Hitherto we have considered the influence of the solvent on the ratio of the *C*- and *O*-isomers in the alkylation of enolates and phenoxides taking into account only the specific solvation of the cation. Another and more interesting possibility in the influence of the solvent on the dual reactivity of ambident anions is associated with the specific solvation of the ambident anion itself. The two reaction centres of enolate and phenoxide ions differ sharply in their electronegativity and the distribution of electron density. The hard oxygen atom serves simultaneously as the centre of the highest electron density. The hardness and electronegativity differences are responsible for the more extensive solvation of the oxygen centre of the enolate ion. Selective solvation of the oxygen atom causes a disproportionate diminution of the nucleophilic properties of the two centres of the ambident anion, which entails an increase of the fraction of the *C*-alkylation products. Thus, like the counter ions in ion pairs formed from enolate and phenoxide ions, solvation effects lead to the shielding of the atom with the higher electron density. "Shielding" plays a major role primarily in a protic medium as a result of the formation of a strong hydrogen bond with the oxygen centre of the ambident anion. Kornblum called this phenomenon "selective solvation"[72,83].

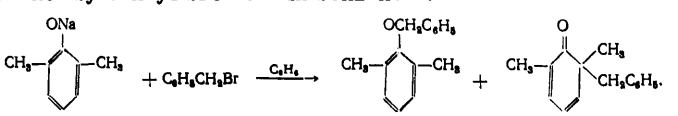
| Phenol | 78 | 22 | — | — |

In the classical studies by Claisen at the beginning of the XXth century, it was shown that phenoxides are alkylated in alcoholic media exclusively at the oxygen atom. When solvents capable of forming stronger hydrogen bonds were used, it was possible to alter the mode of reaction. Thus the addition of water lowers the yield of the *O*-isomer in the reaction of sodium phenoxide with allyl bromide in an alcoholic medium[84]. This effect becomes enhanced when the reaction is carried out in water or phenol. A sharp increase of the ratio of the *C*- and *O*-isomers is observed when fluorinated alcohols are used as solvents[72,83] (Table 9). The increase of the fraction of the *C*-alkylation product takes place in parallel with the increase of the tendency of the solvent towards the formation of strong hydrogen bonds with the oxygen atom of the phenoxide ion. Experimental evidence for the

selective solvation of the heteroatom of the ambident anion in protic media was obtained in a study[85] where a strong hypsochromic shift of the absorption maximum was observed in the ultraviolet spectrum of the anion of 1-nitroindene on passing from dipolar aprotic solvents to water and trifluoroethanol, which is the strongest donor species in the formation of a hydrogen bond.

An analogous effect was noted in the NMR and ultraviolet spectra of alkali metal phenoxides in solvents of different classes[86]. It is striking that the absorption bands of the 1-nitroindene anion in trifluoroethanol and of the *aci*-form of a nitro-compound in water are very similar. This shows that the reactivity of solvated anions of this kind approaches that of the protonated form, as a result of which the activation energy for the substitution reaction involving the other, unshielded centre is also much higher than in any aprotic medium. Indeed, the rate of alkylation of sodium phenoxide in water and trifluoroethanol is extremely low[83]. Selective solvation of the oxygen centre of the anion has been observed also for the enolate ions of β-dicarbonyl compounds. The low yield of the product of the *O*-alkylation of the potassium salt of AAE by diethyl sulphate in ethanol and particularly in *N*-methylacetamide and *N*-methylformamide (Table 7)[80], despite the exceptionally high value of ε and the high solvating capacity of these solvents in relation to alkali metal cations, is undoubtedly due to the selective solvation of the oxygen atom in the AAE anion via hydrogen bonding. A stronger hydrogen bond donor is necessary if selective solvation of the AcAc anion is to be possible. Such an effect is manifested in water and in trifluoroethanol[87]. The ratio of the *C*- and *O*-isomers is almost fully inverted in trifluoroethanol relative to alkylation in ethanol, where the *O*-isomer is virtually the only reaction product. The addition of water to the alcohol also alters the mode of reaction, and in 50% alcohol the only product of the alkylation reaction is 3-ethylacetylacetone. Thus, by altering slightly the reaction conditions, it is possible to change completely the mode of alkylation:

In another study[88], it was shown that the rate constant for the *O*-alkylation of the potassium salt of AAE by ethyl toluene-*p*-sulphonate increases by a factor of 400 on passing from ethanol to HMP, while the rate of *C*-alkylation increases only by a factor of 25. The decrease of the ratio of the *C*- and *O*-isomers by a factor of 16 when alcohol is replaced by HMP as the reaction medium reflects the influence of selective solvation on the mode of alkylation of the ambident AAE anion.



It is of interest to compare data for the selective solvation of various phenoxide and enolate ions. In conformity with the HSAB principle, protic solvents solvate, like hard Lewis acids, the harder oxygen centre of the ambident anion. The harder the oxygen centre of the anion, the harder the acid and the stronger the donor component of the hydrogen bond needed to shield the centre. The AAE anion is solvated selectively by ethanol. In relation to the AcAc ion, ethanol is an insufficiently hard Lewis acid; in this case methanol, trifluoroethanol, and water are effective. When the phenoxide ion is alkylated, the formation of the *C*-isomer is observed only in water, trifluoroethanol, and phenol (Table 9).

## IV. DEPENDENCE OF THE REACTION PATHWAY ON THE STRUCTURE OF THE ELECTROPHILE

The most important factor determining the mode of alkylation of enolates and phenoxides is the nature of the electrophile. Here account must be taken simultaneously of the electronic and steric effects of the alkyl group and of the nature of the leaving group of the alkylating agent. Different ambident anions manifest different sensitivities in relation to the nature of the electrophile; phenoxides and naphthoxides are least sensitive. The alkylation of these salts by alkyl toluene-*p*-sulphonates, dialkyl sulphates, and alkyl halides usually leads to the formation of the corresponding ethers.

### 1. The Structure of the Alkyl Group

Claisen and Eisleb[89] showed that the products of the *C*-alkylation of alkali metal phenoxides can be obtained only when allyl and benzyl halides are used as alkylating agents. However, using the results of the gas–liquid chromatographic (GLC) analysis of reaction mixture, Kornblum and coworkers showed that, when sodium β-naphthoxide is acted upon by methyl iodide in ethanol, 12% of the *C*-isomer is formed and, following the replacement of methyl iodide by propyl bromide, only traces of the *C*-isomer are detected[72]. The use of allyl and benzyl halides as alkylating agents leads to a significant increase of the yield of *o*-substituted phenols. Thus Gomberg and Buchler[90] observed for the first time the formation of 50% of *o*-benzylphenol in the alkylation of sodium phenoxide by benzyl chloride in water. Somewhat later Claisen at al. isolated *o*-benzylphenol as the sole product of the reaction of sodium phenoxide with benzyl bromide in toluene or ether (in 80–90% yield)[91]. The composition of the mixture of benzylation products depends on the nature of the substituent in the benzene ring of benzyl bromide. It has been shown that, in the alkylation of sodium β-naphthoxide in acetone by benzyl bromide and *p*-nitrobenzyl bromide, only benzyl ethers are formed, while alkylation with *p*-methoxybenzyl bromide gives rise to a mixture of 47% of the *O*-isomer and 24% of 1-(*p*-methoxybenzyl)-2-naphthol.[92] The formation of *o*-allylphenol when allyl bromide in ether is used as the alkylating agent was observed by Claisen et al.[91] The yield of the *C*-isomer increases in alkylation by γ-substituted allyl bromides. The alkylation of sodium phenoxide by γ-phenylallyl bromide in benzene leads to the formation of *o*-(γ-phenylallyl)phenol only[93]. A significant increase of the yield of the *C*-isomer (a mixture of *o*- and *p*-alkylphenols) is observed in the alkylation of 2,6-disubstituted phenoxides, although the formation of the *o*-isomer requires in this case the breakdown of the aromaticity of the system. The formation of a considerable amount of dienone was observed in a study of the alkylation of the sodium salt of 2,6-dimethylphenol by benzyl bromide in benzene[94]:

A high yield of the dienone was obtained in the reaction of sodium 2,6-di-(t-butyl)-4-methylphenoxide with methyl iodide[95]. However, the alkylation of alkali metal phenoxides and naphthoxides leads to the formation of *O*-alkylation products except in the case of sterically hindered phenols.

The opposite behaviour is observed in the alkylation with alkyl halides of alkali metal and other metal enolates derived from ketones, esters, and β-dicarbonyl compounds. In this case, *C*-alkylation products are formed preferentially. The influence of the nature of the alkylating agent on the ratio of the *O*- and *C*-isomers has been studied in detail[12] in the alkylation of the sodium enolates of certain alkyl aryl ketones in ethyl ether and glymes (Table 10):

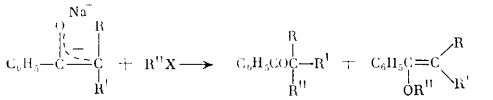


Table 10. The ratio of the products of the *O*- and *C*-alkylation of the sodium enolates of alkyl aryl ketones.

| R | R′ | Solvent | Alkylating agents | | | | | |
|---|---|---|---|---|---|---|---|---|

| $C_6H_5$ | mesityl | t-Butyl alcohol | — | — | 100 | — | — | — |

The data presented in Table 10 show that the ratio of the *O*- and *C*-isomers increases with increase of the length of the alkyl group in the alkylating agent and is very sensitive to the influence of the steric effect in the alkylating agent and the substrate. The fraction of the *O*-alkylation product increases with increase of the bulk of the substituent at the α-carbon atom of alkyl phenyl ketone, which is particularly notable for diphenylacetophenone and mesitylphenylacetophenone, which undergo mainly the *O*-alkylation reaction. *C*-Alkylation is more sensitive to the steric effect, since in this case the carbon atom in the product has the tetrahedral $sp^3$ configuration, in contrast to the planar $sp^2$ configuration arising in the *O*-alkylation of the enolate. Thus steric hindrance favours the *O*-alkylation of alkali metal enolates. The ratio of the *O*- and *C*-isomers increases on moving along Table 10 from left to right and from above downwards, which reflects the influence of the steric effect in the alkylating agent and the substrate on the mode of the alkylation reaction. The sharp increase of the products of the *O*- and *C*-propylation of the sodium enolate of diphenylacetophenone on passing from diglyme to t-butyl alcohol is caused, according to the authors, by the selective solvation of the enolate ion via hydrogen bonding. The influence of the structure of the substituent of the alkylating agent on the mode of the competing *C*- and *O*-alkylation reactions has also been studied for alkali metal salts of β-dicarbonyl compounds. The relative yield of the *O*-isomer in the alkylation of the sodium salt of 1-cyanocyclohexanone increases on passing from methyl iodide to ethyl, n-propyl, and isopropyl iodides (18, 35, 41, and 79% respectively), but falls sharply when allyl and benzyl bromides are used, for which the yields of the *O*-isomers are only 4 and 12%.[96] Bearing in mind that the reaction mixtures were analysed by the preparative separation of the components, presumably some of the data do not reflect the true ratio of the *C*- and *O*-isomers. The yield of the *C*-alkylation products is particularly high for allyl and benzyl halides, which we already noted previously for alkali metal phenoxides and isobutyrophenone enolates. A similar sequence has also been observed in the alkylation of the sodium salt of ethyl β-hydroxycoumarate in alcohol[97], where the ratio of the *C*- and *O*-isomers decreased in the sequence allyl ≫ benzyl > $CH_3$ > $C_2H_5$ > n-$C_3H_7$. When sodium enolate was allowed to react with dimethyl sulphate, only the *O*-alkylation product was isolated. A sharp increase of the yield of the *O*-isomer on passing from methyl iodide to ethyl iodide was also noted in a study of the *C*- and *O*-alkylation of the sodium salts of dihydroresorcinol in alcohols[31]; a further increase of the length of the carbon–carbon chain in the alkyl substituent has only a slight influence on the ratio of the products of *C*- and *O*-alkylation.

An important stage in the study of the dual reactivity of ambident enolate ions was reached with the report[98] that, under the classical conditions of the *C*-alkylation of the sodium salt of AAE by alkyl halides in alcohol (the Conrad method), 6–8% of the *O*-alkylation product is obtained when s-butyl iodide is used. This report stimulated systematic study of the dual reactivity of the enolates of β-dicarbonyl compounds using the most modern methods for the analysis of the reaction mixture. Before the appearance of this report, *O*-alkylation of alkali metal enolates of β-ketoesters and β-diketones was regarded as an unusual and to some extent an exceptional phenomenon. Only isolated examples were known in which *O*-alkylation was the main or at least the competing reaction pathway. In particular, it was known that, in the interaction of the sodium salt of AAE with chloromethyl ether in ethyl ether, ethyl β-alkoxycrotonate is formed[99], the enol ether being the main product of the methylation of AAE and AcAc with diazomethane.[100] Kabachnik and coworkers showed with the aid of GLC analysis[101] that a small amount of the *O*-alkyl derivative is formed even in the alkylation of the sodium salt of AAE by alkyl bromides in alcohol and also in the reaction of the dry sodium salt of AcAc with an alkyl iodide in the absence of solvent. The increase of the content of *O*-alkylation products on passing to reagents with s-alkyl substituents is noteworthy, this being associated with the steric hindrance to the competing *C*-alkylation reaction. The influence of the nature of the alkyl group on the ratio of the *C*- and *O*-isomers was investigated also in the alkylation of the tetrabutylammonium salts of AAE,[25] AcAc,[27] and benzoylmalonic ester[28] by alkyl iodides in chloroform (Table 11). A sharp increase of the yield of the *O*-isomer was also observed on passing to isopropyl iodide. The fraction of the *O*-alkylation product increases significantly when methyl iodide is replaced by ethyl iodide.

A thorough investigation of the influence of the structure of the alkyl group and of the leaving group of the alkylating agent on the mode of the *C*- and *O*-alkylation of the potassium salt of AAE in DMSO and HMP was carried out by Le Noble and Morris[23] (Table 12).

The relative yield of the *O*-isomer for any alkylating agent is significantly higher in HMP than in DMSO. The products of *CO*-dialkylation were detected in the above study with the aid of GLC. As noted previously, steric hindrance is very strongly reflected in the mode of the alkylation reaction. This effect is particularly notable relative to data for alkylation with propyl and isopropyl chlorides and s-butyl chloride, where the ratio of the

*C*- and *O*-isomers varies by a factor >4; neopentyl chloride alkylates the AAE enolate ion only at the oxygen atom. A similar sharp difference is observed on passing from benzyl chloride to diphenylmethyl chloride, whereupon the ratio of the *C*- and *O*-isomers decreases from 6.7 to 1.6. The data presented in Table 12 also indicate the necessity for taking into account the electronic effects in the alkyl group of the alkylating agent. The steric hindrance due to the allyl and propyl groups is approximately the same, but the ratios of the products of the *C*- and *O*-alkylation of potassium enolate under the influence of allyl and s-propyl chlorides nevertheless differ very markedly. It is quite evident that the difference is due to electronic effects. The high polarisability of the allyl group promotes substitution at the carbon atom of the enolate ion—the most polarised centre in the given ambident system.

*The absolute yields of reaction products are quoted.

Extensive experimental data concerning the influence of the nature of the alkyl group on the mode of reaction of phenoxide and enolate ions are inconsistent with Kornblum's rule [102], which predicts the mode of alkylation of the ambident anion. The ratio of the *C*- and *O*-alkylation products should be determined by the competing interaction of the alkylating agent with two nucleophilic centres, as postulated in the classical theory of nucleophilic substitution. The significant difference is that in ambident nucleophiles both centres are linked via the mesomeric effect. According to Kornblum's rule, the fact that the transition state in the reaction between an ambident anion and the alkylating agent is identical with or similar to the $S_N2$ type promotes the formation of products corresponding to substitution at the most polarised reaction centre of the ambident anion; when a mechanism of the $S_N1$ type operates, attack is directed to the most electronegative centre, which behaves simultaneously as the centre of the highest electron density and the lowest polarisability. The formation of a mixture of products implies that the reaction proceeds in the intermediate $S_N1$–$S_N2$ region. The oxygen atom in enolate and phenoxide ions is the centre of maximum electron density and the carbon atom is the most polarised centre. According to Kornblum's rule, a higher ratio of the *C*- and *O*-isomers of the alkylation products was to be expected for allyl and benzyl halides than for other alkyl halides. The transition state in the reaction involving allyl, benzyl, and diphenylmethyl halides occurs as a rule in the boundary region with a much greater contribution of the $S_N1$ mechanism than for methyl, ethyl, and other alkyl halides with an n-alkyl group. [103] In all the examples quoted above, the ratio of the *C*- and *O*-isomers for benzyl and allyl halides is in fact much higher than for n-alkyl halides. Alkylation of alkali metal enolates by n-alkyl chlorides [23,104] is a bimolecular nucleophilic substitution process. However, the main products of this reaction are enol ethers, which is completely contrary to Kornblum's rule in its initial form. Finally, it is known that silylation of alkali metal enolates of carbonyl and β-dicarbonyl compounds [105,106] and certain esters [107] leads to the formation of silyl-substituted enols, despite the fact that this reaction proceeds via an $S_N2$ mechanism.

In a short review devoted to the theoretical principles of the problem of the dual reactivity of ambident anions, Gompper [108] treats Kornblum's rule somewhat differently. As a consequence of Coulombic attraction, a polar electrophile attacks primarily the atom of the ambident system which has the highest electron density. If the electrophile has a slight positive charge on the carbon atom linked directly to the leaving group, there is an enhancement of the role of the London intermolecular interaction dispersion forces, which stabilise the transition state involving the most polarised centre of the ambident anion. It is easily seen that this general formulation is in no way related to the classification according to which there exist two types of mechanisms of substitution at a saturated carbon atom; these mechanisms determine, according to Kornblum's view, the mode of reaction.

In conformity with Gompper's view, many reactions of enolates and phenoxides proceeding via the $S_N2$ mechanism lead to the formation of *O*-alkylation and *O*-acylation products. Gompper's view is close to Pearson's HSAB concept [46,109,110]. In conformity with the main postulate of this principle, an increase of the hardness of the alkyl group should promote *O*-alkylation. The sharp increase of the fraction of the *O*-isomer in the alkylation of alkali metal enolates [99] and enols [100] by chloromethyl ether and diazomethane must be attributed to the introduction into the alkyl group of hard methoxy- and diazo-groups. On the other hand, the tendency of allyl and benzyl halides to form products corresponding to substitution at the carbon atom of the enolate ion can be explained by the presence of the soft allyl or benzyl

group. Thus, knowing the relative hardness of the alkyl group linked to the same leaving group of the alkylating agent, it is possible, in principle, to predict the direction of attack on the ambident anion.

According to a current view, the alkyl group attached to an $sp^3$-hybridised carbon atom exhibits a small $-I$ effect. Certain thermodynamic and kinetic data [111-115] as well as dipole moment data [116] are consistent with this hypothesis. In a paper devoted to the application of the HSAB principle in organic chemistry, Pearson [109] quoted the following series based on the hardness of alkyl groups: t-$C_4H_9$ > iso-$C_3H_7$ > $C_2H_5$ > $CH_3$. However, there are few experimental data showing that the alkyl group attached to a saturated carbon atom has electron-accepting properties; furthermore, they are mainly concerned with the gas phase and it is not clear what situation obtains in the liquid phase. According to earlier and more common idea, based on kinetic data for $S_N2$ reactions in solution, the alkyl group at an $sp^3$-hybridised carbon atom exhibits a small $+I$ effect.

*When RI and RBr are used, only $\alpha\alpha$-dialkyl-AAE derivatives are formed. When the alkylating agents are RCl and ROTs, a mixture of *CC*- and *CO*-dialkylation products is formed.

The ratio of the *C*- and *O*-isomers in the alkylation of enolate ions is determined by both electronic and steric factors, the latter always increasing the fraction of the *O*-isomer. Since it is not possible to estimate separately the contribution of each effect for the same leaving group, it remains obscure whether the increase of the ratio of the *C*- and *O*-isomers in the series s-$C_4H_9$ < iso-$C_3H_7$ < $C_2H_5$ < $CH_3$ [23,27,101] is caused by the simultaneous operation of both factors, which is consistent with the concept of the electron-accepting nature of the alkyl group attached to a saturated carbon atom, or whether the hardness of

*When RI, RBr, and Allyl OTs are used, only the *CC*-dialkylation product is formed. With RCl as the alkylating agent, there is a small admixture (~1%) of the *CO*-dialkylation products.

alkyl groups varies in a sequence which is the inverse of that proposed by Pearson and the electronic and steric effects therefore act in opposition and the ratio of the *C*- and *O*-isomers is determined by the dominant contribution of the steric effect when the leaving group consists of iodide, bromide, or chloride ions. In order to determine the relative hardness of alkyl groups, a study was made of the influence of the alkyl substituent at a saturated carbon atom of the alkylating agent on the ratio of the products of the *C*- and *O*-alkylation of alkali metal enolates of AAE and AcAc by alkyl toluene-*p*-sulphonates in HMP [117,118] (Tables 13 and 14). In this case, the sequence based on the influence of the alkyl group on the ratio of the *C*- and *O*-isomers, namely s-$C_4H_9$ ≥ iso-$C_3H_7$ > $C_2H_5$ > $CH_3$, is exactly the opposite of the sequence observed for halides. This implies that the two effects are opposed and that the polar effect plays a dominant role for alkyl toluene-*p*-sulphonates. The increase of the ratio of the *C*- and *O*-isomers in the sequence s-$C_4H_9$ > iso-$C_3H_7$ > $C_2H_5$ > $CH_3$ shows that the alkyl substituent at the reaction centre of the alkylating agent is electron-donating. Thus the hardness of alkyl groups in the alkylation of enolate ions varies contrary to the Pearson's hardness sequence derived from thermodynamic data. The qualitative identity of the sequence characterising the influence of alkyl groups in the alkylation of alkali metal enolates by alkyl halides and Pearson's hardness sequence implies that the steric effects of alkyl groups play the dominant role for these softer alkylating agents.

2. Effect of the Leaving Group

The nature of the leaving group of the alkylating agent is one of the factors controlling the mode of alkylation of alkali metal enolates. The fraction of the product of the *O*-alkylation of enolate ions increases in the sequence $I^- < Br^- < Cl^- < F^- < SO_4^{2-} < OTs^- < CF_3SO_3^-$. The data presented in Tables 13 and 14 show that the ratio of the *O*- and *C*-isomers in the methylation of the potassium salt of AAE and the sodium salt of AcAc decreases by a factor of $10^2$–$10^3$ when methyl toluene-*p*-sulphonate is replaced by methyl iodide as the alkylating agent[117,118]:

| | | |
|---|---|---|
| X=OTs | 97% | 3% |
| X=I | 3% | 97% |

The effect of the leaving group is distinct although less pronounced also in the ethylation of the two enolate ions. However, for the even softer iso-$C_3H_7$ and s-$C_4H_9$ groups, the nature of the leaving group has only a very weak influence on the mode of reaction. Thus the replacement of toluene-*p*-sulphonate by chloride or bromide in s-$C_4H_9X$ is hardly reflected in the composition of the mixture of the alkylation products and for s-$C_4H_9I$ the ratio of the *O*- and *C*-isomers is actually greater than unity. Thus the effect of the leaving group depends in its turn on the hardness of the alkyl group of the alkylating agent.

The influence of the leaving group on the ratio of the *C*- and *O*-alkylation products has also been investigated in the alkylation of the benzophenone dianion[19]. The fraction of the *O*-isomer increases sharply on passing from methyl iodide to methyl toluene-*p*-sulphonate, for which *O*-alkylation becomes the sole reaction pathway. Although the benzophenone dianion is an extremely unusual ambident system, the overall dependence of the ratio of the *C*- and *O*-isomers on the nature of the leaving group remains the same as for the usual ambident enolate ions: $OTs^- < SO_4^{2-} < Br^- < I^-$. In the alkylation of the lithium salt of buryrophenone by pentyl halides in DMSO, the ratio of the *C*- and *O*-isomers diminishes from 5.0 for $C_5H_{11}I$ to 2.0 for $C_5H_{11}Br$ and to 0.77 for $C_5H_{11}Cl$.[119] In the study by von Auwers[96] quoted previously, it was also shown that, when the sodium salt of 1-cyanocyclohexanone is alkylated by alkyl halides in alcohol, bromides give rise to a higher yield of *O*-alkylation products than iodides. In the alkylation of the enolates of β-dicarbonyl compounds, the same effect of the leaving group is observed as for the enolates of monocarbonyl compounds. Kornblum et al.[120], who investigated the influence of the leaving group in the benzylation of the sodium salt of ethyl β-hydroxycoumarate in DMF, noted that the relative yields of the *O*-alkylation product are 18, 29, and 50% for the iodide, bromide, and chloride respectively. The same sequence has been observed in the alkylation of the potassium salt of AAE by alkyl halides in DMF [77] and in DMSO [22] and also in the alkylation of the sodium salt of a derivative of octalone by benzyloxymethyl halides in dioxan[121]. In all these instances, the fraction of the *O*-alkylation product increases as the leaving group becomes a harder Lewis base. Stetter and Dierichs[31] studied the influence of the leaving group on the ratio of the products of the *C*- and *O*-alkylation of the sodium enolate of dihydroresorcinol in alcohol[31] (Table 15). The ratio of the *C*- and *O*-isomers diminishes by a factor of at least 100 on passing from the iodide to the toluene-*p*-sulphonate. In another study, it was established on the basis of infrared spectroscopic and NMR data that the alkylation of the potassium enolate of AcAc by methyl iodide in acetone entails the formation of the *C*-alkylation product alone, while the use of dimethyl sulphate under analogous conditions leads to the formation also of a certain amount of the *O*-isomer[122]. The employment of triethyloxonium fluoroborate as the alkylating agent has a particularly promoting effect on the formation of a considerable amount of the *O*-alkylation product. Thus the alkylation of lithium enolate derived from 4-t-butylcyclohexanone by triethyloxonium fluoroborate in methylene chloride results in the formation of 23% of the ethyl ether of the enol[123], while the potassium enolates of cyclohexanone and acetophenone give rise to 69% of the enol ether under analogous conditions in DME.[124] Kabachnik and coworkers[125] showed that, when the sodium salt of AAE is treated with triethyloxonium fluoroborate in ether, ethyl β-ethoxycrotonate is also formed in a low (~15%) yield, while the sodium salt of AcAc gives rise to 28.5% of the *O*-isomer under the same conditions.

Table 15. The alkylation of the sodium salt of dihydroresorcinol.

| Yield of *O*-isomer, % | 56.5 | 70 | 100 |

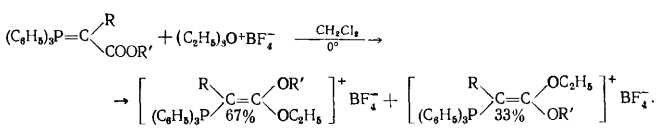
The effect of the leaving group in the alkylation reactions of ambident anions can be explained within the framework of the HSAB principle by the so called symbiotic effect of the stabilisation of the transition state. It is suggested that a group of either several soft bases or several hard ligands at a saturated carbon atom of the alkylating agent should stabilise the transition state and should increase the rate of the process. In other words, the rate of reaction should increase if the entering and leaving groups are simultaneously either soft or hard bases. Pearson and Songstad adduce convincing evidence for the occurrence of the symbiotic effect in bimolecular nucleophilic substitution at a saturated carbon atom[126]. In relation to ambident enolate ions, this implies that the rate of the *C*-alkylation reaction increases if the leaving group in the alkylating agent is a soft base (iodide, bromide). The opposite effect—an increase of the rate of *O*-alkylation—is achieved when the leaving group is a hard base (toluene-*p*-sulphonate, perchlorate, fluoroborate, etc.). In certain cases such a change in the relative rates of the two processes leads to a complete change in the mode of reaction.

The ratio of the rate constants for the *C*- and *O*-alkylation of enolate anions under the influence of alkyl iodides and alkyl toluene-*p*-sulphonates characterises the degree of hardness of the two nucleophilic centres. In the *C*-ethylation of the enolate ion of α-ethylacetoacetic ester in DMF,[127] $k_{I^-}/k_{OTs^-} = 420$. In general, this is the expected result for the soft centre of the enolate ion. It was found that the rate of the competing *O*-alkylation reaction under the influence of ethyl iodide is also higher than in the reaction with ethyl toluene-*p*-sulphonate

($k_{I^-}/k_{OTs^-}$ = 13). Such a change in the rate of reaction on passing from a hard to a soft alkylating agent indicates a considerable softness of the AAE ambident anion. The same behaviour was observed a little later [128]. However, according to the latter data [128], the rate of reaction under the influence of ethyl fluorosulphonate and ethyl trifluoromethanesulphonate ("ethyl triflate") ($CF_3SO_3C_2H_5$) is much higher than for ethyl iodide, i.e. the rate of reaction does not vary in parallel with increasing softness of the leaving group. This anomaly is probably associated with the change in the nature of the interaction between the reacting species from a purely ion–dipole interaction for ethyl toluene-*p*-sulphonate, ethyl bromide, and ethyl iodide to a nearly ion–ion interaction in the case of ethyl fluorosulphonate and ethyl trifluoromethanesulphonate. The ratio of the *C*- and *O*-ethylation products decreases as usual under these conditions on passing from the iodide to the toluene-*p*-sulphonate and further to the trifluoromethanesulphonate ($CF_3SO_3^-$). Thus the fraction of the products of the *O*-alkylation of the enolate ions of carbonyl and β-dicarbonyl compounds increases as the leaving group becomes a harder base.

In other instances, for example in the alkylation of the alkali metal enolates of esters, which are apparently softer Lewis bases, *C*-alkylation products are formed exclusively even on treatment with toluene-*p*-sulphonates, fluorosulphonates, and trialkyloxonium salts. The opposite case is observed in the alkylation of the phenoxides and enolates derived from certain β-diketones (dihydroresorcinol, trifluoroacetylacetone, hexafluoroacetylacetone, etc.) when the *O*-isomer becomes the main reaction product (and sometimes the only product) even when an alkyl iodide is used. Consequently, on the basis of the symbiotic effect alone, one cannot predict in the general case the mode of alkylation of the enolate ion; it is only clear that the ratio of the *C*- and *O*-isomers will decrease as the leaving group becomes a harder base.

## V. THE INFLUENCE OF THE NATURE OF THE AMBIDENT ANION



Analysis of data for the influence of the nature of the electrophile, the metal cation, and the solvent on the dual reactivity of the phenoxides and enolates derived from various carbonyl and β-dicarbonyl compounds and esters shows that there is a certain tendency in the influence of these factors. However, different systems exhibit unequal sensitivities. Certain ambident anions show an enhanced tendency towards *O*-alkylation and *O*-acylation, while for other enolate ions it has not so far been possible to detect the formation of the *O*-isomer. Hence the nature of the ambident system itself determines to an even greater extent than the electrophile the mode of reaction of the ambident enolate anion. Thus the enolates of alkyl phenyl ketones form a much larger amount of the *O*-isomer than the enolates of dialkyl ketones. According to the data of Zook et al. [12], the alkylation of the enolates of acetophenone and butyrophenone in monoglyme and diglyme by alkyl halides leads to the formation of considerable amounts of the *O*-alkylation products (Table 10). Under the same conditions, dialkyl ketones and alicyclic ketones undergo only *C*-alkylation.

The considerable influence on the mode of reaction by the nature of the ambident anion itself is manifested most clearly when data on the alkylation and acylation of the enolate ions of ketones and esters are compared. Whereas the mode of reaction can be altered selectively for the enolates of carbonyl and β-dicarbonyl compounds by choosing an appropriate medium or counter ion or by varying the "hardness" of the leaving group of the alkylating agent, the enolate ions of esters form solely *C*-alkylation and *C*-acylation products for reasons which are little understood. Lithium enolate derived from ethyl acetate and t-butyl acetate is alkylated at the carbon atom when acted upon by the diphenylcyclopropenylium cation [129], alkyl halides, methyl fluorosulphonate, and triethyloxonium fluoroborate [130]. Mainly as a result of studies by Rathke and coworkers and by Cregge and coworkers, excellent general methods have been developed for the *C*-alkylation and *C*-acylation of the lithium salts of esters and dilithium salts of carboxylic acids [131–136]. The lithium salts, obtained by treating the ester with lithium di-isopropylamide or lithium isopropylcyclohexylamide in THF at −78°C, can even be isolated in a pure form in many instances. Lithium enolates in benzene and toluene solutions are stable for several hours at least and, on treatment with an alkyl or acyl halide, give excellent yields of ester homologues or β-ketoesters [137]. A characteristic feature of these processes is the complete absence of dialkylation and diacylation products. The alkylation and acylation of lithium salts of esters is apparently the best preparative method for the synthesis of esters and β-ketoesters in a chromatographically pure form. The formation of mono-*C*-alkylation and acylation products, unaccompanied by the competing reaction involving the oxygen atom of the lithium enolate, has been observed in all cases.

Only three instances of the *O*-alkylation of ester enolates have apparently been described hitherto, among which the formation of a keten acetal was reliably demonstrated in only one case. *O*-Alkylation of an ester was observed for the first time in the intramolecular alkylation of the sodium enolate derived from the β-bromoethyl esters of cyanoacetic, malonic, acetoacetic, and *p*-nitrophenylacetic acids [138]. According to the author, of the four possible reaction pathways, only intramolecular *O*-alkylation actually occurs, leading to the formation of a keten ethylene acetal as the sole reaction product. The structure of the reaction products was demonstrated by infrared spectroscopy. Since the reaction products are derivatives of keten ethylene acetal, their structure could be demonstrated unambiguously by $^1$H NMR data, but these were not quoted [138]. If keten ethylene acetals are indeed formed in the given reaction, as suggested by the author, the intramolecular *O*-alkylation of the ester is determined exclusively by the influence of the entropy factor, since in any other case one would expect the formation of a *C*-alkylation product, bearing in mind that the bromide ion is a soft base.

In another study, the mechanism of the transesterification reaction is accounted for by postulating that the sodium enolate of methyl *O*-(tetrahydropyranyl)mandelate is alkylated at the oxygen atom of the enolate ion under the influence of benzyl and allyl halides with formation of a keten acetal, which is then converted into benzyl or allyl mandelate. The authors do not present any evidence for the formation of a keten acetal as an intermediate. Benzyl and allyl halides are traditional agents for the selective *C*-alkylation of the enolate ions derived from ketones and β-dicarbonyl compounds. The *O*-alkylation of the enolate ion of an ester under the influence of these reagents therefore appears to be an improbable reaction pathway even theoretically. Naturally, the transesterification mechanism may not in fact include a stage where a keten acetal is formed as an intermediate. The only

reliably established example of the *O*-alkylation of an ester is the reaction between triethyloxonium fluoroborate and alkoxycarbonylmethylenetriphenylphosphorane, described by Bestman et al.[140]:

In this case, a mixture of the *cis*- and *trans*-isomers of a keten acetal is formed in a nearly quantitative yield (Table 16). The structure of the reaction products was demonstrated reliably by $^1H$ NMR and infrared spectroscopic data.

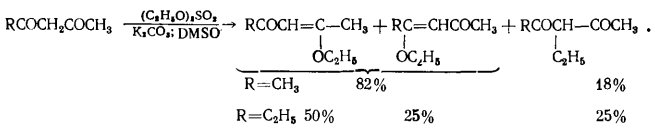


Table 16. The *O*-alkylation of alkoxycarbonylmethylenetriphenylphosphorane with triethyloxonium fluoroborate.

| R | R′ | Yield, % | R | R′ | Yield, % | R | R′ | Yield, % |
|---|---|---|---|---|---|---|---|---|
| H | $CH_3$ | 67 | $C_6H_5CH_2$ | $C_2H_5$ | 97 | $CH_2COOC_2H_5$ | $C_2H_5$ | 98 |
| H | $C_2H_5$ | 68 | $C_6H_5$ | $C_2H_5$ | 99 | $COOC_2H_5$ | $C_2H_5$ | 95 |

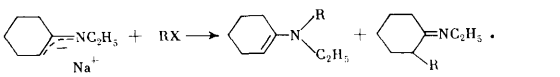
Appreciable differences are observed between the capacities for *C*- and *O*-alkylation in the reactions of the enolates of cyclic and acyclic carbonyl compounds. For example, the ratio of the *C*- and *O*-isomers increases by a factor of 10 on passing from 2-ethoxycarbonylcyclohexanone to the $\alpha$-ethylacetoacetic ester in the alkylation of sodium enolate by isopropyl iodide in DMSO.[141] A similar effect was observed also when data for the alkylation of the sodium salt of AAE and the sodium enolates of cyclic $\beta$-ketoesters by $\beta$-dimethylaminoethyl chloride were compared[142,143].

In a series of cyclic $\beta$-ketoesters, the ratio of the *C*- and *O*-isomers formed depends on the ring size. According to the results of Rhoads and Hasbrouck[144], the ratio of the products of the *C*- and *O*-alkylation of sodium enolates derived from 2-ethoxycarbonylcyclanones with 5–10-membered rings by isopropyl iodide in DMSO varies as follows: 1.74 ($n$ = 3); 1.34 ($n$ = 4); 15 ($n$ = 5); 7.72 ($n$ = 6); 32 ($n$ = 8). Such marked differences between the ratios of the *C*- and *O*-isomers obtained for these compounds and the enhanced tendency of the five- and six-membered systems to undergo *O*-alkylation can be caused by a wide variety of factors: the different p$K_a$ values of the $\beta$-ketoesters, conformational effects, and the different degrees of dissociation of the sodium enolates in DMSO. If the reacting species is not only the enolate ion of the 2-ethoxycarbonylcyclanone but also ion pairs, whose relative contributions for each $\beta$-ketoester may be different, the ratios of the *C*- and *O*-isomers quoted in the above study do not correspond to the dual reactivity of the free enolate ion. Finally, even a change in the formal charge in the ambident system alters markedly its capacity for reaction via two pathways. In contrast to the monoanions, the dianions of $\beta$-dicarbonyl compounds, formed when a $\beta$-diketone or a $\beta$-ketoester is treated with two equivalents of sodium amide in liquid ammonia[145] or after successive treatment with sodium hydride and butyllithium in DHF,[146] form only $\gamma$-*C*-alkylation products regardless of the nature of the alkylating agent. The alkylation of the dianions of $\beta$-dicarbonyl compounds has been investigated in detail by Hauser and coworkers (see the review of Harris and Harris[147]).

It is difficult to find a characteristic of an ambident nucleophile which might serve as a basis for correlation with the reactivity and the ratio of the *C*- and *O*-isomers, at least within the framework of ambident anions of a single class. Presumably, in the absence of steric hindrance, the p$K_a$ of the ketone of the $\beta$-dicarbonyl compound can serve as a quantity of this kind. Indeed, according to Gelin and Rouet[148], the relative yield of the *C*-isomer is somewhat higher in the alkylation of the potassium enolate of acetylpropionylmethane than in the alkylation of the potassium enolate of acetylacetone:

This is consistent with the hypothesis that the ratio of the *C*- and *O*-isomers varies in parallel with the p$K_a$ of the carbonyl compound. The data available at present show, however, that such a regularity does not occur in most instances. Thus, according to Heiszwolf and Kloosterziel[124], in the alkylation of the potassium salts of acetophenone, cyclohexanone, AAE, and AcAc by dimethyl sulphate in DMSO, the ratios of the *C*- and *O*-alkylation products are approximately the same for all the compounds enumerated, although the acidities of ketones and $\beta$-dicarbonyl compounds in DMSO differ by at least 3–7 p$K_a$ units. The ratio of the *C*- and *O*-isomers in the ethylation of the potassium enolate of diacetylacetone also differs insignificantly from the analogous quantity for the weaker acid AcAc.[148]

When data for the alkylation of enolate ions and their closest analogues—ketimines, which also contain a hard nucleophilic centre, are compared, a considerable similarity between the effects of the leaving group is observed. The fraction of the *N*-alkylation product is particularly large when the leaving group of the alkylating agent is a hard base (sulphate, toluene-*p*-sulphonate).[149] In full agreement with the influence of the symbiotic effect, *C*-alkylation predominates for a soft leaving group and a small counter ion[149–151]:



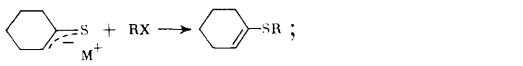


Table 17 lists the relative yields of the products of the *N*-alkylation (enamines) and *C*-alkylation of the sodium salts of certain substituted imines[149]. The ratio of the products of *N*- and *C*-ethylation is seen to be completely inverted for the anion of the acetophenone anil when ethyl iodide is replaced by triethyloxonium fluoroborate as the alkylating agent. The same effect has been observed also for other imines. Enamine is the main reaction product in the alkylation of the sodium salt of diethyl ketone *N*-ethylimine by a hard alkylating agent—dimethyl sulphate, but in the reaction involving a soft alkylating agent only the *C*-isomer was detected in the products, without an admixture of the enamine.

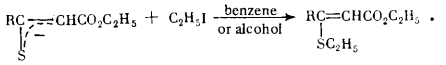
A completely different situation is observed in the alkylation of the sulphur analogues of carbonyl compounds and esters. As already stated, the mode of alkylation of alkali metal enolates of cyclohexanone depends mainly on the nature of the leaving group: alkyl halides form *C*-alkylation products, the *O*-isomer predominating in the reaction products on alkylation with diethyl sulphate

and ethyl toluene-*p*-sulphonate in DMSO.[75] On the other hand, alkali metal salts of tricyclohexanone are alkylated and acylated exclusively at the sulphur atom regardless of the nature of the leaving group[152]:

R = $CH_3$, $C_2H_5$, iso-$C_3H_7$, or $C_6H_5CH_2$; X = Hal or OTs.

The formation of *S*-alkyl derivatives has also been observed in the alkylation of salts of β-thioketoesters[153-155] under conditions such that the enolates of the acetoacetic and benzoylacetic esters are alkylated only at the carbon atom:



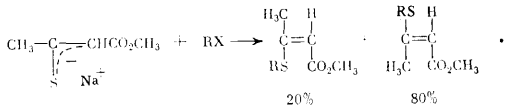


Table 17. The *C*- and *N*-alkylation of the sodium salts of *N*-substituted imines.

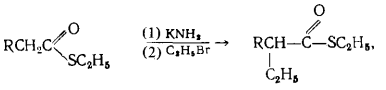
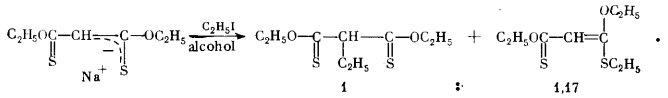


| Solvent | Imine | Alkylating agent | Reaction products, % | | | |
|---|---|---|---|---|---|---|
| | | | unchanged imine | enamine | *C*-alkylated product | poly-alkylated products |
| Diethylcellosolve | Acetophenone anil | $(C_2H_5)_3O^+BF_4^-$ | 8 | 88 | 4 | — |
| | | $(C_2H_5O)_2SO_2$ | 9 | 49 | 42 | — |
| | | $C_2H_5I$ | 5 | 5 | 90 | — |
| HMP | Cyclohexanone *N*-ethylimine | $(C_2H_5)_3O^+BF_4^-$ | 29 | 53 | 18 | — |
| | | $(CH_3O)_2SO_2$ | 11 | 75 | 10 | 4 |
| | | $C_2H_5I$ | 15 | 17 | 56 | 12 |
| HMP | Diethyl ketone *N*-ethylimine | $(C_2H_5)_3O^+BF_4^-$ | 26 | 29 | 42 | 3 |
| | | $(CH_3O)_2SO_2$ | 17 | 57 | 26 | — |
| | | $C_2H_5I$ | 20 | — | 71 | 9 |

The salts of the β-thioketothioester $CH_3CSCH_2COSC_2H_5$ react similarly[153]. The alkylation of the sodium salt of thio-AAE by alkyl bromide or iodide in alcohol results in a mixture of the *Z*- and *E*-forms of β-alkylthiocrotonates in proportions of ~1 : 4 [154]:



20% 80%

An enormous difference between the reactivities of enolates and enethiolates is also manifested in the alkylation of alkali metal salts of esters and their sulphur analogues. Thus, whereas the enolates of thiolo-esters form *C*-alkylation products like ordinary esters, for example[156]:

the enolates of thiono-esters[157,158] and dithioesters behave quite differently. The sodium salt of the thiono-ester of malonic acid reacts with ethyl iodide to form a mixture of the products of the *C*- and *S*-ethylation in approximately equal amounts:

1 : 1.17

The enethiolates of dithioesters are alkylated exclusively at the sulphur atom with formation of keten thioacetals in both polar and non-polar media[159,160]:

The reaction is insensitive both to the influence of the counter ion and to the effect of the leaving group. The different mode of reaction of enethiolates compared with enolates is undoubtedly due to the high polarisability or, in terms of the HSAB principle, the softness of the sulphur atom as the nucleophilic centre. However, the enormous difference in the behaviour of these two classes of ambident anions cannot be accounted for from the standpoint of a purely phenomenological approach, to which the application of the HSAB principle is in essence restricted when it is used to account for the reactivity of ambident anions. This remark applies fully also to the difference between the reactivities of the enolate ions of carbonyl compounds and esters. Evidently, in this case too the problem cannot be solved within the framework of the above concept. All these general theoretical problems require the development of a different approach to the problem of the dual reactivity of ambident systems.

# Organic *N*-Fluoroimines

A.V.Fokin, A.T.Uzun, and V.P.Stolyarov

The available information about the methods of synthesis of *N*-fluoroimines and their reactions with nucleophiles and electrophiles and with oxidants and reductants as well as pyrolytic and photolytic reactions are surveyed. The reaction mechanisms are discussed and certain aspects of the practical applications of the reactions are examined. The bibliography includes 184 references.

## I. INTRODUCTION

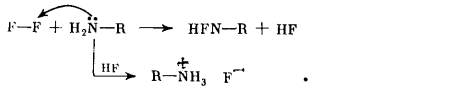
Organic *N*-fluoroimines are characterised by the presence of the C=NF group in the molecule. The first information about the synthesis of fluorine–nitrogen compounds of this class was obtained at the beginning of the 1950s. In subsequent years, the number of publications steadily increased, the most vigorous research in this field having been carried out in the last decade when easy methods for the synthesis of *N*-fluoroimines were developed.

*N*-Fluoroimines exhibit a wide variety of reactivities owing to the presence of the C=N and N–F bonds. Depending on their structures, it is possible to find in the chemical properties of organic *N*-fluoroimines a definite analogy with the chemical properties of familiar classes of organic compounds such as perfluoroketones, carboxylic acid halides, and certain others. On the other hand, the chemistry of these compounds has its distinctive features, so that the study of their chemical properties is of interest both from the standpoint of the deepening of the theoretical ideas about the chemistry of carbon linked by a double bond to a heteroatom and as regards synthetic research. At the same time, compounds of this class can find extensive practical applications.

There have so far been no reviews on organic *N*-fluoroimines. Individual data on the methods of synthesis and chemical properties of these compounds can be found in a number of papers [1-5] and also in monographs [6-10]. The synthesis and reactions of perfluorinated *N*-fluoroimines with nucleophiles have been examined by Dyatkin et al. [11] The present review covers the entire fundamental literature on *N*-fluoroimine published up to May, 1976.

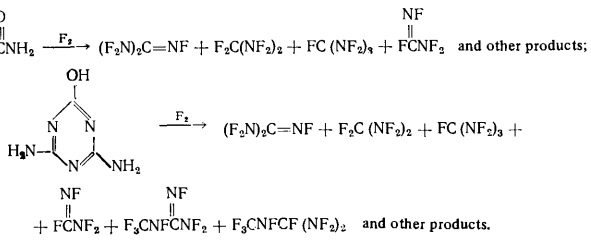
## II. METHODS OF SYNTHESIS

The main methods for the preparation of *N*-fluoroimines are fluorination of nitrogen compounds by elemental fluorine, dehydrofluorination of aminodifluoroalkanes, the interaction of tetrafluorohydrazine with acetylenes, and reductive dehalogenation or difluoroperhalogenoalkylamines. *N*-Fluoroimines are also obtained in reactions of bromine or iodine compounds with tetrafluorohydrazine and in the homolysis of geminal bis(difluoroamino)-derivatives. In addition, there exist examples of the synthesis of individual *N*-fluoroimines which are not general.



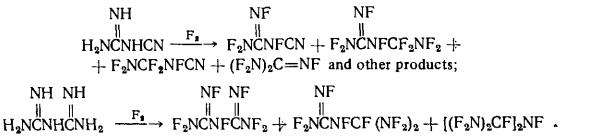
### 1. Fluorination of Nitrogen Compounds by Elemental Fluorine

As early as 1951, Haszeldine [12] fluorinated acetonitrile and trifluoroacetonitrile over gold gauze and obtained, among other products, compounds for which he proposed the structure of perfluoroiminoethane $CF_3CF{=}NF$ and perfluoroformimine $F_2C{=}NF$. The formation of $F_2C{=}NF$ was later noted in the fluorination of acetonitrile [13], methylformamide, and methyl thioisocyanate [14] in the gas phase. The formation of *N*-fluoroimino-derivatives was demonstrated also in the fluorination of perhalogenonitriles [15] and tris(trifluoromethyl)-*s*-triazines [16].

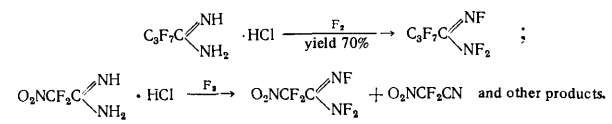


The fluorination of nitrogen compounds by elemental fluorine has become in the last decade one of the fundamental methods for the synthesis of *N*-fluoroimines. This was assisted to a considerable degree by the improvement of the fluorination technique and apparatus and, what is most important, the methods for the isolation and identification of the reaction products. The fact that many unique compounds, highly fluorinated at the nitrogen atom, such as pentafluoroguanidine, tetrafluoroformamidine, *NNN'*-trifluoroamidines, etc., can be obtained by this method has also been enormously important. Various nitrogen compounds may be fluorinated in powder form, as suspensions in an inert organic solvent, and as solutions in aqueous or organic solvents.

The solid-phase fluorination of nitrogen derivatives has been most widely investigated. In order to make the reaction conditions milder, a diluent is used as a rule. Sodium fluoride, which not only plays the role of a diluent but also combines with the hydrogen fluoride evolved in the reaction (the latter is a fluorination inhibitor), is usually employed for this purpose [17-27]. The fluorination mechanism, which is based on the attack on the nitrogen atom by the fluorine molecule [4,5,8], permits the conclusion that the successful occurrence of the process requires that the electron pair at the nitrogen atom should remain free. On the other hand, the presence of hydrogen fluoride in the reaction leads to its inhibiting the process with

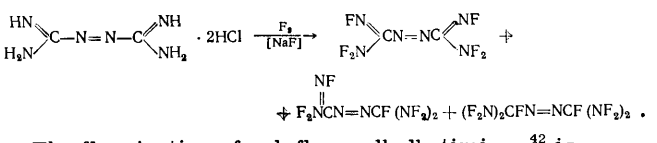


the formation of the corresponding hydrofluoride, which is incapable of further reaction with fluorine:



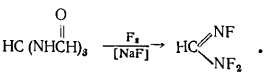
Numerous studies have been devoted to the preparation of pentafluoroguanidine by this method. Guanidine and its derivatives as well as various nitrogen compounds whose molecules contain guanidine structural fragments have been fluorinated, namely guanidinium salts (sulphate, carbonate, hydrochloride, etc.),[21,25,28,29] guanylurea and its sulphate[30-32], biguanide[32-36], ammeline and its salts[17,28,29,32,33,37,38], melamine[33], and cyanoguanidine[26,32]. Fluorination results in the formation of complex mixtures of products, for example:

The maximum yield of pentafluoroguanidine does not exceed 25% under these conditions[25]. Apart from pentafluoroguanidine, the reaction products include various difluoroamino-, fluoroimino-, and difluoroaminofluoroimino-derivatives. The formation of cyanoperfluoroguanidine[19,26,39] and perfluorobiguanide in the fluorination of their hydrogen analogues has been demonstrated[18,20,33,40]:



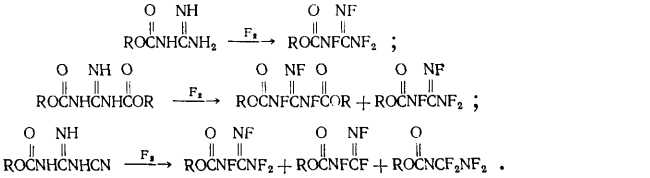
The fluorination of the hydrochlorides of tetrafluorobutyramidine and difluoronitroacetamidine is completed by the formation of the corresponding *NNN'*-trifluoroamidines[27]

The fluorination of the *N*-fluoroamidines of perfluorocarboxylic acids[32], which can be obtained, for example, by the reaction of *N*-fluoroimidoyl fluorides with ammonia, also leads to the formation of perfluoroalkylamidines.



Hexafluoroazodiformamidine (in the form of three isomers), mixed with other products, is formed in the fluorination of azodiformamidinium salts in the presence of sodium fluoride[24,41]:

The fluorination of polyfluoroalkylketimines[42] is completed by the formation of the following reaction products:

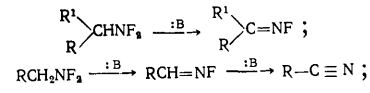


The attempts to obtain unsubstituted *NNN'*-trifluoroamidines $R_HC(=NF)NF_2$ by the solid-phase fluorination of the hydrochlorides of the corresponding amidines were unsuccessful[27]; the alkyl residue of the initial molecule is fluorinated and appreciably degraded. Only the synthesis of *NNN'*-trifluoroformamidine by the fluorination of a mixture of tri-(*N*-formylamino)methane with sodium fluoride is known[23]:

A characteristic feature of the solid-phase fluorination reaction involves the use of various metal fluorides, whose role is apparently not restricted to that of diluents and binders of hydrogen fluoride (see above). It is natural to suppose that metal fluorides behave as catalysts[43]. This property is manifested most distinctly by caesium fluoride in the fluorination of, for example, perfluoroacetone imine[43], which leads to an almost quantitative yield of the saturated perfluoroamino-derivative.

The fluorination of nitrogen compounds in solution, which is a convenient method for the preparation of difluoroaminoalkanes[44], has not found extensive applications in the synthesis of *N*-fluoroimines. However, pentafluoroguanidine has been obtained by the fluorination of aqueous solutions of guanidinium salts[45,46] at pH 8–9 in a thin layer, the formation of which was ensured by a special design of the reactor, The fluorination of alkoxycarbonylguanidines in acetonitrile at 0°C has been shown by Grakauskas and Baum[47,48] to lead to the formation of guanidines fluorinated at the nitrogen atom:

In all cases the yield of fluorination products did not exceed 15%.

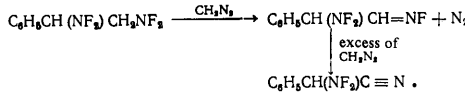


The attempt to use the fluorination of acetonitrile solutions of heptafluorobutyramidine or its hydrochloride in order to synthesis the *NNN'*-trifluoroamidine of heptafluorobutyric acid was unsuccessful[27]. Only the solvent was fluorinated in this reaction.

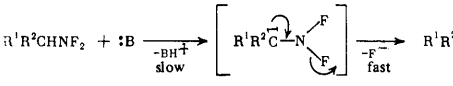
The possibility of employing other fluorinating agents in order to synthesise *N*-fluoroimines has not been studied systematically. There have been only individual reports of the synthesis of *N*-fluoroimines on treatment of nitrogen compounds with mercury(II) fluoride[6,49] and trifluoromethyl hypofluorite[50].

## 2. Dehydrofluorination of Difluoroaminoalkanes

Difluoroamino-compounds with hydrogen atoms in the α-position relative to the difluoroamino-group are capable of dehydrofluorination[3,5,51,52]. By virtue of the unusual amphoteric nature of difluoroaminoalkanes, the reaction can be carried out under the influence of both bases and Lewis acids[2,51]. Basic reagents are used in preparative syntheses. If the initial compound contains the $-CH_2NF_2$ group, the dehydrofluorination takes place in two stages: the first stage leads to the formation of the fluoroimino-group $-CH{=}NF$ and the second is completed by the formation of a cyano-group. If the initial



compound contains the $\rangle CHNF_2$ group, the elimination of an HF molecule from it leads to the formation of the fluoroimino-group $\rangle C{=}NF$, which is incapable of further dehydrofluorination:

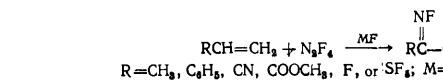


R and $R^1 \neq H$; :B = dehydrofluorinating agent.

When there are no hydrogen atoms in the $\alpha$-position relative to the difluoroamino-group, the latter is as a rule resistant to the action of bases [52,53]. When the molecule of the initial compound contains several difluoroamino-groups, products of incomplete dehydrofluorination can be obtained under certain conditions [51-54].

From the practical point of view, the dehydrofluorination of compounds containing the $\rangle CHNF_2$ group is most important for the synthesis of *N*-fluoroimine. A characteristic feature of the $\rangle CH_2NF_2$ group is its conversion into a cyano-group [51,52,55-59], although the formation of an intermediate *N*-fluoroimine cannot be ruled out, for example [51,52]:

Depending on the conditions, the dehydrofluorination of difluoroamino-derivatives can proceed via different mechanisms. Bearing in mind that in the majority of studies fairly strong bases (triethylamine, pyridine, etc.) have been used for dehydrofluorination, preference should probably be given to the *E1cB* (or similar) mechanism [51, 52,60,61]:

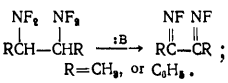


At the same time a bimolecular *E2* mechanism has been proposed for the dehydrofluorination of difluoroamino-alkanes in aqueous organic solutions [53,54,60], this being supported, according to the authors, by the large negative activation entropies and also by the absence of the isomerisation of the diastereoisomers of 2,3-bis-(difluoroamino)-butane in their dehydrofluorination reaction [54]; the latter is of pseudo-first order and has an activation energy of 13–20 kcal mole$^{-1}$ [53,54,60].

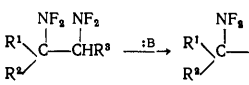
Various dehydrogenating agents are used to remove hydrogen fluoride; they can be arranged in the following sequence in terms of their activities: $C_2H_5OH < H_2O < CH_2N_2 < C_5H_5N < (C_2H_5)_3N < C_2H_5ONa$. [60] Bases such as pyridine [27,51,52,58,62-64], sodium alkoxides [65-69], triethylamine [51,52,70,71], alkali metal fluorides [55,57,59,72-77], and aqueous alkaline solutions [52,56,61,66] are used for the preparative syntheses of *N*-fluoroimines. The employment of the alkaline solutions may be complicated by a series of further reactions (the haloform decomposition, the hydrolysis of cyano-, amide, and ester groups, and decarboxylation) [52,61]. In certain cases, for example in the synthesis of bis(fluoroimino)cyclohexenes [78], specially selected dehydrofluorinating agents are used. Organic solvents, namely chlorohydrocarbons, Freons, acetonitrile, alcohols, etc. are widely used in the synthesis of *N*-fluoroimines.

When bases are allowed to act on vicinal primary-secondary bisdifluoroamino-derivatives, *N*-fluoroimino-nitriles are formed [51,52,58,72]:

The interaction of terminal olefins with tetrafluorohydrazine in the presence of an alkali metal fluoride is a variant of this method [55,57,72]:

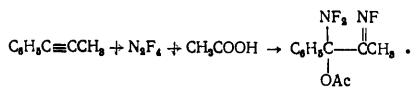


Olefins with electronegative substituents are particularly readily involved in this reaction. Addition products are probably formed initially and are then dehydrofluorinated under the reaction conditions [55].

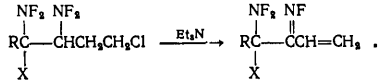


Later this reaction was extended to the synthesis of perfluoroimines [73,74]. For example, when tetrafluorohydrazine reacts with trifluoroethylene in the presence of potassium fluoride, the *N*-fluoroimidoyl fluoride derived from difluoroaminodifluoroacetic acid is formed in a yield exceeding 60%. This product is also formed when 1,2-bis(difluoroamino)trifluoroethane is acted upon by caesium fluoride [76]:

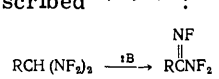
Vicinal bis(fluoroimino)alkanes have been obtained by the dehydrofluorination of vicinal and bis(difluoroamino)-alkanes [53,54,56,62,70,71,77-79], for example:



$\alpha$-Difluoroaminofluoroimines are formed from vicinal bis(fluoroamino)alkanes containing one secondary difluoroamino-group [56,65,66,68,69,71,76,80]:

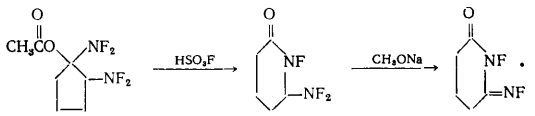


$R^1$, $R^2$=Alk, Ar, Hal, $NF_2$, or $OPO(OR)_2$; $R^3$=Alk, or Ar.



The dehydrofluorination of $\alpha$-acetoxy-$\alpha\beta$-bis(difluoroamino)-derivatives does not lead to the formation of $\alpha$-acetoxy-$\alpha$-(difluoroamino)fluoroimines [61]. Such a fluoroimine has been obtained from methylphenylacetylene, tetrafluorohydrazine, and acetic acid [81]:

*N*-Fluorovinylimines are formed as a result of the simultaneous dehydrofluorination and dehydrochlorination of vicinal bis(difluoroamino)alkanes containing the $\beta$-chloroethyl group [71]:



The synthesis of *NNN'*-trifluoroamidines as a result of the dehydrofluorination of geminal bis(difluoroamino)-alkanes has been described [27,53,63,64]:

A preparative method has been developed for the synthesis of compounds of this kind [27,63,64] using dehydrofluorinating

agents such as pyridine, piperidine, quinoline, and aqueous sodium hydroxide. Best yields are achieved when pyridine is used [27].

3-Fluoroimino-2-fluoro-2-azacyclohexanone has been obtained by the dehydrofluorination of 3-difluoroamino-2-fluoro-2-azacyclohexanone [67]:

The dehydrofluorination of the *cis*- and *trans*-isomers of 9,10-bis(difluoroamino)-9,10-dihydroanthracene leads to the formation of 9,10-bis(fluoroimino)anthracene [82], the *trans*-isomer splitting off hydrogen fluoride more readily than the *cis*-isomer.

When 1,1,2-tris(difluoroamino)alkanes are dehydrofluorinated, the corresponding fluoroimines are formed readily [66,68,71,80]. However, the dehydrofluorination of 1,1,3-tris(difluoroamino)cyclohexane on treatment of the latter with sodium methoxide, undertaken to obtain the corresponding fluorimine, proved unsuccessful [83], probably owing to the instability of the resulting *N*-fluoroimine, caused by the presence of the methylene group with mobile hydrogen atoms [$-C(NF_2)_2CH_2C(=NF)-$].

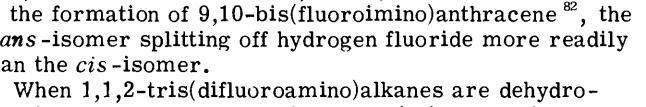
## 3. The Interaction of Tetrafluorohydrazine with Acetylenes

The reaction of tetrafluorohydrazine with acetylenes is a convenient method for the synthesis of $\alpha$-difluoroaminofluoroimines:

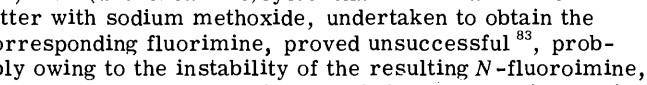
(1)

The first stage involves the formation of a bis(difluoroamino)alkene, which subsequently isomerises to the corresponding *N*-fluoroimine. The rearrangement of difluoroaminoalkenes to *N*-fluoroimines, which was first reported by Bumgardner [84], is based on the higher thermodynamic stability of the C–F and C=N bonds compared with that of the N–F and C=C bonds [85], but there is as yet no unanimous view concerning its mechanism. Many workers support a radical mechanism of this rearrangement, initiated, for example, by heat or ultraviolet light [8]. On the other hand, the stereospecificity of the rearrangement of the products of the addition of tetrafluorohydrazine to allene in the presence of fluoride ions shows that the isomerisation may be based on a heterolytic mechanism [86].

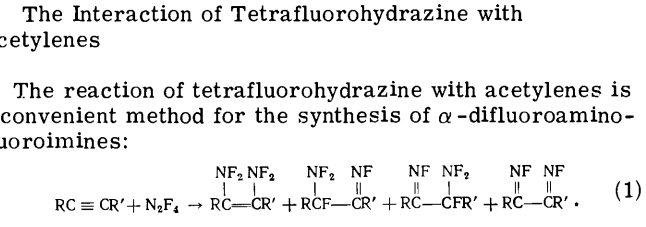
The process is as a rule carried out with heating in a solvent under pressure, best results having been obtained with higher acetylenes (no products were isolated when unsubstituted acetylene was used [85]). In most cases, the main reaction products are $\alpha$-difluoroaminofluoroimines. Bis(difluoroamino)alkenes could be isolated only in the reaction of tetrafluorohydrazine with hex-2-yne [87] and perfluoroacetylenes [86], their formation sometimes constituting the main process in the latter case. Perfluoroderivatives of 1,2-bis(difluoroamino)alkenes can isomerise to the corresponding *N*-fluoroimines on heating or irradiation [86]. When tetrafluorohydrazine interacts with asymmetric acetylenes, the intermediate bis(difluoroamino)-alkenes can arrange with formation of two products. For example, methylphenylacetylene gives rise to both isomers [85]:



However, phenylpropiolyl fluoride yields only one rearrangement product, namely $C_6H_5CF(NF_2)C(=NF)COF$.



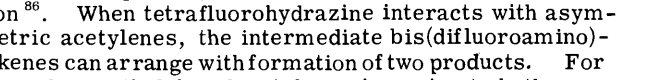
It is of interest that only one mole of tetrafluorohydrazine reacts with hexa-2,4-diyne [85]. This involves 1,2- and not 1,4-addition:



On the other hand isopropenylacetylene gives rise to 1,2- and 1,4-addition products [85]:

The formation of $\alpha$-difluoroaminofluoroimines is also observed in the reaction of tetrafluorohydrazine with allene [85,86]:

When the reaction is catalysed by fluoride ions, the rearrangement of the intermediate product (I) becomes stereospecific, since only the *syn*-isomer (II) is formed together with its dehydrofluorination product [86]:



The reactions of tetrafluorohydrazine with acetylenes can also give rise to 1,2-bis(fluoroimino)alkenes [see Eqn.(1)], whose formation is favoured by prolonged heating and a higher temperature [79]. It has been shown for the synthesis of 2,3-bis(fluoroimino)hexafluorobutane and bis(fluoroimino)succinonitrile that the reaction can be regarded as a convenient method of synthesising vicinal bis(fluoroimino)-derivatives [79].

## 4. Reductive Dehalogenation of Perhalogenoalkyldifluoroamines

Perhalogenoalkyldifluoroamines containing the $NF_2$ group at a primary or secondary carbon atom are converted into *N*-fluoroimines on reductive dehalogenation. The reducing agents most often used are dicyclopentadienyliron (ferrocene) [88–91], iron pentacarbonyl [92–94], and mercury [95–98]; silver or silver nitrite [99] and potassium or tetrabutylammonium iodides [100] are more rarely used.

The process is based on the successive transfer of electrons from the reducing agent to the difluoroamino-derivative accompanied by twofold elimination of the fluoride ion [92]:

The reaction involving perhalogenoalkyldifluoroamines containing the $NF_2$ group at a secondary carbon atom stops at the stage involving the formation of the *N*-fluoroimine [89–91]. As a result of the elimination of a further two

fluoride ions, the corresponding nitriles may be formed from primary perhalogenoalkyldifluoroamines [90,92]. However, by selecting a suitable reducing agent (ferrocene is best) [88-90,101], it is possible to obtain *N*-fluoroimine in this case too:

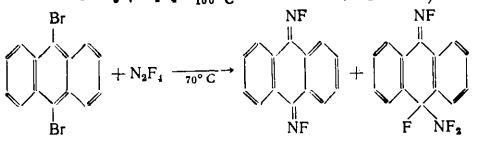
$$R_fCF_2NF_2 \xrightarrow{(C_5H_5)_2Fe} R_fCF{=}NF\ ;$$
$$R_f{=}C_3F_7 \text{ or } CFCl_2\ .$$

The reduction of difluoroaminotrihalogenomethanes with iron pentacarbonyl [93,94] or mercury [95-97] leads to *N*-fluorodihalogenoformimines:

$$F_nCl_{3-n}CNF_2 \xrightarrow{A} F_nCl_{2-n}C{=}NF\ ;$$
$$A{=}Hg \text{ or } (CO)_5Fe;\quad n = 0, 1, \text{or } 2.$$

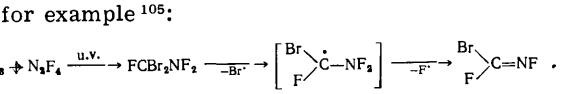
Difluoroaminodichlorofluoromethane reacts best, the reactions involving difluoroaminochlorodifluoro- and difluoroaminotrichloro-methanes proceeding with more difficulty. Ferrocene does not reduce these compounds. When difluoroaminodichloroacetonitrile is reduced with mercury, 1-cyano-*N*-fluoroformimidoyl chloride is formed in a high yield [98].

There have been reports that the reduction of dichlorobis(difluoroamino)methane with silver or silver nitrite leads to dichloro-*N*-fluoroformimine [99], although as a rule the reduction of *gem*-bis(difluoroamino)perfluoroalkanes is completed by the formation of diazirines [88,102,103].



## 5. Reactions of Bromine- or Iodine-containing Compounds with Tetrafluorohydrazine

The formation of *N*-fluoroimines is observed in the reactions of tetrafluorohydrazine with certain bromine- or iodine-containing compounds. These reactions have not so far found wide-scale applications, although they frequently lead to a high yield of *N*-fluoroimines, for example, in the reaction of tetrafluorohydrazine with bromo- and iodo-perhalogenoethylenes [77,104], tribromofluoromethane [105], and 9,10-dibromoanthracene [82]:



$$CBr_2{=}CBr_2 + N_2F_4 \xrightarrow{155^\circ C} CBr_2F{-}CBr(=NF) + F_2NCBrF{-}CBr(=NF)\ ;$$

$$CF_2{=}CFI + N_2F_4 \xrightarrow{100^\circ C} F_2NCF_2{-}CF(=NF) + F_2NCF_2{-}CFINF_2\ ;$$

$$CFBr_2 + N_2F_4 \xrightarrow[100^\circ C]{u.v.} BrFC{=}NF + F_2C{=}NF\ ;$$

$\alpha$-Bromo- or $\alpha$-iodo-difluoroamino-derivatives are formed in the first stages of these reactions. The homolytic elimination of a halogen atom leads to the formation of the radical species $RR^1\dot{C}{-}NF_2$, which is converted into an *N*-fluoroimine as a result of the elimination of a fluorine atom from the difluoroamino-group, for example [105]:

## 6. Homolysis of Geminal Bis(difluoroamino)-derivatives

The homolytic decomposition of difluoroamino-derivatives containing the $-C(NF_2)_2-$ group leads to the formation of *N*-fluoroimines. The reaction begins with the dissociation of the weakest C–N bond [32,106]; the resulting radical $RR^1\dot{C}{-}NF_2$ is stabilised with formation of the corresponding *N*-fluoroimine, the decomposition being usually initiated by ultraviolet irradiation [107] or heat [106,108-110]. Thus photolysis of bis(difluoroamino)-dihalogenomethanes in the presence of $N_2O$ leads to the formation of *N*-fluorodihalogenoformimines [107]:

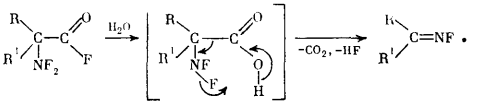
$$XFC(NF_2)_2 \xrightarrow[N_2O]{u.v.} XFC{=}NF\ ;$$
$$X{=}F \text{ or } Cl\ .$$

The thermal decomposition of poly(difluoroamino)-halogenomethanes [32,106,109], tris(difluoroamino)methoxy-methane [109], 2,2-bis(difluoroamino)propane [110], as well as azobis(difluoroamino)fluoromethane and [bis(difluoro-amino)fluoromethylazo]trifluoroformamidine in the presence of carbon monoxide [108] has been described:

$$RC(NF_2)_3 \xrightarrow{\Delta} RC(NF){-}NF_2 \text{ and other products;}$$
$$R{=}NF_2,\ F,\ Cl, \text{ or } OCH_3\ ;$$

$$(CH_3)_2C(NF_2)_2 \xrightarrow[780^\circ C]{} CH_2CF{=}NF + (CH_3)_2C{=}NF + CH_2NF_2 + HCN + HF\ ;$$

$$(F_2N)_2CFN{=}NCF(NF_2)_2 \xrightarrow[160^\circ C]{CO} FN{=}CFN{=}NCF{=}NF\ ;$$

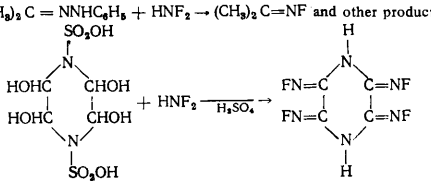


$$(F_2N)_2CFN{=}NCNF_2 \xrightarrow[120^\circ C]{CO} FN{=}CFN{=}NCNF_2\ .$$

The composition of the pyrolysis products depends both on the structure of the initial poly(difluoroamino)-compound and on temperature. Under optimum conditions, the yield of *N*-fluoroimines may reach 60–70% [106,110].

It is noteworthy that formation of *N*-fluoroimines is also observed in the pyrolysis of difluoroaminofluorodiazirine [111] and trifluoronitrosomethane [112] and in the photolysis of azofluoroiminofluoromethane [108].

## 7. Other Methods



Apart from the methods discussed above, a number of reactions leading to the formation of *N*-fluoroimines merit attention. These include primarily the hydrolysis of the fluorides of $\alpha$-difluoroaminoperhalogenocarboxylic acids [113-115]. The formation of $\alpha$-difluoroaminoperhalogeno-carboxylic acid in the first stage is postulated, the acid being subsequently decarboxylated with simultaneous elimination of hydrogen fluoride. A cyclic concerted mechanism has been proposed for the decarboxylation [114,115]:

When aqueous dioxan was allowed to react with difluoro-aminodifluoroacetyl fluoride, the free acid was isolated [114]. The hydrolysis of methyl $\alpha$-cyano-$\alpha$-difluoroamino-propionate apparently proceeds via a similar mechanism with formation of *N*-fluoroiminopropionitrile [61]. When $\alpha$-difluoroaminohexafluoroisobutyryl fluoride is acted upon by caesium fluoride, perfluoroacetone *N*-fluoroimine is formed [116].

Certain *N*-fluoroimines have been obtained with the aid of difluoroamine [117,118]:

$$(CH_3)_2C{=}NNHC_6H_5 + HNF_2 \rightarrow (CH_3)_2C{=}NF \text{ and other products}$$

When sodiomalonic ester reacts with $F_2NOSO_2F$, diethyl *N*-fluoroiminomalonate is formed[119]:

$$NaCH(COOC_2H_5)_2 + F_2NOSO_2F \xrightarrow[CH_3CN]{} FN{=}C(COOC_2H_5)_2 .$$

The formation of *N*-fluoroimines is observed in the reaction of certain α-bromodifluoroamino-derivatives with liquid ammonia[120] or pyridine[48]:

$$C_6H_5CBr_2NF_2 \xrightarrow{\text{liq. } NH_3} C_6H_5CBr(=NF) ;$$

$$C_6H_5CBr(NF_2)CH_2NF_2 \xrightarrow{C_5H_5N} C_6H_5\overset{NF}{\overset{\|}{C}}CN \xleftarrow{C_5H_5N} C_6H_5CBr(NF_2)CN .$$

Treatment of a dialkylfluoroamine (III) with silica gel led to *N*-fluorobenzimidoyl fluoride[121]:

$$\underset{\text{(III)}}{C_6H_5CF_2NFCH(CH_3)CH_2CH_3} \xrightarrow[10^\circ C]{\text{silica gel}} C_6H_5CF(=NF) .$$

*N*-Fluoroimines have been isolated when $F_2NCCl_2SF_5$ was treated in succession with silver(II) fluoride and water[122] and also after the joint pyrolysis of perfluoro-2-azapropene[123] or perfluoropropene[124] with nitrogen trifluoride over caesium fluoride.

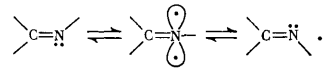
## III. PHYSICOCHEMICAL PROPERTIES

The *N*-fluoroimino-compounds known at the present time are in most cases liquids and more rarely gases or solids. They are stable on storage in dry glass vessels, but in a moist atmosphere they may gradually hydrolyse and interact with the glass.

The most complete physicochemical characteristics have been determined for pentafluoroguanidine[30]:

| | |
|---|---|
| Boiling point, °C | −2, 3 ± 1 |
| Melting point, °C | −148 to −146 |
| Density (Ref.25), g ml$^{-1}$ | 1.51 (0°C) |
| Vapour pressure equation | $\lg p = 7,322 - 1203/T$ |
| Heat of evaporation, kcal mole$^{-1}$ | 5.50 |
| Trouton's constant | 20.3 |
| Enthalpy of formation (Ref.125), kcal mole$^{-1}$ | + 23 |

Liquid column chromatography has been used to isolate pure specimens of this compound[126].



The thermodynamic characteristics of *N*-fluoroimines have been little investigated. It has been found that the enthalpy of formation of *NNN'*-trifluorohexanamidine is $-51.653 \pm 0.14$ kcal mole$^{-1}$.[127] The corresponding quantity calculated for *N*-fluoromethyleneimine by various methods is 12.4 [128] and 16.1 kcal mole$^{-1}$.[128,129] The energy of the $n-\pi^*$ transition has been calculated for *N*-fluoromethyleneimine[130] and has been found to be 6.35 eV.

The geometrical parameters of the C=NF group, calculated for the $H_2C{=}NF$, $HFC{=}NF$, $F_2C{=}NF$,[131] and $FN{=}C{=}NF$ structures[132], can serve as approximate values for the entire class of *N*-fluoroimino-compounds. It follows from the calculations that the C=N bond length is 1.26–1.29 Å, the F–N–C bond angle is in the range 108° to 118°, and the N–F bond length is approximately 1.38 Å (approximately 1.25 Å according to other data, but the authors[132] acknowledge that this value is low). The above geometrical parameters for the C=N–F group are close to the corresponding values of the same parameters for related classes of compounds[2,9,133].

Calculation of the effective charges on the carbon and nitrogen atoms of the C=NF group[131] showed that they vary in the series of compounds $H_2C{=}NF$, $NFC{=}NF$, and $F_2C{=}NF$ from −0.034–+0.389 for the carbon atom and from −0.081 to −0.140 for the nitrogen atom. These results can probably be used, for example, in comparing the reactivities of various *N*-fluoroimines in relation to nucleophiles.

*N*-Fluoroimines containing non-identical substituents at the carbon atom of the C=NF group can exist in two isomeric forms (*syn*- and *anti*-). These isomers have been isolated in many instances. All three possible isomers of 2,3-bis(fluoroimino)butane[62] and αα-bis-(fluoroimino)bibenzyl[70] have been obtained. The *N*-fluoroimine isomers differ in their physicochemical characteristics, but the differences are small. Thus the *syn*- and *anti*-isomers of 1-cyano-*N*-fluoroformimidoyl fluoride have the following properties respectively: boiling point 2° ± 0.5°C and −3° ± 0.5°C; heat of evaporation 6.58 and 6.34 kcal mole$^{-1}$; vapour pressure equation $\lg p = -1440/T + 9.13$ and $\lg p = -1390/T + 8.01$.[55,72] The differences between the retention times of the stereoisomers in gas–liquid chromatography permit their isolation in a pure form. The structures of the *N*-fluoroimine isomers can be reliably determined by $^{19}F$ NMR and mass spectroscopy[27,47,55,62]. In certain cases, *N*-fluoroimines are formed in one (or mainly in one) of the possible isomeric forms. Sometimes this can be explained by the influence of steric factors when one of the substituents at the carbon atom of the fluoroimino-group is large (for example, t-alkyl,[53] $SF_5$, and $COOCH_3$ [55]) and in other cases by the stereospecificity of the formation of the *N*-fluoroimino-compound[47,86].

The stereoisomers of *N*-fluoroimines are fairly stable under the usual conditions and also on moderate heating[27]. Theoretical calculations showed that the energy of the isomerisation of the stereoisomers of *N*-fluoroimines is fairly high. Thus it amounts to 32.5 kcal mole$^{-1}$ for *N*-fluoromethyleneimine[134] and 22.4 kcal mole$^{-1}$ for difluorocarbodiimide[132]. These values were obtained on the hypothesis that the isomerisation mechanism involves the transfer of two non-bonding electrons from the nitrogen atom with an $sp^2$-hybrid orbital to a pure *p* orbital[134]:

Under certain conditions, for example on ultraviolet irradiation, the conversion of one isomeric form of the *N*-fluoroimine into the other may be observed. Thus irradiation of *syn*-bromofluoromethylenefluoroimine[105] and also of *syn,syn*- and *syn,anti*-2,3-bis(fluoroimino)-butanes[62] leads to their isomerisation. The conversion of the *syn*-isomers of *NNN'*-trifluoromonochloroaceto- and *NNN'*-trifluorobutyro-amidines into their *anti*-isomers is observed when the substances are kept in an ethereal solution of HCl.[135] It is suggested that in these instances isomerisation involves the formation of a single C–N bond (which permits rotation of the NF group) via mechanism (2) (on ultraviolet irradiation) or (3) (on treatment with HCl)[134]:

### NMR Spectra

The presence of the fluorine atom makes it possible to investigate *N*-fluoroimines by $^{19}F$ NMR. The $^{19}F$ NMR

spectra have been recorded for the majority of the *N*-fluoroimines describes in the literature and occupy an important place in the determination of their structures.

The chemical shift of the signal due to the $^{19}F$ nucleus in the C=NF group varies within wide limits, from +60 to −90 p.p.m. (relative to $CCl_3F$).[5,136] The upper values of this range are characteristic of *N*-fluoroimines containing the C−F bond at the fluoroimino-group. The signals for other *N*-fluoroimines are as a rule observed in weaker fields. The most intense shielding is observed in perfluoromethyleneimine $F_2C{=}NF$,[105] for which $\delta(NF)$ = +67.0 p.p.m. (relative to $CCl_3F$). The nitrogen and oxygen atoms exhibit a similar shielding effect when they are linked to the C=NF group. The CN group can probably manifest both shielding and deshielding effects[136]. The chemical shifts of the signal due to the $^{19}F$ nucleus in the *syn*- and *anti*-isomers of *N*-fluoroimines are different, which has been used to determine the stereochemistry of these compounds, particularly in combination with $^1H$ NMR spectra[27,55]. The $^{19}F$ NMR spectra of various *N*-fluoroimines have been examined in a review[136].

### Infrared Spectra

Two absorption regions in the infrared spectra are characteristic of *N*-fluoroimines, being associated with the presence in these compounds of both the C=N double bond and the N−F bond. The vibrations of the carbon–nitrogen double bond in the majority of *N*-fluorimines are manifested in the range 1600–1680 $cm^{-1}$. The same absorption region is characteristic also of other compounds with the C=N bond[133]. Hypsochromic and bathochromic shifts of the absorption band due to the multiple bond have been observed for certain *N*-fluoroimines, which is associated with the nature of the substituents at the carbon atom of the fluoroimino-group. For example $\nu$(C−N) is 1745 $cm^{-1}$ for perfluoromethyleneimine[93] and 1553 $cm^{-1}$ for *N*-fluoroiminomalonodinitrile[72].

The vibration of the N−F bond is manifested by one or two bands[55] in the range 840–1000 $cm^{-1}$. When other nitrogen–fluorine bonds are present in the *N*-fluoroimine, the absorption in this region is more complex[5].

The absorption bands corresponding to identical bonds in the geometrical isomers of *N*-fluoroimines have similar positions[53,55,62,72,79,137] and in certain cases the infrared spectra of the isomers may be identical[27].

### Mass Spectra

Mass spectrometry is being used on an increasingly wide scale as a physicochemical method for the investigation of *N*-fluoroimines[23,25,26,28,30,35,39,41,55,62,91,137–139]. However, the number of studies in which mass spectra were used as the main method for the determination of the structures of *N*-fluoroimines is extremely limited. Mention may be made of only one study[62], where mass spectrometry was used to elucidate the structure of the isomers of 2,3-bis(fluoroimino)butane.

### Explosive Properties

Organic *N*-fluoroimines exhibit explosive properties to a greater or lesser extent. Compounds containing difluoroamino-groups together with the fluoroimino-group are particularly sensitive to external influences and properties of this kind are enhanced with increase of the number of difluoroamino-groups[5]. Pentafluoroguanidine is extremely explosive[25]. Explosions of this compound have been observed on friction, impact, and following other external influences, as well as in phase transitions (this happens particularly frequently on fusion). Studies involving such compounds require special precautions.

## IV. CHEMICAL PROPERTIES

Among organic derivatives of nitrogen containing the N−F bond, *N*-fluoroimines have been found to be the most reactive. The wide variety of reactions in which these compounds may be involved is in many respects determined by the presence of the C=N double bond. These include in the first place numerous reactions with nucleophiles and electrophiles and also oxidation, reduction, etc. reactions.

### 1. Hydrolysis

The hydrolysis of pentafluoroguanidine and tetrafluoroformamidine has been investigated in greatest detail[25,30,31,126,140]. In contrast to the hydrolytically stable saturated difluoroaminoalkanes, these compounds are hydrolysed comparatively readily. Pentafluoroguanidine and tetrafluoroformamidine react particularly rapidly and exothermically with aqueous solutions of alkalis[30,140]; the reaction is accompanied by the evolution of an equivalent amount of nitrogen, which is used for the gas-volumetric analysis of these compounds[126]. The hydrolysis of pentafluoroguanidine and tetrafluoroformamidine on treatment with water proceeds over a period of several hours and the compounds react even more slowly with concentrated sulphuric acid. The hydrolysis products in the latter two cases are carbon dioxide, difluoroamine, hydrogen fluoride, and hydroxylamine. When pentafluoroguanidine reacts with concentrated hydrochloric acid, chlorodifluoroamine is also formed[140].

The hydrolysis of *N*-fluoroimidoyl fluorides of perfluorocarboxylic acids leads to the formation of the corresponding acids[16,141]:

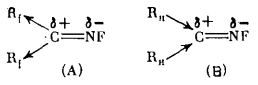
$$R_fCF{=}NF \xrightarrow{H_2O} R_fCOOH\ ;$$

$$R_f{=}CF_3,\ \text{or}\ CF_2NF_2\ .$$

It has been shown for *N*-fluoroimidoyl fluoride derived from difluoroaminodifluoroacetic acid[11,141,142] that the first stage of the reaction involves the formation of the *N*-fluoroimidic acid (IV), whose structure has been demonstrated by $^{19}F$ NMR, infrared spectroscopy, and reaction with diazomethane. The attempts to isolate the *N*-fluoroimidic acid in a free form were unsuccessful:

$$F_2NCF_2\overset{\overset{NF}{\|}}{C}F \xrightarrow[\text{ether}]{H_2O} \left[F_2NCF_2\overset{\overset{NF}{\|}}{C}OH\right] \xrightarrow[\text{ether}]{CH_2N_2} F_2NCF_2\overset{\overset{NF}{\|}}{C}OCH_3\ .$$

(IV)



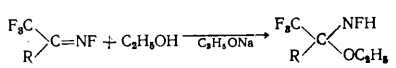
It has also been noted that *C*-chlorodifluoroformimine may be stored over water for 50 h without appreciable decomposition[93], while perfluoroketone *N*-fluoroimines do not change on contact with concentrated sulphuric or fluorosulphonic acid[11].

The hydrolysis of hydrogen-containing *N*-fluoroimines has been described in only two instances. Cyclohexanone was obtained on boiling *N*-fluoroiminocyclohexane with 2 M aqueous sulphuric acid[59]. Similarly, butyl methyl

carbonate is formed in the hydrolysis of butyl methyl *N*-fluoroiminocarbonate[57] with an aqueous-alcoholic solution of HCl.

## 2. Reactions with Nucleophiles

The reactivity of *N*-fluoroimines in relation to nucleophiles is determined by the polarisation of the C=N bond, which is responsible for the electron deficiency at the carbon atom and depends to a large extent on the nature of the substituents linked to this atom. Substituents manifesting a $-I$-effect (A) increase the reactivity of *N*-fluoroimines in relation to nucleophiles, while those with a $+I$-effect (B) reduce it:

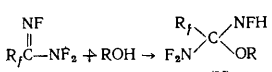


(A) (B)

Substituents such as perfluoroalkyl, $NF_2$, halogeno-, etc. ensure the highest reactivity in relation to nucleophiles.

A diminution of the nucleophilic properties of the given reactant hinders its reaction with the *N*-fluoroimine. This is shown most clearly in the interaction of *N*-fluoroimines with alcohols and amines[143,144]. In the reactions with substances showing reduced nucleophilic properties, basic catalysts are usually employed (triethylamine, pyridine, urea, etc.).

The addition of nucleophiles begins with anionic attack on the positively polarised carbon atom of the C=NF group with a simultaneous shift of the $\pi$ electrons of the C=N bond to the nitrogen atom. On treatment with nucleophiles having a mobile hydrogen atom, which are most frequently used in these reactions (for example alcohols, amines, hydrogen cyanide, nitrous acid, etc.), the corresponding *N*-fluoroamino-derivatives are formed. They are sometimes fairly stable and their presence has been demonstrated by various methods of physicochemical analysis; in other instances, these compounds undergo further reactions, which depend on their structure, reaction conditions, and other factors.



Alcohols. Perfluoroketone *N*-fluoroimines and nitriles of $\alpha$-fluoroiminoperfluorocarboxylic acids are capable of combining with aliphatic alcohols at the C=N bond in the presence of sodium alkoxide[11,142,145,146]. The resulting *gem*-fluoroaminoalkoxy-derivatives are fully stable on storage and distillation:

R=$CF_3$ or CN.

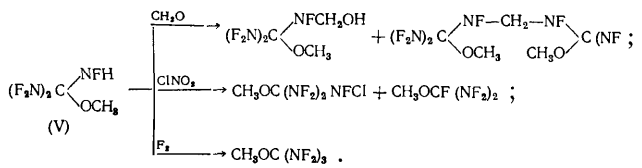
The reaction of perfluoroketone *N*-fluorimines is reversible and, on binding the alcohol (for example, with acetic anhydride) as the acetate[143], the equilibrium may be displaced towards the formation of the initial *N*-fluoroimine.

Pentafluoroguanidine[32,45,143,147-159] and perfluoroamidines[27] also give rise to the addition products (V) in reactions with alcohols:

(V)

$R_f = NF_2$, $C_3F_7$, or $CF_2NO_2$.

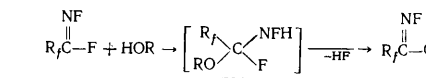
In addition, pentafluoroguanidine is capable of forming adducts also with other compounds containing the hydroxy-group (organic acids, oximes, hydroxamic acid, amidoximes, as well as phenols with electronegative substituents, etc.)[143,154]. Methyl and ethyl alcohols, which are highly nucleophilic, react extremely vigorously with pentafluoroguanidine under the usual conditions. On the other hand, alcohols with electronegative substituents and carboxylic acids require the use of a basic catalyst (urea, triethylamine, and pyridine) for the reaction to reach completion. Trifluoroacetic acid does not react with pentafluoroguanidine under analogous conditions.



The products of the addition of alcohols to pentafluoroguanidine are converted into the corresponding alkoxytrifluoroformamidines on heating or on treatment with metal fluorides (NaF, $AgF_2$) as a result of the elimination of difluoroamine[32,143,154]. In certain other cases, this reaction proceeds spontaneously:

R=$CH_3$, $CH(CH_3)_2$, or $CH_3CO$.

The products of the addition of alcohols to perfluoroamidines are stable only in solutions, from which they cannot be isolated[27].

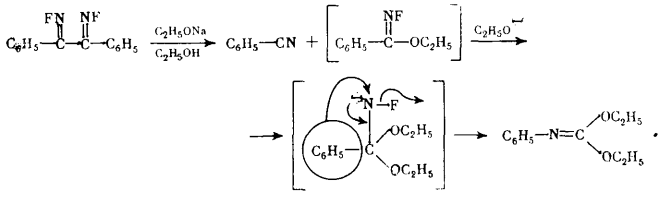


The hydrogen atom of the fluoroamino-group in compounds of type (V) is fairly mobile and capable of being substituted by other atoms or groups of atoms, for example[143]:

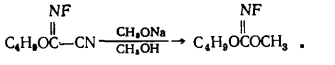
(V)

The last reaction has found extensive applications in the synthesis of tris(difluoroamino)methyl ethers from the corresponding bis(difluoroamino)fluoroaminoalkoxy-derivatives obtained by the interaction of pentafluoroguanidine with alcohols such as ethylene glycol, glycerol[154], methanol and ethanol[143,147,159], ethanol ammonium perchlorate[149,150,155], 2,2-dinitropropane-1,3-diol[157], tris(hydroxymethyl)nitromethane[152], 2,3-bis(hydroxymethyl)oxiran[148,151,153], tetrakis(hydroxymethyl)phosphonium chloride[45], trinitroethanol[158], alcohols containing the difluoroamino-group[154,156], and acetone oxime[143]. Ethers containing the difluoroamino-group have also been obtained by fluorinating the products of the addition of methanol to perfluoroamidines[27].

The products of the interaction of alcohols with *N*-fluoroimidoyl fluorides derived from perfluorocarboxylic acids and 1-cyano-*N*-fluoroformimidoyl fluoride are the corresponding *N*-fluoroimino-ethers[72,74,141,143,145]. It has been suggested[143] that fluoroamino-derivatives (VI) are formed as intermediates:

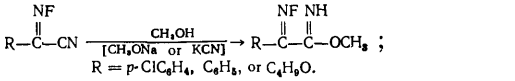


(VI)

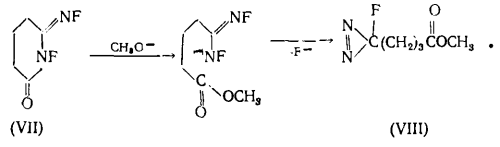


$R_f = CF_3$, $CF_2NF_2$, or CN.

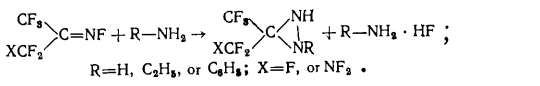
*N*-Fluoroimines containing alkyl or aryl substituents at the carbon atom are less reactive in reactions with alcohols. Thus, whereas *NNN'*-trifluoroamidines derived from perfluorocarboxylic acids combine smoothly with alcohols (see above), *NNN'*-trifluoroamidines derived from non-fluorinated acids do not react with alcohols even in the presence of a catalyst[27].



The reactions of *N*-fluoroimines containing alkyl or aryl substituents proceed as a rule in the presence of an excess of the alkoxide and may be accompanied by the rearrangement of the carbon skeleton of the molecule. Thus, on treatment of α-fluoroiminoarylacetonitriles with an excess of sodium alkoxide in alcohol, mixtures of the corresponding aryl cyanide and *N*-aryliminocarbonates are formed[57,58]. Analogous products have been obtained from αα-bis(fluoroimino)bibenzyl[70]. The reaction mechanism apparently involves a rearrangement similar to that of the Beckmann rearrangement, for example:



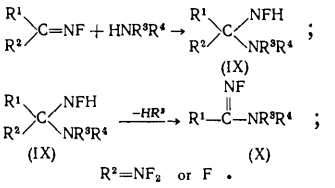
Under analogous conditions, the cyano-group of α-fluoroiminobutoxyacetonitrile exhibits pseudohalogen properties and is replaced by the methoxy-group[57]:



On the other hand, the reaction of α-fluoroiminoaryl- and α-fluoroiminobutoxy-acetonitriles with methyl or ethyl alcohol in the presence of catalytic amounts of potassium alkoxide or cyanide is completed by the formation of the imino-esters of α-fluoroiminocarboxylic acids as a result of the addition of the alcohol to the C≡N group and does not involve the fluoroimino-group[57]:

When the fluoroimine (VII) reacts with sodium methoxide, the diazirine (VIII) is formed[67]:

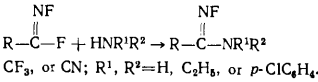
Amines. Perfluoroketone and *N*-fluoroimines react readily with ammonia and primary amines at a temperature as low as −78°C, forming the corresponding diaziridines[11,142,144-146]:



In the reactions with secondary amines, the main products are *NN*-dialkylhydrazones of perfluoroketones[11,142,144,146]:

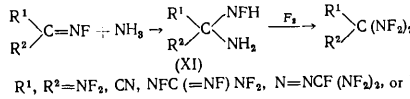
It is suggested that these products are obtained as a result of complex reactions of the unstable geminal amino-fluoroamino-derivatives formed in the first stage[11,144]. The mechanism of these reactions has been examined in detail in a review[11].

The reactions of the nitriles of α-fluoroiminoperfluoro-carboxylic acids with amines usually lead to similar results. However, the reactions with primary amines yield, together with diaziridines, *N*-alkyl-*N'*-fluoro-amidines owing to the manifestation of pseudohalogen properties by the cyano-group[11,142].



The interaction of ammonia and amines with penta-fluoroguanidine[32,144,154,159-162], perfluorobiguanide[161,162], *N*-fluoroiminomalonodinitrile[137], 1-cyano-*N*-fluoroform-imidoyl fluoride[137], cyanoperfluoroformamidine[37,137,159,160,162,163] bis(difluoroamino)fluoromethylazotrifluoroform-amidine[107], α-fluoroiminoperfluorovaleronitrile[37], tetrafluoroformamidine[144], and *N*-fluorotrifluoroacet-imidoyl fluoride[144] has also been investigated. The *N*-fluoroimines enumerated above give rise to products of type (IX) in their reactions with amines. In certain cases, these products can be converted into new *N*-fluoroimines (X) as a result of the elimination of difluoroamine or hydrogen fluoride:

The interaction of *N*-fluoroimines with amines is promoted by the use of polar solvents such as acetonitrile, dimethyl ether, and tetrahydrofuran[144].

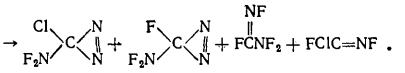


This reaction has been investigated in greatest detail in relation to pentafluoroguanidine, which proved to be reactive with respect to not only amines but also other compounds containing the N−H bond (carboxylic acid amides, imides, and amidines, nitroamines, hydrazine derivatives, etc.)[32,144,159]. The stability of the product of the addition of the amine to pentafluoroguanidine is determined by the nature of the amine involved in the reaction[144]. For example, the interaction of pentafluoroguanidine with ammonia and *p*-cyano- and *p*-trifluoromethyl-anilines gives rise to adducts which are stable at low temperatures. On being heated to room temperature, they lose difluoro-amine with formation of the corresponding trifluoro-guanidines. The products of the addition of more basic amines are unstable even at low temperatures. Thus reactions with n-butylamine and dimethylamine result in the formation of alkyltrifluoroguanidines even at −78°C.

When amines react with *N*-fluoroimidoyl fluorides, *N*-fluoroamidines are formed as a result of the elimination of HF from the intermediate addition product[55,72,144]:

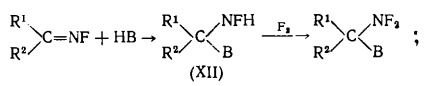
On the other hand, the products of the addition of ammonia to 1-cyano-*N*-fluoroformimidoyl fluoride can apparently exist at low temperatures[128].

Among the entire wide variety of the products of the addition of amines to *N*-fluoroimines, the ammonia addition products (XI) have now found practical application. It has been shown in numerous instances that the hydrogen atoms in the amino- and fluoroamino-groups of these compounds can be substituted by fluorine atoms[37,107,137,144,159-163]:



This reaction led to the synthesis of many new difluoro-amino-derivatives. The reaction with pentafluoroguanidine

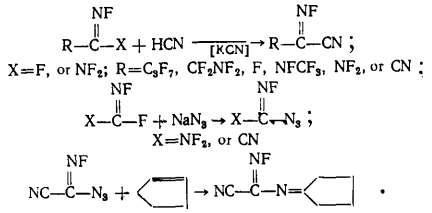
yielded a compound containing the maximum possible number of difluoroamino-groups at a single carbon atom—tetrakis(difluoroimino)methane [144,159-162].



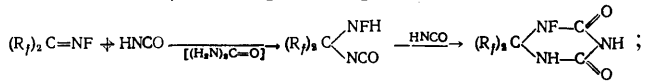
Pentafluoroguanidine reacts with acetone hydrazone and semicarbazide hydrochloride, forming a complex mixture of products as a result of the decomposition and rearrangement of the intermediates [144]:

$$(F_2N)_2C{=}NF + H_2N{-}N{=}C(CH_3)_2 \xrightarrow{25^\circ C} FC(NF_2)_2NH_2 + $$
$$+ F_2C(NF_2)NFH + HNF_2 + N_2O + (CH_3)_2C{=}O\ ;$$

$$(F_2N)_2C{=}NF + H_2NC(O)NHNH_2\cdot HCl \xrightarrow{25^\circ C} \rightarrow$$



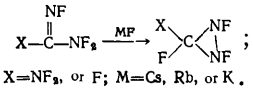
Other nucleophiles. Reactants with less pronounced nucleophilic properties such as $HN_3$, [164] HNCO, [36,165-170] HCN, [11,32,37,137,142] HBr, [138] and HF [143] have also been used in the reactions with *N*-fluoroimines. Their products are mainly the corresponding *N*-fluoroamino-derivatives (XII), which are converted into difluoroamino-compounds on fluorination with elemental fluorine [36,37,138,143,164,167-170]:



(XII)

(a) B=$N_3$; $R^1$=F, or $NF_2$; $R^2$=F, $NF_2$, $N_3$;
(*b*) B=Br, or NCO*, F; $R^1 = R^2 = NF_2$;
(c) B=CN; $R^1$=$R^2$=$CF_3$ (not fluorinated).

The reaction with a nucleophile sometimes results in the formation of a substitution and not an addition product. This happens when hydrogen cyanide reacts with pentafluoroguanidine [32,37,137], cyanotrifluoroformamidine [137], and *N*-fluoroimidoyl fluorides from perfluorocarboxylic acids [11,37] in the presence of catalytic amounts of potassium cyanide and also on treatment of tetrafluoroformamidine [171] and 1-cyano-*N*-fluoroformimidoyl fluoride [55,72] with $NaN_3$. The 1-cyano-*N*-fluoroformimidoyl azide formed in the latter case is stable only in solution; on treatment with cyclopentene, it yields 1-cyano-*N*-cyclopentylidene-*N'*-fluoroformamidine [55,72]:

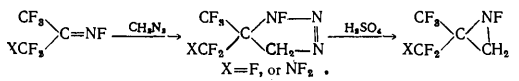


The addition of isocyanic acid to *N*-fluoroimines leads to *N*-fluoroamino-derivatives which react with a second HNCO molecule, forming cyclic products (XIII): [144,165]

(XIII)

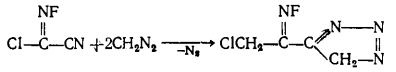
$R_f$=$CF_3$, or $NF_2$.

On treatment with alkali metal fluorides, pentafluoroguanidine and tetrafluoroformamidine isomerise to diaziridines [35,88,172,173]:



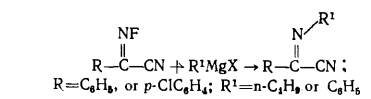
X=$NF_2$, or F; M=Cs, Rb, or K.

† The second fluorination product is $C(NF_2)_4$.



Caesium fluoride is most reactive in this process. The reaction involving tetrafluoroformamidine results in the formation, together with the diaziridine, of a dimer whose structure has not been finally established [172,173].

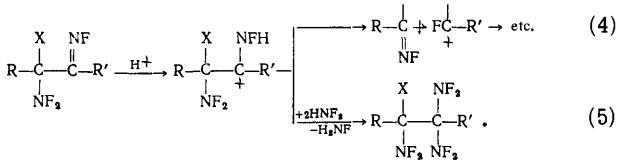
Perfluoroketone *N*-fluoroimines react with diazomethane even in the cold, forming triazolines, which can be converted into the corresponding aziridines [11,142]:



X=F, or $NF_2$.

1-Cyano-*N*-fluoroformimidoyl chloride reacts with two moles of diazomethane [11,142]:

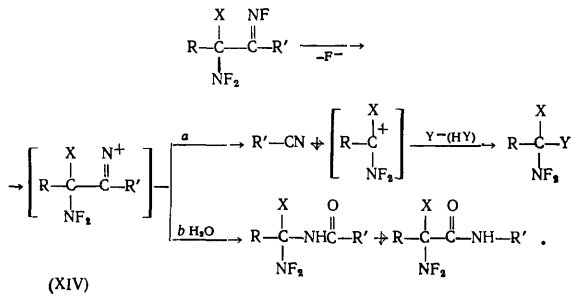
The interaction of α-fluoroiminoarylacetonitriles with organomagnesium compounds leads to *N*-substituted α-iminonitriles in low yields [57]. α-Fluoroiminobutoxyacetonitrile does not undergo this reaction:



R=$C_6H_5$, or p-$ClC_6H_4$; $R^1$=n-$C_4H_9$ or $C_6H_5$

## 3. Reactions with Electrophiles

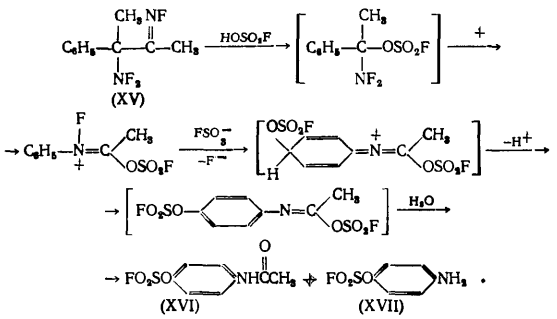
The reactions of *N*-fluoroimines with electrophiles have been less thoroughly investigated. Reactions with electrophiles are characteristic of *N*-fluoroimines in which the carbon atom of the C=NF group is linked to hydrogen-containing alkyl or aryl groups. Among these reactions, those of strong inorganic acids and Lewis acids with α-difluoroaminofluoroimines have been studied in greatest detail [65,66,69,80,174,175].



In principle, the site of attack by the electrophile may be the nitrogen atom or the fluorine atom of the fluoroimino-group. In the former case, treatment with inorganic acids should lead to the formation of the cation $\overset{+}{C}-NFH$. This cation, which has been obtained, for example, from α-(difluoroamino)fluoroimine, could decompose by mechanism (4) (similarly to the decomposition of, for example, 1-diethylphosphato-2-difluoroamino-derivatives in an acid medium [68]); in the presence of a difluoroamine, reaction via mechanism (5) is also possible [66]:

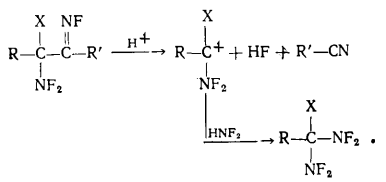
However, this mechanism has not been demonstrated experimentally, although the possibility of its occurrence under certain conditions cannot be ruled out.

It is generally accepted that the primary step in the reactions under consideration is attack by the electrophile on the fluorine atom of the fluoroimino-group, leading to the formation of a complex as a result of donor–acceptor interaction between a molecule of the *N*-fluoroimine and the electrophile [2]. The decomposition of this complex leads to the formation of a cation (XIV) with a sextet of electrons at the nitrogen atom. The carbon skeleton of



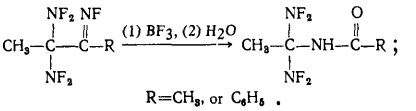
the initial molecule is then cleaved with formation of a carbonium ion (pathway *a*), whose further reaction depends on the reaction conditions. The second pathway (pathway *b*) involves a rearrangement analogous to the Beckmann rearrangement, and is completed by the formation of the corresponding amides. Cases are known where both pathways operate simultaneously:

(XIV)



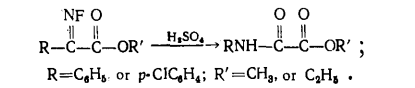
The reaction of $\alpha$-difluoroaminofluorimines with boron trifluoride[66,69] leads to compounds containing a $\rangle C(NF_2)F$ group (pathways *a*).

The mechanism of the reaction between 2-difluoroamino-3-fluoroimino-2-phenylbutane (XV) and fluorosulphonic acid is more complex[65,69,175], the product of this reaction being *p*-fluorosulphonyloxyacetanilide (XVI) and *p*-fluorosulphonyloxyaniline (XVII):

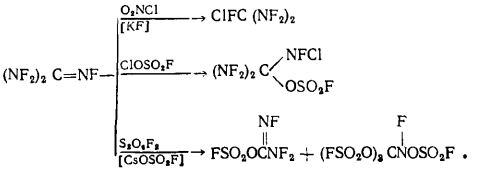


(XV) (XVI) (XVII)

The intermediate $\alpha$-difluoroaminocarbonium ion formed in the reactions is stabilised by combining with fluoride or fluorosulphonate ions. However, it can also be stabilised by reaction with other substances present in the reaction medium[176,177]. Thus difluoroamine is alkylated by the carbonium cation with formation of *gem*-bis(difluoroamino)-derivatives:



This method made it possible to synthesise many hitherto unobtainable geminal derivatives, such as 1-halogeno-1,1-bis(difluoroamino)- and 1,1,1-tris(difluoroamino)alkanes[66,174], which could not be obtained from the corresponding carbonyl compounds. Fluorosulphonic acid proved to be the most effective reagent in these reactions, but in certain cases the best yields of the final products were obtained using concentrated sulphuric acid.

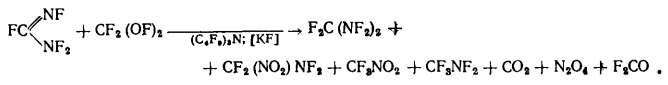


The interaction of $\alpha\alpha$-bis(difluoroamino)fluoroimines with $BF_3$ proceeds via pathway *b* with formation of the corresponding amides[66]:

The interaction of $\alpha$-fluoroiminoarylacetate esters with concentrated sulphuric acid leads to analogous results[57]:

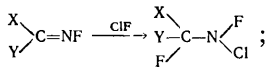
*N*-Fluoroimines containing electronegative substituents at the carbon atom of the C=NF group (perfluoroalkyl, fluoro-, difluoroamino-, and other groups) are less reactive in reactions with electrophiles. This is indicated, for example, by the inertness of perfluoroacetone *N*-fluoroimine in relation to concentrated sulphuric acid and fluorosulphonic acid[11]. At the same time, *N*-fluoroimines of this kind can be involved in reactions with stronger electrophiles. For example, the reactions of pentafluoroguanidine with nitryl chloride[178], chlorine fluorosulphate[179], and peroxydisulphuryl difluoride[180] are known, but their mechanisms have not been elucidated:

## 4. Oxidation and Reduction Reactions



In view of the degree of oxidation of the nitrogen atom in the C=NF group, *N*-fluoroimines are capable of undergoing both oxidation and reduction reactions; reactions of the latter type are more characteristic of these compounds, owing to the presence of the relatively weak nitrogen–fluorine bond (bond energy 65–75 kcal mole$^{-1}$).

In the presence of the $NF_2$ group in the $\alpha$-position relative to the fluoroimino-group, the behaviour of each of these groups with respect to oxidants and reductants will be different, since the nitrogen atom in the difluoroamino-group is in a higher state of oxidation than in the fluoroimino-group. The first stage of the reactions of geminal difluoroaminofluoroimino-compounds with reductants therefore probably proceeds via the $NF_2$ group and that with oxidants via the =NF group.



The available literature information about the oxidation of *N*-fluoroimines is mainly restricted to the reactions of pentafluoroguanidine. Under the usual conditions, pentafluoroguanidine is resistant to the action of gaseous fluorine[166] and also of solid potassium permanganate and silver vanadate[103]. Concentrated nitric acid[103] and aqua regia[99,103,140] decompose pentafluoroguanidine to carbon dioxide, hydrogen fluoride, and nitrogen oxides. In the latter case, dichlorobis(difluoroamino)methane is also formed. When pentafluoroguanidine reacts with manganese dioxide, mainly the *cis*- and *trans*-isomers of difluorodiazine are formed[95].

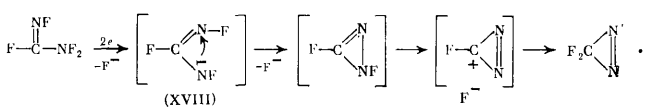
Talbot and Koshar investigated the oxidation of pentafluoroguanidine, trifluoro-*C*-halogenoformamidines, and perfluoroamidines by perfluoroalkyl hypofluorites in the

presence of catalytic amounts of potassium fluoride or cyanide [28,29,139]. These reactions proceed in an extremely complex manner via different pathways and involve the formation of fluorination, oxidation, and degradation products, for example:

When chlorine fluoride reacts with *N*-fluorohalogenoformimines, the corresponding (chlorofluoroamino)-halogenomethanes are formed readily as a result of the addition of a ClF molecule to the C=N bond of the initial imine [97]:

X, Y=F or Cl.

The reaction involving perfluoroacetone *N*-fluoroimine proceeds only in the presence of caesium fluoride [97].

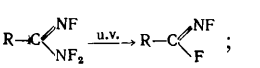


*N*-Fluoroimines readily react with various reductants. For example, they vigorously evolve iodine from aqueous solutions of potassium iodide [32,103,126], which may be used as a qualitative test for these compounds. The products of the reduction of *N*-fluoroimines in these reactions have not been determined in most cases. On the other hand, it has been shown that, when perfluoroacetone *N*-fluoroimine is treated with an aqueous acetonitrile solution of potassium iodide in the presence of acetic acid, perfluoroacetone and ammonia are formed [100].

The reduction of *N*-fluoroimines containing the trifluoroguanyl group by ferrocene [88,102,181], diphenylamine, hydroquinone [88,103,181] and potassium iodide [88,103] in various solvents leads to the formation of diazirines:

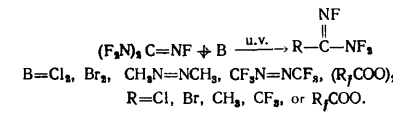
R=F, $NF_2$, $CH_3O$, CN, or NCO;
B= $(C_6H_5)_2Fe$, $(C_6H_5)_2NH$, KI, or $C_6H_4(OH)_2$.

Despite the fact that the yields of products are low, this reaction proved to be convenient for the synthesis of various diazirines [88]. The proposed reaction mechanism includes the reduction of the $NF_2$ group with elimination of the fluoride ion and the formation of the anion (XVIII) capable of cyclising to *N*-fluorodiazirine. The subsequent rearrangement, apparently via the intermediate diazirinium cation, is completed by the formation of the final product [102]:



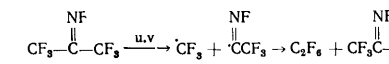
(XVIII)

## 5. Pyrolysis and Photolysis



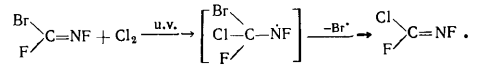
The pyrolysis of *N*-fluoroimines has been studied only in relation to pentafluoroguanidine and tetrafluoroformamidine [25,30,31]. It has been established by differential thermal analysis that these compounds are thermally less stable than the corresponding poly(difluoroamino)perfluoromethanes [30]. Rapid decomposition of pentafluoroguanidine is observed at 243°C and that of tetrafluoroformamidine at 208°C. Slow decomposition of pentafluoroguanidine begins only at 205°C. The main products of the decomposition of these compounds are $CF_4$, $NF_3$, and $N_2$.

The photolysis of *N*-fluoroimines has been studied in greater detail. Thus, it has been found that irradiation of compounds with the trifluoroguanyl group by ultraviolet light leads to the substitution of the difluoroamino-group by fluorine [38]:

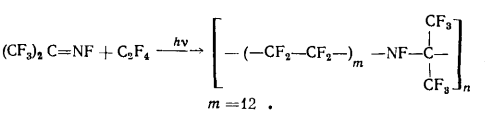


R=F, $NF_2$, or $C_2F_7$.

In the presence of compounds capable of generating a radical species such as chlorine and bromine atoms, trifluoromethyl radicals, etc., the difluoroamino-group can be substituted by them [32,38,88], which constitutes the basis of the method for the synthesis of various *NNN'*-trifluoroamidines from pentafluoroguanidine [32]:

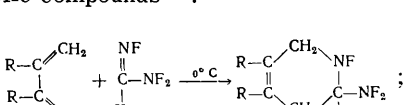


B=$Cl_2$, $Br_2$, $CH_3N{=}NCH_3$, $CF_3N{=}NCF_3$, $(R_fCOO)_2$ etc ;
R=Cl, Br, $CH_3$, $CF_3$, or $R_fCOO$.



When perfluoroacetone *N*-fluoroimine was irradiated with ultraviolet light *in vacuo*, hexafluoroethane was identified in the reaction product; it may be formed via the following mechanism [91]:

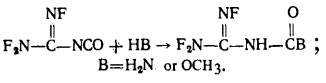
The primary step in the above photolytic reactions is the decomposition of the initial *N*-fluoroimine into two radicals, one of which contains the fluoroimino-group. The recombination of this radical with other radicals leads to various *N*-fluoroimino-compounds. At the same time, the photolytic reactions of *N*-fluoroimines can proceed via a mechanism involving the initial addition of the radical species to the C=N bond. This mechanism has been proposed, for example, for the formation of *C*-chlorodifluoromethyleneimine on irradiation of *C*-bromodifluoromethyleneimine in the presence of chlorine [97]:



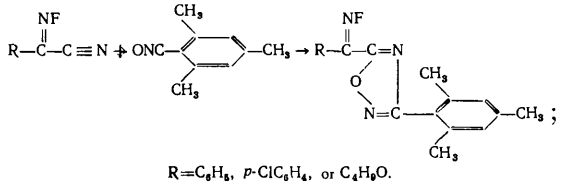
The interaction of perfluoroacetone *N*-fluoroimine with tetrafluoroethylene on $\gamma$-irradiation is completed via the formation of the corresponding copolymer [91]:

*m* =12 .

## 6. Other Reactions

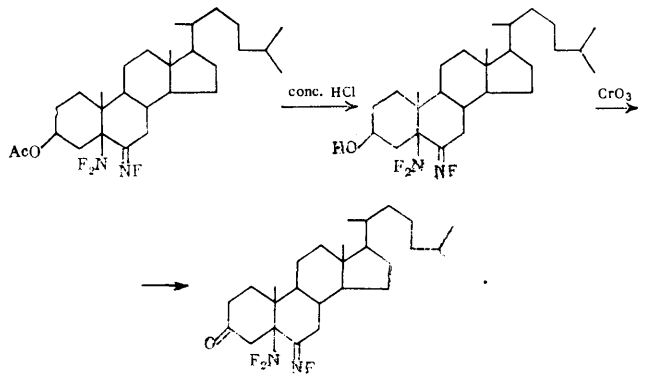


Pentafluoroguanidine and tetrafluoroformamidine readily undergo the Diels–Alder reaction with formation of heterocyclic compounds [182]:

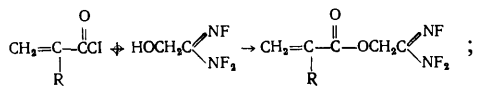


X=F or $NF_2$; R=H, $CH_3$ etc.

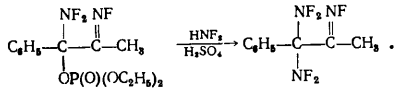
In the presence of catalytic amounts of caesium fluoride, perfluoroguanidine reacts with formaldehyde [183], forming the copolymer $[(F_2N)_2CNF(CH_2O)n]y$, where $n = 1-6$ and $y > 1$.



If the functional group in the *N*-fluoroimine molecule is more reactive than the C=NF group, then frequently only the former reacts, while the C=NF group remains unchanged. Thus, the reaction of trifluoroguanyl isocyanate with methanol and ammonia involves the isocyanate group [184]:



The cyano-group in α-fluoroiminoaryl- and α-fluoroiminobutoxy-acetonitriles can be involved in the 1,3-cycloaddition reactions with a nitrile oxide [57]:



The acetoxy-group in 3β-acetoxy-5-difluoroamino-6-(fluoroimino)cholesterol can be hydrolysed to the hydroxy-group, which may be oxidised to the oxo-group [76]:

2-Difluoroamino-2-fluoroiminoethanol is acylated by acryloyl and methacryloyl chlorides [64]:

When α-(diethoxyphosphoryloxy)-α-difluoroamino-fluoroimines are treated with difluoroamine in the presence of concentrated sulphuric acid, the phosphoryloxy-group is replaced by the difluoroamino-group [66,68]:

α-Acetoxy-α-difluoroaminofluoroimines are decomposed under analogous conditions [66,68,81].

## V. CERTAIN ASPECTS OF PRACTICAL APPLICATIONS

Judging from the literature data, the interest in the synthesis of *N*-fluoroimines is mainly associated with the search for new components of rocket fuels and explosives. *N*-Fluoroimines usually serve as the starting materials for further syntheses. Pentafluoroguanidine is most frequently used for this purpose; it has led to the synthesis of compounds regarded as oxidants of rocket fuels [tetrakis(difluoroamino)methane [144,159-162], tris(difluoroamino)methyl ethers derived from nitroalcohols [152,157,158], bis(difluoroamino)fluoronitromethane [28,139], etc. as well as energetically suitable binders or plasticisers for solid rocket fuels [37,148-151,156,158,182,183]. In certain cases, *N*-fluoroimines are themselves regarded as components of rocket fuels, for example *NNN'*-trifluoroformamimidine [23], 2,3,5,6-tetrakis(fluoroimino)piperazine [118], trifluoroguanyl isocyanate and its derivatives [184], perfluorobiguanide, and 1-[bis(difluoroamino)fluoromethyl]-1,2,3,3,-tetrafluoroguanidine [18-20,40]. A mixture of pentafluoroguanidine with nitrogen oxides has been proposed as an oxidant for rocket fuels [21]. Certain *N*-fluoroimino-compounds containing a large number of oxidising groups have been suggested as explosives [23,24] or as starting materials for the synthesis of the latter [137,160-163].

Physiologically active substances have been found among *N*-fluoroimines. For example, difluoroamino-fluoroiminosteroids inhibit the growth of the prostate gland [76]. Fluoroiminocycloalkanes and fluoroiminocycloalkenes are regarded as intermediates for the synthesis of bactericidal preparations [78].

The use of *N*-fluoroimines as monomers for copolymerisation and as polymerisation initiators is of definite interest. Thus perfluoroacetone *N*-fluoroimines readily copolymerises with tetrafluoroethylene, forming a thermoplastic polymer, whose properties are close to those of Teflon [91]. 1,2-Bis(fluoroimino)-compounds are capable of initiating the polymerisation of, for example, ethylene and tetrafluoroethylene [79]. A number of patents are devoted to the employment of *N*-fluoroimines (mainly perfluoro-derivatives) for the synthesis of diazirines [35,88,99,181], which are potential monomers and sources of biradicals.

Certain *N*-fluoroimines have been suggested as corrosion inhibitors [72], bleaching agents [24], and oxidants in chemical reactions [23].

# Organometallic Catalysis in Stereospecific Polymerisation and Nature of the Active Centres

B.A.Dolgoplosk

Experimental results on the application of individual organic compounds of transition metals for the stereospecific polymerisation of dienes are summarised, and a relation is established between the nature of the metal with its surrounding ligands and the microstructure of the polymer chain. The nature of the active centres responsible for various types of stereoregulation and the mechanism of the formation of chain units are discussed. Aspects of copolymerisation in coordinated systems are considered. Research results on the mechanism of the cleavage of cycloalkenes and the dismutation of alkenes are clarified, arguments are given in favour of a chain process and a carbene character for the active centres, and the mechanism of individual stages in the process is examined. A list of 207 references is included.

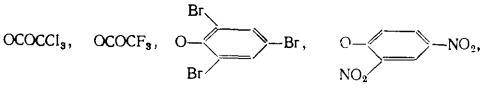
III. Cleavage of cycloalkenes 1083

## I. INTRODUCTION

The present paper summarises experimental results on organometallic catalysis in the stereospecific polymerisation of dienes and cycloalkenes. Research has been devoted mainly to elucidating the nature of the active centres exerting different stereospecific effects in the polymerisation of conjugated dienes, and to studying the mechanism of a novel type of chain reactions—the polymerisation of cycloalkenes and the dismutation of alkenes under the influence of carbene complexes of transition metals. The paper deals mainly with results in this field obtained in the Reviewer's laboratory. It will not be concerned with methods for the preparation of organometallic compounds of transition metals or their specific properties.

## II. POLYMERISATION OF DIENES BY ORGANIC COMPOUNDS OF TRANSITION METALS



Ziegler–Natta systems, comprising mainly organoaluminium compounds and salts of transition metals, have found wide application in industry for the production of stereoregular polymers of alkenes and dienes. An immense number of scientific papers, reviews, and patents have been devoted to these questions. We shall dwell only briefly on the composition of the principal types of systems employed for the stereospecific polymerisation of dienes, and examine certain secondary reactions in the polymer chain leading to disruption of the chain structure.

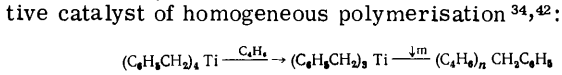
*cis*-Polyisoprene, similar in structure and properties to natural rubber, was obtained[1,2] by means of the classic Ziegler system comprising triethylaluminium and titanium tetrachloride. Various modifications of the system, containing titanium tetrachloride, have since been employed for the industrial production of *cis*-polyisoprene. This system proved insufficiently stereospecific for butadiene.[3] Later investigations have shown that systems containing titanium tetraiodide or mixed halides of titanium increase the content of *cis*-butadiene units[4-6] to 90–95%. Systems consisting of an alkylaluminium halide and a cobalt or nickel salt have also been used to obtain *cis*-polybutadiene.[7-12] Crystalline *trans*-polybutadiene and *trans*-polyisoprene were obtained in the presence of organoaluminium compounds and vanadium halides[13,14] and of higher oxides of chromium deposited on aluminium silicate[15]. Systems based on organoaluminium compounds and a tetra-alkoxytitanium or cobaltous chloride yield stereoregular 1,2-polybutadiene and 3,4-polyisoprene[12,16-19].

Ziegler–Natta systems have been used to obtain *cis*- and *trans*-polypentadienes[20,21], alternating butadiene–propene copolymers[22,23], and several other stereoregular polymers and copolymers of dienes. Many of these systems contain additional components (water, ketones, ethers, esters, Lewis acids, etc.) enhancing their efficiency and stereospecificity of action. As research into the mechanism of the action of the various systems intensified, it became increasingly obvious that the transition metals were the main factor in Ziegler catalysis, and that chain growth occurred at the bond attaching the transition metal to a carbon atom. However, the composition of the systems was too complicated for direct experimental studies of the nature of the active centres and the mechanism of stereoregulation. The most promising approach was to use individual organic compounds of transition metals, so that a direct relation could be established between the nature of the active centres and their stereospecificity. The wide range of action of such compounds is due to the possibility of varying the state of oxidation of the metal and the chemical nature of the ligands surrounding it.

During recent years stable, hydrocarbon-soluble $\sigma$- and $\pi$-allyl compounds of various transition metals—titanium(IV and III), nickel(II), chromium(III and II), molybdenum(IV), vanadium(III), iron(III), and manganese(II)—and the derivatives listed below

1. $(\pi\text{-}C_5H_9)_3Ti$, $[(CH_3)_3SiCH_2]_3Ti$, $\left(\pi\text{-}\bigcirc\right)_3Ti$;
2. $[(CH_3)_3SiCH_2]_4Ti$, $[(CH_3)_3SiCH_2]TiCl_3$, $[(CH_3)_3SiCH_2]_2TiCl_2$;
3. $(C_6H_5CH_2)_4Ti$, $(C_6H_5CH_2)_3TiX$ (X=Cl, Br, I)
4. $\pi$-RNiX (R=$C_3H_5$, $C_4H_7$, $C_5H_9$, , X=Cl, Br, I,

5. $(\pi\text{-}C_3H_5)_3Cr$, $(\pi\text{-}C_5H_9)_3Cr$, $(\pi\text{-}C_3H_5)_2Cr{-}O{-}|SiO_2$,
$(\pi\text{-}C_5H_9)_2Cr{-}O{-}|SiO_2$, $(\pi\text{-}C_5H_9)_2Cr$;



6. $(\pi\text{-}C_5H_9)_3Co$, $(\pi\text{-}C_5H_9)_3Fe$, $(\pi\text{-}C_5H_9)_2Mn$,
$(\pi\text{-}C_5H_9)_3V$;

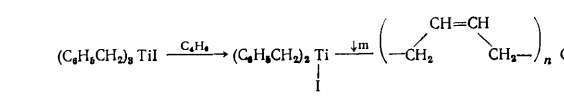
7. $(\pi\text{-}C_3H_5)_4Mo$, $(\pi\text{-}C_3H_5)_3MoX$ (X = Cl, Br, I, OCOCCl$_3$),
$(\pi\text{-}C_5H_5)_4W$ and its derivatives

have been prepared in our laboratory[24-41], most of them for the first time. Compounds in groups 1 and 2, $\pi$-pentenyl and $\pi$-cyclohexenyl complexes of nickel, and especially $\pi$-allyl complexes of chromium chemically combined with silicon dioxide (group 5), were the most stable at 20–50°C. Examination of the catalytic activity and the stereospecificity of action of several individual organometallic compounds permitted a direct study of the nature of the active centres effecting a particular type of stereoregulation.

## 1. Organotitanium(IV) Compounds

Tetrabenzyltitanium in an aromatic solvent is an effective catalyst of homogeneous polymerisation[34,42]:

(A)



↓ m — point of entry of monomer (m).

The active centre (A) retains three benzyl groups and one growing polymer chain at various degrees of polymerisation[42,43]. Titanium remains in the quadrivalent state, which indicates that the organometallic compound is quite stable up to 50°C. In the polymerisation of butadiene the polymer chain consists mainly of 1,2-units[34,42,43], but every possible type of structure (*cis*-1,4, *trans*-1,4, 3,4, and 1,2) is formed from isoprene[44].

Table 1. Stereospecificity of action of tribenzyltitanium halides and effect of donors[43,44].

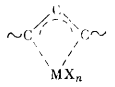
| Monomer | Catalytic system | Microstructure of chain, % | | | |
|---|---|---|---|---|---|
| | | *cis* | *trans* | 1,2- | 3,4- |
| Butadiene | $R_4Ti$ | 20 | 20 | 60 | — |
| | $R_3TiCl$ | 35 | 19 | 46 | — |
| | $R_3TiBr$ | 66 | 13 | 21 | — |
| | $R_3TiI$ | 97 | 0.5 | 2.5 | — |
| | $R_3TiI$ + 10$(C_2H_5)_2O$ | 79 | 17 | 4 | — |
| | $R_3TiI$ + 10 oxolan | 27 | 14 | 59 | — |
| Isoprene | $R_4Ti$ | 0 | 75 | 7 | 18 |
| | $R_3TiCl$ | 19 | 36 | 6 | 39 |
| | $R_3TiBr$ | 69 | 0 | 4 | 27 |
| | $R_3TiI$ | 87 | 0 | 0 | 13 |
| | $R_3TiI$ + 10$(C_2H_5)_2O$ | 16 | 37 | 2 | 45 |
| | $R_3TiI$ + 10 oxolan | 7 | 16 | 9 | 68 |

A more effective catalyst, producing ~95% of *cis*-units, is tribenzyltitanium iodide[42-44]:

(B)

The presence of the iodide anion directly at the reaction centre inverts the stereospecificity of the catalytic effect.

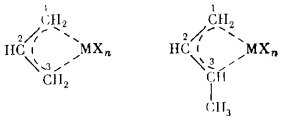
In the active centre (B) titanium is maintained in the quadrivalent state throughout polymerisation. These systems exhibit no fundamental differences from organometallic compounds of alkali and alkaline-earth metals, since chain growth takes place at an ordinary carbon–metal $\sigma$-bond.



Characteristic features of benzyl derivatives of titanium(IV) will be noted below in the discussion of copolymerisation processes. Table 1 gives the chain microstructure in the polymerisation of butadiene and isoprene under the influence of various such derivatives[43,44]. The content of *cis*-1,4-units increases in the sequence

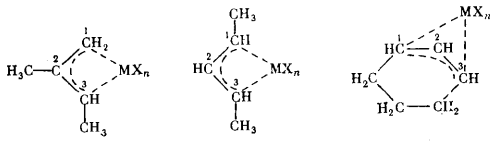
$$(C_6H_5CH_2)_4Ti < (C_6H_5CH_2)_3TiCl < (C_6H_5CH_2)_3TiBr < (C_6H_5CH_2)_3TiI.$$

The last of these compounds is a highly selective catalyst for obtaining *cis*-polymers. Oxygen-containing solvating additives increase the content of *trans*- and 3,4-units. It is possible that the use of tribenzyltitanium iodide under especially pure conditions would have yielded only *cis*-units.



## 2. $\pi$-Allyl Complexes of Transition Metals

It is well known that alkyl derivatives of transition metals are extremely unstable, readily decomposing at the instant of formation[45]. The greater stability of the $\pi$-allyl complexes is due to donor–dative interaction involving $\pi$-electrons of the double bond and non-bonded *d*-electrons of the transition metal[46,47]. $\pi$-Allyl complexes of metals of general formula



represent most closely the structures of the terminal units in an active centre during the polymerisation of dienes, so that study of the specific reactions of such complexes under model conditions is of considerable interest for an understanding of the mechanism of polymerisation: *anti*- and *syn*-configurations of the $\pi$-allyl complexes correspond to *cis*- and *trans*-states of the terminal growing unit. Organomagnesium synthesis in ethereal medium leads to the formation of poly-$\pi$-allyl derivatives $\pi$-$R_nM$, from which exchange with acids and other compounds yields[27,28,48,49] the corresponding derivatives:

(I) (II)

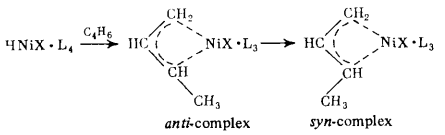
(III) (IV) (V)

The allyl complexes (I), (IV), and (V) are characterised by equivalence of the two carbon–metal bonds and by higher stability, especially complexes (IV) and (V), containing alkyl substituents on the atoms at positions 1 and 3.

Several of the pentenyl complexes of titanium(III), cobalt(III), vanadium(III), chromium(III), iron(II), and manganese(II) synthesised in the Laboratory of Organometallic Catalysis at the Institute of Petrochemical Synthesis of the USSR Academy of Sciences have proved to be stable in solution at room temperature for a long time[24,25,29]. Compounds of type (II) correspond to the growing chain unit of polybutadiene, those of type (III) to the most probable conformation of an isoprene active centre, and (IV) and (V) to pentadiene and cyclohexadiene active centres respectively.

Allyl-, but-2-enyl-, pentenyl-, and cyclohexenylnickel halides have been prepared[50] from the corresponding alkenyl halides and nickel carbonyl:

$$RHal + Ni(CO)_4 \rightarrow RNiHal \ .$$



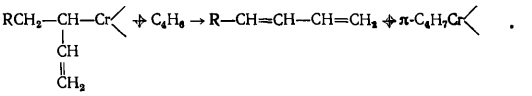
Several specific reactions characteristic of $\pi$-allyl complexes

$$(\pi\text{-}RNiX)_2 \underset{H_2O,oxolan}{\overset{a}{\rightleftharpoons}} \pi\text{-}R_2Ni + \pi\text{-}RNiX \cdot NiX_2$$
$$\downarrow b \qquad\qquad c \downarrow C_4H_6$$
$$R\text{—}R \qquad\qquad Ni + R\text{—}R$$

are of interest for understanding the chemical reactions involved in polymerisation. In the presence of water or oxolan an equilibrium is established (reaction *a*), which can be displaced to the right[51] by distilling off $\pi$-$R_2Ni$ from the system. Reaction (*b*), accompanied by formation of the recombination product R–R, takes place under the influence of various electron-accepting components, especially in aromatic solvents[52,53]. Reaction (*c*) occurs[54] in the presence of dienes with the formation of "bare" active nickel, a catalyst for the cyclic oligomerisation of dienes. Reactions (*b*) and (*c*) illustrate the possibility of the destruction of active centres by recombination during stereospecific polymerisation. This is probably why attack on a growing polymer centre by $CH_3O^3H$ and $^{14}CH_3OH$ in several cases does not result in the appearance of radioactivity in the polymer[55]. The decomposition of $\pi$-but-2-enylnickel chloride by acids leads to the formation of but-1-ene, but hydrogenolysis (and alkaline decomposition) yield *trans*-but-2-ene [56–58]:

$$\pi\text{-}C_4H_7NiX \begin{cases} \xrightarrow{HCl\,(H_2SO_4)} CH_3CH(NiX)\text{—}CH{=}CH_2 \rightarrow \text{but-1-ene (90\%)} \\ \xrightarrow{H_2} CH_3CH{=}CH\text{—}CH_2NiX \rightarrow \textit{trans}\text{-but-2-ene (96\%)} \end{cases} .$$

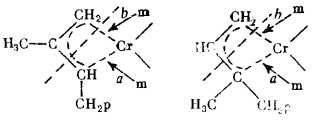
The point of attack and the nature of the "units" formed [but-1(or 2)-ene] depend on the nature of the reagent. Extremely important results were obtained in work[59] showing that the primary addition of butadiene at a hydrogen–nickel bond results in formation of an anti-complex, which then isomerises into the *syn*-complex:



X = sulpho; L = phosphite ligand .

(*a*) Organochromium compounds

Tris-$\pi$-allyl compounds of chromium catalyse the polymerisation of dienes in hydrocarbon solutions[60,61]. All three alkenyl groups are involved in steps of chain growth:



$$\pi\text{-}R_3Cr + 3n\,C_4H_6 \rightarrow [\pi\text{-}R(C_4H_6)_n]_3Cr \ .$$

Three polymer chains are formed on one chromium atom. The resulting polymers have low molecular weights owing to chain transfer to the monomer:

Every "dead" polymer molecule contains a conjugated group of double bonds at the end of the chain.

The butadiene chain contains ~80% of 1,2-units. Every possible type of unit arises in the polymerisation of isoprene. The formation of roughly the same quantities of vinyl and isoprenyl side-groups in polyisoprene (1,2 and 3,4-units) evidently indicates that the two types of centres

are equally probable, where *a* is the point of entry of the monomer into the chain at a carbon–chromium $\sigma$-bond with formation of 1,2- and 3,4-units, while *b* is the point of entry of the monomer on formation of 1,4- and 4,1-units. Hence 1,4-units are randomly arranged "head to tail" in the polyisoprene chain. The polymerisation of isoprene under the influence of $(\pi\text{-}C_5H_9)_2Cr$ in hydrocarbon solution yields a polymer containing only 1,2- and 3,4-units (in roughly equal quantities)[29]. Entry of monomer into the chain is accomplished only by path *a*.

When tris-$\pi$-allylchromium interacts with vacuum-ignited aluminium silicate, silica gel, or aluminium oxide, the organometallic compound passes quantitatively from solution to the surface[30,31]:

$$\pi\text{-}R_3Cr + HO\text{—}|SiO_2 \rightarrow \underset{R}{\overset{R}{>}}Cr\text{—}O\text{—}|SiO_2 + RH$$
(A)

$$\pi\text{-}R_3Cr + \begin{matrix} HO\text{—} \\ HO\text{—} \end{matrix}\Big|Al_2O_3 \rightarrow RCr\begin{matrix} O\text{—} \\ O\text{—} \end{matrix}\Big|Al_2O_3 + 2RH \ .$$
(B)

The reaction with aluminium silicate results in the separation of one RH molecule and the formation of an active centre (A) in which two alkenyl groups are retained by one chromium atom. An important feature is that, in contrast to the initial tris-compound, the new organochromium compound is extremely stable when kept at room temperature for a long time. Since this catalyst causes also the polymerisation of alkenes, it can reasonably be assumed that the $\sigma$-state of the chromium–carbon bond is more characteristic of this organochromium compound. This catalyst was highly stereospecific for the synthesis of *trans*-polyisoprene and *trans*-polybutadiene. Because of the great stability of chromium–carbon bonds, polymerisation takes place by a mechanism of "live" chains without destruction of active centres. Two polymer chains are formed on one chromium atom, with continuous increase in molecular weight with the degree of polymerisation. The reaction of the tris-compound with aluminium oxide produces an active centre (B) in which one carbon–chromium bond is preserved at the chromium atom. In the polymerisation of butadiene and isoprene this catalyst yields polymers containing 92–93% of *cis*-units.

It has thus been shown for chromium compounds that, depending on the electronic state of the transition metal

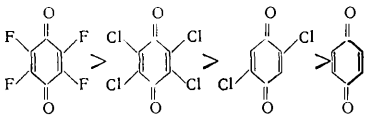
and the nature of the ligands surrounding it, all kinds of microstructures can be realised with great selectivity on the same metal atom. This principal, which is probably common to many transition metals, has been confirmed for compounds of titanium, niobium, cobalt, and nickel. Although the compounds $\pi$-$R_3Cr$, $\pi$-$R_3Nb$, $\pi$-$R_3Co$, etc. behave in exchange reactions as molecules containing the metal in the tervalent state, the latter is in effect present in a more reduced state, in view of its greater electronic saturation in $\pi$-allyl complexes. This principle is consistent with several specific reactions of poly-$\pi$-allyl complexes that are typical of zerovalent metals. In this sense the transitions $\pi$-$R_3M \rightarrow \pi$-$R_2MX \rightarrow \pi$-$RMX_2$ can be regarded as oxidation accompanied by increase in the positive charge on the metal atom, although the exchange equivalent remains unchanged. The systems become *cis*-stereoregulating after one or two alkenyl groups have been replaced by electronegative ligands (Table 1A).

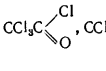
Table 1A.

| Catalyst | Chain microstructure |
|---|---|
| $\pi$-$R_3Cr$ | 81% 1.2-[48,60,61] |
| $\pi$-$R_3Nb$ | 100% 1.2-[48] |
| $\pi$-$R_2CrOSi\equiv$ | 96% *trans*-[30,31] |
| $\pi$-RCr(O—Al≡)(O—Al≡) | 93% *cis*-[30,31] |
| $\pi$-$RCrCl_2$ | 93% *cis*-[49,60,61] |
| $\pi$-$R_2CrOCOCCl_3$ | 93% *cis*-[48,60,61] |
| $\pi$-$R_2NbCl$ | 91% *cis*-[48] |

Higher oxides of chromium ($CrO_3$) on aluminium silicate have long been known as catalysts for the polymerisation of alkenes. Their catalytic action was earlier attributed to the presence of $Cr^{4+}$, $Cr^{5+}$, and $Cr^{6+}$. Detailed investigation of this system [30,31,62] has shown that the active centre effecting polymerisation is identical with the centre (A) obtained in the reaction of $\pi$-$R_2Cr$ with aluminium silicate: i.e. chromium is present in the active centre in a more reduced state than $Cr^{3+}$. In both cases polymerisation takes place by a mechanism of "live" chains with the formation of *trans*-units, and values of the copolymerisation constants $r_1$ and $r_2$ for the pair butadiene–isoprene fully coincide.

(*b*) Organonickel compounds





Research on the use of organonickel compounds for the stereospecific polymerisation of dienes has been published in many papers and reviews [63-65]. We shall consider only a few of the most important results of interest in connection with the mechanism of stereoregulation. The compounds $\pi$-RNiX catalyse the polymerisation of dienes in solution. The nature of the anion X has a significant influence on the stereospecificity of the catalytic effect:

1. $\pi$-RNiX (X=I, Br, Cl, O—C$_6$H$_2$Br$_3$) → Crystalline *trans*-polymers of butadiene and isoprene (Refs. 27, 28, 66-71),

2. $\pi$-RNiY (Y=$OCOCCl_3$, $OCOCF_3$, O—C$_6$H$_3$(NO$_2$)$_2$) → *cis*-Polybutadiene (Refs. 27, 28, 72).

Replacement of X by more electronegative ligands leads to a significant enhancement of the catalytic activity of the system and to a reversal of the stereospecificity. However, systems based on complexes of $\pi$-RNiCl with various electron-accepting compounds proved to be the most effective and *cis*-stereoselective (Table 2). [63,73-77]

Table 2. Complexes of alkenylnickel halides with electron acceptors.

| Complex | Electron-accepting compound (A) |
|---|---|
| $\pi$-$R\overset{(+)}{N}iCl(Br, I)$ ⋮ $A^{(-)}$ |  |
| (charge transfer complexes) | $CCl_3COCCl_3$,  ,  , $CCl_3COOH$, $CF_2COOH$, $I_2$ |
| $\pi$-$RNi^{(+)}[ClA]^{(-)}$ | $AlHal_3$, $TiHal_4$, $SnHal_4$, $ZnHal_2$, $CoHal_2$, |
| (anion-transfer complexes) |  |

Charge-transfer complexes are formed with the aid of halogenoquinones, whose effectiveness is consistent with the redox potential of the quinones, halogenated carbonyl compounds, halogenated acids, etc. Anion-transfer complexes (such as ion-pairs) are formed by various Lewis acids. The reversal of stereospecificity on passing from $\pi$-RNiI to the $\pi$-RNiI–$I_2$ system indicates directly that the effect is not due to replacement of ligands but to increase in the positive charge on the nickel atom.

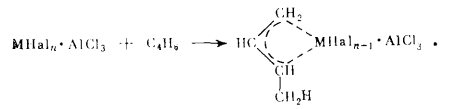
Table 3. Catalytic system and structure of polybutadiene.

| Catalytic system | Chain microstructure, % | | | $[\eta]$, dl g$^{-1}$ | Physical state of polymer | Ref. |
|---|---|---|---|---|---|---|
| | 1,2- | *cis*- | *trans*- | | | |
| $\pi$-$R_3MoCl$ | 90 | 2 | 8 | 3.1 | amorphous | 37 |
| $\pi$-$R_3MoOCOCCl_3$ | 97 | — | 3 | 3.0 | amorphous | 37–39 |
| $\pi$-$R_4Mo + CCl_3COCl$ | 95 | — | 5 | 6.5 | amorphous | 38,39 |
| $\pi$-$R_4Mo$ + chloranil | 95 | — | 5 | 5.4 | amorphous | 38,39 |
| $\pi$-$R_4Mo + C_3H_5I$ | 96 | — | 4 | 2.0 | crystalline | 40 |
| $\pi$-$R_4W + C_3H_5Cl(I)$ | 95 0 | — | 5.0 | | amorphous | 41 |
| $\pi$-$R_4W + O_2$ | 99 5 | — | 0.5 | | amorphous | 41 |

Kinetic investigation of various nickel systems has thus far revealed a fractional order (0.5) with respect to the catalyst only for $(\pi\text{-RNiX})_2$, where X = I, Br, Cl, which indicates that polymerisation involves only a small quantity of monomeric forms in equilibrium with the main, inactive dimeric form [70,71]. The kinetic orders with respect to the catalyst established in *cis*-regulating systems, at least in the case of $\pi$-$RNiOCOCF_3$ and complexes with electron acceptors, indicated that the organonickel centres were fully involved in steps of chain growth [27,28,56,57,78].

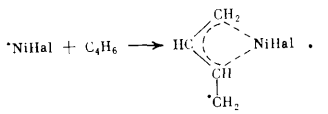
(*c*) Organomolybdenum and organotungsten compounds

Organometallic compounds based on tetra-$\pi$-allylmolybdenum are highly effective catalysts for the production of amorphous and crystalline 1,2-polybutadiene [37-40] (Table 3). The high intrinsic viscosity of the polymer indicates the formation of a very small quantity of long-lived active centres. Detailed study of the $\pi$-$R_4Mo$ + $CH_2:CHCH_2I$ system, which forms crystalline 1,2-polybutadiene, has shown that the active centre is the compound $\pi$-$R_2Mo(I)$-p, which results from the interaction of the above components. Chain growth occurs at the allyl-molybdenum $\sigma$-bond, but transition of the $\sigma$-bond into the stable $\pi$-allyl form is an act of chain termination[37-40].



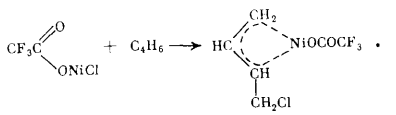
As is shown in Table 3, systems based on $\pi$-allyl derivatives of tungsten also effect 1,2-stereoregulation[41].

3. Formation of Organometallic Compounds during Polymerisation



Transition-metal compounds of the $\pi$-allyl type are formed as a result of diverse reactions because of their relatively high stability. Metal hydrides in the presence of butadiene are converted into the corresponding $\pi$-but-2-enyl complexes, as was proved [79,80] with nickel, cobalt, and chromium:

$$NiH_2 + C_4H_6 \rightarrow (\pi\text{-}C_4H_7)_2Ni\ ,$$
$$CoH_2 + C_4H_6 \rightarrow (\pi\text{-}C_4H_7)_nCo\ ,$$
$$CrH_3 + C_4H_6 \rightarrow (\pi\text{-}C_4H_7)_3Cr\ .$$



Complexes of halides of transition metals (nickel, cobalt, vanadium) with aluminium chloride cause the stereospecific polymerisation of dienes, presumably [81,82] by the reaction

Defect halide salts (subhalides) of nickel, cobalt, and niobium, obtained by heating in a vacuum, effect the polymerisation of dienes with the stereospecificity characteristic of the corresponding $\pi$-allyl complexes. It has been proved for nickel halides that formation of an organometallic active centre involves an intermediate radical-ion stage [83-85]:

Mixed salts react with dienes in several cases with the formation of $\pi$-allyl active centres [86]:

When $CF_3COONi^{36}Cl$ is used, the labelled chlorine atom is incorporated into the polymer chain [87].

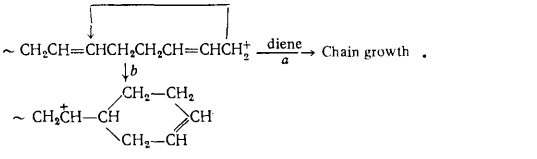
In Ziegler catalysis organic compounds of transition metals are formed by exchange reactions with aluminium alkyls:

$$MX_n + R_3Al \rightarrow RMX_{n-1} + R_2AlX\ ,$$
$$MX_n + R_2AlCl \rightarrow RMX_{n-1} + RAlClX\ .$$

Addition of a diene at the alkyl–metal bond tends to stabilise the resulting organometallic compound as a $\pi$-allyl complex. With titanium(IV) halides a $\pi$-allyl active centre can be formed only after reduction to titanium(III). The alkylaluminium halides probably act subsequently as electron acceptors, forming complexes with $RMX_{n-1}$ and enhancing their effectiveness and stereospecificity, as was established above for $\pi$-allyl complexes of nickel.

4. Nature of Secondary Reactions in Polymer chains during Stereospecific Polymerisation of Dienes by Ziegler Systems

The Ziegler–Natta catalytic systems employed for the stereospecific polymerisation of dienes consist of organoaluminium compounds and halides of transition metals, mainly titanium, nickel, and cobalt. With the first of these metals appearance of the catalytic complex is preceded by reduction of the tetrahalide to the trihalide accompanied by formation of $R_2AlHal$:



$$R_3Al + TiHal_4 \rightarrow R_2AlHal + RTiHal_3\ ,$$
$$RTiHal_3 \rightarrow {}^1/_2R_{-H} + {}^1/_2R_{+H} + TiHal_3\ .$$

Under certain conditions alkylaluminium halides and titanium(IV) chloride are catalysts for cationic processes. In catalytic systems based on nickel and cobalt halides the alkylaluminium halides and water are used in the molar proportions

$$NiCl_2\ (CoCl_2):R_2AlCl:H_2O = 1:150:10$$

In such cases the initial catalytic system is characterised by extremely high cationic activity, as is illustrated by the possible use of its components ($R_2AlCl + H_2O$) to initiate the polymerisation of isobutene [88]. The organometallic active centres that effect the stereospecific polymerisation of dienes are capable of initiating the oligomerisation and polymerisation of alkenes, which indicates the theoretical possibility that double bonds of the polymer chain are involved. The most important results of investigations on these aspects are reported below.

In anionic and coordination polymerisation conjugated dienes are considerably more reactive than the corresponding alkenes. A distinguishing feature of cationic systems is the comparatively small differences in reactivity between dienes and alkenes [89-91]. Thus isopentene ($m_1$) is more reactive than butadiene ($m_2$) on cationic copolymerisation: $r_1 = 0.90$ and $r_2 = 0.38$

Because of the great probability of reaction (*b*) cyclised polymers, less unsaturated than would be expected theoretically, are formed even at low degrees of conversion in the cationic polymerisation of dienes. In dilute solutions of natural rubber and *cis*-polybutadiene intramolecular cyclisation takes place under the influence of the $R_2AlCl$–$H_2O$ system, accompanied by diminution of unsaturation with maintenance of the molecular weights of the polymers [92-94].

It was shown for the model compound 3-methylpent-2-ene [95] that the cation-active components of Ziegler systems initiate the *cis–trans* isomerisation of isoprene

units extremely efficiently (Table 4). Analogous isomerisation effects were observed[92,96,97] in benzene solutions of natural rubber under the influence of ethylaluminium dichloride, diethylaluminium monochloride, and titanium tetrachloride; the coactivators in such processes were traces of water and other compounds.

Table 4. Variation in composition of reaction mixture and structure of 3-methylpent-2-ene (at 60°C).

| Catalyst (mole % on monomer) | Продолжительность реакции, мин | Isolated, % on initial | | Monomer structure, % | |
|---|---|---|---|---|---|
| | | monomer ($C_6$) | dimer ($C_{12}$) | *cis* | *trans* |
| $C_2H_5AlCl_2$ (3.6%) | 0 | 100 | — | 86 | 14 |
| | 25 | 68 | — | 70 | 30 |
| | 60 | 54 | 46 | 60 | 40 |
| | 90 | — | — | 48 | 52 |
| $TiCl_4$ (2.5%) | 8 | 79 | 21 | 66 | 34 |
| | 60 | 46 | 54 | 52 | 48 |
| Equilibrium | — | — | — | 42.2 | 57.8 |

Reactions of a third type occurring under the influence of cationic initiators involved the migration of double bonds in the polymer chain. Such migration takes place in polybutadiene in the presence of titanium tetrachloride and alkylaluminium chlorides[92], until conjugated systems are formed:

$$\sim CH_2CH{=}CHCH_2CH_2CH{=}CHCH_2\sim \xrightarrow{+H^+} \sim CH_2CH_2\overset{+}{C}HCH_2CH_2CH{=}CHCH_2 \sim \xrightarrow{-H^+}$$
$$\rightarrow \sim CH_2CH_2CH{=}CHCH_2CH{=}CHCH_2\sim \xrightarrow{+H^+}$$
$$\rightarrow \sim CH_2CH_2CH_2\overset{+}{C}HCH_2CH{=}CHCH_2 \sim \xrightarrow{-H^+} \sim CH_2CH_2CH_2CH{=}CH{-}CH{=}CHCH_2 \sim .$$

A detailed study of these reactions has been made[98].

Nuclear magnetic resonance spectroscopy of the *cis*-polybutadiene obtained in the presence of the $R_2AlCl$–$CoCl_2$ system showed the presence of : CH.$CH_2$.CH : groups, which characterise the first stage in the migration of double bonds[99].

Research showed the usefulness of introducing into the catalytic systems components that inhibit the development of cationic processes. Such inhibitors may be weak Lewis bases, which do not affect the rate of polymerisation, the molecular weight, or the chain microstructure in the stereospecific polymerisation of butadiene, as was shown for diphenyl ether[100].

In the absence of the monomer (a conjugated diene) migration and isomerisation of double bonds can be effected in model hydrocarbons and in polybutadiene not only by Ziegler systems containing cation-active components but also by organometallic complexes, active centres for stereospecific polymerisation. Thus at room temperature $\pi$-allyl complexes of nickel of general formula $\pi$-RNiHal effect[101,102] the chain isomerisation of hexa-1,5-diene

$$\underset{(A)}{CH_2{=}CHCH_2CH_2CH{=}CH_2} \rightarrow \underset{(B)}{CH_3CH{=}CHCH_2CH{=}CH_2} \rightarrow \underset{(C)}{CH_3CH{=}CH{-}CH{=}CHCH_3}$$

which involves the successive addition and detachment of HNiHal at the double bond. Migration of the double bond (A) → (B) is accompanied by the formation of *cis*–*trans* isomers and by the dimerisation of hexa-1,5-diene, which also involves addition of the organonickel compound at the double bond in the alkene. At room temperature the $\pi$-but-2-enylnickel chloride–chloroanil complex—an effective stereospecific catalyst for the production of *cis*-polybutadiene—causes the isomerisation of but-1-ene and but-2-ene into the equilibrium mixture[103].

Addition of an organometallic active centre at a double bond in the chain during the polymerisation of dienes should lead to the formation of branched polymers. The probability of such reactions is small, for conjugated dienes are considerably more reactive than alkenes in coordinated systems. The appearance of conjugated double bonds in a polymer chain as a consequence of acts of migration is probably one of the main reasons for the formation of branched polymers in the polymerisation of butadiene under the influence of a "cobalt" catalytic system. This system is characterised by very small differences in reactivity between butadiene and its alkyl derivatives (isoprene and 2,3-dimethylbutadiene),[104–106] and the "polymeric" diene formed may be actively involved in copolymerisation with butadiene. It has been demonstrated for cobalt, nickel, and chromium catalytic systems that the main reaction limiting chain growth is chain transfer to the monomer:

$$\sim \pi\text{-}CH_2CH{=}CHCH_2{-}MX_n \xrightarrow[a]{C_4H_6} \text{Chain growth}$$
$$b\downarrow C_4H_6$$
$$\sim CH{=}CH{-}CH{=}CH_2 + \pi\text{-}C_4H_7MX_n \xrightarrow{C_4H_6} \text{Chain growth} .$$

Reaction (*b*) is accompanied by the formation of polymer molecules containing a conjugated system of double bonds at the ends of the chains[60,61,107], whose involvement in polymerisation results in branched macromolecules.

## 5. Some Aspects of Copolymerisation in Coordination Systems and the Effect of Solvating Additives

On copolymerisation under the influence of RLi in hydrocarbon media dienes are considerably more reactive[108–111] than is styrene ($r_1 \gg r_2$). When the same monomers undergo copolymerisation in the presence of RLi in the usual solvating media or of organo-potassium and -sodium compounds in any media, under conditions leading to formation of 1,2- and 3,4-units, styrene has proved to be considerably more reactive[112,113] than dienes. Both phenomena (change in microstructure and reversal of reactivity) are genetically related to enhancement of the polarity of the carbon–metal bond. With compounds of transition metals, independently of the character of the stereoregulation, dienes are always considerably more reactive than styrene (Table 5).

Table 5. Relative reactivities of butadiene ($m_1$) and styrene ($m_2$) and the chain microstructure.

| Catalytic system | Copolymerisation constants | | Chain microstructure, % | | | Ref. |
|---|---|---|---|---|---|---|
| | $r_1$ | $r_2$ | *cis*-1,4 | *trans*-1,4 | 1,2- | |
| RLi in oxolan | 0.20 | 8.0 | 0 | 9 | 91 | 114 |
| RLi in diethyl ether | 0.11 | 1.78 | — | — | — | 114 |
| RLi in toluene | 15.0 | 0.05 | 44 | 48 | 8 | 109 |
| $\pi$-RNiCl–Acceptor | 4.6 | 0.13 | 92 | 6 | 2 | 115 |
| $(\pi\text{-}C_3H_5)_4Mo$–Acceptor | 27.5 | 0,02 | 4 | 5 | 91 | 116, 117 |
| $(\pi\text{-}C_3H_5)_4W$–Acceptor | 10.1 | 0.2 | 0 | 9 | 91 | 116, 117 |
| $(\pi\text{-}C_3H_5)_4Zr$ | 34 | 0.02 | 61 | 4 | 35 | 116, 117 |
| $(C_6H_5CH_2)_4Ti$ | 27 | 0 02 | 15 | 25 | 60 | 116, 117 |

The results indicate a coordination mechanism for the formation of any type of unit on a transition metal. $\pi$-Allyl active centres are considerably more stable than the corresponding styrene derivatives. Entry of styrene into

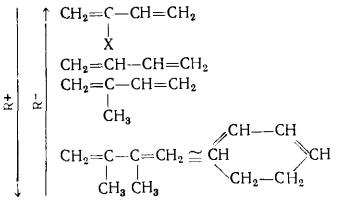


Table 6. Values of $r_1$ and $r_2$ in the copolymerisation of dienes in hydrocarbon media.

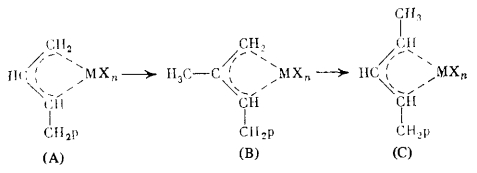
| RLi | 3.38 | 0.47 | 110—111 | | | | | | | | | |



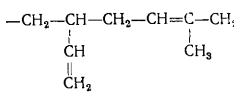
a chain therefore involves a sharp decrease in molecular weight owing to chain-transfer reactions [115]

With respect to relative activity on ionic copolymerisation dienes form the well known sequence

in which X is an electronegative substituent. This sequence breaks down with systems in which the stage of coordination of the diene with the transition metal begins to play a significant part. Table 6 gives data on copolymerisation constants of dienes in various systems. In most cases butadiene is more active than alkylated dienes, which is typical of anionic active centres, but $r_1 = r_2$ in several systems ($R_3Al–TiCl_4$, $R_2AlCl–CoCl_2$, and "chromium" systems) or even $r_2 > r_1$ in the copolymerisation of butadiene with cyclohexadiene effected by π-allyl complexes of nickel. Passage from a butadienyl (A) to an isoprenyl (B) and especially a pentadienyl (C) π-allyl centre

(A) (B) (C)

is extremely advantageous, since the stability of the organometallic compound increases in this sequence. Low values of $r_2$ for pentadiene and isoprene on copolymerisation with butadiene indicate that steric factors in the stage of coordination of the monomer on the transition metal are probably of decisive importance for the reactivity.



The most interesting feature of copolymerisation in coordination systems is the mutual influence of monomers on the character of the stereoregulation. This phenomenon, observed by many workers [104–106,121,122,128] and directly connected with the nature of the active centres and the mechanism of formation of units in them, can be illustrated by a few examples (Table 7). In the $R_2AlCl–CoCl_2$ system the entry of alkylated butadiene derivatives into the chain

Table 7. Microstructure of butadiene units in copolymers [121].

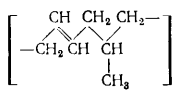
*The remainders are the sums of *cis*-1,4 and *trans*-1,4 units.

is accompanied by a corresponding increase in the proportion of 1,2-butadiene units instead of the *cis*-units characteristic of a butadiene homopolymer. A decrease is observed in the number of 3,4-isoprene units relative to polyisoprene obtained on the same catalyt [104–106,121,128]. Hence linking butadiene and isoprene units in the copolymer have the structure

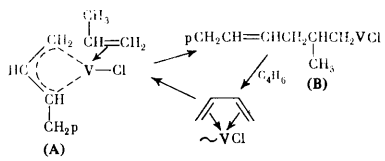
In the $R_3Al–TiI_4$, $R_3Al–TiI_2Cl_2$, and π-RNiX–Acceptor systems the same monomers convert the *cis*-butadiene units predominantly into *trans*-units. Similar effects are produced by electron-donating additives (ethers, esters, sulphides, amines) in the homopolymerisation of butadiene. In the $R_2AlCl–CoCl_2$ system they cause an increase in the number of 1,2-units, but in the other systems they increase the quantity of *trans*-units [129–136].

Chromium-containing systems enable stereoregular *trans*-copolymers of butadiene and isoprene to be obtained in which the structure of the units in the homopolymers is preserved. With *cis*-regulating nickel systems statistical *cis*-copolymers of butadiene and cyclohexadiene can be obtained, for which pair of monomers [36] $r_2 > r_1$.



As noted above, oxygen-containing compounds increase considerably the content of 3,4-, 1,2-, and *trans*-units in the polymerisation of butadiene and isoprene under the influence of organotitanium(IV) compounds. In most cases

the change in stereospecificity in the presence of electron-donating components is accompanied by a considerable decrease in the rate of polymerisation, probably due mainly to the equilibrium



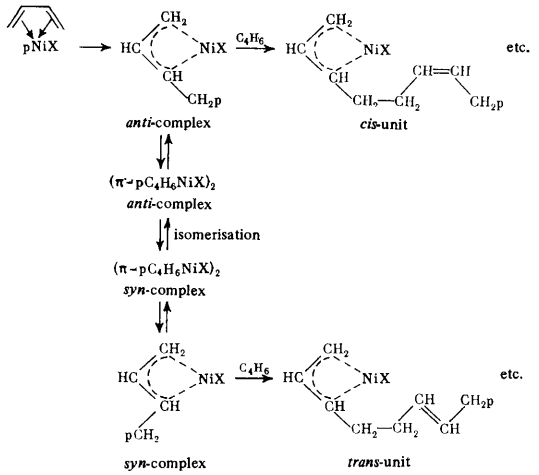
$$\overset{\text{Donor}}{\underset{\downarrow}{\text{pMX}_n}} + \text{Diene} \rightleftarrows \overset{\text{Diene}}{\underset{\downarrow}{\text{pMX}_n}} + \text{Donor} .$$

With sufficiently high concentrations of solvating components or in the case of bidentate complexing additives polymerisation ceases.

In the presence of certain oxygen-containing components at low temperatures systems containing organoaluminium compounds with vanadium and titanium halides yield[22,23] an alternating copolymer in which the butadiene units are mainly in the *trans*-configuration.

With strict alternation of butadiene and propylene units, and the same type of structure for the former, the repeating units in the main polymer chain will contain six carbon atoms instead of the four in natural rubber and in stereoregular polymers of dienes. Vanadium is assumed[22,23] to be bivalent in the active centre, and the mechanism of the process to be

In the $\pi$-allyl complex (A) vanadium retains one coordination position, which is occupied by the alkene. After the latter has entered the chain (B), bidentate coordination of the diene becomes possible. In this way a self-regulating system is established for alternation of the monomers.



## 6. Mechanism of Stereoregulation

### (*a*) Mechanism of formation of *cis*- and *trans*-units

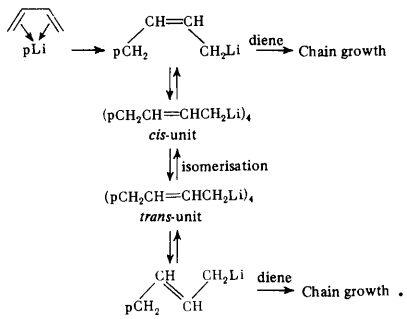
As noted above, the primary addition of butadiene to HNiX yields an *anti*-complex, which then isomerises into a *syn*-complex. The hydrogenolysis of $\pi$-but-2-enylnickel chloride, obtained from but-2-enyl chloride and nickel carbonyl, forms 95% of *trans*-butene with but-1-ene completely absent[58]. Hence the content of the *syn*-form at equilibrium is close to 100%. The rate of *anti–syn* isomerisation of the complex depends, of course, on the nature of the metal and of the ligands. A diene coordinates with a transition metal always as a bidentate ligand: as a unidentate ligand it would give way to the more basic monoenes. This factor is probably decisive in the formation of alternating copolymers of dienes with alkenes: in the presence of two vacancies the diene is coordinated preferentially, but in the presence of one vacancy the alkene. The especially advantageous character of bidentate coordination is illustrated by the fact that compounds of the type $-OCH_2CH_2O-$ or $\rangle NCH_2CH_2N\langle$ on coordination polymerisation are tenfold as effective as oxolan and other solvating agents in influencing the kinetics of polymerisation and the microstructure of the chain. The considerably higher activity of conjugated dienes than of styrene in copolymerisation under the influence of transition-metal compounds and of organolithium compounds in hydrocarbon medium is due to preferential coordination of the diene. In the suggested mechanism of stereoregulation dienes are coordinated as bidentate ligands in a cisoid configuration. We shall first consider systems exhibiting a fractional kinetic order with respect to the catalyst.

The rate of polymerisation of butadiene under the influence of $\pi$-RNiHal is proportional to the square root of the catalyst concentration[70]. Hence polymerisation takes place only on the monomeric forms $\pi$-RNiHal in equilibrium with the main dimeric form $(\pi\text{-RNiHal})_2$, which is not involved in the polymerisation. A dimeric state has been demonstrated[50] for the $\pi$-allyl and $\pi$-but-2-enyl complexes $\pi$-RNiHal.

Primary entry of the diene into the active centre leads to an *anti*-complex, from which the unit is then displaced into the chain as a *cis*-unit. Processes of *anti–syn* isomerisation occur mainly in the "sleeping" dimeric associate, which is not involved in polymerisation. This probably applies also to the polymerisation of dienes under the influence of organolithium compounds in hydrocarbon solution. It is well known that alkyl derivatives of lithium are present as association complexes in hydrocarbon solution. Numerous investigations have shown[137–140] that "live" polymeric organolithium compounds are present in hydrocarbon medium as the association complexes $(pLi)_n$, where $n = 2$ for styrene and $n = 4$ for butadiene and isoprene, the rate of polymerisation being proportional to the concentration $[pLi]^{1/n}$. Hence the ligitimate conclusion was drawn that the stage of chain growth involves the monomeric form of the organolithium compound, whose proportion at equilibrium is extremely small, and that association complexes are not appreciably involved in polymerisation. Recent investigations have shown[141,142] that the microstructure of polybutadiene and polyisoprene depends on the concentration of the organolithium compound in solution, and that *cis*-stereoregulation occurs at vanishingly low concentrations of the latter (Table 8).

The degree of dissociation of the association complexes $(pLi)_n$ into the monomeric forms increases with dilution and with rise in temperature. This suggests that *cis*-units are formed only in the monomeric form pLi, but other types of units in associated forms of pLi, in which the carbon–metal bond is more strongly polarised. The autosolvation effect in association is due to enhancement of the polarity of this bond, and the participation of association complexss in polymerisation should yield structures typical of solvates of pLi with electron-donating

components. It has recently been shown[143] that the polymerisation of dienes from the vapour phase on crystalline ethyl-lithium is very slow, with preferential formation of 3,4-, 1,2-, and *trans*-units. It is therefore highly probable that stereoregulation during polymerisation in hydrocarbon media is accomplished by the scheme[144]



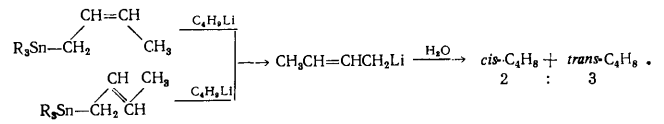


Table 8. Effect of RLi concentration on chain microstructure (in n-heptane at 20°C).

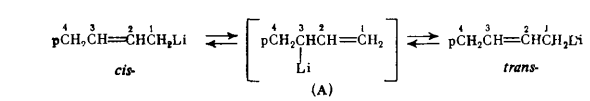

| Monomer | [RLi], M | Microstructure of chain, % | | | | Ref. |
|---|---|---|---|---|---|---|
| | | *cis* | *trans* | 1,2- | 3,4- | |
| Isoprene | 0.061 | 74 | 18 | — | 8 | 141 |

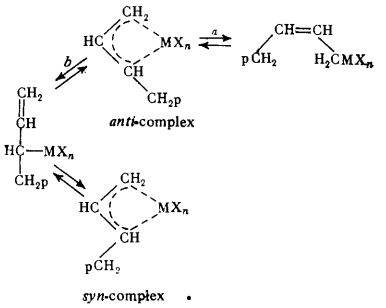
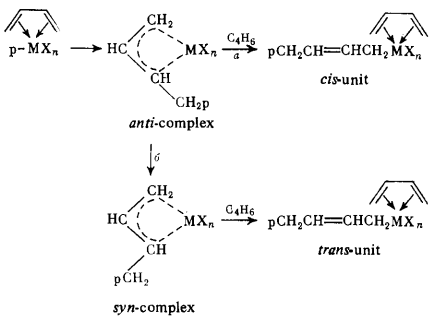
| | 0.00008 | 97 | — | — | 3 | 141 |
| Butadiene | 0.073 | 30 | 46 | 24 | — | 141 |
| | 0.0124 | 44 | 46 | 10 | — | 141 |
| | 0.0003 | 47 | 45 | 8 | — | 141 |
| | 0.000054 | 70 | 28 | 2 | — | 141 |
| | 0.00001 | 86 | 10 | 4 | — | 142 |

Decomposition with water of but-2-enyl-lithium, formed from butyl-lithium and *cis*- or *trans*-but-2-enyltrialkyltin in ether, is a mixture of *cis*- and *trans*-butenes[145] in the proportion 2 : 3:



This ratio of *cis*- and *trans*-units, corresponding roughly to the composition of polybutadiene obtained under the same conditions, is probably close to the equilibrium value for the but-2-enyl-lithium–diethyl ether solvate.



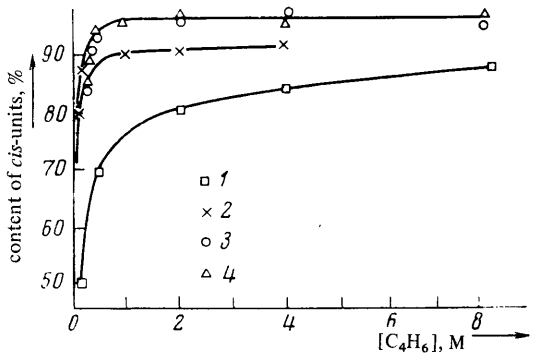
The maximum tendency to coordinate develops on the monomeric forms of pLi (and pNiX), and the diene behaves as a bidentate ligand. Primary acts of addition to the monomeric form of pLi yield a *cis*-unit, but formation of other types of structure is due mainly to isomerisation of the active centre in association complexes, although the latter may to some extent be involved in polymerisation with formation of secondary structures (3,4-, 1,2-, and *trans*-units). Isomerisation of a unit in a solvate would probably involve a stage of migration of lithium to the third carbon atom from the end of the chain

since direct *cis*–*trans* transitions are improbable. In association complexes lithium is able to migrate as a result of intermolecular transitions. The probability of isomerisation in solvates and aggregates increases with the polarisation of the carbon–lithium bond and the degree of charge delocalisation. A content of ~5–10% of 1,2- and 2,3-units when butadiene and isoprene are polymerised under the influence of RLi in hydrocarbon media indicates the presence of reactive structures (A) during polymerisation. An analogy exists between *cis*–*trans* isomerisation during anionic polymerisation and *anti*–*syn* transitions in π-allyl complexes of transition metals. In the latter case isomerisation can evidently take place only through π–σ transitions:

The π–σ equilibrium (*b*) leads to *anti*–*syn* isomerisation. Most catalytic systems based on compounds of transition metals are characterised by the kinetic first order of polymerisation with respect to the catalyst, and the whole of the catalyst, present mainly in the monomeric state, usually takes part in acts of chain growth. In this case the ratio of *cis*- and *trans*-units in the chain should be determined by the ratio of rates of chain growth on the active centre (reaction *a*) and of *anti*–*syn* (*cis*–*trans*) isomerisation of the active centre (reaction *b*):

Although there are at present no direct quantitative data on *anti*–*syn* isomerisation processss, several experimental rules are consistent with the above mechanism of stereoregulation.

(*b*) Effect of monomer concentration on chain microstructure



It follows from the above scheme that, in *cis*-regulating catalytic systems in which the rate of chain growth is proportional to the monomer concentration, fall in the latter should be accompanied by increase in the quantity of *trans*-units. The influence of butadiene concentration on chain microstructure has been studied[146,147] in various systems

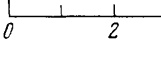
1) $R_3Al + TiI_2Cl_2$ 2) $R_2AlCl + CoCl_2$
3) π-RNiCl · $(CCl_3COO)_2Ni$ 4) π-RNiOCOCF$_3$

characterised by first-order polymerisation with respect to the monomer. Systems (1) and (2) are of Ziegler type

and the individual organonickel compounds (3) and (4) are stereoselective for the *cis*-polymerisation of butadiene.

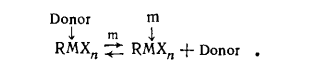
The diagram shows that at low monomer concentrations the quantity of *trans*-units increases considerably at the expense of *cis*-units in all cases. Such *cis–trans* conversion can be explained by variation in the relative rates of chain growth and isomerisation. In cases in which the monomer undergoing coordination affects also the rate of *anti–syn* isomerisation no relation may be observed between monomer concentration and chain microstructure.

Dependence of content of *cis*-1,4 units in polybutadiene on initial concentration of butadiene in the presence of: 1) $TiI_2Cl_2$ + (iso-$C_4H_9)_3Al$; 2) $CoCl_2$ + $R_2AlCl$; 3) $\pi$-$C_5H_9$. .NiCl.Ni$(OCOCCl_3)_2$; 4) $\pi$-$C_3H_5NiOCOCF_3$.



(*c*) Relative rates of chain growth in *cis*- and *trans*-regulating systems

Previous investigations in our laboratory of individual organometallic compounds—of titanium, nickel, chromium, niobium, and cobalt—have shown that all kinds of microstructures can be produced with high selectivity on the same transition metal depending on the nature of the ligands surrounding it[48,49,60,61,63]. From the suggested scheme of stereoregulation it might have been expected that on a given metal *cis*-regulating systems would generally be characterised by considerably higher rates of chain growth than would *trans*-regulating systems. Relative rates of chain growth have been compared[148] in such systems based on chromium(III), nickel(II), and titanium(IV) compounds.



The polymerisation of dienes under the influence of the active centre $R_2Cr–O–|SiO_2$, resulting from the interaction of $\pi$-$R_3Cr$ with hydroxy-groups or ignited aluminium silicate, takes place by a mechanism of "live" chains and yields *trans*-polymers[30–32]. The molecular weight of the polymer is given by the formula $M_b = m/2n$, where $m$ is the quantity of monomer polymerised and $n$ the concentration of the organochromium compound. The active centre formed from $\pi$-$R_3Cr$ and ignited aluminium oxide is a catalyst for *cis*-polymers of isoprene and butadiene. A characteristic feature of this system is the formation of products of very high molecular weight at low degrees of conversion, as a consequence of the high rate of chain growth.

Comparison of molecular weights at a low degree of conversion indicates the ratio $v_a/v_b$ of the rates of chain growth in the systems (Table 9). Published kinetic data[43,56,57,70] have been used to calculate such ratios for nickel and titanium compounds. For systems in which the rate of polymerisation was proportional to the square root of the concentration of the transition metal it was arbitrarily assumed that the quantity of monomeric active centres was 1% of the total quantity of catalyst. Table 9 shows that with a given transition metal inversion of stereospecificity from *cis*- to *trans*-regulating is accompanied by a sharp drop in the rate of chain growth. Any factors tending to "jam" the end-group of a growing chain in an active centre entail increase in the proportion of *anti–syn* isomerisation and hence in the content of *trans*-units in the polymers.

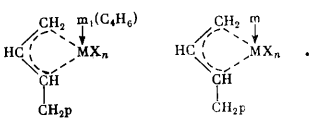


Table 9. Ratio of rates of growth in *cis*- and *trans*-regulating systems.

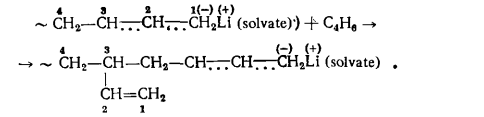
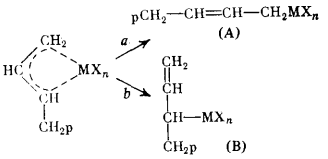
| No. | Catalytic system | Monomer | Microstructure, % | | | | $v_a/v_b$ |
|---|---|---|---|---|---|---|---|
| | | | *cis* | *trans* | 1,2- | 3,4- | |
| 1a |  | isoprene | 95 | 0 | 0 | 5 | ~$10^3$ |
| 1b |  | isoprene | 0 | 95 | 0 | 5 | |
| 2a | $\pi$-RNiCl·$(CCl_3COO)_2Ni$ | butadiene | 97 | 0 | 3 | — | $7.8\cdot10^2$ |
| 2b | $(\pi\text{-RNiI})_2$, $v=k[Ni]^{0.5}$ | butadiene | 0 | 95 | 5 | — | |
| 3a | $(C_6H_5CH_2)_3TiI$, $v=k[Ti]^{0.5}$ | butadiene | 95 | 2 | 3 | — | $7.4\cdot10^3$ |
| 3b | $(C_6H_5CH_2)_4Ti$ | butadiene | 20 | 20 | 60 | — | |

The inversion of stereospecificity from *cis* to *trans* under the influence of electron-donating compounds coordinated with the transition metal is evidently due to increase in the "lifetime" of the terminal unit in conformity with the equilibrium

As noted above, such inversion is accompanied by a considerable decrease in the rate of polymerisation. The mutual influence of monomers on chain microstructure in coordination copolymerisation observed in several investigations can be explained, in terms of the above mechanism of stereoregulation, by variation in the rate of entry of the monomers into the chain

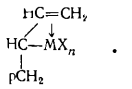


If the rate of entry of $m_2$ (isoprene, pentadiene, etc.) is lower than the rate of entry of butadiene, the "lifetime" of the terminal $\pi$-but-2-enyl unit is increased, as well as the probability of *anti–syn* isomerisation.

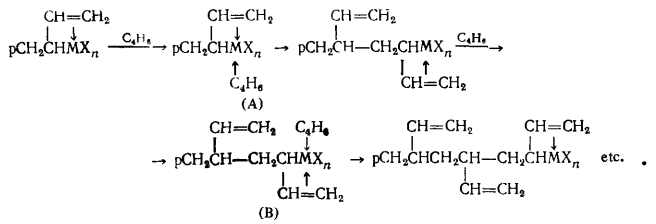


(*d*) Mechanism of formation of 1,2- and 3,4-units

Numerous investigations have established that organolithium compounds in the presence of various solvating compounds (oxolan, etc.), and organopotassium and organosodium compounds in hydrocarbon media, lead to



preferential formation of 1,2- and 3,4-units in the polymerisation of dienes [149-154]. Nuclear magnetic resonance spectroscopy in perdeutero-oxolan has been used [155,156] to study the charge distribution in the terminal unit of polybutadienyl-lithium and polyisoprenyl-lithium. In the absence of the monomer the charge in "live" chains is localised mainly on the terminal carbon atom. In the formation of 1,2- and 3,4-units, however, the reaction centre is established on the third carbon atom from the end of the chain:



In model reactions with water, alcohol, and other compounds the but-2-enyl anion reacts in conformity with the charge distribution to form an equilibrium mixture of butenes containing only ~3% of but-1-ene. [116,117,157] Hence migration of the reaction centre to the third carbon atom evidently occurs under the influence of the monomer. A similar effect is probable in the radical polymerisation of dienes, since the content of 1,2- and 3,4-units in the polymers considerably exceeds the equilibrium value and is independent of the temperature of polymerisation, whereas the ratio of *cis*- and *trans*-structures varies with temperature, approaching the equilibrium value. As noted above, formation of a carbon–metal σ-bond precedes entry of the monomer into the chain in coordination systems:

The formation of 1,2- and 3,4-units evidently corresponds to the case in which the α-form (B) is more advantageous than (A), which may be favoured by coordination of the transition metal with electron-donating solvating components, as in "cobalt" catalytic systems, and by the formation of π-complexes of vinyl groups with the transition metal

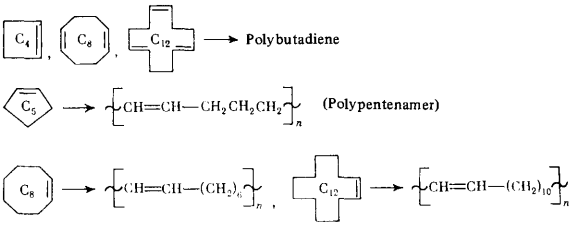
This provides an explanation for the preferential formation of syndiotactic units in the polymerisation of butadiene under the influence of various compounds of transition metals—cobalt, molybdenum, tungsten:

The complexes (A) and (B), formed alternately during chain growth, differ sterically in the position of the π-coordinating double bonds and the monomer. With π-allyl complexes of molybdenum crystalline syndiotactic 1,2-polybutadiene is formed [38-40]. It is noteworthy also that poly-π-allyl complexes of general formula $\pi$-$R_nM$ usually cause predominant formation of 1,2-units, as has been shown for

$(\pi\text{-}C_3H_5)_4Cr$ [60,61], $(\pi\text{-}C_5H_9)_2Cr$ [29], $(\pi\text{-}C_4H_7)_3Ti$ [158], $(\pi\text{-}C_5H_9)_3Ti$ [24], $(\pi\text{-}C_3H_5)_3Nb$ [48].

An exception is $\pi$-$R_3Rh$, which is stereospecific for the production of *trans*-units [48].

## III. CLEAVAGE OF CYCLOALKENES

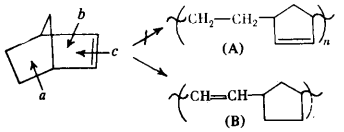


### 1. Mechanism of Dismutation

The cleavage of cycloalkenes is a novel route in coordination catalysis, revealing prospects for the synthesis of rubbers and other polymeric materials that cannot be obtained by the usual methods of polymerisation. The reaction was first described in Refs. 159 and 160. For some time the study of coordination catalysis developed in parallel and independently in the dismutation of alkenes and in the cleavage of cycloalkenes, until their completely identical nature was established with the possibility of initiation by the same systems. The catalysts used consisted mainly of organoaluminium compounds and halides of certain transition metals (tungsten, molybdenum, etc.). These catalytic systems (individual examples are given in Table 10) are closely similar in composition to Ziegler catalysts used for the stereospecific polymerisation of dienes and alkenes, but ineffective for the cleavage of cycloalkenes. An indispensable condition for Ziegler catalysis is formation of an organometallic compound in which chain growth takes place at the carbon–metal bond. It will be shown below that the cleavage of cycloalkenes and the dismutation of alkenes involve a new type of active centres.

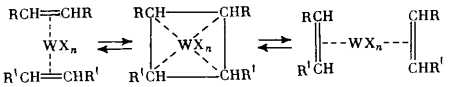
Table 10. Systems used for the dismutation of alkenes and the cleavage of cycloalkenes.

| Catalytic system | Ref. | Catalytic system | Ref. |
|---|---|---|---|
| $RAlCl_2+MoCl_3(NO)_2\cdot(PPh_3)_2$ | 161 | $R_4Sn+WCl_6$ | 166 |
| $RAlCl_2+WCl_2(NO_2)\cdot(PPh_3)_2$ | 161 | $R_2Al+ReCl_5$ | 167 |
| $RAlCl_2+WCl_6$ | 162, 163 | $Mo(CO)_6+Al_2O_3$ | 168 |
| $R_3Al(R_2AlCl)+WCl_6$ | 164 | $MoO_3/Al_2O_3$ | 168 |
| $R_3Al+MoCl_5$ | 164 | $Re_2O_7/Al_2O_3$ | 169 |
| $RLi+WCl_6$ | 165 | | |



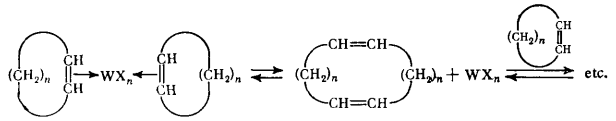
The polymerisation of cycloalkenes with homogeneous systems, which occurs very rapidly at low temperatures, yields products of high molecular weight that preserve the unsaturation of the initial cycloalkene:

The cleavage of cyclobutene, cyclo-octadiene, and cyclododecatriene yields polybutadiene. The possibility of obtaining *cis*-polybutadiene from cyclo-octadiene attracted the attention of research workers in connection with the



small heat of reaction (~8 kcal mole$^{-1}$). The fission of cyclopentene results in *cis*- and *trans*-polymers containing chains of five carbon atoms in the repeating unit and exhibiting rubberlike elasticity [170]. Depending on the ratio of *cis*- and *trans*-units either amorphous rubbers or crystalline *trans*-polymers melting at 73 and 83°C respectively are obtained from the cleavage of cyclo-octene and cyclododecene. The copolymerisation of different rings gives amorphous rubbers containing after completion of the reaction a random distribution of monomeric units in proportions corresponding to the composition of the initial mixture of monomers, independently of their relative reactivities. The reason is that the unsaturated polymer molecule also takes part in redistribution reactions [171-174].

It was supposed initially that cleavage of a cycloalkene results from rupture of a carbon–carbon bond adjacent to the double bond [175]. A study of the structure of polynorbornene.



was adduced in support of such a mechanism. Cleavage of norbornene with rupture of a carbon–carbon bond in direction (*a*) should lead to formation of a polymer containing unsaturated five-membered rings (structure A). From the usual ideas on the nature of active centres of radical and ionic character it might have been assumed that this mode of rupture was the most advantageous, for the active centre would then be conjugated with the double bond. However, experimental data showed that the polymer had structure (B), which led to the conclusion [175] that the reaction followed path (*b*). It has since been established unambiguously [176,177] that ring cleavage takes place in direction (*c*): i.e. the polymerisation of cycloalkenes with ring fission is a particular case of the general reaction of alkene dismutation.

The mechanism suggested [178] for the dismutation of alkenes involved the formation of a "quasi-cyclobutane" intermediate complex of two alkene molecules in the coordination sphere of the transition metal:

This mechanism was transferred [179] to the polymerisation of cycloalkenes:

The above scheme entails a stepwise mechanism of polymerisation, in which dimers, trimers, etc. of comparable reactivity with the initial monomer (in the case of relatively unstrained rings) are formed successively. Hence in the initial stage of polymerisation the reaction system should comprise mainly oligomeric products of low molecular weight.

A chain process differs fundamentally from a stepwise process in the possible formation of products of high molecular weight even in the earliest stage of polymerisation, with a low yield of oligomeric forms. However, investigations of the polymerisation of various cycloalkenes have shown [173,174,180,181], that at the very start of the process—at degrees of conversion of 5–10%—polymers of very high molecular weight are formed (Table 11). The quantity of oligomeric products is small, and they are formed not by polymerisation but by cyclodegradation of polymers. Initial formation of products of high molecular weight is an indication of a chain mechanism and the appearance of extremely active centres effecting the chain process [173,174,182,183]. This conclusion must evidently be extended to the dismutation of alkenes. It is necessary to examine the individual stages of this process.

Table 11. Intrinsic viscosities of polymers obtained from cycloalkenes [173,177,180,181].

| Cycloalkene | Catalytic system | Conversion, % | $[\eta]$, dl g$^{-1}$ |
|---|---|---|---|
| Norbornene | $AlBr_3$—$WCl_6$—thiophen | 13 | 5.5 |
| | $(iso\text{-}Bu)_3Al$—$WCl_6$ | 11 | 2.4 |
| | $(iso\text{-}Bu)_2AlCl$—$WCl_6$ | 9 | 1.8 |
| Cyclopentene | $Si(C_6H_5)_4$—$WCl_6$ | 7.5 | 6.0 |
| | $LiCH_2SiMe_3$—$WCl_6$ | 15 | 5.0 |
| | $PhCHN_2$—$WCl_4$ | 10 | 7.8 |
| Cyclo-octa-1,5-diene | $AlBr_3$—$WCl_6$—thiophen | 12 | 2.3 |
| | $(iso\text{-}Bu)_3Al$—$WCl_6$ | 11 | 1.5 |
| | $(iso\text{-}Bu)_2AlCl$—$WCl_6$ | 12 | 0.9 |
| | $PhCHN_2$—$WCl_6$ | 6 | 4.2 |
| Cyclo-octene | $(iso\text{-}Bu)_2AlCl$—$WCl_6$ | 10 | 0.8 |
| Cyclododecene | $(iso\text{-}Bu)_2AlCl$—$WCl_6$ | 5 | 0.7 |

Table 12. Polymerisation of cycloalkenes under the influence of carbene complexes (at 20°C).

| Catalytic complex | Monomer (m) | $\frac{[m]}{[W]}$ | $\frac{[RCHN_2]}{[W]}$ | Duration of reaction, min | Yield of polymer, % | $[\eta]$, dl g$^{-1}$ |
|---|---|---|---|---|---|---|
| $C_6H_5CH:WX_n$ | cyclopentene | $10^3$ | 0.1 | 1 | 18.2 | 9 |
| | cyclopentene | $10^2$ | 0.005 | 1 | 10 | 7.8 |
| | cyclo-octa-1,5-diene | $5\cdot10^2$ | 0.01 | 1 | 6 | 4.2 |

## 2. Initiation

All hitherto known active centres for chain polymerisation—free radicals, ions, ion-pairs, the usual coordination systems involving organometallic compounds—are ineffective for the cleavage of cycloalkenes and the dismutation of alkenes. We have undoubtedly met active centres of a novel type in the chain cleavage of cycloalkenes, which were regarded hypothetically [182,183] as complexes of carbenes with transition metals. An argument in support of their carbene nature was the formation of cyclopropane and methylcyclopropane when ethylene was kept over a dismutation catalyst [168]. Experimental results have been cited [180,184] that can be regarded as direct proof that monocarbene complexes are able to initiate the chain cleavage of cycloalkenes. The decomposition of phenyldiazomethane and ethyl diazoacetate in the presence of tungsten chlorides initiates the chain cleavage of cyclopentene and cyclo-octadiene with the formation of polymers of very high molecular weight. In the case of phenyldiazomethane the reaction occurs almost instantaneously at room temperature (Table 12).

The decomposition of diazo-compounds in the presence of salts of copper and certain other metals is a classical method for obtaining carbenes. The formation of products of very high molecular weight ($[\eta] = 4$–$9$ dl g$^{-1}$) indicates that the reaction involves very small quantities of long-lived active centres. Ordinary carbenes are extremely reactive in solution, adding non-selectively at C–H, C=C, etc. bonds. Their reactivity diminishes in the sequence

$$RCH:,\ C_6H_5CH:,\ (C_6H_5)_2C:,\ ROC(=O)CH:,\ (ROC(=O))_2C:\ \text{etc.}$$

In several cases carbenes exhibit roughly the same selectivity on incorporation at tertiary, secondary, and primary carbon–hydrogen bonds [185] as do alkyl free radicals in abstracting the hydrogen atom.

Carbenes are stabilised to the greatest extent by coordination with transition metals. Thus many complexes of carbenes with zero- or uni-valent metals—chromium(0), molybdenum(0), tungsten(0), tellurium(0), manganese(I), rhenium(I), rhodium(I)—containing one or two oxygen, nitrogen, or sulphur atoms at the reaction centre $(RO)_2C:M$ are crystalline compounds stable at ordinary temperatures [186,187]. This indicates that coordination with a transition metal is energetically favourable to the formation of carbenes. The selectivity of carbene active centres towards the cleavage of cycloalkenes and the dismutation of alkenes is evidently connected primarily with their stabilisation on the transition metal.

The main types of redox systems involving transition metals and generating free radicals are well known:

$$\left.\begin{aligned} &ROOH + M^n \rightarrow M^{n+1} + RO^{\cdot} + OH^-\\ &ROOH + M^{n+1} \rightarrow M^n + RO_2^{\cdot} + H^+\\ &ROH + M^{n+1} \rightarrow M^n + RO^{\cdot} + H^+\\ &RH + M^{n+1} \rightarrow M^n + R^{\cdot} + H^+ \end{aligned}\right\} \quad (1)$$

$$A + M^{n+2} \rightarrow M^n + B: \quad (2)$$

The formation of free radicals (1) involves one-electron transitions in the course of oxidation or reduction of the metal. Reaction scheme (2) entails the possible formation of a carbene centre by the transfer of two electrons in a single step. Such a redox system, effective for the polymerisation of cycloalkene down to −70°C, has been studied [181,188] in the reactions of certain organolithium compounds—trimethylsilyl- and trimethylgermanyl-methyl-lithium—with tungsten hexachloride. The composition of the reaction products in benzene and $\alpha\alpha\alpha$-trideuterotoluene at 20°C is indicated [181,188] in Table 13. The appearance of trimethylsilyl and trimethylgermanyl chlorides is due to decomposition of an organotungsten compound accompanied by formation of a carbene complex:

$$(CH_3)_3Si\,(Ge)\,CH_2WCl_5 \rightarrow$$
$$(CH_3)_3Si\,(Ge)\,Cl + [CH_2:WCl_4]\ .$$

The absence of deuteromethyltrimethylsilane on decomposition in $\alpha\alpha\alpha$-trideuterotoluene indicates that formation of this compound does not involve the trimethylsilylmethyl radical, which may result from homolytic breakdown of the organotungsten compound. Tetramethylsilane and tetramethylgermane may result [181,188] from disproportionation of two groups:

$$(CH_3)_3SiCH_2{-}WCl_4{-}CH_2Si(CH_3)_3 \rightarrow (CH_3)_4Si + [(CH_3)_3SiCH:WCl_4]\ .$$

This correlates with the increase in the yield of tetramethylgermane produced by raising the ratio of organolithium compound to tungsten(VI) chloride (Table 13).

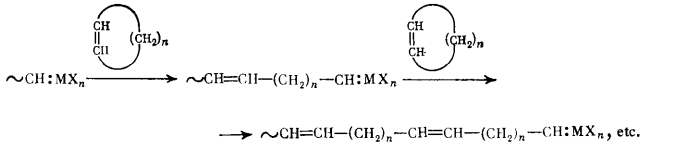
The systems usually employed for the cleavage of cycloalkenes and the dismutation of alkenes—carbene active centres—can be formed in particular by isomerisation of the $\pi$-alkene complex:

$$\begin{matrix} RCH \\ \| \\ RCH \end{matrix} \rightarrow MX_n \longrightarrow \begin{matrix} RC:MX_n \\ | \\ RCH_2 \end{matrix}\ .$$

Such a scheme was suggested [189] to explain the formation of certain stable carbene complexes of platinum. Lower chlorides of tungsten (IV and V) by themselves initiate the polymerisation of cyclopentene when the catalyst is exposed to ultraviolet radiation [190]. The above mechanism for the generation of carbenes may operate in this case. In systems containing alkylating organic compounds of aluminium, tin, or other metals a carbene complex may be produced by the reaction

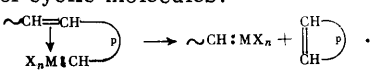
$$CH_3CH_2WCl_5 \rightarrow CH_3CH:WCl_4 + HCl \xrightarrow{R_3AlCl} RH + RAlCl_2\ .$$

This mode of decomposition can occur only in systems in which carbene formation becomes energetically advantageous as a consequence of stabilisation by coordination with a transition metal. Alkyl derivatives of many other transition metals—nickels, chromium, cobalt, etc.—break down [45,191,192] by a mechanism of disproportionation:



$$2RMX_n \rightarrow 2MX_n + R_{-H} + R_{+H}\ .$$

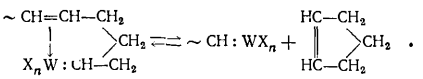
Table 13. Composition of reaction products.



| RLi / $WCl_6$ | Products isolated | Yield from RLi, mole %, in $C_6H_6$ | Yield from RLi, mole %, in $C_6H_5CD_3$ |
|---|---|---|---|
| 1:1 | $(CH_3)_3SiCl$ | 29—33 | 25 |
| | $(CH_3)_4Si$ | 24—26 | 28 |
| 1:1 | $(CH_3)_3GeCl$ | 44 | — |
| | $(CH_3)_4Ge$ | 11 | — |
| 2:1 | $(CH_3)_3GeCl$ | 34.5 | — |
| | $(CH_3)_4Ge$ | 24.0 | — |

## 3. Mechanism of Chain Growth

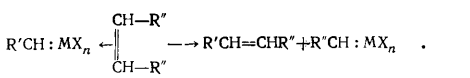
A mechanism suggested [180,182,183] for chain growth under the influence of carbene complexes



involves the formation of linear polymer molecules. As the monomer concentration decreases, reaction of the carbene active centre with double bonds in the chain itself becomes more probable, leading to degradation and the formation of cyclic molecules:

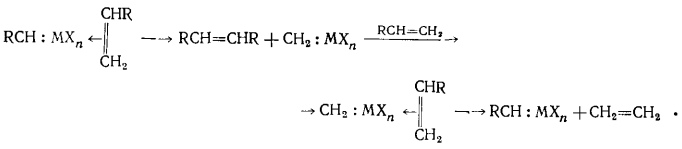
In cases in which complex formation between the transition metal and the nearest double bond in the polymer chain is sterically highly probable, a polymer–monomer

equilibrium is established, as has been found for cyclopentene [193]:



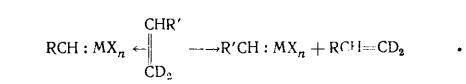
The position of equilibrium depends on the structure of the terminal unit. It lies closer to the monomer in the case of a *cis*-unit than with a *trans*-unit [194]. *cis*-Polypentenamer has been obtained under the influence of the system comprising tetra-allylsilane and tungsten hexachloride. With other cycloalkenes reaction of the active centre with a double bond in the actual chain yields a set of unstrained oligomeric cyclic molecules, the proportion of which increases with fall in the concentration of monomer and polymer in the solution. In dilute solutions linear polybutadiene of high molecular weight and polycyclo-octadiene undergo rapid cyclodegradation in the presence of above catalysts to form a set of cyclic oligomeric molecules (Table 14) [171,172,195]. In several systems equilibrium is established within 10–15 min, its position being determined by the polymer concentration in the solution. Cyclodegradation is characterised by the formation of oligomers having a very wide molecular-weight distribution ($\bar{M}_w/\bar{M}_n > 4$), which is consistent with results obtained by Stockmayer et al. [196] for ester polycondensation.

| Catalytic system | Polymer | Polymer concn., wt.% | $\bar{M}_n$ of initial polymer | Time, min | $\bar{M}_n$ of polymer |
|---|---|---|---|---|---|
| $WCl_6$—$EtAlCl_2$ | *cis*-polybutadiene | 4 | 127 000 | 120 | 3 400 |
| $WCl_6$—$EtAlCl_2$ | *cis*-polybutadiene | 8 | 220 000 | 25 | 9 000 |
| $W(OR)_2Cl_4$—$EtAlCl_2$ | *cis*-polybutadiene | 8 | 220 000 | 30 | 1 000 |
| $W(OR)_2Cl_4$—$EtAlCl_2$ | polyoctadienamer | 8 | $[\eta] = 2.5$ | 30 | 0.20 dl g$^{-1}$ |

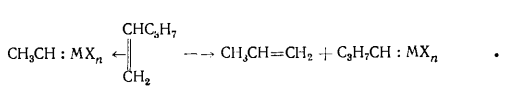


The general rules of the usual processes of radical or ionic copolymerisation are determined by the relative reactivities of the monomers and the corresponding active centres. No data are yet available that would enable us to estimate the relative reactivities of different carbenes coordinated with a transition metal. The nature of the active centres remains unchanged during the copolymerisation of unsubstituted cycloalkenes, since their entry into the chain is always accompanied by regeneration of the same type of active centre $\sim CH : MX_n$. According to their relative reactivities on copolymerisation $r_1$ and $r_2$ these compounds form the sequence [197–199]

The dismutation of unbranched alk-2-enes, like the copolymerisation of cycloalkenes, involves carbene centres of the same type without thermal effects:

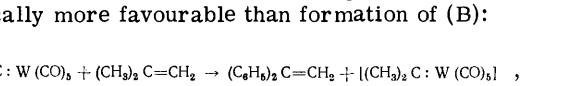


Under the influence of homogeneous catalytic systems this reaction is extremely rapid, as already noted. The dismutation of alk-1-enes in the same systems is very slow. The significance of this phenomenon is [188,200] that redistribution of alk-1-enes can take place only via alternating stages of transfer from secondary to primary carbene complexes:



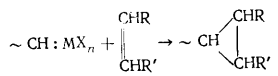
If the secondary carbene complex is rather less reactive than the primary complex, this should lead under conditions of a chain process to marked retardation of dismutation. Alk-1-enes are redistributed even more rapidly than are alk-2-enes with internal double bonds [201,202], but reaction is accompanied only by exchange of methylene groups:

Such a process occurs only with secondary carbene complexes:



Experimental confirmation of the kinetic role of this factor has been obtained from investigation of the primary products of the codismutation of pent-1-ene and but-2-ene present in equimolecular proportions [203]. The homodismutation of pent-1-ene, involving alternating stages of primary and secondary active centres, should yield ethylene. Codismutation via secondary carbene centres seems more advantageous, and in the presence case should give propene:

The investigations [203] have shown that the chief primary reaction product is propene, with hardly any ethylene formed. When competing directions are possile, reaction occurs along the energetically most advantageous path.



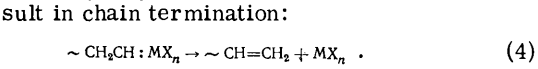
Interaction of the carbene complex $(CO)_5W : C(C_6H_5)_2$ with isobutene gives only 1,1-diphenylethylene, not 2-methyl-1,1-diphenylpropene. The reason can be understood on the basis that formation of the product (A) is energetically more favourable than formation of (B):

The complex (A) then decomposes to form propene. It has since been found [205] that, in the analogous reaction of the carbene complex $(CO)_5W : C(C_6H_4CH_3)_2$ with pent-1-ene, the yield of 1,1-ditolylethylene (and hence of the secondary carbene complex) exceeds 600-fold the yield of 1,1-ditolylpent-1-ene (and of the methylene complex B). It is important to note that diphenyl- and ditolyl-carbenes occupy a single coordination position on the tungsten atom, displacing one carbonyl group.

4. Possible Modes of Termination of Chain Dismutation

The problem of chain termination in dismutation must be considered in terms of the reactions of carbenes. The most specific reaction in solution is the formation of cyclopropane groups:

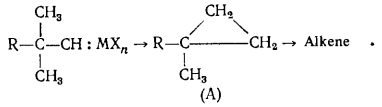
Such reactions occur also with coordinated carbenes. It has been shown[206] for various cyclopropane derivatives (n-pentyl, phenyl, n-butoxy) that under the influence of tungsten hexachloride and other components of catalytic systems they isomerise rapidly into the corresponding alkenes and conversion products of the latter. Thus the formation of cyclopropane groups results in chain termination. The appearance of linear alkenes during the polymerisation of cycloalkenes also lowers the molecular weight of the polyalkenamers, because such alkenes are involved in codismutation reactions.



As in chain reactions of radical and ionic character, the cleavage of cycloalkenes and the dismutation of alkenes may be expected to be retarded or completely inhibited if the system is contaminated with alkenes capable of forming more stable carbene complexes. Possible examples of such compounds are alkyl vinyl ethers and 1,1-diphenylethylene, which are able to form centres of the type $ROCH:MX_n$ and $(C_6H_5)_2C:MX_n$. We have shown[184] that benzoylphenyldiazomethane, whose decomposition with the evolution of nitrogen is catalysed by tungsten(VI) chloride, does not initiate the polymerisation of cyclopentene.

Chain termination might occur also by reduction of the transition metal accompanied by formation of a free radical:

(3)



Migration of a hydrogen atom in the carbene complex will also result in chain termination:

(4)

The fundamental possibility of such a reaction has been demonstrated by Fisher[207] on alkyl-phenylcarbene–pentacarbonyltungsten model compounds.

The formation of polymers of very high molecular weight from cyclopentene in the presence of a diazocomponud and a tungsten halide[180] indicates that the role of reactions (3) and (4) is probably slight. But the probability of reaction (4) is increased by the presence of methyl substituents on the second carbon atom:

(A)

With the above secondary carbene in solution the yield of product (A) reaches 92–97%.[185]

The above ideas on possible ways in which a chain process initiated by a carbene complex can be terminated are based solely on analogies with the behaviour of carbenes in solution. Coordination with transition metals may change the picture significantly, and the specific reactions of such complexes have not yet been studied.

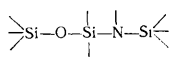
# Organosiloxazanes—A New Line of Advance in the Chemistry of Hetero-organic Oligomers and Polymers

K.A.Andrianov and V.N.Emel'yanov



Organosiloxazanes synthesised by the beginning of 1977 have been classified for the first time (according to their structure and molecular weight). For each of the three main groups—(1) cyclic, (2) linear and cyclolinear, and (3) polymeric—the main methods of preparation and the physicochemical characteristics are surveyed. In conclusion several fields of practical application of the new compounds and materials based on them are considered. [A list of 114 references is included.]

## I. INTRODUCTION

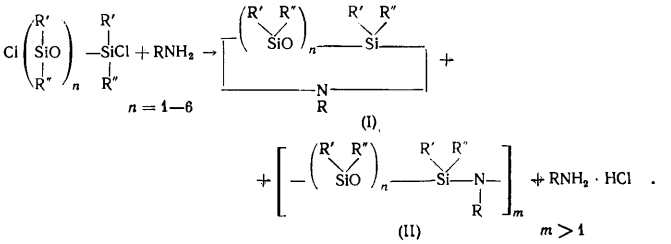
The development of the chemistry of organosilazanes, especially during the past 10–15 years, has been accompanied by a considerable growth in the interest taken in organosilicon compounds containing both organosilazane and organosiloxane groups, i.e.

segments. The trend to a systematic study of compounds of this type originated from the wish to combine the characteristic features of organosiloxanes and organosilazanes. The new compounds show greater possibilities than organosiloxanes for the controlled modification of properties, both from the introduction of an additional element (nitrogen) into the molecules and by variation in the nature of the organic radical attached to the nitrogen atoms.

Organosiloxazane compounds that have been obtained to date can be divided into three main groups—(1) cyclic, (2) oligo-organosiloxazanes of linear or cyclolinear molecular structure, and (3) polyorganosiloxazanes varying in the structure of the molecular chains—according to structure and molecular weight. The present Review surveys the preparation, chemical and physical properties, and possible applications of organosiloxazane compounds in preparative chemistry and in industry.

## II. ORGANOCYCLOSILOXAZANES

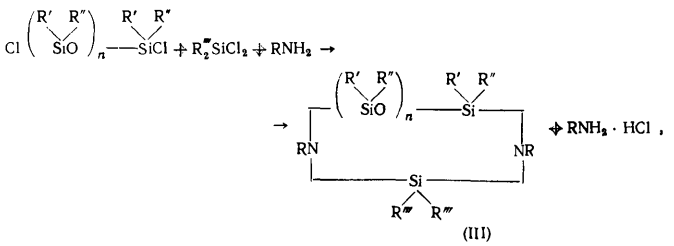
Synthesis of the first individual organocyclosiloxazanes, which initiated the development of the new trend in the chemistry of hetero-organic oligomers and polymers, was accomplished in our country. Investigating the aminolysis of organo-$\alpha$-$\omega$-dichlorosiloxanes, Sokolov[1] was the first to isolate and identify six- and eight-membered heterocycles containing both silazane and siloxane groups in the molecule.



More than 60 six-, eight-, ten-, and twelve-membered heterocycles have now been described, as well as representatives of spiran organocyclosiloxazanes. The homologous series of dimethylsilyl organocyclosiloxazanes is most fully represented in the literature, with reports of all kinds of structural isomers with six and eight atoms in the ring, containing one, two, or three

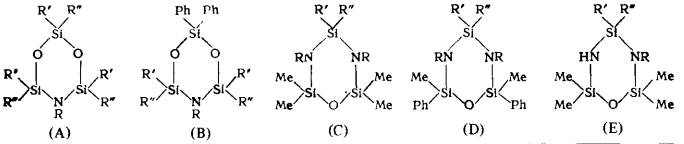
groups, and several compounds having larger ring skeletons have been synthesised (Tables 1–3).

### Methods of Preparation



The most widely used methods for obtaining organocyclosiloxazanes are the ammonolysis[1-11] and the aminolysis[2,5,12,13,15] of individual organo-$\alpha\omega$-dichlorosiloxanes or their mixtures with organodichlorosilanes[14-17]:

Ammonolysis or aminolysis, effected by passing the amine into a solution of the dichlorosiloxane, takes place either by an intramolecular mechanism to give heterocycles (I) containing a single silazane bond or by an intermolecular mechanism giving cyclic compounds (II) comprising two or more siloxazane units. Formation of oligomeric and polymeric as well as cyclic products has been observed in these reactions[7,10,11,13].



In the coammonolysis (coaminolysis) of mixtures of polychloro-organosiloxanes and diorganodichlorosilanes

the desired products are compounds formed by an intermolecular mechanism and containing two or more silazane bonds[14-18]:

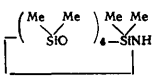
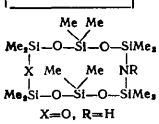
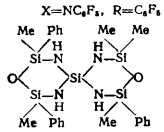
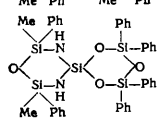
* Isomers.

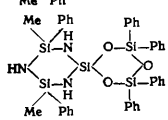
Several studies on the synthesis of organocyclosiloxazanes have examined the variation of the yield of products with temperature[4], nature of solvent[5,15], proportions and mode of introduction of reactants[4,12,19,20], catalysts[5,20], etc.[13] Thus the aminolysis by aniline of $\alpha\omega$-dichlorohexamethyltrisiloxane[15] yields in most solvents merely linear diamino-derivatives. Nor could cyclic organosiloxazanes be obtained by the reaction of $\alpha\omega$-dichlorodimethylsiloxanes with pentafluorophenylaniline[21]. Only the use of dimethylformamide enables the reaction to be directed towards formation of *N*-phenylated six-membered rings[15].

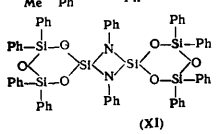




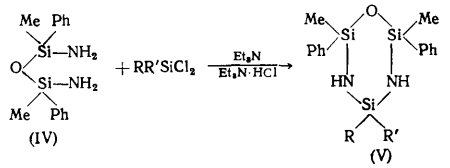








Owing to the formation of linear organosiloxanes having terminal amino-groups[3,12,19,22,23] the homocondensation of amino-derivatives has acquired greater importance in the synthesis of cyclic organosiloxazanes:



where R = H or Alk. Not only heterocycles of types (I) and (II) but also polymeric products have been obtained by homocondensation[19,10]. In the absence of a catalyst

$\alpha\omega$-diamino-derivatives of organosiloxanes readily undergo homocondensation only when the terminal amino-groups are primary[25]. When they are secondary, such reactions either do not take place or give only a low degree of conversion[4,6,7,10,13,19,22]. Ammonium chloride, copper(I) chloride, and certain other catalysts have been used in these reactions[2,4,13,20,22].

**Table 3.** Properties of organocyclosiloxazanes.

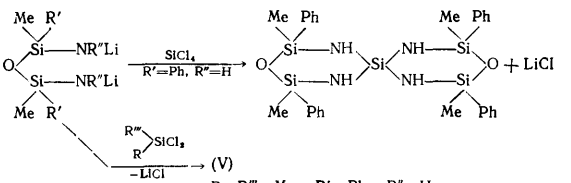
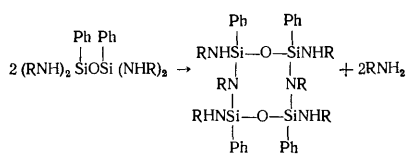
Heterofunctional condensation of organo-$\alpha\omega$-diaminosiloxanes with diorganodihalogenosilanes and tetrachlorosilane yields heterocycles of type (III). Thus the corresponding six-membered organosiloxazanes have been obtained[26,27] by treating tetraorganodisiloxane-1,3-diamines with dimethyldichlorosilane, methylvinyldichlorosilane, and tetrachlorosilane in the presence of triethylamine:

(IV) + RR′SiCl$_2$ $\xrightarrow[Et_3N\cdot HCl]{Et_3N}$ (V)



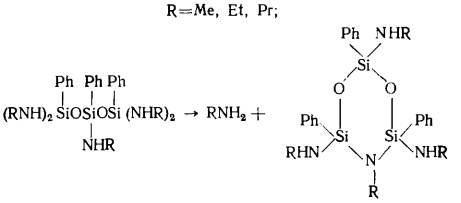
R=R′=Me; R=R′=Cl; R=Me, R′=Vin.

Use of an organodichlorocyclosiloxane instead of a dialkyldichlorosilane in such a reaction yielded a spirosiloxazane[26]:



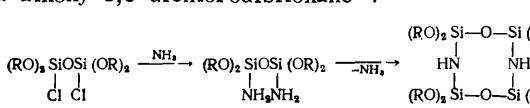
Replacement of (IV) by dimethyldiphenyldisilazane-1,3-diamine led to the formation of a spiro-compound comprising a silazane ring and a siloxane ring[26].

Rings of type (V) have been obtained from dilithium derivatives of (IV) with dimethyl- or methylvinyl-dichlorosilane without the use of a tertiary amine as acceptor of hydrogen chloride, but condensation with tetrachlorosilane gives a symmetrical bicyclic methylphenylspirosiloxazane[26]:

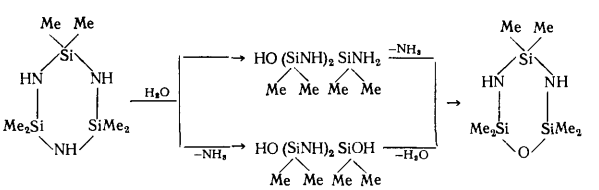


R=R″=Me, R′=Ph, R″=H;
R=Me, R‴=Vin, R′=R″=Me.

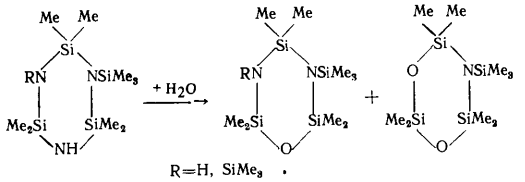
Six- and eight-membered organocyclosiloxazanes containing one amino-group on every silicon atom[25] are the chief products of the homocondensation of organosiloxane-tetra(and penta) amines[19,28]:



R=Me, Et, Pr;

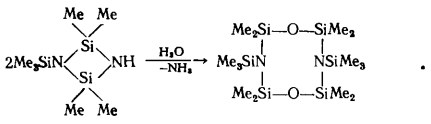


R=Me, Et, Pr, Ph, $C_6H_{11}$.

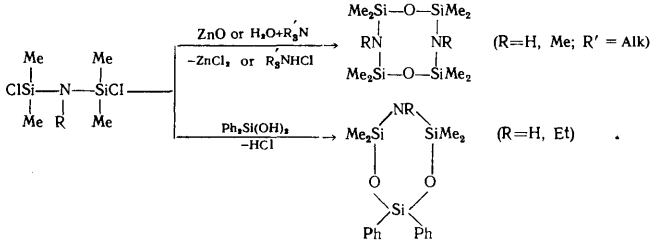


Cyclisation predominates in the condensation of such compounds, as evidenced both by the high yields of individual cyclic compounds and by the absence from the reaction mixture of insoluble polymers having a three-dimensional macromolecular structure. An eight-membered organosiloxazane containing two alkoxy-groups on every silicon atom was first obtained in 1963, from a tetra-alkoxy-1,3-dichlorodisiloxane[29]:

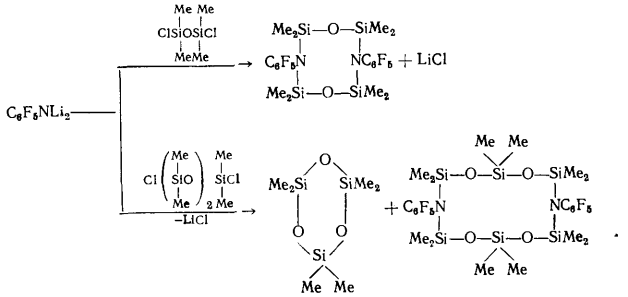
Organocyclosiloxazanes have been obtained also by hydrolysing hexamethylcyclotrisilazane[17]:



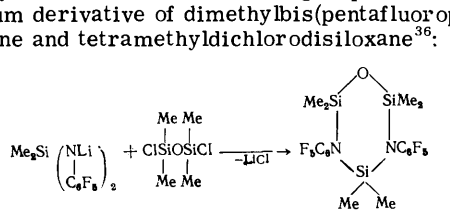
Partial hydrolytic condensation of organocyclosiloxanes in diglyme gave *N*-silylated six-membered organosiloxazanes[30]. This method enabled two of the three silazane groups in the ring to be replaced by oxygen:



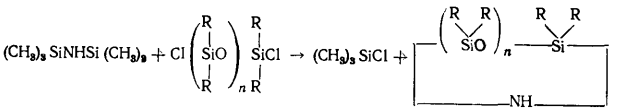
In contrast to the above reactions the partial hydrolysis of a tetramethyldisilazane ring results in the formation not of a four-membered ring



but of the symmetrical eight-membered 1,1,3,3,5,5,7,7-octamethyl-4,8-bistrimethylsilylcyclo-1,3,5,7-tetrasil-2,6-dioxa-4,8-diazane[24,74]:

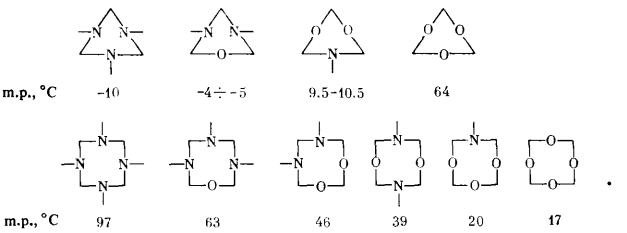


When linear organosilazanes containing halogen attached to the silicon atoms are used to obtain cyclosiloxazanes, the silazane bonds are unaffected, and siloxane units result from the action of water[31-33], zinc oxide[34], or a disubstituted silanediol[35] on the terminal halogen atoms:

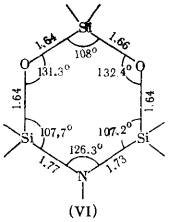


Six-, eight-, and twelve-membered organocyclosiloxazanes have been obtained[21,36] by cyclising $\alpha\omega$-dihalogenated organosiloxanes by the action of $N,N$-dilithium derivatives of amines·

A six-membered organocyclosiloxazane having two perfluorophenyl radicals in the silazane groups is formed from the dilithium derivative of dimethylbis(pentafluorophenylamino)silane and tetramethyldichlorodisiloxane[36]:

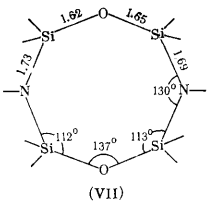


It has been claimed also[37] that linear $\alpha\omega$-dihalogenated organosiloxanes can be converted into cyclic siloxazanes by exchange between the chlorosilyl group and hexamethyldisilazane[37]:



## Physicochemical Properties

Melting points. Tables 1–3 list several physical properties of monocyclic organosiloxazanes. In structural analogues such properties depend on the ratio of the total numbers of Si–O–Si and Si–N–Si bonds in the molecules. This is typified by the variation in melting point in the two homologous series of dimethylsilylene six- and eight-membered ring compounds (with one hydrogen atom attached to every nitrogen atom):



In the first series hexamethylcyclotrisilazane melts 74 deg below hexamethylcyclotrisiloxane, but in the second series the melting point of the dimethylsilylene eight-membered cyclosilazane is lower than that of the corresponding siloxane by 80 deg. The overwhelming majority of heterocycles are readily soluble in aromatic solvents but less soluble in alkanes.

Structure. Among crystalline organocyclosiloxazanes one six-membered ring[38] and one eight-membered ring[39] have been subjected to structural analysis: *N*-ethylhexaphenylcyclo-1,3,5-trisil-2,4-dioxa-6-azane (VI) and 1,3,5,7-tetramethyl-1,3,5,7-tetraphenylcyclo-1,3,5,7-tetrasil-2,6-dioxa-4,8-diazane (VII) have the structures

(VI)

(VII)

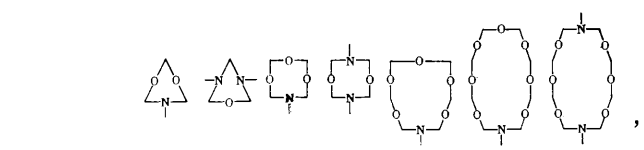
Monoclinic, space group $P2_1/a$; $a = 17.412$; $b = 16.287$; $c = 13.752$ Å; $\beta = 116°31'$;

Orthorhombic, space group $Pbca$, $a = 11.652$; $b = 19.798$; $c = 12.833$ Å; $V = 2960.5$ Å$^3$.

The cyclic skeleton of (VI) departs slightly though definitely from planar and gravitates towards the "boat" form in structure. Compound (VII) has the "chair" conformation. The mean silicon–nitrogen bond length is rather shorter in the eight-membered than in the six-membered ring (1.71 and 1.747 Å). No less interesting is the difference in silicon–carbon bond lengths, obviously due to $p_\pi$–$d_\pi$ interaction of electrons of exocyclic substituents with vacant *d* orbitals of silicon and to hyperconjugation in the

siloxazane ring (Table 4). The position of the phenyl group in (VII) with respect to the siloxazane ring (perpendicular) is regarded[39] as optimal in terms of maximum overlap of the $\pi$-electron systems of the phenyl rings with $3d_{z^2}$ orbitals of silicon, so that the remaining $3d$ orbitals of the silicon atom may be involved in delocalisation of the electron cloud of the siloxazane ring.

Table 4.

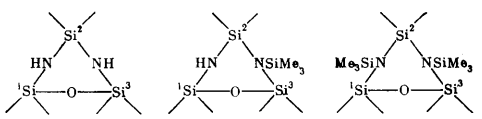


| Compound | Si-C bond length, Å | |
|---|---|---|
| | Ar | Alk |
| (VI) | 1.875 | – |
| (VII) | 1.85 (2) | 1.91 (1) |
| Arylsilanes | 1.843 | – |
| Alkylsilanes | – | 1.875 |

Infrared spectra. The infrared absorption band corresponding to asymmetric siloxane-stretching vibrations is sensitive to variation in the dimensions of the ring. As example, the homologous series of dimethylsilylated cyclosiloxazanes containing one silazane bond

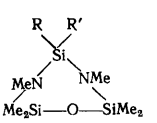
with respectively 2–5 siloxane bonds exhibits a shift in $\nu_{as}$(Si.O.Si) from 983–1023 to 1067–1090 $cm^{-1}$ on passing from six- to eight-, ten-, and twelve-membered heterocycles[2,10,40]. Analogous shifts are exhibited by other six- and eight-membered organocyclosiloxazanes[25,41]. A shift in this band towards higher frequencies occurs with increase in ring size effected not only by additional siloxane groups but also by the introduction of a new silazane bond[2,10,25,40,41].

The series of *SiSi*-dimethylated cyclosiloxazanes suggests that the $\nu_{as}$(Si.N.Si) band is extremely sensitive both to change in the ring size and to the number of cyclic silazane bonds. A regular displacement of this band to higher frequencies is observed either when the number of silazane bonds is increased at the expense of a diminished number of siloxane bonds in a ring of unchanged size or when the ring is expanded while the number of silazane groups remains constant. This is demonstrated by the homologous series



where the corners represent dimethylsilylene groups, and one hydrogen atom is attached to each nitrogen atom.

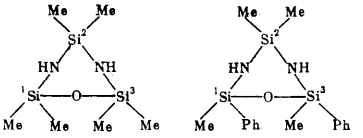
In contrast to an *Si*-substituent, whose effect on the position of the Si.O.Si vibrational band is little apparent in the infrared spectra of most of the organocyclosiloxazanes studied, radicals attached to the nitrogen atom of a silazane group cause characteristic and considerable shifts in the $\nu_{as}$(Si.N.Si) band. In the homologous series of hexamethylcyclo-1,3,5-trisil-2,oxa-4,6-diazanes having the structural formula



variation in the inductive effect of one or two substituents—in the sequence R = H, $Si(CH_3)_3$, $Si(CH_3)_2OSi(CH_3)_3$—led to a shift in the $\nu_{as}$(Si.N.Si) absorption band from 930 to 979 $cm^{-1}$.[41] Similar changes had been observed previously in the spectra of four-membered organodisilazane compounds[42], as well as for other *N*-alkylated (or *N*-arylated) organocyclosiloxazanes[25]. Radicals having a negative inductive effect, such as phenyl, lower the $\nu_{as}$(Si.N.Si) frequency to 907–910 $cm^{-1}$ when attached to the nitrogen atom[15,25].

Nuclear magnetic resonance spectra. The structure of the $^1H$ n.m.r. spectra of cyclic organosiloxazanes is more complicated than with cyclosiloxanes and silazanes. As the spectra became more complex, however, the information potential also became greater, revealing finer structural features. Thus the effect of a trimethylsilyl group on the hydrogen atoms of the dimethylsilylene groups gradually decayed with distance[41]. The following data

show that replacement of a hydrogen atom in an SiNHSi group by trimethylsilyl has different effects on the signals of neighbouring and more remote dimethylsilylene groups. Introduction of a second trimethylsilyl group has the strongest effect on a methyl group attached to $Si_{(2)}$, lying between the two added radicals. Substitution of phenyl for the hydrogen atoms of both silazane groups shifted the signal only of methyl groups located at $Si_{(2)}$ (to $\tau$ = 9.82), while the position of the second signal in the spectrum remained unchanged ($\tau$ = 9.94).[15] An analogous effect was observed furthermore when silazane hydrogen in six-membered rings was replaced by methyl or pentamethyldisiloxanyl substituents, as well as in the case of eight-membered homologues[41].



Radicals attached to the silicon atoms have an appreciably more marked effect on the proton magnetic resonance than on the infrared spectra. Thus the spectra of a series of *NN'*-dimethylcyclotrisiloxazanes of general formula

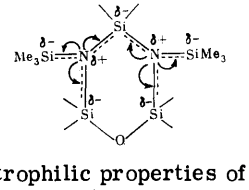
reveal a tendency for the signal to move down field with decrease in the $+I$ effect of the substituents R and R':

| R, R' | Me, Me | Br, Br | Cl, Cl | Vin, Me |
|---|---|---|---|---|
| τ, ppm | 9.93 | 9.85 | 9.83 | 9.73 |

The signal of the methyl hydrogen atoms in methylphenylsilyl derivatives is usually displaced down field in comparison with the dimethylsilyl analogues. This is characteristic also of cyclic organosiloxazanes[26,41]:

| | | |
|---|---|---|
| $Me(Si^1)$ | 9,92 | 9,66 |
| $Me(Si^2)$ | 9,93 | 9,93 |
| $Me(Si^3)$ | 9,92 | 9,66 |

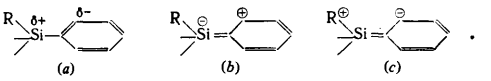
These values of $\tau$ (ppm) show that, when two dimethylsilylene groups are replaced by methylphenylsilylene radicals, the position of the signal corresponding to the hydrogen atoms of the dimethylsilylene group remains unchanged, whereas the signal of the methyl hydrogen atoms in a methylphenylsilylene group is displaced by >0.2 ppm. Nuclear magnetic resonance data have been published also for several other organocyclosiloxazanes[4,10,12,17,31,35].



Mass spectra. Among other physical methods, mass spectrometry has also been used to analyse organocyclosiloxazanes[43].

Interpretation of physicochemical properties and reactivity. The approach to interpreting e.g. the ability to polymerise under the influence of nucleophiles is usually more cautious with organocyclosiloxazanes than with cyclic organosiloxanes and organosilazanes, most probably because of the additional effects arising from the combination of siloxane and silazane groups. Despite the comparatively few data that have accumulated, we can distinguish some of the most important factors governing such properties of cyclosiloxazanes as thermal and hydrolytic stability, ability to rearrange or polymerise.

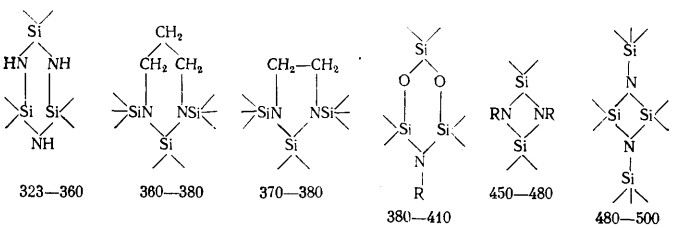
Firstly may be mentioned the inductive and mesomeric effects of substituents attached to the silazane nitrogen. For the series of substituents—hydrogen, methyl, trimethylsilyl, phenyl—the inductive effect changes sign from positive to negative, corresponding to diminished electron density on the nitrogen and enhanced resistance of the



bond to hydrolysis, which usually involves protonation of the nitrogen[44]. Since moreover the negative mesomeric effect of the trimethylsilyl group ($p_\pi$–$d_\pi$ interaction of exocyclic groups with nitrogen) lowers the electron density on the nitrogen and increases it on the silicon atoms, we can explain the high hydrolytic and thermal stability of trimethylsilylated heterocycles. The scheme

shows that the electrophilic properties of silicon are weakened by the above negative mesomeric effect with simultaneous decrease in the basic strength of the nitrogen. Basic properties are completely absent from tris-trimethylsilylamine $((CH_3)_3Si)_3N$.[45]

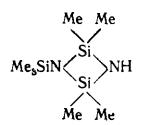
Another important factor—the influence of groups attached to the silicon atoms—can also be considered in terms of mesomeric and inductive effects. In the case of an *Si*-phenyl substituent, for example, the inductive effect guides electrons from the silicon orbitals to the phenyl ring (*a*), whereas the mesomeric effect resulting from interaction of $\pi$ electrons of the phenyl ring with vacant (*b*) orbitals of the silicon atom has the opposite direction (*b*) or transmits electric charge to the *ortho*- and *para*-positions by hyperconjugation (*c*) and thus strengthens the inductive effect[46]:



(*a*) (*b*) (*c*)

Depending on the steric disposition of the phenyl group, $p_\pi$–$d_\pi$ conjugation may be either strengthened or weakened[39].

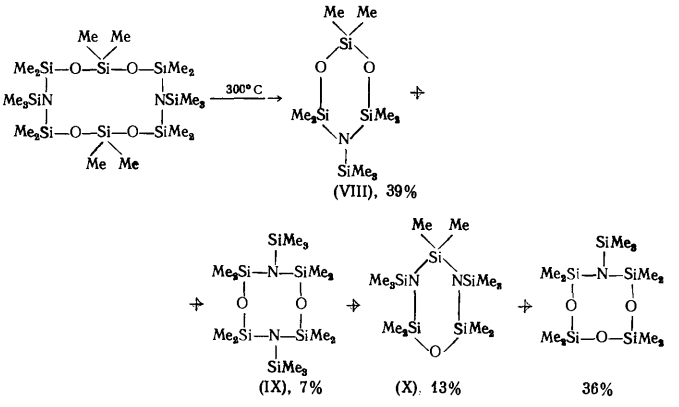
A no less important factor determining the reactivity and the physical properties of organocyclosiloxazanes is hyperconjugation (pseudoaromatisation) within the siloxazane ring, which depends on the size of the ring, its conformation, the regularity of alternation of



units, etc. Study of this problem is not yet sufficient to permit unambiguous interpretation of many regular changes in properties on passing from cyclic organosiloxanes to organocyclosilazanes or organocyclosiloxazanes. Judging from the variation in bond lengths and angles[38,39] and also the diminished basicity of the silazane nitrogen[24] due to its involvement in delocalisation of the electron cloud within the ring, however, hyperconjugation interactions have a considerable influence on the stability and other properties of the compounds. Indeed, in the series of organosilicon heterocycles[47]

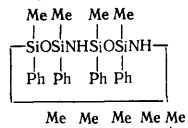
323—360 360—380 370—380 380—410 450—480 480—500

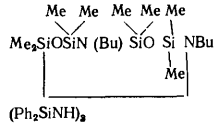
(the temperature ranges of decomposition (°C) are indicated below the formulae) four-membered cyclodisilazanes are the most thermostable. Thus in 1-trimethylsilyl-2,2,4,4-tetramethylcyclodisilazane



the proton attached to the second nitrogen atom exhibits enhanced acidity (and the nitrogen atom is correspondingly less basic), which indicates a considerable contribution to conjugation within the ring by the nitrogen electrons, including those bonding the hydrogen atom with the nitrogen[24].

Thermal stability. Study of organocyclosiloxazanes as a novel type of heterocycles showed[44,48,49] that the thermal stability of organocyclotetrasildioxadiazanes exceeded those of cyclic organosilazanes and organosiloxanes. Perfluorophenylated derivatives of six- and

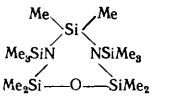


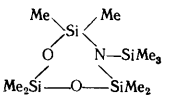


eight-membered heterocycles begin to decompose[21] over the temperature range 400–450°C. The start of the decomposition of hexaphenylcyclotrisiloxazane also lies above 410°C.[50]

Comparison of the thermal stability of *N*-silylated *SiSi*-dimethylated twelve-, eight-, and six-membered cyclosiloxazanes has revealed[41] the extraordinary stability of the six-membered 2,2,4,4,6,6-hexamethyl-5-trimethylsilylcyclotrisil-1,3-dioxa-5-azane (VIII) to isothermal heating at 300°C: whereas the *N*-trimethylsilylated twelve-membered heterocycle underwent the rearrangement

after being heated in a sealed ampoule at 300°C for only 13 h, compound (VIII) remained unchanged after 260 h at the same temperature. Heating (IX) under the same conditions for 120 h led to the formation of approximately equal quantities of (VIII) and (X) (totalling ~90%). The heterocycle (X) suffered only slight losses after the same treatment.





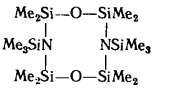


Table 5.

| Compound | $\nu_{as}$(Si.N.Si), cm$^{-1}$ | Rate of disappearance of band at 25°C |
|---|---|---|
| $(Me_2SiNH)_3$ | 925 | 1 h |
| $(Me_2SiNH)_4$ | 941 | 1 h |
| $Ph_2SiOSiMe_2OSiMe_2NH$ | 898 | 1 h |
| $Me_2SiOSiMe_2N(H)SiMe_2OSiMe_2NH$ | 947 | slight changes after 13 h |
|  | 941 | no change after 25 h, slight changes after 7 days |
|  | 904 | no change after 7 days |
| $(Ph_2SiNH)_3$ | 952 | no change after 7 days |

Hydrolytic stability. The resistance of organocyclosiloxazanes to hydrolysis is governed mainly by the nature of the silazane bond, being considerably affected by the substituent on the nitrogen atom. This factor was noted in one of the first preparations of the heterocycles[2]. Table 5 gives relative rates of hydrolytic cleavage of the silazane bond in cyclic organosilazanes and siloxazanes determined from the disappearance of the $\nu_{as}$(Si.N.Si) band from the infrared spectra of 0.25 M solutions of the heterocycles in dimethylformamide containing 5% of water.

Later work has established the great hydrolytic stability of cyclosiloxazanes containing an *N*-phenyl[15] or an *N*-perfluorophenyl[21] group. The accompanying data show that the nature and the bulk of substituents attached to the silicon atoms may also have a considerable influence on the rate of hydrolysis.

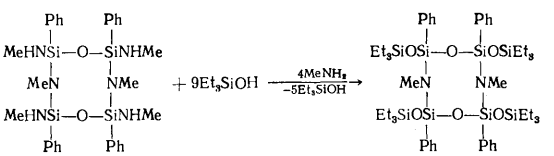

Table 6.

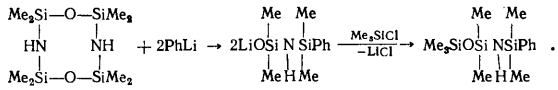
| Compound | Time of hydrolytic cleavage of ring, h | | Rate constant, $k$, h$^{-1}$ |
|---|---|---|---|
| | 50% | 95% | |
|  | — | 20 | — |
|  | 132 | 400 | $5.2\cdot10^{-3}$ |
|  | 66 | 200 | $1.2\cdot10^{-2}$ |

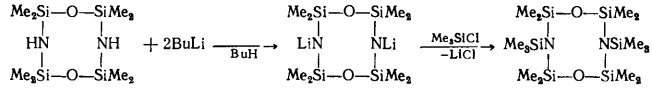
*N*-Trimethylsilylated compounds are among the hydrolytically most stable organosiloxazanes. Parallel tests of the hydrolytic stability of organosilazanes and organosiloxazane heterocycles, made under homogeneous conditions in a boiling solvent (dimethoxyethane) containing excess of water (relative to the silazane bonds), demonstrated rapid breakdown of the cyclosilazanes, whereas the cleavage of *N*-trimethylsilylated organosiloxazane rings occurs considerably more slowly[41] (Table 6).

The resistance of organocyclosiloxazanes and also of cyclic organosilazanes is greater in neutral and alkaline than in acid media[8]. The main hydrolytic condensation products are oligomeric and cyclic organosiloxanes[10].



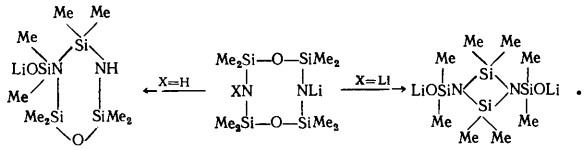
Triethylsilanol acts on organocyclosiloxazanes containing *Si*-amino-groups at temperatures up to 130°C predominantly at these groups[51]:

The cleavage of heterocycles at the silazane bond under the influence of organic primary amines[12] can be regarded as displacement to the left of the equilibrium formation of cyclic organosiloxazanes from organosiloxane-$\alpha\omega$-diamines.

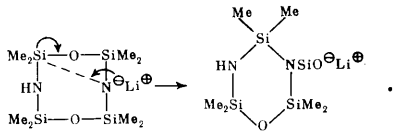


Several investigations have been made on the metallation of organocyclosiloxazanes at the secondary amino-group by means of metal aryls or alkyls[10,41,52–54]. Treatment of symmetrical octamethylcyclotetrasildioxadiazane with phenyl-lithium in ethereal solution at room temperature led to fission of the siloxane bond[10], but

subsequent reaction of the lithium silanolate with trimethylchlorosilane gave the corresponding trimethylsilyl derivative:



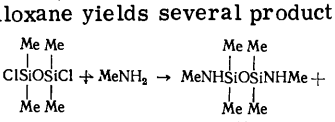
A cyclosiloxazane undergoes a similar reaction with sodamide.



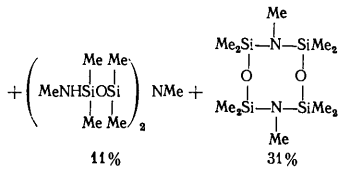
The action of butyl-lithium on the same organocyclosiloxazane has been examined in greater detail[41,53,54]. At low temperatures cleavage of siloxane bonds is not effected, and at −60°C metallation occurs smoothly, to yield mono- or di-*N*-trimethylsilylated products after treatment of the *N*-lithium derivatives with trimethylchlorosilane:

If, however, the di- or mono-lithium derivative is left at a higher temperature (from −30 to +20°C) for some time, it undergoes rearrangement with contraction of the ring, when the dilithium compound passes into a cyclodisilazane, and the monolithium compound into a six-membered organocyclosiloxazane:

The mechanism of the rearrangement most probably involves nucleophilic attack by $N^-$ on silicon, leading to cleavage of the siloxane bond and formation of a new silazane bond:



Rearrangements of this type are transannular interactions, and occur rapidly in 1,2-dimethoxyethane and oxolan; they are far slower in ether and in hexane[53].

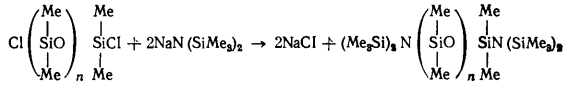


The preparation and certain properties of cyclic organosiloxazanes have been discussed also in several other references[55-57].

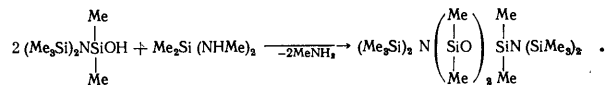
## III. OLIGO-ORGANOSILOXAZANES—LINEAR, CYCLO-LINEAR, AND SPIROCYCLIC

### Methods of Preparation

The methods used are more diverse than for organocyclosiloxazanes. The ammonolysis and aminolysis of organochlorosiloxanes, as well as the homocondensation of organosiloxanes containing *Si*-amino-groups, are common to the two classes of products[6,7,13,58,59]. Thus the introduction of methylamine into a solution of 1,3-dichlorotetramethyldisiloxane yields several products[13]:

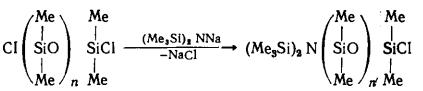


The tendency for heterocycles or linear products to be formed in such reactions depends on the structure of the initial compounds and on the experimental conditions. Homocondensation processes for obtaining such linear oligo-organosiloxazanes take place according to the general scheme[6,7,59,60]



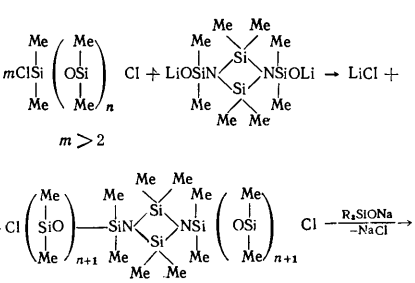
Certain properties of the resulting oligomers are listed in Table 7.

Linear oligo-organosiloxazanes having terminal bistrimethylsilylamino-groups have been synthesised by the action of bistrimethylsilylsodamide on organo-$\alpha\omega$-dichlorosiloxanes[59,61]:

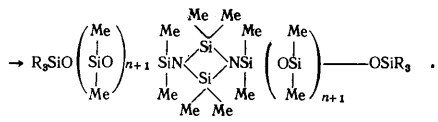


$n = 3, 5, 7, 13.$

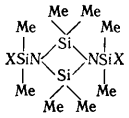
In this reaction both halogen atoms are smoothly replaced by bistrimethylsilylamino-groups only in halogenated siloxanes containing four or more siloxane units[59]. The oligomer of this homologous series having three siloxane units has been obtained by condensing dimethylbismethylaminosilane with bistrimethylsilylaminodimethylsilanol[62]:



When the proportion of bistrimethylsilylsodamide is lowered to equimolecular relative to the organodichlorosiloxane, monosubstituted compounds are formed in yields up to 70%:[6,7,59,61]

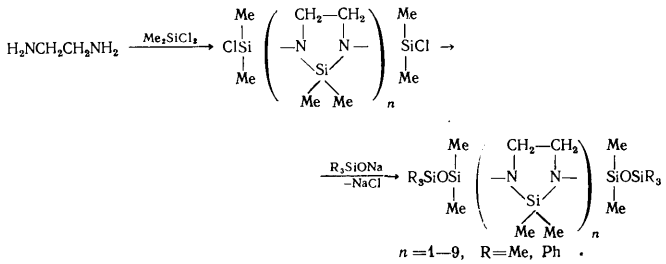


$n = 1, 2, 3, 6.$

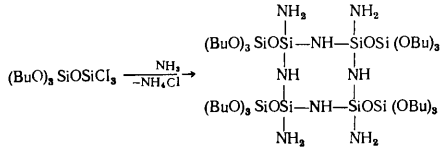


Various derivatives—hydroxysilyl, aminosilyl, etc.—have been obtained from $\alpha$-bistrimethylsilylamino-$\omega$-chlorodimethylsiloxanes.

Exchange of mono- or di-lithium derivatives of cyclodisilazanediols with dimethyldichlorosilane or organo-$\alpha\omega$-dichlorosiloxanes has been used to obtain a series of oligomers containing organodisilazane rings in the molecular chains[63-65]; the terminal halogenosilyl groups in the resulting oligomers were then blocked by means of alkylated (or arylated) silanolates[63]:

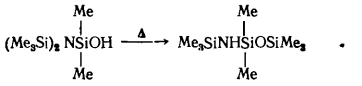


Other methods of heterofunctional condensation used to prepare analogous products include the reactions of organocyclodisilazane derivatives

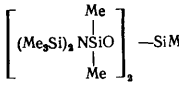


($X = NR_2$ or Cl) with alkyl(aryl) silanols or the corresponding silanolates[66,67].

The same processes based on exchange reactions underlay the method of obtaining "mixed" oligomers of cyclocarbosiloxazane type. Diazasila-alkane rings and polycyclolinear products formed by the action of ethylene-1,2-diamine on dimethyldichlorosilane were used as starting materials[68,69]; treatment of the bischlorosilyl derivatives with trimethylsilanol or triphenylsilanol hence gave cyclolinear carbosiloxazanes having terminal triorganosiloxy-groups:

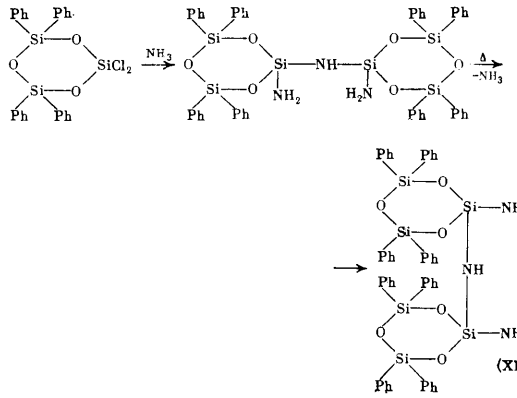


Among oligomers containing eight-membered silazane rings with siloxane units in exocyclic groups the tetrafunctional 1,3,5,7-tetrakistributoxysiloxycyclo-1,3,5,7-tetrasilazane-1,3,5,7-tetramine has been synthesised[70]:



Besides the above condensation methods, oligo-organosiloxazanes can be obtained by cleaving the siloxane bonds in organocyclosiloxazanes by the action of phenyl-lithium or sodamide and then treating the resulting lithium or sodium silanolates with alkylchlorosilanes[10] (see fourth last equation in Section II).

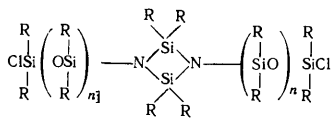
An interesting laboratory preparation of a linear organosiloxazane involved rearrangement[71]: contrary to expectation, when bistrimethylsilylaminodimethylsilanol was heated to 200°C, neither heterofunctional condensation of hydroxysilyl and aminosilyl groups nor homocondensation of hydroxy-groups was observed, but the isomerisation



Yet with dimethylbismethylaminosilane the same reactant gave a 57% yield of the expected linear siloxazane[62]

The above type of rearrangement goes smoothly in the presence of basic catalysts; catalytic additions of sulphuric acid gave bistrimethylsilylaminopentamethyldisiloxane.

The ammonolysis of organopolychlorosiloxanes followed by homocondensation of the amino-derivatives has recently been used[58,72] to synthesise polycyclic systems consisting of fused organosiloxane and organosilazane rings:



(XI)

## Physicochemical Properties

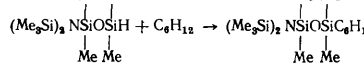


Table 7 shows that most of the oligo-organosiloxanes are liquids that can be distilled in a vacuum. Their viscosity increases with increase both in molecular weight and in the number of cyclic units and phenyl groups in the molecule. All known oligomers containing triphenylsilyl radicals are crystalline compounds melting in the range 100–200°C. The solubility of oligo-organosiloxazanes in polar and non-polar solvents depends on the content of aliphatic and aromatic radicals in the molecule, as well as on the structure and composition of the cyclic segements.

Controlled hydrolysis of oligomers of general formula $((CH_3)_3Si)_2N.[SiR_2.O]_n.SiR_2Cl$ in the presence of acceptors of hydrogen chloride enables the corresponding hydroxy-derivatives to be isolated[6,7,59]. The ammonolysis of oligomers containing an $\alpha$-chlorine atom and an $\omega$-bistrimethylsilylamino-group gives silylated amines with chloro in the above formula replaced by amino, which can be selectively hydrolysed only at one of the silicon–nitrogen bonds[73]. Hydrolysis of oligomers of the series

has enabled the corresponding organosiloxazane-$\alpha\omega$-diols to be obtained[63,65,75] as oily liquids.

The hydride addition of an *SiSi*-dimethylated siloxazane containing a free hydrogen atom to hex-1-ene proceeds smoothly in the presence of chloroplatinic acid to give the expected product—1-bistrimethylsilylamino-3-hexyltetramethyldisiloxane[62]:

The most specific feature of the infrared spectra of oligo-organosiloxazanes is the absorption band corresponding to asymmetric stretching vibrations of the silazane bond. Its spectral position permits reliable identification

**Table 7. Properties of oligo-organosiloxazanes.**

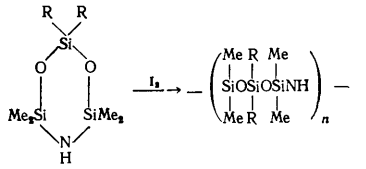
of the structure of the silazane segments[59,66]. Thus linear oligomers containing silazane bonds in terminal bistrimethylsilylamino-groups are characterised by a doublet in the range 940–920 cm$^{-1}$;[59] in the infrared spectra of oligoorganosiloxazanes in which the

units forms a disilazane ring the $\nu_{as}$(Si.N.Si) band is observed in the range 895–870 cm$^{-1}$.

The size and composition of the cyclic segment has an appreciable influence on the position of signals of protons in cyclic dimethylsilylene groups in the $^1$H n.m.r. spectra of the cyclolinear organosiloxazanes studied (~20 compounds). Thus the shift of the peak corresponding to a dimethylsilylene group forming part of a disilazane ring is $\tau$ = 9.70–9.76 ppm.[63] The analogous shift of the peak corresponding to the dimethylsilylene group in a diazasilacyclopentane segement was $\tau$ = 9.86 ppm.[69] No perceptible effect of exocyclic siloxazane or other groups on the position of this signal has been observed.

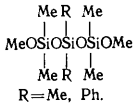
## IV. POLYORGANOSILOXAZANES



Polyorganosiloxazanes have been synthesised with various molecular structures—(1) linear macrochains having an irregular distribution of siloxane and silazane bonds, and also monochain polymers with cyclic segments, (2) branched and three-dimensional macromolecules, and (3) ladderlike or partly ladderlike.

Polymers containing organosiloxazane segments in the macromolecular chains are obtained by the catalytic polymerisation of cyclic compounds, by the condensation of $\alpha\omega$-diamino- or polyamino-organosiloxanes or cyclo-organosiloxazanes containing functional groups attached to silicon atoms, or by hydride migration.

Attempts to apply to cyclo-organosiloxazanes well known methods of polymerisation using potassium hydroxide as catalyst unexpectedly did not yield polymers of high molecular weight[76]. In the action of this alkali on *SiSi*-dimethylated six-, eight, and ten-membered cyclosiloxazanes (5% of alkali on the weight of the heterocycle) at temperatures above 100°C the increase in viscosity of the reaction products was accompanied by the evolution of ammonia and methane[78]. The formation of these gases indicated the simultaneous occurrence of degradation and polycondensation processes at Si–Ni–Si and Si–C bonds. Subsequent heating of the reaction mixture entailed a fall in viscosity, obviously owing to breakdown of oligomeric chains. In contrast to the above processes the use of caustic potash as catalyst in combination with solvating additives such as dimethyl sulphoxide facilitated the synthesis of polymers of high molecular mass[76].

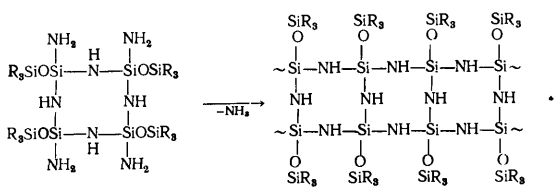


Tetramethylammonium hydroxide, iodine[76,77,79], and ammonium chloride[10] have also proved effective catalysts for the polymerisation of organocyclosiloxazanes. Study of the mechanism of polymerisation in the presence of

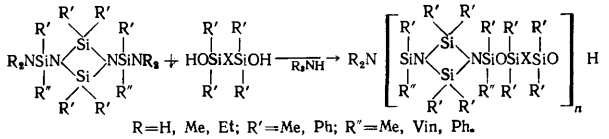
catalytic quantities of iodine showed that the process was highly specific involving cleavage only of silazane bonds:

R=Me, Ph

The intrinsic viscosity of the resulting polymers was $[\eta] = 1.25$.[76,77] Evidence of this course of polymerisation was the formation of a single product—a hexasubstituted 1,5-dimethoxytrisiloxane



R=Me, Ph.



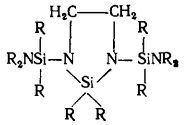
as a result of complete methanolysis of the silazane bonds in the resulting polymer. Chromatographic analysis of analogous methanolysis products from the polymer obtained from hexamethylcyclotrisildioxazane in the presence of tetramethylammonium hydroxide as catalyst indicated also the formation of dimethoxydimethylsilane, 1,3-dimethoxytetramethyldisiloxane, and higher homologues $CH_3O[Si(CH_3)_2O]_nCH_3$ ($n$ = 3–5). The presence of these products was regarded[76] as evidence of the statistical development of polymerisation involving both silazane and siloxane bonds. Individual studies revealed that, among six-membered cyclo-organosiloxazanes, rings in which methyl and phenyl groups were attached to the silicon atoms were least active with respect to polymerisation in the presence of iodine as catalyst[77].

Elastomers of high molecular weight with various contents of silazane groups have been obtained also by the copolymerisation of two eight-membered rings—octamethylcyclotetrasiloxane and octamethylcyclotetrasiltrioxazane—with tetramethylammonium hydroxide as catalyst[80].

The homocondensation of $\alpha\omega$-diamino-, $\alpha\omega$-bismethylamino-, and $\alpha\omega$-bisethylamino-diorganosiloxanes[3,19,23] and of polyamino-organosiloxanes[81] yields polymers in the absence of catalysts. However, no data have appeared on the use of this method to obtain products of high molecular weight. Eight-membered organosilazane rings containing exocyclic siloxane units and a primary amino-group on every silicon atom in the ring are considerably more reactive. When redistilled, they evolve ammonia and form a polymeric organosiloxazane, to which a ladder structure was assigned[70]:

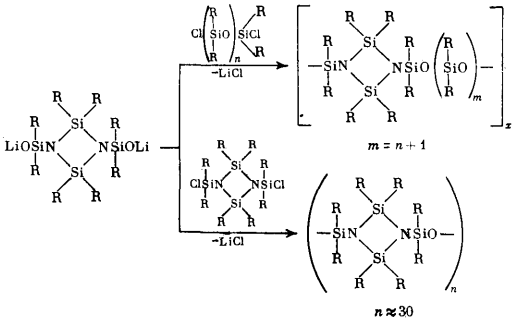
Rather more publications have appeared on the synthesis of cyclolinear organosiloxazanes by heterofunctional condensation. This has most often involved the reaction of cyclodisilazane compounds containing aminosilyl groups with $\alpha\omega$-diol derivatives:

R=H, Me, Et; R′=Me, Ph; R″=Me, Vin, Ph.



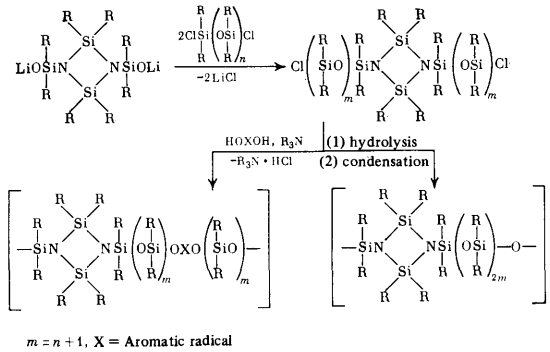
Compounds containing an *SiSi*-dimethylated[47,82–86] or *SiSi*-diphenylated[47,84,86,87] disilazane ring and amino-, dimethylamino-, or diethylamino-silyl groups have been used as cyclic component. The $\alpha\omega$-diols were dimethyl- or diphenyl-siloxane oligomers of various chain lengths[82,84,85], $p$-bishydroxydiorganosilylated benzenes[47,83,86,87], or analogous derivatives of diphenyl ether[86]. The viscosity of the final polymers obtained by the above reaction scheme depended on the reaction conditions and on the nature of the reactants[82]. However, prolonged heating or raising the temperature of the reaction mixture might result in gelation of the polymers.

The probability of the formation of polyorganosiloxazanes having three-dimensional macromolecules is regarded[82] as directly proportional to the probability of cleavage of the disilazane ring (and also the appearance of additional functional groups) under the influence of nucleophilic species formed according to the scheme



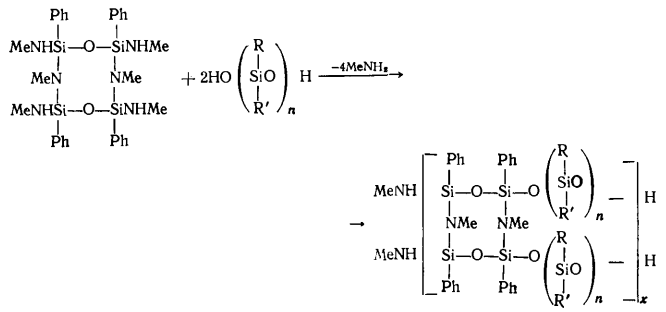
The probability of the appearance of such nucleophilic species should increase with the basicity of the amine, accelerating gel formation by the macromolecules. In the reactions studied a corresponding increase in rate of formation of insoluble polymers has actually been observed according to the nature of R in the sequence $v_H < v_{CH_3} < v_{C_2H_5}$. Reaction between analogous disilazane rings and $p$-bisdiphenylhydroxysilylbenzene in diglyme or xylene goes practically to completion and is not accompanied by fission of cyclic silazane bonds[47].

Polymers have been synthesised by a similar procedure from azasilacycloalkanes of general formula



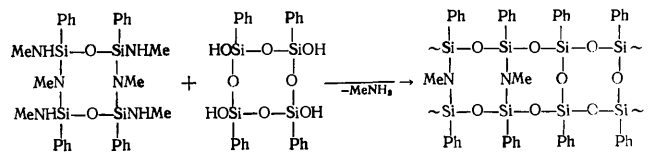
and disubstituted silanediols[88], tetraphenyldisiloxane-1,3-diol, or $p$-bisdiphenylhydroxysilylbenzene[89].

Cyclolinear polymers have been obtained not only by the silanediamine–silanediol type of heterocondensation but also by exchange reactions of cyclic lithium silanediolates with *SiSi′*-dichlorinated cyclodisilazanes or organo-$\alpha\omega$-dichlorosiloxanes[47,65]:



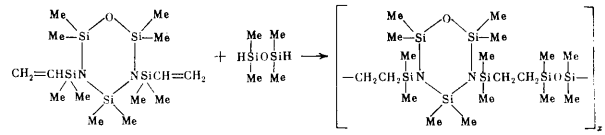
$m = n + 1$

$n \approx 30$



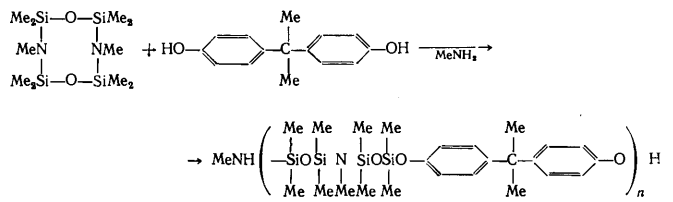
$m = n + 1$, X = Aromatic radical

The use as initial compounds of cyclo-organosiloxazanes of higher functionality ($f = 4$) enables polymers to be synthesised with branched macromolecules or ladderlike siloxazane segments[51]:



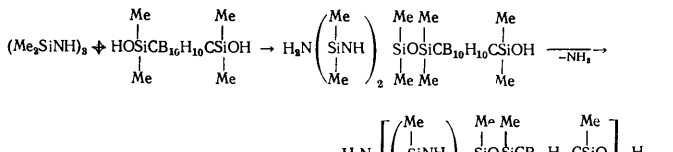
The hydroxylated monomers and oligomers used in these reactions were diphenylsilanediol, tetraphenyldisiloxane-1,3-diol, 1,3-dimethyl-1,3-diphenylsiloxanediol, tetramethyldisiloxane-1,3-diol, decamethylpentasiloxane-1,9-diol, and dimethyl(methylphenyl)siloxane-$\alpha\omega$-diols in which the number average of siloxane units in the molecules was ~100. The nature of the siloxane-$\alpha\omega$-diol—primarily the length and the rigidity of the chain—determined both the course of polycondensation and the structure of the macromolecules. Short and rigid molecules, such as those of diphenylsilanediol and tetraphenyldisiloxane-1,3-diol, caused polycondensation without formation of insoluble polymers having a three-dimensional structure. The use of organosiloxanediols having a very flexible siloxane chain for condensation with cyclic 4,8-dimethyl-1,3,5,7-tetrakismethylamino-1,3,5,7-tetraphenylsil-2,6-dioxa-4,8-diazane, because of the greater mobility of the branches, facilitated long-range intermolecular interaction leading to gel formation. Soluble polymers obtained by this method had molecular weights in the range $(25-30) \times 10^3$.

A polyphenylsiloxazane polymer having a high content of ladderlike segments in the macromolecular chains is formed by the polycondensation of two tetrafunctional cyclic compounds[51]:



The reaction goes almost to completion. Despite the high functionality of the initial monomers, the resulting polymer is a powder readily soluble in aromatic solvents. Light scattering indicates that its molecular weight is $(100-200) \times 10^3$. The use of various organocyclosiloxazanes having functional amino-groups and diphenylpropane-*pp'*-diol has been claimed[90] for obtaining polyphenylated carbosiloxazane polymers by a similar method.

Processes for obtaining polymeric organosiloxazanes by hydride addition have been claimed in the patent literature. In one case this involved reaction of cyclosiloxanes containing vinylsilyl groups with linear or cyclic organosilazanes containing free hydrogen atoms in the presence of chloroplatinic acid[91]. In another process linear organosiloxanes containing terminal hydrogen atoms were heated with vinylsilylated cyclosiloxazanes or cyclo-organosilazanes in the presence of the same catalyst[52]:

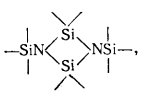


Organosiloxazanes of high molecular weight have been synthesised by splitting some of the silazane bonds in an eight-membered cyclo-organosiloxazane by means of a phenolic hydroxyl[13]:

The elastomeric polycarbosiloxazane obtained had an intrinsic viscosity of 2.7. Polymeric carbosiloxazanes have been synthesised similarly using as hydroxylated compounds fused aromatic diols, bisnitrophenyl sulphone derivatives, and tetraphenylcyclotetrasiloxane-1,3,5,7-tetraol, but polycyclic silazanes were employed together with cyclo-organosiloxazanes[92]. The reduced viscosity of the polymers of this series (0.5% solutions in toluene) lay in the range 0.1–0.95.

The same principle of the partial utilisation of silazane bonds in heterocycles to build up polymer chains underlay the preparation of carborane–siloxazane polymers[108,109]. The reactions of 1,7-bisdimethylhydroxysilylcarborane studied with various heterocycles—hexamethylcyclotrisilazane, octamethylcyclotetrasilazane, hexamethylcyclotrisil-2-oxa-4,6-diazane, octamethylcyclotetrasil-2,6,-dioxa-4,8-diazane, octamethylcyclotetrasil-2,4,6-trioxa-8-azane, and dodecamethylcyclohexasil-2,4,8,10-tetraoxa-6,12-diazane—involved ring cleavage followed by condensation of the linear aminosiloxazanol. With cyclotrisilazane as example the reaction can be written

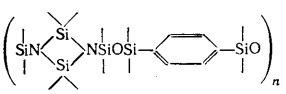
The rate of cleavage of the heterocycles by the hydroxysilylcarborane is significantly affected by the strain in the ring and its content of silazane bonds: the reactivity of the molecule diminished with increase in size of the cyclo-organosiloxazane and decrease in the number of silazane bonds. The specific viscosity of the resulting polymers (1% solutions in benzene) was 0.2–0.3.



The segmental mobility and the elasticity of linear siloxazane macromolecules in which one silazane unit alternated with two siloxane units were closely similar to those for polyorganosiloxanes. Nuclear magnetic resonance data indicated that segmental mobility in a polymer containing the $Si(CH_3)_2OSi(CH_3)_2OSi(CH_3)_2NH$ unit began around −100°C, but in polydimethylsiloxane it began at about −130°C. The energies of viscous flow for these polymers were respectively 4.3 and 3.4 kcal.[79]

The molecular structure of branched cyclic, ladderlike, and three-dimensional polyorganosiloxazanes has been studied by X-ray diffraction, enabling the rigidity of the polymer chain to be assessed[51] from the interplanar spacing $d_1$. The largest spacing $d_1 = 12.0$Å is characteristic of a molecular chain comprising only cyclic tetrasiloxazane and siloxane units (see fourth last equation and polymer formula above). Replacement of the siloxane ring in this reaction by linear organosiloxane-$\alpha\omega$-diols produced a gradual decrease in $d_1$ to 7.5Å with increase in the length and flexibility of the chain of linear organosiloxanes.

Investigation of the stabilising influence of silazane bonds on the thermo-oxidative degradation of organosilicon polymers[93] revealed that the Si–NH–Si group has a significant stabilising effect on the main chains of siloxazane molecules, with considerably less effect on the rate of degradation of organic groups surrounding the main chains. Such a unit serves as a barrier to depolymerisation of the main chain; in its presence, furthermore, fairly intense oxidation of methyl groups attached to silicon atoms has been observed, leading to branching, three-dimensional cross-linking of the polymer, and thus an additional thermostabilising effect.



However, a silazane unit containing a secondary nitrogen atom is less stable than Si–NR–Si (R = Alk or Ar) and $Si–N(SiAlk_3)–Si$ groups not only to hydrolytic cleavage but also in the thermo-oxidative degradation of polyorganosiloxazanes. The presence of organosilazane groups having a secondary nitrogen atom is evidently one reason for the relatively low thermal stability in air of several polycarbosiloxazanes[92].

Cyclodisilazane groupings of the type

when introduced into siloxane chains, not only prevent the development of degradative processes involving stepwise cyclisation but also are "suppressors" of hydroxy-groups appearing during thermo-oxidative reactions. Interaction of one hydroxysilyl group with a cyclodisilazane segment does not entail breakdown of the main molecular chains. In a series of polymers whose macromolecules consist of dimethylsiloxane chains separated by tetramethyldisilazane rings thermo-oxidative degradation begins over the temperature range 400–450°C.[82]

Perphenylated polymers having a minimal content of linear chains remain as yet the most stable polyorganosiloxazanes to both thermal and thermo-oxidative treatment. Examples are cyclodisilazane polymers[47] of general formula

and polymers whose macromolecules have predominantly a ladder structure (see fourth last equation above)[51]. Thermal degradation of the former polymers (in nitrogen at 2.8 deg $min^{-1}$) and thermo-oxidative degradation of the latter (in air at 2.7 deg $min^{-1}$) began in the region of 500°C.

## V. PROSPECTS FOR PRACTICAL APPLICATION

Polyorganosiloxazanes have been tested as protective coatings in the electronics industry[94] and on solar energy installations[95]. The stability of the optical properties of organosiloxazane varnishes on prolonged exposure to light and weathering, combined with good adhesion, moisture resistance, and durability, has permitted these coatings to be recommended for protecting the working surfaces of photocells and concentrators in solar energy technology[95]. Polymers containing organocyclodisilazane segments are among the most thermostable types of binders for paint technology.

Organosiloxazane varnishes and coatings are promising protective materials, exhibiting not only high thermal stability but also the ability to harden under normal conditions by interaction with atmospheric moisture[95,96]. The increasing density of three-dimensional cross-linking of macromolecules during hardening is an obstacle to complete disappearance of silazane groups from the polymeric binder. Several features of film formation by the replacement of some of the silazane bonds by siloxane bonds have been investigated[97]. The drying times in air of coatings used in solar energy technology[95] and recommended for the protection of semiconductor materials and instruments[96] are 0.5–5 h. The adhesion of varnishes to steel and copper surfaces reaches 47 kg $cm^{-2}$ after the coatings have been kept at room temperature for 5 days. The adhesion parameters of the materials can be somewhat improved by heat-treatment. Both Soviet[98–100] and foreign[87,89,101–103] patents indicate not only individual characteristics of the coatings but also fields of application—electrical engineering, electronics, the paper, textile, and leather industries, the protection of glass and silicate surfaces, etc.

Organosiloxazane elastomers are less well represented in the literature. Elastomeric copolymers containing Si–NH–Si units are considerably more thermostable than siloxane rubbers with similar radicals attached to the silicon atoms, but are inferior to the latter in resistance to hydrolytic cleavage[80]. Replacement of secondary-nitrogen silazane bonds in the elastomers by tertiary-nitrogen or especially trisilylamine bonds should improve considerably the resistance of such materials to moisture and to water. Filled organosiloxazane elastomers whose macromolecules contain also carborane and trifluoropropylsilyl groups are distinguished by long fatigue life over the temperature range 300–350°C.[104] Methods for obtaining elastomeric siloxazane materials and for their vulcanisation have been given in patents[5,83,86].

It has been proposed to introduce compounds of boron, phosphorus, titanium, iron, and certain others into organosiloxazane binders to enhance the heat resistance and improve the physicomechanical characteristics[105,106]. On the other hand, additions of methylphenylsiloxazane polymers to stabilising mixtures in the manufacture of polyamides tend to increase the resistance of articles to heat and light[107].

The advisability of using organosiloxazane compounds, primarily organocyclosiloxazanes, to obtain polymeric

organosiloxanes has been noted repeatedly both in the periodical and in the patent literature. In most cases the synthesis is accomplished by the heterocondensation of silazane groups with dihydric phenolic derivatives[110-114].

# Some Aspects of the Coordination Chemistry of the Lanthanides

V.T.Panyushkin, Yu.A.Afanas'ev, A.D.Garnovskii, and O.A.Osipov

A systematic account is given of data (mainly for the period 1965-1975) on the coordination chemistry of the lanthanides: the synthetic, phsysicochemical, and structural aspects of lanthanide complexes, mainly with organic oxygen- and nitrogen-containing ligands are examined. Attention has been concentrated on the application of the physical and physicochemical research techniques in the chemistry of lanthanide complexes.
The bibliography includes 484 references.

## I. INTRODUCTION

Since the publication of the monograph of Yatsimirskii et al.[1], extensive data have accumulated on the coordination chemistry of the lanthanides, their publication being associated not only with theoretical research but also and mainly with the significant expansion of the applications of the lanthanides and their complexes. During the last 10–12 years, reliable methods have been developed for the isolation of all the lanthanides in a pure state[2,3], which extended the possibility of their practical applications in technology in those cases where the purity of the lanthanides is the main requirement (laser and semiconducting materials, glasses of different kinds, ceramics, etc.)[2]. Coordination compounds of lanthanides in general and chelate complexes in particular are used in liquid media lasers (europium and terbium chelates)[4,5]. Lanthanide complexes are used successfully as chemotherapeutic preparations, including anticancer agents[6], although lanthanides (Ln) are not "metals of life"[7]. The use of lanthanide compounds as paramagnetic shift reagents (PSR) assisted the development of NMR spectroscopy[8-11]. Coordination compounds of the lanthanides are also used in Mössbauer spectroscopy[12-13].

Even a brief list of the advances in the employment of lanthanide complexes in various branches of science and engineering demonstrates the necessity for an account of the achievements of the coordination chemistry of the lanthanides during the last 10 years. At the same time the reviews on PSR already published (see, for example, Refs. 8–11) are concerned to only a very limited extent with this field, which is closely related to lanthanide

complexes. This review is virtually not concerned with the problems of complex formation and extraction of the lanthanides and their analytical chemistry. Despite their urgency, these are too broad for inclusion in this review, which is devoted to advances in the synthesis and the study of the physicochemical properties and structure of lanthanide complexes achieved during the 1965–1975 decade.

## II. CHARACTERISTICS OF THE COMPLEX FORMATION REACTIONS

Whereas in the 1950's it was believed that the ability to form complexes is not a characteristic property of the lanthanides, the data which have accumulated during the last two decades created a new chapter in coordination chemistry—the chemistry of lanthanide complexes[14-17].

Certain features of the coordination chemistry of the lanthanides were examined previously by Yatsimirskii[1], Muller[2], Spitsyn and Martynenko[17], and Forsberg[16]. The majority of experimental data on the splitting of the energy levels of the 4*f* electrons of lanthanide ions on complex formation are nowadays interpreted in terms of the parameters of the semiempirical crystal field theory (CFT). The distinctive features of the states of *f* electrons in lanthanide complexes are associated primarily with the fact that they are to a large extent shielded from the ligand theory by the outer *s*, *p*, and *d* electrons and are therefore less subject to its perturbing influence. In those cases the spin–orbital interaction is much more pronounced than for *d* electrons. An unusual version of a weak crystal field therefore arises for *f* electrons, being weaker than the interelectron and spin–orbital interactions[18].

In order to determine the energy states of the lanthanide ion in the crystal field, it is necessary to begin by considering its states with allowance for interelectron and spin–orbital interactions, which are characterised for each state with the given orbital ($L$) and spin ($S$) quantum numbers by the additional quantum numbers $J$ of the total momentum operator. The distribution of the electron cloud in compounds with a total momentum $J$ and the splitting of the levels of the latter under the influence of the electrostatic effect of the ligand field must be calculated by methods of perturbation theory or determined qualitatively by methods of group theory[18]. Quantitative calculations of the splittings of the energy states of *f* electrons are performed similarly to those for *d* electrons[19], but attempts to calculate the CFT parameters for lanthanide compounds with a known structure[20] have demonstrated the impossibility of achieving a satisfactory agreement between the non-empirical values of the CFT parameters and the experimental data.

In the 1960's an attempt was made to describe more realistically the nature of the chemical bonds between lanthanide ions and ligands on the basis of the molecular orbital (MC) theory, which makes it possible to take into account the degree of covalence of the bonds under consideration. It is noteworthy that the accuracy of the calculations performed hitherto is low. Nevertheless it is believed to be an established fact[18,21] that a considerable (if not the major) component of the splitting of the energy levels of the 4*f* shell is due to the influence of the overlapping of the 4*f* orbitals of the lanthanide and the ligand orbitals. The overlap integral between the 4*f* orbital of the lanthanide ion and the valence $np$, $ns$ ligand orbital is an order of magnitude smaller than the overlap integral between the outer vacant orbitals[21]. One may therefore expect that the influence of the overlap of the wave functions of the lanthanide ion and the ligands on the structure of the 4*f* shell is slight.

The influences of the external electrostatic field and the overlap of the 4*f* orbitals with ligand orbitals on the splitting of the energy levels of the 4*f* shell have been compared[20-24]. The *f* electrons shielded by *d* electrons in the lanthanide complexes have been shown to form weak covalent bonds with the ligands. The covalent bonds between lanthanide ions and ligands are formed mainly as a result of the mixing of the occupied ligand orbitals with partially occupied 4*f* orbitals and vacant 6*s*, 6*p*, and 5*d* orbitals of the lanthanide ions. The vacant 6*s*, 6*p*, and 5*d* orbitals are located outside the occupied $5s^2$ and $5p^6$ shells; the pair integrals for the overlap of the orbitals considered with the ligand orbitals are approximately 0.1. Calculations by the MO method in terms of the Wolfsberg–Helmholtz approximation (MWH), for example, for the tetra-acetatoeuropate anion[25], make it possible to infer the properties of the valence shell of the lanthanide. Calculations have been made[25] on the two complex ions $[EuO_8]^-$ and $[EuO_8]^{5-}$ and it was found that the excess charge is concentrated mainly at the oxygen atoms without altering significantly the orbital population of the europium atom. The MO method usually yields a somewhat high covalent contribution to the chemical bond, "equalising" the charges on the atom; nevertheless it can be regarded as established that the charge of the valence shell is quite capable of influencing appreciably the splitting of the energy levels of the 4*f* shell[26].

When the influence of the overlap of the 4*f* orbitals and the valence shell orbitals of the ligand on the splitting of the energy levels of the 4*f* shell is considered within the framework of the LCAO-MO method, it is believed useful[21] to distinguish two effects: the covalent mixing of a partially occupied *f* orbital of the lanthanide ion ($f_\alpha$) with a fully occupied group orbital of the ligand ($\Phi_\alpha$) and the change in the energy of the molecular orbital of the complex ($\psi_\alpha$) owing to the overlap of the $f_\alpha$ and $\Phi_\alpha$ orbitals. Calculation[26] of the energy of the antibonding orbital taking into account both effects yields values in agreement with the observed experimental splitting.

In terms of the MWH approximation, it is also possible to estimate the relative positions of the energy levels of the 4*f* orbitals as a function of the structure of the coordination polyhedron. In conformity with theory[26], an admixture of covalent bonding in an ionic bond should favour the formation of coordination polyhedra with vertices distributed in the direction of the maxima of the hybrid $sp^3d^n$ orbitals. This requirement is satisfied primarily by the nine-coordination polyhedron with $D_{3h}$ symmetry. Among the polyhedra with a coordination number (C.N.) of 8, the dodecahedron with $D_{2d}$ symmetry, in which the σ bonds are formed via the $sp^3d^4$ hybrid orbitals, and the square antiprism ($D_{4d}$ symmetry), where the $sp^3d^4$ or $p^3d^5$ valence orbitals are hybridised, are preferred. There is also the possibility of a nine-coordination polyhedron with $C_{4v}$ symmetry[27].

Calculations[28] have shown that the contribution of the *f* orbital to a coordinate bond is sometimes very high (between 34.8 and 46.2%) and the difference between the contributions of the *f* and *d* orbitals to the structure of the polyhedra diminishes with increasing atomic number of the element in the series of lanthanides. The relation between the existence of three regions of crystal-chemical instability in the series of lanthanides and the extrema on the energy curves of 4*f* orbitals has been discussed[29]. The first region usually corresponds to Pr, Nd, and Sm, the

second to Gd, and the third to Dy, Ho, and Er. The change in structure in the first region of crystal-chemical instability can be accounted for by a sharp decrease of the energies and effective radii of the 4*f* orbitals, calculated [30] by the Thomas–Fermi method. The possibility of the involvement of heavier lanthanides in bonds formed via *f* orbitals is also postulated [29].

It can be regarded as established that the symmetry of the coordination spheres of lanthanide ions sometimes deviates significantly from that predicted for the purely electrostatic model. The characteristics of the geometry of the ligand the capacity of the coordination sphere for mixing play an important role under these conditions: for example, when solvent molecules or those of some other inorganic or organic ligand are coordinated simultaneously in addition to the primary organic ligand.

The study of the relative geometries of lanthanide complexes has also proved convenient in the application of the MO method in terms of the angular overlap approximation [31]. The method is based on the assertion that the destabilisation of the central atom owing to the formation of covalent bonds is proportional to the square of the angular component of the overlap integral, which depends strongly on the geometry of the complex. Since the bonding orbitals in lanthanide complexes are located mainly at the ligands and the antibonding orbitals at the central atom (c.a.), the antibonding effects assume principal importance in the formation of covalent bonds in lanthanide complexes. Thus there is a possibility of estimating the influence of the antibonding effects on the symmetry of the complex. For lanthanide complexes with the $f^0$, $f^7$, and $f^{14}$ electronic configurations, the antibonding effects do not influence the symmetry of the complex, which depends only on the electrostatic metal–ligand interaction.

When the bond between the central atom and the ligand is predominantly ionic, higher coordination numbers, permitted by the relative dimensions of the central atom and the ligand, are preferable (depending on the size of the ligand, coordination numbers of 8–12 and sometimes [14–16] higher are possible for lanthanide compounds); for a given coordination number, the polyhedron with triangular faces is preferable, since it constitutes a closer approximation to the sphere. Thus, whereas for the lanthanides with the $f^0$, $f^7$, and $f^{14}$ configurations the symmetry of the complexes depends only on the ion–dipole electrostatic interaction, for the remaining lanthanides complexes having the composition $LnL_6$, for example, where L is the ligand, are formed comparatively rarely and have the structure of an octahedron and not a trigonal prism (in the latter case, the antibonding effect is a minimum [31]). A detailed consideration [32] has also shown that the antibonding effects for lanthanide complexes with different coordination numbers may determine the fine structure of their coordination polyhedra.

The partly covalent nature of the bond in lanthanide complexes is also to some extent demonstrated by the results of physical measurements: the study of luminescence spectra, absorption spectra in different wavelength ranges [31], Mössbauer spectra [12,22], and the deviation of the symmetry of the complexes revealed by X-ray diffraction analysis from the predictions based on the electrostatic model [18]. The partly covalent nature of the chemical bond in the coordination compounds necessitates the classification of the latter as labile and not as inert complexes. The lability of the lanthanide complexes and the ability of lanthanide ions to form complexes with variable and high coordination numbers create difficulties in the study of coordination compounds of the lanthanides in both the solid state and in solution.

In conclusion yet another interesting feature of the coordination chemistry of the lanthanides must be pointed out. Although the most characteristic oxidation state of the lanthanides is 3+, certain lanthanide ions, namely those of europium(III), ytterbium(III), and samarium(III), exhibit a tendency towards reduction to the bivalent state [33], the europium(III) ion showing the highest electron affinity and being most readily reduced to europium(II). It is thus not fortuitous [34] that europium(II) complexes of *NN*-bis-(1-acetonylethylidene)ethylenediamine have been isolated on a preparative scale.

All the foregoing factors illustrate the complexity and wide variety of the problems involved in the study of the coordination compounds of the lanthanides and demonstrate the necessity for the employment of many methods in the synthesis and physicochemical study of such complexes.

## III. SYNTHESIS OF COORDINATION COMPOUNDS

The isolation of individual lanthanide complexes requires a careful selection of solvents and appropriate variation of the molar ratios of the reactants and the pH of the medium. In water, one of the commonest solvents [4,16,17] for the synthesis of coordination compounds of the lanthanides, complexes are formed mainly with weakly basic chelating organic ligands. This conclusion has been confirmed by numerous examples: chelate lanthanide complexes have been formed with complexones [1,14,35–38], β-diketones [39,40], pyrazolones and their derivatives [41], 8-hydroxyquinoline *N*-oxide [42], as well as complexes of certain monodentate ligands (urea [43], thiourea [44], guanidinium hydrogen carbonates [45]), etc. [1,14,46,47]. As a rule, in addition to the organic ligand, solvent (water) molecules are coordinated at the same time, but complexes without solvent molecules can be isolated from an aqueous medium [48,49].

Similar results can be obtained also in aqueous organic media, since the sequence of solvents in terms of their electron-donating properties relative to the lanthanides ("hard acids") [48] indicates an appreciable stability of the hydrates of lanthanide compounds [50,51]. At the same time anhydrous lanthanide complexes or complexes with a mixed ligand environment can be isolated from aqueous organic media prepared on the basis of oxygen-containing solvents with a higher electron-donating activity than that of water [for example, dimethyl sulphoxide (DMSO) or dimethylformamide (DMF)] [49]. The atomic number of the lanthanide, the nature of the organic solvent, and the component ratio in the water–organic solvent mixture used as a medium for the synthesis of the complexes have a significant influence under these conditions on the composition of the coordination sphere. One of the most suitable media for the synthesis of lanthanide complexes is a water–ethanol mixture in which complexes of lanthanides with complexones [1,6,17] and oxygen-, nitrogen-, and phosphorus-containing ligands [1,14–17,52–55], including tetramethyl sulphoxide [52], salicylidenehydrazine [56], *N*-salicylideneanthranilic acid [54], hexafluoroacetylacetone, 4-methylpyridine [55], chloro-derivatives of *o*-hydroxyacetophenone [58], etc. [1,16,17,49], have been obtained. Crystalline holmium bisdipivaloylmethanate [57] and trisdipivaloylmethanate [58,59], whose existence in solution had been

postulated in an earlier study [60], were synthesised in the same solvent mixture in an alkaline medium from holmium nitrate and dipivaloylmethane.

Table 1. Compositions of lanthanide coordination compounds [72-219].

| Formula | L | X, $n$ | References |
|---|---|---|---|
| $LnL_nX_3$ | Pyridine, 1,2-propylenediamine, 2,4,6-tri-α-pyridyl-1,3,5-triazine, thioxane oxide, tetramethylene sulphoxide | X = Cl, $NO_3$, $ClO_4$; $n$ = 2—9 | 72—78 |
| $LnL_6X_3 \cdot nH_2O$ | Antipyrine, o-phenanthroline, *NN'*-ethyleneurea, tetramethylurea, 1,3-, and 1,1-dimethylurea | X = Cl, Br, I, $ClO_4$, $NO_3$, NCS; $n$ = 0—3 | 79—84 |
| $LnL_8X_3$ | Urea, *NN*-dialkylamide | X = I, NCS | 85—88 |
| $LnL_4X_3 \cdot nH_2O$ | Hydrazine, 1,10-phenanthroline, urea, alkylthiourea, dimethylformamide, dimethylacetoacetamide, *NNN'N'*-tetramethylmalonamide | X = Cl, $NO_3$, $SO_4$, $ReO_4$, NCS, $ClO_4$, $C_2O_4$; $n$ = 0—2 | 89—104 |
| $LnL_3X_n$ | Hydrazine, pyridine, glycolate, acetylacetonate, benzoate, propionate, alkylphosphonothioate, dipivaloylmethanate, α-aminoacids, β-diketones, Schiff bases, cyclopentadiene | X = $H_2O$, EtOH, MeOH; $n$ = 0—4 | 65—67, 105—141 |
| $LnL_2X_3 \cdot n$Solv | 1,10-phenanthroline, 2,2'-bipyridyl, hydrazine, uropropine, antipyrine, α-aminoacids, α-furoin oxime, alkyldiantipyrylmethane, tributyl phosphate, isocyanate | X = Cl, F, I, $SO_4$, $C_2O_4$, $ClO_4$, $NO_3$, SCN, SeCN; Solv = $H_2O$, EtOH, MeOH, $n$ = = 0—5 | 142—154 |
| $LnL_2X \cdot nH_2O$ | Dipivaloylmethanate, phthalocyanine, diphthalocyanine | X = Cl, Br; $n$ = 0—2 | 57—155 |
| $Ln(L)X_m \cdot nH_2O$ | 4,4'-diamino,3,3'-dimethylbiphenyl, 4,4'-di-pyridylbenzimidazole, α-aminoacids, malonate, butyrate, tartrate, hydroxyethyl iminodiacetate | X = Cl, $NO_3$; $m$ = = 0—3, $n$ = 1—6 | 156—169 |
| $LnL \cdot nH_2O$ | Ethylenediaminetetra-acetate, nitrilotriacetate, citrate, alkylphosphonate, trimellitate | $n$ = 0—8 | 170—183 |
| $LnL_3L'_n$ | L = β-diketone, chlorosalicylate, 2-hydroxy-3-naphthoate, 2,2,6,6-tetramethylheptane-3,5-dionate; L' = picoline, pyridine, 1,10-phenanthroline, quinoline, triphenylarsine oxide | $n$ = 1,2 | 184—194 |
| $LnL_3(NO_3)_2(ClO_4)_2$ | 2,2'-bipyridyl | — | 195 |
| $LnL_2X_3 \cdot nH_2O$ | 1,10-phenanthroline, 4,4'-bipyridyl, 2,2'-bi-pyridyl, tetrahydrofuran, thiourea, triglycine | X = Cl, $NO_3$, SCN, SeCN, $C_2H_3O_2$; $n$ = = 0—6 | 196—216 |
| $Ln_2L_3 \cdot nH_2O$ | Malonate, picolinate, quinolinate, diethylmalonate, dihydroxymalonate | $n$ = 1—8 | 217—219 |

Absolute benzene, which exhibits a weak solvating capacity, is frequently used to synthesise anhydrous lanthanide complexes. However, the low solubility of lanthanide salts in benzene makes it necessary to carry out the synthesis using lanthanide alkoxides. Sparingly soluble chelate complexes of the lanthanides with *o*-hydroxyazomethines have been synthesised in the same solvent [61-64]. Complexes of the lanthanides with Schiff bases can be obtained from the lanthanide chlorides in methanol [65-67].

The method whereby lanthanide complexes are obtained in the absence of solvents is extremely convenient. Comparatively unstable complexes of a series of lanthanides with monodentate acids [1,68-71] and nitrogen-containing ligands [16], for example with organic acids [68-70] and aliphatic heterocyclic amines [1,16], are synthesised by this procedure. However, although we believe it is extremely promising as a method for the preparation of non-solvated lanthanide complexes, it has not so far been adequately used in the coordination chemistry of the lanthanides.

When the molar ratio of the reactants (lanthanide salts and ligands) is varied, it is possible to obtain complexes having different compositions and coordination numbers ranging from 6 to 12 (Table 1). [79-219] It has been shown [220] that, for different reactant ratios (1 : 4, 1 : 5, and 1 : 7), the same ligand (antipyrine) in methanol can give rise to the complexes $Y(Ant)_n(NCS)_3$, where $n = 4-6$, and, when the ratio is 1 : 3, the complex is $Y(Ant)_3(NCS).2CH_3OH$. The composition of lanthanide complexes of hydrazine also depends significantly on the reactant ratio [221].

Control of the pH of the medium in which the complexes are obtained is important for the synthesis of lanthanide complexes. Allowance for this factor is particularly necessary when the synthesis is carried out in an aqueous medium: the ligands must be weakly basic compounds incapable of precipitating the lanthanide hydroxide or hydroxo-salt [222-226]. This is why it is impossible to isolate from aqueous and aqueous organic solutions lanthanide complexes with amines which have high $pK_a$ values [16].

The influence of $pK_a$ on the formation of lanthanide complexes with nitrogen-containing ligands was noted by the present authors [169]: $LnCl_3$ (Ln = Sm or Eu) reacts with benzimidazole ($pK_a$ = 5.53) to form the complexes $LnCl_3.L.6H_2O$ in aqueous methanol, while the reaction with imidazole ($pK_a$ = 7.05) results in the formation of lanthanide hydroxides. This is apparently why it is comparatively easy to synthesise lanthanide complexes of weakly basic [227] and oxygen-containing ligands [200-226] in water-containing media. Strict control of the pH of the medium is necessary not only to prevent the possible formation of lanthanide hydroxides but also for the specific synthesis of lanthanide complexes of a particular type. Metal chelates are usually synthesised in weakly alkaline media [1,35,36,42,56,71,228,229], the required pH values being attained by the addition of ammonia or alkali; molecular lanthanide complexes of the type $LnX_3.mL.pS$olv (Table 1) are isolated from nearly neutral solutions; together with adducts of the above type, protonated lanthanide complexes are formed in acid media [230-233].

Reliable synthetic procedures and comprehensive study of the physicochemical properties of a wide variety of lanthanide salts [234-237] made it possible to obtain various coordination compounds of the lanthanides with oxygen- and nitrogen-containing ligands (Table 1) and to determine the influence of many factors on the composition of the complexes and the coordination number of the lanthanide. The highest coordination numbers are attained in lanthanide complexes with neutral ligands when the lanthanide salt anion is a pseudohalide species [108,152,202] or perchlorate [238]. For example, $Ln(phen)_4(ClO_4)_3$ and $Ln(terpy)_3.(ClO_4)_3$ with coordination numbers of 8 and 9 respectively have been synthesised [72,74]. Tris-complexes with bipyridyl and phenanthroline [152,202] have been obtained using the anions $NCS^-$ and $SeCN^-$: according to infrared spectroscopic data [108], the coordination number in such complexes is 9. On the other hand, when the anion is $Cl^-$ or $NO_3^-$, bis-complexes are formed and a coordination number greater than 6 is attained as a result of the binding of solvent molecules [89]. Analysis of X-ray diffraction data for lanthanide complexes with isoelectronic and tetrahedral ($ClO_4^-$, $SO_4^{2-}$, $PO_4^{3-}$, and $SiO_4^{4-}$) and triangular ($NO_3^-$, $CO_3^{2-}$, and $BO_3^{3-}$) anions demonstrated [238] a decrease of the coordination number of the lanthanide with increase of the formal charge of the oxo-anion. At the same time

the coordination number in the series of lanthanide complexes with $EO_4^-$ anions decreases from 9 to 6, while in the case of $EO_3^-$ the decrease is from 12 to 8.

The influence of the nature of the lanthanide on the coordination numbers of the complexes has been discussed in detail by Aslanov and Porai-Koshits[238]. The tendency towards a decrease of the coordination numbers of the lanthanides from lanthanum to lutetium has been known for a long time[1,14,16,17]. The authors[238] note that the coordination numbers of the lanthanides in compounds belonging to the same series (sulphates, phosphates, hypophosphites, and silicates) are higher for the lighter lanthanides than for the heavier lanthanides. This tendency has also been observed for lanthanide complexes with nitrate, carbonate, carboxylate, and also borate anions and with organic acid amides. Having explained these trends, Aslanov and Porai-Koshits, emphasised justifiably that the coordination numbers of the lanthanides and the composition of their complexes depend significantly on the nature of the ligand.

Chelating ligands stabilise complexes with a constant coordination number of the lanthanide regardless of the atomic number of the latter. In this case the coordination number is determined primarily by the geometrical characteristics of the ligand system: the number of members in the metal-containing rings and the number of such rings, the rigidity of their configuration, and other factors resulting from the stability of the metal chelates [239]. Among the factors enumerated, the number of members in the metal-containing rings assumes a particularly important role[238]: four-membered rings promote the formation of lanthanide complexes with coordination numbers of 8–12; five-membered rings lead to complexes with constant coordination numbers (9 for light lanthanides and 8 for heavy lanthanides); six-membered rings give rise to complexes with coordination numbers of 8 (light lanthanides) or 7 (heavy lanthanides).

A constant composition of the complexes over the entire series of lanthanides can arise also for compounds with bulky monodentate ligands (for example a coordination number of 6 is obtained for lanthanide complexes with *NNN'N'*-tetramethylurea)[238]. Extensive reviews of the formation of crystalline lanthanide complexes have been published in monographs[240,241]. Methods of synthesis characteristic of $\pi$-complexes of transition metals predominate in the chemistry of $\pi$-complexes of the lanthanides[242,243].

## IV. THERMODYNAMICS OF COMPLEX COMPOUNDS

After the publication of the monograph of Yatsimirskii et al.[1], numerous studies demonstrating the validity of the approach of these workers to the interpretation of the thermodynamics of lanthanide complexes with a wide variety of ligands were carried out; this makes it possible to take into account, in estimating the stability of lanthanide complexes, the fine structure of the ligand system and the influence of a number of factors on the complex formation process (i.e. on the number and types of reactions) namely the composition of the complex and other factors[244–250].

Calorimetric measurements of the enthalpies of stepwise complex formation, which have many advantages compared with the usual methods for estimating formation constants[244], have recently become important. The calorimetric titration method[245], whereby it is possible to obtain information in many cases about the number and type of reactions occurring simultaneously in the system and also about the concentrations of various reactants involved, is of particular interest. Furthermore, the method permits the determination of the values of $\Delta H$, $\Delta S$, and $\Delta G$ solely on the basis of calorimetric data. For example, a linear correlation between $\Delta H$ and $\Delta S$ has been observed for lanthanide fluoride complexes[247], which makes it possible to regard $LnF^{2+}$ complexes as compounds with predominantly ionic bonds. Positive and fairly high entropies of formation (18–20 e.u.) lead to the conclusion[246–248] that lanthanide fluoride and sulphate complexes have an inner-sphere structure.

All the thermodynamic characteristics of the complex formation reactions of the lanthanides (except promethium) with various organic ligands are now known, namely for propionate, isobutyrate[251], $\alpha$-hydroxyisobutyrate[252], acetate[39], lactate[252], glycolate[251], mercaptopropionate[253], diglycolate[39], ethylenediaminetetra-acetate (EDTA), ethyl sulphate[253,254], nitrilotriacetate (NTA),[255] diethylenetriaminetetra-acetate (DTRA),[256,257] triethylenetetramine[16], triaminotriethyleneamine[258], threonine and hydroxyproline[259], and thioglycolic acid[260], and others.

Examination of the above studies reveals certain general characteristics in the variation of the thermodynamic functions of the complex formation reactions of the lanthanides. The higher values of $\Delta H$ for lanthanide glycolates compared with the acetates, propionates, and isobutyrates can probably be accounted for by the formation of an additional bond with the hydroxy-group of the glycolate anion. Replacement of the oxygen atom by a sulphur atom reduces the stability of the complexes and the $\Delta H$ and $\Delta S$ for the lanthanum, samarium, and erbium thioglycolates, which have been investigated, are very close to those for the lanthanide acetates[252]. The thermodynamic parameters of the lactates and $\alpha$-hydroxyisobutyrates are close to the corresponding parameters of the glycolates:

| | $\Delta H$, kcal mole$^{-1}$ | |
|---|---|---|
| | La | Lu |
| Lactates (Ref.252) | —1.58 | —2.19 |
| α-Hydroxyisobutyrates (Ref.252) | —1.96 | —1.11 |
| Glycolates (Ref.252) | —0.85 | —0.65 |
| Glycolates (Ref.24) | —0.63 | —0.29 (Yb) |

Assuming that diglycolate complexes are formed mainly as a result of the disruption of the hydration shell of the hydrated lanthanide ion, the authors[253] showed that a sharp change in the entropy and hence the disruption of the hydration shell begin approximately in the middle of the lanthanide series.

The heat of the reaction $Ln^{3+} + L^{3-} \rightarrow LnL$, where $H_3L$ = NTA, has been measured for the lanthanides except lanthanum[254]. The heat of formation of LaNTA has been measured by Milyukov and Polenova[255]. In the lanthanum, gadolinium, and lutetium series, there is a maximum (or minimum) in the absolute heat of formation corresponding to gadolinium, as for simpler organic ligands. $\Delta S$ is constant for lanthanides of the cerium group, while in the yttrium group it increases.

The $\Delta H$ for lanthanide complexes of EDTA increase from lanthanum to neodymium, decrease on going to terbium, then increase again, i.e. the overall variation is the same as for other complexes[256,257]. However, there is a significant difference: the dependence of the heat of formation and $\Delta S$ on the atomic number of the lanthanide in LnEDTA has a minimum corresponding to gadolinium (as for LnCDTA complexes[258]). This is most probably associated with the different structures of the complexes

formed by the lanthanides of the cerium and yttrium groups. Data for the variation of entropy in the series of these complexes are consistent with the above hypothesis[259]. The maximum entropy change is observed for the LnCDTA complexes (up to 80–105 e.u.)[258]. The deviation of the $\Delta H$ for the complexes in the lanthanum, gadolinium, and lutetium series from the monotonic variation shows that the complexes LnEDTA are stabilised when the lanthanide belongs to the cerium group and are destabilised when it belongs to the yttrium group.

The available data[249,250,258] show that the variation of the thermodynamic functions with the atomic number of the lanthanide is non-monotonic for all the complexes. There is a definite parallelism in the variation of both thermodynamic functions ($\Delta H$ and $\Delta S$) of lanthanide complexes with the same ligand, but the $\Delta H$ and $\Delta S$ for ligands having different structures and different numbers of binding sites can vary similarly in the given series. Consequently the nature of the variation of the thermodynamic functions is determined by the variation of the properties of the central atoms and not the ligands. The non-monotonic S-shape of the curve relating the enthalpy to the atomic number of the lanthanide is evidence against the view that the interaction between lanthanide ions and ligands is predominantly electrostatic. According to some data[244–246], the variation of the thermodynamic functions in the series of lanthanides may be determined by the variation of the structure of the complex, particularly by the variation of the coordination number and probably the contribution of the *f* orbitals to the formation of the coordinate bond[260].

In the formation of lanthanide complexes with valine (an $\alpha$-aminoacid)[261] in an aqueous medium, the stability constant $K_1$ varies at temperatures from 15° to 55°C in the range from lanthanum to lutetium with a break corresponding to gadolinium. The dependence of $\lg K_1$ on the atomic number of the lanthanide is represented by a convex curve with a maximum in the cerium group, which can be explained by the partial formation of a covalent bond, when account is taken of the extra stabilisation energy, and by the variation of the coordination number in the series of lanthanides. Inner-sphere coordination of the metal and ligand with disruption of the hydration shell of the former has been suggested for lanthanide complexes of glycine and histidine[262,263]. However, these studies[262,263] were performed at high ionic strengths (2 and 3.0 M $NaClO_4$ respectively). One may therefore presume that an increase of the overall concentration in the medium ($NaClO_4$ + ligand) entails a greater degree of disruption of the hydration shell of the metal ion with displacement of solvent molecules from its inner sphere. At an ionic strength of 0.1 (KCl), the hydration shells of the metal ions are not disrupted for cerium-group elements but are involved in the reaction to some extent for the yttrium-group elements, which entails a rapid increase of $\Delta S$ with the atomic number of the lanthanide.

A steady increase of stability from lanthanum to lutetium has been observed for lanthanide complexes of $\beta$-phenyl-$\alpha$-alanine, tyrosine, and tryptophan[264], *NN*-biscarboxymethyl-2-aminoalkanoic acids[265], 1,3-diamino-5,5-dimethylcyclohexane[266], methyl 3-mercaptopropionate[267], and ethylene-*NN'*-diaminediglutaric acid[268]. The observed steady increase of stability from lanthanum to lutetium can be accounted for by the fact that the ionic radius decreases in the La–Lu series and there is a corresponding increase in the electron affinity of the element, which increases in its turn the degree of coordination of the lanthanide to the nitrogen atom (in the $NH_2$ group of the aminoacid).

The stability of the complex is known to be inversely proportional to the dissociation constant of the ligand ($K_d$). This rule is valid also for lanthanide complexes. The stability constants of lanthanide acetates are higher than those of the monochloroacetates, while the $K_d$ of acetic acids increase with increase of the number of chlorine atoms[269]. The same rule has been noted for lanthanide salicylates, anthranilates, acetylacetonates, and 8-hydroxyquinolinates[210,270–286], as well as a wide variety of lanthanide complexonates. For complexes with certain carboxylic acids (for example lanthanide malonates, succinates, and fumarates[286–293]), a linear relation has been observed between $\lg K_1$ and $pK_1$ (for monocarboxylates) and $pK_2$ (for dicarboxylates) of the ligands. This behaviour can break down: thus lanthanide complexes of dinitrosalicylic acid (DNS) are more stable than the lanthanide chloroacetates (CA), although $K_d(\text{DNS}) > K_d(\text{CA})$. The anomaly has been explained[269] by the formation of chelate rings in the lanthanide complexes of DNS. The replacement of carboxy-groups (lanthanide nitrilotriacetates) by the less acidic alcoholic groups (lanthanide hydroxyethyliminoacetates) leads to a decrease rather than an increase of the stability constants of the complexes, which has been attributed[294] to a change in the number of members in the chelate ring.

The number of members and the lack of steric rigidity of the chelate ring are important factors influencing the stability of lanthanide coordination compounds. The stability of complexes of ethylenediamine-*NN'*-disuccinic and ethylenediamine-*NN'*-dimalonic acids is higher than that of ethylenediamine-*NN'*-diglutarates, since the former two complexones form with the lanthanides stable five- and six-membered chelate rings respectively, while ethylenediamine-*NN'*-diglutarates give rise to comparatively unstable seven-membered chelate rings[268]. Europium(III) complexes of cyclohexylenediaminetetraacetic acid (CDTA)[295–298] are formed in the presence of a larger excess of the ligand than, for example, the analogous complexes with ethylenediaminetetra-acetate, which has been attributed to the rigidity of the CDTA structure, hindering the incorporation of the second ligand in the inner sphere of the metal. Because of this, $\lg K_2 \simeq$ const. in the Gd–Lu series for the 1 : 1 complexes with salicylhydroxamic acid[247], 8-hydroxyquinoline, and some of its 5,7-disubstituted derivatives[248], while the variation of $\lg K_1$ exhibits the usual regularities: an increase from La to Sm and from Gd to Lu, $\lg K_1$ for Gd being lower than for Sm.

The values of $K$ for the complexes of 5-sulphosalicylic acid (SSA) with the compositions Ln(Y)$(SSA)_2$, where Y = EDTA–OH, EDTA, or CDTA (*trans*-1,2-cyclohexylenediamine-*NNN'N'*-tetra-acetate), and Ln(Y)$(SSA)_2$, where Y = IMDA (iminodiacetate) or NTA in alcoholic solutions (pH 10.7–11.0) indicate an enhancement of the chelating effect in the EDTA–CDTA–OH (1 : 1 : 1 complexes) and the NTA–HIMDA (hydroxyethyliminodiacetate)–IMDA (1 : 1 : 2 complexes) series[299].

It is of interest to compare the enthalpies $\Delta H_1$ of formation of the 1 : 1 chelate lanthanide complexes of EDTA with the enthalpies of formation $\Delta H_2$ of the 1 : 1 : 1 lanthanide chelates incorporating mixed ligands, namely, EDTA–TP (triphosphate) or ATP (adenosine triphosphate)[300]. The $\Delta H_2$ for the formation of complexes of the Gd–Tm heavy lanthanides are more exothermic than the

values for the corresponding 1 : 1 lanthanide complexes of EDTA; on the other hand, the $\Delta H_2$ for the complexes of light lanthanides, with the exception of lanthanum(III), are less exothermic than the $\Delta H_1$, which can be accounted for by the formation of supercoordinate bonds when heavy lanthanides interact with EDTA (1 : 1 complexes), ATP, or TP. The formation of complexes with mixed ligands by the lighter lanthanides should also be accompanied by a more exothermic $\Delta H_2$, but the energy evolved on abstraction of strongly bound coordinated water and ligand groups diminishes $\Delta H_2$ in this instance. The entropies of formation $\Delta S_2^0$ of 1 : 1 : 1 chelates are relatively small and more negative than the entropies of formation $\Delta S_1^0$ of 1 : 1 chelate lanthanide complexes of EDTA, evidently owing to the repulsive interaction between the negatively charged mixed chelate lanthanide–EDTA complexes formed with the ATP or TP anions, bearing four or five charges. The entropies of formation of the latter increase from La to Pr and then decrease to Tb, increasing subsequently to Er and decreasing again to Tm, which has also been attributed to differences in the degrees of hydration of the lanthanide ion in the above series. As was to be expected, the entropies of formation of the lanthanide complexes with mixed ligands, EDTA–ATP or TP, in the gas phase are much more positive than in solution.

There is relatively little information on the influence of the nature of the electron-donating centre in the ligand molecule on the stability of lanthanide complexes. It is known [13], however, that in terms of their tendency to form complexes with the lanthanides, which are hard acids, electron-donating atoms can be arranged in the sequence O > N > S. This sequence has been confirmed by the difficulty of synthesising lanthanide complexes of nitrogen-containing ligands [16] compared with oxygen-containing donors [1,17,39] and by the virtual absence of reports of lanthanide complexes with ligand systems in which the electron-donating atoms are those of "soft" sulphur, tellurium, phosphorus, and arsenic. The above factor precludes the estimation of the relative "hardness" of lanthanide ions from the standpoint of the concept of hard and soft acids and bases [48]. In order to solve this problem as well as the problems of competitive coordination [301], it is necessary to have information about the stability of lanthanide complexes for a series of ligands containing variable electron-donating centres: O > S > Se and N > P > As, and quantitative estimates of the Lewis acidities of lanthanide salts must be made [302].

The determination of the stepwise complex formation constants for the lanthanides in mixed aqueous organic solutions and non-aqueous media has been attracting increasing attention of investigators: the results of studies of the stability of lanthanide acetate complexes in aqueous ethanol solutions, dioxan, and aqueous dioxan solutions [281–283], of lanthanide salicylate and anthranilate complexes in methanol [270,280], of lanthanide complexes of acetylacetone in methanol and dioxan solutions [281,284], and of the complexes of 8-hydroxyquinoline in 50% n-propyl alcohol [274] are available. These data permit inferences about the variation of the dissociation constants when both the ionic strength of the solution and the composition of the mixed solvent are varied.

Computer calculations of the stepwise stability constants have shown [276] that, with increase of the atomic number of the lanthanide, the stability of its complexes increases monotonically. However, there is no simple relation between the overall stability constant and the stepwise stability constant: in lanthanide solvato-complexes, the complex-formation effect can be divided into the contributions of the inner-sphere and outer-sphere interactions [270–274]. The contribution of the inner-sphere complex formation process depends on the composition of the mixed solvent [271] and the overall complex-formation effect also depends on the nature of the lanthanide salt anion. There exist fairly well developed methods whereby one can calculate the stability constants for the stepwise formation of acid (protonated) lanthanide complexes [295–297, 303–314].

In the presence of an equimolar ratio of neodymium and ethylenediaminediacetic acid (EDDA), there exist in the pH range 5.19–6.01 the aquo-ion and the protonated and normal 1 : 1 complexes, while in the presence of a fivefold excess of the ligand the 1 : 2 complex is present [304]. For comparison with potentiometric pH measurements [315], the stability constants of $NdL^+$ and $NdL^-$ were adjusted to an ionic strength of 0.1. The values $\lg K^{NdL^+} = 6.8 \pm 0.15$ and $\lg K^{NdL^-} = 4.97 \pm 0.08$, found by Bertha and Choppin [314], are lower than those quoted by Thompson [315] (8.06 and 5.63 respectively), possibly because no account was taken in the calculation of the formation of protonated complex. The latter has also been confirmed by a comparison of other data [316,317]. The calculated stability constants of the protonated complexes of hexamethylenediaminetetraacetic and iminodiacetic acids were compared with the stability constants calculated as the arithmetical mean values from three titration curves (the confidence limits of the $\lg K$ did not exceed 0.1) [303]. The similarity of the stabilities of the lanthanide complexes of the above acids shows that the ligands have the same numbers of binding sites; comparison of the data of Kurkina et al. [303] with those of Galaktionov and Astakhov [318] and Kornev and Konyukhov [319] is difficult, because the ionic strengths are not known and because of the different pH values and [Ln] : [L] ratios employed.

The values of $\lg K$ increase, while those of $\lg K_p$ (the logarithms of the protonation constants) steadily decrease in the series of lanthanides from La to Lu. Both effects have been attributed [320,321] to the changes in the effective ionic potential in the same series. The arrest of the increase of stability in this series at gadolinium, which is usual for lanthanide complexes, has also been observed, although the break is not very marked.

Certain general characteristics of the formation of lanthanide complexes have been interpreted [322,323] from the standpoint of the so called tetrad effect.

In conclusion mention must be made of the attempts to employ modern microwave spectroscopic (NMR) and quantum-chemical methods in the determination of the stability constants of lanthanide complexes, the lanthanide–EDTA–Cit (citrate) system has been investigated by $^1H$ NMR. [324] The value $\lg K = 1.2 \pm 0.1$ has been determined from the shift of the signal due to the ethylene protons of EDTA on formation of the mixed complex Lu(EDTA)Cit in the pH range 4–7. This is smaller by two orders of magnitude than the logarithm of the stability constant of the analogous neodymium complex and smaller by an order of magnitude than the logarithm of the stability constant of the complex Lu(EDTA)IMDA ($\lg K = 2.5 \pm 0.4$).

Comparison of the values measured by a potentiometric method at an ionic strength of 0.1(KCl), at 25° ± 0.1°C, and for the ratios [Ln] : [L] = 1 : 2 and 1 : 4 with the values calculated [325] from quantum-chemical data for the charge distribution on the ligand atoms and the mutual polarisability of the lanthanide ion and the ligand atoms [326,327] revealed a satisfactory correlation (Table 2).

## V. INVESTIGATION OF THE MOLECULAR STRUCTURES OF THE COMPLEXES

### 1. X-Ray Diffraction Analysis

Many lanthanide complexes have different types of crystal lattices and transitions from one type to another are observed in different parts of the lanthanide series: for neodymium and gadolinium [328], ytterbium and terbium [329], etc. The lanthanides form a less perfect coordination polyhedron than in the complexes of *d* transition elements with the same ligand: an octahedral configuration, which is extremely characteristic of *d* element complexes, cannot be as a rule achieved in lanthanide complexes (particularly for polydentate ligands [17]), since the large size of the lanthanide ion makes the structure of the inner coordination sphere extremely strained. It has been established that the formation of the crystal structure is influenced by the duration of storage of specimens. Certain coordination compounds of lanthanides are amorphous to X-rays, for example protonated, neutral, and polynuclear species, as well as the dehydration products of many lanthanide complexes [166,218,329]. The hydroxyethyliminodiacetates of yttrium-subgroup lanthanides [329] are amorphous to X-rays with the exception of the europium complexes which has a crystal structure similar to that of other compounds of the cerium-subgroup elements [163].

Table 2. The measured and calculated values of $\lg K_1$ (Feige et al. [325]).

| Ln | Dipeptide (expt.) | Diglycine (calc.) | Tripeptide | | L-Pro-Gly (expt.) |
|---|---|---|---|---|---|
| | | | expt. | calc. | |
| Nd(III) | 2.32 | 2.36 | 1.95 | 2.16 | 2.75 |

Comparison of diffractometer traces has shown that the lanthanides form groups having the same structures, whose number depends on the nature of the ligand. Thus X-ray diffraction analysis of the thiourea complexes of the lanthanides [168] $Ln(C_2H_5C_2)_3.CS(NH_2)_2.nH_2O$, where Ln = La or Ce ($n$ = 2), Pr, Nd, or Eu–Yb ($n$ = 1), and Sm or Lu ($n$ = 0.5), has shown that the complexes can be divided into two series with identical structures: La–Pr and Nd–Eu or Y, each of which gives rise to characteristic diffractometer traces. The thiourea complexes of the yttrium sub-group lanthanides [329] $Ln(C_3H_5C_2)_3.CS(NH_2)_2.nH_2O$, where Ln = Tb, Dy, Ho, Er, or Y ($n$ = 3.5), Tm or Yb ($n$ = 3), and Lu ($n$ = 1), form two groups with the same structures: Tb–Tm or Y and Yb–Lu. Starting with Yb, the crystal lattice of the complexes changes, while the crystal structure of the yttrium compound is close to that of the complexes formed by the elements of the Tb–Tm series.

The nonahydrates of lanthanide benzenesulphonates [223] can be divided into three groups with the same structures: one includes complexes of the elements ranging from La to Nd, the other Sm and Eu complexes, and the third the complexes of the elements ranging from Gd to Lu, including yttrium benzenesulphonate. Four groups with the same structures can be distinguished among the hydrated complexes with a low water content: the first includes La, Ce, Pr, and Nd salts, the second Sm, Eu, Gd, and Tb salts, the third Dy, Ho, Tm, and Y salts, and the fourth Er, Yb, and Lu salts. Comparison of the diffractometer traces for different hydrated benzenesulphonates of the same lanthanide has shown that they are identical for the free ion and the dihydrates of lutetium, cerium, and praseodymium benzenesulphonates and for the free ion and the trihydrate of neodymium benzenesulphonates[223]. Seven molecules (six in the case of neodymium) of the water of crystallisation are apparently not involved in the formation of the crystal structure. On the other hand, the diffractometer traces for the hydrated benzenesulphonates of the lanthanides ranging from Sm to Lu, including yttrium benzenesulphonate, with different water contents, are sharply different, which indicates the involvement of the entire water of crystallisation in the formation of the structure.

In solid lanthanide complexes, there are usually intermolecular hydrogen bonds, which decrease the flexibility of the metal-containing rings. The structure of the hydrates of the protonated complexes changes in the series of lanthanides [107], while the structure of the neutral complexes remains constant. This phenomenon has been attributed [330,331] to the polarising action of the outer-sphere cations.

Calculation of the crystallographic parameters of lanthanide complexonates makes it possible to isolate groups having the same structures in the La–Lu series [331].

### 2. X-Ray Diffraction Analysis

The amorphous behaviour in relation to X-rays or polycrystallinity as well as the extremely low solubility of lanthanide complexes frequently prevent the formation of single-crystal specimens. Nevertheless Porai-Koshits and Aslanov [240,331] have now examined series of compounds with the same structures belonging to 100 structural types: studies have been made of the problems of the relative roles of the Coulombic and covalent components in the stereochemistry of lanthanide complexes, statistical data have been published on their coordination numbers and their coordination polyhedra, a relation has been demonstrated between the latter and the nature of the lanthanide and the ligand, the stereochemistry of lanthanide complexes with six- ($\beta$-diketonates) and four-membered rings (nitrates, carbonates, and sulphates) has been investigated, and a comparative analysis of the stereochemistry of the lanthanides and *d*-transition metals in $\beta$-diketonates, carboxylates, and many other chelate complexes has been carried out.

The structural aspects of six-membered metal-containing lanthanide rings have been elucidated in X-ray diffraction studies on lanthanide diketones [332-340]. Lanthanide tetra-$\beta$-diketonates can exist in two forms: as complex acids and as salts of organic bases [332,334]. The unit cell parameters of the crystals of the $\alpha$-form of piperidinium tetrabenzoylacetonatoeuropate [335] agree satisfactorily with the results of Il'inskii et al. [332] This form may be called a salt, since it contains the cation $Hpip^+$ (pip = piperidine) and the anion $[Eu(BA)_4]^-$. The second compound, described [336] as a solvate, is an acid, in agreement with a number of facts described in the literature [336,337]. In $\beta$-diketonates with electron-donating substituents, the

coordination polyhedron is as a rule a tetragonal antiprism, while in β-diketonates with electron-accepting groups it is a dodecahedron. The conversion of one polyhedron into another is difficult, which conflicts with the view [338] that the solvent plays a decisive role in the formation of the coordination polyhedra of lanthanide tetra-β-diketonates.

Comparison of the structures of tetra-β-diketonates has led to the conclusion [334] that the symmetry of the immediate environment of lanthanide ions depends on the electronic properties of the ligands: in the presence of non-fluorinated ligands [332,339], the characteristic coordination polyhedron of the lanthanide is a tetragonal antiprism, while in the case of fluorinated ligands [339,340] the polyhedron is a dodecahedron. It has been suggested [334] that this type of dependence of the form of the coordination polyhedron on the nature of the ligand can be accounted for by the degree of overlap of the orbitals of the lanthanide atoms and ions.

There have been so far few data concerning the absolute configurations of organic compounds coordinated to lanthanide ions. The study of Porai-Koshits et al. [341], who analysed the geometry of the EDTA anion in complexes and simple salts, merits most attention in this connection. Analysis reveals three configurational possibilities for the ligand: two with the *cis*-disposition of the nitrogen atoms of ethylenediamine (en) (the *gauche*-configuration of the en-ring) and one with the *trans*-configuration of ethylenediamine (planar en-ring). The first group (*E*, *G*/*R* conformation) with the non-planar structure of the en-ring (C.N. = 6–8) has the following polyhedra: octahedron, pentagonal bipyramid, and Chord's dodecahedron. Complexes with the configuration of a single-cap trigonal prism (C.N. = 7) are characteristic of the second group (*E*, *R*/*G* conformation). One of the consequences of the transition *E*, *G*/*R* → *E*, *R*/*G* is the flattening of the $O_RO_GC_GC_GO_R$ tetragon. The *E*, *R*/*G* configuration obtains in the lanthanide complexes of EDTA; the transition to coordination numbers of 9 and 10 entails a further decrease of the endocyclic angles at the metal atom.

The results of X-ray diffraction analysis of lanthanide complexes permits the conclusion that lanthanide(III) ions in the compounds have high and variable coordination numbers. In lanthanide complexes, the coordination number is usually 9 (Table 3). [342–356] Amongst the factors influencing the coordination number, the strength of the Ln–ligand bond and the steric characteristics of the ligand systems have been noted. In particular, it has been suggested [343] that the Ln–O interaction in the hexamethanol complexes of lanthanide nitrates is so pronounced that the coordination number is ≤ 8. However, for the majority of lanthanide complexes of dimethyl sulphoxide [342–344,357,358], where a very strong interaction can also be postulated, no changes have been observed in the coordination number of the metal, contrary to the view of Ramalingam and Saundararajan [359].

X-Ray diffraction data have been used to solve the problem of the location of the coordinate bond in ambident bi- and poly-dentate ligands. As expected [301], only a "hard–hard" interaction takes place with O- and N-donors (in lanthanide nicotinates) [345,360,361], in contrast to the complexes of *d*-transition elements [301,362], and the Ln–C bond is formed. The latter has also been detected in the infrared spectra of lanthanide nicotinates [363].

Analysis of the X-ray diffraction data has shown that chain and isolated group ("island") structures are characteristic of lanthanide complexes. It has been shown that the chains of the complexes are frequently linked together by hydrogen bonds, formed both between coordinated water molecules and with participation of the donor (N, O, and S) atoms of the anions [346,360,364].

Certain regularities in the Ln–A interatomic distances (A is a donor atom) as a function of the nature of Ln–A and the ligand system are known (see Table 3 and the data analysed in the literature [240,331]). The average $Ln-C_{NC_3}$ interatomic distances in the hydrates (2.65 Å) and the dimethyl sulphoxide complexes of lanthanide nitrates (2.64 Å) are approximately equal [357]. However, the $Ln-O_{DMSO}$ distances are much shorter than $Ln-O_{H_2O}$, which cannot be accounted for solely by the lanthanide contraction, which is very slight on passing from Pr to Nd.

The large (compared with the water molecule) negative charge on the oxygen atom in the DMSO molecule apparently enhances the $Ln-O_{DMSO}$ interaction, which leads to a shortening of the bond. The $Ln-O_{DMSO}$ interatomic distances in the $Nd(NO_3)_2.(DMSO)_4$, [343] $Er(NO_3)_3.(DMSO)_3$, [344] and $Lu(NO_3)_3.(DMSO)_3$ structures are on average 2.26 Å, which is significantly less than the $Ln-C_{NC_2}$ bond length

Table 3. The structures of coordination compounds of the lanthanides (the interatomic distances are quoted for the compounds of the underlined lanthanide).

| Composition of complex | Ln(III) | C.N. | Symmetry | Average interatomic distance, Å | | | | References |

(2.50 Å), suggesting that the Ln–$O_{DMSO}$ bond in compounds of this class is stronger than the Ln–$O_{NO_3}$ bond. The Ln–O interatomic distances in lanthanide carboxylate complexes [361,365-367] obey the same rule: the lengths of the bonds between the oxygen atoms of the cyclic bidentate carboxy-group and the lanthanide atoms are longer than the distances between the lanthanide atom and the oxygen atoms of the bidentate bridging carboxy-group.

## VI. SPECTROSCOPIC STUDIES

### 1. Fluorescence Spectra

The coordination compounds of the lanthanides are classified into three groups according to the nature of their fluorescence. The first group includes lanthanum(III), gadolinium(III), and lutetium(III) complexes, which exhibit the fluorescence of the non-metallic ions. The second group comprises dysprosium(III), samarium(III), europium(III), and terbium(III) complexes, which exhibit the characteristic intense fluorescence of the metal ions; each ion has an excited state whose energy is close to that of the triplet level of the ligands. Praseodymium(III), neodymium(III), holmium(III), erbium(III), ytterbium(III), and thulium(III) complexes, which exhibit a weak fluorescence of the metal atoms, constitute the third group; each [metal?] ion in this group has closely spaced energy levels.

Since the electrons of the 4*f* orbitals of the lanthanides are shielded from the action of the ligand field by the $5s^2 5p^6$ electron cloud, the following regularity is observed as regards the intensity of the influence on the lanthanide ion: crystal field < spin–orbital coupling < interelectron repulsion [18].

Theoretical analysis of the symmetry in the lanthanide complexes makes it possible to interpret their fluorescence spectra [368-371]. Europium(III) chelate complexes are most frequently investigated, because in this case the low value of the quantum number $J$ for the most intense lines in the emission spectrum ($^5D_j \rightarrow {}^5F_j$; $J = 0, 1$; $J' = 0, 1, 2$) gives rise to a smaller number of energy levels than the number observed for the majority of other lanthanide ions. The transitions from the $^5D_0$ state are used to investigate the symmetry of the coordination compounds because this energy-emitting state ($J = 0$) cannot be split by the ligand field. Thus the transitions from $^5L_0$ to various $F_j$ states are usually well separated and the transitions to the $J$ states are frequently satisfactorily resolved. The interpretation of the fluorescence spectra of the europium complexes from the standpoint of symmetry agrees with the molecular structure of the complexes [338-349].

The study of the fluorescence spectra of 33 chelate complexes (pyridine derivatives of lanthanide tetrakis-1,3-diketonates) [331] showed that all eight oxygen atoms in the 1,3-diketone are directly linked to the lanthanide, which is confirmed by the analysis of the observed fluorescence spectra from the standpoint of the possible symmetry of the ion in complexes of different compositions which have been investigated. Analysis of the fluorescence spectra yields valuable information about the nature of the interaction of the lanthanide with organic ligands [372-379], the nature of the bond in lanthanide complexes [369-372,380-382], the symmetry of the complexes, and the conformation of the ligands [382-386].

A relation has been established between the probability of the energy transfer ($k_t$) and the degree of overlap of the electron clouds of aromatic ketones and lanthanide ions (Table 4). [387] The probability of energy transfer in the case of benzophenone, acetophenone, and benzoylpyridine (Table 4) reflects the similar changes in their capacity for complex formation, the differences being due to the differences in the donor–acceptor properties of the ketones and the overlap integrals for the spectra. The distinct increase of $k_t$ for ketones having the $^3\Gamma(n,\pi^*)$ state compared with the analogous ligands with the $^3\Gamma(\pi,\pi^*)$ levels constitutes clear confirmation of the role of the overlap of the electron clouds of the excited ketone and the lanthanide ion in energy transfer. Energy transfer with participation of lanthanide ions to the triplet level of organic molecules and away from the latter proceeds via an exchange-resonance mechanism [388].

Table 4. The probabilities of energy transfer from aromatic ketones to lanthanide ions [387] ($T$ = 383 K, acetone, air).

| Ketone | $10^{-3}k$, $M^{-1}$ $s^{-1}$ | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | $Ce^{3+}$ | $Pr^{3+}$ | $Nd^{3+}$ | $Sm^{3+}$ | $Eu^{3+}$ | $Gd^{3+}$ | $Tb^{3+}$ | $Dy^{3+}$ | $Ho^{3+}$ | $Yb^{3+}$ |
| Acetophenone | 4 | 3 | 8 | 0.5 | 2 | 0.10 | 0.66 | 0.6 | 0.6 | 0.8 |
| Benzophenone | — | 5 | 17 | 1.0 | 6 | 0.01 | 0.1 | 0 8 | 0.8 | 0.76 |
| Benzoylpyridine | — | 4.5 | 5.4 | 0.6 | 3 | — | 0.26 | 0.6 | 0.6 | 0.5 |

The luminescence spectra of more than one hundred europium, terbium, and gadolinium complexes with different ligands have now been investigated [373-377]: $Eu(TTA)_4P$, $Eu(BTFA)_4P$, $Eu(o\text{-Cl-5-BTFA})_4Pyrr$, $Eu(DBM)_4P$, $Eu(BTFA)_4DMA$, $Tb(A)_4P$, $Eu(DFDBM)_3$, $Eu(DFDBM)_4P$, etc., where TTA = thenoyltrifluoroacetone, BTFA = benzoyltrifluoroacetone, DBM = dibenzoylmethane, P = piperidine, I = imidazole, Pyrr = pyrrolidine, DMA = dimethylamine, and DFDBM = decafluorodibenzoylmethane. Analysis of the splitting of the lines in the spectra has led to certain conclusions about the symmetry of the crystal field of the lanthanide complexes. If the crystal field has a threefold symmetry axis, three lines correspond to the $^5D_0 \leftarrow {}^7F_2$ transition and two components with the intensity ratio 2 : 1 (the inner coordination sphere is an octahedron with a $D_3$ symmetry axis) correspond to the $^5D_0 \rightarrow {}^5F_1$ transition. For a lower symmetry, the line due to the $^5L_0 \rightarrow {}^7F_1$ transition is split into three components with approximately equal intensities, and there is a weak $^5D_0 \rightarrow {}^7F_0$ transition. Solvent (water) molecules are not linked to the central atom, which is surrounded by six oxygen atoms. On the other hand, in the spectra of the di- and tri-hydrates of europium(III) tri- and tetra-acetylacetonates the line of the $^5D_0 \rightarrow {}^7F_1$ transition is split into three components and that due to the $^5D_0 \rightarrow {}^7F_2$ transition, into five components: the cubic environment, comprising eight oxygen atoms, is distorted to a tetragonal antiprism with a $C_2$ symmetry axis. The degree of hydration has a significant influence on the intensity, width, and Stark splitting of the luminescence bands of the ion in the chelate complexes.

Comparison of the results of the analysis of the luminescence spectra of europium nitrates combined with aromatic amines [358] with X-ray diffraction data showed that the luminescence spectra yield an average pattern of

the charge distribution, so that the real pattern in the structure of the complexes can be obtained solely with the aid of additional data.

The luminescence spectra of europium complexes of aromatic acids [389], complexones [390], and β-diketones [391] have been investigated in very great detail. Analysis of the luminescence spectra of europium β-diketonates using CFT led to the conclusion [391] that the vacant (*in vacuo*) 5*d*-orbitals of the lanthanides are involved in the Eu(III)–L bond.

The use of europium as a luminescence probe is of particular interest [390]. Several types of complexes of Schiff bases, in which covalent bonds are formed between europium and the ligands, were isolated by this method.

The formation of lanthanide complexes with various electron-donating solvents has been studied by the taumetric method based on the phenomenon of the radiationless energy transfer in the fluorescence spectra. It was shown [388] that, when inner-sphere lanthanide complexes are formed, the decisive factors are the relative electron-donating properties of the solvent and the competing ligand, and in outer-sphere complex formation the dielectric constant of the medium is of decisive importance.

## 2. The Absorption Spectra of Lanthanide Complexes

The absorption spectra of lanthanide ions have been investigated in fair detail in solutions of complexes [392-427]. Studies have been made on the intensities and positions of the absorption bands as a function of the nature of the lanthanide, the ligand environment, and the solvent.

In the far ultraviolet (210–300 nm), the ions of certain lanthanides have absorption bands corresponding to the allowed $4f-5d$ transitions; in the visible region, absorption bands associated with the $4f-4f$ transitions of the electrons are observed [392]. In conformity with theory [392, 393], the oscillator strengths $P$ of the $4f-4f$ absorption bands are small, but the intensity of certain bands may increase as a function of the environment.

When the environment of the $Ln^{3+}$ ion is altered, appreciable oscillator strengths are observed only for certain absorption bands, corresponding to the $4f-4f$ electron transitions—the so called hypersensitive transitions (HST). The absorption bands of lanthanide(III) ions corresponding to HST have been listed [392,394,398-415]. The appearance of HST has been explained [385,393] by the influence of the covalent nature of the $Ln^{3+}$–ligand bond (nephelauxetic shift [415-419]) and may be characterised by the CFT parameters.

In the spectra of many complexes of aromatic acids [405], the intensity of the $^7F_0 \rightarrow {}^5D_2$ and $^7F_1 \rightarrow {}^5D_1$ HST bands increases to the same extent (by factors of 1.8 and 1.62 respectively). The oscillator strength $P_{exp}$ of the $^7F_0 \rightarrow {}^5D_2$ transition has been frequently determined as a function of the solvent (water, methanol) [405,406], the lanthanide ion [395,401-405], and the nature of the anion and the ligand [395,404]. Thus $P_{exp} = 0.0004$ for the $^7F_0 \rightarrow {}^5D_2$ transition in an aqueous $Eu(NO_3)_3$ solution, which is smaller by a factor of six than for a $Eu(NO_3)_3$ solution in methanol. The intensity of the $^7F_0 \rightarrow {}^5D_2$ transition increases even more in europium salicylate: $P_{exp}$ is sixty times greater than for the aquo-ion. Consequently the field strength in methanol is greater than in water, and among all the complexes investigated [402-405] it is a maximum for europium salicylate [405].

It has been established that the intensity of the HST absorption bands and the oscillator strengths of lanthanide ions involved in complex formation depend on the chemical nature [395,406-410] and the molecular weight [406] of the ligand. Thus they increase for neodymium(III) and erbium(III) complexes of 8-hydroxyquinoline and its dihalogeno-derivatives (5-chloro-7-iodo-8-hydroxyquinoline and 5,7-di-iodo-8-hydroxyquinoline) with increase of the molecular weight of the ligand [405]. The same behaviour is characteristic of mixed lanthanide complexes formed as a result of the additional coordination of organic ligands [407-410].

Analysis of the intensities of the HST absorption bands of lanthanide ions is an effective means of determining the symmetry [415-421]. A general trend towards a decrease of the symmetry of the solvated lanthanide ions on passing from methanol to 1-propanol has been established [413,419] and the symmetries of many lanthanide complexes in different solvents [420,421] and the changes in the latter on passing from the crystalline phase to the solution [421] have been determined. Comparison [414] of the changes in the HST intensities in the luminescence spectra with the changes observed in the absorption spectra shows that the two sets of quantities are proportional. Thus the influence of the ligand field, which determines the HST intensities, is manifested to approximately the same extent in both absorption and luminescence spectra.

Not only the intensities but also the positions of the bands in the electronic absorption spectra of lanthanide complexes depend significantly on the nature of the ligand (the electron-donating atom) and the nature of the lanthanide cation and anion. The shift of the bands in the spectra of lanthanide complexes is determined by the immediate ligand environment of the central ion. A linear relation between the positions of the spectral bands and the average $R_{Ln-O}$ distance has been observed for lanthanide complexes with ligands coordinated via oxygen atoms [420,422,423]. The positions of the bands in the electronic spectra of lanthanide complexes have been investigated as a function of the nature of the complexones and aminoacids [424-426]. The presence of a single band ($^4I_{9/2} \rightarrow P_{1/2}$ transition) in the spectra of the neodymium complexes with the above ligands [424] and of two bands in those of the erbium complexes [425] permitted the conclusion that the lanthanides are bound in different ways in the complexonates: rigid incorporation of neodymium(III) in the chelating unit of the complexones, which is always of the same type, and different types of binding of erbium(III) to different electron-donating groups of the ligand system. The same data combined with NMR data have been used [426] to determine the location of coordinate bonds in the complexonates.

The influence of the anion of the lanthanide salt on the spectra of the complexes has been investigated in relation to the behaviour of $LnX_3$ (Ln = Nd, Ho, or Er; X = Cl, Br, or $NO_3$) in *NN*-dimethylacetamide [420] and of the solvato-complexes of $EuCl_3$ and $Eu(NO_3)_3$ in water, ethanol, and acetic acid [427]. It was found [427,428] that, when the anion is altered in the sequence $Cl \rightarrow Br \rightarrow NO_3$, a bathochromic shift of the HST bands is observed.

In conclusion we may note that a correlation has been found between the results derived from the electronic and $^1H$ NMR spectra of the lanthanide–complexone complexes investigated [424,425]: the shift of the absorption bands ($\Delta\lambda$) in the electronic spectra and the chemical shift ($\Delta\delta$) of the protons in the $^1H$ NMR spectra increase on formation of a bond between the lanthanide and a nitrogen atom and

diminish from La to Lu when the lanthanide is coordinated to an oxygen atom. This observation may be used to characterise the bonds in lanthanide complexes with ON-ligands and to determine the distance between the lanthanide and the donor centre.

## 3. Infared Spectroscopy of Lanthanide Complexes

The infrared spectra of lanthanide complexes have been studied over a wide wavelength range (40–4000 $cm^{-1}$), mainly in the crystalline phase [422-446]. The long-wavelength region (40–600 $cm^{-1}$) has been studied in order to assign the frequencies, to determine the spectroscopic parameters of the Ln–X bonds (X = Cl, Br, I, O, N, or S), and to discover the location of the coordinate bond. Since lanthanide chlorides belong to the $L_{3h}$ symmetry point group [115], the unit cell may be defined as a double trigonal antiprism. Consequently, four fundamental frequencies, $\nu_1(A_1')$, $\nu_2(A_2'')$, $\nu_3(E_1')$, and $\nu_4(E')$, may be expected for the vibrations of the Ln–Cl bond, the first of which should be inactive in the infrared spectra, since it is the frequency $\nu_S$ of the stretching vibration of the Ln–Cl bond. The observed vibration frequencies and calculation [115] led to the isolation of the following bands active in infrared spectra: $A_2'$ (237 $cm^{-1}$); $E_1'$ (318 $cm^{-1}$); $E'$ (285 $cm^{-1}$). The vibrations of the Ln–Cl bond in bipyridyl and phenanthroline complexes are active in the range 200–260 $cm^{-1}$, while the frequencies of the vibrations of the Ln–Br bond are significantly lower (140–155 $cm^{-1}$).[429]

The vibrational spectra of the complex anions $LnX_6^{3-}$ (Ln = Nd, Eu, Gd, Dy, Er, or Yb; X = Cl or Br) have been investigated in detail using calculated data [430]. In the calculation, the force fields of the molecules were analysed; among these, a modified valence-force field proved to be the most effective and, in the region of stretching vibrations, also a modified Urey–Bradley field. The $LnX_6^{3-}$ anion has six vibrations active in the range 50–260 $cm^{-1}$; the experimental and calculated data have been tabulated in a review [430]. It has been established that (a) the strength of the $LnCl_6^{3-}$ bonds is greater than that of the $LnBr_6^{3-}$ bonds and that (b) the force constant $K_{Ln-Cl}$ of the chlorides decrease in the sequence Yb > Er > Dy > Gd > Nd as the ionic radius of the lanthanide increases; in the case of the bromides, two groups were isolated in terms of the $K_{Ln-Br}$, namely Yb < Er < Dy < Gd and Eu < Nd; finally, (c) the force constant $f$, characterising the repulsion between non-bonded atoms, increases from Cl to Br as the ionic radius of the lanthanide increases.

The vibrations of the Ln–N bonds are active in the range 200–500 $cm^{-1}$ for bipyridyl and phenanthroline [198], 350–380 $cm^{-1}$ for ethylenediamine chelates [450], and 270 to 350 $cm^{-1}$ for isocyanate complexes of the type $[Et_4N]_3.[M(NCO)_6]$. [431] There are so far relatively few data for the vibrations of the Ln–O bonds [129]: in the spectra of praseodymium, neodymium, europium, gadolinium, dysprosium, and erbium acetylacetonates, they are active in the vicinity of 420–432, 304–322, and 620–650 $cm^{-1}$. The bond force constants $f_{Ln-O}$ increase with decrease of the Ln–O bond length. Although the Ln(III)–O bond is believed to be ionic, it has been suggested [129] that the increase of the Ln–O stretching frequencies is due to a slight increase of the degree of covalence in the acetylacetonate complexes as a result of $\pi$-bonding and the increase of the mass of the central ion.

The values of $f_{Ln-O}$ calculated by an empirical method [130] (for example, $f_{Pr-O}$ = 2.98–2.41 mdyn $Å^{-1}$) differ from those ($f_{Pr-O}$ = 2.10) obtained [129] by the more rigorous Urey–Bradley method. It is very likely that the vibrations active at 268–296 and 353 $cm^{-1}$ in the spectra of the tetraethylammonium isocyanate complexes mentioned above [431] are due to the Ln–O bond of the M–OCN group. The "hard–hard" interaction of lanthanides with ambident pseudohalide ions usually leads to the same conclusion [48,301].

The infrared spectra of lanthanide complexes in the range 600–4000 $cm^{-1}$ have been investigated mainly in order to discover the donor centre in the molecules of bi- and poly-dentate ligands (competitive coordination [301]). Infrared spectroscopic data were used to determine its location in lanthanide complexes with many ambident organic ligands: tetramethylene sulphoxide (oxygen atom of the S=O group) [52], salicyl hydrazide (secondary amide nitrogen atom) [53], salicylidene- [54] and naphthylidene-anthranilic acids [228] (O–O rings), $\alpha\beta$-unsaturated $\beta$-ketoimines (NC-chelates) [434], 1,2-ethylenebisdiphenylphosphine and arsine oxides (bridging groups involving the phosphoryl and arsenyl oxygen atoms) [435], *N*-oxides of quinaldinic acid (NO linkage) [436] and of *o*-hydroxyquinoline (the oxygen atom in the hydroxy- and N → O groups) [437], *o*-hydroxyacetophenone [56], and salicylaldehyde (metal-containing OC-ring [437,438], thiourea (S atom) [44], 2,2′-bipyridyl *N*-monoxide (Ln–O bond absorbing at 324 $cm^{-1}$), [439] urea [439] and diphenylformamide [103,441,442] (oxygen atom), butyl phosphate (phosphoryl and ester oxygen atoms) [356, 443-445], protonated methyl iminodiacetates (oxygen atom of the acetyl group and possibly of the non-protonated carboxy-group) [446], various nitrogen-containing six- [16] and five-membered [169] heterocycles (nitrogen atoms of the pyridine type), and aliphatic and aromatic amines (nitrogen atoms of the amino-groups) [16].

With increased interest in the lanthanide complexes of aminoacids and complexones, numerous studies have been made in order to assign the vibrations of the carboxy-group [218,447-452] and to determine the amount of its ionic and covalent character [447,449] as well as the possibility of employing the different $\Delta\nu = \nu^{as}_{CCO} - \nu^{s}_{CCO}$ in order to characterise the relative strength of the Ln–O bond [128,449, 450]. The study of the infrared spectra also proved to be extremely useful in the solution of the problem of the formation of acid or neutral lanthanide salts of aminoacids and complexones [448-452].

## 4. Microwave Spectroscopic Studies

The NMR method is widely used in the coordination chemistry of the lanthanides in order to investigate the composition of the complexes, the mode of coordination, [453-463] the exchange kinetics, and the fine structure of the ligands [459-464]. NMR data have shown that [456] the interaction of the lanthanides with complexones is accompanied by the formation of 1 : 1 and 1 : 2 (La, Lu) complexes; hydroxo-complexes are formed in the alkaline region [451] and protonated complexes are formed in the acid region. The kinetic data obtained in NMR investigations of ligand exchange in lanthanide complexes of a number of nitrogen-containing donors [16] [4,4′-di-n-butylpyridine [462] and tri-($\beta$-aminoethyl)amine [463]] made it possible to determine the parameters of the transition state, the order of the exchange reaction, and structural isomers of the ligands. It was established that the reaction with di-n-butylpyridine [462] is of second order: $\Delta H^{\neq}$ = 10.6 ± 1.3 kcal $mole^{-1}$ and $\Delta G^{\neq}$ = 17.6 kcal $mole^{-1}$.

The kinetics of ligand exchange, including transsolvation, have been studied in detail [457,458]. For ratios $SmCl_3$ : EDTA ≥ 1 : 2, slow exchange is observed between

the free and bound ligand species:

$$SmL + H_nL_1 \rightleftarrows SmL_1 + H_nL \quad (1)$$

$$HSmL + H_nL_1 \rightleftarrows HSmL_1 + H_nL \quad (2)$$

where $n$ is the degree of protonation of EDTA. The entropies, activation energies, and rate constants $K$ for exchange for a ligand containing between two and four protons were determined for reactions of type (1). It was shown that $K$ increases in the sequence $HL < H_2L < H_3L < H_4L$.[464]

It was established[54] that lanthanides are coordinated to the water molecule and the chloride ion in the complexes $[Ln(LH)_2(H_2C)Cl]$, where Ln = La, Ce, Pr, Nd, Sm, Eu, Gd, Dy, Ho, Er, Tm, Yb, or Lu and L = *N*-salicylideneanthranilic acid.

Polycrystalline hydrates having the composition $MLnEDTA.nH_2O$, where M = Na(I), K(I), Rb(I), or Cs(I), Ln = La(III), Lu(III), Nd(III), Eu(III), Gd(III), Dy(III), Er(III), or Yb(III), and $n = 3-9$, were investigated by the low-resolution $^1H$ NMR method[465] at temperatures between $-100°$ and 250°C. In all the cerium-subgroup lanthanide compounds in the range from 0° to 60°C, two groups of water molecules, differing in their mobility in the crystal lattice, were detected; a group of three water molecules is in a rigidly fixed state, while the proton–proton vectors of the remaining molecules are distinguished by a fairly considerable mobility in the crystals. Comparison of the $^1H$ NMR and optical absorption spectroscopic data in the visible region indicates the incorporation of three water molecules in the inner coordination sphere of the lanthanide, which agrees well with X-ray diffraction data. The structure of the hydrates of lanthanide complexonates has also been discussed in other studies[466,467]. The $^1H$ NMR, optical spectroscopic, and X-ray diffraction data led to the conclusion that the number of inner-sphere water molecules in the solid hydrated lanthanide–EDTA complexes decreases in the La–Lu series: whereas three water molecules are incorporated in the inner coordination sphere in the complexes of light lanthanides, ytterbium(III) forms a complexonate with a single molecule of inner-sphere water.

The $^1H$ NMR spectra of europium complexes as well as measurements of magnetic circular dichroism of the praseodymium and neodymium complexes of azomethines obtained from aspartic acid and aromatic aldehydes (pyridoxal, *o*-vanillin, 5-nitro-*o*-vanillin, and 5-bromosalicylaldehyde)[468] are different when optically active aspartic acid and the racemate are used, which shows that each lanthanide ion is linked to more than one ligand molecule.

The employment of NMR data makes it possible to determine the configuration of the coordinated ligand[469,470] and also the geometry of the complexes in solution. $Ln^{3+}$ ions forms complexes and induce in NMR spectra both positive and negative paramagnetic shifts, yielding information about the structure of the ligands and about the contact and pseudocontact mechanism of the shifts. One of the methods developed for the separation of the pseudocontact and contact contributions to the overall shift of the signal in the NMR spectrum makes it possible to investigate the geometry of the complex (in accordance with McConnell's equation[471]). In particular, a conformation has been proposed[472] for the Ln(III) complexes of indoline-3-acetate (Ln = Pr, Nd, Eu, Gd, Tb, Dy, or Ho), in which the carboxylate behaves as a bidentate ligand and the $Ln^{3+}$ ion is located on the bisector of the OCO angle; the calculated Ln–O distance varied in the range 2.2–2.5 Å.

The possibilities of the above method in the determination of the ligand configurations were illustrated by data[473] obtained in the determination of the configurations of the isomers of 2-methoxycarbonyl-4-methyl-5-phenylpenta-2,4-dienecarboxylic acid with melting points of 117°C (I) and 153°C (II), which could not be done by analysing the infrared and ultraviolet spectra recorded under the usual conditions. Analysis of the pseudocontact shifts induced by $Ln^{3+}$ ions in NMR spectra showed that isomer (I) has the *E*,*E* configuration while isomer (II) has the *Z*,*E* configuration. Similar studies involving the analysis of NMR spectra of solutions (in $D_2O$) of α-azetidine-2-carboxylic acid in the presence of praseodymium(III), neodymium(III), and europium(III) nitrates established[474] that the four-membered ring of the azetidinecarboxylic acid has a folded configuration with a dihedral angle of 25°, the carboxy-group occupying the equatorial position. The fact that the above investigations were undertaken is evidence for a considerable interest in the study of the structures of the ligands and the geometry of lanthanide complexes in solutions by analysing NMR spectra. The method[471] based on the analysis of NMR spectra in terms of McConnell's equation is simpler and its accuracy is comparable to that of X-ray diffraction analysis.

Apart from NMR spectra, ESR and Mössbauer spectroscopic data have been used to investigate lanthanide complexes. ESR signals of europium(II) have been detected at frequencies of 9 and 35 GHz in solutions at 25°C; a hyperfine structure due to the europium nuclei appears in the spectra of frozen solutions[475]. The *g*-factors and the temperature variation of the line width in the ESR spectra of gadolinium(III) ions introduced into $Ln(C_2H_5SO_4)_3.9H_2O$ single crystals, where Ln = La, Pr, Nd, Sm, Tb, Dy, Ho, Er, Yb, or Lu, have been discussed[476]. The introduction of $Gd^{3+}$ ions into the above single crystals as well as $Nd_2(SO_4)_3(NH_4)_2.8H_2O$ single crystals[477] makes it possible to observe at room temperature the ESR spectra of two magnetically non-equivalent gadolinium(III) complexes, the symmetry of these centres being tetragonal with unusually low values of the crystal field parameters. A decrease of temperature to 77 K results in the resolution of the gadolinium(III) spectra either owing to a stronger crystal field, leading to a greater zero-point splitting, or owing to a crystallographic phase transition in the above temperature range. As a result of the maximum splitting of the states characterised by the quantum number $J$, the magnetic susceptibilities of the majority of lanthanides in crystals and in solutions differ little from the values in the free state.

Relatively few instances are known in which magnetic resonance was observed in an excited state[478]. Such observations are possible if the difference between the energies of the excited and ground states is less than $kT$. For lanthanides with an odd number of electrons, the Kramers doublet occupies the lowest energy level owing to the presence of an axial crystal field and the spin–orbital interaction. However, the intense spin–orbital interaction in the excited states implies a strong interaction with the environment. For this reason, even in this case the recording of the ESR signal usually requires a temperature of 20 K or less. In lanthanides with an even number of electrons, the crystal field with $C_{3v}$ or $C_{3h}$ symmetry splits each state into singlets and doublets. The splitting associated with the Jahn–Teller effect is usually slight and does not remove the residual degeneracy. It is therefore postulated that the system symmetry is still $C_{3h}$ or $C_{3v}$.

ESR studies of relatively simple systems provide a satisfactory answer to the question of the symmetry of the ion and its distortion. In complex systems, an unambiguous result may require much effort[478].

The spectra of europium[139] in weak, moderate, and strong external magnetic fields have been investigated by the Mössbauer method[479,480] at temperatures in the range 1.2–77 K. The form of the lineas in the Mössbauer spectra (MS) has been discussed on the basis of the relaxation theory and comparisons with calculation have been made: the MS parameters and the properties of the complexes are interrelated. The absence of a magnetic hyperfine structure in MS at temperatures in the range 1.2–77 K indicates the absence of magnetic ordering in $[Eu(NH_3)_6]^{3+}$ even at 1.2 K. The calculated rate of spin–lattice relaxation ($50 \times 10^6$ $s^{-1}$) and other experimental data confirm the $4f^7$ configuration of europium(III). In the europium chelates $EuL_4X$, where L = PhC(O)CH(O)Ph and X = $Et_4N$ (III), $Et_2NH_2$ (IV), or piperidine (V), and in the mixed chelate $EuL_3Phen$, where L = PhC(O)CHC(O)Me (VI), an appreciable Mössbauer effect was not observed at room temperature[22]. The isomeric shifts relative to $Eu_2O_3$ in compounds (III)–(VI) are respectively −0.58, −0.60, −0.50, and −0.58 mm $s^{-1}$ and are independent of temperature. The shifts confirm that $5d$, $6s$, and $6p$ europium orbitals participate in the formation of partly covalent bonds in compounds (III)–(VI). The isomeric shifts in the Mössbauer spectra of europium(III) complexes with nitrogen- and oxygen-containing ligands[12] reveal the following regularity: coordination compounds with N-donors are characterised by lower shifts than compounds with O-donors.

---o0o---

The data which have accumulated during the last decade and which have been discussed in this review, indicate a significant progress in the coordination chemistry of the lanthanides.

At the same time there is still little information about lanthanide complexes in which the oxidation state of the lanthanide is other than three and lanthanide oxide halide and dioxide halide complexes, while the methods of preparation of these halogen-containing compounds are fairly well known[234]. Polydentate macrocyclic ligands (porphyrins[481–483] and crown-ethers[484]) have begun to be used comparatively recently in the synthesis of lanthanide coordination compounds and their promise is evident.

The problems of "competitive coordination"[301] and of the Lewis acidity of lanthanide salts[302] have been inadequately investigated in the coordination chemistry of the lanthanides.

It is of interest to study the equilibria involved in the formation of lanthanide complexes of different types, particularly mixed and polynuclear complexes, to carry out quantum-chemical calculations, and to investigate further the physicochemical properties of lanthanide coordination compounds. The development of research on these and other fields traditional for the chemistry of complexes is the task for the immediate future.

# The Synthesis, Reactivity, and Physicochemical Properties of Compounds with a Tin-Nitrogen Bond

Yu.I.Dergunov, V.F.Gerega, and O.S.D'yachkovskaya

Data on the methods of preparation, properties, and practical applications of organotin compounds with an Sn-N bond are reviewed.
The bibliography includes 343 references.

## I. INTRODUCTION

Organotin compounds with a covalent tin–nitrogen bond have attracted in recent years the continuous attention of investigators and workers in the field of applied chemistry. The study of their properties led to the discovery of new types of processes, for example the reaction involving the insertion of isocyanates in the Sn–N bond. The fields where these compounds have found practical applications are continuously expanding [1-9]. Several reviews [10-17] and a separate chapter in a monograph [18] have been devoted to this problem and the data have been partly surveyed in a book [19].

The aim of this paper is to review the available data on the synthesis, reactivity, physicochemical properties, and applications of organotin compounds with a tin–nitrogen bond, contained in monographs, journal articles, and patents published up to 1975. The main task is to draw the attention of Soviet chemists to this rapidly developing field of organoelemental chemistry, which is promising from both theoretical and practical points of view. The characteristics of the structures, physicochemical properties, and possible applications of nitrogen-containing organotin products have still been inadequately investigated.

These compounds can be divided into two groups [18]. The first includes aminostannanes $\equiv Sn-NR_2$ and the second organotin pseudohalides $\equiv Sn-N-R$ (R = C, N, or P). Compounds belonging to the first and second groups are synthesised by similar methods, but their physicochemical properties and reactivities are very different in certain cases.

The synthesis and properties of aminostannanes have been investigated in detail, while the studies which have been carried out on organotin pseudohalides are much less satisfactory.

## II. THE SYNTHESIS OF COMPOUNDS WITH A TIN–NITROGEN BOND

Organotin amines of the type $R_{4-n}Sn(NR'R'')_n$ ($n = 1-4$) cannot be synthesised by the reactions of amines with organotin halides, in contrast to the corresponding silicon and germanium compounds. The explanation is that the complexes formed in this reaction decompose on heating into the initial reactants [20-21]. The cases where the thermal stability of the complex is high are an exception. For example, triphenylstannylpurine can be synthesised from triphenylstannyl chloride and purine [22].

Organotin amines are obtained by transmetallation and transamination reactions as well as addition and exchange reactions.

### 1. Transmetallation Reactions

Whereas the syntheses of secondary and tertiary aminostannanes have been satisfactorily developed, an acceptable method for the synthesis of primary organotin amines of the type $R_3SnNH_2$ was not proposed until 1974 for t-butyl derivatives [23]. It involves the treatment of tris-(t-butyl)phenylstannane with a solution of potassium amide in liquid ammonia:

$$t\text{-}Bu_3SnPh + KNH_2 \xrightarrow{NH_3} t\text{-}Bu_3SnNH_2 + PhK \quad .$$

Secondary and tertiary aminostannanes are readily obtained by the reaction of lithium salts of amines with organotin halides [4,8,22,24-37]:

$$R_{4-n}SnX_n + n\,LiNR'R'' \rightarrow R_{4-n}Sn(NR'R'')_n + n\,LiX \quad ,$$

where R, R′, and R″ are alkyl or aryl groups and X is a halogen. The reaction proceeds readily and with high yields of the desired products in a dry inert solvent. At the same time the general method has certain characteristic features to which attention must be drawn. In particular, only the reaction of monolithium salts of primary aromatic amines leads to the formation of secondary organotin amines [27,38]:

$$R_3SnX + LiNHR' \rightarrow R_3SnNHR' + LiX \quad .$$

When organotin alkyl derivatives and salts of aliphatic amines were used, the products were the corresponding distannazanes. This can probably be accounted for by the successive transformations of (alkylamino)trialkylstannane:

$$\begin{aligned} 2R_3SnNHR' &\rightarrow (R_3Sn)_2NR' + H_2NR' \quad , \\ R_3SnNHR' + R_3SnX &\rightarrow (R_3Sn)_2NR' + HX \quad . \end{aligned} \qquad (1)$$

Lithium nitrides or amides are used in the synthesis of tris(trialkyl- and triarylstannyl)amines or hydrazine derivatives [33,39-41]:

$$3Me_3SnCl + Li_3N \rightarrow (Me_3Sn)_3N + 3LiCl \quad .$$

Different organotin amines and amides, including derivatives of sulphonamides and heterocyclic compounds (imidazoles, triazoles, etc.) are obtained via the corresponding sodium, potassium[2-4,42-45], and silver[46] salts and dialkylaminomagnesium bromide[47]. Together with organotin halides, the corresponding nitrates and acetates[48] as well as oxide derivatives[49,50] are used:

$$R_3SnX + MNH_2 \xrightarrow{NH_3} (R_3Sn)_3N \quad , \qquad (2)$$
$$X=Cl,\ OR,\ or\ OSnR_3;\ M=Li,\ Na,\ or\ K;$$

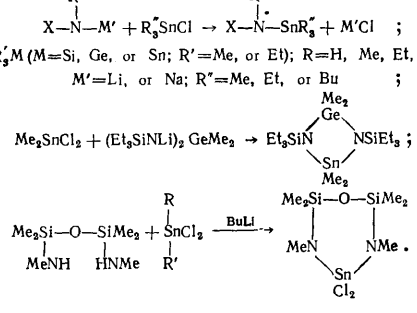
$$R_3SnCl + R'NAg \rightarrow R_3Sn{-}\underset{NO_2}{\underset{|}{N}}{-}R' + AgCl \quad ;$$

$$R_3SnCl + R'_2NMgBr \rightarrow R_3SnNR'_2 + MgBrCl \quad ;$$

Together with the tertiary amine, the secondary amine $(R_3Sn)_2NH$ was obtained in reaction (2).[51] The simultaneous formation of secondary and tertiary aminostannanes was also noted in the reaction of tricyclohexylphenylstannane and hexacyclohexyldistannane with potassium amide[52-54]:

$$2R_3SnC_6H_5 + KNH_2 \xrightarrow{NH_3} (R_3Sn)_2NH + C_6H_6 \quad ,$$

where R is the cyclohexyl group.



The use of organometallic derivatives and salts for the synthesis of aminostannanes is not restricted to Group I and II metals. Four- and six-membered cyclostannazanes[55] and dichlorostannoazosulphonylarenes, the first compounds containing a Sn–N bond[56], have been synthesised via tin(II) chloride:

$$ArSO_2NCl_2 + SnCl_2 \rightarrow ArSO_2{-}\underset{Cl}{\underset{|}{N}}{-}SnCl_3 \xrightarrow{SnCl_2} [ArSO_2N(SnCl_3)_2] \rightarrow$$
$$\rightarrow ArSO_2N{=}SnCl_2 + SnCl_4 \quad .$$

However, there is some doubt about the existence of such products, which are allegedly fairly stable under the usual conditions. From our point of view, these derivatives probably have dimeric or trimeric structures [see reaction (3)].

The transmetallation reaction is widely used also in the synthesis of mixed organotin–organosilicon amines of the type $X{-}\underset{R}{\underset{|}{N}}{-}Y$,[29-31,36,57-61] including cyclic derivatives containing organoelemental germanium and silicon fragments[29,62]:

$$X{-}\underset{R}{\underset{|}{N}}{-}M' + R''_3SnCl \rightarrow X{-}\underset{R}{\underset{|}{N}}{-}SnR''_3 + M'Cl \quad ;$$
$$X=R'_3M\ (M=Si,\ Ge,\ or\ Sn;\ R'=Me,\ or\ Et);\ R=H,\ Me,\ Et,\ or\ X;$$
$$M'=Li,\ or\ Na;\ R''=Me,\ Et,\ or\ Bu \quad ;$$

$$Me_2SnCl_2 + (Et_3SiNLi)_2GeMe_2 \rightarrow Et_3SiN\ \underset{\displaystyle Me_2Ge}{\overset{\displaystyle NSiEt_3}{\diagup\ \diagdown}}\ Sn\ \diagup\ \diagdown\ Me_2 \quad ;$$

Mixed organosilicon aminostannanes can be obtained also by the converse reaction, i.e. from the lithium salts of organic aminotin compounds and trialkyl derivatives of the chlorides of Group IVB elements[63] or from trialkylstannyl-lithium and *N*-bromohexamethyldisilazane[48].

Exchange reactions are quite suitable also for the synthesis of organotin pseudohalides. Trialkyl- and triaryl-stannyl isocyanates[64-68], trialkyl- and triarylstannyl isothiocyanates[64,69,70], dialkyl- and diaryl-tin di-isothiocyanates[71-74], the di-isocyanates, di-isothiocyanates, and hydroxide isothiocyanates of tetra-alkyldistannoxanes $R_2(SCN)SnOSn(NCS)R_2$ and $R_2(SCN)SnOSn.R_2(OH)$,[6,71,75] and triphenylstannyl *N*-selenocyanate[76] have been obtained in this way from organotin halides and cyanates or sodium, potassium, silver, and ammonium thiocyanates. Trialkylstannyl isocyanides, which are converted into isothiocyanates on heating with elemental sulphur[77], have been obtained via potassium cyanide[69]. Triphenyl- and tributyl-stannyl isocyanates may be synthesised also by treating organotin chlorides in xylene with a suspension of sodium *N*-ethylcarbamate[65]:

$$R_3SnCl + NaNHCOOC_2H_5 \rightarrow [R_3SnNHCOOC_2H_5] \rightarrow R_3SnNCO + C_2H_5OH \quad .$$

Trialkyl- and triaryl-stannyl azides[24,43,44,78,79,80,81] and hexa-alkyl-1,5-diazidotristannoxane $N_3Sn(R)_2{-}OSn(R)_2{-}OSn(R)_2N_3$[82] have been obtained by a corresponding procedure via azide salts.

Imino-derivatives of organotin compounds may be synthesised from trialkyltin salts and cyanoiodo-derivatives[28]:

$$Et_3SnLi + Me_2\underset{CN}{\underset{|}{C}}I \rightarrow Et_3SnN{=}C{=}CMe_2 + LiI$$

or from immonium salts and organotin halides[83-85]. Triphenyl- and trimethyl-stannyldicyanamides and bis-(dicyanomido)dimethylstannane have been obtained similarly[41,86,87]:

$$Me_2SnCl_2 + 2NaN(CN)_2 \rightarrow Me_2Sn[N(CN)_2]_2 + 2NaCl \quad .$$

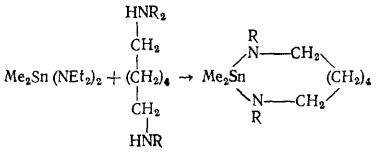
In order to elucidate the structure of organotin compounds containing the carbodi-imide fragment, *NN'*-bis-(triphenylstannyl)carbodi-imide was synthesised via the sodium salt of cyanamide, but the conditions of this reaction and the constants of the products are not quoted by the authors[43]. The syntheses of the corresponding alkyl derivatives[88-91] and of the tetrameric dibutylcarbodi-imidostannane were achieved subsequently[92]:

$$2Me_3SnCl + X_2NCN \rightarrow Me_3SnNCNSnMe_3 + 2XCl \quad ;$$
$$X=H,\ Na,\ or\ Ag \quad .$$

Organotin hyponitrites have also been obtained by the above procedures, but Beck et al.[93] are inclined to the idea, based on dipole moments and infrared spectra, that these compounds do not contain an Sn–N bond and the problem has therefore not been finally solved.

## 2. The Transamination Reaction

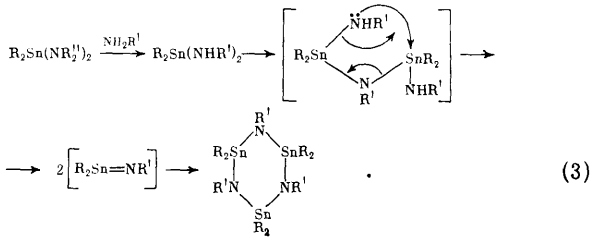
Organotin amines are frequently synthesised by exchange reactions between dialkylaminostannanes and secondary aliphatic amines, which proceed readily and quantitatively[26,27]:



$$R_3SnNR'_2 + HNR''_2 \rightarrow R_3SnNR''_2 + HNR'_2 \quad ;$$
$$R,\ R'\ R''\ =\ alkyls.$$

The order of substitution of the amino-groups in simple aliphatic aminostannanes is[27]

$$NBu_2 > NEt_2 > NMe_2 \quad .$$



This method has also been used on a preparative scale to synthesise not only linear but also cyclic organotin

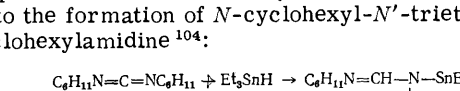
amines [94-99], for example:

Dialkylaminostannanes are transaminated by primary amines [26,27]. When t-butylamine and aniline were used in this reaction, t-butyl- and phenyl-aminostannanes were isolated respectively [100]. On the other hand, the reaction with methyl- or ethyl-amine leads to the formation of only the corresponding distannazanes even in the presence of an excess of the amine. This confirms yet again that the condensation of organotin amines of the type $R_3SnNHAlk$ to distannazanes via reaction (1) proceeds rapidly and irreversibly.

An interesting example of intramolecular transamination is the synthesis of six-membered [24,26,101] and four-membered [102] cyclostannazanes via primary amines. In the former case, the reaction is a four-stage process involving the transamination proper, intermolecular condensation, and nucleophilic 1,3-rearrangement with subsequent elimination and cyclopolymerisation:

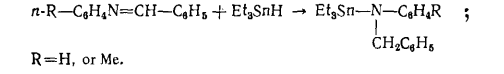
(3)

Like amines, ammonia can be used successfully in the transamination reactions in order to obtain tertiary organotin amines, the ease of substitution decreasing in the sequence [27,103] $H_2N > RNH > R_2N$, where R is an alkyl group.



### 3. Reactions Involving the Addition of Organotin Compounds to Multiple Bonds

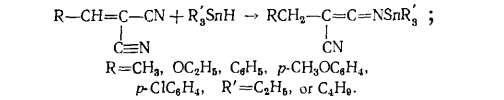
The addition of organotin compounds to multiple bonds is a preparatively convenient method of synthesis of organotin formamides, carbamates, amino- and imino-derivatives, substituted ureas, and related products. This section deals mainly with insertion reactions via the mdchanism



$$\equiv Sn{-}X + N{-}Y \rightarrow \equiv Sn{-}N{-}Y{-}X \quad ,$$

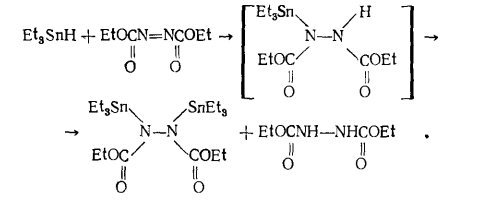
where N–Y is an unsaturated nitrogen compound and X = H, O, N, P, or As. These reactions can be conveniently considered separately for different X.

(a) Insertion in the Sn–H bond. The interaction of triethylstannane with dicyclohexylcarbodi-imide in the presence of azobisisobutyronitrile or zinc chloride leads to the formation of *N*-cyclohexyl-*N'*-triethylstannyl-*N'*-cyclohexylamidine [104]:

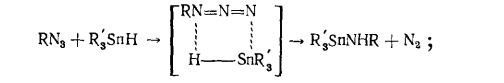


The reaction with azomethines containing aromatic substituents proceeds similarly [104-107]:

R=H, or Me.



Similar reactions of azocarboxylic acid nitriles [28] and the dinitriles of alkylidenemalonic acids [108,109] also lead to the formation of an Sn–N bond:



Triphenyl- and triethyl-stannanes react with azeobenzene in different ways. While the former gives rise to *NN'*-diphenyl-*N*-triphenylstannylhydrazine, the corresponding addition product derived from the latter was not isolated. When aromatic azocompounds of the type RN=NXR' and RXN=NXR' (where X = $SO_2$ or $OCH_2$) are used in this reaction, there is no addition of triethylstannane [110], for example:

In the reaction of triethylstannane with diethyl azodicarboxylate, the primary 1,2-addition product disproportionates to hydrazinedicarboxylate and bis(triethylstannyl)-bis(ethoxycarbonyl)hydrazine [111]:

The synthesis of trialkylstannylaniline and *N*-tributylstannylarenesulphonamides by the reaction of incompletely substituted stannanes with benzene- and arene-sulphonyl azides [63,112] is an example of the intermediate formation of products resulting from addition to the unsaturated nitrogen–nitrogen bond in the molecule of the incompletely substituted stannane:

R=$C_6H_5$, *p*-$CH_3C_6H_4SO_2$, *p*-$CH_3OC_6H_4SO_2$, *p*-$NO_2C_6H_4SO_2$, or $SO_2C_6H_5$; R' = $C_2H_5$, or $C_4H_9$.

The analogous reaction of benzoyl azide is accompanied by the Curtius rearrangement and the formation of phenyl isocyanate, which in its turn gives rise to a urea derivative on interaction with the incompletely substituted stannane [113]. In contrast to the foregoing, when incompletely substituted arylstannanes were allowed to react with triphenylstannane azide, compounds with an Sn–N bond were not isolated [114]. There is no doubt that such products are formed as intermediates [16], but the authors apparently did not select conditions necessary for their isolation.

The reactions of trialkyl- and triaryl-stannanes with isocyanates and isothiocyanates are of greatest interest from the preparative and theoretical standpoints [115-117]. The composition of these products showed that, depending on the nature of the reactant, different types of addition are observed. The reaction between trialkylstannanes and aromatic isocyanates leads to the formation of

trialkyl-*N*-arylformamidostannanes [116]:

$$ArNCO + R_3SnH \rightarrow R_3SnN(Ar)\overset{\overset{O}{\|}}{C}H \ ;$$
$$Ar = C_6H_5,\ p\text{-}ClC_6H_4,\ \text{or}\ p\text{-}NO_2C_6H_4;\ R = C_2H_5,\ \text{or}\ C_4H_9.$$

The reactions of diethylstannane with two moles of phenyl isocyanate and of two moles of triethylstannane with *p*-phenylene di-isocyanate proceed similarly.

The same behaviour has been observed in the reactions of aliphatic isocyanates. For example, the addition of triethylstannane to cyclohexyl isocyanate leads to the formation of compounds with an Sn–N bond [118], although in an earlier study [115] the author believed that the process results in the formation of *N*-cyclohexylcarbamoyltriethylstannane only.

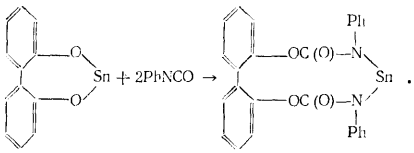
Allyl isocyanate reacts with tributylstannane, this being accompanied by the possible formation of a formamide derivative, which decomposes to tributylstannyl isocyanate and propene [119]. Alkyl and aryl isothiocyanates react with triethylstannane to form alkylstannylthiomethyleneimines. The hydrostannylation of arenesulphonyl isocyanates by tributylstannane takes place similarly [120]. It has been shown by infrared spectrophotometry and thermographically that the *N*-(tributylstannyloxymethylene)-arenesulphonamide (A) is involved in a tautomeric equilibrium with *N*-tributylstannylarenesulphonylformamide (B) [120]:

$$\underset{(A)}{ArSO_2N{=}C(H)OSnBu_3} \rightleftharpoons \underset{(B)}{ArSO_2N(SnBu_3)C(O)H} \ .$$

The use of an excess of triarylstannane in the reaction with aromatic isocyanates leads to the decomposition of the resulting organotin formamide and ultimately to the reduction of the isocyanates to *N*-arylformamides [121].

The study of the mechanism of the hydrostannylation of organic isocyanates and isothiocyanates has demonstrated the occurrence of nucleophilic attack by stannane hydrogen on the carbon atom of the isocyanate in the rate-determining stage of the reaction [117]. It is believed that the reaction proceeds via a polar mechanism [122,123]:

$$R_3SnH + R'N{=}C{=}X \rightarrow \left[\begin{array}{c} R'{-}N{\cdots}C{\cdots}X \\ \vdots \quad\ \vdots \\ H \quad\ SnR_3 \end{array}\right] \rightarrow$$
$$\rightarrow R_3Sn^{(+)} + \begin{array}{l} R'{-}\overset{(-)}{N}{-}CH{=}X \\ R'{-}N{=}CH{-}\overset{(-)}{X} \end{array} \longrightarrow \begin{array}{l} \xrightarrow{X=O} R'{-}N(SnR_3){-}C(O)H \\ \xrightarrow{X=S} R'{-}N{=}CH{-}S{-}SnR_3 \end{array} .$$



The proposed mechanism cannot apparently be unambiguous, because it does not take into account the possible tautomeric transformations of the products.

(b) Insertion in the Sn–O bond. These reactions are not of preparative importance alone. They are important for the understanding of the problem of the mechanism of the catalytic interaction of alcohols with isocyanates in the presence of organotin compounds, which still remains controversial [124–126].

The interaction of isocyanates and alkoxy-derivatives of organotin compounds results in the formation of *N*-stannylcarbamates [118,127–130]:

$$R_3SnOR' + R''NCO \rightarrow R_3SnN(R'')C(O)OR' \ ;$$
$$R = \text{alkyl};\ R' \text{ and } R'' = \text{alkyl or aryl.}$$

Ethyl and phenyl isocyanates react similarly with dibutyldimethoxystannane. The reaction proceeds stepwise with formation of 1 : 1 and 2 : 1 adducts in the first and second stages respectively. The latter adduct disproportionates on heating with dibutyldihalogenostannane, forming halogeno-substituted carbamates [131]. The synthesis of new heterocycles in which tin is bivalent constitutes an interesting example of the insertion of phenyl isocyanate in the Sn–O bond [132]:

The authors [132] give preference to the carbamate form of this compound.

It is noteworthy that the structure of the corresponding organotin imide rather than the carbamate has been attributed to the adduct of acetyl isocyanate and methoxytripropylstannane [133]:

$$CH_3{-}C{=}N{-}C(O)OCH_3 \ .$$
$$\quad\ |$$
$$\quad OSn(C_3H_7)_3$$

Presumably the imide is a result of the isomerisation of the carbamate form to the imide form as a result of the migration of the trialkylstannyl fragment. This idea has been put forward [118,129] but without any evidence for its occurrence. The possibility of the tautomeric transformations of organotin carbamates into imides was confirmed for products of the interaction of arenesulphonyl isocyanates and tributylmethoxystannane [134]:

$$p\text{-}RC_6H_4SO_2NC(O)OCH_3 \rightleftharpoons p\text{-}RC_6H_4SO_2N{=}C\overset{OSn(C_4H_9)_3}{\overset{|}{\underset{OCH_3}{|}}} \ ;$$
$$\quad\ |$$
$$Sn(C_4H_9)_3$$
$$R = H,\ CH_3,\ OCH_3,\ \text{or Cl.}$$

Organotin urea derivatives can be readily synthesised by the reaction of hexa-alkyldistannoxanes and alkyl or aryl isocyanates. The initial step involves the formation of trialkylstannyl *N*-alkyl(or aryl)-*N*-trialkylstannylcarbamates, which are decarboxylated to dialkyl(diaryl)-*NN'*-bis(trialkylstannyl)ureas and stannoxanes on heating [135–137]:

$$(R_3Sn)_2O + R'NCO \rightarrow R_3SnNR'C(O)OSnR_3 \ ;$$
$$2R_3SnNR'C(O)OSnR_3 \xrightarrow[-CO_2]{} R_3SnNR'{-}CO{-}NR'SnR_3 \ ;$$
$$R \text{ and } R' = \text{alkyl or aryl.}$$

Stannylureas are obtained also by the reaction of organotin carbamates with isocyanates on heating [137,138]:

$$R_3SnNR'C(O)OSnR_3 + R''NCO \rightarrow R_3SnNR'{-}CO{-}NR''SnR_3 + CO_2 \ .$$

When the reaction is carried out at room temperature, hexa-alkyldistannoxanes and organic isocyanurates are formed [125,138]. It is of interest that this type of reaction apparently constitutes the basis of the catalytic trimerisation of isocyanates, which occurs in the presence of organotin compounds [125,126].

Like the reactions of arenesulphonyl isocyanates with incompletely substituted stannanes and alkoxy-derivatives, the reaction of the above isocyanates with tributyltin oxide results in the isolation of a mixture of tautomeric compounds to which the structures of the corresponding carbamates and stannoxymethyleneimines [scheme (4)] has been attributed to the basis of infrared spectra. When the isocyanate and the oxide were used in proportions of 2 : 1, it was possible to obtain organotin disulphonylureas [139]:

$$n\text{-}RC_6H_4SO_2NCO + (Bu_3Sn)_2O \longrightarrow \begin{array}{l} \xrightarrow{\quad} n\text{-}RC_6H_4SO_2N(SnBu_3)C(O)OSnBu_3 \\ \xrightarrow{\quad} n\text{-}RC_6H_4SO_2N{=}C(OSnBu_3)_2 \end{array} \ ;$$
$$R = H,\ CH_3,\ OCH_3,\ \text{or Cl.} \qquad (4)$$

The attempt to synthesise triethylstannyl *N*-phenylcarbamate from triethyltin hydroxide and phenyl isocyanate was unsuccessful[136]. On the other hand, the reaction of arenesulphonyl isocyanates with triethyl- and triphenyltin hydroxides proceeds readily and in the case of the ethyl derivative results in formation of organotin arenesulphonamides and, in the presence of the phenyl derivative, a mixture of the corresponding arenesulphonamides and arenesulphonylcarbamates[140].

Organotin ureas can also be obtained by the interaction of hexa-alkyldistannoxanes or alkoxy-tin derivatives with carbodi-imides[94,141]. The latter are more reactive than isocyanates and isothiocyanates. Nitriles containing strong electron-accepting groups react with oxygen-containing organotin compounds to form substituted imides with an Sn–N bond[9,94,131]:

$$Bu_3SnOMe + CCl_3CN \rightarrow Bu_3SnN{=}C(CCl_3)OMe \ .$$

Diarylsulphodi-imides and *N*-sulphinamides readily react with alkylstannoxy derivatives; one or two N=S bonds are ruptured and intermediate products resulting from insertion in the Sn–O bond are formed[142-144]:

$$ArN{=}S{=}NAr + (Bu_3Sn)_2O \rightarrow Bu_3SnN(Ar)SON(Ar)SnBu_3 \ ;$$
$$ArSO_2NSO + R_3SnOR' \rightarrow R_3SnN(SO_2Ar){-}SO{-}OR' \ ;$$
$$Ar = C_6H_5, \text{ or } p\text{-}CH_3C_6H_4 \ .$$

The organotin sulphinyl diamides, sulphimates, and other compounds formed in these reactions are as a rule thermally unstable.

Finally, fairly stable t-butyl *N*-alkyl-*N*-triphenylstannylperoxycarbamates, $Ph_3SnN(Alk)C(O)OOBu\text{-}t$, have been obtained as a result of the reaction of t-butyl triphenylstannyl peroxide with alkyl isocyanates[145].

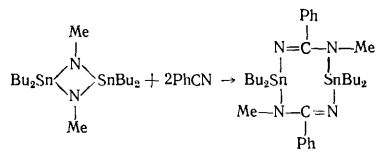
(c) Insertion in the Sn–N bond. The addition of unsaturated compounds to the Sn–N bond is the most typical example of the insertion reaction. It is used to synthesise organotin ureas, imines, imides, sulphinic diamides, and other compounds from aminostannanes and isocyanates, isothiocyanates, organic cyano-derivatives, carbodi-imides, and sulphinyl derivatives[12,26,108,146-149]:

$Me_3SnNMe_2$ + PhNCO → $Me_3SnN(Ph)C(O)NMe_2$
+ PhCN → $Me_3SnN{=}C(Ph)NMe_2$
+ PhNCNPh → $Me_3SnN(Ph)C(=NPh)NMe_2$
+ PhNSO → $Me_3SnN(Ph)S(O)NMe_2$
+ PhNCS → $Me_3SnN(Ph)C(S)NMe_2$ .

The reactions proceed under mild conditions with nearly quantitative yields. Aromatic isocyanates are less reactive in these processes than the aliphatic compounds.

Phenyl isocyanate is capable of adding to *N*-tributylstannyl-*N*-methylformamide and *N*-tributylstannylacetamide, but the adduct obtained as a result of the latter reaction decomposes to tributylstannyl isocyanate and acetanilide[7,150]:

$$Bu_3SnNHC(O)Me + PhNCO \rightarrow [Bu_3SnN(Ph)C(O)NHC(O)Me] \rightarrow$$
$$\rightarrow Bu_3SnNCO + PhNHC(O)Me \ .$$



The reactions of aminostannanes with aromatic *N*-sulphinylsulphonamides[143] and of phenyl isocyanate with diethylaminodimethylstannyl chloride[151] also proceed with formation of unstable adducts. The interaction of alkyl or aryl isocyanates and isothiocyanates with *N*-tributyldiphenylmethyleneiminostannane leads to the formation of the corresponding organotin ureas and thioureas[152]:

$$Bu_3SnN{=}CPh_2 + RNCX \rightarrow Bu_3SnN(R)C(X)N{=}CPh_2 \ ;$$
$$R = Me, Et, Bu, \text{ or } Ph;\ X = O \text{ or } S \ .$$

The addition of heptamethylsilylstannazane to isocyanates and isothiocyanates has been studied in a number of investigations and it has been shown that the structures of the products thus obtained are different[12,153]. Thus the reaction with methyl isocyanate gives rise mainly to the iminoester

$$R_3SnN(CH_3)C\langle {}^{NCH_3}_{OSiR_3} \ ,$$

while the reaction with phenyl isocyanate gives rise to the urea derivative $R_3SnN(Ph)CON.(CH_3)SiR_3$. The reaction of silylstannazane with phenyl isothiocyanate leads to an equilibrium mixture of products with both structures. The reaction involving the insertion of isocyanates in the Sn–N bonds of organotin cyanamides has been used to synthesise organotin cyanoureas, which exhibit biological activity[154]. An interesting example of the addition reaction of the above type is the synthesis of eight-membered organotin heterocycles by the reaction of benzonitrile with diazostannetidines[102]:

A simple method has been proposed for the synthesis of trimethylstannyl *N*-methyl(trimethylstannyl)carbamate by passing carbon dioxide through a solution of heptamethyldistannazane[155]:

$$(Me_3Sn)_2NMe + CO_2 \rightarrow Me_3SnN(Me)C(O)OSnMe_3 \ .$$

(d) Insertion in the Sn–P and Sn–As Bonds. The interaction of isocyanates, isothiocyanates, and phenyl azide with triphenylstannyldiphenylphosphine and triphenylstannyldiphenylarsine may be classified as insertion reactions of the above type[156-158]:

$$Ph_3SnPPh_2 + PhNCX \rightarrow Ph_3SnN(Ph)C(X)PPh_2 \ ;$$
$$X = O \text{ or } S;$$
$$Ph_3SnYPh_2 + 2PhN_3 \rightarrow Ph_3SnN(Ph)Y(=NPh)Ph_2 \ ;$$
$$Y = P \text{ or } As;$$
$$Ph_3SnAsPh_2 + 3PhN_3 \rightarrow Ph_3SnN(Ph){-}As(Ph){-}N(Ph)SnPh_3 \ .$$
$$\|$$
$$NPh$$

## 4. Exchange and Substitution Reactions of Organotin Compounds

Exchange reactions of organotin oxides and hydroxides with nitrogen-containing reagents having an active hydrogen atom have been proposed for the synthesis of compounds with an Sn–N bond, which are fairly resistant to hydrolysis:

$$(R_3Sn)_2O + 2HN\langle \rightarrow 2R_3SnN\langle + H_2O \ .$$

Organotin derivatives of pyrrole, imidazole, benzotriazole[22,43-45], amido-compounds[118,159], nitroamines[46], and trialkylstannyltoluenesulphonamide[42,150] have been obtained via this mechanism. The reaction is used in the preparative methods for the synthesis of organotin isocyanates and isothiocyanates involving the interaction of trialkyl- or triaryl-tin oxides and hydroxides with urea,

## III. REACTIVITY OF COMPOUNDS WITH A TIN–NITROGEN BOND

It has been suggested that the reactions of organotin compounds with an Sn–N bond be divided into these with protic reagents, reactions with organoelemental hydrides, and exchange decomposition and addition reactions [18].

### 1. Reactions with Protic Reagents

The most characteristic property of organotin amines [33,44,47,147,182,190], imines [83,191,192], ureas [130,136], carbamates [127,128,129,145], triazenes [193], amides [112,140,159,182], sulphinic diamides [142], and triphenylstannyldicyanamide [86] is their hydrolytic instability:

$$\equiv Sn{-}N\!\!<\; + H_2O \rightarrow \equiv Sn{-}OH + HN\!\!<\;\; .$$

Aminostannanes containing less bulky substituents are more readily hydrolysed by water as a result of the steric factor [30]. When these reactions are performed in air, hydrolysis is accompanied by carboxylation of the aminostannanes, leading to organotin carbonates [33,47,106,155,194].

Various organotin amino-derivatives are readily cleaved at the Sn–N bond by hydrogen chloride or hydrochloric acid [47,49,145,147,194], hydrogen sulphide [127,129], and hydrogen cyanide [195]. The last reaction is used to synthesise organotin cyanides:

$$R_{4-n}Sn(NEt_2)_n + 2n\,HCN \rightarrow R_{4-n}Sn(CN)_n + n\,HNEt_2\cdot HCN\;;$$
$$R{=}Me,\ Et,\ or\ Bu,\ Ph;\ n = 2,\ 3.$$

When stannylamines [194,196], trialkylstannylketenimines [192], organotin carbamates [127,129,134,139], *NN'*-bis(trialkylstannyl)-sulphinic amides [142], and *NN*-bis(tributylstannyl)benzenesulphonamide [182] react with acetic acid, organotin acetates are formed quantitatively.

Alcohols react readily with aminostannanes [34,141,147,182,194,197,198], *N*-trialkylstannylketenimines [191,192], *NN'*-diaryl-*NN'*-bis(trialkylstannyl)sulphinic diamides [142], and stannyl carbamates [126,129,136,139,175,193] at the Sn–N bond under mild conditions, which leads to the formation of organotin alkoxides and amines. Such reactions are used, for example, to synthesise pure methoxytrimethylstannane [197]:

$$R_{4-n}Sn(NR'_2)_n + n\,R''OH \rightarrow R_{4-n}Sn(OR'')_n + n\,R'_2NH\;\; .$$

Butaneselenol [199,200], butanethiol [201], and silanol [34] react with aminostannanes similarly to alcohols.

The reactions of alcohol with organotin carbamates are particularly interesting from the standpoint of the explanation of the mechanism of the catalysis of the synthesis of urethanes by the latter [129,202]:

$$Bu_3SnOEt + PhNCO \rightarrow Bu_3SnN(Ph)C(O)OEt \xrightarrow{EtOH} Bu_3SnOEt + PhNH{-}C(O)OEt$$

or

$$PhNCO + EtOH \xrightarrow{Sn^{IV}} PhNH{-}C(O)OEt\;\; .$$

However, the lack of quantitative data, on the basis of which the rates of the known catalytic reactions put forward by Bloodworth and Davies [129] could be compared, precludes unambiguous inferences concerning this mechanism. One can only add that a different version of the mechanism of the catalytic formation of urethanes has been considered [124] and its validity demonstrated.

Organic hydroperoxides and peroxides react similarly with aminostannanes. The reaction of t-butyl hydroperoxide with a dialkylaminotrialkylstannane yields the trialkyl-t-butylperoxystannane and the dialkylamine. The main products of the reaction with benzoyl peroxide were the trialkylstannyl benzoate and the *NN*-dialkyl-*O*-benzoylhydroxylamine. The latter reaction does not have a free-radical mechanism despite the use of a typical free-radical generating agent–benzoyl peroxide [203].

Reactions involving the transamination of aminostannanes have already been partly discussed in Section II. It is of interest to consider here the interaction of methyl *N*-phenyl-*N*-tributylstannylcarbamate with ethylamine, the products of which are tributylmethoxystannane and *N*-ethyl-*N'*-phenylurea instead of the expected transamination products [129] [Eqn. (6)]. According to the authors [129], the reaction can proceed via two equally probable pathways. From our point of view, the second pathway is preferable, because the tributylethylaminostannane formed via the first pathway should condense with liberation of distannazanes [Eqn. (1)], which were not detected in the reaction:

$$Bu_3SnN(Ph)C(O)OMe + EtNH_2 \begin{cases} \rightarrow Bu_3SnNHEt + PhNH{-}C(O)OMe \\ \rightarrow MeOH + Bu_3SnNPh{-}CO{-}NHEt \end{cases} \rightarrow$$
$$\rightarrow PhNH{-}CO{-}NHEt + Bu_3SnOMe\;\; . \qquad (6)$$

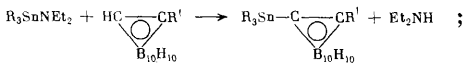
When stannyl *N*-stannyl-*N*-sulphonylcarbamates react with diethylamine, the corresponding substituted ureas and tributyltin oxide are also obtained [139]. The transamination of bis(tributylstannyl)benzenesulphonamide with diethylamine proceeds in the standard manner [182]:

$$Bu_3Sn\,N(PhSO_2)C(O)OSn\,Bu_3 + Et_2NH \rightarrow PhSO_2NH{-}CO{-}NEt_2 + (Bu_3Sn)_2O\;;$$
$$(Bu_3Sn)_2NSO_2Ph + Et_2NH \rightarrow Bu_3SnNHSO_2Ph + Bu_3SnNEt_2\;\; .$$

Stannylamines react with halogenohydrocarbons in different ways depending on the nature of the halogen and the structure of its derivative. Thus when a dialkylaminotrialkylstannane was acted upon by chloroform, bromoform or chloroethylene derivatives, trihalogenomethyl derivatives of tin were obtained [131,204–207]:

$$R_3SnNR'_2 + HCX_3 \rightarrow R_3SnCX_3 + R'_2NH\;;$$
$$R{=}Me,\ Et,\ Bu,\ or\ Ph;\ R'{=}Me\ or\ Et;\ X{=}Cl\ or\ Br.$$

The synthesis of pentafluorophenyltrimethylstannane was achieved by the reaction of dimethylaminotrimethylstannane with pentafluorobenzene in boiling benzene [208]. However, this reaction does not occur with iodo-, fluoro-, or mixed chlorofluoro-derivatives of methane of the type $HCFCl_2$.



The reaction of aminostannanes with acetylene and its derivatives constitutes a preparative method for the introduction of an unsaturated bond into the molecule of an organotin compound. The reaction proceeds quantitatively which is promoted by the possibility of the effective elimination of the volatile alkylamine formed as a product [147,148,194,208,209,210,211]:

$$R_{4-n}Sn(NR'_2)_n + n\,HC{\equiv}CR'' \rightarrow R_{4-n}Sn(C{\equiv}CR'')_n + n\,HNR'_2\;;$$
$$n{=}1{-}4$$
$$R,\ R',\ and\ R''\ =\ hydrocarbon\ groups.$$

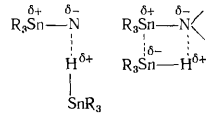
In the reactions with amines of the type $R_2Sn(NR'_2)_2$ acetylene gives rise to a polymeric complex [147,194]. Cyclopentadiene, indene, and their derivatives react with aminostannanes similarly to acetylene [147,194,212].

Other compounds containing an active hydrogen atom attached to a carbon atom (nitriles, nitromethane) are also capable of involvement in proton exchange reactions with aminostannanes [194]. Thus diazomethane reacts with dimethylaminotrimethylstannane, which is followed by the substitution of two hydrogen atoms by organotin fragments [186,213,214], the reactivity of diazomethane derivatives

increasing in the sequence $MeCHN_2 < CH_2N_2 < CH[C(O).OEt]N_2$.[214-216]. *o*-, *m*-, and *p*-Carboranes react similarly[217,218]:

$R = Et$, or Bu; $R' = H$, $CH{=}CH_2$, or $SnR_3$ .

Although decaborane contains an active hydrogen atom, it reacts with aminostannane to form only a complex of the type $[Me_3Sn]^+[B_{10}H_{13}\cdot Me_2NH]^-$.[219] The mechanism of the reactions of aminostannanes with protic reagents has not been elucidated. However, one may postulate that it is based on electrophilic attack by the hydrogen atom of the protic reagent HA on the nitrogen atom of the aminostannane $\equiv Sn-N\lessdot$ followed by the coordination of the A fragment to the tin atom[18].



## 2. Reactions of Amino-Derivatives of Tin with Organoelemental Hydrides

Organotin hydrides react with aminostannanes[220-228], stannylhydrazines[117], and amides[111,226,229] to form di- and poly-stannanes in almost quantitative yields, for example:

$$R_3SnNEt_2 + R'_3SnH \rightarrow R_3SnSnR'_3 + Et_2NH \quad ;$$

$$n\,R_2Sn(NEt_2)_2 + n\,R_2SnH_2 \rightarrow (-SnR_2)_{2n} + 2n\,Et_2NH \quad .$$

The relative reactivity of $R_3SnH$ depends on R and increases in the following sequences[222,224]: t-Bu < iso-Bu < Bu < Ph and $R_3SnSnR_2H < R_3SnH < R_2SnH_2$. On the other hand, the reactivity of aminostannanes in these reactions increases with increasing basicity of nitrogen: $R_3SnNHR'' < R_3SnNR''_2$.[222] The study of the kinetics of the reaction of diethylaminotriethylstannene with triethylstannane showed that it is of second order overall and of first order with respect to each reactant[230]. $S_E2$ and $S_Ei$ mechanisms have been proposed for polar and non-polar solvents respectively[220], the intermediate states being of the following form:

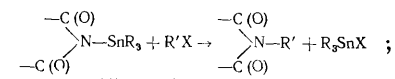
The main reaction is sometimes accompanied by an exchange side reaction, which, however, may be reduced to a minimum[220,222,224]. For example, in the synthesis of compounds with more than two tin atoms, it is best to employ dialkylstannanes and not diaminostannane, because exchange reactions are more probable in the $R_3SnH/R'_2.Sn(NEt_2)_2$ system[224].

Typical examples of the synthesis of compounds with a tin–element bond are the reactions of trialkyldimethylaminostannanes with triphenylgermanes[223,228], phosphines[147,194], arsines[103,147,231], and stibenes[103]:

$$R_3SnNR'_2 + Ph_nXH \rightarrow R_3SnXPh_n \quad ;$$

X = P, As, Sb, or Ge, $n = 2,3$.

The reaction has been used to synthesise tin–germanium derivatives with functional groups by treating tin–germanium amines with water, phenols, acetylene derivatives, and other reagents[228]. At the same time, aminostannanes do not react with trialkylgermanes and trialkyl(or triaryl)silanes, apparently as a consequence of the lower activity of the hydrogen atom in these compounds[157,222,228].



Carbonyl and cyclopentadienyl derivatives of chromium, molybdenum, vanadium, manganese, rhenium, rhodium, platinum, and other metals containing active hydrogen also react with aminostannanes, which makes it possible to synthesise organometallic compounds containing Sn–Cr,[232,233], Sn–Mo,[232-235], Sn–W[232,233,236], Sn–Rh[79,233], Sn–Mn, Sn–Fe, Sn–Co, and Sn–Ni bonds[235]:

$$(\pi\text{-}C_5H_5)(CO)_3M{-}H + R_3SnNR'_2 \rightarrow (\pi\text{-}C_5H_5)(CO)_3M{-}SnR_3 + HNR'_2 \quad ;$$

M = Cr, Mo, or W.

## 3. Substitution Reactions

The substitution reactions of aminostannanes involving the dissociation of the Sn–N bond can be regarded as amination reactions and the organotin amines can therefore be treated as aminating agents[18,237]. Reactions of this type include the alkylation or acylation of organotin derivatives of imides (phthalimide, succinimide, imidazole, and isatin) with the aid of alkyl or acyl halides[238], selective substitution of tributylstannyl groups in organotin tetrazoles by methyl iodide[239], and the synthesis of tris(benzoyl)isocyanurate on treatment of an organotin isocyanurate with benzoyl chloride[193,238]:

R = Alk; R' = Alk, or Ac; X = Hal.

The interaction of tin-containing amino-derivatives with halogenohydrocarbons depends on the nature of the reactants. Thus the explosive reaction of bis(dimethylamino)dimethylstannane with carbon tetrachloride has been reported[240]. When tributyldiethylaminostannane was allowed to react with butyl chloride, tributylamine, triethylamine, and dibutylethylamine were isolated together with butyldiethylamine[241], while the reaction involving dimethylaminotrimethylstannane proceeds with dehydrochlorination and the formation of *cis*- and *trans*-but-2-enes[242]. This was also observed when pentachloroethane[204] and chloromethylacetylene were used[219]. On the other hand, on reaction with fluoroalkanes (or fluoroalkenes) and other fluorine compounds, aminostannanes behave in the usual manner[101,196,237,241,243-246]:

$$Me_3SnNMe_2 + YF \rightarrow Me_3SnF + YNMe_2 \quad ;$$

$Y = C_6F_5$, $C_6F_4Br$, $C_6F_4CN$, CF=CFCl, $BF_2(OC_2H_5)_2$, $PF_2$, $AsF_2$, $SbF_2$, or $TiF_3$.

Organoelemental and inorganic chloro-, bromo-, and iodo-derivatives react similarly[79,196,237,241,242,247]. In contrast to the reactions of aminostannanes with organoelemental hydrides discussed above, which lead to the formation of an element–element bond, metal hydrides and certain hydrogen-containing boron, aluminium, and silicon derivatives give rise to hydrogen-containing stannanes[46,196,237,242,248]:

$$R_{4-n}Sn(NR'_2)_n + R''H \rightarrow R_{4-n}SnH + R''NR'_2 \quad ;$$

R = R' = Alk; R'' = $Et_3N\cdot BH_2$, $B_2H_5$, $Bu_4Al_2H$, or $Ph_2SiCl$.

Substitution reactions between aminostannanes and organoelemental alkyl and alkoxy-derivatives are known[49,196,237,249]:

$$R_3SnNMe_2 + R'_nM \rightarrow R_3SnR' + Me_2NMR_{n-1} \quad ;$$

M = Li, R' = Me, $n = 1$; M = Al, R' = Et, $n = 3$; M = B, R' = Bu, Ph, or OMe, $n = 3$.

The synthesis of disubstituted organoelemental alkylstannanes of the type $R_3SnC{\equiv}CMR_3$ (R = Me, Et, or Ph; M = Si, Ge, or Pb) on heating a mixture of a dialkylaminotrialkyl(or triaryl)stannane, sodium acetylide, and organic derivatives of the chlorides of Group IVB elements can also be included among the reactions of the type under consideration[250].

The interaction of a trialkyldiethylaminostannane with bis(trimethylsilyl)mercury, which leads to the formation of the hexa-alkyldistannane, the diethylaminotrimethylsilane, and metallic mercury is unusual[251].

Aminostannanes also react with esters, but these reactions have not been studied in detail and have not been fully explained[148,196,249,252]. It has been shown that the reactions with methyl methacrylate and alkyl and aryl acetates involve exchange and the dissociation of the bond between the carbon atom of the carbonyl group and the alkoxy-fragment[196,249]:

$$R_3SnNMe_2 + R'C(O)OR'' \rightarrow R_3SnOR'' + R'C(O)NMe_2;$$
R, R' = alkyl or aryl groups.

The similar reaction with vinyl acetate proceeds with formation of the trialkylstannyl acetate and the dissociation of the C–O bond in the alkoxy-group[252]. When aminostannanes were allowed to react with isopropenyl acetate, a trialkylstannyl acetate and dimethylacetamide were obtained[194,253]:

$$Et_3SnNMe_2 + MeC(O)OC(CH_3){=}CH_2 \rightarrow Et_3SnCH_2C(O)Me + CH_3C(O)NMe_2.$$

Certain aldehydes are also involved in the exchange reactions. Thus chloral cleaves the Sn–N bond in a dialkylaminotrialkylstannane, forming the trialkyl(trichloromethyl)stannane and the dialkylformamide[254,255]. The interaction of *N*-phenylhexabutyldistannazane with acetaldehyde proceeds under mild conditions with substitution of the oxygen of the carbonyl group and the formation of ethylideneamine[100]:

$$(R_3Sn)_2NR' + R''CH{=}O \rightarrow \left[\begin{array}{cc} R_3Sn{-}O & SnR_3 \\ | & | \\ R''CH{-}NR' & \end{array}\right] \rightarrow (R_3Sn)_2O + R''CH{=}NR'.$$

## 4. Addition Reactions of Aminostannanes

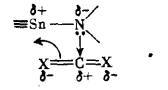
This section gives a systematic account of the reactions of stannylamines with unsaturated compounds which involve the cleavage of the Sn–N bond and the insertion of the unsaturated compounds in accordance with the general mechanism[26,148,155,249]:

$$\equiv Sn{-}N\!\!<\!\!\!\!\diagdown + A \rightarrow \equiv Sn{-}A{-}N\!\!<\!\!\!\!\diagdown$$
A = compounds with a multiple bond.

It has been shown that different versions of the reaction are possible, including 1,1-, 1,2-, 1,3-, and 1,4-insertion reactions.

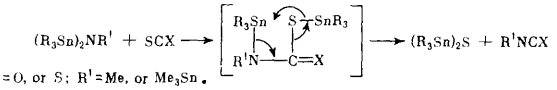
The interaction of dimethylaminotrimethylstannane with *p*-tolyl isocyanide is an example of the 1,1-insertion reaction[148,157]:

$$Me_3SnNMe_2 + p\text{-}CH_3C_6H_4N{=}C \rightarrow p\text{-}CH_3C_6H_4N{=}C\!<\!\!\!\!\diagdown^{SnMe_3}_{NMe_2}.$$

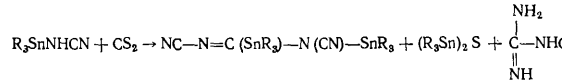


1,2-Insertion has been much more thoroughly investigated. The reactions of aminostannanes with carbon and sulphur dioxides, carbon disulphide, and carbon oxide sulphide are typical; they take place at room temperature and are accompanied by the formation of the corresponding organotin carbamates, thiocarbamates, and related products[26,146,151,155], for example:

$$Me_3SnNMe_2 + CX_2 \rightarrow Me_3SnXC(X)NMe_2;$$
X=O, or S.



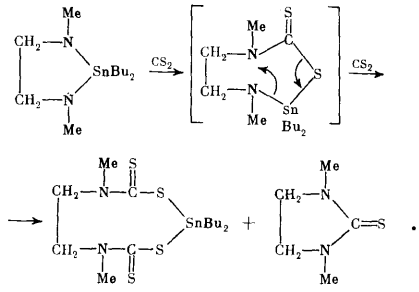
The oxygen-containing compounds are polymers in which the tin atom is coordinated to oxygen. The thioanalogues of carbamates are monomeric in benzene solution, but the tin in these compounds is likewise in a five-coordinated state:



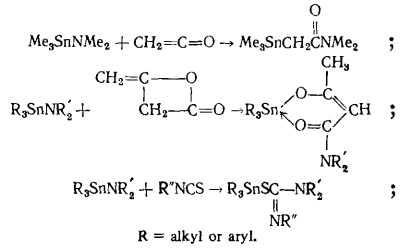
The reactivity of *N*-arylaminostannanes is much lower compared with that of the alkyl derivatives. For example, trimethylphenylaminostannane reacts with carbon dioxide much more slowly and trimethyldiphenylaminostannane does not react with $CO_2$ and $CS_2$ at all. This is consistent with the hypothesis that the mechanism of the insertion reaction involves initial nucleophilic attack by the nitrogen atom of the stannylamine on the positively charged carbon atom of the 1,2-dipole (in the present instance, O=C=O or S=C=S). The aromatic substituent delocalises the free electron pair of the nitrogen atom and hence hinders attack by this atom[146,155]:

At the same time one should note that in certain cases these reactions do not stop at the first stage involving the formation of the insertion product. Thus the reaction of trimethylphenylaminostannane with carbon disulphide results in the formation of bis(trimethylstannyl) sulphide and *syn*-diphenylthiourea, while *N*-methylhexamethyldistannazane and tris(trimethylstannyl)amine react with COS and $CS_2$ to form bis(trimethylstannyl)sulphide and the corresponding organic or organotin isocyanates and isothiocyanates. It has been suggested that an unstable 1,2-adduct is formed only in the first stage of the reaction[155,254,256,257]:

The use of trialkyl(or triaryl)stannylcyanamide in these reactions leads to unexpected products[167]:

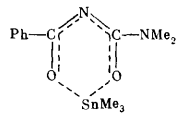


Bis(dialkylamino)stannanes reacts with carbon dioxide and carbon disulphide to form the corresponding biscarbamates and bisthiocarbamates. Tetrakis(dimethylamino)stannane reacts similarly with $CS_2$.[135] When the latter adds to diazostannetidines,



stable dithiostannetanes are formed[102]. The interaction of cyclic diaminostannanes, for example, a 2,2-dialkyl-1,3-diaza-2-stannacyclopentane, with carbon disulphide

proceeds via a 1,2-insertion mechanism, but is accompanied by the simultaneous decomposition of the 1,2-adduct to diazacyclopentanes [258]:



The reactions of amino-derivatives of tin with ketenes [18,146,253,259], diketen [260,261], isothiocyanates [26,146,148,262], isocyanates, and carbodi-imides [149,263,265] are also examples of the 1,2-insertion reaction:

R = alkyl or aryl.

The reaction of dimethylaminotrimethylstannane with benzoyl isocyanate, *N*-benzoyl-*N'*-t-butylcarbodiimide [149,263,264], and thiobenzoyl isocyanate [265] leads to six-membered rings owing to the intramolecular coordination of oxygen with the tin atom:

Processes involving the addition of stannylamines to double and triple carbon–carbon bonds activated by strong electron-accepting substituents belong to insertion reactions of the same type. Acrylate esters, acrylonitrile, acrolein, crotonaldehyde, diethyl acetylenedicarboxylate, 1-chloro-2-diphenylacetylene, etc. have been investigated as the activated reagents [148,243,249,252]. As a rule, the amino-group adds to the $\beta$-carbon atom and the organotin fragment adds to the $\alpha$-atom. The reactions proceed under mild conditions and give high yields of the desired products:

$$CH_2{=}CHC(O)OCH_3 + R_3SnNR'_2 \rightarrow R'_2NCH_2CH(SnR_3)C(O)OCH_3 \quad ;$$

$$C_6H_5C{\equiv}CCl + R_3SnNR'_2 \rightarrow R'_2NC(C_6H_5){=}C(Cl)SnR_3 \quad ;$$

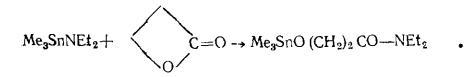
R=R' — alkyl groups.

However, aldehydes with strong electron-accepting substituents add to stannylformamides and stannylureas with dissociation of their C=O bond [138,150]:

$$R_3SnN(R')C(O)R'' + CX_3C(O)H \rightarrow R_3SnOCH(CX_3)-N(R')C(O)R'' \quad ;$$

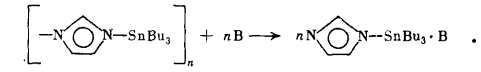
R=Bu, R'=Me, R''=H, X=Cl, or Br;

R=Et, R'=Ph, R''=H, X=Br; R=Bu,



R'=H, R''=Me, X=Br.

Stannylamines and stannyl carbamates can also give rise to a 1,2-insertion product on interaction with acetic anhydride, but it could not be isolated [129,196,252]. Under certain conditions, the extremely weak Sn–N bond can be dissociated by ketones. Here the interaction is complex, as shown by the formation of a hexaalkyldistannoxane, organic amines, mesityl oxide, a trialkylstannylacetone, and other products in the reaction of alkylaminostannanes with acetone [194,296]. The possible pathways in this reaction and the influence on the latter by steric and electronic factors have been investigated [267]. On the other hand, hexafluoroacetone reacts with aminostannanes to form 1,1-adducts [268]. Analogous 1,2-addition products have been obtained in the reaction of trialkyldiethylaminostannane with cyclopentanone and cyclohexanone [244,269]. 1,3-Insertion reactions of aminostannanes have been observed in their interaction with epoxy-derivatives, including epoxybutane, phenyloxiran (styrene oxide), and epoxycyclohexane [270]:

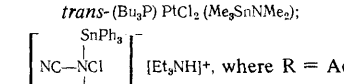


Thi-iran and methylthi-iran give rise to $R_3SnSCH(R'')CH_2.NR'_2$, where R = R' = R'' = Me or Et respectively [243].

The interaction of diethylaminotrimethylstannane with $\gamma$-butyrolactone and $\beta$-propiolactone, which involves ring opening, is an example of 1,4-insertion [271–273]:

## 5. Other Reactions of Aminostannanes

Aminostannanes can exhibit both electron-accepting (tin atom) and electron-donating (nitrogen atom) properties and can thus function both as aprotic acids and aprotic bases. However, such reactions are not characteristics of these compounds and few are known owing to the low strength of the Sn–N bond. *N*-Tributylstannylimidazole forms complexes with basic ligands [18,274] in which tin has a coordination number of five and behaves as a Lewis acid:



Another example of compounds in which tin exhibits electron-accepting properties is provided by organotin derivatives of nitroamine, which have a chelate structure [46].

The properties of aminostannanes as Lewis bases are characterised by the formation of complexes [18,256,275,276]:

$(Me_2N)_4Sn \cdot VOCl_3$; $[(Me_3Sn)_4N]^+Br^-$;

*trans*-$(Bu_3P)PtCl_2(Me_3SnNMe_2)$;

EtCO, Bz, MeOCO, EtOCO, or $PhSO_2$.

The reactions involving the photochemical decomposition of aminostannanes, whose study has only just begun, constitute a group separate from those enumerated above. It has now been shown that the photochemical decomposition of diethylaminotrimethylstannane, investigated by ESR, proceeds with the dissociation of the nitrogen–tin bond and

is a complex multistage process leading ultimately to the formation of hexamethyldistannane, diethylamine, and *N*-ethyliminoethane[277]:

$$Me_3SnNEt_2 \xrightarrow{h\nu} \begin{cases} Me_3SnH + MeCH{=}NEt \\ Me_3Sn^{\cdot} + Et_2N^{\cdot} \end{cases}$$
$$Me_3SnH + Me_3SnNEt_2 \rightarrow (Me_3Sn)_2 + Et_2NH$$
$$2Me_3Sn^{\cdot} \rightarrow (Me_3Sn)_2$$
$$2Et_2N^{\cdot} \rightarrow Me{-}CH{=}NEt + Et_2NH$$
$$Me_3Sn^{\cdot} + Et_2N^{\cdot} \rightarrow Me_3SnH + Me{-}CH{=}NEt \ .$$

## IV. CHEMICAL PROPERTIES OF ORGANOTIN PSEUDOHALIDES WITH A TIN–NITROGEN BOND

Bearing in mind the appreciable differences between the reactivities of aminostannanes and tin pseudohalides, we thought it useful to consider in this Section the specific chemical properties of typical examples of the latter, including organotin azides, isocyanates, isothiocyanates, carbodi-imides, imines, and related compounds.

Investigators noted in the first place the high thermal stabilities of the pseudohalides. Thus triphenylstannyl azide decomposes at a high temperature (>200°C), in contrast to organic analogues, with formation of tetraphenylstannane as the only tin-containing product[278]. Aromatic and aliphatic organotin isocyanates of the type $R_3SnNCO$ are distinguished by an enhanced stability. The latter are stable when acted upon by oxygen, ultraviolet radiation, and prolonged heat up to 200°C. The thermal decomposition of such isocyanates is a complex process, which probably involves both homolytic and heterolytic reactions. The decomposition of tributylstannyl isocyanate takes place at 250°C with the liberation of butane, butene, carbon dioxide, and carbon monoxide and the formation of metallic tin. In the decomposition of triphenylstannyl isocyanate, both disproportionation to tetraphenylstannane and diphenylstannyl di-isocyanate and its decomposition with formation of carbon dioxide and an organotin carbodi-imide were observed[91,163,279]:

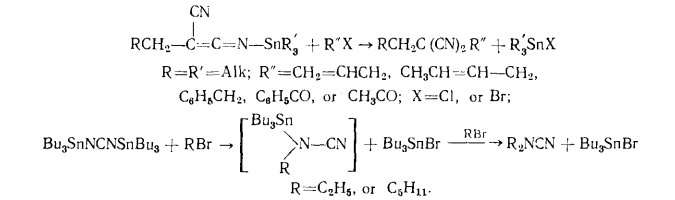
$$(C_4H_9)_3SnNCO \begin{cases} \rightarrow C_4H_8 + C_4H_{10} + N_2 + Sn + CO \\ \rightarrow (C_4H_9)_3SnNCNSn(C_4H_9)_3 + CO_2 \end{cases} ;$$
$$(C_6H_5)_3SnNCO \begin{cases} \rightarrow (C_6H_5)_4Sn + [(C_6H_5)_2Sn(NCO)_2] \\ \rightarrow (C_6H_5)_3SnNCNSn(C_6H_5)_3 + CO_2 \end{cases} .$$

Organotin pseudohalides react in different ways with protic reagents. Under the influence of hydrogen chloride, the Sn–N bond in triphenylstannyl isocyanate is cleaved, but only triphenylstannyl chloride (44%) and tetraphenylstannane (33%) could be isolated from the reaction mixture[163]. On the other hand, *NN'*-bis(tributylstannyl)-carbodi-imide is involved in exchange processes with HCl and acetic and benzoic acids under mild conditions, forming the corresponding organotin derivatives and cyanamide[91,280,281]:

$$Bu_3SnNCNSnBu_3 + 2HX \rightarrow 2Bu_3SnR + H_2NCN \ ;$$
$$X{=}Cl,\ MeC(O)O,\ or\ PhC(O)O.$$

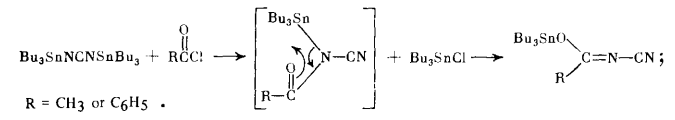
In contrast to aminostannanes, typical organotin pseudohalides (monoisocyanates and carbodi-imides) are as a rule comparatively resistant to hydrolysis, which makes it possible to synthesise them via reactions involving the elimination of water. Nevertheless, the hydrolysis of butyl and phenyl organotin di-isocyanate derivatives leads to high-molecular-weight compounds of the type $Bu_8Sn_4(NCO)_4O_2$, $Bu_8Sn_4(NCO)_2(OH)_2O_2$, and $Ph_4Sn(NCO)_2 \cdot (OH)_2$.[65]

Tributylstannyl isocyanate is wholly hydrolysed with formation of tributyltin hydroxide and urea derivatives only when acted upon by boiling water in the course of 28 h. Alkalis appreciably accelerate this process[91]. The Sn–N bond in *NN'*-bis(tributylstannyl)carbodi-imide is cleaved by water under the same conditions[282].



However, dimethyltin di-isocyanate is readily and completely decomposed by water[283]:

$$Me_2Sn(NCO)_2 + 3H_2O \rightarrow (Me_2SnO)_n + CO_2 + 2NH_3 \ .$$

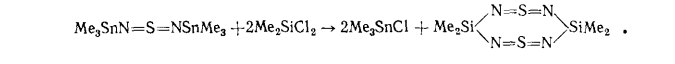


The report that tributylstannyl isocyanate reacts with alcohols and phenols to form organotin carbamates has been confirmed experimentally[160]. It was subsequently established that the adduct obtained when the isocyanate reacts with an excess of methanol or butanol contains the urethane group according to infrared spectroscopic data, but is unstable on heating and cannot be isolated by vacuum distillation[91,284]. When butaneselenol reacts with $Bu_3SnNCO$ in proportions of 2 : 1, the cleavage of the tin–nitrogen bond is accompanied by addition to the isocyanate group and the formation of butylselenourethane[285]:

$$Bu_3SnNCO + 2BuSeH \rightarrow BuSeSnBu_3 + BuSeCNH_2 \ .$$
$$\qquad\qquad\qquad

The reactions of tin pseudohalides with various halogeno-derivatives are of interest. Thus alkyl derivatives of organotin isocyanates exchange the isocyanate group for the halogen on heating with alkyl halides. On the other hand, the phenyl analogues are decomposed by ethyl bromide to triphenylstannyl bromide, the isocyanate fragment undergoing complex transformations, whose nature was not elucidated [133,163]. Chlorotrimethylsilane is involved in an exchange interaction with triphenylstannyl isocyanate, giving a high yield of the corresponding silyl isocyanate [172]. *N*-Trialkylstannylketenimines and *NN'*-bis(tributylstannyl)carbodi-imide react vigorously with organic halogeno-derivatives [91,191,280]. The reactions apparently proceed with transfer of the reaction centre:

When a stannylcarbodi-imide and equimolecular amounts of acetyl or benzoyl chloride are used, only one Sn–N bond in the carbodi-imide is cleaved and there is a simultaneous migration of the organotin group to the oxygen atom. As a result, *N*-[tributylstannoxy(methyl or phenyl)-methylidene]cyanamides were obtained instead of the expected *N*-acetyl(or benzoyl)-*N*-(tributylstannyl)cyanamides [289]:



It is of interest that in the case of benzenesulphonyl chloride, azide, and isocyanate which exhibit pseudohalide properties, this process involves the exchange of only one $R_3Sn$ fragment regardless of the proportions of the reactants [181,290]:

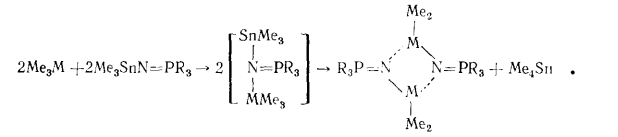
$$Bu_3SnNCNSnBu_3 + PhSO_2X \rightarrow Bu_3SnX + PhSO_2NCNSnBu_3 \quad ;$$
$$X = Cl,\ N_3,\ or\ NCO.$$

It has been shown [291] that the interaction of bis(triphenylstannyl)carbodi-imide with organic halogeno-derivatives proceeds somewhat differently. On heating with benzyl bromide, this reagent yields an isomerisation product—dibenzylcyanamide. When chlorotriphenylmethane, which has three bulky substituents, is used, the process is accompanied by the formation of a non-isomeric compound—*NN'*-bis(triphenylmethyl)carbodi-imide.

The usual exchange processes take place when *NN'*-bis(trimethylstannyl)sulphodi-imide is treated with chlorotrimethylsilane and dichlorodimethylsilane. In the latter case, the product is an eight-membered cyclic compound containing silicon, sulphur, and nitrogen atoms [179,292]:

Group II–IV metal chlorides react with *NN'*-bis(triethylstannyl)carbodi-imide, forming triethylstannyl chloride and metal-cyanamides. The reaction is accelerated in the presence of water [282]:

$$Et_3SnNCNSnEt_3 + MCl_2 \xrightarrow{H_2O} 2Et_3SnCl + MNCN \cdot n\,H_2O \quad ;$$
$$M = Cu,\ Cd,\ Zn,\ Ca,\ or\ Sn;\ n = 1\text{–}3.$$



The interaction of organotin imines of the type $Me_3SnN{=}C(CF_3)_2$ with platinum, rhodium, and iridium halides is accompanied by the formation of metal alkylideneimides [293]. In contrast to this, triphenylstannyl azide forms 1 : 1 adducts with $BBr_3$ and $SnCl_4$. [294]

The reactions of trialkyl(aryl)stannyl azides with aliphatic and aromatic phosphines, which as a rule take place with formation of organotin phosphineimines, have been investigated in fair detail [79,295–297]:

$$R_3SnN_3 + PR'_3 \rightarrow R_3SnN{=}PR'_3 + N_2 \quad ;$$
$$R,\ R' — \text{alkyl or aryl groups.}$$

The reaction of $Me_3SnN_3$ with methyl-, ethyl-, and phenyl-phosphines is complicated by disproportionation reactions and also leads to the formation of *N*-azidodimethylstannyl(phosphine)imine, $Me_3Sn(N_3)N{=}PR_3$, and and tetramethylstannane [295]. Under mild conditions, $Ph_3SnN_3$ does not react with $Ph_3X$ (X = P, As, or Sb). [80]

Organotin phosphine imines are readily decomposed by triethylaluminium, triethylgallium, and triethylindium, which leads to the formation of the dimeric trialkyl-[(dimethylmetal)imino]phosphorane [298].

Bis(triethylgermyl)mercury undergoes an exchange interaction with tributylstannyl isocyanate [299]:

Insertion reactions, which are so typical for aminostannanes, are relatively uncharacteristic of organotin pseudohalides. An example of such reactions is the addition of phenyl isothiocyanate to $Ph_3SnNCNSnBu_3$ and of phenyl isocyanate to $Bu_3SnNCNSnBu_3$, which is accompanied by the formation of the corresponding 1,2-insertion adducts [291,300]. In the latter case, further successive cycloaddition of a second and third isocyanate molecule is observed, which ultimately leads to the formation of an organotin triphenylisoammelide. The addition of tributylstannyl azide to the triple bonds of nitriles and acetylenedicarboxylate esters has been fairly thoroughly investigated, but the reaction proceeds without the cleavage of the Sn–N bond and the function of the azide group under these conditions does not differ from that in organic azides [185,186,301].

In order to investigate the reactivity of the biradical $Ph_3SnN^{\cdot}$, a study was made of the photolysis of aromatic organotin azides, which proceeds with the cleavage of the Sn–N bond and not the N–N bond as suggested by Jappy and Preston [302]. Finally a characteristic property of trialkylstannyl isothiocyanates and dialkyltin di-isothiocyanates is their capacity for complex formation [71,303], with, among others, pyridine, 2,2-bipyridyl, 1,10-phenanthroline and other bases [233,304–306].

The different properties of the pseudohalides and amino-derivatives of tin examined can probably be accounted for by electron redistribution between the tin atom and the $-\ddot{N}{=}C<$ group, which is highly unsaturated and has lone electron pairs. As a result, the trialkylstannyl fragment passivates the N=C bond in nucleophilic substitution reactions. The addition of a second isocyanate group to the tin atom or of an electron-donating substituent to the nitrogen atom diminishes the degree of

redistribution and thereby increases the reactivity of the Sn–N bond in pseudohalides, which approaches that in aminostannanes. Examples of reactions of these compounds were given above. It is noteworthy that detailed studies have not been made of the influence of different substituents on the Sn–N=A linkage, where A = C, O, P or other elements. The available physicochemical data for the strength of the Sn–N bond are summarised in the next section.

## V. PHYSICOCHEMICAL PROPERTIES AND STRUCTURES OF NITROGEN-CONTAINING ORGANOTIN COMPOUNDS

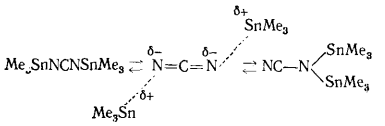
Systematic investigations of the physicochemical properties of organoelemental compounds containing an Sn–N bond were begun comparatively recently. It is therefore not surprising that the published data are sometimes incomplete and contradictory. There are only isolated publications on many key problems concerning the molecular structures of these derivatives (the geometrical configurations of the molecules, the quantum-mechanical description and determination of the energetic parameters of the Sn-N bond). As a result, the available information about the mechanisms of reactions involving compounds of the above type is extremely limited. The physical characteristics quoted in papers on the synthesis of aminostannanes (melting and boiling points, refractive indices, and densities) can serve only for the estimation of the degrees of purity of the products. These parameters have been arranged systematically [18] and additional data have been published elsewhere [307,308].

The majority of nitrogen-containing organotin compounds are volatile liquids, which permitted the conclusion, also on the basis of infrared, Raman, and NMR spectroscopic data, that the Sn–N bond is covalent in products of this kind [33,103,198,309]. However, the problem of the degree of delocalisation of the unshared electron pair of nitrogen owing to the $d_\pi$–$p_\pi$ interaction still remains open. An attempt has been made [310] to solve it by relating it to the basicity of model compounds of the type $Me_3MNMe_2$ and $(Me_3M)_3N$ (where M = Sn, Ge, or Si).

The relative basicities of the above aminostannanes were investigated in the reactions with $CHCl_3$ and $CDCl_3$, which were regarded as pseudoacids. The shifts $\Delta\nu$(C–D) and $\Delta\nu$(C–H) of the frequencies in the infrared spectra of free $CHCl_3$ and $CDCl_3$ and of their complexes with aminostannanes were correlated with the basicities. It was shown that the basicity decreases in the sequence Sn > Ge > Si and for $Me_3SnNMe_2$ it proved to be equivalent to the basicity of the usual aliphatic amines [310]. On this basis, it was concluded that the lone electron pair of nitrogen is fully localised in aminostannanes. It has been noted [31] that the delocalisation of the electron pair of nitrogen in $Me_3MN(GeMe_3)Me$ (M = Si, Ge, Sn, or Pb), investigated by NMR, decreases in the sequence Si > Ge > Sn > Pb. The same sequence of decreasing basicities of aminostannanes has been found by Mack and Yoder [311]. The number of parameters correlated with the basicities has been extended, but unambiguous results have not been obtained [312,313]. This led to the conclusion that the experimental data fail to confirm the occurrence of $d_\pi$–$p_\pi$ conjugation in organotin amines [313]. However, the considerable polarity of the Sn–N bond has been explained by the delocalisation of the lone electron pair of nitrogen on the basis of measurements of the dipole moments ($\mu$ = 1.7) of the Sn–N bond in a large series of compounds having the general formula $R_{4-n}Sn(NR'_2)_n$ (R = $CH_3$, $C_2H_5$, $C_4H_9$, or $C_6H_5$; R′ = $CH_3$ or $C_2H_5$; $n$ = 1–4). [314] It has been shown that this effect makes a significant contribution to the energy of the Sn–N bond [315]. An appreciable shift of the lone electron pair of nitrogen has also been observed in aromatic fluoro-derivatives of aminostannanes [316].

The thermal stability of aminostannanes decreases in the sequence $R_3SnNR'_2 > RSn(NR'_2)_3 \simeq Sn(NR'_2)_4 > R_2Sn.(NR'_2)_2$. [244] The heat of combustion $-\Delta H^\circ_c$, L = 1883 ± 1 kcal mole$^{-1}$ of liquid $(C_2H_5)_3SnN(C_2H_5)_2$ permitted the calculation of the standard heat of formation of this compound ($-\Delta H^\circ_{f,L}$ = 50 kcal mole$^{-1}$) and the average dissociation energy of the Sn–N bond [$\bar{D}$(Sn–N) = 62 kcal mole$^{-1}$] [317]. The last value is somewhat higher than those of $E$(Sn–N) obtained previously for $(CH_3)_3SnN(CH_3)_2$, $[(CH_3)_3Sn]_2NCH_3$, and $[(CH_3)_3Sn]_3N$, which are 43.5, 48.7, and 40.0 kcal mole$^{-1}$ respectively [11,18]. According to Zhuravlev et al. [318], the energies of the Sn–N bond in tributylstannyl isocyanate and *NN′*-bis(tributylstannyl)carbodi-imide are much greater, amounting to 102 ± 5 and 100 ± 5 kcal respectively, which indicates a differenee in the nature of these bonds in organotin isocyanates and carbodi-imides compared with aminostannanes. The dissociation energy of the M–N bond (M = Si, Ge, or Sn) decreases from Si to Sn [317] (79.9 kcal mole$^{-1}$, [319] 63.4 kcal mole$^{-1}$, [18] and 40 kcal mole$^{-1}$ [18]) which indicates a relatively weak Sn–N bond in aminostannanes.

The successful employment of infrared spectroscopy for the determination of the molecular structures of Sn–N derivatives [33,43,44,116,146,148] and for the investigation of the rates of reactions involving Sn–N bonds [111] has been noted. The absorption bands in spectra of compounds of the type $R_3SnNR'_2$, $(R_3Sn)_2NR'$, and $R_2Sn(NR'_2)_2$ have been calculated and assigned [320]. Nevertheless, it has still not been fully decided whether the stretching vibrations of the Sn–N bonds are characteristic and their bands have not been fully assigned. The frequency $\nu_{asym}$ for $(R_3Sn)_3N$ has been found in the range 712–728 cm$^{-1}$; $\nu_{sym}$ is believed to be below 400 cm$^{-1}$. [33] The 510 cm$^{-1}$ band in the spectrum of $Me_3SnN(Ph)CONMe_2$ has been assigned to $\nu$(Sn–N). [146] In the infrared spectra of $(CH_3)_3SnNH(C_6H_5)$ containing the $^{14}N$ and $^{15}N$ isotopes, the 843 and 835 cm$^{-1}$ bands correspond to $\nu$(Sn–$^{14}$N) and $\nu$(Sn–$^{15}$N) respectively; the 535 and 508 cm$^{-1}$ bands are believed to be due to the $\nu_{sym}$ and $\nu_{asym}$ vibrations of the $SnC_3$ skeleton [321]. Analysis of the infrared and Raman spectra showed in its turn that the skeleton has $C_{3v}$ pyramidal symmetry and not $D_{3h}$ [$C_{3h}$] symmetry [103]. The highly polarised band in the Raman spectrum at 514 cm$^{-1}$ has been assigned to $\nu_{sym}(Sn_3–N)$ and the 672 cm$^{-1}$ band has been assigned to $\nu_{asym}(Sn_3–N)$.



Other examples of the assignment of the bands to the stretching vibrations of the Sn–N bond are as follows: 596 and 592 cm$^{-1}$ for $Ph_3SnN(Ph)P(=NPh)Ph_2$ and $[Ph_3Sn.SnN(Ph)]_2P(=NPh)Ph$ [157]; 880 cm$^{-1}$ for $\nu_{asym}(Sn–N_2)$ in the spectra of $R_2Sn(NR'_2)_2$ [322]; 479, 480, and 472 cm$^{-1}$ for $Me_3SnN(SiMe_3)(CMe_3)$, $R_3SnN[CMe_2(SiMe_3)]$ and $Me_3C.(Me_3Si)NSnMe_2Cl$ respectively [32]; 480 cm$^{-1}$ for $Me_3Sn.NCO$ [323]; $\nu_{asym}$ = 690 cm$^{-1}$ and $\nu_{sym}$ = 602 cm$^{-1}$ in the spectra of $Bu_2Sn(NR_2)_2$ (where R = Me, Et, or Bu). [320] Similar information has also been published elsewhere [33,43,69,86,92,103,313]. One should note the virtually complete absence of publications devoted to studies of the band intensities in the vibrational spectra of nitrogen-containing organotin compounds.

Studies have been made on the NMR spectra of the compounds investigated [31,32,40,57–59,60,61,95,97,98,210,309,312,313,324–326] and on the Mössbauer effect [46,323,327–329]. In all cases, the interpretation of the spectra is consistent with

the proposed molecular structures. Data have also been published for $J_{119}Sn-H$ and $J_{117}Sn-H$ in the Sn–N–C–H systems [30,95,198,309]. For $R_nSn(NEt_2)_{4-n}$ (R = Ph or Me), such interaction was not observed in the range $0 \leq n \leq 3$ [198,309] and band splitting was not observed even at −50°C. [95] However, band splitting in the spectrum of $Et_3SnNMe_2$ was noted at low temperatures, disappearing at 150°C. [324]

The physicochemical characteristics of nitrogen-containing organotin pseudohalides have been studied much less than the corresponding quantities for aminostannanes. Analysis of the Mössbauer spectra of alkyltin isocyanates has shown that the Sn–N bond is covalent, the tin atom is in the four-coordinated state, and the compounds have the iso-structure [323]. However, $Ph_3SnNCO$ is associated via bridging NCO groups and the tin atom is in the five-coordinated state [327].

Intermolecular coordination has also been suggested for *NN'*-bis(trimethylstannyl)carbodi-imide [330]. According to the authors [88,330], this compound has a structure intermediate between the carbodi-imide, cyanamide, and ionic forms:

However, the study of infrared spectra and dipole moments of organotin ethyl– and butyl-carbodi-imides indicates unambiguously a carbodi-imide structure of such products [90,308].

Investigation of the structures of organotin isothiocyanates by infrared and Mössbauer spectroscopy has shown that the compounds exist in the isocyanate form and that the tin atom is in the five-coordinated state [68,69,331–333]. The occurrence of intermolecular donor–acceptor interactions has been noted also for dimethyltin di-isocyanate, which is a polymer with chains of weakly linked molecules [334], for bis(dicyanamido)dimethylstannane, which has the carbodi-imide structure [86,87], for [polymeric] dibutyltin-carbodi-imidostannane [92], and for distannoxanes of the type

## VI. APPLICATIONS OF NITROGEN-CONTAINING ORGANOTIN COMPOUNDS

The use of nitrogen-containing organotin compounds is in many respects traditional for organotin derivatives, which are widely used in practice as herbicides, disinfectants, polymer stabilisers, and catalysts.

It has been suggested that triphenylstannyl and tributylstannyl isocyanates [1,336], and *NN'*-bis[trialkyl(aryl)-stannyl]carbodi-imides [337,338] be employed as stabilisers of poly(vinyl chloride). The stabilising effect of mixtures of organic phosphines with trialkyl(aryl)stannyl isocyanates and isothiocyanates in the thermal degradation of poly(vinyl chloride) has been studied in detail [339,340]. Aminostannanes are suitable for the stabilisation of rubbers [2,3] and as fungicides, bactericides, and herbicides [8,9,37], and plasticisers [7]. It has been suggested that organic carbodi-imides be synthesised via amino-derivatives of tin [262]. Numerous data have been obtained on the applications of the compounds under consideration in the catalysis of the reactions of isocyanates with compounds having an active hydrogen atom [4–6,341,342]. It has been shown [343] that, when the reaction of butyl isocyanate with phenol is acted upon jointly by organotin compounds and amines as catalysts, a synergistic effect is observed. The use of tin- and nitrogen-containing compounds as catalysts of the synthesis of urethanes [344] instead of the familiar organotin derivatives of aliphatic acids can be definitely economical in view of the low cost and high availability of initial nitrogen-containing products such as amines, urea, cyanuric acid, and their derivatives, compared with organic acids.

The applications of aminostannanes and their analogues have not been studied widely because convenient preparative methods for their synthesis became available comparatively recently.

# Reactions of Carbanions and Halogenocarbenes in Two-phase Systems

M.Mąkosza

The review surveys studies on a new two-phase catalytic method whereby reactions between carbanions and halogenocarbenes can be carried out. Numerous examples of the successful application of this method to various (mainly alkylation) reactions of carbanions and halogenocarbenes are given and the advantages, disadvantages, and limitations of the method compared with the traditional single-phase or pseudo-single-phase methods are discussed. Also considered are possible mechanisms of catalysis by ammonium salts in these systems.
The bibliography includes 261 references.

IV. Conclusion 1158

## I. INTRODUCTION

The reactions of carbanions and halogenocarbenes with various compounds are widely used to form new C–C bonds, which constitutes one of the most important problems in organic synthesis. In this connection, the development of new highly effective methods for the generation of carbanions and halogenocarbenes is of considerable interest.

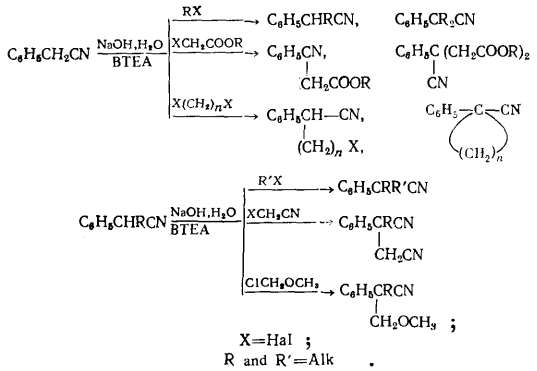
The principal method for the generation of carbanions involves the abstraction of a proton from a carbon atom in an organic molecule; this process is also the first stage in the formation of halogenocarbenes in the so called $\alpha$-elimination reaction. Many different bases, the majority of which are very sensitive to moisture and air, require the use of considerable amounts of thoroughly dehydrated organic solvents, are explosive, and expensive, have been used for this purpose. It is therefore desirable to carry out the process in a homophase system, which is by no means always possible. Even when the system is apparently single-phase, it is frequently in essence a pseudo-homogeneous system in which the solution of a base or carbanion is colloidal, the molecular weights of the species amounting to thousands of units.

Many of the difficulties and disadvantages enumerated above are eliminated when the synthesis is carried out in a two-phase catalytic system where a concentrated solution of sodium hydroxide in the presence of catalytic amounts of quaternary ammonium compounds plays the role of the base which abstracts protons from the C–H acid in the organic phase. This method, which was introduced into laboratory practice mainly by the present author[1], proved to be extremely effective for many types of reactions of carbanions and particularly halogenocarbenes. The large-scale application of two-phase systems in the chemistry of carbanions and halogenocarbenes began as late as 1970, but since then more than two hundred original publications and several reviews have appeared[2-7]. This provides a good illustration of the increasing interest in these procedures and their extensive possibilities.

The first example of the known use of a two-phase system in the chemistry of anions is provided by Jarousse's[8] brief communication about the possibility of the benzylation and ethylation of phenylacetonitrile by the corresponding chlorides in the presence of 50% aqueous sodium hydroxide and 20 mole % of benzyltriethylammonium chloride. The catalytic action of certain tetra-alkylammonium salts on the alkylation of acetoacetic and malonic esters in the presence of aqueous potassium hydroxide was subsequently described by Babayan[9,10]. Using these data, the present author developed a catalytic method for the alkylation of phenylacetonitrile and its derivatives[1] and the catalytic system was subsequently applied to other reactions of carbanions and also for the generation of halogenocarbenes.

Brändström and Junggren[11] subsequently demonstrated the considerable possibilities in organic chemistry of the method involving the extraction of ion pairs and applied it to the reaction of enolate anions (mainly alkylation reactions). A distinctive feature of the ion pair extraction method, for example "extractive alkylation", is the use of an equimolar amount of a tetra-alkylammonium compound, which in many cases makes it possible to isolate the tetra-alkylammonium–carbanion pair. In 1971 Starks[12] used the concept of "phase-transfer catalysis", based on the transfer of the regulating species by tetra-alkyl-ammonium or phosphonium cations from one phase to another (usually from the aqueous to the organic phase) in reactions involving inorganic atoms. The above methods are based on the formation of ion pairs comprising the tetra-alkylammonium cation and an organic or inorganic anion, which are soluble in organic non-polar solvents. It has been recently discovered that, apart from tetra-alkylammonium or phosphonium salts, crown ethers, which form very stable endocyclic complexes with potassium or sodium ions, can also play the role of catalysts in the two-phase system considered[13]. Potassium and sodium ions are capable of forming ion pairs, soluble in non-polar solvents, with organic and even inorganic anions[14].

The subject of the present review is reactions of carbanions and halogenocarbenes in liquid two-phase systems. The influence of tetra-alkylammonium salts or crown ethers on the reactions of anions in homophase systems as well as on the reactions of inorganic anions in two-phase systems will not be considered.

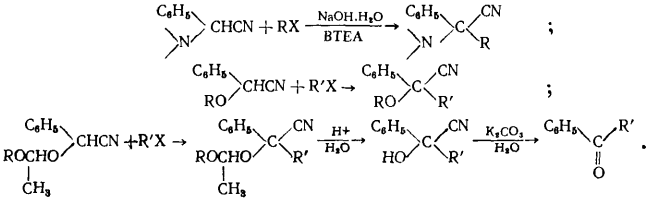


## II. REACTIONS OF CARBANIONS

### 1. Alkylation of Arylacetonitriles

The two-phase catalytic method was first widely used to alkylate phenylacetonitrile and its derivatives. This process is important from the practical point of view, since the structural elements of phenylacetic acid are frequently encountered in drugs, natural products, etc. Compared with previously available procedures, the method is extremely simple[15]: the nitrile, the alkylating agent, and an excess of 50% aqueous sodium hydroxide solutions are stirred vigorously, usually at room temperature, in the presence of ~1 mole % of a quaternary ammonium compound. Benzyltriethylammonium chloride (BTEA) is usually employed, being most readily available and convenient, although it does suffer from a number of disadvantages. In particular, the stability of BTEA is limited in a highly basic medium and it can act as an alkylating agent itself. Alkylation proceeds with a moderate exothermicity, giving high yields of the expected compounds. Despite the fact that the process proceeds in an aqueous solution of alkali, appreciable hydrolysis of phenylacetonitrile begins under these conditions only at temperatures above 90°C; the majority of alkylating agents are also fairly stable under these conditions.

Thus, catalytic alkylation of phenylacetonitrile can be achieved using alkyl and alkenyl halides[16-18], halogenoacetates derived from secondary and tertiary alcohols[19], halogenonitriles[20-21], and certain other substituted halogenoalkanes[17,22]. Even α-chloroalkyl ethers are fairly stable under these conditions and can be used as effective alkylating agents[23]. Alkylation by dihalogenoalkanes makes it possible to obtain ω-halogenoalkyl derivatives, iso- and hetero-cyclic nitriles, dinitriles, etc.[24-26]



Analogous alkylation reactions proceed successfully in the case of diphenylacetonitrile[23,27-31] and phenylalkylacetonitriles[18,23,28,30,32]. In almost all the instances enumerated above, the results of alkylation (the yield and purity of the products) are much superior to those obtained by traditional methods.

X=Hal ;
R and R′=Alk .

The two-phase method also gave excellent results in the alkylation of phenylacetonitrile derivatives substituted in the aromatic ring[33-35] and of naphthylacetonitrile[36]. Alkylation of phenylacetonitrile by *p*-nitrobenzyl chloride in the presence of dilute alkali (2 *N* NaOH) and a tetraalkylammonium catalyst is believed[37] to proceed via an electron transfer stage as a free-radical process. In the present author's view, typical conditions (50% NaOH) are more suitable for the alkylation of arylacetonitriles by *o*-, *m*-, and *p*-nitrobenzyl chlorides, the electron transfer stage being non-obligatory[38]. Brändström's "extraction of ion pairs"[39] gives very satisfactory results in the alkylation of phenylacetonitrile, but the use of an equimolar amount of expensive tetrabutylammonium hydrogen sulphate makes this method less convenient in practice than the catalytic procedure.

Alkylation of phenylacetonitrile derivatives substituted in the α-position by dialkylamino- or alkoxy-groups, whose properties are similar to those of cyanohydrins, is important for organic synthesis. The alkylation of these compounds in the presence of an aqueous solution of NaOH and BTEA proceeds without difficulty[40,41]. The example of the mixed acetal of benzaldehyde cyanohydrin, which gives rise to aryl ketone cyanohydrins (which are in essence unobtainable by other methods) after alkylation and mild hydrolysis, is particularly interesting[42]. Attempts at the alkylation of aliphatic aldehyde cyanohydrins in a two-phase system led to only moderate yields of cyanohydrin esters: *C*-alkylation was not observed[43]:

Reissert compounds, which are structurally related to α-acylamino-derivatives of phenylacetonitrile, are also readily alkylated in the presence of an aqueous solution of concentrated alkali and BTEA.[44]

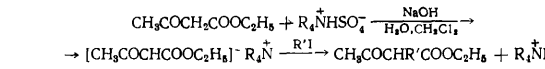
Thus the advantages of the two-phase system do not consist solely in the simplicity of the reactions, the use of a cheap base, and the elimination of experimental difficulties associated with the consumption of amides, hydrides, organometallic compounds, etc. A factor which is no less important is the improvement of yields and the high selectivity of the reactions, as a result of which it is possible to avoid difficulties in the synthesis of monoalkylated phenylacetonitrile derivatives which are important in practice. This is clearly illustrated by the following scheme:

| RX | $CH_3I$ (I) | $C_2H_5Br$ (II) | $C_6H_5CH_2Cl$ (III) |
|---|---|---|---|
| I, % | 21;6 | 15;6 | 31;21 |
| II, % | 50;86 | 70;90 | 33;52 |
| III, % | 19;8 | 15;4 | 30;19 |

In each column, the first set of numbers characterises the composition of the alkylation products obtained in the presence of $NaNH_2$ in liquid ammonia[45,46] and the second set characterises the product compositions in a two-phase catalytic system[46]. The main cause of the high selectivity of alkylation under catalytic conditions is apparently the low concentration of the carbanions present simultaneously in the system, which does not exceed the concentration of the catalyst[46].

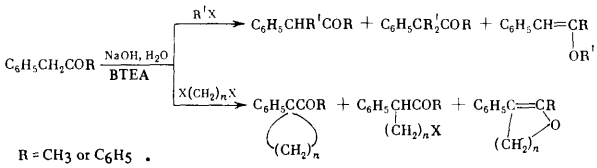
Unsubstituted aliphatic nitriles, which are very weak C–H acids, do not form carbanions under these conditions and are naturally incapable of being alkylated. The presence of carbanion-stabilising substituents, such as the arylthio-group in *S*-phenylthioglycolonitrile, permits

the alkylation of these nitriles in the presence of an aqueous solution of NaOH and BTEA [47]:



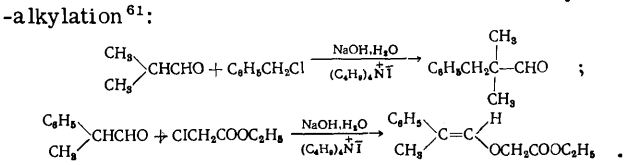
Under analogous conditions, the nitriles of aliphatic 3-chloro-3-nitroacids cyclise to form a three-membered ring [48].

## 2. Alkylation of Carbonyl Compounds



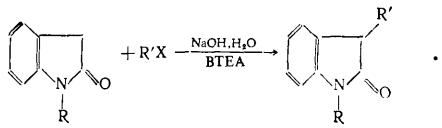
The ester group is usually readily hydrolysed by an aqueous solution of alkali, which hinders the alkylation of malonic, acetoacetic, and cyanoacetic esters. Nevertheless, Babayan succeeded in alkylating these esters in the presence of an aqueous KOH solution [9,10].

The method based on the extraction of ion pairs (the so called extractive alkylation), requiring the use of fairly dilute alkali and equimolar amounts of tetrabutylammonium hydrogen sulphate, gives excellent results in such instances [11,39,49,50]:



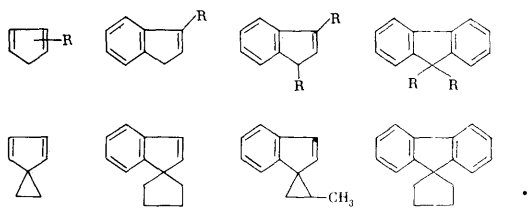
A typical catalytic process requires the use of concentrated alkali, which causes the hydrolysis of methyl or ethyl esters. t-Butyl esters are much more resistant to base hydrolysis and t-butyl malonates, phenylacetates, and diphenylacetates can be alkylated with high yields under these conditions [51].

The two-phase catalytic system is very convenient for the alkylation of $\alpha$-phenylketones, such as desoxybenzoin or phenylacetone [52-54]. A high yield was also obtained when a crown ether was used as the catalyst [55]. The method of the extraction of ion pairs also gives satisfactory yields in such cases [39]. Cyclic $\alpha$-arylketones, acenaphthenone [56], and $\beta$-tetralone [57] usually form dialkylation products under these conditions. The results of the alkylation of ketones by dihalogenalkanes, which leads to the formation of iso- and hetero-cyclic structures, $\omega$-halogenoketones, etc., are particularly interesting [53,54]:

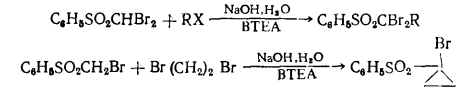


Alkylation by $\alpha$-chloroesters yields mainly *O*-derivatives [58].

Even simple ketones may be successfully alkylated by allyl chlorides in a two-phase catalytic system [59]. Direct alkylation of $\alpha$-substituted aliphatic aldehydes in the presence of concentrated alkali and a tetrabutylammonium salt gives unexpectedly satisfactory results [60]. The use of chloroacetate esters in such cases leads exclusively to *O*-alkylation [61]:



$\beta$-Diketones, which exhibit a high acidity, can be readily converted into tetrabutylammonium derivatives by extraction from aqueous solutions into chloroform or methylene chloride with subsequent alkylation to give a very high yield of the product [62,63]. The same ion pair extraction procedure is the most suitable for the alkylation of $\alpha$-ketosulphones [64,65], benzoylmalonic ester [66], and acetopyruvic acid [67]. The problem of *CO*-alkylation was also thoroughly investigated in the above studies. Certain C–H acid heterocycles, for example 2-hydroxyfuran, 2-hydroxythiophen [68], and derivatives of 2-hydroxybenzothiophen [69], are capable of being alkylated by Brändström's extractive method. Many oxindoles substituted in the 1-position can be alkylated catalytically with excellent yields [70]:



An interesting example of liquid–solid two-phase systems has been described in a study [71] where sodioacetoacetic ester, which is insoluble in the solvents employed, was alkylated in the presence of a tetra-alkylammonium salt. A detailed study has been made of the alkylation of acetoacetic ester by ammonium salts in a two-phase system [72].

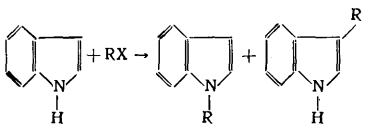
## 3. Alkylation of Hydrocarbons and Other Compounds

Hydrocarbons of the cyclopentadienyl series (cyclopentadiene, indene, and fluorene) are sufficiently acid to be converted into carbanions under our conditions. These carbanions may be successfully alkylated by mono-, and di-halogenoalkanes. The alkylation of indene proceeds particularly satisfactorily [73]. Fluorene is alkylated with somewhat more difficulty because of its lower acidity [74]:

The present author found that the C–H acidity of aryl halogenomethyl and aryl dihalogenomethyl sulphones is sufficient for the formation of carbanions when they react with an aqueous solution of sodium hydroxide in the presence of BTEA. These carbanions are fairly stable, so that their alkylation usually takes place with satisfactory yields [75]:

Although the possibilities of these reactions are far from having been elucidated, presumably the alkylation products will serve as useful starting materials in many syntheses.

## 4. Compounds Forming Heteroanions

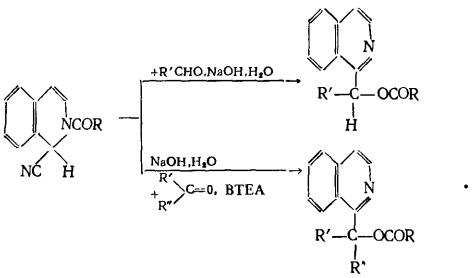


Despite the fact that the subject of the present review is the reactions of carbanions in two-phase systems, it is useful to quote certain examples of the alkylation of heteroanions. In the first place, mention should be made of Babayan's study of the influence of tetra-alkylammonium

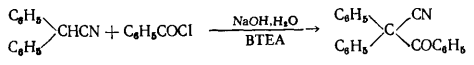
salts giving rise to the exclusive *O*-alkylation of phenoxide anions in an aqueous two-phase system[76]. Systematic studies of the alkylation of phenoxide anions in a catalytic two-phase system have been described[78] and the problem of *CO*-alkylation has been discussed[72].

In the presence of a tetra-alkylammonium catalyst, an aqueous solution of sodium hydroxide is a very convenient condensing agent in the synthesis of ethers by Williamson's method[79].

Ammonium catalysts and crown ethers catalyse very effectively the formation of acetates by the alkylation of potassium acetate in benzene or acetonitrile[80,81]. The use of tributylhexadecylphosphonium proved very convenient for the preparation of dialkyl and alkyl aryl sulphides[82].



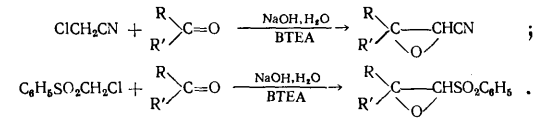
The alkylation of compounds containing N–H acid groups is of considerable practical importance. *N*-Alkylation of phenothiazine, diphenylamine, carbazole, indole, etc. proceeds satisfactorily under two-phase catalytic conditions[83]:



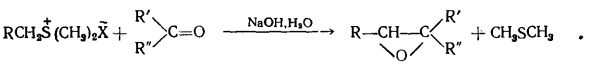
The ambident indole anion forms small amounts of *C*-alkylation products in this reaction. The formation of the aziridine ring by the intramolecular alkylation of *N*-ethoxycarbonyl-β-iodoethylamine has also been described[84].

## 5. The Reactions of Carbanions and Ylids with Polar Double Bonds.

The condensation of Reissert compounds with aldehydes, which results in the formation of isoquinolinyl methyl esters, is carried out mainly in the presence of bases such as butyl-lithium or sodium hydride[85]. This reaction proceeds much more satisfactorily in the presence of concentrated aqueous alkali in a two-phase system even without a quaternary ammonium catalyst, which, however, is necessary for the reaction of a Reissert compound with a ketone[86]:

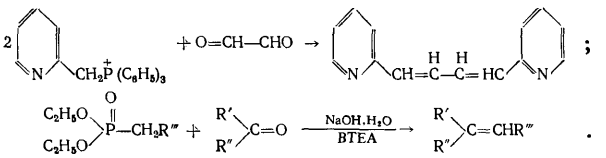


The reaction of the carbanion takes place in the organic phase, as shown by the finding that diphenylacetonitrile is acylated by benzoyl chloride with a high yield[29]:

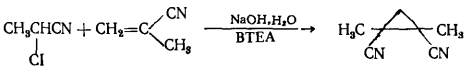


Two-phase catalytic conditions are very convenient for the reaction of α-chloronitriles with aldehydes and ketones (the Darzens reaction). The corresponding nitriles of glycidic acids are usually formed in high yields[87]. The condensation of α-chlorocarbonyl compounds (t-butyl chloroacetate, phenacyl chloride, etc.) proceeds less effectively under these conditions.

Excellent yields of epoxides substituted by an arenesulphonyl group have been obtained by the condensation of α-halogenosulphones with carbonyl compounds[75].



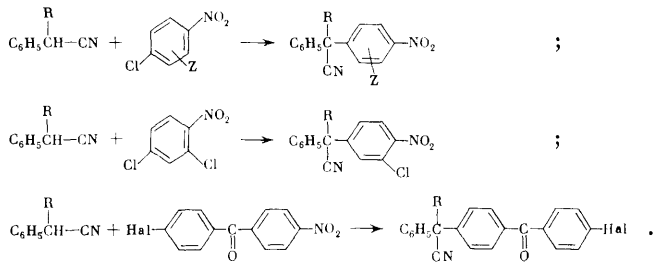
Two-phase systems in which an aqueous solution of sodium hydroxide plays the role of the base are very convenient and effective for the generation of ylids from sulphonium and phosphonium compounds. Since these compounds contain an onium cationic centre, the reactions of ylids in a two-system usually do not require catalysts. Thus Hatch[88] found that dimethylalkylsulphonium chlorides react with benzaldehyde in the presence of concentrated aqueous alkali to form epoxy-compounds. Analogous reactions have been described for many other aldehydes and ketones[89–91]:



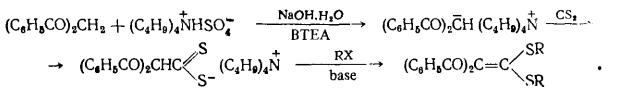
Nevertheless the conversion of trimethylsulphonium or trimethylsulphoxonium salts into ylids requires the use of tetra-alkylammonium salts[92].

Although according to generally accepted views phosphonium ylids are very sensitive to moisture, the benzene–aqueous sodium hydroxide solution system is extremely convenient for carrying out the Wittig reaction with aldehydes[93,94]. The methylene chloride–concentrated aqueous NaOH solution system is particularly suitable for the synthesis of dienes in the reactions of ylids with glyoxal[95] and for the reaction of a stabilised allyl ylid with aldehydes[96]. The use of this system for the Wittig–Horner reaction has also been described[97]:

The α-halogenonitrile carbanions generated in a two-phase system[98] and sulphonium ylids[92] also react with activated double bonds, forming the corresponding cyclopropane derivatives. Particularly satisfactory results were obtained for α-chloropropionitrile:

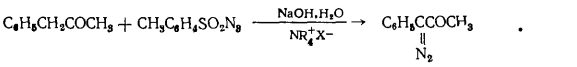


The cyanoethylation of 1-chloronitroethane in a two-phase system can lead directly to a substituted nitrocyclopropane[48].

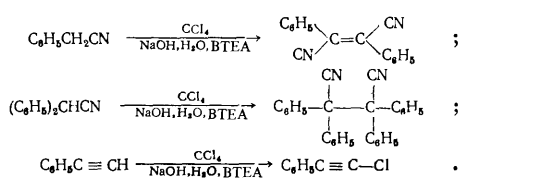


## 6. Reactions of Carbanions with Various Electrophiles

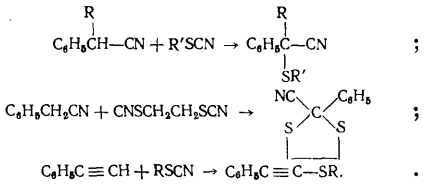
Two-phase catalytic conditions are the most convenient for the nitroarylation of alkylphenyl- and diphenylacetonitriles by *o*- and *p*-halogenonitrobenzenes and their derivatives. The substitution of the halogen atom by the carbanions derived from these nitriles results in the formation of compounds containing *o*- or *p*-nitroaryl



groups, as a rule with high yields. Under other conditions, the yields are small and considerable amounts of tar are formed. The presence of many substituents (halogen, >CO, $CH_3$, $NO_2$, COOR-t, etc.) in *o*- or *p*-halogenonitro-compounds does not interfere with the nitroarylation reaction [13,44,99-102]. Alkylphenylacetonitrile carbanions substitute mainly the chlorine atom in the *p*-position relative to the nitro-group in 2,4-dichloronitrobenzene [102]. Alkylphenylacetonitrile carbanions are capable of substituting not only the halogen atom, but also aromatic nitro-groups in the *o*- or *p*-positions relative to strong electrophilic substituents. For example, their reaction with 4-halogeno-4′-nitrobenzophenones involves exclusively the substitution of the nitro-group [101,103]:

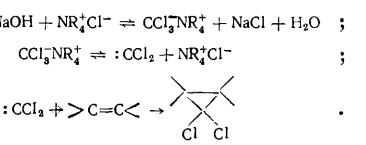


In the reaction of 3,4-dinitrochlorobenzene, the 3-nitro-group is substituted [101]. Sometimes substitution of the halogen or the nitro-group is accompanied by electron transfer, being particularly characteristic of the reaction of the diphenylacetonitrile carbanion, which forms tetraphenylsuccinonitrile [101,103]. Many β-dicarbonyl compounds react with carbon disulphide under the ion pair extraction conditions with formation of salts of the corresponding dithiocarboxylic acids. In the presence of an excess of the base, these salts are converted into dianions whose alkylation leads to the formation of keten mercaptals [104,105]:



Similar reactions can also be carried out with acetophenone [107]. The use of a two-phase system for the synthesis of aliphatic diazo-compounds is very promising [108]:

Phenylacetonitrile also reacts with carbon tetrachloride, forming *trans*-dicyanostilbene. Under analogous conditions, diphenylacetonitrile is converted into tetraphenylsuccinonitrile [109] and phenylacetylene is converted into phenylchloroactylene [110]:

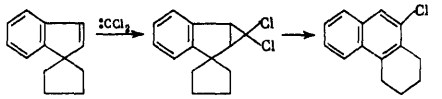


The direct introduction of an alkylthio-group into an organic molecule, usually as a result of the reaction between carbanions and disulphides, has aroused considerable interest in recent years. The present author found that excellent agents for the introduction of alkylthio-groups are the much more readily available thiocyanates, which effectively introduce alkylthio-groups into many C–H acids under two-phase catalytic conditions [110,111]:

## III. REACTIONS OF HALOGENOCARBENES AND POLYHALOGENOCARBANIONS

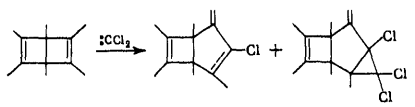
The use of two-phase catalytic systems in the chemistry of polyhalogenomethyl carbanions and halogenocarbenes gave particularly satisfactory results and has aroused much attention. In 1969 the present author developed a method for the synthesis of dichlorocyclopropanes by the addition to alkenes of dichlorocarbene generated by treating chloroform with concentrated alkali in the presence of benzyltriethylammonium chloride [112].

Despite the fact that this reaction proceeds in an aqueous medium, only an insignificant proportion of the resulting dichlorocarbene is hydrolysed. For example, equimolar amounts of styrene and chloroform give approximately 90% of a substituted dichlorocyclopropane and only 7% of the chloroform is hydrolysed. Dichlorocarbene is formed in the organic phase as a result of the decomposition of the tetra-alkylammonium derivative of the trichloromethyl carbanion as a consequence of the high rate of reaction of dichlorocarbene with hydroxide ions and water. Doering and Hoffman [113], who attempted to obtain the products of the addition of dichlorocarbene to alkenes in the presence of a concentrated aqueous KOH solution, observed mainly hydrolysis. The yield of the desired product did not exceed 0.5%. These fundamental differences are a consequence of the presence of the quaternary ammonium cation, which transports the trichloromethyl anion into the bulk of the organic phase in the form of an ion pair soluble in a non-polar medium. The subsequent formation of dichlorocarbene takes place in the organic medium, as a result of which it is capable of reacting effectively with the alkene:



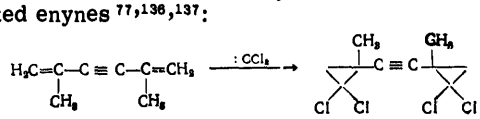
The method immediately found extensive applications in many reactions of halogenocarbenes and is now believed to be one of the most convenient.

### 1. Generation and Reactions of Dichlorocarbene

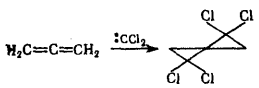


Examples of reactions of dichlorocarbenes in a two-phase system are particularly numerous. In most cases the authors note that the yields of the products of its addition to monoalkenes are usually higher than in cases where other methods were used [12,13,112,114-124]. In some studies it is emphasised that dichlorocarbene, generated by the two-phase catalytic method, is also much more

reactive and gives high yields of adducts, even with alkenes having weakened nucleophilic properties, such as *trans*-stilbene, and with certain acetylenes [114]. These data conflict somewhat with the results of the determination of the relative rates of addition of dichlorocarbene, generated in a catalytic system, to various alkenes, which, according to Starks' study [12], do not differ from the relative rates measured for dichlorocarbene obtained by other methods. These apparent contradictions will be discussed below.

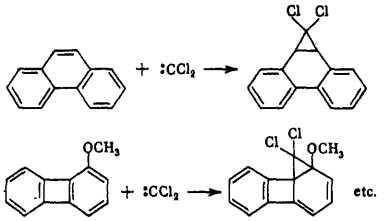


At the end of 1974, Isagawa et al. reported that the addition of dichlorocarbene to alkenes in a two-phase system is very effectively catalysed by trialkylamines [125]. This unexpected catalytic effect is apparently due to the formation of an ammonium ylid at the interface [126]. The addition of dichlorocarbene to cyclopentenes is usually accompanied by a rearrangement with formation of six-membered rings. The addition reaction carried out in a two-phase catalytic system proceeds in the same way [119-121,127-129]. Interesting transformations have been observed in the reactions of dichlorocarbene with indene derivatives [130]:

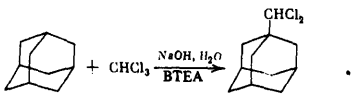


The increased reactivity of dichlorocarbene generated in a two-phase system, noted above, makes it an ideal reagent for the conversion of polyenes into polydichlorocyclopropanes. Bisadducts with divinylbenzene [131], conjugated dienes [114,132], and polyenes [115] have been obtained by single-stage syntheses using this procedure. It also proved possible to obtain a bisadduct with cyclopentadiene [132] and a tetra-adduct with cyclo-octatetrane [133]. By regulating appropriately the reactant ratio and the reaction time, it is possible to obtain mono-, di-, and tri-addition products [133,134]. Hexamethyl Dewar benzene forms under these conditions bisadducts, which undergo further transformations during the reaction [132,135]:

Dichlorocarbene adds exclusively to the double bond of conjugated enynes [77,136,137]:



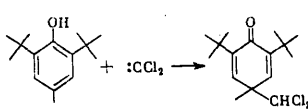
Polyadducts of dichlorocarbene have been obtained in a single stage also as a result of reactions with allenes and other higher cumulenes [114,138-140]:



The addition of dichlorocarbenes in a two-phase system to vinyl ethers [141-143] and enol ethers and esters [121,129,144] gives very satisfactory results, although some workers believe that these compounds are insufficiently stable in an aqueous medium [145]. The limitations associated with instability in the presence of aqueous alkali have apparently been overestimated, since, according to Miller, even trimethylsilyl derivatives of alkenes combine with dichlorocarbene in a two-phase system to give excellent yields of products [146].

Dichlorocarbene generated in a two-phase system reacts effectively with many aromatic compounds—phenanthrene [115,147-149], alkyl derivatives of benzene and naphthalene [150,151], 1,4,5,8-tetramethoxynaphthalene [152], 1-methoxybiphenylene [153], etc. This results in the formation of both primary dichlorocarbene addition products as well as the products of their subsequent transformations:

One of the characteristic reactions of dichlorocarbene is insertion in C–H bonds. Usually only thermally generated dichlorocarbene gives acceptable yields of insertion products. In a two-phase system the reactivity of dichlorocarbene is also considerable, as a result of which it is successfully inserted in the C–H bonds in the bridgeheads of adamantane [154,155] and other polycyclic hydrocarbons [156], giving satisfactory yields of the corresponding dichloromethyl derivatives. In the reactions with simpler hydrocarbons (isopropylbenzene, decalin, etc) the yields of dichloromethyl derivatives are moderate, but the reaction may nevertheless be of practical importance, since the unreacted initial compounds are almost completely recovered [157,158]:



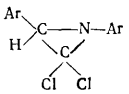
Dichlorocarbene generated in a two-phase system undergoes an unusual reaction with higher alcohols, substituting the hydroxy-group by chlorine with high yields [159]:

Lower aliphatic alcohols give rise to a multiplicity of products. The reaction with ethyl alcohol, where the main product is ethyl orthoformate, is of practical importance [160]:

Various types of transformations have been observed also in the reaction with $\alpha$-diols [161]. Nevertheless many allyl alcohols react with dichlorocarbene under these conditions to form products of addition to the double bond without involving the hydroxy-group [162]. There are as yet no data concerning the influence of tetra-alkylammonium catalysts on the interaction of phenoxide anions with dichlorocarbene (the Reimer–Tiemann reaction). Nozaki and coworkers [163] found that polyalkylphenols form dichloromethyl derivatives of cyclohexadienones:

The reaction of dichlorocarbene with benzaldehyde results in a high yield of mandelic acid [164].

Reactions with nitrogen compounds. On reacting with chloroform in the presence of alkali, primary amines form isonitriles. This reaction, which



has been known for approximately one hundred years, has not found practical synthetic applications. The use of a catalytic two-phase system greatly improved yields and made it useful in practice [165-168]:

$$RNH_2 + :CCl_2 \rightarrow RNC \quad .$$

Simple formylation of secondary amines by dichlorocarbene in a two-phase system may also find practical applications [169].

Tertiary amines also react with dichlorocarbene under these conditions. The ammonium ylids formed initially rearranges in at least three ways, giving rise to formyl derivatives of secondary amines, carboxylic acid dialkylamides, alkyl chlorides, etc, [170] Polycyclic tertiary $\alpha$-diamines are cleaved by dichlorocarbene to bis-*N*-formyl derivatives [171]. 1-Methyl-1,2-dihydroisoquinoline reacts with dichlorocarbene to form addition and insertion products, but is not cleaved [172]. Despite the fact that enamines and Schiff bases are fairly unstable in the presence of aqueous alkali, their reactions with dichlorocarbene take place successfully under conditions of two-phase catalysis. Depending on the structure of the initial substance, it is possible to isolate the primary addition products—dialkylamino-derivatives of dichlorocyclopropane [173] and dichloroaziridines [174]—or the products of their further transformations:

$$Ar{-}CH{=}N{-}Ar + :CCl_2 \rightarrow$$

.

The enamines derived from certain bicyclic ketones form relatively stable adducts with dichlorocarbene [175].

Dichlorocarbene generated in a two-phase catalytic system may serve as a vigorous dehydrating agent, which converts amides, oximes, and thioamides into nitriles [176,177]:

$$RCONH_2 + :CCl_2 \rightarrow RCN \quad ;$$

$$RCH{=}NOH + :CCl_2 \rightarrow RCN \quad .$$

Webber and coworkers recently used successfully a two-phase system with BTEA or a crown ether in order to obtain diazomethane by treating hydrazine with dichlorocarbene [178]. This method will undoubtedly prove to be of practical importance:

$$N_2H_4 + :CCl_2 \rightarrow CH_2N_2 \quad .$$

The addition of dichlorocarbene to vinyl sulphides proceeds in the usual way with formation of the corresponding dichlorocyclopropane derivatives [179], but certain allyl sulphides rearrange under these conditions with cleavage of the C–S bond, giving rise to monothiocarboxylate esters [180].

The high reactivity of dichlorocarbene generated in a two-phase catalytic system undoubtedly requires explanation. Dichlorocarbene is formed in the organic phase, where its precursor (the trichloromethyl anion) exists in the form of a soluble ion pair with the tetra-alkylammonium cation. Since alkali metal cations are absent from the organic phase, the formation of the corresponding carbenoids is impossible. Despite the fact that the system as a whole is heterogeneous, dichlorocarbene is formed and reacts in a homogeneous medium—the organic phase. An equivalent amount of a tetra-alkylammonium chloride, which is also soluble in the organic phase, is formed simultaneously with dichlorocarbene. As a result of this, the rapid reversible reaction

$$CCl_3^-NR_4^+ \rightleftharpoons NR_4^+Cl^- + :CCl_2$$

ensures the existence of sufficient amounts of dichlorocarbene over a relatively long period, to enable it to react with relatively unreactive compounds. This cannot occur when, for example, dichlorocarbene is generated by treating chloroform with potassium t-butoxide, since the solubility of the potassium derivative of the trichloromethyl anion (and even more so that of potassium chloride) is apparently insignificant in a non-polar medium. This explanation is confirmed by the finding that the overall rate of disappearance of chloroform in a two-phase system is low in the absence of an alkene and depends on its nucleophilic properties.

## 2. Reactions of Trichloromethyl Anions

Trichloromethyl anions are fairly short-lived, but they can be trapped successfully by suitable electrophiles. Catalytic conditions are particularly convenient for these reactions, since both reacting species—the trichloromethyl anion and the organic electrophile—are dissolved in the organic phase. Thus it has been found that two-phase catalytic conditions are the most suitable for the Michael reaction between chloroform and electrophilic alkenes (acrylonitrile, acrylate, esters, vinyl sulphones, vinyl acetate, etc.)[181-183]:

$$CH_2{=}CH{-}Y + CHCl_3 \xrightarrow[\text{BTEA}]{NaOH,H_2O} CCl_3CH_2CH_2Y \quad ;$$

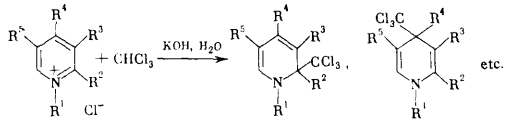
$$Y{=}CN,\ COOR,\ \text{or}\ SO_2R \quad .$$

The yields of the corresponding trichloromethyl derivatives are usually high, greatly exceeding the yields of the same compounds obtained by other methods. When the acceptors Y are moderately electrophilic, the simultaneous addition of trichloromethyl anions or dichlorocarbenes is observed. The mode of these competing reactions depends mainly on the structure of the acceptor and to some extent also on the way in which the reaction is performed. Thus, on diluting the organic phase with an inert solvent (for example, methylene chloride), the reaction may be driven towards the addition of dichlorocarbene. In a detailed study of this reaction, Dehmlow and Höfle observed further interesting transformations of the compounds formed initially [184]:

.

Polymethylated vinyl ketones combine exclusively with dichlorocarbene and not with the trichloromethyl anion [185].

Organic thiocyanates are very effective electrophiles, trapping trichloromethyl anions. Their CN group is substituted and trichloromethyl sulphides are formed in satisfactory yields [111]:

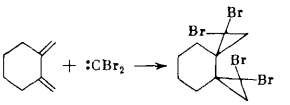


$$CHCl_3 + RSCN \xrightarrow[\text{BTEA}]{NaOH,H_2O} RSCCl_3 \quad .$$

However, standard two-phase conditions proved to be unsuitable for the synthesis of trichloromethylphenylmercury—an important source of dichlorocarbene under neutral conditions. The difficulties in the application of the two-phase method in this synthesis were overcome by replacing the concentrated solution of alkali by a mixed

solution of sodium hydroxide and potassium fluoride in water [186]:

$$C_6H_5HgCl + CHCl_3 \xrightarrow[BTEA]{NaOH,KF,H_2O} C_6H_5HgCCl_3 \quad .$$



Krőhnke and coworkers [187] found recently that certain *N*-benzylpyridinium chlorides combine with the trichloromethyl anion, forming 2- and 4-trichloromethyldihydropyridine derivatives:

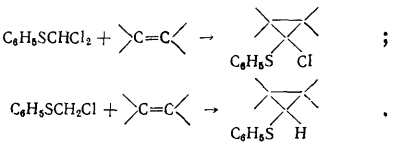
A more detailed study of this reaction showed that it proceeds at the interface [188].

### 3. The Formation and Reactions of Other Carbenes

Two-phase catalytic conditions proved to be very convenient for the conversion into carbanions and then into carbenes of all the remaining trihalogenomethyl derivatives of methane with the exception of fluoroform, which is too weak a C–H acid. The yields of dibromocyclopropane derivatives, obtained from bromoform and alkenes under standard two-phase catalytic conditions, are usually moderate [114,189,190]. Nevertheless, this method has been frequently used for the addition of dibromocarbene to dienes and polyenes [133,136,191]:

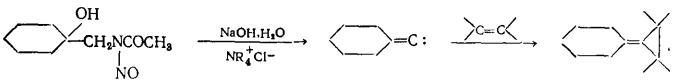
The yields increase in the presence of a considerable excess of bromoform [192,193] or when 1–2 mole % of lower alcohols is added to the reaction mixture [194–196].

The reaction with dibromocarbene has been used to substitute the hydroxy-group by bromine in hydroxyadamantanes [197]. Two-phase conditions have been used successfully to achieve the addition of tribromomethyl anions to electrophilic alkenes and, after some modification of the conditions (aqueous NaOH solution with addition of potassium fluoride instead of concentrated alkali), for the synthesis of tribromomethylphenylmercury [186]. A certain degree of stabilisation of tribromomethyl anions by small amounts of alcohols, mentioned above, makes it possible to achieve their alkylation by reactive alkylating agents, but the yields are low [198]:



$$CHBr_3 + C_6H_5CH_2Cl \xrightarrow[BTEA]{NaOH,H_2O} C_6H_5CH_2CBr_3 \quad .$$

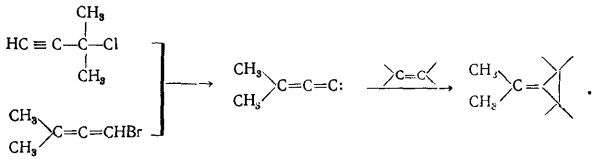
The formation of derivatives of chlorofluoro-, bromofluoro-, [199] and fluoroiodo-cyclopropanes [200] as a result of the reaction of the corresponding trihalogenomethanes and alkenes in the presence of aqueous sodium hydroxide and BTEA has also been described. Chlorofluorocarbene has been used successfully to synthesise chlorofluorocyclopropyl alcohols [201] and enamines [175] from the corresponding unsaturated compounds:



$$H_2C{=}CHCH_2OH + CHCl_2F \xrightarrow[BTEA]{NaOH,H_2O} H_2C(Cl,F)CHCH_2OH \quad .$$

Even di-iodocarbene can be obtained by treating iodoform with an aqueous solution of alkali and BTEA in the presence of alkenes [202].

Dichloromethyl sulphides are relatively close analogues of haloforms, since the 3*d* orbital effect of bivalent sulphur presumably stabilises the carbanions similarly to the influence of chlorine or bromine. Thus, on treatment with a concentrated aqueous solution of alkali in the presence of BTEA, dichloromethyl phenyl sulphide forms the corresponding carbanion and then phenylthiochlorocarbene, which reacts with alkenes to form phenylthiochlorocyclopropane derivatives [203]. The same has also been found for dichloromethyl methyl sulphide [204]. It must be emphasised that even chloromethyl phenyl sulphide is capable of abstracting a proton under these conditions and of converting alkenes into phenylthiocyclopropane derivatives [205]:



This result is to some extent unexpected, because it indicates a greater ability of the phenylthio-group to stabilise carbanions than that of chlorine, since methylene chloride is incapable of forming a carbanion and monochlorocarbene under these conditions [2]. Unfortunately, the problem of trapping the corresponding carbanions—precursors of alkyl(aryl)thiocarbenes—was not considered by the authors. The two-phase catalytic method gave very satisfactory results in the generation of unsaturated carbenes. Newman and coworkers used this method to convert *N*-(β-hydroxyalkyl)-*N*-nitrosoacetamides into alkylidenecarbenes and found that under these conditions the yields of the products of addition to alkenes or inorganic anions are considerably higher than those of any other products [206,207]:

The alkylidenecarbenes generated in this way also react with carbonyl compounds [208].

The successful addition of vinylidenecarbenes under these conditions to dienes (cyclopentadiene, norbornadiene) [209] and enol ethers [210] has been described. Dimethylvinylidenecarbene has been obtained by the same procedure from methylallenes [211] and butynes [212,213]:

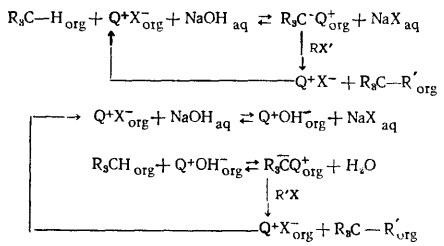
## IV. CONCLUSION

### 1. Applications of the Method

Numerous examples of the use of two-phase catalytic systems and of the ion pair extraction method in many reactions of carbanions and halogenocarbenes constitute a good illustration of the scope and importance of these methods for organic synthesis. However, the two-phase method has many serious limitations. The most important one is that only relatively strong C–H acids may be converted into anions by treatment with aqueous sodium

hydroxide. Naturally, owing to the presence of two phases and catalysts, the acid–base equilibrium is displaced towards the formation of organic anions, but the methods are nevertheless inapplicable to C–H acids whose $pK_a$ is greater than 22. For example, fluorene can be alkylated, while acetonitrile cannot.

The second limitation is a consequence of the instability of certain C–H acids or electrophiles in the presence of an aqueous solution of alkali (for example, the hydrolysis of esters or other functional groups). This limitation can be frequently eliminated by employing more stable t-butyl esters and a less concentrated solution of sodium hydroxide or by increasing the amount of the tetra-alkylammonium salt up to an equimolar proportion. Compounds reacting with carbanions or halogenocarbenes should also be stable in the presence of aqueous alkali. On the other hand, one must not overestimate these limitations, since many readily hydrolysable compounds have been used successfully in the reaction under these conditions.



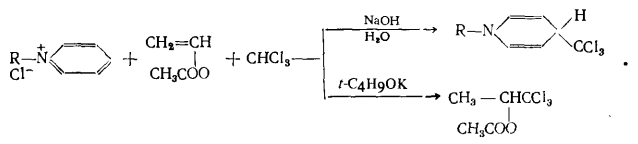
An important limitation of the use of the two-phase catalytic method is that the reaction product cannot be more acid than the initial compound. Otherwise it is converted into the anion more readily than the initial compound and forms a relatively unreactive ion pair with the ammonium cation, whereupon the catalytic reaction stops. Under these conditions and even in the presence of relatively strong C–H acids, the use of equimolar amounts of quaternary ammonium salts, recommended in the ion pair extraction method, appears to be more convenient. Catalytic reactions are frequently inhibited by inorganic anions with a low charge density and poorly solvated by water ($I^-$, $ClO_4^-$, etc.), which restricts the application of iodides as alkylating agents. This is a consequence of the high solubility of the corresponding tetra-alkylammonium salts in organic solvents. Nevertheless, this inhibiting effect is not always observed. It is unimportant when the extraction of ion pairs is employed.

## 2. The Possible Mechanisms of Catalysis in Two-Phase Systems

All the reactions discussed above consist of at least two stages. The first stage involves the formation of a carbanion by the abstraction of a proton from the C–H acid, and the second involves subsequent transformations of the carbanion (reaction with electrophiles, conversion into a carbene, etc.). One of the most important problems is that of the site where the processes occur: in the aqueous phase, in the organic phase, or at the interface. There is no doubt that the second and subsequent stages take place in the organic phase, where the carbanions exist as ion pairs with tetra-alkylammonium cations. This is frequently observed and in fact constitutes the essential feature of catalytic and extractive two-phase methods. The behaviour of these ion pairs in non-polar solvents has been discussed in detail by Brändström[6].

It is much more difficult to determine where the proton is abstracted from the C–H acid and the ion pair is formed. The majority of workers do not consider this problem and refer to all catalytic reactions of carbanions in two-phase systems as "phase-transfer catalysis"[2], a term which was introduced by Starks[12,215]. It arises from the following considerations: two reactants present in two immiscible liquid phases and insoluble in the other phase are unable to react with one another, since they cannot come into direct contact. A third component, capable of transferring one of the reactants from one phase to the other, and thereby enabling the reaction to occur, acts as the catalyst (the "phase-transfer agent"). This approach is well illustrated by the cyanation of alkyl halides in hydrocarbons by an aqueous solution of sodium cyanide. Vigorous stirring of this two-phase system does not lead to the exchange reaction even at an elevated temperature. On the other hand, the addition of catalytic amounts of a quaternary ammonium or phosphonium compound, capable of transporting $CN^-$ ions in the form of the ion pairs $NR_4^+CN^-$ into the organic phase, gives rise to a vigorous reaction. In the reactions of halogenocarbenes or carbanions (derivatives of relatively weak C–H acids) in the presence of a concentrated aqueous sodium hydroxide solution the role of phase transfer catalysis reduces to the transfer of hydroxide anions in the form of tetra-alkylammonium or phosphonium hydroxides from the aqueous to the organic phase.

Thus, according to the mechanism involving transfer from one phase to the other, the abstraction of a proton from C–H acids, and the formation of the carbanion–tetra-alkylammonium cation ion pair should occur in the organic phase. This hypothesis concerning the generation of trichloromethyl anions and dichlorocarbene in a two-phase catalytic system via the formation of a quaternary ammonium base, which then reacts in the organic phase, was put forward by the present author in 1969[1,12]. However, many observations and the results of careful analysis agree better with the hypothesis that the first stage of the carbanionic reaction—the abstraction of a proton and the formation of ion pairs in the two-phase systems under consideration—takes place at the interface. The ion pairs then diffuse into the bulk of the organic phase, where all further transformations, involving the simultaneous liberation of the ammonium cation, take place. These two alternative mechanisms are represented schematically as follows:



Evidently in the case of relatively strong C–H acids, which are capable of forming anions to a significant extent in the presence of a dilute aqueous NaOH solution, the quaternary ammonium compound acts mainly as a phase-transfer agent, transferring organic anions from the aqueous to the organic phase. However, the most important application of two-phase catalytic systems involves the reaction of weak C–H acids, which do not form water-soluble sodium derivatives. In such cases we are dealing with a distinct immiscibility of the two phases. For example, in the phenylacetonitrile–50% aqueous NaOH solution system the concentration of the first component in the aqueous phase is less than 2 p.p.m., while that of sodium hydroxide in terms of $Na^+$ ions is less than 5 p.p.m. in the organic phase. These values rule out the extraction of carbanions from the aqueous phase, of the kind that can occur in the case of more acid compounds and a dilute NaOH solution.

Thus two possibilities remain: the abstraction of a proton in the organic phase, into which $NR_4^+OH^-$ is transferred as the base, or at the interface. Numerous experiments on the extraction of ion pairs with inorganic anions have shown that in an organic solvent (for example, benzene or acetonitrile)–50% aqueous NaOH solution two-phase system more than 99% of benzyltriethylammonium chloride remains in the organic phase as the chloride and that each anion in the series $SO_4^{2-}$, $F^-$, $OH^-$, $Cl^-$, $Br^-$, and $I^-$ is almost quantitatively displaced from the organic phase by its right-hand neighbour. In view of the small amounts of catalysts used in preparative experiments and the formation of considerable amounts of the $Cl^-$ and $Br^-$ anions in the reaction, the concentration of $OH^-$ anions (i.e. $NR_4^+OH^-$) in the organic phase is presumably negligible. Nevertheless, the rate of attainment of the acid–base equilibrium is usually high compared with other reactions, so that one cannot fully rule out the possibility of the formation of carbanions by the extraction of $NR_4^+OH^-$, although it is unlikely. On the other hand, the possibility of the attainment of the acid–base equilibrium and the formation of carbanions at the interface has been satisfactorily demonstrated by the present author's experiments, in which many reactions of carbanions in a two-phase system without catalysts were observed.

Numerous weak C–H acid exchange hydrogen for deuterium as a result of stirring with a concentrated solution of sodium hydroxide in $D_2O$. Owing to the almost complete immiscibility of the phases, the formation of the carbanion and its reaction with $D_2O$ presumably take place at the interface. The present author found that certain synthetically impotrant reactions of carbanions occur in a two-phase system without catalysts. Bearing in mind the above miscibility data, one may conclude that the reactions occur at the interface. They include mainly those actions of Reissert's compounds with aldehydes [86], Darzens-type condensations of aldehydes with $\alpha$-halogenosulphones [75] and $\alpha$-halogenonitriles, and the addition of $CCl_3^-$ anions to *N*-alkylpyridinium salts [187,188]. The latter reaction is particularly interesting, since pyridinium salts resemble to a considerable degree the catalysts used in the reactions of carbanions.

The formation of adducts of the trichloromethyl anion is not accompanied by the formation of tar. This is evidence against the extraction of $OH^-$ anions into the organic phase, since the products of their addition to pyridinium salts are very unstable. However, the main evidence that the adducts of the trichloromethyl anion are formed at the interface was obtained in competition experiments, where vinyl acetate competed with pyridinium salts for addition to trichloromethyl anions. In a two-phase system, trichloromethyl anions add exclusively to the pyridine ring, while in a homogeneous or pseudohomogeneous system in the presence of potassium t-butoxide, trichloromethylethyl acetate is formed exclusively (when there is competition with styrene, a substituted dichlorocyclopropane is formed) [188]:

Thus it may be regarded as proved that the addition of the $CCl_3^-$ anion to pyridinium salts takes place at the interface, by-passing the ion pair formation stage. Presumably the recently described reactions of dichlorocarbene catalysed by tertiary amines are to some extent associated with the formation of this anion at the interface, where the reaction with the tertiary amine results in the formation of an ammonium ylid. The latter is capable of diffusing into the organic phase, where further transformations occur.

The above observations and considerations permit the conclusion that in a two-phase system comprising a relatively weak C–H acid (in an organic solvent or without it) and a concentrated sodium hydroxide solution, a proton is abstracted with formation of a carbanion even in the absence of a catalyst. However, these carbanions are incapable of leaving the interface, since the sodium cations accompanying them are highly solvated in the aqueous phase and only very slightly in the organic phase; they are therefore incapable of passing to the latter. In this to some extent adsorbed state, carbanions are very unreactive, and react only with strong or positively charged electrophiles. Quaternary ammonium cations react with these carbanions, forming ion pairs soluble in the organic phase. After their migration into the bulk of the organic phase, the ion pairs undergo further transformations. This mechanism is naturally highly simplified. Tetra-alkylammonium cations are in all probability directly involved in the stage where carbanions are formed, lowering the energy of the transition state in the proton abstraction reaction, as a result of the influence of the positive charge from the opposite side of the reaction centre. Not only tetra-alkylammonium and phosphonium compounds but also alkali metal cations, which are highly solvated by certain organic solvents [dimethylformamide (DMF), hexamethylphosphoramide (HMP), etc.], can serve as catalysts in two-phase systems. These solvents in fact catalyse the formation of carbanions in two-phase systems:

$$(C_6H_5)_2CHCN_{org} + NaOH_{aq} \rightleftarrows [(C_6H_5)_2\bar{C}CNNa^+_{solv.}]_{org} + H_2O_{aq}$$

| Solvent | $C_6H_6$ | $CH_3CN$ | DME | THF | Pyridine | DMF | HMP |
|---|---|---|---|---|---|---|---|
| Concn. of carbanion, % | 0 | 1 | 3 | 3 | 12.5 | 88 | 94 |

Crown ethers proved to be very powerful neutral ligands, binding alkali metal cations [14,215]. The stable crown . $Na^+$ complex behaves as an organic cation, forming with many anions ion pairs which are soluble in non-polar organic solvents. This remarkable property of crown ethers has found an interesting application in many reactions involving inorganic anions in non-polar solvents (reactions of "naked" anions) [80,216-218]. In most cases crown ethers were partly converted into a solid sodium or potassium salt in a benzene or acetonitrile solution. The present author showed that crown ethers are very effective catalysts of the reactions of carbanions in a two-phase system. They are no less active than quaternary ammonium salts, but are more stable than the latter [13,55]. The use of diazapolyoxamacrobicyclic compounds as catalysts in liquid–liquid or liquid–solid two-phase systems is also very promising, because their activity in binding cations into complexes with formation of the so called cryptates is much higher than that of crown ethers [219,220].

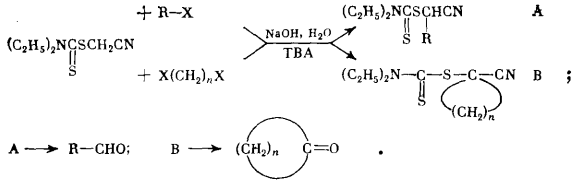
Summarising the foregoing, it is possible to distinguish three different types of catalytic action of quaternary ammonium salts in two-phase systems, each of which is based on the formation of ion pairs soluble in the organic phase.

1. Extraction of inorganic anions from the aqueous phase into the organic phase—true-phase transfer catalysis, which is observed mainly in reactions of inorganic anions ($CN^-$, $SCN^-$, $MnO_4^-$, etc.) with organic compounds (alkyl and alkenyl halides, etc.).

2. Extraction (into the organic phase) of the carbanions of relatively strong C–H acids formed on treatment with dilute aqueous solutions of sodium hydroxide or water-soluble sodium derivatives of these acids. There is no doubt that such extraction displaces the acid–base equilibrium in the direction of the formation of the carbanion. This corresponds either to phase-transfer catalysis or to the extraction of ion pairs as a function of the amount of quaternary ammonium salt consumed (catalytic or equimolar).

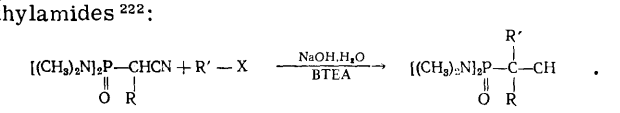
3. The formation of ion pairs soluble in the organic phase and incorporating carbanions located at the interface, with a more or less active involvement of the proton abstraction stage. This pathway is the main one in the carbanionic reactions of relatively weak C–H acids, regardless of whether catalytic or equimolar amounts of tetra-alkylammonium salts are used.

It is impossible to separate clearly these three versions; each plays the main role in individual instances. Some workers include the two-phase reaction considered here with those occurring in cationic micelles ("cages")[4]. Despite the apparent similarity of the systems considered to micellar systems, the essential feature of the catalytic action of onium compounds is different from that of micellar catalysis and their catalytic activity does not vary in parallel with surface activity. Nevertheless one cannot completely reject the possibility of the involvement of phenomena similar to those in micellar catalysis, particularly in reactions occurring at the interface.



o0o

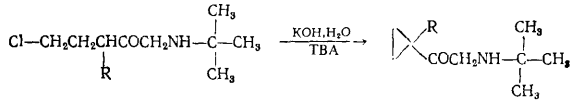
Two-phase catalytic systems have been used in reactions of carbanions and halogenocarbenes for only about ten years, and they have become more common only in the last five years. The present author's views concerning the potential possibilities of the applications of these methods are therefore by no means exhaustive. In almost all the examples described, both two-phase catalytic methods and methods based on the extraction of ion pairs proved to be better than all other known procedures as regards simplicity, selectivity, yields, etc. Presumably they will be widely used in the immediate future as methods of organic synthesis.



## ADDENDUM

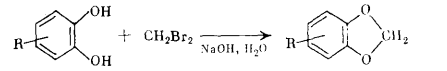
Numerous studies have been published recently, in which the two-phase method of generating carbanions and halogenocarbenes was developed further. The most important results are presented below.

2.1. *S*-Cyanomethyl *NN*-diethyldithiocarbamate can be alkylated with excellent yields in the presence of aqueous alkali and an ammonium catalyst. Since both functional groups are readily split off on hydrolysis, the reaction can be used to synthesise aldehydes and ketones[221]:



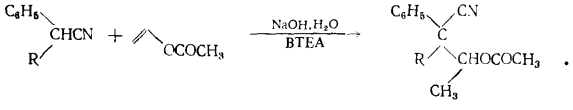
A two-phase catalytic system has been used successfully in the alkylation of cyanoalkylphosphonic tetramethylamides[222]:

Reeves and Hilbrich reported that the alkylation of phenylacetonitrile and phenylacetone in a two-phase system is catalysed by tertiary amines, which are capable of forming quaternary salts under the reaction conditions[223].

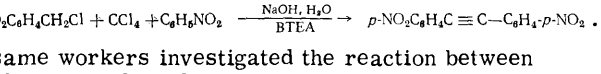


2.2. Using an equimolar amount of BTEA, Singh and Danishefsky[224] alkylated diethyl malonate with ethylene bromide in the presence of concentrated aqueous alkali and obtained directly cyclopropane-1,1-dicarboxylic acid. The application of a two-phase catalytic system in the synthesis of cyclopropyl ketones has been described[225]:

2.3. A two-phase catalytic system proved to be very effective in the alkylation of compounds containing the isonitrile group[226], for example toluene-*p*-sulphonylmethyl isocyanide[227]:

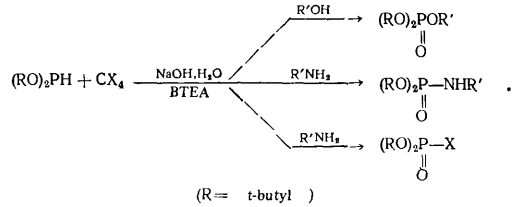


This method gave excellent results in the reaction of methylene bromide with phenols[228,229]:



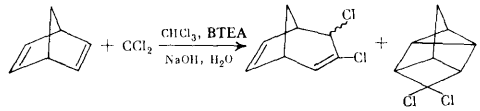
A detailed study of the synthesis of ethers under two-phase conditions has been described[230]. This method has been used in the synthesis of the ethers and acetals of certain sugars[231]. Studies dealing with two-phase *N*-alkylation of indole[232,233], amides[234], phenylhydrazones[235], and aziridine[236] have been published.

2.4. Using aqueous alkali, it was possible to carry out the Wittig reaction with formaldehyde[237]. Among many examples of the Wittig–Horner reaction[238], carried out under two-phase conditions, processes apparently occurring at the interface without catalysts have been discussed[240]. A two-phase catalytic system is very effective in the synthesis of unsaturated compounds by the condensation of aryl methyl sulphones[241], 2-methylbenzothiazoles[242], and similar carbon acids with aromatic aldehydes. Certain carbanions add to vinyl acetate under these conditions[243]:



2.5. Using a two-phase system, a direct synthesis of di-(*p*-nitrophenyl)acetylene was achieved[244]:

The same workers investigated the reaction between phenylacetonitrile and nitrobenzene in the presence of aqueous NaOH and BTEA.[245]



Excellent results were obtained when the Atherton–Todd reaction was carried out under catalytic two-phase conditions. Alcohols, phenols[246], and amines[247] are

phosphorylated with a yield of about 90% and the products do not require additional purification. When t-butyl phosphite is used, it is also possible to obtain the corresponding acid halide[248]:

(R= t-butyl )

3. Dichlorocarbene generated under two-phase catalytic conditions gives rise to products of 1,4-homoaddition to polycyclic hydrocarbons[249,250]:

The high reactivity of dichlorocarbene in a two-phase system can be modified by employing as the catalyst an ammonium salt containing a hydroxy-group[251], which makes the reaction with polyalkenes more selective. Dichloroethane generated under two-phase catalytic conditions is capable of eliminating oxygen from epoxy alkanes[252] and the resulting alkene then combines with dichlorocarbene.

Apart from the studies indicated above, many others have been published in which a two-phase system was used for the synthesis of dihalogenocyclopropanes[253,254].

4. The fact that methyl phenyl sulphone and even dimethyl sulphone[255] react with benzaldehyde in the presence of aqueous NaOH and BTEA demonstrates the considerable ability of this system to abstract a proton. On the other hand, these compounds react only with aromatic aldehydes, so that the existence of carbanions in the organic phase is doubtful. The reactions apparently take place at the interface. New evidence has been obtained for the formation of carbanions at the interface. It has been shown that alkyl iodides are capable of alkylating phenylacetonitrile without a catalyst and that the process takes place at the interface.

The possibility of inducing optical activity by means of an optically active ammonium catalyst has aroused interest. Nazaki's report of a high degree of induced activity in the synthesis of phenyloxiran (styrene oxide) from benzaldehyde and sulphoxonium imide[257] proved to be erroneous. The induction of optical activity in the reaction of dichlorocarbene with styrene is also doubtful[258]. A moderate stereospecificity has been observed in the alkylation of 2-ethoxycarbonylcyclohexanone[259]. Quaternary ephedrinium salts were used as the chiral catalysts in all cases.

Finally, the use as catalysts of quaternary ammonium salts[260] as well as crown ethers[261] attached to solid polymers has been reported. The term three-phase catalysis has actually been proposed[260].

# Organosilicon Carbonates and Chlorocarbonates

V.D.Sheludyakov and V.F.Mironov

A systematic account is given for the first time of the methods of synthesis, properties, and practical applications of silicon-containing derivatives of carbonic acid—carbonates and chlorocarbonates (chloroformates). Together with monomeric compounds, oligomeric and polymeric products are discussed as well as other compositions from which new organosilicon articles with valuable practical properties, for example with a highly effective gas-separating capacity, have been made.
The bibliography includes 426 references.

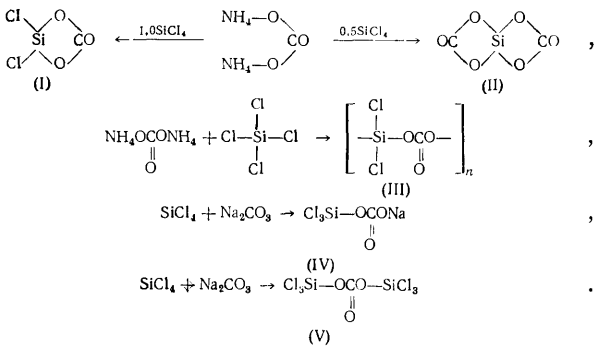
IV. Silicon-containing polycarbonates 1175
V. Practical applications of silicon-containing polycarbonates and related compounds 1179

## I. INTRODUCTION

New organic and organosilicon polymeric materials and intermediates in their synthesis are now attracting an increased amount of attention [1-12]. This review is part of a series of previously published reviews dealing with carbonic acid derivatives: organosilicon isocyanates [13], ureas [14], and urethanes [15].



The chemistry of organic chlorocarbonates and carbonates has frequently been the subject of special and general reviews [16-21], but they were all published before studies on the synthesis of the corresponding silicon-containing derivatives were made and therefore naturally do not describe them or anticipate the possibility of their formation. Furthermore, in the last published review [22], the already available extensive data on this problem were not described. A fairly considerable amount of attention has been devoted to silicon-containing carbonic and chlorocarbonic acid esters in a number of studies [23-32], but the latter were incomplete, since they were devoted to specific problems. Carbonates are esters of carbonic acid which does not exist in a free state. Chloroformates may be regarded as esters of chloroformic or more correctly chlorocarbonic acid, because from the chemical point of view the transition from carbonic to its acid chloride is more apt than the transition from formic acid to chloroformic acid.

Depending on the relative positions of the ester $-OC(O)O-$ and silyl groups, silicon-containing carbonates (silyl carbonates) can be divided into two independent classes—compounds in which the above groups are linked directly (*O*-silyl carbonates) and organosilicon carbonates with carbofunctional substituents in which these fragments are separated by a carbon or similar bridge (*C*-silyl carbonates).

## II. COMPOUNDS WITH THE CARBONATE GROUP AT THE SILICON ATOM

### 1. Methods of Synthesis

When $SiCl_4$ reacts with ammonium and alkali metal carbonates, the products are trichlorosilanol and chlorosiloxanes and not *O*-silyl carbonates [33], for example, compounds (I)-(V):

Nor were silyl esters of carbonic acid isolated in the interaction of inorganic carbonates $M_2CO_3$ (M = Li, Na, K, Rb, or Cs) with reactive finely divided silicon [34], since the process proceeded via the following mechanism:

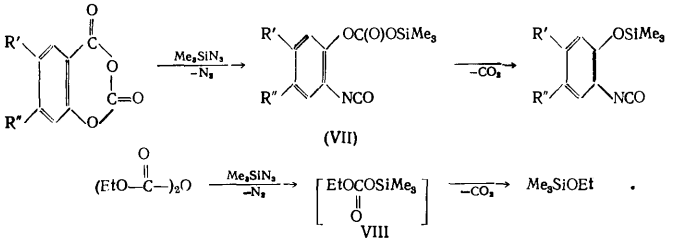
and was accompanied by oxidation-reduction side reactions:

$$2CO \rightarrow CO_2 + C \quad ,$$
$$2M + CO \rightarrow M_2O + C \quad ,$$
$$Si + 2CO \rightarrow SiO_2 + 2C \quad .$$

The formation of $(Me_3SiO)_2CO$ as a result of an electrochemical reaction was observed by Butts and Rainey [35] by chromatographic and mass-spectrometric and analytical methods. However, the product was not isolated in a pure state.

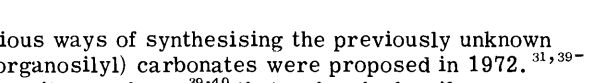
At the end of 1971, Yamamoto and Tarbell [36] were the first to synthesise mixed alkyl trimethylsilyl carbonates [36]:

$$RONa \xrightarrow{CO_2} ROC(O)ONa \xrightarrow{Me_3SiCl} \underset{(VI)}{ROC(O)OSiMe_3} \quad ;$$



R = Et, iso-Pr, n-Bu, t-Bu, or iso-$Pr_2CH$.

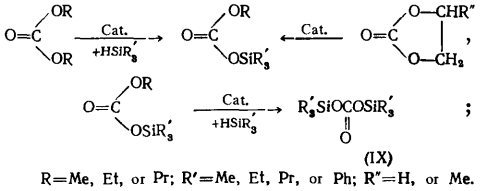
Thio-analogues of the carbonates (VI) as well as the corresponding derivatives of other Group IVB elements, for example germanium, tin, and lead, are formed when alkyl thiocarbonates of alkali metals are acted upon by $R'_3MX$: [36,37]



$$ROC(O)SM' + R'_3M{-}X \rightarrow ROC(O)SMR'_3 + M'X \quad ;$$

R = Et or t-Bu; M = Si, Ge, Sn, or Pb; M′ = K or Na; R′ = alkyl.

The asymmetric carbonates (VII) and (VIII) are unstable intermediates in the reaction of $Me_3SiN_3$ with carboxylic acid anhydrides [38]:



(VII)

VIII

Various ways of synthesising the previously unknown bis(triorganosilyl) carbonates were proposed in 1972. [31,39-42]. Thus it was shown [39,40] that, when hydrosilanes are made to react with dialkyl or alkylene carbonates in the presence of the Ni/$Et_2S$ (or $NiCl_2$/$Me_3SiSiMe_3$) catalyst [43], stepwise displacement of the organic groups by triorganosilyl groups is observed, for example:

(IX)

R=Me, Et, or Pr; R′=Me, Et, Pr, or Ph; R″=H, or Me.

Compounds of type (IX) have been synthesised [31,41,42] by combining reactions involving treatment with phosgene, carboxylation, and protection by silyl groups:

$$R_3SiOH + COCl_2 \xrightarrow[-HCl]{Et_3N} \underset{(IX)}{R_3SiOC(O)OSiR_3} \leftarrow R_3SiONa + COCl_2 \quad ,$$

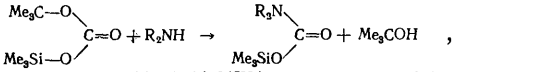
$$R_3SiONa \xrightarrow{CO_2} R_3SiOCONa \xrightarrow[-NaCl]{R_3SiCl} R_3SiOC(O)OSiR_3 \quad .$$

The last reaction served as the basis of the synthesis of *O*-silyl carbonates with different organosilyl groups [44]:

$$Et_3SiOH \xrightarrow[20°C]{NaH/THF} Et_3SiONa \xrightarrow[2.\ Me_3SiCl]{1.\ CO_2} \underset{(X)}{Et_3SiOCOSiMe_3} \quad .$$

A mixed anhydride of carbonic acid and triorganosilylcarbonic acid (XI) was obtained in the same investigation by treating $Et_3SiOC(O)ONa$ with phosgene:

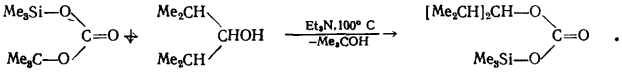
$$Et_3SiOC(O)ONa + COCl_2 \rightarrow \underset{(XI)}{Et_3SiOCOCOSiEt_3} \quad .$$



## 2. Physical Properties

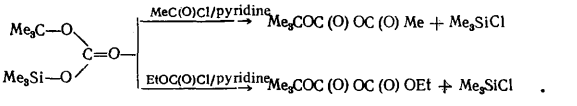
The organosilicon carbonates $R_3SiOC(O)OR'$, $R_3SiOC(O)OSiR_3$, and $R_3SiOC(O)OSiR'_3$ (where R, R′, and R″ are alkyl groups) are colourless, transparent liquids or low-melting crystalline substances which can be vacuum-distilled without decomposition. Exceptions are $(Ph_3SiO)_2CO$, which melts at 160°C, $Me_3SiOC(O)OBu$-n, which decomposes with evolution of $CO_2$, and n-$BuOSiMe_3$, which decomposes even at room temperature [31,36,39-42,44]. The infrared spectra of the carbonates $R_3SiOC(O)OR'$ have $\nu$(CO) bands in the ranges 1755–1760 and 1720–1730 $cm^{-1}$. The bands in the spectra of the compounds $R_2SiOC(O)OSiR_3$ are somewhat closer together and are located at 1705 to 1707 and 1740 $cm^{-1}$. The $(Ph_3SiO)_2CO$ spectrum has only a singlet at 1765 $cm^{-1}$. The calculated and observed molecular refractions are similar [39].

The $^1H$ NMR and mass spectra of silyl carbonates have been described [31,36,39,41,44].



## 4. Chemical Properties

It has been shown [36] that, on treatment with primary and secondary amines, the carbonate $Me_3SiOC(O)OCMe$ is converted into the corresponding silyl carbamate esters†:



$R_2$=$(CH_2)_4$; $(CH_2)_5$; $(CH_2)_2O(CH_2)_2$; Ph and H; or Ph and Me.

while on reaction with a high-boiling alcohol it is transesterified:

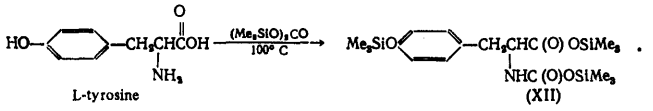
This is evidence for a greater lability of the CO–C bond compared with SiO–C.

On the other hand, treatment with MeC(O)Cl and EtOC(O)Cl results in the cleavage of the Si–O bond:

Pyrolysis of the *O*-silyl carbonates (VI) and (IX) leads to alkoxysilanes and disiloxanes respectively [44]:

$$(VI) \xrightarrow{t_1} R_3SiOR' + CO_2 \quad ,$$
$$(IX) \xrightarrow{t_2>t_1} R_3SiOSiR_3 + CO_2 \quad .$$

† Phosphorus-containing carbonates behave similarly: the C–(O)OEt bond is cleaved by ammonia in preference to the C–(O)OP bond [45]:



Hydrolysis of the carbonates (IX) in a neutral medium takes place at a moderate rate with formation of $R_3SiOH$ and $CO_2$. In the presence of inorganic acids, the process is sharply accelerated [31,39,41]:

$$(R_3SiO)_2CO + H_2O \xrightarrow[pH<7]{Me_2CO} R_3SiOH + CO_2 \quad .$$

The Grignard reaction with silyl carbonates proceeds via exactly the same mechanism as in the case of organic carbonates [46].

Bis(trimethylsilyl) carbonate behaves as a siloxycarbonylating and silylating agent on interaction with aminoacids [44]. For example, the reaction with L-tyrosine gave the tris(trimethylsiloxy)-derivative (XII):

L-tyrosine (XII)

## 4. β-Elimination Reactions

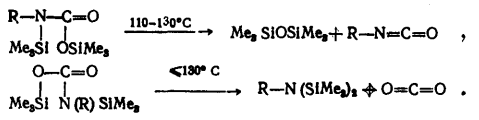
The products of the reaction of $R_3SiH$ with dialkyl or alkylene carbonates contain alkoxysilanes and disiloxanes, which are apparently formed as a result of the β-decomposition of the intermediate and final organosilicon carbonates. The decomposition of the molecules is the final result of the electron redistribution in the system of σ bonds in the structural fragment $\equiv Si-O-C(O)-X$ (where X = OR or $OSiR_3$) as a consequence of the intramolecular coordination O: $\rightarrow Si\equiv$ in the four-membered transition complex:

$$\rightarrow O=C=O + \equiv Si-X \quad .$$

In this respect organosilicon carbonates show similarities with stannyl carbonates [47-50]:

$$Bu_3Sn-OC(O)-OMe \xrightarrow{60-80° C} Bu_3Sn-OMe + O=C=O \quad ,$$
$$R_3Sn-OC(O)-OSnR_3 \xrightarrow{\sim 90° C} R_3SnOSnR_3 + O=C=O \quad ,$$

and plumbyl carbonates [48]:



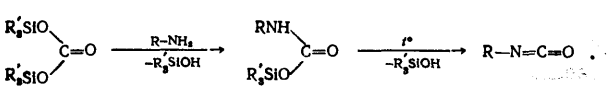
$$Ph_3Pb-OC(O)-OMe \xrightarrow{<110° C} Ph_3PbOMe + O=C=O.$$

The available data already permit the conclusion that the thermal stability of the compounds $R_3EOC(O)OR'$ and $(R_3EO)_2CO$ diminishes in series of similar compounds in the following sequence: C > Si > Sn > Pb. On the other hand, as for the compounds $\equiv Si-N(R)-C(O)-X$ (X = Cl, OR, or $OSiR_3$), [51] the thermal and chemical stability of the $R_3E-OC(O)-X$ (E = C, Si, Sn, or Pb) groups falls sharply with increasing electronegativity of X. A striking example of this is provided by the compound $Me_3C-OC(O)Cl$, which does not exist at room temperature [52-54], and by its silicon [28,31,55,56] and tin analogues, which are undoubtedly formed in the course of the following chemical reactions:

$$R_3SiCH_2CH_2OC(O)Cl \xrightarrow{C_2H_4} R_3SiOC(O)Cl \xrightarrow{-CO_2} R_3SiCl \quad ,$$
$$(R_3Sn)_2O + COCl_2 \xrightarrow{-R_3SnCl} R_3SnOC(O)Cl \xrightarrow{-CO_2} R_3SnCl \quad .$$

Qualitative observations [57-66] have also shown that the replacement of the carbonyl group in the $\equiv Si-O-C(O)-X$ unit by $CH_2$, $C(CF_3)_2$, $SO_2$, or $PO_2$‡ stabilises the molecule as a whole (for example in relation to heating). Subsequent experiments showed that $Me_3SiOC(O)OBu\text{-}n$, $Me_3SiOC(O)OEt$, and $2\text{-}NCOC_6H_4OC(O)OSiMe_3$ [38] evolve $CO_2$ close to room temperature; $Et_3SiOC(O)OAlk$ and $(Et_3SiO)_2CO$ are slowly decarboxylated during synthesis (105–130°C) and more rapidly at 150–200°C. [39] This implies that silyl carbonates are thermally less stable than silyl *NN*-dialkylcarbamates. For example, $Me_3SiOC(O)NEt_2$ can be boiled for a long time without decomposition at 177–178°C. [68]

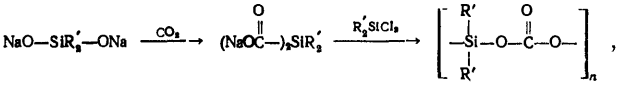
It is striking that, on passing from $Me_3SiOC(O)NEt_2$ to $Me_3SiOC(O)N(Et)SiMe_3$, [69] the tendency towards thermal decomposition increases and, of the two systems of conjugated bonds present simultaneously in the latter compound, namely $\equiv Si-OC(O)-X$ [X = $-N(Et)SiMe_3$] and $\equiv Si-N(Et)C(O)-Y$ (Y = $OSiMe_3$), the latter is the more labile:



$$R-N(SiMe_3)-C(=O)-OSiMe_3 \xrightarrow{110-130°C} Me_3SiOSiMe_3 + R-N=C=O \quad ,$$
$$R-N(SiMe_3)-C(=O)-N(R)SiMe_3 \xrightarrow{\leqslant 130° C} R-N(SiMe_3)_2 + O=C=O \quad .$$

Thus compounds with the $\equiv Si-OC(O)-X$ and $\equiv Si-NC(O)-X$ bond systems and in a more general form with $\equiv Si-O-E-X$ and $\equiv Si-N-E-X$ (where X is an electronegative group and E a Group II–VIII element) extend Nesmeyanov's classical concept concerning the unusual properties of organoelemental compounds with β-carbofunctional groups and their tendency to undergo β-elimination reactions. These properties are probably characteristic in general of organoelemental compounds with β-functional groups having the general formula $R_{n-1}M^n-E_1-E_2-X$ (where *n* is the valence of the element M and $E_1$ and $E_2$ are group II–VIII elements).

## 5. Practical Applications



As already mentioned, the silyl carbonates (VI) and (IX) can be used in the synthesis of silyl carbamate esters, aminoacid derivatives, mixed anhydrides of carboxylic and siloxy(alkoxy)carbonic acids, etc. [36] and as mild silylating agents [44], which is extremely important in the study of natural products.

In view of the simplicity with which *O*-silyl carbonates can be obtained, they may serve as a basis for a method of synthesising lower aliphatic isocyanates by a fully phosgene-free method with recycling of the silanol:

$$R'_3SiO-C(=O)-OSiR'_3 \xrightarrow[-R'_3SiOH]{R-NH_2} RNH-C(=O)-OSiR'_3 \xrightarrow[-R'_3SiOH]{t°} R-N=C=O \quad .$$

The synthesis of poly-(*O*-silyl carbonates) by the phosgene-free method,

$$NaO-SiR'_2-ONa \xrightarrow{CO_2} (NaOC(=O)-O)_2SiR'_2 \xrightarrow{R'_2SiCl_2} \left[-Si(R')_2-O-C(=O)-O-\right]_n \quad ,$$

is of theoretical interest because, owing to the ease of decarboxylation on acidification, they can be used in the manufacture of polysiloxane foam materials.

‡ The compound $Me_3SiOSeO_2Cl$ may be unstable owing to its insufficient purity. On the other hand, the stability at a high temperature of $Me_3SiOAlCl_3$ (b.p. 226–236°C) [67] and similar derivatives can be accounted for by their existence in an associated form.

## III. ORGANOSILICON CHLOROCARBONATES AND CARBONATES WITH CARBOFUNCTIONAL GROUPS

Organosilicon chlorocarbonates with carbofunctional groups are intermediates in the synthesis of silicon-containing mono-, oligo-, and poly-urethanes, a wide variety of carbonates, carbazinic acid derivatives, etc. and for this reason will be considered before carbonates.

### 1. Methods of Synthesis of Chlorocarbonates

The hydrosilylation reaction of alkenyl (alkenylaryl) chlorocarbonates is remarkable in that it makes it possible to obtain organosilicon chlorocarbonates with one, two, and three carbofunctional groups at the silicon atom, which are important for subsequent chemical reactions [28,29,31,42,70-75]

$$X_nR_{3-n}SiH + >C{=}C< — Q — OC(O)Cl \xrightarrow{Cat.} X_nR_{3-n}Si — \underset{H}{\overset{|}{C}} — \underset{|}{C} — Q — OC(O)Cl ;$$

X = Cl, OAlk, OSi≡; R = Alk, Ar; Q = alkylene or arylene; $n \leqslant 3$.

Peroxides or Speier's compounds are used as catalysts of the reaction [76]. Its disadvantage is that, in the case of the most readily available compound AllOC(O)Cl§, the addition of hydrosilanes is accompanied by vigorous evolution of $CO_2$ and propene [77-79] (see also Refs. 76, 80, 81)¶ and the greater part of the initial silane is converted into a more highly chlorinated compound.

The data on the hydrosilylation of AllOC(O)X (where X = H, Cl, OMe, or OAll) [28,29,31,42,70-75] have shown that $CO_2$ and $C_3H_6$ are not formed by the reduction of the initial or final chlorocarbonates to unstable formates [82-85] or by the addition of H—Si≡ to the C=O group of the chlorocarbonate with subsequent elimination of siloxy-derivatives via the β-decomposition mechanism. They are produced as a result of double β-decomposition of β-chlorocarbonatopropylsilanes—the products of the addition of H—Si≡ to AllOC(O)Cl in accordance with the Markovnikov rule:

$$\equiv Si — CH(Me)CH_2 — OC(O)Cl \xrightarrow[-C_3H_6]{} \equiv Si — OC(O) — Cl \xrightarrow[-CO_2]{} \equiv Si — Cl .$$

Furthermore, it has been noted that the hydrosilylation of AllOC(O)Cl is sensitive to the conditions of synthesis [31]. For example, when Speier's catalyst [t-butyl peroxide] is added to the entire reaction mass (A), the yield of the desired chlorocarbonate is low. It increases appreciably when the catalyst and a portion of the mixture of reactants is kept in contact until gas evolution ceases and then the remaining portion of the mixture (B) is added. A mixture (C) of t-butyl and dicumenyl peroxides acts even more selectively in the required direction (see Table).

The reaction of phosgene with organosilicon alcohols and phenols containing carbofunctional groups has been studied in detail since 1965. [24,29-31,42,74,75,86-96]. The reactions with alcohols and glycols proceed vigorously regardless of the position of the hydroxy-group relative to the silicon atom [29,31,42,75,87,89,92] via the mechanism

$$O\left[-\underset{Me}{\overset{Me}{\overset{|}{\underset{|}{Si}}}}-R'-OH\right]_2 \xrightarrow{COCl_2} O\left[-\underset{Me}{\overset{Me}{\overset{|}{\underset{|}{Si}}}}-R'-OC(O)Cl\right]_2 +$$

(XIII) (XIV)

$$+ Cl-\underset{Me}{\overset{Me}{\overset{|}{\underset{|}{Si}}}}-R'-OC(O)Cl + Cl-\underset{Me}{\overset{Me}{\overset{|}{\underset{|}{Si}}}}-R'-Cl ,$$

(XV) (XVI)

(a) R′=$CH_2$; (b) R′=$(CH_2)_3$; (c) R′=$(CH_2)_4$; (d) R′=$CH_2O(CH_2)_2$.

Hydrosilylation of allyl chlorocarbonate [31].

| Hydrosilane | Method of synthesis and yields of carbonates, % | | |
|---|---|---|---|
| | A | B | C |
| $Cl_2SiH$ | 23 | 62 | 60 |
| $Cl_2MeSiH$ | 24 | 46 | 51 |
| $ClMe_2SiH$ | 22 | 37 | 45 |

The appearance of products (XV) and (XVI) is due to the presence of HCl in the reaction mixture, whose removal by flushing with nitrogen or with the aid of a tertiary amine sharply suppresses side reactions and increases the yield of the required bischlorocarbonates (XIV).

In contrast to alcohols, silicon-containing phenols are inert at moderate temperatures in relation to phosgene. In order to avoid their thermal rearrangement, to phenoxysilanes [30,97] as well as other similar reactions involving the bonds formed by the silicon atom, chlorocarbonates are therefore synthesised in the presence of organic bases, for example [29-31,42,91]:

$$HMe_2SiC_6H_4OH + COCl_2 \xrightarrow[-HCl]{EtN} HMe_2SiC_6H_4OC(O)Cl ,$$

(XVII)

$$\left[X-C_6H_3(OH)-R-\underset{Me}{\overset{Me}{\overset{|}{\underset{|}{Si}}}}-\right]_2O \xrightarrow[-R_3N\cdot HCl]{COCl_2/R_3N} \left[X-C_6H_3(OC(O)Cl)-R-\underset{Me}{\overset{Me}{\overset{|}{\underset{|}{Si}}}}-\right]_2O ;$$

(XVIII) (XIX)

(a) R = single bond and X = H; (b) R = $CH_2O$ and X = Cl; (c) R = $(CH_2)_3$ and X = H.

Treatment of silyl ethers derived from silicon-containing alcohols and phenols with phosgene is in many cases preferable on a preparative scale to the direct reactions of phosgene with the alcohols and phenols discussed above.

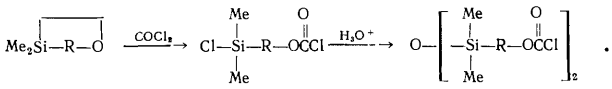
Firstly, when the reaction comes to an end, the reaction mixture does not contain the corrosive HCl, instead of which $Me_3SiCl$, which can be readily removed and which does not cleave the ≡Si—O—Si≡ and ≡Si—O—C≡ bonds, is formed, for example [29-31,86,88,90,91,94,95]:

$$O\left[-\underset{Me}{\overset{Me}{\overset{|}{\underset{|}{Si}}}}-(CH_2)_nOSiMe_3\right]_2 \xrightarrow[20-25^\circ C]{COCl_2} O\left[-\underset{Me}{\overset{Me}{\overset{|}{\underset{|}{Si}}}}-(CH_2)_nOC(O)Cl\right]_2$$

(XIV)

$n$=1,3.

Secondly, the advantage of this method compared with the treatment of phenols with phosgene in the presence of HCl acceptors is that the formation of both carbonates and



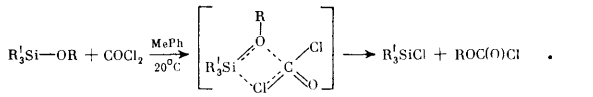
§ Here and henceforth All = allyl.

¶ The evolution of propene during the addition of hydrosilanes to various allyloxy-derivatives was frequently noted also in earlier studies [77-79] and has been described in reviews of the hydrosilylation reaction [76,80,81].

alkylchlorosilanes under the influence of tertiary amines is fully ruled out.

Thirdly, the reaction of $COCl_2$ with alkoxy(alkenoxy, alkynoxy)silanes makes it possible to obtain purely organic chlorocarbonates without HCl, which must usually be removed by special procedures.

The complex (owing to the reversibility of the reaction at high temperatures) stage involving the isolation of organosilicon glycols with carbofunctional substituents (XIII, a–c), (XVIII, b and c), etc. (which are diffiult to obtain in a pure state) during their synthesis from the corresponding silyl ethers (XXI)–(XXIV)†, namely $[-(CH_2)_mOSiMe_2-]_n$ [XXI: (a) $m = 3$, $n = 1$; (b) $m = 4$, $n = 1$; (c) $m = 5$, $n = 1$; (d) $m = 3$, $n \simeq 7-9$; (e) $m = 1$, $n = 2$], $o$-$C_6H_4OCH_2SiMeO$ (XIII), $o$-$C_6H_4(CH_2)_3SiMe_2O$ (XXIII), $o$-$C_6H_4(CH_2)_3SiPh_2O$ (XXIV), etc. is frequently eliminated, because bischloroformates of the disiloxane series can be obtained on a preparative scale by a simpler method involving a combination of the treatment of silyl ethers with phosgene with subsequent hydrolysis of the intermediate monochloroformates:



In this connection, it became necessary to investigate in detail the reactivity of the Si–O bonds in various silyl ethers—potential sources of mono- and bis-chloroformates in reactions with phosgene and chloroformates. The reactivity of Si–O bonds in reactions with phosgene depends on many factors and varies within wide limits [31,94]. Thus $Me_3Si$ derivatives of aliphatic alcohols demonstrate a decrease of reactivity: (a) in parallel with the increase in the bulk of the alkyl group: $Me_3SiOMe > Me_3SiOEt \gg Me_3SiOPr\text{-}n > Me_3SiOBu\text{-}n$; (b) on passing to alcohols with a branched structure and to a greater extent the closer the branched site to the reaction centre and the greater the degree of branching: $Me_3SiOPr\text{-}n > Me_3SiOPr\text{-}iso > Me_3SiOcyclohexyl$; $Me_3SiOBu\text{-}n > Me_3SiOBu\text{-}iso > Me_3SiOBu\text{-}s > Me_3SiOBu\text{-}t$.

In the series of trimethylsilyl ether of unsaturated alcohols, the rate of reaction is lower the greater the degree of unsaturation (a): $Me_3SiOPr\text{-}n > Me_3SiOCH_2CH{=}CH_2 > Me_3SiOCH_2C{\equiv}CH$, $Me_3SiOcyclohexyl > Me_3SiOPh$, and the greater the length and degree of branching of the group (b): $Me_3SiOCH_2CH{=}CH_2 > Me_3SiOCH_2CH{=}CHPh > Me_3SiOCH_2C(CH_3){=}CH_2$.

By varying the substituents at the silicon atom, the reactivity of the molecule can also be altered: $CH_2{=}CHCH_2OSiMe_3 > CH_2{=}CH_2CH_2OSiMe_2H$, $MeOSiMe_3 > MeOSiMe_2CH_2Cl$, $Me_3SiOMe > Et_3SiOMe$. Despite the bulky substituents attached to the metal atom, the methoxy-derivatives $Et_3GeOMe$ and $n\text{-}Bu_3SnOMe$ react exothermically with $COCl_2$ and much faster than $Me_3SiOMe$. Conversely, $Me_3SiOCMe_3$ and $Me_3SiOSiMe_3$, as well as certain other disiloxanes vigorously absorb and retain $COCl_2$, but remain unchanged even on heating [31,94,135]. $Me_3SiOMe$ and $Me_3SiOPh$ are resistant to the action of $COF_2$ (at 20°C). [55]

† The principal methods for the synthesis of organosilicon alcohols, phenols, silaoxacycloalkanes, etc. can be found in the following publications (including the attached bibliographies): (a) alcohols [26,27,29–31,98–114]; (b) phenols [29–31,110,114]; (c) silaoxacycloalkanes [29–31,113–115].

The nucleophilic substitution of the alkoxy-group in the silanes $R^1_3SiOR$ in a non-polar medium evidently proceeds via an $S_Ni\text{–}Si$ mechanism with formation of a quasi-cyclic transition complex [136]:

Other conditions being equal, the rate of reaction is therefore determined by the nucleophilic properties of $ROSiR^1_3$, which are in this case determined by the overall influence of the inductive and steric effects of the substituents R and R′ and the effect of the ($p$-$d$) $\pi$-dative interaction via the Si–O bond [137]. Acyloxytrimethylsilanes, where, in contrast to $AlkOSiMe_3$, the lone $p$ electrons of the oxygen atom are involved also in the reverse coordination to the carbonyl oxygen atom: $\equiv Si \leftarrow O\text{—}C(O)R$, therefore exhibit a reduced reactivity. Furthermore, the introduction of electronegative substituents at the silicon atom or the carbonyl group reduces the reactivity of the molecule towards phosgene to an even greater extent [31,94]. For example, acetoxytrimethylsilane reacts faster than $ClCH_2Me_2SiOC(O)Me$, which is in its turn more reactive than $Me_3SiOC(O)CF_3$.

The retardation of the reaction with phosgene on passing from alkoxy- to acyloxy-derivatives can also be followed for germanium and tin compounds, while for acetates of the type $R_3EOC(O)Me$ the rate decreases in the following sequence as a function of E: Sn > Ge > Si [31,94].

The above regularities hold also on treating with phosgene compounds having endocyclic Si–O bonds, although the reaction as a whole acquires a number of new specific features [31]. The main characteristic of such a reaction is that the product of the insertion of $COCl_2$ accompanied by ring opening is formed. The rate of reaction is determined by the size of the heterocycle and the nature of its constituent structural elements. For example [28–31], in the series of silaoxacycloalkanes $Me_2Si(CH_2)_nO$ the rate of ring opening decreases sharply with increase of $n$: compound (XXIa) ($n = 3$) reacts vigorously even in the cold; although the ring of silaoxacyclohexane (XXIa) ($n = 4$) opens spontaneously, the rate of this process at room temperature is low:

$$Me_2Si(CH_2)_nO + COCl_2 \rightarrow ClMe_2Si(CH_2)_nOC(O)Cl \quad ; \quad n \geqslant 3 \ .$$

The oligomeric macrocyclic product (XXId) ($m = 3$, $n \simeq 7-9$) does not react with $COCl_2$ even at 150°C and only in the presence of catalytic amounts of $ZnCl_2$, $AlCl_3$, $FeCl_3$, etc. is it possible to convert it at 100–130°C into the corresponding chlorocarbonate (XVb), but in a low yield (18%). On the other hand, treatment of the products of the thermal depolymerisation of the oligomer (XXId) with phosgene in the presence of $ZnCl_2$ made it possible to increase the yield of the chlorocarbonate to 60%.

However, catalysts of the type of Lewis acids also have a side effect—they initiate the decomposition of the desired chlorocarbonates to alkyl chlorides. Another group of initiators, whose action is based on the cleavage of the Si–O bonds with formation of a free HO group, was therefore proposed [31,88]: treatment of the HO group with phosgene is accompanied by the evolution of HCl, which maintains the reaction. Inorganic acids or hydroxylated organic compounds are used as initiators of this kind.

The decrease of the reactivity of silaoxacycloalkanes in the sequence (XXId) > (XXIa) > (XXIII) ≫ (XXII) > (XXIII) is caused, as in the case of linear silyl ethers, by the reduced nucleophilic properties of the O atom in the siloxy-group. This happens, for example, on passing from compound (XXIe) to (XXIa), eliminating the influence of the *p* electrons of the second oxygen atom, which competes with the conversion of the Si—O linkage into a double bond. For compounds (XXIII) and (XXIV), the cause is different—the involvement of the *p* electrons of the oxygen atom in conjugation with the aromatic ring. The simultaneous presence in the molecule of compound (XXII) of the epoxy- and siloxyaryl groups or the combination in compound (XXIV) of the $SiOC_{Ar}$ fragment with the bulky phenyl substituents at the silicon atom retard sharply the reactions with $COCl_2$.

Thus the reaction of phosgene with silyl ethers, which are intermediates in the synthesis of glycols and bisphenols of the siloxane series, is of preparative value for derivatives of alcohol and is of limited value in the case of a compound with a $Si-OC_{Ar}$ linkage.

The reaction of phosgene with epoxysilanes is of interest as an independent method for the synthesis of organosilicon chlorocarbonates[71]:

$$\equiv Si(CH_2)_3OCH\!-\!CH_2 + COCl_2 \rightarrow \equiv Si(CH_2)_3OCH(Cl)CH_2OC(O)Cl \quad ,$$

a distinctive feature of which is the complete absence of side products.

## 2. Methods of Synthesis of Carbonates

The hydrosilylation of alkenyl carbonates is used to obtain monomeric, oligomeric, and polymeric products containing simultaneously the carbonate and organosilyl groups[29,31,138–145]. The reaction was described for the first time by Haluska in 1976:[138,141,143,144]

$$ROC(O)OA \xrightarrow[H_2PtCl_6]{} \begin{cases} \xrightarrow{HSiR'_nX_{3-n}} ROC(O)OR''SiR'_nX_{3-n} \\ \xrightarrow{HSi(R'_n)O_{(3-n)/2}} ROC(O)OR''Si(R'_n)O_{(3-n)/2} \end{cases} ;$$

R = Alk or Ar; A = alkenyl, $n$ = 1-3; X=OC(O)Me, $NMe_2$, ON=$CMe_2$ etc.

However, since the course of the reaction is treated as unambiguous even in those cases where the initial compounds contain functional groups chemically reactive relative to one another, for example:

$$\equiv Si-H + HOSi \equiv \rightarrow H_2 + \equiv SiOSi \equiv \quad ,$$
$$\equiv Si-H + CH_2=CHSi \equiv \rightarrow \equiv SiCH_2CH_2Si \equiv \quad .$$

the above scheme cannot be regarded as correct. It has been shown[31,145] that the formation of equimolar amounts of $CO_2$, $C_3H_6$, and the corresponding methoxysilanes in addition to $\gamma$-adducts (40–60%) is observed in the hydrosilylation of AllOC(O)OMe. Such proportions of the products of the accompanying reactions have been interpreted as evidence for the formation of unstable $\beta$-adducts, which decompose via a double $\beta$-decomposition mechanism:

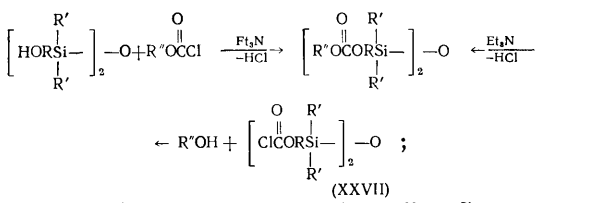
$$\begin{matrix} O\!-\!Me \\ | \\ O\!=\!C \\ | \\ O\!-\!All \end{matrix} \xrightarrow[H_2PtCl_6]{R_nCl_{3-n}SiH} \begin{cases} \longrightarrow MeOC(O)OCH_2CH_2(Me)Si \equiv \xrightarrow[2.\ -CO_2]{1.\ -C_3H_6} MeOSi \equiv \\ \longrightarrow MeOC(O)O(CH_2)_3Si \equiv \end{cases}$$

R=Me, Et, or Ph; $n$ = 0 — 3.

Tetramethyldisiloxane and AllOC(O)X (where X = OMe or H) react stepwise via both Si—H bonds, the main and side reactions leading respectively to symetrically and asymmetrically substituted disiloxanes:

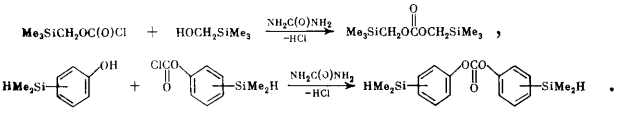
$$O\!-\!\left[\begin{matrix} Me \\ | \\ -Si(CH_2)_3OC(O)X \\ | \\ Me \end{matrix}\right]_2 \qquad \begin{matrix} Me\ Me \\ | \quad | \\ X\!-\!SiOSi(CH_2)_3OC(O)X \\ | \quad | \\ Me\ Me \end{matrix} .$$

A general feature of the hydrosilylation of the allyl ethers AllOC(O)X (where X = H, OMe, OAll, or Cl) by hydrosilanes of the same type is a decrease of the fraction of side products as a function of the nature of the group X in the sequence Cl > OMe > H > OAll. For example, diallyl carbonate reacts with hydrosilanes like AllOC(O)OMe, but the liberation of gaseous products in side reactions is observed to a lesser extent, the yield of product (XXV) increasing with increase of $n$ from 56 to 76%:[31,145]



$$Cl_nMe_{3-n}SiH + (AllO)_2CO \rightarrow [Cl_nMe_{3-n}Si(CH_2)_3O]_2CO \quad ; \quad n=1-3 \ .$$
(XXV)

On the other hand, the yield of reaction products diminishes for each AllOC(O)X on passing from $Cl_3SiH$ ($n$ = 3) to less chlorinated hydrosilanes. The tendency towards a decrease of the yield of silyl carbonates with accumulation of alkyl radicals in the initial silane is manifested most clearly by $Et_3SiH$: approximately 14% of the hydrosilane is consumed in the formation of the main product, while the remainder is involved in side reactions with formation of $\beta$-adducts, detected as the products of their $\beta$-decomposition, for example, $Et_3SiOSiEt_3$ and $Et_3Si(CH_2)_3OSiEt_3$.[31,145] Theoretically, these compounds might be formed together with $CO_2$ and propene via the mechanism of the reaction of hydrosilanes and organic carbonates discussed above[39,40]. However, experiments failed to confirm this hypothesis, because the reaction products do not contain $Et_3SiPr$-n and $Et_2SiPr$-iso, which should have been inevitably formed together with the main products.



Treatment of organosilicon alcohols and phenols with phosgene leads to symmetrical carbonates if the process does not stop at the stage involving the formation of chlorocarbonates (see Section III, 1). In view of the difficulty of replacing the second chlorine atom in phosgene by an ester group, the reaction is carried out in the presence of organic bases[29–31,42,92,146], for example:

$$HMe_2SiC_6H_4OH + COCl_2 \xrightarrow{Et_3N} (HMe_2SiC_6H_4O)_2C=O \quad .$$
(XXVI)

The reactions of chloroformates with alcohols and phenols lead to symmetrical and asymmetric carbonates with the silicon atom in one or both organic groups [34,138,141,143,144,147-150], for example:

$R=(CH_2)_3$, $(CH_2)_4$, or $(CH_2)_3OCH_2CH(Me)$; $R'=Me$ or Ph; $R''=Me$, n-Bu, $Cl_3C$, or All.

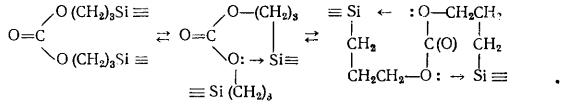
The heterofunctional condensation reaction with participation of siloxy-derivatives and chlorocarbonates makes it possible to obtain organic and organosilicon carbonates and polycarbonates [31,42,55,95]. Compared with phosgene, aliphatic and aromatic chlorocarbonates are less reactive in relation to silyl ethers derived from alcohols and phenols. The reaction proceeds at an appreciable rate only at a temperature of the order of 120–220°C even for alkoxytrimethylsilanes which are most readily cleaved by phosgene:

$$\equiv Si{-}OR + ClC(O)OR' \xrightarrow{t} \equiv Si{-}Cl + ROC(O)OR' .$$

As in the case of $COCl_2$, the $\equiv Si{-}OC_{Ar}$ bond is less reactive than $\equiv Si{-}OC_{Alk}$. On the other hand, the surprising inertness of 1,3-bis(trimethylsiloxymethyl)-1,1,3,3-tetramethyldisiloxane in relation to the bischlorocarbonates (XIVa) and (XIVb) may be a consequence of the steric effect of the $Me_3Si$ group and the stronger $(p\text{-}d)$ $\pi$-interaction via the linkage

$$Me_3Si\overset{\curvearrowleft}{-}O,$$

due to the influence of the second organosilyl group, which usually increases the electron density at the heteroatom in the $\alpha$-position [114].



It is of interest that fluorocarbonates are more reactive than chlorocarbonates [55]: ROC(O)F (R = Et, n-Pr, or n-Bu) reacts with $Me_nSi(OR)_{4-n}$ ($n$ = 2, 3) even at 0–20°C with formation of the corresponding carbonates [55].

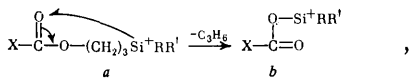
## 3. The Properties of Organosilicon Chlorocarbonates and Carbonates with Carbofunctional Groups

The available data on the chemical reactions of organosilicon chlorocarbonates and carbonates with carbofunctional groups and their physicochemical properties are fairly extensive and have already been partly surveyed [31]. They make it possible to isolate a number of properties distinguishing this group of compounds from their purely organic analogues.

(a) Infrared spectra. The $\nu(CO)$ band in the infrared spectra of chlorocarbonates and acetates is located respectively in the ranges 1775–1783 and 1739–1786 $cm^{-1}$. The absorption by the carbonyl group in the formates $R_2Si(CH_2)_3OC(O)H$, where $R_3Si$ = $Cl_3Si$, $Cl_2MeSi$, $ClMe_2Si$, $Et_3Si$, $PhCl_2Si$, $(EtO)_3Si$, or $HC(O)OSiMe_3-OSiMe_2$, and in the carbonates $R_3Si(CH_2)_3OC(O)OMe$ and $R_3Si(CH_2)_3OC(O)O(CH_2)_3SiR_3$, where $R_3Si$ = $Cl_3Si$, $Cl_2MeSi$, $ClMe_2Si$, $Et_3Si$, $Cl_2PhSi$, $(EtO)_3Si$, $Me_2(MeO)Si$, or $Ph(EtO)_2Si$, is constant for each series and almost independent of the substituents at the silicon atom: the absorption band in the spectra of the formates is located in the range 1720–1722 $cm^{-1}$ and that in the spectra of the carbonates is in the range 1748–1752 $cm^{-1}$. Comparison showed that, in the series of compounds $\equiv Si(CH_2)_3OC(O)H$, $\equiv Si(CH_2)_3OC(O)OMe$, and $\equiv Si(CH_2)_3OC(O)Cl$, the absorption band is displaced towards shorter wavelengths with increasing electronegativity of the substituent at the carbonyl carbon atom (Cl > OMe > H).

The appearance of a doublet in the region of the $\nu(CO)$ absorption in the spectra of the dicarbonates may be caused by reversible intramolecular coordination:

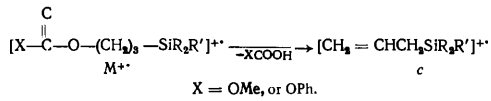
(b) $^1H$ NMR spectra. Analysis of the integrated spectra for the stable forms of organosilicon chlorocarbonates, carbonates, formates, and intermediate acetates having the general formula $Cl_nMe_{3-n}SiC_3H_6OC(O)X$ (X = H, Cl, OR, or Me), synthesised in different ways, confirms the structure with the trimethylene bridge between the silicon atom and the functional group [28,31,72,73,145].



The deshielding influence of the silyl group is a maximum for Si-methylene protons, decreasing with increase of the number of alkyl groups at the silicon atom and decaying rapidly along the chain. The influence of the nature of the substituent X on the $\equiv SiCH_2$ group varies unambiguously both on passing from formates to carbonates and chlorocarbonates for the same silyl substituent and when the silyl group $ClMe_2Si$ is replaced by $Cl_2MeSi$ and $Cl_3Si$ keeping X unchanged. For the protons of the $\beta$- and $\gamma$-methylene groups, the influence of the silyl and X groups is more complex.

Comparison of the chemical shifts of the protons in the $(CH_2)_3$ group in the series of carbonates $(Cl_nMe_{3-n}SiCH_2CH_2O)_2CO$ shows that, on passing from asymmetric to symmetrical carbonates, the deshielding influence of similar silyl groups on the protons in the $\alpha$- and $\beta$-positions relative to the silicon atom diminishes. A decrease is also observed in the degree of deshielding of the $\beta$-protons, the deshielding differing appreciably from the approximately constant value for mono-, di-, and tri-chlorosilyl derivatives of asymmetric carbonates. On the other hand, the tendency towards a decrease of the degree of partial dissociation of $\gamma$-protons in the series of $ClMe_2Si$-, $Cl_2MeSi$-, and $Cl_3Si$-substituted asymmetric carbonates is replaced by the opposite tendency for the symmetrical analogues.

(c) Mass spectra‡. The following features were observed in the study of the mass spectra of the organosilicon formates $R'R_2SiCH_2CH_2CH_2OC(O)H$ [where $R'R_2Si$ = $Me_2ClSi$, $MeCl_2Si$, $Cl_3Si$, $PhCl_2Si$, $(EtO)_3Si$, $Et_3Si$, etc.]

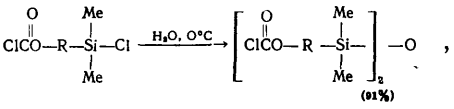


‡ For a comparison of the mass spectra of organic carbonates, see Brown and Gunther [152].

and methylorganosilyl carbonates of the type $R'R_2Si(CH_2)_3.OC(O)OMe$ [where $R'R_2Si = Cl_3Si$, $MeCl_2Si$, $Me_2ClSi$, $(EtO)_3Si$, $Et_3Si$, $MeOMe_2Si$, etc.][31,151]: (a) there are no molecular ion peaks; (b) the peak of the $Si^+R_2R'$ ion has the maximum intensity in all cases, except for the formate with the $(EtO)_3Si$ substituent. The intensities of the $a(M-R)^+$ and $a'(M-R')^+$ ions are low. These ions are sometimes altogether absent. However, the $b(a-C_3H_6)$ and $b'(a'-C_3H_6)$ ions formed via the mechanism

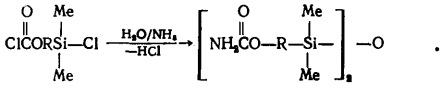
were always observed. This is the mechanism of the rearrangement of trimethylsilylcarboxylic acid esters and chlorides[153,154].

A second characteristic pathway in the decomposition of organosilylcarbonates under the influence of electron impact involves the loss of X–COOH molecules and the formation of the ions c:



X = OMe, or OPh.

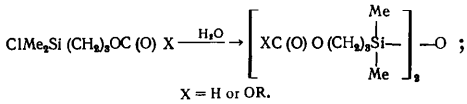
The relative contribution of the decomposition to the ion b or the ion c depends on the nature of the substituents at the silicon atom: with increase of the number of Cl atoms, the contribution of the pathway leading to the ion a increases.



The mass spectrum of $(Me_3SiCH_2O)_2CO$ contains peaks due to the molecular ion with $m/e$ 234 and the $(M-CH_3)$ ion typical for $Me_2Si$ derivatives with $m/e$ 219.

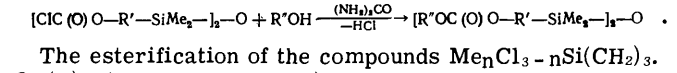
(d) Chemical properties. Organosilicon chlorocarbonates and carbonates may react via the C- and Si-functional centres both separately and simultaneously. Thus hydrolysis of the chlorocarbonates $ClMe_2SiROC(O)Cl$ by ice water leads to the corresponding bischlorocarbonates[28,31,42,86]:

(91%)



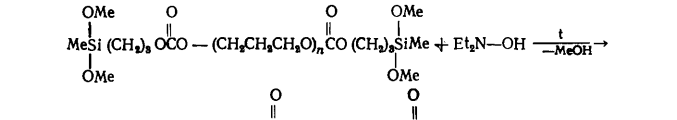
while treatment with aqueous ammonia converts them into the corresponding biscarbamates[28,31,42,75,86,89]:

The latter reaction actually constitutes the specific synthesis of organosilicon carbamates and biscarbamates, which Fessenden and Coon[148,149] obtained by the ammonolysis of the corresponding carbonates and biscarbonates:



Formates and carbonates are hydrolysed similarly to chlorocarbonates[31,72,145]:

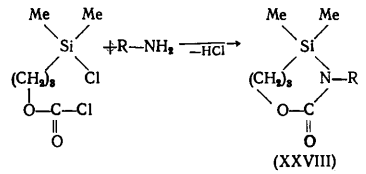
X = H or OR.



Chlorocarbonates and bischlorocarbonates react with alcohols and phenols to form carbonates and biscarbonates[29–31,91]:

The esterification of the compounds $Me_nCl_{3-n}Si(CH_2)_3.OC(O)X$ (X = H, Cl, or OR) is accompanied by heterofunctional condensation[31,145] via Si–Cl and Si–OR bonds, for example§:

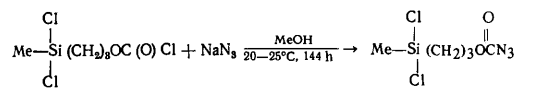
When $Me(MeO)_2Si$-substituted polyoxyalkylene dicarbonates are treated with *NN*-dialkylhydroxylamines, methanol is displaced[140]:



In the presence of toluene-*p*-sulphonic acid or acid ion-exchange resins, organosilicon carbonates are transesterified by the excess methanol, like the acetates and formates[31,72], for example:

X = H, OMe, OAll.

Mono- and bis-chlorocarbonates react with ammonia and organic amines to form carbamates, for example:[28,30,42,89,92,155]



(XXVIII)

Bischlorocarbonates react with hydrazine, aliphatic dihydrazines, acylhydrazines, and diamines in the presence of HCl acceptors to form oligourethanes[31,32,156–160]. It is more convenient to *N*-silylate polyamines in this reaction¶, since the necessity for the removal of corrosive hydrogen chloride and ammonium salts is then obviated[31,32,157].

A similar principle holds in the synthesis of carbonates and polycarbonates, where it proved more convenient to use the silyl ethers derived from alcohols and phenols (rather than the latter themselves) in the reaction with chloroformates[31,96,164] (see below) and in the synthesis of oligosiloxanes with terminal anhydride groups[27], for example from trimellitic acid chloride.

Chlorocarbonates react with alkali metal azides to form the corresponding azidocarbonates[70,71]:

§ Disiloxane may also be formed owing to the presence of $H_2O$ formed by the reaction MOH + HCl → MCl + $H_2O$.

¶ The reactivity of the Si–N bonds in various aminosilanes in relation to organic chlorocarbonates has been studied[161,162].

In the presence of an organic base, t-BuOOH esterifies chlorocarbonates like alcohols [165]:

$$(MeO)_3Si(CH_2)_3OC(O)Cl + HOOBu\text{-}t \xrightarrow[0°,\ 3\ h]{Py,\ Et_2O} (MeO)_3Si(CH_2)_3OC(O)OOBu\text{-}t.$$

The specific synthesis of this peroxide consists in the hydrosilylation of AllOC(O)OOBu-t in the presence of Speier's catalyst [165]:

$$(MeO)_3SiH + CH_2=CHCH_2OC(O)OOBu\text{-}t \xrightarrow[3\ h]{50°C} (MeO)_3Si(CH_2)_3OC(O)OOBu\text{-}t.$$

Bis(organosilylalkyl)-substituted percarbonates have been synthesised from organosilicon chlorocarbonates and hydrogen peroxide [166]:

$$(MeO)_3Si(CH_2)_3OCCl + HOOH \xrightarrow[10°C]{Py} (MeO)_3Si(CH_2)_3OC(O)OO(O)C(CH_2)_3Si(OMe)_3 .$$

The chlorocarbonate $Me_3Si(CH_2)_3OC(O)Cl$ and its organic analogues [167] can be converted into the corresponding aldehydes [31,95]:

$$Me_3Si(CH_2)_3OCCl \xrightarrow{DMSO} \left[Me_3Si(CH_2)_2CH_2-O-C(=O)-S(Me)(Me)\right]Cl^- \xrightarrow[CO_2]{Et_3N} Me_3Si(CH_2)_2C(O)H.$$

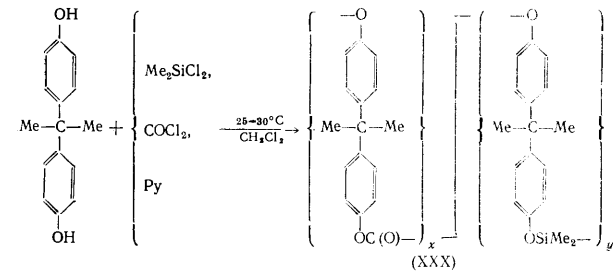
However, the sulphoxonium salt derived from $Me_3SiCH_2OC(O)Cl$ forms $ClCH_2SiMe_3$, which is probably due to the enhanced basicity of the oxygen atom in the $\alpha$-position relative to the $Me_3Si$ group:

$$\left[Me_3SiCH_2-O-C(=O)-S(Me)(Me)\right]Cl^- \xrightarrow[-CO_2]{Et_3N} [Me_3SiCH_2OSMe_2]Cl^- \xrightarrow[-Me_2SO]{} Me_3SiCH_2Cl .$$

It is also extremely significant that the steric effect of the $Me_3Si$ group prevents the abstraction of a proton under the influence of $Et_3N$.

(e) Practical importance. It is seen from the foregoing that chlorocarbonates are used to synthesise mono- and bis-carbonates, mono- and bis-carbamates, mono- and bischlorocarbonates, azidocarbonates, organosilicon peroxides, alcohols, diols, aldehydes, heterocyclic compounds, etc. Bischlorocarbonates serve as the basis for the synthesis of silicon-containing polyurethanes and polycarbonates. Positive results have been obtained when carbonates and formates were used as vulcanising agents in the cold hardening of silicon rubbers [31]. Polysiloxanes with carbonatoalkyl(aryl) substituents in the side chains, at the ends of the chains, or in the main polymer chain are obtained from mono- and bis-carbonates with hydrolysable groups at the silicon atom.

All these examples of the practical employment of carbonates are considered in detail in Sections IV and V.

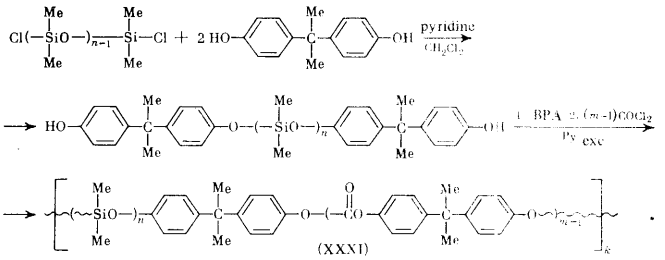


## IV. SILICON-CONTAINING POLYCARBONATES

The overall group of silicon-containing polycarbonates (SCPC) includes statistical copolymers, block copolymers, and other compositions.

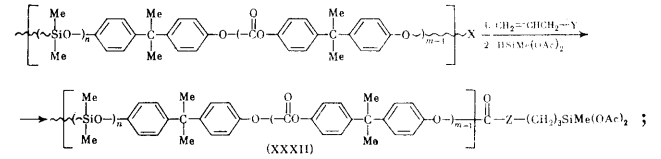
### 1. Methods of Synthesis

The SCPC are obtained by treatment with phosgene, transesterification, hydrosilylation, radical polymerisation, and other methods.



(a) Treatment with phosgene. Two procedures have been proposed for the synthesis of SCPC: firstly, by replacing parts of the phosgene in the treatment of bisphenol A (BPA) with the latter in pyridine by dichlorodimethylsilane (DCDMS), copolymers (CPL) containing bisphenol-carbonate and bisphenol-siloxy-groups were obtained [168-170] (Goldberg's method):

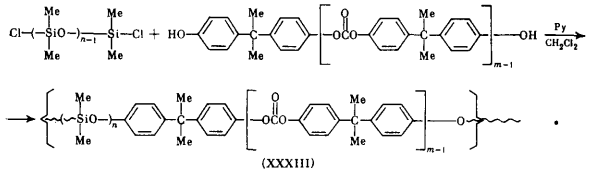
(XXX)



In the second version of the synthesis, an oligocarbonate with $\alpha\omega$-hydroxy-groups is obtained and made to react with DCDMS in the presence of pyridine [168]. When $Me_3SiCl$ is present in the reaction mixture, organic polycarbonates with terminal $Me_3SiO$ groups are obtained [171].

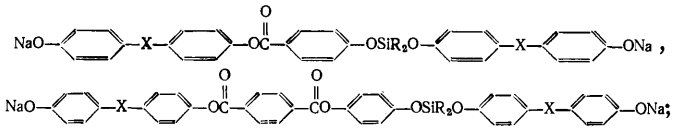
However, these procedures have found only limited applications [172-175] and were subsequently modified [176-203]. Siloxane-carbonate block copolymers, used to make gas-separating membranes, have now been synthesised by the modified method. The modification involves the replacement of DCDMS by an oligosiloxane with terminal Si–Cl bonds (Vaughn's method), which makes it possible to obtain a copolymer with a predetermined content of siloxane blocks whose size is known beforehand [176,180,188,195]:

(XXXI)



A logical development of this research was a method for the synthesis of block copolymers of type (XXXI) with terminal hydroxy (in the presence of an excess of BPA) or chlorocarbonate (in the presence of an excess of $COCl_2$) groups. After treatment with AllNCO in the former case and with AllOH or allylphenol in the latter, the products are forepolymers capable respectively of being hardened either directly or after hydrosilylation, for example with diacetoxymethylsilane [177,178,184,185,187]:

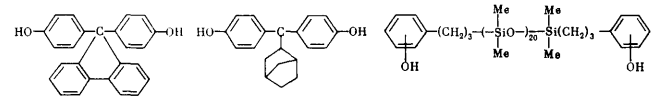
(XXXII)



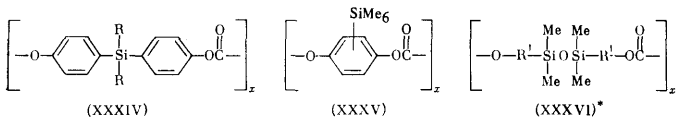
(a) X = OH, Y = NCO, Z = NH; (b) X = C(O)Cl, Y = OH, Z = O .

A variety of this method consists in the copolycondensation of a $\alpha\omega$-dichloropolydimethylsiloxane oligomer with a BPA-carbonate oligomer[197]:

(XXXIII)



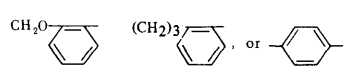
The synthesis of SCPC by treating aryloxysilanes of the type



R = Alk or Ar; X=S, O, SO, $SO_2$ etc.

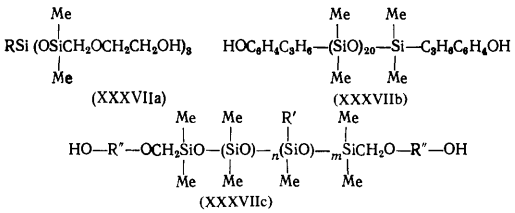
with phosgene has been reported[204].

In the vast majority of studies, BPA or tetrachloro-BPA is used as the bisphenol in the synthesis of SCPC by the above method, while hydrogen chloride is bound by pyridine. The compounds



etc. have been recently proposed[186,205] as the dihydroxy-compounds and pyridine has been replaced by $NH_3$ [182] or alkali metal hydroxides[181]. Dichloromethane is a generally used solvent in the stage involving treatment with phosgene. The copolymers are obtained in a pure form by precipitation from solutions with lower alcohols. In all the studies enumerated, polymers were obtained with an Si–OAr bond susceptible to hydrolysis. In order to eliminate this disadvantage, a study was made of the treatment with phosgene of organosilicon diols and bisphenols containing carbofunctional groups and a fundamentally new set of SCPC [(XXXIV),[206,207] (XXXV),[208] and (XXXVI)[31,96,116,209]] was obtained:

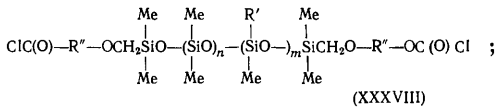
(XXXIV) (XXXV) (XXXVI)*



R = Me or Et; R' = $(CH_2)$, $(CH_2)_3$, $CH_2O(CH_2)_2$, $CH_2S(CH_2)_3$,

Apart from the direct treatment of dihydroxy-derivatives with phosgene, modified syntheses of SCPC have been carried out: (a) with partial replacement of the silicon-containing diol or bisphenol by BPA or 1,1-bis-(4-hydroxyphenyl)-cyclohexane (BHPC),[31,96] (b) with partial replacement of $COCl_2$ by silicon-containing bischlorocarbonates with carbofunctional groups[31,96], and finally (c) with complete replacement of $COCl_2$ by a mixture of organic and organosilicon bischlorocarbonates† [164,210].

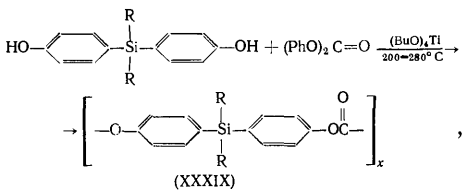
† Dihydroxy-derivatives with R = $CH_2O(CH_2)_2$, $CH_2S(CH_2)_3$, $CH_2O-C_6H_4$, etc. are considered in this section in view of the similarity of their properties with organosilicon diols and bisphenols containing other carbofunctional groups.



In many cases, oligosiloxanes containing hydroxyalkyl and hydroxyaryl substituents at the silicon atom are used in order to increase the content of siloxy-units in the SCPC:[23-27,164,187,205,211]

(XXXVIIa) (XXXVIIb)

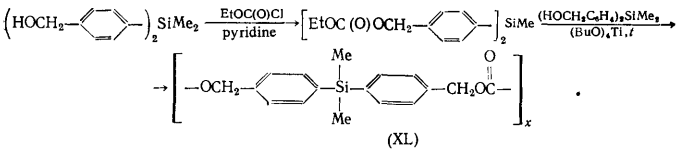
(XXXVIIc)



or the corresponding bischlorocarbonates (XXXVIII) are employed, for example[164,210]:

(XXXVIII)

a) R=Me, $m = 0$, $n = 10$; (b) R = vinyl, $n = 6$, $m = 2$;
(c) R=Me, $n = 56$, $m = 0$; (R'' = $-CH_2OCH_2CH_2-$) throughout.

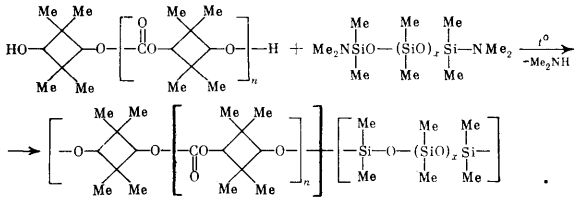


(b) Esterification, hydrolytic, etc. reactions. SCPC are obtained by the transesterification of organic carbonates[206,207] by organosilicon dihydroxy-compounds:

(XXXIX)

where R = Me or Et.

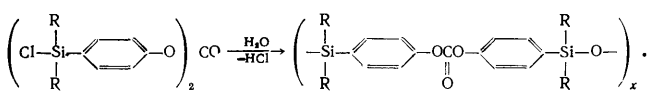
It has been shown[150] that silicon may be present in both initial reactants:



(XL)

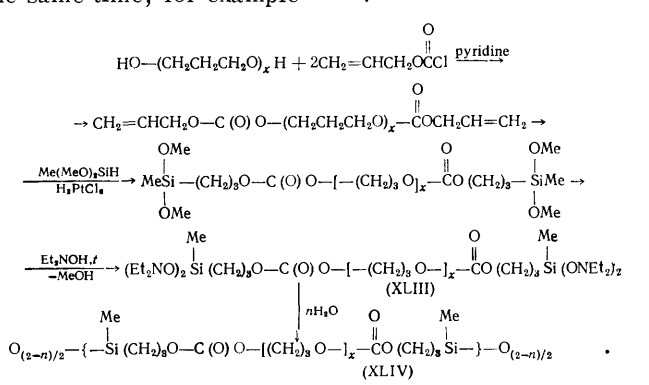
It is of interest that compounds of the type $Ph_4Si$ and $Ph_2(EtO)SiH$ are used as catalysts of the reaction of carbonic acid esters with aromatic dihydroxy-compounds both separately, in combination with one another, or in mixtures with alkali metal fluoroborates[212-214]. Presumably they are involved in dehydrocondensation, esterification, and transesterification reactions and probably form part to some extent of the composition of the final polymer in a chemically combined form.

Block copolymers based on a polycarbonate (PC) with terminal $\alpha\omega$-hydroxy-groups and an organopolysiloxane (PS) with 2–4% of Si–OH groups are obtained by heating the initial components in tetrahydronaphthalene at its boiling point. The initial mixture can also include a polyester based on a mixture of tris(hydroxymethyl)propane with ethylene glycol and dimethyl terephthalate. In the latter case, tolylene di-isocyanate or its adduct with tris(hydroxymethyl)propane is added in order to harden varnish compositions, for example[215,216].



Polyoxyalkylene (POA) with a terminal carbonate group and PS blocks may be linked chemically in the presence of the corresponding combinations of functional groups in pairs (≡Si–H/alkenyl, ≡Si–H/HOC–, and ≡Si–OAlk/HO–C≡) by hydrosilylation, dehydrocondensation, and transesterification reactions[217-222]. It has been reported that αω-$(HO)_2$-PC esterify αω-$Cl_2$-PS in the presence of a tertiary amine, after which the copolymer is made to undergo heterofunctional polycondensation with $MeSi(OAc)_3$ via the ≡Si–Cl groups introduced in excess[223,224].

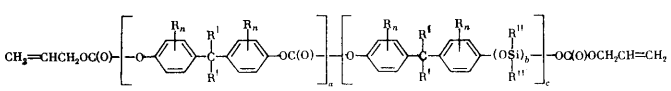
However, the method of synthesis of SCPC based on the interaction of αω-$(Me_2N)_2$-PS and αω-$(HO)_2$-PC, carried out in a homogeneous medium with formation of the readily removed volatile dimethylamine, has attracted more attention[218,220,221]:



(XLI)

Hydrolysis of organosilicon carbonates containing carbofunctional substituents with participation of the functional groups at the silicon atom is a general method for the synthesis of organopolysiloxanes containing carbonate groups in the polymer side chain, for example[138,143,144,146,216,225]:

(XLII)



(c) The hydrosilylation reaction. This reaction has a wide scope in the synthesis of SCPC.[139,140,142,177,178,185,218,219,225-231] Its main purpose is to link together the organic and organosilicon components of the polymer. However, the no less important problem of imparting to the adduct the capacity for being vulcanised via the simplest possible scheme is frequently solved at the same time, for example[142,230]:

(XLIII)

(XLIV)

(d) Radical polymerisation. Copolymeric organopolysiloxane-polycarbonates with terminal allyl carbonate groups[139,140,142,177,178,185,228-231]

are mixed with an organosilicon dithiol selected from a group of compounds of the type $[HS(CH_2)_3]_2SiMe_2$, $[HS(CH_2)_n]_2SiMeEt$, and $[HS(CH_2)_3SiMe_2]_2O$, a suitable solvent is added (ethyl methyl ketone, $CH_2Cl_2$), and the system is hardened by irradiation with light in the range 100–20 000 Å at 0–50°C. Vulcanisation takes place as a result of the addition of HS groups to the double bonds[232].

The introduction of a polysiloxane containing vinyl groups has a favourable effect on the properties of the copolymer of diallyldiglycol carbonate and methyl methacrylate. The copolymerisation is carried out in the presence of peroxide catalysts or under the influence of ultraviolet light[233]. The possibility of the copolymerisation of a BPA-based polycarbonate with an unvulcanised silicon rubber in the presence of kaolin (filler), a naphthalene plasticiser, hydroquinone, and a mixture of benzoyl and t-butyl peroxides has been demonstrated[234]. For example, organosiloxane elastomers are obtained by the interaction of the mixture obtained on copolymerising $(Me_2SiO)_4$ and $(MeVinSiO)_4$, $SiO_2$, $Ph_2Si(OH)_2$, and the ester $[BuOCH_2CH_2OC(O)OCH_2CH_2]_2O$ containing a carbonate group in the presence of benzoyl peroxide or on heating[235].

Organic percarbonates and organosilicon percarbonates with carbofunctional groups are used for the vulcanisation of polysiloxane materials[165,236-240].

(a) Other compositions based on silicon-containing polycarbonates. Complex compositions incorporating a wide variety of components and containing both a carbonate group and a silicon atom are known. The effective operational characteristics of these compositions are sometimes retained for a long time, although chemical bonding between the components is either not evident or absent altogether. For example, in order to increase the ultimate strength of plastic lubricants, the latter are thickened with finely dispersed amorphous $SiO_2$ and $C_2$–$C_{18}$ alkylene carbonate is added as the dispersing agent. The resulting lubricant has a penetrability of 251 and can be used successfully at high temperatures[241]. $(SiO)_n$ ($n$ = 1, 2) can form part of the composition based on a high-molecular-weight linear polycarbonate[242].

Polycarbonate-siloxane compositions, which do not adhere to the mould during compression moulding or casting, are obtained by combining an aromatic polycarbonate with solid crystalline phenylcyclosiloxanes[243]. The introduction of a polysiloxane into a polycarbonate is carried out in mixers of the usual type, for example, in a screw-conveyor granulator[243]. The introduction of a polysiloxane into a polycarbonate lowers the viscosity of the melt, increases its resistance to the action of moisture, and reduces its adhesion to the surfaces with which it is in contact and thereby facilitates its processing by pressing, casting under pressure, extrusion, and other methods[235,243-248]. The addition of a polysiloxane and 0.1–2.0% of an alkali or alkaline earth metal carbonate to a polycarbonate also ensures a high resistance of the composition to the action of light at an elevated temperature[249].

The intermediate formation of silyl carbonates is possible during the hardening of αω-$Cl_2$-PS with the aid of a mixture of $CaCO_3$, $SiO_2$ of type U-333, $(EtO)_4Si$, and ethanolamine[250,251] and also in the preparation of moulded foam silicate articles with the composition thickened before foaming (when liquid sodium glass is treated with organic chlorocarbonates as the gel-forming agents)[252].

Silicon may be introduced into the composition of carbonate-containing articles by employing organosilicon compounds as surface-strengthening agents or binders [253-257]. It is also introduced into polycarbonate compositions together with glass fibre (frequently employed for reinforcement [10,11,230,258-261]), silicon carbide [230], and magnesium silicate [262]. In order to modify their surface properties, polycarbonate articles are coated by a solution of an organopolysiloxane with functional substituents [263].

SCPC compositions have been developed in which one of the components is a polycarbonate or poly(vinyl chloride), while the second component is a polycarbonate containing at least one organic substituent with an imide group [264]. Silicon compounds are effective stabilisers of the properties of polycarbonates. For example, the addition of 0.002–0.005% of a high-molecular-weight linear polysiloxane to a polycarbonate makes it possible to obtain homogeneous transparent films. The fibre-forming properties of polycarbonates are improved at the same time [245]. The introduction of 0.1–25.0% of organosilicon halogen-containing compounds into polycarbonate compositions imparts to the latter thermal stability, capacity for internal plasticisation, and self-quenching properties [265].

In order to stabilise the colour of the polycarbonate during its processing, ultramarine and triphenyl or trihexyl-silane are added in amounts of 0.1 and 0.01% respectively [266]. Instead of compounds of the type $R_3SiH$, it is possible to use for this purpose a polysiloxane, for example, methylphenylpolysiloxane, or $SiO_2$ with a hydrophobic coating [267]. Polycarbonates stabilised in this way are resistant to the action of atmospheric moisture, heat, solvents, and wear.

It is believed that the hardening of $\alpha\omega$-$Cl_2$-PS is accelerated in the presence of ammonium carbonate and bicarbonate [268], guanidinium carbonate [269], $(HOCH_2CH_2.NMe_3)_2CO_3$, [236] and Group I, II, and VIII metal carbonates [140,178,205,217,229,230,249-251,271-279].

## 2. Physicochemical Properties of SCPC

The physicochemical properties of SCPC must be considered separately for polysiloxane-polycarbonate block copolymers and similar compounds, SCPC based on organosilicon monomers with carbofunctional groups, and other types of mixed compositions.

(a) Properties of polycarbonates with ≡SiOCAr linkages. Conditions have been found for the preparation of polycarbonates with ≡SiOCAr linkages in the form of single crystals and their physical properties have been investigated [170-175,193-204,260,279-285]. It has been established that the single crystals of SCPC block copolymers have a hexagonal unit cell [197,199], in contrast to BPA-PC and PDMS, which crystallise with a helical structure containing unit cells of the orthorhombic and monoclinic types respectively [281,282].

The changes in the mechanical, optical, and dielectric characteristics of the block copolymers have been studied in detail as a function of the size and the relative contents of the polycarbonate and polysiloxane blocks in the macromolecule [170-175,193-204,260,279,280]. The study of the equilibrium swelling of SCPC specimens having different compositions, swelling as a function of the deforming stress and deformation frequency, small- and large-angle X-Ray scattering, double refraction, and optical dichroism for block copolymers in the swollen and solvent-free states established that there is a distinct tendency towards the association of the polycarbonate blocks into discrete randomly distributed domains. According to X-ray diffraction and electron microscope data, the average distances between the domains are 50–500 Å. [196,201] It has been established that the dielectric losses of the copolymers with short blocks are greater than for those with large blocks [285]. At the same time, the strength of the block copolymer films increases with increasing content of polycarbonate units and the elongation coefficient diminishes correspondingly [195]. With increase of the content of siloxy-groups in copolymers, the softening temperature falls and the intrinsic viscosity decreases [170,172-175].

The thermal decomposition of SCPC begins to develop at an appreciable rate at 350°C owing to the rupture of the ≡Si–O–C≡ linkages. The ultimate tensile strength of the polymer at 100°C is lower by a factor of two than at 20°C. Cooling to −150°C is accompanied by the brittle rupture of the film specimens [174,175]. At the air–water interface, the block copolymers form a monolayer comprising polysiloxane blocks, while the polycarbonate blocks protrude above the interface [193,198]. The surface activity of mixtures of BPA-based polycarbonates and block copolymers deposited in the form of thin, strong films on glass was studied by determining the wetting angles by means of a telescope having a low resolving power and fitted with a goniometer eyepiece [200]. The wetting angles for water on certain copolymer films are in the range between 90 and 100°, which is analogous to the values for PDMS films adsorbed on surfactants [286].

It has been established that the wetting effect depends strongly on the copolymer concentration, the polysiloxane content, and the length of the blocks. After the removal of the films from the surface of glass, the wettability of the latter resembled that of the homopolymer. Consequently the copolymer is absorbed on the glass–polymer interface during the casting process and remains on the surface after the removal of the film. This is confirmed by the finding that a copolymer film with a high polysiloxane content can be removed from the glass by heating or by treatment with a solvent.

For a comparative analysis, one should bear in mind the study [287] of monomolecular films of polymethyl(n-alkyl)siloxanes on organic liquids, including propylene carbonate.

(b) The properties of SCPC based on organosilicon bischlorocarbonates. SCPC in which the silicon atoms are combined exclusively with carbon apart from being involved in SiOSi linkages have been obtained by interfacial condensation at the boundaries between phases based on the organosilicon diols (XIIIa), (XIIIb), (XIIId), (XXVIIa), and (XXXVIIc) and the bisphenols (XVIIIb), (XVIIIc), and (XXXVIIb) with partial or complete replacement of $COCl_2$ by the corresponding bischlorocarbonates (XIVa), (XIVb), (XIVd), (XXXVIIIa), (XXXVIIIb), (XXXVIIIc), (XIXb), and (XIXc). [31,96,116,164,201,206,207,209,210,288,289] 1,1-Bis-(4-hydroxyphenyl)cyclohexane (BHPC) [31,96,288] and BPA [164,201,289] were used as the aromatic dihydroxy-compounds (DHC).

A characteristic property of the SCPC obtained from BHPC and the bischlorocarbonates (XIVa), (XIVd), (XIXb), and (XIXd) in a mixture with $COCl_2$ is a tendency towards a decrease of the intrinsic viscosity, the softening temperature, and the yield with increasing mole fraction of the bischlorocarbonate in the initial mixture of acid chlorides.

Turbidimetric titration data indicate the formation of copolymers with a fairly narrow molecular weight distribution. X-Ray diffraction analysis of the copolymers [31] reveals a low degree of order in their structure regardless of the nature of the bischlorocarbonate employed, which has been explained by the steric effect of the cyclohexyl group of BHPC, which prevents the crystallisation of the macromolecules.

Thermomechanical curves [31] show that the introduction of ≡Si–O–Si≡ groups into the macromolecule of a BHPC-based homopolycarbonate causes a monotonic decrease of $t_g$ and $t_{flow}$, which confirms the determinations of $t_{soft}$ in a capillary. A characteristic feature of these curves is the presence of small regions corresponding to the viscoelastic state.

Data for the thermo-oxidative degradation (thermogravimetric analytical method) [31] of copolymers based on BHPC and the bischlorocarbonate (XIVa) show that both the initial rate of gas evolution and the total amount of gaseous products increase. Methane, ethylene, etc. were detected in the decomposition products, which indicates the elimination of the $Si-CH_3$ groups together with CO, $CO_2$, etc., whose liberation is associated with the degradation of the $-OC(O)O-$ groups.

The amount of water absorbed by the film ($E$, %) [31] decreases from 0.2% for homopolycarbonate obtained from BHPC to 0.01% for the copolymer based on the bischlorocarbonates (XIVa) and (XIVb), while for the bischlorocarbonates (XIXa) and (XIXb) it is in general close to zero. Furthermore, the copolymers exhibit a higher resistance to the action of aqueous alkali compared to organic polycarbonates. Among the series of specimens investigated, the copolymers with 30% of organosilicon fragments showed the greatest resistance to hydrolysis [31]. An important property of the copolymers obtained is their effective adhesion to glass [31].

Protective films made of the copolymers deposited on silicate glass by immersion in 3–5% solutions in chloroform do not impair the optical properties of the glass but at the same time increase its resistance to impact and wear by erosion under dynamic conditions.

The study of the dielectric characteristics of the copolymer based on BHPC and its analogues modified with the bischlorocarbonates (XIVa) and (XIVb) showed [31] that the volume resistivities $\rho_V$ of both copolymers are in the range $(3.0-4.0) \times 10^{15}$ Ω cm; when the frequency increases from 100 to $1 \times 10^6$ Hz, tanδ for SCPC modified by the bischlorocarbonate (XIVa) rises from $4 \times 10^{-3}$ to $9.7 \times 10^{-3}$, while that of the specimen modified with the bischlorocarbonate (XIVb) rises from $2.7 \times 10^{-3}$ to $7.6 \times 10^{-3}$. The dielectric constant remains virtually unchanged (2.3) in the same frequency range. At 50 Hz, the dielectric strengths of the copolymers are 300 and 210 kV $mm^{-1}$ respectively for the SCPC incorporating the $O[SiMe_2CH_2-]_2$ and $O[SiMe_2CH_2OCH_2CH_2-]_2$ groups.

The copolymers are formed in the form of viscous transparent liquids (which can be drawn into filaments), waxy masses, or colourless powders soluble in benzene, toluene, chlorohydrocarbons, etc. Depending on the method of synthesis and the type and ratio of the organic and organosilicon components of the initial mixture, the softening temperature varies from 25° to 175°C and is lower the greater the number of siloxy-units in the copolymer. The copolymers are resistant to hydrolysis.

The transparency of films 40–50 μm thick, cast from solution, to light in the visible region reaches 80–85%. An increase of transparency with increasing content of siloxane groups has been noted.

It is noteworthy that both elastic [31] and brittle [164] SCPC have been obtained from the bischlorocarbonate (XIVa). Elastic and at the same time strong films have been made from bischlorocarbonates with a higher silicon content.

Furthermore, in contrast to the SCPC with $\equiv SiOC_{Ar}$ fragments where an increase of the number of ≡Si–O linkages leads to a decrease of thermal stability [173], the copolymers based on organosilicon bischlorocarbonates containing carbofunctional substituents lose weight starting from 300°C and decompose vigorously at 400–450°C.

Consequently, the introduction of siloxane-containing fragments into the macromolecules of rigid-chain polycarbonates increases to some extent the elasticity of the copolymer and reduces $t_{soft}$ and $t_{flow}$, which is of great practical importance, when the thermal stability is maintained, since it simplifies the conditions necessary for the processing of the polycarbonates by casting under pressure. The capacity of the copolymer for adhesion combined with effective optical characteristics, impact strength, and erosion resistance suggests that they may prove to be valuable constructional materials. The decrease of the amount of water absorbed by the films due to the hydrophobic organosilicon components can probably be used to reduce the hygroscopicity of the polycarbonate when it is stored in granular or powder form.

## V. PRACTICAL APPLICATIONS OF SILICON-CONTAINING POLYCARBONATES AND RELATED COMPOUNDS

By virtue of the successful combination of the practically useful properties characteristics of polysiloxanes and polycarbonates, the SCPC and related compounds, mixtures, and compositions may find and are already finding extensive applications in various branches of science and engineering.

Silicon-containing polycarbonate resins possess effective mechanical [31,96,138,143,164,170,175,176,179,181–185,188,194,196,197,201–204,220,221,285,290,291,294], optical [31,64,96,170,172,175,181,182,201,206,210,216,288,292], and dielectric [31,96,164,168,172,221] properties, exhibit thermal stability and resistance to thermal oxidation [10,11,31,96,164,168,172–174,179,180,184,185,199,204,218,220,261,294,295], are fire- [204,262,295] dirt-, oil-, petrol-, and water-resistant [31,96,257,263], etc. which, considered as a whole, makes it possible to regard them as a new independent group of silicone materials [6,12,26,27,96,142,144,150,164,169,170,173–177,181–185,187,188,190,191,195,205,210,218,220,221,223,226,246,255,256,291,294,296].

The SCPC specimens investigated have molecular weights up to 150 000 [96,164,175,196,199,201] and can be readily converted into fibres, films, and other articles. For example, the film-forming properties of the SCPC [31,144,164,168,176,177,180–185,188,192,193,197–200,206,207,216,220,221,297] are used nowadays to obtain protective coatings on wood, paper, metals, glass, textiles, plastics, etc. [31,96,142,164,184,185,188,216,218,230,254,298–301], which can be soft or hard depending on the type and composition of the polymer [31,204,292,293], may be resistant to light and chemical and thermal effects, and may exhibit viscoelastic properties. Even in a thin layer, they are distinguished by impact strength [31,96,138,143,204,292–294], resistance to erosion [31,96], capacity for adhesion to the support [31,96,172,188,225,228], and a unique gas separating capacity [9,31,302–318]. The Dupont and Owens Companies (USA) developed new coatings of the "Glas resins", "Absite", "Sierracin 311", and "Sierracin 900" types, which serve to protect the glass in aeroplane navigation lights, the coating being resistant to scratching

and friction and the action of solvents, fuels, and sea-water [299,300]. Non-misting coatings with satisfactory adhesion to glass and a high transparency [319], hardness, thermal stability, resistance to the action of acetone and dirt [259,263], and capacity to increase the resistance of glass to the frontal pressure of a shock wave [301] are known.

SCPC are used as foam stabilisers in the manufacture of foam polyurethanes [139,217,219,228,229,231], in the manufacture of electrical insulators, dielectric solutions for condensers (KUS 13°), etc. [168,169,177,320], as finishing compositions for sewing thread [321], packing materials, varnishes, binders, hermetically sealing compounds, moulding materials, cements [165,168,177,215,230,233,255-257,322], hair-treatment agents [222], and water-repellent filamental additives to granulated polycarbonates [248]. By virtue of the combination of transparency, softness, wettability, and permeability to oxygen, SCPC are used as materials for optical lenses correcting astigmatism [292].

The presence of silicon in SCPC in a chemically bound form or as an additive to the polycarbonate facilitates the conditions required for their processing, since it lowers the softening temperature and the viscosity, increases the thermal stability, homogeneity, transparency, and moisture resistance, improves the fibre-forming properties, imparts to the material the capacity for internal plasticisation and self-quenching properties, and stabilises the fundamental technical operational characteristics with respect to time [170,171,212-214,235,243-247,261,262,265-267,275,295,323]. Ammonium, substituted ammonium, guanidinium, and alkaline earth metal carbonates facilitates the hardening of polyorganosiloxanes and at the same time play the role of fillers [178,219,229,236,250,251,268-276,278,324]. There is then a possibility of the formation of low-modulus specimens of silicone rubber and of elastic polymeric materials with a low contraction coefficient, improved thermal stability, and adhesion, and other useful properties [276]. Silicon oxides mixed with aluminium and magnesium oxides or separately, silicon carbide, fibreglass, and alkali metal chlorides and bromides are introduced into polycarbonate compositions to promote structure formation, for their reinforcement, to make them fire-resistant, etc. [10,11,142,235,242,258-261,295,325]. Organic and organosilicon percarbonates are used as initiators of the polymerisation of PDMS and their copolymerisation with other monomers, for example styrene and acrylonitrile [165,166,237-240]. After structure formation and hardening, SCPC can be used as moulded articles [218,224,251,252]. The main practical application of SCPC, which has led to a vigorous search for ways of synthesising these polymers and to a comprehensive investigation of their properties, is for the separation of mixtures of gases and vapours. The employment of the gas-separating capacity of SCPC in medicine has been considered in a review [312]. It remains to add that, according to the advertising leaflets of the General Electric Company (USA), the films and capillaries made of block copolymers based on polysiloxanes and polycarbonates of type "MEM-213" combine permeability to gases close to that of the most permeable silicone rubbers [326-347] with a high gas-separating selectivity, which led to the inclusion of these copolymers among the 100 most important industrial products in 1969. [311] They proved to be suitable for use not only in medicine but also in space, under water, etc. [305-310] It has been shown that, when nitriles, vinyl monomers, or aromatic hydrocarbons are deposited by the plasma method on these copolymers in the form of ultrathin coatings with a thickness $\leq 0.5$ μm, the ratio of the permeabilities to $H_2$ and $CH_4$ increase appreciably (from 0.87 to 33 for PhCN). [305]

A method has been developed for the preparation of ultrathin gas-permeable membranes with a thickness of ~1 μm. [303] It is known that "MEM-213" can form part of more complex polymeric compositions for the same purpose [353]. On the other hand, the search for improved copolymers has continued using other dihydroxy-compounds, including silicon-containing ones [186]. It has been shown that polysiloxanes mixed with hydrated polycarbonates are suitable for the removal of carcinogenic polycyclic hydrocarbons from tobacco smoke [302].

During the preparation of the manuscript for the press, additional studies on the subject of this review were published [354-425].

There are new examples of the synthesis of SCPC [355-358,368-374,405,406,421-423,425] and methods have been described for the preparation of a wide variety of compositions with various properties [373-387,389,399,401,402,413,418-424].

The structure of SCPC has been investigated by X-ray diffraction [360,417], light absorption, light scattering in the presence of various types of deformations [360], and $^1H$ NMR. [362] Studies have also been made on the chemical, physicomechanical, and dielectric properties of SCPC, the phenomena at interfaces [358,359,361,364,367,388,400,407,410,413,415], and permeability to gases [354,366,412,416].

SCPC have been used in articles required for membrane techniques [354,363,366,407-409,411,412] in electrophotography [389], in medicine in the oxygenation of blood, and in astronautics and aquonautics [354,363,365]. Data have been published on the preparation of SCPC-based film coatings on articles [367,398]; SCPC have also been used to prevent the dyeing of polycarbonates [373] and to stick together the components of various materials [388,396-399,410].

It has been shown that BPA-based polycarbonates are adsorbed from solutions on aerosil [394] and that alkali metal carbonates can serve as fillers for polysiloxanes and as catalysts of their hardening [387], while $Ph_3SiCl$ and $Me_3SiCl$ have been recommended for the regulation of the molecular weights and thermal stabilisation of polycarbonates [424]. Oligomeric bischlorocarbonates have been used in the synthesis of silicon-containing polyurethanes [403,404]. The practical properties of SCPC have been examined in detail in a review [426].

# Photoelectric Phenomena in Polymeric Selenium Structures

Yu.A.Cherkasov and N.B.Zakharova

In order to clarify the phenomenon of non-photoactive absorption in molecular solids we have analysed the relationship between the spectra of photoelectric phenomena in selenium and the molecular (and supermolecular) structures of selenium. Non-photoactive absorption is shown to arise from the photo-generation of charge carriers through the state of bound electron-hole pairs (excitons), which is structure-sensitive and dependent on quantum energy, temperature, and applied field intensity. 109 references.

## I. INTRODUCTION (THE PROBLEM OF NON-PHOTOACTIVE ABSORPTION IN MOLECULAR SOLIDS)

Photoelectric phenomena are among the most important manifestations of the interaction between light and matter, underlying many biological processes (photosynthesis, colour vision) as well as the fixation of optical images (photographic processes). Recent systematic studies of the absolute quantum yield of photoelectric phenomena in molecular (polymeric) photoconductors have led to the hypothesis of non-photoactive edge absorption in these materials, in contrast to the classical crystalline semiconductors such as germanium and silicon. Non-photoactive absorption, extending partly into the depth of the absorption band, has been observed in molecular photoconductors of various classes, including organic (anthracene) and inorganic (selenium) crystalline photoconductors, amorphous inorganic photoconductors (amorphous selenium structures and selenium structures with tellurium, arsenic, and germanium hetero-atoms), organic poly-conjugated polymeric photoconductors (polyacetylenes), organic saturated polymeric photoconductors (vinyl polymers), and also dye-sensitised organic polymers[1-5]. The basic factor which determines the appearance of non-photoactive absorption in these photoconductors is the photo-generation of charge carriers through the state of a bound hole–electron pair (exciton), depending on the quantum energy, the temperature, and the strength of the applied electric field. The effect is found to be structure-sensitive: some selenium structures (both crystalline and amorphous) do not show non-photoactive absorption over a wide range of quantum energy, giving an internal photo-effect with a very high quantum yield (approaching 100%) over the whole visible region of the spectrum.

In this review we shall analyse the relationship between the molecular (and supermolecular) selenium structures and the spectra of the photoelectric phenomena in selenium. Amorphous, amorphous–crystalline, and crystalline selenium structures will be considered, with special emphasis on the photoelectric phenomena in the presence of external electric fields: photoconductivity (electrophotographic sensitivity) in strong fields, which collect all the light-generated carriers and allow us to measure one of the most important characteristics of the interaction of light with matter (the quantum yield of the internal photo-effect, equal to the number of hole–electron pairs created by each quantum of light absorbed), and photoconductivity in weak electric fields, in particular at very high frequencies, which allows us to minimise the influence of contacts and to study photoconduction with very small "displacements" of the charge carriers. We shall also discuss photoelectric phenomena in the absence of applied electric fields, and in particular the diffusion of photocarriers along a concentration gradient (capacitive photo-e.m.f. and contact potential difference).

The modern view of the structure of selenium is of an inorganic polymer which can easily change its molecular and supermolecular structure[6]. A clear understanding of the correlation between the structure and the properties of such an inorganic polymer, which is highly photosensitive over a wide spectral region, should help us to formulate methods of controlling the physical properties of polymers in general, and in particular it should suggest ways of improving the photosensitivity of organic polymers.

## II. CRYSTAL STRUCTURES OF SELENIUM

### 1. Structure of the Molecule and Allotropic Forms

Selenium forms complex molecules easily altered under the influence of various factors. This feature of selenium is responsible for the existence of several allotropic forms of selenium in the solid state, able to coexist over a wide range of temperature[7]. The state of the outer electrons in an isolated selenium atom corresponds to the $4s^2 4p^4$ configuration. Of the six outer electrons, two (paired) are in the $s$-state, and two (paired) in the $p$-state, and do not take part in bond formation. The bond between atoms is created by the two unpaired electrons. The electron clouds of the unpaired $p$-electrons of each atom overlap the $p$-clouds of the neighbouring atoms to give filled $p$-orbitals. The bond angle (105.5°) causes the atoms to adopt a helix configuration in the molecular chain, or alternatively to form eight-membered rings. We note that selenium can have a valence of 4 or 6 as a result of the transition of two or four unpaired electrons from $p$ (or $s$ and $p$) orbitals into a $d$-orbital[8]. The interatomic bonding within

the molecule is strong and covalent, though the nature of the intermolecular bonds is still controversial. Some workers[9,10] argue, in view of the low melting point and of the easy cleavage of the crystal along planes parallel to the molecular chains, that the intermolecular forces must be of the Van der Waals type. Others[11] stress that the distance between chains in selenium is too short for Van der Waals interactions and that the coordination number is greater than the maximum possible number of $p$-bonds, and conclude that rotary resonance of the chemical bonds is present in selenium crystals. Bond hybridisation is postulated, extending over four atoms of the second coordination sphere of different molecular chains. Hybrid orbitals have a greater bond energy than non-hybridised orbitals, and therefore their stability is higher[12]. Furthermore we expect intermolecular energy barriers to be lowered by the presence of hybridised bonds[12].

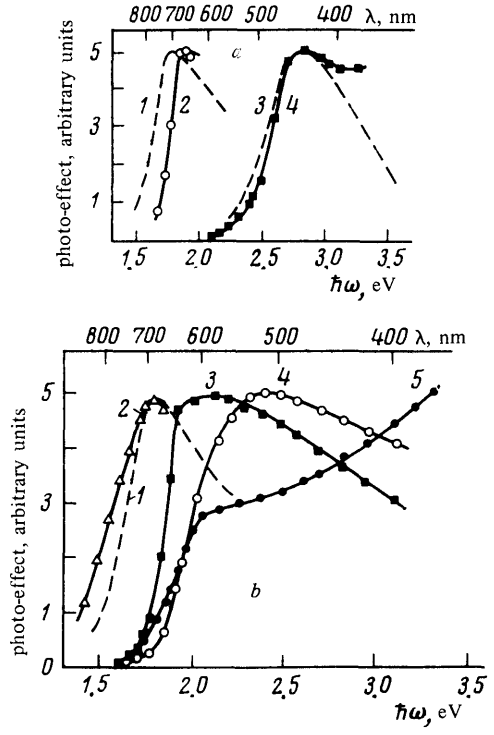

**Figure 1.** Photo-effect spectra of the crystalline selenium structures and of the corresponding amorphous analogues: (*a*) *1*) trigonal selenium, *2*) its amorphous analogue, *3*) monoclinic selenium, *4*) its amorphous analogue; *1*) and *3*) d.c. photoconductivity, *2*) and *4*) electrophotographic sensitivity[23]; (*b*) trigonal selenium; *1*) d.c. photoconductivity[24], *2*) and *3*) electrophotographic sensitivity of a polycrystalline sample[1] and of microcrystals dispersed in an organic matrix[23] respectively, *4*) photo-e.m.f., *5*) contact potential difference.

The most stable crystalline form of selenium is the trigonal modification. The monoclinic ($\alpha$ and $\beta$) and the cubic ($\alpha$ and $\beta$) modifications, with different elementary cells in different space groups, are also true crystalline phases[7]. The structural features of the crystalline forms are largely determined by the molecular structure of selenium[13]. The basic structural element of trigonal selenium is a polymeric helical molecular chain with an interatomic distance of 2.32 Å and a bond angle of 105.5°. A parallel orientation of such chains, with an axial separation of 3.48 Å, creates a hexagonal lattice with parameters $a = 4.35$ and $c = 4.94$ Å.[14] Another crystal form ($\alpha$ and $\beta$ monoclinic selenium) is formed from eight-membered, puckered selenium molecules (closed rings in the $\alpha$ modification, open rings in the $\beta$ modification) with an interatomic distance of 2.3 Å,[15] a spacing of 2.9 Å between rings, and lattice parameters $a = 9.1$, $b = 9.1$, $c = 11.6$ Å, $\varphi = 90°16'$ for $\alpha$-monoclinic selenium[16-18]. Both modifications are molecular crystals. For the cubic modifications[19,20] we have $a = 2.97$ Å (for the $\alpha$-cubic lattice) and a bond length of 2.97 Å.

## 2. Photoelectric Phenomena

The photoelectric properties of crystalline selenium have been studied by various methods, including photoconductivity in strong electric fields (electrophotographic (EP) sensitivity)[21], photoconductivity at ultra-high ($10^{10}$ Hz) frequency[22], capacitive photo-e.m.f., influence of light on the contact potential difference, etc.[23-26]. Spectral curves for the photo-effects observed by the above methods in monoclinic and trigonal selenium are shown in Fig. 1. The EP sensitivity spectrum (curves *2* and *3* of Fig. 1*b*) extends over the whole visible region of the spectrum up to 800 nm. Its long-wavelength edge is close to the edge of the photoconductivity spectrum of polycrystalline layers of trigonal selenium (curve *1* of Fig. 1*b*). We should note that the EP sensitivity (curve *3* of Fig. 1*b*) is discussed in terms of a model consisting of a dispersion of trigonal selenium microcrystals (of micrometre dimensions) in an organic matrix based on styrene copolymers[21]. Single crystals of trigonal selenium have zero EP sensitivity because their resistance is too low to give an acceptably long relaxation time. Transverse current can be obtained in these heterogeneous layers in fields of $10^4$–$(2 \times 10^5)$ V cm$^{-1}$ if the gaps between crystallites are not too great (a few nanometers).

The photo-e.m.f. and contact potential difference spectra (curves *4* and *5* of Fig. 1*b*) are displaced towards shorter wavelengths, as are the corresponding spectra of organic photoconductors[27]. On the other hand, the EP sensitivity curve of polycrystalline trigonal selenium (curve *2* of Fig. 1*b*) has a maximum at 700 nm, characteristic of the single crystals and coinciding with the photoconductivity maximum of the individual microcrystals measured at a frequency of $10^{10}$ Hz.[22] In these measurements the red edge of the photoconductivity lies at longer wavelengths than the red edge of other photoelectric effects. By comparing the EP sensitivity and the photoconductivity curves we conclude that the low EP sensitivity in the long-wavelength part of the spectrum arises from the specific structure of the heterogeneous (amorphous–crystalline) system, resulting in a particular field distribution. Because of the short Debye screening length, the electric field penetrates into the selenium microcrystals to a depth of only 0.1 μm, and only the surface regions of the crystals are able to contribute to the EP sensitivity of the system. Generation of hole–electrons pairs in the depth of the crystals cannot contribute to the EP sensitivity if the applied electric field is excluded from these regions. The range of quantum energy in which the EP sensitivity is

found to fall corresponds to a decrease in the absorption coefficient from $10^5$ $cm^{-1}$ (for 2.1 eV) to $10^4$ $cm^{-1}$ (for 1.8 eV). Exciton effects associated with non-photoactive absorption cannot be excluded, but while the results do not contradict this interpretation they do not positively confirm it.

In contrast to trigonal selenium, with the monoclinic form of selenium the spectra of the photoelectric effects are shifted (curves *3* and *4* of Fig. 1*a*) towards the centre of the absorption band (curve *7* of Fig. 5*a*).

The crystal structure of selenium consisting of long helical molecules (trigonal selenium) differs from that consisting of closed eight-membered rings (monoclinic selenium) in having an internal photo-effect with a quantum yield close to 100% over a wide region of the spectrum (see curve *1* of Fig. 6*a*).[28] This is the only known example of a molecular crystal in which the yield of the internal photo-effect is maximal over a wide spectral range.

## III. AMORPHOUS AND AMORPHOUS–CRYSTALLINE SELENIUM STRUCTURES (MICROCRYSTALLINE PHASE AND PHASE BOUNDARY)

### 1. Amorphous–Crystalline Structures

The essential feature of the structure of matter in an amorphous state is the absence of long-range order in the arrangement of its atoms or molecules. The term order (long-range or short-range) denotes the correlation in the mutual disposition of atoms or molecules in the solid: a correlation at a distance of the same order as the mean interatomic spacing is termed short-range order, whereas a correlation without limit as to distance is termed long-range order. Amorphous and amorphous–crystalline selenium structures can be prepared both from the gas phase (by thermal evaporation in a vacuum) and from the liquid phase (by quenching)[6,29].

*a*) Molecular composition of the melt. As we have already pointed out, the crystal lattices of all the known modifications of selenium are built up from different structural units. Hence these structural units must be present as equilibrium forms[7] when selenium is crystallised (from the vapour, the liquid, or the amorphous state) to give one or other of the crystalline modifications of the element. However we do not clearly understand the conditions of formation of these structural units, their stability, or their mutual interconversion. The main difficulty is the presence of molecules of different structure and size in selenium samples at any temperature below the melting point (220°C). Several workers have found that the liquid phase consists of closed rings and molecular chains of different size, whereas selenium vapour (up to 1000°C) consists of a mixture of molecules (containing eight, six, four, or two atoms) and single atoms. Liquid selenium retains all the attributes of a molecular liquid down to 200°C,[29-32] and is reported[33] to be associated.

Existing information on the form and relative amount of the different molecules in liquid selenium is contradictory. Some workers[34] state that liquid selenium consists of helical molecular chains, while others[35,36] suggest that parallel orientation of the chains persists up to 300°C. X-ray diffraction studies[32,35] have shown that six- and eight-membered rings are present in liquid selenium. More recent work[37,38] has led to the suggestion that eight-membered rings are in equilibrium with polymeric chains in liquid selenium. The formation of long polymeric chains begins at a critical temperature (83°C) well below the melting point of selenium, the rate of formation increasing with temperature. It is reported[38,39] that at the melting point the chains contain at least $10^2$–$10^4$ atoms of selenium. Other workers[40] find that at 220°C the mean chain length in pure selenium is $2 \times 10^5$ atoms. The high-polymer nature of liquid selenium has been demonstrated by viscosity measurements[41], according to which the polymeric chains contain up to 500 atoms at temperatures up to 220°C.

Contradictory information has been published also on the temperature dependence of the melt composition. Measurements of magnetic susceptibility[35,36,42] suggest that the dissociation of the selenium molecules is insignificant in the region of 230–650°C. On the other hand, substantial structural changes in liquid selenium have been observed[33,43] over the range 300–320°C, but the nature of these changes is unknown. Thus practically all the structural units of the crystalline forms are present in liquid selenium, including[32,35] small regions of normal hexagonal lattice. Selenium samples prepared from the liquid or the vapour phase are believed to include equilibrium structural units of the different crystalline modifications, which can subsequently undergo crystallisation or formation of an amorphous state[7].

In spite of the apparent simplicity of the vacuum evaporation method, the deposition of thin films of amorphous selenium gives poorly reproducible results, and the relationship between the deposition conditions and the structure and physical properties of the films is still not clear. A great deal of information has been published on metallic films[44,45], but the deposition of a material like selenium in the form of thin films differs radically from the deposition of metal films, because the beam of evaporating material is molecular in the former case and atomic in the latter[45]. The structure of films resulting from the condensation of vapour produced by vacuum evaporation depends on the physicochemical properties of the solid source and on the evaporation conditions: residual pressure in the vacuum chamber, rate of deposition, temperature and structure of the substrate, etc.[44] The molecular composition of the vapour is by no means the least important condition[46].

*b*) Effect of the molecular composition of the vapour on film structure. The molecular structure of selenium vapour depends on its temperature. Above 1500°C selenium molecules dissociate into atoms: the selenium–selenium bond energy of diatomic molecules, determined from spectroscopic data and from the heat of dissociation[6], is 2.9 ± 0.2 eV. When the temperature is lowered to 1000°C the vapour phase includes molecules of all degrees of complexity between monatomic and eight-atomic, the relative amounts depending on temperature. Molecular complexes and quasi-crystalline formations apparently exist in the vapour phase at not too high temperatures. The evaporation of selenium as molecular complexes, which persist in the vapour phase up to 680°C, enables the molecular and super-molecular forms present in the source material to be transported to the condensing layer[43,47]. Nesmeyanov[48] critically reviewed published work on the temperature dependence of the pressure and composition of selenium vapour, and concluded that insufficient information is available on vapour composition at temperatures close to the melting point. Two papers[49,50] are selected[48] as the most reliable. One of these[49] treats the evaporation of selenium as the formation of an equilibrium mixture of diatomic and six-atomic molecules, the

proportion of diatomic molecules increasing with temperature from 12% (at 185°C) to 25% (at 684°C, the boiling point of selenium). According to the second paper[50] selenium vapour at 550–900°C contains tetra-atomic and eight-atomic molecules in addition to diatomic and six-atomic, the relative amount of each species being a function of temperature. Molecules containing eight atoms have been shown to be present in small amounts at temperatures below 500°C by a vapour density method, and the formation of a small amount of atomic selenium at temperatures near 1000°C has been confirmed by the same method[51,52]. Electron-diffraction studies[53] have shown that selenium vapour at ~ 450°C consists mainly of six-membered molecular rings in the "chair" configuration, with a smaller number of diatomic molecules.

Thus at the evaporation temperatures (300–500°C) normally used for the deposition of thin films of amorphous selenium the vapour consists mainly of six-atomic molecules. Diatomic molecules are also present, at lower concentration. The structural, electrical, and photoelectric properties of amorphous selenium layers are reported[46] to be very sensitive to the temperature of the selenium vapour (in the range 200–900°C) from which the layers are deposited. The phenomenon is ascribed partly to the role of the thermal velocity of the molecules, and partly to the degree of dissociation of the molecules. Unfortunately these two factors could not be separated in the experiments described.

*c*) Effect of residual gas pressure on film structure. Another important parameter influencing the structure of amorphous selenium layers is the pressure of residual gases in the chamber[54]. Thus, with a residual air pressure $> 6 \times 10^{-2}$ mmHg we obtain sooty, rough layers of low average density with a fibrous surface structure. Other gases (e.g. oxygen and argon) have a similar effect on the macro-structure of the layer when present at pressures $> 6 \times 10^{-2}$ mmHg. At pressures $< 2 \times 10^{-2}$ mmHg, where the mean free path of the evaporating molecules becomes comparable to the distance between the evaporator and the target, the residual gas molecules cease to affect the condensation of selenium, and dense layers with a mirror-smooth surface are obtained by vacuum evaporation. However the properties of these layers are still strongly dependent on the nature of the residual gas.

It has been suggested[54] that molecules or atoms of the residual gas can be incorporated in the condensing layers, thus influencing their microstructure or acting as electrically active impurities (which influence the electrical and photoelectric properties of the layers). Unfortunately no systematic study of the effect of residual gas pressure on the microstructure of amorphous selenium layers appears to have been reported. Electron-microscopic measurements[55] failed to show any structural difference between layers deposited at different residual gas pressures in the range from $10^{-3}$ to $10^{-6}$ mmHg. Furthermore, if the residual gas in the chamber has a high affinity for selenium we can expect compound formation at high substrate temperatures and high background pressures. Hence the preparation of dense and pure films of amorphous selenium should only be attempted in a vacuum of $10^{-5}$ mmHg or better.

*d*) Effect of rate of deposition on film structure. The rates of condensation used in the preparation of amorphous selenium films are quite high and usually in excess of 1 $\mu$m min$^{-1}$ (i.e. about 100 atomic layers per second). These high rates of condensation lead to the evolution of substantial amounts of latent heat, and because of the low thermal conductivity of amorphous selenium ($\sim 3 \times 10^{-4}$ cal cm$^{-1}$ s$^{-1}$ K$^{-1}$) this effect gives the molecules of condensate a high surface mobility and assists structural rearrangements within the layer[46]. However experiments[46] at rates of condensation between 0.5 and 2.5 $\mu$m min$^{-1}$ failed to reveal any difference in the electrical and photoelectric properties of amorphous selenium films. This suggests that the structure of amorphous selenium becomes insensitive to deposition rate at these high rates of deposition.

*e*) Effect of substrate temperature on the structure. The structure of the selenium layers is affected most markedly by the temperature of the substrate during deposition[8,15,56–62] and by the subsequent annealing conditions[8,37,38,63–65]. The effect of substrate temperature (in the range 0–100°C) on the structure of the selenium layers has been studied[57] by electron microscopy and by X-ray and electron diffraction. Layers prepared at substrate temperatures between 0 and 10°C had a pale grey surface, changing to red when the substrate temperature was raised to 35–40°C. The surface of layers prepared at low substrate temperatures is covered with hillocks. At higher substrate temperatures the layers develop a dark red colour and a mirror-smooth surface. X-ray and electron diffraction studies[57] and optical studies in polarised light[8,15,57] have confirmed that the structure of these layers is amorphous immediately after preparation. The proportion of crystalline phase in samples prepared at a substrate temperature of 90–100°C is only 7–8%.

## 2. Amorphous Forms of Selenium

Nabitovich and coworkers point out[57] that layers prepared at low (20–30°C) and intermediate (50–60°C) substrate temperatures have different amorphous structures: both the height and the width of the diffraction peaks are different in the X-ray and the electron diffraction patterns. The presence of different amorphous structures in selenium has been reported also by other workers[29,32,58,61,63]. Electron diffraction studies of the structure of thin layers of amorphous selenium deposited on cellulose nitrate substrates at 20°C have shown[63] the presence of two forms of amorphous selenium, characterised by different coordination numbers and different radii of the coordination sphere. The first is formed at substrate temperatures around 20°C, the second becomes predominant at substrate temperatures of 60–70°C. A gradual transition from one form to the other can be achieved at intermediate temperatures without going through a crystalline form. At 30–40°C the deposited layer is a mixture of approximately equal amounts of the two forms. Nabitovich and coworkers[15,16] evaluated the short-range order parameter in different forms of amorphous selenium and determined their molecular structure. Condensation on substrates at 20°C produces the first form of amorphous selenium, consisting mainly of eight-membered molecular rings; the second form, consisting mainly of long molecular chains of selenium, is obtained at substrate temperatures of 50–55°C. The crystallisation processes of these two forms of amorphous selenium are also quite different[15].

Some earlier workers[29,58] also reported two different forms of amorphous selenium, detected by X-ray diffraction, but differing in structure from those reported in Refs. 15 and 63. Thus selenium deposited on substrates

cooled to −180°C was found[29] to have an amorphous "packet" structure consisting of six-membered molecular rings. This report was later confirmed[56]. The authors[29] were led to the hypothesis of a packet structure of six-membered rings by an analysis of the diffraction patterns of films obtained under different condensation conditions (in particular, the molecular composition of the vapour and the substrate temperature during deposition). The second form of amorphous selenium is observed[58] when selenium is evaporated on to substrates at 20°C, and consists mainly of molecular chains similar in structure to those of trigonal selenium. Furthermore, selenium samples prepared at room temperature often contain micro-crystals of trigonal selenium[29,58]. The presence of molecular chains in the layers was confirmed by neutron diffraction and X-ray diffraction studies of amorphous selenium structures[67].

In contrast to these findings, Richter and Herre[29] report that selenium layers formed at 20°C consist of a mixed phase of molecular chains, six-membered rings, and elements of the normal hexagonal selenium lattice. Richter later showed by X-ray structural analysis[68] that selenium layers are predominantly in one of three amorphous forms, depending on the method of preparation: all three forms have the chain structure characteristic of trigonal selenium but the interatomic distance within the chain is different in the three cases. In an earlier investigation[69] the X-ray data obtained from similar samples had been interpreted as evidence for an amorphous selenium structure composed of eight-membered rings (characteristic of monoclinic selenium).

## 3. Crystallisation of Amorphous Selenium

The vapour deposition of selenium at substrate temperatures above 60°C invariably produces layers containing some crystalline phase[8,59,70]: on raising the temperature of the substrate the concentration of the crystalline phase increases[8,59], and at substrate temperature of 80–90°C a continuous layer of trigonal selenium is formed on the substrate surface[8,60,62]. We should note that amorphous selenium crystallises spontaneously to an appreciable extent even at room temperature[8,59,70,71]. Crystallisation is fastest in amorphous layers prepared on substrates at temperatures below 20°C: such layers are fully crystalline after a few months.

It is well established that the crystallisation of amorphous selenium occurs in two steps: nucleation and crystal growth. The optimum nucleation temperature is 130°C, whereas the best temperature for crystal growth is 210°C. According to Krebs[30,41] crystallisation begins at specific sites in the amorphous selenium, where small ordered regions of parallel chains (micelles) are formed. On raising the temperature the micelles can grow at the expense of the amorphous selenium. On the other hand, selenium often forms spherulites[30,41]—a special type of rounded, textured polycrystalline formation growing from a single centre, often encountered in the crystallisation of polymers. The temperature range of spherulitic crystallisation for amorphous selenium is 70–150°C.

The rate of crystallisation of selenium is strongly influenced by the annealing schedule, by the purity of the starting material, and by some external conditions. Increase of temperature produces a sharp increase in the rate of crystallisation, the time for complete crystallisation varying from several hours at 70°C to 2–3 min at 217°C. Impurities such as thallium, antimony, indium, alkali metals, oxygen, and halogens catalyse the conversion of amorphous into trigonal selenium.

The action of light, electrons, positive ions, $\gamma$-rays, electric fields, and various organic or inorganic solvents also favours the conversion of amorphous selenium into a thermodynamically more stable crystalline state[6].

Selenium layers prepared under uncontrolled or special conditions may contain all the known amorphous and crystalline phases. Thus layers prepared by the sublimation method[72–76] are evaporated on to the substrate from another surface held at 185°C, the substrate temperature is then raised to 83°C and the layer is held at this temperature for approximately 15 min to stabilise the structure. Films prepared in this way contain a layer of trigonal selenium (adjacent to the surface of the substrate), and a layer of glassy selenium consisting of the amorphous forms. It has been shown[62,77,78] that vacuum evaporation of selenium on a substrate at ~ 85°C produces small islands of crystalline selenium[77] which merge into a continuous sublayer of trigonal selenium at a higher substrate temperature (98°C). The thickness of the crystalline sublayer depends on the temperature of the substrate[78,81]: ~ 0.1 μm at 70°C and 0.8 μm at 90°C. At a substrate temperature of 70–80°C the crystalline layer is fairly smooth, but at higher temperatures we observe dendritic growth to a diameter of 1 μm (at 90°C) and to a depth of 1–2 μm into the layer. At 70–80°C we find, between the trigonal and the amorphous layer, a layer 0.1–0.4 μm thick consisting of a mixture of the monoclinic and the trigonal modification, which is gradually converted into the trigonal modification at room temperature.[80] At 50–60°C the continuous crystalline layer is not formed, but separate crystalline inclusions up to several hundred $\mu m^2$ in area are produced. Crystallisation can be retarded by depositing a sublayer of arsenic triselenide 0.2–0.5 μm thick[79]. Evidently, the same result is obtained using a layer of cellulose nitrate[82,83], which stabilises the properties of layers prepared at 65°C.

Following Nabitovich[7] we can summarise our understanding of the selenium structures as follows. It is now well established that the structure of selenium films is determined first and foremost by the technological conditions used in their preparation. When the films are prepared by vacuum condensation of a molecular vapour on an isotropic substrate the structure is determined by the temperature of the melt, the condensation time, the substrate temperature, and the post-deposition annealing conditions. Immediately after deposition these layers can be in three states: crystalline, supercooled, or amorphous. Condensation of selenium on a substrate at 97–100°C invariably yields crystalline layers, irrespective of the rate of condensation. Selenium layers condensed on substrates at 60–100°C and rapidly cooled to room temperature are always in a supercooled metastable state.

## 4. Photo-electric Phenomena in Amorphous Selenium Structures

Amorphous selenium structures show photosensitivity in the region of $\lambda < 600$ nm (Fig. 2). The photosensitivity spectrum in the visible region has two more or less sharply defined maxima[1] at 370 and 470 nm (curves *1* and *2* of Fig. 2*b*). The photosensitivity increases as the wave length decreases to 140 nm (Fig. 2*a*). This increase arises from the multiplication of the photo-generated

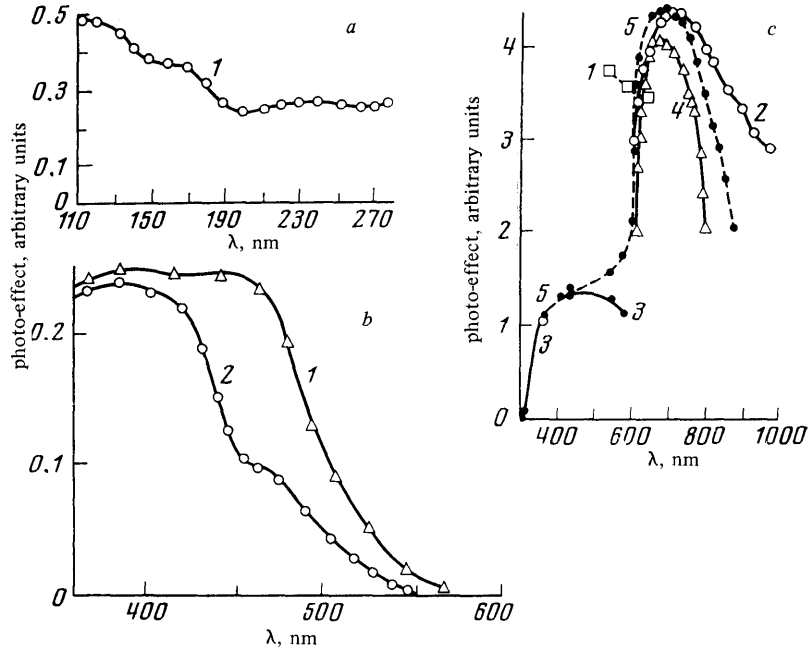

**Figure 2.** Photo-effect spectra of the amorphous and amorphous–crystalline selenium structures: (*a*) and (*b*) d.c. photoconductivity (electrophotographic sensitivity) of amorphous selenium[91]; (*b*) *1*) layer prepared at 300 K, *2*) 120 K; (*c*) photoconductivity at $10^{10}$ Hz[22]: *1*) amorphous selenium (second amorphous form), *2*) amorphous selenium containing 30% of trigonal selenium, steady illumination, *3*)–*5*) modulated illumination, amorphous selenium with different amounts of crystalline phase (*3*) 1–2%, *4*) > 10%, *5*) 30%). The curves for steady (*2*) and modulated (*5*) illumination are normalised to the same peak value; a logarithmic scale is used for the photo-effect.

current carriers at photon energies greater than the forbidden energy gap of selenium in the absence of concentration-dependent recombination. Lowering the substrate temperature during deposition to −150°C lowers the photosensitivity in the spectral region above 400 nm (curve *2* of Fig. 2*b*). Conversely, heat treatment of the amorphous selenium layer, leading to the appearance of a crystalline phase, increases the photosensitivity in the long-wavelength region of the spectrum (Fig. 2*c*). Heat treatment of the layers in air at 60°C for 24 h extends the region of photosensitivity to 880 nm.

The sensitivity spectra of the amorphous and the crystalline phase in heterogeneous selenium layers have been studied by photoconductivity measurements at ultra-high frequencies[22] with steady illumination[85] and with light modulated at 200 Hz.[86] These measurements make clear the relationship between the bulk photoconducting properties and the molecular and supermolecular structure of the selenium sample under conditions which minimise the effect of contacts and allow the photoconductivity to be studied with small "displacements" of the carriers. The basic characteristics of the photoconductivity, i.e. its magnitude, spectral distribution, and temperature dependence, are a function of the amount of crystalline phase in the amorphous selenium. Thus, with 1–2% of crystalline phase photoconductivity (with positive photo-carriers) is observed in the region of 300–600 nm (curve *3* of Fig. 2*c*). The photoconductivity limits of the layers are different for a frequency of $10^{10}$ Hz ($\Delta\sigma_{\sim}$) and for direct current ($\Delta\sigma_{=}$). With direct current $\lambda_{\frac{1}{2}} \simeq 500$ nm,[25,87] i.e. well within the optical absorption band (absorption edge ~ 600 nm). The $\Delta\sigma_{\sim}$ limit, as shown in curve *5* of Fig. 2*c*, occurs at the wavelength $\lambda_{\frac{1}{2}} \simeq 750$ nm, i.e. beyond the absorption edge. Increasing the amount of crystalline phase to 10–30% produces a large (approximately 1000-fold) increase of $\Delta\sigma_{\sim}$ in the red region of the spectrum as well as extending the photoconductivity to even longer wavelengths (up to 1100 nm) with a maximum at 690 nm (modulated illumination, curve *5*) or at 710 nm (steady illumination, curve *2*). The photosensitivity in the spectral region beyond 700 nm is higher with steady than with modulated illumination, showing that the contribution to $\Delta\sigma_{\sim}$ from slow processes is considerable in this region. The maximum of $\Delta\sigma_{\sim}$ coincides with the maximum of $\Delta\sigma_{=}$ of trigonal selenium crystals[88], and is shifted far into the long-wavelength region as compared with the $\Delta\sigma_{=}$ maximum of polycrystalline layers (630 nm).[25]

On lowering the temperature $\Delta\sigma_{\sim}$ is found to decrease, unlike $\Delta\sigma_{\sim}$ for layers with a low content of crystalline phase. The temperature dependence of $\Delta\sigma_{\sim}$ is described by the expression $\Delta\sigma_{\sim} = \Delta\sigma^{0} \exp(-\Delta E/kT)$, where the thermal activation energy $\Delta E = 0.03$ eV is the same for carriers photo-generated in the bulk ($\lambda = 600$ nm) or at the surface ($\lambda = 436$ nm) of the layer. The activation energy is needed, apparently, for the photo-carriers to overcome intermolecular (but not intercrystalline) energy barriers. In practice the displacement of the carriers at a frequency of $10^{10}$ Hz in a field of $10^{2}$ V cm$^{-1}$ is less than 50 Å (the

carrier mobility in amorphous selenium is much less than 50 $cm^2 V^{-1} s^{-1}$). Thus the carrier displacement is much smaller than the size of the micro-crystals, which are usually several thousands of Ångstroms in diameter.

Many of the phenomena which we have discussed can be interpreted by the exciton model of photo-generation in selenium, as we shall show below. Here we only need to point out that the changes in the "structure–property" relationship observed at ultra-high frequency have provided a solution to the opposite problem: the use of photoconductivity at ultra-high frequency as a method of studying the degree of heterogeneity of glassy selenium[90].

## IV. AMORPHOUS ANALOGUES OF SELENIUM CRYSTAL STRUCTURES

### 1. Structure

It may be assumed that if a molecular solid can exist in several crystalline modifications, with different types of short-range order, the solid should also exist in several amorphous structures with different types of short-range order (and therefore with different energy spectra). Among the possible examples of substances (or, indeed, elements) showing several amorphous structures selenium is a particularly good choice, because it can also exist in several crystalline modifications differing in molecular structure and therefore in short-range order.

Selenium layers prepared from a molecular vapour at a given temperature, at a given rate of condensation and substrate temperature, and homogenised under prescribed conditions, can form an amorphous state with two different amorphous structures (the amorphous forms of selenium) or consisting of a mixture of these two amorphous structures[7]. In contrast to the supercooled state, the short-range order in amorphous selenium manifests itself as a constant interatomic distance and also as an arrangement of atoms in definite configurations, leading to a diffraction pattern with several sharp maxima.

The first amorphous form of selenium is formed by evaporating the element from a melt at 220–270°C, condensing the vapour on a substrate at 18–40°C, and annealing the layer in a vacuum at room temperature for 30 h. This structure has a definite diffraction pattern. Its structural units are distorted structural units of the crystal lattice of the monoclinic $\alpha$ and $\beta$ modifications: molecular rings consisting of eight atoms. During the formation of the structure these rings polymerise into agglomerates responsible for the "cobble-stone" outline of the sample surface.

The second amorphous form of selenium is formed by evaporation from a melt at a temperature above 350°C, condensation of the vapour on a substrate at 50–80°C, and subsequent annealing of the layers at 50°C in a vacuum for 20–30 min. This structure also gives a well defined diffraction pattern. The structural units of the second amorphous form are distorted structural units of the crystal lattice of trigonal selenium: short molecular chains. During the formation of the structure, the predominant process is polymerisation of the short molecular chains into long polymeric chains, randomly interweaved and looped.

The intermediate amorphous state of selenium is formed at moderate rates of evaporation on a substrate at 40–60°C, with slow cooling of the layer to room temperature. The diffraction pattern of this structure depends on the relative numbers of units of the first and of the second amorphous form. Using electron-diffraction results on the radii of the coordination spheres and on the coordination numbers, and making allowance for the presence of atomic selenium in the intermediate state, Nabitovich[7] concluded that the intermediate amorphous state includes not only ring and chain molecules of different size but also a significant number of selenium atoms, which tend to attach themselves to other atoms or to the ends of other molecules in a tetrahedral configuration. The first and the second amorphous form contain ~ 10% of these atoms, which join together the distorted ring or chain molecules and allow them to polymerise. Hence the main difference between the amorphous structures and the crystalline lattices is that the structural units in the former lack the parallel arrangement of the latter.

### 2. Photoelectric Phenomena in the Amorphous Analogues of the Selenium Crystal Structures

The first study[23] of the photoelectric properties of the amorphous analogues of selenium crystal structures aimed to explain the influence of short-range order on the photoelectric properties of various amorphous structures and to compare them with the properties of the corresponding crystalline structures. The measurements were made on layers of amorphous selenium with two types of molecular structure, prepared by vacuum evaporation of selenium of $B_4$ grade (99.9999% Se) with controlled melt and vapour temperature (230–250°C), deposition rate ($\leqslant 30$ Å $s^{-1}$), residual gas pressure ($10^{-6}$ mmHg), and substrate temperature (20°C for the first type of structure, consisting mainly of ring molecules, and 55°C followed by vacuum annealing for the second type of structure, consisting mainly of chain molecules). Great care was taken to ensure the absence of crystalline phase in the layers. The structure of the surface of the layer, and of that of the sub-layer adjacent to the substrate, was investigated by the carbon replica method in an EM-5 electron microscope (20 000 × magnification). Fig. 3 shows some micrographs of amorphous selenium layers obtained by this method (*e*, *f*) and by scanning electron microscopy (*a*, *b*, *c*, *d*). The layer surface, the cross-section of the layer, and the substrate surface are clearly visible in the SEM pictures (*a*, *b*, *c*, *d*). With amorphous selenium films the surface of the layer and that of the sub-layer on the side of the substrate are smooth, specular, and free from microscopic inclusions of crystalline selenium, and the electron diffraction patterns (Fig. 3*g* and 3*h*) are typical of amorphous structures, with two or three diffuse rings (clearly visible in the microdensitometer traces of Fig. 3*j* and 3*k*). After heat treatment of these layers at 70°C microscopic inclusions of crystalline selenium appear in the amorphous selenium. These are clearly visible in the micrographs, and they are accompanied by the formation of spots on the diffraction pattern (Fig. 3*i*).

We should note that these methods of structural analysis can detect crystalline inclusions in the amorphous selenium layers only a few tens of Ångstroms in diameter. The reflection electron diffraction method is the most "non-destructive" method of studying amorphous selenium structures, and is therefore preferable to the simpler transmission method. By varying the thickness of the layers and by examining structurally both the free surface and the surface in contact with the substrate (after removing the layer from the substrate), and also by studying both surfaces and the cross-section of the layer with an electron

microscope, using shadowed carbon replicas, we have obtained reliable information on the amorphous forms of selenium[23,104] confirming the results of the leading workers on the amorphous selenium structures (Nabitovich, Richter, Herre, and others)[7,29,68].

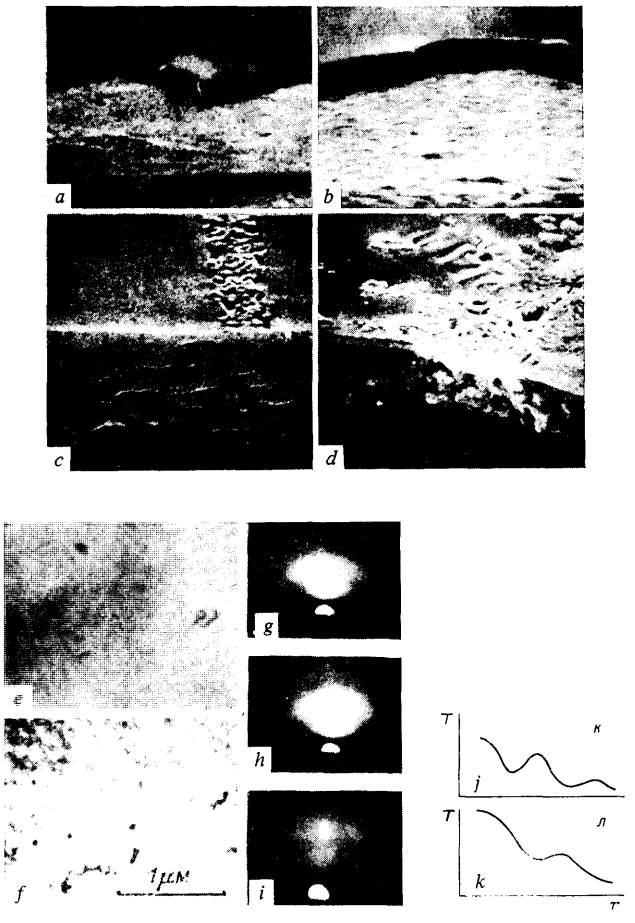

**Figure 3.** Electron diffraction patterns and micrographs of amorphous selenium structures[21,104]: *a*) and *e*) amorphous analogue of monoclinic selenium (free surface and substrate interface respectively), magnification × 14 000; *b*) and *f*) amorphous analogue of trigonal selenium; *c*) and *d*) for comparison, amorphous selenium containing some crystalline phase; *g*), *h*), and *i*) electron diffraction patterns for *a*), *b*), and *c*) respectively; *j*) and *k*) microdensitometer traces of the diffraction patterns of the amorphous analogues of monoclinic (*g*) and trigonal (*h*) selenium.

Studies of the spectral distribution of photoconductivity in strong electric fields (electrophotographic sensitivity), of photoconductivity at ultra-high frequency ($10^{10}$ Hz), of the capacitive photo-e.m.f., and of the effect of light on the contact potential difference, made on the same samples over the spectral region 360–800 nm, have shown substantial differences in photoelectric properties between the two amorphous structures of selenium (Fig. 4). Firstly, the photo-effect spectra for selenium in one of the amorphous structures (curves *1*(*2*), *2*(*2*), *3*(*2*) of Fig. 4) show a marked shift towards the long wavelength region in comparison with the other amorphous structure (curves *1*(*1*), *2*(*1*), *3*(*1*), *4*(*1*) of Fig. 4). Secondly, the amorphous selenium structures have different photoconductivity types: one of the amorphous structures conducts mainly by positive holes, the other mainly by electrons. Thirdly, one of the amorphous structures has a fairly high photoconductivity at $10^{10}$ Hz (curve *2*(*2*) of Fig. 4).

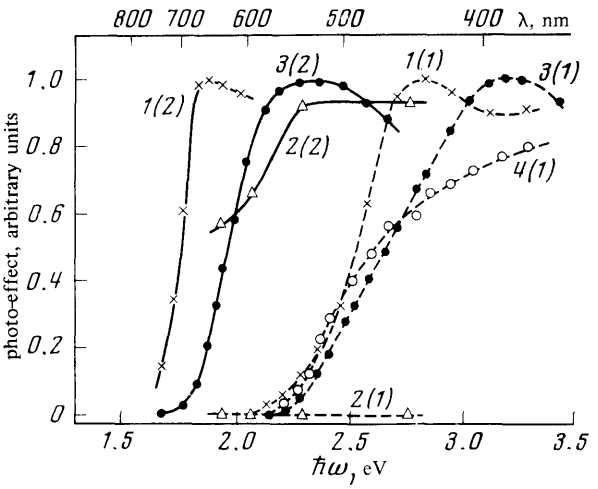

**Figure 4.** Isoenergetic spectra for the photo-effect in the amorphous analogues of the crystalline selenium structures[23]: *1*) d.c. photoconductivity (electrophotographic sensitivity), *2*) photoconductivity at $10^{10}$ Hz, *3*) photo-e.m.f., *4*) contact potential difference; in all curves (*1*) denotes the amorphous analogue of monoclinic selenium and (*2*) the amorphous analogue of trigonal selenium.

Comparison of the photo-properties of the amorphous and the crystalline structures has shown[23,92,104] that the two amorphous selenium structures with different short-range order are the amorphous analogues of the known crystalline structures of selenium (monoclinic and trigonal). The transition from crystal to amorphous analogue shows the theoretically predicted shift of the absorption edge towards longer wavelengths (Fig. 4).

The work described above has confirmed the crucial importance of short-range order in determining the properties of materials, and it has shown that short-range order in disordered materials can be controlled by varying the molecular structure: the survival of the molecular structure of molecular (polymeric) solids during the crystal–glass transition enables the glass to "remember" the short-range order (and the properties) of the crystal and to "forget" the long-range order.

To conclude this section we shall consider to what extent the photoelectric properties of amorphous selenium could be due to an undetected crystalline phase.

Existing methods of analysis by electron microscopy and electron diffraction methods, coupled with solid-state photoelectric spectroscopy, offer a fairly extensive and sensitive check on the phase composition and the molecular

state of selenium samples. As stated above, the following non-crystalline selenium structures (with different properties) have been recognised: amorphous (glassy) selenium, amorphous–crystalline selenium (amorphous selenium containing some crystalline phase), amorphous–crystalline selenium with a phase boundary (an amorphous layer with a crystalline sub-layer), and amorphous analogues of the crystalline selenium structures (monoclinic and trigonal). The role of the crystalline phase in the amorphous and amorphous–crystalline selenium structures has been discussed above. The existence of amorphous forms of selenium with structural units of crystalline selenium, demonstrated by Richter, Nabitovich, and others, is no longer in doubt. Recent work has shown[23] that the amorphous forms of selenium are true analogues of the corresponding crystalline structures, and that the crystal–glass transition in the appropriate pairs is accompanied by the theoretically predicted changes in optical and photoelectric properties.

Hence the properties of the amorphous analogues differ from those of amorphous selenium with crystalline inclusions or with a crystalline sub-layer in the following respects: the photoconductivity spectra at $10^{10}$ Hz, the spectra of the light-induced changes in contact potential difference and in capacitive photo-e.m.f., the photosensitivity spectra in the EP regime, the photoluminescence spectra (many lines in trigonal selenium[84] and a broad band in the amorphous analogue), the temperature dependence of the optical absorption edge[3], and the shape of the thermally stimulated conduction spectra[93].

## V. PHOTOSENSITIVITY AND THE STRUCTURAL SENSITISATION OF THE PHOTO-EFFECT

Studies of non-photoactive absorption in molecular (polymeric) solids have led to the discovery of the phenomenon which we have termed structural sensitisation of the photo-effect[91]: a dependence of the spectral distribution and magnitude of the quantum yield for the internal photo-effect of molecular photoconductors upon the molecular and super-molecular structure of the solid. The phenomenon stems essentially from the photogeneration of current carriers in molecular photoconductors (in contrast to the photogeneration in classical semiconductors of the germanium and silicon type) through the state of a bound hole–electron pair (or exciton) over a wide spectral region. The features of the molecular and super-molecular structure determine the probability of generating free charge carriers from the bound state[28].

Let us consider in greater detail the photogeneration of free carriers in the amorphous analogues of the crystalline selenium structures. The theory of excitons in disordered semiconductors has been developed by Bonch-Bruevich[94] in recent years. We know at least three reasons for the lack of sharp absorption lines when excitons are present in disordered semiconductors. Firstly we have small-scale fluctuations in the electric field, which broaden the exciton lines; there is also strong scattering of the electrons, resulting in non-conservation of the quasi-momentum; lastly, the absorption coefficients are not additive, so that if an additional spectrally dependent absorption mechanism is present (in parallel with the exciton mechanism) the exciton structure of the absorption spectrum becomes blurred. However, the coulombic field must be acting on the electron and the hole as it does in crystals, and it must lead to the formation of bound states. Furthermore many disordered structures have relatively small dielectric constants, and if the effective mass of the carriers is not too small this should result in a large binding energy.

The presence of excitons had been previously suggested by various workers (Hartke, Regensburger, Siemsem, Fenten, Stuke, Davis, Boon) to account for various properties of amorphous selenium[84,95,96,100,101]. Our more recent investigation[92] differed from the earlier work on amorphous selenium in combining measurements of optical properties and of the quantum yield of the internal photo-effect as a function of quantum energy, temperature, and applied field on the same samples in order to reveal exciton effects. Layers of amorphous selenium were prepared by the molecular beam method in a vacuum[23] as analogues of monoclinic (first amorphous form, I AF) and trigonal (II AF) selenium, with different molecular structures (eight-membered rings and linear molecules up to several hundreds of atoms in length).[23] The thickness of the layers was varied between 0.1 and 10 $\mu$m. Tests for the absence of crystalline phases were made by electron microscopy and electron diffraction: this combination of methods could detect crystalline inclusions a few tens of Ångstroms in diameter within the amorphous layers. The quantum yield of the internal photo-effect ($\eta$) was measured in the electrophotographic regime; the low-field photoconductivity was measured with extremely small displacements of the charge carriers (a few Ångstroms) using a frequency of $10^{10}$ Hz with both steady and modulated illumination. The diffuse reflectance and the transparency of the layers were measured with and without an applied electric field of $2 \times 10^5$ V cm$^{-1}$; the kinetics of photo-discharge (in the EP regime) and of luminescence were studied at quantum energies in the range 1.5–3.3 eV and temperatures in the range 4.2–300 K, using SF-4 and SF-8 spectrophotometers and a cryostat designed to allow all the measurements to be done on the same sample.

The temperature shift of the absorption edge of the amorphous forms of selenium (Fig. 5*a* for I AF, curves *1* and *2* of Fig. 5*b* for II AF), unlike the temperature shift for crystalline selenium (curves *3* and *4* of Fig. 5*b*), depends on the quantum energy, falling to zero as the energy of the quantum increases[3]. The application of an electrostatic field of up to $2 \times 10^5$ V cm$^{-1}$ shifts the absorption towards smaller quantum energies (Franz–Keldysh effect), but the change in transparency of the film due to this effect is less than 1%. Toyazawa's theory of localised excitons was used to analyse the temperature shift of the absorption edge. Transition probabilities for non-photoactive absorption, which can be compared with theory, were calculated by the method of Hartke and Regensburger[95], which is convenient for the case of several independent mechanisms of optical absorption. The experimentally determined transition probabilities $\epsilon_2^H \cdot (\hbar\omega)^2$, where $\epsilon_2^H$ is the imaginary part of the dielectric constant $\epsilon$, corresponding to the non-photoactive absorption process (indicated points in curves *4–6*), agree quite well with theoretical predictions (solid curves *4–6* of Fig. 5*a*). The calculation is correct for the edge region of the non-photoactive absorption, for which the quantum yield of the internal photo-effect is $\eta \simeq 0$, and it explains the temperature dependence of the position of the absorption edge and its Urbach behaviour in terms of localised excitons.

When $\hbar\omega$ increases the excitons (of the Wannier–Mott type) dissociate in a strong field to give free charge carriers, and $\eta$ becomes a function of quantum energy, electric field, and temperature. The $\eta$ spectra (Fig. 6*a*)

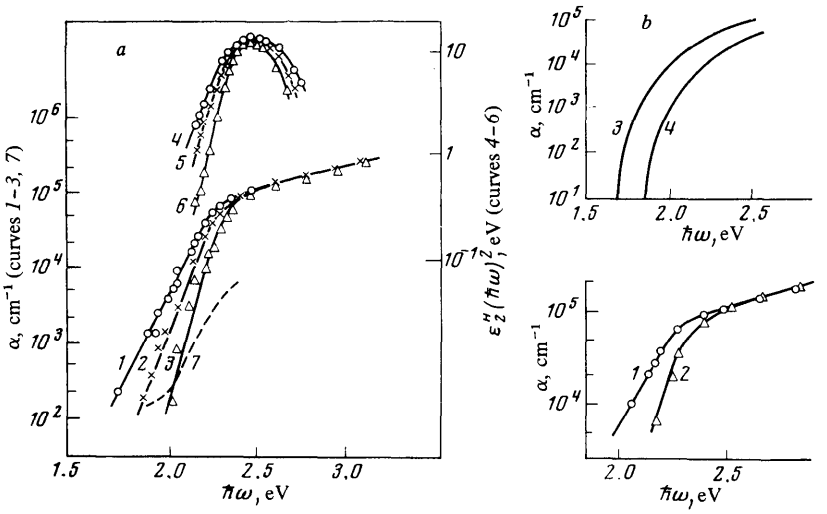

**Figure 5.** Optical properties of the amorphous analogues of crystalline selenium structures[103]: (*a*) absorption coefficient $\alpha$ of the amorphous analogue of monoclinic selenium: *1*) 300, *2*) 200, *3*) 95 K; *4*)–*6*) are the probabilities of the photoconducting transitions (*4*) 300, *5*) 200, *6*) 95 K, field $2 \times 10^5$ V cm$^{-1}$); *7*) absorption coefficient $\alpha$ of monoclinic selenium[24]; (*b*) absorption coefficient $\alpha$ of the amorphous analogue of trigonal selenium: *1*) 300, *2*) 95 K. The $\alpha$ values of trigonal selenium[109] are also shown for comparison: *3*) 300, *4*) 93 K.

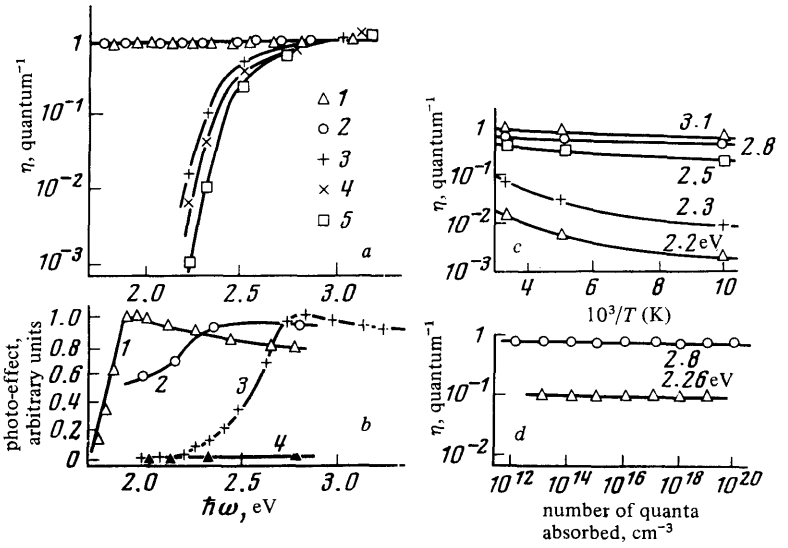

**Figure 6.** Quantum yield (*a*) of the internal photo-effect (*b*) and its temperature (*c*) and concentration (*d*) dependence[92]: (*a*) *1*) trigonal selenium and *2*) its amorphous analogue, field $2 \times 10^5$ V cm$^{-1}$, $T = 300$ K; *3*)–*5*) amorphous analogue of monoclinic selenium: *3*) 300, *4*) 200, *5*) 95 K, field $2 \times 10^5$ V cm$^{-1}$; (*b*) photo-effect in the highest possible (*1*, *3*) and in low (*2*, *4*) fields for the amorphous analogues of trigonal (*1*, *2*) and monoclinic (*3*, *4*) selenium; *c*) and *d*) refer to the amorphous analogue of monoclinic selenium.

and their dependence on temperature (Fig. 6*c*) and on field (Fig. 6*d*) are quite different for the two amorphous forms of selenium. For II AF (curve *1* of Fig. 6*a*), as for trigonal selenium (curve *2* of Fig. 6*a*), the $\eta$ value is close to unity and practically constant in the region of 1.7–3.1 eV, i.e. up to the absorption edge, the carriers being generated in pairs. Conversely, for I AF (curves *3–5* of Fig. 6*a*) $\eta$ decreases as the quantum energy, the temperature, and the field decrease, reaching zero at fields of the order of $10^2$ V cm$^{-1}$ (curve *4* of Fig. 6*b*), while the spectrum is shifted into the centre of the absorption band (the "red anomaly" according to Moss). Under these conditions, with a field of $2 \times 10^5$ V cm$^{-1}$ and quantum energies between 2.8 and 2.26 eV, $\eta$ is independent of the number of quanta absorbed over a range of eight orders of magnitude up to $10^{20}$ cm$^{-3}$ (Fig. 6*d*), showing that concentration-dependent recombination is absent and that the carriers are generated in pairs.

The features observed for the I AF form of selenium, including carrier generation in pairs, independence of $\eta$ upon ionisation density, increase of $\eta$ with quantum energy, and variation of the activation energy of $\eta$ (Fig. 6*c*) with quantum energy (falling to zero at the higher quantum energies), all suggest an exciton mechanism of photogeneration through the state of a coulombically bound pair. The results[92] are consistent with the theory of photogeneration in selenium developed by Pai[97,108], Ing[97], Tabak[98], Warter[98,99], Davis[100], and Vishchakas and Montrimas[102].

For the amorphous analogue of trigonal selenium we may again assume that carrier generation occurs through an exciton stage, but in this case the excitons are effectively dissociated by a small electric field in accordance with the theory of Bonch-Bruevich. In this model the quantum yield should not be lowered substantially by a decrease in the applied field: as shown in curve *2* of Fig. 6*b*, the quantum yield does not fall to zero (in contrast to the case of the analogue of monoclinic selenium).

Both amorphous structures give luminescence bands at 4.2 K, but the luminescence is quenched by increase of temperature[103]: in both cases the width of the band is 0.23 eV. However the position of the band relative to the forbidden gap $E_{opt}$ and the spectral distribution of the luminescence yield are very different in the two cases. For I AF (Fig. 7*a*) the quantum energy corresponding to the peak of the luminescence band is 1.80 eV, and $E_{opt}$ = 1.88 eV[104] (see Table); the quantum yield of the luminescence $\varphi_{lum}$ depends on the energy of the quantum, falling to zero as the quantum increases, as well as varying in a sense opposite to that of $\eta$. We must stress three facts. Firstly, at low values of $\hbar\omega$ and at low fields $\eta \simeq 0$, and $\varphi_{lum} = 0$, showing that the luminescence arises from annihilation of bound pairs rather than from recombination of free carriers. Secondly, increasing $\hbar\omega$ leads to $\eta \simeq 1$, but in this case $\varphi_{lum} = 0$, i.e. the free carriers do not contribute to the luminescence. Lastly, the changes in opposite sense of the $\eta$ and $\varphi$ spectra follow unambiguously from the alternative mechanisms: annihilation of the exciton, with luminescence, or dissociation with formation of free current carriers.

Optical and photoelectric forbidden gap ($E$) of selenium with different molecular structures.

| $E$, eV | Eight-membered ring | | Polymeric chain | |
|---|---|---|---|---|
| | crystal | glass | crystal | glass |
| $E_{phot}$ | 2.48 | 2.53 | 1.78 | 1.79 |
| $E_{opt}$ | 2.0 | 1.88 | 1.78 | 1.81 |

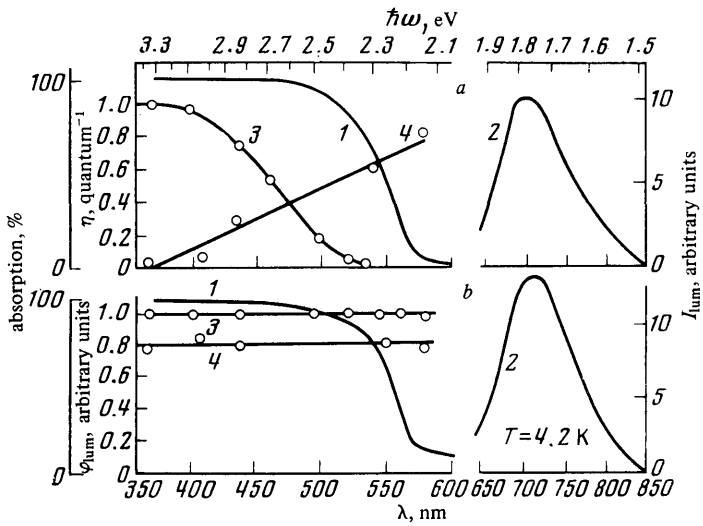

**Figure 7.** Spectra of the photo-processes in the amorphous analogues of the crystalline selenium structures (*a*) monoclinic, *b*) trigonal)[103]: *1*) absorption, *2*) photoluminescence ($I$), *3*) quantum yield of the internal photo-effect $\eta$ (extrapolated from 30 K), *4*) quantum yield of the photoluminescence $\varphi$.

The observed luminescence cannot be due to impurities, which could not explain the specific effects discussed above, and would also be inconsistent with the fact that Urbach's rule is found to apply up to absorption coefficients greater than $10^4$ cm$^{-1}$.[96] However participation of impurities or defects in the luminescence of amorphous selenium is possible in principle, but only if we retain the assumption of interaction via excitons: in this way the luminescence can be interpreted as exciton luminescence. The ground state of the exciton, measured[92] from the luminescence spectrum ($E_{exc}$ = 1.80 eV), lies 0.08 eV below the bottom of the conduction band ($E_{opt}$ = 1.88 eV). We note that $E_{opt}$ was determined according to Sturge's criterion for $\alpha$, corresponding to the mobility threshold ($\sim 10^3$ cm$^{-1}$), whereas $E_{phot}$ was determined by the Moss criterion[104]. The photon energy corresponding to $E_{exc}$ according to Toyazawa's theory and measured from the photoconductivity spectrum was 2.44 eV,[3] i.e. 0.09 eV lower than $E_{phot}$ = 2.53 eV. It may be assumed that the difference between the $E_{exc}$ values measured in absorption and in emission is due to energy dissipation by the excited pair.

In amorphous selenium with a molecular chain structure the quantum energy at the luminescence maximum (1.75 eV) is close to $E_{opt}$ = 1.78 eV, and the $\varphi_{lum}$ spectrum is correlated to the $\eta$ spectrum and does not depend on $\hbar\omega$. This behaviour, and also the very high quantum yield $\eta$ of unity, allow us to interpret the luminescence as recombination-induced, of a type previously observed in amorphous chalcogenide semiconductors[105-107]. As Fig. 7 shows, no exciton absorption peak is observed in either amorphous structure at temperatures down to 4.2 K.

---o0o---

The optical and photoelectric properties of amorphous selenium structures discussed above indicate the existence of exciton effects in disordered polymeric semiconductors.

By comparing the roles of exciton effects in the photogeneration of charge carriers in organic and in inorganic polymeric photoconductors[28] we conclude that these effects are weaker in inorganic photoconductors because the coulombic interaction of the hole–electron pair created by the absorption of a light quantum is more effectively screened in these materials.

# Gas-chromatographic Analysis of Products of the Decomposition of Proteins and Nucleic Acids

A.N.Korol'

Various gas-chromatographic methods for analysing amino-acids, nucleic acid bases, nucleosides, and nucleotides, and also the use of pyrolytic gas chromatography to determine the composition of proteins and nucleic acids, are surveyed critically. A comparison is made of the best analytical results for mixtures of the above compounds by the use of gas-liquid chromatography and high-pressure liquid chromatography. A list of 243 references is included.

## I. INTRODUCTION

Molecular biology and kindred disciplines are unable to develop if the structures of proteins and nucleic acids, i.e. the sequences of monomeric units (amino-acids and nucleotides) in their molecules, are not established. Such a procedure is extremely laborious because of the high molecular weight of biopolymers. Therefore automation and acceleration of such determinations are highly significant.

Methods of liquid chromatography are widely used in separating mixtures of proteins and nucleic acids and in the qualitative and quantitative analysis of their decomposition products. However, the classic forms of such methods are laborious and insensitive, so that, immediately following the discovery of gas-liquid chromatography[1], research workers became interested in the possibility of using it to separate mixtures of amino-acids[2]. But the need to convert the latter into relatively unstable volatile derivatives presented considerable difficulties in the application of gas-liquid chromatography to their analysis.

In 1958 an automatic method was developed for analysing mixtures of $\alpha$-amino-acids by ion-exchange chromatography[3-6] with a photocolorimeter to detect the amino-acid derivatives; the time required for a complete analysis was a few hours, when the sensitivity of a determination reached $10^{-7}$ mole. By the end of the 1960s the first models of high-pressure liquid chromatographs were manufactured with an ultraviolet-absorption detector, which shortened to 1 h the time required to analyse a mixture of $\alpha$-amino-acids and improved the sensitivity to $10^{-9}$ mole. A limitation of these instruments is the need to obtain aromatic derivatives of amino-acids for detection by their ultraviolet spectra. It might appear that they would displace gas-liquid chromatography completely from laboratory research on biopolymers. However, this method possesses certain advantages over the high-pressure chromatographs—sensitivity enhanced by factors of $10^2$–$10^3$, incomparably greater separating power, and cheaper apparatus (Table)—which explains the development of research on its application to the analysis of breakdown products of biopolymers and its widespread use together with high-pressure liquid chromatographs in practical biochemical investigations.

Comparison of optimum characteristics of gas-liquid chromatography and high-pressure liquid chromatographs in the analysis of degradation products from proteins and nucleic acids.

| Characteristic | Gas-liquid chromatography | High-pressure liquid chromatograph |
|---|---|---|
| Separation of amino-acid mixtures: | | |
| time of separation of 20 protein amino-acids | 15 min | 70 min |
| detection limit—average | $10^{-8}$ g* | $10^{-7}$ g |
| minimum | $10^{-12}$ g** | $10^{-8}$ g |
| stability of derivatives for analysis | moderate | high |
| resolution of optical isomers | possible | impossible |
| total duration of one determination | < 1 h | ~1 h |

Aspects of the gas-chromatographic analysis of amino-acids and nucleic-acid bases (here and subsequently the Reviewer uses the term "nucleic-acid bases" for brevity to cover purine and pyrimidine bases, major and minor,

present in nucleic acids and their fragments—nucleotides and nucleosides) have been considered in > 500 papers. However, reviews on this topic either have become out of date[6-14] or deal with individual aspects[15-17]: relatively complete reviews of the gas–liquid chromatographic analysis of amino-acids have appeared only recently[18-20]. One of these[19] is concerned mainly with quantitative aspects of the analysis of amino-acids, and hardly mentions pyrolytic gas–liquid chromatography and the separation of hydantoin derivatives of the acids. Furthermore, several fundamentally new methods for the analysis of amino-acids and nucleic-acid bases have appeared during the past one or two years.

The present Review surveys critically methods for the gas-chromatographic analysis of amino-acids, nucleic-acid bases, nucleosides, nucleotides, peptides, proteins, and nucleic acids, and compares the best gas-chromatographic methods with results obtained by other chromatographic methods. Most of the above compounds cannot be determined directly by gas chromatography because they are non-volatile, so that attention is directed mainly to quantitative methods for obtaining volatile decomposition products of biopolymers†.

## II. PREPARATION AND SEPARATION OF VOLATILE DERIVATIVES OF AMINO-ACIDS

Twenty α-amino-acids—termed "protein amino-acids"—may be present in proteins. Several other amino-acids are also met in Nature, and some derivatives are hormones. Amino-acids can be classified according to reactivity, which depends on the radical R attached to the amino-acid grouping $H_2N.CH.COOH$; the different groups are characterised by differences in the difficulty of obtaining volatile derivatives and of their gas-chromatographic separation. The first group—glycine, alanine, valine, leucine, isoleucine, methionine, phenylalanine, and proline—exhibit minimal reactivity. A second group comprises threonine, serine, lysine, tyrosine, asparagine, and glutamine. The most active amino-acids—arginine, cysteine, tryptophan, and histidine—form the third group. In addition, several other amino-acids are encountered, e.g. norvaline, α-aminobutyric acid, norleucine, and cystine. Some amino-acids contain iodine (tyrosines); many contain sulphur.

When heated, amino-acids undergo decarboxylation to the corresponding amines. Over the temperature range 180–240°C members of the first group other than isoleucine are converted into amines containing one carbon atom fewer than in the original amino-acid; this applies also to threonine, serine, and norvaline[10]. Raising the temperature to 300°C forms complexes of ammonia with amines containing 1–5 carbon atoms[10]. Complete thermal decomposition of amino-acids results in the evolution of nitrogen, which was used earlier[10] for the qualitative identification of amino-acids. It is now more advisable to employ for this purpose thermionic detectors that are selective for nitrogen[21].

Deamination yields finally aldehydes, which are comparatively easy to determine by gas–liquid chromatography. The oxidation of amino-acids by sodium hypochlorite was examined[10] with α-aminobutyric acid, norvaline, valine, norleucine as examples, the resulting aldehydes being separated on a dinonyl phthalate column at 92°C. However, sodium hydrochlorite proved to be too strong an oxidant, causing degradation of the carbon skeleton, so that the yield of aldehyde from an amino-acid was not quantitative.

Ninhydrin was used to convert leucine and isoleucine into aldehydes, which were then separated on silicone oil at 69°C. Alanine, valine, isoleucine, leucine, norleucine, methionine, threonine, and α-aminobutyric acid were converted quantitatively into aldehydes after reaction for 15–30 min; glycine and phenylalanine were also converted into aldehydes. The amino-acids were oxidised by ninhydrin in a reaction vessel[10-22] comprising a column filled with a solid carrier impregnated with ninhydrin. Alanine, valine, norvaline, leucine, isoleucine, and norleucine were converted[10] into aldehydes with the reaction vessel at 125°C; the aldehydes were then separated on a glycerol–silicone oil column at 65°C.

Although the aldehyde method has not been successful with all protein amino-acids, it is extremely attractive in regard to the ease of separation of volatile derivatives. A recent paper[23] has reported the conversion of amino-acids into aldehydes by means of aqueous silver picolinate for analysis of a mixture of alanine, valine, leucine, isoleucine, proline, glycine, and norleucine, the aldehydes being separated on a polyethylene glycol 4000 column. A suggestion[10] that aldehydes obtained from amino-acids should be oxidised with permanganate to acids and then determined on a polypropylene glycol column at 150°C is hardly advisable, since acids are considerably more difficult than aldehydes to determine chromatographically. Attempts to use ninhydrin to obtain aldehydes from the second and third groups of amino-acids have proved unsuccessful.

Deamination occurs also on the addition of sodium nitrite in acetic acid; the resulting acid is esterified with diazomethane, and the methyl esters are separated on a silicone-oil column with temperature programming[18]. Examination of a mixture of glycine, alanine, valine, leucine, asparagine, and glutamine has shown[24] that the reaction is not quantitative, although the systematic error is constant within the range 2–10%. Esters of isoleucine, threonine, methionine, phenylalanine, histidine, and arginine have been obtained by the same method. The methyl esters from five amino-acids of the first group were separated on a capillary column with Apiezon L at 130°C.[18]

Decarboxylation of amino-acids by *N*-bromosuccinimide has been used to analyse derivatives of alanine, valine, leucine, phenylalanine, and norvaline[18]; the ratio of nitriles and aldehydes obtainable by this reaction varies within wide limits, but the former predominate. The products from alanine, valine, leucine, isoleucine, norleucine, norvaline, and α-aminobutyric acid were separated on a silicone-oil column. Nitriles of amino-acids are formed also by treating them with iodosobenzene; the reaction products were separated on polyethylene glycol and 1,2,3-tris-(2-cyanoethoxy)propane.[18]

The carboxy-group of an amino-acid is reduced to hydroxyl by lithium tetrahydroaluminate with formation of the corresponding aminoalcohol. Reduction products from the first group of amino-acids (other than proline) were separated on a column with 20% of SE-96 or SE-52 silicone oil over the range 155–200°C.[10] Under these conditions the aminoalcohol obtained from tryptophan does not emerge from the column, while the corresponding glycine derivative is masked by the solvent peak. A polar

†Because of limitations of space some of the references to original papers (mostly examples of applications) are quoted from published reviews.

stationary phase—polyethylene glycol 3000—has also been used to separate these products. This method has been employed to establish the composition of the hydrolysate from peptides [18].

Treatment of the first group of amino-acids with a mixture of hydrochloric and nitric acids yields α-chloro-derivatives, whose methyl esters are separated on a mixture of polyethylene glycol with silicone oil and stearic acid [18], a method used to detect norleucine and norvaline in natural products and to establish the structure of dipeptides [18]. Derivatives corresponding to phenylalanine and methionine are not recorded on the chromatogram when the amino-acids are converted into the methyl esters of α-chloro-acids, and treatment of serine gives two peaks. *N*-Thiocarbonyl derivatives have been obtained from the n-propyl esters of amino-acids; tryptophan does not undergo this reaction, while cystine and cysteine form only thiocarbamates [25].

Even the latter comparatively mild methods for obtaining volatile derivatives of amino-acids by removing active groups have not found application in practical analysis, owing to the difficulty of quantitative conversion of the second and third groups of amino-acids.

In the preparation of methyl esters of amino-acids in the presence of hydrogen chloride as catalyst the hydrochlorides of the esters are usually obtained. The free esters are formed by shaking the methanolic solution of the salt with an ion-exchange resin: the resulting solutions remained unchanged for 1–24 h. [10] Methyl esters containing a free amino-group were separated on a column of 2% of poly(neopentyl glycol succinate) on Fluoropak-80; diatomaceous carriers proved to be active for these systems. Great difficulties arose in the chromatographing of the methyl esters of tyrosine, histidine, and tryptophan. Attempts to convert the hydrochlorides into the free esters by thermal dissociation in the heated injector of the chromatograph have proved unsuccessful. Columns with the above sorbent have been used to separate derivatives of isomeric hydroxyprolines. Esters of amino-acids with $C_{2-4}$ alcohols are relatively non-volatile and therefore less suitable for gas–liquid chromatography. Mass-spectrometric investigation of the structure of the ethyl esters of several amino-acids has shown [18] that all these derivatives are indeed ethyl esters, with the exception of ornithine, which cyclises into a lactam.

The most common method for obtaining esters is to treat the amino-acid with the anhydrous alcohol in the presence of hydrogen chloride; sometimes hydrogen bromide and sulphuric acid are used as catalyst. Alcohols can be replaced by derivatives of diazo-compounds. Moisture must be absent from reagents and from initial specimen for quantitative esterification. Small quantities of aqueous amino-acids can be dried by means of an electrically heated platinum spiral [26] in an atmosphere of an inert gas. Esterification is quantitative at 70°C after 30 min [23], although other régimes have been reported: 1.25 *N* methanolic hydrogen chloride at 20°C required 30 min [27]; the n-propyl ester of an amino-acid is formed by treatment with 8 *N* propanolic hydrogen chloride at 100°C for 20 min [28]. Acetyl chloride with methanol and an orthoformate in methanolic hydrogen chloride are also used as esterification catalysts. Another process for obtaining esters is to reflux an amino-acid and an alcohol in the presence of an ion-exchange resin [18]. Methylation by refluxing with dimethyl sulphite in methanolic hydrogen chloride is quantitative and rapid [18,29]; it can be effected also by thionyl chloride with methanol [30].

The sparing solubility of amino-acids in high alcohols complicates their esterification, and this applies especially to cysteine, lysine, and histidine. It has been proposed [18] to overcome such difficulties by initially obtaining the methyl esters and then transesterifying (e.g. with 1.25 *N* n-butanolic hydrogen chloride at 100°C for 150 min [23]). In practical analysis a more common method for dispersing amino-acids in $C_{3-5}$ alcohols is the use of ultrasound: a suspension of the amino-acid in n-butanol was subjected to ultrasonic treatment for 15 s. [31] Recently, however, it has been found [32] that only 50% of the total quantity of amino-acid is esterified under these conditions, and therefore treatment of the suspension for 5 min is recommended, but more complete dissolution of the amino-acid can be effected by adding dichloromethane (10% on the total quantity). Esterification with n-butanol is accomplished in 3.5 *N* hydrogen chloride at 150°C for 15 min [32]; isoleucine is the most difficult to esterify (by 85%), but tryptophan is 15% decomposed; when esterification is prolonged to 2.5 h, isoleucine is completely esterified, but then tryptophan is also completely decomposed [31-36]. The dissolution of amino-acids in alcohols can be improved by adding trifluoroacetic acid; lysine hydrochloride is then completely esterified in a stream of dry hydrogen chloride at 108°C. [37] Amino-acids can be esterified also by means of isodobutane in the presence of methanolic phenyltrimethyl- or tetramethyl-ammonium hydroxide; this reaction takes place in dimethylformamide at room temperature within 10 min. [38]

Thus almost all derivatives of the protein amino-acids can be obtained quantitatively by esterifying the carboxy-group. However, such esters are either hydrochlorides or free esters of the amino-acids with free amino-groups: i.e. they contain at least one active group, which lowers the volatility of the derivative and causes appreciable adsorption on diatomaceous carriers of the compounds to be separated.

Formic acid in acetic anhydride has been used to acylate the second active group [10]. The resulting derivatives were separated on a column with 25% of a high-vacuum oil at 194°C, when conversion into the *N*-formylated methyl esters was at least 95%. The latter compounds contain no hydrogen atoms capable of forming a hydrogen bond, but such esters are highly polar, which prevents their effective chromatographic separation. Indeed, the molecule of an α-amino-acid comprises a radical and an amino-acid group, and such acids differ only in the nature of the radical, so that their successful separation by gas–liquid chromatography requires that the effect of the amino-acid group (free or esterified and acylated) on the retention of the compound should be minimal. This requirement is satisfied only when the amino-acid group is attached to the stationary phase merely by dispersion forces, i.e. with complete shielding of polar bonds by alkyl radicals. A methyl group usually shields polar bonds only to a slight extent. These considerations were confirmed by experiment: comparison of the gas-chromatographic behaviour of *N*-formyl and *N*-acetyl esters revealed [39] comparable retention times, but separation of the latter esters was incomparably better than that of the former, so that use of the *N*-formyl esters to analyse mixtures of amino-acids had to be rejected. The logarithm of the retention time of an ester of a $C_{2-5}$ alcohol with an *N*-acetylated amino-acid is proportional to the molecular weight of the alcohol, whether the stationary phase used is polar or non polar [40]; this indicates fairly complete shielding of polar groups by the ethyl radical.

Acetic anhydride must be used to obtain acetyl derivatives, but its acylating power is not strong enough to acylate quantitatively the hydrochloride of an arginine ester even at 150°C. It is therefore proposed[28] to pass this ester through an ion-exchange resin or to neutralise the salt with an alkali-metal carbonate; it is also possible to convert arginine enzymatically into ornithine, and histidine by ozonolysis into asparagine[18], but such methods are too laborious to be recommended. It is more advisable to acylate amino-acid esters with a mixed reagent comprising acetone, triethylamine, and acetic anhydride in the proportions 5 : 2 : 1 [41] at 60°C for 30 s; arginine then undergoes 78% acylation reproducibly.

The gas-chromatographic behaviour has been studied of methyl and ethyl esters of *N*-acetylated amino-acids[10,39], propyl and isopropyl esters [10,28,41-44], butyl and isobutyl esters [10,44], and pentyl and isopentyl esters [10,45].

The best results for the separation of a mixture of protein amino-acids have been obtained[42] by esterifying the acids in 8 *N* n-propanolic solution at 110°C for 20 min, and acylating with a 5 : 2 : 1 mixture of acetone, triethylamine, and acetic anhydride at 60°C for 30 s. At room temperature the resulting esters do not decompose for several days, and at 4°C they can be kept for several months. The injector unit and the detector were respectively at 250 and 300°C, and the temperature of the column was programmed to rise from 125 to 180°C at 8 deg $min^{-1}$, and from 180 to 250°C at 32 deg $min^{-1}$. A column 90 cm in length and 3 mm in diameter was filled with a sorbent comprising a mixed stationary phase (0.31% Carbowax 20 M + 0.28% Silar 5CP + 0.06% Lexan) deposited on Chromosorb W. Before application of the stationary phase the carrier was heated at 400°C for 1 h. The efficiency of the column was 2250–2400 theoretical plates with respect to a tryptophan derivative, with norleucine as standard. The sample was introduced by means of a Perkin–Elmer automatic capsule injector. Under these conditions derivatives of all three groups of protein amino-acids were separated, as well as ornithine and hydroxyproline, with a detection threshold of $10^{-12}$ mole; the reproducibility of a quantitative analysis was 2–5%. Certain difficulties arose in the analysis of cystine, which have been overcome[46] by first converting cystine and cysteine into their *S*-methoxycarbonyl derivatives, when the sum of these amino-acids is determined. Similar mixtures had been separated in earlier work[43,44], but with poorer results. Separation of amino-acids as *N*-acetylated n-propyl esters has only recently been made possible by the appearance of new equipment and the development of new forms of high-temperature chromatography; in the early stages of the development of gas–liquid chromatography efforts were directed mainly at preparing more volatile derivatives of amino-acids, such as esters of the perfluorinated acids. The emergence of these derivatives from the column is more rapid than that of their non-fluorinated analogues by factors of 3–6, which is why amino-acids were analysed for a long time as such perfluorinated derivatives. The preparation and the gas-chromatographic properties of methyl esters of *N*-trifluoroacetylated amino-acids have been reported[18,35,47-56]; although derivatives of all 20 proteins amino-acids could not be separated in a single analysis, these investigations enriched significantly the experience of working with derivatives of perfluorinated esters. It was observed in particular that *O*- and *S*-trifluoroacetylated amino-acids decompose on polar stationary phases such as polyethers and cyano-derivatives.

Acylated amino-acid esters can in principle be obtained in two ways: (*a*) the ester is obtained initially, and then acylated; or (*b*) initial acylation is followed by esterification. In the latter case esters of hydroxy-acids are not formed, and arginine and histidine do not give volatile products; hence the first method is used for quantitative analysis. Hydrochloride salts of methyl esters of amino-acids are acylated quantitatively with trifluoroacetic anhydride at 120°C in 20 min[10]. It has been recommended[33,34,36] that the dry ester be acylated with a 50-fold excess of the anhydride at 180°C for 5 min; the most difficult to acylate are the arginine and histidine esters, while derivatives of cysteine and of a hydroxylated amino-acid are most liable to hydrolysis. It must be borne in mind that trifluoroacetylated esters are extremely sensitive to moisture, so that it is advisable to introduce the reaction mixture into the chromatograph injector without preliminary vaporisation of the reagents and the solvent. Evaporation of the solvent may involve an indeterminate loss of the most volatile esters of alanine, glycine, and valine, so that the temperature of the mixture should not exceed 0°C during removal of the solvent. Since the histidine derivative is the least stable, it is recommended[57] that it be converted into the *N*-ethoxycarbonyl-*N*-trifluoroacetylated n-butyl ester, which greatly improves its detection. Several authors[58-60] advise that, to prevent hydrolysis of the histidine derivative, excess of the acylating agent should be added before the sample is introduced, since its partial vaporisation from the reaction medium is responsible for the appearance on the chromatogram of a peak due to the mono-acylated histidine derivative[61]. At room temperature all protein amino-acids other than arginine and histidine are acylated within a short time.

In the temperature-programmed analysis of *N*-trifluoroacetylated methyl esters of the 20 protein amino-acids on a column with neopentyl glycol succinate, glycine and leucine remained unresolved, as well as glutamine and phenylalanine; furthermore, the arginine derivative gave three peaks, and considerable difficulties were experienced in the analysis of cysteine and histidine[18]. The best separation of *N*-trifluoroacetylated methyl esters of amino-acids is obtained with a column 3.25 m long full of Diatoport S with 1.5% of a mixed stationary phase (silicone oils XE-60, QF-1, and MS-200 in the proportions 46 : 27 : 27), the temperature being programmed from 90 to 231°C; under these conditions the histidine derivative does not emerge from the column. The time of separation is 85 min.

Widespread use of methyl esters is typical of the first stages in the application of perfluorinated derivatives of amino-acids, but their high polarity impairs separation, while the great volatility diminishes the accuracy of quantitative analysis, especially for the alanine, valine, glycine, and leucine derivatives. As a consequence of these disadvantages attention was directed to esters of alcohols having higher boiling points—ethyl[10], isopropyl[10,62,63], n-propyl[18,44], s-butyl[18,19,64,65], n-butyl[18,31,33,34,58,66-71], n-pentyl and isopentyl[18,37,72-74], and benzyl—as well as to vinyl esters[18].

The n-butanol derivatives have been most widely used for gas-chromatographic analysis, largely because of the work of the Gehrke school. The quite large alkyl radical shields the polar ester group well, and the derivatives possess moderate volatility. Such amino-acid derivatives have been completely separated[33,34] on two columns both 1.5 m long, one filled with Supelcoport impregnated with 2% of silicone oil OV-17 and 1% of silicone oil OV-210,

and the other filled with Chromosorb W impregnated with 0.65% of polyethylene glycol adipate, with temperature programming of the columns from 60 to 225°C. Histidine, arginine, and cysteine do not emerge from the latter column: the former column serves for their determination. Furthermore, hydroxyproline and ornithine are also separated, as well as all the protein amino-acids. With chromatograms from the two columns recorded in parallel the total time for separation does not exceed 30 min. The life of the columns is 2–6 months. Other workers have somewhat varied the quantities of stationary phases on these carriers [75], with 1% of polyethylene glycol adipate and 4.5% of silicone oil OV-17.

In the chromatographic analysis special attention is paid to absence of contact between vapours of the amino-acid derivatives and heated metal surfaces: the injector, the column, and the inlet to the detector should be made of glass. The carrier gas is dried with molecular sieves (the glutamine and asparagine derivatives are the first to be hydrolysed). All glass surfaces in contact with vapours of amino-acid derivatives, including the glass wool used to seal the columns, should be silylated with a 10% solution of dimethyldichlorosilane in toluene at room temperature for 10–12 h, then washed with methanol and toluene, and subsequently dried at 200°C. When not in use, the apparatus should be purged with the carrier gas at 200°C.

The above methods involve the use of small quantities of the stationary phase on a carrier. Under such conditions, however, the form of the retention volume is especially strongly influenced by the various adsorption effects due to the presence of active interfaces in the chromatographic column. The influence of interfacial adsorption on the retention volume of amino-acid derivatives is so great that variation in the quantity of stationary phase on the carrier over the range 0.5–2% changes the sequence in which the methionine, hydroxyproline, and phenylalanine derivatives emerge, as well as the leucine–isoleucine pair [76]. Such effects are extremely undesirable in establishing reliable reproducible methods for commercial analyses. The chief active interface in the separation of amino-acid derivatives is that between the solid carrier and the stationary phase, so that special care is required in the choice of carrier. When polyethylene glycol is used as stationary phase, the inertness of the carrier towards the derivatives increases in the sequence—Chromosorb W AW, Chromosorb W AW DMCS, Gasochrome Q, Chromosorb W HP or G HP [28,77]—but sometimes by no means the most inert carriers, e.g. Chromosorb W AW, [78] have proved quite unexpectedly to be the best. The arginine derivative emerges from a column with OV-17 deposited on Chromosorb W HP, but does not separate when a sorbent based on Chromosorb G HP is used.

A two-column scheme of analysis is not the optimum arrangement, for in particular two pen-recorders are required. The amino-acid derivatives could have been analysed successively on each column, and recorded on a single instrument, but this would lengthen to 50 min the time required for an analysis. The use of switches to transfer the recording from one column to the other and some staggering of the time of introduction of the sample into each column enables this time to be shortened to 35 min.[79]

The chief obstacle to a single-column analysis of protein amino-acids is the poor selectivity of stationary phases having little or no polarity; polyether stationary phases possess good selectivity for the separation of these compounds, but they react with *O*- and *S*-trifluoroacetylated amino-acids. A mixture could be separated only by increasing the quantity of stationary phase (Apiezon M) in the column to 10% on the weight of Chromosorb W.[80] Such quantities of stationary phase lower adsorption effects, which makes the method more reproducible. Eighteen derivatives of protein amino-acids, including cystine and hydroxyproline, have been separated in 35 min on a 2.5 m column with such a sorbent and the temperature programmed to rise from 90 to 260°C. A proportion of the derivatives (14% of methionine, 37% of histidine, and 54% of cysteine) does not emerge from the column, but these quantities are reproducible and do not diminish the value of the quantitative method. The relative error of a determination is 5%.

The use of simple devices to remove excess of reagent and solvent [62] enables down to $10^{-9}$ g of amino-acid to be determined by means of a flame-ionisation detector, and down to $10^{-12}$ g with an electron-capture detector. A thermal ionisation detector with rubidium salts, which detects nitrogen-containing compounds, is intermediate in sensitivity [81]. This last detector is extremely convenient for numerical calculations, since its signal is proportional to the number of nitrogen atoms in the molecule of the test compound, so that preliminary calibration is unnecessary; the sensitivity of such a detector exceeds that of a flame-ionisation detector by factors of 3–20. The sensitivity of the determination of amino-acids can be enhanced by acylation with a chlorophosphate in diethyl ether or in acetonitrile in the presence of triethylamine; the reaction takes 30 min at room temperature, although not all amino-acids give a quantitative yield of products. These derivatives are detected by means of a thermal ionisation detector having a threshold of $10^{-12}$ g.[82] Such derivatives of the first group of amino-acids, asparagine, glycine, and $\beta$-alanine are separated on a 2-m column containing 6% of silicone oil OV-17 on Chromosorb G HP with the temperature programmed from 210 to 250°C. This method has been used to establish the amino-acid sequence in the proteins of gramicidin S.

The extremely high sensitivity of gas chromatography has enabled amino-acids to be determined in specimens of the moon's surface brought back by the crews of Apollo 11 and 12.[83]

The time consumed in preparing volatile amino-acid derivatives is comparable with that required to separate these compounds: a series of papers therefore appeared on accelerating the preparation of samples. For example, three separately heated aluminium blocks can be used having depressions for ampoules, in which all operations to prepare derivatives are conducted [84]. The most radical solution to the problem was suggested to obtain methyl esters of *N*-heptafluorobutyrylated amino-acids [85] using an MS-41 (Perkin–Elmer) automatic capsule injector. The specimen and the methylating reagents were placed in a gold capsule, which was then closed; the process was conducted at 80°C for 10 min. The capsule was then opened, and moisture was removed by azeotropic distillation with dichloromethane. Hydrochlorides of methyl esters of amino-acids can be kept in a desiccator for a long time. Before an analysis an acylating agent was added to the capsule, and reaction occurred in the closed capsule at an elevated temperature; the cooled capsule was placed in the carrier of the automatic injector. Subsequent analytical operations and calculation of the results were effected automatically.

The search for amino-acid derivatives suitable for gas–liquid chromatography was not confined to the trifluoroacetyl compounds: acylation with pentafluoropropionic[59,86-89] and with heptafluorobutyric[59,61,85,86,90,91] acids was tried. The use of derivatives containing a large number of fluorine atoms enhances the sensitivity of an electron-capture detector, and enlarging the non-polar radical has a favourable influence on the selectivity of columns. The diminished polarity of the heptafluorobutyryl derivatives tends to shorten the retention time by 35% in comparison with the trifluoroacetyl compounds. The former are not so sensitive to moisture as the latter, and can be washed with organic solvents without danger of hydrolysis, while removal of the excess of reagent and solvent from the reaction mixture presents no difficulties[91]. For example, solutions of n-propyl esters of heptafluorobutyrylated amino-acids can be evaporated without risk of a change in quantitative composition of the amino-acid derivatives; at the same time the tendency of the solvent peak to mask the most volatile components of the amino-acid mixture becomes less marked. Among the disadvantages of heptafluorobutyric anhydride are its high cost, its toxicity, and its persistent unpleasant odour.

n-Propyl esters of heptafluorobutyryl derivatives of 19 protein amino-acids have been separated in 35 min on a glass capillary column with chemically bound polydimethylsiloxane and the temperature programmed from 70 to 230°C[159]; isoleucine forms two peaks, one due to isoleucine itself, and the other to alloisoleucine. Such esters from 18 amino-acids, including hydroxyproline and cystine, have been separated in 43 min on a 3.6-m glass column with 3% of silicone oil OV-1 and the temperature programmed from 100 to 250°C.[185] Determination of histidine is improved by introducing into the column, after addition of the sample, a small quantity of acetic anhydride; methionine and asparagine are not completely separated.

Eighteen protein amino-acids, pipecolic acid, ornithine, kynurenine, and cystine have been separated in 35 min as the isopentyl esters of the heptafluorobutyryl derivatives on a 3.5-m glass column with 3% of silicone rubber SE-30 and the temperature programmed from 70 to 240°C [18]; the sensitivity of the determination by means of a flame-ionisation detector is $10^{-10}$ g of the amino-acid. Large quantities of glutamine in the mixture impair its separation with lysine and tyrosine. Somewhat poorer results in separating the same amino-acid derivatives have been obtained[91] on a glass column 2.4 m long full of a carrier with 15% of Dexsil-300 and the temperature programmed from 140 to 270°C; serine and valine are not separated, but hydroxyproline gives two peaks, one of which corresponds to its allo-isomer. Isopentyl esters of heptafluorobutyryl derivatives have been regarded[61] as most suitable for the analysis of amino-acids, because preparation of the samples involves no loss of ester by vaporisation.

Perfluoroacyl derivatives esterified with various alcohols are widely used in the analysis of mixtures of non-protein amino-acids—those of peat[92], metabolites of tyrosine and tryptophan[93], iodinated[94] and cyanoethylated[18] amino-acids, mixtures of hydroxyproline and proline[18], and mixtures containing β-alanine[95]—and several publications[96-99] have dealt with the separation of acylated esters in the determination of amino-acids in various biological materials and individual aspects of such analyses. Thus esterification and acylation enable volatile derivatives to be obtained quantitatively from all protein and many non-protein amino-acids. Although a large proportion of the investigations have been concerned with separating volatile esters of perfluorinated acids, the most rapid determinations have been made by separating n-propyl esters of *N*-acetyl derivatives.

Because the use of acylated esters has the important disadvantage of involving two stages, efforts have been made to develop a single-stage process for obtaining volatile compounds, primarily trimethylsilyl derivatives of amino-acids. Silylating agents react both with the carbonyl and with amino- and hydroxy-groups, which makes it possible to conduct the whole treatment in a single stage. The amino-group is most difficult to silylate, which limits the overall rate. The first report on trimethylsilyl derivatives of amino-acids appeared in 1959,[100] almost simultaneously with the start of investigations on the separation of acylated esters. Trimethylchlorosilane was used as silylating agent for the first group of amino-acids, when the process was quantitative. All these derivatives, other than the methionine and proline esters, were separated on a column with silicone oil at 165°C; the cysteine, lysine, and histidine derivatives underwent partial decomposition in the column.

All silyl derivatives of amino-acids are extremely sensitive to moisture and to oxygen[15,101]: even a fresh rubber washer for the injector must be conditioned two or three times before an analysis to remove moisture. The great lability of trimethylsilyl derivatives of amino-acids and the difficulties of quantitative silanisation of all protein amino-acids led to a prolonged interruption of research on their application in gas–liquid chromatography. To increase the stability of the trimethylsilyl derivatives the starting materials must be carefully purified and the diethylamine that is formed must be removed from the reaction zone. Because of the inadequate silylating power of trimethylchlorosilane a search was begun for optimal silanising agents. A mixture of trimethylchlorosilane with hexamethyldisilazane has been used[15]. Leucine, serine, and asparagine are then the most difficult to silanise; their silanisation is improved by the use of trimethylsilyldiethylamine in the presence of aluminium and silicon oxides as catalysts. Detailed investigation showed that derivatives containing different numbers of trimethylsilyl groups are formed, those with more groups being less volatile, so that it is advisable to arrest the process in the early stages[102]. Various compounds—trimethylsilyldiethylamine, trimethylsilylamine, bistrimethylsilylacetamide, bistrimethylsilyltrifluoroacetamide, and *N*-methyl-*N*-trimethylsilylacetamide—have been proposed as silanising agents.

Amines proved the best agents when non-polar solvents were used[103]. *N*-Trimethylsilylimidazole and trifluoro-*N*-methyl-*N*-trimethylsilylacetamide have also been tried[15]. When polar solvents have been used, the best results have been obtained with amides[104], especially bistrimethylsilylacetamide. In separation on silicone stationary phases, however, the peaks of the glycine and alanine derivatives are masked by the solvent peak, so that the use of bistrimethylsilyltrifluoroacetamide is preferable[105,106]. A mixture of such derivatives of all protein amino-acids has been separated in 42 min on a 2-m column full of Supelcoport with 10% of silicone oil OV-11 and the temperature programmed from 80 to 210°C.[107-109]; ornithine and arginine are not separated. Lengthening the column to 6 m enables good separation to be obtained for all the mixture components and ornithine. Polyether stationary phases are not used in the separation of trimethylsilyl derivatives of amino-acids, since they

cause decomposition[110]. The separation of such derivatives of 18 protein amino-acids on a 3.7-m glass column with 3% of silicone oil DC-550 and the temperature programmed from 60 to 280°C required 24 min [111-113]; proline and glutamine were not separated.

Careful choice of esterification parameters is necessary in obtaining trimethylsilyl derivatives of amino-acids. The principal difficulties in quantitative esterification lie in the need for control at the stages of mono- and di-substitution in the amino-group; this is especially important with glycine, tryptophan, and lysine. If a non-polar solvent is used for silylation, glycine gives only the mono-substituted product, but arginine does not react; addition of 1% of trimethylchlorosilane to bistrimethylsilyltrifluoroacetamide enables arginine to be silanised, but disubstituted products of other amino-acids appear. In a polar solvent (acetonitrile) addition of trimethylchlorosilane can be avoided, but the time required for complete silanisation at 150°C is 2.5 h. With a polar solvent under optimum conditions the reaction is conducted for 1.5 h, which sharply diminishes the content of disubstituted products, with some incompleteness of reaction.

Several non-protein amino-acids undergo structural changes during silanisation. Thus cyclic products are formed from glutamic and $\alpha\gamma$-diaminobutyric acids[114]; derivatives of $\omega$- and $\alpha\omega$-amino-acids emerge from the column as two peaks with different numbers of trimethylsilyl groups in the molecule.

Like the acylated ester derivatives, the trimethylsilyl compounds can be prepared in hermetically sealed gold capsules, which are then introduced into the chromatograph by means of an automatic injector.

The time required for the separation of protein amino-acids as their trimethylsilyl derivatives is double that required for the acylated esters. An undoubted advantage of the former is that they can be obtained in a single stage, but the duration of silanisation is far longer than for esterification and acylation. Furthermore, trimethylsilyl derivatives are rather less stable than the acylated esters; arginine is difficult to silanise, but histidine and tryptophan do not readily yield acylated esters; and the composition of a mixture of amino-acids can be determined more reliably by combining these two methods. Flame-ionisation and thermoionic detectors with a threshold of $\sim 10^{-9}$ g are usually employed for trimethylsilyl derivatives of amino-acids.

Trimethylsilyl derivatives of the amino-acids containing sulphur and selenium that are necessary for the efficient nutrition of animals can be separated by means of columns with silicone elastomer SE-30: at 117°C derivatives of cysteine, methionine, and their sulphur and selenium analogues are separated[115]. Selenium-containing amino-acids decompose when heated with bistrimethylsilylacetamide, and therefore the reagent "trisil" is used for their silanisation. With cysteine, cystine, homocystine, cysteic acid, and *L*-2-thiohistidine dark-coloured oxidation products appear on silanisation.

Trimethylsilyl derivatives of amino-acid esters have also been investigated[15]: silanised n-butyl esters of the 20 protein amino-acids have been separated in 32 min on a glass column containing glass beads with 0.2% of OV-17 at from 90 to 225°C; cysteine emerges together with hydroxyproline. However, the involvement of yet another stage, esterification, cannot be regarded as desirable for analytical work.

The difficulty of obtaining trimethylsilyl derivatives and their instability have resulted in continuous search for mild new methods of obtaining amino-acid derivatives. It has been proposed[116] that treatment of the hydrochlorides of the methyl esters with sodium carbonate, isobutyraldehyde, and a hydrogen sulphite should be followed by reduction to give stable esters resistant to hydrolysis. Another suggestion[117,118] is to introduce trifluoroacetylated amino-acids directly into the heated zone of the chromatograph injector, when volatile oxazolin-5-ones are formed. Eleven oxazolines of the first and second groups of amino-acids have been separated on a column with polyethylene glycol adipate deposited on Chromosorb W HP with the temperature programmed from 40 to 140°C. Cyanoethyl and cyanobutyl esters of amino-acids have been examined[119]. A mixture of dimethylformamide with a dialkyl acetal and 1,3-dichlorotetrafluoroacetone has been used to obtain volatile derivatives of amino-acids in a single stage[120]. This reagent alkylates the carboxyl and condenses with the amino-group; however, hydroxy-groups do not react, and additionally require acylation. The total time of the reaction is ~1 h, and the greatest difficulties are encountered in obtaining the asparagine derivative.

Halogenated acetones provide an extremely promising method for obtaining volatile derivatives of amino-acids. A rapid procedure developed recently[121] involves condensation with dichlorotetrafluoroacetone in weakly alkaline medium at room temperature to give a cyclic structure within a few minutes; both hydroxy-groups and also $\omega$-amino-groups must be acylated. These derivatives are stable for several months, but the acylated derivatives for only a week (when kept at 4°C). A column 1.8 m long with 5% of silicone elastomer SE-30 and the temperature programmed from 150 to 230°C has been used; satisfactory separation is achieved also by means of silicone oil OV-17.[122] Amino-acids containing iodine have been determined by these methods.

It has been proposed[123] to determine tryptophan as the trimethylsilyl derivative of 2,3,4,5-tetrahydro-*S*-carboline-4-carboxylic acid on silicone elastomer SE-30. Methyl esters of *N*-isobutoxycarbonylated amino-acids (protein amino-acids other than arginine) have been separated on a column containing 0.7% of a mixed stationary phase (Poly-A-101A, Poly-A-103, and FFAP in the proportions 3 : 3 : 1).[124]

The above survey of various methods for obtaining volatile derivatives of amino-acids has shown that a convenient single-stage method is not yet available. However, the development of several methods, e.g. cyclisation, will probably enable stable volatile derivatives to be obtained in the near future.

## III. SEPARATION OF OPTICAL ISOMERS OF AMINO-ACIDS

Optical isomers are resolved mainly by two methods: (1) derivatives of amino-acids with optically active reagents are obtained, and are resolved on the usual stationary phases; (2) volatile derivatives obtained without the use of optically active reagents are separated on an optically active stationary phase. A necessary condition for resolution by gas–liquid chromatography was the presence of at least two asymmetric carbon atoms either in the sorbate molecule or in a molecule of the stationary phase. This rule enables derivatives of hydroxy-amino-acids to be separated on the usually stationary phases[18], since the molecules of such amino-acids contain two optically active carbon atoms.

1. Separation of an Optically Inactive Stationary Phase

Any optically active alcohol, e.g. butan-2-ol or a homologue, can be used as reagent. Esterification is accomplished in a 4–8 *N* solution of hydrogen chloride in the alcohol at 100°C for 1 h. Esters of secondary alcohols and amino-acids of the first group, including asparagine, lysine, glutamine, and hydroxyproline, acylated with trifluoroacetic anhydride, were separated on a 50-m capillary column with polypropylene glycol or fluorosilicone oil FS-1265.[125,126] Optical isomers of derivatives of octan-2-ol are separated better than are those of butan-2-ol, but the former are less volatile, and amino-acids are sparingly soluble in the latter alcohol. Optical isomers of s-butyl esters of *N*-trifluoroacetylated protein amino-acids, other than histidine, arginine, and cysteine, were separated on a capillary column with polyethylene glycol or Yukon LB-550X.[127,128] Partial resolution of optical isomers of a mixture of alanine, valine, leucine, threonine, serine, cysteine, phenylalanine, and tyrosine as the s-butyl esters of the *N*-trifluoroacetylated derivatives has been effected on a 1.8-m column full of the carrier with 0.65% of polyethylene glycol adipate and the temperature programmed from 80 to 215°C. All these compounds, together with isoleucine, proline, and methionine, have been separated[129] under the same temperature conditions but with a lower content (0.32%) of polyethylene glycol adipate on the carrier. Splitting of peaks into optically active components was not observed for lysine and ornithine. The total time required to separate isomers of 17 amino-acids was 80 min. The use of sorbents with a small quantity of stationary phase is open to the same objections as in the separation of acylated esters.

Gas-chromatographic separation of optical isomers of amino-acids as s-pentyl and s-butyl esters has been regarded[129-133] as more advisable. The influence of the structure of the alcohols on the resolution of optically isomeric amino-acids has been examined with phenylalanine as example[134]: increasing the length ratio of the radicals attached to the asymmetric atom in the ester improves the resolution; elimination of branching of the carbon chain from the optically active carbon has a similar effect. The best separation has been obtained with the 1,2,2-trimethylpropyl esters, which forms the basis[135] of a method for separating optical isomers of 16 amino-acids (arginine, histidine, and cysteine were not studied). Volatile derivatives of these amino-acids were separated on a 3-m column full of Chromosorb W with 10% of silicone oil OV-17. Esters of other alcohols have also been used—those of pentan-2-ol to resolve valine isomers, methyl esters[2], and t-butoxycarbonyl derivatives treated with (*D*)-1,3-dimethylbutylamides.[18]

Esters of $C_{5-8}$ secondary alcohols and acyl derivatives from trifluoroacetic, pentafluoropropionic, and heptafluorobutyric anhydrides have been examined[130] to determine optimum conditions for the gas-chromatographic separation of isomeric amino-acids. Optical isomers of asparagine (*N*-trifluoroacetylated 1,2,2-trimethylpropyl and *N*-perfluorobenzoylated s-butyl esters) have been resolved on a capillary column 50 m long with Yukon LB-550X [136-141] and with polyethylene glycol.[128]

An alternative method for obtaining optically active volatile derivatives of amino-acids is acylation with optically active agents. The carbonyl chlorides—α-chloropropionyl,[136,142,143] α-bromopropionyl,[144] α-chloroacetyl,[142,143] *N*-trifluoroacetylthiazolin-4-ylcarbonyl,[145] and *N*-trifluoroacetylprolyl [146-152]—have been used for this purpose. The applicability of the chlorides of various α-chloro-carboxylic acids for acylating amino-acids has been studied[143-153], and use of a polar stationary phase shown to give the best separation of isomers. α-Bromopropionic derivatives gave the best resolution of optical isomers of phenylalanine on a capillary column 46 m long with polypropylene glycol or silicone oil XE-60 [154]; however, difficulties were noted in preparing the optically pure reagent. Acylation of methyl esters of amino-acids with *N*-trifluoroacetyl-*L*(or *D*)-prolyl chloride is most widely used in practical analysis; this reagent is prepared by treating the *L*-proline with thionyl chloride[146]. Although the preparation is made under very mild conditions, racemisation of the product is not excluded[147]. Measures have been suggested[147] to control individual stages in the preparation with the aim of preventing racemisation.

Hence either esterification with optically active alcohols or acylation with optically active agents can be used to obtain optically active volatile derivatives of amino-acids for their subsequent separation by gas–liquid chromatography. Only capillary columns are normally employed in the former method, because of the small differences in the retention of optical isomers. Differences in the retention times of derivatives are larger in the latter case, and their separation is usually accomplished on packed columns.

2. Separation on Optically Active Stationary Phases

Optically active stationary phases can be divided into three groups—(*a*) ureides, (*b*) ethers, and (*c*) dipeptides—among which the last group find the greatest analytical use.

The separation of optically active isomers of amino-acids was first accomplished as their *N*-trifluoroacetyl-*L*-prolyl derivatives on an optically active stationary phase[146,154,155]; it was later shown that the best stationary phase is the cyclohexyl ester of *N*-trifluoroacetyl-*L*-valyl-*L*-valine.[156-158] The upper temperature limit at which this stationary phase can be used is 110°C, which rises by 10 deg when the same ester of *N*-trifluoroacetyl-*L*-phenylalanyl-*L*-leucine is employed[159,160]. Some results[161-165] indicate that the latter stationary phase retains its effectiveness up to 140°C, when the use of perfluoropropionylated isopropyl derivatives of amino-acids enables retention times to be shortened considerably. Mixtures of optical isomers of 17 amino-acids have been separated on short and long capillary columns (30 and 120 m) under isothermal conditions at temperatures of 110–125°C.[156-160]

The separation of derivatives of optical isomers of amino-acids on an optically active stationary phase has been attributed to the formation of triple hydrogen bonds between the interacting molecules, steric hindrance to hydrogen bonding being minimal if sorbate and sorbent belong to the same optical class. The selectivity of stationary phases is increased by using esters of alcohols having branched chains. Comparison of the separating properties of cyclohexyl esters of *N*-trifluoroacetyl-*L*-valyl-*L*-valine and *N*-trifluoroacetyl-*L*-valyl-*DL*-valine showed that better results are obtained when the latter stationary phase is used[168].

An appreciable disadvantage of optically active stationary phases is their low thermal stability: the maximum temperature at which tripeptides can be used does not exceed 120°C, while solid polypeptides, though stable up to 200°C, are incapable of resolving optically active isomers[18]. If the formula of an amino-acid derivative is

written $CF_3.CO.NH.CHR.COOR'$, the achievement of maximum isomeric selectivity requires that $R > COOR'$.[169,170]

Since differences in the retention of optical isomers are small, it is preferable to use capillary columns. For example, isobutyl esters of *N*-trifluoroacetamido-acids have been separated on a dipeptide optically active stationary phase in a capillary column 120 m long; a time of 70 min did not result in complete separation of the isomers of alanine, valine, threonine, isoleucine, serine, and leucine; and tyrosine and arginine isomers were resolved on a short (12 m) column[159]. Isoproyl esters of *N*-trifluoroacetamido-acids were separated on capillary columns 30–150 m long with the cyclohexyl ester of *N*-trifluoroacetyl-*L*-valyl-*L*-valine [108]; on the cyclohexyl ester of *N*-trifluoroacetyl-*L*-valyl-*L*-leucine at 110°C mixtures of isomers of valine, alanine, threonine, isoleucine, leucine, and proline were separated with a column length of 30 m in 130 min[167]. A mixture of isomeric isopropyl esters of *N*-trifluoroacetylated alanine, valine, threonine, isoleucine, leucine, serine, proline, and glycine has been separated on a column 120 m long with cyclohexyl *N*-trifluoroacetyl-*L*-$\alpha$-aminobutyrate at 100°C.[136] Optical isomers of such ester derivatives of amino-acids have been resolved also on a glass column with the cyclohexyl ester of *N*-trifluoroacetyl-*L*-valyl-valine at 110°C,[171] a procedure that has been used for several applied investigations[18].

Each of the above methods for determining optically active isomers of amino-acids has its advantages. However, the first method requires reagents of high optical purity, and a highly efficient column must be used to separate esters of branched alcohols and amino-acids. The second method does not demand high optical purity of the stationary phase, but its possibilities are restricted by the relatively low limiting temperature at which such stationary phases can be used.

## IV. SEPARATION OF PEPTIDES

The same methods as for amino-acids are used to protect active groups in peptides, while the thermal stability of the derivatives is limited by the temperature of rupture of peptide bonds (200–250°C). The possibility of the gas-chromatographic separation of peptides as volatile derivatives is interesting from the two aspects of (*a*) the extent to which large polymeric molecules possess the required volatility and (*b*) the separating power needed by a chromatographic column to separate all dipeptides (400 are possible for protein amino-acids). The reduction of peptides with lithium tetrahydroaluminate gives polyaminoalcohols, which are separated on a column with 8% of Apiezon L. This procedure has been used to separate mixtures of di-, tri-, and tetra-peptides.[18,160] Methyl esters of *N*-trifluoroacetylated penta- and hexa-peptides have been obtained, and finally volatile derivatives of peptides containing up to 12 amino-acids have been reported[172]. The thermal stability of peptides is largely determined by the nature of the monomer units, so that not all tri- and poly-peptides can be analysed by gas–liquid chromatography. Volatile derivatives of these compounds have been described[173–178].

Methyl esters of *N*-trifluoroacetylated dipeptides have been separated at 180–220°C, and the corresponding derivatives of tripeptides at 250°C.[18] The gas-chromatographic separation of esters of acetylated, trimethoxyacetylated, trifluoroacetylated, and pentafluoropropionylated derivatives of 37 dipeptides has been examined on various stationary phases[179]. Separation of dipeptides as their *N*-trifluoroacetylated esters is usually accomplished by high-temperature gas–liquid chromatography with a small quantity of stationary phase on the carrier and with temperature programming. Peptides containing arginine form volatile derivatives with difficulty. In several cases the inertness of the solid carrier surface plays a decisive part in separating volatile derivatives of dipeptides: the first few samples are chemisorbed, and preliminary introduction of three or four samples into the column is necessary to obtain quantitative information.

A highly promising approach is to combine mass spectrometry with gas chromatography to determine the composition of di- and poly-peptides. In contrast to liquid chromatography, the great efficiency of gas–liquid chromatography enables many isomeric compounds to be separated, and then their structure to be established mass-spectrometrically; moreover, by withdrawing separate portions of the chromatographic zones emerging from the column, it is possible by means of a mass spectrometer to establish the presence of unseparated compounds.

The above results indicate the great possibilities of the gas-chromatographic method for separating peptides containing up to 12 monomer units in the molecule. An especially promising approach to the analysis of peptides is to combine high-pressure liquid chromatographs and gas–liquid chromatography, which in many respects are complementary.

## V. APPLICATION OF PYROLYTIC GAS CHROMATOGRAPHY

The principle of pyrolytic gas chromatography consists in almost instantaneous decomposition of a microsample (0.1–1 mg) at a controlled temperature. Only products of the initial degradation reactions are then observed, so that the composition of the test substance can be determined unambiguously. It is a qualitative method, suitable mainly for identifying a single compound or for establishing its structure.

Studies in which volatile derivatives of amino-acids were obtained by heating to 300°C were mentioned at the beginning of the Review. The use of higher temperatures in pyrolytic gas chromatography enables characteristic spectra of decomposition products (pyrograms) to be obtained[180–182]. With pyrolysis on a platinum spiral heated to redness and use of a squalane separating column, for example, several characteristic peaks were observed[183] for phenylalanine and alanine. In the absence of temperature control of the spiral, however, this method of pyrolysis is not generally applicable: histidine, tryptophan, and tyrosine do not form volatile products, and about half the protein amino-acids do not give characteristic pyrograms. Only the use of pyrolysers with strict temperature control (e.g. with ferromagnetic heaters having a definite Curie point or with electronic temperature control of the spiral) has enabled characteristic pyrograms to be obtained for amino-acids. Pyrolysis of protein amino-acids at 700°C with mass-spectrometric identification of the products will yield characteristic pyrograms, which show that the chief decomposition products from amino-acids are nitriles[184–187].

Lowering the pyrolysis temperature and using a column 2.4 m long with 5% of 1,2,3-tris-(2-cyanoethoxy)propane and temperature programming from −180 to 125°C gave different products[188,189]. The same study showed that the

pyrolysis spectra of ten different dipeptides were combinations of the characteristic pyrograms of their constituent amino-acids.

Investigation of the pyrolysis of equimolecular mixtures of amino-acids in an atmosphere of nitrogen at 850°C indicates [190-192] that the addition of non-aromatic amino-acids to those containing aromatic rings lowers appreciably the quantity of aromatic hydrocarbons among the pyrolysis products. However, this does not prevent qualitative determinations, since only the proportions of the decomposition products change, but the characteristic peaks on the pyrograms do not disappear. Hence the pyrolysis of peptides will provide information on their amino-acid composition; the temperature of pyrolysis may be either low (300°C) or high (about 800°C), and this temperature influences the composition of the products [193-196].

The determination of pyrolysis products is of interest also for study of the mechanism of the thermal breakdown of biopolymers. In several investigations [197-199] the products of pyrolysis at 500°C were identified by means of a mass spectrometer, and separation was effected on the polymeric sorbent Tenax with the temperature programmed from 25 to 285°C. At these temperatures aliphatic amino-acids undergo decarboxylation with the formation of amines and several other compounds; this is accompanied by condensation of the amino-acids with their conversion into dipeptides and subsequent formation of the corresponding dioxopiperazine. While losing ammonia, $\beta$-amino-acids are converted into unsaturated acids, whereas $\gamma$- and $\omega$-amino-acids form on pyrolysis 2-oxopyrrolidines and 2-oxopiperidines respectively. The presence of large quantities of hydrogen cyanide among the pyrolysis products as a consequence of cyclisation reactions provides evidence of such a mechanism [197]. Since dioxopiperazines are quite volatile, it is of interest to use them as derivatives of the dipeptides for gas-chromatographic analysis. Thus products of the pyrolysis of dipeptides at 400°C have been separated on a column with 5% of silicone liquid OV-17 at 240°C. [198] The dioxopiperazine method is restricted by the need for condensation of the amino-acid (in the determination of individual amino-acids). This can be effected e.g. by heating the methyl esters of the amino-acids in molten phenol at 150°C. [192] Silanisation of the pyrolysis products with bistrimethylsilylacetamide at 80°C for 10 min permits the time required for the analysis to be greatly shortened and the symmetry of the peaks to be improved, which removes the difficulties encountered [19] in determining dioxopiperazines.

Pyrolytic gas chromatography has been used to determine the sequence of amino-acids in peptide molecules: pyrolysis of the initial peptide is followed by detachment of the terminal amino-acid and then pyrolysis of the product, when comparison of the two pyrograms enables the terminal amino-acid to be identified [200]. This method has been used to establish the primary structure of the proteins in four actinomycins [198]. Several amino-acid phenylthiohydrantoins have been studied by pyrolytic gas chromatography [201].

Pyrograms of proteins and nucleic acids have been obtained with pyrolysis temperatures of 800°C; although they contain the same numbers of characteristic peaks, the proportions of the latter can be used to identify the macromolecules. Such determination of proteins and nucleic acids is considerably simplified by use of a thermal ionisation detector sensitive to nitrogen; the pyrograms contain a total of six characteristic peaks, the relative heights of which enable the molecule to be identified. Furthermore, pyrolytic gas chromatography has proved an extremely effective procedure for classifying proteins, nucleic acids, individual cells, viruses, etc.; combination with mass spectrometry is widely used to study the nature of biopolymers [18].

## VI. DETERMINATION OF THE SEQUENCE OF AMINO-ACIDS IN PROTEINS

Several methods of successively detaching terminal amino-acids have been developed to establish the primary structure of protein molecules. Pyrolytic gas chromatography can be used to determine the amino-acid composition of proteins, but the amino-acid sequence can be studied only by the application of mild methods. From two to five successively combined amino-acids can be determined in a single procedure: since the molecular weight of proteins may reach several millions, determination of the primary structure of a protein is obviously a most laborious operation.

Among several methods of detachment the most widely used is Edman's [18], in which the starting material is treated with phenyl isothiocyanate, after which the terminal group is split off in hydrochloric-acid medium; the final product is a phenylthiohydantoin, whose bicyclic molecule contains an imino-group, a carbonyl group, and the radical of the original amino-acid. The absence of a carboxy-group enhances the volatility of the derivative, while the presence of the benzene ring is extremely useful for application of a high-pressure liquid chromatograph, with which an ultraviolet detector is used. The phenylthiohydantoin derivative of only one amino-acid is obtained after each unit operation, so that the task of gas–liquid chromatography is to establish the nature of the derivatives from retention data. Demands on the analytical technique are increased when it is necessary to determine in one sample the products of 2–5 detachment stages without elution.

Amino-acids can be divided into three groups according to the volatility of the phenylthiohydantoin derivatives: (*a*) asparagine, glutamine, and cysteine give low volatility, and silanisation is necessary for their gas-chromatographic determination; (*b*) serine, threonine, and histidine give moderate volatility, and silanisation is desirable; and (*c*) silanisation of the remaining amino-acid phenylthiohydantoin derivatives makes no appreciable difference to their volatility. Silanisation is effected in a mixture of bistrimethylsilyltrifluoroacetamide with acetonitrile (1 : 1) and added pyridine [202]. The first separation of phenylthiohydantoin derivatives of amino-acids revealed [176,203] considerable difficulties in analysing the derivatives of serine, threonine, tyrosine, and hydroxylated amino-acids. The separation of 18 such derivatives has been reported [204]; silanisation has been used to increase their volatility [205]. These techniques have been applied to determine the sequence of amino-acids in proteins [18].

The analytical procedure for phenylthiohydantoin derivatives of amino-acids has been described in some detail [206]. As with the esters, contact with heated metal surfaces must be avoided. Silanisation of the derivatives directly in the column by successively injecting the silanising agent is recommended, but under these conditions not all such derivatives react: in particular, it is advisable to silanise those of asparagine, cysteine, and glutamine before introduction of the sample, while those of lysine and *S*-carboxymethylcysteine are extremely

difficult to silanise. The trimethylsilylated phenylthiohydantoin derivatives of asparagine, glutamine, and cysteine are adsorbed appreciably on the carrier, while the phenylthiohydantoin derivatives of tyrosine and tryptophan are not very volatile. A mixture of derivatives can be separated on a mixed stationary phase (11% SP-400 + 8% silicone liquid OV-210 + 1% OV-225) in a 1.2-m column with temperature programming from 165 to 270°C; complete separation is found with 13 derivatives. The sample is analysed twice—the initial mixture and the silanised products—to ensure reliable identification. Although the phenylthiohydantoin derivatives of serine, threonine, histidine, glutamine, asparagine, and lysine are partly decomposed in the column, this is not significant for qualitative analysis. The total time of separation is 40–50 min.

Trimethylsilylated phenylthiohydantoin derivatives of protein amino-acids can be partly separated on a column 3.25 m long containing 5% of silicone liquid OV-17 and 1% of Dexsil-300.[207] Nineteen of the twenty trimethylsilylated amino-acid phenylthiohydantoins have been separated on a capillary column of length 4.5 m and diameter 0.13 mm with a mixture of silicone liquids OV-101 and OV-225; the phenylthiohydantoin of histidine is evolved only at high temperatures, cysteine was converted into cystine, and arginine into ornithine[208]. Special difficulties arise in analysing the trimethylsilylated phenylthiohydantoin of arginine: on no stationary phase could escape of this derivative be achieved. The peak of the arginine phenylthiohydantoin emerges only after the derivative has been acylated with a mixture (4 : 1) of acetic anhydride and pyridine at 100°C for 5 min [209]; acylation can be effected also by introducing the phenylthiohydantoin sample with acetic anhydride directly into the heated injector of the chromatograph. Such derivatives have been used to establish the molecular structure of several proteins[18].

Volatile derivatives of amino-acid phenylthiohydantoins have been obtained also by treating proteins with perfluorophenyl isocyanate[210]. These derivatives of protein amino-acids other than arginine and histidine have been separated on a 1.2-m column full of Chromosorb W with 10% of silicone liquid DC-500 and 2% of OV-25 with temperature programming from 160 to 240°C.

The sensitivity and the selectivity of the gas-chromatographic determination of amino-acid phenylthiohydantoins are considerably enhanced by use of a flame-photometric detector, which records only compounds containing sulphur. This enables the aggregate fractions from removal of terminal amino-acids to be analysed successfully without the need to wash away the products after each stage. The sensitivity of a determination is $10^{-9}$ g of amino-acid phenylthiohydantoin.

Methylthiohydantoins have also been used to determine the amino-acid sequence in proteins; the process of sequencing is then simplified, and the greater volatility of these derivatives compared with the phenylthiohydantoins favours their gas-chromatographic separation. Silanisation is not essential at least for 16 amino-acid methylthiohydantoins, which can be separated on two columns, with silicone elastomer SE-30 and silicone liquid OV-17.[211] Five other methylthiohydantoins—those of asparagine, serine, arginine, and cystine—are determined only after silanisation, which is conducted in the same way as for the phenylthiohydantoins[207,212]. It is recommended[213] that a solution of bistrimethylsilylacetamide in acetonitrile be used at 20°C for 5 min; the yield of the histidine ester is doubled by introducing the sample with excess of the silylating agent. To complete the reaction the temperature is raised to 100°C and the exposure is extended to 10 min.[214,215] Nineteen amino-acid methylthiohydantoins have been separated[208] in 55 min on a capillary glass column 4.5 m long full of a mixed stationary phase (95% of silicone liquid OV-101 and 5% of OV-225) with the temperature programmed from 120 to 280°C. The initial compounds were treated with a mixture of bistrimethylsilyltrifluoroacetamide and 2% of trimethylchlorosilane, when several of the methylthiohydantoins formed disubstituted derivatives; that of arginine could not be determined. Optimum conditions for the separation of methylthiohydantoins of amino-acids (other than arginine) involve[214,215] a column 1.65 m long full of Gasochrome Q with 2% of silicone liquid OV-17 and the temperature programmed from 145 to 230°C, when the time of the determination is 45 min. Further separation of the pair of methylthiohydantoins of asparagine and phenylalanine requires 4.5 min.

The greatest difficulties arise in the silylation of the methylthiohydantoins of arginine and histidine. It is therefore recommended that these derivatives should be extracted with ethyl acetate, and then silanised and separated independently[204].

Another method used to determine the primary structure of proteins is 2,4-dinitrophenylation of the amino-acids[18]. The methyl esters of such derivatives of 13 amino-acids were separated on a 4-m column with 1.5% of silicone elastomer SE-30 and temperature programming from 170 to 230°C [216]; the threonine and serine derivatives were not separated. This method has been used to determine the amino-acid sequences in the proteins of malformin A and gramicidin A.[18]

## VII. SOME APPLICATIONS OF GAS–LIQUID CHROMATOGRAPHY TO THE DETERMINATION OF AMINO-ACIDS IN BIOLOGICAL MATERIALS AND IN GEOLOGY

Difficulties arise in the analysis of biological media in connection with preparation of the sample and removal of interfering impurities. The most convenient procedure[35] for the gas-chromatographic analysis of a protein hydrolysate involves initial ultrasonic removal from the sample of air, which would impede the determination of methionine and cysteine. The protein is hydrolysed in 6 *N* hydrochloric acid at 145°C for 4 h (whereas in the usual process this operation lasts 18–24 h, with tryptophan, theonine, serine, tyrosine, methionine, and cysteine partly decomposing, while the links with valine and leucine are not completely hydrolysed). Inorganic acids are removed from the hydrolysate by means of an ion-exchange resin, and the residue is dried, esterified, and acylated. The amino-acid composition of ribonuclease and the protein of grains and fish has been determined in this way, in good agreement with analytical results obtained by other methods.

Protein hydrolysates have been analysed[217–219] by means of the isopropyl esters of the *N*-acetylated amino-acids, with 2,2-dimethoxypropane added to the initial mixture to diminish hydrolysis. The threshold of detection of amino-acids is $5 \times 10^{-8}$ g. Gas–liquid chromatography has been used to analyse the amino-acid composition of diverse proteins, in particular of fossil animals, soil, and antibiotics.[18]

In addition, free amino-acids in various media can be determined by gas–liquid chromatography. It is recommended[33,34] that 0.1–0.4 ml of plasma be denatured with

4 volumes of saturated aqueous picric acid, the solution centrifuged, and the filtrate passed through a column with an ion-exchange resin (the column is washed first with water and then with aqueous ammonia). The view has been expressed[220,221] that this method is unsuitable for arginine and lysine, and it is therefore proposed that 0.1 ml of plasma be diluted with 10 volumes of 1 *N* acetic acid and passed through the ion-exchange column, whence amino-acids are washed out with water and aqueous ammonia; this involves loss of part of the amino-acids.

Histidine, histamine, *N*-methylhistamine, and *N*-dimethylhistamines have been separated as their trimethylsilyl derivatives and their trifluoroacetylated and heptafluorobutyrylated esters by means of silicone liquid OV-17.[222] The methyl esters of *N*-nitroso-derivatives of proline, sarcosine, and pinacolinic acid have been separated on a diethylene glycol succinate column at 180°C.[223]

Trimethylsilyl derivatives are widely used for analysing hormones and products of vegetable origin[18].

The extraordinarily high sensitivity of the gas-chromatographic method permits use of the component determination of amino-acids in microquantities on various materials, as well as in objects of extraterrestrial origin[224].

## VIII. SEPARATION OF BASES OF NUCLEIC ACIDS, NUCLEOSIDES, AND NUCLEOTIDES

Heterocyclic bases—purines and pyrimidines—are present in nucleic acids. The carbonyl group is readily enolised, which is the reason for strong hydrogen bonding and correspondingly diminished volatility. Volatile derivatives of nucleic-acid bases are obtained mainly by silanisation.

The first studies on the separation of methylated derivatives of adenosine and uridine by gas–liquid chromatography appeared in 1964.[225,226] Better results were obtained with silanised derivatives[227]. Noteworthy attempts were made to separate nucleic-acid bases as triacetates[228]. Separation of trimethylsilyl derivatives of adenosine, cytidine, adenosine 5′-sulphate, 5′-monopropionate, and 2′-, 3′-, and 5′-monophosphates, and nicotinamide–adenine dinucleotide (NAD) has been accomplished[15] on a column with silicone elastomer SE-30 at temperatures from 228 to 249°C; silanisation may yield[229,230] several derivatives with different numbers of trimethylsilyl groups attached to the amino-nitrogen atom. Treatment of five nucleic-acid bases with bistrimethylsilylacetamide at 150°C for 45 min gives quantitative yields of trimethylsilyl derivatives; bistrimethylsilyltrifluoroacetamide reacts under the same conditions, and the reagent peak is more sharply distinguished from the product peaks. Trimethylsilyl derivatives of nucleic acids were separated on a 1-m column with 4% of silicone elastomer SE-30 and temperature programming from 95 to 230°C in 24 min; xanthin, 5-methylinosin, and hypoxanthin were also determined[212]. The minimum detectable quantity of nucleic-acid bases is $3–5 \times 10^{-9}$ g. A mixture of uridin, inosin, adenosine, xanthosin, and cytidine was separated under the same conditions, with an error of 3% in the determination; cytidine gave two peaks, and silylation of adenosine produced small quantities of a tetrakistrimethylsilyl derivative[229].

In the silanisation of thymin it is proposed[231] to deactivate excess of the silylating agent with methanol and remove in a vacuum substances that tend to promote hydrolysis. In the gas-chromatographic determination of trimethylsilyl derivatives of guanosine and adenosine it was recommended[175] first to obtain the methoxy-derivatives, and then to silanise them. Bistrimethylsilyltrifluoroacetamide derivatives of several minor nucleosides were obtained, and separated by gas–liquid chromatography[230]. A comprehensive investigation of the gas-chromatographic behaviour of trimethylsilyl derivatives of 32 nucleosides has used[232] two silicone stationary phases—OV-17 and SE-30.

Gas-chromatographic methods of analysing bases of nucleic acids and nucleosides are widely used in practical analysis[19,233–236].

In a technique[56] for the gas-chromatographic investigation of hydrolysates from ribonucleic and deoxyribonucleic acids at three levels—micro, semimicro, and semiquantitative analysis, with samples respectively of $10^{-3}$, $10^{-4}$, and $5 \times 10^{-7}$ g—the hydrolysate is freed from perchlorates, phosphates, and other inorganic ions on an ion-exchange column, where ribose, which interferes with the determination, is also removed. Results of gas-chromatographic analysis agree well with those obtained by other methods.

Nucleic-acid bases are usually analysed by combining thin-layer chromatography with spectrophotometry, when semiquantitative results are obtained with a detection limit of $10^{-4}$ g, the time taken being considerably longer than in gas-liquid chromatography. Electrophoretic methods enable down to $5 \times 10^{-5}$ g of nucleic-acid bases to be detected[18]. Gas-chromatographic determination of these bases enables the sensitivity of detection to be improved by factors of $10^2$ and separation to be effected in a short time (24 min). An appreciable disadvantage of gas–liquid chromatography is the need to silylate the initial substances and the attendant difficulties.

Phosphorus was determined in nucleotides and nucleic acids[237–242] by silylating salts of phosphates of hexadimethyldisilazane with trimethylchlorosilane in pyridine at high temperatures. Derivatives are obtained also by treating the initial substance with a 10–20-fold excess of bistrimethylsilylacetamide or bistrimethylsilyltrifluoroacetamide, and are determined on a 1.8-m column containing silanised Chromosorb W impregnated with 5% of silicone liquid OV-101 at 155°C.[243]

Recent achievements of gas–liquid chromatography and high-pressure liquid chromatographs in the determination of proteins, nucleic acids, and their breakdown products enable conclusions to be reached on the limits of the application of these methods. With the time required for preparation of the sample taken into account, analysis of the 20 protein amino-acids is quicker by the former method, but derivatives for the latter are obtained more easily and are more stable. However, the separating power of gas–liquid chromatography is incomparably greater, so that this procedure is more advisable for analysing mixtures of protein and non-protein amino-acids; its greater separating power also enables optical isomers of amino-acids to be resolved. Sequencing is appreciably less laborious than with high-pressure liquid chromatographs. The extraordinarily high sensitivity makes gas–liquid chromatography unique in analysing traces of amino-acids, and combination with mass spectroscopy enables the structure of unknown amino-acids and peptides to be established.

The possibilities of gas–liquid and high-pressure liquid chromatography in separating nucleic-acid bases are comparable, but again the former is more sensitive. The Table lists comparative characteristics of the two methods

in analysing degradation products of proteins and nucleic acids. It is evident that these methods are largely complementary, but not mutually exclusive. The choice of method depends on the problems involved, the skill of the investigator, and the availability of the necessary equipment.
