a two-electron process) [83]:

$$RR'C{=}NYR'' \xrightarrow{2\bar{e};\,2H_2O} RR'CHNHYR'' + 2OH^-. \qquad (31)$$

The mechanism of the generation of the kinetic limiting current in the reduction of hydrazones when the solution contains the corresponding adducts has been considered [34] on the basis of the scheme

$$\begin{array}{ccccc} M & \xrightarrow{\text{diff.}} & M & & \\ \uparrow\downarrow & & \uparrow\downarrow k'_{-1}\ k'_{+1} & & \\ & & H^+;\,k''_{+1} & & \\ U & \xrightarrow[\text{diff.}]{} & U & \underset{k''_{-1}}{\rightleftharpoons} & U^+ \xrightarrow{\text{red.}} \end{array}, \qquad (32)$$

which takes into account both the slow protonation of U and the slow dehydration of M. A kinetic equation has been derived (in the presence of a large excess of the nucleophile when virtually the entire carbonyl compound is converted into M and U): [34]

$$\lg \frac{\bar{i}^0_{lim}}{(\bar{i}^0_{lim})_d - \bar{i}^0_{lim}} = \lg \frac{k''_{+1}[k'_{+1}(L_M + L_U) + \bar{\varkappa} L_U]}{\bar{\varkappa}\,(k'_{+1}(L_{M^+}L_U) + (k'_{-1} + \bar{\varkappa})(L_M + L_U) + k''_{+1}L_M[H^+]\}} - pH, \qquad (33)$$

where $(\bar{i}^0_{lim})_d$ is the limiting diffusion current and $\bar{\varkappa}$ is the Ilkovič constant. Since under these conditions $k'_{-1} \gg k'_{+1}[H^+]$ and $k'_{-1} \gg \bar{\varkappa}$ or $k'_{-1} \gg k''_{+1}[H^+]$ and $k'_{+1} \gg \bar{\varkappa}$ (enhancement of base catalysis at the hydration–dehydration stages) [89,90], Eqn.(33) assumes the following form [34] with increase of pH ($L_U/L_M = k'_{+1}/k'_{-1}$):

$$\lg \frac{\bar{i}^0_{lim}}{(\bar{i}^0_{lim})_d - \bar{i}^0_{lim}} = \lg \frac{k''_{+1}\,L_U}{\bar{\varkappa}\,(L_M + L_U)} - pH; \qquad (34)$$

when $L_U \gg L_M$, whereupon the dehydration product predominates {[U] ≫ [M]}, we obtain

$$\lg \frac{\bar{i}^0_{lim}}{(\bar{i}^0_{lim})_d - \bar{i}^0_{lim}} = \lg \frac{k''_{+1}}{\bar{\varkappa}} - pH. \qquad (35)$$

It is noteworthy that Eqns.(33)–(35) are applicable to both bulk-phase and surface protonation processes [91] when the Henry adsorption isotherm holds. Eqns.(34) and (35) correspond to mechanism (32) with a fairly rapid adduct dehydration stage. Here kinetic inhibition is due solely to the stage involving the protonation of the dehydration product U.

Eqn.(33) has been confirmed [34] for the reduction of the products of the reaction of formaldehyde with $NH_2NH_2$. .($\overset{+}{N}H_3NH_2$) in the pH range 5.5–8.0. Thus formaldehyde hydrazone is reduced even in the acid pH range with considerable kinetic limitation owing to the slow dehydration of the adduct present in a considerable amount (Table 5). With increase of pH, the retardation of the process at the protonation stage was also observed. This inhibition predominated at pH ≥ 7.0 [see Eqn.(34)]. [34] Since the concentration of the adduct was extremely low, the limiting current for the hydrazones of other aliphatic carbonyl compounds at pH ≤ 6.5 had a diffusional origin, while at pH > 6.5–7.0 kinetic process inhibition, due to the retardation of the stage involving the protonation of the dehydration product, was manifested. The applicability of the usual equation for the polarographic dissociation curve [Eqn.(35)] to these hydrazones has been demonstrated [34], this being characteristic also of thiosemicarbazones [92].

In order to find the true rate constants from Eqns. (33)–(35), the Koutecký equation has been used [34,92]. For the formaldehyde adduct, the true dehydration rate constant $k' = 0.4\ s^{-1}$ at pH ~ 6, which is close to the result obtained from a chronopotentiometric study [93]. The rate constants for the protonation reaction are listed in Table 10. Surface protonation [34,87,91,92] with participation of adsorbed species is characteristic of the majority of these compounds, as shown by the unduly high rate constants (Table 10). The rate constant for the bulk-phase process may have been

found only for the anions of levulinic acid owing to the insignificant adsorption of the hydrazone anion at $E = -1.3 - -1.6$ V (here and henceforth potentials relative to the normal calomel electrode are quoted) (Table 10). Surface protonation is also characteristic of oximes [94]. The semicarbazonium ion may participate in the protonation reaction [95,96].

Table 10. The true ($K_{U^+}$) and apparent (polarographic) ($K'_{U^+}$) acid dissociation constants of the dehydration products and the rate constants $k$ (based on the Koutecky equation with a coefficient of 0.886) for their protonation at 25°C.

[a] The dropping period of the dropping mercury electrode was $t_1 = 3.0$ s; [b] Eqn.(34), $L_M = 1.9 \times 10^9$ and $L_U = 5.8 \times 10^8$ (Table 5).

The plot of $\bar{i}_{lim}$ against pH for the limiting current corresponding to the equilibrium $Q + A(A^+) \rightleftharpoons M(M^+) \rightleftharpoons U(U^+)$ passes [30,34] through a maximum, which has been explained [30,34], on the one hand, by the increase of the concentration of the reaction products with increasing pH (because $L_M \gg L_{M^+}$ and $L_U \gg L_{U^+}$) and, on the other hand, by the opposed effect due to the enhancement of inhibition at the product U protonation stage. The calculated $\bar{i}_{lim}$–pH curves obtained with the aid of Eqn.(23) (for $c_A \gg c_Q$) are close to the experimental curves [34]. Expressions have also been found [34] for $pH_{max}$ {subject to the condition $d\bar{i}_{lim}/d[H^+] = 0$} at which $\bar{i}_{lim}$ reached a maximum value. The expression for $pH_{max}$ corresponding to reactions involving the appreciable formation of M (formaldehyde) together with U is [34]

$$pH_{max} = -\frac{1}{2} \lg \frac{(L_M + L_U)(k'_{+1} + k'_{-1} + \bar{\varkappa})\bar{\varkappa} c_A}{k''_{+1}(k'_{+1} + \bar{\varkappa})(1 + L_G)}. \quad (36)$$

The following expression has been obtained for reactions where the concentration of M compared with U may be neglected [34]:

$$pH_{max} = -\frac{1}{2} \lg \frac{K_{A+}(1 + L_G + c_A L_U)\bar{\varkappa}}{k''_{+1}(1 + L_G)}. \quad (37)$$

The values of $pH_{max}$ have been calculated [34] with the aid of Eqns.(36) and (37) and the maximum limiting currents $(\bar{i}_{lim})_{max}$ have been obtained with the aid of Eqn.(22) for $c_A \gg c_Q$ using the values of $\bar{i}^0_{lim}$ and $[H^+]_{max}$. $pH_{max}$ and $(\bar{i}_{lim})_{max}$ are close to the experimental values for a series of hydrazones (Table 11) (the values of $L_G$ were taken from Tables 2–7).

The influence of the nature of the hydrazones of aliphatic carbonyl compounds on the half-wave potential $E_{1/2}$ is determined to a large extent (Table 12) by the inductive effects of the substituents in the carbonyl compound, as shown by the shift of $E_{1/2}$ towards negative values with increase of the electron-donating effect of the substituents. A similar conclusion follows also from the correlation analysis of the half-wave potentials for many other compounds with the azomethine group [97]. With the exception of formaldehyde hydrazone, the limiting current constants in the acid pH range (Table 12) correspond to a diffusion process.

Table 11. Comparison of the experimental and calculated values of $pH_{max}$ and $(\bar{i}_{lim})_{max}$ [34] ($c_Q = 1.0 \times 10^{-4}$ M; $c_A = 1.0 \times 10^{-3}$ M).

Data from Ref. 35; in the remaining cases, data from Ref. 93 were used.

We shall now proceed to the consideration of the mechanism of the polarographic reduction of adducts–aminocarbinols. For the formation of aminocarbinols with participation of formaldehyde, Matoušek [22] proposed a mechanism involving the reduction of the adduct M with dissociation of the C–O bond (first wave):

$$\text{>NCH}_2\text{OH} \xrightarrow{H^+} \text{>NCH}_2\overset{+}{\text{O}}\text{H} \rightarrow H_2O + \text{>N}\overset{+}{\text{C}}\text{H}_2 \xrightarrow{2\bar{e};\ H^+} \text{>NCH}_3, \quad (38)$$

and reduction with dissociation of the N–C bond (second wave, which coincides with the formaldehyde reduction wave):

$$\text{>NCH}_2\text{OH} \xrightarrow{H^+} \text{>N}\overset{+}{\text{H}}\text{CH}_2\text{OH} \rightarrow \text{>NH} + \overset{+}{\text{C}}\text{H}_2\text{OH} \xrightarrow{2\bar{e};\ H^+} CH_3OH. \quad (39)$$

These mechanisms are based [22] on data concerning the nature of the chemical reduction of the corresponding hydroxymethyl derivatives and also pulse volt-amperometric data at different frequencies. In addition to reaction (38), attention should also be directed to the possibility of the intermediate formation and reduction of an ammonium derivative:

$$\text{>NCH}_2\text{OH} \xrightarrow{H^+} \text{>NCH}_2\overset{+}{\text{O}}\text{H} \rightarrow H_2O + \text{>}\overset{+}{\text{N}}\text{=CH}_2 \xrightarrow{2\bar{e};\ H^+} \text{>NCH}_3. \quad (40)$$

The occurrence of a two-electron process of type (38) or (40) was demonstrated[26] by a microcoulometric study of the sum of the products of the reaction between formaldehyde and $\overset{+}{N}H_3OH$. Since this reaction gives rise[26] to the mono- and bis-hydroxymethyl derivatives $HO\overset{+}{N}H_2.CH_2OH$ and $HO\overset{+}{N}H(CH_2OH)_2$, the reduction of only one hydroxymethyl group in both the mono- and bis-hydroxymethyl derivative should correspond to the two-electron process:

$$HO\overset{+}{N}H(CH_2OH)_2 \xrightarrow{H^+} HO\overset{+}{N}H(CH_2OH)\,CH_2\overset{+}{O}H \rightarrow H_2O + HO\overset{+}{N}H(CH_2OH)\,\overset{+}{C}H_2 \xrightarrow{2e;H^+} \rightarrow HO\overset{+}{N}H(CH_2OH)\,CH_3. \quad (41)$$

This is most probably associated with the fact that there is insufficient time for the product of the two-electron reduction, namely $HO\overset{+}{N}H(CH_2OH)CH_3$ to undergo a repeated dehydration stage with further reduction at the electrode surface.

Presumably the reduction with dissociation of the C–O bond [reaction (38)] or the C–N bond [reaction (39)] is activated by the formation of a six-membered cyclic hydrate of type (29). Although protonation is inhibited under these conditions, the enhancement of the mutual inductive effect of the RR'N and OH groups facilitates the reduction. This probably constitutes the main difference in the electrochemical behaviour of aminocarbinols with the amino-group in the 1-position compared with other aminocarbinols, which are incapable of being electrochemically reduced.

In an acid medium (pH ≤ 2), where the adduct M(D, T) is almost completely protonated at the nitrogen atom, the dehydration stage preceding the electrochemical reduction process is either catalysed by repeated protonation (at the oxygen atom[24]) or there is intramolecular catalysis owing to a hydrogen bond:

$$RR'C(HO\cdots H)-N^+HX \rightleftarrows RR'C(HO-H^+)-NHX. \quad (42)$$

Since the limiting kinetic current is independent of pH in this range of the latter for many hydroxymethyl derivatives of aminoacids[24], intramolecular catalysis appears to be more likely. The independence of $\bar{i}$lim of pH in fairly acid solutions also shows that the kinetic current is caused by inhibition at the dehydration stage [mechanism (38)],[22] while the stage involving the protonation of the oxygen atom [mechanism (42)] is fairly rapid (is close to equilibrium). The nature of the substituent X in the nucleophiles (Table 1) has an effect under these conditions, manifested mainly by displacement of equilibrium (42) [the distance from the dissociating $C-\overset{+}{C}$ bond than in the decomposition of the adduct into the initial substances is greater]. An increase of the $-I$ effect of the substituent X (the inductive and steric influences) as well as an increase of the $+I$ effect (the dominance of steric influences) displaces equilibrium (42) to the right; hence follows an increase of $\bar{i}$lim and its correlation with the constants $k_{-1}$ and $K'_{A^+}$ (Table 1). Starting with norvaline, $\bar{i}$lim approaches the diffusion value (Table 1).

Over a wide range of pH values with $c_Q$ = const. and $c_A$ = const., $\bar{i}$lim passes through a maximum as a function of pH,[22,28,73,95,96,98-101] as in the reduction of semicarbazones[30] and hydrazones[34] in an equilibrium mixture. This is caused by the increase of the concentrations of the adducts ($L_M \gg L_{M^+}$, $L_D \gg L_{D^+}$, $L_T \gg L_{T^+}$) with increasing pH, the opposite effect due to the decrease of the concentrations of the forms of the adducts protonated at the nitrogen atom, and inhibition either at stage (42) or at the stage involving the protonation of the adduct at the nitrogen atom. The occurrence of one of the above inhibiting effects with increasing pH is indicated by the confirmation of the validity[28] of Eqn.(35) for the reduction of M + D + T (for the reaction of formaldehyde with $NH_4^+$). Under these conditions, the $\bar{i}$lim–pH curve is described by Eqn.(26) when account is taken of Eqn.(35). As for hydrazones[34], $pH_{max}$ was found from the condition $d\bar{i}lim/d[H^+] = 0$ [28] and it was shown theoretically that $pH_{max}$ should shift towards lower pH values with increasing $c_Q$, which agrees with experimental data[99]. This is also characteristic[100] of the adducts obtained by the reaction of formaldehyde with aminoacids (Table 13). In the presence of a not unduly large excess of formaldehyde, the changes in $(\bar{i}lim)_{max}$ and in $E_{1/2}$ at a constant pH (Table 13) are caused mainly by the inductive and steric effects of substituents in similar (α- or β-) aminoacids, which leads to a correlation between $(\bar{i}lim)_{max}$ and $E_{1/2}$ and between $K_{A\pm}$ and $K_{M\pm}$ (Table 13). The influence of the inductive effect on $E_{1/2}$ at a constant pH (the displacement of $E_{1/2}$ towards positive values with increasing $-I$ effect) is also illustrated by the data in Table 14.

## IV. ANALYTICAL APPLICATIONS

The reactions under consideration are widely used for the indirect polarographic determination of carbonyl and nitrogen compounds. Distinct polarographic waves are observed, while under the usual conditions the reduction of many compounds is either partly or fully masked by the discharge of the supporting electrolyte. This applies particularly to nitrogen compounds and many aliphatic and cyclic carbonyl compounds. Even when the carbonyl compound is reduced relatively readily (formaldehyde, etc.), a valuable feature of the reaction is that the reduction wave of the product M(D, T) or U occurs at potentials much more positive than the reduction potentials of the carbonyl compounds, which makes it possible to use a large excess of the latter and hence increase the sensitivity of the determination of the nitrogen compounds. On the other hand, in the determination of the carbonyl compounds, a large excess of the nitrogen compound (ammonia, semicarbazide, hydrazine, etc.) is also permissible, because the nucleophile employed is frequently polarographically completely inactive under the given conditions.

It must be emphasised that, in the selection of the concentration of the reactant, one need not endeavour to ensure the complete conversion of the component being analysed into the polarographed product. It is sufficient to obtain an equilibrium mixture, because the limiting current in the presence of an excess of the reactant at a constant concentration of the latter and a constant pH is proportional to the concentration of the substance analysed [Eqns. (25) and (26)]. Naturally, in the analysis it is important to achieve reaction equilibrium rapidly, which is usually done by selecting the optimum pH in the solution. For this purpose and also in order to increase the sensitivity of the determination of the carbonyl compound, a supporting electrolyte buffer solution was used with a pH close to the $pK_{A^+}$ of the nucleophile present in excess [8,12,13]. The optimum pH of the supporting electrolyte corresponding to the maximum limiting current is frequently selected for analysis [98-101]. In order to attain equilibrium rapidly and increase the sensitivity of the determination, the reaction has been carried out [102,103] in an alkaline medium and the polarographic measurements have been made in an acid solution. This method is suitable only when the reaction products are very slowly decomposed in the acid solution into the initial substances (aminoacids with the amino-group not in the $\alpha$-position) [24,102,103]. It has been shown [104] that the rate of equilibration in the carbonyl–amine interaction increases sharply in anhydrous acetic acid, which is probably due mainly to catalytic factors.

The selectivity of the methods is achieved either by selecting appropriate reagents (*N*-alkylhydroxylamines [105], hydrazine [106]) or by altering the pH of the supporting electrolyte [107,108].

From the analytical point of view, it is also important that, with the aid of the reactions under consideration, it is possible to trap easily the component analysed in the gas phase [109,110] or extract it fairly completely from a non-aqueous solution [106,111]. One should also note that suitable direct analytical reactions with carbonyl compounds have not been found for many nitrogen compounds [51,73,98,102,112-117], because of their weak nucleophilic properties, so that it has been suggested (see below) that the nitrogen compounds be subjected to preliminary hydrolysis with subsequent conversion of the hydrolysis products in the presence of the carbonyl compound into the polarographed substances. Preliminary hydrolysis has also been used [118] for vinyl acetate with conversion of the resulting acetaldehyde (reaction with hexamethylene-1,6-diamine) into the polarographed product. The conversion of organic nitrogen compounds into the inorganic ammonium ion with its subsequent polarographic determination in the presence of formaldehyde has been achieved [119] in order to improve the familiar Kjeldahl method. The nitrogen-containing reagent (an aminoacid) to be used for the determination of a carbonyl compound has been obtained [120] by the hydrolysis of the substance to be analysed—polycaproamide.

Analytical determinations are usually based on cathodic waves, but anodic waves for the products of the interaction of carbonyl compounds with *o*-phenylenediamine have also been used [121-124].

### 1. Determination of Carbonyl Compounds

Reactions with Girard reagents (the formation of hydrazones) have been used [101,125-132] to determine aliphatic and cyclic ketones, ketosteroids, terpenes, and other carbonyl compounds. Analytical reactions belonging to an analogous class have been carried out on the basis of hydrazine [15,21,106,114,133-142], phenylhydrazine [143], semicarbazide [17,21,109,110,144-150], maleic acid monohydrazide [151], aminoguanidine [151], and 2,4-dinitrophenylhydrazine [152-155] (either an excess of the reagent [153] was determined [153,154] or an amperometric titration was carried out [154]). It is noteworthy that, whereas the use of hydrazine for the determination of aliphatic carbonyl compounds was unsuccessful owing to the use of an unduly acid supporting electrolyte [133] (in contrast to the determination of sugars [134]), starting with the work of Baranova et al. [114] and Yuan-Hsiao Lin and Chen-Ya Wang [135] the problem has been solved successfully (determination of carbonyl compounds in the wash water from the manufacture of isoprene [114] and determination of acetone in vinyl acetate [135]; supporting electrolytes at pH 6.3 [114] and 7.2 [135] have been used).

This application has been developed in other investigations [106,136-142] and included the separate determination of a series of aliphatic aldehydes and ketones in the manufacture of synthetic rubber monomers [106,136,139], formaldehyde has been determined in cellulose ethers [140,141], and a highly sensitive method has been developed for the determination of acetaldehyde in commercial ethanol without the need for the preliminary concentration (distillation) of the former [142]. The use [156] of reactions based on semicarbazide, thiosemicarbazide, and phenylhydrazine for the adsorption concentration of aliphatic and aromatic aldehydes on a stationary mercury drop, which permitted an appreciable increase of the sensitivity of the determination (oscillographic polarography), is of interest. An increase of the sensitivity of the determination with the aid of similar reagents has also been achieved by using oscillographic difference polarography [157].

The reactions with hydroxylamine and its alkyl derivatives (the formation of oximes) have been used for the polarographic determination of carbonyl compounds: the determination of aliphatic aldehydes [105], aldoses [21,144], pyridoxals [158], vanillin [159,160], furfural [161,162], crotonaldehyde [163], and acetone [164].

The reactions with ammonia [8,12,13,165-167], glycine [8,12,13,168], methylamine [13], n-butylamine [20], isobutylamine [124], ethylenediamine [169], 1,6-hexamethylenediamine [118,169-172], monoethanolamine [73,173], and *o*-phenylenediamine [121,124,174-178] are also of definite importance in the polarographic determination of carbonyl compounds. Nevertheless, in many cases preference must be given to substituted and

unsubstituted hydrazines and hydroxylamines as reagents because of the much larger reaction equilibrium constant (see Section II).

## 2. Determination of Nitrogen Compounds

The possibility, in principle, of the polarographic determination of an aminoacid on the basis of its reactions with pyruvic acid or acetone was already demonstrated in earlier investigations [11,12]. Subsequently methods were developed for the determination of methylamine in the presence of dimethylamine (reaction with piperonal) [179], aminoacids and ammonium ions (reactions with phthalic anhydride) [180,181], hydrazine and its derivatives (reactions with benzaldehyde) [182], and primary amines (reaction with isobutyraldehyde) [183].

Starting with the work of Matoušek [22] and Tur'yan and coworkers [38,102], formaldehyde has found extensive applications as a reagent in the indirect polarography of nitrogen compounds. It is used to determine aminoacids [98,100,102,103,107,108,184,185], caprolactam [98,102,103,186,187] (hydrolysis to $\epsilon$-aminocaproic acid), $N$-methylpyrrolidinone [116] (hydrolysis to $N$-methylaminobutyric acid), ammonium ions [28,99,108,119,188], hexamethylenetetramine [73,113] (hydrolysis to ammonium ions, but is can also be determined from the formaldehyde formed—reaction with monoethanolamine [73])†, acetonitrile [40,115] (hydrolysis to ammonium ions), primary and secondary amines [40,114,190-195], dimethylformamide [40,114] (hydrolysis to methylamine), hydroxylamine [26,51,196,197], cyclohexanone oxime [26,51,112,197] and other oximes [117] (hydrolysis to hydroxylamine), hydrazine, and formylhydrazine [138]. The successful employment of formaldehyde is due, firstly, to the high equilibrium constants for the reactions (Section II) combined with the possibility of creating a relatively high concentration of the reagent in the supporting electrolyte and, secondly, the fact that, in the presence of an excess of formaldehyde, several polarographically active products are formed (in the general case, mono-, bis-, and tris-hydroxymethyl derivatives), which also increases the sensitivity of the methods. Even in a very acid medium, where the nucleophile is almost completely protonated, formaldehyde behaves as a fairly active reagent [26,51,112,196].

Certain nitrogen compounds (diamines [198,199], hydrazine and its derivatives [200], semicarbazide [200], and hydrazides [201,202]) have been determined successfully using acetone as the reagent. Other carbonyl compounds have also been employed to determine hydrazides [203-205] and thiosemicarbazides [206].

The determination of 2,2'-bis-(3-amino-4-hydroxyphenyl)propane in polymers on the basis of its reaction with benzaldehyde has been reported [207].

# Arynes and Carbenes Derived from Organoelement Compounds

O.M.Nefedov, A.I.D'yachenko, and A.K.Prokof'ev

The literature data on the methods for the synthesis of unstable intermediate species (arynes and carbenes) from organoelement compounds, mainly from *o*- and α-halogeno-derivatives, are surveyed and examined critically. It is shown that the ease of decomposition of the initial compound is determined by the possibility of the formation in the transition state of the coordinate bond between the groups or atoms eliminated and the theoretical proof of this mechanism is given. The bibliography includes 322 references.

## I. INTRODUCTION

The chemistry of the reactive molecules having two electrons and two non-bonding orbitals in one carbon atom (carbenes) or two electrons and two weakly bonding orbitals in neighbouring carbon atoms (arynes, cycloalkynes) has been recently transformed into an independent field of organic chemistry, the development of which has been reflected in a number of monographs[1-6] and reviews[7-9]. Organoelement compounds, which are important and sometimes the only precursors of many of the above unstable species, play an extremely important role in the chemistry of arenes and carbenes.

The aim of this review is to survey the available literature data on the decomposition reactions of organoelement compounds which result in the formation of arynes and carbenes. Since the methods of generation of the unstable species from organic derivatives of alkali metals, magnesium, zinc, and mercury have already been considered in detail in fundamental monographs[2-6] and reviews[7-9], the present review includes only the main achievements in this field, and also the results obtained in recent years (1968–1974). The data on the organic derivatives of other metals are treated in detail. For a more complete understanding of the available results, the review presents the fundamental information about the structures and reactivities of dehydrobenzene (DHB) and carbene.

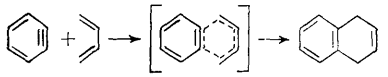
## II. THE STRUCTURE AND REACTIVITY OF DEHYDROBENZENE (DHB)

DHB (I), postulated for the first time by Wittig in 1942[10] as an unstable intermediate in the reaction of fluorobenzene with phenyl-lithium, is the simplest aromatic hydrocarbon, one of the C–C linkages of which is formally a triple bond:

(I) *S* *A* (II)

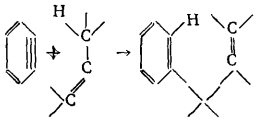
The steric strain arising following the introduction of a triple bond into the rigid aromatic system of benzene is responsible for such a high reactivity that DHB, like other arynes, is a short-lived intermediate product under the conditions of the usual chemical reactions, the involvement of which in the reaction is usually inferred from various indirect features. However, as a result of the application of special methods to the investigation of unstable species, it has become possible to achieve the direct spectroscopic detection of DHB. Thus the ultraviolet and mass spectra of DHB, recorded using flash photolysis, have now been investigated[11-13], and the infrared spectrum of DHB stabilised in a solid argon matrix has been described[14]. The possibility of the stabilisation of DHB by chemical methods has been demonstrated by synthesising a stable complex with nickel carbonyl[15]. The observed spectroscopic characteristics of DHB agree with the theoretical ideas about structure and thus provide the final evidence for the actual existence of arynes.

Qualitative ideas about the electronic structure of DHB can be readily derived by considering the results of the hypothetical reaction involving the homolytic dehydrogenation of benzene. Evidently, when the $H_2$ molecule is abstracted from neighbouring carbon atoms in benzene, the residual fragment $C_6H_4$ must have a pair of degenerate hybrid σ orbitals ($\sigma_1$ and $\sigma_2$) in which two electrons are accommodated. The interorbital interaction between $\sigma_1$ and $\sigma_2$ removes the degeneracy, leading to a pair of molecular orbitals (MO), the lower orbital (*S*), of the type $\sigma_1 + \sigma_2$, being symmetrical relative to the $C_2$ axis and the upper orbital (*A*), of the type $\sigma_1 - \sigma_2$, being antisymmetric. Depending on the relation between the energy of repulsion of the electrons in the *S* orbital and the energy of the promotion of an electron from *S* to *A*, the ground state of DHB can be either the singlet $c_1(S)^2 + c_2(A)^2$ ($c_1 > c_2 \geq 0$) or the triplet $(S)^1(A)^1$. Naturally, when only qualitative hypotheses are used, it is impossible to assign correctly the ground and first excited states, although one must bear in mind that, for orbitals of the type $\sigma_1 + \sigma_2$, the electron correlation energy is small ($\leq 1$ eV) and the splitting between the *S* and *A* levels is considerable, despite the rigidity of the ring. On the other hand, it is already clear from the above discussion that the structure of the dipolar ion (II), frequently discussed when the reactivity of DHB is described, cannot correspond either to the ground or to the first excited state of the molecule.



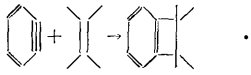
Theoretical calculations on DHB using modern quantum-chemical methods have shown that the molecule has a singlet ground state. Thus, according to calculations based on the extended Hückel method (EHM),[16] the energy of the singlet–triplet splitting ($E_{ST}$) is 35 kcal mole$^{-1}$ for the DHB molecule, the skeleton of which has the geometry of the benzene molecule. The use for the calculation on the DHB molecule of the semi-empirical SCF INDO/2 method, assuming the same geometry, led accordingly to a lower value of $E_{ST}$ (12.5 kcal mole$^{-1}$), although a somewhat higher value (20 kcal mole$^{-1}$) has been postulated for the real molecule[17]. Calculation on the molecule with the same non-equilibrium geometry by the semiempirical LCAO-MO SCF method led to $E_{ST}$ = 17 ± 5 kcal mole$^{-1}$ and the calculated parameters of the ultraviolet spectrum obtained in the same study[18] agreed satisfactorily with the experimental data[12].

The optimum geometrical parameters of the DHB molecule have been calculated by the MINDO/2[19] and MINDO/3 methods taking into account the configuration interaction[20]. According to these calculations, the molecule has the shape of an irregular hexagon with a markedly shortened distance between the C$_{(1)}$ and C$_{(2)}$ atoms; the bond lengths calculated by the two methods are in satisfactory agreement: $r_{1-2}$ = 1.256, $r_{2-3}$ = 1.344, $r_{3-4}$ = 1.399, and $r_{4-5}$ = 1.402 Å in the first set[19] and $r_{1-2}$ = 1.291, $r_{2-3}$ = 1.384, $r_{3-4}$ = 1.417, and $r_{4-5}$ = 1.419 Å in the second set[20]. One should note that the heat of formation of DHB (114.3 kcal mole$^{-1}$),[20] calculated by the most effective of the modern semiempirical methods (SCF MINDO/3), agrees extremely well with the experimental value 118 ± 5 kcal mole$^{-1}$,[21] which suggests that the geometrical and energetic parameters found for the molecule by Dewar and Li[20] ($E_{ST}$ = 12.4 kcal mole$^{-1}$, ionisation potential of 8.5 eV) are close to the real values. The low value of $E_{ST}$ is indicated by the extremely rapid conversion of the triplet DHB molecule into the singlet molecule[22].

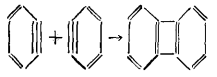


Thus, according to quantum-chemical calculations, the DHB molecule, which is in the singlet ground state, is characterised by a high energy of the highest occupied molecular orbital (HOMO), which is unique for hydrocarbons, and a low energy of the lowest vacant molecular orbitals (LVMO), the boundary orbitals being centred between the C$_{(1)}$ and C$_{(2)}$ atoms and being formed from weakly overlapping σ orbitals of the two atoms. As a consequence of this, the molecule should exhibit a high electrophilic reactivity in relation to unsaturated systems and also an ability to enter into reactions characteristic of both singlet biradicals and unsaturated compounds.

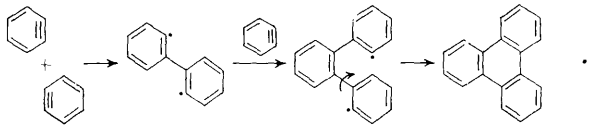
The available data on the reactivity of DHB are fully consistent with this conclusion: it readily reacts as a dienophile in the Diels–Alder reaction, enters into many other cycloaddition reactions, and is capable of being inserted into single C–H, C–metal, and other bonds[2,3].



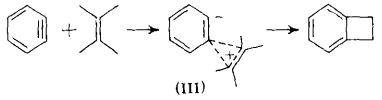
The mechanism of the interaction of DHB with planar conjugated *cis*-dienes is consistent with a concerted 2*s* + 4*s* cycloaddition reaction[23-25]:



The reaction involving the 1,4-cycloaddition of DHB to aromatic systems proceeds via the same mechanism[26]. The above reactions with non-planar cyclic polyenes, for which the 2*s* + 4*s* cycloaddition reactions are not so energetically favourable, compete with the so called ene addition[27,28], which is also characteristic of the reactions of DHB with olefins:

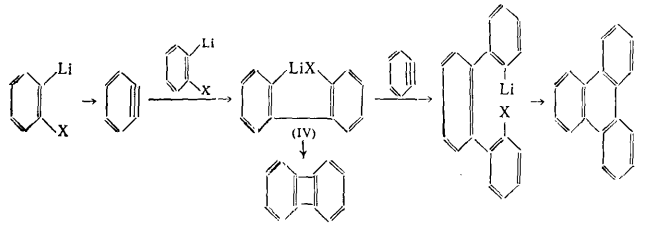


The simultaneous formation of benzocyclobutene is also usually observed under these conditions:



Judging from the dependence of its stereoselectivity on the nature of the olefin[24,25,29], this reaction can proceed as concerted 2*s* + 2*s* cycloaddition when $E_{ST}$ for the transition state is small[30]. In view of the evidently low value of $E_{ST}$ for the transition state, this mechanism should also operate in the dimerisation of DHB to biphenylene, which is usually formed as the main product in the gas-phase generation of DHB[2]:

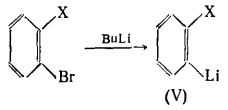
The formation of terphenylene—another product of these reactions—proceeds either via the concerted 2*s* + 2*s* + 2*s* cycloaddition or, more probably, via a stepwise biradical process due to the transoid approach of the reactants:



Analogous cyclodimerisation and cyclotrimerisation reactions are characteristic of cycloalkynes[31,32], and higher cycloalka-1,2-dienes[34], which also have a singlet ground state[35]. In the absence of acceptors, cyclohexa-1,2-diene in the triplet ground state[35] forms a tetramer[36]. According to calculated data[37], the addition of DHB to ethylene can proceed with the intermediate formation of a dipolar phenonium ion (III):

(III)

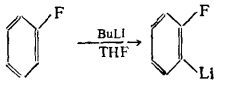
During its generation from organometallic compounds, DHB is readily inserted in the C–metal bond of the initial compound, which also leads to biphenylene and terphenylene, but naturally via a different pathway:



(IV)

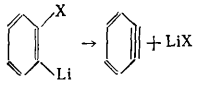
In contrast to the majority of thermolytic gas-phase reactions, the main product here is usually terphenylene,

while biphenylene is formed in trace amounts. Since the cyclisation of compound (IV) requires the flattening of the biphenyl molecule, the yield of biphenylene under these conditions may be greatly increased by carrying out the reaction in the presence of aromatic hydrocarbons or adsorbents promoting such flattening[39].



## III. ARYNES DERIVED FROM ORGANOMETALLIC COMPOUNDS

Among the organometallic precursors of DHB and its substituted derivatives, *o*-halogenolithiobenzenes (V, X = F, Cl, or Br) have been most thoroughly investigated. The first representatives of compounds of this class were synthesised as early as 1956, by the low-temperature reaction of aliphatic organolithium compounds with the corresponding *o*-dihalogenobenzenes in ether or tetrahydrofuran (THF)[40]:

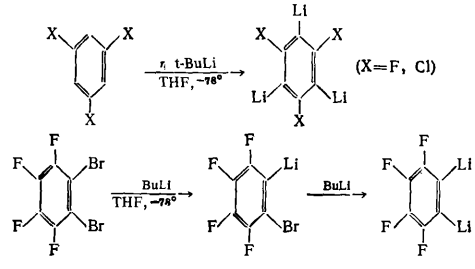


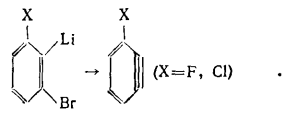
(V)

A large number of organolithium aryne precursors, the information about the thermal stability of which is presented in Table 1, have now been synthesised. Together with the exchange of a halogen atom for lithium, the H-metallation reaction is used in the synthesis of compound (V), for example[2]:

Compounds (V, X = F, Cl, or Br) without other substituents are labile, exist in solution only at low temperatures, and readily split off LiX with formation of DHB:

It follows from cryoscopic and NMR data[41-44] that in ether–hydrocarbon solutions *o*-fluorophenyl-lithium is a tetrameric tetraetherate, $(o\text{-}FC_6H_4Li)_4(R_2O)_4$, whose structure is analogous to that of the etherates of aliphatic organolithium compounds[45]. According to the results of differential thermal analysis, the stability of this compound, determined like that of other compounds (V), by the decomposition temperature $T_d$ in solution, depends on the nature of the ether $R_2O$ (Table 1), while in media without ethers, the compounds decompose at the instant of their formation[41,44]. Judging from the $^1H$ and $^{19}F$ NMR data, the carbon–lithium bond in the *o*-fluorolithiobenzene molecule is not appreciably polarised under the influence of the neighbouring fluorine atom, although both atoms [lithium and fluorine?] interact appreciably through space[39]. The influence of the lithium atom on the mobility of halogen atoms linked to the benzene ring under conditions ensuring the stability of halogenolithiobenzenes is in its turn apparently also small, since in some cases polylithio-compounds can be obtained by treatment with an excess of a lithium alkyl under extremely mild conditions, for example[46,47,48]:





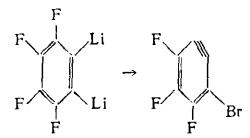


**Table 1.** Thermal stabilities of organolithium aryne precursors.

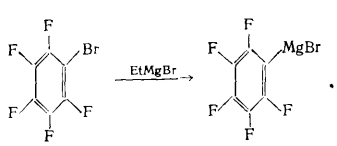
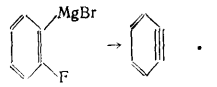
| Compound | Solvent | Stability characteristic | References |
|---|---|---|---|
| 1 | 2 | 3 | 4 |
| *o*-Fluorolithiobenzene | acyclic ethers | $T_d = -48° \text{--} -50°C$ | 41, 42 |
| | cyclic ethers | $T_d = -19° \text{--} -21°C$ | 41, 42 |
| *o*-Chlorolithiobenzene | acyclic ethers | $T_d = -70° \text{--} -73°C$ | 41, 42 |
| | cyclic ethers | $T_d = -50° \text{--} -52°C$ | 41, 42 |
| *o*-Bromolithiobenzene | acyclic ethers | $T_d = -83° \text{--} -85°C$ | 41, 42 |
| | cyclic ethers | $T_d = -73° \text{--} -75°C$ | 41, 42 |
| 2,6-Difluorophenyl-lithium | THF | stable at -65°C | 54 |
| 2,4,6-Trifluorophenyl-lithium | THF | stable at -70°C | 47 |
| 3,4,5,6-Tetrafluorophenyl-lithium | THF, $Et_2O$ | stable at -55°C | 55 |
| 2,4,5,6-Tetrafluorophenyl-lithium | $Et_2O$ | stable at -75°C | 56 |
| 2,3,5,6-Tetrafluorophenyl-lithium | THF | stable at -55°C | 55 |
| Pentafluorophenyl-lithium | THF | polymerises at 0°C | 57 |
| Pentafluorophenyl-lithium | $Et_2O$ | decomposes at 15°C, partly stable at 20°C | 51 |
| 2-Fluoro-1-lithionaphthalene | THF | $T_d = -30°C$ | 58 |
| Octafluoro-4,4'-dilithio-biphenyl | THF, $Et_2O$ | decomposes at -5° -0° | 59 |
| Octafluoro-2,2'-dilithio-biphenyl | $Et_2O$ | decomposes at 0°C | 60 |
| Pentafluorophenylpenta-fluoro-4-lithiophenyl ether | THF | decomposes via the aryne mechanism at -30°C | 61 |
| 4,4'-difluoro-3,3'-dilithio-biphenyl | THF, $Et_2O$ | stable at -78°C | 62 |
| 2-Bromo-3,4,5,6-tetra-fluorophenyl-lithium | $Et_2O$ | decomposes in 8 h at 0°C | 48 |
| 2,4,6-Trifluoro-1,3-dilithio-benzene | THF | stable at -78°C | 47 |
| Tetrafluoro-1,2-dilithio-benzene | THF, $Et_2O$ | stable at $T \leqslant -55°C$ | 55 |
| Tetrafluoro-1,4-dilithio-benzene | THF, $Et_2O$ | stable at $T \leqslant -65°C$ | 54 |
| Tetrafluoro-1,3-dilithio-benzene | $Et_2O$ | stable at $T \leqslant -75°C$ | 56 |
| 3,5-Dichloro-2,4,6-trifluoro-phenyl-lithium | $Et_2O$ | stable at $T \leqslant -75°C$ | 56 |
| 5-Chloro-2,4,6-trifluoro-1,3-dilithiobenzene | $Et_2O$ | stable at $T \leqslant -75°C$ | 56 |
| 3-Chloro-2,4,5,6-tetrafluoro-phenyl-lithium | $Et_2O$ | stable at $T \leqslant -75°C$ | 56 |
| 2,4,6-Trifluoro-1,3-trilithio-benzene | THF | $T_d \approx -60°C$ | 47 |
| 2,4,6-Trichlorophenyl-lithium | THF | stable at -65°C | 46 |
| 2,3,5,6-Tetrachlorophenyl-lithium | $Et_2O$ | stable at -10°C | 63 |
| 2,3,4,5-Tetrachlorophenyl-lithium | $Et_2O$ | stable at -20°C | 63 |
| Pentachlorophenyl-lithium | $Et_2O$ | decomposes slowly in the presence of furan at ~ 20°C; | 52 |
| ditto | | stable in crystalline state at 20°C in air | 53 |
| Nonachlorolithiobiphenyl | THF | stable at -30°C | 64 |
| Octachlorodilithiobiphenyl | THF | stable at -30°C | 64 |
| 2,4,6-Trichloro-1,3-dilithio-benzene | THF | stable at -65°C | 46 |
| 2,4,6-Trichloro-1,3,5-trilithio-benzene | THF | stable at -65°C | 46 |
| Tetrachloro-4-lithiopyridine | $Et_2O$ | stable at ~ 20°C | 65 |
| 2,3,6-Trichloro-4-lithio-pyridine | $Et_2O$ | stable at -20°C | 63 |
| Pentabromophenyl-lithium | $Et_2O$ | stable at -15°C | 52 |
| | benzene | stable at 80°C | |
| 2'-Bromo-2-lithiobiphenyl | $Et_2O$ | stable at 20°C | 53 |

In the majority of known cases, the ease of decomposition of compounds (V) with formation of arynes increases with decrease of the C–X bond energy, so that the decomposition temperatures of compounds of the type *o*-$XC_6H_4Li$ decrease in the following series of X : F > Cl > Br. The same relation has been observed for 2,6-dihalogenolithiobenzenes with different halogen atoms[2]:

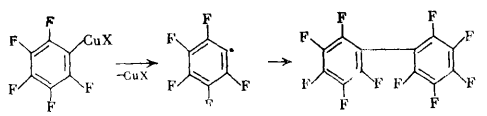


However, the accumulation of fluorine atoms in the molecule of the initial polyhalogenolithiobenzene alters the mode of elimination of LiX. For example, the only product of the decomposition of 2-bromo-3,4,5,6-tetrafluorophenyl-lithium is bromotrifluorodehydrobenzene (VI),[49] which may be attributed to thermodynamic control of the reaction[50,51]:



An interesting feature of pentahalogenolithiobenzenes, usually obtained by the reaction of lithium alkyls with penta- or hexa-halogenobenzenes, is their high thermal stability, compared with *o*-halogenolithiobenzenes (V), which is usually attributed[2] to stabilisation of the corresponding phenyl anions by the halogen atoms. However, comparison of the decomposition temperatures of $C_6X_5Li$ and the corresponding compounds (V) shows that this explanation is not exhaustive. Thus pentafluorophenyl-lithium, the anion of which should be the most stable species of this kind, decomposes slowly in an ethereal medium at 0°C, i.e. at a temperature only slightly higher than for *o*-fluorophenyl-lithium ($T_d$ = −20°C in THF). On the other hand, pentachlorophenyl-lithium is entirely stable under the usual conditions and can be stored at 20°C and even higher temperatures in the crystalline state, while *o*-chlorophenyl-lithium decomposes in THF at −50°C.[41,53] A similar difference between stabilities has also been noted for the corresponding bromo-derivatives ($T_d$ = 0°C for pentabromophenyl-lithium compared with −75°C for *o*-bromophenyl-lithium in THF).[52] It is noteworthy that the decomposition of pentahalogeno-derivatives of phenyl-lithium with formation of arynes is appreciably complicated by reactions of the $S_N2$ type, which are much less common for monohalogenolithiobenzenes[2].

Together with halogeno-derivatives of organolithium compounds, the analogous *o*-halogenophenylmagnesium halides behave as common organometallic precursors of arynes. Compounds of this type are obtained either by the reaction of dihalogenobenzenes with metallic magnesium in ether or THF or by an exchange interaction between aromatic halogeno-derivatives and aliphatic organomagnesium compounds[66,67]:



Halogeno-derivatives of aromatic organomagnesium compounds are more stable than the corresponding organolithium compounds[68,69] and in most cases decompose at a moderate rate only at the boiling point of the solvent (ether or THF):

Like the analogous lithium compounds, pentahalogenophenylmagnesium halides are more stable than the corresponding monohalogenophenyl derivatives. However, the main pathway in the reactions of these compounds in ethereal media involves intermolecular reactions of the $S_N2$ type, as a result of which they are widely used to introduce pentahalogenophenyl groups into various compounds. The aryne decomposition of pentahalogenophenyl magnesium halides is achieved in a hydrocarbon medium at extremely high temperatures (approximately 200°C)[52,70].

*o*-Iodophenylmercury iodide or bis-2-iodophenylmercury decompose at approximately 200°C, which leads to DHB according to Hoffmann[2]. On the other hand, bis-pentachlorophenyl- and bis-pentafluorophenyl-mercury are stable at higher temperatures[2] and even bis-(2-bromo-3,4,5,6-tetrafluorophenyl)mercury enters into various reactions at 230°C without undergoing the aryne decomposition[71].

Numerous pentahalogenophenyl derivatives of many other elements (Zn, Cu, Ag, B, Al, In, Tl, Si, Ge, Ti, Co, Fe) have been synthesised from pentahalogeno-derivatives of lithium and magnesium, but the thermolysis products of these compounds were not investigated, although in most of the known cases they exhibit a thermal stability characteristic of the analogous phenyl derivatives or higher[2,72], which apparently indicates their low tendency to undergo the aryne decomposition. For the less stable halogenophenyl compounds of copper, silver, cobalt, and titanium, the most probable thermolytic pathway is homolytic rupture of the carbon–metal bond with formation of free radicals[33,73–76], for example:

Pentafluorophenyl derivatives of boron, aluminium, and indium, among which $(C_6F_5)_3B$ and $(C_6F_5)In$ are fully stable and can be readily synthesised by the exchange reaction between pentafluorophenyl-lithium and the corresponding halides, possess interesting properties[77]. On the other hand, trispentafluorophenylaluminium can only be obtained in the form of the etherate, which decomposes explosively when any attempt is made to remove the ether even at a relatively low temperature (approximately 20°C). The attempt to synthesise $(C_6F_5)_3Al$ in an ether-free medium leads to the same result and the product of the decomposition of this compound is presumably the corresponding aryne.

On heating $(C_6F_5)_2TlBr$ with various elements, pentafluorophenyl derivatives of the type $(C_6F_5)_nM$ (where M = S, Se, Te, P, As, Sb, Sn, Zn, or Cd) were obtained, being fully stable at approximately 200°C.[78]

$W(C_6F_5)_5$[79] as well as compounds of the type $C_6F_5HgX$ (where X represents iron, manganese, and molybdenum carbonyls) are also resistant to aryne decomposition[80].

## IV. THE STRUCTURE AND REACTIVITY OF CARBENES

Like other molecules containing carbon atoms with an incomplete shell, the carbenes CRR′ exhibit an enhanced reactivity and are involved in chemical reactions as short-lived intermediates. Nevertheless, the use of special physical and physicochemical methods has now made it possible not only to demonstrate reliably the involvement of carbenes in many reactions (particularly in the decomposition of halogeno-derivatives of organometallic compounds[81,82]) but also to determine the thermodynamic and structural parameters of many of them[83,84].

Since the central atom of the carbene has two non-bonding orbitals accommodating two electrons, the CRR′ molecule may exist in singlet or triplet states characterised by parallel and antiparallel spins of the free electrons. The spin state of the carbene determines to a large extent its reactivity, since compounds in the triplet state have a reactivity close to that of free radicals, and those in the singlet state can exhibit properties of both compounds with a free electron pair as well as compounds having a vacant orbital, i.e. they can behave as nucleophiles or electrophiles, depending on the nature of the substituents R and R′. For this reason, the main theoretical problem of the chemistry of carbenes is the relation between the structural parameters and the spin state of the molecule.

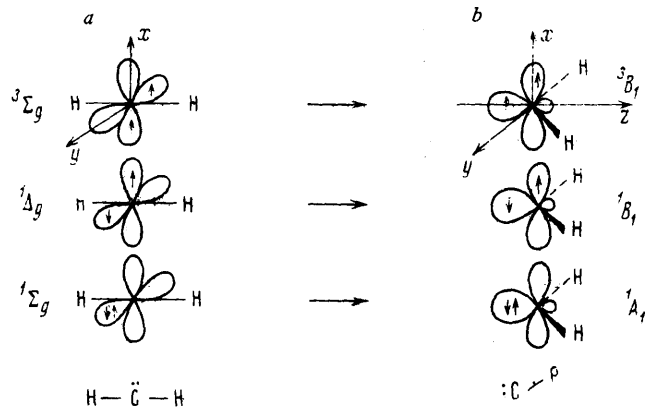


Figure 1. The spin states of methylene: *a*) linear form; *b*) bent form.

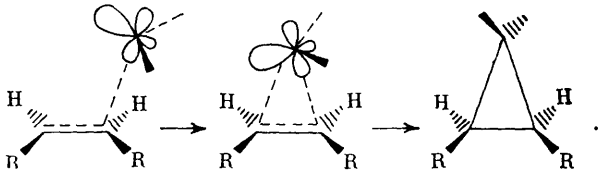
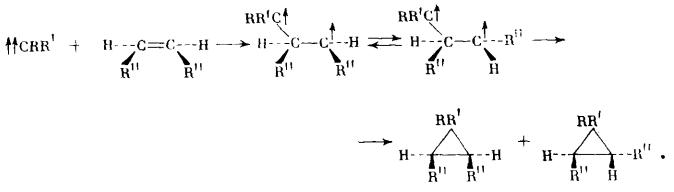
In broad outline, this problem may be examined even in relation to the simplest carbene—methylene[85]. Evidently the carbon atom of the linear $CH_2$ molecule can have two *sp* hybrid orbitals involved in the formation of C–H bonds and two non-bonding *p* orbitals ($p_x$ and $p_y$) accommodating two electrons. According to the Pauli principle, the possible states of this molecule ($D\infty h$ symmetry point group) should be arranged in the following sequence in terms of their energies: $^3\Sigma_g < {}^1\Delta_g < {}^1\Sigma_g$, so that the linear $CH_2$ molecule should have a triplet ground state. A decrease of the H–C–H valence angle, i.e. the bending of the molecule, for example in the *yz* plane, as shown in Fig. 1, removes the degeneracy of the $p_x$ and $p_y$ orbitals, since the former, being symmetrical relative to the *yz* plane, remains a pure *p* orbital under these conditions, while the latter acquires some *s* character, being converted into a hybrid $\sigma$ orbital. This change in the shape of the molecule alters its symmetry point group to $C_{2v}$ with the possible states $^3B_1$, $^1B_1$, and $^1A_1$. Evidently, on transition from the $^3\Sigma_g$ and $^1\Delta_g$ states to the corresponding $^3B_1$ and $^1B_1$ states, the energy of one of the free electrons is reduced. When this effect is greater than the decrease of the energy of the C–H bond owing to the reduction of the amount of *s* character of the corresponding hybrid atomic orbitals, the $^3B_1$ and $^1B_1$ states will be energetically more favourable than the $^3\Sigma_g$ and $^1\Delta_g$ states respectively. The molecule will therefore "strive" to increase the valence angle until the associated energy gain is compensated by the energy of repulsion between the hydrogen atoms. Since the analogous transition between the $^1\Sigma_g$ and $^1A_1$ singlet states is associated with approximately twice as great an energy gain as the transition between the first two states, presumably the equilibrium valence angle in the molecule in the $^1A_1$ state should be smaller than in the molecule in the $^3B_1$ or $^1B_1$ state.

Thus, general considerations arising from valence theory lead to the conclusion that the methylene molecule must have a triplet ground state in which it is bent and an excited singlet state with the same or smaller valence angle. On passing from methylene to other carbenes, which naturally have more bulky substituents, one must expect an increase of the valence angles in any state of the molecule. It is also evident that the interaction of the occupied orbitals of the substituents R and R′ of the CRR′ molecule with the $p_x$ orbital of the central atom should lead to a specific stabilisation of the $^1A_1$ singlet state (or another state of the $\sigma^2$ type), and the existence of carbenes in a singlet ground state should therefore be caused by a fairly strong interaction of this type[86].



The results of many experimental[5,84] and theoretical[5,85–88] studies devoted to the problem of the structure of carbenes are in full agreement with these considerations. It has now been established that methylene and its alkyl alkenyl, alkynyl, and aryl derivatives have triplet ground states and singlet first excited states. On the other hand, singlet ground and triplet first excited states have been found for dihalogenocarbenes, the maximum value of *E*ST (39–47 kcal mole$^{-1}$[88,89]) corresponding to the $CF_2$ molecule, where the extent of the interaction of the *p* electrons of the substituents and the $p_x$ orbital of the carbon atom is greatest. In all known cases, the experimental R–C–R′ valence angles vary in the range 130–180° for triplet molecules and 100–115° for singlet molecules[5,84]. In particular, the formation of singlet dichlorocarbene with a Cl–C–Cl angle of approximately 106° in the decomposition of $LiCCl_3$[81] and $PhHgCCl_3$[82] has been demonstrated by infrared spectroscopy using the technique of matrix isolation of unstable molecules.

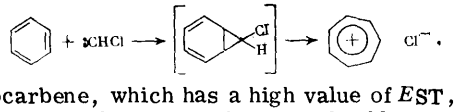
The majority of the known methods for the generation of carbenes are based on the decomposition of stable initial molecules in the ground electronic state. In those cases where the decomposition of the precursor is a single-stage reaction, the carbene is therefore formed in a singlet state owing to spin conservation regardless of whether it is the ground or an excited state. Thus the reactivity of carbenes in the triplet ground state is determined to a large extent by the possibility of a singlet–triplet transition under the conditions of their generation—in the absence of such transition, they react in an excited singlet state.



Like arynes, singlet carbenes have a low-lying LCMO. Accordingly, the reactivity of singlet carbenes is to some extent analogous to that of arynes, which was discussed

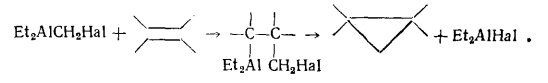
above: they are active electrophiles in relation to unsaturated organic compounds with which they readily form adducts—compounds of the cyclopropane or cyclopropene series. Furthermore, a characteristic feature of carbenes as a whole is their ability to undergo reactions involving insertion in various single bonds and also dimerisation to the corresponding olefins.

The reaction of carbenes which is most important in practice—addition to the double bonds of olefins—is stereospecific for singlet CRR′ with retention of the configuration of the initial olefin in the cyclopropane formed. Such a reaction, which is undoubtedly a single-stage process, is allowed by the orbital symmetry conservation rules in the form of a non-linear cheletropic process[90]. According to calculations[91-93], a reaction of this kind begins with electrophilic attack by the $p_X$ orbital in the carbene on one of the carbon atoms of the $\pi$-system of the olefin and further mutual approach of the reactants is accompanied by the rotation of the carbene fragment about the axis passing through its central carbon atom at right angles to the plane of the three-membered ring being formed:



In contrast to singlet carbenes, triplet carbenes add to multiple bonds in the course of the two-stage reaction involving the intermediate formation of a triplet trimethylene biradical. The cyclisation of the latter to the corresponding cyclopropane is caused by the possibility of spin inversion and, according to Skell's postulate[94], such a biradical has a lifetime sufficiently long for the attainment of the conformational equilibrium, which entails the loss of stereoselectivity:

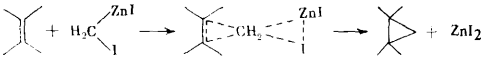
Thus Skell's postulate makes it possible to determine the spin state of the reacting carbene from the stereochemical result of the conversion of olefins into cyclopropanes, which is widely used in the study of carbene reactions.



Since carbenes manifest properties of electrophiles in cycloaddition to unsaturated systems, their reactivity is determined by the energy of the LUMO and is greater the lower the energy level of this orbital. Accordingly, carbenes whose singlet state has been stabilised as a result of the raising of the LUMO level show the least reactivity in these reactions. Thus dichlorocarbene is incapable of adding to benzene[95], although this reaction does proceed with methylene[96] and monochlorocarbene[95,97,98], for example:

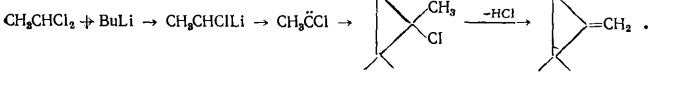
Difluorocarbene, which has a high value of $EST$, shows altogether little tendency to undergo cycloaddition reactions.

Like cycloaddition to olefins, the dimerisation of singlet carbenes begins, according to calculations[99], with electrophilic attack by the $p_X$ orbital of one :CRR′ molecule on the $\sigma$ orbital of another, as a result of which further mutual approach of the molecules involves the rotation of at least one of them. Further, one may expect that both reactions (dimerisation and conversion of olefins into cyclopropanes) proceed via the shortest pathway as a result of configuration interaction in the transition state[30], because the values of $EST$ for the majority of singlet carbenes are small (for example 1–1.5 eV or $:CCl_2$).[86]



However, the above considerations concerning the mechanism of the formation of cyclopropanes and olefins are by no means applicable to all reactions in which labile organometallic compounds are used as carbene precursors. Thus organoaluminium compounds of the type $Et_2AlCH_2Hal$ exhibit, according to Hoberg's data[100], a greater tendency towards the addition of olefins to the C–Al bond than towards the elimination of methylene, as a result of which the cyclopropanes are formed in this case via a $\gamma$-elimination mechanism:

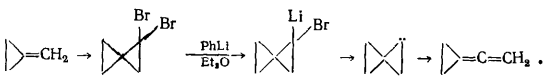
In the decomposition of certain halogenolithiomethanes, for example $LiCH_2Cl$ or $LiCHCl_2$,[101] the main reaction pathway appears to be the insertion of the carbene formed in the C–Li bond, occurring within the cage formed by the association complex of the initial organolithium compound[39,102,103]. As a consequence of this, the reaction product is a formal carbene dimer formed via $\beta$-elimination, for example:



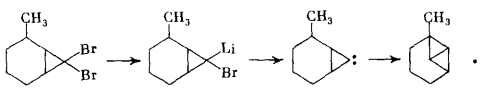
According to Blanchard and Simmons[104], the conversion of olefins into cyclopropanes via the Simmons–Smith mechanism, in which the methylene group is transferred at the instant of attack by the olefin on an organozinc compound, also proceeds without the formation of kinetically independent methylene:

The presence of a low-lying LUMO and a high HOMO determines the ability of carbenes, containing more than one carbon atom, to undergo various intramolecular rearrangements. The commonest reaction of this type is the so called carbene–olefin isomerisation, which is one of the examples of symmetry-allowed sigmatropic rearrangements[90,105]†:

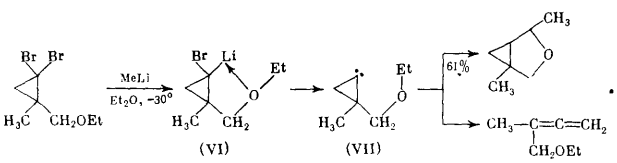
At low temperatures, this isomerisation can be avoided in certain cases. The recently proposed method for synthesising methylenecyclopropanes is in fact based on this finding[106]:



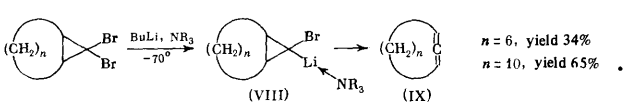
† According to calculations by the MINDO/2 method[109], the isomerisation of ethylidene to ethylene proceeds without activation energy.



The carbene–olefin isomerisation of cyclopropylidene and a wide variety of its substituted derivatives proceed with ring opening, which results in the formation of the corresponding allenes[107]:



In view of the availability of *gem*-dihalogenocyclopropanes, this reaction constitutes a convenient general method for the synthesis of allenes, many of which cannot be obtained by other methods, for example[108]:



According to calculated data[110], the rearrangement of cyclopropylidenes to allene proceeds with a somewhat higher activation energy than the addition of the carbene to the double bond. Accordingly, in certain cases it is possible to observe also carbene reactions of cyclopropylidenes, for example the addition to olefins with formation of the corresponding spiropentanes[111]. Norcarylidene, which is formed by the reaction of 7,7-dibromonorcarane with metallic lithium in THF between −20° and −60°C, reacts with the solvent without a rearrangement, giving rise to 7-(α-tetrahydrofuryl)norcarane[112]. It is interesting to note that the analogous reaction of 3-methylnorcarylidene leads to a bicyclobutane derivative[113], with a 90% yield:

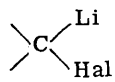
The formation of substituted bicyclo[1,1,0] butanes, which competes with the cyclopropylidene–allene isomerisation, has been noted also for certain di- and tetra-alkylcyclopropylidenes[114,115], the ratio of the bicyclic and allene reaction products being determined by the positions and nature of the substituents. The preferential insertion of the carbene centre of cyclopropylidene in the C–H bond has also been noted for compound (VII), where the proximity of the reaction centres is apparently ensured by the intramolecular coordinate bond Li ← O in the organometallic precursor (VI)[116]:

Accordingly, the use in this type of reaction of an optically active amine, (-)-sparteine, which forms a chiral complex with the intermediate bromolithio-derivative (VIII), leads to optically active cyclic allenes (IX), albeit with a low optical purity[117]:

It evidently follows from these data that the cyclopropylidene generated from a halogeno-derivative of an organolithium precursor rearranges at the instant of formation.

Another interesting example of the isomerisation of a carbene, synchronised with the decomposition of the organometallic precursor, is the Frisch–Buttenberg–Wieche rearrangement:

Judging from the process selectivity (only the aryl or cyclopropyl group R′ in the *trans*-position relative to the halogen atom migrates[118,119]), the rearrangement apparently takes place at the instant of the decomposition of the halogeno-derivative of the organometallic compound, which is accelerated by the interaction of the π-orbital of the migrating group with the σ*-orbital of the C–X group.



## V. CARBENES DERIVED FROM ORGANOMETALLIC COMPOUNDS

### 1. Halogenoalkyl Derivatives of Alkali Metals

Aliphatic organometallic compounds containing in the α-position a halogen atom or another group tending to be split off in the form of an anion exhibit in many instances a capacity for thermal α-elimination with formation of carbenes:

The ease of this reaction is determined mainly by the nature of the eliminated M and X groups. In particular, many compounds of this type, capable of generating carbenes at low or moderate temperatures (between −100° and +100°C), which are particularly convenient for liquid phase reactions, are known. The comparative availability of numerous compounds of the type RR′CMX together with the ease of their decomposition make them important and widely used sources of carbenes.

Halogenolithiomethanes and related compounds containing the  group are the most thoroughly investigated compounds of this type. Halogenomethyl derivatives of lithium are usually obtained by treating the corresponding halogenomethanes with lithium alkyls or phenyl-lithium at low temperatures. The ease of exchange of the substituents at the carbon atom for lithium in an ethereal medium diminishes in the sequence I > Br > H > Cl.[120,121] It follows from the observation of the effects of the chemically induced polarisation of nuclei observed in NMR spectra that the exchange reaction in lithium alkyl–alkyl halide systems[122,123] proceeds at least partially with intermediate formation of free radicals:

Exchange reactions are catalysed by Lewis bases forming complexes with organolithium compounds (ethers and amines)[45,124] and in some cases the nature of the solvent influences also the mode of reaction. Thus, when methyl-lithium is allowed to react with benzylidene bromide in ether, the bromine atom is substituted and the product is α-lithiobenzyl bromide, which decomposes subsequently with formation of phenylcarbene. However, the analogous reaction in THF proceeds as H-metallation,

leading to α-lithiobenzylidene bromide and further to bromophenylcarbene[125,126]:

$$PhCHBr_2 \begin{cases} \xrightarrow[Et_2O]{} PhCHLiBr \xrightarrow[-LiBr]{} :CHPh \\ \xrightarrow[THF]{} PhCLiBr_2 \xrightarrow[-LiBr]{} :CBrPh \end{cases}.$$

Benzylidene chloride is metallated by methyl-lithium in ether preferentially at the hydrogen atom[127]:

$$PhCHCl_2 \xrightarrow{MeLi} PhCLiCl_2 \xrightarrow[-LiCl]{} :CClPh .$$

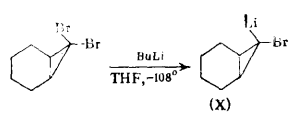
A mixture of similar amounts of $LiCBr_3$ and $LiCHBr_2$ is formed in an analogous manner as a result of the reaction of butyl-lithium with bromoform in THF[128,129], whereas in a hydrocarbon medium the exchange of bromine for lithium takes place exclusively[129]:

$$CHBr_3 + BuLi \begin{cases} \xrightarrow[-BuH]{} LiCBr_3 \xrightarrow[-LiBr]{} :CBr_2 , \\ \xrightarrow[-BuBr]{} LiCHBr_2 \xrightarrow[-LiBr]{} :CHBr , \end{cases}$$

$$CHBr_3 + BuLi \xrightarrow[-BuBr]{hexane} LiCHBr_2 \xrightarrow[-LiBr]{} :CHBr .$$

The analogous reaction of chloroform in ether leads to $LiCCl_3$,[130] the decomposition of which results in the formation of dichlorocarbene, and, when the reaction is carried out in a hydrocarbon medium, the product is a mixture of $LiCCl_3$ and $LiCHCl_2$.[129]

Under the influence of lithium alkyls, dihalogenomethanes $CH_2X_2$ (X = Cl, Br, or I) in hydrocarbons exchange only halogen atoms for lithium[102,103,131], with subsequent formation of methylene. However, in an ethereal medium, $CH_2Cl_2$ undergoes exclusively H-metallation, being converted into $LiCHCl_2$—a precursor of monochlorcarbene[132,133]:



$$CH_2Cl_2 + BuLi \xrightarrow[-BuH]{Et_2O} LiCHCl_2 \xrightarrow[-LiCl]{} :CHCl .$$

This change in the mode of metallation on passing from a hydrocarbon medium to an ethereal medium can be explained[129] by a weakening of the C–H bond owing to the formation of complexes of the type $X_3C...H...OR_2$.

The reaction of phenyl-lithium and its substituted derivatives with $CH_2Cl_2$ in ether, which also leads to the intermediate formation of monochlorcarbene, constitutes the basis of a convenient method for the generation of arylcarbenes[134]:

$$CH_2Cl_2 + ArLi \xrightarrow[-ArH]{} LiCHCl_2 \xrightarrow[-LiCl]{} HClC: \xrightarrow{ArLi} ArCHLiCl \rightarrow ArHC: .$$

Bicyclic *gem*-dibromo-derivatives, namely 7,7-dibromonorcarane, 7,7-dibromo-2-oxanorcarane, and related compounds, exchange the *endo*-halogen preferentially for lithium in the reaction with lithium alkyls[135]:

(X)

On the other hand, 7,7-dichloronorcarane forms under analogous conditions (THF, −115°C) a mixture of *endo*- and *exo*-lithio-derivatives with the *exo*-isomer predominating appreciably[136].

A simple general method for the generation of halogenocarbenes is based on the reactions of di-, tri-, and tetra-halogenomethanes and similar compounds with metallic lithium or sodium in THF[137] at temperatures between −40° and +40°C, i.e. under conditions where the majority of α-halogenolithiomethanes are unstable:

$$RR'CXX' \xrightarrow[THF]{Li} RR'CLiX \xrightarrow[-LiX]{} RR'C: \rightarrow \text{(norcarane)}(R)(R') ,$$

where X and X′ are halogens and R,R′ = H, halogen, aryl, alkyl, etc.

It has been shown[127] that $PhCHCl_2$ reacts with lithium in THF even at −90°C; heating of the reaction mixture in the presence of cyclohexene leads to a high yield of 7-chloro-7-phenylnorcarane, which undoubtedly demonstrates the intermediate involvement of $PhCLiCl_2$. It is interesting to note that $CH_2Cl_2$, $CHCl_3$, $PhCHCl_2$, and $CHBr_3$ react with lithium only via the hydrogen atom under these conditions, whereas the reaction with $CH_2Br_2$ involves bromine[112,138]. In contrast to lithium alkyls and metallic lithium, lithium amides are capable of exchanging lithium only for hydrogen atoms in polyhalogenomethanes. Thus, when dibromomethane is treated with lithium di-isopropylamide in THF, the following reaction takes place unambiguously[139]:

$$CH_2Br_2 + iso\text{-}Pr_2NLi \rightarrow LiCHBr_2 + iso\text{-}Pr_2NH .$$

Such selectivity is evidently proof that the reaction is thermodynamically controlled, since the exchange of the halogen should have led in this case to labile *N*-halogenoamines.

The halogenolithiomethanes formed via H- or X-metallation reactions at low temperatures (at approximately −100°C) in an ethereal medium undergo intermolecular reactions involving not only the C–Li bond but also the exchange of halogen atoms[140]:

$$LiCBr_3 + LiCCl_3 \rightarrow LiCBrCl_2 + LiCBr_2Cl .$$

The exchange reactions of halogenolithiomethanes with lithium halides have also been reported[141]. Numerous halogenolithiomethanes and their substituted derivatives have now been synthesised by the methods examined above (Table 2).

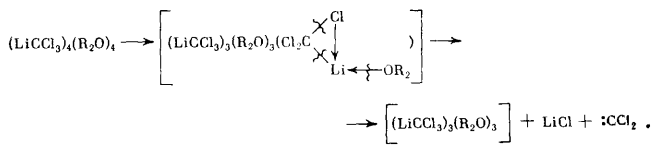


Table 2. Thermal stabilities of halogenolithiomethanes.

| Compound | Solvent* | $T_d$, °C | References |
|---|---|---|---|
| $LiCF_3$ | $Et_2O$ | −75 to −50 | 142 |
| $LiCH_2Cl$ | THF | −110 | 101 |
| $LiCHCl_2$ | THF | −30 | 143 |
| | $Et_2O$ | −100 | 133 |
| $LiCCl_3$ | THF and other cyclic ethers | −65 | 42, 130 |
| | $Et_2O$ and other acyclic ethers | −84 to −88 | 42 |
| | monoglyme, TMEDA | −75 | 42 |
| $LiCHBr_2$ | THF | −73 | 144 |
| $LiCBr_3$ | THF | −77 | 144 |
| $LiCH_2I$ | THF | −110 | 145 |
| $LiCHI_2$ | THF | −110 (slow) | 145 |
| $LiCHI_2$ | THF | −95 | 146 |

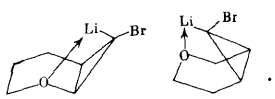

Table 2 shows that halogenolithiomethanes are relatively stable, like halogenolithiobenzenes, only in solutions containing ethers or trialkylamines. According to D'yachenko and Nefedov[147], trichloromethyl-lithium exists, like lithium alkyls and other aliphatic organolithium compounds[124], in the form of the tetrameric complex $(LiCCl_3)_4 \cdot (R_2O)_4$ in an ether–hydrocarbon medium. It follows from the results of two investigations[102,131] that

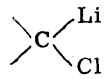
there is also a possibility of the existence of mixed association complexes of butyl-lithium with monohalogenolithiomethanes. The complex of trichloromethyl-lithium with tetramethylethylenediamine having the composition $LiCCl_3.(CH_3)_2NCH_2CH_2N(CH_3)_2$ has been obtained in a crystalline state[148].

Association and the formation of complexes by halogenolithiomethanes in solution have a significant influence, as for halogenolithiobenzenes, on the stability and reactivity of these compounds. Thus the study of the thermal stability of trichloromethyl-lithium in various solvents showed that this compound decomposes with formation of dichlorocarbene as a consequence of a synchronous reaction, the rate of which is determined by the strength of the Li ← $OR_2$ coordinate bond[42]:

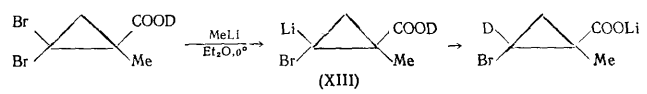
A similar conclusion follows also from the comparison of the stabilities of cyclic and *gem*-bromolithio-compounds, namely *endo*-7-bromo-7-lithionorcarane (X) and its 2-oxa-analogue (XI). According to Seyferth and Lampert[135], compound (X) is unstable in THF above −90°C, while compound (XI), where there is a possibility of the formation of the relatively stable Li ← O intramolecular coordinate bond owing to the proximity of the oxygen and lithium atoms, does not decompose in ether even at −20°C, being one of the most stable of the α-halogeno-derivatives of organolithium compounds. *endo*-7-Bromo-7-lithio-3-oxanorcarane (XII), in certain conformations of which the Li–O distance is shorter by 0.2–0.3 Å than in compound (XI), is still more stable. One should note in this connection that compound (XII) is the only known halogeno-derivative of an organolithium compound which is stable in a hydrocarbon medium[149]:

(XI) (XII)



On the other hand, trichloromethyl-lithium obtained by the reaction of $CCl_4$ with atomic lithium in a solid argon matrix, which is known to be monomeric and not bound in a complex, proved to be unstable even at −230°C,[81] while in THF solutions, for example, it is stable up to approximately −70°C.[41,42]

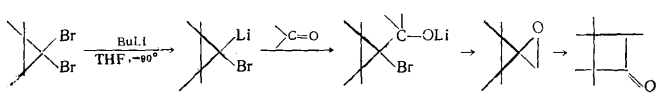
The association of halogenolithiomethanes has a definite influence also on their reactivity. While the majority of compounds of this type are thermolysed to carbenes and are capable of undergoing their characteristic reactions (the formation of the kinetically independent dichlorocarbene from $LiCCl_3$ was demonstrated by the method of competition kinetics[148,150]), certain halogenolithiomethanes, for example $LiCH_2Cl$ or $LiCHCl_2$, give rise to the formal dimers ($CH_2{=}CH_2$, CHCl=CHCl) on thermal decomposition in solution instead of the kinetically independent carbenes[101,143]. This type of reaction is apparently associated with the rapid insertion of the highly reactive carbene (:$CH_2$, :CHCl) in the carbon–lithium bond of the initial compound within the cage of the initial association complex, for example, $(LiCH_2Cl)_4(R_2O)_4$:



This was confirmed by the observation[147] that even the much less reactive dichlorocarbene formed on decomposition of the mixed association complex $LiCCl_3.(PhLi)_3.(THF)_4$ reacts almost completely with phenyl-lithium (forming $PhCLiCl_2$ and then tolane[127]) without emerging from the cage of the initial association complex.

It follows from the data in Table 2 that the stability of halogenolithiomethanes depends on the nature of the halogen. Evidently, as for halogenolithiobenzenes, there is a tendency for the stability of halogenolithiomethanes and related compounds to decrease with increase of the atomic number of the halogen, but in many instances this type of dependence is masked by other factors and it is extremely difficult to trace it on the basis of the available literature data. According to Talalaeva and Kocheshkov[142], $LiCF_3$ in ethereal solution has $T_d$ = −50–75°C and certain fluorolithiomethanes decompose in the same temperature range[151]. Perfluoroisopropyl-lithium is stable in ether only at −78°C.[152]

Trifluoromethyl-lithium decomposes in THF at −65°C[42]. Similar values of $T_d$ (−65–75°C) are characteristic of αα-dichlorobenzyl-lithium, a series of its substituted derivatives, and many other compounds containing the  group[136,153,154]. However, $LiCHCl_2$ is a much more stable compound ($T_d$ = 30°C in THF) and *exo*-7-chloro-7-lithionorcarane and $LiCH_2Cl$ are more labile ($T_d$ = 110°C). According to Kobrich[7], the lability of chloromethyl-lithium is caused by its high basicity, which ensures its autocatalytic decomposition via an *Elcb* mechanism.



Bromo-derivatives of methyl-lithium, i.e. $LiCHBr_2$ and $LiCBr_3$, have decomposition temperatures $T_d$ close to those of $LiCCl_3$ and the majority of other chloro-derivatives; however, slow decomposition of these compounds is observed at much lower temperatures (approximately −100°C).[144] The acid (XIII), formed when equimolar amounts of methyl-lithium and of the corresponding dibromo-acid react in ether, exhibits some stability even at 0°C. The rate of exchange of bromine for lithium exceeds the rate of the corresponding salt formation reaction to such an extent that the latter is an intramolecular process[155]:

(XIII)

The exact values of $T_d$ for the two known iodolithiomethanes $LiCH_2I$ and $LiCHI_2$[145,146] have not been determined, but it has been shown that these compounds are relatively stable between −90° and −100°C.

Owing to the development of simpler (particularly hydrolytic[156]) methods for the generation of carbenes from halogenomethanes, the decomposition reactions of halogenomethyl derivatives of lithium are nowadays rarely used for the conversion of olefins into cyclopropanes. On the other hand, complex carbenes, mainly different substituted cyclopropylidenes (see above), are still generated almost exclusively by methods of organolithium chemistry. In some cases halogeno-derivatives of organolithium compounds are used at low temperatures also as organolithium reagents, for example[157]:

Many halogenolithiomethanes with different organoelement groups have been synthesised and characterised by the exchange reactions of organolithium compounds with organoelement derivatives (particularly halogen-containing derivatives). However, the majority of these compounds, particularly the trimethylsilyl and trimethylstannyl derivatives of chlorolithio- and bromolithio-methanes, are readily involved in intermolecular reactions of the $S_N2$ type instead of undergoing the carbene decomposition[158,159]. On the other hand, the decomposition of $Ph_3PbCCl_2Li$, formed when $(Ph_3Pb)_2CCl_2$ is treated with butyl-lithium, apparently proceeds with the intermediate formation of extremely interesting metallocarbenes[160]:

$$Ph_3PbCCl_2Li \begin{cases} \longrightarrow Ph_3PbCl + Li\ddot{C}Cl, \\ \longrightarrow Ph_3Pb\ddot{C}Cl \rightarrow Ph_3PbCl + :C: . \end{cases}$$

The available data about the halogenomethyl derivatives of other alkali metals are so far limited to the report of the synthesis of several sodium and potassium compounds, which are readily formed when halogenomethanes are treated with the corresponding bistrimethylsilylamides, for example[161]:

$$(Me_3Si)_2NNa + HCBr_3 \rightarrow NaCBr_3 + (Me_3Si)_2NH .$$

In contrast to lithium compounds, the analogous sodium and potassium derivatives proved to be more stable in ether than in THF. Furthermore, contrary to expectation, they are more stable in the majority of cases than the corresponding lithium and even magnesium compounds (Tables 2–4).

**Table 3.** Thermal stabilities of halogenomethyl derivatives of sodium and potassium in ether[161].

| Compound | $T_d$, °C |
|---|---|
| NaCClBrH | −30 (slow decomp.) |
| $NaCHBr_2$ | −30 (slow) |
| $NaCBr_3$ | −77 (slow) |
| $KCHBr_2$ | −65 (very fast) |
| $KCBr_2SiMe_3$ | −25 (fast) |
| $KCBr_3$ | ←120 |

**Table 4.** Thermal stabilities of halogenomethyl derivatives of Grignard reagents.

| Compound | $T_d$, °C | | References |
|---|---|---|---|
| | THF | THF + 20% HMP | |
| $CF_3MgCl$ | decomposes at instant of formation at −115°C | decomposes at instant of formation at −115°C | 164 |
| $CCl_3MgCl$ | −65 (very fast) | −65 (very fast) | 164 |
| $CBr_3MgCl$ | — | −75 (very fast) | 164 |
| $CHBr_2MgCl$ | −55 | −45 | 164 |
| $CH_2BrMgCl$ | −55 (slow) | — | 164 |
| $CH_2IMgCl$ | −55 | −45 | 164 |
| $CHI_2MgCl$ | −85 | | 146 |

A general method for the synthesis of monobromocyclopropanes has been developed on the basis of the decomposition of $NaCHBr_2$:[162]

$$(Me_3Si)_2NNa + CH_2Br_2 \xrightarrow[-(Me_3Si)_2NH]{} NaCHBr_2 \xrightarrow[-NaBr]{} :CHBr \longrightarrow \text{(Br, H)} \quad (30-50\%) .$$

## 2. Halogenomethyl Derivatives of Magnesium

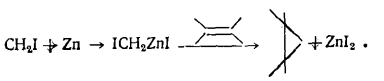
Like their lithium analogues, compounds of the type $CX_3MgX$ are obtained by the exchange reaction of the corresponding halogenomethanes with stable Grignard reagents at low temperatures in an ethereal medium[163,164]. Owing to their extremely low basicity, Grignard reagents are not involved in H-metallation reactions and are capable of substituting only halogen atoms in halogenolithiomethanes[164]:

$$CHBr_3 + \text{iso-PrMgCl} \rightarrow CHBr_2MgCl + \text{iso-PrBr},$$
$$CHBr_2Cl + \text{iso-PrMgCl} \rightarrow CHBrMgCl + \text{iso-PrBr} .$$

Like the analogous lithium compounds, halogenomethyl derivatives of organomagnesium compounds are stable only in solution and at extremely low temperatures (Table 4), decomposing on heating with formation of the corresponding carbenes:

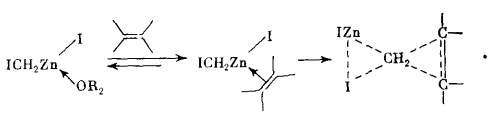
$$CX_3MgX \rightarrow :CX_2 + MgX_2 .$$

The decomposition of $CCl_3MgBr$, formed when $CCl_4$ is treated with EtMgBr or PhMgBr at relatively high temperatures (20–60°C), proceeds not only via the carbene pathway but also via a free-radical pathway[165]. It follows from the data in Table 4 that halogenomethyl Grignard reagents have thermal stabilities very similar to those of the corresponding lithium compounds. Thus the decomposition temperatures $T_d$ of $CCl_3MgCl$ and $CBr_3MgCl$ correspond to those of $LiCCl_3$ and $LiCBr_3$ (Table 2). On the other hand, $CHBr_2MgCl$ is somewhat more stable than $LiCHBr_2$, while $CF_3MgCl$ is characterised by a much lower stability than $LiCF_3$, being in general one of the least stable halogeno-derivatives of organometallic compounds. An increase of the polarity of the medium [the replacement of THF by 20% solution of hexamethylphosphoramide (HMP)] leads to an increase of the stability of certain halogenomethyl derivatives of cadmium, which is believed[164] to indicate intramolecular halogen–magnesium coordination. However, the stabilisation may also be a consequence of the strengthening of the $Mg \leftarrow OR_2$ coordinate bond, the dissociation of which must precede the carbene decomposition according to some of the present authors' data[41,42].



Like the corresponding organolithium compounds, Grignard reagents of the type $R_3MCHXMgX$ (M = Si or Sn; X = halogen) do not tend to undergo the carbene decomposition, forming readily in solution products of reactions of the $S_N2$ type[159].

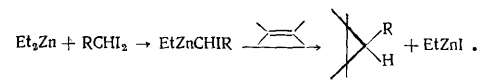
## 3. Organozinc and Organocadmium Compounds



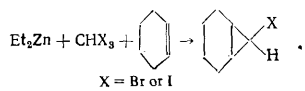
Organozinc compounds are widely used as reagents for the introduction of the methylene group, the so called Simmons–Smith reaction[8,166,167], based on the employment of methylene halides (usually $CH_2I_2$) and activated zinc powder, being of greatest preparative value. In view of the lower activity of the metal, halogenomethyl derivatives of zinc of the type $XCH_2ZnX$ show a higher thermal stability than the corresponding derivatives of alkali metals and magnesium. It has been shown[104] that $ICH_2ZnI$, formed by the reaction of methylene iodide with activated zinc in ether, is completely stable in solution at 0–20°C, decomposing slowly with liberation of ethylene at the boiling point of the solvent.

In the presence of olefins, the decomposition of this compound leads to the corresponding cyclopropanes. The Simmons–Smith reaction, usually carried out by refluxing

a mixture of methylene iodide and an olefin with the zinc–copper couple in ether, is at present one of the commonest methods for synthesising cyclopropane hydrocarbons:



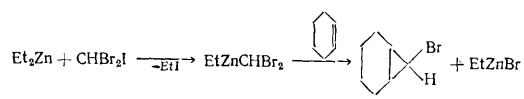
According to Blanchard and Simmons[104], the formation of cyclopropanes by the Simmons–Smith reaction is a stereoselective process in which the olefin is attacked by the electrophile, which corresponds to the possibility of the involvement of singlet methylene or its complex. The composition of the side products of the reaction, among which ethylene and a number of compounds usually formed on reaction of singlet methylene with the solvent have been detected, is also consistent with this hypothesis. On the other hand, the reaction is of second order overall (of first order with respect to the organozinc compound and the olefin), while the intermediate has more stringent steric requirements than the free methylene[104]. Accordingly, it has now been assumed that the Simmons–Smith reaction proceeds without the formation of kinetically independent methylene and the $CH_2$ fragment is transferred from the organozinc compound to the olefin via a five-centre transition state[6,8,104]. On the other hand, the dependence of the ease of decomposition of $ICH_2ZnI$ on the solvent is analogous to that observed for halogeno-derivatives of organolithium compounds: despite the much higher temperature, this compound is completely stable in boiling THF, but causes the introduction of the methylene group into olefins in ether. In conformity with the above ideas, this implies that the decomposition of the organozinc methylene precursor includes the interaction of the halogen electron pair with the free orbital of the metal, arising when the Zn ← O etherate linkage is ruptured. In this case, the second order of the reaction may be a consequence of the displacement of the ether by the olefin and the subsequent rapid decomposition of the resulting unstable complex:



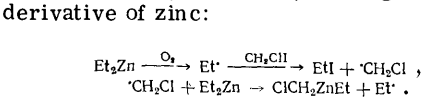
Under mild conditions, methylene halides do not react with ordinary zinc powder and the nature of the initial substances, the yields of the products of the Simmons–Smith reaction, and its duration depend to a large extent on the method used to activate the zinc. The galvanic zinc–copper couple with a low copper content, prepared by treating zinc powder with aqueous solutions of copper salts (sulphate[166–168] or acetate[169]), is usually employed for the reaction. A mixture of zinc powder with copper(I) chloride also exhibits a high activity in the reaction[170].

The zinc–copper couple, prepared using $CuSO_4$, reacts in ether only with $CH_2I_2$ and $CH_2ClI$.[167] On the other hand, when zinc is activated by copper acetate, it is possible to involve in the reaction also $CH_2Br_2$.[169] However, the most effective method of carrying out the Simmons–Smith reaction is associated with the use of the zinc–silver couple followed by the removal of the salts formed during the reaction as the pyridine complexes[171]. This mode of reaction makes it possible to introduce the methylene group (with a high yield of cyclopropanes) not only into olefins but also into many compounds with functional groups, for example unsaturated ketones, ethers, enol ethers, and enamines.

The conversion of olefins into cyclopropanes as a result of the joint treatment with diethylzinc and *gem*-di-iodoalkanes proceeds via a similar pathway—with the intermediate formation and decomposition of halogenomethyl derivatives of zinc[172]:

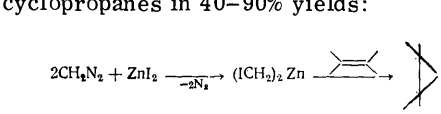


When this reaction is carried out with dihalogenoiodomethanes of the type CHIXY (X, Y = F, Cl, or Br), the corresponding monohalogenocyclopropanes are formed in yields up to 90%;[173] monoiodo- and monobromo-cyclopropanes are obtained in high yields by this reaction from $CHI_3$[174] and $CHBr_3$:[175]



In the presence of benzene and its alkali derivatives, the corresponding cycloheptatrienes are obtained from $CHBr_3$ and $Et_2Zn$.[175] An attempt to involve chloroform in a reaction of this type has been described: 7,7-dichloronorcarane was synthesised in a low yield when cyclohexene was treated jointly with $CHCl_3$ and diphenylzinc[176].

When trihalogenomethanes containing different halogen atoms in the same molecule were used in the reaction with diethylzinc, the nature of the product was determined by the mobility of the halogen in the exchange reaction[120,121]. Thus 7-bromonorcarane can be obtained from $CHBr_2I$, diethylzinc, and cyclohexene, ethyl iodide being formed exclusively in the first stage of the reaction[172]:



The interaction of organozinc compounds with methylene halides or haloforms is catalysed by oxygen[177]. Thus the reaction of $Et_2Zn$ with $CH_2ClI$ in nitrogen leads to norcarane in 61% yield after 6 h in the presence of cyclohexene; when dry air is passed through the reaction mixture, the same reaction proceeds to the extent of 99% in 30 min. This result undoubtedly indicates the involvement of free radicals in the exchange reaction, leading to a halogenomethyl derivative of zinc:

The involvement of free radicals in this reaction has also been demonstrated by the observation of the considerable polymerisation of styrene when an attempt was made to introduce the bromomethylene group into the latter by treatment with diethylzinc and bromoform in air[175].

Like the halogenomethyl derivatives of zinc described above, symmetrical compounds of the type $Zn(CHRX)_2$, which can be readily obtained by the thermolysis of the corresponding diazoalkanes in the presence of zinc salts, are also active agents for the introduction of the methylene group[178–180]. Thus, bis(iodomethylzinc), formed by the reaction of diazomethane with $ZnI_2$, reacts with olefins to form cyclopropanes in 40–90% yields:

$ZnCl_2$ reacts similarly with diazomethanes, forming the tetrameric etherate $[Zn(CH_2Cl)_2(OEt_2)_2]_4$,[179] the interaction of which with cyclohexene in ether gives rise to norcarane. The decomposition of bis(chloromethyl)zinc is appreciably catalysed by the addition of $ZnCl_2$ and proceeds at an appreciable rate in the presence of this salt even at 0°C, which indicates a weakening of the coordinate bond in the etherate of the $ClZnCH_2Cl$ formed.

An effective agent for the introduction of the methylene group is obtained on decomposition of diazomethane in the presence of zinc benzoate and $ZnI_2$:[181]

$$(PhCOO)_2Zn \xrightarrow{CH_2N_2} (PhCOOCH_2)_2Zn \xrightarrow{ZnI_2} \rightarrow PhCOOCH_2ZnI \longrightarrow \text{(yield 66\%)} .$$

Aryl- and diaryl-diazomethanes[182-184] are also readily decomposed by zinc salts, forming the corresponding arylhalogenomethyl derivatives of organozinc compounds, the decomposition of which in the presence of olefins leads to cyclopropanes. The stability of the zinc compounds formed in this reaction decreases as a function of the nature of the halogen in the sequence Cl > Br > I.[183]

Bis(dichloromethyl)zinc was obtained by treating $ZnCl_2$ with dichloromethyl-lithium[143]:

$$2LiCHCl_2 + ZnCl_2 \rightarrow (Cl_2CH)_2Zn + 2LiCl .$$

Like $ICH_2ZnI$, this compound is completely stable in boiling THF, but is converted into 7-chloronorcarane in a low yield on prolonged refluxing with cyclohexene in benzene.

Diethylcadmium reacts with *gem*-di-iodoalkanes similarly to diethylzinc, forming the corresponding cyclopropanes in the presence of olefins[185]:

$$Et_2Cd + RCHI_2 \longrightarrow \text{(R=H, Me, Ph)} .$$

The yields of the reaction products for zinc and cadmium compounds with analogous structures are similar.

Virtually identical mixtures, containing 30–40% of 1-chloropropane, were obtained also in the reactions of diethylzinc and diethylcadmium with $CHCl_3$ and $CCl_4$.[186] The formation of 1-chloropropene apparently indicates the intermediate generation and subsequent carbene decomposition of compounds of the type $RMCCl_2Et$:

$$RMCCl_2Et \xrightarrow{-RMCl} :CClEt \rightarrow ClCH{=}CHMe ;$$
$$R = Et, \text{ or } Cl;\ M{=}Zn,\ Cd .$$

Virtually exclusive formation of propene, which is apparently also a consequence of the carbene–olefin isomerisation, has been observed in the reaction of 1,1-di-iodopropane with the zinc–copper couple in the presence of cyclohexene[168].

Like zinc salts, $CdI_2$ reacts with diazomethane to form $ICdCH_2I$, which, however, is a much less active agent for the introduction of the methylene group than $IZnCH_2I$.[179]

## 4. Organomercury Compounds

The halogenocarbenes, formed when trihalogenomethyl compounds react with bases or on thermolysis of salts of trihalogenoacetic acids, are readily inserted into the Hg–X bonds of compounds of the type RHgX (R = aryl, alkyl, or halogen; X = halogen), giving rise to the corresponding $RHgCX_3$, for example:

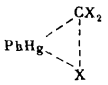
$$PhHgCl + CHCl_3 + t\text{-}BuOK \rightarrow PhHgCCl_3 + t\text{-}BuOH + KCl ,$$
$$PhHgBr + Cl_3COONa \rightarrow PhHgCCl_2Br + CO_2 + NaCl .$$

These compounds decompose at moderate rates in the temperature range which is extremely convenient for carrying out chemical reactions (20–80°C) with formation of RHgX and the corresponding carbene:

$$PhHgCCl_3 \rightarrow PhHgCl + :CCl_2 .$$

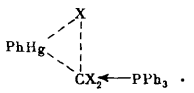
The decomposition of such compounds, carried out in solvents (dimethoxyethane, benzene, THF, $CH_2Cl_2$, etc.) which are inert with respect to the carbenes generated, leads to the corresponding cyclopropane compounds in the presence of unsaturated compounds. Owing to the neutral medium and the absence of other reactive intermediates (for example $CX_3^-$ anions), the reaction proceeds exceptionally smoothly, giving high yields of cyclopropanes, not only with olefins but also with many of their derivatives having functional groups, being complicated only by the formation of $CX_2{=}CX_2$ dimers owing to the occurrence of reactions of the type

$$RHgCX_3 + :CX_2 \rightarrow RHgCX_2CX_3 \rightarrow RHgX + CX_2{=}CX_2$$



to a slight extent. Furthermore, since the carbene decomposition of trihalogenomethyl derivatives of mercury is reversible and the RHgX compounds formed on decomposition can be readily used virtually without loss for the regeneration of the initial reagent, compounds of this type are regarded nowadays as the most convenient agents for the transfer of carbenes to unsaturated compounds.

The study of the kinetics of the thermolysis of $PhHgCl_2Br$,[187] leading to PhHgBr and the corresponding *gem*-dichlorocyclopropanes with almost quantitative yields in the presence of olefins, showed that in the initial stage the reaction is of first order with respect to the organomercury compound and of zero order with respect to the olefin. On the other hand, the rate of reaction diminishes following the addition of PhHgBr and depends to some extent on the nature of the olefin, which can be readily interpreted by postulating a sequence of two stages, the slow stage involving the reversible formation of free dichlorocarbene:



$$PhHgCCl_2Br \overset{slow}{\rightleftharpoons} PhHgBr + :CCl_2$$
$$:CCl_2 + \text{(olefin)} \xrightarrow{fast} \text{(dichlorocyclopropane)} .$$

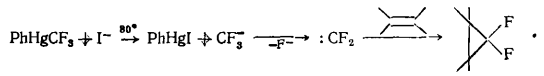
The involvement in this reaction of the kinetically independent carbene was also confirmed by the virtual identity of the relative rates of introduction of the dichloromethylene group into various olefins (determined by the method of competition kinetics) in the generation of dichlorocarbene by the thermolysis of $PhHgCCl_3$, $LiCCl_3$, and $CCl_3COONa$, by treating $CHCl_3$ with t-BuOK,[150] and by the high-temperature pyrolysis of chloroform[148]. The intermediate formation of singlet $:Cl_2$ is also indicated by the explicit electrophilic mechanism of the conversion of olefins into dichlorocyclopropanes by treatment with $PhHgCCl_2Br$ [188] and $PhHgCCl_3$.[148,150,188] Since the rate of decomposition of compounds of the type $RC_6H_4HgCCl_2Br$ depends to only a slight extent on the nature of R (R = H, *p*-F, *p*-Cl, *p*-MeO, or *p*-Me), it is suggested that this reaction proceeds similarly to the decomposition of other organometallic compounds discussed above, in a single stage via a transition state produced as a result of the

coordination of the halogen electron pair to the free metal orbital[189]:

Since the bulky central mercury atom in the compounds $RHgCX_3$ is incapable of forming sufficiently stable complexes with weak Lewis bases, the rate of decomposition of these compounds is to a large extent independent of the nature of the solvent (benzene, dimethoxyethane, THF). Furthermore, in contrast to the analogous compounds of complex-forming metals, the decomposition of the mercury compounds is accelerated in the presence of strong Lewis bases (amines and phosphines), apparently owing to the formation of the complex involving the free orbital of the carbene[187]:

On the other hand, as for the $\alpha$-halogenomethyl derivatives of other metals, the stability of the mercury compounds under consideration is determined by the nature of the halogen: in conformity with the strength of the C–X bond and the radius of the X atom, the rate of decomposition of $PhHgCX_3$ increases in the sequence $F \ll Cl < Br < I$. The same relation determines also the mode of decomposition of mixed trihalogenomethyl compounds of the type $PhHgCXY_2$ and PhHgCXYZ (Table 5).

**Table 5.** Thermal stabilities of trihalogenomethyl derivatives of phenylmercury[9].



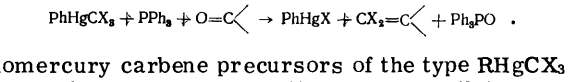
| Compound | Carbene | Total decomposition time in benzene | |
|---|---|---|---|
| | | at 80°C | at 20°C |
| $PhHgCCl_2I$ | $CCl_2$ | instantaneous | 24 h |
| PhHgCClBrI | CClBr | 3 min | 4 days |
| $PhHgCBr_3$ | $CBr_2$ | – | 15–16 days |
| $PhHgCClBr_2$ | CClBr | – | 15–16 days |
| $PhHgCFBr_2$ | CFBr | 20 min | 3 days |
| $PhHgCCl_2Br$ | $CCl_2$ | 2 h | 11 days |
| $PhHgCCl_3$ | $CCl_2$ | 48 h | — |
| $PhHgCCl_2F$ | CClF | 48 h | — |

According to the mechanism adopted for the decomposition reaction, a decrease in the electronegativity of the group R in $RHgCX_3$ should lead to the destabilisation of the molecule. Indeed alkyl and cycloalkyl derivatives of trihalogenomethylmercury are less stable than the corresponding aromatic compounds[190,191]. In particular, cyclo-$C_6H_{11}HgCX_3$, formed when the corresponding cyclo-$C_6H_{11}HgX$ reacts with $CHX_3$ (X = Cl or Br) and t-BuOK in THF at $-60°C$,[191] are so reactive that they are much less readily available than iodo-derivatives of the type $PhHgCX_2I$.

In contrast to the corresponding iodo-, bromo- and chloro-derivatives, trifluoromethylphenylmercury and other trifluoromethyl derivatives of mercury, which are readily obtained by the pyrolysis of the corresponding trifluoroacetates[102],

$$Hg(OCOCF_3)_2 \xrightarrow{200°} CF_3HgOCOCF_3$$

do not decompose with formation of $:CF_2$ even at relatively high temperatures. Thus $PhHgCF_3$ does not change on heating in solution for eleven days up to 140°C.[9,192] On the other hand, like other $RHgCX_3$ derivatives, these compounds readily form carbenes in the presence of NaI;[192–194] however, in this case the reaction proceeds with the intermediate formation of the $CX_3^-$ anions:



The formation of carbanions under these conditions was demonstrated by the formation of the corresponding trihalogenomethyldimethylmethanols on decomposition of $PhHgCCl_3$ and $PhHgCCl_2Br$ in the presence of NaI in acetone[195]. In contrast to $PhHgCF_3$, the compounds $ClHgCF_3$ and $BrHgCF_3$ do not decompose in the presence of NaI owing to the formation of stable complexes of the type $NaClIHgCF_3$ and $Na_2ClI_2HgCF_3$.[104]

**Table 6.** Carbenes obtained from halogenomethyl derivatives of mercury.

| Organomercury compound | Carbene formed | Refs. | Organomercury compound | Carbene formed | Refs. |
|---|---|---|---|---|---|
| 1 | 2 | 3 | 1 | 2 | 3 |
| $Hg(CH_2Br)_2$ | $CH_2$ | 196 | cyclo-$C_6H_{11}HgCClBr_2$ | CClBr | 191 |

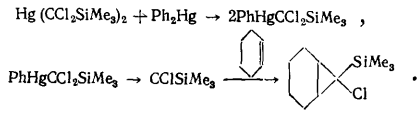
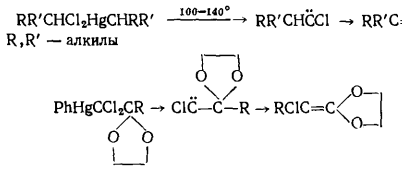
* R=Me, Et

The method of the liquid-phase thermolysis of halogenomethyl derivatives of mercury is widely used nowadays to synthesise various cyclopropane derivatives, many of which are formed in quantitative or nearly quantitative yields (Table 6), including the reaction involving weakly nucleophilic olefins. Among the applications of the carbene decomposition of organomercury compounds, mention should be made of the synthesis of numerous organic derivatives of other elements[9] and also the single-stage version of the Wittig reaction[215]:

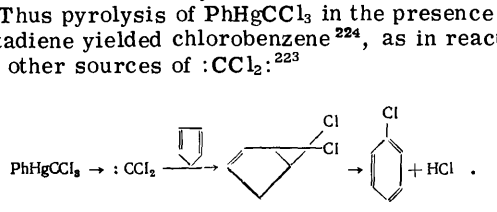


Organomercury carbene precursors of the type $RHgCX_3$, containing electronegative substituents R, exhibit a reduced reactivity and in some cases do not form free carbenes on liquid-phase thermolysis. Thus $Hg(CH_2Br)$ withstands prolonged boiling in benzene without appreciable decomposition, but readily introduces the methylene group

into olefins under the same conditions, evidently via the formation of an intermediate complex of the type[216]

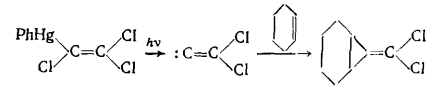


$BrHgCH_2Br$, which can introduce the methylene group into olefins only with low yields and under more severe conditions, is still more stable. However, it has been shown[196] that thermolysis of this and certain other stable halogenomethyl derivatives of mercury is greatly accelerated in the presence of $Ph_2Hg$ owing to a redistribution reaction with formation of the corresponding substituted derivatives of phenylmercury. Thus $Hg(CCl_2SiMe_3)_2$ reacts with cyclohexene at 120°C to form 7-chloro-7-trimethylsilylnorcarane in 24% yield, while in the presence of $Ph_2Hg$ the yield is 62%:[214]



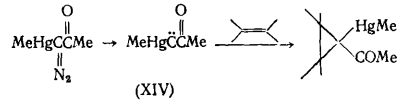
$:CBrSiMe$[217] and $:CHSiMe_3$[217,218] can be generated similarly from the corresponding symmetrical compounds.

More complex carbenes can also be generated from α-halogeno-derivatives of organomercury compounds by the method of liquid-phase thermolysis, but these species usually isomerise to the corresponding unsaturated compounds, for example[219-221]:



Instead of the carbene decomposition, 1,1-dichloroethylphenylmercury undergoes thermal dehydrochlorination with formation of chlorovinylmercury[222].

Trihalogenomethyl derivatives of mercury generate dihalogenocarbenes not only in the liquid but also in the gas phase. Thus pyrolysis of $PhHgCCl_3$ in the presence of cyclopentadiene yielded chlorobenzene[224], as in reactions involving other sources of $:CCl_2$:[223]

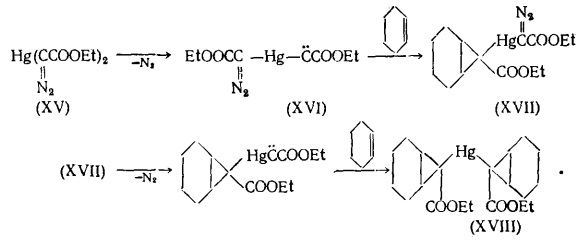


The intermediate formation of dihalogenocarbenes in the gas-phase pyrolysis (at 250–550°C) of $PhHgCClBr_2$, $PhHgCCl_2Br$, $PhHgCCl_3$, $Hg(CCl_3)_2$, and $ClHgCCl_3$ was demonstrated by their low-temperature stabilisation in an argon matrix with subsequent investigation using infrared spectroscopy[82,224-228]. The valence angle of this carbene (106° ± 4°) was found from the isotopic splitting of the $:CCl_2$ stretching vibration bands and the singlet state of this species was thereby demonstrated[82].

In contrast to the liquid-phase reactions, the gas-phase pyrolysis of trihalogenomethyl derivatives of mercury leads to the corresponding dihalogenomethyl radicals as well as carbene. The rate of formation of the radicals depends on the nature of the initial compound and generally increases with temperature[228], owing to the high degree of excitation of the vibrational-rotational levels of the molecule, which hinders the formation of the halogen–mercury bond in the transition state of the carbene decomposition reaction. Nevertheless the carbene pathway in the pyrolytic decomposition of these compounds predominates up to very high temperatures (about 500°C). In conformity with these ideas, the more vigorous excitation of molecules attainable following the ultraviolet irradiation of $PhHgCCl_3$ and $Hg(CCl_3)_2$ proceeds with the exclusive formation of trihalogenomethyl radicals[229,230]. On the other hand, in certain cases ultraviolet photolysis of α-halogeno-derivatives of organomercury compounds leads also to the formation of carbenes, for example[231]:

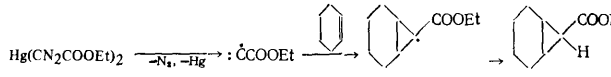
The above examples of the generation of carbenes from organomercury compounds are based on the use of α-halogeno-derivatives, a characteristic reaction pathway for which is α-decomposition. However, there are also examples in the literature of carbene-type photochemical decomposition of other organomercury compounds, particularly α-mercuri-derivatives of diazo-compounds.

Ultraviolet photolysis ($\lambda > 335$ nm) of methylmercuridiazoacetone ($MeHgCN_2OMe$) proceeds analogously to the photolysis of other diazo-compounds, leading to the metal-containing carbene $MeHgC\ddot{C}OMe$ (XIV), which interacts with olefins to form the corresponding cyclopropane derivatives in yields of 70–90%:[232]



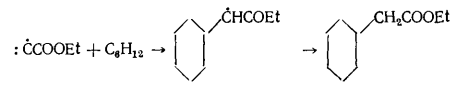
(XIV)

Like the other carbenes formed in the photolysis of diazo-compounds, compound (XIV) is probably generated in the triplet state, which rapidly relaxes to the singlet state (by virtue of the presence of the heavy metal atom next to the carbene centre), which can be inferred from the stereospecificity of the reaction with olefins and the absence from the reaction mixture of products of the Wolf rearrangement, which is characteristic of triplet ketocarbenes[233].



Analogous photochemical decomposition at $\lambda > 335$ nm, with formation of mercury-containing singlet carbenes, is also characteristic of many other compounds of the type $RHgC(N_2)X$ (where R = Me, Et, iso-Pr, t-Bu, Ph, or $PhCH_2$ and X = Me, Ph, CN, COMe, or COOMe), which are readily formed when RHgOEt reacts with diazo-compounds $XHCN_2$.[234] When the energy of the irradiation ($\lambda < 280$ nm) of a compound of this type increases, the mercury-containing fragment is split off together with a nitrogen molecule, forming intermediate compounds of formally univalent carbon—carbene-radicals or carbynes $:C\dot{X}$.

Similar relations are also observed in the ultraviolet photolysis of bis(diazoethoxycarbonylmethyl)mercury [$Hg(CN_2COOEt)_2$] (XV).[235-237] Thus compound (XV) initially splits off one nitrogen molecule on long-wavelength irradiation ($\lambda > 335$ nm) with formation of the singlet mercury-containing carbene (XVI), which reacts with cyclohexene to form the corresponding norcarane (XVII),



the subsequent decomposition of which, followed by the reaction with cyclohexene, leads to compound (**XVIII**):

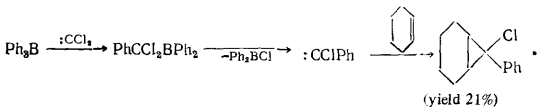
The reaction involving the insertion of compound (**XVI**) in the allylic C–H bond of cyclohexene takes place simultaneously. More severe irradiation ($\lambda < 280$ nm) results in extensive decomposition of (**XV**), giving rise to the formation of ethoxycarbonylcarbyne (:CCOOEt) (in the doublet $^2\Pi$ ground state), which undergoes stereoselective addition to the C=C bonds of olefins like singlet carbenes. The ethoxycarbonylcyclopropyl radicals formed as a result of this reaction, subsequently deprotonate the initial olefin molecule, being converted into the corresponding ethoxycarbonylcyclopropane, for example:

The same intermediate species is probably formed also in the thermolysis of $Hg(CN_2COOEt)_2$.[235] Photolysis of this compound in cyclohexane leads to products of the insertion of ĊCOOEt in the C–H bond:

## 5. Halogenomethyl Derivatives of Group III Elements

The halogenomethyl derivatives of Group III elements have been inadequately investigated as potential sources of carbenes, although the available literature data definitely indicate the validity also for this series of compounds of the fundamental relations determining the reactivity of organometallic carbene precursors.

Thus trifluoromethyldifluoroborane reacts with amines to form the extremely stable complexes $CF_3BF_2.NR_3$, but decomposes in a free state with formation of polymeric difluoromethylene[238]:

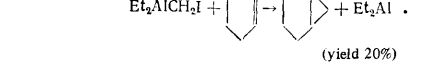


In contrast to the $\alpha$-decomposition reactions of halogenoderivatives of organometallic compounds discussed above, the latter reaction is catalytic and proceeds vigorously in the presence of traces of oxygen, moisture, and certain organic compounds. In the absence of these promoting agents, $CF_3BF_2$ is stable at room temperature[238]. $CF_3BBu_2$ exhibits a similar reactivity[238].

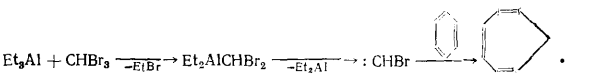
Compounds of the type $(RCH_2CH_2)_2BCCl_2CH_2CH_2R$ (R = Me or Et), formed in the thermolysis of $PhHgCCl_2Br$ in the presence of the corresponding trialkylboranes (80°C, benzene), are unstable under the conditions of their formation and decompose as a result of a series of transformations with elimination of the carbene $(RCH_2CH_2)_2C$:, which isomerises to an olefin. The reaction proceeds with a high degree of conversion and can serve as a preparative method for the synthesis of olefins with an inner double bond[239]:

The analogous reaction with triphenylborane leads to $\alpha\alpha$-dichlorobenzyldiphenylborane, which decomposes slowly at 80°C with formation of chlorophenylcarbene:

Chlorophenylnorcarane is formed from $PhB(OMe)_2$ in a somewhat higher yield by an analogous reaction[239].



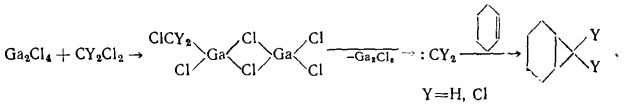
The method of synthesis of halogenophenyl derivatives of organoelement compounds by the decomposition of diazomethane in the presence of the corresponding halide salts, which was discussed above, is inapplicable to boron compounds, because they give rise to polymethylene exclusively. However, the analogous reaction with $AlCl_3$ in ether yields, together with polymethylene, a mixture of the etherates of chloromethyl derivatives of aluminium of the type $Al(CH_2Cl)_nCl_{3-n}OEt_2$ ($n = 0-3$) and the reaction of $CH_2N_2$ with $R_2AlX$ (R = alkyl; X = Cl, Br, or I) under the same conditions gives high yields of etherates of the type $R_2AlCH_2X.OEt_2$. These etherates are fairly stable and do not decompose up to 100°C. On the other hand, the free $R_2AlCH_2X$ formed when this reaction is carried out in a hydrocarbon medium are extremely labile and decompose at a high rate even at −10°C:



The free $RAl(CH_2X)_2$ species formed in the decomposition of $CH_2N_2$ in the presence of $RAlX_2$ [240,241] exhibit a similar reactivity.

A characteristic feature distinguishing $\alpha$-halogenomethyl derivatives of aluminium from similar compounds of other metals is the ease with which they add to the multiple bonds of olefins and acetylenes: $R_2AlCH_2X$ forms the corresponding $\gamma$-halogenopropyl compounds even at −50°C in the presence of unsaturated hydrocarbons; these products then decompose with formation of cyclopropane derivatives.

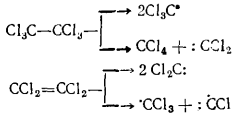
Like the "diethylzinc (or diethylcadmium) + $CH_2I_2$" systems[185], the "triethylaluminium + $CH_2I_2$" system introduces the methylene group into olefins, probably via the intermediate formation of $Et_2AlCH_2I$:[242]



The ability of halogenomethyl derivatives of aluminium to decompose with formation of carbenes is indicated by the analogous reaction of $Et_3Al$ with bromoform in benzene, which leads to bromocycloheptatriene:

The reactions of $R_3Al$ (R = Et or iso-Bu) with $CHI_3$, $CHCl_3$, $CBr_4$,[242] and $CCl_4$ [242,243] also proceeds with the intermediate formation of carbenes.

Carbene decomposition is known to occur also for the analogous compounds of heavier Group III elements. Thus the formation of norcarane and 7,7-dichlorononorcarane was observed in the interaction of $Ga_2Cl_4$ with $CH_2Cl_2$ and $CCl_4$ in the presence of cyclohexene[244]:



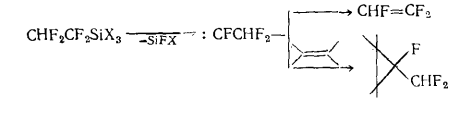
Like the boron and aluminium compounds, triethylthallium reacts with dichlorocarbene to form $\alpha\alpha$-dichloropropyldiethylgallium, which is unstable and decomposes via the carbene mechanism[190,245,246]:

The reaction of $Et_3Tl$ with $CCl_4$ or $CHCl_3$ (the latter reaction takes place on heating) gives rise to $Et_2TlCCl_3$—an unstable compound which decomposes with formation of dichlorocarbene[190,245,246]. The same intermediates are readily formed when $CHCl_3$ interacts with $Et_2TlOCMe$ or $Et_2TlNMe_2$ at 0°C. The analogous reaction with $CH_2Cl_2$ leads to the unstable $Et_2TlCHCl_2$, which decomposes, probably with formation of CHCl. The indium compounds $Et_2InOCMe_3$ and $Et_2InNMe_2$ react with chloroform under much more severe conditions (100–150°C) also forming trichloromethyl compounds which decompose with formation of dichlorocarbene under the reaction conditions[246].

## 6. Compounds of Group IV Elements

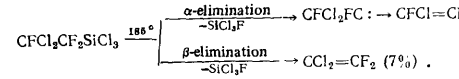
It follows from the above data that the majority of $\alpha$-halogenomethyl derivatives of Group I–III metals are thermolabile compounds, which decompose via the coordination of the free electron pair of the halogen to a vacant $p$ orbital of the metal ($n$–$p$ coordination). Since the elements of Group IV and subsequent Groups do not have vacant $p$ orbitals in the ground state, the single-stage $\alpha$-decomposition of the halogenomethyl derivatives of these elements can take place only via the coordination of $p$ electrons of the halogen to higher sublevels of the metal, which entails an appreciable increase of the activation barrier. On the other hand, the single-stage carbene decomposition of compounds of the elements in the First Period is possible only via the coordination of the $n$-electron pair to the $d$ orbital of the next electronic level, which conflicts with the principle of the non-intersection of potential surfaces. As a consequence of this, the thermolysis of such compounds occurs only under very severe conditions, and proceeds exclusively via the homolytic dissociation mechanism, for example[223,249]:

The $\alpha$-decomposition of compounds of the elements in the higher Fourth–Sixth Periods involves $n$–$d$ coordination, as a result of which $\alpha$-halogenomethyl derivatives of these elements are quite stable under the usual conditions, and decompose via the carbene mechanism only at relatively high temperatures (100–400°C). Thus the trichloromethyl derivatives of silicon [$Cl_3CSiCl_3$,[247,248] $CCl_3SiCl_2OEt$, $CCl_3SiCl(OEt)_2$, $CCl_3Si(OEt)_3$, $CCl_3SiMeCl_2$, $CCl_3SiCl_2CCl_3$, and $CCl_3SiF_3$ [248]] form the corresponding *gem*-dichlorocyclopropanes in yields of 30–80% on heating with olefins (100–250°C). A study of the kinetics of the reaction[248] showed that it is of first order and that its rate is independent of the nature of the olefin. Hence it follows that the initial reaction product is free dichlorocarbene:



Furthermore, dichlorocarbene and $SiCl_4$ have been detected directly by infrared spectroscopy in an argon matrix as the primary products of the pyrolysis of $CCl_3SiCl_3$ (together with small amounts of the corresponding free radicals).[249]

In contrast to compounds of other elements, the fluoromethyl derivatives of silicon decompose at much lower temperatures than their chloro-analogues. Thus $CF_3SiF_3$ smoothly splits off $:CF_2$ even at 100°C:[250]

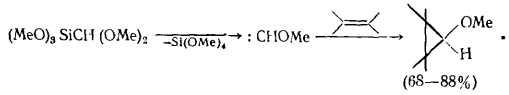


The cause of the reduced stability of fluoromethyl derivatives of silicon is undoubtedly associated with the considerable energy gain due to the unique stability of the Si–F bond formed (energy 170 kcal mole$^{-1}$ [251]). Possibly $H_3SiCH_2F$ is unstable for the same reason even at 20°C, although other compounds of the type $H_3SiCH_2X$ (X = Cl, Br, or I) are fully stable[252].

In conformity with the greater thermal stability of $\beta$-fluoroalkylsilanes, decomposing with formation of olefins only in the range 150–300°C,[253,254] compounds of the type $CHF_2CF_2SiX_3$ (X = F or Me) undergo mainly $\alpha$-decomposition on thermolysis, forming fluoro(difluoromethyl)carbene. In contrast to alkylcarbenes, the latter converts olefins into cyclopropane derivatives in quantitative yields and isomerises to $CHF{=}CF_2$ only in the absence of unsaturated acceptors[254]:

The difficulty of the carbene–olefin isomerisation was also noted for perfluorovinylidene, generated from an organomercury precursor[255].

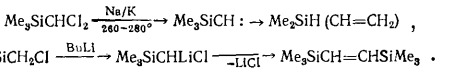
When the alkyl chain of substituted silanes contains simultaneously F and Cl atoms, the thermolysis proceeds only with migration of the fluorine atom[247]:



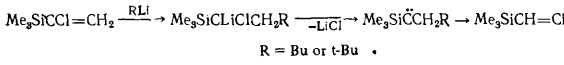
Certain compounds of this type have been found to undergo an exchange of Cl and F atoms prior to decomposition[256]. Such an exchange reaction, which is thermodynamically an extremely favourable process, occurs with $CH_3CF_2SiCl_3$ even at 100°C and is in no way complicated by the $\alpha$-decomposition[256]:

The acetals of silyl-substituted ketones[257] and aldehydes[258] apparently also have low thermal stabilities owing to thermodynamic causes[258]. Thus $(MeO)_3SiCH(OMe)_2$, readily obtained by the reaction of $Cl_3SiSiCl_3$ with $HC(OMe)_3$, decomposes under extremely mild conditions (125°C) with formation of an interesting carbene (methoxymethylene),

which converts olefins into the corresponding methoxycyclopropanes stereospecifically and with high yields[258]:

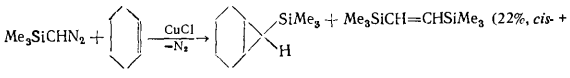


Kinetic data (overall first-order reaction) confirm the formation of free :CHOMe under these conditions.

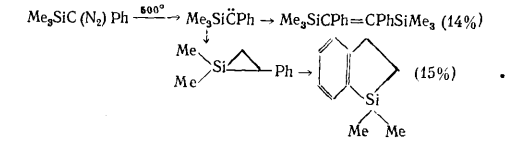


Monomethoxymethylsilanes have a higher thermal stability than the dimethoxy-derivatives but they too are capable of decomposing via the carbene mechanism[257]:

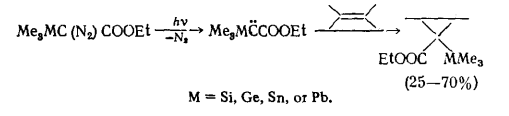
Certain organosilicon carbenes, whose reactivity and particularly their capacity for isomerisation are to a large extent determined by the lability of the C=Si bond, have been obtained from substituted silanes by the methods usually employed for the generation of carbenes. Thus, depending on the method and temperature of its generation, trimethylsilylcarbene isomerises to dimethylvinylsilane[259] or dimerises to 1,2-bis(trimethylsilyl)ethylene[260]:



$\beta$-Alkylation of $\alpha$-chlorovinyldimethylsilane probably also proceeds with the intermediate formation of a carbene[261]:



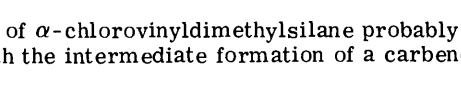
R = Bu or t-Bu .



The thermocatalytic decomposition of trimethylsilyldiazomethane under the influence of CuCl in the presence of cyclohexene gives a high yield of trimethylsilylnorcarane, the dimers of the corresponding carbene being formed simultaneously[262]:

The thermolysis of phenyltrimethylsilyldiazomethane also leads to a carbene dimer together with 1,1-dimethyl-1-silaindan—the product of the isomerisation of the carbene, which probably proceeds via the corresponding silacyclopropane[263]:

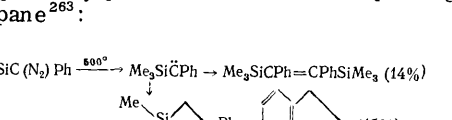
Photolysis of trimethylsilyldiazoacetate and of the analogous germanium, tin, and lead compounds leads, as in the case of the similar organomercury compounds, to substituted ethoxycarbonylcarbenes capable of introducing methylene groups into olefins with high yields[264,265]:



M = Si, Ge, Sn, or Pb.

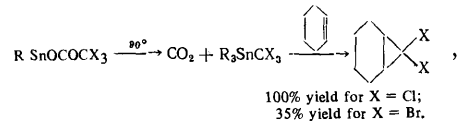
Siloxycarbenes have been suggested as intermediates in the photolysis of acylsilanes[266]:

When this reaction is carried out in the presence of carbonyl compounds, the corresponding oxirans are formed, i.e. siloxycarbenes exhibit nucleophilic properties[267].

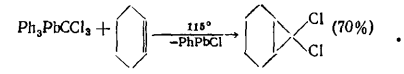


Owing to the considerable coordination unsaturation of the central atom, $\alpha$-halogenomethyl derivatives of heavy Group IV elements undergo carbene decomposition in general at somewhat lower temperatures than the corresponding silicon compounds (with the exception of the fluoro-derivatives). The thermolysis of $Ph_2CClGeCl_3$ at 150–220°C leads to $Ph_2C{=}CPh_2$, which is probably formed as a result of the dimerisation of the corresponding triplet carbene[268]. Dichlorocarbene, which gives rise to adducts with cyclohexene and cyclo-octene, is formed in the thermolysis of $CCl_3GeCl_3$ (200–400°C).[268,269] The formation of $:CCl_2$ in the pyrolysis of $Cl_3CGeCl_3$ has also been demonstrated by the matrix isolation method[270]. Possibly the thermolysis of $CHCl_2GeCl_3$, observed only under severe conditions (700°C) and leading to toluene in the presence of cyclohexene, may also proceed via the carbene pathway[268]. On heating, trifluoromethyltri-iodogermane forms difluorocarbene[271]:

Thermolysis of tri(fluoromethyl)trimethyltin (at 150°C) in the presence of $CF_2{=}CF_2$ leads to perfluorocyclopropane in a quantitative yield[272]. Like the decomposition of trifluoromethyl derivatives of mercury[192–194], this reaction is catalysed by NaI: difluorocarbene adducts are obtained in this way even at 80°C:[273,274]

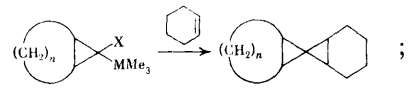


It is of interest that 2*H*-hexafluorocyclobutyltrimethylstannane is unstable and is converted into pentafluorocyclobutene even at 20°C, evidently via the corresponding carbenopentafluorocyclobutane[275]:



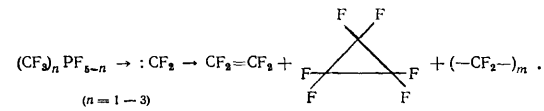
Like the mercury compounds, $Me_3SnCCl_2Br$ and $Me_2SnCCl_3$ are effective sources of dihalogenocarbenes[276,277]; however, their thermal stability is somewhat greater (the reaction is carried out at 140°C). In contrast to $PhHgCCl_2Br$,[187,188] $Me_3SnCCl_2Br$ gives on thermolysis a certain amount of :CClBr together with $:CCl_2$.[276] The carbene decomposition of dichlorobenzyltrimethylstannane also proceeds under the same conditions[277]:

Thermolysis of compounds of the type $R_3SnOCOCX_3$ (R = alkyl; X = Cl or Br) takes place in two stages[278,279]:



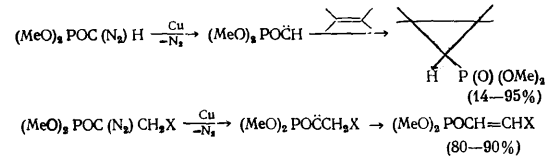
100% yield for X = Cl;
35% yield for X = Br.

Trichloromethyltriphenylplumbane undergoes the carbene decomposition under comparatively mild conditions[280]:



Substituted 1-bromo(iodo)-1-trimethylstannyl and 1-bromo-(iodo)-1-trimethylplumbylcyclopropanes decompose on thermolysis with formation of the corresponding cyclopropylidenes, which are capable of converting olefins into spiropentanes[281]:

X = Br, or I; M = Sn or Pb.



## 7. Compounds of Group V Elements

The numerous and widely used methods of synthesis of cyclopropane derivatives from compounds of Group V and VI elements belong to the ylid chemistry and are not the subject of the present review. Few examples of carbene reactions proper have been described for these compounds. Thus thermolysis of $(CF_3)_3Sb$ at 180–220°C and of $Ph_2SbCCl_3$ at 120°C as well as the decomposition of the unstable $(CCl_3)_3Sb$ proceed, judging from the reaction products, with the intermediate formation of the corresponding dihalogenocarbenes[282,283]. Free difluorocarbene is undoubtedly formed also in the thermolysis of perfluoromethylphosphoranes[284,285]:

$(n = 1-3)$

$\alpha$-Dimethylphosphonodiazoalkanes $RC(N_2)PO(OMe)_2$ are thermally extremely stable compounds which decompose under the influence of metallic copper with formation of the corresponding phosphonocarbenes, capable of converting olefins into cyclopropanes or (depending on R) of rearranging to the corresponding unsaturated compounds, for example[286-288]:

Diazo-compounds of the type $Ph_2POC(N_2)R$ (R = H, Ph, $CONH_2$, or COOEt) undergo ultraviolet photolysis to form the carbenes $Ph_2POCR$, which undergo the Wolff rearrangement, like carbonylcarbenes, leading to $O{=}P(Ph){=}CPhR$; the decomposition of these diazo-compounds under the influence of copper takes place without a rearrangement[289].

## 8. Carbenes Derived from Transition Metal Compounds

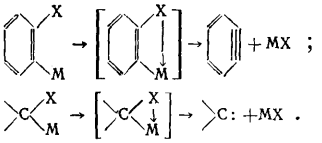
The most characteristic feature of transition metals is their exceptional tendency to fill their vacant atomic orbitals with the electron pairs of ligands; in particular, the occupied molecular orbitals of various organic compounds can play the role of electron pairs. For this reason, organic derivatives of transition metals in which all the coordination vacancies are occupied show the greatest stability. The above condition is satisfied by the carbene complexes of transition metals of the type $(CO)_5MCR(Y)$ (where M = Cr, Mo, or W; Y = OR or $NR_2$; R = alkyl or aryl), formed when the corresponding hexacarbonyls interact with RLi, this being followed by the methylation or aminomethylation of the adduct $(CO)_5MCR.(OLi)$.[290] Owing to the formation of the normal C–M$\sigma$ bonds and the coordinate bond involving nitrogen or oxygen $p$ electrons, compounds of this type are quite stable and can dissociate with formation of the nucleophilic carbenes :CYR only at elevated temperatures. Thus $(CO)_5CrCPh.(OMe)$ forms a mixture of stereoisomeric $\alpha\alpha'$-dimethoxystilbenes—dimers of the carbene :CPh(OMe)—only at 135°C.[291] However, the same compound is capable of converting crotonate esters into cyclopropane derivatives even at 80°C and $Ph_2SiH_2$ into $Ph_2SiHCH(OMe)Ph$ (albeit with a low yield) even at 55°C.[292,293] Under the influence of pyridine, the complex $(CO)_5CrC(OEt)Me$ decomposes at 60°C with the intermediate formation of the carbene :CMe(OEt), which does not, however, form the corresponding cyclopropane derivatives on reaction with olefins and isomerises wholly to methyl vinyl ether[294]. Complexes of the type $(CO)_5MCPh(OMe)$, where M = Cr, Mo, or W, convert the esters of $\alpha\beta$-unsaturated acids into cyclopropane derivatives at 90–140°C and alkyl vinyl ethers are converted into cyclopropanes even at 50°C in the presence of CO under pressure, the isomeric composition of the cyclopropane derivatives formed depending on the nature of the metal[295,296]. On being refluxed with $PhHgCX_3$ in benzene, the complex $(CO)_5Cr(OMe)Ph$ forms mixed dimers of electrophilic and nucleophilic carbenes of the type $Ph(MeO)C{=}CX_2$.[297] The compound $(CO)_5WCPh_2$ converts ethyl vinyl ether at 37°C and isobutene only at 100°C into cyclopropane derivatives[298].

The facts enumerated above undoubtedly show that in the vast majority of cases the transfer of the carbene from its transition metal complex takes place without the formation of the kinetically free carbene and is a consequence of the reaction of the complex with the substrate. This is confirmed by the fact that the chiral complex (–)-(*R*)-$MePrPhP(CO)_4CrPh(OMe)$ reacts with diethyl fumarate to form the optically active 2,3-diethoxycarbonyl-1-methoxy-1-phenylcyclopropane[299].

Several $\alpha$-chloromethyl compounds of transition metals, which behave as the precursors of the corresponding carbenes like the analogous compounds of other metals, are known. Thus, when $CrBPh_4$ or $(C_6H_6)_2CrBPh_4$ was heated with $CCl_4$ in the presence of cyclohexene, 7,7-dichloronorcarane was obtained in 50–54% yields. The reaction apparently proceeds with the intermediate formation of the trichloromethyl derivative of chromium $CCl_3CrClBPh_4$.[300] The chloromethyliridium compound $(Ph_3P)_2(CO)IrCH_2Cl$ interacts with styrene to form a mixture of phenylcyclopropane and 2-methylstyrene but is incapable of introducing the methylene group into cyclohexene[301]. In the presence of hydrochloric acid, the iron complex $(\pi\text{-}C_5H_5).(CO)_2FeCH_2OMe$ introduces the methylene group into cyclohexene at 50°C with a high yield; it has been suggested that $(\pi\text{-}C_5H_5)(CO)_2FeCH_2Cl$ is an intermediate in

this reaction. The same methoxymethyl derivative of iron as well as $(\pi\text{-}C_5H_5)(CO)_3MoCH_2OMe$ introduce the methylene group into cyclohexene on treatment with $HBF_4$ even at 0°C.[302]

Thermolysis of the iridium complexes $(Ph_3P)_2(CO)IrCl.(OCOCF_2Cl)X$, where X = H or $CHF_2$, proceeds with the elimination of $CO_2$ and difluorocarbene judging from the formation of compounds of the type $(Ph_3P)_2(CO)IrCl_2X$, but attempts to obtain by this reaction the adducts of difluorocarbene with olefins were unsuccessful[303]. On the other hand, the trifluoromethyl derivative of iron $CF_2Fe(CO)_4I$ decomposes at 100°C, forming difluoro- and perfluorocyclopropanes on reaction with ethylene and tetrafluoroethylene respectively[304].



The complex $(CO)_5WCPh_2$, mentioned above, and the analogous chromium complex react with isobutene at 100°C to form not only the corresponding cyclopropane but also (mainly) 1,1-diphenylethylene. The analogous reaction with $\alpha$-methoxystyrene also gives $CH_2{=}CPh_2$ and the stable complexes $(CO)_5MC(OMe)Ph$. The reaction of the carbonyl complexes of diphenylcarbene with olefins thus proceeds via a redistribution of the fragments of the C=C bond, i.e. is an analogue of the metathesis of olefins[298]. The intermediate involvement of carbene complexes has been recently suggested in the discussion of the mechanism of the metathesis reaction proper[305].

The methylene complex of tantalum $(\pi\text{-}C_5H_5)_2Ta(CH_3).CH_2$, which was synthesised recently[306], disproportionates slowly at 25°C, forming the corresponding ethylene complex $(\pi\text{-}C_5H_5)_2Ta(CH_3)C_2H_4$, but the reaction apparently proceeds without the involvement of free $CH_2$. It is of interest that the methylene entering into the composition of this complex manifests nucleophilic and not electrophilic properties. According to NMR data, the barrier to the rotation of $CH_2$ about the Ta–C bond is approximately 20 kcal mole$^{-1}$.[307]

## VI. THE MECHANISM OF THE DECOMPOSITION OF HALOGENO-DERIVATIVES OF ORGANOMETALLIC COMPOUNDS‡

The data presented for the thermal stabilities of *o*-halogenoaryl and $\alpha$-halogenomethyl derivatives of organometallic compounds demonstrate convincingly that their decomposition with formation of arynes and carbenes proceeds with participation of a vacant orbital of the metal. Indeed, numerous lithium, magnesium, boron, aluminium, zinc, and transition metal compounds are much more stable in the form of their complexes with *n*-donor ligands, which is not observed for compounds of metals with a lone electron-accepting capacity (for example, mercury). The finding that halogeno-derivatives of organic Group I–III elements having vacant *p* orbitals are on the whole much less stable than their analogues formed from elements in Group IV and subsequent Groups is undoubtedly also associated with the involvement of a free metal orbital in the reaction.

On the other hand, analysis of the literature data shows that the reactions under consideration can be readily carried out as single-stage processes only when the second eliminated group contains a free electron pair. The generality of these conclusions suggests that the most probable pathway in the decomposition of organometallic precursors of arynes and carbenes is intramolecular coordination[308,309], being apparently the pathway involving least migration[310]:

This conclusion can evidently be justified theoretically on the basis of the simple theory of molecular orbitals and their interactions, the applicability of which (particularly of the principle of the conservation of the key properties of the molecular orbitals during the reaction[105]) to the related problems of the mechanisms of the reactions of organometallic compounds has been demonstrated recently[311].

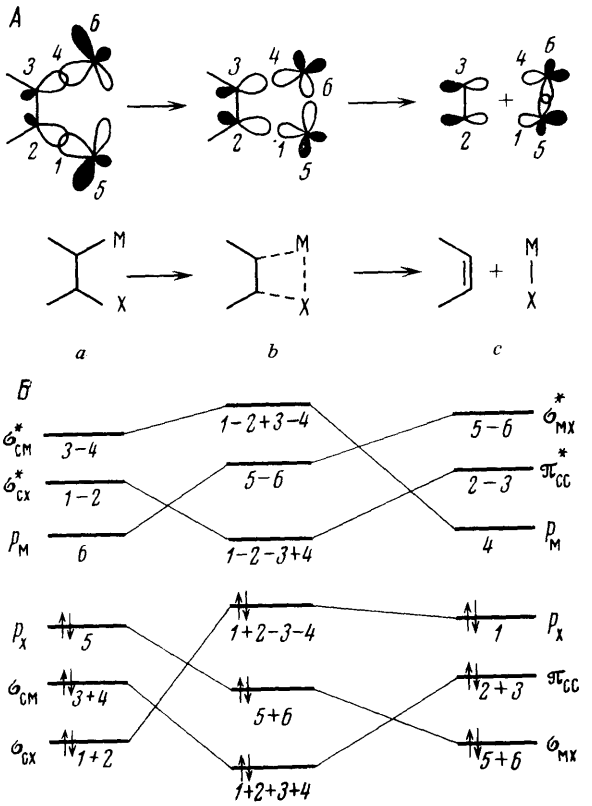


**Figure 2.** *A*) Changes in the molecular orbitals during the concerted decomposition of vicinal halogeno-derivatives of organometallic compounds [*a*) initial compound; *b*) transition state; *c*) reaction products]; *B*) correlation diagram (after Zimmerman[105]); the numerals on the diagram correspond to the numbering of the atomic orbitals.

It follows from the correlation diagram that the decomposition of vicinal (and similarly also geminal) halogeno-derivatives of organometallic compounds is symmetry-allowed when the coordinating orbitals are the boundary orbitals of the system (Fig. 2). In contrast to this, the

‡This section was written jointly with A.I. Ioffe.

synchronous decomposition of compounds of this type, which proceeds with participation of the molecular orbitals of the C–X and C–H bonds only, is symmetry-forbidden as a (2*s* + 2*s*) cyclodecomposition process[90]. It is quite evident that the characteristics of the reactions considered are consistent with the hypothesis that symmetry-allowed processes take place preferentially.

In considering the factors determining the stability of halogeno-derivatives of organometallic compounds, one must therefore take into account the fact that the activation energies for the decomposition reactions must depend not only on the heat of reaction (according to the Bell–Evans–Polanyi principle but also on a number of factors determining intramolecular coordination: on the energy gap between the molecular orbitals of the donor and acceptor (the *p* orbitals of the halogen and metal atoms respectively), on the distance between the M and X atoms in the molecule of the initial compound, and on the strength of the metal–ligand coordinate bond (when the reaction is carried out in the appropriate solvents). The first two factors determine the position of the transition state on the reaction coordinate, since it is formed sooner (and the activation energy is correspondingly smaller) the greater the sum of the valence radii of the M and X atoms and the smaller the difference between the corresponding orbital ionisation potentials. For this reason, the most important factors determining the stability of the compounds under consideration include their capacity for the formation of associated species, since an extremely effective decrease of the X–M distance is thereby achieved (for example the Li–F distance is 3.3 Å in the $C_6H_4LiF$ monomer, while the corresponding distance in the tetramer having a structure analogous to that of methyl-lithium[312] is only 2.0 Å). The analogous effect should also be observed for dimers and one may therefore expect that associated halogeno-derivatives of organometallic compounds should be less stable (in the presence of a free metal orbital) than the corresponding monomeric compounds.

Owing to the lack of thermochemical data, the correct calculation of the heats of the reactions considered ($Q = D_{MX} + D_{CC} - D_{CM} - D_{CX}$, where $D$ are the heats of dissociation of the corresponding bonds)—undoubtedly the most important factor determining the activation energy—is so far impossible. However, for compounds of a single metal decomposing in the same medium with formation of the same unstable species (for example, the process $o\text{-}XC_6H_4Li \rightarrow LiX + C_6H_4$), the relative heats of reaction (and hence the ratio of the activation energies) for reactions involving different X may be estimated from the differences $\Delta D$ between the heats of dissociation of the M–X and C–X bonds. Owing to the lack of the necessary data for the heats of dissociation of the C–M bonds, the effects of various metals in their compounds may be estimated qualitatively using the data for the corresponding M–H bonds, the heats of dissociation of which are usually close to those of the C–M bonds[251]. Only a qualitative allowance for the remaining factors influencing the stability of halogeno-derivatives of organometallic compounds is at present possible.

Since the C–X bond strength is only one of the factors determining the heat of reaction, the attempts to relate the stability of halogeno-derivatives of organometallic compounds to this quantity alone usually do not lead to correct predictions. Virtually the only examples of a satisfactory correlation between $D_{CX}$ and $T_d$ are provided by the compounds $o\text{-}XC_6H_4Li$, whose decomposition temperatures $T_d$ decrease in the following sequence of X: F > Cl > Br,[40] and by $LiCHX_2$ (Cl > Br > I).[133,144,145] However, in these cases too the values of $\Delta D$ represent more satisfactorily the sequence in which the temperatures $T_d$ diminish as a function of X (F > Cl > Br) than do the values of $D_{CX}$ (F ≫ Cl > Br). The correlation usually drawn between $T_d$ and the polarity of the C–M bond is inapplicable to thermolytic reactions and comparison of the values of $D_{CM}$ as criteria of the stability of compounds of different metals usually leads to incorrect estimates. Thus the values of $D_{CM}$ for the C–Li and C–Hg bonds are similar [62 kcal mole$^{-1}$ for $CH_3Li$ and 56 kcal mole$^{-1}$ for $(CH_3)_2Hg$ [251,313]], while the decomposition temperature $T_d$ of $LiCCl_3$ is lower than that of $C_6H_5HgCCl_3$ by approximately 300°C.[81,188] Much more reasonable correlations are obtained in the analysis of the heats of reaction. Thus the sharp increase of stability observed on passing from alkali metals and magnesium to heavy metal derivatives is associated with a decrease of $D_{MX}$, so that $\Delta D$ = 30 – 50 kcal mole$^{-1}$ (for virtually constant values of $D_{CM}$).

When the relative stabilities of compounds of more similar metals are considered, one must take into account also the differences between the values of $D_{CM}$. It follows from the known values of $D_{MH}$ that the differences between the $D_{CM}$ for alkali metal and magnesium compounds should not exceed 10 kcal mole$^{-1}$. Examination of the values of $\Delta D - D_{MH}$ makes it possible to estimate the heats of the decomposition reactions of the analogous lithium, sodium, potassium, and magnesium compounds, the results showing their extreme similarity; the highest heat and hence the smallest activation energy should be observed for lithium and magnesium compounds, which is usually the case. Thus the decomposition temperatures $T_d$ of the compounds $MCHBr_2$ lie in the sequence Na ≃ MgX > K ≃ Li and those of the compounds MCBr lie in the sequence Na ≃ MgBr > Li ≃ K.[144,161,164] The difference between the heats of reaction of magnesium and lithium compounds, having virtually the same values of $\Delta D$, is determined by the difference between the values of $D_{CM}$, which (together with the difference between the heats of dissociation of the M–O etherate linkages) probably also determines the relative stabilities of the corresponding trifluoromethyl compounds: $CF_3MgBr \ll CF_3Li$.[142,164,314] One should note that, when an ionic mechanism obtains, the stability should in all cases follow the sequence XMg > Li > Na > K.

The relative stabilities of compounds whose decomposition leads to different molecules are greatly influenced by $D_{CC}$—the energy of the C–C bond formed in an unstable molecule. In particular, owing to the much smaller energy of the triple bond in cyclopentyne than in cyclohexyne and cycloheptyne, 2-bromo-1-lithiocyclopentene is much more stable than the corresponding six- and seven-membered compounds[31–33,315]. For the same reason, compounds such as 1-lithioperfluoronorbornene[315], halogeno-1,2-dilithioferrocenes[317], and lithio-derivatives of halogenothiophens and furans[318,319] are also stable. $D_{CC}$ for carbenes is equivalent to $E_{ST}$; according to calculations[88,89], this quantity is a maximum for $CF_2$ and a minimum for $CH_2$, while its value for $CCl_2$ has been estimated as being intermediate[86]. This sequence of values of $D_{CC}$, which is the reverse of that of $\Delta D$, evidently equalises the decomposition temperatures $T_d$ for $LiCX_3$ (F ≃ Cl ≃ Br)[40,130,142,144] and is the reason why the relative stability of $LiCHCl_2$ is much greater than that of $LiCH_2Cl$.[101,133]

The influence of the distance between the eliminated groups undoubtedly causes the decomposition temperature of $KCBr_3$ to be smaller than that of $NaCBr_3$.[161] In contrast

to monohalogeno-compounds, pentachloro- and pentabromo-phenyl-lithium should be monomeric or should form less strongly bound associated species for steric reasons, as a result of which the halogen–metal distance in these compounds should be greater. In conformity with these considerations, pentachloro- and pentabromo-lithiobenzenes are much more stable than the monohalogeno-compounds.[42,52,53] Stabilisation of this kind is observed also for pentahalogenophenyl Grignard reagents[52,66-70,74,320,321] and for biphenyl[59,60,322], phenyl ether[61], and pyridine[65] derivatives. 2-Bromo-2-lithiobiphenyl, in the stable conformation of which the planes of the benzene rings are mutually perpendicular and the distance between the Li and Br atoms exceeds 4.3 Å, are stable even on boiling in ether[53].

It appears evident that the energetic and structural factors examined are the main ones among those which determine the resistance of halogeno-derivatives of organometallic compounds to carbene or aryne decomposition. At the same time, the correct treatment of this problem must take into account also many other factors, such as the change in bond energy under the influence of substituents, the stability of reaction products, their heats of solvation, etc., which does not appear possible at the present time.

# The Electronic Structures and Properties of Polymeric Molecules with Conjugated Bonds

I.A.Misurkin and A.A.Ovchinnikov

Modern ideas about the electronic structure of the long molecules of polymers with conjugated bonds (CBP) are examined and their various physicochemical properties are discussed from the standpoint of these hypotheses.
The bibliography includes 162 references.

## I. INTRODUCTION

The modern theory of the electronic structure of molecules with conjugated bonds has had significant achievements in the qualitative and quantitative explanation of the properties of such systems. The possibility of applying semiempirical methods in order to explain and predict the properties of small molecules has been examined in reviews [1,2]. For large molecules (polymers), the employment of the usual quantum-chemical methods becomes impossible mainly owing to the large amount of computational work involved. On the other hand, methods usually employed in statistical physics and in solid-state physics are effective in such systems.

Large molecules have properties which their individual units or components do not possess [3]. Some of these properties are associated with the mechano-statistical properties of the macromolecular units joined together in succession and others are due to the continuous conjugated system or the appearance of long-range order. Irregularity of structure, defects, and heteroatoms have a considerable influence on the observed properties of large molecules and hinder their explanation.

In the present review, we shall consider the achievements and difficulties encountered in semiempirical theories when an attempt is made to explain and predict special properties (optical, magnetic, etc.) of long molecules of polymers with conjugated bonds (CBP). As for small molecules with conjugated bonds, the theoretical analysis of the properties of CBP macromolecules is based on the $\pi$-electron approximation using the corresponding model Hamiltonians [1,2].

Interest in long molecules with conjugated bonds has recently increased sharply after the work carried out by Little [4], who put forward the idea of synthesising on the basis of CBP an organic superconductor having a high critical temperature. These hopes were not fulfilled because CBP possess properties quite different from those postulated by Little. However, the idea of using organic compounds, one-dimensional and quasi-one-dimensional systems, in order to obtain substances with unusual properties is extremely fruitful. This is confirmed by the detection of metallic conduction in complexes of tetracyanoquinodimethane (TCNQ) with tetrathiafulvalene (TTF), *N*-methylphenazine (NMP), and alkali metals, for example TCNQ-TTF, NMP-TCNQ, Rb-TCNQ, etc. where the conduction is strongly anisotropic and takes place along stacks of TCNQ and acceptor species [5,6]. Stacks of identical molecules are weakly bound to one another, which makes it possible to employ for the analysis of such systems the same models as for CBP macromolecules. However, we may note that charge transfer in these donor–acceptor crystals leads to the need to take into account the Coulombic interaction throughout the bulk of the crystal. It has been found that the Coulombic energy of the crystals or the Madelung energy influences significantly the nature and degree of charge transfer from the donor to the acceptor [7,8], complicating the overall physical picture. Nevertheless, one-dimensional systems manifest their characteristic properties in any situation.

The unusual properties of CBP or quasi-one-dimensional systems are the first consequence of the "unidimensionality" of these systems. Naturally all such systems consist of three-dimensional atoms or molecules, so that the macromolecules or molecular stacks possess not only length but also "width" and "thickness". However, electrons or excitations (electronic or vibrational) in such systems can migrate only along a chain of atoms or a stack of molecules. Thus the motion of electrons or excitations is one-dimensional and in this sense the corresponding systems—macromolecules, chains of atoms, and stacks of molecules—are one-dimensional or quasi-one-dimensional. The prefix "quasi" emphasises that the systems are in fact three-dimensional, although

their most significant physicochemical properties are associated with the one-dimensional motion of electrons and excitations.

The limitations imposed on the number of spatial dimensions in which electrons or excitations can migrate diminish the number of possible situations and, in terms of the language of statistical physics, alter the phase volume. For example, when one electron is scattered by another, the electron moments before and after the collision are located on the same straight line. This finding permits the exact solutions for certain models of one-dimensional systems, since it is possible to recalculate all possible situations arising in the interaction of electrons.

The unidimensionality of the system leads to the appearance of interesting properties, which are much more rarely encountered in three-dimensional systems. A comparatively small number of quasi-one-dimensional systems, which manifested their unusual properties, as it were, at random, have so far been investigated. Now that the relation between the quasi-unidimensionality of the systems and their unusual properties has been understood, the problem arises of a purposeful search for and synthesis of quasi-one-dimensional systems and of the investigation of their properties. In the solution of this problem, theoretical ideas formulated at the present time will prove useful. They are in fact the main subject of the present review in relation to CBP macromolecules.

One-dimensional models have been fairly widely investigated in the theory of the condensed state of matter to test various theoretical constructions and approximations. Starting with the work of Bethe[9], Hulten[10], Orbach[11], and others[12,13], the investigators of one-dimensional models have been attracted by the possibility of obtaining exact solutions, so that these studies were in the main of methodological interest. However, the number of real one-dimensioal systems started to increase recently. Numerous CBP have been synthesised[14-17] and organometallic compounds with chains of metal atoms[18,19] and charge-transfer complexes based on TCNQ[5-8,20] have become available. Intensive investigation of the properties of polymers has begun; in particular the $-(SN)_n-$ polymer has been found to exhibit superconduction, albeit with a fairly low critical temperature ($T = 0.3$ K).[21] However, we may note that it became clear very soon that the polymeric sulphur nitride is not a quasi-one-dimensional crystal owing to the significant contribution of interchain interactions[22].

In the study of the properties of real quasi-one-dimensional systems, both the most rigorous and approximate methods have been used. The old theoretical results, which were seemingly obtained in the course of purely academic research, unexpectedly provided a key to the explanation of the properties of macromolecules which had been previously rejected. The sudden success of the theory can be explained or, more correctly, is associated with fairly general features of the development of modern science. On the one hand, physical chemistry accumulated numerous interesting facts about the properties of one-dimensional systems, mainly CBP molecules. In order to explain these facts, all the known concepts of quantum-chemistry were used, but they proved to be inadequate and we now understand that the reason is that the correct allowance for the interaction of electrons (electronic correlations) is the key factor in these problems. The problem of the interaction of electrons has been usually solved in quantum chemistry for small molecules and the consequences of allowing for the interaction of electrons in macromolecules, for which semi-empirical versions of the self-consistent field (SCF) approximation were usually employed, were not evident. On the other hand, various models for one-dimensional systems have been discussed for a long time in theoretical physics in order to discover the qualitatively new features resulting from a more accurate allowance for the interaction of electrons. These models have names which are fairly unusual for chemists and even quantum chemists: the Ising model, the Heisenberg chain, the spin Hamiltonian... For a long time, the results of these two groups of investigations were published independently in the form of two separate streams of informations addressed to different scientific circles. In the middle 1960s, these two streams finally combined and, as a result, it was possible to achieve considerable progress both in the solution of exact problems and in the explanation and prediction of physicochemical properties. This process has continued, since it became possible to synthesise specific substances with unusual properties.

In order to create quasi-one-dimensional systems and new types of polymers, it is necessary to employ the rich experience gained in modern organic chemistry. For this purpose, one must begin at least with the formulation of a general scientific view concerning the problem as a whole. At the present time investigators prefer to work on "projects", whose likely outcome is known *a priori*. We believe that in such a situation the synthesis of a one-dimensional or quasi-one-dimensional compound is a still more favourable project, because one is very likely to obtain a substance with unusual properties.

An interesting example is the observation of the very high hyperpolarisability $\chi^{(3)}$ of single crystals of polydiacetylene (PDA), which makes the substance very promising for use in non-linear optics and laser engineering[23]. PDA single crystals are large, contain no amorphous phase, and are almost free from defects and impurities[24,25], which is to a large extent caused by the method of their synthesis by solid-phase polymerisation from the crystalline phase of the initial monomers at a moderate temperature[26].

Returning to the problem of the electronic structure of CBP, one should note that the description of this problem in Soviet and foreign literature lags far behind the actual present level of its understanding. This is due to a phenomenon, familiar in science, where whole blocks of references are transferred from one source to another when books, papers, and handbooks are written, which temporarily protects the given research field from being penetrated by new concepts and ideas. One of the aims of the present review is to shorten this period.

## II. THE EVOLUTION OF VIEWS ON THE STRUCTURE OF CBP MACROMOLECULES

The first quasi-one-dimensional object investigated was a polyene chain, to which the theoretical studies by Lennard-Jones[27] and Coulson[28] were devoted. At that time it was known that the bond lengths in short polyenes alternate in accordance with the familiar Kekulé structures. The problem of whether the alternation of bond lengths in the polyene persists with increase of its length or whether the bond lengths become equalised, formulated in the above investigations, was solved using the "bond length–bond order" formula obtained by Lennard-Jones[27] in terms of the Hückel molecular orbital approximation for $\pi$ electrons,

taking into account the elasticity of the $\sigma$ skeleton [the Hückel–Lennard-Jones (HLJ) approximation].

At the same time Broocker and coworkers[29-35] investigated the absorption spectra of compounds with polyene chains, which made it possible to establish[36] the following relations. In the spectra of symmetrical cyanine dyes with an odd number of carbon atoms in the polyene chain, the wavelength of the first electronic transition increases by $\lambda_C = 1000 \pm 50$ Å following the addition of each CH=CH group to the polyene chain. This "red" shift does not diminish with increase of the length of the polyene chain, so that the energy of the first optical excitation $\Delta E$ tends to zero with increase of the length of the polyene chain. On the other hand, in asymmetric dyes with an even number of carbon atoms in the main conjugation chain and in polyenes with an even number of atoms, the intense optical absorption band ceases to shift with increase of the conjugation length, so that $\Delta E$ tends to a finite limit. The limiting value for polyenes $\Delta E_\infty \simeq 2.25$ eV (Fig. 1) has been obtained by extrapolating data obtained in studies on linear polyenes and annulenes[37-40].

The behaviour of $\Delta E$ for symmetrical dyes appeared natural from the standpoint of the molecular orbital method[41,42] or the metallic model[43,44]. According to these ideas, the distance between the levels and hence $\Delta E$ is inversely proportional to the chain length and a satisfactory theoretical estimate of the "red" shift was obtained: $\lambda_C \simeq 900$ Å.[32,43,44] From this point of view, the finite value of $\Delta E_\infty$ for polyenes and asymmetric dyes was completely incomprehensible. This constituted a serious theoretical problem, since it did not concern a hypothetical infinite polyene, as in the earlier investigations[27,28], but real molecules with finite dimensions: a limiting value of $\Delta E(N)$ was approcched when the number of atoms was $N \simeq 10$–12 (Fig. 1).

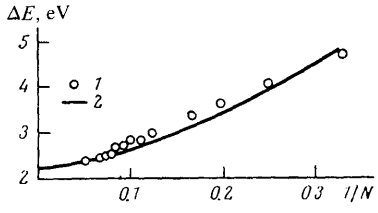

**Figure 1.** Dependence of the energy of the first electronic transition $\Delta E$ on $1/N$ in the polyene $(CH)_{2N}$: 1) experimental values[37]; 2) line drawn through points calculated by Eqn. (14).

The hypothesis of the alternation of bond lengths as the cause of the appearance of a $\Delta E_\infty$ gap in the spectra of excited polyenes was put forward for the first time by Kuhn[43,45,46], who proposed a model in which the non-interacting $\pi$ electrons migrate in a field with a sinusoidal potential, the minima of which correspond to the region of double bonds. By selecting a parameter $V_0$ associated with the amplitude of the potential, it was possible to make the $\Delta E$–$N$ relation consistent with experiment. However, it remained obscure which factors distinguish the double bonds in the chain. If we note that the early investigations[27,28] indicated that the bond lengths in an infinite polyene are equalised (a result which appeared erroneous in the light of the above ideas), then, apart from the intuitive feeling associated with Kekulé structures, there is no reason why the double bonds should be distinguishable. The problem of bond lengths in a polyene was soon solved in terms of the SCF approximation[47]. It was found that in the HLJ model[27,28] a long polyene with equal bond lengths passes to the energetically more favourable state with alternating bond lengths, provided that $N > N_{cr}$, where $N_{cr}$ depends on the model parameters.

In terms of the Hückel approximation, the energies of the molecular orbitals of $\pi$ electrons are given by

$$\varepsilon_n = \alpha_0 + 2\beta_0 \cos\frac{\pi n}{N}, \quad n = -N+1, \ldots, N, \qquad (1)$$

where $\alpha_0$ is the Coulomb integral and $\beta_0$ the resonance integral for the C–C bond. The total energy of the molecule is

$$E = E_\pi + E_\sigma,$$

where the energy of the $\sigma$ skeleton is additive with respect to the bonds:

$$E_\sigma = \sum_l E_{\sigma l}$$

and the energy of $\pi$ electrons is given by

$$E_\pi = 2\sum_{n=-\nu}^{\nu} \varepsilon_n, \quad \nu = \frac{N-1}{2}.$$

The number of levels (1) is equal to the number of $\pi$ electrons, so that in the ground state exactly half of the band defined by Eqn. (1) is occupied by two electrons in each molecular orbital. When the bond lengths alternate, the energies of the occupied molecular orbitals diminish and those of vacant orbitals increase, so that a gap $\Delta E_{alt}$ appears and $E_\pi$ decreases. However, under these conditions $E_\sigma$ increases because of the necessity to expend work against the elastic forces of the $\sigma$ skeleton during the extension and construction of bonds. As a result, the total energy minimum is reached for certain values of the alternating bond lengths. In the solid state theory, the alternation of bond lengths in a one-dimensional metal became known as the "Peierls theorem"[48]. In quantum chemistry, this result has been formulated in relation to polyenes[49-51].

In the light of the above ideas, it was natural to identify the optical gap with the gap obtained as a result of alternation:

$$\Delta E_\infty = \Delta E_{alt}. \qquad (2)$$

This view has been reflected in monographs[14-17,39] and became firmly established in the literature on CBP for a long time.

We may note that the alternation of bond lengths in the SCF or HLJ model is only fortuitously consistent with the ideas in theoretical chemistry on the alternation of double and single bonds. In fact, the bonds alternate (in the given models) because the number of $\pi$ electrons is equal to the number of atoms and the polyene $\pi$ band (1) with equal bond lengths is exactly half-filled; for this reason the gap $\Delta E_{alt}$ arises precisely above the filled band with a reduction of the energy of the latter, which is energetically favourable. If the polyene $\pi$ band (1) was one-third or two-thirds filled, then the state in which groups of three different bonds alternate forming three bands with a gap above the filled band, etc. would have become favourable for the same reasons. This problem has been investigated by the present authors[52].

In terms of the Hückel approximation, the spectrum of the molecular orbital energies of the polyene $(CH)_2N$ with alternating bond lengths (we shall consider a cyclic model to avoid the complication due to end effects) has the following form:

$$E_{\pm}(k) = \alpha_0 \pm [\beta_1^2 + \beta_2^2 + 2\beta_1\beta_2 \cos(\pi k/N)]^{1/2} \quad -\nu \leqslant k \leqslant \nu, \quad \nu = (N-1)/2, \tag{3}$$

where $\beta_1$ and $\beta_2$ are two resonance integrals corresponding to short and long bonds. In the ground state, the $E_-(k)$ levels are twice filled [with the minus sign before the root in Eqn. (3)], so that the gap is given by

$$\Delta E_{alt} = 2\,|\beta_1^2 + \beta_2^2 + 2\beta_1\beta_2 \cos(\pi\nu/N)]^{1/2} \simeq 2\,|\beta_1 - \beta_2|$$

for $N \to \infty$. Since the differences between the bond lengths are small ($R_2 - R_1 \simeq 0.04$ Å),[47,51] $\beta_1$ and $\beta_2$ can be expressed approximately in terms of the following expansions:

$$\beta_1 = \beta(R_1) = \beta_0 + \beta'\Delta R + \beta''\Delta R^2/2,$$
$$\beta_2 = \beta_0 - \beta'\Delta R + \beta''\Delta R^2/2,$$

where

$$\Delta R = R_2 - R_0 = R_0 - R_1, \quad \beta' = (\partial\beta/\partial R)_{R=R_0},$$
$$\beta'' = \left(\frac{\partial^2\beta}{\partial R^2}\right)_{R=R_0}$$

and $R_0$ is an average length equal to the C–C bond length in benzene. Then

$$\Delta E_{alt} = 2\,|\beta_1 - \beta_2| = 4\beta'\Delta R. \tag{4}$$

The main idea of the critical analysis of the scheme with alternation, carried out by the present authors[52-54], involved a test of the theory for the consistency of the semiempirical parameters. According to the alternation hypothesis (Eqns. (2) and (4)], $\Delta E_\infty$ is expressed in terms of $\beta'$, i.e. it depends on the form of the function $\beta(R)$. In vibrational excitations of molecules, the bond lengths also change, so that the vibration frequencies of molecules with conjugated bonds depend on the form of the same function $\beta(R)$. In order to secure information about the real parameters, expressions were obtained[53] for six frequencies of the in-plane vibrations of benzene in terms of three parameters of the HLJ model. Comparison with the experimental frequencies makes it possible to find these three parameters quite reliably: two elastic constants—for the extension of the bond ($k_1$) and the changes in the angle between adjoining bonds ($k_2$)—and (the third constant) the ratio

$$\beta'^2/\beta_0 = -1.23 \cdot 10^5 CGSE = -7.7 \text{ eV Å}^{-2}.$$

For the generally accepted value $\beta_0 = 2.4$ eV, we obtain $\beta' = 4.3$ eV Å$^{-1}$. This value of $\beta'$ agrees with X-ray diffraction data for bond lengths in conjugated molecules. Indeed, the following formula has been obtained[54] in terms of the same approximation for the C–C bond in a conjugated molecule:

$$R = R_0 - \frac{2\beta'}{k_0 + 2\beta''P} P, \tag{5}$$

where $P$ is the $\pi$-electron bond order, $R$ the bond length, $k_0$ the elastic constant of the $\sigma$ bond, and $R_0$ a constant. This formula is virtually identical with the familiar Coulson formula[55]

$$R = 1.517 - 0.18P, \tag{6}$$

which has been used effectively in calculations on conjugated systems. The coefficient 0.18 in Eqn. (6) is obtained from Eqn. (5) for $P \simeq 2/3$, $\beta' \simeq 4.3$ eV Å$^{-1}$, and $k_1 = k_0 + 2\beta''P \simeq 47.5$ eV Å$^{-2}$.

As a result, we obtain from Eqn. (4) $\Delta E_{alt} \simeq 0.3$ eV, which is smaller by a factor of ~10 than the experimental value of $\Delta E_\infty$ for polyene. This result can be understood on the basis of simple qualitative considerations: the energies associated with the distortion of bond lengths with alternation must be comparable in order of magnitude to the vibration energies, i.e. must amount to a fraction of an electron-volt. The above analysis shows that the considerable magnitude of the gap in the spectra of polyenes ($\Delta E_\infty \simeq 2.2$ eV) cannot be associated with the interactions of electrons with atomic vibrations and rearrangements of atomic configurations. At the same time, the necessity arises for the employment of a self-consistent set of semiempirical parameters. All these factors make it possible to interpret correctly the results obtained by methods more rigorous than the HLJ approximations. For example, in calculations of the first transition energies in a polyene[56], the Pariser–Parr–Pople (PPP) approximation was used, while another study[57] involved a method taking into account a limited number of excited configurations. A satisfactory agreement with experiment for the $\Delta E - N$ relation for polyenes with alternating bond lengths was achieved in this case using parameters which had not been adjusted for consistency with experiments on vibrations and with structural data. The same inconsistency between the parameters is characteristic of studies[16,58] where a semiempirical version of the SCF method was used to calculate the band structure of polyenes. Here too the agreement between the calculated energy gap and experiment did not demonstrate the validity of the alternation hypothesis.

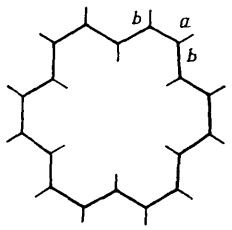

**Figure 2.** 18-Annulene. The group of three bonds *b*, *a*, *b* is repeated.

Analysis of experimental and calculated data for 18-annulene (Fig. 2) provided evidence against the alternation hypothesis. According to X-ray diffraction data[59], in this molecule 12 "inner" bonds have the length $b = 1.382 \pm 0.003$ Å and six outer bonds have the length $a = 1.419 \pm 0.004$ Å, i.e. a group of three bonds is repeated periodically and not a group of two, as in alternation. For such a structure, there is no gap in the spectrum, since among the three $\pi$-electron bands, the middle one is half-filled[52]. Nevertheless, the energy of the first transition in $C_{18}H_{18}$, which is $\Delta E = 2.77$ eV,[39,60] does not divide from the general relation (Fig. 1). Calculations by the PPP method, taking into account a large number of excited configurations, could not explain the observed absorption spectrum of 18-annulene; the energy of the first transition was much lower than the experimental value[60]. This did not naturally imply that the PPP method is inapplicable to many-electron molecules. Calculations on the spectra of coronene (24 $\pi$ electrons) and ovalene (32 $\pi$ electrons) by

the PPP method yielded excellent results[61]. It now became clear that the cause of the failure of the calculations on the spectrum of 18-annulene was that electron correlations are significant in one-dimensional chain molecules, and these are not taken into account in any way in the PPP method, where the ground state is described, as in the SCF or Hückel method, by a single configuration of $\pi$ electrons. The example of 18-annulene also showed that structural factors (bond lengths) do not have a significant influence on the energies of electronic optical excitations.

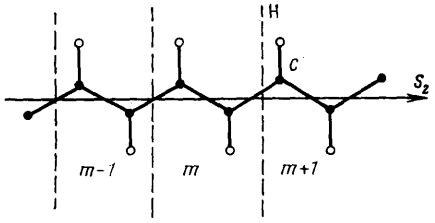

Figure 3. Schematic illustration of a polyene. The $(...m-1, m, m+1,...)$ cells into which the polyene was divided in the calculation in Ref. 62 and the mirror-rotational twofold symmetry axis $S_2$ are shown.

In conclusion of this section, we shall discuss the unexpected result obtained by Andre and Leroy[62], who investigated the electronic structure of a polyene by the SCF method taking into account all the valence electrons (the *ab initio* method in terms of the Hartree–Fock approximation). For a given polyene chain with equal C–C bond lengths, two $\pi$ electron bands were obtained (filled and vacant), separated by a gap of ~4 eV. This result, obtained *ab initio* from analytical basis functions in conjunction with computer calculations in accordance with a specified program, commanded respect and gave rise to the hope that latent causes exist for the appearance of $\Delta E_\infty$, which were overlooked in simpler semiempirical calculations. The authors[62] carried out calculations on a polyene with a structure close to the real structure taking into account hydrogen atoms (Fig. 3). The question arises if the cause involved the allowance for the interaction with the hydrogen atoms or the unusual structure of the real polyene. As frequently happens, numerical calculations did not provide an answer to such questions. The doubts were resolved in an elegant study by Ukrainskii [63], who analysed the method of calculation used by Andre and Leroy[62]. It was found that the latter workers artificially subdivided the polyene into CH–CH cells (Fig. 3) and, having specified the limiting distance for which the computer program no longer took into account the Coulombic interaction between the electrons, the computation was based on the number of neighbouring cells (in particular, it was restricted to three or five neighbouring cells). This condition artificially infringed the actual symmetry of the interaction and was equivalent to the superposition of an effective external field having a period with respect to the cells, which led to a pattern with two $\pi$-electron bands. The analysis showed[63] that the polyene illustrated in Fig. 3 possess a mirror-rotational twofold axis and that, in terms of the SCF approximation, the $\pi$ bands (filled and vacant) in a long polyene should adjoin in this case. In order to obtain this result, the authors[62] should have taken into account in their calculation a much larger number of neighbouring cells, since the Coulombic interaction weakens very slowly over large distances.

## III. THE INTERACTION BETWEEN ELECTRONS AND THE NATURE OF THE GROUND STATE OF CBP MACROMOLECULES

In a number of studies, an attempt was made to attribute the pronounced maximum in the absorption spectra of polyenes to the plasma vibrations of $\pi$ electrons. A large system with a regular structure can be excited to a state with regular changes in electron density at the atoms, which are characterised by a spatial period (wavelength) and frequency (energy) of the vibrations, referred to as the plasma vibrations. From the standpoint of the methods of quantum chemistry, plasma excitations are not fundamentally new types of excitations: their energies may be calculated in terms of the PPP approximation. Since the latter is fairly cumbersome when applied to large systems, other methods are effective in this instance: the random phase approximation (RPA), methods involving density matrices or Green functions, etc. The considerable similarity of the PPP and RPA approximations was discovered in calculations on small molecules where both approximations led to virtually identical energies and oscillator strengths for the excited states[64]. The relation between the PPP method and the plasma or RPA approximation has been analysed by Mestechkin[65].

It has been found[66,67] that, in one-dimensional systems of the type of polyene, the plasma vibration frequencies start from zero (in a polyene with equal bond lengths) or from the gap $\Delta E_{alt}$ (in a polyene with alternation). The specific features of one-dimensional systems were manifested by the absence of distinct plasma vibration frequencies, in contrast to a three-dimensional metal, where the plasma vibration frequencies have energies of the order of several eV and can be distinguished from other excitations. The calculations[66,67] were based on the SCF approximation for the ground state, which predetermined the resulting spectrum of plasma excitations.

The study of spin excitations in a polyene, where the spin density changes regularly at the atoms (the $\pi$-electron density remains unity) revealed the instability of the SCF state of the system in relation to the transition to an energetically more favourable state with alternating spin densities at the atoms[68]. In order to describe such a state, it was necessary to go outside the framework of the SCF approximation or the Hartree–Fock approximation in which two electrons with opposite spins occupy the same molecular orbital. Quantum chemistry already had at its disposal the corresponding approximate methods, but these were used mainly for the calculation of spin densities in radicals[2]. We have in mind primarily the method of alternant molecular orbitals (AMO) proposed by Löwdin[69,70] for the calculation of the electronic structures of molecules and crystals. The ideas concerning the distribution of electrons with different spins in different molecular orbitals used by Löwdin were applied for the first time by Hyleraas[71] in calculations on the helium atom and by Weinbaum[72] in calculations on the hydrogen molecule. The AMO method is also known as the method of different orbitals for different spins (DODS).[73] The DODS and AMO methods have been used in various calculations of the

electronic structures of solids [74-78] and conjugated systems [2,79]. The relation between the AMO method and the method of geminals was analysed by Kapuy [80]. Certain aspects of these methods have been discussed by Larson [81,82]. In all methods of the AMO type, allowance for the Coulombic repulsion of two electrons with different spins in the same atom is important. As a result, electrons with different spins "avoid" one another, which reduces the energy and favours the appearance of a spin structure of the antiferromagnetic type.

A generalised Hartree–Fock method (GHFM), which is a version of the AMO method adjusted for self-consistency, has been proposed [83,84] for the investigation of the electronic structures of long molecules with conjugated bonds. The Hamiltonian of the system of $\pi$ electrons for a cyclic polyene $(CH)_{2N}$ has the following form in terms of secondary quantisation†:

$$H_{\text{Hub}} = \alpha_0 \sum_{n\sigma} c^+_{n\sigma}c_{n\sigma} - \beta \sum_{n\sigma} (c^+_{n\sigma}c_{n+1,\sigma} + c^+_{n+1,\sigma}c_{n\sigma}) + \frac{\gamma}{2}\sum_{n\sigma} c^+_{n\sigma}c_{n\sigma}c^+_{n,-\sigma}c_{n,-\sigma}. \quad (7)$$

Here $\alpha_0$ is the Coulombic integral in the Hückel method, $-\beta$ the resonance integral of the C–C bond ($\beta > 0$), $\gamma < 0$ the parameter of the Coulombic repulsion of two $\pi$ electrons in a single carbon atom, and $c^+_{n\sigma}(c_{n\sigma})$ are the operators for the generation (annihilation) of an electron in the $n$th atom in the state with the $\varphi_n(r)$ basis function and the spin $\sigma = \pm 1/2$. The Hamiltonian defined by Eqn.(7) is called Hubbard's Hamiltonian [85] and differs from the PPP Hamiltonian defined by Eqn. (17) by the absence of terms with long-range Coulombic interaction. The use of Hubbard's Hamiltonian [Eqn. (7)] leads to a qualitatively correct description of the properties of polyene, although allowance for long-range Coulombic interaction may be important for other systems [86] (see Section VI below).

In terms of the GHFM approximation with the Hamiltonian defined by Eqn. (7), the variational wave function for the ground state of the polyene depends on the single variational parameter $\delta$ and has the following form:

$$|\Phi\rangle = \prod_{\sigma,|l|\leqslant\nu} f^+_{l\sigma}|0\rangle, \quad f^+_{l\sigma} = c^+_{l\sigma}\cos\theta_l + \lambda(\sigma)\, a^+_{l+N\sigma}\sin\theta_l, \quad (8)$$

where $\theta_l$ is defined by the formula

$$\sin 2\theta_l = \gamma\delta/[(\gamma\delta)^2 + 4\beta^2\cos^2(\pi l/N)]^{1/2}.$$

The operators $f^+_{l\sigma}$ correspond to the generation of an electron in the molecular orbital specified by the GHFM and are expressed in terms of the operators $a^+_{l\sigma}$ for the generation of an electron in the molecular orbital specified in the SCF approximation, the latter orbitals having the following form:

$$\psi^l_\sigma(r) = \frac{1}{\sqrt{2N}}\sum_n \exp(i\pi ln/N)\,\varphi_n(r)\sigma,$$

where $\delta$ is the spin function. The operators $a_{l\sigma}$, $c_{n\sigma}$, and $f_{l\sigma}$ are related by the following expressions:

$$c_{n\sigma} = \frac{1}{\sqrt{2N}}\sum_l \exp(i\pi ln/N)\, a_{l\sigma},$$
$$c_{n\sigma} = \sum_{l=-\nu}^{\nu} c^l_{n\sigma} f_{l\sigma} + \sum_{l=-\nu}^{\nu} c^{l+N}_{n\sigma} f_{l+N,\sigma}, \quad (9)$$
$$\nu = \frac{N-1}{2}.$$

†There are a few explanatory comments on secondary quantisation in quantum chemistry in the present authors' previous review [1].

Here the coefficients $c^l_{n\sigma}$ and $c^{l+N}_{n\sigma}$ are defined by the formulae

$$c^l_{n\sigma} = \frac{1}{\sqrt{2N}}[\cos\theta_l \exp(i\pi ln/N) + \lambda(\sigma)\sin\theta_l \exp(i\pi n(l+N)/N)],$$
$$c^{l+N}_{n\sigma} = \frac{1}{\sqrt{2N}}[-\lambda(\sigma)\sin\theta_l \exp(i\pi nl/N) + \cos\theta_l \exp(i\pi n(l+N)/N)], \quad (10)$$

where $\lambda(\sigma) = 2\sigma$ ($\sigma = \pm 1/2$), which corresponds to the ground state with alternation of spin densities at the atoms; the spin density at the $n$th atom is

$$\langle\Phi|(c^+_{n,1/2}c_{n,1/2} - c^+_{n,-1/2}c_{n,-1/2})|\Phi\rangle = -(-1)^n 2\delta. \quad (11)$$

This state will be conventionally referred to as the state with spin waves (SW). As will be shown below (Section III), in a long polyene this state has an antiferromagnetic spin structure, although the spin densities at the atoms disappear after the projection of the function (8) on the state with the total spin $S = 0$.

When $\lambda(\sigma) = 1$, Eqns. (8)–(10) define the state which we shall conventionally call the state with charge waves (CW). It may become the ground state for quasi-one-dimensional systems when account is taken in the Hamiltonian of terms with $\gamma_{mn}$, which will be described below (in Section VI).

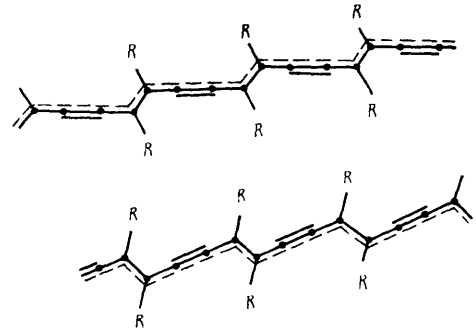

**Figure 4.** Schematic illustration of continuous conjugation (dashed lines) in the macromolecules of a polydiacetylene single crystal. The additional continuous lines indicate triple bonds.

The parameter $\delta$ for the polyene is determined from the equation

$$\frac{p}{2N}\sum_{l=-\nu}^{\nu}[(p\delta)^2 + \cos^2(\pi l/N)]^{-1/2} = 1, \quad p = \gamma/(2\beta), \quad (12)$$

which always has a solution $\delta \neq 0$. The molecular orbital energies are given by an expression of the type

$$E_{l\sigma} = \alpha_0 + \gamma/2 \pm [(\gamma\delta)^2 + 4\beta^2\cos^2(\pi l/N)]^{1/2}. \quad (13)$$

In the ground state, all the levels are filled, which corresponds to the minus sign before the root in Eqn. (13), so that the energy of the first electronic transition assumes the following form in terms of the GHFM approximation:

$$\Delta E(N) = 2[(\gamma\delta)^2 + 4\beta^2\cos^2(\pi\nu/N)]^{1/2}. \quad (14)$$

When $\beta = 2.4$ eV and $\gamma = 5.42$ eV, Eqn. (14) describes satisfactorily the energies of the first transitions in polyenes (Fig. 1). The value of $\gamma$ adopted is smaller by a factor of ~2 than that of $\gamma_{nn}$ in the PPP method, which is a consequence of the use of the approximation $\gamma_{mn} = 0$ (see Section VI). It follows from Eqn. (14) that $\Delta E_\infty = 2\gamma\delta$ when $N \to \infty$.

Recent experiments on the absorption of light by polydiacetylenes (PDA)[87] showed that $\Delta E_\infty \simeq 2$ eV for these polymers, which is in full agreement with the fact that the PDA macromolecule is in essence a polyene chain in which each fourth bond is somewhat shortened and close in properties to a triple bond (Fig. 4) owing to the presence in this bond of an additional pair of $\pi$ electrons in a molecular orbital at right angles to the polyene $\pi$-electron system corresponding to continuous conjugation in the polymer. The shortening of the individual bonds does not affect the nature of the ground state and the CBP absorption spectra, which is confirmed yet again by the example of PDA.

The optical gap $\Delta E_\infty$ in the absorption spectrum is virtually identical with the activation energy or the semiconductor gap of the CBP. For polymers of the type of a polyene[88] and crystalline PDA[89], it was found that the electrical conductivity $\Omega$ has a temperature dependence typical for an intrinsic semiconductor:

$$\Omega = \Omega_0 \exp(-E_{act}/(2kT)),$$

with an activation energy $E_{act} \simeq \Delta E_\infty \simeq 2$ eV. The activation energy for photoconduction in PDA[89] is also close to $\Delta E_\infty$.

## IV. THE SPIN STRUCTURE OF CBP MACROMOLECULES

In the discussion of the spin properties of CBP, we shall note in the first place that the function of the $\pi$ electrons of the polyene $|\Phi\rangle$ [see Eqns. (8)–(10)] with $\lambda(\sigma) = \sigma$ is an eigenfunction of the operator of the $z$-component of the total spin $\hat{S}_z$ with the eigenvalue $S_z = 0$, but is not an eigenfunction of the operator of the square of the total spin $\hat{S}^2$. This is a deficiency of the approximation, because the ground state should have a definite spin and, as a rule, this spin is zero (the singlet state). The average values of the components of the total spin in the $|\Phi\rangle$ state are zero:

$$\langle\Phi|\hat{S}_x|\Phi\rangle = \langle\Phi|\hat{S}_y|\Phi\rangle = \langle\Phi|\hat{S}_z|\Phi\rangle = 0,$$

but the average value of the square of the total spin is not zero[90]:

$$\langle\Phi|\hat{S}^2|\Phi\rangle \sim N.$$

One can say that in this sense $|\Phi\rangle$ is a state isotropic with respect to spin but not a singlet state. The variational solution for $|\Phi\rangle$ is close to the exact state with respect to energy (see Section VIII) and, in order to make it close to the exact state with respect to spin properties, it is necessary to project $|\Phi\rangle$ on to the state with the spin $S = 0$ or to isolate from $|\Phi\rangle$ the component with the total spin $S = 0$. This can be done in various ways[90–92]. The function $|\Phi_0\rangle$, which depends on a single parameter $\delta_0$ and has a more complex form than $|\Phi\rangle$, has been obtained[90,91]. It was found that in the $|\Phi_0\rangle$ singlet state the total energy, $\delta_0$ and the gap in the spectrum $\Delta E_\infty$ differ from the corresponding values for the $|\Phi\rangle$ state only by an amount $\sim 1/N$ for high values of $N$. It is important to know this in calculations, which can be carried out much more simply with a function of the $|\Phi\rangle$ type. However, the spin properties of the $|\Phi_0\rangle$ and $|\Phi\rangle$ states differ to a greater extent. The spin densities at the atoms in the $|\Phi_0\rangle$ state are zero, so that we have instead of Eqn. (11)

$$\langle\Phi_0|(c^+_{n,1/2}c_{n,1/2} - c^+_{n,-1/2}c_{n,-1/2})|\Phi_0\rangle = 0.$$

Nevertheless the $|\Phi_0\rangle$ singlet state will have an antiferromagnetic spin structure. This is because the average value of the spin correlation operator

$$\hat{K}(m) = \frac{1}{N}\sum_{n=1}^{2N}(\hat{S}_n\hat{S}_{n+m}),$$

where $\hat{S}_n$ is the spin operator at the $n^{th}$ atom, or the spin correlation function

$$K(m) = \langle\Phi_0|\hat{K}(m)|\Phi_0\rangle/\langle\Phi_0|\Phi_0\rangle$$

exhibit the following asymptotic behaviour when $m \to \infty$:

$$K(m) \simeq (-1)^m\delta^2.$$

This result indicates the presence of long-range antiferromagnetic spin order in a long polyene. We may note that the correlation function $K(m)$ has the same form for the $|\Phi\rangle$ and $|\Phi_0\rangle$ states[90,91].

A few other comments may be made concerning the unusual properties of antiferromagnetism in general and for organic molecules in particular. If we consider a small molecule ($H_2$, benzene, etc.), the corresponding correlation function $K(m)$ will be non-zero for any value of $m$ and in any approximation (ranging from the SCF approximation to the exact solution). This demonstrates simply the presence of spin correlation in the molecules, if only as a consequence of the Pauli principle. However, whatever the form of $K(m)$, it would be incorrect to speak of antiferromagnetism in such small molecules, because antiferromagnetism is in essence a property of a large and even infinite system with a regular steric structure when the spin structure is characterised by an antiferromagnetic long-range order. For example, when $K(m) \simeq (-1)^m \times$ const. for $m \to \infty$ in a system as large as in our case, we have an antiferromagnetic long-range spin order. For $K(m) \simeq$ const. and $m \to \infty$, we would have a ferromagnetic long-range spin order. The case where $K(m) = 0$ for $m \to \infty$ corresponds to the state without a spin structure and without a long-range spin order.

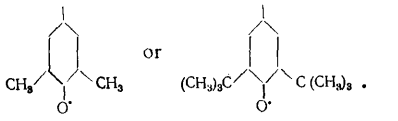
It would be incorrect to assume that the antiferromagnetic spin structure in long polyenes and other CBP macromolecules appears as a result of the application of the AMO method for which such a structure is typical. The AMO method is not optimal for the description of any alternant system with conjugated bonds. The method leads to a decrease of energy only for small molecules (where the concept of antiferromagnetism has no significance) or for large quasi-one-dimensional systems of the type of polyene, polyacene, etc. (see Section VII below). For the two-dimensional network of graphite the AMO state is unfavourable as regards energy[93]. For two- and three-dimensional systems, the parameters of the Hamiltonian defined by Eqn. (7) must satisfy very rigorous requirements to make a state of the AMO type favourable. These conclusions are in full agreement with the finding that in nature antiferromagnetism is an exception rather than the rule and at the same time leads to the conclusion that antiferromagnetism is a property characteristic of quasi-one-dimensional systems.

For small molecules, the state with a function of the AMO type is energetically favourable mainly as a consequence of the spin projection procedure. For example, the AMO state for $H_2$ or for the ethylene $\pi$ electrons is favourable only when special relations obtain between the parameters of the Hamiltonian, while the energy of the state with a singlet component of the AMO function for these molecules is always smaller than the energy of the state in the MO SCF approximation.

For large systems, the AMO energy also falls after spin projection. However, it has been shown[91] for a polyene that the energy of a large system decreases after spin projection by the constant $C_0 > 0$, which is independent of the number of electrons in the system $N$. As a result, it is found that, when the AMO method (without projection) is unfavourable compared with the MO SCF method, which is usually the case for two- and three-dimensional systems, then spin projection does not correct the situation. In fact, if we suppose that $E$(MO) and $E$(AMO) are the energies of a system of $N$ electrons in the MO and AMO methods without spin projection and that

$$E\,(\mathrm{MO}) \equiv \varepsilon\,(\mathrm{MO}) \cdot N < E\,(\mathrm{AMO}) \equiv \varepsilon\,(\mathrm{AMO}) \cdot N,$$

where $\epsilon$ is the energy per particle in both methods, spin projection diminishes the right-hand side of the inequality by the constant $C_0 > 0$, but does not infringe the inequality. We always have



$$\varepsilon\,(\mathrm{MO}) \cdot N < \varepsilon\,(\mathrm{AMO}) \cdot N - C_0,$$

because

$$\varepsilon\,(\mathrm{MO}) < \varepsilon\,(\mathrm{AMO}) - C_0/N$$

for fairly large values of $N$.

The antiferromagnetic spin structure in CBP molecules is a consequence of the mutual repulsion of electrons with different spins in the same atom. If these two electrons did not repel one another (in conformity with the Coulomb law) and effectively attracted one another (which might be promoted by an electron–phonon interaction or some other interaction), we would obtain a superconductor and not an antiferromagnetic material. Since electron repulsion in the CBP marromolecules is considerable, the introduction of side groups with a high polarisability does not transform electron repulsion into attraction[94]. For this reason, the mechanism of superconduction proposed by Little[4] does not operate in CBP macromolecules. Antiferromagnetism in hydrocarbons is a fairly unexpected property, but unfortunately so far it has been found to be fairly useless. However, one cannot rule out the possibility that the spin structure may be "manifested" following the introduction of side groups into the polyene chain. These may be phenoxy-groups:

If, for example, phenyl substituents in polyphenylacetylene (PPA) are replaced, if only partially, by these groups so that the latter are linked to only even (or only odd) atoms of the polyene chain, then a macromolecule of this kind should become ferromagnetic, because all the unpaired spins of the phenoxy-groups are polarised in the same direction via the central chain. Organic ferromagnetic substances are discussed in greater detail in Section XII.

## V. COMPETITION BETWEEN TWO TYPES OF STATES—WITH ALTERNATING BOND LENGTHS AND WITH SPIN WAVES

We may note that the nature of the ground state of a polyene depends significantly on semiempirical parameters. For self-consistent values of the parameters of the polyene, it was actually found that $\Delta E_{\mathrm{alt}} \ll \Delta E_\infty(\mathrm{GHFM}) \simeq \Delta E_\infty$. The state with spin waves was then found to be energetically more favourable as a result of taking into account the significant contribution of the correlation energy. Bearing in mind other quasi-one-dimensional systems, it is natural to formulate problems concerning the possibility of a situation in which the alternation of bond lengths is favourable and concerning the coexistence of states of two types. For the $\pi$ electrons of a long polyene with Hubbard's Hamiltonian and an elastic $\sigma$-skeleton at the temperature $T = 0$, these problems have been solved by Popov[95] and Falikov and Harris[96] in terms of the GHFM approximation. It was found that the state with alternating bond lengths and a gap $\Delta E_{\mathrm{alt}}$ is more favourable energetically when interactions between electrons and atomic vibrations predominate in the chain or when the inequality

$$\gamma/(2\beta) < 4\beta'^2/(\beta k_1). \tag{15}$$

holds. If Coulombic repulsion between electrons is more significant in the chain or

$$\gamma/(2\beta) > 4\beta'^2/(\beta k_1), \tag{16}$$

an antiferromagnetic state obtains with identical bond lengths and the gap $\Delta E_\infty$(GHFM). In infinitely long chains, either type of state may obtain depending on the relative values of the parameters: there is no coexistence between the states of the two types. Since formula (16) holds for conjugated hydrocarbons with a large store of energy,, the nature of the ground state will be determined by the electron interaction and, despite the appreciable differences between bond lengths, which usually alternate by virtue of boundary effects, mainly the state with spin waves arises in not unduly long polyenes; this can also be concluded in view of the similarity of the energy of the first electronic transition $\Delta E(N)$ to $\Delta E_\infty$ for not very large values of $N$ (Fig. 1). These conclusions concerning the competition between the two types of states have been extended to non-zero temperatures[97].

## VI. THE INFLUENCE OF THE LONG-RANGE COULOMBIC INTERACTION ON THE PROPERTIES OF CBP MACROMOLECULES

Fukutome[98] showed that the long-range Coulombic interaction in long CBP molecules can lead to a ground state with spin waves (SW) or with charge waves (CW). However, the energies of these two types of ground states were not calculated, so that it remained unknown which type actually obtains.

In order to investigate this problem, the present authors[86] used the variational function of the GHFM approximation (Eqn. (8)] for a cyclic polyene with a PPP Hamiltonian:

$$H_{\mathrm{PPP}} = H_{\mathrm{Hub}} + \frac{1}{2}\sum_{\substack{mn\\(m\neq n)}}\sum_{\sigma\sigma_1}\gamma_{mn}c^+_{m\sigma}c_{m\sigma}c^+_{n\sigma_1}c_{n\sigma_1} - \sum_{mn}\sum_{\sigma}\tilde{\gamma}_{mn}c^+_{n\sigma}c_{n\sigma} + \frac{1}{2}\sum_{\substack{mn\\(m\neq n)}}\tilde{\tilde{\gamma}}_{mn}, \tag{17}$$

where $H_{\mathrm{Hub}}$ is Hubbard's Hamiltonian [Eqn. (7)], $\gamma_{mn}$ are the parameters of the Coulombic repulsion of the electrons in the $m$ and $n$ atoms, $\tilde{\gamma}_{mn}$ are the parameters of the attraction of an electron from the $n$ atom to a positive $m$ ion, and $\tilde{\tilde{\gamma}}_{mn}$ are the parameters of the repulsion of $m$ and $n$ ions. In terms of the PPP approximation, all the parameters with identical $m$ and $n$ are equal[99]:

$$\gamma_{mn} = \tilde{\gamma}_{mn} = \tilde{\tilde{\gamma}}_{mn}.$$

As noted above, function (8) depends only on the single parameter $\delta$ and describes a state of the SW type when $\lambda(\sigma) = 2\sigma$ and a state of the CW type when $\lambda(\sigma) = 1$. The total average energy of the ground state $E(\mathrm{PPP}, \delta)$ depends on $\delta$ and the parameters of the PPP Hamiltonian, only one term in the expression for the total energy depending on the choice of $\lambda(\sigma)$:

$$E(\mathrm{PPP}, \delta) = A_0 - WB_0^2. \qquad (18)$$

where $A_0$ and $B_0$ are known functions and $W = 1$ when $\lambda(\sigma) = 2\sigma$ (SW type) or $W = 4M - 1$ when $\lambda(\sigma) = 1$ (CW type), $M$ being the Madelung sum for the chain:

$$M = -\sum_{t=1,2,\ldots} (-1)^t \gamma_{m+t,m}/\gamma > 0.$$

Analysis of Eqn. (18) for the total energy yields the following criterion of the type of the ground state: the SW type obtains for $M < 0.5$ and the CW type obtains for $M > 0.5$. This criterion, which is independent of $\delta$, can be understood: when $M$ is fairly large ($M > 0.5$), it is favourable for the systems to pass to a state with charge waves, since the gain in the Coulombic energy from the alternating charges, which is proportional to $M$, will be fairly large.

For Hubbard's Hamiltonian [Eqn. (7)], $M = 0$ and the ground state is always of the SW type. For the PPP Hamiltonian [Eqn. (17)], which is closer to the real Hamiltonian, $M$ depends both on the geometrical configuration of the chain and on the type of the semiempirical relation for $\gamma_{mn}$. It was found that, for many real configurations of the polyene chain and when the generally accepted formulae are used for $\gamma_{mn}$,[100,101] $M < 0.5$ is always obtained. This implies that the ground state of a long polyene has a structure with spin waves. Furthermore, the size of the gap in the spectrum of one-particle excitations proved to be[86] $\Delta E_\infty \simeq 2$ eV [in good agreement with experiment and with the results based on Hubbard's model (Section III)] when the Nishimoto–Mataga formula[101] is used:

$$\gamma_{mn} = 1.2935\,\gamma/(1.2935 + R_{mn}), \quad \gamma = 11.13\ \mathrm{eV}.$$

Hence one may conclude that Hubbard's model with its parameters gives a correct qualitative description of the experimental situation in polyenes and apparently in other conjugated macromolecules.

We may also note that the dependence of the type of ground state on $M$ makes it possible to formulate a hypothetical situation where the nature of the ground state and of its characteristic properties may change in a macromolecule following an alternation in its geometrical configuration (under the influence of external forces).

## VII. THE ELECTRONIC STRUCTURES OF CERTAIN CBP

The electronic structures of a number of quasi-one-dimensional systems of hydrocarbons and of the planar two-dimensional network of graphite have been calculated in terms of the GHFM approximation with Hubbard's Hamiltonian[90,102].

### 1. Polyacenes

The first members of the series of polyacenes in which the number of rings is $N = 2$, 3, 4, 5, and 6 are respectively naphthalene, anthracene, tetracene, pentacene, and hexacene. The experimental spectra[103] appeared to indicate the existence of a finite limit to the first electronic transition energy. A group of four atoms $a$, $b$, $c$, and $d$ is repeated periodically in the polyacene molecule (Fig. 5), so that the system is quasi-one-dimensional in the direction of an increase in the number of rings. In terms of Hückel's approximation, among the four $\pi$-electron bands two are filled and the third (vacant) adjoins the second closely. The alternation of the lengths of the outer bonds does not reduce the energy and does not lead to the appearance of a gap between the second and third bands[104]. However, transition to the state with spin waves is energetically favourable and in the ground state two bands of levels are filled:

$$E_l^{1,2} = \gamma/2 - [(\gamma\delta)^2 + [\beta_2 \pm \sqrt{4FF^* + \beta_2^2}]^2/4]^{1/2},$$
$$F \equiv \beta_1 (1 + \exp(i2\pi l/N)), \quad l = 1, 2, \ldots N.$$

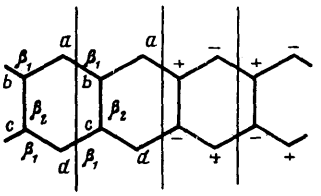


**Figure 5.** The polyacene cell with the designation of the opposite (+ and −) directions of the spin at carbon atoms and with an indication of the resonance integrals.

The third, vacant band is separated from the second (for $N \to \infty$) by a gap $\Delta E_\infty = 2\gamma\delta$ where $\delta$ is determined from the corresponding self-consistency equation. According to estimates, $\Delta E_\infty \simeq 1$–2 eV in polyacenes, which does not conflict with experimental data[103]. The antiferromagnetic spin structure in very long polyacenes (the opposite directions of the spins in the atoms are indicated by the plus and minus signs for atoms belonging to two of the periodically repeated polyacene cells in Fig. 5) must be understood in the same sense as for polyenes (see Section IV). Polyacenes are an example of quasi-one-dimensional systems differing from a linear chain of atoms.

### 2. Graphite

When aromatic rings are added in different directions and not in a single direction as in polyacenes, we obtain the planar hexagonal network of two-dimensional graphite. The properties of two- and three-dimensional graphite have been examined in detail in a review[105]. Here we shall consider the example of two-dimensional graphite in order to show how the "dimensionality" of the system is manifested in the calculation of its properties. It has been shown[90,102] that the two-dimensional network of graphite ($2N^2$ atoms) may exist in a state of the SW type if the GHFM self-consistency equation

$$\frac{\gamma}{2N^2}\sum_{j,k}[(\gamma\delta)^2 + |\varepsilon(jk)|^2]^{-1} = 1,$$
$$\varepsilon(jk) = \beta(1 + \exp(i2\pi k/N) + \exp(i2\pi j/N)),$$

has a solution $\delta \neq 0$. The function $|\epsilon(jk)|$ becomes zero in accordance with a linear law at two points in the region of variation of $(j, k)$, so that for double summation (a two-dimensional integral) these points are non-singular when $\delta \to 0$. The existence of a solution $\delta \neq 0$ therefore requires the fulfilment of the condition

$$\frac{\gamma}{2N^2}\sum_{j,k}|\varepsilon(j,k)|^{-1} \geqslant 1.$$

Hence we find that transition to a state with a spin structure is possible only for parameters satisfying the condition

$$\gamma/(2\beta) > (\gamma/2\beta)_{\text{crit}} \simeq 1.13, \qquad (19)$$

while in quasi-one-dimensional systems such a transition is possible for any parameters $\gamma/\beta \neq 0$. The "dimensionality" of the system is manifested in this sense.

The parameters of graphite are close to those of polyenes, for which the approximate equation

$$\gamma/(2\beta) \approx (\gamma/2\beta)_{\text{crit}}$$

holds. This leads to the following conclusions.

(1) The parameters of the electron interaction in graphite apparently do not satisfy inequality (19), so that the antiferromagnetic state does not occur (in agreement with experimental data).

(2) On the one hand, the closeness of the parameter $\gamma/(2\beta)$ to the critical value prevents conflict between the theory and experiment and, on the other, it indicates that graphite could make a transition to an antiferromagnetic state if it were possible, say, to extend somewhat all the bonds, to diminish $\beta$, and to satisfy inequality (19).

## 3. Cumulenes

Cumulenes are linear $=(C=C)_N=$ macromolecules consisting of carbon atoms and constituting in essence a third form of carbon (in addition to diamond and graphite [106-112]). In cumulene there are two mutually perpendicular subsystems of $\pi$ electrons (coupled systems of $2p_x$ and $2p_y$ functions; $z$ is the molecular axis). Each is analogous to the $\pi$-electron system of a polyene.

The electronic structure of cumulenes has been calculated [113] in terms of the SCF approximation on the hypothesis that the bond lengths alternate. However, as in polyenes, the effects of different bond lengths in cumulenes cannot play an appreciable role compared with the effects of electronic interactions. According to calculations in terms of the GHFM approximation [90,102], each of the $\pi$-electron subsystems of a long cumulene with identical bond lengths exists in a state with an antiferromagnetic spin structure and a gap in the spectrum of one-particle excitations, allowance for the Coulombic and exchange integrals $\gamma_{xy} = \langle xx|yy\rangle$ and $\tilde{\gamma}_{xy} = \langle xy|xy\rangle$ at each carbon atom leading to a correlation between the spin structures of these subsystems. As a result, the one-particle levels of each of the $\pi$-electron subsystems have the following form:

$$E_l = \gamma_{xy} \pm (\gamma - \tilde{\gamma}_{xy})/2 \pm [(\gamma \pm \tilde{\gamma}_{xy})^2\delta^2 + 4\beta^2\cos^2(\pi l/N)]^{1/2},$$

where the filled orbitals have the minus sign before the root and the vacant orbitals have the plus sign. The size of the gap in the spectrum of a long cumulene is

$$\Delta E_\infty = 2(\gamma \pm \tilde{\gamma}_{xy})\delta,$$

where $\delta$ is determined from the "polyene" Eqn. (12) but with another parameter: $p = (\gamma + \tilde{\gamma}_{xy})/(2\beta)$.

In order to estimate $\Delta E_\infty$, we shall assume that $\gamma = 5.42$ eV (as in polyenes), $\beta = k\beta_0$, where $k \simeq 1.5$, which corresponds, according to Streitwieser [114] to the C=C bond length in cumulene ($R = 1.28$ Å), [110,113] and $\beta_0 = 2.4$ eV. The value $\tilde{\gamma}_{xy} = 0.62$ eV was estimated from the formula $\tilde{\gamma}_{xy} = (\gamma_{xx} - \gamma_{xy})/2$, where the parameters $\gamma_{xx}$ and $\gamma_{xy}$ were found by analysing the spectra of atomic carbon and carbon ions [115,116]. We obtain as a result $\Delta E_\infty \simeq 1.2$ eV, in agreement with experiment [113] [$\Delta E_\infty$(exp) = 0.8–1.0 eV]. The state with spin waves ($\delta \neq 0$) is more favourable than the usual state ($\delta = 0$) for molecules with $N \geqslant 11$, i.e. for cumulene chains containing more than 22 carbon atoms.

In the crystalline phase, cumulene chains may contain several hundreds of atoms [110]. The results presented in Section V showed that the presence of an antiferromagnetic state in a long cumulene rules out the possibility of the alternation of bond lengths, since the bond lengths in long cumulenes are identical in the region remote from the ends of the chains.

It was convenient to use cumulenes for the investigation of the antiferromagnetic spin structure by the method of inelastic scattering of polarised neutrons, because they do not contain hydrogen atoms, whose nuclei interact strongly with neutrons. However, such studies are at present outside the scope of the available experimental technique.

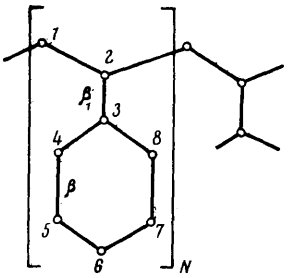

**Figure 6.** The elementary unit of polyphenylacetylene.

## 4. Polyphenylacetylene

The ground state of a long PPA molecule (Fig. 6) is characterised by an antiferromagnetic spin structure both in the central (polyene) conjugation chain of PPA, and in the benzene rings [117,118]. In conformity with the number of carbon atoms, there are in the elementary unit of PPA eight energy bands $E_{kl\sigma}$ ($k = 1,2,\ldots,8$), where $l = 1,2\ldots,N$ is the number of the level in the band and $N$ is the number of PPA units. For electrons with different spins and different values of $\sigma$, the molecular orbital energies are different (there is no such difference in polyenes, cumulenes, and polyacenes). The bands of cyclic PPA with $N = 17$ are illustrated schematically in Fig. 7. In the ground state, the levels of the bands with $k = 1$, 2, 3, and 4 are filled. Depending on the degree of conjugation of the benzene rings with the continuous conjugation chain (or on the resonance integral $\beta_1$; see Fig. 6), the limiting energy of the first one-particle excitation in the PPA

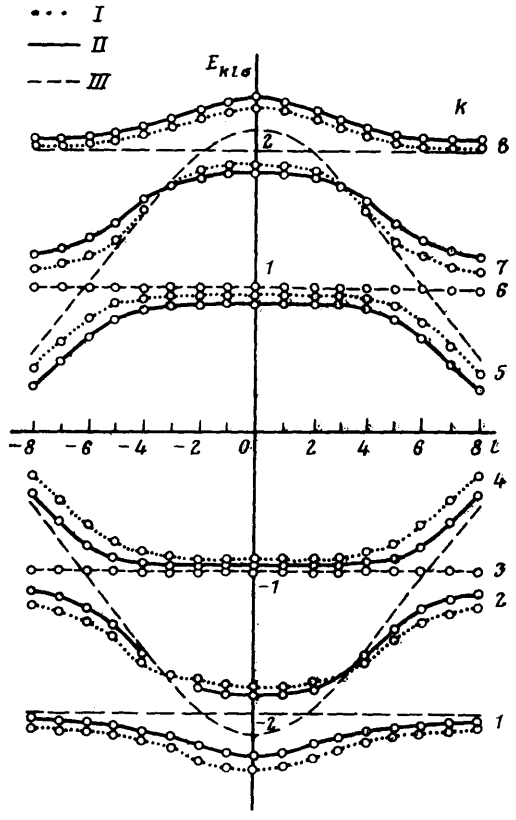

Figure 7. The one-electron energies (in units of $\beta$) $E_{kl\sigma}$ (circles) of cyclic PPA with $N = 17$ and $\beta_1/\beta = 0.875$ according to Refs. 117 and 118; $\sigma = -1/2$ (I) and $\sigma = 1/2$ (II); lines (III) correspond to $\beta_1 = 0$.

macromolecule changes from $\Delta E_{\infty}^{\min} = 1.6$ eV ($\beta_1 = \beta$, complete conjugation) to $\Delta E_{\infty}^{\max} = 2.2$ eV ($\beta_1 = 0$) when PPA is converted into a polyene with isolated benzene rings.

## VIII. EXACT METHODS FOR THE INVESTIGATION AND SYSTEMATIC TREATMENT OF EXCITED STATES

Despite the advances achieved in the application of GHFM approximation in order to explain the properties of long conjugated molecules, justified doubts remain about the adequacy of this approximation. In fact, it was known that a quasi-one-dimensional system described by Hubbard's Hamiltonian [Eqn. (7)] has excitations whose energies are not separated by a gap $\Delta E_{\infty}$ and approach the energy of the ground state for $\gamma/\beta \to \infty$, i.e. in the limiting case of isolated atoms. The energies of these states may be obtained by the diagonalisation of the effective Hamiltonian, which is called the Heisenberg spin Hamiltonian [119] and can be obtained from Hubbard's Hamiltonian [Eqn. (7)] for $\gamma/\beta \gg 1$, in the following form:

$$H_{\text{сп}} = \frac{4\beta^2}{\gamma} \sum_n \left( \hat{S}_n \hat{S}_{n+1} - \frac{1}{4} \right), \qquad (20)$$

where $\hat{S}_n$ is the spin operator at the $n$ atom. The eigenfunctions (states) for this Hamiltonian are called homeopolar (for $\gamma/\beta \gg 1$) or quasi-homeopolar (for the real values of the parameters). The spin Hamiltonian method for the description of the excigations of conjugated molecules was proposed by Bulaevskii [120,121]. Kohn [122] and Bulaevskii [120,121] found that the optical transitions from the ground to the quasi-homeopolar states are forbidden or their intensity is low. The GHFM approximation does not yield states of this type; however, it is shown below (Section IX) how triplet states of this type can be obtained in terms of the GHFM approximation.

The reliability of the GHFM approximation, the spin Hamiltonian methods, and other approximate methods was finally elucidated after obtaining the exact solutions for a one-dimensional system with Hubbard's Hamiltonian [Eqn. (7)]. The unidimensionality of the system is important for the exact solutions. Examination of a one-dimensional classical gas consisting of identical solid spheres which can move in only one direction before and after elastic collisions may help to understand the cause of this. By virtue of the energy and momentum conservation laws, when two spheres collide in a single dimension, they can only exchange velocities but cannot alter the values. Consequently in such a system the set of velocities of the spheres does not vary with time, i.e. the distribution function for the spheres with respect to momenta is an integral of motion. The appearance in a one-dimensional system of an additional conservation law analogous to that discussed above ensures the possibility of an exact solution of our quantum problem.

Only a few words need be said about the exact solution; it has been described in greater detail in the review of Ovchinnikov et al. [123]. Using the ideas put forward by Bethe [9], who obtained an exact solution for the ground state spin Hamiltonian [Eqn. (20)], Gaudin [124], Yang [125], and Lieb and Wu [126] obtained an exact expression for the eigenfunction of Hubbard's Hamiltonian [Eqn. (7)]. It has the following form:

$$\Psi(n_1, n_2, \ldots n_N) = \sum_P [Q, P] \exp\left( i \sum_j k_{P_j} n_{Q_j} \right);$$
$$n_{Q_1} \leqslant n_{Q_2} \leqslant \ldots \leqslant n_{Q_N},$$

where $n_Q$ are the coordinates of the electrons (the numbers of atoms in which the electrons are located), $k_{P_j} = k_1, k_2, \ldots, k_n$ is a set of quasi-momenta, which are the quantum numbers for the system, in conformity with the above comments on a one-dimensional gas, $Q = (Q_1, Q_2, \ldots, Q_n)$ and $P = (P_1, P_2, \ldots, P_n)$ are transpositions among the coordinates and quasi-momenta respectively. Furthermore, $[Q, P]$ are coefficients which depend on $Q$ and $P$; they are determined from the Schrödinger equation and the symmetry requirements. The total energy of the system is very simply expressd in terms of the quasi-momenta $k_j$:

$$E = -2\beta \sum_{j=1}^{N} \cos k_j. \qquad (21)$$

However, the quasi-momenta are determined from the solution of a system of transcendental equations and depend on certain quantum numbers. By an appropriate choice of these numbers, it is possible to find sets of quasi-momenta $k_j$ and to calculate the energies of the required states from Eqn. (21).

The exact energy of the ground state for an $N$-atom chain with Hubbard's Hamiltonian [Eqn. (7)] has been found by Lieb and Wu [126]:

$$E = -4N\beta \int_0^{\infty} \frac{\mathcal{J}_1(\omega) \cdot \mathcal{J}_0(\omega)\, d\omega}{\omega(1 + \exp(\omega p))}, \quad p = \frac{\gamma}{2\beta}, \quad N \gg 1.$$

where $\mathcal{J}_0(\omega)$ and $\mathcal{J}_1(\omega)$ are Bessel functions. The results of the exact calculation of the energy of the ground state are compared in Fig. 8 with the GHFM results for different ratios $\gamma/\beta$. We may note that, for real parameters $\gamma/\beta \simeq 2$, the energy gain (GHFM or exact) is small compared with the simple molecular orbital or Hartree–Fock approximation, but the rearrangement of the ground state is significant.

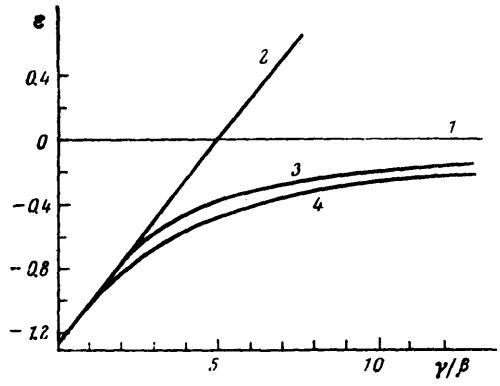

**Figure 8.** The energies of the ground state of the polyene $(CH)_{2N}$ $\pi$ electrons per electron $\epsilon = E/(2N\beta)$ in Hubbard's model as a function of the $\gamma/\beta$ ratio: 1) isolated atoms; 2) Hartree–Fock (MO SCF) method; 3) GHFM; 4) exact solution[127].

Hubbard's model, which is susceptible to an exact solution, makes it possible to carry out a complete qualitative investigation of the excitation spectrum of an $N$-atom model chain. All the states of the system with $\gamma/\beta \gg 1$, i.e. for large distances between the atoms, are subdivided into groups of states with similar energies. The first group consists of $2^N$ states of a quasi-homeopolar type, the energies of which, including the ground state, are also described by the spin Hamiltonian defined by Eqn. (20). For real parameters ($\gamma/\beta \simeq 2$), other approximations or exact methods are preferable. The exact spectrum of triplet excitations of the quasi-homeopolar type has been found by Ovchinnikov[128]. The first energy levels with the numbers $n = 1, 2, \ldots \ll N$ are equivalent:

$$\varepsilon_n^T = \frac{u}{N} n, \tag{22}$$

where

$$u = 4\pi\beta I_1(2\pi\beta/\gamma)/I_0(2\pi\beta/\gamma). \tag{23}$$

Here $I_0$ and $I_1$ are Bessel functions of an imaginary argument. The energy of each triplet excitation [Eqn. (22)] is inversely proportional to the number of atoms $N$ in a continuous conjugation chain and therefore may be smaller than $\Delta E_\infty$, approaching zero with increase of $N$. If $\beta = 2.4$ eV and $\gamma = 5.42$ eV,[84] then $u = 24.5$ Ev. For $\beta$-carotene (in this molecule the light absorption is determined by a linear polyene chain with $N = 22$), experiment gives[129] $\epsilon_1^T$(expt.) = 1.1 eV, while according to Eqns. (22) and (23) we have $\epsilon_1^T = 1.12$ eV. We shall describe below approximate methods for the calculation of $u$ in CBP (Section IX) and the influence of triplet states on the properties of CBP (Sections X and XI).

Apart from triplet states, the first group includes singlet quasi-homeopolar states, whose spectrum resembles that of triplet states (Fig. 9). The energies of the first singlet and triplet excitations are similar:

$$\varepsilon_1^S - \varepsilon_1^T \simeq N^{-3}; \quad N \to \infty.$$

A weak long-wavelength absorption of CBP is associated with the excitation of these singlet states[130]. In estimating the absorption coefficient $k(\omega)$, account was taken of the fact that polymers possess a broad molecular-weight distribution (MWD) in which it is important to know $p(N)$ (the density of macromolecules with a large number of atoms $N$ in a continuous conjugation chain) for the long-wavelength absorption:

$$p(N) = \frac{1}{\bar{N}} \exp(-N/\bar{N}), \tag{24}$$

where $\bar{N}$ is the MWD parameter. Assuming that only the first level $\epsilon_1^S = u/N$, to which corresponds an oscillator strength $f(N) \propto N$ and the line form parameter $\delta(\hbar\omega - \epsilon_1^S)$, is excited in each molecule and averaging with respect to MWD [Eqn. (24)], it is possible to derive the following formula for $k(\omega)$ [130]:

$$k(\omega) \propto \int \hbar\omega\, f(N) \cdot \exp(-N/\bar{N})\, \delta(\hbar\omega - u/N)\, dN. \tag{25}$$

The integration in Eqn. (25) is carried out with the aid of familiar rules for $\delta$-functions. As a result, we obtain the following relation between the absorption coefficient (proportional to the extinction coefficient) and the wavelength $\lambda$ of the absorbed radiation:

$$k(\lambda) = k_0 \lambda^2 \exp(-\lambda/\lambda_0), \qquad \frac{1}{\lambda_0} = \frac{u}{\bar{N}} \frac{1}{2\pi\hbar c}, \tag{26}$$

where $c$ is the velocity of light and $\hbar$ Planck's constant.

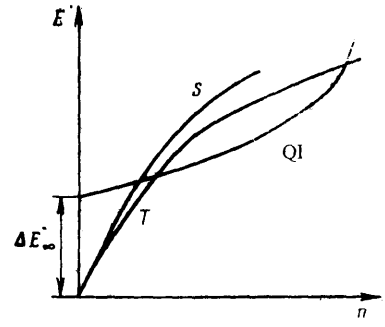

**Figure 9.** Schematic illustration of the energies $E$ of the excited states of a quasi-one-dimensional system; quasi-homeopolar singlet ($S$) and triplet ($T$) levels of the first group; quasi-ionic (QI) levels of the second group; $n$ is the number of the level.

The experimental absorption spectrum for PPA in the wavelength range from 700 to 1500 nm [131] is described with an adequate degree of approximation by Eqn. (26), whence it is possible to determine the ratio $u/\bar{N} \simeq 1.4$ eV. Thus the study of the long-wavelength absorption makes it possible to determine the MWD characteristics for CBP.[130] As will be seen below (Section X), the ratio $u/\bar{N}$ also

determines the paramagnetism of CBP at room temperature [130].

The second group of levels of the Hamiltonian defined by Eqn. (7), which becomes separated for $\gamma/\beta \gg 1$, consists of $N \times 2^N$ quasi-ionic states with excitation energies $\sim\gamma$. For the formation of such states, an electron of one atom must be transferred to another, where an electron is already present, which requires the expenditure of energy $\sim\gamma$ ($\gamma$ is exactly equal to the energy of repulsion of two electrons in the same atom). The resulting pair of charges (+ and −) on different atoms ensures the appearance of conduction, as a result of such excitations and justifies the term "quasi-ionic". This group of levels includes optically active excited states. Single-particle excitations, associated with electron transfer from a filled to a vacant GHFM band, describe very acuurately optically allowed excitations of states in the second group. The exact spectrum of quasi-ionic excitations has been found [132]. It was discovered that the latter have a gap in the spectrum (for $N \to \infty$):

$$\Delta E_\infty(\text{exact}) = \gamma - 4\beta + 8\beta \int_0^\infty \frac{\mathcal{J}_1(\omega)}{\omega} \frac{d\omega}{1+\exp(p\omega)}. \qquad (27)$$

This implies that the GHFM approximation reproduces correctly the situation with a gap in the spectrum of optically allowed excitations of long conjugated molecules. It has been found [128] that, for $\gamma/\beta \to 0$, we have

$$\Delta E_\infty(\text{exact}) \simeq \frac{8(\gamma\beta)^{1/2}}{\pi} \exp\left(-\frac{2\pi\beta}{\gamma}\right), \qquad (28)$$

whereas the GHFM approximation yields for the same limiting case

$$\Delta E_\infty(\text{GHFM}) \simeq 16\beta \exp\left(-\frac{2\pi\beta}{\gamma}\right).$$

The experimental value $\Delta E_\infty \simeq 2.2$ eV for polyenes is satisfactorily reproduced by Eqns. (27) and (28) with the parameters $\beta = 2.4$ eV and $\gamma = 8.5$ eV, which do not differ very greatly from the optimum GHFM parameters.

The third group of levels of the Hamiltonian defined by Eqn. (7), which becomes isolated for $\gamma/\beta \gg 1$, consists of $N(N-1) \times 2^{N-1}$ states with energies $\sim 2\gamma$ and a wave function having doubly ionic structures (with two pairs of + and − charges). The levels of this group (and all other groups) can occur in the visible and ultraviolet parts of the spectrum for real values of the parameters regardless of the number of the group.

We shall examine from the standpoint of this systematic treatment the excited states of the benzene molecule, paying attention to the covalent-ionic structure of the wave function, which were found by the exact numerical solution of the problem of benzene in the π-electron approximation (a six-atom chain) with the PPP Hamiltonian [68,133]. The ground state $^1A_{1g}$, the triplet state $^3B_{1u}$ (3.7 eV) and the singlet state $^1B_{2u}$ (4.8 eV) are quasi-homeopolar because the wave function of these states includes a contribution of covalent structures. The wave functions of the $^1B_{1u}$ (6.1 eV) and $^1E_{1u}$ (6.8 eV) states include no contributions of covalent structures and are therefore quasi-ionic [68,133]. The experimental excitation energies are indicated in brackets.

## IX. AN APPROXIMATE METHOD FOR THE CALCULATION OF THE SPECTRUM OF TRIPLET EXCITATIONS

The exact methods for the calculation of excitation energies are too complex to be applied to systems more complicated than polyene. Because of this, various approximations are as a rule used for real molecules. An approximate method, based on the calculation of the structure of CBP macromolecule in terms of the GHFM approximation and employing the technique of Green functions in a minimum volume, has been proposed [117,118,134] and applied to PPA and polyene chains (linear and closed). The fact that the Hartree–Fock equation for the Green function of a system of π electrons has solutions for both the ground and excited states is used in essence in this method. The proposed method of calculation is equivalent to the random phase approximation, which was shown by the identity of the secular equations for the excitation spectrum of a one-dimensional chain obtained by the two methods [74,75,117,134]. The study of the secular equations of the method of Misurkin and coworkers [117,134], which are not quoted here because of their cumbersome nature and the large number of new symbols, showed that they make it possible to find the energies of the singlet and triplet excitations of the system.

The energies of singlet excitation $\epsilon_i^S \geqslant E_\infty$. Transitions to these singlet states involve changes in electron density at the atoms and are responsible for the strong absorption in the optical region ($\hbar\omega \geqslant \Delta E_\infty$). The energies $\epsilon_i^S$ can be calculated with satisfactory accuracy in terms of the GHFM approximation as the difference between the energies of the corresponding molecular orbitals. However, the singlet excitations with energies $\epsilon_n^S < \Delta E_\infty$ are not described by this approximate method, so that in practice the only available information about these states has been obtained by exact methods for simple chains of the polyene type [128,132].

The spectrum of low-energy triplet excitations, obtained by the approximate method, is of the same form as that produced by the exact method [see Eqn. (22)]:

$$\epsilon_n^T = \frac{u}{N} n, \quad n = 1, 2, \ldots \ll N,$$

where $u$ is found by the numerical solution of the corresponding secular equations. These equations have been obtained and solved for cyclic and linear polyenes and for a cyclic model of the PPA macromolecule [117,118,134]. As an illustration, we quote below the secular equation for cyclic PPA with $N$ elementary units:

$$\sum_{m=1}^{8} A(mn \mid u) \cdot f(m) = f(n), \quad n = 1, 2, \ldots 8.$$

This system of linear equations has a non-trivial solution for $f(n)$, i.e. $f(n) \neq 0$, when one eigenvalue of the $A(mn|u)$ matrix is unity. From this condition, it is possible to find $u$ by means of a computer. The $A(mn|u)$ matrix has the following form:

$$A(mn \mid u) = A_1(mn \mid u) + \Delta(mn) \cdot A_2(mn \mid u),$$

$$A_1(mn \mid u) = -\frac{\gamma}{N} \sum_l \sum_{k=1}^{4} \sum_{p=5}^{8} \left[ \frac{c_{m\eta}^{k,l+1} c_{m\mu}^{pl} c_{n\eta}^{k,l+1} c_{n\mu}^{pl}}{E_{k,l+1,\eta} - E_{pl\mu} - u/2N} + \frac{c_{m\eta}^{p,l+1} c_{m\mu}^{kl} c_{n\eta}^{p,l+1} c_{n\mu}^{kl}}{E_{kl\mu} - E_{p,l+1,\eta} + u/2N} \right],$$

$$A_2(mn \mid u) = -\frac{\gamma}{N} \sum_{k=1}^{4} \sum_{p=5}^{8} \left[ \frac{c_{m\eta}^{k,-\nu} c_{m\mu}^{p\nu} c_{n\eta}^{k,-\nu} c_{n\mu}^{p\nu}}{E_{k,-\nu,\eta} - E_{p\nu\mu} - u/2N} + \frac{c_{m\eta}^{p,-\nu} c_{m\mu}^{k\nu} c_{n\eta}^{p,-\nu} c_{n\mu}^{k\nu}}{E_{k\nu\mu} - E_{p,-\nu,\eta} + u/2N} \right],$$

$$\eta = 1/2, \quad \mu = -1/2,$$

$$\Delta(mn) = 1 - 2(\delta_{n1} + \delta_{m1} - 2\delta_{m1}\delta_{n1}), \quad -\nu \leqslant l \leqslant \nu - 1, \quad \nu = (N-1)/2.$$

Here $m$ and $n$ are the numbers of atoms in the PPA unit ($m, n = 1, 2, \ldots, 8$), $k$ and $p$ are the numbers of filled and vacant MO bands, $l$ is the number of the molecular orbital in the band, and $c_{n\mu}^{pl}$ is the LCAO-MO coefficient for an electron with the spin $\mu = -1/2$ in a molecular orbital with the energy $E_{pl\mu}$. The remaining details and symbols are

described in the relevant papers [117,118]. Similar equations can be obtained and solved for any systems, both periodic and non-periodic: linear CBP, CBP with various defects, etc. The possibility of determining the energies of triplet excitations in long CBP molecules is particularly important, because properties of CBP such as paramagnetism at room temperature and catalytic properties are associated with these triplet states. Comparison of the results of the approximate and exact methods for a polyene with real values of the parameters [117,134] showed that they yield virtually the same values of $\epsilon_n^T$ (to within 6%).

## X. THE NATURE OF THE PARAMAGNETISM IN CBP

The presence of the electron spin (paramagnetic) resonance (ESR) signal is one of the characteristic properties of CBP. [135] The fairly complex dependence of the electronic structure of CBP on the conformation of macromolecules determines the complex nature of the dependence of the ESR signal on many external factors and makes it difficult to describe fully the paramagnetic properties of these polymers. A typical temperature dependence of the paramagnetic susceptibility $\chi$, measured by the ESR method for a PPA specimen, is illustrated in Fig. 10 (curve *1*) [136].

The paramagnetism of CBP is usually attributed to the presence of structural defects in the macromolecular chain [137-139], the presence of charge-transfer complexes (CTC), [140,141] and excitations to biradicals (triplet) states [142]. However, all these paramagnetic states have a formation energy which is too high (1–2 eV) and this precludes an explanation of the sharp increase of the ESR signal intensity on moderate heating in the region of room temperature. In fact, for the formation of biradical states the fragment of the macromolecule must be rotated about the conjugated bond by ~90°, which requires more than 1 eV [143] and leads to a triplet state with an odd number of $\pi$ electrons in each of the resulting fragments. In the condensed phase, this energy expenditure increases owing to steric hindrance. On formation of CTC, an electron is transferred from the highest occupied molecular orbital of one macromolecule to the lowest vacant molecular orbital of another, which requires the same energy expenditure as in the one-particle excitation, i.e. 1.5–2 eV (see Sections III and VII above). Nevertheless, stable paramagnetic defects of this type [137-142] can be formed in the synthesis of CBP and can contribute significantly to paramagnetism at low temperatures.

We may also note that, with increase of temperature, relaxation effects appear in the ESR signal of CBP, which cannot be explained, for example, by the recombination of paramagnetic centres. When the temperature is varied in the range 275–350 K, the ESR signal intensity varies in parallel with temperature, assuming initially an intermediate value, which continues to change slowly as the specimen is maintained at a given temperature. The ESR signal intensity or $\chi(T)$ reaches its limiting value (curve *1* in Fig. 10) after a time of the order of tens of minutes or hours, which depends strongly on temperature.

It has been suggested [144,145] that the thermal population of triplet states [with energies of the type defined by Eqn. (22)] in CBP macromolecules is responsible for a significant contribution to the paramagnetism of CBP at room temperature. A formula for the static paramagnetic susceptibility $\chi_N(T)$ per $\pi$ electron was obtained in the same investigations for a molecule with $N$ atoms in a continuous conjugation chain:

$$\chi_N(T) = \frac{2\mu_B^2 g^2}{kT} \exp\left(-\frac{u}{kTN}\right), \quad \frac{u}{kTN} \gg 1, \tag{29}$$

where $\mu_B = e\hbar/2mc$ is the Bohr magneton, $g = 2$, and $e$ and $m$ are the charge and mass of an electron. In the derivation of Eqn. (29), only the form of the triplet excitation spectrum [Eqn. (22)] was significant. The calculation of $u$ was described above (Section IX). For PPA, $u$ varies from 5.7 $\beta$ for $\beta_1 = \beta$ to 9.65 $\beta$ for $\beta_1 = 0$ (see Fig. 6 and Section VII above) [117,118]. CBP with a long continuous conjugation chain, for which triplet energies are smallest and their populations and contributions to paramagnetism are greatest, are important under the conditions of the thermal population of triplet states. Averaging of the quantity defined by Eqn. (29) with respect to the MWD [Eqn. (24)] for macromolecules with a large number of atoms leads to the following formula for the contribution of thermally excited triplet states to the static paramagnetic susceptibility [144,145]:

$$\chi(T) = \frac{2\mu_B^2 g^2}{kT} n_\pi \left(\pi^2 \frac{u}{\bar{N}kT}\right)^{1/4} \exp\left[-2\left(\frac{u}{\bar{N}kT}\right)^{1/2}\right], \tag{30}$$

where $n_\pi$ is the number of $\pi$ electrons in the CBP conjugation chain per gram.

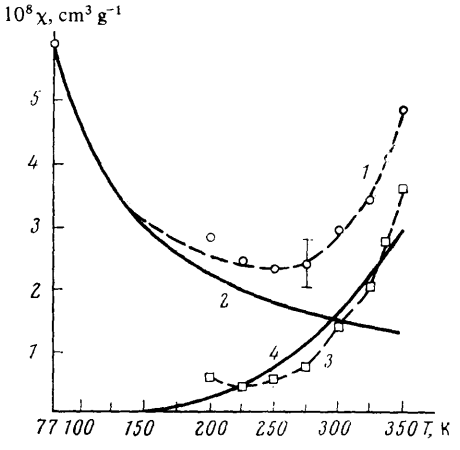

**Figure 10.** Dependence of the static paramagnetic susceptibility $\chi$ of PPA on the temperature T: 1) $\chi^{exp}(T)$ with an indication of the typical experimental error; 2) contribution of paramagnetic defects, $\chi_D = aT^{-1}$; 3) contribution of thermally excited triplet states, $\chi^{exp}(T) - aT^{-1}$; 4) theoretical dependence of the contribution of thermally excited triplet states according to Eqn. (30) with $n_\pi = 1.2 \times 10^{22}$ g$^{-1}$ and $u/\bar{N} = 0.76$ eV.

Since $\chi^{exp} \propto 1/T$ at low temperatures and $\chi^{exp}$ increases with increasing temperature when $T \geqslant 250$ K, $\chi^{exp}(T)$ has been represented [136] by the sum of two contributions with different temperature dependences:

$$\chi^{exp}(T) = aT^{-1} + bT^{-3/4} \exp(-cT^{-1/3}). \tag{31}$$

The first contribution, which obeys the Curie law, is due to different types of stable paramagnetic defects, CTC,

etc., which were discussed above. The contribution defined by the second term of Eqn. (31) is determined by the population of the triplet states and corresponds to Eqn. (30). The Curie constant $a$ was determined from the ESR signal intensity at 77 K where the contribution of the thermally excited paramagnetism is negligible: $a = 4.5 \times 10^{-6}$ cm$^3$ K g$^{-1}$. If the Langevin formula

$$a = n_D g^2 \mu_B^2 S(S+1)/3k$$

is used for $a$ and it is assumed that the paramagnetic defects have the spin $S = 1/2$, then the concentration of defects is $n_D = 6 \times 10^{18}$ g$^{-1}$. This implies that one defect corresponds to ~1000 PPA units.

Analysis showed that the experimental temperature dependence of the contribution of thermally excited triplets $\chi^{exp}(T) - aT^{-1}$ (Fig. 10, curve *3*) is described satisfactorily by the second term of Eqn. (31) (Fig. 10, curve *4*), provided that the theoretical expressions derived by identifying Eqn. (30) with the second term of Eqn. (31) are used to calculate the coefficients $b$ and $c$.[136] It has been found that $b = 1.03$ and $c = 187.7$ for the theoretical value $n = 1.2 \times 10^{22}$ g$^{-1}$ and the ratio $u/\bar{N} = 0.76$ eV, obtained for the values $u \simeq 14$ eV and $\bar{N} \simeq 18$, which are typical for PPA.[117,118,130]

Different types of paramagnetic centres should be reflected in the shape of the ESR signal. For PPA at room temperature, the signal consists of a superposition of at least two lines with $g = 2$ and having comparable intensities: one line has the width $\Delta H_1 = 5$–$8$ G and the other has $\Delta H_2 = 2$–$3$ G.[146] The hyperfine structure (HFS) of the first line resembles that of the PPA radical-anions arising following electron transfer from alkali metal atoms to PPA molecules[147]. The first line is apparently associated with stable paramagnetic defects or CTC and the second with thermally excited triplets, its small width being due to the considerable delocalisation of the triplet excitation over the macromolecule.

The problem of the relaxation of the ESR signal intensity in CBP is of interest and its investigation can yield useful information. The observed relaxation with characteristic times of the order of tens of minutes or hours is hardly associated with the intrinsic lifetimes of the excited triplet states, as has been suggested[144,145], because there are at present no adequate grounds for believing that these lifetimes are quite so long. The relaxation of the ESR signal can be explained more realistically by slow configurational distortions of the macromolecular skeleton, which partly alter the degree of bond conjugation.

In order to investigate this problem, a study was made[136] of a polyene chain with randomly distorted bonds, which have the resonance integrals

$$\beta_i = \beta_0 (1 - 0.1 q x_i), \quad i = 1, 2, \ldots 2N,$$

where $x_i$ are random numbers ($0 \leqslant x_i \leqslant 1$) and $q > 0$ is the disorder parameter. Calculations by the method described in Section IX showed that the parameter $u$, determining the extent of triplet excitation [Eqn. (22)], decreases almost linearly with increasing $q$ at a rate $\Delta u/\Delta q \simeq -\beta_0 < 0$. Using the dependence of $\beta_i$ on $\Delta R_i$ (increase in the length of the $i$th bond) or on $\Delta\varphi_i$ (the angle of rotation about the $i$th bond), estimates were made of the chain deformation energies using familiar semiempirical formulae[54,143]. It was found that the thermal energy at 300–350 K is in principle sufficient for deformations of macromolecules which lead to a change in the ESR signal intensity by 15–30%.

The deformation energy may be transmitted to the macromolecule from its environment and, according to the change in the ESR signal, only the deformations of very long molecules are appreciable, since only they contribute appreciably to the paramagnetism. The observed relaxation time is therefore the time during which very long molecules receive sufficient thermal energy and reach thermodynamic equilibrium with the molecules of the environment. The higher the temperature, the greater should be the number of small defects in the continuous conjugation chain. In other words, an increase of temperature entails an increase of the degree of disorder $q$ and hence a decrease of $u$, since the contribution of thermally excited triplet states to $\chi(T)$ should increase with $T$ faster than predicted by Eqn. (30) with a constant value of $u$. The systematic discrepancies between curves *3* and *4* in Fig. 10 for $T > 250$ K appear to confirm this view.

## XI. CATALYTIC ACTIVITY AND REACTIVITY OF CBP

The existence of triplet states with low excitation energies makes it possible to re-examine the known facts about the catalytic activity of CBP.[148–152] The catalytic activity of small amounts of added CBP in the *cis–trans* isomerisation of dimethyl maleate[149] has been examined theoretically[153]. During isomerisation, rotation about the central double bond results in an increase of the energy of the singlet state of the molecule and, in the vicinity of the angles of rotation $\varphi \simeq 70°$ and 110°, the singlet state intersects the triplet state, which has a significantly lower energy in the vicinity of $\varphi \simeq 90°$. A transition to the triplet state is therefore natural and this is interfered with only by the strong prohibition as regards multiplicity. When a long PCB molecule adjoins the molecule involved in the *cis–trans* transformation, the overall multiplicity of the complex may be conserved, provided that, simultaneously with the transition to the triplet state in the first molecule, there is also a transition to the triplet state in the CBP molecule[153]. As a result of the removal of prohibition of change in multiplicity, there is a significant increase (by a factor of $10^7$) in the pre-exponential factor in the expression for the rate of reaction, while the activation energy of the complex hardly changes and is given by

$$E_a = E_a^0 + \eta \frac{u}{N} - V_{13},$$

where $E_a^0$ is the activation energy for the non-catalytic reaction, $u/N$ the energy of the first triplet excitation [Eqn. (22)], $V_{13} = 0.1$–$0.3$ eV the exchange energy of the interaction of two molecules of the complex, and $\eta \simeq 0.5$ a coefficient which depends on the form of the intersection of the energy surfaces. The following expression has been obtained for the coefficient of the acceleration of the reaction $\kappa_N$ or the reaction rates in the presence of the catalyst ($W_{cat}$) and in its absence ($W_0$):

$$\kappa_N = W_{cat}/W_0 = 10^7 \exp(V_{13}/kT) \cdot \exp(-u/2NkT). \qquad (32)$$

At $T = 400$ K with the chosen values of the parameters $V_{13}$, $\eta$, and $u$ (Section X), we obtain $\kappa_N \simeq 10^{10} \times 10^{-160/N}$. Molecules with $N \geqslant 20$ can therefore catalyse the reaction at an appreciable rate. After averaging the quantity defined

by Eqn. (32) with respect to MWD [Eqn. (24)], we obtain the final expression for the acceleration coefficient [153]:

$$\varkappa = 10^7 \exp(V_{19}/kT) \cdot \left(\frac{u\pi^2}{2\bar{N}kT}\right)^{1/4} \cdot \exp\left[-2\left(\frac{u}{2kT\bar{N}}\right)^{1/2}\right]. \qquad (33)$$

For the chosen values of the parameters, $\kappa \simeq 10^5$.

CBP molecules with high values of $N$ catalyse the reaction either by the mechanism described above, without the involvement of a paramagnetic steady state, or as a result of the removal of prohibition of change in multiplicity in the presence of triplet species. The known examples of catalysis on graphite and with participation of CBP may be associated with both mechanisms. In terms of the ideas which have been developed, the correlation between the catalytic activity of CBP and their paramagnetic properties is understandable. One can also postulate that, in the presence of such correlation, the catalytic reaction requires the removal of prohibition of change in multiplicity. As an example, one may consider the reaction

$$CH_3CHOHCH_3 \rightarrow \begin{cases} CH_3{-}CH{=}CH_2 + H_2O \\ CH_3COCH_3 + H_2, \end{cases}$$

which is catalysed by CBP activated by charcoal and graphite [150]. The reaction apparently proceeds via a triplet state.

In conclusion, we shall consider the problem of the reactivity of CBP in addition reactions. According to a general postulate [154], the reactivity of $\pi$ systems in such reactions increases with increasing degree of conjugation. However, deviations from this rule are known, for example in reactions of the Diels–Alder type, where conjugation with the dienophile does not increase the reactivity [155]. It has also been suggested that the reactivity of polyenes longer than butadiene in addition reactions diminishes [156], despite the general postulate. Nevertheless, calculation on the model reaction involving the addition of the methyl radical to a polyene confirmed the validity of the general rule [157]. It was found that the stabilisation energy, which constitutes an effective reactivity index in this reaction decreases monotonically, tending to a definite limit as the length of the polyene increases. The activation energy $U$ also diminishes monotonically. According to the experimental data, $U_2 = 8$ kcal mole$^{-1}$ for the addition of the methyl radical to ethylene and $U_4 = 4.1$ kcal mole$^{-1}$ for its addition to butadiene. For a polyene with 20 carbon atoms, $U_{20} = 1.8$ kcal mole$^{-1}$, [157] which is virtually equal to the limiting value for the infinite polyene. One should note that the Hückel approximation was used in the calculation [157], because the activation energy is related to the differences between the total energies and the contribution of the correlation energy to this difference is insignificant.

## XII. THE MULTIPLICITY OF THE GROUND STATES OF LARGE ALTERNANT ORGANIC MOLECULES WITH CONJUGATED BONDS. ORGANIC FERROMAGNETIC SUBSTANCES [158]

In the first place, we shall specify more exactly what is understood by an alternant system. If the conjugated system is alternant, all its atoms can be divided into two groups, $A^0$ and $A^*$, in such a way that any $A^0$ atom has only $A^*$ atoms as neighbours and any $A^*$ atom has only $A^0$ neighbouring atoms. We assume that $A^0$ (or $A^*$) atoms may include chemically different atoms (C, N, O, etc.), so that our definition of alternant conjugated systems is wider than the generally accepted definition in which only conjugated hydrocarbons are considered.

When the problem of the multiplicity of the ground states of alternant conjugated systems is examined, a significant factor is, as shown by Bulaevskii [159], that the description of conjugated hydrocarbons by the spin Hamiltonian method is very exact when the ground state of the system and the quasi-homeopolar excited states with the lowest energies are considered. In order to determine the energies of all these states, it is necessary to find the spectrum of the Heisenberg Hamiltonian of the molecule:

$$H = \sum_{ll'} I_{ll'}\left(\hat{S}_l\hat{S}_{l'} - \frac{1}{4}\right), \qquad (34)$$

where $\hat{S}_l = (\hat{S}_l^x, \hat{S}_l^y, \hat{S}_l^z)$ is the spin operator ($S = 1/2$) of the carbon atom with the index $l$, the summation is carried out with respect to the neighbours $l$ and $l'$,

$$I_{12} = \frac{1}{2}\{((\gamma_{11} - \gamma_{12})^2 + 16\beta_{12}^2)^{1/2} - (\gamma_{11} - \gamma_{12})\};$$

and $\gamma_{11}$, $\gamma_{12}$, and $\beta_{12}$ are the usual parameters of the PPP Hamiltonian. We may note that, for large distances between atoms, we have $\gamma_{12} \ll \gamma_{11}$ and $\beta_{12} \ll \gamma_{11}$ and in this limiting state we obtain

$$I_{12} \simeq 4\beta_{12}^2/\gamma_{11},$$

so that the Hamiltonian defined by Eqn. (34) assumes the form defined by Eqn. (20). For the real parameters $\gamma ll'$, and $\beta_{ll'}$, the Hamiltonian defined by Eqn. (34) yields, for example, an energy of the first triplet excitation of benzene which differs by only 10% from the experimental value or the energy calculated in terms of the PPP approximation. This is in fact the accuracy of the spin Hamiltonian method which we postulated.

For an alternant conjugated system with the Hamiltonian defined by Eqn. (34), it is possible to prove the theorem that the ground state of such a system is non-degenerate [158]. In the derivation of this proof, which is not described here, the Hamiltonian defined by Eqn. (34) is expressed in the form

$$H = \frac{1}{2}\sum_{ll'} I_{ll'}^{(1)}(S_l^+S_{l'}^- + S_l^-S_{l'}^+) + \sum_{ll'} I_{ll'}^{(2)}\hat{S}_l^z\hat{S}_{l'}^z, \qquad (35)$$

$$S_l^{\pm} \equiv \hat{S}_l^x \pm i\hat{S}_l^y,$$

where

$$I_{ll'}^{(1)} = I_{ll'}^{(2)} = I_{ll'} > 0,$$

and use is made of the ideas put forward by Lieb et al. [160] and the fact that the system is alternant.

If $I_{ll'}^{(1)}$ and $I_{ll'}^{(2)}$ are now treated as independent parameters and it is assumed that $I_{ll'}^{(1)} = 0$, we obtain from Eqn. (35) the so called Ising Hamiltonian for which the ground state is one with spins directed upwards in $A^0$ atoms and downwards in $A^*$ atoms. If the number of $A^0$ atoms is not equal to the number of $A^*$ atoms, then $z$ — the projection of the total spin of the system in the Ising limit for the Hamiltonian defined by Eqn. (35) with $I_{ll'}^{(1)} = 0$ — will be non-zero and defined by the expression

$$S_z = \frac{|n_{A^0} - n_{A^*}|}{2},$$

so that the total spin is

$$S \geqslant \frac{|n_{A^0} - n_{A^*}|}{2},$$

where $n_A$ is the number of A atoms. Since according to the above theorem the ground state is non-degenerate, the

spin of the ground state will be the same whatever the value of $I_{ll'}^{(1)}$ and $I_{ll'}^{(2)}$. Hence it follows that, for the real spin Hamiltonian defined by Eqn. (35) or (34), the ground state will have the following total spin;

$$S \geqslant \frac{|n_{A^0} - n_{A^*}|}{2}. \qquad (36)$$

as for the Ising Hamiltonian. Examination of different examples showed that the following equality holds:

$$S = \frac{|n_{A^0} - n_{A^*}|}{2}. \qquad (37)$$

Thus, in order to determine the spin of the ground state of an alternant conjugated system, it is necessary to compute the numbers $n_{A^0}$ and $n_{A^*}$ and to use Eqn. (37).

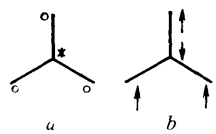

Figure 11. The trimethylmethylene molecule: *a*) atoms belonging to two groups, A* and A°; *b*) the arrangement of spins in the atoms in the ground state in the Ising limit.

We shall now analyse several examples. In the Ising limit, trimethylmethylene (Fig. 11*a*) has the configuration in the ground state with the arrangement of spins illustrated in Fig. 11*b*. Hence we have $S = 1$ for this molecule [in conformity with Eqn. (37)] and not $S = 2$, because the molecule can be obtained from an allyl radical ($S = 1/2$) and a carbon atom ($S = 1/2$) [carbyne radical (Ed. of Translation)] and, according to the moment addition rules, the combined spin can be either zero or one. The only possibility compatible with inequality (36) is $S = 1$.

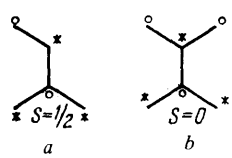

Figure 12. Hydrocarbon molecules having the total spins $S = 1/2$ (*a*) and $S = 0$ (*b*) in the ground state.

The molecules illustrated in Fig. 12 have the spins $S = 1/2$ and $S = 0$. The latter molecule is diamagnetic despite the fact that it has no Kekulé structure. Consequently an alternant molecule may not have a Kekulé structure and may be diamagnetic in the ground state.

Fig. 13 illustrates three isomeric hydrocarbons: (a) Chichibabin's hydrocarbon which Syrkin and Dyatkina[161] showed both experimentally and theoretically to be diamagnetic in the ground state but which has a small energy of excitation to the triplet state; (b) the Schlenk–Brauns hydrocarbon, which is firmly believed (according to the literature) to be a biradical, i.e. it has $S = 1$ in the ground state. This conflicts with our prediction, according to which this molecule should have $S = 0$ in the ground state. Hydrocarbons (a) and (b) have planes of symmetry with respect to the replacement of A* atoms by A° atoms, like the hydrocarbon illustrated in Fig. 12*b*. In the presence of such symmetry, the ground state always has $S = 0$. The third hydrocarbon (Fig. 13*c*), which does not have such symmetry, should have $S = 1$ in the ground state according to Eqn. (37).

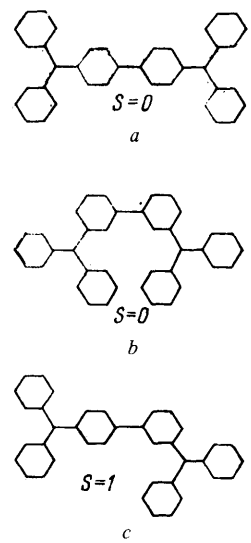

Figure 13. Large isomeric molecules: a) Chichibabin's hydrocarbon; b) Schlenk–Brauns hydrocarbon; c) hydrocarbon in which the number of atoms in one group is not equal to that in the other.

Next, Leo's triradical (Fig. 14) should have $S = 3/2$ in the ground state according to Eqn. (37). The condensed aromatic system illustrated in Fig. 15 has a total spin $S = (L - 1)/2$ which depends on the number of rows $L$ (with increasing number of rings in each succeeding row) (the fragment illustrated in Fig. 15 has $L = 5$ and $S = 2$). Other examples of polyradicals can be found in Buchachenko's book[162].

We shall now consider polymeric systems the total spin of which is proportional to their size. If these systems are synthesised, they will prove to be organic ferromagnetic substances. This can be seen from the preceding examples, one of which is discussed in Section IV; an unusual feature of these ferromagnetic substances is that the spins at neighbouring atoms are opposed, so that the spin order is the same as in an antiferromagnetic substance. However, the total number of atoms with the spins directed upwards is not equal to the number of atoms with the spins directed downwards and the difference between these numbers increases monotonically with increase in the size of the system; the total spin of the system is therefore proportional to its size. Fig. 16 illustrates several polymeric systems of

this kind. Either bivalent O, S, etc. atoms or some other stabilising groups can be selected as the substituent R. These systems are not hydrocarbons, but the above claims are valid also for alternant systems with heteroatoms.

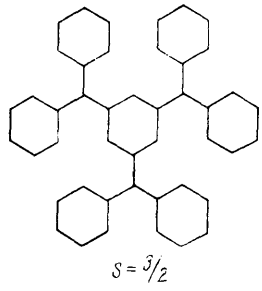

Figure 14. Leo's triradical.

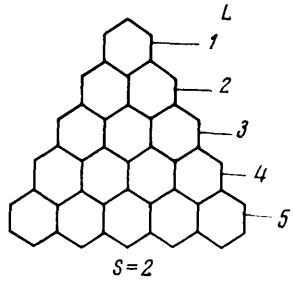

Figure 15. A triangular condensed aromatic system containing $L$ rows of rings ($L = 5$).

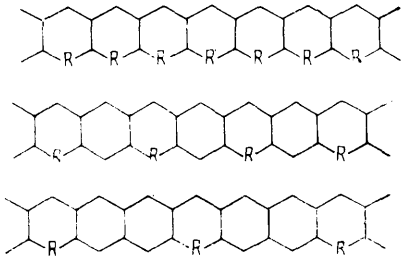

Figure 16. Macromolecules of hydrocarbons with periodically inserted heteroatoms (R = O or S).

Fig. 17 presents examples of two-dimensional infinite systems in which the total spin in the ground state is infinite: these are also ferromagnetic substances. The above systems can be constructed from the graphite network having replaced some of the carbon atoms by boron or nitrogen atoms. We may note that the graphite networks with boron atoms inserted at random have been known for a long time. The synthesis of all the structures of the above type will give rise to organic ferromagnetic substances.

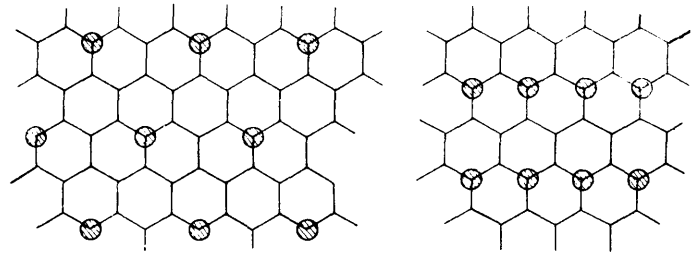

Figure 17. Two-dimensional structures obtained from the graphite structure by the replacement of the designated carbons atoms by boron or nitrogen atoms.

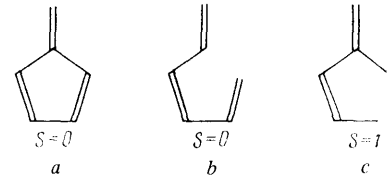

Figure 18. The fulvene molecule ($a$) and two alternant molecules obtained from the latter on dissociation of different bonds of the five-membered ring with $S = 0$ ($b$) and $S = 1$ ($c$).

The above theorems are invalid for non-alternant systems. However, some conclusions can be reached about them also. Consider, for example, the fulvene molecule (Fig. 18$a$). Its ground state has the spin $S = 0$, which has been demonstrated experimentally and by calculations. On opening the ring (Fig. 18$b$), the molecule is converted into a linear alternant system where the spin in the ground state is $S = 0$, while for another mode of ring opening (Fig. 18$c$) fulvene is converted into an alternant system with $S = 1$ in the ground state. Thus, using the ideas developed above, one may predict that the ring opening reaction in the $b$ molecule may occur under thermal conditions, while that in the $c$ molecule may occur with excitation to the triplet state, i.e. photochemically.

# The Structure and Properties of Block Copolymers and Their Solutions

L.Z.Rogovina and G.L.Slonimskii

The characteristics of the microphase structure of block copolymers and the decisive role of the incompatibility of the components of the block copolymer in this structure are examined and the factors influencing the type of structure and the size of the structural elements are discussed. A close relation is demonstrated between the segregation processes in dilute solutions and micelle formation on concentrating the solution, on the one hand, and the colloidal properties of solutions of copolymers determined by micelle formation and the structures of the solid polymers, on the other. The mechanical and physical properties of block copolymers are considered mainly in relation to thermo-elastomers.
The bibliography includes 254 references.

## I. INTRODUCTION

Block copolymers constitute a specific class of polymers, the main chains of the macromolecules of which consist of two or more sections (blocks) each of which is in its turn made up of many identical units. The macromolecule is usually constructed of blocks of different types, so that it exhibits diphilic properties: This type of structure (in contrast to statistical copolymers characterised by a random alternation of units) leads to a combination of heterogeneous properties (for example the occurrence of two glass points) and even to the summation instead of the averaging out of the properties of the homopolymers. By varying the molecular weights of the blocks and their ratios within wide limits and hence the structure of the block polymers, which is determined by these parameters, it is possible to obtain polymers with specified properties.

The possibility of such modification of polymers together with the grafting of one polymer on another was suggested for the first time by Mark[1] at the beginning of the 1950s and since then research in this field has been developing vigorously[2-6]. Mechanochemical and other methods for the synthesis of block copolymers were used initially[7]. The discovery of anionic polymerisation and "live" polymers[8,9], whereby it is possible to obtain rigorously unimolecular block with any required molecular weight and to combine them with one another, was of fundamental importance for the successful development of this field. The method has been widely used to synthesise two-block (AB) and three-block (ABA) copolymers with a wide variety of compositions, the majority of which have been listed by Fetters[10]. A highly regular molecular structure is essential for the creation of long-range supermolecular order, which determines, as will be shown below, the most valuable properties of block copolymers. The polycondensation method was later used to obtain many-block polymers[11-14], whose molecular structure is not, however, quite so regular and this leads to certain characteristic features of these block copolymers, which will be considered below.

It is noteworthy that (despite the limited number of factual data available at the time) Soviet investigators Kargin, Plate, and coworkers were the first to conclude as early as 1960 that the occurrence of two glass points of a block copolymer, characteristic of its components, and in general the independent behaviour of these components can be accounted for solely by aggregation processes and the segregation of each component in the form of microphases or microregions[15,16]. Subsequently these ideas were extensively developed[17-19].

The formation of a two-phase structure and the degree of layer formation are determined by the degree of incompatability of the components constituting the blocks. The properties of block polymers are to a large extent determined by the size, form, and relative disposition of its structural elements. Microlayer formation processes and the formation of a structure occur as a rule in the solution from which the block copolymer is obtained and the properties of the solid block copolymer are therefore determined by those of the solution and the thermodynamic properties of the solvent. In connection with the foregoing, we shall consider the following problems in this review: (1) relation between the microlayer formation process in block copolymers and the incompatibility of its components and comparison of the relation with layer formation in mixtures of polymers; (2) dependence of the conformation of the macromolecules of block copolymers in dilute solutions on the segregation process and the relative conformational and thermodynamic properties of block copolymers and statistical copolymers; (3) transition from intramolecular to intermolecular aggregation as the solution becomes more concentrated, the formation of micelles, and the consequent manifestation of colloidal properties by block copolymers and their solutions; (4) dependence of the type of structure of the block copolymer on a number of factors; the possibility of predicting this dependence by means of models designed on the basis of statistical thermodynamic theories; the influence of the structure of the block copolymer on its mechanical and physical properties.

## II. CHARACTERISTICS OF THE MICROLAYER FORMATION PROCESS IN BLOCK COPOLYMERS

Having applied the Flory–Huggins theory of solutions [20], Scott obtained the following expression for the free energy of mixing of two polymers [21]:

$$\Delta G_{mix} = \frac{RTV}{V_r}\left(\frac{v_A}{x_A}\ln v_A + \frac{v_B}{x_B}\ln v_B + \chi_{AB} v_A v_B\right), \quad (1)$$

where $V$ is the total volume of the system, $V_r$ the volume per lattice site, $v_A$ and $v_B$ are the volume fractions of components A and B in the mixture, $x_A$ and $x_B$ the degrees of polymerisation of these components, and $\chi_{AB}$ is the interaction parameter, which is the fundamental characteristic of the miscibility of the components, i.e. their thermodynamic compatibility (or incompatibility).

The parameter $\chi_{AB}$ is frequently expressed in terms of Hildebrand's solubility parameters, which are listed in handbooks [22]:

$$\chi_{AB} = \frac{V_r}{RT}(\delta_A + \delta_B)^2, \quad (2)$$

where $\delta_A$ and $\delta_B$ are the solubility parameters of components A and B.

For critical conditions, corresponding to layer formation in the system, we have $\partial^2\Delta G_{mix}/\partial v_A^2 = \partial^3\Delta G_{mix}/\partial v_A^3 = 0$, and

$$(\chi_{AB})_{cr} = \frac{1}{2}\left[\frac{1}{x_A^{1/2}} + \frac{1}{x_B^{1/2}}\right]^2, \quad (3)$$

$$(v_A)_{cr} = \frac{x_B^{1/2}}{x_A^{1/2} + x_B^{1/2}}; \quad (v_B)_{cr} = \frac{x_A^{1/2}}{x_A^{1/2} + x_B^{1/2}}, \quad (4)$$

where $(v_A)_{cr}$ and $(v_B)_{cr}$ are critical layer-formation concentrations.

Eqn. (3) shows that $\chi_{AB}$ depends on the molecular weight of the polymer. A large value of the latter for polymers results in a corresponding value of $\chi_{AB}$, which is always small, so that the majority of polymers should be incompatible. This has been confirmed experimentally: of the enormous number of pairs of polymers investigated, the majority of which (102 pairs) have been listed in a review [23], only a few pairs proved to be compatible; all others formed layers starting from a definite critical concentration [defined in terms of Eqn. (4)] over a shorter or a longer period [24]. The application of Scott's theory to ternary polymer A–polymer B–solvent systems showed that the incompatibility in mixtures diminishes significantly with increasing molecular weights of both polymers and is independent of the solvent; however, this postulate is valid only in the sense that polymers which form layers in one solvent also form layers in another. The critical concentration proved to be different in different solvents and the difference is manifested to a greater extent the bigger the role played in the polymers by specific interactions with the solvent.

Similar relations have also been observed for block copolymers [25,26]. Krause [27] examined the case of phase layer formation in block copolymers when all the A–B contacts have been disrupted under the condition of an average ratio of components A and B and identical molecular weights of all the molecules. She obtained the following expression for $(\chi_{AB})_{cr}$:

$$(\chi_{AB})_{cr} = -\frac{V_r}{V_A n_A v_B}\ln[(v_A)^{v_A}(v_B)^{v_B}], \quad (5)$$

where $v_A$ and $v_B$ are the volume fractions of components A and B, $V_A$ is the molar volume of the A repeating unit, and $n_A$ is the number of these units. Calculation of the compatibility of polymers having the same molecular weight and taken in the same proportions in the mixture and in the block copolymer enabled the author [27] to conclude that the two components are more incompatible in a block copolymer than in a mixture of polymers. This conflicted with other theoretical studies [28], but subsequently, when account was taken of the surface free energy at the boundary between the microphase regions, Krause also concluded [29] that layer formation in the mixture proceeds more readily than in the block copolymer. Furthermore, it was shown [29] that, for the same molecular weight of the block copolymer, the formation of layers becomes increasingly more difficult with increase of the number of blocks, owing to the increase of the surface energy and of the number of segments at the boundary of the microphases, which leads to a decrease of the freedom of their movement and of the total entropy.

As in mixtures of polymers, a better compatibility of components A and B in block copolymers is achieved in solvents whose affinities for each component are most similar, i.e. the incompatibility of the pair of polymers is determined by the selectivity of the solvent in relation to them [30]. An unusual feature of the microlayer formation process in block copolymers and their solutions, compared with macrolayer formation in solutions of mixtures of polymers, is the retention of the integrity of the block copolymer specimen (i.e. the impossibility of the formation of two layers in its solution) owing to the combination of heterogeneous blocks in the block copolymer macromolecules via covalent bonds.

We may note that the blocks of A and B may be regarded as individual components only when their thermal motions are mutually independent. This requires a sufficient length and flexibility of at least one of the blocks and a decrease of flexibility requires an increase of length, i.e. of the degree of polymerisation of the block. With decrease of the size of the block, boundary conditions play an increasing role.

## III. CONFORMATIONS OF THE MACROMOLECULES OF BLOCK COPOLYMERS IN DILUTE SOLUTIONS

The fundamental conformational characteristics of the macromolecule in solution are the mean square distance between its ends and its unperturbed dimensions in a $\theta$-solvent, while one of the parameters used to estimate the degree of interaction between the polymer and the solvent in dilute solutions is the degree of swelling of the coil. According to the Fixman–Stockmayer equation [31], the unperturbed dimensions of the macromolecule are related to the intrinsic viscosity by the expression

$$[\eta]M^{-1/2} = K_\theta + 0.51\Phi_0 B \cdot M^{1/2}, \quad (6)$$

where $K_\theta = \Phi_0(\overline{R}_0^2/M)^{3/2}$, $\Phi_0 = 2.68 \times 10^{23}$ is Flory's constant, $\overline{R}_0^2$ the mean square distance between the ends of the chain, $B = 2(1/2 - \chi)/V_1\rho^2 N_a$ the long-range interaction parameter, $\chi$ Flory's interaction parameter, $M$ the molecular weight of the polymer, $V_1$ the molar volume of the solvent, $\rho$ the density of the solvent, and $N_a$ the Avogadro number.

For homopolymers, the slope of the plot of $[\eta]M^{1/2}$ against $M^{1/2}$ (i.e. the parameter $B$) is different in different solvents, but $K\theta$ (equal to the intercept which the plot makes on the ordinate axis), which characterises the $\theta$-conditions, is a constant and is independent of the nature of the solvent. In statistical copolymers, $K\theta$ is not constant and does depend on the solvent, so that the

conditions for the compatibility of such polymers also depend on the solvent. In this connection, Dondos and Benoit note [32], that $\theta$-conditions do not actually exist for statistical polymers. This is because of the hetero-contacts between groups A and B leading to a deviation from the Gaussian distribution and to a significant increase in the size of the chain compared with the corresponding homopolymers.

The situation in block copolymers is different. It is known [20] that the following relations hold under $\theta$-conditions with $\chi_{AB} = 0$ for a Gaussian conformation of a linear polymer chain consisting of two components:

$$\overline{R}^2_\theta = (\overline{R}^2_A)_\theta + (\overline{R}^2_B)_\theta \,, \quad (7)$$

$$[\eta]_\theta = [(x[\eta_A]_\theta)^{2/3} + \{(1-x)[\eta_B]_\theta\}^{2/3}]^{3/2} \,. \quad (8)$$

For $\chi_{AB} \neq 0$, these equations are valid when fairly long blocks A and B are completely separated in space, so that the Gaussian conformation holds for each [33]. This form of separation of heterogeneous blocks has been called segregation and the conformation itself, in which blocks A and B are separated in space and intramolecular heterocontact are reduced to a minimum, is called the segregated conformation.

Thus the more complete the segregation, the closer the chain size of the block copolymer to the sum of the sizes of the homopolymers making up these blocks. Under these conditions, the intrinsic viscosity of the block copolymer in effective solvents is intermediate between the intrinsic viscosities of the two homopolymers A and B, whose molecular weight is equal to that of the block copolymer; the $\theta$-temperature, the degree of swelling of the coil, the second virial coefficient, and the precipitation point obtained when a precipitant is added to a solution of the block copolymer are also usually intermediate between the corresponding values for the homopolymers [25,33-54]†. In the absence of segregation, these quantities exceed the corresponding values for the two homopolymers. Comparison of the intrinsic viscosities and chain sizes calculated by Eqns. (7) and (8) with the experimental quantities indicates the degree of segregation in solution.

The segregation of block copolymers in solution was first pointed out by Burnett et al. [55] They showed that the thermodynamic and hydrodynamic parameters of the block copolymer macromolecule also depend on the ratio of the overall masses of the blocks. Plots of the $\theta$-temperature, the entropic and energetic components of the free energy of solution, the intrinsic viscosity, and unperturbed size, and the swelling coefficient of the coil pass through a maximum as a function of the composition of the block copolymer, which corresponds to the component ratio A : B = 1 : 1. This behaviour was subsequently confirmed by other workers [56].

The majority of studies on the conformations of block copolymers were carried out using the same systems—two- and three-block copolymers of polystyrene and poly(methyl methacrylate) in different solvents without varying the component ratio, but the data obtained by different workers conflict; the intrinsic viscosity is consistent with Eqn. (8) in some cases, while in others it is greater or smaller than the calculated value. Thus, either owing to the different degrees of incompatibility of the blocks, manifested in the experiments of different workers, or owing to the quality of the given solvent (the incompatibility increases particularly when the solvent is selective with respect to one of the blocks [25,33,48]), or owing to the different molecular weights of the blocks or their ratio, the conformation of the molecule may be fully segregated, partly segregated, or pseudo-Gaussian, in which there is interpenetration of heterogeneous blocks [33, 45,52]. Froelich [38] showed that, under the conditions of complete separation, the chain length of the block copolymer is 15% greater than in the absence of segregation.

The fully segregated conformation of a two-block polymer can have the form of a "molecular micelle" [57], which comprises a nucleus, consisting of the coiled insoluble block surrounded by the soluble extensible block (Fig. 1*a*), or it has the shape of a loop [34], the size of which is smaller the longer the coiled block (Fig. 1*b*).

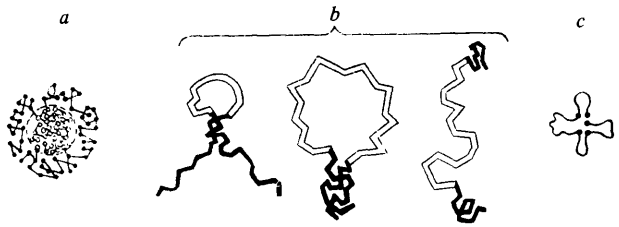

**Figure 1.** Various conformations of the aggregated macromolecule in solution: *a*) two-block copolymer—"molecular micelle" [77]; *b*) three-block copolymer with different block lengths—"loop" conformation (the insoluble block is indicated by the continuous line) [35]; *c*) a many-block copolymer—"bead" conformation (the circles indicate the insoluble blocks and the lines the soluble blocks) [58].

Bresler et al. [58] proposed a model for the segregation of many-block copolymers on the basis of the block copolymer of styrene and isoprene with a block ratio of 4 : 5 which they investigated. In an effective solvent, such a macromolecule obeys Gaussian statistics, while in a selective solvent the insoluble blocks are "precipitated" from solution, forming a rigid nucleus surrounded by the flexible "filaments" of the dissolved blocks. An example of such segregation is illustrated in Fig. 1*c*. Since, depending on the solvent employed, different blocks are "precipitated", the properties of the block copolymer obtained from solution depend significantly on the nature of the solvent. There has been yet another study on the properties of many-block polymers in dilute solutions [59]: the authors compared the block copolymers of styrene and isoprene with a rigorously constant molecular weight in which the number of blocks was varied from two to nine (with a corresponding change in the length of the blocks) in solution in toluene and its mixtures with methanol and iso-octane. It was found that the intrinsic viscosity increases with decrease of chain length and hence with increase of the number of blocks, since an increasing number of the latter "avoid" one another, which leads to an increase of the size of the macromolecule.

The same behaviour has been observed also when the properties of two- and three-block copolymers were

† It is noteworthy that the possibility of achieving $\theta$-conditions [38-40,49] for all block copolymers is not evident and requires further investigation.

compared. Overall, the properties of their dilute solutions differ little, but the intrinsic viscosity of a three-block copolymer is frequently greater than that of a two-block copolymer having the same molecular weight; this indicates a less complete segregation in a three-block copolymer and is consistent with the theoretical conclusion that layer formation in a block copolymer is hindered with increase of the number of blocks (see above).

Measurements of intrinsic viscosities in dilute solutions of block copolymers also make it possible to estimate qualitatively the degree of incompatibility of their components. The application of the equations of statistical thermodynamics to solutions of polymers is known to be capable of yielding a relation between the hydrodynamic parameters of the macromolecule (i.e. the ratio of the intrinsic viscosities in the given solvent and in a $\theta$-solvent), on the other hand, and quantities characterising the thermodynamic interaction of the polymer with the solvent, on the other[60]. Relations have been proposed for copolymer solutions which also include quantities characterising the interaction of the components with one another[61,62]. It was found that in many instances the theories developed for dilute solutions of homopolymers are also valid for solutions of block copolymers in a solvent which is effective in relation to both components. Deviations from these relations are associated with the action of selective solvents, which lead to a significant alteration of the conformations of the block copolymers.

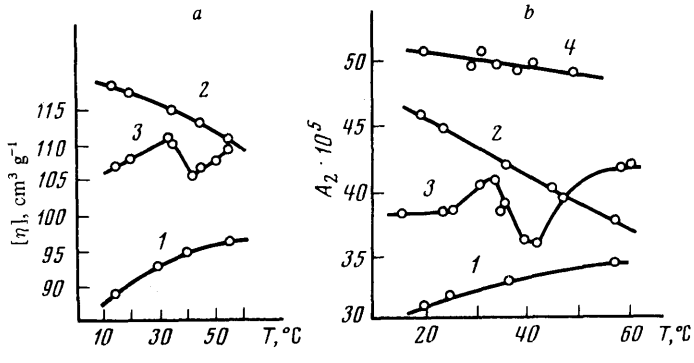

Figure 2. Dependence of the intrinsic viscosity (*a*) and the second virial coefficient (*b*) on temperature in homopolymers [poly(methyl methacrylate) (curves *1*) and polystyrene (curves *2*)], in a methyl methacrylate–styrene block copolymer (curves *3*), and in a statistical copolymer (curve *4*).[52,63]

The change in the conformation of the macromolecules of block copolymers with temperature, which is expressed in the temperature dependence of the intrinsic viscosity $[\eta]$ and of the second virial coefficient $A_2$ (determined by the light scattering method), characteristic of block copolymers alone, is of considerable interest. Fig. 2*a* shows that, with increase of temperature, the intrinsic viscosity of the copolymer increases initially to a maximum and then falls sharply, after which it again begins to increase. The nature of this variation is always the same, but the degree of the increase of the viscosity, the size of the peak, and the corresponding temperature depend significantly on the solvent and also on the ratio of the blocks and their molecular weights. All the observed transitions are fully reversible with respect to temperature. The peak is attributed to a conformational transition[45,52,63,64]. The segregated conformation exists below the transition temperature and the insignificant increase of viscosity is associated with the formation of a certain number of heterocontacts with increase of temperature, while the decrease of viscosity beyond the transition is due to the interpenetration of previously separated segments, which leads to a decrease of the volume of the macromolecule.

The validity of this treatment is confirmed, for example, by the fact that a film of a polystyrene–polyisoprene block copolymer, prepared below the transition temperature (i.e. when the segregated conformation of the copolymer obtains), has two glass points corresponding to the two separate blocks, while in a film prepared above the transition temperature, where the separation of the blocks is less pronounced, the glass point of polystyrene is appreciably displaced towards lower temperatures (the shift depends on the component ratio)[64]. The temperature of this conformational transition should be close to the glass point of the block copolymer, which is closely related to the degree of incompatibility of its components in the given solvent (i.e. the greater the incompatibility, the higher the glass point[33]). For example, it has been shown[32] that $\chi_{AB} = 0.031$ in benzene, 0.046 in tetrahydrofuran, and 0.053 in *p*-xylene for styrene–methyl methacrylate copolymers. The transition temperature of this block copolymer is smallest in benzene, where the incompatibility is a minimum. Urwin and Giralomo[64] believe that the transition temperature is near the $\theta$-temperature of the copolymer and may be the most important characteristic of the block copolymer.

The temperature dependence of the second virial coefficient $A_2$ is analogous to that of the intrinsic viscosity, as can be seen from Fig. 2*b*, where data for a statistical copolymer and a block copolymer are also compared.

When a precipitant is added to the solvent, i.e. when the quality of the latter is impaired, the transition temperature increases, in conformity with the ideas described above[52]. On the other hand, at a constant temperature, the addition of a precipitant (particularly one selective for one of the blocks) to a dilute solution of the block copolymer leads to a sharp decrease of the intrinsic viscosity[12,65–67], which is associated with the coiling of the insoluble blocks and their displacement to the interior of the macromolecule. It is of interest that, in solutions of polystyrene–poly(methyl methacrylate) block copolymers treated with a precipitant specific to poly(methyl methacrylate)[67], the same content of precipitant gives a lower intrinsic viscosity of the block copolymer regardless of its composition than the solution of poly(methyl methacrylate) alone. This demonstrates the decisive role of the blocks insoluble in the given system, which become coiled, and the independence of their behaviour of the presence of polystyrene blocks; they apparently form microgel particles in the soluble polystyrene. On the other hand, owing to the stronger interaction between the components as the concentration of the component which becomes insoluble following the addition of the precipitant is reduced, in a statistical copolymer the viscosity

increases with increase of the concentration of the precipitant—this is yet another manifestation of the difference between the conformations of block copolymers and statistical copolymers.

However, a decrease of the viscosities of both homopolymers and block copolymers is not observed in all solvent–precipitant mixtures. It has been shown [63] that this effect depends on the parameter $\chi_{12}$ of the interaction between the solvent and the precipitant: when $\chi_{12} > 0$, the addition of the precipitant causes a fall of the viscosity, while under conditions where $\chi_{12} < 0$, the addition of the precipitant results in an increase of the viscosity.

We shall consider yet another approach to mixtures of polymers and block copolymers. The solvent in which component B is dissolved behaves as a less effective solvent in relation to component A than the pure solvent itself owing to the incompatibility of these components. From this it follows that the intrinsic viscosity and the size of the macromolecule of A will decrease in the presence of component B. This has been confirmed by systematic studies on mixtures of polymers by viscometric and light scattering methods [68–73]. Such joint study of the solvent and component B as a single solvent for component A made it possible to apply the so called method of invisible species in order to determine the molecular weight of one of the components in the presence of the other: if the solvent and component B have the same refractive indices, the solution of component A in this mixture is optically a two-component system and light is scattered solely by component A, whose molecular size and weight can thus be determined by measuring the light scattering parameters. The aggregation of the system can be followed by the same procedure—from the change in the molecular weight of component A in the presence of component B. This method can also be used to determine the molecular weights of block copolymers.

In connection with the possibility of determining the molecular weight of a block copolymer by the light scattering method, we shall mention briefly the general approach to the estimation of the molecular weights and the microheterogeneity of copolymers proposed for the first time by Benoit and coworkers [74,75] and widely used by many investigators [76]. Since the increments in the refractive indices of the copolymer components are different, for a correct measurement of the molecular weight of the block copolymer it is necessary to know the increment of the refractive index in the given solvent for each component. The relation between the measured apparent molecular weight $M_{app}$, the true molecular weight of the block polymer $M_W^{AB}$, and the molecular weights of the individual blocks $M_W^A$ and $M_W^B$ is expressed by the following equation:

$$M_{app} = (\nu_A^2/\nu^2) M_w^A x + (\nu_B^2/\nu^2) M_w^B (1-x) + 2(\nu_A \nu_B/\nu^2) M_w^{AB}, \quad (9)$$

or the equivalent equation

$$M_{app} = M_w^{AB} + 2[(\nu_A - \nu_B)/\nu] P + [(\nu_A - \nu_B)/\nu]^2 Q, \quad (10)$$

where $\nu_A$, $\nu_B$, and $\nu$ are the increments in the refractive indices of the homopolymers A and B and of the block copolymer AB respectively, $x$ is the weight fraction of component A, and $P$ and $Q$ are parameters characterising the inhomogeneity of the composition of the copolymer. By determining the molecular weight of the block copolymer in three different solvents, we obtain a system of three equations from which the values of $M_W^{AB}$, $M_W^A$, and $M_W^B$ can be determined.

## IV. COLLOIDAL PROPERTIES OF BLOCK COPOLYMERS AND THEIR SOLUTIONS

Gallot et al. [77] noted that the following cases of the dissolution of block copolymers in selective solvents are possible. If the soluble block is short or if its content in the copolymer is unduly low and its affinity for the solvent is insufficient, the block copolymer does not dissolve at all. If the degree of solvation of the soluble blocks and their number are sufficient for the dissolution of the polymer, the latter results either in a molecular dispersion (the solution is then completely transparent), or a polymolecular dispersion, or a micellar solution. The molecular dispersion corresponds to solution of the "macromolecular micelles" mentioned above; a coiled insoluble block in such a solution is fully surrounded by a shell of the uncoiled soluble block, which prevents it from coming into contact with other insoluble blocks. With increase of the concentration of the polymer, intermolecular contacts arise between the insoluble blocks and, when combined, the latter give rise to a lyophobic nucleus surrounded by fairly flexible lyophilic blocks (Fig. 3*a*), i.e. micelles analogous to soap micelles in aqueous solutions are formed. Thus, at moderate concentrations, solutions of block copolymers are typically colloidal.

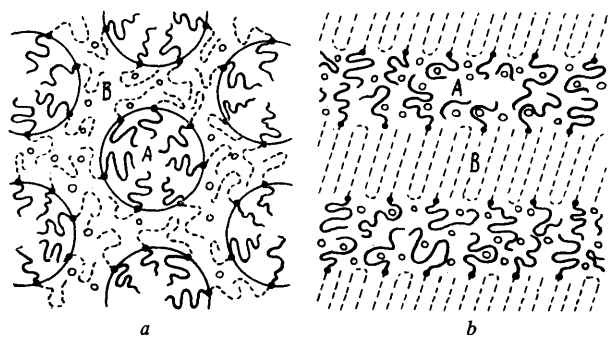

Figure 3. Types of colloidal micelles of block copolymers. The influence of the solvent on the type of micelles of a styrene (A)–ethylene oxide (B) block copolymer; solvent: *a*) nitromethane; *b*) dibutyl phthalate (the solvent molecules are shown as circles) [98].

A very important consequence of the micellar nature of solutions of block copolymers is the possibility of varying the type of micelles, i.e. the composition of the nucleus and the shell, by selecting various precipitants. Thus Merrett showed for the first time [78,79], in relation to a graft copolymer of natural rubber and poly(methyl methacrylate), that it is possible to obtain a "hard" or "soft" form of the polymer by inducing the formation of micelles and the subsequent precipitation of either poly(methyl methacrylate) or the rubber. Virtually at the same time, Korotkov [9] and Bresler [58] obtained analogous results for a styrene–isoprene block copolymer. Such studies were frequently carried out subsequently [80–82] and established the possibility of varying within wide limits the properties of objects obtained from solutions, by altering the nature of the binary solvent.

The critical concentration for micelle formation (CCM) depends on the chemical structure and the number of blocks in the polymer, the phase state, the molecular weight, and the quantitative ratio of the blocks as well as the thermodynamic properties of the solvent in relation to the polymer [77,83-86].

The selectivity of the solvent is usually achieved by adding a $\theta$-solvent which is effective for both components or a substance which does not dissolve one of the blocks [83]. For example CCM for styrene–butadiene block polymers in toluene amounts to 9%, [84] while after the addition of ethanol to dioxan in the same block copolymer micelles are formed starting from a concentration of 1%. [83] CCM and its dependence on the nature of the solvent are closely related to the degree of segregation of the macromolecules of block copolymers in dilute solutions in various solvents: the more pronounced the segregation in the given solvent, the lower the value of CCM in the latter.

In order to assess micelle formation, light scattering measurements are used in the first place [87-91] as well as viscosity and diffusion measurements, the determination on their bases of the ratio of the hydrodynamic particle radii [83,87] and the study of sedimentation in an ultracentrifuge [89]. The characteristic variation of the intensity of the scattered light during micelle formation as the temperature is altered is seen in Fig. 4. A molecular solution is formed at 65°C in a block copolymer of polystyrene and polyisoprene with a block ratio of 1 : 3 in n-decane, which is a selective solvent for polyisoprene; when it is cooled to 55–40°C, the intensity of the scattered light increases sharply, indicating the appearance of large scattering particles and a further increase of their dimensions, while below 25°C the scattering intensity is again constant and corresponds to the establishment of a stable micellar solution [88].

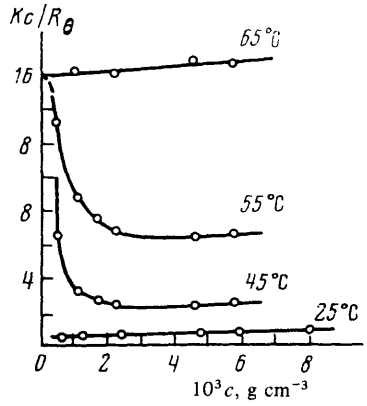

**Figure 4.** Dependence of the light scattering intensity $R\theta$ in a solution of a polystyrene–polyisoprene block copolymer on temperature and concentration [87].

The molecular weight of the micelles is usually greater by two orders of magnitude than that of the individual macromolecules ($10^6$ in the example under consideration compared with $10^4$), but their radius of inertia is extremely small (~200 Å) which demonstrates their compact nature. This is also indicated by the intrinsic viscosity and the Huggins constant [83]. The weight fraction of the micelles in solution increases with increase of the polymer concentration and impairment of the quality of the solvent, but their molecular weight remains constant under these conditions [83].

A characteristic property of micellar solutions of block copolymers is their similarity to lyotropic liquid crystals. The manifestation of this phenomenon involves the double refraction [84,91,92], optical anisotropy [91], and rainbow colours [84,93] of such solutions. Vanzo showed that below CCM (to which a light transmittance maximum corresponds), the solution is colourless, while above CCM it acquires various colours, which depend on the concentration (ranging from pale blue to green and pink) [84]. In 1% solutions of the polystyrene–poly(ethylene oxide) block copolymer in solvents selective with respect to both blocks, the Kerr effect is observed [75]. All these characteristics indicate the formation in moderately concentrated solutions of block copolymers having specific ordered structures which do not exist in solutions of homopolymers.

These microheterogeneous highly ordered structures were investigated in particular detail by Skoulious and coworkers for polystyrene–polyvinylpyrrolidinone (both components are amorphous) [92,94-97] and polystyrene–poly(ethylene oxide) or polystyrene–poly(propylene oxide) (one of the components crystallises) [97-107] block copolymers. At certain concentrations in selective solvents, these systems form gels, which the authors referred to as mesomorphic phases characterised by a high degree of order. The structure of these gels depends on the nature of the solvent and the concentration of the block copolymer. For example, in nitromethane, which is a solvent for poly(ethylene oxide) but does not dissolve polystyrene, the insoluble phase forms discrete structural elements in the form of cylinders in a continuous dispersion medium consisting of a solution of poly(ethylene oxide) blocks in nitromethane (Fig. 3*a*). In dibutyl phthalate, which dissolves polystyrene but not poly(ethylene oxide), the crystallising poly(ethylene oxide) forms structural elements in the form of plates in a solution of polystyrene in dibutyl phthalate (Fig. 3*b*). We shall consider the structures of these gels in greater detail below in connection with the general characteristics of structure formation in block copolymers. On solidifying the block copolymer, by evaporating the solvent, the structural elements or micelles involved in an ordered arrangement remain dispersed in the dispersion medium or matrix consisting of soluble blocks. These micelles have the same compositions, constituting regions of a microheterogeneous system with interfaces, which are, however, linked by chemical bonds with the continuous dispersion medium. In order to indicate their difference from the usual phase particles and the usual micelles, these "micelles" can be called microphase regions. In the non-Soviet literature, the term "domain" is used for this purpose.

The wide variety of the colloidal properties of solutions of block copolymers is also manifested by their emulsifying action in oil–water systems, by the increase of the mutual compatibility of the homopolymers, by the stabilisation of organic latexes, etc. [108-118] The compatibility of block copolymers with homopolymers having the same structures as the blocks constituting the block copolymer and the acquisition of some compatibility in the presence of block copolymers by polymers which are usually incompatible are due to a kind of solubilisation, i.e. the dissolution of the homopolymer in the corresponding "micelle" of the block copolymer. Riess et al. [108] and

subsequently other workers[109,110] suggested that the transparency of the resulting films be used as a criterion of the compatibility of the systems obtained. These data can be conveniently represented graphically on triangular diagrams in which the transparency of the film is plotted against the composition of the ternary systems block copolymer (with a specific block ratio)–homopolymer A–homopolymer B. It was found that, for a ratio of blocks A and B in the block copolymer of 80:20 or 20:80, there is no solubilisation at all; it occurs when the amounts of the blocks are more similar and is a maximum for the 50:50 ratio[108].

This procedure can be used to increase the compatibility of only those homopolymers whose molecular weight is lower than that of the corresponding blocks, which is important for solubilisation. Furthermore, solubilisation is more pronounced, the most distinct the segregation of the micelles in the solution of the block copolymer[111]. For example, polyisoprene is solubilised in polyisoprene micelles and its solubilisation therefore occurs for the compositions of the block copolymer in the solvents or their mixtures which promote the segregation of the polyisoprene micelles in the block copolymer. Polystyrene is solubilised most effectively under conditions where polystyrene blocks are segregated as a discrete phase; it has been shown that up to 30% of polystyrene may be solubilised[111]. Despite the turbidity of the solubilised solutions, they are extremely stable[111].

If the molecular weight of the homopolymer exceeds that of the corresponding block, it is not solubilised and may be dispersed in the continuous phase, but after a time it is separated in the form of a gel[112]. The size of the spherical regions of the block copolymer where solubilisation takes place increases and they are frequently converted into an elliptical form[111]. It has been shown by the light scattering method that, although the molecular weight of the mixed micelles of the styrene–isoprene block copolymer and a styrene homopolymer increases from $10^6$ for the block copolymer to $10^{10}$, their size increases comparatively little and does not exceed 300 Å.[111]

The same solubilisation phenomenon has been observed by the low-angle X-ray scattering method[113]. It has been shown that it is common for structures of any type—not only spherical but also cylindrical and lamellar (see below), and in all cases the size of the structural elements of the block copolymer increases on solubilisation and in many instances there is a change in the conformation of the block copolymer macromolecule. Homopolymer molecules become ordered under these conditions, like the blocks of the block copolymer, and a case has been described[113] where homopolystyrene with a molecular weight of 60 000 is solubilised, apparently as a result of a change in the conformation of the homopolymer molecules on solubilisation in a polystyrene block with a molecular weight of 40 000.

It is noteworthy that the increase of the compatibility of the polymers is observed only in the presence of block copolymers; neither statistical nor graft copolymers give rise to this effect. According to Molau and Wittbroadt[86], this effect cannot be regarded as a true increase of compatibility; it is purely colloidal in nature and is associated with the formation of a finer dispersion of one phase in the other.

A thermodynamic study by Unoue and coworkers[109,110] showed that, when CCM is found outside the binodal curve separating the region of the homogeneous solution from the region corresponding to its separation into layers comprising solutions of the block copolymer and the homopolymer, solubilisation occurs and the resulting solution is homogeneous; on the other hand, when CCM is found within the binodal curve, layer formation occurs even before a film is produced from the solution and there is no solubilisation.

Block copolymers are used as emulsifying agents both in order to obtain emulsions of high-molecular-weight substances in organic solvents and to prepare emulsions of low-molecular-weight substances. The first case includes emulsions obtained on polymerisation of a monomer in which a polymer of another type is soluble[114-117]. This entails the formation of a homopolymer and a graft or block copolymer, which prevents the separation of the two polymers into layers and promotes the formation initially of an emulsion of the polymer in the monomer (for example, of natural rubber in styrene), which then becomes fixed after the polymerisation of styrene. One such example is impact-resistant polystyrene, obtained by this procedure, in which natural rubber particles are dispersed in solid polystyrene.

The emulsifying effect of the polystyrene–poly(ethylene oxide) block copolymer on the water–toluene system has been investigated[118] and it has been shown that 1% of the block copolymer is sufficient for the formation of the emulsion, that the most stable emulsions are obtained in the region of phase reversal, and that a three-block copolymer makes it possible to emulsify a larger amount of toluene in water than does a two-block copolymer.

Thus it follows from the foregoing that the colloidal properties of solutions of block copolymers are manifested starting from extremely low concentrations of the latter. Such colloidal nature of the block copolymer solutions make it possible, on the one hand, to employ them in many specific applications and, on the other, it constitutes the basis for the formation of the structures of solid block copolymers obtained from these solutions.

## V. THE TYPES OF STRUCTURES OF BLOCK COPOLYMERS AND THE FACTORS INFLUENCING THEM

The structure of solid block copolymers, which can be of three main types (spherical, cylindrical, or lamellar phase formations), constitutes an extremely unusual manifestation of the supermolecular organisation, which is characteristic of polymers in general—not only in the crystalline but also in the amorphous state. As a result of the fairly considerable length of the block, whose macromolecules are homogeneous, the structural elements with interfaces formed under conditions where the blocks are incompatible are not only homogeneous with respect to size but are also arranged in a very regular manner. Despite the amorphous nature of the components constituting the block copolymer, its structure is therefore in most cases characterised by long-range order and the presence of a lattice with long periods, which is usually characteristic of single crystals only; spherical structural elements are packed in a cubic lattice, cylindrical elements are in a hexagonal lattice, and plates are arranged parallel to one another in the plane of the film[119-123]. Similar instances of the presence of long-range order in non-crystalline materials are also known for certain non-polymeric systems: soaps, minerals[124], latexes[125], silica gel[126], etc. The detection of such order in block copolymers, where the microheterogeneity of the system leads to a distinct two-phase state, and the study of the characteristics of such structure formation are therefore of great interest.

The principal methods for the investigation of the structures of block copolymers are electron microscopy [127-132] and low-angle scattering of X-rays [133-139]. A distinct representation of the structure of electron microscope photographs is achieved by shading thin films of block copolymers containing double bonds with the aid of $OsO_4$ vapour in order to increase the difference between the electron densities of the microphases [140]. If the experimental conditions are such that the electron photomicrographs of thin films show structural elements in only one plane, then the volume fraction of these aggregates can be calculated from their shape and distribution. On the basis of the conditions governing the packing of the aggregates, the volume fractions of different types of structures are defined by the following relations [121]:

$$\varphi_{sph} = 0.74\left(\frac{D_{sph}}{A_{sph}}\right)^3, \quad (11)$$

$$\varphi_{cyl} = 0.91\left(\frac{D_{cyl}}{A_{cyl}}\right)^2, \quad (12)$$

$$\varphi_{lam} = \frac{D_{lam}}{A_{lam}}, \quad (13)$$

where $D$ is the size and $A$ the distance between the aggregates. The volume fractions calculated in this way agree well with the results of the chemical analysis of the block copolymer.

The method of low-angle X-ray scattering makes it possible to determine the average dimensions and the distribution of the numerous aggregates. Its advantage is that it permits the study of the structure of films in the presence of a solvent and when the temperature is varied. The quantitative assessment of the structure and of the type of packing by this method is based on a comparison of experimental scattering diffractometer traces with scattering by various model structures for which formulae have been proposed [134,137,139]. Each type of structure is characterised by a definite number of reflections and a definite distance between them. Thus diffractometer traces with five or seven reflections, the reciprocals of the Bragg radii of which are in the ratios $1:2:3:4:5:6:7$, correspond to lamellar structures; the ratios of the reciprocal radii $1:\sqrt{3}:\sqrt{4}:\sqrt{7}:\sqrt{9}$ correspond to hexagonal packing of cylinders and the ratios $1:\sqrt{2}:\sqrt{3}:\sqrt{4}$ correspond to cubic packing of spheres. In order to reveal these structures more effectively, Keller extruded specimens of the block copolymers. Extrusion leads to the formation in amorphous block copolymers of structures with a particularly high degree of order, usually encountered only in single crystals and therefore referred to as supercrystals [141,142]. The results of both methods discussed above are usually in good agreement [130,132,138]. The size of the structural elements may be determined also from the scattering of polarised light [143]. The dimensions of the structural elements vary from 60 to 1000 Å as a function of the structure of the block copolymer and the conditions under which it is obtained, but usually they are in the range 200–300 Å. [119,120,130,137]

The type of structure of the block copolymer depends on many factors: on the ratio of the blocks in the copolymer, on the molecular weight of the blocks, on the concentration of the copolymer in solution, on the nature of the solvent, and on the temperature conditions under which the specimen is obtained. The dependence of the structure on the component ratio is clearly illustrated in the styrene–butadiene block copolymers obtained from an effective solvent (toluene) [119]. With increase of the weight fraction of butadiene from 20 to 80%, five types of structures, illustrated in Fig. 5, are observed: spherical polybutadiene domains dispersed in the polystyrene matrix; hexagonally distributed cylindrical polybutadiene domains in the polystyrene matrix; layer structures consisting of alternating polystyrene and polybutadiene plates (or lamellae) in the region where the concentrations of both types of block are similar and where phase reversal takes place; on further increase of the concentration of polybutadiene, the latter forms a continuous phase in which cylindrical polystyrene domains are dispersed and, when the concentration of polystyrene is lowered further, its domains become spherical. Similar structures have been detected also in other systems [138,144,146].

The change in the length and number of blocks (from two to four) for the same component ratio does not lead to a significant change in the structure [119]. As a rule, in

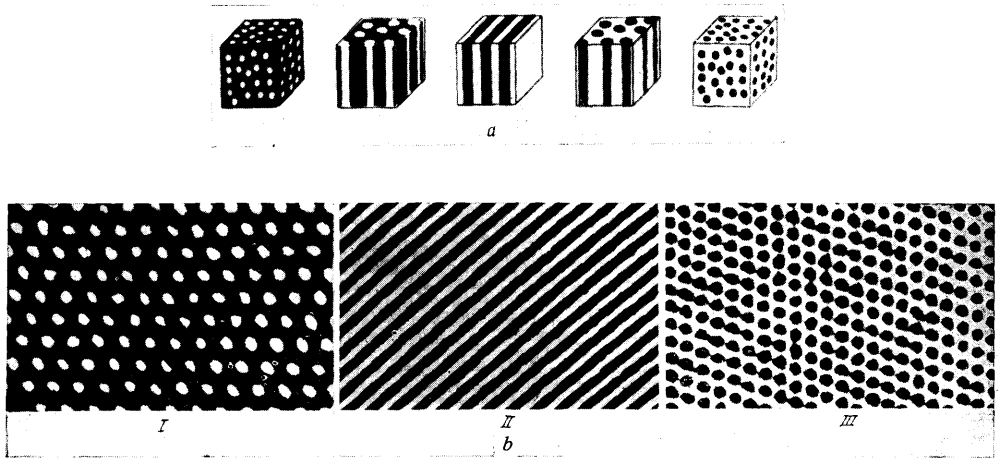

**Figure 5.** Types of structures of block copolymers as a function of the ratio of the blocks: *a*) schematic representation; *b*) electron microscope photographs of styrene–butadiene block copolymers containing different percentages of polystyrene [145]: I) 28.3; II) 61; III) 69.5.

the middle range of compositions of block copolymers obtained from solution in toluene (which is an effective solvent for polystyrene and polydienes), these block copolymers form alternating lamellar structures; from other solvents, less distinct structures of the "islands in a matrix" type are obtained[92]. The resulting structure is insensitive to temperature changes in the range 20° to 60°C.[105]

A specific feature of block copolymers is that the type of solvent plays just as important a role in the formation of their structure as the composition of the polymer. By a suitable choice of selective solvents, it is possible to achieve phase reversal for the same composition of the block copolymer, i.e. as already stated above, blocks which are insoluble in the given solvent are "precipitated" as a discrete phase[78-82], which has a sharp effect on the properties of the block copolymer.

A large series of studies designed to determine the structures of block copolymers in solution has been carried out by Skoulious, Gallot, and coworkers, mainly by the low-angle X-ray scattering method[147-152]. One structural dimension—the distance between the structural elements—can be determined directly from X-ray diffractometer traces; the size of the structural elements (the diameter of the sphere or cylinder and the thickness of the layer in the plate occupied by each block) can be calculated from the measured distance, the polymer concentration in the solution, the ratio of the blocks in the polymer, and the densities of the blocks and the solvent. For the hexagonal packing of cylinders, two versions of such structure are possible: either the cylinders are formed by the block insoluble in the given solvent and the continuous medium consists of the soluble block together with the solvent or the cylinders are filled by the solvent together with the soluble block and the continuous medium consists of the insoluble block.

The study of the dependence of the size of the cylinders (and other structural elements) on solvent concentration and on the molecular weights of the blocks helps to establish which specific type of structure obtains. As the solvent is varied, the structure is reversed. The concentration of the solvent has different effects on the structure for different block copolymers. The formation of a distinct ordered liquid-crystal structure, i.e. the mesomorphic gel already mentioned, proceeds from a polymer concentration of 40–60%, while at a lower concentration there is no structure at all. On further alteration of solvent concentration, either only the dimensions of the structural elements and of the distances between them change (in different directions determined by the solvent selectivity) or the very type of structure is altered. Thus cylindrical structures have been detected in polystyrene–polyvinylpyrrolidinone block copolymers with a polymer concentration of 70%, while at a higher concentration lamellar structures were found. When the monomer is used as the solvent and is subsequently polymerised, it is possible to obtain solid polymeric systems with a fixed highly ordered structure of the gel or the solution at any stage during its concentration. In such systems, it is more convenient to investigate by electron microscopy the block copolymer structure obtained on passing from a solution to the solid state than in films obtained from solutions at different concentrations by evaporating the solvent. It has been shown by this method that, regardless of the polymer concentration in the initial solution (between 0.8 and 10%), the same structure is observed in films of the styrene–isoprene block copolymer obtained from toluene[153], which enabled the authors to regard it as the equilibrium structure produced at the critical concentration for micelle formation.

Kinetic phenomena play a major role in the formation of the structure of block copolymers[121,154]. Thus an increase of the molecular weight of the block copolymer leads to a decreased regularity of its structure and to an increase of the distances between the structural elements as a consequence of the increased viscosity of the solution, which hinders the attainment of a state of equilibrium[122]. The temperature and the rate of removal of the solvent on formation of the film are just as important. When the solvent is removed rapidly, the size and distribution of the microphase regions in the film are insufficiently homogeneous and are far from equilibrium. The films formed from solution are therefore annealed at temperatures above the glass points of both blocks, the structure being rearranged during the annealing process[122,154,156]. Under these conditions, the distance between the domains decreases and the plates frequently become thicker. On the other hand, annealing at a temperature somewhat below the glass point frequently leads to some breakdown of order in the structure and the appearance of an intermediate phase[153,155]. Extremely interesting data concerning the dependence of the time required for the attainment of the equilibrium degree of order in an SBS (styrene–butadiene–styrene) block copolymer on the annealing temperature have been published[122]:

| Annealing temp., °C | Time, min |
|---|---|
| 120 | 5 |
| 110 | 25 |
| 90 | 180 |
| 80 | 1800 |
| 70 | 3600 |

It is significant that this temperature dependence of the rate of rearrangement of the structural elements of polystyrene is similar to the temperature dependence of the viscosity of polystyrene near the glass point.

In certain cases, particularly when one of the components of the block copolymer is crystallisable, the nature of the structure formed depends also on the temperature at which the film is formed from solution. For example, films of the polythiacyclobutane–polyisoprene–polythiacyclobutane block copolymer[157] obtained at room temperature are isotropic, while a highly regular hexagonal packing of cylinders at right angles to the plane of the film is observed in the films obtained at 60°C, which is clearly manifested in their mechanical properties. This is associated with the kinetics of the crystallisation of polythiocyclobutane and the superposition of two processes: liquid microlayer formation, which is usual for block copolymers, and the formation of a crystalline phase.

Owing to the complexity of the structure of the block copolymers, there is a possibility of different types of phase equilibria in polymer–solvent systems.

Phase diagrams of two types have been described in the literature: (1) those characterising the transition from the liquid-crystal (highly ordered) state to an isotropic (structureless) solution and (2) those characterising the compatibility of the components and the liquid layer formation in the system polymer–selective solvent for the first block–selective solvent for the second block or in the system first block–second block–solvent. When a crystallisable block is present in the block copolymer, the regions corresponding to the appearance (disappearance) of the crystalline phase are indicated on phase diagrams of both types. Diagrams of the first type have been obtained by French investigators (Gallot, Douy, and

Gervais)[158-162] by plotting the temperature of the disappearance of the liquid-crystal (and crystalline) phase (determined by scanning calorimetry) against solvent concentration. Fig. 6*a* illustrates an example of this type of diagram for the polystyrene–poly(ethylene oxide) block copolymer, which is characterised by the presence of regions corresponding to the existence of a crystalline lamellar poly(ethylene oxide) phase [the form of the chains in the latter is analogous to pure crystalline poly(ethylene oxide)], an amorphous lamellar phase, and isotropic solution. Investigations showed that the nature of the blocks in the polymer determines the number of mesophases and the nature of the solvent determines the region where they are stable (i.e. the greater the affinity of the solvent for the polymer, the greater the reduction of the transition temperature caused by it).

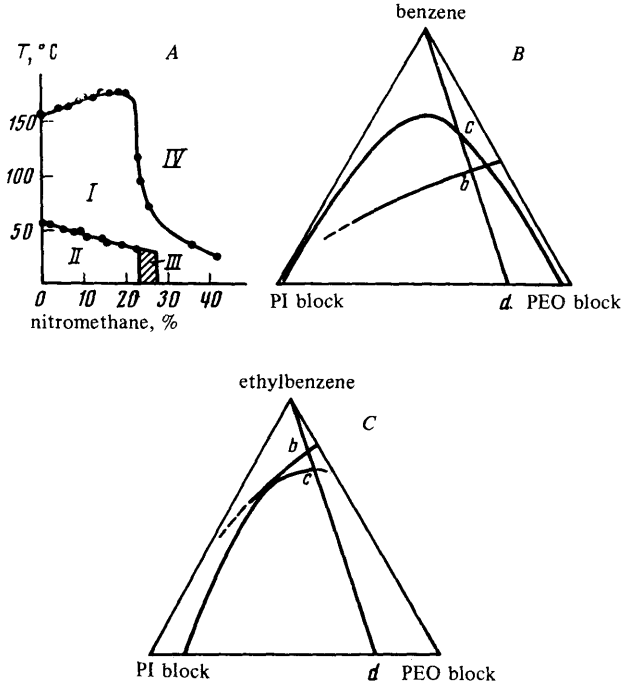

Figure 6. Phase diagram for polystyrene–poly(ethylene oxide) block copolymers (A)[162] [I) lamellar amorphous structure; II) lamellar crystalline structure; III) transitional region between them; IV) isotropic solution] and a polyisoprene (PI) and poly(ethylene oxide) (PEO) block copolymer in benzene (B) and ethylbenzene (C); curve *c* represents CCM for the block copolymer with the composition *d* and curve *b* represents the critical concentration for the crystallisation of the block copolymer having the same composition[144].

The ternary diagrams illustrated in Figs. 6*b* and 6*c* for the poly(ethylene oxide) (PEO)–polyisoprene (PI) block copolymers in two selective solvents are an example of diagrams of the second type[144]. Fig. 6 shows that in benzene, an effective solvent for PEO, the critical concentration of the latter at which it crystallises (point *c*) is much higher than the critical concentration for micelle formation at which the phases are separated into layers (point *b*), while in ethylbenzene, a poor solvent, the opposite situation obtains. Accordingly, crystallisation in the effective solvent for PEO takes place after microlayer formation and therefore has little effect on the structure of the block copolymer, while in the poor solvent crystallisation precedes microlayer formation and determines the structure of the block copolymer. For example, fibrils of almost the same shape and thickness as in the crystallisation of pure polytetrahydrofuran are observed in the block copolymer of styrene and crystallisable polytetrahydrofuran[163]. The nature of the kinetic curves for the crystallisation of polytetrahydrofuran in the block copolymers remains the same, but, with increase of the content of the amorphous component, the crystallisation of the crystallisable component is retarded; the degree of crystallinity and the melting point decrease monotonically with decrease of the fraction of the crystallisable component in the block copolymer.

The study of the kinetics of the crystallisation of polystyrene–poly(ethylene oxide) block copolymers from dilute solutions, carried out by both structural methods and by dilatometric and calorimetric methods[164-169], showed that both the nature of the crystallisation and the morphology of the crystalline formations in the block copolymers correspond to those of pure PEO. The same behaviour was confirmed for block copolymers containing crystallisable polyphenylenesiloxanes[170,171] and polyurethanes[172]. However, a decrease of the size of the block below a definite limit and an increase of the content of the solvent lead to the disappearance of the ability of the block to crystallise[168]. For example, poly(ethylene oxide) with a molecular weight in the range 1000–20 000 does not crystallise in the block copolymer of poly(ethylene oxide) and polycarbonate[11].

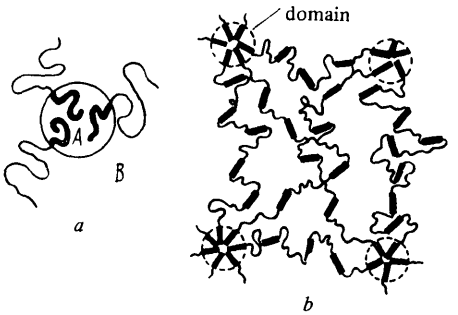

Figure 7. Models of the structure of block copolymers: *a*) Meier's model[28]; *b*) LeGrand's model for a polycarbonate–polydimethylsiloxane many-block copolymer[223].

The influence of the above factors on the type of structures formed can be treated theoretically by applying statistical thermodynamics to various selected models. This approach makes it possible to predict the type of structures arising under different conditions. Thus, in Meier's theory[28,173,174], attention is concentrated on the uniform filling of space by blocks in order to achieve a uniform density within the domains. In his model, which is illustrated in Fig. 7*a*, all the units A are distributed within the domain, while all the units B are outside it. Since contacts between heterogeneous units occur only at

the boundaries of the domains, the author estimated exactly the limits to the configurational entropy corresponding to the domain morphology. Using the general diffusion equation of statistical thermodynamics, he calculated the probability of the distribution of chains within the domain as function of their size and hence obtained the stable size of the domain corresponding to a conventionally uniform density. This stable size depends on the shape of the domain and amounted to $1.33\alpha\ KM^{1/2}$ for spheres, $1.00\alpha\ KM^{1/2}$ for cylinders, and $1.40\alpha\ KM^{1/2}$ for plates (where $M$ is the molecular weight of the polymer forming the domain, $K$ a constant relating the unperturbed dimensions of the polymer to the molecular weight, and $\alpha$ a parameter characterising the degree of perturbation of the chains). Thus, in order to maintain the conditions for a uniform density, the distance between the ends of the chains must differ from that for a Gaussian coil. The observed relation between the size of the domain and the size of the macromolecule was confirmed experimentally by low-angle X-ray scattering in polystyrene–polybutadiene–polystyrene block copolymers [130,175,176].

Subsequently Meier expressed the free energy of the above system as the sum of three components: the surface energy, the enthalpy of formation of the domains, and the change in entropy owing to volume restrictions and elastic deformations of the A and B blocks. By minimising the free energy, taking into account the shape of the domains, he obtained the conditions for microlayer formation and morphological transitions from one shape of the domain to another, expressed in terms of the dimensions of the blocks and their ratio.

The critical size of the polystyrene block thus obtained for the polystyrene–polybutadiene block copolymer proved to be greater by a factor of 2–2.25 than the critical molecular weight determined experimentally for macrolayer formation in mixtures of the same polymers. After introducing simplifying assumptions, Fedors [176] found that the minimum molecular weights of the blocks for which incompatibility is manifested amount to 2500 for polystyrene and 6000 for polybutadiene. The estimation of these quantities plays a major role in block copolymers of the ABA type, since the stabilising effect of the rigid component is shown only as a consequence of microlayer formation, i.e. when the dimensions of the blocks exceed the critical values indicated.

The critical dimensions of the blocks depend significantly on the nature of the polymer and on the affinity of the polymers for one another. Thus in polydimethylsiloxane–polysulphone block copolymers, incompatibility begins to be manifested starting from a molecular weight of polydimethylsiloxane of 2000, [80,178] while in polycarbonate–polydimethylsiloxane block copolymers it appears starting from a molecular weight of 875. [179] Furthermore, the size of the block should exceed the size of the segment for each polymer, determined by the condition that the glass point ceases to depend on the molecular weight. According to Kanig [177], this value is 12 000 for polystyrene. The greater of the two quantities—the size of the segment and the critical molecular weight for microlayer formation—determines the minimum size of the block which can be usefully employed in a block copolymer. For a given component ratio in the block copolymer, determined by the volume fraction $\Phi_A$ of one of the components, which is related to the molecular weights $M_A$ and $M_B$ and the densities $\rho_A$ and $\rho_B$ of the blocks by the expression

$$\Phi_A = \frac{2M_A\rho_B}{2M_A\rho_B + M_B\rho_A}, \qquad (14)$$

the selected molecular weight of one of the blocks determines the molecular weight of the second block.

Inoue and coworkers [153,180] expressed the surface free energy of formation of microphase regions in terms of their geometrical dimensions, their volume fraction (for different shapes of these regions—spherical, cylindrical, and lamellar), and the parameters of the interaction of the blocks with the solvent. The total free energy consists of the surface free energy and a term related to the entropy change:

$$G_{sph} = 6V_A^{2/3}(1/D_{sph})\ \Delta W + {}^3/_2 kTN\left\{\frac{D_{sph}^2}{4}\left[\frac{(1-V_A^{1/3})^2}{\sigma_B^2 n_B a_B^2} + \frac{V_A^{2/3}}{\sigma_A^2 n_A a_A^2}\right] - 2\right\} \qquad (15)$$

$$G_{cyl} = 4V_A^{1/2}(1/D_{cyl})\ \Delta W + {}^3/_2 kTN\left\{\frac{D_{cyl}^2}{4}\left[\frac{(1-V_A^{1/2})^2}{\sigma_B^2 n_B a_B^2} + \frac{V_A^{2/3}}{\sigma_A^2 n_A a_A^2}\right] - 2\right\} \qquad (16)$$

$$G_{lam} = 2(1/L)\ \Delta W + ({}^3/_2) kTN\left\{\frac{L^2}{4}\left[\frac{(1-V_A)^2}{\sigma_B^2 n_B a_B^2} + \frac{V_A^2}{\sigma_A^2 n_A a_A^2}\right] - 2\right\} \qquad (17)$$

where $L_{sph}$ and $D_{cyl}$ are the diameters of the sphere and the cylinder, $L$ is the length of the plate, $\Delta W$ the energy of the surface contact per unit surface, $V_A$ the volume fraction of the domain occupied by block A, $\sigma_A$ and $\sigma_B$ are the swelling parameters of the blocks characterising the ratio of their mean square distances in solution and in the free state (i.e. the interaction of the polymer with the solvent), $n_A$ and $n_B$ the degrees of polymerisation of the blocks, and $a_A$ and $a_B$ the sizes of the blocks.

Since the first terms on the right-hand sides of Eqns. (15)–(17) lead to a decrease of free energy and the second terms lead to its increase with increased geometrical size of the microphase region, the dependence of the free energy on the size of the microphase region is characterised by a minimum corresponding to a specific size of the region. The presence of this minimum shows that the microphase separation is thermodynamically the most stable process, in contrast to macroscopic phase separation in mixtures characterised by zero free energy of mixing. Since microphase regions having mainly the shape corresponding to the smallest relative free energy minimum are formed for the given weight fraction of block A, it follows (as can be seen in Fig. 8) that, with increase of the weight fraction of block A, there should be a transition from spherical to cylindrical and then to lamellar forms, which, as stated above, has been confirmed by numerous experimental data. The weight fraction of block A, corresponding to the transition from one type of structure to another, is found to depend on $\sigma_A/\sigma_B$, i.e. on the relative solvating capacity of the solvent in relation to each type of block, or on the selectivity of the solvent.

The size of the microphase region corresponding to the free energy minimum is expressed by the product of the surface tension and a function of three quantities: the degree of polymerisation of block A, its weight fraction, and the parameter $\sigma_A$. The concentration of the block copolymer in solution is not included among these parameters and therefore has little influence on the size of the microphase region. Two- and three-block polymers are characterised by identical thermodynamic features; the only difference is that in three-block polymers account must be taken of the possibility of a different disposition of the ends of the chain on the surfaces of the microphase regions (the two ends of the middle block may be located at the boundaries of the same or different regions). The size of the structural elements in three-block copolymers should be greater, other conditions being equal, than in two-block copolymers.

As the block structure becomes more pronounced, the conditions for the free energy minimum are significantly complicated, because microlayer formation does not go to completion (see Section II) which entails a less ordered form and distribution of the aggregates and in general a less distinct heterogeneous structure [176,181]. A similar theoretical examination of the transition temperatures in a three-block styrene–butadiene copolymer has been carried out [170,171] on the basis of approximately the same model for different types of structure and under different structure formation conditions. These temperatures proved to be in good agreement with the transition temperatures determined experimentally under the same conditions by scanning calorimetry, by turbidity measurements, and by electron microscopy.

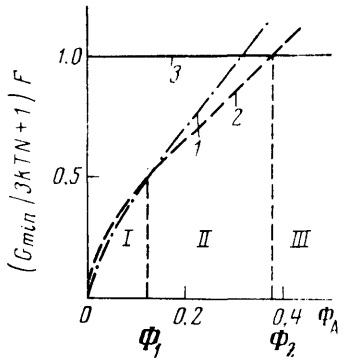

Figure 8. Dependence of the minimum in the free energy for layer formation on the composition of the block copolymer for spherical (line *1*), cylindrical (line *2*), and lamellar (line *3*) structures [153]; $F = (8/3)^{1/3}[(na^2\sigma_A^2)^{1/3}/\gamma^2]$, where $a$ is the size of block A, $n$ the degree of polymerisation of block A, $\sigma_A$ the swelling parameter of block A, and $\gamma$ the surface tension. The Roman numerals denote the regions corresponding to the existence of the lamellar (I), cylindrical (II), and spherical (III) formations.

Thus it follows from the above that a theoretical treatment involving statistical thermodynamics makes it possible to predict all the main properties of block copolymers (see also Refs. 153, 184, 185).

## VI. RELATION BETWEEN THE STRUCTURE OF BLOCK POLYMERS AND THEIR MECHANICAL AND PHYSICAL PROPERTIES

The vast majority of the published studies on the mechanical and other physical properties of block copolymers refer to two- and three-block copolymers of polystyrene with elastomers because, as already mentioned above, three-block copolymers of this class, in which the elastomeric (polybutadiene, polyisoprene) block is located between two blocks of the thermoplastic polymer, for example polystyrene, have found important practical applications as thermoelastoplastic materials [143,186–189]. The mechanical and physical properties of the block copolymer are determined by those of the continuous phase. The microphase regions in polystyrene, which consist of particles of the filler dispersed in the continuous elastomer matrix whatever the disposition of the blocks, tend to increase the strength of the elastomer [177]. However, only in polystyrene–elastomer–polystyrene block copolymers do the polystyrene domains serve simultaneously as nodes of a three-dimensional network between which the elastomeric blocks making up the matrix are deformed. Such polymers are therefore much stronger and less brittle than polymers of the elastomer–polystyrene–elastomer type having the same composition [17,123,143]. This makes it possible to obtain non-vulcanised rubbers with a fairly considerable strength, whose mechanical properties and the temperature range where they can be usefully employed are determined by the degree of microlayer formation, the perfection of the microphase structure of the block copolymer, and the glass points of the corresponding homopolymers. Above a definite polystyrene content, phase reversal takes place, which leads to a transition from thermoelastoplastic to thermoplastic polymers accompanied by a sharp increase of strength and the loss of viscoelasticity. Thermoelastoplastic properties have also been observed in other three-block copolymers, for example poly(ethylene sulphide)–polyisoprene [190] and polyster–poly(methyl methacrylate) [191] copolymers.

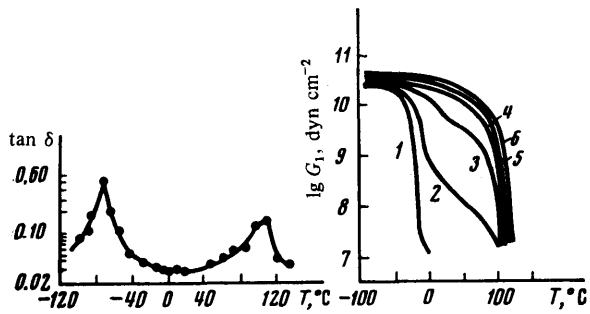

Figure 9. Temperature variation of tan δ (*a*) [195] and the dynamic modulus of elasticity (*b*) [198] for a polystyrene–polybutadiene block copolymer; percentage of polystyrene by volume: 1) 0; 2) 20; 3) 42; 4) 60; 5) 80; 6) 100.

The most characteristic property of block copolymers, which follows from their separation into individual microphases, is the presence of two glass points, reflecting the individual properties of each block. These two glass points are usually revealed by two maxima on plots of the temperature dependence of the mechanical [192–197] losses and two corresponding transitions on plots of the dynamic modulus against temperature [198–205]. The transition temperatures in block copolymers are also determined by differential thermal analysis and by scanning calorimetry [183]. There are block copolymers in which the glass points correspond fairly exactly to those of each component. Thus two loss peaks, at −80° and +100°C, are observed in the polybutadiene–polystyrene block copolymer (Fig. 9*a*), the polybutadiene glass point being independent of the composition and arrangement of the blocks [195]. Similar properties have been observed also for the polydimethylsiloxane and polyarylate block copolymers [14]. At the

same time the loss and dynamic modulus peaks depend on the composition of the block copolymer, starting from a definite fraction of polystyrene [192]. Fig. 9*b* illustrates the temperature dependence of the modulus of elasticity for styrene–butadiene block copolymers of different compositions. Evidently, at a fixed temperature the modulus varies sharply in the range of compositions corresponding to phase reversal.

However, complete microphase layer formation is by no means always observed and in many-block polycondensation copolymers is normally absent. Owing to the interpenetration of the blocks at the microphase interfaces, the glass points in the block copolymer are in most cases somewhat displaced: the glass point of the low-temperature block is higher and that of the high-temperature block is lower than for the pure components, the shift depending on the composition of the block copolymer. Whereas the glass point of the low-temperature, usually viscoelastic block, which in many cases constitutes a continuous matrix, usually changes by only several degrees (for example, the glass point of polydimethylsiloxane in the block copolymers of the latter with polysulphone [178], polycarbonate [179], and poly-$\alpha$-methylstyrene [206]), that of the high-temperature rigid block frequently decreases sharply (by many tens of degrees) with increase in the concentration of the second component (for example, the glass point of polysulphone in its block copolymers with polydimethylsiloxane [178]). In this respect, the polyblock polydimethylsiloxane–polyarylate copolymer is an exception, probably as a consequence of the marked incompatibility of the components. Only one glass point is frequently observed in the block copolymer, diminishing significantly with increase of the content of the low-temperature block [207-209]. This usually occurs in block copolymers where there is no microlayer formation owing to the mobility of both blocks (at a temperature below the glass points of both homopolymers) and the system consists of a single phase [210,211]. In those cases where the degree of interpenetration of the blocks is fairly considerable in systems with layer formation, a third, intermediate phase is produced, as in mixtures of polymers, this being indicated by the appearance of an intermediate maximum on the plot of the temperature variation of the tangent of the loss angle [212]. The existence of an intermediate phase in the majority of block copolymers is indicated by an increasing amount of data [213-217]; according to various estimates, its thickness is 13–15 Å and the ratio of the difference between the radii of the sphere surrounding this domain and of the domain itself, i.e. the thickness of the intermediate layer, to the radius of the domain is 0.1–0.2. [212]

In certain block copolymers, mainly polycondensation copolymers, the properties of the individual components are not manifested at all and, when the composition is altered, there is a gradual transition from the properties of one component to that of the other. Thus, whereas the double refraction arising on deformation of a thermoelastoplastic specimen, for example in a styrene–butadiene block copolymer, is determined by the elastic polybutadiene matrix and increases with increasing polystyrene content (as a result of the formation and orientation of an elastic network of polystyrene domains [217-222]), in the polydimethylsiloxane–polycarbonate block copolymer the optical stress coefficient is intermediate between the corresponding values for the pure components [223]. A model has been proposed for this block copolymer, according to which the intermediate phase is not concentrated around discrete microphase regions and its presence is manifested by the fact that some of the polycarbonate blocks are segregated into individual microregions, while others form part of the continuous matrix, alternating with dimethylsiloxane blocks (Fig. 7*b*). Models and equations (proposed for the theory of two-phase systems consisting of spheres immersed in a continuous matrix), whereby the fraction of each component in the continuous and discrete phases of homopolymers and block copolymers can be determined from the moduli of elasticity or stress corresponding to the transformation of the material into an elongated shape with a constriction (neck) (or some other parameter), have been used by Robeson et al. [80] Faucher [224] calculated the moduli of elasticity of block copolymers from the volume fractions of the components alone without taking into account the presence of microphases and the calculated data agreed fairly satisfactorily with experiment.

The presence of an intermediate phase is also revealed by relaxation phenomena in block copolymers. The experimental dependence of the relaxation of stress has been described satisfactorily [225-229] from the standpoint of the superposition of several relaxation mechanisms—mechanisms characteristic of homopolymers as well as additional mechanisms. One of the latter is associated with the simultaneous movement of the elastic and plastic segments at the grain boundaries, i.e. the boundaries of the microphase regions. The segments of the soft component become less mobile in this intermediate region, while those of the rigid component become more mobile, the molecular order in the segment being the same as in statistical copolymers. Another, additional relaxation mechanism is associated with the flow of the entire block copolymer after the fusion of the domains. The constants for these relaxation mechanisms depend on the component ratio in the block copolymer.

The microheterogeneity and the operation of several relaxation mechanisms lead to numerous transitions in block copolymers and cause the principle of the temperature–time superposition to be inapplicable [230]. It has been shown for a three-block thermoelastoplastic styrene–butadiene copolymer [231] that, below a specific temperature, where the polystyrene microregions play the role of an inert filler in the elastomer, both relaxation and creep obey a reduction formula with constants close to those of polybutadiene; above the polystyrene glass point, a reduction formula is again valid, but this time with constants close to those of polystyrene; between these temperatures, the temperature dependence of the relaxation times and hence of the reduction factor is quite different, which indicates the operation of a new relaxation mechanism. Creep in block copolymers is manifested to a greater extent the lower the degree of order in the microregions [232].

Despite the distinct microheterogeneity of block copolymers, one of their specific properties is a high degree of transparency, which distinguishes them from mixtures of polymers and which is caused by the limited size of the microregions (as pointed out above, their diameter does not exceed the length of the polystyrene block and reaches 200–300 Å) and by their regular arrangement [188,221,222].

One of the most characteristic mechanical properties of polymers is the relation between stress and elongation, characterising the modulus of elasticity, the characteristics of the deformation of the system, and its strength. A specific feature of block copolymers is that the nature of the plots of stress against elongation depends mainly on the ratio of the blocks. The size of the individual blocks and the molecular weight of the block copolymer have

comparatively little influence on its mechanical properties. With increased content of polystyrene, there is a transition from the properties of the pure elastomer to those of pure polystyrene, which is clearly shown in Fig. 10*a*.

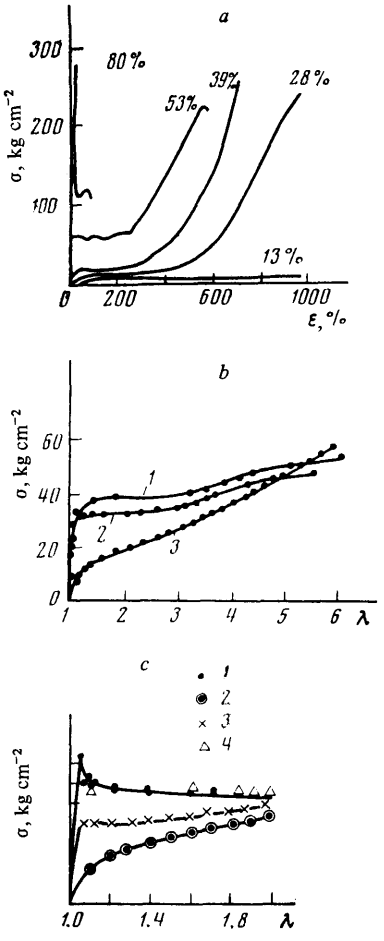

**Figure 10.** Dependence of the stress on deformation in films of SBS block copolymers having different compositions (*a*) [188], cast from different solvents (*b*) [236], and subjected to re-extension and annealing (*c*) [196];
*a*) for different polystyrene contents shown by the numerals against the curves;
*b*) [1) from ethyl methyl ketone; 2) from toluene; 3) from heptane];
*c*) [1) first extension; 2) repeated extension; 3) annealing for 8 min; 4) annealing for 41 days; λ is the relative elongation equal to the ratio of the final and initial lengths of the specimen].

This transition and the increased modulus of elasticity of the block copolymer are particularly marked when the content and the molecular weight of polystyrene are such that it is segregated as a separate phase [188], which depends to a considerable degree, as mentioned above, on the quality of the solvent, determining the conditions governing the incompatibility of the components. It follows from the results of Hendus et al. [130] that this happens in the presence of 50% of polystyrene in the polystyrene–polybutadiene system obtained from a solvent which is effective for both components. In films obtained from selective solvents, this phenomenon occurs in the presence of a much lower content of polystyrene.

The mechanical properties of block copolymers depend very significantly on the solvent from which the film has been cast [196,235–240]. The general rule is that the properties of the block copolymer approach those of the block in relation to which the given solvent is selective [80]. For example, Fig. 10*b* shows [241] that the properties of the film obtained from heptane, which is a selective solvent for isoprene, are typical for an elastomer, whereas the film obtained from ethyl methyl ketone, which is a selective solvent for polystyrene, has properties characteristic of polystyrene. In this case, this is manifested by the modulus of elasticity and the nature of the deformation, while the tensile stresses and deformations of the polymer are similar. In polysulphone–polydimethylsiloxane block copolymers obtained from various solvents, the strength varies from 130 to 220 kgf cm$^{-2}$ and the deformation is in the range from 310 to 517%. [80,165] The solvent has a particularly marked influence on polydimethylsiloxane–polyarylate block copolymers, while the deformation with rupture on passing from chloroform to a chloroform–hexane or chloroform–toluene mixture increases by a factor >3 (from 120 to 400%) with a comparatively small decrease of strength [242].

Thus, owing to the change in the conformation of the macromolecule and in the structure of the block copolymer when the quality of the solvent in relation to each block is altered, one can achieve in the general case, without altering the composition of the block copolymer, a transition from "rigid" systems to "soft" systems and conversely. In connection with the discussion of the influence of the solvent, it is interesting to note that, when the film is placed in a selective solvent where the entire block copolymer does not dissolve but merely swells vigorously, there is a significant increase in the elasticity of the film after subsequent drying and a simultaneous decrease in its strength (for example, the deformation of the polymethylsiloxane–polysulphone block copolymer increases from 410 to 970% after swelling in carbon tetrachloride, while its strength diminishes from 220 to 150 kgf cm$^{-2}$). [178]

The presence of a quasi-network in thermoelastoplastic materials leads to additional characteristics of their mechanical properties. One of their manifestations is different forms of the plots of the stress against elongation for primary and secondary deformation [196]. Primary deformation is characterised by the development of a neck, of the type characteristic of the plastic component of the block copolymer; on repeated deformation, when the rigid structure formed by the network of polystyrene microregions has been disrupted, the extension curve is typical of an elastomer. After a long time, particularly when the specimen is annealed at an elevated temperature, the plot recovers its initial form (Fig. 10*c*), which indicates the restoration of the network structure. Annealing also leads to the disappearance of the apparent residual deformations from the block copolymer [176].

Another characteristic feature of the mechanical properties of thermoelastoplastic materials consists in the dependence of the nature of the deformation on its extent. For small deformations, the system behaves as a "soft" system, i.e. only the elastic block is deformed, while the

rigid domains are either not deformed at all or undergo an extremely insignificant extension; for large deformations, the system becomes "rigid", i.e. the rigid blocks undergo plastic deformation, which leads to the disruption of the network nodes. As a result, the system again becomes "soft" for still larger deformations, i.e. is purely viscoelastic [188].

The rate of relaxation processes in block copolymers is lower than in statistical copolymers [243,244]. It is independent of temperature and deformation up to certain values of the latter, but, on further increase of these parameters and of the stress, the rate increases owing to the disruption and plastic flow of the polystyrene domains. The gradual disruption of the network nodes with increase in the degree of deformation also affects the linear increase of the optical stress coefficient with increase of deformation [208]. This effect is very small for homopolymers (non-cross-linked polybutadiene and polystyrene) and reaches its maximum value in the presence of a polystyrene content such that its domains create most effectively a network ensuring a rubber-like state of the system [209]. The size of the elastic block $M_c$ between the nodes of the quasi-network under consideration can be calculated using the statistical theory of viscoelasticity [20], applying this theory [245] with allowance for the dependence of the stress on the volume fraction of the filler, or using the Flory–Rehner theory [20], from the swelling of the block copolymer in the solvent interacting solely with the elastic matrix. However, one should note that the value of $M_c$ determined in this way is significantly smaller than the actual length of the elastic block. The possibility of applying the Flory–Rehner equation on swelling of block copolymers has not been demonstrated unambiguously [157,196,235], in particular it has been questioned in a theoretical study [247] where a significant dependence not only of the magnitude but also of the nature of the swelling on the shape of the structural elements in the block copolymer was demonstrated. The final solution of this problem requires further study.

The two-phase structure of the block copolymer is retained up to temperatures much above the glass point of polystyrene. This results in a maximum on the curve relating the viscosity of the melt to the composition of the block copolymer in the presence of the polystyrene content for which the network structure is most marked below the glass point [244]. However, this structure is shown much more clearly above the glass point; this is readily seen from the fact that at 100°C the moduli of elasticity of the block copolymer and the statistical copolymer having the same composition are identical, but on cooling the modulus of elasticity of the block copolymer increases sharply. The presence of a two-phase structure in the block copolymer melt is manifested by the existence of two different states of the melt, distinguished by the activation energy for viscous flow, which at 100°C is closer to the activation energy for polystyrene and at 200°C is closer to that for polybutadiene, this being associated with the onset of the flow of polystyrene domains above 120°C. [188,244] Hence it follows that the viscosity of the melts of block copolymers is extremely sensitive to a change of temperature: when the latter is raised from 80° to 180°C, the viscosity falls from $10^{10}$ to $10^5$ P. In contrast to the deformation properties of solid block copolymers, the viscosity of the melt depends very strongly on the molecular weights of the blocks and the entire block copolymer and to a lesser extent on its composition [244]. The viscosities of block copolymers can be measured not only above but also below the glass point; their finite values at 25°C indicate a fairly high degree of instability of the polystyrene domains.

The flow of block copolymers is non-Newtonian [248]. It has been shown [244] that the flow curves depend on the number and arrangement of the blocks for the same molecular weight of the polystyrene–polybutadiene block copolymer, namely the viscosity corresponding to the same stress decreases in the sequence SBS > SB > BSB, the differences being greater the lower the temperature. The dependence of the viscosity on stress in SBS is weaker than for other block copolymers, since the elastomeric blocks in this substance are clamped between the network nodes, but, for stresses exceeding $10^6$ dyn $cm^{-2}$, the temperature dependence of the viscosity is manifested to the greatest extent in this polymer. The influence of stress on the viscosity and rate of relaxation is of the same type and is related to the disruption of the polystyrene microregions.

Specific rheological characteristics are also shown in concentrated solutions [249–251] and gels of block copolymers. The gels are formed either on swelling of the block copolymers in selective solvents or following the addition of a selective precipitant to a solution of the block copolymer in an effective solvent. Apart from the polystyrene–poly(ethylene oxide) gels already described (see Section V), the following systems have been obtained: poly(methyl methacrylate)–polyacrylonitrile–chloroform; starch–polystyrene–water; poly(methyl methacrylate)–poly(vinylidene chloride)–benzene; polytetrafluoroethylene–poly(methyl methacrylate)–chloroform [81]. In the second method, the addition of the precipitant causes increased aggregation of the insoluble blocks, which leads to the formation of a continuous network in solution in the case of three- and many-block copolymers. In this type of structure formation process, there is a sharp increase of viscosity, in contrast to solutions of homopolymers and statistical copolymers, where the viscosity diminishes after the addition of the precipitant [252]. Solutions of polystyrene–polybutadiene block copolymers in n-decane exhibit a Newtonian viscosity up to a concentration of 30%. When they are treated with decalin, the non-Newtonian viscosity is shown at decreasing concentrations, a maximum appears on the curves relating the stress to time for a constant rate of shear, characteristic of the gel-like state, a limiting shear stress appears, the elasticity increases, and the system becomes thixotropic [253]. Analogous changes have been observed also in a many block polydimethylsiloxane–polyarylate copolymer.

One of the important physical properties of block copolymers is their permeability to gases, which depends, like mechanical properties, on the composition of the block copolymer and changes sharply in the region of phase reversal [254]. This makes it possible to combine the effective permeability of one homopolymer and the mechanical properties of another for a definite composition of the block copolymer. Such materials are extremely promising for use as gas-separating membranes.

---o0o-

The above data demonstrate the exceptionally unusual structures and properties of the polymeric materials formed by macromolecules consisting of two or more blocks. The properties of solutions and gels of block copolymers are no less interesting.

These unusual combinations of properties are already used in engineering and give rise to the prospect of an extremely wide variety of applications of polymers of this

class. The most interesting and important practical application of block copolymers involves their use as thermoelastoplastic materials, whereby one may obtain cast articles with adequate strength from non-vulcanised rubbers. The wide-scale employment of thermoelastoplastic materials is delayed by their low thermal stability, determined by the glass point of polystyrene, which gives rise to the problem of finding the optimum chemical structure of the block copolymer. Other technical applications of block copolymers include their use as the so called pluronics—(rubbers based on polyethylene–polypropylene block copolymers having the properties of surfactants), as well as the use of block copolymers to increase the miscibility of homopolymers, to increase the stability of emulsions of both low- and high-molecular-weight compounds, as gas-separating membranes, and for many other purposes.

# Recent Equilibrium and Kinetic Studies of the Adsorption of Gases and Vapours by Microporous Adsorbents

M.M.Dubinin

Thermodynamic theories of adsorption equilibrium in micropores are discussed with special reference to the osmotic theory of adsorption, based on the vacancy solution model, and to the analogy between adsorption and osmotic equilibria. A thermal adsorption equation is derived, and its special cases are discussed, thus giving a quantitative description of adsorption on microporous adsorbents over a wide range of pressure and temperature. New methods of investigating the kinetics of vapour adsorption on microporous adsorbents and of describing the process theoretically by the bipore model are reviewed. Good agreement between experiment and theory is obtained. 40 references.

## I. INTRODUCTION

This review describes the most important results obtained in recent years in the Sorption Processes Section of the Institute of Physical Chemistry of the USSR Academy of Sciences. We shall discuss the theoretical and experimental studies of equilibrium physisorption carried out by Bering and Serpinskii with the cooperation of Yakubov and Fomkin, and the studies of the kinetics of physisorption on adsorbents with a bipore structure by Zolotarev and Voloshchuk with Erashko, Gorlov, Shen, and Ulin.

## II. ADSORPTION EQUILIBRIA ON MICROPOROUS ADSORBENTS

Zeolites are typical microporous adsorbents. The similarity in size between the micropores and the adsorbed molecules produces a marked increase in the adsorption potential associated with dispersion forces. The presence of cations in the zeolite holes causes a large increase (by electrostatic interactions) in the energy non-uniformity of the adsorption sites of the micropores as compared with similar but chemically different adsorbents (e.g. carbons).

Our experimental and theoretical studies of the equilibrium adsorption of various vapours on micropores, started in 1946, have gradually led to the concept of a qualitative difference between adsorption in micropores and adsorption on non-porous or coarsely porous surfaces of a similar chemical nature. The theory of volume filling of micropores was proposed as a reasonable approximation to the description of adsorption in micropores [1-4]. We shall outline below only those aspects of this theory which are needed for the later discussion.

The most important function used in this theory is the differential molar heat of adsorption $A$,

$$A = -\Delta G = RT \ln (p_s/p), \quad (1)$$

which expresses the negative change in the Gibbs free energy $G$ when the standard state is defined as the normal liquid at temperature $T$ in equilibrium with its saturated vapour. In general the equilibrium vapour pressure and the saturation vapour pressure are replaced by the corresponding fugacities in order to correct for the non-ideality of the vapour.

The limiting adsorption $a_0$ corresponds to filling of the micropore volume, which can be treated as constant to a good approximation. Hence the temperature dependence of $a_0$ can be expressed as

$$a_0 = a_0^0 \exp [-\alpha (T - T_0)], \quad (2)$$

where $\alpha$ is the volume expansion coefficient of the adsorbate, which can be calculated approximately from the physical properties of the substance to be adsorbed (adsorband) [4]. If the adsorption at the equilibrium pressure $p$ and temperature $T$ is $a$, the coverage $\theta$ is defined as $a/a_0$.

The fundamental theoretical postulate of temperature invariance

$$(\partial A/\partial T)_\theta = 0 \quad (3)$$

was taken as an experimental fact from the work of Polanyi [5,6]. However the interpretation of the function $A$ [Eqn. (1)] as an adsorption potential and the attempt to justify the postulate (3) in terms of adsorption layers in micropores with equipotential surfaces are not entirely convincing. It should be noted that the experimental evidence for Eqn. (3) was obtained [4] not with relatively coarsely porous (e.g. mesoporous) adsorbents as expected but with typically microporous adsorbents such as active carbons.

By treating the temperature-independent characteristic adsorption equation $\theta = f(A)$ as a distribution of coverages with respect to differential molar free energy of adsorption, expressed in the form of the statistical Weibull equation, we arrive at the thermal adsorption equation

$$a = a_0 \exp[-(A/E)^n], \quad (4)$$

where $E$ is the characteristic adsorption energy ($E = A$ for $\theta = 1/e$) and $n$ is a small integer having a value between 2 and 6 in the main variant of the theory [2]. The temperature independent parameters of the distribution function of $E$ and $n$ are also parameters of Eqn.(4). This equation, combined with Eqns.(1) and (2), gives the thermal adsorption equation

$$a = a_0 \varphi(p/p_s, T). \quad (5)$$

We have shown [3,4] that both the adsorption equilibria and the corresponding differential heats of adsorption $Q(\theta)$ are satisfactorily described by Eqn.(4) in many adsorption systems involving microporous adsorbents, and in particular in zeolites. However the assumed temperature invariance of $A$ is only a rational approximation, which can be applied with acceptable precision only in the most favourable cases and in the temperature range 100° to 150°C. Furthermore it can predict only a decrease in differential heat of adsorption with increasing coverage. Heats of adsorption increasing with coverage lie outside the scope of the theory.

These considerations point to the need for a more perfect model of the equilibrium adsorption of vapours in micropores and for theoretical and computational approaches free from the above shortcomings. Bering and Serpinskii have developed and experimentally validated a more general theory of the thermodynamics of adsorption equilibria which has been termed the osmotic theory of adsorption [7]. We shall discuss the main variant of the theory with reference to microporous adsorbents.

## III. FUNDAMENTALS OF THE OSMOTIC THEORY OF ADSORPTION IN MICROPORES

Hill has shown [8] that physisorption equilibria between an adsorbent and a gas phase can be described either by adsorption thermodynamics or by solution thermodynamics. The adsorbent is usually assumed to be thermodynamically inert towards adsorption, and the methods of adsorption thermodynamics are used. However in microporous adsorbents like zeolites the linear dimensions of the crystallites vary during adsorption [9]. In this case the chemical potential of the adsorbent also varies, and it becomes more convenient to use the methods of solution thermodynamics.

This approach to the description of adsorption equilibria is particularly successful when used in conjunction with the solution model which has been termed the "vacancy solution". In this model the so-called adsorption vacancies are treated as one of the components of the solution in place of the solid adsorbent [10]. The term adsorption vacancy denotes the free elementary volume of the adsorption space of the micropores which is filled by one molecule of adsorbate during adsorption. Since the adsorption space of the micropores is limited by the micropore volume, we can define a maximum number of vacancies (equal to the limiting number of adsorbed molecules) per unit mass of the adsorbent. The adsorption tends asymptotically towards this number as the pressure of adsorband in the gas phase rises towards infinity. At any finite equilibrium pressure of the adsorband the adsorption space of the micropores contains adsorbed molecules and adsorption vacancies, which constitute the binary vacancy solution. At constant temperature the relationship between the equilibrium pressure in the gas phase and the mole fraction of solute (adsorbate), i.e. the extent of adsorption, is equivalent to a partial pressure curve for the vacancy solution or to an adsorption isotherm. Thus adsorption equilibrium between the adsorbent and the gas phase is equivalent to equilibrium between the vacancy solution and the same gas phase. In this model all the properties of the adsorbent are treated as properties of the vacancies, i.e. of the solvent. An adsorption equilibrium of this type is most conveniently analysed by solution thermodynamics.

These ideas have proved to be very fruitful because a physical as well as a formal thermodynamic analogy exists between adsorption equilibrium and osmotic equilibrium. This analogy was first recognised, for the simplest case of adsorption at a liquid surface, by Frumkin [11] in 1925, and it was subsequently formulated in detail by Adam [12]. Unfortunately it was not developed further.

Let us consider the physical basis of this analogy. We shall denote the number of moles of adsorbate and the number of vacancies per unit mass of the adsorbent by $a$ and $a^*$ respectively. For any equilibrium situation we have

$$a + a^* = a_m, \quad (6)$$

where $a_m$ is the limiting adsorption, assumed to be independent of temperature. We now define the mole fractions of adsorbate ($x$) and of vacancies ($x^*$) in the vacancy solution as

$$x = a/a_m, \quad x^* = a^*/a_m. \quad (7)$$

We shall treat the equilibrium between a microporous adsorbent and a gas phase as an equilibrium between two vacancy solutions at different concentration. One of these is the vacancy solution in the micropores, the other is a solution of adsorband molecules in a vacuum. In the latter solution the role of "solvent" is played by vacancies in the gas phase. Two solutions of the same components at different concentration can be in equilibrium only if one of them is exposed to an external potential field. It can easily be shown that the effect of this field is formally equivalent to a difference in hydrostatic pressure between the solutions. This difference is termed the osmotic pressure in solution theory.

We shall write expressions for the chemical potentials of the vacancies in these two solutions, using the subscript $\alpha$ to denote the quantities relating to the gas phase. The vacancy solution corresponding to the gas phase is always very dilute, and can be treated as an ideal solution:

$$\mu_\alpha^* = \mu_{\alpha 0}^* + RT \ln x_\alpha^* + p_\alpha V^*, \quad (8)$$

$$\mu^* = \mu_0^* + gRT \ln x^* + pV^*, \quad (9)$$

where $V^*$ is the molecular volume of the vacancies and $g$ is the osmotic coefficient which characterises (like an activity coefficient) the non-ideality of the vacancy solution in the micropores [13].

At equilibrium $\mu_\alpha^* = \mu^*$, and from Eqns.(8) and (9) we have

$$\mu_{\alpha 0}^* + RT \ln x_\alpha^* + p_\alpha V^* = \mu_0^* + gRT \ln x^* + pV^*. \quad (10)$$

When $x_\alpha^* = 1$, i.e. at zero concentration of the adsorband in the gas phase, we can write $x^* = 1$, $g = 1$, and $p_\alpha = p$.

Hence $\mu^*_{\alpha 0} = \mu^*_0$ in Eqn.(10). Defining the osmotic pressure as

$$\Pi = p - p_a, \tag{11}$$

we obtain

$$\Pi V^* = -gRT \ln x^* + RT \ln x^*_a. \tag{12}$$

As was pointed out above, the vacancy solution in the gas phase is very dilute, and $x^*_\alpha \simeq 1$: therefore the second term in Eqn.(12) can be ignored. If $W$ is the volume of micropores per unit mass of adsorbent the ratio $W/V^*$ is the limiting adsorption $a_m$:

$$W/V^* = a_m. \tag{13}$$

From Eqns.(12), (13), and (7) we obtain

$$W\Pi = -a_m gRT \ln (1 - a/a_m). \tag{14}$$

We now write the Gibbs–Duhem equation for the vacancy solution in the micropores, taking unit mass of the adsorbent at $T$ = const:

$$a\,d\mu + a^*\,d\mu^* = W\,d\Pi, \tag{15}$$

where $\mu$ is the chemical potential of the adsorbate. Since this solution is in osmotic equilibrium $d\mu^* = 0$, and therefore

$$a\,d\mu = W\,d\Pi. \tag{16}$$

Hence $\Pi = (1/W)\int_0^a a\,d\mu = \Phi/W$, where $\Phi$ is the integral of the Gibbs adsorption equation calculated from the adsorption isotherm. Obviously the value of $\Phi$ is proportional to the osmotic pressure of the vacancy solution in the micropores.

Introducing the only non-thermodynamic assumption of our argument—constancy of the osmotic coefficient $g$ at $T$ = const—we obtain the adsorption isotherm equation from Eqns.(14) and (16). Eqn.(14) is differentiated to give $d\Pi$ which is inserted into (16), from which we obtain an expression for $d\mu$:

$$d\mu = \frac{a_m gRT}{a(a_m - a)}\,da. \tag{17}$$

Integration of Eqn.(17) gives

$$\mu = \mu^0 + RT \ln p = gRT \ln \frac{a}{a_m - a} + K, \tag{18}$$

leading to the adsorption isotherm

$$p^{1/g} = \frac{a/\beta}{a_m - a}, \tag{19}$$

where $K$ is an integration constant and $\beta$ is a constant, or

$$a = a_m \beta p^{1/g}/(1 + \beta p^{1/g}). \tag{20}$$

Eqn.(20) has been used for a long time as an empirical adsorption isotherm with three parameters $a_m$, $\beta$, and $g$ (see, for example, Ref.14). The successful use of this equation over a wide range of coverages $a/a_m$ confirms the validity of our assumption of a constant osmotic coefficient $g$ at constant temperature.

The only temperature-dependent parameters of the adsorption isotherm equation (20) are $g$ and $\beta$. Expressions for their temperature dependence can be obtained from two almost self-evident non-thermodynamic assumptions. By analogy with the osmotic equilibrium we assume that the osmotic coefficient $g$ is a linear function of reciprocal temperature[15]:

$$g = C\left(1 - \frac{b}{T}\right), \tag{21}$$

and we further assume that this expression is a good approximation over a wide range of coverage. To express the temperature dependence of the parameter $\beta$ we assume that the adsorption isostere is linear at half-coverage (i.e. for $a = 0.5a_0$):

$$\ln p_{0.5} = C_{0.5} - \frac{L_{0.5}}{T}. \tag{22}$$

Introducing the symbol

$$\varphi(a) = \ln \frac{a}{a_m - a}, \tag{23}$$

and taking logarithms of Eqn.(19) we find

$$\ln p = g\varphi(a) - g \ln \beta. \tag{24}$$

Since $\varphi(a) = 0$ at $a = 0.5a_m$ we can write in this case

$$\ln p_{0.5} = -g \ln \beta. \tag{25}$$

Equation (26) for the temperature dependence is obtained in the form $f(a, p, T) = 0$ of the osmotic theory of adsorption by inserting $g$ from (21) and $\ln p_{0.5}$ from (25) into Eqn.(24), with allowance for Eqn.(22):

$$\ln p = C_{0.5} - L_{0.5}/T + C(1 - b/T) \ln \frac{a}{a_m - a}. \tag{26}$$

This equation can be written

$$\ln p = C_a - L/T, \tag{27}$$

where

$$C_a = C_{0.5} + C\varphi(a) \tag{28}$$

and

$$L = L_{0.5} + Cb\varphi(a) \tag{29}$$

are temperature-independent parameters. However their relationship to the amount of adsorption can be shown explicitly by using Eqn.(23).

Thus the thermal adsorption equation (26) has been obtained from the known adsorption isotherm (19), the thermodynamic variation of the osmotic coefficient with temperature (21), and the empirically justified assumption (22). The equation corresponds to linear isosteres over a wide range of adsorption values: linearity of the adsorption isosteres is known to be a universal property of adsorption equilibria, and is usually observed experimentally.

We note that in the initial portion of the adsorption isotherm, when the adsorption is very small and the vacancy solution approaches ideal behaviour at infinite dilution, the osmotic coefficient $g$ tends towards unity and the parameter $b$ tends towards zero. Thus it can be assumed that $g = 1$ in the initial portion of any adsorption isotherm, but as $a$ increases this coefficient rapidly changes to some other value which remains constant over a wide range of adsorptions.

## IV. EXPERIMENTAL FOUNDATIONS OF THE THERMAL EQUATION OF THE OSMOTIC THEORY OF ADSORPTION

The thermal adsorption equation (26) contains five parameters: $a_m$, $L_{0.5}$, $C_{0.5}$, $C$, and $b$, and in order to determine their values we need at least two experimental adsorption isotherms for temperatures $T_1$ and $T_2$, which must not be too close. The parameter $a_m$ can be evaluated from one of the isotherms (see below), and corresponding values of $\ln p_1$ and $\ln p_2$ are then found from the isotherms, by interpolation, for two or three suitable

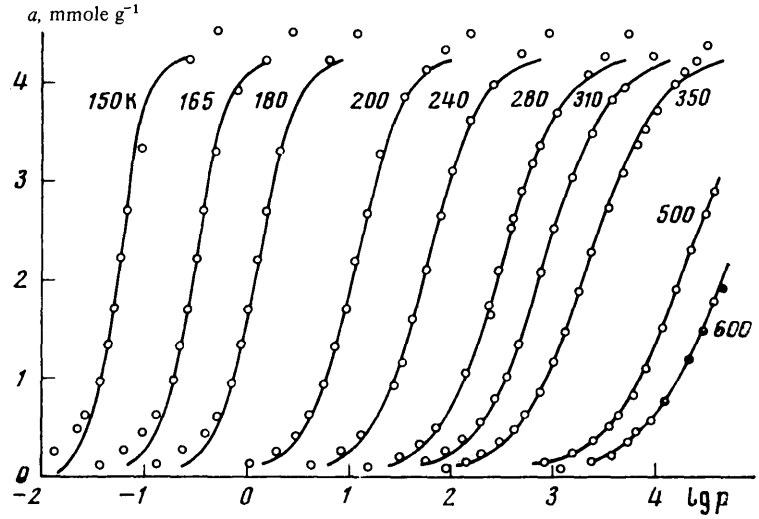

**Figure 1.** Adsorption isotherms of Xe on NaX zeolite. Full lines are calculated by Eqn. (26), circles are experimental.

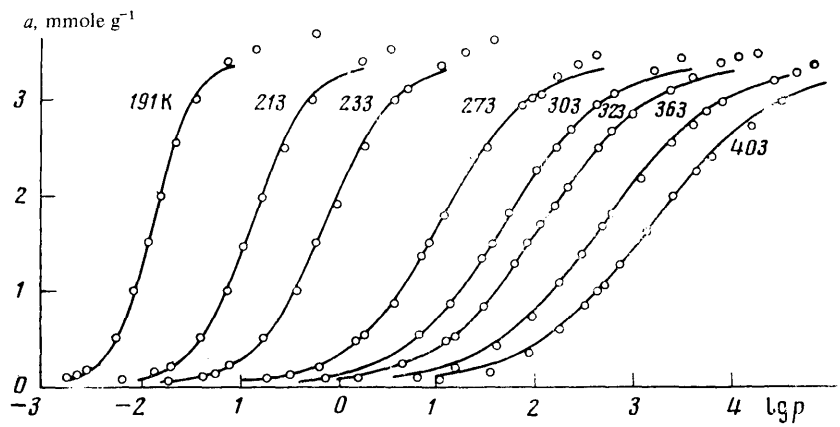

**Figure 2.** Adsorption isotherms of $CF_3Cl$ on NaX zeolite. Full lines are calculated by Eqn. (26), circles are experimental.

values of the adsorption. The parameters $C_a$ and $L$ are calculated by Eqn. (27) for the chosen values of $a$ = const, and $C_{0.5}$ and $C$ are determined by Eqn. (28). $L_{0.5}$ and $b$ are determined similarly by Eqn. (29).

The thermal equation (26) of the osmotic theory of adsorption gives a very accurate description of adsorption equilibria of gases and vapours on different microporous adsorbents such as zeolites and active carbons over a wide range of temperature and pressure. We shall illustrate the agreement between theory and experiment by considering two of the systems which have been studied in the writer's laboratory[16,17]: Xe on NaX zeolite and $CF_3Cl$ on NaX zeolite. This work is experimentally interesting because the apparatus developed for it has proved suitable for precise measurements of adsorption equilibria over very wide ranges of pressure (from $\sim 10^{-2}$ mmHg to 100 atm) and of temperature (from 150 to 600 K).

Plots of $a$ against lg$p$ in Fig. 1 show as full lines the adsorption isotherms of Xe on crystals of NaX zeolite calculated for different temperatures by Eqn. (2) with the following values of the parameters: $a_m$ = 4.30 mmole g$^{-1}$, $L_{0.5}$ = 1225 K, $C_{0.5}$ = 6.76, $C$ = 1.14, and $b$ = 109 K. The agreement between theory and experiment is good in the range of coverage ($a/a_m$) from 0.09 to 0.93 for a wide range of temperature (150–600 K) including the critical temperature of the adsorband ($T_c$ = 290 K). An analogous family of isotherms for the adsorption of $CF_3Cl$ on the same sample of NaX zeolite is shown in Fig. 2. The parameters $a_m$ = 3.40 mmole g$^{-1}$, $L_{0.5}$ = 1850 K, $C_{0.5}$ = 7.80, $C$ = 2.38, and $b$ = 154 K were used for calculations by Eqn. (26). The experimental temperature range again

includes the critical temperature ($T_c$ = 302 K), and the agreement between theory and experiment is again good for coverages between 0.09 and 0.97.

It is important to note that the adsorption isosteres are linear in both systems for this range of coverage. The thermal adsorption equation (26) applies at temperatures both above and below the critical temperature with the same set of parameters. The excellent agreement between the calculated and the experimental adsorption isotherms and the linearity of the isosteres (e.g. for $a = 0.5a_m$) are direct experimental confirmation of the validity of the basic assumptions of the osmotic theory of adsorption: constancy of the osmotic coefficient $g$ at $T$ = const and linearity of the standard adsorption isostere.

## V. THERMODYNAMIC ADSORPTION EQUILIBRIUM FUNCTIONS

Expressions for the main thermodynamic functions of the adsorption equilibrium in the range of $p$ and $T$ values for which the gas phase can be treated as almost ideal are easily obtained from Eqns.(22) and (29). According to Eqns.(24) and (25) the differential Gibbs free energy $G$ is given by the expression

$$G = RT \ln p = G_{0,s} + gRT\varphi(a). \quad (30)$$

Differentiating this expression with respect to $T$ with $a$ = const, and allowing for the temperature dependence of $g$ [Eqn.(21)], gives an expression for the differential entropy of adsorption $S$:

$$S = -(\partial G/\partial T)_a = S_{0,s} - CR\varphi(a). \quad (31)$$

If the equilibrium gas phase is ideal we have $RL = Q$, where $Q$ is the differential heat of adsorption. Hence, from Eqn.(29),

$$Q = Q_{0,s} + CbR\varphi(a). \quad (32)$$

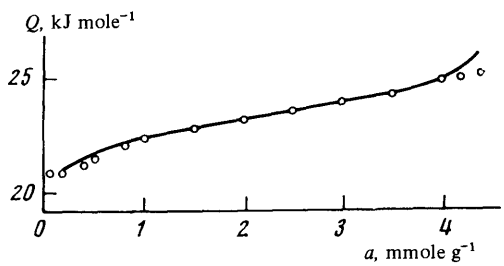

Figure 3. Differential heat of adsorption of Xe on NaX zeolite against $a$. The full line is calculated by Eqn.(32), the circles are experimental values of $Q$.

It can be shown by thermodynamic arguments that the parameter $C$ in formula (21) cannot be negative. Hence it follows from Eqn.(32) that for $T$ = const the dependence of the heat of adsorption $Q$ on $a$ is determined by the sign of the parameter $b$. For $b > 0$, $Q$ increases with adsorption (and coverage), whereas for $b < 0$ $Q$ decreases as $a$ increases.

The variation with adsorption of the differential heat calculated by Eqn.(32) (full line) is compared in Fig. 3 with experimental results for the Xe–NaX system at $T$ = 165 K in the region of $p$ values for which the gas phase can be treated as ideal. The agreement between calculation and experiment is satisfactory.

Thus the osmotic theory of adsorption equilibria leads to a thermal adsorption equation which allows us to express the isotherms, isosteres, and thermodynamic equilibrium functions in terms of a single set of parameters.

## VI. COMPARISON OF CALCULATIONS USING VARIOUS EQUATIONS OF ADSORPTION IN MICROPORES

A computer study has shown[18] that the parameters of the adsorption equations given by the micropore volume filling theory and the osmotic theory of adsorption can be optimised to enable Eqns.(4) and (20) to describe accurately the same experimental results over a wide range of coverage:

$$a_m = \varkappa a_0 \quad (33)$$

$$g = \frac{E}{RT}F \quad (34)$$

$$\ln\beta = \left[\frac{\ln(2/\varkappa)}{F}\right]^{1/n} - \frac{1}{g}\ln p_s. \quad (35)$$

Table 1. Conversion coefficients.

***TVF denotes calculation by the equation of the theory of volume filling, OTA denotes calculation by the equation of the osmotic theory of adsorption.

The conversion coefficients $\kappa$, $F$, and $y$ for the adsorption systems to which Eqn.(4) is applicable are listed in Table 1, together with the ranges of coverage $\theta = a/a_m$ within which formulae (33)–(35) can be used with adequate

precision at temperatures between 100 and 150 K. As an example, points on the isotherm for the adsorption of methane on zeolite L calculated by Eqns. (4) and (20) for 156 K are compared in Table 2. The range of coverages $\theta$ lies within the limits given in Table 1 for $n = 3$. The results of the calculations are almost indistinguishable. However the osmotic theory of adsorption allows us to describe adsorption equilibria in microporous adsorbents over wider ranges of pressure and temperature, and in particular above the critical point.

## VII. THE BIPORE MODEL OF MICROPOROUS ADSORBENTS IN THE KINETICS OF PHYSICAL ADSORPTION

Pores in adsorbents can be classified[4,19] according to the mechanism of the adsorption and of the capillary phenomena in the adsorbent grains into micropores ($r < 6-7$ Å), supermicropores ($6-7 < r < 15-16$ Å), mesopores ($15-16 < r < 1000-2000$ Å), and macropores ($r > 1000-2000$ Å). The symbol $r$ denotes the equivalent pore radius, equal to twice the ratio of the normal cross-sectional area to the perimeter of the pore.

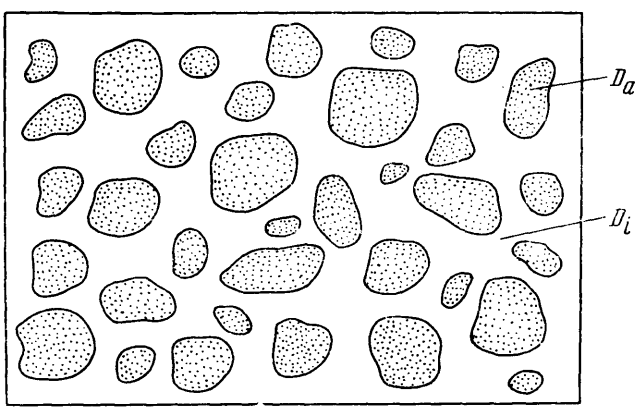

Figure 4. Model of the biporous adsorbent.

In many practical cases we can simplify the structure of the adsorbent and consider only two types of pore with very different properties: adsorption pores (micro- and supermicropores) and transport pores (meso- and macropores). This bipore model of the adsorbent, which can be applied successfully to zeolites, is illustrated in Fig. 4. The grey areas represent microporous regions of the adsorbent, consisting exclusively of adsorption pores. The transport pores are located in the region between the microporous regions.

The adsorption kinetics of biporous adsorbents have been studied by other workers[20-24] as well as in our laboratories[25-39]. The equations of inner diffusion in biporous adsorbents have been investigated for the general case of non-linear adsorption isotherms, and generalised for microporous regions (crystals) of difference size with a finite diffusional resistance to the entry of molecules into the crystal[26,28,31,32]. The latter resistance arises from the potential barrier at the boundary of the microporous region which the molecules must overcome. By using the statistical moment method fairly simple analytic expression can be obtained relating the characteristic times of diffusion in adsorption pores ($\tau_a$) and in transport pores ($\tau_i$) to the moments of the kinetic curves[28-33]. For inner-diffusion kinetics in microporous regions of equal size the first- and second-order moments are

$$M_1 = g_{v1}\tau_i + g_{\mu 1}\tau_a,$$
$$M_2 = g_{v2}\tau_i^2 + 4g_{v1}g_{\mu 1}B\tau_i\tau_a + g_{\mu 2}B\tau_a^2. \qquad (36)$$

In these equations $\tau_i = L^2(1+\Gamma)/D_i$, $\tau_a = r_0^2/D_a$, $\Gamma = a_0/c_0$, $L$ and $r_0$ define the size of the granule and of the microporous regions, $D_i$ and $D_a$ are the diffusion coefficients for the transport pores and for the microporous regions respectively, $a_0$ is the equilibrium value of the adsorption, $c_0$ is the concentration of adsorband at the surface of the granule. For industrial adsorbents we can take $B = 1$. The coefficients $g_{v1}$, $g_{\mu 1}$, $g_{v2}$, $g_{\mu 2}$ are determined by the geometric shape of the granule and of the microporous regions: their values for various assumed geometries are tabulated, for example, in Ref. 33. We have discussed and generalised Eqns. (36) by allowing for a distribution of crystal sizes and for the finite diffusional resistance to the entry of adsorbate molecules into zeolite crystals[31,32]. We have also developed a method of determining the coefficients in biporous adsorbents by monitoring the diffusion of the adsorband between two vessels through a granule of the adsorbent[34]. The diffusion coefficients for the adsorption pores and the transport pores have been determined separately by using the above expressions, and the transport mechanism in real microporous adsorbents such as zeolites and active carbons has been analysed[33,34]. The analysis has confirmed the validity of the bipore model of real microporous adsorbents.

A comparison[35] of calculated and experimental results has shown that the equations of the bipore model can be used to describe the sorption kinetics of low-molecular compounds (benzene, hexane) on two-phase polymer systems such as block copolymers and mixed polymers for the case of a linear adsorption isotherm. Furthermore these polymer systems can be treated as real models of a biporous medium, since their diffusional, structural, and sorption characteristics can be quantitatively determined by independent methods.

Considerable interest has been shown in the direct calculation of $\gamma(t)$ kinetic curves (where $\gamma$ is the relative adsorption averaged over a grain) for a biporous adsorbent with different ratios of the $\tau_i$ and $\tau_a$ relaxation times. Computer calculations for linear adsorption isotherms and spherical, cylindrical, or flat adsorbent grains have been reported[36,37].

## VIII. KINETICS OF PHYSISORPTION ON BIPOROUS ADSORBENTS FOR SHARPLY CONVEX ADSORPTION ISOTHERMS

The inner diffusion equations for biporous adsorbents have been studied in our laboratory for the case of linear adsorption isotherms[25,26,28-33] and also for sharply convex isotherms quickly approaching saturation ("rectangular" isotherms)[39,40]. We examined the case of cylindrical (or prismatic) adsorbent grains with an impermeable side surface, and we studied changes in the local concentration of adsorbate in the grain as a function of time [$a(x)$, where

$x$ is the distance from the end-face of the grain] as well as changes in the relative adsorption averaged over the grain [$\gamma(t)$, the kinetic curve]. The result is strongly dependent on the ratio of the characteristic times for the establishment of adsorption equilibrium in the transport pores and in the microporous regions ($\tau_i$ and $\tau_a$ respectively).

With sharply convex isotherms we can obtain a clear picture, which confirms the validity of the bipore model of zeolites and microporous active carbons, by studying the adsorption kinetics of vapours which give X-ray contrast under irradiation with X-rays [25,27,33]. The main advantage of this method is the possibility of visual observation of the formation and propagation of an adsorption front in the adsorbent grain. Consider a cylindrical grain of zeolite in which the side surface and one of the end faces are impermeable, and adsorption of an X-ray contrasting vapour is proceeding from the other end-face (Fig. 5). If the rate of adsorption is determined by diffusion in the zeolite crystals ($\tau_a \gg \tau_i$) the X-ray pictures show a gradual darkening of the entire adsorbent granule (Fig. 5*a*). On the other hand if the process is limited by diffusion in the transport pores ($\tau_i \gg \tau_a$) we expect a sharp adsorption front to be created in the case of a sharply convex adsorption isotherm, i.e. the zeolite granule should be filled "layer by layer" (Fig. 5*c*). In this case the adsorption wave $a(x)$ is almost rectangular in shape, and the kinetic curve is $\gamma(t) \propto \sqrt{t}$.

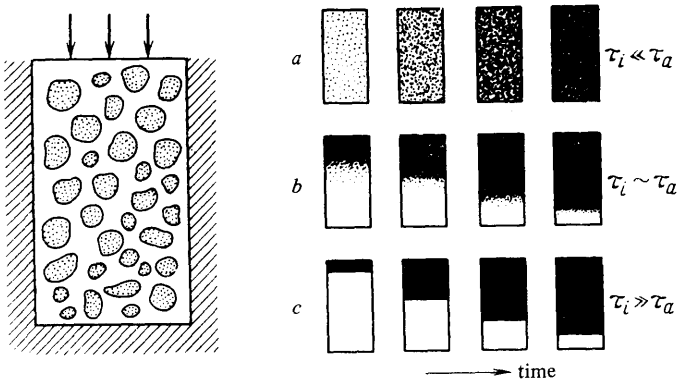

Figure 5. Granule of formed zeolite with an impermeable side surface (adsorption flow is indicated by arrows) and distribution of adsorbate in the adsorbent granule for different relative values of $\tau_a$ and $\tau_i$.

In the intermediate case (when $\tau_i$ and $\tau_a$ are comparable) we observe the formation and propagation through the grain of an adsorption wave [$a(x)$] with a diffuse front (Fig. 5*b*). In this case theory predicts [38,39] a $\gamma(t)$ variation more complex than a simple $\sqrt{t}$ law. The exact form of the $\gamma(t)$ relationship is determined by the form of the kinetic function describing the filling of the microporous regions such as the zeolitic crystallites within the grain [$\varphi(t)$, where $0 \leqslant \varphi(t) \leqslant 1$]. We have obtained, for this case, an approximate integral equation for the law of motion of the leading front of the adsorption wave $l(t)$ (Fig. 6):

$$\hat{l}^2(s) = \frac{2D_i}{s^2[(a_0/c_0)\, s\hat{\varphi}(s) + 1/6]}, \qquad (37)$$

where

$$\hat{l}^2(s) = \int_0^\infty e^{-st} l^2(t)\, dt \text{ and } \hat{\varphi}(s) = \int_0^\infty e^{-st}\varphi(t)\, dt \qquad (38)$$

are the transforms of the functions $l^2(t)$ and $\varphi(t)$. In particular, an analytic solution was obtained for the kinetic functions $\varphi(t) = 1 - \exp(-t/\tau_a)$ and $\varphi(t) = 6\sqrt{t/\pi\tau_a}$, where $\tau_a = r_0^2/D_a$ is the characteristic time for diffusion in the micropores, which provide a model of the diffusional mechanisms operating in the initial and the final stages of adsorption in the microporous regions. If the function $\varphi(t)$ is more complex, $l(t)$ can be obtained from Eqn. (37) by numerical inversion of the Laplace transform. The deviation from the true solution introduced by the use of Eqn. (37) is less than 5% in the limiting case ($\tau_a = 0$). In principle Eqn. (37) allows us to determine the kinetics of adsorption in the microporous regions [$\varphi(t)$] from the known equation of motion of the leading front of the adsorption wave [$l(t)$], and vice versa. The equation can also be used to calculate the diffusion coefficients.

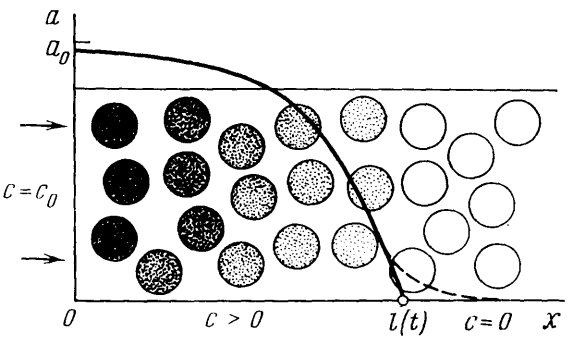

Figure 6. Adsorption front in a granule of biporous adsorbent. The filling of the crystals is indicated qualitatively by the darkening of the circles.

We have also studied theoretically the time dependence of the width of the front of the adsorption wave in the intermediate case ($\tau_i = \tau_a$). [39] For a rectangular adsorption isotherm we found that this quantity ($\Delta t$) decreases with time. The exact form of the falling function $\Delta(t)$ depends on the form of the kinetic function which describes the filling of the micropores [$\varphi(t)$]. In particular, if $\varphi(t) = 1 - \exp(-t/\tau_a)$, we have

$$\Delta(t) = \sqrt{\frac{2D_i\tau_a c_0}{a_0}}\left[\sqrt{\frac{t}{\tau_a} + \ln(1-\varepsilon_1) + 1} - \sqrt{\frac{t}{\tau_a} + \ln\varepsilon_1 + 1}\right]. \qquad (39)$$

In this expression $\epsilon_1 > 0$ is a small quantity used in the definition of the width of the adsorption wave front $a(x)$:

$$\Delta(t) = x_2(t) - x_1(t)$$
$$a(x_1)/a_0 = 1 - \varepsilon_1, \quad a(x_2)/a_0 = \varepsilon_1. \qquad (40)$$

The theoretical prediction of a changing width of the adsorption wave front can be tested experimentally by studying the adsorption kinetics of substances opaque to X-rays. We have used this method to study the adsorption kinetics of ethyl iodide, ethyl bromide, and bromobenzene from a stream of nitrogen on CaA, CaX, and NaX zeolites, and on active carbons. Adsorption on the type-X zeolites and on active carbons from a stream of carrier

gas gave a clear indication of "layer by layer" filling of the granules (Fig. 5*c*). With CaA zeolites containing different binders and with granules formed in different ways all three cases were observed (Fig. 5). The intermediate situation ($\tau_i \simeq \tau_a$, Fig. 5*b*) is most easily observed in the adsorption of bromobenzene and xenon from a one-component gas phase on microporous active carbons with molecular-sieve properties [33,40]. The results of these experiments are shown in Fig. 7. Initially the adsorption front is quite diffuse in all the series of photographs, but it becomes sharper with time and at long enough times we observe "layer by layer" filling of the granules.

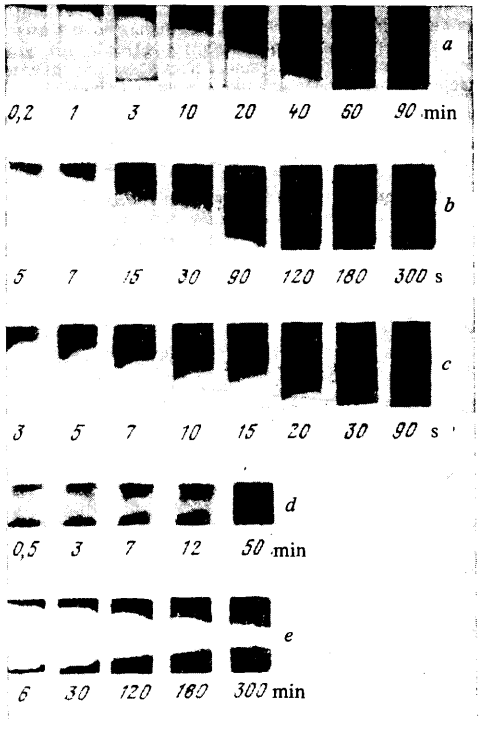

Figure 7. Distribution of xenon (*a*, *b*, *c*) and bromobenzene (*d*, *e*) in a granule of active carbon at successive times. The temperature is $T$ = 195 K (*a*, *b*, *c*) or $T$ = 303 K (*d*, *e*); pressure of adsorband $p$ = 0.9 kPa (*a*), 13.3 kPa (*b*), 26.6 kPa (*c*), 27 Pa (*d*), concentration of adsorband $c$ = 10 mg litre$^{-1}$ (*e*).

## IX. THE STATISTICAL MOMENT METHOD AND ANALYSIS OF EXPERIMENTAL DATA ON ADSORPTION KINETICS

The statistical moment method has been widely used in recent years for analysing quantitatively experimental data on the kinetics of adsorption on biporous adsorbents with linear adsorption isotherms. It can be shown that in the case of rectangular adsorption isotherms the statistical moments of the kinetic curve $M_k$ can also be related to the law of motion of the boundary $t_*(x)$ and to the moments of the kinetic filling function of the microporous regions $M_{\varphi k}$ by analogous expressions, which in this case take the form

$$M_1 = M_{\varphi_1} + \frac{1}{R}\int_0^R t_*(x)\,dx, \qquad (41)$$

$$M_2 = M_{\varphi_2} + 2M_{\varphi_1}\frac{1}{R}\int_0^R t_*(x)\,dx + \frac{1}{R}\int_0^R t_*^2(x)\,dx \qquad (42)$$

where $R$ is the characteristic dimension of the adsorbent grains.

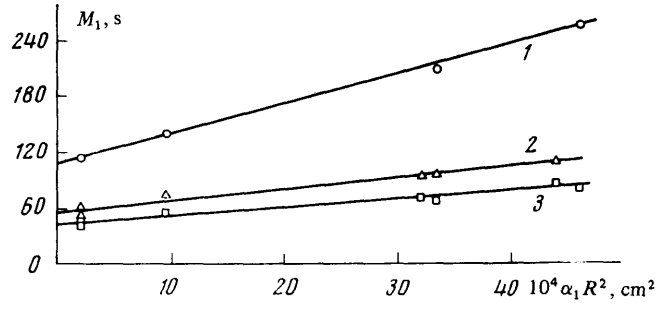

Figure 8. Moments of the kinetic curves ($M_1$) against $\alpha_1 R^2$; xenon on MSC-5A; 195 K; $p$ = 0.8 kPa (*1*), 13.3 kPa (*2*), 26.6 kPa (*3*).

These expressions can be combined with the law of motion of the boundary to analyse experimental data on the adsorption kinetics of biporous adsorbents. In particular, it follows from Eqn. (41) that if the adsorption kinetics in the microporous regions are exponential and the characteristic time $\tau_a$ is not too great (more strictly, $\tau_a < R^2 a_0/2D_i c_0$) we can write

$$M_1 = \frac{\tau_i}{6} + \frac{2}{3}\tau_a\sqrt{\frac{2\tau_a}{\tau_i}}, \quad \tau_i = \frac{a_0}{c_0}\frac{R^2}{D_i}. \qquad (43)$$

The result of a gravimetric study of the adsorption kinetics of xenon by granules of active carbon of different size are illustrated in Fig. 8, where the first moments of the kinetic curves ($M_1$) are plotted against $\alpha_1 R^2$. $\alpha_1$ is the shape factor of the granules. The moment of the kinetic function for the microporous regions $M_{\varphi 1}$ can be determined by extrapolation as the intercept on the vertical axis. We stress that Fig. 8 relates to the analytically more demanding situation of intermediate adsorption kinetics, when the characteristic diffusion times in the adsorption pores ($\tau_a$) and in the transport pores ($\tau_i$) are comparable. The integral of Eqn. (41) can be calculated from plots of $l(t)$ or $t_*(x)$ (Fig. 9), constructed from the radiographs of Fig. 7. The total moments $M_1$ calculated from Eqn. (41) agree with the experimental values.

The law of motion of the adsorption front $l(t)$, which can be determined for example by X-radiography, allows us to evaluate not only the integral characteristics of the kinetic function ($M_{\varphi k}$) but also the function $\varphi(t)$ itself. This involves solving the integral equation (37) with respect to $\varphi(t)$. The solution of this problem (inversion of the integral Laplace transform) is unstable towards small changes in the initial function $l(t)$, and therefore the experimental determination of $l(t)$ must be made with great care. This requirement is typical of the present

state of adsorption studies, with measurements of the microscopic properties of the adsorbent aimed not only at the integral properties of the adsorption process but also at its local characteristics (for example, as in this case, the distribution of adsorbate within the grain of adsorbent).

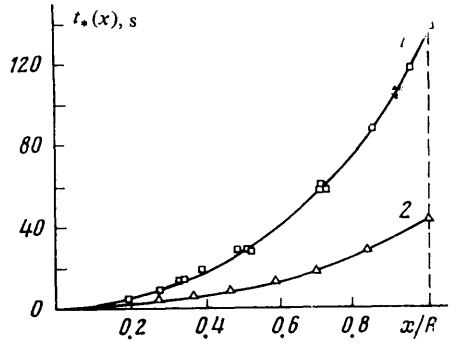

Figure 9. Plots of $t_*(x)$: $p$ = 13.3 kPa (*1*) 26.6 kPa (*2*).

Work in our laboratory [25-40] and elsewhere [20-24] has shown that the bipore kinetic model offers some important advantages in the study of adsorption kinetics on real adsorbents, and in particular on formed zeolites. It gives a correct interpretation of the experimental results, free from the limitations of the classical quasi-diffusional model. However our model needs further experimental confirmation, particularly as regards the mechanism of mass transport in the microporous regions. The bipore model should ultimately lead to a rational choice of real adsorbents with the most favourable pore structure.

# Present State of the Chemistry of Technetium

V.I.Spitsyn, A.F.Kuzina, and A.A.Oblova

We review recent work in the Soviet Union and abroad on the chemistry and technology of technetium which allows the properties of this element to be discussed in the light of Mendeleev's Periodic Law. A section outlining the history of the discovery of technetium is included because of the many inaccuracies in the published accounts of the search for this element. 129 references.

## I. INTRODUCTION

The rapid development of nuclear energy has highlighted the problems associated with the treatment of nuclear fuels, including the regeneration of uranium and plutonium and the extraction from the waste products of the nuclear industry of valuable isotopes for use in various technological processes.

Among the most interesting fission products of uranium is the isotope technetium-99, the first artificially radioactive element, found in nature in insignificant amounts. It can be prepared from waste products of the atomic energy industry[1,2]. Technetium has some unique superconducting[3], anti-corrosion[4,5], and catalytic properties[6,7], as well as a high melting point (2200°C)[8] and boiling point (4700°C),[9] and therefore it offers a number of possibilities as a new technological material for refractory, corrosion-resistant, and superconducting structures.

Table 1. Unit cell parameters of technetium and rhenium compounds.

| Compound | Cell parameter, A | Reference |
|---|---|---|
| $K_2[TcCl_6]$ | $a=9.89$ | 12 |
| $K_2[ReCl_6]$ | $a=9.84$ | 12 |
| $[TcO_2Py_4]Cl\cdot 2H_2O$ | $a=14.40$; $b=12.34$; $c=15.06$ | 13 |
| $[ReO_2Py_4]Cl\cdot 2H_2O$ | $a=13.95$; $b=12.04$; $c=15.04$ | 13 |
| $[ReO_2Py_4]Cl\cdot 2H_2O$ | $a=13.592$; $b=11.973$; $c=15.55$ | 14 |
| $K_3[Tc(CN)_6]$ | $a=12.106$ | 15 |
| $K_3[Re(CN)_6]$ | $a=12.033$ | 15 |
| $K_2TcH_9$ | $a=9.64$; $c=5.56$ | 16–18 |
| $K_2ReH_9$ | $a=9.607$; $c=5.508$ | 16–18 |

The study of the properties of technetium—a transition element with an unfilled outer electronic *d*-shell—should help to clarify the nature of its chemical bonding. Technetium, like its subgroup and period analogues, forms a multiplicity of structurally unusual complexes which are difficult to synthesise because of their low stability and also because of the radioactivity of the element. In addition to the classical tetrahedral and octahedral structures we find technetium compounds obeying new structural rules, such as the cluster compounds (binuclear complexes)[10,11].

Structural studies of technetium and rhenium compounds have shown that the unit cell of technetium compounds is larger than that of the isostructural rhenium compounds, although the technetium atom is smaller than the rhenium atom (Table 1). This effect can be ascribed to the higher ionicity of the technetium–ligand bond as compared to the rhenium–ligand bond in which the covalent contribution is predominant.

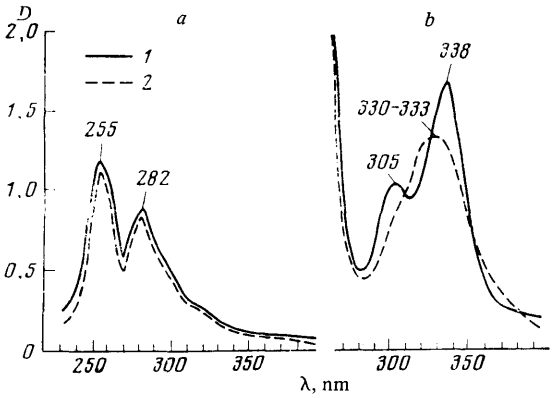

Figure 1. Time changes of absorption spectra: *a*) $(PyH)_2[ReCl_6]$, *b*) $(PyH)_2[TcCl_6]$; *1*) freshly made compound, *2*) after 1 day.

The rhenium compounds are more stable in solution, as shown by a spectrophotometric study[19] of the complexes $(PyH)_2[ReCl_6]$ and $(PyH)_2[TcCl_6]$ (Fig. 1).

Technetium belongs to a group of elements showing strongly developed complex-formation properties[20]. Its ability to form coloured complexes with high molar extinction coefficients has been exploited in the analytical chemistry of the element (Fig. 2).[2] Methods of extracting technetium from industrial solutions, of purifying it from radioactive and stable elements, and of preparing it in a

metallic form have all been based on complex formation. Thus the chemistry of technetium is essentially the chemistry of its complexes, but unlike the "typical" complex-forming elements of the platinum group, technetium forms relatively unstable compounds, resembling rhenium in this respect. Nevertheless it has been shown experimentally that technetium compounds can exist (under certain conditions) both in solution and in the solid state.

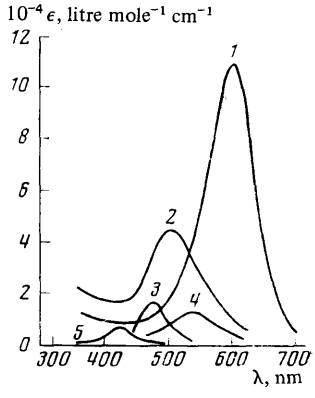

Figure 2. U. v. spectra of technetium complexes with: *1*) Methyl Violet, *2*) thiocyanate, *3*) α-benzildioxime, *4*) α-furyldioxime, *5*) 1,2-dioxime.

This review aims to discuss the properties of technetium in relation to those of its nearest period and group analogues: no attempt is made to describe in detail all the published work on the chemistry of technetium, which includes over 1000 publications.

## II. HISTORY OF THE DISCOVERY OF TECHNETIUM

The existence of element "43" was predicted by Mendeleev on the basis of his Periodic Law[21]. Several workers claimed to have discovered an analogue of manganese, and even proposed new names for it: ilmenium (Hermann, 1846),[22] devium (Kern, 1877),[23] lucium (Barriere, 1896),[24] and nipponium (Ogawa, 1908).[25]

In 1925 Noddack, Tacke, and Berg[26] described the physical properties of eka-manganese by interpreting the properties of its neighbouring elements in the Periodic Table. They made a comprehensive study of the X-ray spectra of various ore concentrates including those of the platinum minerals (columbite etc.). They claimed to have obtained a preparation containing 0.5% of eka-manganese, for which they proposed the name masurium. Their claim was soon refuted by Prandtl[27]: however, the element rhenium was discovered during the search for element "43"[26]. In 1927 Zvyagintsev and coworkers re-examined a range of platinum minerals and concluded that element "43" was absent[28].

Work on the structure and properties of the atomic nucleus led to the suggestion that elements which had not yet been discovered in Nature were unstable and could be obtained only by synthesis. By using the arguments of the Periodic Law, and by applying recent developments in atomic physics (atomic reactors and accelerators), Perrier and Segre[29,30] were able to prepare technetium after 70 years' unsuccessful attempts to discover the element in Nature. These workers demonstrated the possibility of preparing elements artificially by transmutation.

The first minute quantities of the element ($\sim 10^{-10}$ g) were prepared in the Berkeley cyclotron by the reactions

$$^{92}_{42}\mathrm{Mo}\,(d,\ n)^{93}_{43}\mathrm{Tc};\quad ^{92}_{42}\mathrm{Mo}\,(d,\ 2n)^{92}_{43}\mathrm{Tc}$$

In 1938 Seaborg discovered the long-lived isotope $^{99}$Tc, which was later isolated from uranium fission products by Segre and coworkers[30].

16 technetium isotopes are now known, with masses ranging from 92 to 107, and 6 isomers[31]. All the technetium isotopes are radioactive, as expected from the Shchukarev–Mattauch rule.

The possibility of finding primary technetium in the earth's crust is excluded by the half-lives of the technetium isotopes. The small trace of technetium ($10^{-9}$ g per kilogramme) detected[32] in pitchblende is the result of spontaneous fission of uranium; traces of technetium may be present in other minerals through the interaction of cosmic neutrons with molybdenum, ruthenium, or niobium.

Thus the primary technetium which existed in Nature several billion years ago when the Earth was formed has now disappeared by radioactive decay. If any technetium exists at present it has been formed by secondary nuclear reactions on the Earth. However, weak lines of ionised technetium have been detected in the Sun's spectrum[33] and in that of some of the younger stars[34,35]. The presence of technetium in some stars in amounts comparable with that of its analogues suggests that technetium is being formed in stars at the present time. This observation is of the utmost importance to the cosmological theory of the development of the chemical elements, which denies the hypothesis of pre-stellar formation of the elements and states that stars are continuously active "factories" of chemical elements.

## III. SOURCES AND METHODS OF PREPARATION

The knowledge that technetium is a transition element able to form a variety of complexes enables us to develop methods of preparing the element.

Technetium-99 at present is obtained from the fission products of uranium-235, among which it was first detected by Hahn and Strassmann[36] in 1939. It can also be produced by the action on slow neutrons on molybdenum:

$$^{98}_{42}\mathrm{Mo}\,(n,\gamma) \rightarrow {}^{99}_{42}\mathrm{Mo} \xrightarrow[T_{1/2}=6.7\ \mathrm{h}]{\beta,\gamma} {}^{99}_{43}\mathrm{Tc} \xrightarrow[T_{1/2}=6.1\ \mathrm{h}]{\text{i.p., }\bar{e},\gamma} {}^{99}_{43}\mathrm{Tc} \xrightarrow[T_{1/2}=2.12\cdot10^{5}\ \mathrm{years}]{\beta} {}^{99}_{44}\mathrm{Ru}_{\text{stable}}$$

It is very difficult to obtain a high yield of technetium-99 from this source. Thus, irradiation of 1 kg of molybdenum for 1 year in a flux of $\sim 8\times10^{13}$ neutrons cm$^{-2}$ s$^{-1}$ yields approximately 60 mg of Tc.[37]

The technetium can be isolated from this source by various methods, which can be classified in the following order of effectiveness: extraction, ion exchange, precipitation, distillation, electrodeposition. Under industrial conditions combined methods are often used: for example, precipitation and extraction, ion exchange and extraction, etc.

Technological methods of preparing technetium from solutions used in the atomic energy industry have been developed over a number of years both in the Soviet Union and abroad. We shall mention only those which have

yielded appreciable amounts of technetium[38-42]. Among the foreign developments the most interesting is the American technology for the isolation of technetium during the treatment of uranium hexafluoride in a gaseous diffusion plant[39,40]. The method depends on the similarity in physicochemical properties of the two volatile compounds (uranium and technetium hexafluorides) formed during the fluorination of uranium being regenerated. The two fluorides are separated by a sorption method and the technetium is finally purified by extraction.

The isolation of technetium from industrial atomic energy solutions is a complex technological problem, with special emphasis on the problem of waste solutions. Any increase in the volume of these solutions as a result of additional treatments aimed at concentrating the technetium must be avoided. Only the sorption technology in conjunction with ion exchange can satisfy this requirement.

Ion-exchange methods of concentrating technetium by the use of highly basic resins have been patented[41,42]; the eluent is nitric acid, and the product is purified by extraction with ethyl methyl ketone. The ion-exchange method has been developed and applied also in the Soviet Union, in conjunction with acetone extraction and precipitation as technetium heptasulphide[2,38]. An important advantage of ion exchange over all other methods of separating technetium is its ability to separate technetium from ruthenium. Both high-basicity and low-basicity organic resins have been shown[38-44] to be usable, in a variety of chemical compositions and structures.

Treating the ion-exchange properties of technetium in the light of the periodic classification of the elements we note that the perrhenate ion and the pertechnetate ion are both readily adsorbed by anion exchange resins over a wide range of solution pH. The permanganate ion is reduced by these resins, and therefore ion exchange is not applicable in the presence of manganese(VII). Manganese(II) is adsorbed to a moderate extent by cation exchange resins.

The selectivity of the resins towards the $[TcO_4]^-$ ion arises partly from the properties of the resins themselves and partly from the special structure of the ion, its tendency towards complex formation, and its low degree of hydration.

## IV. CHEMICAL PROPERTIES

The structure of the outer electron shells of the technetium atom, whose configuration is given as $4d^65s^1$ ($S$ 9/2)[45,46] or $4d^55s^2$ ($S$ 5/2)[47,48], is responsible for the properties of the element as a transition metal of the second series of the $d$ group (Zr, Nb, Mo, Tc, Ru, Rh, Pd, and Ag).[49] This electronic structure makes possible several oxidation states, from +7 to −1, and it explains the tendency towards disproportionation, hydrolysis, hydride formation, formation of compounds with metal–metal bonds, and complex formation, all of which play an important part in the chemistry of the element.

The chemical properties of technetium are similar to those of rhenium, but they are quite different from those of manganese in spite of some analogy in the stereochemistry of several of their compounds: the oxo-anions $[MO_4]^-$, $[MO_4]^{2-}$, the oxides $M_2O_7$, $MO_2$, the hexa-halogen complexes $[MX_6]^{2-}$, and the $\pi$-complexes $[M(CN)_6]^{5-}$, $M_2[CO]_{10}$, $M[CO]_5Cl$. However manganese tends to favour the lower oxidation state+2, which is more stable than manganese(VII), $d^0$, as a result of the configuration involving unpaired spins with a $d^5$ electronic shell. Manganese(II), $d^5$, occurs mainly in a series of high-spin complexes and in simple cationic compounds, usually with an ionic bond. In the heptavalent state manganese is unstable, and behaves as a strong oxidising agent. On the other hand technetium and rhenium typically adopt the heptavalent $d^0$ state with a weak tendency towards reduction, as shown by their standard redox and ionisation potentials:

| Redox potentials, V | | Ionisation potentials, eV (Ref.5) | |
|---|---|---|---|
| $[MnO_4]^-/MnO_2$ | −1.695(Ref.50) | Mn | 122 |
| $[TcO_4]^-/TcO_2$ | −0.738(Ref.51) | Tc | 95 |
| $[ReO_4]^-/ReO_2$ | −0.510(Ref.52) | Re | 79 |

This difference between the properties of technetium and rhenium is explained by the difference between the electronic shells of these elements. The main feature of the $4d$ shell of the technetium atom, and also of the $5d$ shell of its nearest analogue, rhenium, is that the electrons in these shells are much further from the nucleus than the electrons in the $3d$ shell of manganese. As a result the interaction between the positive nucleus and the outer electrons is much weaker, the pairing of the electrons is enhanced, and the splitting of the levels by the ligand field is increased, leading to the formation of the characteristic low-spin complexes of technetium and rhenium. Manganese forms high-spin complexes as a rule. Typical of these are the halogen $o$-phenylene-*bis*-dimethyldiarsine complexes of Tc(II), $[TcDiars_2Hal]^0$,[54] with the $d^5$ configuration, spin paired with $\mu_{eff} = 1.9–2.1\ \mu_B$, corresponding to the presence of one unpaired electron. The analogous complex of manganese(II) is a spin-free complex. The low-spin complexes of Mn(II) with one unpaired electron, of composition $[Mn(CN)_6]^{4-}$ and $[Mn(CN)_5NO]^{3-}$, are exceptional in the chemistry of manganese; the Mn(III) complex $[Mn(CN)_6]^{3-}$ with two unpaired electrons is also known[49]. In all these complexes the pairing of the electrons is governed by a strong ligand field.

The partly filled $d$-shell and the presence of "spare" electrons (not involved in bond formation with the ligand) in increasing numbers as the oxidation state of technetium and rhenium decreases tend to favour the interaction between electrons of the metal atoms and the formation of metal–metal bonds. Rhenium and technetium begin to display a tendency to form compounds of this type when in the oxidation state +4 (as $ReO_2$ and $TcO_2$).[55]

It has been reported that aquo-ions do not play a significant part in the chemistry of technetium and rhenium[49], although they are characteristic of manganese and of the whole of the first group of transition elements. However more recent work[56,57] has shown that aquo-complexes are formed by rhenium and technetium in the oxidation states +2, +3, and +4. In the highest oxidation state Tc(VII), having the $d^0$ configuration, forms complexes with a coordination number of 4 as the $[TcO_4]^-$ ion, analogous not only to manganese(VII), $[MnO_4]^-$, and rhenium(VII), $[ReO_4]^-$, but also to chlorine(VII), $[ClO_4]^-$, iodine(VII), $[IO_4]^-$, bromine(VII), $[BrO_4]^-$, ruthenium(VII), $[RuO_4]^-$, and neptunium(VII), $[NpO_4]^-$.[49,58,59]

Studies by vibrational spectroscopy have shown that a tetrahedral ion such as $[TcO_4]^-$ with a $T_d$ point symmetry is stable in aqueous solution[63], but undergoes changes in crystalline compounds[62,64,65]. The nature of the cation has a strong influence on the structure of the anion, as shown by an analysis[62] of the vibrational spectra of pertechnetates, according to which the crystal field decreases as the ionic radius of the cation increases.

Pertechnetic acid forms dark red, hygroscopic crystals of composition $H[TcO_4]$.[68] The structure of this compound has not yet been established, and it is not known whether the anhydrous acid corresponds to the stereochemical composition $Tc_2O_7.H_2O$ or $HTcO_4$: it would be

interesting to resolve this question. The acid strength of Group VII elements falls on going from the main subgroup to the secondary subgroup. It is known that $H[ClO_4]$ is a very strong acid in aqueous solutions, and that the oxidising power of perchlorates is higher than that of permanganates; $H[MnO_4]$ has an acid strength comparable to that of HCl, and $H[TcO_4]$ is weaker than these acids but stronger than $H[ReO_4]$.

All three acids $H[ReO_4]$, $H[TcO_4]$, and $H[MnO_4]$, like their isostructural acid $H[ClO_4]$, form sparingly soluble salts with the cations $Tl^{3+}$, $Cs^+$, nitronium, tetraphenylarsonium $[(C_6H_5)_4As]^+$, and tetraphenylphosphonium $[(C_6H_5)_4P]^+$. The salts of all four acids are isomorphous.

Alkali metal and ammonium pertechnetates crystallise in the scheelite structure (tetragonal system), but $Cs[TcO_4]$ is rhombic, like $Tl[TcO_4]$ ($D_{2h}^{16}$–$Pnma$, $z = 4$, the so-called pseudo-scheelite type)[60,61].

Pertechnetates (like perrhenates) are colourless in solution, unlike the salts of permanganic acid which have a violet–red colour: the chromophoric power decreases steeply from Mn to Tc and Re. The colour of the pertechnetates of some organic cations (berberinium, Methyl Violet) is due to the chromophoric properties of the cations themselves.

An interesting property of pertechnetates is the formation of crystal hydrates as the cation changes from the Group I metals to metals of Groups II and III. The solubility along the subgroups decreases as the ionic radius of the cation increases ($K[TcO_4]$ 2.130 g/100 g, $Cs[TcO_4]$ 0.412 g/100 g of solution).[47]

The following compounds of technetium(VII) have been synthesised in recent years: $Pr[TcO_4]_3$, $Pr[TcO_4]_3.4H_2O$, $Pr[TcO_4]_3.3H_2O$, $Nd[TcO_4]_3.4H_2O$;[66] $Ba_3[TcO_5]_2$, $Sr_3[TcO_5]_2$, $Ca_3[TcO_5]_2$, $Ba[TcO_4]_2$, $Sr[TcO_4]_2$, $Ca[TcO_4]_2$, $Ba_5[TcO_6]_2$, $Sr_5[TcO_6]_2$, $Ca_5[TcO_6]_2$, $Ba[Na_{0.5}Tc_{0.5}]O_3$, $Sr[Na_{0.5}Tc_{0.5}]O_3$, $Ba[TcO_4]_2.2H_2O$, $Sr[TcO_4]_2.2H_2O$, $Ca[TcO_4]_2.2H_2O$, $Ca[TcO_4]_2.H_2O$, $Sr[TcO_4]_2.H_2O$.[67]

The Group VII elements of the main subgroup behave as non-metals in both the higher and the lower oxidation states, whereas the elements of the secondary subgroup (Mn, Tc, Re) show definite metallic properties in the lower valence states but retain their non-metal character in the heptavalent state. The elements of this subgroup, unlike those of the main subgroup, show a great deal of similarity with elements in the same period.

The oxide $Mn_2O_7$ is a dark green oily liquid; $Tc_2O_7$ and $Re_2O_7$ are orange–yellow crystalline compounds. Their relative stabilities are indicated in Table 2. $Tc_2O_7$ crystallises in the orthorhombic system with lattice parameters $a = 13.756$, $b = 7.439$, and $c = 5.617$ ($z = 4$). A full X-ray diffraction analysis of this oxide[69] has shown that the centro-symmetrical $Tc_2O_7$ molecule has a tetrahedrally coordinated metal atom and a linear Tc–O–Tc bond. The structure of technetium heptoxide is more similar to the layer structure of $CrO_3$, $RuO_4$, and $OsO_4$ than to the polymeric layer structure of $Re_2O_7$. The $Tc_2O_7$ lattice is not isostructural with the $Re_2O_7$ lattice. The compound $Tc_2O_7$ is weakly paramagnetic. It is readily soluble in dioxan, and it forms $H[TcO_4]$ when dissolved in water[68].

The oxyhalides of technetium(VII), $TcO_3F$[72] and $TcO_3Cl$,[73] have both practical and scientific interest. The latter has not been isolated in a pure form.

An important role in the technological separation of technetium is played by the heptasulphide $Tc_2S_7$, a dark brown sparingly soluble compound precipitated from 2–4 *N* solution of HCl or $H_2SO_4$,[2,74] unlike rhenium sulphide, which is obtained from more concentrated acid solutions. This property of technetium is related to its reduction to lower oxidation states, whose sulphides are soluble in mineral acids. In this respect technetium is similar to manganese.

Technetium(VI) exists in both cationic and anionic forms. The most stable are the fluorine and chlorine compounds $TcCl_6$,[75] $TcF_6$,[76] $TcOF_4$,[77] and $TcOCl_4$.[73,78]

Table 2. Physicochemical properties of oxides[53].

| Oxide | Heat of formation from the elements, kcal mole$^{-1}$ | Melting point, °C | Thermal behaviour |
|---|---|---|---|
| $Mn_2O_7$ | 177 | 6 | Decomposes explosively at 90°C |
| $Tc_2O_7$ | 266 | 120 | Decomposes at 260°C and sublimes |
| $Re_2O_7$ | 296 | 296 | Boils without decomposition at 362°C |

Astheimer and Schwochau[79] have reported a coulometric synthesis of oxygen-containing complexes of technetium(VI), rhenium(VI), and manganese(VI) with an organic cation, using the controlled potentials $E_{\frac{1}{2}} = 1.74$, 2.3, and 0.6 V respectively. They obtained complexes of composition $[(CH_3)_4N]_2MO_4$, crystallising in the cubic system with lattice parameters $a = 11.20$ Å (Tc), 11.35 Å (Re), and 11.09 Å (Mn).

The formation of Tc(VI) had been observed previously[2] during coulometric treatment of a weakly acid solution of Tc(VII) (1 *M* KCl + $4 \times 10^{-4}$ *M* HCl + $0.9 \times 10^{-5}$ *M* $NH_4TcO_4$). The u.v. absorption spectrum of the solution was shown to have a maximum at 231 nm.

By comparing the properties of the technetates, manganates, and rhenates we conclude that the six-valent state of all three analogues (Tc, Mn, and Re) is unstable and undergoes disproportionation by the reaction

$$3M\,(VI) \rightarrow 2M\,(VII) + M\,(IV).$$

The electronic structure of the manganate and rhenate is still unknown, and therefore we cannot predict their properties from the ligand field theory because of the excessive overlap of the metal and oxygen orbitals[49]. No attempt has been made to describe the properties of the technetate ion in terms of its electronic structure.

Derivatives of pentavalent technetium, like those of technetium(VI), are known in the form of cationic and anionic complexes. The most stable are the halogen compounds[77] $TcF_5$, $NaTcF_6$, and $KTcF_6$, isostructural with the corresponding ruthenium salts but different from the rhenium salts.

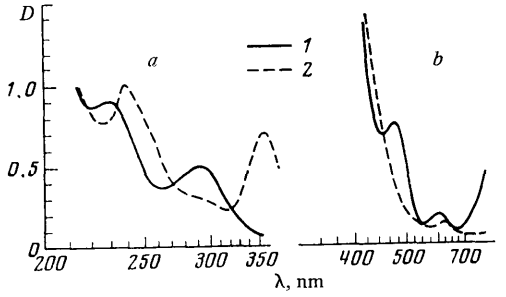
Compounds of the anion $[TcO_4]^{3-}$ have not been prepared, though the manganese analogues are known (prepared by thermal decomposition of the permanganate). Rhenium(V) forms both tetrahedral ions with a coordination number of 4, $[ReO_4]^{3-}$, and ions of composition $[Re_2O_7]^{4-}$ and $[ReO_3]^-$.[80]

The synthesis of the following complexes has been reported: technetium oxide tribromide $TcOBr_3$,[75] technetium oxide trichloride $TcOCl_3$,[78,81] and tetrachlorodi-*o*-phenylene-bis-dimethylarsinetechnetium chloride $[TcDiars_2Cl_4]Cl$.[82] Technetium is eight-coordinated in the latter complex.

The reaction between the $[TcO_4]^-$ ion and concentrated hydrochloric acid is very interesting. This reaction clearly illustrates the position of technetium in the

Periodic Table. Thus, Mn(VII) in the form of the $[MnO_4]^-$ ion is reduced to Mn(II), $[ReO_4]^-$ does not react with HCl, and the $[TcO_4]^-$ ion reacts with HCl to give the complex ion $[TcCl_6]^{2-}$ as the final product[2,83-85]. This anion can be obtained at room temperature[19].

The reduction of the $[TcO_4]^-$ ion by hydrochloric acid has been studied in detail, and shown to involve an intermediate step: the formation of Tc(V). The compounds $(NH_4)_2[TcOCl_5]$,[83] $K_2[TcOCl_5]$, and $K_2[TcO(OH)Cl_4]$ [84] have been isolated in a solid crystalline form. The absorption band of the $[TcO(OH)Cl_4]^{2-}$ anion in the u.v. spectrum is shifted towards longer wavelengths, showing that the hydrolysed compound is less stable than the $[TcOCl_5]^{2-}$ complex anion (Fig. 3).



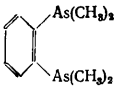


Figure 3. Adsorption spectra in (*a*) the u.v. and (*b*) the visible region of: *1*) $K_2[TcOCl_5]$, *2*) $K_2[TcO(OH)Cl_4$.

The effect of an organic ligand on the stability of technetium(V) compounds has been demonstrated by the synthesis of dioxotetrapyridinetechnetium chloride $TcO_2Py_4Cl$ [19] and tetrachlorodi-*o*-phenylene-bis-dimethylarsinetechnetium perchlorate $[TcDiars_2Cl_4]ClO_4$.[54] The latter contains no unpaired electrons ($\mu_{eff} = 0.7\ \mu_B$), as expected from its formula with a coordination number of eight. This coordination allows the use of the chelating arsine group of *o*-phenylene-bis-dimethylarsine

which is widely used as a ligand in transition metal complexes (including technetium compounds).

The compounds $[TcO_2Py_4]Cl$ and $[TcO_2Py_4]Cl.2H_2O$,[19] which are isostructural with the analogous rhenium compounds $[ReO_2Py_4]Cl$ and $ReO_2Py_4Cl.2H_2O$,[86] are formed in neutral solution. The powerful stabilising effect of the water of crystallisation in these compounds has been demonstrated by i.r. spectral studies[19].

The compounds of technetium(IV) have been investigated most fully because in this valence state the *d*-shell is half full and as a result the complexes are structurally stable[87]. A series of stable technetium compounds with the formula $[TcHal_6]^{2-}$, analogous to the manganese, rhenium, platinum, molybdenum, and tungsten compounds, is known. The anion of the salts of hexachlorotechnetic acid, $[TcCl_6]^{2-}$, is a regular octahedron with a halogen atom at each apex and a technetium atom at the centre. The octahedra of the crystalline salt are located at the corners and at the face centres of an elementary cubic cell, with cations at the centres of eight octants[88-92].

These compounds are spin-free, and are strongly paramagnetic. In the presence of an inorganic cation their magnetic moment is strongly temperature dependent[12,93] (Table 3).

Table 3. Magnetic properties of technetium(IV) compounds.

| Compound | *T*, K | $\mu_{eff}$, $\mu_B$ |
|---|---|---|
| $K_2[TcCl_6]$ | 78—398 | 2.93—3.88 |
| $(PyH)_2[TcCl_6]$ | 84.7—289 | 3.97—3.97 |
| $(ChH)_2[TcCl_6]$ | 78—291 | 3.78—3.78 |

Hexachlorotechnetic acid, which was recently synthesised by the present writers, is a typical member of the class of technetium complexes containing the $[TcHal_6]^{2-}$ anion. A structural study of this compound[94] has shown that the phase $H_2[TcCl_6].9H_2O$ crystallises in the triclinic system. This low symmetry is due to the hydrogen bonds of the water molecules, which distort the $[TcCl_6]^{2-}$ octahedron (Fig. 4), whereas the ionic forces acting on the structural units in the alkali metal salts tend to preserve the octahedral structure of the anion[92].

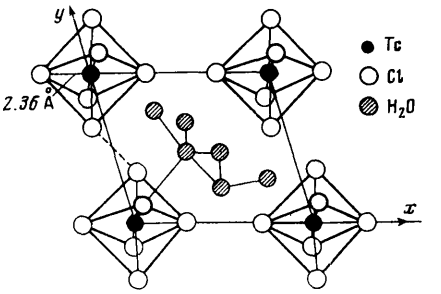

Figure 4. Projection of the $H_2[TcCl_6].9H_2O$ structure on the *xy* plane.

A comparative study of the salts of hexachlorotechnetic acid with inorganic cations ($K_2[TcCl_6]$, $Na_2[TcCl_6]$, $(NH_4)_2[TcCl_6]$) and with organic cations ($(PyH)_2[TcCl_6]$, $(ChH)_2[TcCl_6]$, $(DpH)_2[TcCl_6]$) has shown that the latter crystallise in a low-symmetry system, whereas the former have a cubic structure[88,90-92]. The magnetic moments of $(PyH)_2[TcCl_6]$ and $(ChH)_2[TcCl_6]$ are independent of temperature (Table 3). It is thought[93] that the decreased exchange interaction in the complexes with organic cations gives rise to some measure of diamagnetism.

The thermal stability of the $[TcCl_6]^{2-}$ anion is not very high: the compound $(NH_4)_2[TcCl_6]$ begins to decompose at 350°C; the decomposition is rapid at 420°C, and is complete at 535°C, with formation of the metal without intermediate steps (Fig. 5).

In dilute acid solutions the $[TcHal_6]^{2-}$ anion is readily hydrolysed. Formation of the monaquo- and diaquochloro-complexes $[TcCl_5(H_2O)]^-$ and $[TcCl_4(H_2O)_2]^0$ has been confirmed by paper chromatography[57]. A binuclear complex of composition $K_4[Tc_2OCl_{10}]$ has been synthesised[47]; the alternative formula $K_2[Tc(OH)Cl_5]$ has been suggested for this compound[97].

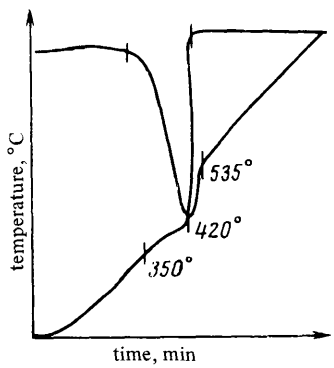

Figure 5. Thermogram of $(NH_4)_2[TcCl_6]$.

The compound $TcO_2$ is fairly stable and can exist in a hydrated and a non-hydrated form. Technetium dioxide $TcO_2$, like the analogous rhenium compound, crystallises in the monoclinic system with a metal–metal bond length of 2.5 Å. The technetium (or rhenium) atoms lie at the centres of oxygen octahedra[55]. These compounds are weakly paramagnetic. Unlike the rhenium and manganese dioxides, technetium dioxide can be sublimed in a vacuum without decomposition at 900–1100°C,[12] but it decomposes to the metal at 600°C in a stream of CO (0.75% CO).[71]

Compounds of tervalent technetium were known only in solution for a long time. They were detected during polarographic reduction of the $[TcO_4]^-$ ion at a dropping mercury cathode[2,119], and in micro-cocrystallisation experiments[95], but the pure compounds were not isolated.

Technetium(III) compounds have been obtained more recently. Like rhenium(III) and manganese(III), technetium(III) forms complexes, but only manganese(III) has yielded a large number of simple compounds. Simple compounds of rhenium(III) and manganese(III) are not known. Among the known compounds of technetium(III) are the complexes with *o*-phenylene-bis-dimethyldiarsine of composition $[TcDiars_2Hal_2]Cl$,[54] which were successfully obtained on the theory that spin-paired technetium complexes in low states of oxidation are favoured by the use of ligands having a strong field, such as *o*-phenylene-bis-diarsine.

However it was shown more recently that compounds of technetium in a low oxidation state can be obtained with a ligand as simple as the $Cl^-$ ion. The very interesting compounds of the octachloroditechnetate ion $[Tc_2Cl_8]^{3-}$, with a metal–metal bond and an oxidation number of 2.5, have been synthesised by two methods. In the first method[10] zinc was used to reduce the pertechnetate ion in concentrated HCl solution, whereas the second method uses molecular hydrogen under pressure[11]. Both methods yield binuclear complexes consisting of a slightly distorted tetragonal prism with chlorine atoms at the corners and two technetium atoms within the prism (Fig. 6). The anions are held by a weak Tc–Cl bond 3.54 Å long. Water molecules are not accommodated in the inner sphere of the $K_3[Tc_2Cl_8].2H_2O$ complex. The Tc–Tc distance is 2.14 Å, as compared to 2.73 Å in metallic technetium[96]. The octachloroditechnetate ion $[Tc_2^{2.5+}Cl_8]^{3-}$ and the octachlorodirhenate ion $[Re_2^{3+}Cl_8]^{2-}$ belong to the same structure type of binuclear complexes, with $D_{4h}$ symmetry, but they have different states of oxidation. The analogous technetium(III) binuclear complex, with the anion $[Tc_2Cl_8]^{2-}$, has recently been prepared[128].

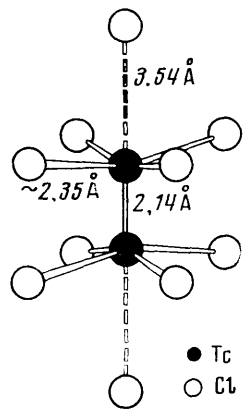

Figure 6. Structure of $[Tc_2Cl_8]^{3-}$ complex (cluster) anion.

Tc(II) is known to form a halogen-diarsine complex of octahedral structure, analogous to the rhenium and manganese complexes of composition $[MDiars_2Hal_2]^0$.[54] The $d^5$ electronic configuration, corresponding to a valence state of two, is theoretically a stable configuration. However only the Mn(II) compounds are spin-free, whereas the Tc(II) and Re(II) complexes have a spin-paired configuration with one unpaired electron.

Eakins and coworkers[10] have isolated a complex of composition $[Tc^{2+}(NH_2OH)_2(NH_3)_3]Cl_2$, dihydroxylaminetriamminetechnetium dichloride, which has no analogues among the manganese and rhenium compounds and has not yet been characterised physicochemically. This compound can form stable aqueous solutions.

Using the $CN^-$ ion as a strong-field ligand, Herr and Schwochau[98] obtained the diamagnetic cyano-complex of univalent technetium $K_5[Tc(CN)_6]$, isomorphous with the known rhenium and manganese analogues.

The binuclear carbonyl $Tc_2(CO)_{10}$ has been synthesised[99] and shown to have a distorted octahedral structure[100]. In carbon tetrachloride solution this compound reacts with halogens to give pentacarbonyls and tetracarbonyls by the reaction

$$Tc_2(CO)_{10} + Hal_2 \rightarrow 2Tc(CO)_5Hal \xrightarrow[100°C,\ 1000\ atm]{} [Tc(CO)_4Hal]_2 + 2CO$$

The dibenzenetechnetium complex cation $[(C_6H_6)_2Tc]^+$,[101] formed by the $\beta$-decomposition of $^{99}Mo(C_6H_6)_2$, and the diamagnetic bis-dicyclopentadienyltechnetium $[Tc(C_5H_5)_2]_2$, consisting of golden yellow crystals unstable in air[102], have been reported. The latter is an analogue of the complex $ReH(C_5H_5)_2$,[103,104] which has a Re–H bond: although

this bond is absent in the technetium compound, the bond between the ring and the metal is similar in the compounds $[Tc(C_5H_5)_2]_2$ and $ReH(C_5H_5)_2$, and it differs from the metal–ring bond in the paramagnetic $MnH(C_5H_5)_2$ complex[105].

Metallic technetium is a dark grey powder which acquires a silvery sheen when heated to 1000°C. It is similar to rhenium, molybdenum, and platinum in external appearance, unlike manganese, which is similar to iron. The physical and mechanical properties of metallic technetium have been studied in our laboratory[106]: the metal can be formed into rods, tape, foil, and wire by cold working, with recrystallising anneals. Its cold working properties are better than those of many familiar metals. The highest strength is obtained by cold working, the highest ductility by annealing at 1000°C. The thermal expansion coefficient at right angles to the rolling direction is 8.9 (sic.).

Metallic technetium crystallises in the hexagonal system and is close-packed. Each atom is surrounded by twelve nearest neighbours at a distance of 2.73 Å. Important new information on the structure of technetium was obtained[107] in a study of sputtered thin films of the metal. Technetium films less than 150 Å thick consist of a new modification, stable at room temperature, with a face-centred cubic structure (lattice parameter $a_0 = 3.68 \pm 0.05$ Å).

Studies of the physical properties of metallic technetium[3,108] showed that this metal is superconducting, like rhenium but unlike manganese. For technetium $T_{cr} = 8.2$ K[108]. The neighbours of technetium and rhenium in the Periodic Table (ruthenium and osmium respectively) also show superconducting properties. Technetium is one of the refractory metals (m.p. = 2200°C).[8]

The chemical activity of metallic technetium is lower than that of manganese but somewhat higher than that of rhenium. In the electromotive force series technetium lies to the right of hydrogen and copper, and (like rhenium) it is not attacked by HCl, whereas manganese lies to the left of hydrogen—between magnesium and zinc—and reacts readily with water and acids. At elevated temperatures technetium reacts with chlorine, fluorine, and carbon. The metal burns in oxygen, forming $Tc_2O_7$. It is easily oxidised by aqua regia and by nitric acid (with formation of $H[TcO_4]$), and it is also oxidised by solutions of hydrogen peroxide, bromine water, and sulphuric acid.

Technetium(VII) exists as the $[TcO_4]^-$ ions in aqueous solutions over a wide range of solution acidity or alkalinity. The $[TcO_4]^-$ ion, like its analogues, has the stable tetrahedral configuration. In aqueous solution the $[TcO_4]^-$ ion is strongly absorbing in the u.v. region; its spectrum is similar to those of the isoelectronic forms $[ReO_4]^-$, $[RuO_4]^-$, and $[MnO_4]^-$.

There are many published reports of the tendency of technetium(VII) to be reduced to lower valence states by various reducing agents: hydrazine, hydroxylamine, and ascorbic acid. These reactions have been studied by spectrophotometric, paper chromatography, and polarographic methods[129]. Technetium(VII) is reduced by hydrochloric acid solutions. In concentrated hydrochloric acid the first step of the reduction is instantaneous, with formation of technetium(V) oxide chloride $[TcOCl_5]^{2-}$, which is slowly converted into $[TcCl_6]^{2-}$. An additional reducing agent—hydrogen—is needed for more complete reduction, which can be achieved by electrochemical reduction methods or by autoclave techniques.

The $[TcO_4]^-$ ion can be extracted[95,109–117] by various organic solvents from acid, neutral, or alkaline solutions. Alcohols, ethers, ketones, and nitrogen- and phosphorus-containing organic compounds have been used successfully. Technetium(VII) is extracted as solvated pertechnetic acid in the form of complex salts. The $[TcO_4]^-$ ion can form ionic associations containing large organic cations such as tri- and diphenylguanidinium, tetraphenylarsonium, and tetraphenylphosphonium, which are easily extracted by non-polar solvents (chloroform, Chlorex, etc.). The mechanism of extraction in this case depends on the high solubility of the association in the non-polar solvent. Cyclohexanol, cyclohexane, tributyl phosphate, trioctylphosphine oxide, and trioctylamine can extract the $[TcO_4]^-$ ion from acid solution[109]. The following reactions occur during extraction with amines and tributyl phosphate:

$$[R_4NNO_3]_{org} + [TcO_4]^- \rightleftarrows [R_4NTcO_4]_{org} + NO_3^- ,$$

$$H^+ + NO_3^- + n(H_2O) + n[TBP] + TcO_4^- \rightleftarrows HTcO_4(H_2O)_n \cdot (TBP)_n + NO_3^- .$$

An interesting extraction scheme involves trimethyloctylammonium chloride[117] and pyridine[114]. A detailed study[116] of the extraction of technetium(VII) from alkaline solutions by quinoline and by pyridine derivatives (2-methylpyridine, 2,4-dimethylpyridine, 2-methyl-5-ethylpyridine) has shown that the distribution coefficient of technetium in these solvents is much higher than in pyridine. However the use of 2-methylpyridine as an extractant for technetium is limited in practice by the high solubility of this compound. Extraction methods continue to be the most widely used in the technology of technetium separation at the refining stage.

Polarographic studies of the oxidation–reduction reactions of oxygen-containing anions of the Group VII elements yield a great deal of information on the reactivity of these species and on their oxidation state in solution. Many papers have already been published on this topic. The earliest work[118] gave contradictory results, but a later paper[119] showed that the $[TcO_4]^-$ ion is reduced to Tc(IV) at a dropping mercury electrode in neutral solution. Sharp reduction waves are not obtained in strongly acid solutions, and in alkaline solutions a two-electron reduction process is observed, with formation of Tc(V). Similar results were obtained by other workers[120–123].

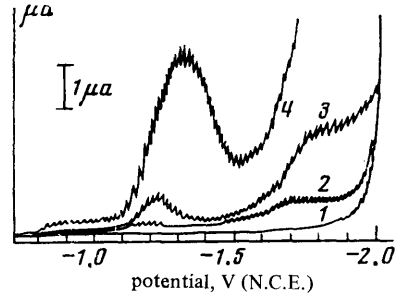

Figure 7. Catalytic waves on the polarograms of the $[TcO_4]^-$ ion in neutral $NH_4TcO_4$ solution; base electrolyte 1 *M* KCl + 0.01% gelatine, technetium concentration: *1*) 0, *2*) $4.3 \times 10^{-6}$, *3*) $8.6 \times 10^{-6}$, *4*) $2.5 \times 10^{-5}$ *M* $NH_4TcO_4$.

The electrochemical reduction of the $[TcO_4]^-$ ion at a dropping mercury electrode was studied[119–123] over a wide range of acidity and alkalinity, and the following general features were noted. Reduction of the $[TcO_4]^-$ ion is by

the diffusion and catalytic mechanism, irrespective of the nature of the base electrolyte and of different media. The polarograms show maxima due to the fast evolution of hydrogen on metallic technetium. The height of the waves showing these maxima is greater than the current corresponding to the maximum possible (eight-electron) reduction (Fig. 7). These waves are similar to the catalytic waves in the polarograms given by rhenium [124,125]. The hydrogen maxima have been ascribed [124] to a lowering of the hydrogen overvoltage upon the formation of the rhenide ($Re^-$) ion. According to Zhdanov and coworkers [123] metallic technetium is formed by the reduction of $[TcO_4]^-$.

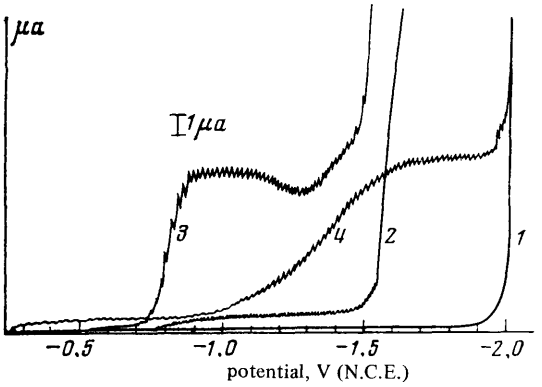

Figure 8. Effect of hydrogen peroxide on the polarogram of the $[TcO_4]^-$ ion in alkaline solution. Composition of solutions: *1*) base electrolyte 0.58 *M* HCl + 0.3 M KOH + 0.01% gelatine, *2*) base electrolyte + $8.0 \times 10^{-5}$ *M* $NH_4TcO_4$, *3*) base electrolyte + $8.0 \times 10^{-5}$ *M* $NH_4TcO_4$ + $8.1 \times 10^{-4}$ *M* $H_2O_2$, *4*) base electrolyte + $8.1 \times 10^{-4}$ *M* $H_2O_2$.

Catalytic waves occur in all media, and are independent of the nature of the base electrolyte with the exception of ammoniacal solutions in which the waves disappear [122]. Catalytic currents are produced also by the interaction of an oxidising agent with the products of electrochemical reduction of technetium. This type of wave is observed only in alkaline peroxide solutions (curve *3* of Fig. 8). A comparative study of the polarograms of $[MO_4]^-$ ions of the three analogues rhenium, technetium, and manganese has shown [118,126,127] that the electrochemical behaviour of the three elements is quite different during reduction at a dropping mercury electrode.

---o0o---

In conclusion we note that technetium is among the most interesting of all the elements from the standpoint of its chemical properties. It exhibits many valence states, it is readily converted from one state into another, and it can exist in solution in different valence states at the same time. The other important properties of this element are its tendency towards disproportionation, complex formation, and hydrolysis.

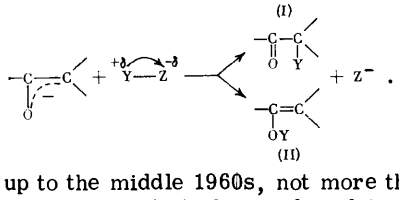
# Advances in the Chemistry of Ambident Enolate and Phenoxide Ions

O.A.Reutov and A.L.Kurts



The reactivities of ambident enolate and phenoxide ions in alkylation reactions are examined. It is shown that the mode of *C*- and *O*-alkylation of an ambident anion is determined by the structures of the alkyl group and the group eliminated from the alkylating agent, the nature of the solvent, and the type of counter ion. The influence of each of these factors on the dual reactivity of the enolates of carbonyl and β-dicarbonyl compounds and esters as well as phenoxides and naphthoxides is analysed in detail.
The bibliography includes 160 references.

## I. INTRODUCTION

Enolate ions are the most important type of ambident anions. Without exaggeration, one may claim that enolate ions are the key reagents in organic synthesis. When faced with the problem of forming a new carbon–carbon bond, the organic chemist usually turns to the large group of reactions (alkylation, acylation, aldol and ester condensations, and Dieckmann and Michael condensations) of alkali metal enolates. On the other hand, enolate ions, being typical representatives of the class of ambident anions, should manifest a dual reactivity in reactions with electrophiles, forming not only *C*-substitution products (I) but also *O*-substitution products (II).

Nevertheless up to the middle 1960s, not more than 3–4 examples of *O*-alkylation of alkali metal enolates of carbonyl and β-dicarbonyl compounds and esters were known. Systematic studies on the factors determining the mode of reaction of enolate ions were begun only in the last decade. This became possible, firstly, owing to the discovery of exact methods for the analysis of the composition of the reaction mixture (gas–liquid chromatography and $^1$H NMR) and, secondly, following the introduction into practical organic synthesis of dipolar aprotic solvents. Bimolecular nucleophilic substitution reactions between anions and neutral molecules (the alkylation of enolate ions) are much faster in dipolar aprotic solvents than in a proton-donating medium. This difference is determined primarily by the weak solvation of the anions in dipolar aprotic solvents. For many enolate ions in solvents such as monoglyme, dimethylformamide (DMF), and dimethyl sulphoxide (DMSO), *O*-alkylation reactions were carried out for the first time. In the general case, the mode of reaction of the enolate ion is determined by the following main factors: (1) the nature of the counter ion; (2) the nature of the solvent; (3) the nature of the electrophile; (4) the structure of the ambident anion.

The influence of each of the above factors on the ratio of the products of the *C*- and *O*-alkylation of metal derivatives of carbonyl and β-dicarbonyl compounds and esters will be examined in succession. The reaction products have been analysed quantitatively during the last 10–15 years and attention will be concentrated on this research. Ambident phenoxide ions are in all respects very close analogues of enolate ions. In order to emphasise the close relation between these two classes of ambident anions, data on the *C*- and *O*-alkylation of phenoxide ions have been included.

## II. DEPENDENCE OF THE MODE OF THE ALKYLATION REACTION ON THE NATURE OF THE CATION

An important factor influencing the ratio of the alkylation products of metal enolates and phenoxides is the nature of the cation. The influence of the nature of the alkali metal cation on the ratio of the *C*- and *O*-isomers has been investigated in greatest detail. In this case, the problem reduces in essence to the solution of the problem of the state of these salts in solution. Alkali metal enolates can exist in solution in the form of associated species comprising ion pairs with different degrees of aggregation, and, in a fairly basic and polar solvent, in the form of monomeric ion pairs of different types and as free ions. Naturally, the nature of the solvent has a decisive influence on the position of equilibrium between the different forms of ionic species. The degree of association of ion pairs depends also on the size, charge density, and hardness of the cation and anion. Sodium and potassium alkoxides form, for example, associated species of the type $(ROM)_3$ even in a basic and polar solvent such as DMSO.[1,2] The degree of association in a less polar medium and also for small cations with a high charge density ($Li^+$, $Mg^{2+}$, etc.) is even greater[2-5]. As regards the tendency towards self-association, alkali metal enolates occupy an intermediate position between alkoxides and alkali metal salts of carbanions, which are monomeric in solvents, coordinating effectively alkali metal cations[6]. The molecular weight of the sodium salt of n-butyl malonate (in 0.1 *N* solution in benzene) exceeds 11 000 which corresponds to the formation of a monodisperse

micelle comprising 40–50 monomeric ion pairs of this salt, i.e. almost a colloidal particle [7,8]. However, in a more polar and, what is more important, a more basic medium, the degree of association decreases sharply. Thus the sodium salt of butyrophenone in ether exists in the form of a three-dimensional association of ion pairs [9], while in dimethoxyethane (DME) [10] the degree of association is lower still. The addition of small amounts of dipolar aprotic solvents such as DMF [8,11], DMSO [12], and hexamethylphosphoramide (HMP) [13] to solutions of alkali metal enolates in media of low polarity breaks up the ionic association complexes until the formation of monomeric ion pairs. The same effect is achieved by the introduction of strong complex-forming agents: polyglymes and macrocyclic polyesters [14]. In dipolar aprotic solvents at concentrations below 0.2 M, alkali metal enolates (with the exception of lithium salts) are hardly associated. In the ion pair of an alkali metal enolate, the cation is coordinated to the hard oxygen centre of the enolate ion and the electrostatic interaction between the two oppositely charged ions is intensified with decrease of the radius and with increase of charge density in the sequence $Cs^+ < Rb^+ < K^+ < Na^+ < Li^+$ i.e. with increase of the hardness of the cation. Ion association has a marked influence on the reactivity of the anion. The electrostatic interaction between the ions in the ion pair in media of moderate polarity is very considerable; the free ion is as a rule the most reactive species and ion association therefore causes an appreciable decrease of nucelophilic reactivity. For ambident anions, association of the cations with one of the reaction centres causes a disproportionate diminution of the nucleophilic properties of both reaction centres. In an ion pair with an enolate ion, the alkali metal cation is associated with a hard oxygen centre, which leads to an increase of the fraction of the product of *C*-alkylation of the ion pair relative to the free anion.

The ratio of the *C*- and *O*-isomers increases particularly markedly on association of ions pairs into dimers, trimers, and larger aggregates. The agglomeration of ion pairs is undoubtedly the main cause responsible for the exclusive formation of the products of *C*-alkylation and *C*-acylation of alkali metal enolates of carbonyl and β-dicarbonyl compounds in benzene, dioxan, petroleum ether, and other non-polar and weakly basic solvents. In the general case the ratio of the *C*- and *O*-isomers in the alkylation of alkali metal enolates in an aprotic medium should decrease in the sequence $Li^+ > Na^+ > K^+ > Rb^+ > Cs^+ > NR_4^+$, but the effect should be smoothed out on passing to more basic and polar solvents.

Curtin et al. [15] showed that, in the alkylation of sodium and potassium 2,6-dimethylphenoxides with allyl bromide in ether, the dienone/ether ratio diminishes from 1 to 0.5 when $Na^+$ is replaced by $K^+$. A detailed study of the influence of the nature of the cation in the alkylation of phenoxides has been carried out using β-naphthol salts as an example [16] (Table 1).

The yield of the *O*-isomer increases in the sequence $MgBr^+ \ll Na^+ < K^+ < N(CH_3)_4^+$; the exclusive formation of the *C*-alkylation product from magnesium β-naphthoxide is striking. An increase of the fraction of the *O*-alkylation product for tetraalkylammonium enolates was noted by Nesmeyanov and Sazonova in the methoxymethylation of alkali metal derivatives of ββ-diphenylpropiomesitylene. [17] In the alkylation of ammonia-saturated acetoacetic ester (AAE) with chloroacetone in ether, Hurd and Wilkinson detected only the *O*-isomer; when the same alkylating agent reacts with the sodium salt of AAE in alcohol, only the *C*-alkylation product is formed [18]. An appreciable increase of the ratio of the *C*- and *O*-isomers, from 3.4 to 7.7, was observed also in the alkylation of alkali metal salts of the benzophenone dianion with methyl iodide in liquid ammonia when the potassium counter ion was replaced by sodium [19]. The influence of the alkali metal cation has also been studied for the alkylation of the enolates of cyclic β-ketoesters with ethyl α-bromopropionate in a 2 : 5 DMF–benzene binary mixture [20]. The results show that, regardless of the size of the ring, the yield of the *O*-alkylation product increases for all the β-ketoesters in the series of cations $Li^+ < Na^+ < K^+$. The ratio of the *O*- and *C*-isomers increases most sharply on passing from the sodium enolate of 2-ethoxycarbonyl-1-indanone to the potassium enolate.

Table 1. The alkylation of β-naphthol salts with benzyl bromide.

| Cation | Solvent | Total yield, % | Relative yield, % | |
|---|---|---|---|---|
| | | | *O*-isomer | *C*-isomer |
| $K^+$ | Dioxan; 100° | 46 | 58 | 42 |
| $Na^+$ | Dioxan; 100° | 49 | 48 | 52 |
| $Li^+$ | Dioxan; 100° | 47 | 47 | 53 |
| $MgBr^+$ | Dioxan; 100° | 64 | — | 100 |
| $K^+$ | Alcohol–benzene (1 : 1) | 47 | 84 | 16 |
| $NMe_4^+$ | Alcohol–benzene (1 : 1) | 50 | 91 | 9 |

In dipolar aprotic solvents, where alkali metal enolates are partly dissociated, the influence of the alkali metal cation is extremely weak [21–24]. For example, the ratio of the *C*- and *O*-isomers of the products of the alkylation of alkali metal enolates of acetylacetone (AcAc) with ethyl toluene-*p*-sulphonate in HMP at 20°C is almost independent (with the exception of the lithium salt) of the nature of the counter ion [24]. The above ratio also does not change with decrease of the concentration of the enolate and when HMP is replaced by another solvent containing the phosphine oxide group (diaphos, mediphos). When ethyl toluene-*p*-sulphonate is replaced by ethyl bromide and particularly ethyl iodide, the yield of 2-ethoxypent-2-en-4-one decreases sharply, but remains constant for sodium, potassium, and tetrabutylammonium enolates. This means that the reactive species is the "free" AcAc anion. In a more differentiating solvent (DMF), the relative yield of the *O*-alkylation product increases in the series of cations $Li^+ < Na^+ < K^+ \sim Cs^+$, i.e. not only the ions but also the ion pairs of acetylacetonates participate in the reaction.

The fraction of the *O*-alkylation products of enolates increases particularly markedly on passing to quaternary ammonium enolates. The formation of the products of the *O*-alkylation of tetrabutylammonium enolates of AAE, AcAc, and benzoylmalonic ester has been noted even in a weakly basic medium such as chloroform and methylene chloride [25–27].

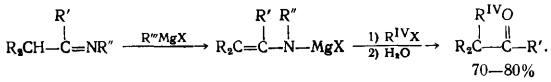
The counter ion has been found to have an unusual influence in the alkylation of alkali metal enolates of 2-ethoxycarbonylcyclopentanone in DMSO. [28] On alkylation with isopropyl iodide or butyl bromide, the sodium enolate unexpectedly gives rise to a greater amount of the *O*-isomer than does the potassium enolate. These data are in sharp conflict with those of other studies concerning the influence of the cation on the ratio of the *C*- and

*O*-isomers in an aprotic medium. If it is supposed that the main reactive species is in this case the ion pair of the alkali metal enolate, the different types of behaviour of the sodium and potassium enolates must be associated with the different degrees of solvation of the cation in ion pairs. The ion pair of sodium enolate may prove to be more reactive, since DMSO is coordinated more effectively to the sodium cation than to the potassium cation[29].

Strictly speaking, all the above data yield only a quantitative and extremely superficial picture of the influence of the alkali metal cation on the ratio of the *C*- and *O*-isomers in the reaction products. This ratio is determined by at least two processes involving the free enolate ion and ion pairs (and in some cases there is also a possibility of their agglomeration), and by the relative contribution of each process. In order to characterise quantitatively the influence of the cation, it is necessary to determine $(C/O)_p$—the ratio of the isomers in the alkylation of the ion pair of the alkali metal enolate. $(C/O)_{obs}$ and $(C/O)_p$ can, in principle, differ fairly markedly. Table 2 presents the ratios $(C/O)_{obs}$, $(C/O)_p$, and $(C/O)_{ion}$ for the alkylation of alkali metal salts of methyl 3-hydroxybenzofuran-2-carboxylate with methyl iodide in methanol[30]. The data presented in Table 2 clearly demonstrate significant differences between these quantities as a function of the nature of the cation; at the same time, it is easily seen that the general sequence in the variation of the quantities $(C/O)_p$ and $(C/O)_{obs}$ as function of the nature of the counter ion does not change. This factor is very significant, since it justifies the hypothesis that $(C/O)_{obs}$ can serve as a criterion in the estimation of the influence of the nature of the cation on the dual reactivity of alkali metal enolates. The data in Table 2 also reveal a considerable difference in the influence of the nature of the counter ion in aprotic and protic media. The ratio of the *C*- and *O*-isomers in the methylation of salts of the β-hydroxycoumarate ester in methanol decreases on passing from $Li^+$ to $Na^+$, but increases again for potassium and bispiperidinium salts.

Table 2.

| Cation | $(C/O)_{obs}$ | $(C/O)_p$ | $(C/O)_{ion}$ | Cation | $(C/O)_{obs}$ | $(C/O)_p$ | $(C/O)_{ion}$ |
|---|---|---|---|---|---|---|---|
| $Li^+$ | 5.9 | 5.0 | 6.0 | $K^+$ | 4.4 | 2.63 | 6.0 |
| $Na^+$ | 3.5 | 2.1 | 6.0 | Bipy* | 5.0 | 4.1 | 6.0 |



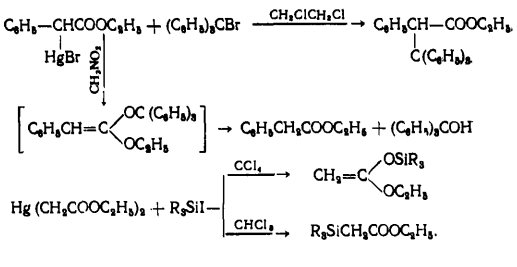
*Bipy = bispiperidinium cation.

The data obtained by Stetter and Dierichs[31] for the alkylation of the lithium, sodium, and potassium salts of dihydroresorcinol with butyl bromide in methanol serve as a very clear example of this difference. The ratio of the *C*- and *O*-isomers decreased in the sequence $K^+ > Na^+ > Li^+$, which is the opposite to that corresponding to the influence of the cation in an aprotic medium. The interpretation of data for the influence of the nature of the counter ion in protic solvents is very difficult. As will be shown below, proton-donating solvents solvate selectively and effectively the oxygen centre of the enolate ion, which promotes the reaction at the second centre of the ambident anion. Thus the selective solvation of the enolate ion via hydrogen bonding as well as the shielding of the oxygen centre in the ion pair owing to the electrostatic interaction with the alkali metal cation lead to an increase of the ratio of the *C*- and *O*-isomers in the alkylation products. In principle, a situation may arise in which the shielding of the oxygen atom of the enolate ion by solvent molecules owing to hydrogen bonding is stronger than the electrostatic interaction with the cation in the ion pair, which is particularly likely for large cations with a low charge density ($Cs^+$, $NR_4^+$, $AsPh_4^+$, etc.), i.e., in contrast to an aprotic medium, in a protic medium the case where $(C/O)_{ion} > (C/O)_p$ is quite real[30] (Table 2).

Many examples of the alkylation of covalent metal derivatives of carbonyl and β-dicarbonyl compounds are known. A change in the amount of ionic character of the bond has a very strong influence on the ratio of the *C*- and *O*-alkylation products. In addition, one must also take into account the structure of metallic derivatives of keto-enols. Whereas the enolate structure has been generally acknowledged for alkali metal, alkaline earth metal, and thallium derivatives[32], there is convincing evidence that the mercurated carbonyl and β-dicarbonyl compounds exist in the keto-form[33-37]. Derivatives of tin and germanium, where a metallotropic equilibrium between the *O*- and *C*-forms has been demonstrated, constitute an intermediate group[38-41]. It has been suggested, although without adequate arguments, that the magnesium derivatives of certain ketoenols also exist in the form of a mixture of two metallotropic forms[42-45].

In the solution of the problem of the structure of metal derivatives of carbonyl compounds, the application of Pearson's principle of hard and soft acids and bases (HSAB)[46] has been extremely fruitful. Alkali metal cations and the $Mg^{2+}$, $Tl^+$, and $R_3Si^+$ cations, which belong to the group of hard acids, should be coordinated to the hard oxygen centre of the enolate ion, while soft Lewis acids, for example the mercury cation, should be coordinated to the soft carbon centre. For an intermediate group ($R_3Ge^+$ and $R_3Sn^+$), there is a possibility of the existence of both forms with different equilibrium positions between them.

Magnesium enolates and magnesium salts of aldehyde and ketone derivatives are alkylated solely at the carbon atom. Stork and Dowd[47] found that the alkylation of the magnesium derivative of an imine is one of the best methods for the selective mono-*C*-alkylation of carbonyl compounds. Asymmetric ketones are alkylated at an unsubstituted carbon atom:



The alkylation of the magnesium salts of various ketoenols in HMP has been investigated in greatest detail. It has been shown[48] that, on treatment with a wide variety of alkylating agents, products of *C*- and di-*CC*-alkylation only are formed with high yields. The alkylation of thallium enolates by alkyl halides without a solvent[49] or in benzene[50] also gives rise to high yields of *C*-isomers. Taylor et al.[50] suggested that this reaction be used as a preparative method for the mono-*C*-alkylation of ketoenol systems. Their data permit the conclusion that the alkylation of thallium(I) enolates is the best method for the synthesis of *C*-isomers in a chromatographically pure form. However, it has been recently reported[51] that the alkylation of the thallium(I) salt of dihydroresorcinol gives rise to the *O*-alkylation products regardless of the nature of the solvent. Evidently, depending on the $pK_a$ of the β-dicarbonyl compound, a change in the mode of reaction

in the alkylation of thallium(I) enolate is to be expected, in which the compound with the lower $pK_a$ undergoes preferential *O*-alkylation. Hooz and Smith[52] reinvestigated the alkylation of the thallium enolates of AAE and AcAc by methyl, ethyl, and isopropyl iodides. Their data are in striking conflict with those of Taylor et al. Firstly, the selective mono-*C*-alkylation of the enolate was not observed in any instance and the reaction mixture always contained mono- and di-alkylation products. Secondly, *C*-ethylation and *C*-isopropylation is accompanied by the competing *O*-alkylation reaction. The latter factor is particularly surprising bearing in mind that magnesium enolates are alkylated at the carbon atom. Thus thallium(I) used as a counter ion in the alkylation reaction resembles the lithium cation more closely than an alkaline earth metal cation.

Silver enolates are known to exhibit an enhanced tendency towards the formation of *O*-alkyl derivatives. For example, when alkyl halides interacted with the silver derivatives of dihydroresorcinol[53], AcAc [54], AAE [55], and certain bicyclic triketones[56], *O*-alkylation products were isolated. At the same time the alkylation of the silver and mercury salts of the diazoacetic ester by benzyl and allyl bromides in ether leads to the formation of *C*-alkylation products with retention of the diazo-group[57]. The alkylation of tin derivatives of ketoenols has been studied in relation to an extremely limited number of examples and only *C*-alkylation products could be detected (with a low yield) in the reaction mixture[58-62].

Numerous studies have been made on the alkylation of $\alpha$-mercurated derivatives of carbonyl compounds. It has been established that these compounds do not react with the majority of alkylating agents, positive results being obtained solely when mild alkylating agents were used: allyl, benzyl, and trityl halides. $\gamma$-Mercuribis-AAE gives rise to a low yield of a mixture of $\alpha$-allyl- and $\alpha\alpha$-diallyl(benzyl)-AAE on alkylation with allyl and benzyl iodides[63]. A high yield of the products of the alkylation of mercury derivatives of oxo-compounds has been observed only when trityl halides were used as the alkylating agents[64-67]. An important condition for the occurrence of this reaction is nucleophilic cooperation by the leaving group of the alkylating agent. Thus ethyl $\alpha$-bromo-mercuriphenylacetate does not react with trityl perchlorate, but is alkylated under the influence of bromotriphenylmethane, which involves the nucleophilic cooperation of bromine[66]; the mode of the alkylation reaction depends very strongly on the nature of the solvent:

The reaction is very sensitive to a change in the structure of the alkylating agent. Thus mercuribisacetylaldehyde interacts with chlorotriphenylmethane to form $\beta\beta\beta$-triphenylpropionaldehyde, while the analogous reaction with chlorotri-(*p*-nitrophenyl)methane gives rise to the enol ether as the only product[35]. The above examples illustrate the extremely high sensitivity of the mode of reaction to factors whose influence cannot be predicted beforehand.

## III. THE INFLUENCE OF THE SOLVENT ON THE RATIO OF THE *C*- AND *O*-ALKYLATION PRODUCTS

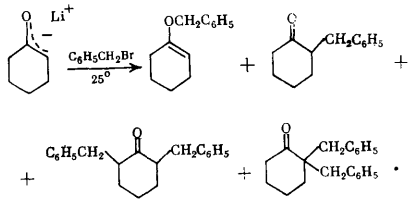
The solvent has an extremely marked influence on the rate and mode of alkylation of phenoxides and enolates. In the early stages of the study of the problem of the dual reactivity of ambident systems, it was already noted that a change of solvent can alter completely the mode of reaction. Thus Claisen et al.[68] showed that the alkylation of sodium phenoxide by allyl bromide in alcohol or acetone leads to the formation of allyl phenyl ether, while in benzene and ether the product is *o*-allylphenol.

In the assessment of the influence of solvents on the dual reactivity of the salts of ambident anions, one must distinguish two types of interaction of the solute with the solvent: the specific solvation of the cation and the interaction of the solvent with the ambident anion proper. Alkali metal enolates are to some extent associated to ion pairs and more complex aggregates of ion pairs in the majority of organic solvents. The degree of association of alkaline earth metal enolates and phenoxides is undoubtedly even greater. The derivatives of other metals must be evidently regarded as covalent compounds with different amounts of ionic character. As noted above, the position of equilibrium between different forms of ionic species depends to a large extent on the nature of the solvent. In weakly polar and weakly basic solvents (hydrocarbons, ether, dioxan, etc.), the ion pairs of alkali metal enolates are highly associated, which is the reason for the formation of *C*-alkylation products in these media. The introduction of dipolar aprotic solvents and linear polyethers (glymes) into the medium where alkali metal enolates exist as associated species causes the disruption of the latter to ion pairs. The disruption of ionic association complexes is accompanied by an appreciable acceleration of the alkylation of alkali metal enolates. Zaugg and coworkers[7,69] showed that the addition of even small amounts ($<5\%$) of certain dipolar aprotic solvents to a benzene solution of the sodium enolate derived from the n-butylmalonic ester causes a sharp acceleration of *C*-alkylation under the influence of butyl bromide. The acceleration of the reaction is caused by the specific solvation of the cation by molecules of the dipolar aprotic solvent; in the presence of the polar component, the reaction rate constant varies in parallel with the basicity of this solvent. The continuous increase of the rate of reaction with increase of the DMF and DMSO concentrations in binary mixtures with benzene[69] is evidently due to the gradual disruption of the associated species following the introduction of the polar component[8]. The ratios of the rates of reaction in benzene, tetrahydrofuran (THF), DME, DMF, and DMSO are 1 : 14 : 80 : 970 : 1420 respectively[69]. In dipolar aprotic solvents, alkali metal enolates apparently exist as ion pairs and free ions. A study of the alkylation of alkali metal enolates in an aprotic medium revealed a general feature: an increase of the basicity of the aprotic solvent promotes *O*-alkylation; the ratio of *C*- and *O*-alkylation products is not correlated with the dielectric constant of the aprotic solvent and is determined mainly by the capacity of the solvent for the specific solvation of the cation, which depends in its turn on the basicity of the solvent. The quantity $\Delta\delta_\infty$—the change in the chemical shift of the chloroform proton at an infinitely low concentration of chloroform in the given solvent—may serve as a measure of the basicity of the aprotic solvent[70]; the quantity $\Delta H_{solv}$—the enthalpy of solvation of the sodium cation—may serve as a more reliable characteristic of the basicity of the solvent[71] (Table 3)

The fraction of the product of the *O*-alkylation of the sodium salt of 2,6-dimethylphenol increases in the sequence benzene < toluene < $O(C_3H_7)_2$ < $O(C_2H_5)_2$.[15] The influence of the solvent is more clear-cut in the reaction of sodium β-naphthoxide with benzyl bromide and methyl iodide[79] (Table 4).

Table 3. The values of $\Delta\delta_\infty$ and $\Delta H_{solv}$ for certain aprotic solvents[70,71].

| Solvent | $\Delta\delta_\infty$, p.p.m. | $\Delta H_{solv}$, kcal mole$^{-1}$ | Solvent | $\Delta\delta_\infty$, p.p.m. | $\Delta H_{solv}$, kcal mole$^{-1}$ |
|---|---|---|---|---|---|
| HMP | —2.03 | —0.58 | Acetonitrile | —0.63 | 0 06 |
| N-Methylpyrrolidinone | —2.03 | — | DME | —0.84 | —0.45 |
| Tetramethylurea | —1.37 | — | Tetraglyme | — | —4.82 |
| DMSO | —1.34 | —0.34 | Sulpholane | —0.68 | — |
| DMF | —1.30 | —0.23 | THF | —0.80 | —0.08 |
| Acetone | —0.94 | 0.00 | Dioxan | —0.64 | —0.06 |



The increase of the yield of the *O*-isomer on passing to dipolar aprotic solvents has also been observed in the alkylation of the sodium salt of dimethyloctalone by benzyloxymethyl chloride[74].

Table 4. The *C*- and *O*-alkylation of sodium β-naphthoxide.

| Solvent | Yield of isomers*, % | | | |
|---|---|---|---|---|
| | *O*-isomer | *C*-isomer | *O*-isomer | *C*-isomer |
| | Benzyl bromide | | Methyl iodide | |
| DMF | 97 | — | 91 | 4 |
| DMSO | 95 | — | 90 | 3 |
| DME | 70 | 22 | 86 | 10 |
| THF | 60 | 36 | 80 | 13 |

*The absolute yields are quoted.

A similar effect has been observed[75] in the methylation and ethylation of the potassium enolates derived from acetophenone, cyclohexanone, cyclopentanone, and other ketones by dimethyl and diethyl sulphates. A very small amount of the enol ether (~3%) is formed even in the benzylation of the lithium enolate derived from cyclohexanone in HMP, while in ether and DME a complex mixture of products of *C*- and *CC*-alkylation is formed[76].

| | | | | |
|---|---|---|---|---|
| Ether | — | 45% | 5% | 5% |
| Dimethoxyethane | — | 51% | 4% | 9% |
| Hexamethylphosphoramide | 3% | 27% | 5% | 20% |

The ratio of the *C*- and *O*-products obtained from alkali metal enolates derived from β-dicarbonyl compounds also diminishes when weakly polar aprotic solvents are replaced by dipolar aprotic solvents. It has been shown[77] that the yield of the *O*-isomer in the alkylation of the potassium salt of AAE by butyl chloride at 100°C increases on passing from acetone to dipolar aprotic solvents (Table 5).

Table 5. The alkylation of the potassium salt of AAE with butyl chloride.

| Solvent | Yield of *O*-isomer, % | Solvent | Yield of *O*-isomer, % |
|---|---|---|---|
| N-Methylpyrrolidinone | 51 | DMSO | 47 |
| NN-Dimethylacetamide | 49 | Acetonitrile | 19 |
| DMF | 46 | Acetone | 10 |

The influence of the solvent on the ratio of the products of the *C*- and *O*-alkylation of the tetrabutylammonium salt of AcAc by isopropyl iodide is less pronounced (Table 6)[78]. The low ratios of the *C*- and *O*-products in weakly polar and weakly basic media are probably associated with the large interionic distance in the ion pair of the tetrabutylammonium salt (the Stokes radius of the $NBu_4^+$ cation is independent of the nature of the solvent and amounts to 3.85 Å).[79]

Table 6. The *C*- and *O*-alkylation of the tetrabutylammonium enolate of acetylacetone with isopropyl iodide.

| Solvent | Yield of isomer, % | | Ratio of *C*- and *O*-isomers | Solvent | Yield of isomer, % | | Ratio of *C*- and *O*-isomers |
|---|---|---|---|---|---|---|---|
| | *C*-isomer | *O*-isomer | | | *C*-isomer | *O*-isomer | |
| DMSO | 42 | 58 | 0.72 | Chloroform | 51 | 49 | 1.04 |
| Acetone | 42 | 58 | 0.72 | Dioxan | 63 | 37 | 1.91 |
| Acetonitrile | 48 | 52 | 0.92 | Toluene* | 69 | 5 | 13.8 |

*26% of the enolate was recovered unchanged.

The influence of the nature of the solvent on the mode of alkylation of alkali metal enolates has been investigated in greatest detail for the AAE and AcAc enolates[80]; the experimental data are presented in Tables 7 and 8. These show in the first place that the influence of aprotic solvents is determined mainly by the values of $\Delta\delta_\infty$ and $\Delta H_{solv}$ for the sodium cation in the given medium and not by the dielectric constant. The ratio of the *C*- and *O*-ethylation products is correlated quite satisfactorily with the above parameters of the solvent basicity. The comparatively low yield of β-ethoxyethyl crotonate in tetraglyme and the higher yield of the *O*-isomer in acetonitrile then in monoglyme show that the basicity of the solvent is not the only factor determining the ratio of the isomers. The polarity of the medium also plays a definite role. The solvent basicity is of decisive importance in the disruption of ionic association complexes into monomeric ion pairs, while the medium polarity influences mainly the position of the equilibrium between ions and ion pairs. Aprotic solvents can be approximately divided into four groups in terms of their influence on the process: 1. highly basic dipolar aprotic solvents (HMP, diaphos, mediphos), in which the reacting species is the enolate ion and the isomer ratio is determined by its mesomerism. 2. Dialkylamides, DMSO, and pyridine, in which the reactive species

are not only ions but also K–AAE and Na–AcAc ion pairs. 3. Moderately polar and weakly basic solvents (acetonitrile, acetone, and sulpholane). The coordinating capacity of these solvents in relation to alkali medium cations is low, so that the contribution of ion pairs and possibly also of higher association complexes increases sharply, which leads to an increase of the ratio of the *C*- and *O*-products by a factor greater than 2. 4. Weakly polar solvents (ether, dioxan, THF, methylene chloride) in which *C*-alkylation takes place exclusively. The reacting species is apparently an association complex comprising several ion pairs. In DME and tetraglyme, which effectively solvate alkali metal cations but are at the same time insufficiently polar, a certain amount of the *O*-isomer is formed. It has been found that the addition of even small amounts of complex-forming agents such as glymes and particularly of macrocyclic crown polyethers alters significantly the ratio of the *C*- and *O*-alkylation products[81,82]. Thus the fraction of the *O*-alkylation product obtained in the alkylation of the potassium salt of AAE with ethyl toluene-*p*-sulphonate in benzene, ether, and dioxan increases approximately by a factor of 100 after the introduction of an equimolar amount of dicyclohexyl-18-crown-6 ether[81].

Table 7. The ethylation of the potassium enolate of acetoacetic ester with diethyl sulphate ($c_0$ = 0.33 M, $t$ = 20°C).
