The problem of the effective utilisation of natural raw materials is of fundamental importance in modern chemistry. The high selectivity and rate of a chemical reaction involving a low expenditure of energy and apparatus of minimum size have become the main criteria of the practical usefulness of a chemical process. The solution of the problem of the optimisation of a process presupposes the knowledge of the kinetic parameters and mechanism of the given chemical reaction, i.e. the chemical kinetics. Thus chemical kinetics have become the scientific basis of chemical engineering.

This review is devoted to the problem of the selectivity of simple and complex (including a large number of elementary stages) chemical reactions and the physicochemical and kinetic factors which determine the selectivity.

II. SELECTIVITY, CONVERSION, AND REACTION YIELD

The concept of the "quantitative yield" of the reaction product, which is frequently employed, corresponds to the idea of a high process selectivity. However, the quantitative definition of the term "selectivity" must be more rigorous, particularly in view of the fact that different definitions are stated in the literature.

The integral selectivity S_P (with respect to the product P) of the reaction

$$\underset{\text{initial compounds}}{A, B, \ldots} \longrightarrow \underset{\text{intermediates}}{\pi_1, \pi_2 \ldots\ldots} \quad \underset{\text{final products}}{P, P_1 \ldots}$$

is defined by the relation

$$S_P(t) = \frac{f\Delta P}{\Delta A} = \varphi_P / C_A = \frac{f\int\limits_0^t w_P \, \mathrm{d}t}{\int\limits_0^t |w_A| \, \mathrm{d}t}, \tag{1}$$

where ΔP is the amount (or concentration when the volume is constant) of the product P formed, w_P the rate of its accumulation, ΔA the amount of unreacted initial substance A in relation to which the selectivity is determined, $|w_A|$ the absolute rate of consumption of A, f a normalising factor related to the stoichiometric coefficients of the chemical equation, $\varphi_P = f\Delta P/A_0 = \int_0^{f\Delta P} \mathrm{d}P/A_0$ the yield of the product P (A_0 is the initial amount of substance A), and $C_A = \Delta A/A_0$ the degree of conversion of substance A; the form of the function $w(t)$ is determined by the specific reaction mechanism.

Thus the selectivity characterises the fraction of the initial substance converted into the product P. It is a function of time and hence also of the degree of reaction, the rate constants for the elementary processes, and the concentrations of the substances involved in the reaction.

The relation between S and C, i.e. between the selectivity and the degree of conversion, can be formulated thus:

$$S(C) = \frac{f}{C_A}\int\limits_0^{\Delta P} \frac{\mathrm{d}P}{A_0} = -\frac{1}{C_A}\int\limits_0^{C_A} \frac{f\,\mathrm{d}P}{\mathrm{d}A}\,\mathrm{d}C_A = \frac{1}{C_A}\int\limits_0^{C_A} \sigma\,\mathrm{d}C_A, \tag{2}$$

since $\mathrm{d}C_A = -\mathrm{d}A/A_0$, $C_A = 0$ when $A = A_0$, and the degree of conversion is equal to C_A when $A = A_0 - \Delta A$.

The quantity

$$\sigma = -\frac{f\,\mathrm{d}P}{\mathrm{d}A} = -\frac{f\,\mathrm{d}P/\mathrm{d}t}{\mathrm{d}A/\mathrm{d}t} = -\frac{fw_P}{w_A} \tag{2a}$$

is called the differential selectivity. In relation to reactions in flow systems, σ may be used as an independent selectivity criterion. For an ideal mixing reactor, Eqn. (2a) reduces to a formula analogous to Eqn. (1). In a flow system under steady-state conditions at constant volume of the reaction mixture, the following relations hold:

$$w_P = v_P\,[P]_{st},$$
$$w_A = v_0\,[A]_0 - v_A\,[A]_{st},$$

where v_0, v_A, and v_P are the specific rates of supply and removal of A and of removal of the product P respectively. We then have

$$\sigma = \frac{fw_P}{|w_A|} = \frac{fv_P\,[P]_{st}}{|v_0\,[A]_0 - v_A\,[A]_{st}|}\;; \tag{3}$$

where $v_0 = v_A = v_P$, we find

$$\sigma = f\,[P]_{st}/([A]_0 - [A]_{st}) = f\,[P]_{st}/(\Delta\,[A])_{st},$$

i.e. in the steady state the differential selectivity is identical with the integral selectivity.

In closed systems σ does not characterise the selectivity adequately and may actually become negative. In certain cases (heterogeneous catalytic processes) an integral selectivity criterion is used in the form

$$S' = \Delta P_i \Big/ \sum_{j\neq i} \Delta P_j = \int\limits_0^t w_{P_i}\,\mathrm{d}t \Big/ \int\limits_0^t \sum_{j\neq i} w_{P_j}\,\mathrm{d}t, \tag{1a}$$

where ΔP_i is the amount (concentration) of the product P_i and $\sum_{j\neq i} = \Delta P_j$ is the total amount of all the reaction products with the exception of P_i.

III. SELECTIVITY OF REACTIONS OF SIMPLE TYPES

In chemical kinetics the entire wide variety of chemical reactions reduce to a limited number of kinetic types: reactions of simple orders and simple consecutive, parallel, reversible, autocatalytic, and chain processes. Complex chain reactions are frequently described by simple kinetic laws, so that the problem of selectivity is considered primarily in relation to a set of first-order reactions occurring simultaneously.

1. Reaction of the type

$$A \xrightarrow{k} mP\ .$$

In this case

$$-\mathrm{d}\,[A]/\mathrm{d}t = f\mathrm{d}\,[P]/\mathrm{d}t,$$

i.e. $|w_A| = fw_P$, where $f = 1/m$, and, according to Eqns. (1) and (2), we have $S(t) = 1$ and $S(C) = 1$.

Thus the selectivity of simple chemical reactions taking place in one stage and leading to the formation of a single desired product only is always equal to unity throughout the chemical reaction (Fig. 1).

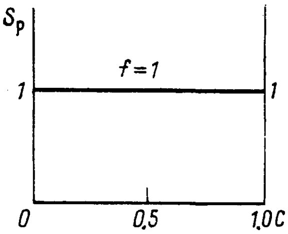

Figure 1. The selectivity in a simple irreversible reaction.

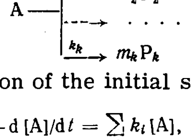
2. The parallel reactions



$$A \left\{ \begin{array}{l} \xrightarrow{k_1} m_1 P_1 \\ \xrightarrow{k_2} m_2 P_2 \\ \dashrightarrow \;\cdot\;\cdot\;\cdot\;\cdot \\ \xrightarrow{k_k} m_k P_k \end{array} \right.$$

The rate of consumption of the initial substance A is given by

$$-\mathrm{d}\,[A]/\mathrm{d}t = \sum_i k_i\,[A],$$

and the formula

$$\mathrm{d}[\mathrm{P}_j]/\mathrm{d}t = m_j k_j [\mathrm{A}].$$

expresses the rate of accumulation of P_j. Consequently

$$S_{\mathrm{P}_j}(t) = S_{\mathrm{P}_j}(C) = f_j k_j \Big/ \sum_i k_i = \text{const},$$

where $f_j = 1/m_j$. Evidently, the selectivities $S(C)$ and $S(t)$ of parallel first-order reactions are also independent of both the time and the degree of reaction (they remain constant throughout the reaction) and are determined by the stoichiometry of the reaction and the rate constants for the individual stages.

When the order n of even one of the parallel stages (l) is other than unity ($n \neq 1$), we have

$$-\mathrm{d}[\mathrm{A}]/\mathrm{d}t = \sum_{i\neq l} k_i [\mathrm{A}] + nk_l [\mathrm{A}]^n,$$

$$\mathrm{d}[\mathrm{P}_j]/\mathrm{d}t = m_j k_j [\mathrm{A}],\ \mathrm{d}[\mathrm{P}_l]/\mathrm{d}t = m_l k_l [\mathrm{A}]^n;$$

$$S_j(t) = \frac{f_j \int\limits_0^t k_j [\mathrm{A}]\,\mathrm{d}t}{\int\limits_0^t \Big(\sum\limits_{i\neq l} k_i [\mathrm{A}] + nk_l [\mathrm{A}]^n\Big)\,\mathrm{d}t} \quad (\text{for } j \neq l),$$

$$S_l(t) = \frac{f_l \int\limits_0^t k_l [\mathrm{A}]^n\,\mathrm{d}t}{\int\limits_0^t \Big(\sum\limits_{i\neq l} k_i [\mathrm{A}] + nk_l [\mathrm{A}]^n\Big)\,\mathrm{d}t},$$

where $f_j = 1/m_j$ and $f_l = n/m_l$.

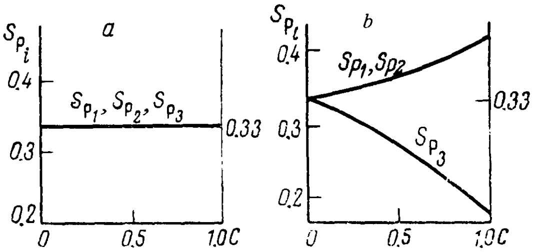


Figure 2. The selectivity in parallel reactions: *a*) three first-order reactions ($k_1 = k_2 = k_3$); *b*) two parallel first-order reactions and one second-order reaction $\{k_1 = k_2 = k_3[\mathrm{A}]_0\}$.

Although these equations can in fact be integrated, they lead to complex formulae, so that it is much more convenient to calculate the function $f_j(C)$. The expressions for differential selectivity required in these calculations are formulated as follows:

$$\sigma_{j(j\neq l)} = \frac{f_j k_j}{\sum\limits_{i\neq l} k_i + nk_l [\mathrm{A}]^{n-1}} = \frac{f_j k_j}{\sum\limits_{i\neq l} k_i + nk_l [\mathrm{A}]_0^{n-1} (1-C)^{n-1}} \tag{4}$$

for all the products formed in first-order reactions and

$$\sigma_l = \frac{f_l k_l}{\sum\limits_{i\neq l} k_i [\mathrm{A}]^{1-n} + nk_l} = \frac{f_l k_l}{\sum\limits_{i\neq l} k_i [\mathrm{A}]_0^{1-n} (1-C)^{1-n} + nk_l} \tag{5}$$

for the product formed in the nth order reaction.

It is seen from Figs. 4 and 5 that, as the initial substance A is consumed, the differential process selectivity with respect to any product changes monotonically. When $n > 1$, the quantity σ_j ($j \neq 1$) increases monotonically with the degree of reaction and σ_l diminishes monotonically; on the other hand, when $n < 1$, σ_j diminishes and σ_l increases. It follows from Eqn. (2) that, for the monotonic variation of the differential selectivity σ, the integral selectivity S varies in parallel with the latter. Accordingly, when $n > 1$, an increase in the degree of conversion entails an increase of S_j and a decrease of S_l, while under conditions where $n < 1$, the opposite situation obtains, i.e. S_j decreases and S_l increases (Fig. 2). For integral values of n, the expressions for the integral selectivities may also be obtained in terms of quadratures, for example, for $n = 2$ and $m_j = 1$, we have

$$S_j = \frac{k_j}{2k_l [\mathrm{A}]_0 C} \ln\left(1 - \frac{k_l [\mathrm{A}]_0 C}{\sum\limits_{i\neq l} k_i + 2k_l [\mathrm{A}]_0}\right);$$

$$S_l = 2\left\{1 + \frac{\sum\limits_{i\neq l} k_i}{2k_l [\mathrm{A}]_0 C} \ln\left(1 - \frac{2k_l [\mathrm{A}]_0 C}{\sum\limits_{i\neq l} k_i + 2k_l [\mathrm{A}]_0}\right)\right\}.$$

3. A sequence of first-order reactions:

$$\mathrm{A} \xrightarrow{k_1} m_1\pi_1 \equiv \pi_1 \xrightarrow{k_2} m_2\pi_2 \equiv \pi_2 \longrightarrow \cdots \equiv \pi_{k-1} \xrightarrow{k_k} m_k\mathrm{P}\,.$$

The system of differential equations for this process is of the form

$$\left.\begin{aligned} -\mathrm{d}[\mathrm{A}]/\mathrm{d}t &= k_1 [\mathrm{A}], \\ \mathrm{d}[\pi_1]/\mathrm{d}t &= m_1 k_1 [\mathrm{A}] - k_2 [\pi_1], \\ &\cdots\cdots\cdots\cdots\cdots \\ \mathrm{d}[\pi_{k-1}]/\mathrm{d}t &= m_{k-1} k_{k-1} [\pi_{k-2}] - k_k [\pi_{k-1}], \\ \mathrm{d}[\mathrm{P}]/\mathrm{d}t &= m_k k_k [\pi_{k-1}]. \end{aligned}\right\} \tag{6a}$$

Accordingly the differential selectivities are given by

$$\left.\begin{aligned} -\sigma_{\mathrm{P}_1} &= \frac{f_1\,\mathrm{d}[\pi_1]}{\mathrm{d}[\mathrm{A}]} = -1 + \frac{k_2}{m_1 k_1} \cdot \frac{[\pi_1]}{[\mathrm{A}]}, \\ &\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\ -\sigma_{\mathrm{P}_{k-1}} &= \frac{f_k\,\mathrm{d}[\pi_{k-1}]}{\mathrm{d}[\mathrm{A}]} = \frac{f_{k-1} m_{k-1} (k_{k-1} [\pi_{k-2}] - k_k [\pi_{k-1}])}{k_1 [\mathrm{A}]}, \\ -\sigma_{\mathrm{P}_k} &= \frac{f_k\,\mathrm{d}[\mathrm{P}]}{\mathrm{d}[\mathrm{A}]} = \frac{f_k m_k k_k [\pi_{k-1}]}{k_1 [\mathrm{A}]}, \end{aligned}\right\} \tag{6}$$

where $f_k = 1 \Big/ \prod\limits_{i=1}^{k} m_i$.

By integrating Eqns. (6), it is possible to obtain an expression for the integral selectivity $S(C)$ corresponding to any product. The selectivity with respect to π_1

$$S_{\pi_1}(C) = m_1 \frac{(1-C)^{k_2/k_1} - (1-C)}{(1 - k_2/k_1)\,C} \tag{7}$$

decreases from 1 to 0 with increase of the degree of conversion (Fig. 3). For $k_2/k_1 < 2$, $S_{\pi_1}(C)$ changes relatively little up to high degrees of conversion [the plot of the function $S_{\pi_1}(C)$ has a convex region]. For $k_2/k_1 > 2$, $S_{\pi_1}(C)$ varies sharply under the conditions of low values of C [the function $S_{\pi_1}(C)$ is concave].

For selectivity with respect to π_2, we have

$$S_{\pi_2}(C) = \frac{m_1 m_2 k_1 k_2}{(k_2 - k_3)} \cdot \frac{1}{C} \left\{ \frac{(1-C)^{k_2/k_1}}{k_2 - k_1} - \frac{(1-C)^{k_3/k_1}}{k_3 - k_1} + \frac{(1-C)(k_2 - k_3)}{(k_2 - k_1)(k_3 - k_2)} \right\}.$$

When $t \to 0$ and $t \to \infty$, the function $S_{\pi_2}(C) \to 0$, so that the maximum selectivity with respect to π_2 is attained for an optimum degree of conversion of the initial substance (Fig. 3).

For all subsequent intermediates, S also passes through a maximum, but the formulae for selectivity become more cumbersome. Naturally the process selectivity with respect to any product is higher the lower the rate of its consumption. This is clearly seen from Eqns. (6): the lower the constant k_k the higher the value of $\sigma_{\pi_{k-1}}$ and hence also of $S_{\pi_{k-1}}(C)$.

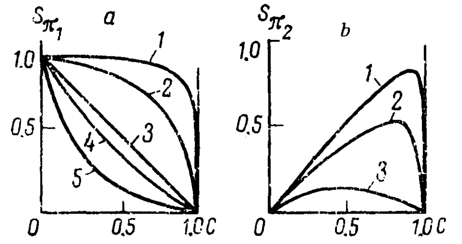

Figure 3. The selectivity in the formation of products in a first-order consecutive reaction $A \rightarrow \pi_1 \rightarrow \pi_2 \rightarrow P$: *a*) for the first intermediate and different rate constant ratios k_2/k_1 [1) 0.1; 2) 0.5; 3) 2; 4) 3; 5) 10]; *b*) for the second intermediate, $k_2/k_1 = 2$ and different k_3/k_1 ratios [1) 0.1; 2) 0.5; 3) 10].

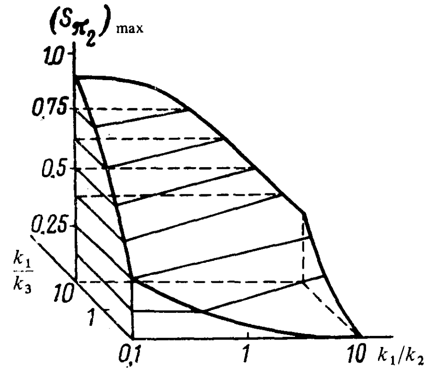

Figure 4. Selectivity with respect to the second intermediate in consecutive first-order reactions as a function of the ratio of the rate constants for individual stages.

A high selectivity with respect to an intermediate may be obtained if the rate constant for its consumption is significantly lower than the rate constant for its formation. Fig. 4 shows how the maximum process selectivity with respect to the second intermediate $(S_{\pi_2})_{\max}$ varies for different ratios of the rate constants k_1, k_2, and k_3. Evidently, the highest selectivities are attained when $k_1 \gg k_3 \ll k_2$. The selectivity with respect to the final product

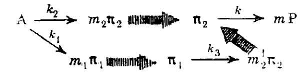
$$S_P(C) = 1 - \sum_{i=1}^{k-1} S_{\pi_i}$$

decreases monotonically with increase of C.

In order to achieve the transformation into the function $S(t)$, it is sufficient to use the time variation of the degree of conversion, i.e. the equation of the kinetic curve. In the case where the consumption of the initial substance follows first-order kinetics, the relation between C and t is

$$C = (1 - e^{-k_1 t}).$$

4. Consecutive-parallel reactions. The selectivity in the formation of any products of a complex consecutive-parallel reaction is determined by the stability of the reaction products and the probability that the reaction proceeds via different parallel pathways. For example, in the complex consecutive-parallel reaction



the differential process selectivity σ_1 with respect to the first product π_1 is determined by the factor associated with the parallel mechanism of the conversion of A into this product, namely $\alpha_{(A \rightarrow \pi_1)} = k_1/(k_1 + k_2)$, and the factor associated with the instability of the product π_1, namely $\beta_1 = k_3[\pi_1]/k_1[A]$, and can be formulated as follows:

$$\sigma_1 = \alpha(1 - \beta_1) = \alpha\gamma_1. \tag{8a}$$

The quantity $\gamma_1 = 1 - \beta_1$ characterises the accumulation of π_1 and may be called the accumulation factor.

The second product is formed via two pathways: directly from A and from the first intermediate π_1. The selectivity in the formation of π_2 is therefore determined by the sum of the selectivities in its formation via the two pathways. The selectivity in the formation of π_2 directly from A is determined from a formula analogous to Eqn.(8a):

$$\sigma_2(A \rightarrow \pi_2) = (1 - \alpha)\gamma_2 = (1 - \alpha)(1 - \beta_2),$$

where

$$\beta_2 = k[\pi_2]/(k_2[A] + k_3[\pi_1]),$$

The selectivity in the formation of π_2 via the second pathway, i.e. from π_1, is determined by the product of the factor associated with the parallel mechanism of the formation of π_1 from A (α), the π_1 instability factor (β_1), and the π_2 accumulation factor (γ_2):

$$\sigma_2(\pi_1 \rightarrow \pi_2) = \alpha\beta_1(1 - \beta_2) = \alpha\beta_1\gamma_2;$$

i.e.

$$\sigma_2 = \gamma_2(1 - \alpha + \alpha\beta_1). \tag{8b}$$

If the selectivity with respect to π_2 is proportional to the π_2 accumulation factor, then the selectivity with respect to the product P is proportional to the π_2 instability factor and is given by

$$\sigma = \beta_2(1 - \alpha + \alpha\beta_1). \tag{8c}$$

Eqns. (8a), (8b), and (8c) form a system of differential equations, the substitution of the solution of which in Eqn. (2) yields expressions for the integral selectivities with respect to all products.

The integral selectivity with respect to π_1 is described by a formula analogous to Eqn. (7):

$$S_{\pi_1}(C) = \alpha \frac{(1 - C)^{k_3/(k_1 - k_2)} - (1 - C)}{(1 - k_3/(k_1 + k_2))\,C} \tag{9}$$

and decreases from 1 to 0 with decrease in the degree of conversion, as for the product π_1 of the consecutive reaction (Fig. 5). The selectivity with respect to the product π_2 varies in accordance with the equation

$$S_{\pi_2}(C)=m_2\frac{k_1}{C}\left\{\frac{[k_2/k_1+k_3/(k_3-k_2-k_1)](1-C)}{k_1+k_2-k}+\right.$$
$$\left.+\frac{k_3}{(k_3-k_2-k_1)(k_3-k)}(1-C)^{k_3/(k_1+k_2)}+\frac{[k_2/k_1+k_3/(k_3-k)]}{k-k_2-k_1}(1-C)^{k/(k_1+k_2)}\right\}.$$

$S_{\pi_2}(C)$ may pass through a maximum for $k_2/k_1 < k_3/k$ (Fig. 5). Under these conditions, the product π_2 is formed predominantly owing to the conversion of π_1, i.e. is in essence the second intermediate in the sequence of transformations.

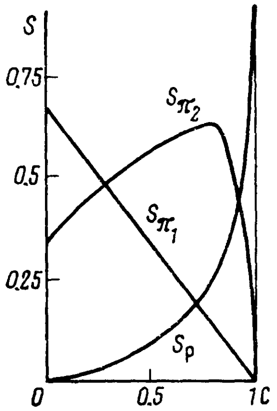


Figure 5. Selectivity in consecutive-parallel reactions. Calculation carried out for $k_1 = 2k_2$, $k = 1.5k_2$, and $k_3 = 6k_2$.

The selectivity with respect to the final product P_1 in this mechanism, as in any other sequence of reactions, increases with increased degree of conversion. Here the time variation of the degree of conversion

$$C=(1-e^{-(k_1+k_2)t})$$

makes it possible to transform the $S(C)$ relation into the expression for the time dependence of the selectivity in the formation of the products $S(t)$.

Expressions for the selectivities in the formation of products in a chemical process of any complexity may be obtained similarly.

IV. KINETIC ANALYSIS OF THE GENERAL SCHEME FOR A RADICAL-CHAIN REACTION AND SELECTIVITY

The kinetic mechanism of a chain process includes elementary steps of three types: (1) the formation of active centres propagating the chain; (2) chain propagation (steps involving the chain transformation of the substance, chain interconversion of the active chain-propagating centes), and (3) chain termination (destruction of active centres)[1-3]. If the chains are fairly long, then chain termination has almost no influence on the composition of the reaction products. The products formed during the process may interact with any active centres in the system, giving rise to secondary active species, whose reactivity as a rule differs from that of the primary species. Thus chain interaction assumes a significant importance.

The general mechanism of the radical-chain process can be represented in the following form when account is taken of the chain interaction mechanism (A) (see also Fig. 6).

Sources of free radicals:

$$\begin{array}{cccc} A, B, \dots\,; & \pi_j \Longrightarrow & r_0^{\cdot},\ r_j^{\cdot} \Longrightarrow & R_k^{\cdot} \\ \text{initial substances} & \text{intermediates} & \text{primary radicals} & \text{radical chain} \\ \text{(initiation)} & \text{(degenerate} & & \text{carriers} \\ & \text{branching)} & & \end{array}.$$

Chain formation:

$$A(B)\xrightarrow{k_0} r_i^{\cdot} \quad \text{(chain initiation)},$$
$$\pi_k \xrightarrow{k_{3k}} f\, r_k^{\cdot} \quad \text{(chain branching by the product } \pi_k\text{)},$$
$$A(B)+r_i^{\cdot}\xrightarrow{k_1} R_0^{\cdot}+P \quad \text{(formation of chain-propagating radical } R_0^{\cdot}\text{)}.$$

Chain propagation

$$\left.\begin{aligned} A+R_0^{\cdot} &\xrightarrow{k_{2.1}} \pi_1+R_0^{\cdot\prime} \\ B+R_0^{\cdot} &\xrightarrow{k_{2.2}} R_0^{\cdot} \end{aligned}\right\} \quad \text{(main chain in the conversion of the initial substance)}$$

$$\pi_i+R_i^{\cdot}\xrightarrow{k_2^{ii}} \pi_l+R_i^{\cdot} \quad \text{(secondary chain in the conversion of intermediates)}$$

$$\left.\begin{aligned} A+R_k^{\cdot} &\xrightarrow{k_{2.k}} \pi_s+R_0^{\cdot\prime} \\ \pi_j+R_0^{\cdot} &\xrightarrow{k_2^{0j}} \pi_1+R_j^{\cdot} \\ \pi_i+R_k^{\cdot} &\xrightarrow{k_2^{ki}} \pi_s+R_i^{\cdot} \end{aligned}\right\} \quad \text{(chain interaction)},$$

Chain termination

$$R_i^{\cdot}+R_j^{\cdot}\xrightarrow{k_{4.1}} P_{\text{term}} \quad \text{(quadratic chain termination in the interaction of active centres)}$$

$$R_i^{\cdot}\xrightarrow{k_{4.2}} P'_{\text{term}} \quad \text{(linear chain termination, for example in the interaction between a radical and the inhibitor).}$$

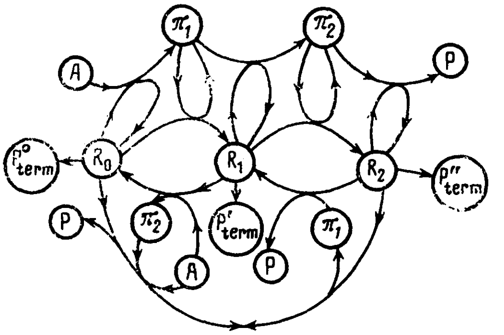

Figure 6. The pathways in a consecutive radical-chain reaction.

In this formulation the general mechanism for a chain reaction has a distinct structure, which emphasises the presence in the system of many sources of free radicals, distinguishes the units of the main and secondary chains and the interaction steps between the chains, and contains traditional types of elementary stages such as chain branching and termination†.

In examining the characteristics of a chain process use was made of fundamental concepts such as chain length ν and the rate of formation of radicals w_i in the chain initiation and branching stages. The length of the chain in the consumption of the initial substance A $[\nu_-^{(A)}]$ or in the consumption of any intermediate π_j $[\nu_-^{(\pi_j)}]$ is equal to the ratio of the rate of interaction of A or π_j with the free radicals to the rate of destruction of the latter, w_{term}. Since w_{term} in chain processes is usually equal to w_i, we have the following expressions for the chain lengths in the consumption process:

$$\nu_-^{(A)} = \left(\sum_i k_{2.i}\,[\dot{R}_i]\right)[A]/w_i,$$

$$\nu_-^{(\pi_j)} = \left(\sum_i k_2^{ij}\,[\dot{R}_i]\right)[\pi_j]/w_i, \tag{10}$$

where $k_{2.i}$ and k_2^{ij} are the rate constants for the interaction of the radicals with A and π_j. If the intermediate π_k is formed as a result of the interaction of an active centre $\dot{R}_l$ with any substance involved in the process, the chain length in the formation of π_k is proportional to the concentration of $\dot{R}_l$ and is determined by the relation

$$\nu_+^{(\pi_k)} = \left(\sum_i k_2^{li}\,[\pi_i]\right)[\dot{R}_l]/w_i, \tag{11}$$

where $\pi_0 = A$.

The chain lengths in the formation (ν_+) and consumption (ν_-) of the same substance are not identical and the difference between them characterises the change in the concentration of the substance during the process (the concentration of the latter increases and falls respectively when $\nu_+ > \nu_-$ and $\nu_+ < \nu_-$). The ratio of the rates of formation and consumption of the substances involved in the process is determined by the relative concentrations of the active centres in the system. For fairly long chains, the steady-state concentration of radicals is established as a result of their interconversion during the interaction between the chains. The rate of formation of the given radical in the chain is equal to the rate of its chain transformation:

$$\left(\sum_i k_2^{ij}\,[\dot{R}_i]\right)[\pi_j] = \left(\sum_i k_2^{ki}\,[\pi_i] + k_{2.k}\,[A]\right)[\dot{R}_k] \tag{12}$$

where π_j is the substance from which the active centre $\dot{R}_k$ is formed as a result of the interaction with the active centre $\dot{R}_i$.

Eqns.(12) constitute a system of algebraic linear homogeneous equations, whose number is equal to the number of types of radicals involved in the process. The rank of the coefficients matrix for this system of equations is smaller by unity than the number of equations. The relative concentration of any active centre can therefore be determined from Eqns.(12):

$$[\dot{R}_j] = \frac{D_{ij}}{D_i}\,[\dot{R}_i], \tag{13}$$

where D_i is the determinant corresponding to the coefficients matrix of Eqns.(13), from which the ith row and the ith column have been eliminated and D_{ij} is the determinant, analogous to D_i, obtained from the initial matrix by the transposition of the ith and jth columns.

On substituting Eqn.(13) into Eqns.(10) and (11) and then into Eqn.(2), we find an expression for the dependence of the process selectivity on the degree of conversion of the initial substance for a purely chain process when the contribution of molecular processes is insignificant:

$$S_{\pi_j} = \frac{1}{C}\int\limits_0^C \frac{\sum\limits_i (k_2^{ki}\,[\pi_i]\,D_{0k} - k_2^{kj} D_{0i}\,[\pi_j])\,\mathrm{d}C}{D_0 \sum\limits_i k_2^{0i}\,[\pi_i]}. \tag{14}$$

Eqn.(14) for the selectivity in the formation of any substance in an arbitrary chain process permits the following conclusions.

1. The selectivity is independent of the absolute concentration of the active centres in the system, i.e. of the rate of their formation (the integrand does not contain the absolute concentration of active centres).

2. Since the selectivity is independent of the absolute concentration of active centres, the factors which alter the rates of a chain process by altering the absolute concentration of active species (the effects of initiators and weak inhibitors) do not affect the process selectivity.

3. In the common instance where the reactivity of a radical in its reaction with molecules is independent of the nature of the radical and the rate constant for this reaction is determined solely by the properties of the molecules, the ratio

$$k_2^{ij}/k_2^{ik} = \varphi_{jk} = \text{const}$$

for the given j and k. The selectivity of a chain process of this kind is determined in the same way as the selectivity in a non-chain process proceeding via the same pathway without the participation of active centres. For a non-chain process, the ratios of the rate constants for the interconversion of the substance φ_{jk} are equal to the ratios of the rate constants for the interaction of the substances with the active centres in the chain process.

The selectivity of the chain process $S_{P_{term}}$ with respect to the product P_{term} formed in the chain initiation or termination step is a function of the chain length in the consumption of the initial substance:

$$S_{P_{term}} = \frac{n}{C}\int\limits_0^C \frac{\mathrm{d}C}{\nu_-^{(A)} + m}, \tag{15}$$

where n is the number of molecules of P_{term} formed in a single chain termination step and m the number of molecules of the initial substance consumed during the initiation and termination of a single chain. The maximum selectivity with respect to termination products is attained for the minimum chain lengths $[\nu_-^{(A)} = 1]$. For non-linear chain termination, the quantity $\nu_-^{(A)}$ is a function of the rate of initiation and the process selectivity depends in this instance on the rate of initiation.

---

† In the text below the following numbering of the rate constants for individual elementary steps has been adopted: k_0 is the chain initiation rate constant, $k_{2.i}$ the rate constant for the ith reaction propagating the chain in the consumption of the initial substance, $k_{3.i}$ the rate constant for the ith chain branching reaction, and $k_{4.i}$ the rate constant for the ith chain termination reaction. The constants k_2^{ij} refer to secondary reaction chains; the first superscript refers to the reacting radical and the second to the given substance.

The absolute selectivity in the formation of P_{term} in a process with long chains is low, since the differential selectivity in the integrand of Eqns.(15) is inversely proportional to the chain length. At advanced stages of the reaction the chain length in the consumption of the initial substance diminishes owing to the decrease of the concentration of the latter. The integrand of Eqn.(15) then increases and there is a corresponding increase of the process selectivity with respect to the product P_{term}. For short chain lengths, the rate of initiation begins to influence also the process selectivity with respect to the products formed in the chain propagation reaction.

The case discussed above refers to processes where the formation and consumption of all the initial substances and reaction products take place only with participation of free radicals, (i.e. via a chain mechanism). When molecular reaction pathways or short chains occur, the characteristics of the variation of $S(C)$ and $S(t)$ change somewhat, in particular the process selectivity begins to depend on ν and w_i. A quantitative calculation of the selectivity of a chain process during which the chain length becomes small involves the solution of non-linear integrodifferential equations even in the simplest cases.

As an example of such a process, we shall consider a degenerate branched chain oxidation reaction where the hydrocarbon is consumed via a single pathway:

$$\begin{gathered}
\mathrm{ROOH} \xrightarrow{k_3} (\mathrm{RO^{\cdot}} + \mathrm{OH^{\cdot}}),\\
\mathrm{RO^{\cdot}} + \mathrm{RH} \xrightarrow{+\mathrm{O_2}} \mathrm{ROH} + \mathrm{RO_2^{\cdot}},\\
\mathrm{OH^{\cdot}} + \mathrm{RH} \xrightarrow{+\mathrm{O_2}} \mathrm{H_2O} + \mathrm{RO_2^{\cdot}},\\
\mathrm{RO_2^{\cdot}} + \mathrm{RH} \xrightarrow{k_2} \mathrm{ROOH} + \mathrm{RO_2^{\cdot}},\\
\mathrm{RO_2^{\cdot}} + \mathrm{RO_2^{\cdot}} \xrightarrow{k_4} \mathrm{R'{=}O} + \mathrm{ROH} + \mathrm{O_2}.
\end{gathered} \tag{B}$$

Application of the principle of the quasi-steady-state nature of the process with respect to the concentrations of the radicals $RO_2^{\cdot}$, $OH^{\cdot}$, and $RO^{\cdot}$, yields a system of differential equations describing the process kinetics:

$$\begin{gathered}
\mathrm{d}[\mathrm{ROOH}]/\mathrm{d}t = k_2[\mathrm{RO_2^{\cdot}}][\mathrm{RH}] - k_3[\mathrm{ROOH}],\\
\mathrm{d}[\mathrm{RH}]/\mathrm{d}t = k_2[\mathrm{RO_2^{\cdot}}][\mathrm{RH}] - fk_3[\mathrm{ROOH}],\\
[\mathrm{RO_2^{\cdot}}] = (fk_3[\mathrm{ROOH}]/k_4)^{1/2},
\end{gathered}$$

(f is the probability of the release of radicals into space during the hydroperoxide decomposition step) and hence the equation relating the concentration of the hydroperoxide and the hydrocarbon:

$$\frac{\mathrm{d}[\mathrm{ROOH}]}{\mathrm{d}[\mathrm{RH}]} = \frac{\nu - 1/f}{\nu + 1}, \tag{16}$$

where

$$\nu = \frac{k_2[\mathrm{RH}]}{(fk_3k_4[\mathrm{ROOH}])^{1/2}}.$$

The concentration of the hydroperoxide at any concentration of RH may be calculated by Eqn.(16) and the process selectivity may be determined for different degrees of conversion. The highest selectivity in a process of this kind is attained when $1 \ll \nu \gg 1/f$. Fig.7 presents the results of a numerical calculation of S_{RCOOH} for different values of the parameter $k_2[\mathrm{RH}]_0/(k_3k_4)^{1/2}$ ($f = 1$).

In this process the hydroperoxide is the first intermediate and, as in a usual consecutive reaction, the selectivity in its formation decreases monotonically with increased degree of conversion of the initial substance. However, in contrast to a non-chain process, the decrease of selectivity is not associated with the consumption of the hydroperoxide but with the decrease of the chain length in its formation caused by the increase of its concentration and by the corresponding increase of the rate of initiation. The form of the function $S_{ROOH}(C)$ is therefore independent of the rate constant for the decomposition of the hydroperoxide, but depends on the parameter determining the oxidation chain length $\{k_2[\mathrm{RH}]_0/(k_3k_4)^{1/2}\}$ and on the probability of the release of radicals into space during the hydroperoxide decomposition step (f). For this reason, the greatest change in selectivity for any values of the parameters occurs at the beginning of the process, for low degrees of conversion of RH, where the concentration of the hydroperoxide and the rate of initiation vary to the maximum extent.

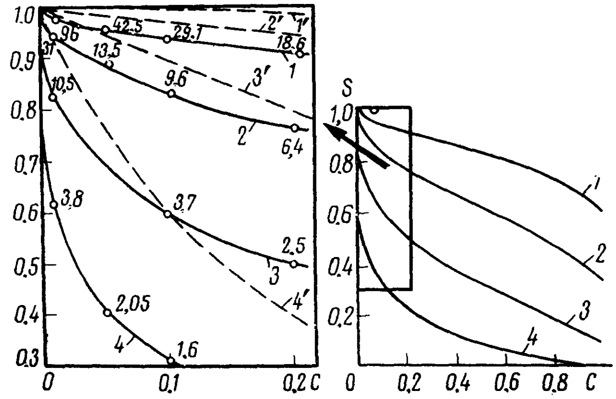

Figure 7. The selectivity in the formation of the hydroperoxide in a degenerate branched chain process as a function of the degree of conversion of the hydrocarbon oxidised for $f = 1$ and different values of the parameter $k_2[\mathrm{RH}]_0/(k_3k_4)^{1/2}$: 1) 10; 2) 3.16; 3) 1; 4) 0.316. The numerals opposite the calculated points denote the chain lengths under these conditions: 1')–4') the selectivities in the formation of the first intermediate in a simple consecutive reaction for the rate constant ratios k_2/k_1 = 0.1, 0.5, 2, and 10 respectively.

Fig. 7 presents the variation of the selectivity of the chain process discussed above and in a non-chain consecutive reaction (with the same sequence in the formation of products) for low degrees of conversion. In a consecutive reaction with low rate constants for the consumption of the first intermediate ($k_2/k_1 < 2$) the process selectivity corresponding to low degrees of conversion varies little and the function $S_{\pi_1}(C)$ is convex (Fig. 3). In a chain process the function $S_{ROOH}(C)$ is always concave for low degrees of conversion, i.e. $S_{ROOH}(C)$ changes sharply for low values of C. This form of the relation is due to the decrease of the chain length in the formation of the hydroperoxide owing to the increase of the rate of formation of active centres.

Thus kinetic analysis of the mechanism of a radical-chain process shows that the selectivity for the formation of chain propagation products in a reaction with long chains is independent of the rate of chain initiation and the absolute concentration of radicals. The characteristics of the variation of $S(C)$ are then largely analogous to those observed for the selectivity in a non-chain process proceeding via the same pathway. For short chains, S begins to depend on w_i and hence on ν. The selectivity in the formation of chain termination products P_{term} always depends on the rate of initiation (chain length) and assumes significant values only for fairly short chains.

V. FACTORS CONTROLLING SELECTIVITY

The best indication of the importance of chemical kinetics in experimental and practical research is the effective employment of kinetic parameters for controlling the rates and selectivities of chemical reactions.

For a long time the set of available factors capable of influencing a chemical reaction remained almost unchanged—the action of heat (heating, temperature rise), the influence of sunlight and chemical additives, and catalysis. Towards the end of the XXth century progress in science and engineering introduced into chemistry the action of ionising radiation, laser radiation, shock waves, the use of low temperatures (in contrast to the usual endeavour to increase the reaction temperatures), continuous processes, and modification and immobilisation of enzymes and cells as factors influencing the reaction. The principles of chemistry were given a profound and rigorous theoretical basis. This led to considerable possibilities in controlling chemical reactions, provided that their kinetics and mechanisms have been established, and to the possibility of altering the mechanism and kinetics when it is necessary and desirable from the scientific or technical point of view.

According to the formulae for selectivity, temperature as a rule influences the factors associated with a parallel-reaction mechanism (α) and the instability of the intermediate (β). Selective inhibition of undesirable and coupled processes leads to a change of α. In coupled processes these quantities depend on the relative activities of the radicals propagating the oxidation chain.

The introduction of complex forming agents (including solvents) also alters α and β owing to the decrease of the reactivity of the active centres. In certain cases (for short chains) the selectivity in a radical-chain processes depends on the chain length ν, which may be varied by the introduction of initiating additives or inhibitors which increase the rate of chain termination. The latter procedure is used in polymerisation, where a change in the viscosity and structural properties of the medium makes it possible to increase the molecular weight of the polymer and to alter the nature of the molecular weight distribution. The procedure involving the increased lifetime of the radical in the solid polymer led to the discovery of a new type of polymerisation—the radiation-induced graft polymerisation.

A new factor which increases selectivity is associated with the technique in which the reaction is carried out at low and ultralow temperatures (down to ~100 K) where many processes show high rates and high selectivities in the region corresponding to the transition of the system from the vitreous to the supercooled liquid state.

In the region of heterogeneous catalysis new possibilities arose in connection with the use of modified catalysts which propagate the process via a purely heterogeneous mechanism. A characteristic feature of such modified catalysts is the possibility of activating only one of the species involved in the chemical reaction (for example, O_2 in an oxidation process) and, conversely, a decrease of the ability of the catalyst to form complexes with other species (for example, the decreased rate of decomposition of the hydroperoxide in the autoxidation of hydrocarbons). In the presence of such catalysts the process selectivity is as a rule very high.

Homogeneous catalysis has become a fairly effective factor for influencing the selectivity in many chemical processes. The increase of the selectivity of radical-chain processes in the presence of homogeneous catalysts is associated with the selective acceleration of individual elementary stages.

Fundamentally new possibilities for increasing selectivity have arisen from the employment of catalysts which make it possible to propagate the process with participation of radicals bound in a complex with the catalyst (Lewis acids in polymerisation, dinuclear iron complexes in chlorination, etc.). In the presence of such catalysts reactions as a rule take place in the coordination sphere of the metal with a high selectivity.

Research based on the principles of the simulation of enzymatic systems has developed. The application of multicomponent homogeneous catalytic systems has led to many reactions which proceed with a selectivity which is actually higher than that in enzymatic processes.

The application of infrared laser chemistry has already given rise to instances where the reactivities and rates of conversion of individual substances were increased. These effects are used, in particular, for isotope enrichment. Thus under the influence of a HF laser, which emits coherent radiation in the region of 2.7 μm, CH_3OH molecules undergo selective excitation in a CH_3OH-CD_3OH mixture, and then become capable of reacting with Br_2 at high rates[4]:

$$CH_3OH + nh\nu \rightarrow CH_3OH^*,$$
$$CH_3OH^* + Br_2 \rightarrow \text{bromination products.}$$

By employing a 90 W HF laser, it is possible to enrich an equimolar CD_3OH-CH_3OH mixture to a 95% deuteromethanol content over a period of 1 min. Unfortunately laser chemistry has not as yet found applications in the solution of problems of increasing the selectivity in radical-chain processes to an extent which it merits.

Reactions in strong magnetic and electromagnetic fields will probably become common. The first examples of the use of magnetic and electric fields showed that the method is likely to be useful for increasing the selectivity in many chain processes.

The possibility of increasing the selectivity in chemical processes arising in connection with the employment of reactors where the reaction takes place under continuous conditions (ideal mixing and plug flow vessels) is beginning to attract much attention. Many reviews and monographs have been devoted to the simulation and optimisation of chemical reactors[5-7]. However, a fundamental deficiency of these studies is the employment of overall reaction mechanisms in the calculations, whereas knowledge and use in the calculations of specific chemical schemes for the elementary reaction rate constants might be very important. The importance of this approach becomes evident when account is taken of the fact that the method used to carry out the process may have a significant influence on the characteristics of the individual stages and hence the entire process. For example, a significant factor is that, by carrying out the reaction in an open system, one may promote the attainment of steady-state concentrations differing from those corresponding to thermodynamic equilibrium. Thus, for a simple reversible first-order reaction $A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} P$ in an open system, the ratio of the steady-state concentrations of P and A is

$$\frac{[\mathrm{P}]_{\mathrm{st}}}{[\mathrm{A}]_{\mathrm{st}}}=\frac{k_1([\mathrm{A}]_0+[\mathrm{P}]_0)+v[\mathrm{P}]_0}{k_{-1}([\mathrm{A}]_0+[\mathrm{P}]_0)+v[\mathrm{A}]_0}\neq\frac{k_1}{k_{-1}},$$

where $[\mathrm{A}]_0$ and $[\mathrm{P}]_0$ are the concentrations of A and P in the solutions supplied to the vessel and v is the flow rate.

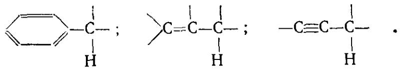
Thus analysis of specific chemical mechanisms plays in all cases an important role in the solution of problems associated with the optimisation of chemical processes. Certain specific examples of selective reactions and methods of increasing selectivity are considered below in relation to oxidation, polymerisation, cracking, and halogenation of organic substances.

VI. LIQUID-PHASE OXIDATION REACTIONS

Liquid-phase reactions involving the oxidation of organic substances are exceptionally widely used as objects of theoretical and experimental studies in the field of radical chain reactions and they are therefore important for chemical practice.

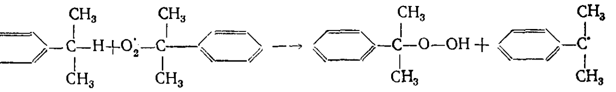
1. Dependence of Reaction Selectivity on Chain Length

A high selectivity in the formation of hydroperoxides at low temperatures is characteristic of the chain oxidation of aromatic alkyl derivatives, α-olefins, and other hydrocarbons with reactive C–H bonds activated by conjugation with an aromatic ring or with unsaturated carbon–carbon bonds:



In this case the process is a degenerate branched chain reaction proceeding via mechanism (B) (see Section IV).

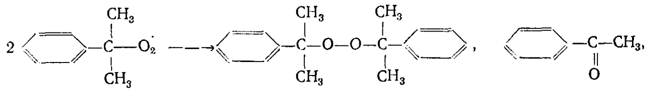
In the oxidation of cumene the chain propagation reaction



$$\mathrm{C_6H_5C(CH_3)_2H}+\dot{\mathrm{O}}_2\mathrm{C(CH_3)_2C_6H_5}\longrightarrow\mathrm{C_6H_5C(CH_3)_2{-}O{-}OH}+\mathrm{C_6H_5\dot{C}(CH_3)_2}$$

leads to the formation of a single primary product—isopropylphenyl hydroperoxide.

The recombination of radicals results in the formation of other oxygen-containing products (dicumenyl peroxide, acetophenone, methylphenylmethanol, etc.):



$$2\,\mathrm{C_6H_5C(CH_3)_2{-}O_2^{\cdot}}\longrightarrow\mathrm{C_6H_5C(CH_3)_2{-}O{-}O{-}C(CH_3)_2C_6H_5},\quad\mathrm{C_6H_5{-}C(=O){-}CH_3},$$

O_2 etc.

In the low-temperature initiated oxidation of hydrocarbons the initiator serves as the source of free radicals in the system and the hydroperoxide does not undergo further transformations. For low degrees of conversion of the hydrocarbon and the initiator, the chain length is almost constant and can be altered by varying the rate of initiation. Under the conditions considered, Eqns.(14) and (15) are transformed as follows:

$$\left.\begin{aligned}S_{\mathrm{ROOH}}&=\frac{\nu}{\nu+m}=\frac{\nu_-^{(\mathrm{O_2})}}{\nu_-^{(\mathrm{O_2})}+1.5}\to 1\\ S_{\mathrm{P_{term}}}&=\frac{1}{\nu+m}=\frac{1}{\nu_-^{(\mathrm{O_2})}+1.5}\to 0\end{aligned}\right\}\ (\text{when } \nu_-^{(\mathrm{O_2})}\gg 1.5).$$

If the rate of reaction is followed from the absorption of oxygen $[\nu=\nu_-^{(\mathrm{O_2})}]$, the coefficient m proves to be 1.5, since two O_2 molecules are absorbed in the chain initiation stage for each free radical formed and evolution of one half of an O_2 molecule corresponds to each $RO_2^{\cdot}$ recombination step.

Fig. 8 presents the dependence of the selectivity in the low-temperature sensitised oxidation of isopropylbenzene on chain length. Evidently, in conformity with the above analysis, for long chains $[\nu_-^{(\mathrm{O_2})}>10]$, the selectivity in the formation of the hydroperoxide is almost independent of ν. For short chains $[\nu_-^{(\mathrm{O_2})}<10]$, a dependence of this kind does appear. The reaction selectivity with respect to chain termination products changes much more, whatever the chain length ν, than the selectivity with respect to the hydroperoxide.

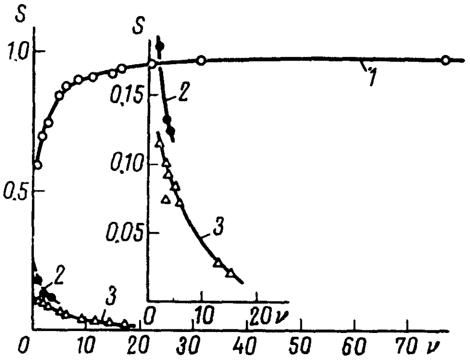


Figure 8. The yields of hydroperoxide (curve *1*), dicumenyl peroxide (curve *2*), and acetophenone (curve *3*) in relation to the amount of absorbed oxygen (in mole %) for different chain lengths in the initiated oxidation of isopropylbenzene. Initiator—azobisisobutyronitrile; solvent—chlorobenzene; temperature 60°C.

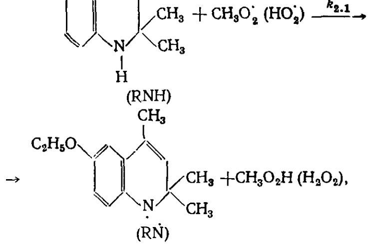
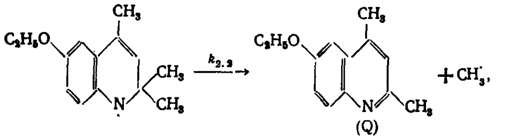
The chain oxidation of 6-ethoxy-2,2,4-trimethylethyl-1,2-dihydroquinoline (ethoxyquin, RNH) in chlorobenzene at a temperature >100°C is distinguished by a high selectivity in the formation of 6-ethoxy-2,4-dimethylquinoline (Q).[8] The chain propagation and termination can be represented by the following reactions:

(2.1)



(2.2)



(2.3) $$CH_3^\cdot + O_2 \xrightarrow{k_{2.3}} CH_3O_2^\cdot ,$$

(4) $$RN^\cdot + RN^\cdot \xrightarrow{k_4} \text{products.}$$

The unit of the ethoxyquin oxidation chain consists of a sequence of reactions (2.1), (2.2), and (2.3).

The high selectivity in the oxidation of ethoxyquin to the quinoline at high temperatures is due to the fact that in this process ethoxyquin reacts solely via the reactive N–H bond and the free radical RN$^\cdot$ decomposes via only one pathway (α = 1). Quinoline does not undergo further transformations and is the final reaction product: $\beta = w_-^{(Q)}/w_+^{(Q)} = 0$. The reaction chain length is high ($\nu \geqslant 50$ units) and the selectivity in the oxidation of ethoxyquin to quinoline is more than 95–97 mole % (Fig. 9). The radical RN$^\cdot$ decomposes [reaction (2.2)] with a high activation energy (~20 000 cal mole^{-1}), so that at low temperatures (<50°C) there is virtually no chain oxidation of ethoxyquin. At low temperatures ethoxyquin is used as an effective antioxidant. The high inhibiting activity of ethoxyquin is due to the high rate of reaction (2.1), which takes place with participation of peroxy-radicals ($RO_2^\cdot + RNH \rightarrow RO_2H + RN^\cdot$) and with virtual absence of the decomposition of the RN$^\cdot$ radical.

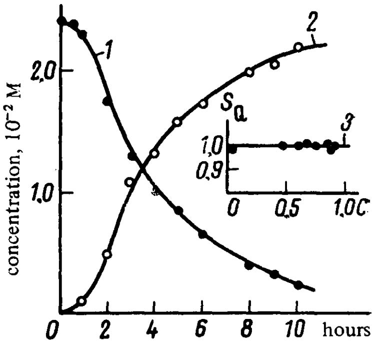


Figure 9. Kinetic curves for the consumption of 6-ethoxy-2,2,4-trimethyl-1,2-dihydroquinoline in the oxidation process (curve *1*) and for the accumulation of 6-ethoxy-2,4-dimethylquinoline (curve *2*); curve *3* represents the selectivity in the formation of quinoline for different degrees of conversion of ethoxyquin. Solvent—chlorobenzene; temperature—120°C.

2. The Influence of Thermal Molecular Decomposition and Chain Consumption of Hydroperoxides on the Selectivity of the Hydroperoxide Oxidation of Hydrocarbons

A high selectivity in the formation of hydroperoxides from aromatic alkyl-substituted hydrocarbons (ethylbenzene, isopropylbenzene, etc.) may obtain at elevated temperatures under conditions where the process occurs in the absence of initiating additives. Active centres are formed in this case when the hydrocarbon reacts with oxygen (chain initiation) and in the decomposition of intermediates (degenerate branching).

Fig. 10 presents kinetic curves for the accumulation of α-phenylethyl hydroperoxides and the consumption of ethylbenzene {Δ[RH]} during its autoxidation[9]. The selectivity in the oxidation of ethylbenzene to the hydroperoxide and its variation with the degree of conversion of the hydrocarbon were calculated from these data (Fig. 10, curve *3*). When the degree of conversion reaches 0.2, the selectivity in the formation of the hydroperoxide falls to 0.82. This decrease cannot be explained solely by the increased rate of initiation in the system, as in the example discussed above [see Fig. 7, Eqn. (16)], since the parameter $k_2[RH]_0/(k_0k_4)^{1/2} = 36M^{1/2}$ in ethylbenzene under the given conditions. According to the calculated data presented in Fig. 7, the process selectivity should greatly exceed 0.9 when C = 0.2.

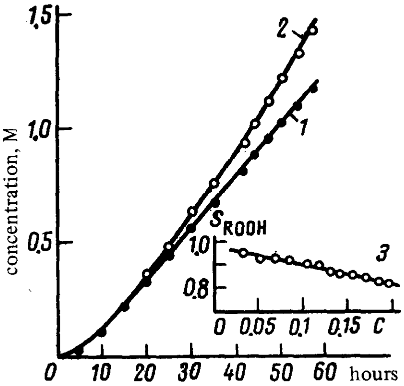

Figure 10. Kinetics of the autoxidation of ethylbenzene at 120°C: 1) the consumption of ethylbenzene Δ[RH]; 2) the accumulation of hydroperoxides; 3) dependence of reaction selectivity with respect to the hydroperoxide $S = [ROOH]/\Delta[RH]$ on the degree of conversion of the hydrocarbon $\Delta[RH]/[RH]_0$. The amount of unconsumed hydrocarbon was calculated from the total amount of products.

The decrease of selectivity during the reaction is caused by the increase of the rates of secondary transformations of the hydroperoxide, which as a rule involves thermal and chain decompositions:

$$RO_2^\cdot + ROOH \xrightarrow{k_2^{01}} R^{\cdot\prime} + \text{alcohol, ketone (chain decomposition),}$$

$$R^{\cdot\prime} + RH \xrightarrow[(+O_2)]{} R'H + RO_2^\cdot .$$

Taking this reaction into account and also the thermal decomposition of the hydroperoxide, the oxidation of ethylbenzene may be represented as a consecutive chain reaction:

$$RH \xrightarrow{+RO_2} ROOH - \left[\begin{array}{l} \xrightarrow[\text{chain decomposition}]{+RO_2^\cdot} \\ \\ \xrightarrow[\text{molecular decomposition}]{} \end{array} \right\} \text{products.}$$

Eqn.(2) for the dependence of process selectivity on the degree of conversion of the initial substance with allowance for chain interaction may be put in the following form:

$$S = \frac{1}{C}\int \frac{\nu(1-\beta)}{(\nu+1+\nu')}\, dC,$$

where $\nu + \nu'$ is the chain length in the consumption of the hydrocarbon and ν is the chain length in the formation of the hydroperoxide. The selectivity with respect to the hydroperoxide must be to a large extent determined by its instability factor:

$$\beta_{ROOH} = \frac{w_-^{(ROOH)}}{w_+^{(ROOH)}} = \frac{k_2^{01}[RO_2^{\cdot}][ROOH] + k_3[ROOH]}{k_2[RO_2^{\cdot}][RH]} = \frac{\nu' + 1/f}{\nu},$$

where $w_-^{(ROOH)}$ is the overall rate of consumption of the hydroperoxide and $w_+^{(ROOH)}$ is the rate of its formation. The quantity β changes during the process (Fig. 10) from 0.06 to 0.4 (for $C = 3-20\%$), which reduces the reaction selectivity with respect to the given product. Paraffins and naphthenes are oxidised at measurable rates at higher temperatures than aromatic alkyl-substituted hydrocarbons. The rate constants for the thermal and chain decomposition of the hydroperoxide are also higher. Under these conditions, β_{ROOH} may be large for lower degrees of conversion of the hydrocarbon, so that the selectivity in the oxidation of paraffins to hydroperoxides is lower than for aromatic alkyl-substituted derivatives. The main cause of the decrease of selectivity in the oxidation of cyclohexene to the monohydroperoxide is its subsequent chain oxidation to the dihydroperoxide, which occurs, like the oxidation of the initial cyclohexene, with participation of the reactive α-C–H bond[10]:

In contrast to the chain consumption of the hydroperoxides of aromatic alkyl-substituted hydrocarbons discussed above, in this elementary stage the OOH functional group of the monohydroperoxide is preserved. Together with the unimolecular decomposition of the hydroperoxide into free radicals and the chain consumption of the hydroperoxide in a secondary chain (with the rate constant k_2^{01}), the oxidation of cyclohexene involves the thermal decomposition of cyclohexenyl hydroperoxide via the reaction

$$RO_2H + HO_2R \overset{K}{\rightleftharpoons} [ROOH \ldots HOOR] \xrightarrow{k_{3.1}} RO^{\cdot} + H_2O + RO_2^{\cdot}.$$

However, the rate of the chain consumption of the hydroperoxide is significantly higher than the rate of its thermal molecular decomposition, so that the cyclohexenyl hydroperoxide "instability factor" may be formulated thus:

$$\beta_{ROOH} = (k_{eff} + k_2^{01}[RO_2^{\cdot}])[ROOH]/\alpha_{(RH\to ROOH)}\, k_2[RO_2^{\cdot}]\cdot[RH] \simeq$$
$$\simeq k_2^{01}[ROOH]/\alpha_{(RH\to ROOH)}\, k_2[RH],$$

where $k_{eff} = k_{3.1}K$ is the effective rate constant for the decomposition of ROOH and $\alpha(RH \to ROOH) = k_{2.1}/(k_{2.1} + k_{2.2})$ is the factor associated with the parallel-reaction mechanism of the main chain in the oxidation of cyclohexene to the monohydroperoxide [$\alpha(RH \to ROOH)$ at 0.7 at 70°C].

Fig. 11*a* presents kinetic curves for the consumption of cyclohexene and the accumulation of cyclohexenyl monohydroperoxide and dihydroperoxide. It is seen from the nature of the kinetic curves that the monohydroperoxide is an intermediate and the dihydroperoxide is a product of the subsequent transformation of the monohydroperoxide. The selectivity in the oxidation of cyclohexene to the monohydroperoxide diminishes from 70 to 20 mole % as the reaction proceeds owing to the increase of the parameter βROOH as C increases from 0 to 60% (Fig. 11*b*).

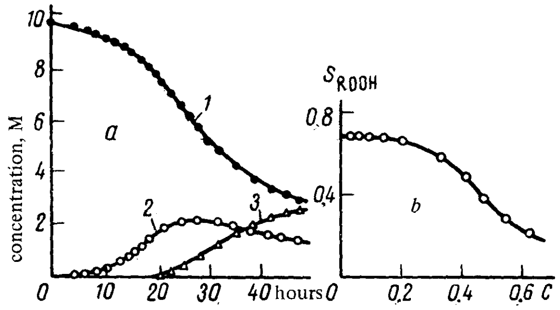

Figure 11. *a*) Kinetic curves for the consumption of cyclohexene (curve *1*) and the accumulation of cyclohexenyl monohydroperoxide (curve *2*) and dihydroperoxide (curve *3*) in the autoxidation of cyclohexene at 70°C; *b*) variation of the selectivity with respect to the monohydroperoxide with increase in the degree of conversion of the hydrocarbon.

3. The Selectivity in a Chain Reaction for the Parallel Consumption of the Hydrocarbon Via Different Pathways

In the general case the hydrocarbon molecule may contain several reaction centres (C–H, C=C, and other bonds), which have different reactivities or their reactivities in relation to reactions with free radicals are similar. The selectivity in the conversion of hydrocarbons into a particular product depends on the ratio of the rate constants for the parallel pathways in the consumption of the hydrocarbon (the quantity α_i). As an example, we may consider the autoxidation of cyclohexene for low degrees of conversion[10]. Cyclohexene is consumed via two parallel pathways with participation of the C–H and C=C bonds and different active centres ($RO_2^{\cdot}$ and $PO_2^{\cdot}$, $RO^{\cdot}$):

$$(2.1)\quad \begin{cases} RO_2^{\cdot} + RH \xrightarrow[(+O_2)]{k_{2.1}} ROOH + RO_2^{\cdot}, \\ PO_2^{\cdot} + RH \xrightarrow[(+O_2)]{k_{2.1}} POOH + RO_2^{\cdot}, \end{cases}$$

$$(2.2)\quad \begin{cases} RO_2^{\cdot} + RH \xrightarrow{k_{2.2}} P^{\cdot}, \\ PO_2^{\cdot} + RH \xrightarrow{k_{2.2}} P^{\cdot}, \end{cases}$$

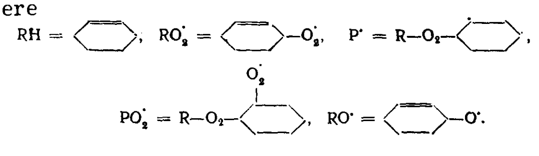
$$(2.3)\quad P^{\cdot} - \begin{cases} \xrightarrow{k_{2.3}} RO^{\cdot} + \text{epoxycyclohexane}, \\ \xrightarrow[(+O_2)]{k'_{2.3}} PO_2^{\cdot}, \end{cases}$$

$$(2.4)\quad RO^{\cdot} + RH \xrightarrow[(+O_2)]{k_{2.4}} ROH + RO_2^{\cdot},$$

$$(2.5)\quad RO^{\cdot} + RH \xrightarrow{k_{2.5}} P^{\cdot},$$

$$\left.\begin{array}{ll} (4.1) & RO_2^{\cdot} + RO_2^{\cdot} \xrightarrow{k_{4.1}} \\ (4.2) & PO_2^{\cdot} + PO_2^{\cdot} \xrightarrow{k_{4.2}} \\ (4.3) & RO_2^{\cdot} + PO_2^{\cdot} \xrightarrow{k_{4.3}} \end{array}\right\}\ \text{products;}$$

where



Analysis of this scheme on the assumption that $k_{2.1}/(k_{2.1} + k_{2.2}) = k_{2.4}/(k_{2.4} + k_{2.5})$ and $k_{4.1} = k_{4.2} = k_{4.3} = k_4$ leads to the following expressions for the concentration of free radicals

$$[\mathrm{R\dot{O}_2}] = \frac{\alpha}{[\alpha + \alpha'(1-\alpha)]}(w_i/k_4)^{1/2},$$

$$[\mathrm{P\dot{O}_2}] = \frac{(1-\alpha)\alpha'}{[\alpha + \alpha'(1-\alpha)]}(w_i/k_4)^{1/2},$$

$$[\mathrm{RO^{\cdot}}] = \frac{k_p}{k_a}\frac{(1-\alpha')(1-\alpha)}{[\alpha + \alpha'(1-\alpha)]}(w_i/k_4)^{1/2},$$

where $k_p = k_{2.1} + k_{2.2}$ and $k_a = k_{2.4} + k_{2.5}$ are the overall rate constants for the consumption of cyclohexene in the interaction with peroxy- and alkoxy-radicals respectively, $\alpha = k_{2.1}/k_p$ and $1 - \alpha = k_{2.2}/k_p$ are the factors associated with the parallel-reaction mechanism of the consumption of cyclohexene involving the participation of the C–H and C=C bonds respectively and $\alpha' = k'_{2.3}[O_2]/\{k_{2.3} + k'_{2.3}[O_2]\}$ is the factor associated with the parallel-reaction mechanism of the consumption of the radical P' via the pathway leading to the formation of PO_2. As in the case considered above, one of the pathways [reaction (2.1)] involves the formation of cyclohexenyl hydroperoxide and products containing a terminal hydroperoxy-group (ROOH), while the other leads to the formation of products resulting from the "saturation" of the carbon–carbon double bond (polymeric peroxide products, epoxycyclohexane, etc.).

The rates of formation of the sum of products [ROOH] + [POOH] + [ROH]‡ = Δ[C–H] and the sum of products which do not contain double bonds {Δ[C=C]} are given by the expressions

$$\mathrm{d}\Delta[\mathrm{C-H}]/\mathrm{d}t = \alpha\nu w_i,$$
$$\mathrm{d}(\Delta[\mathrm{C=C}])/\mathrm{d}t = (1-\alpha)\nu w_i,$$

where

$$\nu = \{k_p([\mathrm{R\dot{O}_2}] + [\mathrm{P\dot{O}_2}]) + k_a[\mathrm{RO^{\cdot}}]\}[\mathrm{RH}]/w_i = k_p[\mathrm{RH}]/(w_ik_4)^{1/2}[\alpha + \alpha'(1-\alpha)] -$$

is the chain length in the consumption of cyclohexene. For a low degree of conversion, where the degrees of the secondary reactions of the products ROOH and POOH are negligibly small, and subject to the condition that the chain is long ($\nu + 1 \simeq \nu$), we have the following relations according to Eqn.(2):

$$S_{[\mathrm{ROOH}]+[\mathrm{POOH}]+[\mathrm{ROH}]^{*}} = S_{\Delta[\mathrm{C-H}]} = \frac{1}{C}\int_0^C \frac{\mathrm{d}([\mathrm{ROOH}] + [\mathrm{POOH}] + [\mathrm{ROH}])}{\mathrm{d}[\mathrm{RH}]}\mathrm{d}C = \alpha,$$

$$S_{\Delta[\mathrm{C=C}]} = \frac{1}{C}\int_0^C \frac{\mathrm{d}(\Delta[\mathrm{C=C}])}{\mathrm{d}[\mathrm{RH}]}\mathrm{d}C = (1-\alpha).$$

If the rate constants for the parallel reactions involving the consumption of the hydrocarbon are associated with different activation energies, the selectivities vary with temperature. Indeed, when

$$k_{2.1} = k^0_{2.1}\exp(-E_1/RT),\ k_{2.2} = k^0_{2.2}\exp(-E_2/RT) \text{ and } E_1 \neq E_2$$

the selectivities are given by the following relations:

$$S_{\Delta[\mathrm{C-H}]} = 1\Big/\left[1 + \frac{k^0_{2.2}}{k^0_{2.1}}\exp(-\Delta E/RT)\right],$$

$$S_{\Delta[\mathrm{C=C}]} = 1\Big/\left[1 + \frac{k^0_{2.1}}{k^0_{2.2}}\exp(\Delta E/RT)\right],$$

where $k^0_{2.1}$ and $k^0_{2.2}$ are pre-exponential factors and $\Delta E = E_2 - E_1$ is the difference between the activation energies. According to these formulae, when $\Delta E > 0$, the selectivity of the reaction via pathway (2.1) decrease with increase of temperature and the selectivity of that via pathway (2.2) increases. This case obtains in the oxidation of cyclohexene. The rate constants for the elementary chain propagation reactions are

$$k_{2.1} = 2.7 \cdot 10^5\exp(-7000/RT) \text{ litre mole}^{-1}\,\mathrm{s}^{-1},$$
$$k_{2.2} = 1.44 \cdot 10^9\exp(-14\,000/RT) \text{ litre mole}^{-1}\,\mathrm{s}^{-1}.$$

Fig. 12*a* presents data for the selectivity in the oxidation of cyclohexene corresponding to degrees of conversion not exceeding 20 mole %, where the rates of the molecular and chain consumption of hydroperoxides are low, i.e. $\beta_{\mathrm{ROOH}} \simeq 0$.[10] It is seen that $S_{\mathrm{ROOH}} = 0.7$ (70%) and $S_{\Delta[\mathrm{C=C}]} = 0.3$ (30%) at 70°C and $S_{\mathrm{ROOH}} = S_{\Delta[\mathrm{C=C}]} = 0.5$ (50%) at 100°C. Fig. 12*b* presents the variation of the selectivity over a wide temperature range. In conformity with the formulae quoted above, the selectivity in the oxidation of cyclohexene to hydroperoxides diminishes and that for the oxidation to products formed as a result of the addition of peroxy-radicals to the C=C bond increases.

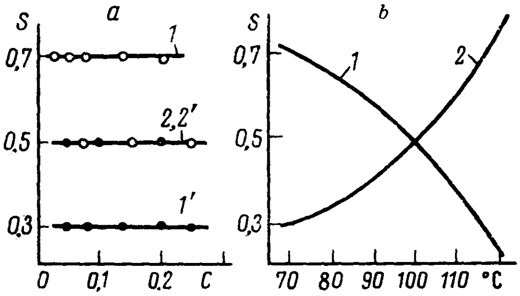


Figure 12. *a*) Dependence of the selectivity in the autoxidation of cyclohexene to the hydroperoxide (S_{ROOH}) (lines *1* and *2*) and to products formed as a result of the oxidation of the C=C bond ($S_{\Delta[\mathrm{C=C}]}$) (lines *1'* and *2'*) on the degree of conversion of the hydrocarbon $C = \Delta[\mathrm{RH}]/[\mathrm{RH}]_0$ at 70°C (lines *1* and *1'*) and 100°C (lines *2* and *2'*); *b*) temperature variation of the selectivities S_{ROOH} (curve *1*) and $S_{\Delta[\mathrm{C=C}]}$ (curve *2*) (calculated data).

4. Selective Inhibition of Undesirable Chain Pathways

In chain reactions proceeding via several active centres with different activities and reactivities, there is a possibility of several parallel pathways some of which lead to the desired product:

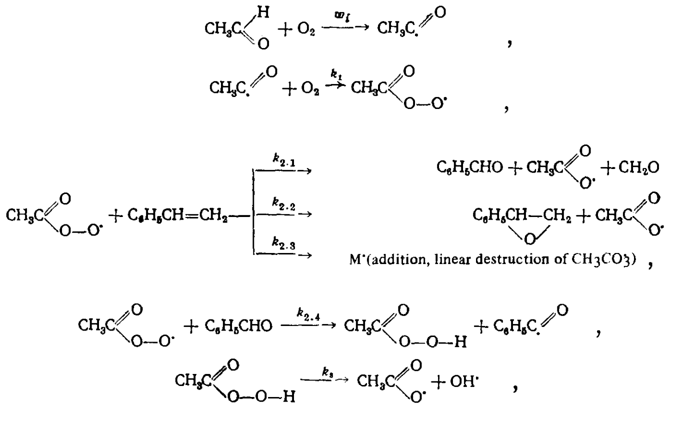
$$\mathrm{r^{\cdot}} + \mathrm{A} - \left[\begin{array}{l} \rightarrow \pi \xrightarrow{\mathrm{r^{\cdot}}} \mathrm{P} \text{ (desired product),} \\ \rightarrow \mathrm{M^{\cdot}} \xrightarrow{\mathrm{A}} \mathrm{P_1} \text{ (side product).} \end{array}\right.$$

This also happens when the reactant exhibits a dual reactivity and can be consumed via several pathways under the reaction conditions.

---

‡ Account is taken of the alcohol formed solely as a result of reactions (2.3) and (2.4).

The conditions governing the possibility of the selective inhibition of the undesirable chain pathway are a difference between the activities of the radicals r· and M· and the absence of their interconversion (the radicals belong to different chains which do not interact). This case obtains in the joint oxidation of styrene and acetaldehyde[11]:

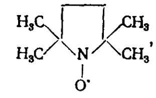


$$\left.\begin{array}{l} M^{\cdot} + O_2 \xrightarrow{k_1'} MO_2^{\cdot} \\ MO_2^{\cdot} + C_6H_5CH{=}CH_2 \xrightarrow{k_2'} M^{\cdot} \end{array}\right\} \text{polymerisation pathway,}$$

etc.

$$MO_2^{\cdot} + MO_2^{\cdot} \xrightarrow{k_{4.1}} P_{term} \ .$$

Stable iminoxy-radicals Im·, in particular tanol



which react with alkyl radicals (M· and $CH_3\dot{C}=O$) at much higher rates than with peroxy-radical $\left(MO_2^{\cdot} \text{ and } RC\begin{smallmatrix}{\diagup\!\!\!\diagup O}\\ {\diagdown O-O^{\cdot}}\end{smallmatrix}\right)$ may be used as the inhibitors of the undesirable polymerisation pathway in this process. Additional chain termination reactions then occur in the system:

$$R\dot{C}{=}O + Im^{\cdot} \xrightarrow{k_{4.2}} P'_{term} \ ,$$

$$M^{\cdot} + Im^{\cdot} \xrightarrow{k_{4.3}} P''_{term} \ .$$

Selective inhibition of the polymerisation pathway is possible when the following condition is fulfilled:

$$w_1 > w_{4.2} \text{ and } w_1' < w_{4.3} \ . \tag{17}$$

Ultimately this implies that the rate of linear termination by the $RO_2^{\cdot}$ radicals must exceed the rate of the interaction of $R\dot{C}{=}O$ with Im·, while the rate of recombination of $MO_2^{\cdot}$ must be much lower than the rate of destruction of M· radicals by the inhibitor:

$$w_{2.3} > w_{4.2} \text{ and } w_{4.1} < w_{4.3} \ . \tag{18}$$

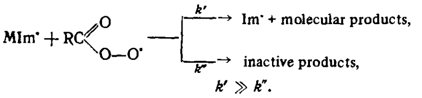
Conditions (17) and (18) hold at an inhibitor concentration

$$\frac{(k_{2.1} + k_{2.2})\,[C_6H_5C_2H_3]}{k_{4.3}} > [Im^{\cdot}] > \frac{(w_0 k_{4.1})^{1/2}}{k_{4.3}} \ . \tag{19}$$

As a rule, condition (19) is fulfilled at very low concentrations [Im·] and requires the artificial maintenance of a steady-state inhibitor concentration in the system during the process.

The inhibition of the polymerisation pathway by the addition of tanol may be achieved by maintaining a steady-state concentration [Im·] as a result of the regeneration of the inhibitor via the mechanism

$$M + Im^{\cdot} \rightarrow MIm^{\cdot},$$



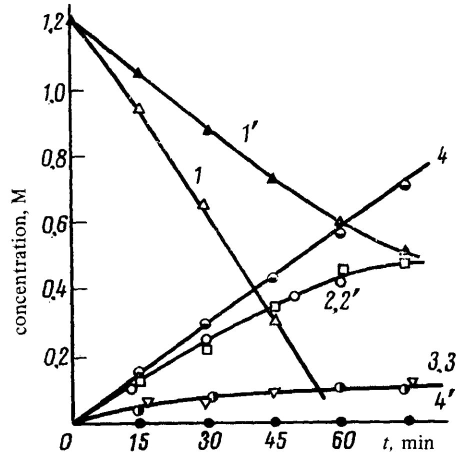


Figure 13. Kinetic curves for the consumption of styrene (curve *1*) and the accumulation of benzaldehyde (curve *2*), 1-phenyloxiran (styrene oxide) (curve *3*), and the polymer (curve *4*) in the joint oxidation of styrene and acetaldehyde in benzene at 70°C; the primed numerals have the same significance but in the presence of 0.002 M of tanol. The instant when the induction period ends was adopted as the time $t = 0$.

Table 1.

Reaction	Required product	Degree of conversion, mole %	Selectivity w.r.t. unsaturated compound which has reacted, mole %	
			without inhibitor	in the presence of Im
Coupled oxidation of styrene and acetaldehyde	1-Phenyloxiran	80.0	40.0	80.0
Coupled oxidation of aryl chloride and acetaldehyde	Chloromethyloxiran	6.0	7.0	65.0
Liquid-phase oxidation of methylacroleine	Methacrylic acid	50.0	30.0	80.0

Fig. 13 presents kinetic curves for the consumption of styrene and the accumulation of its conversion products in the joint oxidation of styrene and acetaldehyde without an inhibitor and in the absence of the iminoxy-radical. Evidently the inhibition of the consumption of styrene is associated with the suppression of its polymerisation (curves *1* and *1'*). To facilitate the comparison, the instant when the consumption of the initial substances begins is adopted as the time $t = t_0$ in both cases. Selective inhibition makes it possible to increase greatly the selectivities of many oxidation processes (Table 1).

5. Homogeneous Catalysis in Oxidation Reactions

Activation of oxygen. One of the possible ways of increasing the rates and selectivities of chemical processes involves the use of homogeneous catalysts—variable-valence metal compounds. This has been established by the activation of O_2, $RO_2^{\cdot}$, or ROOH when they are incorporated in the coordination sphere of the metal. The formation of complexes with all these species has been recorded by various physical procedures. The formation of a complex of O_2 with vitamin B_{12} [a cobalt(II) complex], which involves the generation of the Co(III).$O_2^{\overline{\cdot}}$ species, has been established by ultraviolet spectroscopy (Fig.14*a*),[12] the formation of complexes of Co(II)L_2 with ROOH has been demonstrated by NMR (Fig.14*b*),[13,14] and the formation of complexes of Ni^+ with $RO_2^{\cdot}$ has been demonstrated by ESR (Fig. 14*c*).[15]

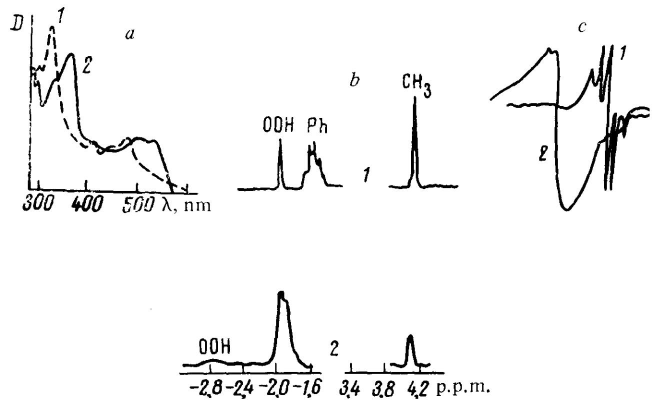

Figure 14. *a*) The spectra of vitamin B_{12} [Co(II)] in methanol at −80°C in an anaerobic medium (curve *1*) and of the B_{12}–oxygen complex formed at p_{O_2} = 1 atm (curve *2*); *b*) the NMR spectra of cumenyl hydroperoxide (c = 0.45 M) in the 1 : 1 CCl_4–CH_2Cl_2 mixed solvent in the absence of a catalyst (curve *1*) and after the addition of 0.0245 M bis-(*o*-vanillideneanisidine)cobalt(II) (curve *2*) at −20°C; *c*) EPR signals due to the nickel(I) species formed in the $Ni(acac)_2 + Al(C_2H_5)_3$ system (curve *1*) and the complex $(CH_3)_3$–C–OȮ.Ni(I) (curve *2*). Solvent—benzene; temperature—23°C.

The use of metal salts rarely leads to an appreciable increase of process selectivity when catalysts of this kind form complexes with virtually all active species and oxygen-containing reaction products (particularly with hydroperoxides and alcohols), since under these conditions the reactions of all the intermediates are accelerated non-selectively. For this reason, the use of metal-complex catalysis is most promising for increasing the selectivity. In this case the use of appropriate ligands or electron-donating additives makes it possible to alter the structure and properties of the catalyst in such a way that the incorporation of one of the reacting species in the coordination sphere becomes unfavourable, and, conversely, the degree of coordination of other substances to the catalyst is enhanced.

Electron-donating ligands greatly increase the ability of cobalt compounds to form adducts with oxygen. The formation of such adducts may be observed by EPR (Fig. 15).[16] The equilibrium constant K_{O_2} for the formation of the complex $Co^{\delta+}L_2(B).O_2^{\delta-}$ via the reaction

$$CoL_2(B) + O_2 \overset{K_{O_2}}{\rightleftharpoons} Co^{\delta+}L_2(B) \cdot O_2^{\delta-}$$

increases with increase of the basicity constant of the base B. Fig. 1 illustrates the dependence of K_{O_2} on the basicity constant of B (pK_B) for the *NN'*-ethylenebis-(benzoylacetoneiminato)cobalt(II) complexes with various electron-donating additives. The inclusion of electron-donating molecules of B in the coordination sphere of cobalt simultaneously lowers the oxidation potential of the complex. There is a correlation between K_{O_2} and the polarographic half-wave potential of the complex. The greater the basicity of B, the lower the value of $E_{1/2}$, i.e. the higher the capacity of the complex $CoL_2(B)$ for being oxidised and hence the higher the degree of electron transfer in $Co^{\delta+}L_2(B).O_2^{\delta-}$, which must increase the activity of the oxygen complex in the formation of free radicals:

$$Co^{\delta+}L_2(B)\,O_2^{\delta-} + RH \rightarrow CoL_2(B)^{\cdot} + HO_2^{\cdot} + R^{\cdot} \quad .$$

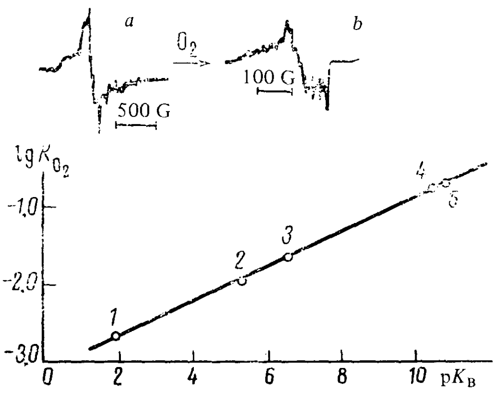

Figure 15. Dependence of the equilibrium constant K_{O_2} for the formation of the O_2 complexes of the adducts of *NN'*-ethylenebis(benzoylacetoneiminato)cobalt(II) with different bases B [1) cyanopyridine; 2) pyridine; 3) 3,4-lutidine; 4) isobutylamine; 5) n-butylamine] on the basicity constants of the latter. The EPR spectra of the adducts *NN'*-ethylenebis(benzoylacetoneiminato)cobalt(II) with pyridine Co(II)L_2Py (*a*) and the complex Co(II)L_2Py.O_2 (*b*).

The decomposition of hydroperoxides by complexes incorporating electron-donating molecules may be retarded owing to steric hindrance to the formation of complexes with the hydroperoxide. There is accordingly an increase of selectivity in the oxidation of hydrocarbons to hydroperoxides. Thus ethylbenzene is oxidised to the hydroperoxide in the presence of cobalt naphthenate with a selectivity $S \simeq 5$ mole % for a degree of conversion $C \simeq 6$ mole %.[17] The introduction of a chelating ligand with pronounced electron-donating properties (quinolinecarboxylic acid) into the solution increase S to 18.9 mole % for C = 8.2 mole % (Table 2).[17]

Nickel compounds, which exhibit a low activity in the decomposition of hydroperoxides but are capable of greatly activating oxygen, make it possible to carry out the oxidation of ethylbenzene with an appreciable selectivity for comparatively high degrees of conversion (Table 2). The selectivity in the oxidation of cyclododecane to ROOH in the presence of bis(acetylacetonato)nickel reaches 46.8 mole % for a degree of conversion of 26.1 mole %.[18] When ethylbenzene is oxidised in the presence of the same catalyst, the selectivity S_{ROOH} = 70 mole% for C_{RH} = 10 mole %. The introduction into the system of small amounts of electron-donating ligands (such as dimethylformamide and NaSt) retards the decomposition of the hydroperoxide and leads to a corresponding appreciable increase of process selectivity (Fig. 16).[19]

Table 2. Selectivity in the oxidation of hydrocarbons to hydroperoxides.

Catalyst	Hydrocarbon	C, mole %	S_{ROOH}, mole %
Cobalt naphthenate	Ethylbenzene	5.9	5.0
Chelate complex of cobalt naphthenate and quinolinecarboxylic acid (B)	Ethylbenzene	8.2	18.9
Bis(acetylacetonato)nickel	Ethylbenzene	10.0	70.0
Bis(acetylacetonato)nickel	Cyclododecane	26.1	46.8

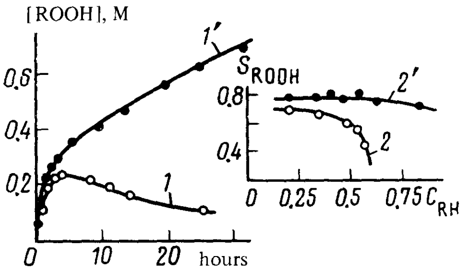

Figure 16. Kinetic curves for the accumulation of hydroperoxides (curves *1* and *1′*) and the dependence of the selectivity in the formation of the hydroperoxide S_{ROOH} on the degree of conversion of the hydrocarbon (curves *2* and *2′*) in the oxidation of ethylbenzene in the presence of 0.003 M Ni(acac)$_2$ (curves *1* and *2*) and a mixture of 0.003 M Ni(acac)$_2$ and 0.003 M dimethylformamide (curves *1′* and *2′*) at 120°C.

The selectivity in the formation of hydroperoxide decomposition products. The composition of the products formed in the decomposition of hydroperoxides in the presence of a catalyst depends on the nature of the solvent[20,21]. The decomposition in the ROOH–catalyst system proceeds via two pathways: with formation of free radicals and molecular products. Both pathways proceed via the formation of a single intermediate complex in accordance with the mechanism[22]

$$\mathrm{Co\,(acac)_2 + ROOH \rightarrow Co\,(acac)_2\,ROOH} \rightarrow$$

$$\rightarrow \underset{\text{(cage)}}{[\mathrm{Co\,(acac)_2^+,\ OH^-,\ RO^{\cdot}}]} \begin{cases} \xrightarrow{k'} \mathrm{Co\,(acac)_2\,OH + RO^{\cdot}} \\ \xrightarrow[k'']{} \mathrm{Co\,(acac)_2 + R'COR'' + H_2O} \end{cases} ,$$

The rate constant ratio k''/k' which determines the fraction of molecular decomposition, depends on the rate of diffusion of RO$^{\cdot}$ from the solvent cage, and increases with increase of the viscosity of the medium (Fig. 17). The ratio of the rate constants for the molecular and radical decompositions of hydroperoxides, which lead in many instances to the formation of different products, depends on the nature of the catalyst, the hydroperoxide, and the solvent[22] (Table 3).

Table 3.

Catalyst	Hydroperoxide	Solvent	$\frac{W_p}{W_\Sigma}\times$ ×100%	Catalyst	Hydroperoxide	Solvent	$\frac{W_p}{W_\Sigma}\times$ ×100%
CoSt$_2$	Tetralinyl	Chlorobenzene	1.2	Ni(acac)$_2$	Tetralinyl	Chlorobenzene	2.0
CoSt$_2$	Cumenyl	Chlorobenzene	36.4	Ni(acac)$_2$	α-phenylethyl	Benzene	4.1
CoSt$_2$	t-Butyl	Benzene	100.0	NiSt$_2$	α-phenylethyl	Ethylbenzene	1.2
Co(acac)$_2$	Cumenyl	Benzene	96.0				

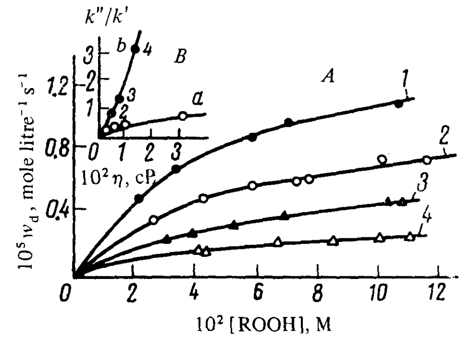

Figure 17. *A*) Dependence of the rate of decomposition of cumenyl hydroperoxide in the presence of 5 × 10^{-4} M Co(acac)$_2$ on [ROOH] in benzene (curve 1) and in solvents with mobile C–H bonds [2) ethylbenzene; 3) a mixture of 60 vol.% of tetralin and benzene; 4) tetralin]; *B*) dependence of k''/k' on η for the decomposition of cumenyl hydroperoxide in inert solvents (*a*) and in solvents with mobile C–H bonds (*b*). Points *2*, *3*, and *4* were obtained from the data represented by curves 2, 3, and 4 in Fig. *A*.

Cumenyl hydroperoxide decomposes in the presence of CoSt$_2$ via a chain mechanism with formation of dimethylphenylmethanol and acetophenone:

$$\mathrm{C_6H_5C\,(CH_3)_2\,OOH + CoSt_2 \rightarrow C_6H_5C\,(CH_3)_2\,CO^{\cdot} + Co(OH)St_2},$$

$$\mathrm{C_6H_5C\,(CH_3)_2\,OOH + Co\,(OH)\,St_2 \rightarrow C_6H_5C\,(CH_3)_2\,OO^{\cdot} + CoSt_2 + H_2O},$$

$$\mathrm{C_6H_5C\,(CH_3)_2\,OOH + C_6H_5C\,(CH_3)_2\,O^{\cdot} \rightarrow C_6H_5C\,(CH_3)_2\,OH + C_6H_5C\,(CH_3)_2\,OO^{\cdot}},$$

$$\mathrm{2\,C_6H_5C\,(CH_3)_2\,OO^{\cdot} \rightarrow C_6H_5C\,(CH_3)_2\,OH + C_6H_5C(=O)CH_3}\ .$$

The stoichiometric equation for the process is

$$3\,C_6H_5C(CH_3)_2OOH \rightarrow 2\,C_6H_5C(CH_3)_2OH + C_6H_5C(=O)CH_3 .$$

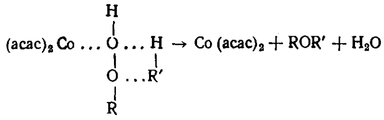
As expected on the basis of the mechanism, the process selectivity with respect to dimethylphenylmethanol $S_{C_6H_5C(CH_3)_2OH} \simeq 70$ mole %.

The selectivity in the chain decomposition of the hydroperoxide may be increased by adding hydrogen donors which react readily with peroxy-radicals and lead to a change in the chain termination mechanism. For example, the introduction of an inhibitor leads to the replacement of the $RO_2^{\cdot}$ (the source of the ketone) recombination reaction by the reaction

$$C_6H_5C(CH_3)_2OO^{\cdot} + InH \rightarrow C_6H_5C(CH_3)_2OOH + In^{\cdot}.$$

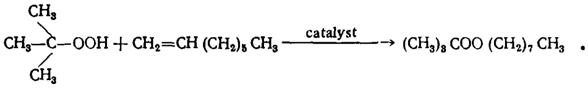
The experimental process selectivity then increases to 95 mole %.[4]

The activation of the hydroperoxide in the catalyst sphere makes it possible to achieve many bimolecular reactions of ROOH with hydrocarbons. In the decomposition of cumenyl hydroperoxide in the presence of hydrocarbons with a mobile C–H bond, there is an appreciable increase in the contribution of molecular decomposition of the hydroperoxide, although the overall rate of decomposition remains constant. The ether ROR′ is then formed in the system as a result of the reaction between the hydrocarbon and the activated hydroperoxide via the mechanism[23]



$$(acac)_2Co \ldots O(H)(OR) \ldots H(R') \rightarrow Co(acac)_2 + ROR' + H_2O$$

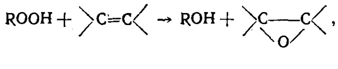
where ROOH = $C_6H_5C(CH_3)_2OOH$ and R′H = . When ROOH interacts with the hydrocarbon R′H, there is a possibility of the formation of the asymmetric peroxides ROOR′:



$$CH_3-C(CH_3)_2-OOH + CH_2{=}CH(CH_2)_5CH_3 \xrightarrow{\text{catalyst}} (CH_3)_3COO(CH_2)_7CH_3 .$$

In the decomposition of t-butyl hydroperoxide in cyclohexene, oct-1-ene, or cumene in the presence of copper, manganese or cobalt salts the selectivity in the formation of asymmetric peroxides reached 90 mole %.[25]

Molybdenum, vanadium, and tungsten compounds are known to catalyse the bimolecular reaction[26,27]



which constitutes the basis of the highly selective synthesis of olefin oxides (the "chalcone process"). It has been shown recently that this reaction proceeds via the intermediate formation of a complex of ROOH with the catalyst. The formation of such complexes is indicated by the broadening of the absorption band of the hydroperoxide protons in the NMR spectrum of t-butyl hydroperoxide under the influence of dioxobis(cyclohexanediolato)molybdenum[28,29] and bis(acetylacetonato)molybdenyl[30].

The change in the hydroperoxide decomposition pathway and the increased selectivity of this process are the most important factors, which make it possible to increase the selectivity in oxidation reactions.

The change in the chain reaction pathway. The high selectivities (above 95 mole %) in the oxidation of aromatic alkyl-substituted hydrocarbons to organic acids may be achieved by employing cobalt bromide in acetic acid as the catalyst. Manganese(II) compounds are used as promoting additives, which lead to an additional increase of reaction selectivity. The mechanism of catalysis by cobalt compounds in the presence of bromide ions still remains controversial.

Although the specific mechanism of the formation of acids is not clear, it may be that the oxidation proceeds via a radical-chain mechanism where the catalyst is involved in the chain propagation reaction according to the following mechanism:

Formation of cobalt bromide:

$$CoAc_2 + NaBr \rightleftharpoons CoAcBr\,(Co\,(II)\,Br^-) + NaAc.$$

Chain initiation:

$$ROOH + Co\,(II) \rightarrow RO^{\cdot} + Co\,(III) \xrightarrow{RH} ROH + R^{\cdot} + Co\,(III),$$

$$ROOH + Co\,(III) \rightarrow RO_2^{\cdot} + Co\,(II).$$

Chain propagation:

$$R^{\cdot} + O_2 \rightarrow RO_2^{\cdot},$$

$$RO_2^{\cdot} + RH \rightarrow ROOH + R^{\cdot},$$

$$RO_2^{\cdot} + Co\,(II) \xrightarrow{HAc} ROOH + Co\,(III),$$

$$RO_2^{\cdot} + Co\,(II)\,BrH^+ \rightarrow ROOH + Co\,(III)\,Br^- \rightarrow ROOH + Co\,(II)\,Br^{\cdot}.$$

Bromide chain propagation:

$$Co\,(III)\,Ac_3 + Co\,(II)\,Br^- \rightarrow Co\,(II)\,Ac_2 + Co\,(III)\,Br^-Ac \rightarrow Co\,(II)\,Br^{\cdot}Ac$$

$$Co\,(II)\,Br^{\cdot}Ac + RH \rightarrow Co\,(II)\,Ac_2 + HBr + R^{\cdot} \rightarrow Co\,(II)\,\dot{B}r^-Ac + HAc + R^{\cdot}.$$

Overall reaction:

$$Co\,(III)\,Ac_3 + RH \rightarrow Co\,(II)\,Ac_2 + HAc + R^{\cdot} .$$

Chain termination:

$$RO_2^{\cdot} + RO_2^{\cdot} \rightarrow R'-CO(R'') + ROH + O_2 .$$

In the presence of the cobalt bromide catalyst, the chain oxidation pathway, consisting in alternate reactions of the $R^{\cdot}$ radicals with O_2 and of $RO_2^{\cdot}$ radicals with the hydrocarbon, is replaced by a new more complex chain pathway which leads to a higher process selectivity.

This apparently occurs as a result of the suppression of the undesirable pathways involving the formation of peroxy-radicals and the hydroperoxide.

6. Simulation of Enzymatic Processes

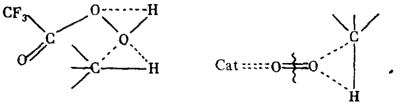
In the development of selective oxidation processes it is frequently proposed to use the principles of the simulation of enzymatic oxidation which in many cases involve a high selectivity with respect to the substrate oxidised. A characteristic feature of the mechanism of an enzymatic process is activation of the reactants, coupling of the reactions, and a highly organised matrix [templet] nature of the process.

Hydroxylation. In biological systems this process takes place under the influence of mono-oxygenases as a coupled reaction involving the oxidation of the substrate and on organic reductant AH_2 present in the system[31]:

$$AH_2 + RH + O_2 \rightarrow A + ROH + H_2O .$$

The ratios of the amounts of the alcohol formed, the unconsumed organic reductant, and the oxygen absorbed are 1 : 1 : 1. The selectivity in the oxidation reaction with respect to the substrate reaches 100 mole % for low degrees of conversion.

It is suggested that the enzymatic oxidation of hydrocarbons proceeds via the oxenoid mechanism [32] in a concerted process in which an oxygen atom of the O_2 molecule, activated by the enzyme, is inserted in a C–H bond of the substrate without the formation of free radicals. In chemical systems the oxenoid mechanism can occur when acyl hydroperoxides react with RH and in the catalytic epoxidation of olefins by hydroperoxides:



Depending on the nature of the enzyme and the substrate, the oxidation proceeds via different mechanisms. In the hydroxylation of 2,6-di-t-butyl-4-methylphenol, catalysed by an enzymatic system containing cytochrome P-450, the accumulation of the hydroperoxide was observed at early stages of the oxidation process. It appears that in this instance oxygen is inserted, without the association of the O–O bond, via the mechanism [33]

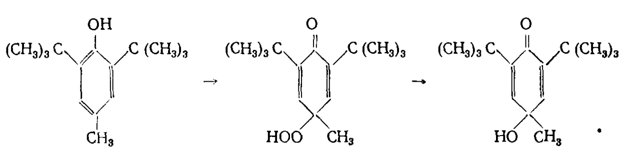


Table 4. Coupled oxidation of cyclohexane (S_1 and S_2 are respectively the selectivities in the formation of the alcohol and the ketone in terms of consumed cyclohexane and S_3 is the selectivity in the formation of the alcohol in terms of the consumed reductant).

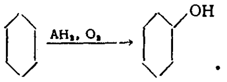
System	S_1, mole%	S_2, mole %	S_3, mole %	System	S_1, mole %	S_2, mole %	S_3, mole %
Mono-oxidase	100	—	100	$SnCl_2$	100	—	5
Fe^{2+} + ascorbic acid	75	25	4	$TiCl_2$	95	5	8
Haemin + thiosalicylic acid	60	40	8	$FeCl_2$	80	20	9

In recent years numerous attempts were made to simulate enzymatic oxidation processes. The condition which must be met by such simulation is believed to be the simultaneous transfer of two electrons to the O_2 molecule [34]. Such electron transfer is possible in the oxidation of a metal capable of transferring two or more electrons [for example, $SnHPO_4$, $SnCl_2$, $MoCl_3$, and $Mo(CO)_6$ in Table 4] or of a ligand in a system of the Fe^{2+}–ascorbic acid type. However, in the known model systems there is at present no direct evidence for the occurrence of the oxenoid hydroxylation mechanism, characteristic of enzymatic systems, i.e. O is inserted in a C–H bond in a single step. On the other hand, model systems make it possible to hydroxylate alkanes with a high selectivity (Table 4) under mild conditions. In such systems the process apparently proceeds via a coupled radical chain mechanism.

The principle of the coupled oxidation of hydrocarbons and tin compounds has been used for the selective oxidation of hydrocarbons to alcohols (hydroxylation):



The selectivity in the formation of alcohols with respect to the hydrocarbon is close to 100 mole %. [34,35] This result has been obtained in the coupled oxidation of cyclohexane and $SnCl_2$ in acetonitrile at 20°C with formation of cyclohexanol as the only cyclohexane conversion product. The kinetic mechanisms for the oxidation of cyclohexane in the absence of $SnCl_2$ and after the introduction of bivalent tin into the reaction are compared below:

"Classical" oxidation mechanism	Coupled oxidation of RH and tin
(0) $RH \rightarrow R^{\cdot}$	(0) $\begin{cases} Sn(II) + O_2 \rightarrow Sn(III) + HO_2^{\cdot} \\ HO_2^{\cdot} + RH \rightarrow H_2O_2 + R^{\cdot} \end{cases}$
(1) $R^{\cdot} + O_2 \rightarrow RO_2^{\cdot}$	(1′) $R^{\cdot} + O_2 \rightarrow RO_2^{\cdot}$
(2) $RO_2^{\cdot} + RH \rightarrow ROOH + R^{\cdot}$	(2′) $RO_2^{\cdot} + Sn(III) + H_2O \rightarrow ROH + Sn(IV)OH^-$
(3) $ROOH \rightarrow RO^{\cdot}$	(3′) $ROOH + Sn(II) \rightarrow RO^{\cdot} + Sn(III)OH^-$
(4) $RO^{\cdot} + RH \rightarrow ROH + R^{\cdot}$	(4′) $RO^{\cdot} + Sn(III) + H_2O \rightarrow ROH + Sn(IV)OH^-$
(5) $ROOH \rightarrow$ ketone	(5′) $ROOH + Sn(II) + H_2O \rightarrow Sn(IV)(HO^-)_2 + ROH$
(6) $RO_2^{\cdot} + RO_2^{\cdot} \rightarrow$ molecular products	(6′) $Sn(III) + Sn(III) \rightarrow Sn(II) + Sn(IV)$

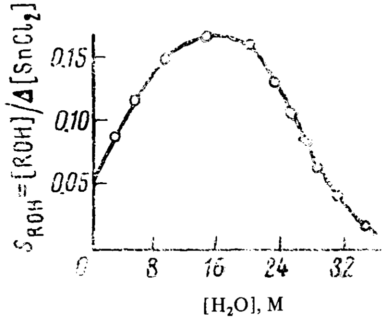


Figure 18. Dependence of the selectivity in the formation of cyclohexanol with respect to unconsumed $SnCl_2$ on the concentration of water in the coupled oxidation of cyclohexane and $SnCl_2$ at 20°C.

The high process selectivity is due to the replacement of the chain propagation reaction (2) involving the hydrocarbon by reaction (2′) involving Sn(III) in the reaction chain and is also due to a change in the hydroperoxide decomposition pathway. In the presence of tin(II) the hydroperoxide decomposes via a molecular pathway with formation of an alcohol [reaction (5)]. The selectivity of this process with respect to the reductant ($SnCl_2$) is low (up to 5 mole %), which may imply a considerable consumption of the reductant in processes which are useless from the standpoint of the formation of the desired product (the alcohol). The selectivity in the utilisation of the reductant may be somewhat increased by altering the composition of the medium. Thus, when the reaction is carried out in a mixed solvent (acetonitrile–water), the reaction selectivity with respect to the reductant increases to 20 mole % (Fig. 18).

Epoxidation of olefins. The coupled oxidation reactions may become a promising method for increasing the selectivity of processes of this type. In order to obtain the required product, active centres propagating a parallel chain process involving the conversion of the second component of the coupled pair are employed.

Catalytic systems for the direct oxidation of propene to epoxypropane are being actively sought at the present time. A yield of epoxypropane not less than 75 mole % relative to the unconsumed propene is believed to be economically useful. In the absence of a catalyst in glass, Teflon, or titanium reactors the selectivity in the direct oxidation of propene to epoxypropane does not exceed 50 mole % relative to the unconsumed propene (even for a low degree of conversion—up to 10–20 mole %).[36]

Fig. 19 presents kinetic curves for the oxidation of propene in chlorobenzene at 150°C and 50 atm. When propene is oxidised under these conditions, more than 20 products are formed, 14 of which are listed in Fig. 19; others are formed as impurities. In view of such complex mixture compositions, the isolation of the individual products presents significant technical difficulties.

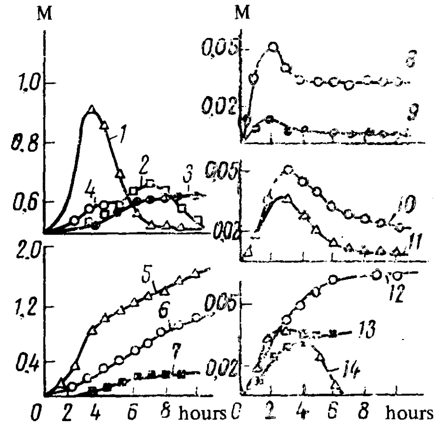

Figure 19. Kinetic curves for the accumulation of propene oxidation products: 1) epoxypropane; 2) propylene glycol; 3) propylene glycol formate; 4) CO_2; 5) formic acid; 6) acetic acid; 7) methyl formate; 8) acetaldehyde; 9) peroxide; 10) isopropyl alcohol; 11) allyl alcohol; 12) acetone; 13) methanol; 14) acrolein.

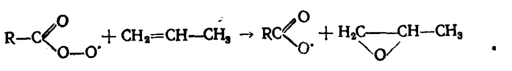
In the coupled oxidation of propene and acetaldehyde the epoxidation of the double bond proceeds with participation of acylperoxy-radicals formed as a result of the oxidation of the aldehyde[37]:



This reaction has a close analogy with enzymatic oxidation processes, since an oxygen atom is inserted (in a single elementary step) in the molecule of the substance undergoing oxidation with dissociation of the O–O bond. The coupled process proceeds at comparatively low temperatures (50–70°C) and is distinguished by high selectivities in the formation of acetic acid from acetaldehyde (~100%) and of epoxypropane from propene (~100%) (Fig. 20).

The main disadvantage of systems simulating enzymatic oxidation is the consumption of the reductant together with the main process. In many instances the selectivity relative to the unconsumed reductant proves to be very low. Consequently the main task involved in increasing the selectivity of the oxidation reaction is not so much the simulation of enzymatic processes as the creation of new effective catalytic systems which are in general highly effective and do not require the consumption of the second component (the reductant).

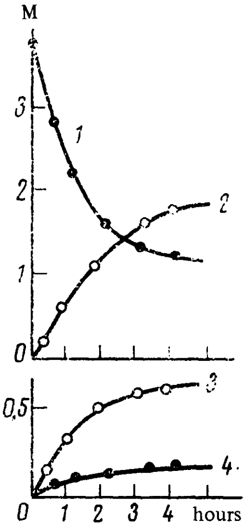


Figure 20. Kinetic curves for the consumption of acetaldehyde (curve 1) and the accumulation of acetic acid (curve 2) epoxypropane (curve 3), and propylene (curve 4) in the coupled oxidation of propene and acetaldehyde at 50 atm and 70°C.

All the enzymatic and model reactions discussed above involve the dissociation of the O–O bond. Catalytic processes in which oxygen adds via a hydrocarbon (olefin) activation stage are apparently more effective. Here oxygen is transferred to the substrate from water or adds on directly. The oxidation of olefins to carbonyl compounds catalysed by palladium(II) salts using $CuCl_2$ as a cocatalyst is an example of reactions of this type. The selectivity in the formation of low-molecular-weight aldehydes in such a process is >95 mole %.[38] The process develops via the mechanism

$$PdCl_4^{2-} + C_2H_4 + H_2O \rightarrow Pd^0 + CH_3CHO + 2H^+ + 4Cl^- ,$$

$$Pd^0 + 2Cu^{2+} + 8Cl^- \rightarrow PdCl_4^{2-} + CuCl_2^- ,$$

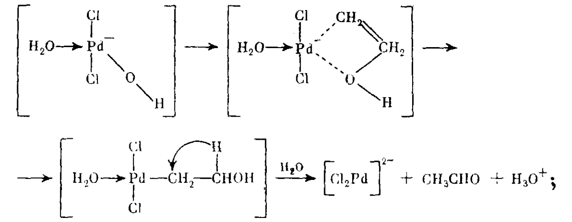
$$2\,CuCl_2^- + 1/2O_2 + 2H^+ \rightarrow 2Cu^{2+} + H_2O + 4Cl^- .$$

The overall reaction is

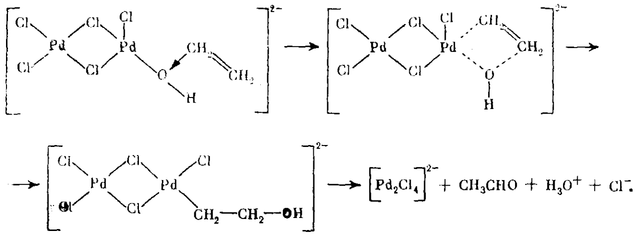
$$C_2H_4 + 1/2O_2 \rightarrow CH_3CHO + 52.26 \text{ kcal mole}^{-1}.$$

A significant factor is the formation in the system of π-complexes $(C_2H_4)PdCl_2(OH^-)$, which undergo further transformations via two possible pathways:

pathway I:



pathway II:



Studies where heteropolyacids of complex composition and containing molybdenum and vanadium ions are used instead of $CuCl_2$ have developed[39]. This makes it possible to eliminate Cl^- ions from the process. The oxidation then proceeds with a high selectivity because of the absence of parallel chlorination reactions in which a considerable proportion of the unreacted hydrocarbon is consumed in the oxidation of higher olefins.

Alcohols and ketones are selectively oxidised to acids in alkaline media in the presence of copper complexes of *o*-phenanthroline (*o*-phen). The oxidation of methanol in the presence of $Cu(o\text{-phen})_2^{2+}$ in alkaline media leads to the formation of formaldehyde and acetic acid at very high rates even at 25–30°C.[40,41] Under the same conditions, certain aliphatic ketones (ethyl methyl ketone) are selectively oxidised to acids[42]. The process develops via the intermediate formation of a complex of the carbanion $CH_3C(O)\bar{C}HCH_3$ (A^-) with $Cu(o\text{-phen})_2^{2+}$:

$$[Cu(o\text{-phen})_2\,A^-]^+ \rightleftharpoons [Cu(o\text{-phen})_2A^\cdot]^+,$$

$$[Cu(o\text{-phen})_2A^\cdot]^+ + O_2 \rightarrow [Cu(o\text{-phen})AO_2^\cdot]^+,$$

$$[Cu(o\text{-phen})_2AO_2^\cdot]^+ + [Cu(o\text{-phen})_2]^{2+} + OH^- \rightarrow 2[Cu(o\text{-phen})_2]^+ + 2CH_3COOH.$$

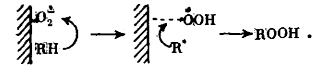
The last two cases may be regarded as examples of oxidation processes which are more favourable from the standpoint of their selectivity than even enzymatic processes.

7. Heterogeneous Catalysis in Oxidation Reactions

The liquid-phase oxidation of hydrocarbons in the presence of heterogeneous catalysts proceeds via two different mechanisms.

I. A heterogeneous-homogeneous process with formation of radicals on the surface of the catalyst and their subsequent transfer to the liquid phase[43-45]. The catalyst merely initiates the chain reaction, the process selectivity remaining the same as in the absence of the catalyst and only the rate of reaction being altered. The liquid-phase oxidation of ethylbenzene in the presence of Ag_2O may serve as an example[46]. The reaction proceeds via a chain mechanism with short chains and the formation of methylphenylmethanol and acetophenone in the chain termination steps. These catalysts are active in the decomposition of the hydroperoxide and the selectivity in the formation of ROOH is as a rule low.

II. A heterogeneous process without the liberation of radicals to the bulk phase[47] may proceed via the mechanism



The formation of the $O_2^{\dot{-}}$ species has been demonstrated in gas-phase oxidation in the presence of deposited catalysts and in the liquid-phase oxidation of cumene (Fig. 21).[48,49] The possibility, in principle, of obtaining high yields of peroxides then arises, since such catalysts do not as a rule decompose ROOH and free radicals are not formed in the bulk phase (the hydroperoxide does not decompose via a chain mechanism).

The conditions under which the $RO_2^\cdot$ radicals are not released into the bulk phase and hydrocarbons are oxidised on the catalyst surface as a result of the activation of oxygen are achieved by employing the method of the donor–acceptor modification of the catalyst[49]. The catalyst is modified by the introduction of additives to the gas, liquid, and solid phases. This entails a change in both the rate of the process and in its selectivity. When the Ag_2O catalyst is used, electron-accepting properties are shown by oxygen, the hydroperoxide, alcohol, 2,4,6-dicyanomethylenetrinitrofluorenone, etc. The activity of the modified catalysts in relation to the decomposition of the hydroperoxide is highly suppressed and the process selectivity with respect to the hydroperoxide is significantly increased.

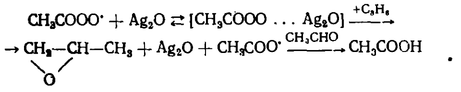
Table 5. Selective catalytic systems for the oxidation of aromatic alkyl-substituted hydrocarbons to hydroperoxides.

Catalyst	Additive	S_{ROOH}, mole %	S_{ROH}, mole %	$S_{RC(O)R}$, mole %	C, mole %
	Oxidation of ethylbenzene				
Ag_2O	—	20.0	50.0	30.0	1.3
Ag_2O	Cumenyl hydroperoxide (Na salt)	81.0	11.0	8.0	0.5
Ag/Al_2O_3	—	20.0	50.0	30.0	2.5
Ag/Al_2O_3	Acetophenone + methylphenylmethanol	77.0	19.2	3.8	1.8
Ag/Al_2O_3	0.2 at.% Ca	54.5	19.5	26.0	0.6
Ag/Al_2O_3	0.2 at.% Ca + acetophenone + methylphenylmethanol	96.0	3.0	1.0	0.6
	Oxidation of tetralin				
Ag_2O	—	10.0	26.0	64.0	6.0
Ag/SiO_2	—	18.0	36.0	46.0	7.5
Ag/SiO_2	Tetralinol + tetralinone	93.0	2.2	1.8	6.3

Modification also occurs under the influence of the reaction products (Table 5). In this case the process selectivity increases with increased degree of conversion. Thus in the oxidation of tetralin the reaction is non-selective at early stages—the hydroperoxide, ketone, and alcohol accumulate in equal amounts[50]. With increase in the degree of conversion of tetralin, the decomposition of the hydroperoxide ceases and only oxygen is activated on the catalyst modified by the oxidation products, as a result of which tetralinyl hydroperoxide becomes the only reaction product (Table 5).

In order to increase the selectivity of the oxidation process, deposited catalysts are modified. The modification of the Ag/Al_2O_3 deposited catalyst by the addition of calcium makes it possible to increase the selectivity in the oxidation of ethylbenzene to the hydroperoxide from 20 to 54.5 mole %, while modification by the 0.2 at.% Ca–acetophenone–methylphenylmethanol system increases the selectivity S_{ROOH} to 96 mole %.[50]

Heterogeneous catalysis in coupled oxidation[51]. An important parameter of the synthesis of epoxypropane and acetic acid is the "coefficient of the utilisation of active oxygen", i.e. the selectivity in the formation of epoxypropane with respect to the aldehyde which has reacted (γ). In the absence of a catalyst (at 70°C in benzene under a pressure of 50 atm) $\gamma = 0.3$. The use of silver oxide as the heterogeneous catalyst makes it possible to increase γ considerably (Table 6). In this case the process proceeds with participation of complexes formed by peroxy-radicals with the catalyst:



$$CH_3COOO^{\cdot} + Ag_2O \rightleftarrows [CH_3\dot{C}OOO \ldots Ag_2O] \xrightarrow{+C_3H_6}$$
$$\rightarrow \underbrace{CH_2-CH}_{O}-CH_3 + Ag_2O + CH_3COO^{\cdot} \xrightarrow{CH_3CHO} CH_3COOH \quad .$$

Table 6. Coupled oxidation of propene and acetaldehyde at 70°C and 50 atm (solvent—benzene).

System	Selectivity, mole %		
	w.r.t. C_3H_6	w.r.t. CH_3CHO	w.r.t.CH_3CHO
	Epoxypropane		Acetic acid
Without catalyst	95.0	23.0	92.0
Ag_2O (1.0 g $litre^{-1}$)	98.0	63.0	96.0

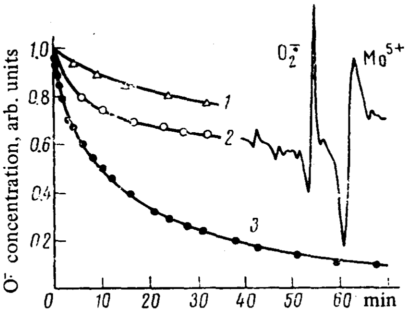


Figure 21. The EPR spectrum of the O_2^- radical-anion detected in the liquid phase on the surface of the Mo(V)/MgO heterogeneous catalyst and kinetic curves for its consumption in various hydrocarbons at 20°C:
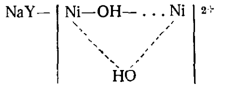
1) ethylbenzene; 2) cumene; 3) cyclohexene.

Catalysis of oxidation on zeolites. Nickel-zeolite is a highly effective catalyst of the gas-phase oxidation of methanol by oxygen (350°C).[52] The process selectivity depends on the conditions in the preparation of the catalyst, particularly on the pH of the medium. In acid media the nickel on the zeolite exists in the form of isolated ions ($NaY\ldots Ni^{2+}$). The process on the catalyst then proceeds with formation of dimethyl ether as the main reaction product (acid–base mechanism).

When media close to neutrality (at pH from 7 to 7.6) are used, the nickel on the zeolite exists in the form of the complex



$$NaY-\left|\begin{matrix} Ni-OH-\ldots Ni \\ \diagdown\quad\diagup \\ HO \end{matrix}\right|^{2+} \quad .$$

This complex exhibits a high magnetic susceptibility and an oxidation-reduction process proceeds on the catalyst. The presence of the OH group in the catalytic complex facilitates the electron transfer and the formation of formaldehyde and other oxidation products (Fig. 22). Thus, by altering the magnetic susceptibility of the catalyst, it is possible to influence the selectivity of oxidation processes.

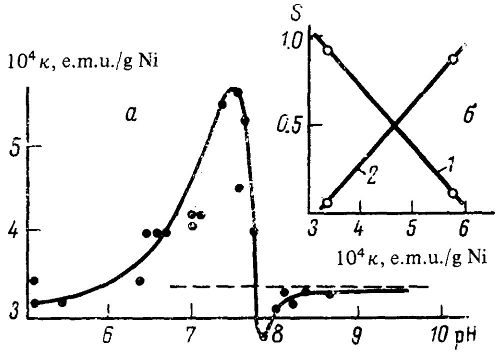


Figure 22. *a*) Dependence of the magnetic susceptibility of nickel (κ) in zeolites on the pH in the ion-exchange process; the dashed line represents the magnetic susceptibility of nickel ions; *b*) selectivity in the conversion of methanol: 1) into dimethyl ether CH_3OCH_3; 2) into oxidation products (CO_2, CO, and formaldehyde) as a function of the magnetic susceptibility of nickel-zeolite.

VII. RADICAL POLYMERISATION PROCESSES

The concept of selectivity applied to polymerisation processes may be considered in two ways: (1) the formation of a definite molecular structure for homopolymers or a definite tacticity, regularity, branching, and inhomogeneity of composition for copolymers; (2) the formation of a product with a specified molecular weight distribution (MWD) and specified average molecular weights (the distribution moments M_{N}).

The classical mechanism of radical polymerisation includes the following stages:

1. Initiation

$$R_0^{\cdot} + M \rightarrow M_1^{\cdot} \quad .$$

2. Chain propagation:

$$M_n^{\cdot} + M \rightarrow M_{n+1}^{\cdot} \quad ,$$
$$M_n^{\cdot} + X \rightarrow P_n + R_1^{\cdot} \quad \text{(chain transfer).}$$

3. Chain termination:

$$\dot{M}_n + \dot{M}_m \rightarrow P_{n+m} \quad \text{(recombination)},$$
$$\dot{M}_n + \dot{M}_m \rightarrow P_n + P_m \quad \text{(disproportionation)}.$$

The narrowest MWD for the polymer is obtained under isothermal conditions of synthesis and the width of the distribution is determined by the mechanism of the termination of the growing chains. Termination owing to the recombination of radicals leads to the so-called Schultz distribution ($\bar{M}_W/\bar{M}_N = 1.5$), while termination via the disproportionation of radicals leads to the normal distribution ($\bar{M}_W/\bar{M}_N = 2.0$). The reaction involving chain transfer to the monomer, solvent, initiator, etc. leads to an exponential distribution.

The width of MWD in radical polymerisation may be increased by various procedures which may be of practical importance in the industrial synthesis of products with the required physicochemical and rheological properties, provided that the "optimum" properties of the material occur in the region of broad MWD. It appears that this happens in the case of the main thermoplastics synthesised on a large scale: high- and low-density polyethylene, poly(vinyl chloride), and polystyrene. In order to improve the rheological properties of melts of these materials, the MWD must be fairly broad ($\bar{M}_W/\bar{M}_N \geqslant 2.0$).

1. Regulation of the Rates of Chain Termination in Radical Polymerisation

The classical concept of the mechanism of radical polymerisation as a typical chain reaction in which the chain length is regulated by the rate of chain termination makes it possible to control the polymerisation process by altering the rate of chain initiation[53]. It is also possible to control the elementary stages of the process by the interaction of the monomer and the chain propagation radical with the reaction medium.

The reactivities of monomers and radicals change as a result of their combination with the molecules of the medium. Certain modifying agents may alter the conjugation energy and the distribution of electron densities in the monomer and the radical. If the modifying agents participate in the formation of a transition complex, they naturally influence its energy, configuration, and chemical nature. This changes the free-radical chain propagation mechanism to a complex-radical mechanism. However, the influence of the medium cannot be reduced solely to chemical aspects of the interaction.

Regulation of the rates of chain termination. The use of the gel-effect. The influence of initiating additives. The elementary reaction involving the bimolecular destruction of macroradicals at early stages of homogeneous liquid-phase polymerisation is controlled by physical factors and depends on the physical characteristics of the reaction medium and the macromolecules formed.

The Norrish–Trommsdorff effect (gel-effect—acceleration of radical polymerisation after the accumulation in the system of a sufficient amount of the dissolved polymer) is an example of the dominant influence of physical factors on the kinetics of homogeneous polymerisation processes. The manifestation of the gel-effect is attributed to the aggregation of macromolecules and the formation in the polymerising system of a continuous three-dimensional fluctuation network, in which the macro-radicals are "stuck"[54,55]. This retards the destruction of the active centres via recombination or disproportionation. On the other hand, the active centres are accessible to the monomer molecules and the growth of the polymer chain continues for some time. For high degrees of conversion, the chain propagation reaction passes to the diffusion-dependent region.

The nature of the diffusion-dependent limitations imposed on the elementary reactions in radical polymerisation is determined by the physical characteristics of the macromolecules and the macroradicals and also by the intermolecular interactions in the system. Using the effects associated with the interaction of the monomers and radicals with the reaction medium, it is possible to control the elementary stages of radical polymerisation by means of both chemical and physical factors.

By creating a highly viscous system, by using low monomer concentrations, or by introducing additives which ensure high rates of chain initiation, it is possible to alter the rate of the biradical chain termination. An increase of the concentration of the initiator in the polymerising mixture makes it possible to maintain a specified MWD up to high degrees of conversion of the initial monomer. Such a system may approach "live" (without termination) polymerisation.

2. Polymerisation in the Devitrification of Reaction Mixtures (Supercooled Liquid)

Radical-chain polymerisation processes hardly occur when the system is in the vitreous state owing to the low mobility of the species and the low temperature despite the high concentration of active centres. However, these reactions proceed very effectively when the system passes from the vitreous to the supercooled liquid state. The fairly high viscosity of the supercooled liquid prevents the bimolecular destruction of the active centres and the reaction develops via a "live" chain mechanism (Table 7). The interaction of the reacting centre with the matrix of the monomer (for example, methyl acrylate) plays an important role in the selectivity of such reactions[56,57]. In the devitrification of the alcohol matrix the macroradical has a specific conformation which ensures its long life. As a result, intense polymerisation takes place in the system.

Table 7. Chain propagation rate constants (cm^3 s^{-1}).

Polymerisation	$10^{12}\cdot k_p^0$	E, cal mole^{-1}	$10^3\cdot k_p^0$	E, cal mole^{-1}	$10^{18}\cdot k_p^0$	E, cal mole^{-1}
	Crystal		Devitrification		Liquid	
Acrylic acid	6	11 000	5	10 700	20	3000
Methyl acrylate	—	—	1	10 000	2	4700
Methyl methacrylate	—	—	Does not polymerise		0.8	4700

Fig. 23 presents the EPR spectra of free polymer radicals obtained on γ-irradiation of frozen solutions of acrylic acid in ethanol (17%), recorded at different temperatures (with a gradual increase of the temperature of the solution). Spectrum I was obtained at 77 K and represents a superposition of the EPR spectra of the radicals $CH_3\dot{C}HOH$ and $CH_3\dot{C}HCOOH$. The stabilised electron also makes some contribution to the structure of the spectrum. When the specimen is heated to 110 K (supercooled liquid), the radical concentration diminishes (the intensity of the spectrum falls). The EPR spectrum of the radical measured for the same system (spectrum II) consists of five well resolved components with the intensity ratios 1 : 2 : 2 : 2 : 1, which corresponds to the *B* conformation of the radical with the angle $\varphi = 75°$. In this system the interaction between the alkyl group and the COOH(*x*) group is weakened, which is the reason for the long life of the radicals (the formation of "live" radicals). With increase of temperature above 120 K, the polymer chain acquires the capacity for translational migrations. The macroradical coils up and has the usual conformation (*A* in Fig. 23) with the angle $\varphi = 15°$, which corresponds to a triplet EPR spectrum (spectrum III).

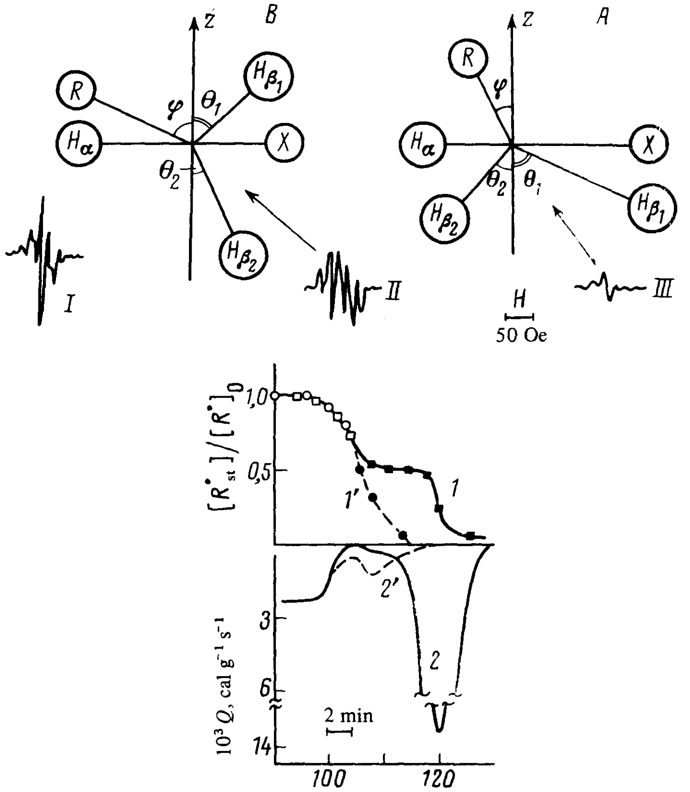

Figure 23. Temperature dependence of the steady-state concentration of radicals (curves *1* and *1'*) and of the rate of polymerisation (calorimetric curves *2* and *2'*) in γ-irradiated frozen solutions of acrylic (curves *1* and *2*) and methacrylic (curves *1'* and *2'*) acids in ethanol: I)–III) EPR spectra arising on heating the γ-irradiated acrylic acid solution in ethanol to 77, 110 (*B* conformation) and 125 K (*A* conformation) respectively.

The polymerisation of acrylic acid at 100–110 K with devitrification of the matrix (i.e. under conditions where "live" radicals are formed in the system) proceeds at very high rates. Curve *2* in Fig. 23 represents the change in the rate of polymerisation measured calorimetrically during the heating of the specimen. After a characteristic "step" associated with the transition to the supercooled liquid state, heat is evolved due to polymerisation. The radical concentration in this temperature range changes only slightly (Fig. 23, curve *1*). In the polymerisation of methacrylic acid the conformation corresponding to "live" radicals is not formed, since the presence of the methyl group prevents the interaction of the radical with the alcohol matrix. The lifetime of the radical is short, the radical concentration decreases monotonically with increase of temperature (Fig. 23, curve *1'*), and the post-polymerisation effect is not observed (Fig. 23, dashed curve *2'*).

In the viscous supercooled liquid formed on devitrification, the duration of mutual contact between the reactants is much longer than in the gas and liquid phases. For this reason, the composition of the copolymer obtained in a viscous supercooled liquid is independent of the relative reactivities of the comonomers and is determined solely by their initial concentrations[58]. The composition of the acrylic acid–acrylamide copolymer does indeed fully correspond to the initial solution on devitrification of the alcohol matrix, while in solution the copolymerisation constants for these monomers are different and the composition of the copolymer differs from that of the initial solution. Thus the method makes it possible to synthesise polymers with a specified homogeneity of composition.

Structure formation by macromolecules. By controlling the macromolecular structure formation processes during the polymerisation, it is possible to exclude fully the reaction involving the destruction of macroradicals and thus pass to an outwardly homogeneous liquid system with radical polymerisation via the "live" chain mechanism[59–63].

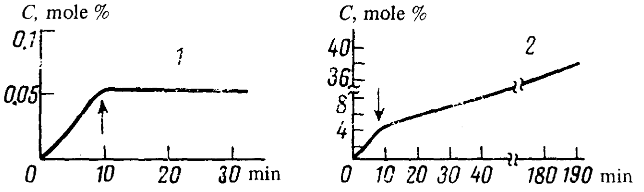

Figure 24. Kinetics of the polymerisation (*C* is the degree of conversion) of methyl methacrylate in bulk (curve *1*) and in a mixture with orthophosphoric acid (curve *2*). The arrow indicates the instant when light was switched off.

It has been shown that in the photoinitiated polymerisation of methyl methacrylate (MMA) in a mixture with orthophosphoric acid the reaction continues, after switch-off the initiation source, at a constant albeit somewhat lower rate up to high degrees of conversion (Fig. 24). The number of chains remains unaltered during post-polymerisation. The reaction proceeds as a result of the accumulation in the "light stage" of poly(methyl methacrylate) (PMMA) macroradicals, which are not involved in the bimolecular termination reaction[59,64,65]. The introduction of another monomer after the exhaustion of the initial methyl methacrylate leads to the renewal of polymerisation and the formation of block-copolymers[66]. The cause of the preservation of the number of growing chains (macroradicals) in these outwardly homogeneous solutions is the formation of a stable fluctuation network with participation of PPMA macroradicals, strengthened by a network of hydrogen bonds between the $COOCH_3$ groups in the PMMA units and H_3PO_4.

Radical post-polymerisation without termination may be achieved also by the slow heating of vitreous monomers or their mixtures with complex-forming agents subjected to preliminary irradiation at −196°C with γ-rays or ultraviolet light. The post-polymerisation of butyl methacrylate in the presence of $ZnCl_2$ may serve as an example of such a process. These processes may be followed by EPR and calorimetric methods[67]. In the transition through the devitrification regions some of the radicals accumulated as a result of irradiation are destroyed, while the remaining radicals continue to grow and further post-polymerisation proceeds virtually via a mechanism without chain termination.

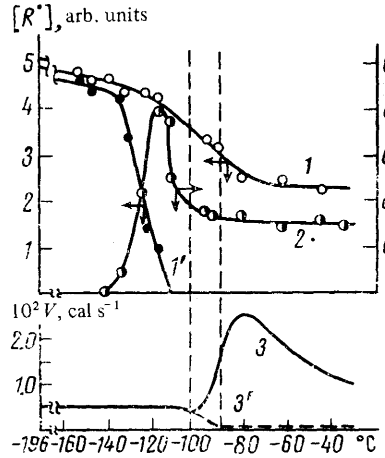

Figure 25. Post-polymerisations in the γ-irradiated butyl methacrylate (BMA)−$ZnCl_2$ system (1 : 0.45). Variation of the concentration of the sum of the radicals (curves *1* and *1'*) and oligomeric $(BMA)_n^{\circ}$ radicals (curve *2*) and of heat evolution (curves *3* and *3'*) in the system on polymerisation in the presence of $ZnCl_2$ (curves *1*–*3*) and in the absence of a complex-forming agent (curves *1'*–*3'*). The dashed lines are the limits of the devitrification region.

The post-polymerisation proceeds with participation of oligomeric radicals. Irradiation of frozen solutions (−196°C) of butyl methacrylate (BMA) leads to the formation of monomeric radicals, the EPR spectrum of which consists of seven lines (ΔH = 22.5 G). On raising the temperature to between −150° and −130°C, a monomer molecule adds to the radical and oligomeric radicals are produced. The concentration of monomeric radicals falls and oligomeric radicals accumulate in the system. At temperatures between −130° and −110°C the system contains only oligomeric radicals (Fig.25).

In the range between −100° and −80°C the main bulk of the radicals recombine, but, in contrast to the polymerisation of BMA in the absence of $ZnCl_2$, a steady-state concentration $[(BMA)_n^{\bullet}]$ is established in the system, which ensures rapid post-polymerisation at this temperature. This results in the formation of polymers with a fairly narrow MWD, whose molecular weights are specified by the irradiation dose and are defined by the formula

$$\overline{M}_n = \frac{q[BMA]}{[R^{\bullet}]},$$

where q is the degree of conversion, [BMA] the monomer concentration, and $[R^{\bullet}]$ the concentration of radicals.

Thus one of the problems involved in increasing the selectivity of polymerisation processes, namely the formation of a product with a specified molecular weight distribution, may be solved by influencing the rate of recombination of macroradicals by changing the reaction temperature, irradiation of the solution, or the introduction of complex-forming agents.

Radiation-induced graft polymerisation. Using the influence of the viscosity of the medium on the rate of bimolecular chain termination, it was possible to develop a new method of radiation-induced graft polymerisation[68]. The usual radiation-induced polymerisation of the monomer is comparatively slow or leads to the formation of a polymer with a low molecular weight. If a small polymer "seed" is subjected to preliminary irradiation and then introduced into the monomer, the degree of conversion increases by a factor of several hundred and a polymer with a high molecular weight is formed. The essential feature of the effect is that the radicals formed in the solid "seed" and propagating the polymerisation chain hardly recombine. As a result, the yield of the polymer and its molecular weight increase by several orders of magnitude.

The method has been applied to the synthesis of Teflon by the polymerisation of tetrafluoroethylene[68]. Irradiation of tetrafluoroethylene with a dose of 0.05 Mrad leads to the formation of Teflon with a low yield and a low molecular weight. The employment of a "seed" increases the yield of Teflon by a factor of 200 and its molecular weight by two orders of magnitude.

3. Polymerisation in Continuous Operation Reactors

An important factor influencing the MWD arises when the reactions are carried out in ideal mixing or plug flow reactors[69,70]. The broadening or narrowing of the MWD when the process passes from the periodic to the continuous-operation regime depends under these conditions on the lifetime of the active centre. A criterion of the broadening of the MWD on passing to the continuous-regime is the inequality $\tau_c \ll \tau$, where τ_c is the average lifetime of the active centres and τ the residence time of the species in the ideal mixing reactor. The method used to carry out the reaction also has a regulating effect on the composition of the polymer in copolymerisation.

Whereas the monomers reacting at different rates in a periodic-operation reactor give rise to a variable-composition copolymer, in an ideal mixing reactor the process proceeds at a constant rate, which results in the formation of a copolymer with a homogeneous composition[71]. In certain cases it is useful to carry out the polymerisation in a cascade of reactors with different process regimes.

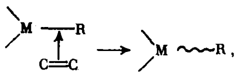
The optimum process conditions are determined in this instance by analysing the kinetic model of the process using mathematical simulation methods.

Such studies have been carried out for the radical polymerisation of styrene in bulk[72]. It was established that the optimum composition of the polymer may be achieved by carrying out the polymerisation in a cascade of reactors consisting of two series-connected ideal mixing reactors, in which the process is carried out in different temperature regimes, and an ideal plug flow reactor with an adiabatic regime.

The MWD of the final product is somewhat narrower compared with the calculated distribution owing to the mechanochemical effects in the extrusion of the melt. This procedure yields a product with $\bar{M}_W/\bar{M}_N = 2.7-3.0$, which is fairly close to the empirically observed "optimum" in the mechanical and rheological properties of a thermoplastic of this type.

4. Homogeneous Catalysis

The molecular weight distribution of the macromolecules may be narrowed by polymerising olefins in the presence of soluble catalysts. In such cases the polymer chain is grown in the coordination sphere of a transition metal:



i.e. the macroradical is linked to the metal throughout the entire polymerisation process. In contrast to purely radical processes, chain termination takes place mainly via unimolecular reactions. The chain-transfer reactions in these processes are inhibited and there is virtually no branching of the macromolecules.

The narrowest molecular weight distributions of polyethylene may be obtained by use of the soluble catalytic systems $(C_2H_5)_2TiCl_2 + AlR_2Cl$, in which the catalytic centres are homogeneous[73,74]. The general polymerisation mechanism can be represented as follows:

$$X^{\cdot} + M \xrightarrow{k_i} M_1^{\cdot},$$
$$M_1^{\cdot} + M \xrightarrow{k_p} M_2^{\cdot},$$
$$M_j^{\cdot} + M \xrightarrow{k_p} M_{j+1}^{\cdot},$$
$$M_j^{\cdot} \xrightarrow{k_t} r_j + X^{\cdot},$$
$$M_j^{\cdot} \xrightarrow{k_d} r_j,$$

where $X^{\cdot}$ and M are the active centre and the monomer and k_i, k_p, k_t, and k_d are the initiation, chain propagation, chain transfer, and chain termination constants. The theoretical form of the molecular weight distribution is defined by the expression

$$L_j = \{M_j + r_j\}_1^{\infty},$$

where M_j and r_j are the concentrations of "live", i.e. growing, and non-growing ("dead") chains. The theoretical MWD may be compared with experimental data using the integral expression[74]

$$\frac{jL_j}{\sum\limits_{j=1}^{\infty} jL_j} \cdot 100 = W_j' = \frac{w_i}{2} + \sum_{\alpha=1}^{j-1} w_{\alpha}.$$

Calculations have shown that the ratio $\bar{M}_W/\bar{M}_N = 1.8-2.2$. The values obtained agree satisfactorily with the experimental ratios $\bar{M}_W/\bar{M}_N$.

Fig. 26 presents the MWD for polyethylene obtained by radical catalytic polymerisation. Evidently the use of a homogeneous catalyst leads to a sharp narrowing of the MWD, i.e. to an increase of the polymerisation selectivity.

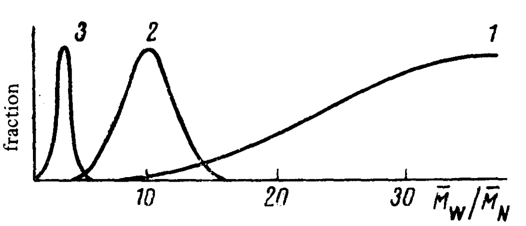


Figure 26. Molecular weight distributions for high-pressure (curve *1*) and medium-pressure (curve *2*) polyethylenes and in catalytic polymerisation in the presence of a homogeneous catalyst (curve *3*).

A narrow molecular weight distribution ($\bar{M}_W/\bar{M}_N \leq 2$) in polypropylene was obtained in a study[75] where propene was polymerised in heptane at low temperatures (between −20° and −60°C) in the presence of the $VCl_4 + AlEt_2Cl$ catalytic system, which exists in a homogeneous state under these conditions. With increase of temperature (above −10°C), the solid catalyst appeared and the MWD was greatly broadened ($\bar{M}_W/\bar{M}_N$ increased to 30).

Catalysis of radical addition. Regulation of the composition of copolymers. Radical copolymerisation is usually regarded as a statistical process in which the probabilities of the addition of monomers to the growing chain are determined by their concentrations and the nature of the substituent at the double bond. In this case copolymerisation proceeds via the mechanism

$$(1.1)\ m_1^{\cdot} + M_1 \xrightarrow{k_{1.1}} \sim m_1m_1^{\cdot}\,(\sim m_1^{\cdot}),$$
$$(1.2)\ m_1^{\cdot} + M_2 \xrightarrow{k_{1.2}} \sim m_1m_2^{\cdot}\,(\sim m_2^{\cdot}),$$
$$(2.1)\ m_2^{\cdot} + M_1 \xrightarrow{k_{2.1}} \sim m_2m_1^{\cdot}\,(\sim m_1^{\cdot}),$$
$$(2.2)\ m_2^{\cdot} + M_2 \xrightarrow{k_{2.2}} \sim m_2m_2^{\cdot}\,(\sim m_2^{\cdot}),$$

where $m_1^{\cdot}$ and $m_2^{\cdot}$ are the terminal units of the growing polymer chain formed by the addition of the molecules M_1 and M_2 respectively; the first subscript in the constants refers to the terminal monomeric unit of the macroradical.

The composition of the copolymer depends on the rate constant ratios $k_{1.1}/k_{1.2} = r_1$ and $k_{2.2}/k_{2.1} = r_2$ and is defined by the formula

$$\frac{d[m_1^{\cdot}]}{d[m_2^{\cdot}]} = \frac{[M_1]}{[M_2]} \cdot \frac{r_1[M_1] + [M_2]}{r_2[M_2] + [M_1]}\ . \tag{20}$$

There exist many binary systems where copolymerisation leads to the formation of copolymers with a rigorous alternation of monomeric units ($m_1m_2m_1m_2$), i.e. the limiting selectivity in the chain propagation reaction is reached. In certain cases this occurs also without the use of any special additives by virtue of the chemical nature of the specific monomer pairs. In particular, α-olefins, certain dienes, and vinyl ethers (M_1) form on radical initiation rigorously alternating copolymers with maleic anhydride, certain other maleic acid derivatives, and SO_2 (M_2).

However, combinations of this kind are more likely to be exceptional. In most instances the reactivities of the monomers do not promote a rigorous alternation of elementary steps of types (1.2) and (2.1) in the mechanism quoted above. In particular, α-olefins, vinyl ethers, and dienes are incapable of forming alternating copolymers with the majority of known monomers. Furthermore, the double bonds in olefins and vinyl ethers are relatively inactive and enter with difficulty into reactions of types (1.2) and (2.1). Their involvement in radical copolymerisation is therefore in general difficult. Finally, an additional obstacle arises in the case of α-olefins—degradative chain transfer to the monomer leading to the formation of relatively inactive radicals of the allyl type and the corresponding sharp decrease of the probabilities of all four chain propagation reactions.

The above complications can be overcome and rigorously alternating copolymers can be obtained from the above monomers of the M_1 group with vinyl monomers of the type $CH_2{=}CHX$, where X = COOR, CN, or C(O)R (acrylates, methacrylates, acrylonitrile, etc.) by carrying out the radical copolymerisation in the presence of complex-forming agents—Lewis acids ($AlRCl_2$, $SnCl_4$, $ZnCl_2$, etc.).

It has been shown by a number of methods, in particular by direct observations with the aid of EPR of the sequence of elementary steps (initiation and chain propagation) leading to the formation of the molecules of alternating copolymers, that the polymerisation is in all cases a radical-chain reaction initiated by monoradicals [64]. Depending on the nature of the monomers and the reaction conditions, chain propagation takes place via the consecutive addition of either individual monomers molecules or of donor–acceptor complexes ($M_1 \ldots M_2$) to the growing chain radical via the mechanism

$$(1.2)\quad \sim \dot{m}_1 + M_2 \xrightarrow{k_{1.2}} \sim m_1\dot{m}_2\,,$$

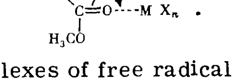
$$(2.1)\quad \sim \dot{m}_2 + M_1 \xrightarrow{k_{2.1}} \sim m_2\dot{m}_1\,,$$

$$(1.2\ \text{c})\quad \sim \dot{m}_1 + (M_2 \ldots M_1) \xrightarrow{k^c_{1.2}} \sim m_1m_2\dot{m}_1\,,$$

$$(2.1\ \text{c})\quad \sim \dot{m}_2 + (M_1 \ldots M_2) \xrightarrow{k^c_{2.1}} \sim m_2m_1\dot{m}_2\,.$$

The copolymerisation of maleic anhydride with 2,3-dimethylbutadiene [67,76] and phenyl vinyl ether [64], of methyl methacrylate with 2,3-dimethylbutadiene in the presence of $Al(C_2H_5)_2Cl$, [67,76,77] etc. are examples of systems where reactions (1.2) and (2.1) predominate. Chain propagation takes place via the addition of donor–acceptor complexes of the comonomers [reaction (1.2c) and 2.1c)] in the copolymerisation of SO_2 with 2,3-dimethylbutadiene or vinyl acetate [76] and of maleic anhydride with butyl vinyl ether [64]. All types of chain propagation reactions coexist simultaneously in many instances (copolymerisation of maleic anhydride with vinyl acetate [64,79]).

The mechanism of copolymerisation in the presence of Lewis acids includes the formation of a complex of the Lewis acid with free polymeric radicals ($\sim \dot{m}_1$ or $\sim \dot{m}_2$) or monomers [80–82]:



The formation of complexes of free radicals with $AlCl_3$, $AlBr_3$, etc. has been demonstrated by EPR on the basis of the systematic changes occurring in the EPR spectra of radicals in the presence of these compounds [80] (Figs. 27*A* and 27*B*).

Quantum-mechanical calculations have shown that donor–acceptor interactions between the radical and the species which adds to it lower the free energy of formation of the transition complex in the reactions

$$\sim \dot{m}_1 + M_2 \rightarrow (\sim m_1 \ldots M_2) \rightleftarrows (\sim m_1^- \ldots M_2^+) \rightarrow \sim m_1\dot{m}_2$$

or

$$\sim m_1 + (M_2 \ldots M_1) \rightarrow (\sim m_1 \ldots \dot{M}_2 \ldots M_1) \rightleftarrows (\sim m_1^- \ldots M_2^+ \ldots M_1) \rightarrow$$
$$\rightarrow \sim m_1m_2\dot{m}_1\ .$$

Table 8. Copolymerisation of butyl methacrylate with 2,3-dimethylbutadiene in the presence of Lewis acids.

Initiator	Temp., °C	$[MX_n]/[M_1]$	r_1	r_2	r_1r_2
		$MX_n = ZnCl_2$

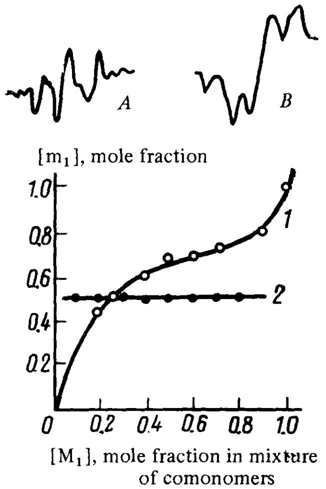

Figure 27. Copolymerisation of butyl methacrylate (M_1) with 2,3-dimethylbutadiene (M_2) at 23°C in the presence of $Al(C_2H_5)_2Cl$ for different $[Al(C_2H_5)_2Cl]/[M_1]$ ratios: 1) 0.10; 2) 0.55; *A* and *B* are the EPR spectra of the polymeric radical $\sim \dot{m}_1$ and the complex $[\sim \dot{m}_1 \ldots AlBr_3]$ for $[AlBr_3]/[M_1] = 1$.

As a result of the increase of the rate constants $k_{1.2}$ and $k_{2.1}$, the quantities r_2 and r_1 (see above) decrease with increased concentration of the complex-forming agent, which in this case actually behaves as the selective catalyst of radical addition (Table 8). For very low values of r_1 and r_2 ($r_1 \rightarrow 0$ and $r_2 \rightarrow 0$), the ratio of the monomeric units m_1 and m_2 in the copolymer is according to Eqn.(20)

$$d[m_1]/d[m_2] = 1 \text{ and } [\overline{m}_1] = [\overline{m}_2]\,,$$

and a fully alternating copolymer is formed regardless of the initial concentrations of the comonomers in solution. Fig. 27 illustrates the dependence of the copolymer composition (the fraction of m_1) on the composition of the mixture of comonomers in the copolymerisation of butyl methacrylate (M_1) with 2,3-dimethylbutadiene (M_2) in the presence of $Al(C_2H_5)_2Cl$.[80] With increase of catalyst concentration, there is an increase in the selectivity of the copolymerisation. For fairly high values of $[Al(C_2H_5)_2Cl]$, it is possible to attain conditions under which a fully alternating polymer is formed $\{[m_1] = [m_2] = 0.5\}$ over a wide range of monomer content M_1 in the mixture (from 5 to 95%). Alternating copolymerisation via reactions (1.2c) and (2.1c) is the limiting case of non-statistical radical processes.

It has been observed[64] in the copolymerisation of SO_2 with buta-2,3-diene that the nature of the terminal unit of the growing radical is specified by the nature (donor–acceptor properties) of the initiating radical and does not change in the course of chain propagation. Depending on the type of initiating radical, the radicals $\sim SO_2^{\cdot}$ and $\sim CH_2-\underset{CH_3}{C}\overset{\cdot}{\dashrightarrow}\underset{CH_3}{C}\overset{\cdot}{\dashrightarrow}CH_3$, which propagate two independent polymerisation chains, can therefore exist in different proportions. In the case under consideration, the introduction of the catalyst enhances the differences between the reactivities of the radicals in relation to the comonomers (r_1, $r_2 \rightarrow 0$ after the addition of the catalyst).

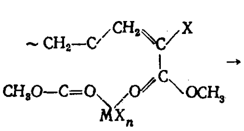
In the copolymerisation of monomers having functional groups of the same type (for example, COOR) in the presence of Lewis acids there is a possibility of another limiting case—the "disappearance" of the differences between the reactivities of the monomers in the chain propagation reaction ($r_1 \rightarrow 1$ and $r_2 \rightarrow 1$). This effect was observed in the copolymerisation of methyl methacrylate with methyl acrylate in the presence of $ZnCl_2$ and $AlBr_3$ [83] and was subsequently confirmed in certain other systems[64].

Table 9. Copolymerisation of methyl methacrylate (M_1) with methyl acrylate (M_2) in the presence of complex-forming agents at 50°C.

Initiator	$\frac{[MX_n]}{[M_1]+[M_2]}$	r_1	r_2
	$MX_n = ZnCl_2$		
[ABIBN] = 0.005 M	0	2.23±0.13	0.36±0.1
	0.15	1.33±0.03	0,70±0.03
	0.45	0.90±0.03	0,90±0,09
	$MX_n = AlBr_3$		
u.v. (λ > 313 nm)	0.075	1.75±0.04	0.78±0.05
	0.15	1,11±0.04	0,91±0.1
	0.40	0,96±0,05	0.96±0.11

Table 9 lists the effective constants for the copolymerisation of methyl methacrylate (M_1) with methyl acrylate (M_2) in the presence of $ZnCl_2$ and $AlBr_3$.[83] When the catalyst MX_n is added, the composition of the copolymer, initially relatively enriched in M_1 units, approaches that of the mixtures of the monomers and becomes virtually identical with it when $[MX_n]/\{[M_1] + [M_2]\} = 0.2-0.5$; under these conditions, the effective copolymerisation constants are $r_1 = r_2 = 1$ (Fig. 28).

The equalisation of the relative activities of the comonomers following the introduction of complex-forming agents can be naturally accounted for within the framework of the hypothesis that chain propagation proceeds via a stage involving a cyclic transition complex with simultaneous coordination of the radical and the monomer to the MX_n molecule:



→ chain propagation.

The mutual approach and appropriate orientation of the reaction centres of the monomer and the radical promote rapid addition. The probability of addition virtually ceases to depend on the true reactivities of the radical and the monomer. The mechanism of chain propagation in radical homo- and co-polymerisation in systems of this kind is in principle analogous to the typical mechanisms of coordination-ionic polymerisation. The stability of the complex of the modifying agent and the terminal unit of the growing radical increases owing to the delocalisation of the unpaired electron of the radical to the metal ion in MX_n.[80] The resulting possibility of the migration of MX_n with retention of the complex at the terminal unit of the growing chain increases the analogy with coordination-ionic polymerisation still further.

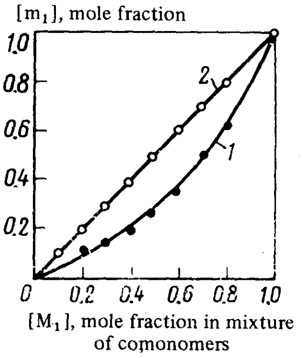


Figure 28. Copolymerisation of methyl methacrylate (M_1) with methyl methacrylate (M_2): 1) in the absence of complex-forming agent; 2) after the introduction of zinc chloride; $[ZnCl_2]/\{[M_1] + [M_2]\} = 0.25$; temperature 50°C.

5. The Influence of Magnetic and Electric Fields

An urgent problem in polymer chemistry is the synthesis of stereoregular and crystalline polymers. The selective formation of highly oriented polymers in radical polymerisation is promoted by the preliminary structural organisation of the medium in which the process is carried out, which may be achieved by applying a magnetic field or by the fixation of the monomeric liquid-crystal structure.

Fig. 29 presents the diffraction patterns for polymers obtained by the radical polymerisation of acryloyloxybenzoic acid in the liquid crystal phase (curve *1*) and in isotropic solution in heptyloxybenzoic acid (curve *2*).[84] Curve *1* is characterised by a series of sharp diffraction maxima. The degree of crystallinity of the polymer is 40% according to X-ray diffraction data, while polymerisation in solution leads to the formation of a polymer with an amorphous structure.

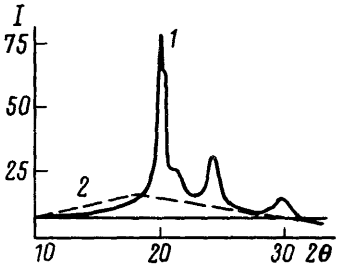

Figure 29. Diffractometer traces for polyacryloyloxybenzoic acid specimens obtained in the radical polymerisation of heptyloxybenzoic acid in bulk (curve *1*) and in solution in the monomer (curve *2*).

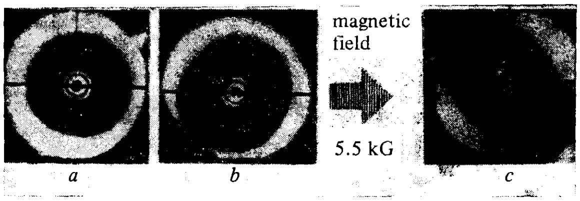

Figure 30. X-Ray diffraction patterns for the polymer of 4-n-hexyloxyphenyl 4′-acryloyloxybenzoate obtained by polymerisation from the isotropic phase (*a*), the liquid-crystal phase (*b*), and the liquid-crystal phase with application of a 5.5 G permanent field (*c*).

In the polymerisation of 4-n-hexyloxyphenyl 4′-acryloyloxybenzoate it was possible to obtain polymers with a high degree of orientation of the macromolecules by employing the intrinsic orientation order in the liquid crystal phase of the monomer as well as a magnetic field of 5.5 kG.[85] X-Ray diffraction patterns for the polymer obtained by radical polymerisation from the isotropic phase (*a*), the liquid-crystal phase (*b*), and the liquid-crystal phase with application of a steady magnetic field (*c*) are presented in Fig. 30.[85] The presence of denser regions on the diffraction rings indicates an increase in the anisotropy (degree of axial orientation of the macromolecules) of the specimens on passing from *a* to *c*. The polymer formed exhibits only axial orientation.

Magnetic and electric fields make it possible to influence the microstructures of polymeric specimens. Fig. 31 illustrates the changes in the isomeric composition of polybutadiene on polymerisation of butadiene under the influence of a magnetic field with the specimen (20% of butadiene in benzene) irradiated by ultraviolet light[86]. Dibenzothiazolyl sulphide was used as the sensitiser. Evidently, the polybutadiene obtained by polymerisation in the absence of a field contains ~30% of the *trans*-1,4-form. When a 5 kG magnetic field is applied, the content of *trans*-1,4-polybutadiene increases to 50%.

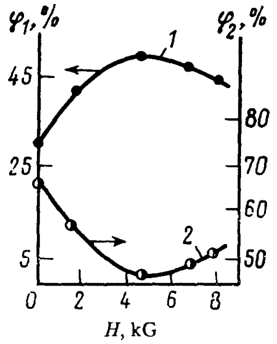

Figure 31. The influence of the magnetic field on the microstructure of polybutadiene formed on photochemical polymerisation at 25°C; sensitiser—dibenzothiazolyl sulphide (φ_1 and φ_2 are the yields of *cis*- and *trans*-polybuta-1,4-dienes).

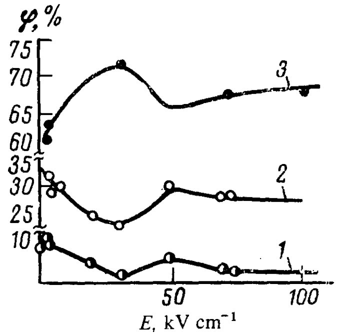

Figure 32. The contents of isotactic (curve *1*), heterotactic (curve *2*), and syndiotactic (curve *3*) triads in the polymerisation of methyl methacrylate in a permanent electric field at 60°C; initiator—azobisisobutyronitrile.

The mechanism of the phenomenon apparently includes the formation of an intermediate complex of the isomerising molecules with the free radical produced on photolysis of the sensitiser. The C=C bonds in the *trans*-position in the complex are ruptured and there are singlet–triplet transitions in the radical pairs. The role of the magnetic field is additional removal of the singlet–triplet degeneracy of the Zeeman interaction energy and an increase in the probability of the *cis–trans* isomerisation through the triplet state via an adiabatic pathway.

The application of a permanent electric field, like that of a magnetic field, can influence strongly the tacticity of the poly(vinyl acetate) formed in the polymerisation reaction[87]. Fig. 32 illustrates the influence of the electric field on the stereoregularity of the poly(vinyl acetate) formed by radical polymerisation in the presence of azobisisobutyronitrile as the radical initiator at 60°C. A sharp increase of the tacticity of the polymer is seen at an electric field strength of ~ 30 kV cm^{-1}.

The above examples suggest that magnetic and electric fields are promising factors whereby the selectivity of polymerisation processes may be influenced.

6. Thermodynamic Properties of the Monomer and the Formation of the Crystal Structure of the Polymer

Changes in the thermodynamic properties of monomer solutions (concentration, solvent, and temperature) may alter the crystal structure of the resulting polymer. At high concentrations of the monomer (for example, trioxan) macromolecules with a high molecular weight are formed in solution.

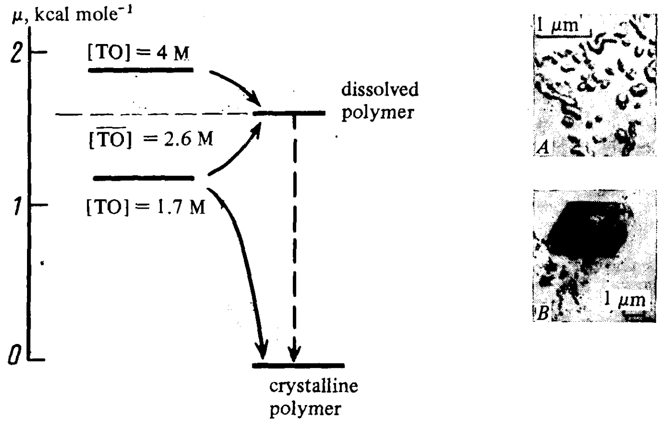

Figure 33. Thermodynamics of the polymerisation of trioxan; *A* and *B*—specimens of crystals formed on crystallisation of trioxan from solutions with [TO] > [$\overline{TO}$] and [TO] < [$\overline{TO}$]; {[$\overline{TO}$] = 2.6 M}.

Fig. 33 shows that the thermodynamic potential of trioxan (TO) in methylene chloride at a concentration of 4 M exceeds that of the polyformaldehyde macromolecule in this medium. The final product is formed in two stages—the macromolecule is formed initially and this is followed by its crystallisation from solution. At low concentrations of the monomer its thermodynamic potential is lower than that of the dissolved polymer molecule. The polymer molecules formed do not dissolve as the chain length increases and give rise to the solid crystalline phase almost immediately. Because of this, a cryptocrystalline polymer is formed in the former case, while in the latter case large crystals are produced (Fig. 33).[88,89]

The thermodynamic potentials of the polymer and the monomer also vary under the influence of temperature and the nature of the solvent.

Thus there are new possibilities for a thermodynamic approach to the regulation of the supermolecular structure of the polymer. The reaction is carried out under conditions close to the polymer ⇌ monomer equilibrium position. It is found that the formation of a polymer with an undesirable structure is thermodynamically impossible under these conditions.

7. Polymerisation Under the Influence of Shock Waves

The usefulness of shock waves in polymerisation reactions of many organic compounds has been demonstrated in recent years[90]. When a shock wave passes through solid organic monomers, even substances which do not undergo polymerisation under the usual conditions do polymerise (for example, benzene)[91]. The reaction is carried out in special "storage containers", the design of which makes it possible to protect substances subjected to compression by shock waves from decomposition (Fig. 34). Under these conditions, polymerisation is observed only at shock wave pressures exceeding a threshold value. The degree of reaction during the passage of the shock wave and the threshold polymerisation amplitude depend on the nature of the monomer.

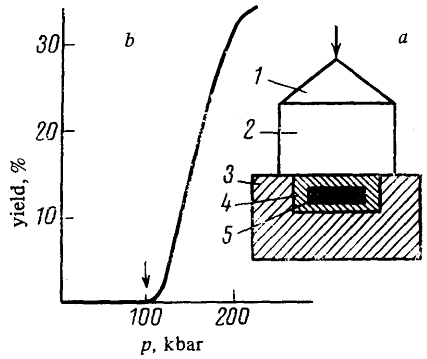

Figure 34. *a*) Schematic illustration of polymerisation under the influence of a shock wave: 1) generator of a planar detonation wave; 2) explosive; 3) housing; 4) container; 5) monomer; 6) dependence of the yield of polyacrylamide on the shock wave pressure. The arrow indicates the threshold pressure.

The use of shock waves makes it possible to obtain polymers with a much higher molecular weight than in the usual polymerisation. Thus, in the polymerisation of trioxan in a shock wave, the molecular weight of the polymer reaches 1.3×10^6, while in catalytic polymerisation it is 10^5. Depending on the conditions, polymerisation in a shock wave makes it possible to synthesise polymers with different structures.

The mechanisms of polymerisation in a shock wave cannot be reduced to a simple combination of compression and heating and apparently involves a new specific type of influence. The application of shock waves may be regarded as one of the possible factors for increasing process selectivity.

VIII. RADICAL PROCESSES IN THE CRACKING OF HYDROCARBONS

The selectivity in the formation of products in the cracking of hydrocarbons is determined by their structure. In paraffins and isoparaffins the difference between the energies of primary, secondary, and tertiary C–H bonds is as a rule small (390–410 kJ mole^{-1}). The energy of the C–C bond is virtually constant along the hydrocarbon skeleton (330–340 kJ mole^{-1}), its value being slightly higher only for the abstraction of terminal methyl groups (350–360 kJ mole^{-1}).[92] For this reason, the process at low temperatures (up to 500°C) is non-selective and leads to the formation of a wide range of products, for example[92a]:

$$\text{(0)} \quad CH_3{-}CH_2CH_2{-}CH_3 \rightarrow 2C_2H_5^{\cdot},$$

$$\text{(0')} \quad CH_3{-}CH_2CH_2{-}CH_3 \rightarrow CH_3^{\cdot} + C_3H_7^{\cdot},$$

$$\text{(2.1)} \quad C_2H_5^{\cdot} + C_4H_{10} \rightarrow C_2H_6 + C_4H_9^{\cdot},$$

$$\text{(2.2)} \quad CH_3^{\cdot} + C_4H_{10} \rightarrow CH_4 + C_4H_9^{\cdot},$$

$$\text{(2.3)} \quad C_3H_7^{\cdot} + C_4H_{10} \rightarrow C_3H_8 + C_4H_9^{\cdot},$$

$$\text{(2.4)} \quad C_2H_5^{\cdot} \rightarrow H^{\cdot} + C_2H_4,$$

$$\text{(2.5)} \quad C_3H_7^{\cdot} \rightarrow CH_3^{\cdot} + C_2H_4,$$

$$\text{(2.6)} \quad H^{\cdot} + C_4H_{10} \rightarrow H_2 + C_4H_9^{\cdot},$$

$$\text{(2.7)} \quad CH_3{-}\dot{C}H{-}CH_2CH_3 \rightarrow C_3H_6 + CH_3^{\cdot},$$

$$\text{(2.8)} \quad \dot{C}H_2{-}CH_2{-}CH_2CH_3 \rightarrow C_2H_4 + C_2H_5^{\cdot},$$

$$C_2H_5^{\cdot},\ C_3H_7^{\cdot},\ C_4H_9^{\cdot} \rightarrow \text{chain termination.}$$

1. The Influence of Temperature and Reactant Concentrations on Selectivity in Cracking

It is seen from the overall cracking mechanism that free radicals are transformed via several pathways in the chain propagation stages: unimolecular decomposition via reactions (2.4) and (2.5) and bimolecular interaction with the initial substance via reactions (2.1) and (2.3). Individual elementary stages are characterised by different activation energies, so there is the possibility, in principle, of altering the ratios of the rates of parallel elementary stages by changing the temperature (the selectivity is influenced via the value of α).

In the cracking of butane, the processs selectivity is determined by the competition between reactions (2.4) and (2.5), which lead to the formation of ethylene, and between reactions (2.1) and (2.3), which lead to the accumulation in the system of low-molecular-weight alkanes as side products. Table 10 presents the rate constants for these elementary stages[92].

The rate ratios $w_{2.4}/w_{2.1}$ and $w_{2.5}/w_{2.3}$, calculated using the above constants, increase with temperature and, when $t > 800$°C and the butane concentration in the gas phase $[C_4H_{10}] \simeq 10^{-3}$ mole cm^{-3}, the rate of the unimolecular decomposition of alkyl radicals is significantly greater than the rates $w_{2.1}$ and $w_{2.3}$ of the bimolecular conversion of $C_2H_5^{\cdot}$ and $C_3H_7^{\cdot}$ respectively. A decrease in the concentration of butane (for example, by diluting it with an inert gas) decreases the temperature at which the conditions $w_{2.4} > w_{2.1}$ and $w_{2.5} > w_{2.3}$ hold. Thus it is possible to increase the selectivity in the cracking of butane to ethylene by raising the temperature and by diluting butane with an inert gas. This procedure is used in industry, where pyrolytic processes, designed to obtain ethylene, are carried out at high temperatures and with dilution by steam.

Table 10. The rate constants for the chain propagation reactions in the cracking of butane.

Reaction	lg k_0 (cm^3 mole^{-1} s^{-1})	E, kJ, mole^{-1}	Reaction	lg k_0 (cm^3 mole^{-1} s^{-1})	E, kJ, mole^{-1}
(2.1)	2.0	42	(2.4)	14.2	126
(2.3)	9.8	40	(2.5)	15.4	142

2. Coupled Cracking. Transfer of the Reaction to a New Pathway

The transfer of the reaction to a new chain pathway by coupling processes makes it possible to alter the nature and activity of the radicals propagating the main chain and hence the selectivity in the cracking process. This principle has been used to increase the selectivity in the cracking of piperylene. At 650–700°C the cracking of piperylene proceeds with formation of cyclopentadiene (the selectivity $S_c \simeq 30$ mole % relative to the unconsumed piperylene) and butadiene ($S_b = 50$ mole %) (Table 11) and involves the mechanism[93]

$$C_5H_8 \rightarrow C_5H_7^{\cdot} + H,$$

$$\text{(1.1)} \quad C_5H_7^{\cdot} + C_5H_8 \xrightarrow{k_{1.1}} C_5H_9^{\cdot} + C_5H_6,$$

$$\text{(2.1)} \quad H^{\cdot} + C_5H_8 \xrightarrow{k_{2.1}} C_5H_9^{\cdot},$$

$$\text{(0.1)} \quad C_5H_9^{\cdot} \xrightarrow{k_{0.1}} CH_3^{\cdot} + C_4H_6 \ \text{(butadiene)},$$

$$\text{(3.1)} \quad CH_3^{\cdot} + C_5H_8 \xrightarrow{k_{3.1}} C_5H_7^{\cdot} + CH_4,$$

$$(CH_3^{\cdot},\ C_5H_9^{\cdot},\ C_5H_7^{\cdot}) \rightarrow \text{chain termination.}$$

The introduction of hydrogen into the reaction causes the replacement by hydrogen atoms of the $CH_3^{\cdot}$ radicals whose subsequent transformation leads to the formation of cyclopentadiene. As a result, the unit of the cracking chain consisting of the sequence of reactions (1.1), (0.1), and (3.1) is replaced by the sequence of reactions (2.1), (0.1), and (3.2):

$$\text{(3.2)} \quad CH_3^{\cdot} + H_2 \xrightarrow{k_{3.2}} CH_4 + H\ .$$

Table 11. The selectivity in the cracking of piperylene.

System	S_c, mole %	S_b, mole %	System	S_c, mole %	S_b, mole %
In the absence of H_2	30	50	In the presence of added H_2	10	70

This change in the pathway increases the process selectivity with respect to butadiene (Table 11). When account is taken of the reaction involving chain transfer by $CH_3^{\cdot}$

radicals [reaction (3.2)], the above mechanism of the cracking of piperylene makes it possible to obtain expressions for the integral selectivity S_b in the formation of butadiene.

According to Eqn.(2a), the differential selectivity in the formation of butadiene is

$$\sigma_{C_4H_6} = \frac{k_{0.1}[C_5H_9^{\cdot}]}{k_{1.1}[C_5H_7^{\cdot}] + k_{2.1}[H] + k_{3.1}[CH_3^{\cdot}]} \quad . \tag{21}$$

By expressing the concentrations of all the active centres in terms of the concentration of $CH_3^{\cdot}$ radicals and assuming that the chain is long, we find

$$[C_5H_7^{\cdot}] = k_{3.1}[CH_3^{\cdot}]/k_{1.1};\ [H^{\cdot}] = \frac{k_{3.2}[H_2]}{k_{2.1}[C_5H_8]}[CH_3^{\cdot}];$$

$$[C_5H_9^{\cdot}] = \frac{k_{3.1}[C_5H_8] + k_{3.2}[H_2]}{k_{0.1}}[CH_3^{\cdot}] \quad .$$

On substituting the values obtained in Eqn.(21), we obtain an expression relating the differential selectivity with respect to butadiene to the concentrations of the initial substances C_5H_8 and H_2:

$$\sigma_{C_4H_6} = (k_{3.1}[C_5H_8] + k_{3.2}[H_2])/(2k_{3.1}[C_5H_8] + k_{3.2}[H_2]) \quad .$$

In the absence of hydrogen S_b is independent of C and is equal to 0.5. As the hydrogen concentration increases, the differential process selectivity rises from 1/2 to 1. There is a corresponding change also in the integral selectivity. In the presence of hydrogen

$$S_b(C) = \frac{1}{2}\left[1 - \frac{k_{3.2}[H_2]_0}{2k_{3.1}[C_5H_8]_0 C}\ln\left(1 - \frac{2k_{3.1}[C_5H_8]_0 C}{k_{3.2}[H_2]_0 + 2k_{3.1}[C_5H_8]_0}\right)\right] .$$

With increase of the degree of conversion, S_b changes from

$$S_b = \frac{1}{2}\left(1 - \frac{k_{3.2}[H_2]_0}{k_{3.2}[H_2]_0 + 2k_{3.1}[C_5H_8]_0}\right)$$

for very low degrees of cracking ($C \to 0$) to

$$S_b = \frac{1}{2}\left(1 - \frac{k_{3.2}[H_2]_0}{2k_{3.1}[C_5H_8]_0}\ln\left[1 - \frac{2k_{3.1}}{k_{3.2}}\left(\frac{[H_2]_0}{[C_5H_8]_0} + \frac{2k_{3.1}}{k_{3.2}}\right)^{-1}\right]\right)$$

for the degree of conversion $C = 1$. For example, calculation showed that, for the rate constant ratio $2k_{3.1}/k_{3.2} = 0.5$ and an equimolar mixture of piperylene and hydrogen $\{[H_2]_0/[C_5H_8]_0 = 1\}$, the process selectivity $S_b = 0.85$, while in the absence of hydrogen $S_b = 0.5$ regardless of the degree of conversion of the hydrocarbon, since both products—butadiene and cyclopentadiene—are formed simultaneously in the first stage of the chain unit [reaction (1)] when $[H_2O]_0 = 0$. Thus in the presence of added hydrogen there is an increase also of the integral process selectivity with respect to butadiene. This result is consistent with the data in Table 11. Consequently the procedure involving the introduction of hydrogen makes it possible to increase the process selectivity S_b with respect to butadiene and to decrease the selectivity S_c with respect to cyclobutadiene. The selectivity with respect to cyclobutadiene may be increased by introducing hydrogen atom acceptors (for example, HCl). In many instances the cracking of ethane coupled with the main process may be used as a source of hydrogen atoms.

The mechanism of the cracking of a toluene–ethane mixture[94] may be formulated in the following form:

$$H^{\cdot} + C_6H_5CH_3 \to CH_3^{\cdot} + C_6H_6,$$
$$CH_3^{\cdot} + C_6H_5CH_3 \to CH_4 + C_6H_5CH_2^{\cdot},$$
$$2C_6H_5CH_2^{\cdot} \to C_6H_5CH_2{-}CH_2C_6H_5,$$
$$C_2H_6 + C_6H_5CH_2^{\cdot} \to C_6H_5CH_3 + C_2H_5^{\cdot},$$
$$C_2H_5^{\cdot} \to C_2H_4 + H^{\cdot},$$
$$CH_3^{\cdot} + CH_3^{\cdot} \to C_2H_6.$$

The competitions between the fourth and fifth reactions determines the yield of biphenyl and that between the first two reactions determines the yield of benzene. Enrichment of the mixture in ethane leads to an increase in the concentration of hydrogen atoms and hence of the yield of benzene formed by the interaction of hydrogen atoms with toluene. The selectivity in the cracking of toluene to benzene increases (Table 12). The increase of the cracking selectivity with respect to styrene is association with the reactions

$$C_6H_5CH_2^{\cdot} + CH_3^{\cdot} \to C_6H_5C_2H_5 \to C_6H_5CH{=}CH_2 + H_2,$$
$$C_6H_5^{\cdot} + C_2H_4 \to C_6H_5C_2H_4^{\cdot} \to C_6H_5CH{=}CH_2 + H^{\cdot},$$
$$C_6H_5^{\cdot} + C_2H_3^{\cdot} \to C_6H_5CH{=}CH_2.$$

In the absence of ethane C_2H_4 and $C_2H_3^{\cdot}$ are not formed in appreciable amounts during the reaction.

Table 12. The selectivities in the formation of the main products of the coupled cracking of toluene (mole %; 840°C; contact time in flow system 0.1 s).

Cracking product	Toluene	43:57 toluene–ethane mixture (wt.%)	32:68 toluene–H_2 mixture (wt.%)

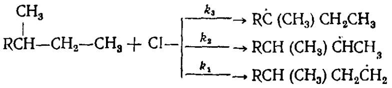
Bibenzyl	20	2	—

IX. HALOGENATION OF HYDROCARBONS

The chlorination of hydrocarbons constitutes a sequence of chain reactions involving the chlorination of the initial hydrocarbon and its various chloro-derivatives formed during the process. The hydrocarbon chlorination processes have as a rule a low selectivity and proceed via the mechanism[95,96]

$$Cl_2 \to 2Cl^{\cdot},$$
$$RCH_3 + Cl^{\cdot} \to RCH_2^{\cdot} + HCl,$$
$$RCH_2^{\cdot} + Cl_2 \to RCH_2Cl + Cl^{\cdot},$$
$$RCH_2^{\cdot} + HCl \to RCH_3 + Cl^{\cdot},$$
$$RCH_2Cl + Cl^{\cdot} \to RCH_2^{\cdot} + Cl_2,$$
$$Cl^{\cdot} + Cl^{\cdot} + M \to Cl_2 + M,$$
$$Cl^{\cdot} + RCH_2^{\cdot} \to RCH_2Cl,$$
$$RCH_2^{\cdot} + RCH_2^{\cdot} \to \text{molecular products},$$
$$Cl^{\cdot} \to \text{destruction on the wall},$$
$$RCH_2Cl + Cl_2 \to RCHCl_2^{\cdot} + HCl.$$

When there is a possibility of the parallel formation of several positional isomers in the system owing to the similar reactivities of the primary, secondary, and tertiary C–H bonds (390–410 kJ mole^{-1}), it is extremely difficult to alter the ratio of the isomers (and hence to increase the process selectivity with respect to one of the isomers, i.e. to alter the quantity $\alpha = k_i/\Sigma k_j$). The ratio of positional isomers as a rule assumes the statistical value. The small differences between the strengths of the primary, secondary, and tertiary C–H bonds in the hydrocarbon chain have almost no influence on the isomer ratio owing to the high reactivity of Cl atoms. However, the selectivity of the chlorination reaction may be significantly increased by carrying out the latter in solution and by reducing thereby the reactivity of chlorine atoms as a result of complex formation with the solvent. Chlorine atoms with a reduced reactivity are capable of "distinguishing" the C–H bonds in different positions, although the energies of the latter still do not differ greatly. The ratio of monochloro-derivatives (primary, secondary, and tertiary), formed at early stages in chain chlorination reactions, is determined by the rate constants for the reactions:



$$RCH(CH_3)-CH_2-CH_3 + Cl \xrightarrow{k_3} R\dot{C}(CH_3)CH_2CH_3;\quad \xrightarrow{k_2} RCH(CH_3)\dot{C}HCH_3;\quad \xrightarrow{k_1} RCH(CH_3)CH_2\dot{C}H_2$$

$$S_{-CH_2Cl} = k_1/(k_1+k_2+k_3),$$
$$S_{>CHCl} = k_2/(k_1+k_2+k_3),$$
$$S_{\geqslant CCl} = k_3/(k_1+k_2+k_3),$$

i.e. $S_{-CH_2Cl} : S_{>CHCl} : S_{\geqslant CCl} = k_1 : k_2 : k_3$.

It has been established experimentally that the use of different solvents, forming complexes with atomic chlorine and reducing its reactivity, leads to a greater process selectivity. Table 13 lists the rate constant ratios for the elementary steps in the interaction of chlorine atoms with C–H bonds in alkanes and aromatic alkyl-substituted hydrocarbons. Evidently, when the reaction is carried out in a solvent, the rate constant ratio increases sharply. The ratio k_3/k_1 for 2,3-dimethylbutane increases from 6 to 225 in CCl_4 (at 25°C) and from 3.7 to 18.4 (at 55°C) in anisole, i.e. when the reaction is carried out in a complex-forming solvent, the relative rate of the interaction of Cl with the t-C–H bond increases compared with the reaction involving the primary bond. There is a corresponding increase of the selectivity in the formation of 2-chloro-2,3-dimethylbutane. (In this calculation no account was taken of the possibility of further chlorination of the monochloro-derivatives.)

The regulating influence of the solvent increases with increase of its concentration owing to the shift of the equilibrium

$$Cl^{\cdot} + SH \rightleftarrows \dot{C}l \cdot SH$$

towards the formation of the complex.

Table 13. The relative rate constants for the abstraction by a chlorine atom of tertiary and primary hydrogen atoms from 2,3-dimethylbutane (k_3/k_1) and α- and β-hydrogen atoms from aromatic hydrocarbons (k_α/k_β) in chlorination by molecular chlorine at 55°C.[96]

*Chlorination temperature 25°C.

1. Selectivity of the Halogenation Reaction at Low Temperatures

By carrying out the reactions at low temperatures, it is possible to obtain high selectivities because of the possibility of increasing the sensitivity of the reaction to the energetic parameters of different stages[97]. It is possible to obtain the desired product in a high yield even for very low differences between the activation energies for the main and side reactions (ΔE). For example, in the parallel reactions

$$A - \begin{cases} \xrightarrow{k_1} P_1\ (k_1 = k_{10}e^{-E_1/RT}), \\ \xrightarrow{k_2} P_2\ (k_2 = k_{20}e^{-E_2/RT}) \end{cases}$$

with $E_1 - E_2 = \Delta E$ = 3 kcal mole^{-1} (750 J mole^{-1}) and the pre-exponential factor ratio $k_{10}/k_{20} = 5$, the ratio of the selectivities in the formation of P_1 and P_2 is

$$\frac{S_{P_1}}{S_{P_2}} = \frac{k_1}{k_2} = \frac{k_{10}}{k_{20}} e^{-\Delta E/RT} = 5 \cdot e^{-3000/RT}.$$

At 300°C the ratio $S_{P_1}/S_{P_2} = 1.42$, so that $S_{P_1} = 0.59$ and $S_{P_2} = 0.41$ (the process is non-selective). In the same case at 100 K we have $S_{P_1}/S_{P_2} = 0.114$, $S_{P_1} = 0.10$, and $S_{P_2} = 0.90$, i.e. a high selectivity with respect to P_2 is achieved.

The wide-scale use of low temperatures has been retarded hitherto by the conviction that below 250 K the rates of chemical reactions are extremely low. However, studies in the last two decades have disproved this view. Many processes involving halogens occur at very high rates at 77–100 K, for example. Fig.35 shows that the liquid-phase chlorination of olefins at low temperatures is faster than in the gas phase. Even in the solid phase at ~100 K, the reaction proceeds at appreciable rates. The selectivity data for the reaction between ethylene and Cl_2 illustrated in Fig. 35 show that substitution processes are completely suppressed at low temperatures, i.e. processes involving the dissociation of the C–H bond are altogether absent and high quantitative yields of 1,2-addition products are obtained.

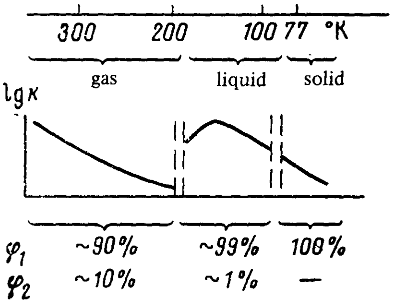

Figure 35. Chlorination of olefins in the gas phase, a supercooled liquid, and in the solid phase; k—rate constant for the dark reaction; φ_1 and φ_2—yields of addition and substitution products respectively.

The mechanism of the low-temperature reaction may be represented as follows:

$$C_2H_4 + Cl_2 \rightleftarrows C_2H_4 \cdot Cl_2 \quad (\Delta H \leqslant 10\ \text{kJ mole}^{-1}),$$

this being followed by the molecular rearrangement

$$C_2H_4 \cdot Cl_2 \rightarrow \quad \text{cyclic transition state} \quad \rightarrow C_2H_4Cl_2$$

and the chain process

$$C_2H_4{\cdot}Cl_2 \rightarrow C_2H_4Cl^{\cdot} + Cl^{\cdot} \rightarrow C_2H_3Cl + HCl.$$

The selective course of the process is associated with the involvement in the reactions of molecular complexes capable of a synchronous rearrangement under certain conditions to the reaction products or active radical species. The chain mechanism of the process at low temperatures is to a large extent suppressed owing to energy-dependent selectivity (based on the differences between the activation energies). When the low-temperature reaction is carried out in a solvent with pronounced complex-forming properties (HCl), the radical-chain component can be almost completely suppressed.

In liquid HCl, the process develops via the mechanism

$$Cl_2 + HCl \rightleftarrows Cl_2{\cdot}HCl,$$
$$Cl_2{\cdot}HCl + C_2H_4 \rightleftarrows (C_2H_4{\cdot}Cl_2{\cdot}HCl) \rightarrow C_2H_4Cl_2 + HCl.$$

Its activation energy is $E = 10-20$ kJ mole^{-1}.

The yield of the 1,2-dichloro-derivative is limited by the purity of the reactants and may be raised to 100%. In reactions with participation of halogens in non-polar media a negative temperature coefficient is frequently obtained. This effect can be accounted for by the occurrence of rapid reversible stages, in particular, complex formation stages. The activation energy for a consecutive reaction

$$A + B \overset{K}{\rightleftarrows} A{\cdot}B \xrightarrow{k} P,$$

where $K = K_0e^{-\Delta H/RT}$ ($\Delta H < 0$) and $k_0e^{-E/RT}$ ($E > 0$), is the sum of the positive activation energy E and the negative enthalpy of complex formation ΔH: $E_{obs} = E - |\Delta H|$. If $|\Delta H| > E$, a negative temperature coefficient is observed. The reaction proceeds with acceleration as the temperature is reduced to a value T_{max}, after which the rate begins to fall. The relation between T_{max} and E and ΔH is given by the equation

$$\frac{1}{T_{max}} = \frac{4.57}{|\Delta H|} \lg\left(\frac{|\Delta H| - E}{E}\right) + \frac{\Delta S}{|\Delta H|}.$$

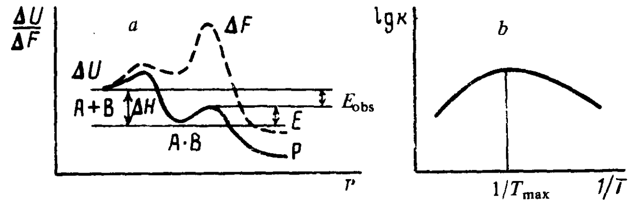

Figure 36. *a*) Reaction pathway characterised by a negative temperature coefficient (continuous line) and variation of ΔF in this process (dashed line); *b*) temperature variation of the rate constant for the reaction proceeding via the formation of a complex; T_{max} corresponds to complete binding of the components in the complex.

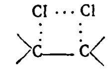
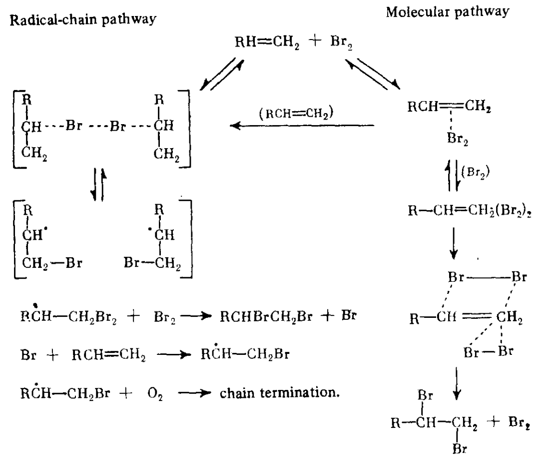
Fig. 36 illustrates the "energy–reaction pathway" scheme for a process with $E_{obs} < 0$ (the activation energy E_{obs} is an effective value). The reaction proceeds via this pathway when the complex AB (Fig. 36) is converted into the product via a cyclic transition state, for example



in the chlorination of olefins.

A high negative activation entropy is characteristic of processes of this kind, as a result of which the potential energy well for this type of transition state lies below the energy level of the initial molecules and $E_{obs} < 0$. When the temperature is reduced rapidly, the reactants are completely bound in an extremely stable complex AB. Many systems are known for which negative values of E_{obs} have been found: chlorine–olefin, bromine–olefin, iodine chloride and bromide–olefins, bromine–α-hydroxycyclopropanes, bromine–arylcyclopropanes, NOCl–epoxides, etc. The values of E_{obs} for the above processes are in the range between 0 and 60 kJ mole^{-1} and the maximum rate of the process is reached at 230–170 K. Thus there is a possibility of carrying out many reactions at high rates even at very low temperatures. Cryochemistry leads to new possibilities for selective reaction conditions.

In reality the interpretation of the nature of the negative temperature coefficient in halogenation is more complex[97]. At low temperatures energy-dependent selectivity is accompanied also by selectivity based on mechanisms in principle associated with the energetics of parallel reactions. The bromination of olefins at room temperature takes place simultaneously via two pathways:



$$R\dot{C}H{-}CH_2Br_2 + Br_2 \longrightarrow RCHBrCH_2Br + Br$$
$$Br + RCH{=}CH_2 \longrightarrow R\dot{C}H{-}CH_2Br$$
$$R\dot{C}H{-}CH_2Br + O_2 \longrightarrow \text{chain termination.}$$

The process may proceed via a synchronous rearrangement of the 2 : 1 bromine-olefin complex (molecular pathway). The existence of such complexes has been demonstrated experimentally and their structure has been confirmed by quantum-mechanical calculations. The rate in the molecular olefin transformation pathway is

$$w_m = k'[RCH{=}CH_2][Br_2]^2 \quad (E'_{obs} = -15 \div -30 \text{ kJ mole}^{-1}) \; .$$

On the other hand, the synchronous process involving the dissociation and formation of bonds in the complex may lead to the formation of radicals (the radical-chain pathway). The rate in the radical-chain pathway is

$$w_c = k[RCH{=}CH_2]^2[Br_2]^2.$$

The mechanism of the chain process involves reversible stages, for example, the reaction of bromine atoms with an olefin molecule:

$$Br + CH_2{=}CHR \rightleftarrows [Br{\cdot}CH_2{=}CHR].$$

For this reason, a negative temperature coefficient is also observed in the radical-chain reaction and is greater than in the molecular reaction. Depending on the nature of the group R, the activation energy E_{obs} varies from -20 to -60 kJ mole^{-1}. The ratio of the rates in the radical-chain and molecular pathways of the reaction with olefins is proportional to the olefin concentration:

$$w_c/w_m = (k/k') \cdot [\mathrm{RCH{=}CH_2}].$$

The two processes give rise to different products (Table 14). By reducing the temperature and increasing the olefin concentration, it is possible to isolate the radical pathway, while the addition of inhibitors makes it possible to isolate the molecular pathway. Thus by altering the experimental conditions, one can isolate selectively the different pathways in the low-temperature halogenation reactions. Table 14 presents as an example data for the bromination of hex-1-ene. Analogous results were obtained in the chlorination of olefins and in reactions of halogens with epoxides and arylcyclopropanes.

Table 14. Hex-1-ene bromination products at 300 K (% of sum of products formed via a given pathway).

Product	Molecular pathway	Radical pathway
$\mathrm{CH_2BrCHBr(CH_2)_3CH_3}$	97	50
$\mathrm{CH_2BrCH{=}CH(CH_2)_2CH_3}$	3	34
$\mathrm{CH_2{=}CH{-}CH{-}Br(CH_2)_2CH_3}$	—	12
$\mathrm{CHBr{=}CH(CH_2)_3CH_3}$	—	4
$\mathrm{CH_2{=}CBr(CH_2)_3CH_3}$		

The pathways in the low-temperature reactions can be additionally regulated by introducing complex-forming additives or solvents into the system. A high selectivity in additive chlorination has been noted when the reaction was carried out in liquid HCl. The role of the additive usually reduces to binding electron-accepting species (halogen atoms and molecules) in a complex, reducing their electrophilic properties, and increasing the process

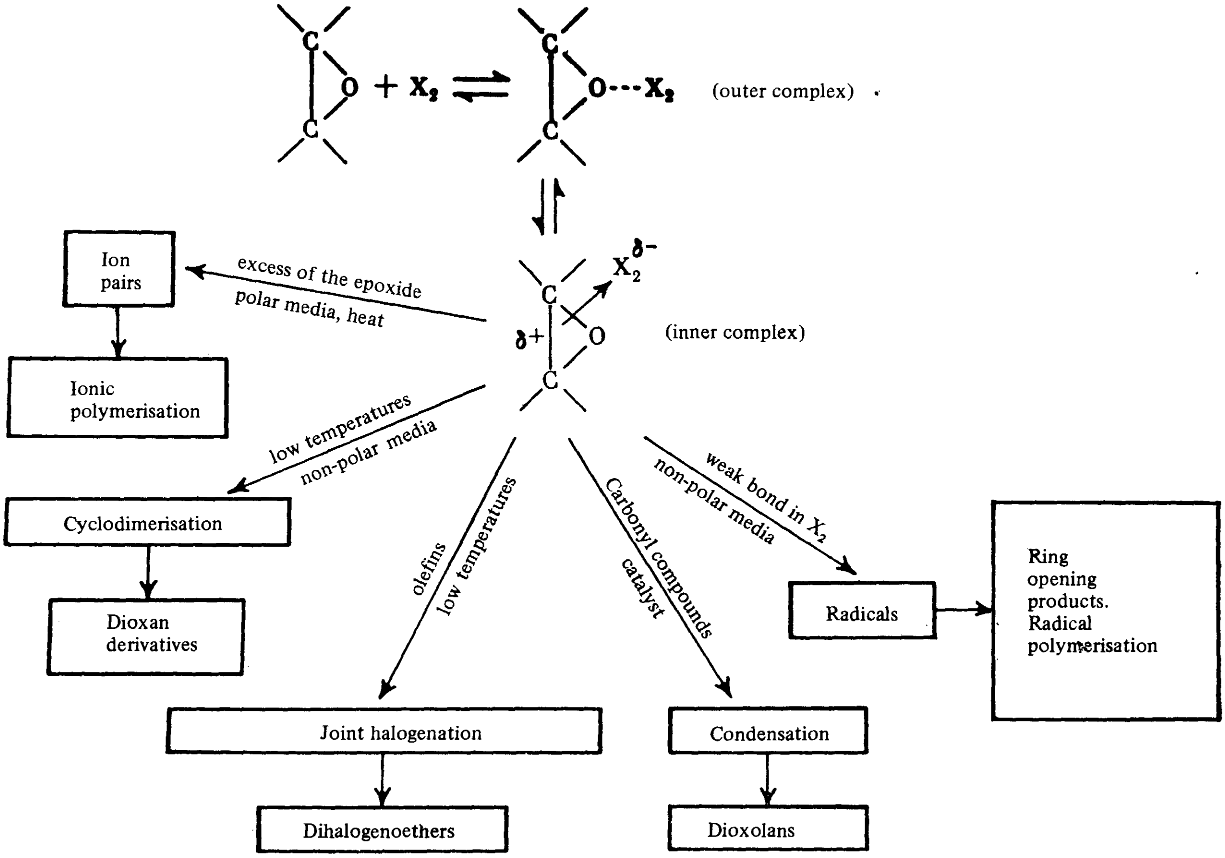


Figure 37. Reaction pathways in the halogen (X_2)—epoxide system.

selectivity. Selection based on different mechanisms can be achieved with the aid of complex-forming agents. Thus the addition of electron-donating compounds in the bromination of hex-1-ene suppresses the radical-chain pathway and makes it possible to obtain selectively the 1,2-addition product. The role of complex formation in energy-dependent selection was examined by Russell[98] as early as the 1960s. At low temperatures, where the energy-dependent selection is manifested most strikingly, these effects become particularly appreciable. When additive and substitutional chlorination of alkanes and chloroalkanes is carried out at 200–230 K in the presence of, for example, aromatic additives, 100% selectivity may be achieved.

The reactions of halogens with epoxides involve complex formation at the obligatory initial stage. Subsequent reaction of the complex proceeds via different pathways depending on the conditions: ionic polymerisation, molecular cyclodimerisation, and a radical-chain reaction involving the opening of the epoxide ring. In the presence of a third component (olefin, carbonyl compound, etc.) there is also a possibility of competition between the ionic, molecular, and radical mechanisms[99,100] (see the scheme in Fig. 37).

By varying the temperature and experimental conditions within wide limits, it is possible to isolate the molecular, radical, or ionic pathway in the halogenation reaction virtually in any system and hence one can obtain the product or the sum of products corresponding to only one of the possible pathways.

On transition of the system from the liquid to the frozen state, a new effective factor becomes available for controlling the rate and mechanism of the chemical reaction.

2. Catalytic Chlorination of Hydrocarbons

A common procedure for increasing the selectivity in radical reactions involves the introduction into the initiating systems of catalysts (organic or inorganic compounds), which behave as electron or ligand transferring agents. This approach does not always lead to the desired results, since the free radical in solution interacts not only with the catalytic transferring agent but also with other components of the medium.

A new approach to the solution of the problem of the selective synthesis of chloroalkanes involves carrying out the reactions under conditions where the reactants interact via the formation of radicals stabilised in the coordination sphere of a metal. It has been found that many halogen-containing iron compounds, where the metal ions exist in different oxidation states, for example hexakisacetonitrileiron(II) bis(tetrachloroferrate) $\{[Fe(II).(CH_3CN)_6][Fe(III)Cl_4]_2\}$, as well as other iron complexes, containing dimethylformamide or dimethyl sulphoxide as the neutral ligand, exhibit a high catalytic activity in the synthesis of chloroalkanes and make it possible to obtain different chloro-derivatives with a high selectivity[101]. The catalytic effect of dinuclear iron complexes has been demonstrated in chlorination by molecular chlorine, for example, in the reaction

and, when other chlorinating agents are used (for example, CCl_4):

$$CH_2{=}CH_2 + CCl_4 \rightarrow CCl_3(CH_2{-}CH_2)_nCl \quad \text{or}$$

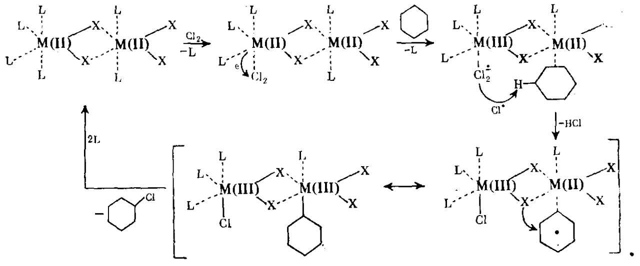
$$CH_2{=}CH{-}CH{=}CH_2 + CCl_4 \rightarrow CCl_3(CH_2{-}CH{=}CH{-}CH_2)_mCl \; .$$

Depending on the conditions under which it is synthesised and isolated and the conditions in the course of the catalytic reaction, the complex $[Fe(II)(CH_3Cl)_6][Fe(III)Cl_4]_2$ undergoes an intramolecular electronic transition, which leads to the formation of two different forms of Fe(II):

$$[Fe(II)L_6]\cdot[Fe(III)X_4]_2 \rightleftarrows [Fe(III)L_6]\cdot[Fe(II)X_4]\cdot[Fe(III)X_4] \rightleftarrows$$
$$\rightleftarrows [Fe(II)L_6] + [Fe(III)L_6] + [Fe(II)X_4] + [Fe(III)X_4] \; ,$$
$$[Fe(II)X_4] + [Fe(II)L_6] \rightleftarrows [Fe(II)L_6]\cdot[Fe(II)X_4] \; ,$$
$$[Fe(II)L_6][Fe(II)X_4] \rightleftarrows L_4Fe(II)X_2Fe(II)L_2X_2 \; ,$$
$$(X{=}Cl;\ L = CH_3CN;\ (CH_3)_2NCHO;\ \text{or}\ (CH_3)_2SO) \; .$$

In the presence of catalysts containing at least two Fe(II) atoms the chlorination reactions proceed via the intermediate formation of the radical-anions $Cl_2^{\overline{\cdot}}$ and $CCl_4^{\overline{\cdot}}$ in the coordination sphere of the metal.

After the transfer of the ligand to the substrate (cyclohexane, ethylene, and butadiene) coordinated to a neighbouring metal atom or after the elimination of a hydrogen atom, the reactions proceed via the formation of a metal–carbon bond or a radical resonance-stabilised in the coordination sphere of the metal. The close proximity of the reacting species in the coordination sphere of a dinuclear bridge complex increases sharply the process selectivity or leads to the appearance of new chlorination pathways. Thus, in the chlorination of cyclohexane the selectivity in the formation of the monochloro-derivative via the radical-chain mechanism does not exceed 80 mole %. In the presence of catalysts of the above type the selectivity in the formation of cyclohexyl chloride reaches 98–99 mole %.[101] The process involves the formation of $C_6H_{11}^{\cdot}$ radicals, bound in a complex, via the mechanism

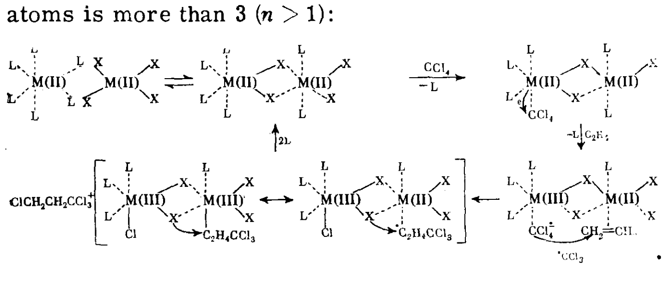


The chlorination of ethylene by carbon tetrachloride involves the reaction

$$CH_2{=}CH_2 + CCl_4 \rightarrow CCl_3(CH_2CH_2)_nCl$$

in which products with $n = 1$, 2, and 3 are formed.

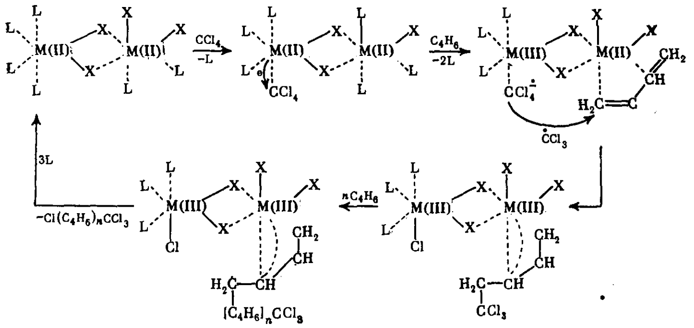
The use of a catalyst makes it possible to increase the selectivity in the formation of 1,1,1,3-tetrachloropropane ($n = 1$) from 30 to 95%. The catalytic process takes place in the coordination sphere of the metal, preventing the formation of isomers in which the number of carbon atoms is more than 3 ($n > 1$):



In the chlorination of butadiene[102] by CCl_4,

$$CH_2{=}CH{-}CH{=}CH_2 + CCl_4 \rightarrow Cl\,(CH_2CH{=}CHCH_2)_nCCl_3$$

the use of a catalyst leads to the formation of a chlorine-containing oligobutadiene—1,1,1,21-tetrachlorohenelcosane-3,7,11,15,19[$CCl_3(C_4H_6)_5Cl$, $n = 5$] with a selectivity of 95 mole %:



In the absence of the catalyst the above product is not formed at all.

It is seen from the examples quoted that the use of catalysts which propagate the process via an inner sphere mechanism in the coordination sphere of the metal constitutes an extremely effective procedure for altering the selectivity of chlorination reactions.

The Structure and Reactivity of Phosphorus Pentachloride

S.V.Fridland and B.D.Chernokal'skii

Data are presented on the reactions of phosphorus pentachloride with compounds containing oxa- and oxy-groups (ethers, acetals, oxetans, tetrahydrofuran, 1,3-dioxans, dioxolans, dihydropyrans, and alcohols). The structure of phosphorus pentachloride in various solvents and its influence on the course of reactions are considered. The mechanisms proposed for the reactions under discussion are analysed.

The bibliography includes 119 references.

CONTENTS

I. Introduction 742

III. Phosphorylation by phosphorus pentachloride of compounds without multiple bonds 743
IV. The mechanisms of the reactions of phosphorus pentachloride 745

I. INTRODUCTION

Interest in methods of synthesis of organophosphorus compounds containing a phosphorus–carbon bond is due to the practical importance of phosphonates and phosphinates and the development of theoretical ideas concerning the cause of the redistribution of old and the formation of new bonds.

The possibilities of phosphorylation with phosphorus pentachloride have been greatly expanded in recent years in connection with the use in this reaction of many ethers and a wide variety of oxa-compounds. A common feature of the latter reactions is that they proceed via a stage involving the formation of an α-halogeno-ether, which is capable of undergoing further dehydrochlorination. Definite advances have been achieved in the interpretation of the mechanisms of the interaction of phosphorus pentachloride with nucleophiles.

The history of the development of studies on the reactions of phosphorus pentachloride is described in Kabachnik's review[1] and has been supplemented by Pudovik and Khairullin[2].

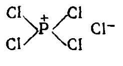
Thus the character of this review differs somewhat from that of the above publications and, apart from the description of syntheses, includes data on the structure of phosphorus pentachloride and the proposed mechanisms.

II. THE STRUCTURE OF PHOSPHORUS PENTACHLORIDE

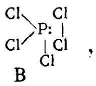
In many cases the phosphorus atom is capable of expanding its valence shell, probably by employing vacant $3d$ orbitals. It is believed that the problem of the degree of involvement of d orbitals in σ and π bonds should be solved separately for each specific instance[3]. The hybridisation of s and p orbitals with d orbitals leads to several geometrical shapes which are determined by different angular functions of the d orbitals[4]. One of the possible forms is a bipyramidal dsp^3-hybrid structure[5].

Studies on phosphorus pentachloride in the vapour state by electron diffraction[6,7] indicate a trigonal bipyramid. Phosphorus pentachloride molecules in the liquid phase have a similar structure, which has been confirmed by conductimetric and Raman spectroscopic studies[8]. The spectra proved to be characteristic of molecules with a trigonal bipyramidal structure[9-11]. The bipyramidal sp^3d-hybrid structure is believed to be energetically the most favourable[5] for derivatives of five-coordinated phosphorus and has been confirmed by the existence of many covalent compounds in which the phosphorus atom is linked to five ligands: PF_5, PF_3Cl_2, PCl_5, $P(OC_6H_5)_5$, and $P(C_6H_5)_5$.[12-15]

However, the involvement of d orbitals in the formation of bonds is not indisputable and the problem still remains controversial. The ionisation potential of the s electron in the free atom is ~19 eV.[5] Calculations have shown that the energy evolved on formation of five P–Cl bonds is less than the excitation energy required for the transfer of $3s$ electrons to the $3d$ level[16]. Pauling[17] suggested that PX_5 molecules are stabilised by means of five resonance structures[17] of type A and six structures of type B:



A



B

The Cl–Cl bond in structure B is longer than the usual bond and its formation does not entail an appreciable decrease of molecular energy. According to Pauling's hypothesis, the five atoms in structure A are linked as a result of the hybridisation of the $3s$ and $3p$ orbitals and as a result of the electrostatic attractions between the P^+ ion and the single negative charge distributed between the five electronegative atoms. The energetic feasibility of the structure was demonstrated by Hudson[18] in relation to the formation of phosphorus pentachloride:

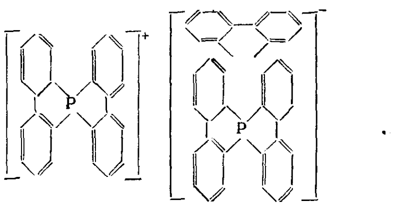
$$\ddot{P}Cl_3 \xrightarrow{-e} Cl_3P^{\dot{+}} \xrightarrow[-D_{P-Cl}]{Cl\cdot} Cl_4\overset{+}{P} \xrightarrow[-E_{Cl}]{e;+Cl\cdot} \overset{+}{P}Cl_4\overset{-}{Cl} \rightarrow Cl_4\overset{+}{P} \ldots \overset{-}{Cl} ,$$

where D_{P-Cl} is the dissociation energy and E_{Cl} the electrostatic interaction energy.

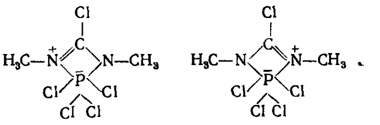
If it is assumed that $3d$ orbitals are involved in the formation of bonds in five-coordinated phosphorus compounds, then the formation of derivatives of six-coordinated phosphorus is also possible. This high valance is manifested in the PF_6^- and PCl_6^- ions corresponding to sp^3d^2 hybridisation[19,20]. Comparison of non-empirical calculations led Bochvar et al.[21] to the conclusion that the invocation of d orbitals in order to account for the electrophilic properties of phosphorus and the structure of its compound is not necessary. The authors believe that the bonds with axial ligands can be formed with participation of the p_z orbital of phosphorus and the atomic orbitals of the ligands, so that the hypothesis of the expansion of the valence shell of the phosphorus atom and of the existence of its sp^3d and sp^3d^2 valence states is not essential to account for the structure of phosphorus pentachloride and the PX_6^- anion. However, the conclusions in the above study[21] are not categorical; for this reason, we think it permissible to assume the involvement of *d* orbitals in bond formation.

The salt-like structure of phosphorus pentachloride has been confirmed by X-ray diffraction and by the determination of transport numbers in phosphorus pentachloride solutions in nitrobenzene[22,23]. According to ^{31}P NMR data, phosphorus pentachloride exists in the vapour state in a pentacovalent form (the chemical shift is +80 p.p.m.)[24]; in conformity with the ionisation hypothesis, two signals occur in a polar solvent: −91 p.p.m., which has been attributed to the $\overset{+}{P}Cl_4$ cation, and +281 p.p.m., attributed to the $\overset{-}{P}Cl_6$ anion. The phosphorus atom in the cation exists in the sp^3-hybrid state and the cation has a tetrahedral geometrical structure; the anion is a tetragonal bipyramid, which corresponds to sp^3d^2-hybridisation. The existence of tetrachlorophosphonium cations has been observed not only in the crystal lattice of phosphorus pentachloride but also in salt-like complexes, which have been examined by Horing and Baum[25] and studied in connection with ion transport in a nitrobenzene solution in the presence of aluminium trichloride and iron(III) chloride.[26,27] X-Ray diffraction analysis of crystalline compounds having the general composition $PCl_5.NbCl_5$ and $PCl_5.TaCl_5$, which showed that these compounds have heteropolar structures and consist of the $\overset{+}{P}Cl_4$ cation and the $NbCl_6$ and $TaCl_6$ anions respectively, led to the conclusion that the phosphorus is present in an ionic state[28].

The existence of phosphorus as a cation and an anion has been confirmed by an interesting reaction of phosphorus pentachloride with 2,2-dilithiobiphenyl and by a study of the resulting crystalline 'onium complex; the complex includes two phosphorus atoms with chemical shifts of −26.5 p.p.m. and +186.5 p.p.m.,[29] which corresponds to the structure:



X-Ray diffraction and ^1H and ^{31}P NMR spectra showed that the structure of the crystalline product [obtained by reaction of *N,N'*-dimethylchloroformamidine hydrochloride with PCl_5, $C_3H_6Cl_5N_2P$ (Ed. of translation)] with phosphorus in the six-coordinated state[30] may be represented by the formula



Thus, depending on the conditions, the phosphorus atom in PCl_5 may exist in both pentacovalent and ionic states. The nature of the structure is determined by external factors: the phase state, the type of solvent, and temperature. Thus it is believed that PCl_5 dissolved in carbon tetrachloride exists in a dimeric form while in methylene chloride it is monomeric[30-32]. It has been found[33] that PCl_5 in carbon tetrachloride is monomeric, the distortion being caused by the formation of associated species with the solvent. Analogous studies have been made for phosphorus halides R_nPX_{5-n} by NMR in solvents of different polarity and it has been concluded that these compounds have a pentacovalent structure in non-polar solvents[34]. The tendency to retain the pentacovalent structure falls in the sequence of substituents F > Cl > Br > I. Finally mention should be made also of the proposed structure (of the molecular complex type) of $PCl_3 \cdot Cl_2$, which is quite capable of existing under certain conditions: it has been detected for halides at a reduced temperature, but it is as a rule unstable on heating to room temperature[35-37].

Definite information about the structure of phosphorus halides is provided by nuclear quadrupole resonance (NQR). The ^{35}Cl NQR spectra of crystalline phosphorus pentachloride contain two groups of signals, which are similar within each group[37]. The NQR spectral frequencies quoted in the Table for phosphorus halides indicate the chemical non-equivalence of the chlorine atoms linked to phosphorus, which may be attributed to the non-equivalence of the axial and equatorial positions in the bipyramid[38]. The most bulky substituents occupy the equatorial positions, but this is probably not a general rule: thus the trichloromethyl groups is in the axial position. It is noteworthy that the structure of phosphorus pentabromide has not aroused controversy and is treated as ionic: $\overset{+}{P}Br_4\overset{-}{Br}$.[40] Phosphorus pentafluoride is treated as a pentacovalent compound[41].

The NQR spectra of phosphorus halides.

III. PHOSPHORYLATION BY PHOSPHORUS PENTACHLORIDE OF COMPOUNDS WITHOUT MULTIPLE BONDS

1. Phosphorylation of Ethers

Reactions of these types have been discovered and investigated recently and are not included in the reviews quoted above. A series of studies on phosphorylation by phosphorus pentachloride was stimulated by the investigation of Petrov et al.[42], who demonstrated the possibility of the phosphorylation of ethers, and suggested that the reaction proceeds via a stage involving the formation of an α-halogeno-ether, which gives rise to a multiple bond on dehydrochlorination:

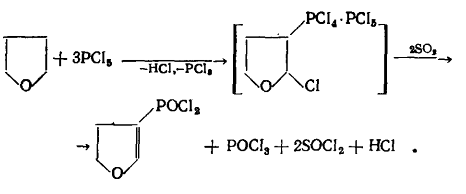
$$ROCH_2CH_3 + PCl_5 \xrightarrow{-HCl} [ROCHClCH_3 \xrightarrow{-HCl} ROCH{=}CH_2] + 2PCl_5 \rightarrow$$
$$\rightarrow [ROCHClCH_2PCl_3]^+ P\bar{C}l_6 \xrightarrow{SO_2} ROCH{=}CHP(O)Cl_2 + POCl_3 + SOCl_2 + HCl.$$

This was confirmed by a study of the reactions of phosphorus pentachloride with α-halogeno-ethers, which led to the isolation of the corresponding phosphonates[42-44].

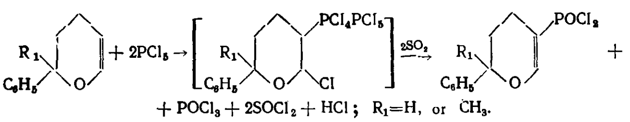
2. Phosphorylation of Cyclic Oxa- and Dioxa-compounds

These reactions, which were carried out for the first time with four-membered cyclic compounds, did not make it possible to synthesise phosphorus-containing products. The reactions with oxetans terminated with formation of di-(γ-chloropropyl) ethers:

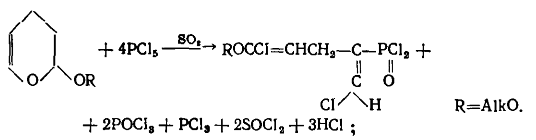
The reactions with tetrahydrofuran led to the synthesis of a phosphorylated product[45]:



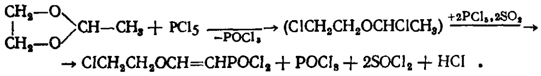
The reactions with dihydropyrans were also of the usual type:



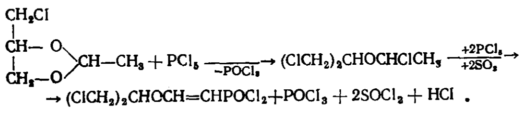
However, with R=AlkO the process occurred in such a way that the oxygen of the pyran ring was involved in the reaction, which was accompanied by consecutive chlorination and dehydrochlorination processes[46]:



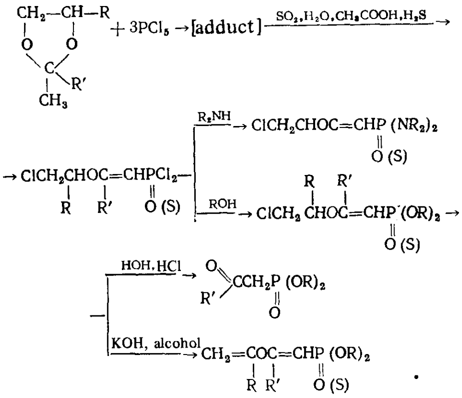
The first reactions with 4-methyl-1,3-dioxolan did not allow the isolation of products with a phosphorus–carbon bond[44]. On the other hand, a wide variety of derivatives of dioxolans and dioxans, containing substituents in the 2-position, led to phosphonates, confirming the general mechanism[47,48]:



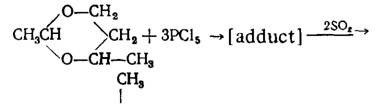
The properties of β-chloroethoxyvinyldichlorophosphonic acid agreed with data for the product synthesised by the reaction of β-chloroethyl vinyl ether with phosphorus pentachloride[49]. The characteristics of this reaction confirm its electrophilic mechanism. Electropositive substituents in the 2- and 4-positions facilitate the process appreciably and increase the yield of the final phosphonate[50]. An electron withdrawing substituent in the 4-position lowers the rate of the process and makes it possible to isolate the intermediate α-halogeno ether[51]:



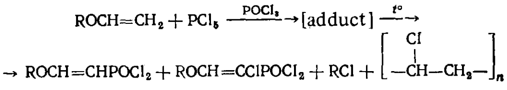
When the product is decomposed by hydrogen sulphide, derivatives of phosphonothioic acids are obtained. Thus the possibilities associated with these reactions can be described schematically as follows:



Derivatives of 1,3-dioxan containing an alkyl substituent in the 2-position react similarly with phosphorus pentachloride[52]:



In contrast to adducts with vinyl ethers, complexes with the above dioxolans and dioxans lead to the formation of phosphonates on heating[53]. This is caused by the phosphoryl chloride formed in the initial stages:

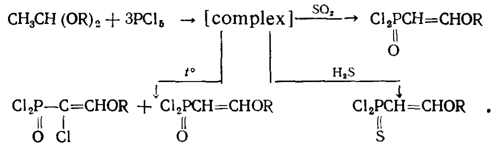


$$\mathrm{ROCH{=}CH_2 + PCl_5 \xrightarrow{POCl_3} [adduct] \xrightarrow{t^\circ}}$$

$$\mathrm{\rightarrow ROCH{=}CHPOCl_2 + ROCH{=}CClPOCl_2 + RCl + \left[\begin{matrix} Cl \\ | \\ -CH-CH_2- \end{matrix}\right]_n} .$$

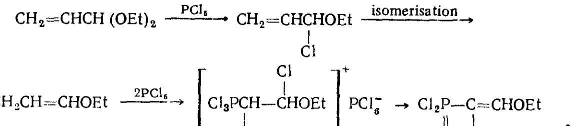
3. Phosphorylation of Acetals, Mercaptals, Hemiacetals, and Hemimercaptals

Oxa- and hydroxy-derivatives of hydrocarbons have been phosphorylated by phosphorus pentachloride[55]. The authors demonstrated the error of the earlier views[56] concerning the retention of the acetal group in the reaction and proposed the following mechanism for the phosphorylation of acetals:



They suggest that β-alkoxyvinylphosphonic dichloride and β-alkoxyvinylphosphonothioic dichloride are formed via an α-chloro-ether, as suggested previously[41]. The formation of β-alkoxy-α-chlorovinylphosphonic dichloride was explained by the occurrence of consecutive reactions: chlorination of the multiple bond of β-alkoxyvinylphosphonic dichloride and dehydrochlorination on heating during distillation. It was shown subsequently that ketals and acetals react with phosphorus pentachloride[57]. Bromoacetals do not enter into this reaction, most probably owing to the difficulty of the dehydrochlorination of the $\alpha\beta$-dihalogeno-ethers. Nor was it possible to isolate a phosphonate in the reaction with ethoxyacetal.

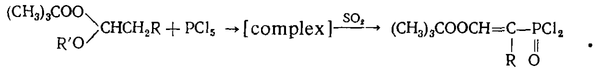
The reaction of acrolein acetals, which have two nucleophilic centres (the multiple bond and the acetal group) is interesting[58]. Studies on the structure of the final product, which is 1-chloro-3-ethoxyprop-2-enylphosphonic dichloride (the dichloride of 1-chloro methyl-2-ethoxyvinylphosphonic acid) suggested the following reaction mechanism:



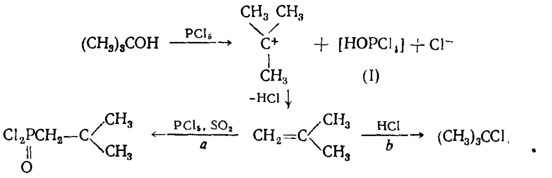
$$CH_2{=}CHCH(OEt)_2 \xrightarrow{PCl_5} CH_2{=}CH\underset{\substack{|\\ Cl}}{C}HOEt \xrightarrow{\text{isomerisation}} \rightarrow ClCH_2CH{=}CHOEt \xrightarrow{2PCl_5} \left[Cl_3P\underset{\substack{|\\ CH_2Cl}}{C}H-\overset{\substack{Cl\\ |}}{C}HOEt \right]^+ PCl_6^- \rightarrow Cl_2\underset{\substack{\|\\ O}}{P}-\underset{\substack{|\\ CH_2Cl}}{C}{=}CHOEt \;.$$

The reaction can be carried out with hemiacetals and hemimercaptals without their isolation and involves in essence the treatment with phosphorus pentachloride of mixtures of the alcohol (mercaptan) and aldehyde.[59] The yield of phosphonic dichlorides was, however, very low.

Phosphorus-containing unsaturated peroxides were obtained by the reaction of phosphorus pentachloride with acetals, acetates, and allyl ethers of α-hydroxyalkyl t-butyl peroxides[60]. It is of interest that the peroxy-group is preserved in this reaction:



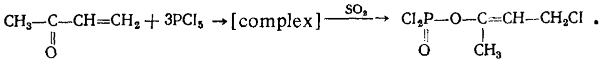
Many tertiary alcohols and their derivatives (ethers and esters) proved to be capable of being phosphorylated by phosphorus pentachloride under mild conditions[61,62]. The substitution of the hydroxy-group by chlorine proved to be a competing reaction under these conditions. It is suggested that in both cases the process begins with electrophilic attack by phosphorus pentachloride on the nucleophilic oxygen of the hydroxy- or ether group. This results in the formation of an olefin via a carbonium ion and complex (I). The decomposition of complex (I) into phosphoryl chloride and hydrogen chloride tends to increase the content of butyl chloride; a decrease of temperature lowers the rate of decomposition of the complex and promotes *C*-phosphorylation:



The phosphorylation of methyl phenyl ketone has been observed by Dogadina et al.[63], while Fokin et al.[64] showed that this possibility also exists for aliphatic ketones. It has been noted that 2-chloroalkenylphosphorus chlorides are formed in very small amounts. The reaction leads to the synthesis mainly of chloro-derivatives by the mechanism:

$$RC(O)CH_3 + PCl_5 \rightarrow RCCl_2CH_3 \xrightarrow{-HCl} RCCl{=}CH_2 \xrightarrow[-HCl]{+PCl_5} \rightarrow RCCl{=}CHPCl_4 \xrightarrow[-PCl_3]{} RCCl{=}CHCl \;.$$

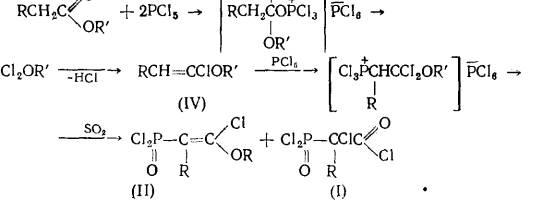
Methyl vinyl ketone reacted via the 1,4-addition mechanism, as in the phosphorylation of dienes[65]:



$$CH_3-\underset{\substack{\|\\ O}}{C}-CH{=}CH_2 + 3PCl_5 \rightarrow [\text{complex}] \xrightarrow{SO_2} Cl_2\underset{\substack{\|\\ O}}{P}-O-\underset{\substack{|\\ CH_3}}{C}{=}CH-CH_2Cl \;.$$

4. Phosphorylation of Esters

The reactions of phosphorus pentachloride with esters have been investigated in detail[66,67]. Analysis of the yields of products as a function of the reaction of the complex led the authors to the quite justified conclusion that the reaction proceeds via the addition of phosphorus pentachloride to the carbonyl group of the ester and that the adduct gradually decomposes to the $\alpha\alpha'$-dichloro-ether (III), which is dehydrochlorinated under the reaction conditions to the unsaturated α-chloro-ether (IV). This product undergoes further phosphorylation, similar to that of di-(α-chloroethyl) ether, by phosphorus pentachloride[68]:



Phosphorylation by phosphorus pentachloride is not restricted to the examples indicated above. It was found that dialkyl sulphides[69] also react with phosphorus pentachloride. The reaction has its characteristic features, because it gives rise to two types of phosphonic dichlorides as a function of temperature:

$$R-S-CH{=}CH\underset{\substack{\|\\ O}}{P}Cl_2 \quad \text{or} \quad R-S-\underset{\substack{|\\ Cl}}{C}{=}CH\underset{\substack{\|\\ O}}{P}Cl_2 \;.$$

The formation of β-alkylthio-β-chlorovinylphosphonic dichloride was noted for the first time[70].

The synthetic possibilities of the reactions with phosphorus pentachloride are very extensive and have been confirmed by the latest communications[71,72] concerning the reduction of phosphorus pentachloride–olefin adducts by reaction with silanes containing one or several Si–H bonds. The dichlorophosphines evolved under these conditions serve as the starting materials for the synthesis of a whole series of products.

The results of recent years examined above demonstrate the exceptional reactivity of phosphorus pentachloride and the wide scope of its use for the synthesis of phosphonates, which have found practical applications[73].

IV. THE MECHANISMS OF THE REACTIONS OF PHOSPHORUS PENTACHLORIDE

1. The Chlorination Reactions

Consideration of the chemical properties of phosphorus pentachloride suggests that it is an electrophile. This has been strikingly demonstrated by its reactions with alcohols, water, and organic acids. In relation to tertiary amines, phosphorus pentachloride exhibits the properties of a Lewis acid and yields salt-like adducts[74]. Acid properties are also shown in the reaction of phosphorus pentachloride with various derivatives of four-coordinated phosphorus containing the phosphoryl group and the reaction then involves the latter[75,76]:

$$PCl_5 + R_3P{=}O \rightarrow [Cl_5\bar{P}-O-\overset{+}{P}R_3] \;.$$

The five-coordinated derivatives of phosphorus are hard Lewis acids and form stable six-coordinated neutral complexes[77]. It is believed[78] that phosphorus pentachloride forms a negative ion even on reaction with hydrogen chloride:

$$PCl_5 + HCl \rightleftarrows H^+PCl_6^- \ .$$

The weakening of acid properties in the series of halides leads to a gradual substitution of the halogen by hydrocarbon groups[79,80]:

$$RPX_4 > R_2PX_3 > R_3PX_2; X = F, \text{or Cl}.$$

The pentahalides exhibit basic properties much more rarely. In these reactions they are converted into structures with a lower coordination [number]. Such processes include the above examples of reactions with aluminium chloride and iron(III) chloride. The following mechanism has been proposed in an interesting communication[75]:

$$F_3B \cdot NH_2CH_3 + 2PCl_5 \rightarrow CH_3N\begin{smallmatrix} \diagup \overset{+}{P}Cl_3 \\ \diagdown \overset{-}{B}Cl_3 \end{smallmatrix} + PF_3Cl_2 + 2HCl \ .$$

The lack of broad and specific studies on the reaction stages and of data on the structure of phosphorus pentachloride at the instant of the reaction precludes a unique representation of the mechanisms of reactions with its participation.

The mechanism of the interaction of phosphorus pentachloride with ketones has been deduced[81] on the hypothesis that it reacts in an ionic form and undergoes a series of successive transformations:

$$2PCl_5 \rightleftarrows \overset{+}{P}Cl_4\overset{-}{P}Cl_6 \ , \tag{1}$$

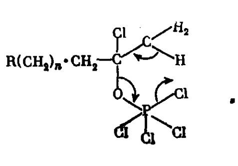
$$RCOCH_3 + \overset{+}{P}Cl_4 \leftrightarrows \left[\begin{array}{l} R\overset{+}{C}CH_3 \\ \ \ | \\ \ \ OPCl_4 \end{array}\right] , \tag{2}$$

$$\begin{array}{l} R\overset{+}{C}-CH_3 \\ | \\ OPCl_4 \end{array} + Cl^- \rightarrow \left[\begin{array}{c} Cl \\ | \\ R-C-CH_3 \\ | \\ OPCl_4 \end{array}\right] , \tag{3}$$

$$\begin{array}{l} \ \ Cl \\ \ \ | \\ RC-CH_3 \\ \ \ | \\ OPCl_4 \end{array} - \begin{cases} \xrightarrow{a} \begin{array}{l} \ \ Cl \\ \ \ | \\ RC{=}CH_2 + POCl_3 + HCl \end{array} \\ \xrightarrow{b} \begin{array}{l} \ \ Cl \\ \ \ | \\ R\underset{+}{C}-CH_3 + POCl_3 + Cl^- \end{array} \end{cases} , \tag{4}$$

$$\left[\begin{array}{c} Cl \\ | \\ R-\underset{+}{C}-CH_3 \end{array}\right] + Cl^- \rightarrow RCCl_2CH_3 \ . \tag{5}$$

The reaction begins with electrophilic attack on the carbonyl oxygen. The stage involving the formation of the chloro-olefin can, however, be represented, as in a later study[82], by a six-membered cyclic intermediate:



The different results obtained in the interaction of ketones with phosphorus pentachloride, using different solvents, were explained[83] by the different forms in which phosphorus pentachloride can exist: dimeric or monomeric. Depending on this factor, mechanisms were proposed for the reaction with benzylidenedeoxybenzoin. The influence of the solvent on the mechanism of the reaction with ketones was noted also in subsequent investigations.

Together with these mechanisms, the possible radical chlorination of benzene homologues[84] via the mechanism

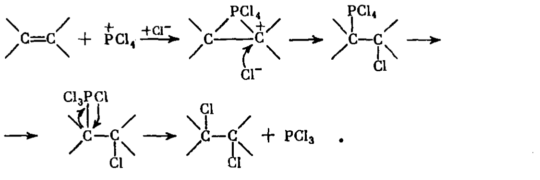
$$PCl_5 \rightleftarrows PCl_3 + Cl_2; \quad Cl_2 \rightleftarrows 2Cl^{\cdot}$$

or

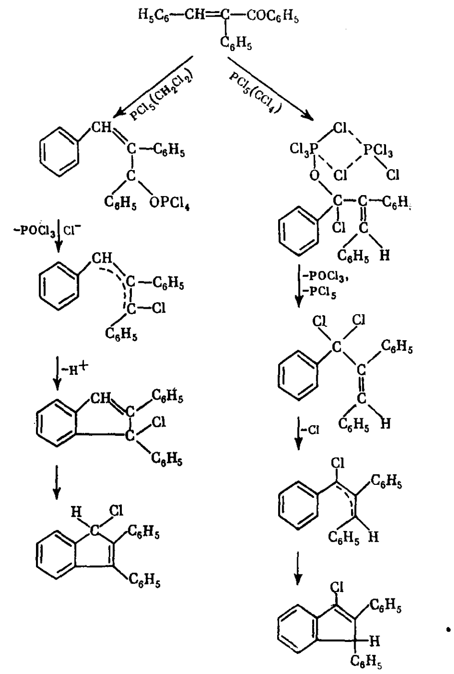
$$PCl_5 + R^{\cdot} \rightarrow RCl + {}^{\cdot}PCl_4; \ PCl_4 + RH \rightarrow R + HPCl_4; \ HPCl_4 \rightarrow PCl_3 + HCl$$

when a catalyst is present, has been reported.

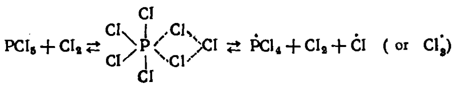
The following competing ionic mechanism has been put forward[84]:



The mechanism of the interaction of benzylidenedeoxybenzoin with phosphorus pentachloride in CCl_4 and CH_2Cl_2 is as follows:



It is believed[85] that catalysts of reactions involving chlorination by phosphorus pentachloride is due to its ability to be coordinated to a chlorine molecule, which favours the homolysis of the Cl–Cl bond:



Disregarding the numerous communications where the chlorinating activity of phosphorus pentachloride is reported[86], we shall examine the existing views on the mechanisms of its interaction with various types of hydrocarbons, which results in the formation of the phosphorus-carbon bond. Since studies on the phosphorylation by phosphorus pentachloride of compounds containing a multiple bond have already been described in other reviews[1,2], we shall examine below studies concerning the process mechanism.

2. The Phosphorylation Reactions

The most systematic studies, carried out by Bergman and Bondi[87], showed that the addition of phosphorus pentachloride occurs readily in reactions with asymmetrically substituted ethylene derivatives and leads to the formation of products whose hydrolysis gives rise to unsaturated phosphonic acids and the following mechanism was proposed:

$$RCH{=}CH_2 + PCl_5 \rightarrow RCHClCH_2PCl_4 \xrightarrow[-5HCl]{3H_2O} RCHCHP({=}O)(OH)_2\ .$$

The authors[87] did not isolate the intermediate, but noted that high yields require at least a twofold excess of phosphorus pentachloride.

Later studies[88,89] showed that the addition of phosphorus pentachloride to a multiple bond takes place in such a way that the $\overset{+}{P}Cl_4$ group adds to the most hydrogenated carbon atom, while the chlorine atom adds to the least hydrogenated carbon atom. The addition products can be regarded as binary compounds with phosphorus pentachloride:

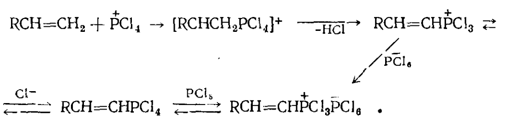
$$RCH{=}CH_2 + 2PCl_5 \rightarrow RCHClCH_2PCl_4 \cdot PCl_5\ .$$

It has been suggested[90] that the reaction of phosphorus pentachloride with unsaturated hydrocarbons may proceed without the formation of β-chlorophosphonic acid derivatives via an ionic mechanism:

$$RCH{=}CH_2 + {}^{+}PCl_4 \rightarrow R\overset{+}{C}HCH_2PCl_4 \xrightarrow[-HCl]{} RCH{=}CH\overset{+}{P}Cl_3 \xrightarrow{+{}^{-}PCl_6} RCH{=}CH\overset{+}{P}Cl_3PCl_6.$$

The formation of the intermediate addition product $ArCHClCH_2.PCl_4$ is believed to be unlikely[90]. In the reaction with styrene the structure $C_6H_5CH{=}CH\overset{+}{P}Cl_3\overset{-}{P}Cl_6$ is attributed to the complex, which takes into account its ability to interact with sulphur dioxide, styrene, and red phosphorus. These reactions are regarded as confirmation of the structure of the complex.

Grechkin and Kalabina[91] treat the above reaction as electrophilic substitution of hydrogen. They suggest that the reaction begins with the formation of a π-complex of the olefin and the $\overset{+}{P}Cl_4$ cation, which is stabilised after the elimination of hydrogen chloride. The resulting cation can react, according to the authors, with a Cl^- ion, whereby it is converted into alkenyltetrachlorophosphorane, or with a PCl_6^- ion, giving rise to a salt-like product. The mechanism is outwardly similar to that described by Fedorova and Kirsanov[90]:



$$RCH{=}CH_2 + \overset{+}{P}Cl_4 \rightarrow [RCHCH_2PCl_4]^+ \xrightarrow[-HCl]{} RCH{=}CH\overset{+}{P}Cl_3 \rightleftarrows$$
$$\xrightleftharpoons{Cl^-} RCH{=}CHPCl_4 \xrightleftharpoons{PCl_5} RCH{=}CH\overset{+}{P}Cl_3\overset{-}{P}Cl_6\ .$$

These mechanisms take into account the fact that, in the interaction with styrene or vinyl ethers[92], the addition of the phosphorus pentachloride-chlorine fragment to the multiple bond is not observed.

The authors concluded[90,91] that an electrophilic substitution mechanism operates solely on the grounds that no-one has isolated β-chloro-β-phenylethylphosphonate on phosphorylating styrene and that the reaction always leads to a compound with a multiple bond—styrylphosphonic dichloride (this also applies to the products of the interaction of phosphorus pentachloride with vinyl ethers). However, this cannot be regarded as proof of the mechanism, because the proton in the α-position relative to the phosphoryl group is known to be highly mobile, which was noted for the first time by Kabachnik[93,94]. As regards vinyl ethers, we may note the enhancement of the mobility of chlorine under the influence of the alkoxy-group. The elimination of hydrogen chloride from a series of α-halogeno-ethers is known to occur under very mild conditions[95]. In the intermediate phosphorylation products these substituents act in concert, leading to the formation of phosphonates containing a multiple bond. The halogenation of β-alkoxyvinylphosphonic dichlorides may serve as a model[96-98]:

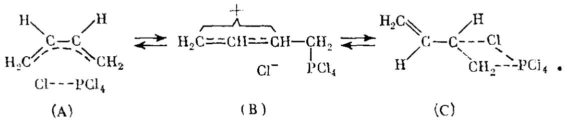
$$RO\overset{R'}{\overset{|}{C}}{=}CHPOCl_2 + Hal_2 \rightarrow \left[RO\overset{Hal}{\overset{|}{C}}{-}\overset{Hal}{\overset{|}{C}}HPOCl_2\right] \xrightarrow[-HHal]{t^\circ} RO\overset{R'}{\overset{|}{C}}{=}\overset{Hal}{\overset{|}{C}}POCl_2\ .$$

The phosphorylation of aliphatic olefins leads correspondingly to products without a multiple bond[99]:

$$RCH{=}CH_2 + PCl_5 \rightarrow [\text{adduct}] \xrightarrow[-SOCl_2]{SO_2} RCHClCH_2POCl_2$$
$$RCH{=}CHPOCl_2 + Br_2 \rightarrow RCHBrCHBrPOCl_2\ .$$

In a series of studies[100,102] on the phosphorylation of diene and acetylene derivatives by phosphorus pentachloride carried out in recent years a molecular reaction mechanism is postulated. It is believed that, in the reaction of phosphorus pentachloride with unsaturated hydrocarbons, several mechanisms may operate, differing in the degree of charge separation in the transition state and in the lifetime of the polarised structure, which leads, depending on the initial hydrocarbons, to the formation of products whose structure is determined by the process kinetics (acetylenes) or thermodynamics (dienes).

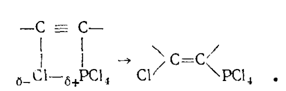
On the grounds of stereochemical considerations, the transition state in the reaction with dienes is believed to be highly polar and to incorporate the covalent structures A and C and structure B with separated charges:



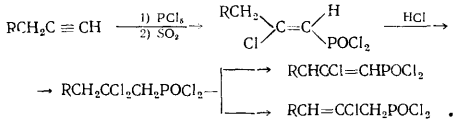
In the case of dienes the transition state is closer to the polarised structure B and this is sufficient for the occurrence of a rearrangement and the formation of thermodynamically more favourable isomers.

The stereospecific *cis*-addition to an isolated triple or double bond is believed[103] to be a confirmation of the addition of the phosphorus pentachloride molecule in a pentacovalent form.

The nature of the influence of substituents at the multiple bond on the mode of addition of the phosphorus fragment shows unambiguously that the addition process has an electrophilic mechanism and probably proceeds via a four-membered cyclic transition state:



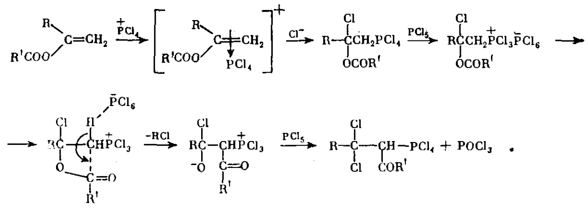
The possibility of a prototropic rearrangement in the reaction with acetylenic derivatives, leading to 2-chloroalk-2-enylphosphonic acids, has been examined[104]: however, other workers[105] reject the possibility of isomerisation, particularly since a prototropic rearrangement takes place in the presence of bases[106]. Bearing this in mind, Meisters and Swan[104] believe that the alk-2-enyl isomer is formed as a result of the addition-elimination of a further hydrogen chloride molecule:



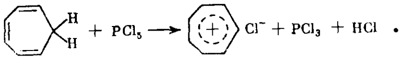
The results of the latest studies by Rybkina et al.[107] support a molecular mechanism of addition to multiple bonds. In their studies on the phosphorylation of olefins in different aprotic solvents the authors showed that in polar solvents, promoting the existence of phosphorus pentachloride in the form of an ionic dimer, the yields of the reaction products are a minimum, while in non-polar solvents, where phosphorus pentachloride exists in a molecular form, they are a maximum.

Finally, in connection with the discussion of the mechanisms of the phosphorylation reactions of ethers, acetals and cyclic oxa- and dioxa-compounds, we shall consider briefly studies where the dehydrogenating activity of phosphorus pentachloride was noted. This pathway was observed for the first time in the reaction of α-benzylstilbene with phosphorus pentachloride, which resulted in ring closure and the formation of 2,3-diphenylindene.[87,107]

In a study of the phosphorylation of esters containing a multiple bond by phosphorus pentachloride, Lutsenko and coworkers[109-114] included a deprotonation stage in the process mechanism:



Phosphorus pentachloride behaves similarly in the reaction with cycloheptatriene, which results in the formation of tropylium chloride, phosphorus pentachloride being reduced to the trichloride[115]:



In conclusion we shall consider the role of the formation of a complex by phosphorus pentachloride with an electrophile and nucleophilic centres: oxygen or a multiple bond. The transformations of the adducts of phosphorus pentachloride with vinyl ethers[54], styrene derivatives, and α-alkoxystyrene[116,117] may be regarded as an indirect confirmation of the formation of molecular donor–acceptor complexes by phosphorus pentachloride:

$$C_6H_5CH{=}CH_2 + PCl_5 \xrightarrow{t^\circ} C_6H_5CH{=}CClPCl_2 + 2HCl \;;$$

$$C_6H_5C(OR){=}CH_2 + PCl_5 \xrightarrow{t^\circ} C_6H_5CCl{=}CH_2 + POCl_3 \;;$$

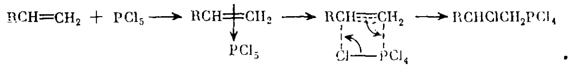
$$ROCH{=}CH_2 + PCl_5 \rightarrow [\text{adduct}] \xrightarrow{t^\circ} \text{chlorinated products};$$

$$2ROCH{=}CH_2 + PCl_5 \xrightarrow{POCl_3} [\text{adduct}] \xrightarrow{t^\circ}$$

$$\rightarrow ROCH{=}CHPOCl_2 + POCl_3 + RCl + [\overset{|}{C}H{-}CH_2{-}]_n + HCl \;.$$

Phosphorus-containing substances are formed only in those cases where it is possible to postulate the coordination of phosphorus pentachloride to a multiple bond (styrene). α-Alkoxystyrene and vinyl ethers react with phosphorus pentachloride to form only chlorination products, possibly owing to the formation of a complex involving the coordination of the alkoxy-group to an oxygen atom. The introduction of phosphoryl chloride into the reaction mixture in the process involving vinyl ethers promotes the formation of phosphorus-containing vinyl ethers.

The data examined suggest that the interaction of phosphorus pentachloride with olefins involves the following probable stages: (a) the formation of a donor–acceptor complex; (b) electrophilic addition of fragments of phosphorus pentachloride (Cl and PCl_4) to the double bond:



$$RCH{=}CH_2 + PCl_5 \rightarrow \underset{PCl_5}{RCH{=}CH_2} \rightarrow \underset{Cl{-}PCl_4}{RCH{=}CH_2} \rightarrow RCHClCH_2PCl_4 \;.$$

During the preparation of the review for the press, new original reports were published. Studies on keten[118] showed that phosphorus pentachloride interacts with it to form a phosphorus–carbon bond. The possibility of the simultaneous formation of bonds with two carbon atoms has been illustrated[119] in relation to the reaction with bis(α-chloromethylvinyl) sulphide.

In conclusion we may note that the preparative possibilities of phosphorus pentachloride in the syntheses of compounds with a phosphorus–carbon bond continue to expand. Among carbon-containing compounds, studies are being made not only on compounds with a multiple bond but also on those which are capable of forming multiple bonds under the influence of phosphorus pentachloride. It would be premature to express any definite view concerning the mechanism. The reactions with phosphorus pentachloride are complex and probably have a whole range of different mechanisms. It appears essential to investigate in greater detail the individual stages of the reactions, in the first place complex formation, and to elucidate the role of the third agent—sulphur dioxide, hydrogen sulphide, etc.

Heterogeneous Metal Complex Catalysts

A.Ya.Yuffa and G.V.Lisichkin

The review is devoted to methods of synthesis and catalytic properties of heterogeneous metal complex catalysts in which the selectivity and activity of homogeneous metal complexes and the technological advantages of traditional heterogeneous catalysts are combined. The adsorption and chemical interactions between the transition metal complexes and solid carriers (organic and mineral) are discussed and the activities and selectivities of heterogeneous metal complex catalysts and their homogeneous analogues are compared. Studies published up to 1976 are considered.
The bibliography includes 203 references.

I. INTRODUCTION

We are witnessing a vigorous growth of research in the field of homogeneous metal complex catalysis. Catalysis by transition metal complexes (TMC) is finding an increasing number of new applications as regards both theoretical and applied aspects: oxidation of hydrocarbons, stereospecific polymerisation, homogeneous hydrogenation, hydroformylation, and fixation of molecular nitrogen. This is by no means a complete list of the fields in which metal complex catalysts are used. However, although they have definite advantages over the traditional heterogeneous catalysts (high overall activity and selectivity), homogeneous catalysts suffer from significant disadvantages: their application requires the introduction into the process of a stage in which the reaction products and the catalyst are separated. The difficulty of isolating the catalyst from the reaction mixture and the difficulties associated with its reuse are responsible for the relatively small contribution of homogeneous catalytic processes to industry. The only exception is the polymerisation process in which the catalyst remains incorporated in the high-molecular-weight compound, which, incidentally, has an undesirable influence on the quality of the latter.

There is no doubt that in the foreseeable future heterogeneous catalysis will become dominant in industrial processes. Consequently catalytic systems involving heterogeneous catalysts based on transition metal complexes will be vigorously developed. Catalysts of this kind have come to be referred to as "hybrid"; it is believed that they are capable of ensuring the high selectivity and activity characteristic of homogeneous metal complexes and the technological usefulness characteristic of traditional heterogeneous catalysts. The development of studies in this field is hindered by the inadequacy of the theoretical ideas concerning the nature of the action of hybrid catalysts. For example, the problems of the influence of ligands on the catalytic activity of the metal ion, of the dependence of the catalytic activity on the carrier structure and on the number of transition metal atoms in the active centre, and the possibility of the occurrence of reaction on metal complexes in the absence of a solvent, etc. remain unsolved. A number of reviews have been devoted[1-16] to the synthesis and properties of heterogeneous catalysts obtained as a result of the conversion of transition metal complexes into heterogeneous formations on mineral and polymeric carriers.

Commereuc and Martino[13] suggest that heterogeneous catalytic systems be classified on the basis of three features: (1) the type of initial compound containing the transition metal atom; (2) the method used to activate the heterogeneous system; (3) the nature of the carrier-matrix. Although such classification is undoubtedly useful, it does not provide any information about the nature of the bond between the TMC and the carrier, which is very important from the standpoint of both the stability of the hybrid catalyst obtained and the interpretation of the results. Heterogeneous metal complex catalysts can be divided into the following types in terms of the nature of the bonds between the TMC and the carrier: (1) adsorption fixation of the TMC on the carrier; (2) binding of the TMC by ion-exchange resins; (3) π-coordination of the TMC on the carrier, which plays the role of a macroligand; (4) σ-binding of the TMC by the functional groups of the carrier; (5) the incorporation of the TMC in polymer gels.

It is readily seen that the methods used to convert the TMC into heterogeneous systems have much in common with those for the immobilisation of enzymes[17]. The main difficulty arising in the formation of heterogeneous systems from TMC is that the catalytic activity of the complex is caused either by the presence of a weakly bound ligand in the coordination sphere or the presence of a free coordination site. The interaction of the TMC with the carrier usually occurs via this "weak unit", which inevitably entails a loss of catalytic activity.

We shall consider below various methods for the conversion of the TMC into heterogeneous systems, noting, incidentally, the nature of the catalytic activity and, wherever possible, comparing the hybrid catalysts with their homogeneous analogues.

II. ADSORPTION BINDING OF TRANSITION METAL COMPLEXES

The first studies on the conversion of TMC into heterogeneous systems were concerned with the physical adsorption of such complexes on mineral carriers[18-23]. The general principle underlying the preparation of catalytic systems of this kind may be considered in relation to the study of Acres et al.[18] The familiar homogeneous isomerisation catalyst[24-26] $RhCl_3.3H_2O$ was dissolved in ethylene glycol and the resulting solution was added to a suspension of silica gel in methanol; after the removal of methanol, the catalyst showed a high activity in the isomerisation of pent-1-ene. Using the same method, Rony[21,27] compared the $(PPh_3)_2Rh(CO)Cl/SiO_2$ catalyst, which propagates the hydroformylation of propene. A similar catalytic system was prepared by Bond[28], who deposited the complex $RhH(CO)(PPh_3)_3$ on silica gel.

The study of the influence of the conditions of the catalytic process on the properties of the catalyst showed that four complexes converted into heterogeneous systems on a mineral carrier [$RhCl_3$ in the isomerisation reaction and $(PPh_3)_2Rh(CO)Cl$, $(AsPh_3)_2Rh(CO)Cl$, and $Co_2(CO)_6(PBu_3)_2$ in the hydroformylation reaction] are more active in the liquid-phase process, while Wilkinson's catalyst $(PR_3)_3.$ $.PhCl$ is more active under the conditions of a gas-phase process[29].

TMC have been deposited on mineral carriers also by controlled adsorption from the gas phase. Vasserberg and coworkers[30] prepared a nickel–alumina catalyst by the adsorption of nickel tetracarbonyl on alumina at a reduced pressure. After reduction with hydrogen (at 400° C for 12 h), the activity of the specimen was investigated in the reduction of carbon dioxide to methane and proved to be higher than that of specimens with the same amount of metal but obtained by precipitation or by impregnation of silica gel with nickel salts. This result can probably be accounted for by the significantly higher degree of dispersion of the metallic nickel obtained from the carbonyl.

A catalyst for the disproportionation of propene,

$$2C_3H_6 \rightarrow C_4H_8 + C_2H_4$$

has been obtained[31] from molybdenum hexacarbonyl. The authors found that the degree of reaction is highest in the range 290–340° and were also able to show that the active centre is the complex $Mo(CO)_x(C_3H_6)_{6-x}$ $(x = 3, 4)$.

The catalysts obtained by the deposition of $Mo(CO)_6$ on oxide carriers have also been studied[32-34]. Later investigations yielded more precise data on the nature of the active centres of deposited catalysts based on molybdenum hexacarbonyl[35,36] and the influence of poisons on their activity[37]. It is noteworthy that, when transition metal carbonyl compounds are adsorbed on oxide carriers, physical adsorption does not occur in all cases. Parkyns' study[38] of the interaction of nickel carbonyl with silica gel and alumina showed that, whereas the usual physical adsorption is observed on the former carrier, on the latter the vibration frequencies of the CO group in the infrared spectrum correspond to the vibrations of carbon monoxide adsorbed on nickel.

A number of studies have been made recently on the conversion of carbonyl cluster complexes into heterogeneous systems on mineral carriers[39-42]. The most interesting study[42] is that undertaken to compare the catalytic activities of the complexes Cp_2Ni, $Cp_2Ni_2(CO)_2$, and $Cp_3Ni_3(CO)_2$ ($Cp = \pi\text{-}C_5H_5$) "heterogenised" on silica gel. The nickel catalysts obtained by the decomposition of adsorbed complexes *in vacuo* at 80–120° C showed significant differences in their catalytic properties. Thus the catalyst obtained by the decomposition of nickelocene adsorbed on silica gel is active in the trimerisation of acetylene to benzene, unlike cluster systems. On the other hand, the H_2–D_2 exchange reaction and the hydrogenation of ethylene and benzene take place much more readily in the presence of polynuclear catalysts, while the hydroformylation reaction occurring in the presence of cluster catalysts does not take place at all in the presence of specimens obtained by the decomposition of adsorbed nickelocene.

The use of cluster compounds in catalysis opens new pathways in the formation of highly selective catalysts as well as catalysts capable of propagating structurally hindered processes[41,42]. From the standpoint of the theory of catalysis, a detailed study of such systems will make it possible to determine the structures of the active centres of traditional catalysts in various processes.

Catalysts based on cobalt, copper, silver, and platinum have been obtained by impregnating mineral carriers with TMC solutions[43-45]. A study of the low-temperature conversion of carbon monoxide over the CuO/SiO_2 and CuO/Al_2O_3 catalysts established that[43] specimens obtained from the amminecopper complex exhibit a higher activity than those obtained by impregnating alumina and silica gels with copper nitrate. Comparison of the catalytic activities[46] of the $RhCl_3.3H_2O$/C(act.) and Rh_2O_3/C(act.) systems[47] in the carbonylation of methanol

$$CH_3OH + CO \xrightarrow[CHI_3(\text{ind.})]{} CH_3COOH$$

yielded a similar result[46]. By studying the kinetics of this reaction in the presence of the $RhCl_3.3H_2O$/C(act.) catalyst and by comparing them with those of the homogeneous catalytic carbonylation of methanol in the presence of the free rhodium complex, the authors[46] found that the process mechanisms are the same in the two instances.

An interesting method of synthesis of hybrid adsorption catalysts was proposed by Mochido et al.[48] Using the Cu(II)–Y zeolite, obtained by ion exchange in an ammonia solution, as the carrier, they treated it in one case with ethylenediamine (EDA) and in another with dimethylglyoxime (DMG). The study of the infrared spectra showed that copper chelate complexes are formed with the organic reagents; the systems can be represented as Cu–DMG/Cu–Y and Cu–EDA/Cu–Y. The authors[48] studied the catalytic properties of the specimens in the decomposition of hydrogen peroxide and established that one complex molecule on the surface decomposes approximately 400 H_2O_2 molecules. It was observed that the activity of the Cu–EDA/Cu–Y catalyst is five times higher than the activity of the zeolite untreated with EDA; on the other hand, the Cu–DMG/Cu–Y specimen exhibits a lower activity than the initial zeolite.

A comparative study of the dimerisation of propene in the presence of homogeneous and heterogeneous catalytic systems incorporating nickel acetylacetonate and an organoaluminium compound has been carried out[49,50]. The authors were able to show that the adsorption of the catalyst on porous mineral carriers with a high specific surface leads not only to an increase of the stability of the action of the catalysts, but also to an increase of their thermal stability.

In conclusion of this Section one should note that a common deficiency of the adsorption methods for the conversion of TMC into heterogeneous systems is the low strength of the bond between the physically adsorbed complex and the carrier, which leads to the elution of the TMC from the carrier surface during the reaction. Furthermore, physical adsorption may entail the formation of polymolecular TMC layers, which lowers the efficiency of the active compound and may cause agglomeration of the complex, which also reduces the efficiency.

III. THE BINDING OF TRANSITION METAL COMPLEXES BY ION-EXCHANGE RESINS

The interaction of a cation-exchange resin with acid sodium tungstate led to the synthesis of a catalyst for the oxidation of maleic acid[51,52]:

A number of carbonylation, hydrogenation, and hydroformylation catalysts, obtained by the conversion of Group VIII transition metal complexes into heterogeneous systems on ion-exchange resins, have been patented[53-60]. Thus a method has been described[55] for the preparation of catalysts based on $[Pd(NH_3)_4]^{2+}$ with low- and high-molecular-weight counterions; the former catalysed the interaction of allyl chloride with carbon monoxide in a homogeneous system and the latter catalysed the same reaction in a heterogeneous system:

$$CH_2{=}CH{-}CH_2Cl + CO \rightarrow CH_2{=}CH{-}CH_2COCl\ .$$

It was found that both catalysts exhibit comparable activities and selectivities in the above reaction.

Hanson and coworkers[61,62] prepared hybrid catalysts using a sulphonated styrene–divinylbenzene copolymer containing sodium phosphinate groups as the ion exchanger. They investigated the reduction of the catalysts by hydrogen and hydrazine after the interaction of the ion exchangers with ammine complexes of platinum, palladium, nickel, and silver and the catalytic activities of the resulting catalysts in the oxidation of ethanol. A similar study has been made[63-66] using hydroxylated Amberlite A-27 as the carrier. The $PdCl_4^{2-}$/A-27, $RhCl_6^{3-}$/A-27, and $Pd(PPh_3)_4^{2+}$/A-27 catalysts, which are active in the hydrogenation of unsaturated compounds, were obtained.

Berenblyum and coworkers[67-70] obtained an effective hybrid catalyst for the hydrogenation of olefins on the basis of a new water-soluble complex $NaH_3[(acac)Rh(O_2)_2.$ $.Rh(OH)(H_2O)]$, by converting it into a heterogeneous system on an ion-exchange resin containing amino-groups.

Hybrid catalysts obtained by converting metal complex ions into heterogeneous systems on ion exchangers have an important advantage over physically adsorbed TMC, which consists in a greater binding strength. A disadvantage of these heterogeneous hybrid catalysts is the impossibility of using them to prepare uncharged complexes, particularly zero-valent complexes, which are widely used.

IV. π-COORDINATION OF TRANSITION METAL COMPLEXES TO POLYMERIC PHOSPHINO-MACROLIGANDS

Manassen[5] suggested that the catalytic activities of free TMC and TMC bound to a polymer chain should exhibit differences due to the orientation of the polymeric ligand, steric hindrance, and the change in the stability constant of the complex. According to Patchornik and Kraus[71], the bond between a TMC and a stereoregular insoluble polymer restricts the motion of the active centre on the surface; if the distance between the active centres is sufficiently large, it is possible to achieve a dilution such that they do not interact with one another. The rate of reaction should be higher in this case than in the usual homogeneous catalysis, because, according to the authors[71], catalyst molecules in solution lose part of their energy as a result of mutual collisions. Having adopted this view, one must suppose that fixation on the carrier promotes an increase of the activity of homogeneous catalysts. However, as will be shown below, this is by no means always the case.

The most frequently used polymeric carrier for conversion into heterogeneous systems by coordination is the styrene–divinylbenzene copolymer containing the diphenylphosphine group. This carrier-macroligand is synthesised as follows[72-76]:

(1)

The presence of phosphino-groups in the polymer makes it possible to coordinate the TMC to the phosphorus atom. Thus a number of workers[73,77-81] converted the familiar homogeneous Wilkinson's catalyst[82] into a heterogeneous system on a phosphinated styrene–divinylbenzene copolymer, having replaced one of the triphenylphosphine ligands in each molecule of the complex by the polymer-diphenylphosphino-group of the carrier:

Their method involves the establishment of equilibrium between the TMC converted into the heterogeneous system and the TMC in the inert solvent from which the complex is deposited; at room temperature such equilibrium is established in 2–4 weeks[73].

The study of the catalytic activity of the catalyst thus prepared in the hydrogenation of olefins demonstrated a significant dependence of the reaction rate on the size of the substrate molecules. While the relative rates of hydrogenation *w* of hex-1-ene, 2-cholestene, octadecene, cyclo-octene, and cyclododecene on the homogeneous Wilkinson's catalyst are comparable, when the hybrid catalyst is used, they (*w*′) differ strongly:

Olefin	Cyclohexene	Hex-1-ene	Δ^2-Cholestene	Octadecene	Cyclo-octene.	Cyclododecene
w′	1.00	2.55	0.03	0.50	0.40	0.23
w	1.00	1.40	0.71	0.71	1.00	0.67

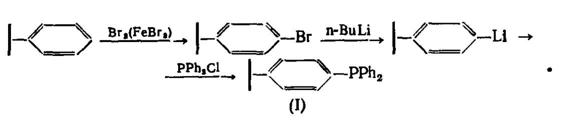
Thus it follows from the above investigation[73] that the conversion of a homogeneous catalyst into a heterogeneous system makes it possible to increase significantly its selectivity while retaining its high overall activity.

Analogous catalytic systems based on the styrene–divinylbenzene copolymer and different phosphine and chloride complexes of rhodium have been investigated[83,84]. The authors studied the possibility of using hybrid catalysts in hydroformylation and hydrosilylation reactions in addition to hydrogenation. By varying the low-molecular-weight ligands at the rhodium atom, the authors were able to choose catalysts for the selective hydrogenation of hept-1-ene, having almost completely excluded the parallel reaction involving the migration of the double bond. The catalyst —  $CH_2PPh_2...RhCl_x$ proved to be highly active in the hydrogenation reaction. An analogous catalyst had been obtained somewhat earlier[55].

Active hydroformylation catalysts were prepared by the above procedure from dicarbonylrhodium acetylacetonate and cobalt carbonyl[85,86]. The study of their catalytic activity in the hydroformylation of olefins[85] showed that they ensure 99% selectivity of conversion into an aldehyde for an overall degree of reaction of 87%.

Using Haag and Whitehurst's method[53], Bruner and Bailar[87,88] prepared a carrier based on the chloromethylated Amberlite HAD-4, containing benzyldiphenylphosphino-groups on the surface. Palladium and platinum chloride complexes were then coordinated to the phosphorus atom. The resulting catalysts were investigated in the hydrogenation of polyunsaturated hydrocarbons, and it was established that, for example, the palladium–polymer catalyst is extremely active in the selective hydrogenation of such hydrocarbons to mono-olefins. In addition, it has been found[87] that the hydrogenation of conjugated diene hydrocarbons proceeds faster than that of non-conjugated compounds. The platinum–polymer catalyst exhibits an activity under more severe conditions and its use requires the obligatory presence of tin chloride in proportions of Pt : Sn = 1 : 10.

Yet another method of synthesis of the polymer matrix has been proposed by Collman and coworkers[89]:



(I) (2)

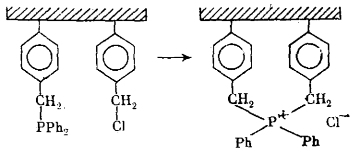
An advantage of this method is the possibility of grafting the diphenylphosphino-groups directly to the benzene rings of the styrene–divinylbenzene polymer. The reaction of compound (I) with $Rh_4(CO)_{12}$ and $Rh_6(CO)_{16}$ yields polynuclear heterogeneous metal-complex catalysts. Collman et al.[89] showed that hybrid catalysts having the general formula $MClL_3$ (where M = Rh or Ir and L = I) are more active than their homogeneous analogues.

The above method has been modified[90] by brominating the benzene rings of the polymer in the presence of thallium(III) ions:

The authors[90] then coordinated Wilkinson's catalyst and obtained a hybrid hydrogenation catalyst. The degree of binding of the complex to the polymer in the above study[90] was 0.53 mmole g^{-1}, which is somewhat less than in the study of Collman et al.[89] The composition of the active centre may be represented by the formula

 By comparing the activities of the hybrid catalyst with Wilkinson's catalyst, the authors[90,91] established the following characteristics of the hydrogenation of olefins: (1) olefins with a terminal double bond are hydrogenated faster than those containing a double bond within a carbon chain; (2) *cis*-olefins are hydrogenated faster than the *trans*-isomers; (3) olefins are hydrogenated faster than acetylenes. The dependence of the rate of hydrogenation of two double bonds in conjugated cyclic dienes on the ring size (cyclo-octa-1,3-diene > cyclohexa-1,3-diene) was demonstrated, that for the hybrid catalyst being significantly more pronounced than for the homogeneous catalyst. The authors[90] also studied the appreciable difference between the ratio of the *cis*- and *trans*-isomers of *p*-menthanes obtained by the hydrogenation of 1,(7)-*p*-menth-1(7)-ene. Thus the ratio is 2.0 : 1 for tris-triphenylphosphinerhodium chloride, while for the hybrid catalyst it amounts to 3.1 : 1, i.e, in this case the use of the hybrid catalyst entails a shift towards a higher selectivity.

A hybrid catalyst based on the phosphinerhodium complex fixed on a polystyrene macroligand has been synthesised by Mitchell and Whitehurst[92]. The catalyst was found to have a low activity in the hydroformylation reaction, which the authors explain by the presence on the polymer surface of a quaternary phosphorus atom which is incapable of coordinating the transition metal:

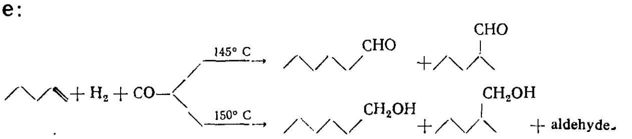


The activities of hybrid and homogeneous catalysts have also been compared in studies[7,93] where cobalt and nickel complexes grafted to the styrene–divinylbenzene copolymer were synthesised and investigated:

(II)

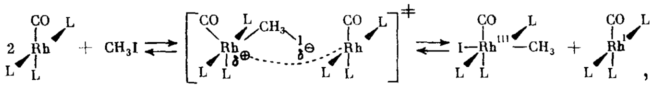
(III)

The former proved to be active in the isomerisation and hydroformylation reactions and the latter proved to be active in the cyclo-oligomerisation reaction. It is noteworthy that at high pressures the selectivity of the hydroformylation reaction is effectively regulated by temperature:



The hydroformylation of pent-1-ene has been studied[94] in the presence of the TMC $RhCl(CO)(PPh_3)_2$ and $RhH(CO).(PPh_3)_3$, converted into heterogeneous systems on a styrene–divinylbenzene matrix containing surface phosphino-groups. It was found that the catalytic activity and selectivity of the hybrid catalysts are the same as those observed for their homogeneous analogues.

In the general case the mechanisms of the action of the homogeneous and the corresponding hybrid catalysts are presumably the same, since the natures of their active centres are the same. However, it has been shown in relation to the carbonylation of methanol in the presence of the $RhCl(CO)(PPh_3)_2$ complex bound to a polymer[95] that the mechanisms of the homogeneous and heterogeneous catalytic reactions may differ. The difference was manifested by the change of the first order of the reaction with respect to rhodium to the second (for the hybrid catalyst), while the reaction was of zero order with respect to methanol and carbon monoxide and of first order with respect to methyl iodide (playing the role of a promoting agent) in reactions of both types. In view of their results, the authors[95] suggested that two rhodium centres are involved in the rate-limiting stage of the reaction in contrast to the mechanism of the homogeneous catalytic reaction:

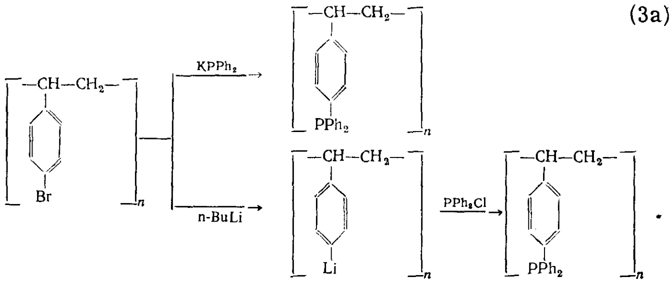


where L are polymeric and low-molecular-weight ligands which were not detected in the active form of the complex. According to this mechanism, the carbon of the CH_3I group undergoes nucleophilic attack by Rh(I) in the complex acting as a Lewis base; the second Rh(I) centre acts as a

Lewis acid, stabilising the transition state. This mechanism explains (although not completely) the possibility of the stereochemical formation of a transition state of this kind.

A large series of studies on the conversion of TMC into heterogeneous systems on polymeric carrier-macroligands containing phenylphosphino-groups have been carried out by Allum and coworkers[96-100], who showed[96] that, depending on the method of synthesis of the polymeric macroligand, it is possible to vary within wide limits the number of phosphino-groups fixed on the polymer. Thus, after treatment with potassium phenylphosphide, the polymer obtained by polymerising *p*-bromostyrene in the presence of benzoyl hydroperoxide contains 3.4 wt.% of phosphorus. A polymer containing 6 wt.% of phosphorus is obtained on synthesis via mechanism (3b), analogous to that proposed by Collman et al.[89] [see reaction (2) above]:

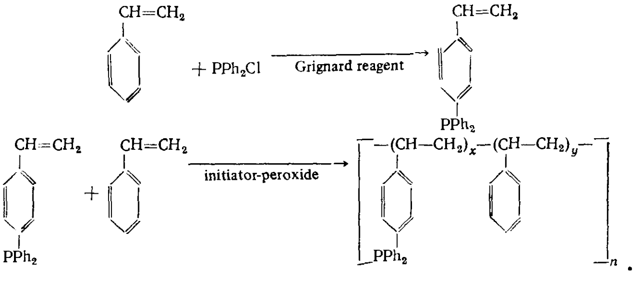
(3a)



(3b)

A somewhat smaller number of surface phosphino-groups is obtained in the synthesis of the matrix via reaction (1). In this case the polymer contains 4–5 wt.% of phosphorus.

A polymeric polystyrene matrix containing phosphino-groups can be obtained[5,93] by the polymerisation of *p*-diphenylphosphinostyrene[5,93]:



The preparation of other polymeric carrier-macroligands, suitable for the synthesis of hybrid catalysts and containing phosphino-groups, has been described[96-100]; poly(vinyl chloride), polychloroprene, polybutadiene, poly(vinyl alcohol), and other polymers have been used. Phosphino-groups were introduced into the first two polymers by direct reaction with $KPPh_2$. The phosphorus contents were respectively 11 and 3 wt.%. After preliminary treatment with hydrogen bromide, polybutadiene was treated with potassium diphenylphosphide, which yielded a product containing 6–8 wt.% of phosphorus. A phosphinated polybutadiene can also be obtained by the interaction of the initial polymer with diphenylphosphine under the influence of ultraviolet light[98]. Chlorodiphenylphosphine and dichlorophenylphosphine were used as phosphinating agents in the study with poly(vinyl alcohol). In the first case the polymer contained 1.7 and in the second 6–7 wt.% of phosphorus[96]. The authors suggest that the bond between phosphorus and carbon is formed via oxygen. The ready hydrolysability of this bond limited the practical application of the carrier. Nevertheless the above matrix makes it possible to employ phosphite groups in the conversion of TMC into heterogeneous systems.

Table 1. The composition of heterogeneous transition metal complexes.

Initial polymer	Polymeric ligand *P*, wt.%	TMC for conversion into heterogeneous form	
		TMC	metal, wt.%
Poly-*p*-bromostyrene	5.9	$CoCl_2$	0.7
Non cross-linked polystyrene	4.7	$CoCl_2$	4.3
Cross-linked polystyrene	4.35	$CoCl_2$	2.8
Amerlite HAD-2	2.0	$Ni(C_8H_{12})_2$	0.3
Amberlite HAD-2	2.0	$Rh(acac)\ (CO)_2$	2.0
Amberlite HAD-2	2.2	$[RhCl(C_8H_{12})]_2$	2.7
Poly-(vinyl chloride)	4.3	$CoCl_2$	4.6
Poly-(vinyl chloride)	4,75	$Rh(acac)\ (CO)_2$	7,3
Polybutadiene	7,9	$CoCl_2$	3.1

Table 1 presents the compositions of a series of heterogeneous TPM obtained by Allum et al.[96] It is noteworthy that complete information about the catalytic activity is available only for the TMC made heterogeneous on Amberlite, because only such hybrid catalysts are completely insoluble in the reaction media. It was found that the proportions of the phosphino-groups of the macroligand and the heterogeneous TMC may influence significantly the rate of the catalytic process. Thus the catalytic activity of a fixed iridium complex has been compared[101] with that of the analogous homogeneous catalyst in the hydrogenation of cyclo-octa-1,5-diene (1,5-COD) and the result shows that for P : Ir = 1 : 1 the degree of conversion of 1,5-COD in the presence of the polymer-bound catalyst is greater than for P : Ir < 5 (Table 2). The lower rate of the heterogeneous reaction compared with the homogeneous process for large P : Ir ratios was explained[101] by the low mobility of the heterogeneous complex.

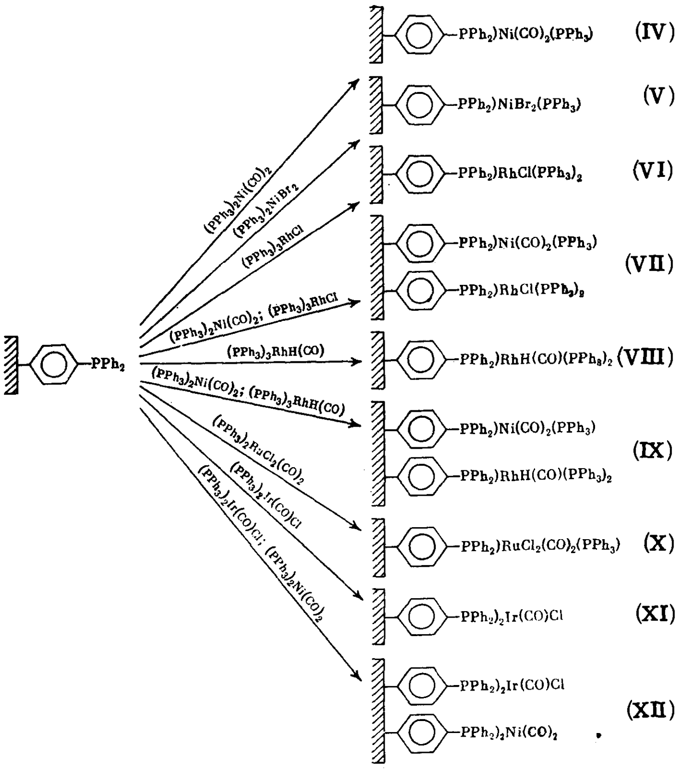
The influence of temperature on the catalytic activity of the hybrid catalyst was also noted[101]. The ratio of the activities at 170° and 80°C changed from 0.8 to 5 over the entire range of phosphorus contents in the polymer (from 1.91 to 10.28 wt.%). For a homogeneous catalyst, the ratio is always greater and lies in the range 8–10. Assuming the same mechanism of the catalytic activity over the entire temperature range, the authors explain this effect by the high mobility of the diphenylphosphino-groups fixed on the polymer.

Thus it becomes evident that, in the study of the properties of hybrid catalysts containing a carrier-macroligand and when they are compared with homogeneous analogues, it is necessary to take into account factors such as the concentration and mobility of the surface-active groups responsible for the coordination of the TMC. This creates additional difficulties in comparing hybrid and homogeneous catalysts and in simulating catalysts with specified properties.

The studies of Pittman and coworkers[102,105] on the preparation of hybrid catalysts which propagate a sequential multistep catalytic process are of considerable interest. The idea of devising such catalysts was put forward by Mossbach[106], who immobilised simultaneously hexokinase and glucose-6-phosphate isomerase on polystyrene and achieved the sequential conversion of glucose, initially into glucose-1-phosphate and then into glucose-6-phosphate. Thus the product of the first enzymatic reaction became the substrate of the second. Pittman and coworkers attempted to apply this concept to "heterogenised" TMC. In order to elucidate the nature of the influence of different "heterogenised" TMC on one another, catalysts were prepared[102] by the joint coordination of different metal complexes on a polystyrene–divinylbenzene copolymer containing phosphino-groups and by mixing catalysts prepared beforehand; the hybrid catalysts investigated are listed below.

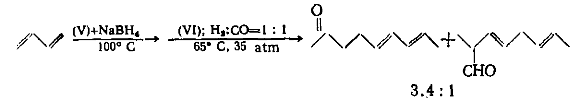
The oligomerisation of buta-1,3-diene was the model reaction in the studies of Pittman and coworkers. The data obtained for the activity of catalyst (IV) and the proportions of the reaction products were satisfactorily reconciled with those obtained earlier[107,108] for the activity of the homogeneous $(PPh_3)_2Ni(CO)_2$ catalyst. The complete correspondence of the homogeneous-catalytic reaction to the heterogeneous-catalytic process was explained[102–105] by the absence of steric hindrance for the small molecule of the diene hydrocarbon.

Catalyst (V), reduced by two equivalents of $NaBH_4$ to give polymer-bound zero-valent nickel, retained 90% of its activity and proved to be highly selective (98%) in the linear dimerisation of buta-1,3-diene[109]:



This result is inconsistent with data obtained in a study of the activity of the homogeneous $(PPh_3)_2NiBr_2$ catalyst[110], in the presence of which a whole series of products are obtained.

When catalyst (V) modified by sodium tetrahydroborate is mixed with catalyst (VI), an active catalyst, which selectively oligomerises and hydroformylates buta-1,3-diene, is obtained:



The combination of the oligomerising catalyst (IV) with the hydrogenating catalyst (VI), which has been suggested as catalyst (VII) on a common matrix, proved to be successful:

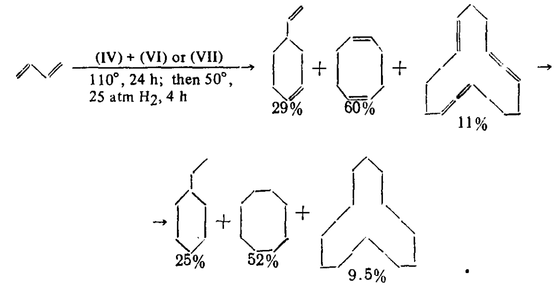


Table 2. Comparison of the rates of hydrogenation of 1,5-COD in the presence of the hybrid and homogeneous $Ir(CO)Cl(PPh_3)_2$ catalysts in benzene (170°C; 10 atm).

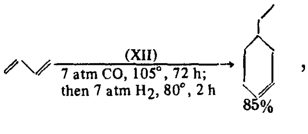
Catalyst	P:Ir	Total *P* content on polymer, wt.%	Time, h	Conversion	
				cyclooctene, %	cyclooctane, %
Homogeneous	3	—	33	37	3
Hybrid	3	4.02	0.25	57	4
Homogeneous	4	—	48	44	3
Hybrid	4	10.28	0.25	69	5
Homogeneous	6	—	72	68	11
Hybrid	7	4.02	93	5	0
Hybrid	7	1.25	0.20	68	6
Homogeneous	14	—	72	50	1
Hybrid	12	2.53	94	19	2
Hybrid	12	4.02	96	6	0
Homogeneous	22	—	72	15	0
Hybrid	22	4.02	93	18	2

By employing different version of hybrid catalysts based on $(PPh_3)_2Ni(CO_2)_2$ and $(PPh_3)_2RuCl_2(CO)_2$ [(IV) + (X)], it proved possible to obtain mono-olefins with a high degree of selectivity via the oligomerisation stage. It is noteworthy that homogeneous catalysts propagate the process analogously under the same conditions.

By varying different catalysts, Pittman and coworkers[102] obtained complete and partial hydrogenation, oligomerisation, and hydroformylation products from buta-1,3-diene, and the hybrid catalyst, obtained on a common matrix and carrying two different catalytically active groups, propagated the process in the same way as the catalyst obtained by mixing two complexes made heterogeneous separately.

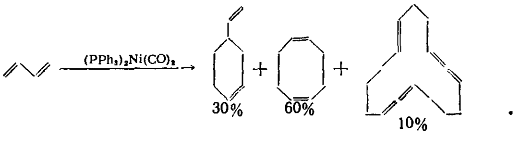
The observation of the process



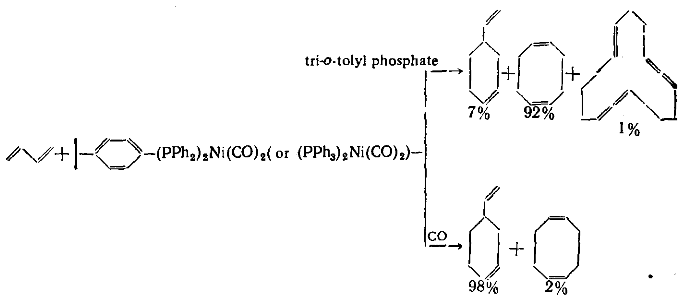
which occurs on catalyst (XII) with high yields, must be recognised as one of the most important results obtained[102].

The attainment of a high selectivity of the hybrid catalysts which propagate a consecutive multistage catalytic process increases significantly the effectiveness of such systems; this explains the attention which Pittman and coworkers[109,111,112] devoted to the preparation of selective oligomerisation and hydrogenation catalysts.

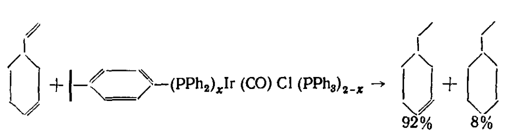
Conditions under which butadiene selectively dimerises either to 4-vinylcyclohexene (4-VCH) or to cyclo-octa-1,5-diene have been described[111]. The proportions of the butadiene oligomerisation products in the presence of the $(PPh_3)_2Ni(CO)_2$ homogeneous catalyst may be represented as follows[107,108]:



The promotion of this homogeneous catalyst or its "heterogenised" analogue by carbon monoxide or phosphite may alter significantly the selectivity of the catalytic system:

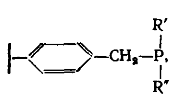


A catalyst capable of the selective propagation of the hydrogenation stage—the Vasko's complex "heterogenised" on a phosphinated styrene–divinylbenzene copolymer, i.e.



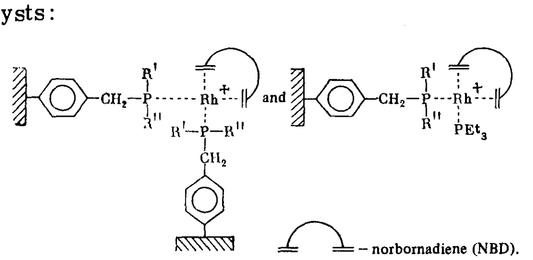
has been proposed[111] and the possibilities of this selective hydrogenation catalyst have been studied in detail[111,112].

By varying the substituents at the phosphorus atom of the polymer matrix, Graziani and coworkers[113,114] attempted to obtain a high selectivity of a hybrid phosphino-polymer catalyst, on which a transition metal complex had been deposited, in the hydrogenation of the double bond and the carbonyl group:



$$\text{—}C_6H_4\text{—}CH_2\text{—}P(R')(R'')$$

where R′ = R″ = Ph, or R′ = Me and R″ = Ph, or R′ = menthyl and R″ = Ph. The rhodium complexes [Rh(NBD).(acac)] and $[Rh(NBD)(PEt_3)_2]^+$ were fixed on the surface of the matrix, which resulted in the formation of the following catalysts:

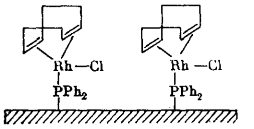


These deposited catalysts proved to be selective in the hydrogenation of the carbonyl group and the double bond of the olefin. It was noted[113,114] that the increase of the basicity of the phosphine coordinated to the rhodium atom increases the activity of the catalyst in the reduction of the carbonyl group, diminishing at the same time its activity in the hydrogenation of the olefin. It is noteworthy that in the study of the reduction reaction certain results may be partly distorted owing to the presence of the liberated metal.

Dumont et al.[115] investigated yet another ketone conversion reaction—catalytic hydroxylation. The hybrid catalyst consisted of a rhodium(I) complex "heterogenised" on a complex polymer matrix. The effectiveness of this catalytic system proved to be very similar to that of the corresponding homogeneous system. The possibility of repeated utilisation of the heterogeneous catalyst was noted as its main advantage.

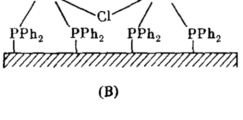
In conclusion we shall examine the structure of the active centres in the hybrid catalysts obtained. When complexes are "heterogenised" there is a possibility of two types of binding, in the first of which the phosphinated polymer plays the role of a monodentate macroligand, and in the second it chelates the TMC. It is noteworthy that this question is not as yet entirely clear.

Thus, on "heterogenising" the same complex $[RhCl(COD)]_2$ on phosphinated polystyrene, Collman et al.[89] and Grubbs et al.[116] reached different conclusions concerning the nature of the binding of the transition metal to the polymeric macroligand. According to Collman et al.,[89] when this complex is "heterogenised" on cross-linked (to the extent of 2%) polystyrene, the process reduces to the rupture of a Cl bridge, and the formation of the adduct

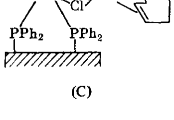


(A)

Grubbs et al.[116] established that, when the complex is "heterogenised" on a polymer with the same degree of cross-linking, two moles of COD are liberated per mole of the TMC, which may be represented by the surface structure B. For higher degrees of cross-linking of the polymer (20%), the way in which the rhodium complex is rendered heterogeneous alters, since 1.4 moles of cyclo-octadiene are evolved per mole of the adsorbed compound, which can be accounted for by the formation of the set of surface structures B and C:

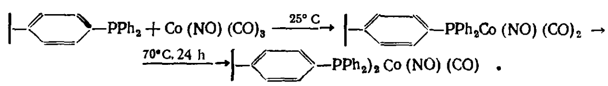


(B)



(C)

A study of the coordination of carbonyl TMC on phosphinated polystyrene matrices established[89,93] that, although in the majority of cases chelation by the carrier takes place, in certain cases a mixed type of coordination occurs [for example, when the complex $Rh_4(CO)_{12}$, to the active centres of which the structure  $(PPh_2)_{1.5}.$ $.Rh_4(CO)_{10.5}$ has been attributed, is made heterogeneous[80]] as well as monodentate binding, which may be transformed into chelate binding under more severe conditions[89]:



Collman et al.[89] also described the possibility of tridentate binding of the complex $RhCl(PPh_3)_2(CH_2 = CH_2)$ by the polymeric macroligand, which leads to the formation of a complete polymeric analogue of Wilkinson's complex.

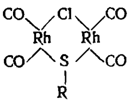
Thus one may conclude that the structure of the surface centres in the "heterogenised" complexes may depend on (1) the nature of the polymer, the structure of its surface group, and the degree of cross-linking, (2) on the composition and structure of the "heterogenised" transition metal complex, and (3) on the conditions under which the complex is "heterogenised".

V. THE BINDING OF TRANSITION METAL COMPLEXES TO OTHER POLYMERIC MACROLIGANDS

The preparation of hybrid catalysts based on polymers with phosphino-groups was examined above. Attempts have been made to achieve the coordination of the complex also to other groups.

The conversion of olefins into aldehydes and alcohols in the presence of rhodium-containing complexes on *p*-substituted polystyrenes, where the substituents were $-N(CH_3)_2$, $-CH_2N(CH_3)_2$, $-P(C_4H_9)_2$, $-CH_2PPh_2$, or -SH, has been studied[117] and it has been found that the hybrid catalysts and their homogeneous analogues have approximately the same selectivities in the formation of aldehydes. The phosphinerhodium complexes exhibited a very high selectivity in the formation of an aldehyde, while the aminerhodium complexes showed a high selectivity in the formation of an alcohol. On the other hand, the activity of the hybrid amino-catalyst in the above reaction proved to be much higher than that of its homogeneous analogue.

The cleavage of the dimeric rhodium complex $[Rh(CO_2)Cl]^2$ by monomeric amines and phosphines has been investigated[118]. When the complex was rendered "heterogenised" on a polymer, a hybrid catalyst propagating the hydrogenation and hydroformylation reactions was formed. The study of the influence of monomeric and polymeric thiols on the cleavage of the heterogeneous complex showed that monomeric thiols do not cleave the complex molecule, giving rise to $[Rh(CO)_2RS]_2$, while polymeric thiols yield a product having the following structure:

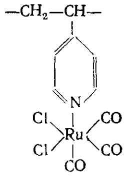


Mitchell and Whitehurst[92] rendered a rhodium carbonyl complex heterogeneous on a polystyrene polymer containing ethylamino-groups:

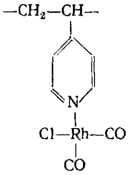
The catalyst thus obtained showed a very low activity in the hydrogenation of methyl linoleate, but exhibited an exceptionally high selectivity in the selective hydrogenation of a single double bond: it propagates the hydrogenation of terminal double bonds significantly faster than that of inner double bonds.

Moffat's studies[119,120] led to new possibilities in the employment of finished polymers as matrices for the fixation of transition metal complexes in order to obtain hybrid catalysts. When cobalt carbonyls were made heterogeneous on poly-2-vinylpyridine, it proved possible to obtain an active hydroformylating system and it was established that only approximately 40% of the nitrogen atoms of the polymeric carrier are capable of participating in complex formation with cobalt carbonyl. The hydroformylation of hex-2-ene in the presence of such a system at 165–170°C takes place to the extent of 50% (p = 124 atm, $H_2 : CO = 1:1$).

Braca et al.[121] prepared a hybrid catalyst by attaching the complexes $[RuCl_2(CO)_3]_2$ and $[RhCl(CO)_2]_2$ to linear poly-4-vinylpyridine (P4VP):

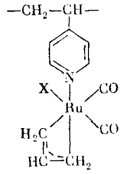


(XIII)



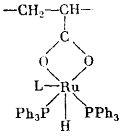
(XIV)

However, the metal-polymer complex catalysts obtained proved to be relatively inactive and operated only under very severe conditions. Thus the first of two catalysts (XIII), used in the synthesis of ethers from propene, CO, and methanol, propagated the process at 30 atm and 190°C. Under these conditions, the complex was rapidly split off from the polymeric matrix and the polynuclear complex $Ru_3(CO)_{12}$ was formed[122]. In an attempt to obtain a higher activity of a hybrid ruthenium complex catalyst, the authors[123,124] fixed the $RuCl(\pi-C_3H_5)(CO)_3$ and $RuBr(\pi-C_3H_5)(CO)_3$ complexes[123,124] to P4VP and the complex $RuH_9(PPh_3)_3L$ (where L = PPh_3 or CO) to polyacrylic acid:



(X = Cl, or Br)

(XV)



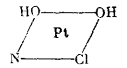
(XVI)

(L = PPh_3, or CO).

The hybrid catalyst (XV) proved to be active under relatively mild conditions (100°C) in many reactions employing unsaturated hydrocarbons as substrates (for example, in the isomerisation of but-1-ene), the complex remaining attached to the polymer under the reaction conditions. By comparing the activities of hybrid complexes (XV) with their homogeneous analogues in the isomerisation of but-1-ene, Braca et al.[121] established that, while their selectivity remains the same, the activity of the catalysts deposited on the polymer is in many cases higher than that of the homogeneous TMC. In the isomerisation and hydrogenation of pent-1-ene in the presence of complex (XVI) the hybrid catalyst is significantly less active than its homogeneous analogue, which the authors attributed to the steric hindrance to the reaction arising in the presence of the polymeric catalyst.

A whole series of catalysts for the hydrosilylation of alkenes, alkynes, and alkadienes, active in liquid and gaseous phases, have been prepared[84,125-129] by "heterogenising" certain TMC (for example chloroplatinic acid and tetracarbonylrhodium dichloride) on styrene–divinylbenzene copolymers with surface dimethylamino- and cyano-groups.

Studies of the catalytic properties of platinum, iridium, rhodium, and palladium chloride complexes deposited on nylon (where the transition metal atom is coordinated to the nitrogen atom of the peptide group in nylon) in the hydrogenation of benzene established[130-132] that, in order to obtain an active catalyst, the presence of a hydroxy-group in the coordination sphere of the complex is necessary. The structure of the catalytically active platinum complex obtained by depositing H_2PtCl_6 on nylon is[130]

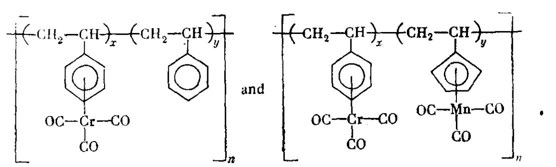


.

When the catalytic activities of metal–nylon complexes with respect to benzene hydrogenation products, referred to 1 gram-atom of the metal, are compared, the metals can be arranged in the following sequence: Ir > Pt > Rh > Pd.[132]

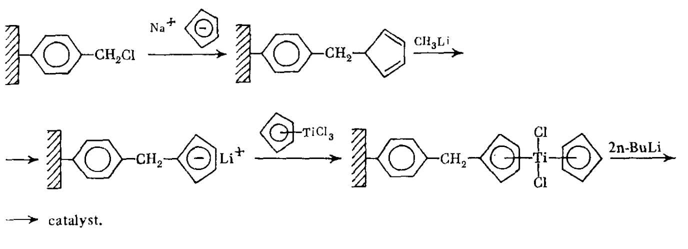
One must note that the hydrogenation of metal-complexes on a polymeric support does not always lead to the formation of a hybrid catalyst. Thus Kraus and Tomanova[133], who attached $PdCl_2$ to a styrene–divinylbenzene copolymer containing $-CH_2-CN$ surface groups, did not obtain a catalyst active in relation to olefins.

Transition metal complexes can be bound to a polymeric matrix by a procedure other than via heteroatomic groups specially introduced into the polymer and coordinating the transition metal. For example, by employing the benzene rings of polystyrene as a π-coordinating agent and synthesising polymers with a specified structure, Pittman and coworkers[124,125] obtained complexes having the following composition:

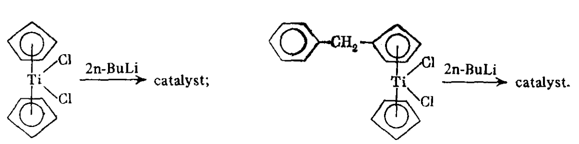


The first catalytic system proved to be active in the selective hydrogenation of methyl sorbate to methyl-3-hexenoate in cyclohexane at 160°C and 35 atm.[134]

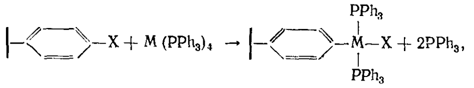
Grubbs et al.[116] synthesised a styrene–divinylbenzene copolymer with attached titanocene, which was thus made heterogeneous:



This system proved to be six times more active in the hydrogenation of cyclohexene than the corresponding homogeneous catalytic systems:



Mizoroki et al.[136] proposed a new method for converting transition metal complexes into heterogeneous systems on a polymer by the formation of a σ-bond between the transition metal atom and a carbon atom in the polymeric matrix. This approach is based on studies[137-139] in which σ-aryl complexes of nickel, palladium, and platinum were obtained by the oxidative addition of an aryl halide to the corresponding tetrakis(triphenylphosphine) complexes of transition metals. The reaction with halogenated polystyrene was carried out as follows[140]:



where M = Ni, Pd, or Pt and X = Br or I.

The complexes prepared in this way were treated with boron trifluoride etherate in the presence of small amounts of water and were investigated as catalysts of the dimerisation of ethylene and propene[136,141]. The former reaction was studied using the catalyst in the liquid phase and the latter was studied in the vapour phase in the presence of a hybrid catalyst—activated by BF_3OEt_2/H_2O (in proportions of 10 : 1). As regards the nature of the catalytic activity, these systems are identical with their low-molecular-weight analogues, although their activities are somewhat lower.

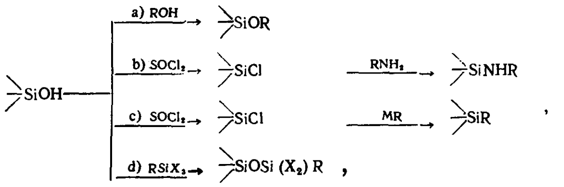
VI. CONVERSION OF TRANSITION METAL COMPLEXES INTO HETEROGENEOUS SYSTEMS ON MINERAL CARRIERS

The employment of polymeric carriers in order to convert TMC into heterogeneous systems makes it possible to apply a wide variety of synthetic methods. However, all the above catalysts suffer from one common disadvantage: the polymeric base of the systems is responsible for their low thermal stability and low resistance to the action of oxidants. Mineral carriers are free from this disadvantage. Studies dealing with the deposition of TMC on mineral carriers can be divided into two groups: (1) conversion into a heterogeneous system via a coordination reaction using organosilicon compounds as agents fixing the TMC to the surface; (2) conversion of TMC into heterogeneous systems directly on the mineral carrier via the functional groups of the latter.

The most widely used mineral carrier is coarsely porous silica gel subjected to preliminary hydroxylation, although it has been stated[142-144] that alumina gel and crystalline and amorphous aluminosilicates have been used to "heterogenise" TMC.

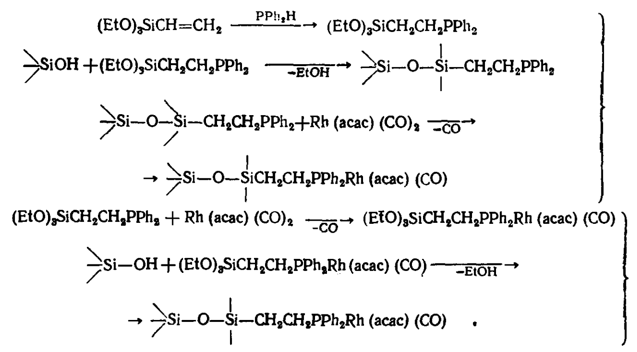
1. Conversion into Heterogeneous Systems Using Organosilic Compounds

Functional groups can be grafted to silica gel in several ways:



where R is an organic hydrocarbon group, X a readily hydrolysable group such as Cl, OR, or OCOR, and MR an organometallic compound such as LiR or XMgR. The synthesis of macroligands for hybrid catalysts by methods (a)–(c) has not been described in the literature, but there are data concerning the preparation of a carrier for TMC by method (d), which is probably due to the greater thermal stability and greater resistance to hydrolysis of the Si–C bond compared with those of the Si–O–C and Si–N–C linkages. Furthermore, the attachment of the functional group by method (d) can be readily achieved in a single stage under mild conditions and makes it possible to employ a large set of modifying agents.

The investigations of Allum and coworkers[145–153] of the preparation of hybrid catalysts based on silanised silica gel must be regarded as the first studies of this kind. Such catalysts are synthesised in accordance with the following schemes[145,149]:



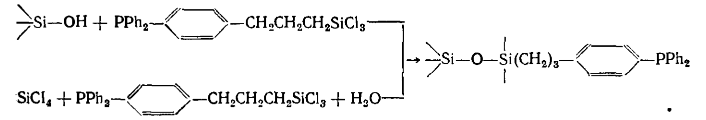
(4)

(5)

It is noteworthy that not only the rhodium acetylacetonate complex but also other rhodium, palladium, and platinum complexes may be converted into heterogeneous systems[152].

The catalysts prepared in this way were used in hydrogenation and hydroformylation processes[145,150], but their activity was somewhat lower than that of the corresponding low-molecular-weight analogues. By "heterogenising" other transition metal complexes, the limits of the applicability of such heterogeneous catalysts are expanded and they can be used for the isomerisation and acetoxylation of olefins, for the oligomerisation of dienes, for the polymerisation and cyclo-oligomerisation of acetylenes[149], and for the hydrosilylation of olefins[151–153]. Apart from the phosphino-group, the following "anchor" groups have been used: $-CH_2CH_2CN$, $-CH_2CH_2CH_2NH_2$, $-CH_2CH_2CH_2NEt_2$, $-CH_2CH_2CH_2SH$, $-CH_2CH_2CH_2CH_2-$  $CH_2N(CH_2PPh_2)_2$, and $-CH_2CH_2CH_2N$.[150–152]

Moreto et al.[90] prepared a phosphine-containing silica gel matrix to which they subsequently coordinated $RhCl(PPh_3)_3$ and $[RhCl(C_2H_4)_2]_2$:



The study of the catalytic activity of rhodium complexes fixed on a phosphinated silica gel support in the hydrogenation of *p*-menth-1(7)-ene showed that the ratio of the *cis*- and *trans-p*-menthanes obtained in the reaction is 9.2 : 1, which indicates a higher selectivity of the catalyst compared with homogeneous Wilkinson's catalyst and the rhodium complex "heterogenised" on polystyrene (see Section IV)[90].

Thus one may claim that in many instances a fairly high process selectivity may be achieved on synthesising hybrid catalysts by coordinating TMC to a phosphinated silica gel.

Comparison of the catalytic activities of complexes "heterogenised" on a phosphinated polymer and on a mineral carrier, which makes it possible to estimate the influence of the support on the catalytic properties of the systems, is of great interest. The data of Michalska and Webster[154], who established that the rate of hydrogenation of pent-1-ene in the presence of $RhH(CO)(PPh_3)_3$ attached to a phosphinated silica gel is six times higher than in the presence of a complex bound to a polystyrene matrix, provides one of the few examples of such a comparison. The authors[154] explained this effect, which has been observed also by other investigators[80,103], by the hindered diffusion of the substrate molecules to the active centres within the polymer pores. Furthermore, they established[154] that the activities of the complex $RhH(CO)(PPh_3)_3$ "heterogenised" on silica gel and its homogeneous analogue are virtually indistinguishable. The rates of hydrogenation of pent-1-ene are in proportions of 1.3 : 1.4. Similar results were also obtained in another investigation[80].

We believe that the similarity in the behaviour of catalysts "heterogenised" on silica gel and the homogeneous catalysts can be explained by the fact that the silicon–hydrocarbon support to which the complex is attached creates conditions for the additional mobility of the active centre, as a result of which the properties of the "heterogenised" complex on a mineral support approach those of the homogeneous complex and differ from the complex bound to a polymer.

2. Conversion into a Heterogeneous System with Formation of a σ-Bond between the Transition Metal and the Carrier

The disadvantages of the preparation of hybrid catalysts by the method described above include the large number of stages in the synthesis and its long duration as well as insufficient stability of the bond between the TMC and the matrix. These disadvantages may be eliminated by the direct interaction of TMC with the mineral carrier, which results in the formation of stable σ-bonds between the central metal atom and the carrier.

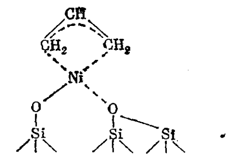
The first studies in this field include those described in Refs.155–158. Here we shall only mention that, by modifying the surface of aluminosilicate with tris-π-allylchromium, Shmonina and Stefanovskaya prepared a catalyst which proved to be active in the *trans*-1,4-polymerisation of butadiene and isoprene. Subsequently the copolymerisation of butadiene and isoprene was achieved in the presence of the same catalytic system[159,160].

Detailed systematic studies have been made on the structures and catalytic activities of catalysts obtained by modifying mineral carriers with π-allyl complexes of transition metals[158,161-170,172-187]. A general method for the preparation of such catalysts has been examined in relation to the fixation of bis-π-allylnickel in the presence of silica gel[158,173]:

$$\geqslant Si-OH + Ni(C_3H_5)_2 \rightarrow \geqslant Si-O-Ni(C_3H_5) + C_3H_6 \ .$$

It was shown that this is the main type of binding, involving the elimination of one propene molecule, although at a higher concentration of the organometallic compound or in the presence of silica gel heated at a higher temperature, binding to the oxygen groups of the carrier is possible (see also Skupinsky and Malinovski[188]):

Square coordination obtains in a surface organonickel complex:



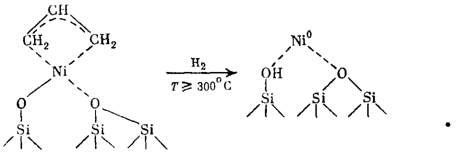
Ermakov et al.[161] established an interesting feature of the π-allyl linkage in the surface complex. They found that, in terms of a number of properties, it differs significantly from the linkage in bis-π-allylnickel, being thermally more stable, but at the same time showing a greater tendency towards hydrolysis. Thus the heterogeneous complex reacts with water at 20°C to give propene.

It has been shown[158] that surface compounds may be used as catalysts of different processes in three states.

1. In the initial state, i.e. directly after treating the carrier with the π-allyl complex. Such surface coordination compounds can serve as active centres in the polymerisation of olefins and dienes[162-164,166,167] and the disproportionation of olefins (propene)[168,169,184]. Comparison of the catalytic activities of hybrid catalysts with those of their homogeneous analogues showed that, whereas bis-π-allylnickel[170] and tetrakis-π-allylmolybdenum[171] do not induce the polymerisation of butadiene, the allyl complex of nickel deposited on silica gel gives rise selectively to the *cis*-1,4-polymer, $Ni(C_3H_5)_2/Al_2O_3$ produces the *trans*-1,4-polymer, while $Mo(C_3H_5)_4$ deposited on carriers gives rise to a polymer having a mixed structure. Furthermore, butadiene is known to polymerise in the presence of π-allylnickel halides with the preferential formation of the *trans*-1,4-polymer[172], while the π-allylnickel halide system on silica gel induces *cis*-1,4-polymerisation[162].

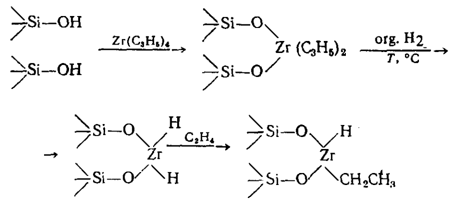
Thus one may claim that hybrid catalysts are more capable of increasing significantly the activity and of altering the selectivity, compared with their homogeneous analogues.

2. In the reduced state, where the low-valence state of the transition metal atom is stabilised by the surface groups of the carrier. The reduction of the surface allyl complex of nickel is described by the scheme



It is of interest that the stabilisation of nickel atoms by the oxygen atoms of the silica gel matrix is so pronounced that it protects them from further agglomeration to large crystals. This follows from data obtained in a study of the magnetic susceptibilities of specimens of nickel catalysts[158]. The catalysts obtained in the reduced state proved to be active in hydrogenation reactions[158,173], while a deposited and reduced molybdenum complex was active in ammonia synthesis[174].

An interesting study has been made on the stabilisation of highly dispersed platinum on silica gel (obtained after the deposition and reduction of π-allyl complexes) by molybdenum prepared similarly. The formation of Pt-Mo clusters has been suggested and then proved by X-ray photoelectron spectroscopy; such clusters protects the platinum atoms from further migration and agglomeration to form crystals[180,183]. A catalyst of the polymerisation of ethylene, whose structure and the mechanism of its action have been determined mass-spectrometrically, has been prepared in the reduced state by depositing tetrakis-π-allylzirconium on silica gel[175,176]:



3. A hydrogen oxidation catalyst has been prepared in the oxidised state[165]:

$$(\geqslant SiO-)_2MoO_2 \ .$$

Not only allyl complexes of transition metals but also their chloride complexes have been "heterogenised"[166]; the $TiCl_3/SiO_2$ catalyst proved to be active in the polymerisation of ethylene. Studies[189,190] on the polymerisation of ethylene on "heterogenised" cyclopentadienyl, arene, and allyl complexes of chromium are closely related to those of Ermakov and coworkers[165,166]. Zhorov and coworkers[191,192] employed the same approach as Ermakov and coworkers[165,166] and deposited benzonitrilepalladium complexes on silica gel. In their earlier study of the activity of these compounds in homogeneous systems[193,194] they had established that the complex $(PhCN)_2PdCl_2$ is exceptionally active in the migration of the double bond and that the addition of methanol appreciably accelerates this reaction. A significant disadvantage of the introduction of methanol into the system is rapid decomposition of the complex with liberation of metallic palladium.

Zhorov et al.[191] established that the complex attached to silica gel is 100 times more active in the isomerisation of pent-1-ene than its homogeneous analogue and that the introduction of methanol into the heterogeneous system does not affect its activity. The results led to the hypothesis that the deposition results in the formation of the stable complex $>$Si-O-PdClLL′ or $>$Si-O-PdClL$_2$ (where L′ = benzonitrile and L = labile olefin ligand), while in the presence of methanol added to the homogeneous system, unstable compounds having the composition CH$_3$O-PdClL$_2$ are formed.

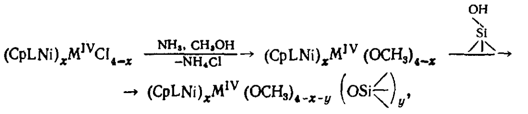
The study of the activities of hybrid catalysts demonstrated a distinct maximum at a specific metal complex concentration, which was explained by an optimum amount of (PhCN)$_2$PdCl$_2$ for hydrogenation, above which the reaction

$$2L'_2PdCl_2 + 2L \rightarrow (LPdCl_2)_2 + 4L',$$

takes place, and the benzonitrile liberated as a result competes in coordination, lowering the overall activity of the catalyst.

It is noteworthy that the results of Zhorov et al.[191] require further confirmation, since only exact data on the structure of the surface groups make it possible to demonstrate unambiguously the structure of the catalyst.

Another approach was used by Lisichkin and coworkers[195-198] in the preparation of hybrid catalytic systems, the essential feature of which is that complexes of nickel bound to a Group IVA element are used as the organometallic compounds:



$$(CpLNi)_xM^{IV}Cl_{4-x} \xrightarrow[-NH_4Cl]{NH_3,\ CH_3OH} (CpLNi)_xM^{IV}(OCH_3)_{4-x} \xrightarrow{\text{HO-Si}} \rightarrow (CpLNi)_xM^{IV}(OCH_3)_{4-x-y}\left(OSi\lessdot\right)_y,$$

where L = PPh$_3$, PBu$_3$, or CO, M^{IV} = Si, Ge, or Sn, x = 1 or 2, and y = 1, 2, or 3. The strength of the Ni-M^{IV} and M^{IV}-O bonds is responsible for the absence of the aggregation of nickel atoms on the silica gel surface up to 250°C. Treatment of the fixed complexes with hydrogen at an elevated temperature leads to partial elimination of the ligands and to the appearance of catalytic activity.

Since tin and germanium can combine not only with one but also with two nickel atoms, Lisichkin et al.[198] were able to compare the activities of mono- and di-atomic nickel centres in the hydrogenation of olefins. It was found that catalysts with diatomic centres are not only more active but also more stable.

By varying the nature of the ligands at the nickel atom, it was possible to alter specifically the selectivity of the catalysts. Thus it was shown[197] that the usual impregnated nickel catalyst, modified with triphenylphosphine, exhibits the same selectivity as the triphenylphosphine-nickel complex fixed on silica gel.

VII. INCORPORATION OF METAL COMPLEXES IN POLYMER GELS

In 1971, Kabanov[199] suggested that the catalytic systems consisting of grains of polymer gels in the bulk phase of which the corresponding active centres are immobilised be used as catalytic systems. A characteristic feature of such catalysts is the possibility of the occurrence of reactions not only on the surface of the grain, but also throughout the bulk of the swollen polymer particle. In such systems the effectiveness of the utilisation of the active centres should be just as high as in heterogeneous catalysts. At the same time the reaction products should be readily removable from the catalytic gel.

Subsequently Kabanov and coworkers[200] undertook a series of studies devoted to the formation of metal complex gel-like polymerisation catalysts. They showed that catalysts of this type exhibit a high stability, polymerising, for example, ethylene at elevated temperatures up to 200°C, i.e. under conditions where the usual catalysts of the Ziegler-Natta type are deactivated very rapidly. After the catalyst had been used for 2000 h, virtually no decrease of activity was observed. The yield of the polymer after this period may reach up to 500 kg per gram of the transition metal. It is extremely significant that the polyethylene obtained in the presence of gel-like catalysts contains virtually no transition metal compounds, i.e. does not require washing. Each catalyst grain consists in essence of a tiny reactor from which the polymer formed diffuses to the surrounding solution, while the metal compounds forming part of the composition of the active centre remain firmly bound inside.

The use of catalytic systems of this kind requires, however, particular attention to processes involving the diffusion of the reaction product from the gel-like particle. Clearly, in the synthesis of polymer molecules with a high molecular weight the reaction rate begins to be limited by the rate of diffusion.

The literature data presented in this review show that the "heterogenised" TMC are likely to be very useful in catalysis. Despite the fact that there is still a long way to go before a detailed understanding of the action of deposited metal catalysts is achieved, certain important conclusions may already be made.

Fixation of TMC on mineral and polymeric carriers to form heterogeneous systems makes it possible to retain to a large extent the activity and selectivity of the corresponding homogeneous catalysts.

In many instances conversion into heterogeneous systems, makes it possible to increase significantly the activity of the homogeneous catalyst owing to the greater stability of the coordination-unsaturated state of the transition metal atom on the surface and the absence of agglomeration of the active particles.

Conversion of TMC into a heterogeneous form gives rise to great possibilities for the development of catalysts with the structure of active centres specified beforehand by varying the nature of the metal, the mode of binding to the carrier, the nature of the ligand, etc.

The improvement of methods for the conversion of TMC into heterogeneous systems will apparently make it possible to synthesise heterogeneous catalysts with complex but entirely identical active centres, i.e. to solve the problem of the formation of catalysts the selectivity of the action of which is similar to that of enzymes.

During the period when the manuscript was with the editors, numerous new studies devoted to "heterogenising" TMC on both organic and mineral carriers were published. A fairly complete list of publications on the "heterogenisation" of TMC up to the middle of 1977 is given in the bibliographic guide published by the Institute of Catalysis of the Siberian Division of the USSR Academy of Sciences[201]. The great interest of investigators in the problem of the synthesis and study of hybrid catalysts is indicated by the proceedings of the conferences held in Novosibirsk (June, 1977)[202] and Lyons (November, 1977)[203]. One can apparently conclude that heterogeneous metal complex catalysis is one of the principal fields in which modern catalytic chemistry will develop.

Analysis of studies published recently shows that the following main trends have arisen: (1) the synthesis of hybrid catalysts without homogeneous analogues; (2) the development of methods of synthesis of bi- and polyfunctional catalysts; (3) the use of organometallic compounds for the synthesis of highly dispersed deposited metallic catalysts; (4) the conversion of metal complex cluster compounds into a heterogeneous form.

One should bear in mind that the possibilities of catalysis by transition metal complexes fixed on a surface have been by no means fully utilised. The use of hybrid catalysis containing a fixed chiral centre has given rise to considerable possibilities for asymmetric catalytic synthesis.

There have been virtually no studies concerning the application of metal complex catalysis to processes which can be achieved only at elevated temperatures. The use of stable "heterogenised" complexes on mineral carriers will make it possible to solve this problem.

Advances in the Chemistry of Verdazyl Radicals

O.M.Polumbrik

Data relevant to the methods of synthesis of various verdazyl mono-, bi-, tri-, and poly-radicals as well as their analogues (tetra-azapentenyl, tetrazolinyl, and phototetrazolinyl radicals) are discussed, and the reactions of verdazyls not involving the free valence are considered; data are presented on the structures, spectra, and physical and chemical properties of verdazyls. Attention has been concentrated on problems of the kinetics and mechanisms of chemical reactions involving verdazyls. Problems of the practical applications of verdazyls in chemical, physical, and biological research (inhibition of free-radical reactions, stabilisation of polymeric materials, spin labels, redox indicators, galvanic cells, etc.) as well as the prospects for the development of this new class of stable radicals are discussed.

The bibliography includes 242 references.

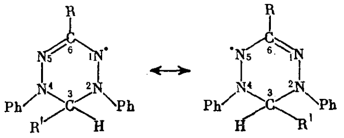
I. INTRODUCTION

Verdazyls (tetrahydrotetrazinyls) occupy a special place amonst stable radicals. The striking stability of verdazyls, the ease with which their reactions may be studied by spectroscopic methods, and their ready solubility make them suitable objects for the solution of many chemical and physicochemical problems. Since the discovery of verdazyls by Kuhn and Trischmann[1-3] (1963), more than 150 papers have been published on the synthesis, structures, and physicochemical properties of verdazyls. Certain aspects of the chemistry and physicochemical properties of verdazyls are dealt with in a number of publications[4-6].

In the present review attention has been concentrated on the structures, methods of synthesis, reactivities, and practical applications of verdazyls; other problems (EPR, NMR, and quantum-chemical calculations) are dealt with in less detail.

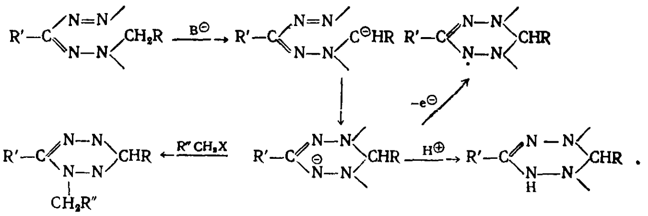
II. METHODS OF SYNTHESIS OF VERDAZYLS

Verdazyls were discovered in studies on the alkylation of formazans[7,8]. A characteristic feature of verdazyls is the obligatory presence in the 2- and 4-positions of aromatic substituents (the substituents at the carbon atoms in the 3- and 6-positions may be varied[9,10]):

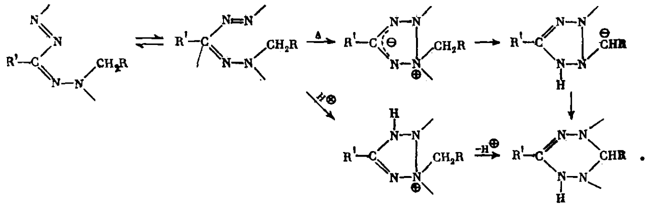


(I) $R' = H, R = Ph$;
(II) $R' = H, R = p\text{-}X\text{-}C_6H_4$;
(III) $R' = CH_3, R = Ph$;
(IV) $R' = H, R = (CH_3)_3$.

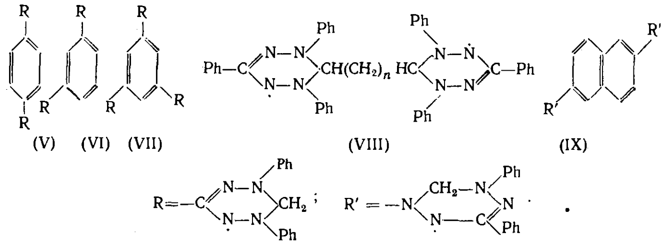
The alkylation reaction is the main method for synthesising verdazyls. The cyclisation of *N*-alkylformazans with the formation of tetrahydro-*syn*-tetrazines (leucoverdazyls), which constitutes formally the addition of the alkyl group to the –N=N– bond, has been studied in detail[11]. The capacity of *N*-alkylformazans for cyclisation depends greatly on the size of the substituents at the central carbon atom, which influences the *trans*-(*anti*-*syn*) isomerisation of formazans[12,13]. Bulky substituents (phenyl, t-butyl) tend to fix the chelate form with a strong intramolecular hydrogen bond, while alkyl substituents weaken the hydrogen bond and lead to the opening of the chelate ring (*trans*-*anti*-form). Thus the energy of the intramolecular hydrogen bond is approximately 7 kcal mole^{-1} in triphenylformazan and approximately 2 kcal mole^{-1} in diphenylformazan[14]. The cyclisation of *N*-alkylformazans can proceed under the influence of strong bases (NaOH, t-BuK, $NaOC_2H_5$), acids, or thermally. The *N*-alkylformazan anion formed under the influences of bases cyclises to the leucoverdazyl anion, which undergoes further transformations:



The rate of thermal cyclisation of *N*-alkylformazans follows first-order kinetics and increases rapidly with temperature ($\Delta H = 25$ kcal mole^{-1}). It is suggested[11] that the rate-limiting stage in such cyclisations is the formation of a delocalised zwitter-ion, which is converted into the isomeric ylid and then into the leucoverdazyl via the Stevens rearrangement. The ease of cyclisation of *N*-alkylformazans under the influence of acids is associated with the formation of a protonated form of the delocalised zwitter-ion:

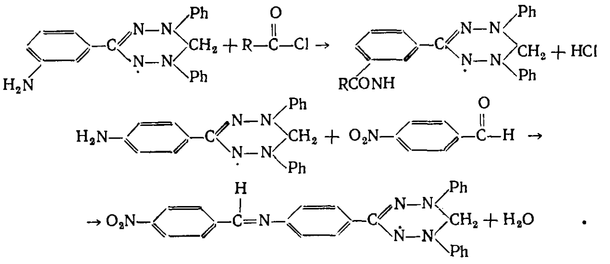


Under the influence of oxidants [$FeCl_3$, $K_3Fe(CN)_6$, PbO_2], leucoverdazyls are dehydrogenated to verdazyls. In many cases *N*-alkylformazans are stable[15-17] and cyclise only at high temperatures. Under the influence of alkalis, verdazyl salts may recyclise[9,18,19]. Compound (I) is also obtained by the reduction of tetrazolium salts with diazomethane[9]. Verdazyls can give rise to bi- and tri-radicals by being joined together in the 3-, 6- and 4-positions:

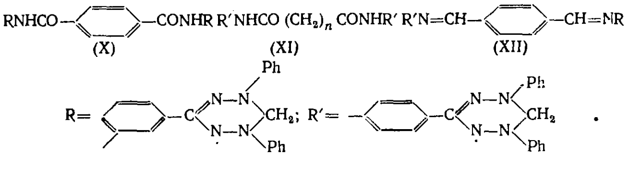


(V) (VI) (VII) (VIII) (IX)

Many mono-, bi-, and tri-verdazyls have now been synthesised from the corresponding formazans[20-23]. Aminoalkylation of formazans yields verdazyls with amino-groups in the 3-position[9]. It has been found recently[24] that 6-aminoverdazyls may be acylated by acyl chlorides or may be converted into imines by reaction with aldehydes without involving their free valence (reactions of this type are well known for *N*-oxide radicals[25]:

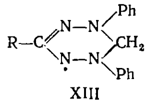


(In order to avoid the disproportionation of verdazyls under the influence of the hydrogen chloride liberated, the first reaction is carried out in the presence of triethylamine.) Bifunctional acyl chlorides or aldehydes give rise to verdazyl biradicals:



(X) (XI) (XII)

Aldose formazans have been used to synthesise water-soluble verdazyls[26]:



XIII

where R = D-*galacto*pentahydroxypentyl, D-*gluco*pentahydroxypentyl, D-*manno*pentahydroxypentyl, L-*rhamno*tetrahydroxypentyl, D-*arabino*tetrahydroxybutyl, or D-*xylo*tetrahydroxybutyl.

The photochemical formation of triphenylformazan on irradiation of (I),[2] on oxidation of (I) with atmospheric oxygen in the presence of activated charcoal[27], and when 3-aminoverdazyls are acted upon by acids and alkalis[9] constitutes chemical proof of the retention in verdazyl of the order of atoms in the initial formazan chain.

After long heating (at 80°C), (I) decomposes with formation of leucoverdazyl and 5-anilino-1,3-diphenyl-1,2,4-triazole in 1 : 1 proportions[28]. On thermal decomposition of (I) (at 200°C), aniline is formed in addition to these products[2]. Photochemical irradiation of (I) yields aniline, leucoverdazyl, and 1,3-diphenyl-1,2,4-triazole[29].

Formazans containing heteroaromatic substituents in the 1-, 5-, or 3-positions tend to undergo amine–imine tautomerism[30]. Formazans in which the heterocycle is not involved in tautomerism are most suitable for the synthesis of verdazyls[30-35].

Polymeric verdazyls and oligomers containing verdazyls in a polymer matrix are obtained by alkylating formazans or substituting them, by the anionic polymerisation of vinyl- and methacryloyl-verdazyls, and by the substitution of diaminoverdazyls with terephthalic aldehyde, terephthalic acid chloride, or styrene–maleic anhydride copolymers[36-45]. Polyurea containing verdazyls in the main chain has been obtained by the polyaddition of diverdazyldiamine and phenyl di-isocyanate[39]. Polycondensation of bisformazan with *p*-phenylenedimethylene dibromide yielded oligomers containing verdazyls[36]. A polymeric chelate, a polyverdazyl, and a polytetrazolium salt (a polymeric redox indicator) have been obtained by the polymerisation of polyvinylformazan[38]†:

III. STRUCTURE AND SPECTRA

The geometry of the verdazyl skeleton was established by X-ray diffraction[46-49]. The heterocyclic verdazyl ring has the shape of an asymmetric boat with four coplanar nitrogen atoms and the $C_{(3)}$ and $C_{(6)}$ atoms at distances of 0.590 and 0.099 Å from the plane of the nitrogen atoms. The verdazyl heterocycle has a structure close to that of the planar *sym*-tetrazine and 3,6-diphenyl-*sym*-tetrazine[50,51]. The verdazyl ring contains N and C atoms of different valence, which leads to differences between the C–N distances in different parts of the ring (1.443 Å in the saturated component and 1.338 Å in the aromatic component). Fig. 1 presents the bond lengths and angles in radical (I) obtained by the X-ray diffraction analysis of a single crystal. The benzene rings at the $N_{(2)}$ and $N_{(4)}$ atoms are somewhat deformed owing to intermolecular forces and the planes of the rings deviate from the plane of the nitrogen atoms by 9° and 12°. The $N_{(1)}C_{(6)}N_{(5)}$ angle is close to the trigonal value, as a result of which the structure of the radical is favourable for the delocalisation of the unpaired electron. The benzene rings at the $N_{(2)}$, $N_{(4)}$, and $C_{(6)}$ atoms are also rotated relative to the $N_{(2)}$–CAr, $N_{(4)}$–CAr, and $C_{(2)}$–CAr bonds by 23°, 13.1°, and 1.6°. The appreciable dipole moment of (I) (2.94 D in benzene)[2] shows that the radical has a non-planar configuration in solution.

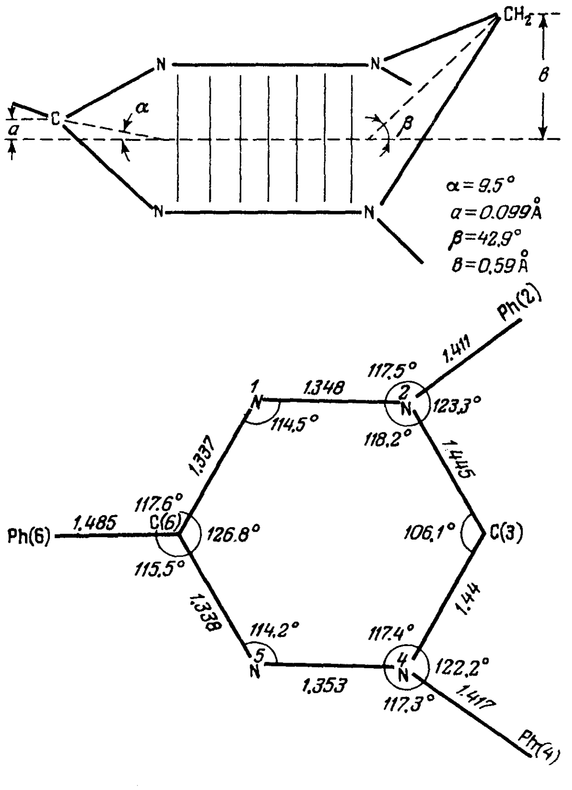

Figure 1. The bonds length and angles in the 2,4,6-triphenylverdazyl radical[46,47].

The electronic structures of verdazyls and the bond orders have been calculated by the simple and extended Hückel method[52-55] and also by the self-consistent field method in terms of the INDO approximation[56]. Calculation of ρ^{π} in radical (I) and in 2,4-diphenyltetrahydro-*sym*-tetrazinyl (XVI) by the Hückel method showed that the unpaired electron is localised mainly at the nitrogen atoms, where the spin densities are approximately the same (Fig. 2). The spin densities at the nitrogen atoms in the bi- and tri-radicals differ little from those in monoverdazyls[52].

We carried out a quantum-chemical calculation on the heterocycle in verdazyls by the unrestricted Hartree-Fock method in terms of the INDO approximation with complete optimisation of the geometry on the basis of a program employing a gradient method to find the proton energy minimum[216]. Fig. 3 presents the optimised bond lengths and angles in the boat conformer of a model verdazyl radical (the benzene rings have been replaced by hydrogen atoms). The calculations made it possible to explain satisfactorily the dipole moment found for triphenylverdazyl and the spectroscopic equivalence of the four nitrogen atoms of the verdazyl ring.

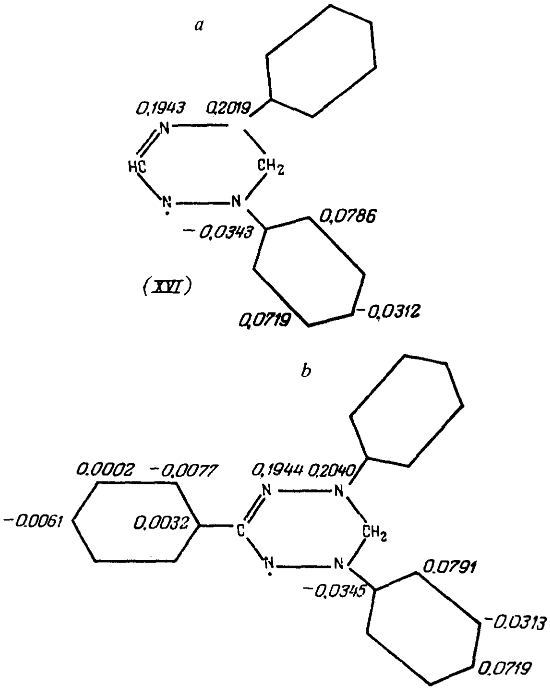

Figure 2. Distribution of spin densities: *a*) in the diphenylverdazyl radical (XVI); *b*) in the triphenylverdazyl radical[52].

The EPR spectrum of radical (I) consists of nine broad lines with a binomial intensity distribution (1 : 4 : 10 : 16 : 19 : 16...), which is due to the interaction of the unpaired electron with the four equivalent nitrogen atoms of the verdazyl ring[2,57]. The hyperfine interaction (HFI) constant $a^{N} \simeq 6$ G and the *g*-factor is 2.0033–2.0036.

The introduction of substituents in the *o*- and *p*-positions in the benzene rings of (IV) leads to the non-equivalence of the nitrogen atoms in pairs; the dependence of $a^{N}_{2,4}$ on the properties of the substituents then obeys the Hammett equation, while the constants $a^{N}_{1,5}$ are virtually independent of the nature of the substituent[22]. Arylverdazyls into which F, Cl, D, and Br atoms have been introduced selectively give rise to well resolved EPR spectra at room temperature. Splittings are observed due to protons in the equivalent benzene rings attached to the $N_{(2)}$ and $N_{(4)}$ atoms: $a^{H}_{o} = a^{H}_{p} = 1.06-1.09$ G; $a^{H}_{m} = 0.41-0.49$ G.[15]

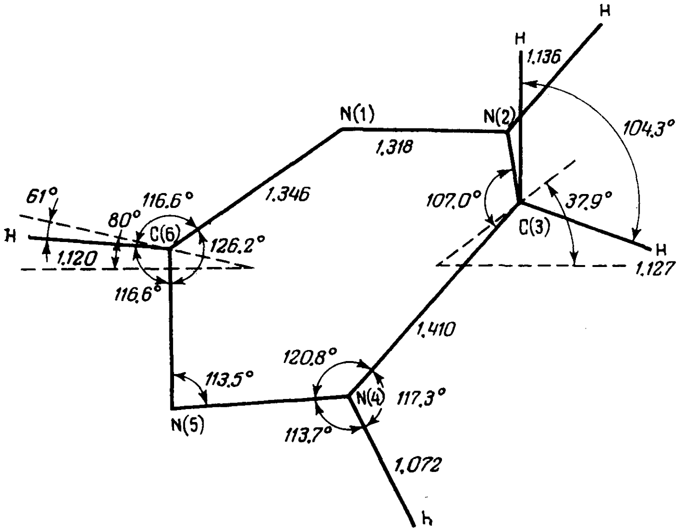

Figure 3. The steric structure of a model verdazyl radical[216].

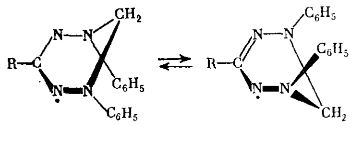
The paramagnetic shifts relative to diamagnetic leucoverdazyls have been determined from the NMR spectra for many verdazyl radicals with aliphatic substituents and the isotropic HFI constants have been found[10,53,58–61]. The HFI constants (in G) have been obtained from the NMR spectra of (I) in $CDCl_3$ for all its protons[53]: for the protons of the benzene rings attached to $N_{(2)}$ and $N_{(4)}$ ($a^{H}_{p} = 1.195$, $a^{H}_{o} = 1.12$, $a^{H}_{m} = 0.425$), for the protons of the $C_{(6)}$–benzene ring ($a^{H}_{p} = 0.31$, $a^{H}_{o} = 0.425$, $a^{H}_{m} = 0.16$), and for the $C_{(3)}$-methylene protons ($a^{H} = 0.027$)[53]. The electronic-nuclear double resonance (ENDOR) spectra of dilute liquid solutions of verdazyls have been investigated[62]; the constants for the hyperfine interaction with the protons in the *o*-, *m*-, and *p*-positions in the aromatic rings agree with the values measured previously by EPR and NMR (Table 1). The signs and values of the HFI constants found by the NMR method agree with the spin densities calculated from the experimental data using the McConnel and Stone–Maki equations[15,53], and with the spin densities obtained by the Hückel and McLachlan quantum-chemical calculations[52]. The constant for the hyperfine interaction with the protons of the CH_2 group in the 3-position of the verdazyl ring is positive for all the monoverdazyls and amounts to 0.027–0.031 G.[15,58,62] The temperature dependence of the NMR spectrum of this group indicates the inversion of the verdazyl ring[10,60]:



,

Hyperfine interaction with protons located at large distances from the point at which the initial spin density is localised (separated by 3–4 σ bonds) has been observed for verdazyls with aliphatic substituents in the 3- or 6-positions and in the *p*-positions in the *N*-phenyl rings (Table 2). The characteristics of the distribution of spin density in verdazyl σ systems depend on the geometrical structure of the radicals[53,58–61].

Table 1. The hyperfine splitting constants of verdazyls (G) measured by the ENDOR method[62].

* According to EPR data in 2-methyltetrahydrofuran.

^{19}F dynamic nuclear polarisation (DNP) has been investigated in solution in the presence of verdazyls. The heterocyclic group of verdazyls has a high spin density and readily forms complexes with C_6F_6, the contact interaction making a significant contribution to the polarisation[63,64].

The EPR spectra of the polymers based on verdazyl radicals are non-characteristic and usually consist of a single or several broadened lines[37,38,65].

The EPR spectra of verdazyl bi- and tri-radicals[20,21,24] are less well resolved than those of the monoradicals, which is primarily due to the electron–electron interaction‡. A detailed study of the verdazyl biradicals (V) and (VI) by EPR and NMR showed that the constant for the

---

‡ An increase in molecular size can also lead to an impairment of the averaging of the anisotropic HFI.

hyperfine interactions with the protons of the aromatic rings joining the verdazyl moieties are equal to the average HFI constants for the corresponding protons in monoverdazyl, while the temperature dependence of the paramagnetic shifts is linear. Hence it follows that the exchange energy in the verdazyl biradicals obeys the relation $RT > J > a^N$. In the spectra of radicals (XI) with $n = 0$ splitting by the eight equivalent nitrogen atoms is observed ($a^N = 2.9$ G) but, when $n = 6$, the usual spectrum of verdazyl monoradical is observed (four N atoms, $a^N = 5.8$ G). The exchange interaction energy J then changes from $J > 6$ G ($n = 0$) to $J \simeq 0$ ($n = 6$).[24] In dilute solid solutions of verdazyl bi- and tri-radicals, dipole splitting is observed. The dipole interaction constants D of the electrons in verdazyl biradicals are 10–55 Oe, depending on the structure[66–69]. The values of D for (V) and (VI) are respectively 43.1 and 52.7 G, whence the average distances between the paramagnetic centres (8.7 and 8.1 Å) were found.

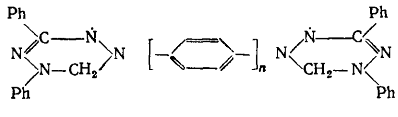
* The positions of the atoms relative to the radical centre are as follows:

The study of EPR spectra and magnetic susceptibility over a wide temperature range showed that radicals (VIII) ($n = 4$) and (V) are biradicals with a virtually degenerate singlet–triplet ground state, while triradical (VII) has a virtually degenerate doublet–quartet ground state[6,67]. Biradicals (IX) and (XVII),



(XVII) $n = 2, 3, 4,$

exhibit a decrease of paramagnetism on reducing the temperature, which is believed[21] to be a result of equilibrium with the corresponding diamagnetic zwitter-ionic forms.

In order to study diverdazyl radicals in frozen solid solutions (toluene or polystyrene matrices at 77 K), two- and three-pulse EPR spectroscopy has also been used[70]. Transitions from the triplet level (for which $\Delta M = 1$) are then observed.

In order to find the parameters of the g-tensor and the tensor of the HFI constants, a study was made of the EPR spectra of radical (I) in a 2,4,6-triphenylbenzene diamagnetic single crystal matrix[71]. When the single crystal is rotated in a magnetic field, the EPR spectrum changes and additional splitting (seven lines), attributed to radical pairs and three-membered radical clusters, is observed. Studies of this kind are of interest from the standpoint of using verdazyls as paramagnetic probes in studies on molecular mobility in crystals and phase transitions.

Like other stable radicals, verdazyls catalyse the ortho-para conversion of hydrogen; the catalytic property depends strongly on the magnetic moment and structure of the verdazyl[72–74].

The characteristics of the behaviour of magnetic susceptibility in crystalline verdazyl radicals, determined by the exchange interaction of the electrons, have been studied[21,48,49,75,76]. The magnetic susceptibility of verdazyls obeys the Curie–Weiss law with negative θ constants [$\theta = -14.6$ K for (I)], over a wide temperature range (300–30 K). However, below 30 K the curves for the temperature dependence of this susceptibility have maxima indicating the occurrence of antiferromagnetic interactions [at 6.9 K for (I) and at 12 K for (III)]. At temperatures below $T_{\max}$ the EPR lines are broadened and the g-factor shifts, which indicates the occurrence of magnetic phase transitions. The magnetic properties of the radicals are extremely sensitive to the distribution of the unpaired electron and to the way in which the molecules are packed in the crystal. The different magnetic properties of (I) and substituted triarylverdazyls are associated mainly with the different types of molecular packing of the radicals. Azuma and coworkers[48,49] showed that verdazyls are linear spin systems and can serve as convenient model compounds for the investigation of ferromagnetic interactions in stable radicals.

The study of the frequency and temperature dependence of the EPR line width in the spectrum of (I) yielded information about the exchange and dipole–dipole interactions[77]. The EPR line width for (I) is independent of frequency and temperature (in the range 300–100 K) and approaches the limit corresponding to maximum narrowing. The spin exchange frequency (111 GHz) and the upper limit for the dipole interaction ($D = 288$ G) have been estimated[77]. The high spin exchange frequency is associated with the strong intermolecular overlapping of the $2p\sigma$ and $2p\pi$ orbitals of the aromatic rings of the verdazyl radical in the solid state.

According to Dahne[78], verdazyls are electrically neutral polymethine cyanines having the general formula

$$X{-}N\left[\overset{|}{=}C{-}\right]_n\ddot{N}{-}X \longleftrightarrow X{-}\ddot{N}\left[{-}\overset{|}{C}{=}\right]_n N{-}X$$

where the CH_2 bridge links the ends of the cyanine chain in the *cis-cis* positions with formation of a six-membered ring. Monoverdazyls[2,9,22,79] as well as verdazyl bi-, tri-, and poly-radicals[21,36–45] absorb in the visible region of the spectrum (at 400 and 700 nm). In polar solvents the bands undergo a bathochromic shift which makes it possible to assign them to $\pi \to \pi^*$ transitions[29]. A bathochromic shift of both bands has been observed for triarylverdazyls with electron-donating or electron-accepting substituents, because this entails an increase in the conjugation system, which stabilises the first excited state to a greater extent than the ground state and thus reduces the excitation energy regardless of the nature of the substituent[22]. The substituent in the 3-position, which is not involved in the conjugation system, causes a small hypsochromic shift (20–30 nm) of the long-wavelength absorption band. For the colourless leucoverdazyls substituted in the *p*-position of the $C_{(6)}$-phenyl ring, the shift of the long-wavelength absorption band maximum (~330 nm) is satisfactorily correlated with the Hammett σ constants for the substituents[80].

Verdazyl cations are regarded as azacyanine cations having the general formula

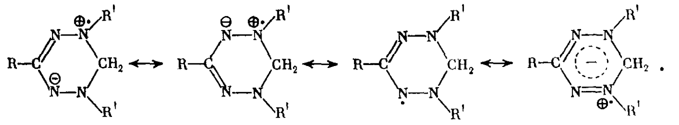
$$>N-N=\overset{|}{C}-N=\overset{\oplus}{N}< \longleftrightarrow >\overset{\oplus}{N}=N-\overset{|}{C}=N-N<$$

in which two $-CR=$ groups have been replaced by $-N=$.[22,78] The introduction of substituents in the $C_{(6)}$-ring of triarylverdazyl cations leads to a bathochromic shift of λ_{max} in the presence of electron-donating substituents and to a small hypsochromic shift in the presence of electron-accepting substituents[22,79,81]: NO_2 (535 nm), Cl (545 nm), H (548 nm), CH_3 (553 nm), and OCH_3 (576 nm). Solutions of verdazyl radicals, cations, and leuco-bases obey the Beer–Lambert law. The monomeric state of verdazyl radicals in solutions has also been demonstrated by EPR.[82] Quantum-chemical calculations (LCAO-MO and SCF LCAO-MO in terms of the INDO approximation)[52–56] do not provide an interpretation of the electronic absorption spectra of verdazyls.

The infrared spectra of verdazyls and their cations and leuco-bases have been studied in detail[2,54,55,83–86]. The similarity of the atomic weights of carbon and nitrogen leads to a strong interaction of the vibrations, so that the interpretation of the spectral lines in terms of the vibrations of individual bonds is not sufficiently rigorous[54]. When the ^{15}N label is introduced into (I) all the bands in the infrared spectrum are displaced towards longer wavelengths compared with the species containing ^{14}N, which indicates the presence of a conjugation chain in the verdazyl system[6]. The infrared spectra of the leuco-bases showed the characteristic bands of the N–H bonds (~3300 cm^{-1}). The bands in the region of 1600 cm^{-1} have been assigned to the vibrations of the $C_{(6)}=N_{(5)}$ bond; in triphenylverdazyl and its leuco-base it is intense, while in the cations it is weaker (these bands, which are superimposed on the vibration bands of benzene rings, become resolved in the presence of the ^{15}N label[6]). The 1155–1165 cm^{-1} band, assigned to the $-N=N-$ stretching vibrations, characterises the distribution of electron density in the ring. The spectrum of (I) shows in this region a doublet at 1122–1165 cm^{-1}, which is absent from the spectra of the leuco-bases. The intense 1260 cm^{-1} band, assigned to the $N_{(5)}-C_{(6)}-N_{(1)}$ bond[54,55,83–86], is observed for verdazyl radicals and cations but not for the leuco-forms. It is located at a higher level than in the spectra of formazans having the symmetrical $N_{(2)}-C_{(3)}-N_{(4)}$ linkage[87]. The infrared spectra of verdazyls in general confirm a symmetrical distribution of the unpaired electron.

IV. CHEMICAL PROPERTIES

Verdazyls belong to the class of the most stable free radicals. Crystalline (I) remains unchanged for many years. This is due to the strong delocalisation of the unpaired electron, which lowers the energy of the ground state of the radical, and to the steric shielding of the verdazyl ring. It can also be accounted for on the basis of the principle of the "merostabilisation" of free radicals[88]:



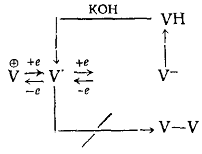
The stability of verdazyls is to a large extent determined by the ability of the 6-substituent in the 6-position to cause the steric stabilisation of the verdazyl ring[6] and varies in the sequence[2,10,15,57,89]

$$RS < H < CH_3 < COOR < C(CH_3)_3 < C_6H_5.$$

The introduction of alkyl or phenyl substituents in the 3-position increases the stability of the verdazyl radical[6,27]. Leucoverdazyls are readily dehydrogenated by other stable radicals—DPPH and tri-t-butylphenoxyl[90]. In the reaction with 2,2,6,6-tetramethylpiperidin-1-yloxy-radical the equilibrium is displaced towards (I). Thus the stability of triarylverdazyls greatly exceeds that of phenoxy- and hydrazyl radicals and is not inferior to that of the ultrastable iminoxy-radicals.

1. Electrochemical Reactions

The polarographic oxidation-reduction of substituted triarylverdazyl radicals ($V^{\cdot}$) in solution in DMF, CH_3CN, and propylene carbonate (PC) at a dropping mercury electrode takes place reversibly with transfer of one electron and may be described schematically as follows[91–93]:



The half-wave oxidation and reduction potentials ($E_{1/2}$) for (II) depend on the nature of the substituents (Table 3). As was to be expected, as the electron-donating properties become more pronounced, the oxidation-reduction half-wave potential shifts towards lower values. The effect of the substituent is described satisfactorily by the modified Hammett–Zuman equation: $\Delta E_{1/2} = E^{X}_{1/2} - E^{0}_{1/2} = \rho_{\pi}\sigma$. The reaction constants characterising the polarisability of the electrochemically active group depend little on the nature of the solvent (Table 4). However, in methanol ρ_{π} for the reduction reaction changes sign, which indicates an electrophilic mechanism. It appears that the kinetics of the protonation in the electrode field preceding electron transfer play a decisive role in the reduction[94]. Comparison of the oxidation-reduction half-wave potentials of (I) and the water-soluble verdazyl (XIII) (R = D-*galacto*-pentahydroxypentyl), whose molecules are capable of forming an intramolecular hydrogen bond, shows that the oxidation half-wave potentials in various solvents differ little (within the limits of the differences between the potential of the liquid compound and the value in solvents and water)[94]. However, there is a difference between the reduction half-wave potentials of (I) and (XIII). The formation of an intramolecular hydrogen bond is accompanied by a small change in $E_{1/2}$ (intramolecular protonation). Thus, when (XIII) is transferred from CH_3CN to CH_3OH, $E_{1/2}$ increases by 0.08 V, while the corresponding increase for (I) is by 0.51 V,[91,94] the reduction half-wave potentials of triarylverdazyls depending to a greater extent on the specific solvation effects than on the substituent effects. This is apparently associated with the involvement of mobile hydrogen atoms of alcohols in the potential-determing stage of the electrode process. Indeed the reduction half-wave potentials of (I) and (XIII) vary in parallel with pK_a for the autoprotolysis of the organic solvents[91,94]. These data demonstrate the importance of taking into account the proton transfer reactions when the reactivities of verdazyls are considered.

Comparison of electrochemical data for stable radicals makes it possible to estimate qualitatively their donor–acceptor properties. The radicals can be arranged in the following activity series in terms of their reducing capacity: perchlorodiphenylmethyl[95], tri-t-butylphenoxyl[96], DPPH,[97] di-t-butylnitroxide[98], *N*-oxides[99], triphenylmethyl[100], triphenylverdazyl[91].

In this series the most powerful electron donor is the triphenylverdazyl radical, which must be regarded as a Lewis base. Thus chlorinated triphenylmethyl radicals are virtually inert with respect to powerful electrophiles such as the halogens and concentrated nitric acid[5,101], phenoxyls are oxidised only under the influence of powerful oxidants ($SbCl_5$ and other metal halides)[102], while (I) or triphenylmethyl radicals react almost instantaneously with halogens to form cations[2,101].

2. One-Electron Transfer Reactions

One-electron transfer reactions play an important role in the mechanisms of the elementary steps of many organic and bio-organic reactions[103]. Model reactions involving triphenylverdazyls and their salts, in which the one-electron transfer stage has been clearly detected by physicochemical methods, are discussed below. Verdazyls are some of the most powerful nucleophiles and in their reactions with electrophiles give up an electron and are converted into stable cations. Such reactions include those of (I) with halogens[2,104], Lewis acids[2,21,79,105-107], and various inorganic oxidants[2,108]. When a green solution of (I) is mixed with oxidants, a violet verdazyl salt is formed instantaneously. The stability of the diamagnetic cation depends on the nature of the substituent in the radical, the nature of the oxidant and the medium, and other conditions.

* Triarylverdazyl radicals (X–R) and their salts $(X\text{–}R)^+$ substituted in the *p*-position of the $C_{(6)}$-phenyl ring.

** The average isokinetic temperature determined by various methods (from the relation between E_a, on the one hand, and $\Delta S^{\neq}$, $\lg k_{2,T_1}$, and $\lg k_{2,T_2}$, on the other, and between ρ and $1/T$, etc.).

*** 3,5-Diethoxycarbonyl-2,6-dimethyl-4(X)-1,4-dihydropyridines.

The influence of the nature of the substituent in (II) and of the polarity of the medium on the kinetics and mechanism of the reaction

$$\dot{V} + C(NO_2)_4 \begin{cases} \longrightarrow \overset{\oplus\ominus}{VC}(NO_2)_3 + N\dot{O}_2 & \text{(non-polar solvents),} \\ \longrightarrow \overset{\oplus\ominus}{VC}(NO_2)_3 + \overset{\oplus\ominus}{VNO_2} & \text{(polar solvents)} \end{cases}$$

has been studied[107] in relation to the model reaction involving electron transfer from triarylverdazyl to tetranitromethane (TNM). In polar solvents radicals (II) react with $NO_2^{\cdot}$ in a solvent cage {the stoichiometry corresponds to $[(II)]/[TNM] > 1$}. The reaction is characterised by relatively small activation parameters E_a = 3–5 kcal mole^{-1} and $\Delta S^{\neq}$ = –35–20 e.u. The rate of reaction $v = k_2[V^{\cdot}][TNM]$ depends significantly on the polarity and solvating capacity of the solvent (on passing from cyclohexane to propylene carbonate, k_2 increases by a factor greater than 10^3). The effect of the substituent in the *p*-position relative to the $C_{(6)}$ -phenyl ring of (II) can be described satisfactorily in terms of the Hammett equation (Table 4). The solvation of (II) by tetrahydrofuran molecules[109] leads to an appreciable decrease of the influence of the polar properties of substituents (Table 4). The rates of reaction of (II) with TNM are also satisfactorily correlated with the polarographic oxidation potentials of (II) (Dimroth's equation) (Table 4). This type of relation between the kinetic and thermodynamic parameters of the reaction with high proportionality coefficients is regarded as evidence for electron transfer in the rate-determining stage[110].

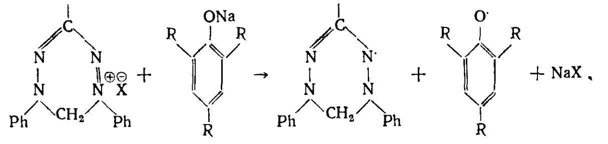
When (I) interacts with tetracyanoethylene and chloranil, which gives rise to stable radical-anions on reduction, the EPR spectra of (I) and the oxidant radical-anion are superimposed, the intensity of the former decreasing with time and that of the latter increasing; the electronic spectra show clearly the absorption band due to the verdazyl salt[108,111]. When the difference between the donor–acceptor properties of the free radicals is fairly large, their interaction may occur via the transfer of one electron and may lead to the formation of a corresponding cation and anion. We observed this in the reaction of (II) with acyloxy-radicals formed in the decomposition of diacyl peroxides[112,113] ($PhCOO^{\cdot}$, $C_6H_{13}COO^{\cdot}$, $C_{11}H_{23}COO^{\cdot}$), NO_2,[107] and acetyl radicals formed in decomposition of lead tetraacetate[108]. Radical (I) recombines with active radicals such as $^{\cdot}CH_2Ph$, $(CH_3)_2\dot{C}COCH_3$, radicals derived from monomers[114-117], $(CH_3)_2\dot{C}CN$,[118], and $^{\cdot}CH_3$,[119] forming addition products (tetrazines). Such recombination makes it possible to classify $^{\cdot}CH_3$ and 1-cyano-1-methylethyl radicals as nucleophiles, which agrees with the view of Ingold and Roberts[120]—halogen-containing free radicals and the majority of radicals with the free electron centred on O or S atoms are classified by these workers as electrophiles, while triethylstannyl, methyl, cyclohexyl, and 1-cyano-1-ethyl radicals are classified as nucleophiles.

In 1973 we attempted[93] to carry out a similar classification for stable radicals and discussed the problem of one-electron transfer in a pair of verdazyl radicals differing greatly in their donor–acceptor properties.

Verdazyls do not react with trityl radicals (but they do react with Ph_3COO), DPPH, and the 2,2,6,6-tetramethyl-4-oxopiperidin-1-yloxy-radical, apparently owing to the presence of bulky substituents in the region of the reaction centres[65,116]. However, (I) reacts with phenoxy-radicals via one-electron transfer with the formation of the corresponding salt[108,111,121,122]. The rate of reaction of substituted phenoxy-radicals with (I) increases with increase of the electron-accepting capacity of the substituent in the *p*-position of the benzene ring, with decrease of $E_{1/2}$ for the polarographic reduction of phenoxy-radicals, and with increase of electron density in the *p*-position of the phenoxy-radical[111].

Like verdazyl monoradicals, the biradicals are readily oxidised by Lewis acids and peroxy-compounds, being converted into diamagnetic salts. It has been shown[123] that the polarographic oxidation of (VI) is reversible, with successive transfer of two electrons. Presumably the oxidation of verdazyl biradicals by strong oxidants also takes place via consecutive one-electron transfer.

In contrast to the radicals, verdazyl salts exhibit pronounced electron-accepting properties. One-electron reduction of verdazyl salts is one of their characteristic reactions and, in view of the high stability of verdazyls, the reaction frequently stops at this stage. Verdazyl salts are used as electrophilic components in order to confirm the hypothesis of one-electron transfer in the interaction of two diamagnetic substances (reactions with tetramethyl-*p*-phenylenediamine and with sodium tri-t-butylphenoxide)[79,108,124]



R = t-butyl.

The resulting EPR spectrum corresponds to the superposition of the spectra of two radicals: (I) and tri-t-butylphenoxyl. When verdazyl salts interact with leucoverdazyls, two verdazyl radicals are also formed[79,90]. If metallic potassium or sodium, an alkali metal alkoxide, or an alkali metal phenoxide is used as the donor, the reaction with verdazyl salts proceeds almost instantaneously[108]. In the reaction with alcohols the verdazyl salt is reduced to the initial radical (methanol is then oxidised to formaldehyde)[125].

Reactions involving one-electron transfer to verdazyl salts occur readily when aromatic and aliphatic amines are used as the donors[81,124,126,127]. The rate of oxidation of amines by verdazyl salts is almost independent of the nature of the salt counterion and of the replacement of H by D in the amino-group[126]. The activity of amines is determined by both electronic and steric effects; they depend to a large extent on the nucleophilic properties of the amine. On passing to aliphatic amines[127], the rate of oxidation of verdazyl salts increases by 2–4 orders of magnitude compared with aromatic amines due to the decrease of E_a (aliphatic amines are much stronger nucleophiles). It is noteworthy that in the reactions with amines the yield of radical (II) is approximately 70–80% for $PhNR'_2$ and aliphatic amines, approximately 60–70% for $PhNR'H$, and approximately 10–15% for $PhNH_2$ (this is apparently due to side reactions of verdazyl salts[2,18]). The amine radical-cation formed in the elementary electron transfer step readily splits off a proton and is converted into an amine radical, which then either reacts with (II) in the solvent cage or emerges from the latter, which entails the accumulation of (II). The rate of oxidation of anilines is relatively insensitive to the electronic effects of the substituent in the salt (Table 4). In the oxidation of *p*-substituted anilines by verdazyl salts Hammett's, Dimroth's, and Brønsted's correlation equations are found to hold (Table 4). The occurrence of such correlations shows that the mechanisms of all the reactions have a feature in common, believed nowadays to be one-electron oxidation-reduction (*SET* mechanism)[103,110].

The foregoing considerations show that verdazyl radicals may be used in chemistry as one-electron reductants, while verdazyl salts can be used as one-electron oxidants.

3. Reactions of Verdazyls with Acids

The majority of stable radicals react with protic acids; the possibility of such reactions is determined to a large extent by the nucleophilic properties of the radicals. This can explain the high stability of perfluorodimethylnitroxide, di-(4-nitrophenylaminoxyl), 3-imidazolinyl, and porphyrexide in relation to inorganic acids[128]. Being strong nucleophiles, verdazyls are readily oxidised by various acids and, depending on the proton-donating properties of the acid, there is a gradual transition from proton and electron transfer to homolytic substitution reactions[90].

The reaction of (II) with carboxylic acids involves the reversible formation of the cation and the verdazyl leuco-base[2]:

$$2V^{\cdot} + R'CO_2H \overset{K_p}{\rightleftarrows} VH + V^{+}R'COO^{\ominus}$$

The state of equilibrium in the acid-base interaction depends on the donor-acceptor properties of the reactants, their structure and concentration, the nature of the solvent, and temperature[90,129]. When (I) interacts with inorganic (H_2SO_4, HBr, HNO_3) and strong organic acids (CF_3CO_2H, CCl_3CO_2H), the equilibrium is greatly displaced towards the formation of the products, VH being oxidised to the radical and being thus gradually converted into a salt[2]. A study of the equilibrium between (II) and $ClCH_2CO_2H$ showed[130] that, depending on the nature of the solvent, the effective equilibrium constant depends on the concentration of the acid (in alcohol) or on its square (in DMF), or on the concentration of the acid dimer(in benzene), and, depending on the substituent in the *p*-position of the $C_{(6)}$-phenyl ring of (II), the equilibrium constant changes by several orders of magnitude[131,217]. In alcohol and DMF the equilibrium constants are satisfactorily correlated with Hammett's σ constants of the substituents and the polarographic oxidation potentials of verdazyls (Table 4). Verdazyls enter into this reaction as electron donors and the high coefficients in the correlation equations indicate an appreciable charge separation in the activated complex of the reaction. The solvent effect is associated mainly with the change in the proton-donating properties of the acid[129]. There is a linear relation between the disproportionation constants of (II) and the pKa of the acids (Brønsted's equation) (Table 4). Since the ionisation of acids reduces to proton transfer from the acid to the solvent and the reaction of HX with triarylverdazyls apparently involves partial proton transfer from HX to (II), it is clear that the free energies of the two processes are related. The proportionality coefficient in Brønsted's equations indicates the decisive role of proton transfer[132] in the reaction of (II) with protic acids.

The reaction of (II) with protic acids is believed to proceed via a series of consecutive equilibria[90,217]. The formation of hydrogen-bonded complexes (*a*), proton transfer via the hydrogen bond with formation of a close ion pair (*b*), the dissociation of ion pairs (*c*), electron transfer from the free verdazyl radical to the protonated radical (*d*), and protonation of the resulting leuco-base (*e*):

$$V^{\cdot} + HX \underset{a}{\rightleftarrows} V^{\cdot} \ldots HX \underset{b}{\rightleftarrows} VH^{\oplus\cdot} \ldots X^{\ominus} \underset{c}{\rightleftarrows} VH^{\oplus\cdot} + X^{\ominus} \underset{d}{\overset{V^{\cdot}}{\rightleftarrows}} VH + V^{\oplus}X^{\ominus} \underset{e}{\rightleftarrows} VH_2^{\oplus}X^{\ominus} + V^{\oplus}X^{\ominus}$$

The equilibrium constant for stage *b* depends on the strength of the acid HX and the base $VH^{\oplus}$ and can be estimated approximately in terms of the quantity $\Delta pK_a = pK_{VH^{\oplus}} - pK_{HX}$. The solvent participates in processes *a*–*e* as an active proton donor. Electron-accepting substituents in verdazyls reduce the basicity of both $V^{\cdot}$ and VH, the equilibria in processes *b*, *c*, and *d* being displaced to the left in the direction of the initial reactants. The thermodynamic parameters of the reaction of (II) with acids ($\Delta H^{\circ} = -2-5$ kcal mole^{-1}, $\Delta S^{\circ} = -5-20$ e.u.)[90,129] are consistent with the parameters of the proton transfer reaction in the interaction of amines with carboxylic acids. In DMF, chloroacetic acids apparently form 1 : 2 ion pair complexes i.e. $[VH^{\oplus}][HX(X^{\ominus})]$ [in the reaction of (II) with carboxylic acids the equilibrium in process *e* is apparently fully displaced to the left]. Comparison of the pK values for free radicals shows that verdazyls are the most basic species: p$K \simeq 1$ for triphenylphenoxyl, p$K = 5.5 \pm 2$ for 2,2,6,6-tetramethylpiperidin-1-yloxyl[133], and p$K \simeq 6.2$ for (XIII).[26]

An experimental study of the kinetics of the disproportionation of (II) in the presence of carboxylic acids showed[134] that the rate of reaction is determined by the stage involving electron transfer from free $V^{\cdot}$ to the solvated species: $v = k_3[V^{\cdot}]^2[R'CO_2H]$. The reaction with hydrogen halides may be used for the potentiometric determination of verdazyl[65]. The use of triarylverdazyls in the study of the kinetics of the ionisation of t-butyl halides in organic solvents is based on this factor[135-140]:

$$(CH_3)_3CX \rightarrow (CH_3)_3C^{\oplus}X^{\ominus} \rightarrow (CH_3)_2 = CH_2 + HX \quad .$$

The hydrogen halide formed reacts rapidly and quantitatively with (II).

The presence of protonated silanol groups on the surface of dispersed silica induces the reverse transition from the radical to the verdazyl cation[141].

The interaction of triarylverdazyls with thio-acids (dehydrogenation of the S–H bond) has been studied in relation to thiophenols. In polar solvents the reaction proceeds via the mechanism[142]:

$$V^{\cdot} + H{-}S{-}Ph \rightarrow VH + \dot{S}Ph \quad ,$$

$$\dot{S}Ph + \dot{S}Ph \rightarrow Ph{-}S{-}S{-}Ph \quad .$$

In non-polar solvents the reaction is reversible:

$$2V^{\cdot} + H{-}S{-}Ph \overset{K_p}{\rightleftarrows} VH + V{-}S{-}Ph \quad .$$

In the reaction with thiophenols triarylverdazyls behave as dehydrogenating agents in polar solvents and also as acceptors of the $PhS^{\cdot}$ free radicals in non-polar solvents[90,142]. The rate of dehydrogenation of thiophenols $v = k_2[V^{\cdot}][PhSH]$ depends on the nature of the substituent in the *p*-position of thiophenol and increases on passing from unsubstituted to substituted thiophenols, which is apparently due to the increase of stability after the introduction of substituents into the intermediate thiol radicals. In the reaction with thiophenols verdazyls behave as electron donors, and the effect of the substituent in the radical is satisfactorily described by the Hammett equation (Table 4)[218].

4. Dehydrogenation by Verdazyl Radicals and Cations

Verdazyls are readily reduced either in an acid medium[26,130] or when compounds with mobile hydrogen, for example hydrazine and phenylhydrazine, are used[2,80,90,143]. A characteristic feature of the reduction of triarylverdazyls as well as iminoxyls[25] is that their occurrence requires the presence of not only an electron donor, but also a proton donor[80,90]. Leucoverdazyls are readily oxidised by atmospheric oxygen to radicals and in the presence of alkalis the rate of oxidation increases sharply; thus verdazyls may be regarded as dehydrogenation catalysts:

$$V^{\cdot} + BH \rightarrow VH + B^{\cdot};\ VH \xrightarrow[O_2]{KOH} V^{\cdot} \quad .$$

Hydrazobenzene (HB) is a powerful reductant in relation to (II). The reaction kinetics have been studied in detail[144]. The rate of reaction is described by the equation $v = k_2[V^{\cdot}][HB]$ and depends little on the nature of the solvent§; as the electron-donating properties of the radical become more pronounced, the rate increases and there is a correlation of the rate constants both with σ constants and with the electrophilic σ^+ constants[147] (Table 4). There is also a correlation between $\lg k_2$ and the polarographic oxidation potentials of verdazyls (Table 4). The excellent correlation between the HB dehydrogenation rate constants and the electrophilic constants of substituents and the negative reaction constants ρ and α in Dimroth's equation shows that the structure $X^{\delta-}-H\ldots{}^{\delta+}V^{\cdot}$ makes a significant contribution to the transition state. It has been shown[90,129] that radicals (II) readily dehydrogenate compounds with acid or weakly basic properties.

The radical mobility of the hydrogen atom in the C–H bond has been studied in relation to the reaction of (II) with 1,4-dihydropyridines (DP), which are weak bases[148]. DP are analogues of biologically active compounds—coenzymes and dihydrocoenzymes. They exhibit striking electron- and hydrogen-donating properties and behave as hydrogen transferring agents in biological oxidation-reduction processes[148]. The kinetics of the reaction of (II) with *N*-benzyl-1,4-dihydronicotinamide (BDN) and 3,5-diethoxycarbonyl-2,6-dimethyl-1,4-dihydropyridine (Hantzsch ester, HE) have been studied in detail[90,129,149-156]. The rate of reaction is described by the equation $v = k_2[V^{\cdot}][DP]$ and depends significantly on the nature of the substituent in the 4-position of DP. For triarylverdazyls substituted in the *p*-position of the $C_{(6)}$-phenyl ring, a complete inversion of the activity series is observed on passing from DMF to C_2H_5OH [the values of k_2(rel.) are listed below]:

	bis-CH_3O*	CH_3O	H	Cl	NO_2
		DMF, 25°			
BDN	1	1.6	1.8	2.2	2.8
HE	1	1.9	2.0	2.2	2.7
		Alcohol, 25°			
BDN	2.9	1.7	1.4	1.1	1
HE	5.1	4.3	1.8	1.6	1

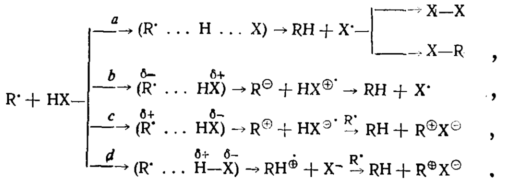
* 2,6-bis-(4-methoxyphenyl)-4-phenylverdazyl.

Such unusual behaviour of verdazyl radicals is associated with the enhancement of their nucleophilic properties on passing from DMF to alcohol[90]. The rate constants for the reactions in DMF and alcohol are correlated respectively with the σ and σ^+ constants of the substituents and the polarographic reduction and oxidation potentials of radicals (II) (Table 4). In DMF the verdazyls (II) behave as electron acceptors, while in alcohol they behave as electron donors. Variation of ρ and the zero value of the latter have been observed recently for reactions involving the abstraction of hydrogen from substituted toluenes on passing from methyl to t-butyl and heptyl radicals, which the authors also explained by the enhancement of the nucleophilic properties of the radicals[157].

The observed small effects of the substituents in the verdazyls can be explained by the closeness of the experimental temperature to the isokinetic temperature β [158] [when β is traversed, the activity of (II) is reversed[90] (Table 4)]. It must be emphasised that the isokinetic or isoequilibrium relations are some of the most important characteristics of reactions, being particularly necessary for the interpretation of the polar effects of substituents, whose influence on the rate of reaction depends significantly on the experimental temperature and on β.

Data for the dehydrogenation of the C–H bonds of DP by verdazyls show that the rate of abstraction of hydrogen is in this case lower than in the reaction with O–H and S–H acids and also with HB (N–H bonds). It appears that the polarity of the dissociated bond is important for hydrogen transfer reactions involving (II). Presumably in the first stages of the dehydrogenation reaction, radical (II) is solvated (a hydrogen bond is formed) by the molecule with which it subsequently reacts. In this case the formation of the hydrogen bond precedes the formation of the activated complex and such association facilitates the reaction to a large extent[5,159]. When hydrogen is abstracted from polar X–H bonds, the increasing contribution of the Coulombic interaction between $V^{\cdot}$ and X–H leads to a decrease of the barrier¶. In the transition state of the dehydrogenation reaction there is a possibility of a shift of electron density and of proton migration via the hydrogen bond, depending on the donor–acceptor properties of the reactions[160]. The rate of dehydrogenation of (II) is influenced mainly by the specific solvation of radicals, which thus exerts the principal influence on the initial state. The solvation of the activated complex is apparently slight[90]. For verdazyls, which are some of the most stable free radicals, the main role should be played by the polar effects of the reactants and the polarisability of the hydrogen donor molecule, in conformity with Hammond's postulate.

Examination of data for reactions involving the abstraction of hydrogen by stable radicals makes it possible to represent these reactions by the following schemes[5,90,129,159]:



$$R^{\cdot} + HX \xrightarrow{a} (R^{\cdot}\ldots H\ldots X) \rightarrow RH + X^{\cdot} \rightarrow X{-}X \text{ or } X{-}R \ ,$$
$$R^{\cdot} + HX \xrightarrow{b} (\overset{\delta-}{R^{\cdot}}\ldots \overset{\delta+}{HX}) \rightarrow R^{\ominus} + HX^{\oplus\cdot} \rightarrow RH + X^{\cdot} \ ,$$
$$R^{\cdot} + HX \xrightarrow{c} (\overset{\delta+}{R^{\cdot}}\ldots \overset{\delta-}{HX}) \rightarrow R^{\oplus} + HX^{\ominus\cdot} \xrightarrow{R^{\cdot}} RH + R^{\oplus}X^{\ominus} \ ,$$
$$R^{\cdot} + HX \xrightarrow{d} (R^{\cdot}\ldots \overset{\delta+}{H}{-}\overset{\delta-}{X}) \rightarrow \dot{R}H^{\oplus} + X^{-} \xrightarrow{R^{\cdot}} RH + R^{\oplus}X^{\ominus} \ .$$

They describe the possible pathways in free-radical substitution. Pathway *a* presupposes radical abstraction of hydrogen via the intermediate formation of a symmetrical activated complex. The interaction of $R^{\cdot}$ with hydrogen donors can proceed with appreciable charge separation in the transition state (*b*, *c*, and *d*). The radical behaves as an electron acceptor (*b*), an electron donor (*c*), and a proton acceptor (*d*) (*c* and *d* differ little). The choice of reaction pathway depends on the donor–acceptor properties of the reactants, the polarity of the medium, and other reaction conditions. The structure $X^{\delta-}-H^{\delta+}\ldots R^{\cdot} \rightleftharpoons X^{\delta-}\ldots HR^{\cdot\delta+}$ may contribute significantly to the transition states of the (II) dehydrogenation reactions. However, it is not clear how to reconcile the low reaction constants (Table 4) and the correlation with the σ^+ constants, indicating the localisation of a large positive charge at the reaction centre[161].

---

§ This was also observed in the dehydrogenation of the tetrazines (II).[145,146]

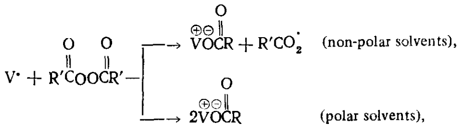
¶ In this case E_a increases in the following sequence of bonds: O–H < N–H < S–H < C–H.

In the excited state (I) readily dehydrogenates various hydrocarbons with which it does not react under the usual conditions[29].

The possibility of acid catalysis of radical reactions was demonstrated for the reactions of nitrogen oxides with amines and diamines[5]. Acid catalysis of reactions involving verdazyls takes place particularly readily because of the high rate of reaction of (II) with acids. The radical reaction pathway then changes to an ionic pathway, and the rate of reaction increases markedly[129,162]. The rate of dehydrogenation of DP on passing from (II) to verdazyl salts increases by a factor of 10^6–10^7.[90,129,155,163] The substituent in the 4-position of HE has a significant influence on the rate of reaction, which changes by a factor of 10^5 when R=H is replaced by R = C_6H_5.[164] In the reaction with a verdazyl salt the effect of the substituent in the *p*-position of the phenyl ring in the 4-position in HE is described by the Hammett and Dimroth equations (Table 4). The ease of the hydride shift reaction is due to the conversion of DP into a stable pyridinium salt[148]. The data obtained for the influence of the substituent in the 4-position in DP on the rate of reaction with (II) and verdazyl salts are in good agreement with quantum-chemical calculations, showing that the most reactive atom in the pyridine ring is the carbon atom in the 4-position[148]. Different catalytic processes occurring with participation of coenzyme models are also determined by the presence of this carbon atom. It appears that the rest of the molecule—the adenine ring and the phosphate chain—merely facilitates fixation on the protein. The use of verdazyls in the study of electron and hydride transfer with participation of DP may be of interest for the elucidation of the causes of the catalytic action of enzymes incorporating various coenzymes[148].

5. Reactions of Verdazyls with Peroxy-Compounds

The reaction of verdazyl radicals with peroxy-compounds is regarded as bimolecular homolytic substitution $S_{H}2$ at the oxygen atom[125]. It has been shown[109,112,113,125,165–169] that verdazyls readily induce the decomposition of diacyl peroxides:



$$V^{\cdot} + R'\overset{O}{\overset{\|}{C}}O O\overset{O}{\overset{\|}{C}}R' \begin{cases} \longrightarrow \overset{\oplus\ominus}{V}O\overset{O}{\overset{\|}{C}}R + R'CO_2^{\cdot} & \text{(non-polar solvents),} \\ \longrightarrow 2\overset{\oplus\ominus}{V}O\overset{O}{\overset{\|}{C}}R & \text{(polar solvents),} \end{cases}$$

where R′ = Ph, C_6H_{13}, or $C_{11}H_{23}$. The benzoyloxy-radical $PhCO_2^{\cdot}$, formed in non-polar solvents, has been identified on the basis of its decomposition products[125]. The verdazyl salts $V^{\oplus}{}^{\ominus}O_2CR'$ are relatively unstable and undergo further reactions associated with the opening of the verdazyl ring and the formation of formazans[125]. The rate of reaction of (II) with diacyl peroxides is described by the second-order equation $v = k_2[V^{\cdot}][\text{peroxide}]$, the stoichiometry of the reaction being represented by $[(II)]/[\text{peroxide}] = 1:1$ in non-polar solvents [this made it possible to recommend (I) as an analytical reagent for the determination of low concentrations of benzoyl peroxide (BP)][170] and ~2 : 1 in polar solvents[165,166], which is due to the stability of the radical $R'CO_2^{\cdot}$. Thermal decomposition of diacyl peroxides takes place at an appreciable rate only at elevated temperatures (70–80°C). Thus $k_1 = 4.8\times10^{-8}\ s^{-1}$ and $E_a = 30$ kcal $mole^{-1}$ for BP in benzene at 30°C;[171] the decomposition of BP induced by (II) is approximately 10^9 faster, which is due to the sharp decrease of E_a to 5–8 kcal $mole^{-1}$.

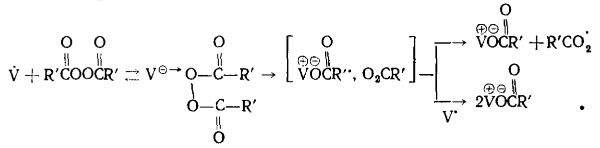
The rate of oxidation of verdazyls by BP depends little on the nature of the solvent, and the changes in the rate are not associated with the influence of the polarity of the medium, but are due to the specific solvation of (II). The relatively low activation entropy $\Delta S^{\neq} = -(29–33)$ e.u. indicates the formation of a fairly ordered transition state. In an alcoholic medium the reaction with BP leads to the regeneration of (I),[172] which is associated with the interaction of the reaction products (verdazyl salts) with alcohol molecules, the process being strongly accelerated by alkali (KOH).[125]

The rate of reaction of (II) with diacyl peroxides depends little on the nature of the substituent in the $C_{(6)}$-phenyl ring of (II) and increases as the electron-donating properties of the substituents become enhanced. The validity of the Hammett and Dimroth correlation equations and the isokinetic relation (Table 4) indicates a unique oxidation mechanism for all verdazyl radicals.

As the electron-accepting properties of substituents in BP become more marked (i.e. as the peroxy-oxygen becomes more electrophilic), the rate of reaction rises and the effect of the substituent is described by the Taft equation (which is probably associated with attack on the peroxy- and not the carbonyl oxygen atom) (Table 4). The rates of reaction of substituted BP with radicals (II) are satisfactorily correlated with the potentials $E_{1/2}$ for the reduction of peroxides[173]. The high values of α in the Dimroth equation, amounting to approximately 30, are striking (Table 4).

Special experiments established that the molecular rearrangement of the peroxide (carboxy-inversion) takes place very slowly and does not affect the rate of the reaction with verdazyls considered here[174].

On the basis of the results, the following mechanism has been proposed for the interaction of verdazyl radicals with diacyl peroxides[125]:



$$\dot{V} + R'\overset{O}{\overset{\|}{C}}O O\overset{O}{\overset{\|}{C}}R' \rightleftarrows V^{\ominus}\!\rightarrow O\!-\!\overset{O}{\overset{\|}{C}}\!-\!R' \atop \quad\;\; O\!-\!\underset{\underset{O}{\|}}{C}\!-\!R' \rightarrow \left[\overset{\oplus\ominus}{V}O\overset{O}{\overset{\|}{C}}R'^{\cdot},\ O_2CR'\right] \begin{cases} \longrightarrow \overset{\oplus\ominus}{V}O\overset{O}{\overset{\|}{C}}R' + R'CO_2^{\cdot} \\ \xrightarrow[V^{\cdot}]{} 2\overset{\oplus\ominus}{V}O\overset{O}{\overset{\|}{C}}R' \end{cases}.$$

In the rate-determining stage of the reaction (II) attacks the peroxy-oxygen. Experiments using BP labelled with ^{18}O in the carbonyl group have shown that attack by trialkylstannyl and triphenylmethyl radicals also takes place at the peroxy-oxygen[120]. Quantum-chemical calculations, indicating a deficiency of electron density in the peroxy-linkage, are consistent with this finding[175]. The weak influence of the polarity of the medium and the low reaction constants ρ in the Hammett and Taft equations may indicate the formation of a weakly polar transition state in this reaction, i.e. the rate-limiting stage is the formation of a complex and electron transfer takes place in subsequent rapid stages. In weakly polar solvents the radical-ion pair formed is unstable and undergoes further transformations, while in polar and $R'CO_2^{\cdot}$ stabilising solvents, $R'CO_2^{\cdot}$ reacts with a second verdazyl radical.

It is noteworthy that the mechanism involving electron transfer in the rate-limiting stage (*SET*) has been quite adequately demonstrated for reactions involving the oxidation of amines by organic peroxides[171,176]. According to the authors, the validity of this mechanism is proved by correlations of the Hammett, Taft, and Dimroth types, as well as correlations between the rate constants and the ionisation potentials and electron affinities. Furthermore, the reactions of free radicals and peroxides may involve either homolytic substitution or electron transfer, but one cannot draw a sharp boundary between them. When a complex is formed, a structure with charge separation, the extent of which is determined by the donor–acceptor properties of the reactants and other reaction conditions, may make a considerable contribution to the transition state. In many cases, the reaction is preceded by the formation of a loose complex between the reactants, and electron transfer is the rate-limiting stage[177]. A weak influence of the dielectric constant ϵ of the medium may be observed when the energy of the transition state is closer to the initial state on the reaction coordinate than to the final state. The structure of the transition state then resembles that of the initial compounds and the polar effects of the medium play a small role according to Hammond's postulate.

It is noteworthy that neither the reaction products, nor the effect of solvent polarity[177], nor the existence of various correlation equations, nor the coefficients in these equations[167] can serve as exclusive evidence for reactions involving a one-electron transfer mechanism and do not allow a choice of a particular mechanism.

6. Complex Formation

The solvent is known[5,178] to be capable of influencing significantly the kinetics and mechanism of radical liquid-phase reactions, which is attributed mainly to its ability to form hydrogen-bonded and π- or n-complexes. The formation of complexes of stable radicals with solvent molecules† as a rule leads to an appreciable decrease of their reactivity. The experimentally observed effective rate constant is expressed by a complex combination of the rate constants for the reactions of non-solvated and solvated molecules, the equilibrium constants for the complex formation reactions, and the coordination numbers of the solvate[5,178]. The formation of π-complexes is well known for many stable radicals[5]. The rates of dehydrogenation of HB [144] and dihydropyridines[90,156] and of the reactions with BP [165] and with lauroyl peroxide[109], involving triarylverdazyls, decrease appreciably on passing from hydrocarbons to π- and n-donor solvents.

The formation of π- and n-complexes of triphenylverdazyl and the kinetic manifestations of such complex formation have been investigated by spectroscopic and kinetic methods for reactions carried out in mixed solvents[109,156,169,179]. As for other stable radicals[5,178], association with only one molecule of the complex-forming solvent is significant for (I). The rate constants for the solvated radicals (I) are smaller by 1–2 orders of magnitude than those for the non-solvated radicals[109,156,169]. With increase of the concentration of the π- and n-donor solvents in the mixture, there is a parallel increase of E_a [90,109] (which may be attributed to the necessity for the dissociation of the radical–solvent complexes) and of $\Delta S^{\neq}$ (desolvation preceding the formation of the transition state leads to disordering of the system[5,178]). The formation of π-complexes of (I) in aromatic solvents is accompanied by a bathochromic shift of the $\pi \rightarrow \pi^*$ absorption band, and a decrease of the molar extinction coefficients at λ_{max} compared with spectra recorded in hexane[156,169]. The thermodynamic constants for the formation of the complexes as well as the difference between the bond energies of the complex in the ground and excited states[108], i.e. $\Delta H_g - \Delta H_e = h(\nu_0 - \nu_S)$, where ν_0 and ν_S are the frequencies at the electronic band maxima of (I) in hexane and in a solvating solvent, as well as the equilibrium constants for the solvation of (I) in the ground and excited states, i.e.

$$V^{\cdot} + S \overset{K_g}{\rightleftarrows} V_s^{\cdot} \quad ,$$

$$V^{\cdot *} + S \overset{K_e}{\rightleftarrows} V_s^{\cdot *} \quad ,$$

where K_g and K_e are the equilibrium constants for the solvation of (I) in the ground and excited states and S is the solvent, may be determined from the absorption spectra of (I) in mixed solvents. The formation of π-complexes by (I) with benzene and pyridine causes a bathochromic shift; $\Delta H_e - \Delta H_g$ is 2.4 kcal mole^{-1} in benzene and 4.0 kcal mole^{-1} in pyridine[156,169], i.e. the stabilities of the π-complex of the excited (I) in benzene and pyridine exceed by 2.4 and 4.0 kcal mole^{-1} respectively the stability of the π-complex in the ground state. There is an increase in the equilibrium constants for solvation in the excited state [$\ln K_e/K_g = (\Delta H_e - \Delta H_g)/RT$][180] and the dipole moment (~9 D) [29] on photoexcitation of (I).[29]

Table 5. Thermodynamic parameters of the complexes of stable radicals with organic solvents[219].

Solvent	$K_{25°}$ *, litre mole^{-1}	$-\Delta H°$, kcal mole^{-1}	$-\Delta S°$, e.u.	$\Delta G°$, kcal mole^{-1}

* At the isoequilibrium temperature $\beta = 283$ K, we have $\ln K_p = 1.0 \pm 0.4$, which does not allow sufficiently rigorous inferences concerning the isoequilibrium conditions[158].

** 2,4,6-Tri-t-butylphenoxyl.

*** 2,6-Di-t-butyl-4-phenylphenoxyl.

**** Galvinoxyl

Since the initial state in radical reactions frequently involves a higher degree of solvation than the transition state, an increase of solvation causes an increase of E_a and makes the process less exothermic[109,156,169]. Solvation also leads to a weakening of the electrophilic or nucleophilic properties of the radicals and to a diminution of the role of polar influences[90,107,178].

---

† The dissolution of any substance B is accompanied, in principle, by solvation and the formation of a solvate complex having the average composition $B_{solid} + nS \rightleftharpoons BS_n$.

Table 5 presents the thermodynamic parameters for the formation of complexes by (I) and other stable radicals in π-donor solvents (the solvation equilibrium constants were determined from chromatographic[181], kinetic[182], and spectroscopic data[183]). The enthalpies and entropies of the complex formation reactions vary in parallel—the higher the heat of formation of the complex the lower the value of $\Delta S°$. The most stable complex is that of t-butyl mesityl nitroxide with methyl acrylate. The relation between $\Delta H°$ and $\Delta S°$ for the π-complex formation reactions of stable radicals (14 complexes) is satisfactorily described by the equation[219]

$$\Delta H^0 = 0.283\Delta S^0 - 0.535 \; (r = 0.992, \; s_0 = 0.377).$$

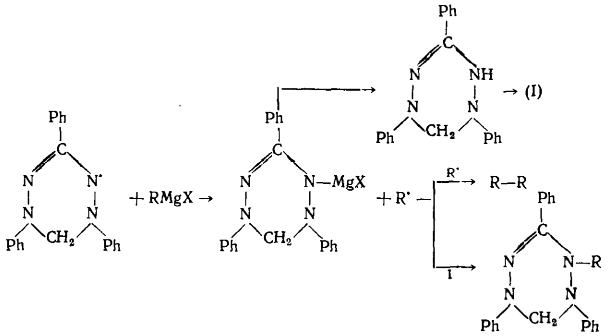
The isoequilibrium temperature β = 283 K. The free energies of formation of the complexes change comparatively little ($\Delta G°$ = 0.8 ± 0.4 kcal mole^{-1}), which is due to the closeness of the experimental temperature to β. Presumably the linear relation between $\Delta H°$ and $\Delta S°$ is a characteristic feature of the thermodynamics of the formation not only of complexes of the donor–acceptor type[184] but also of other complexes having similar structures and compositions.

The elucidation of the nature of the complexes formed by radicals with the molecules of organic solvents is important for the theory of reactivity. It has been observed for certain radicals, particularly DPPH and phenoxyls[178], that the hyperfine interaction in the EPR spectra depends on the nature of the solvent. This indicates partial electron transfer on complex formation. Virtually no changes in the hyperfine interaction constants in electron-donating solvents have been observed for (I).[90,109,156] Specific intermolecular interactions (van der Waals and dipole–dipole interactions as well as interactions involving polarisation forces) may play a significant role in the formation of complexes by radicals with solvent molecules[185]. When a π-complex of the radical and solvent molecules is formed, the π orbitals of the radical and the ligand overlap, which leads to paramagnetic shifts of the NMR lines and a change in the T_1 and T_2 relaxation times of the ligand nuclei, and is responsible for dynamic nuclear polarisation (DNP).[5] DNP studies on many radicals in electron-donating solvents have shown that the degree of transfer of the unpaired electron in the π-complex is small[5,178]. A DNP study on verdazyls led to the discovery of a large contribution of the contact interaction to nuclear polarisation, which is associated with the high spin density in the verdazyl ring[63,64]. The presence of a spin density in the ligand causes either spin polarisation of the C–H bonds or the density spreads via a hyperconjugation mechanism.

The steric orientations of the radical and the ligand are very important in the delocalisation of the unpaired electron. The orientations of the complexes of radicals with solvent molecules obey a statistical distribution[186]. The most stable configuration in this distribution is not optimal either from the standpoint of charge transfer or the pre-reaction complex. There is no reaction within the π-complex, as shown by Russell in chlorination reactions and by Buchachenko and Sukhanova[187] in the reaction involving the abstraction of hydrogen from ethylbenzene by an *N*-oxide radical.

7. Reactions of Verdazyls with Organometallic Compounds

Kinoshita and coworkers[40,43] showed that polymers incorporating the tetrazine structure are formed in the initiation of the anionic polymerisation of vinyl monomers incorporating the verdazyl structure by Grignard reagents, alkyl-lithium compounds, and sodionaphthalene. It is suggested that the reactions of triarylverdazyls with organolithium compounds (EtLi, BuLi), organoaluminium compounds [$Al(C_2H_5)_3$, $Al(C_2H_5)_2Cl$, $Al(t\text{-}C_4H_9)_3$, or Grignard reagents (ethyl-, isopropyl-, or butyl-magnesium bromides, benzylmagnesium chloride) proceed via the intermediate formation of a metallic salt of the verdazyl and be treated as free-radical substitution at the nitrogen atom[188-191]. The following mechanism of the reaction with (I) has been proposed for organomagnesium compounds, for example on the basis of the analysis of the reaction products:

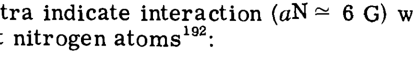


R=C_2H_5, iso-C_3H_7, n-C_4H_9, iso-C_4H_9, t-C_4H_9, CH_2Ph, or CH_2CH_2Ph.

Metal salts of the verdazyl (I) are unstable and readily hydrolyse with formation of leuco-bases, which are oxidised to (I).

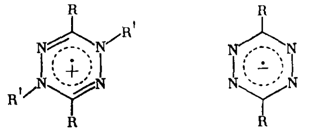
V. TETRAZINYL RADICAL-IONS AND TETRA-AZAPENTENYL, TETRAZOLINYL, AND PHOTOTETRAZOLINYL RADICALS

Cyclic compounds with four nitrogen atoms (tetrazines and tetrazolium salts) as well as their linear analogues (formazans and tetra-azapentenyls) show a very high tendency towards the formation of radical structures, because of the possibility of a marked delocalisation of the unpaired electron, which lowers the energy of the ground state of the system. Thus stable (withstanding boiling) radicals are formed readily in dioxan solutions of copper dithizonate and diphenylcarbazonate complexes. The EPR spectra indicate interaction (aN ≃ 6 G) with the four equivalent nitrogen atoms[192]:



$$R{-}S{-}C{\begin{smallmatrix} \nearrow N{-}\dot{N}{-}Ph \\ \searrow N{=}N{-}Ph \end{smallmatrix}} \qquad H{-}O{-}C{\begin{smallmatrix} \nearrow N{-}\dot{N}{-}Ph \\ \searrow N{=}N{-}Ph \end{smallmatrix}} \quad R{=}H,\ CH_3 \cdot$$

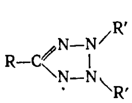
The *sym*-tetrazine/1,4-dihydro-*sym*-tetrazine system is of the oxidation-reduction type (like the quinone/hydroquinone system) and readily forms radicals[193-195]. The one-electron oxidation of 1,4-dihydro-*sym*-tetrazines leads to relatively stable radical-cations. The hyperfine interaction constants are $a^N_{1,5}$ = 7.4–8.0 G and $a^N_{2,4}$ = 3.4–4.5 G depending on the substituents. When *sym*-tetrazines are reduced by alkali metals, fairly stable radical-anions are formed:



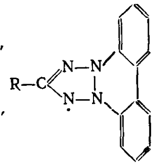
R = CH$_3$, or Ph, R' = H; R, R' = Ph;

R = Me, Et, iso-Pr, or (Ph)$_2$CH .

The first stable tetrazolinyl and phototetrazolinyl radicals [(XVIII) and XIX) respectively] were synthesised by Kuhn and coworkers[196]:

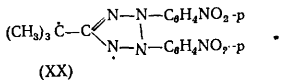


(XVIII)



(XIX)

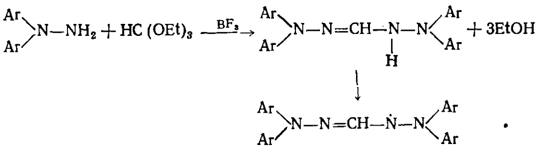
The triphenyltetrazolinyl radical is stable in air and its EPR spectrum indicates the interaction of the unpaired electron with the two pairs of equivalent nitrogen atoms ($a^N_{2.3}$ = 7.5 G, $a^N_{1.4}$ = 5.6 G). The radicals are readily obtained on reduction of tetrazolium and phototetrazolium salts or on homolytic abstraction of hydrogen from formazans, or on their oxidation to tetrazolium salts[197–199]. Intramolecular electrochemical cyclisation of formazans to tetrazolium salts proceeds via the intermediate formation of radical-cations[200]. It has been shown that the tetrazolium radicals formed on oxidation of formazans, on reduction of tetrazolium salts, on disproportionation of a mixture of a formazan and a salt, and on homolytic abstraction of hydrogen from formazan have cyclic structures[201]. Only one stable tetrazolinyl radical, namely radical (XX), has been isolated in a crystalline state[202]:



(XX)

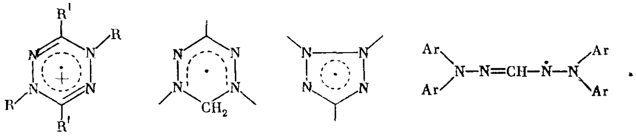
A study of the magnetic susceptibility of (XX) showed that[198] it is monomeric in solution. The stability of tetrazolinyl radicals increases as the electron-accepting properties of the substituents in the N-phenyl rings become more pronounced and $a^N_{2.3} > a^N_{1.4}$ for both tetrazolinyl and phototetrazolinyl radicals.

Apart from cyclic radicals with four nitrogen atoms, their linear analogues (tetra-azapentenyl radicals) are also known[203–205]. They are obtained by oxidising with oxygen, silver oxide, or lead dioxide the products of the condensation of orthoformic ester with an asymmetric hydrazine:



These radicals have a bluish-green colour (λ_{max} = 600–700 nm) and are much less stable than their cyclic analogues. Some of them, for example 1,1,5,5-tetraphenyl-1,2,4,5-tetra-azapentenyl, are stable and can exist for weeks in a crystalline form. In solution tetra-azapentenyls are monomeric and obey the Beer–Lambert law.

Comparison of the EPR spectra of verdazyls, tetrazinyl radical-ions, tetrazolinyl radicals, and tetra-azapentenyls illustrates the significant influence of the delocalisation of the unpaired electron on the stability of the radicals. All the radicals and radical-ions have seven π electrons and an insignificant spin density at the ring carbon atoms:



Most of the spin density is located at the terminal nitrogen atoms of the hydrazidinyl system[6]: $a^N_{1.5}/a^N_{2.4}$ is ~1 for verdazyls, ~1.7 for tetra-azapentenyls, and ~2 for tetrazinyl radical-cations; $a^N_{2.3}/a^N_{1.4}$ is ~1.3 for tetrazolinyls and ~2 for phototetrazolinyls. Electron-accepting substituents in the benzene ring cause a partial withdrawal of electron density from the central ring and tend to make the nitrogen atoms equivalent; the stability of tetrazolinyls and phototetrazolinyls then increases.

VI. PRACTICAL ASPECTS OF THE CHEMISTRY OF VERDAZYL RADICALS

The vigorous development of the chemistry of verdazyls is associated with the important role which they play in the solution of various theoretical and practical problems.

Verdazyls proved to be convenient objects for the solution of many problems in theoretical chemistry (the determination of the mechanisms of elementary chemical reactions, the determination of the relation between the reactivity and structure of reagents, and the study of the propagation of π- and σ-electron spin density, intermolecular interactions, weak exchange interactions of electrons, ferromagnetic interactions, etc.). In many cases it has been possible to elucidate in relation to verdazyls the influence of solvent polarity, π- and n-complex formation, and hydrogen bonds on the kinetics of liquid-phase radical reactions. The important role of polar factors (and of the isokinetic temperature in their interpretation) in the kinetics and mechanisms of homolytic reactions has been demonstrated. Verdazyls are convenient spin labels for the study of the dynamic structures of polymers in solutions; verdazyl bi- and tri-radicals are used to study the structures and molecular motions in isotropic and liquid-crystal solutions[206,207], which is of interest for structural chemistry, because it makes it possible to determine the number of unpaired electrons and the average distance between them.

As a result of the discovery of methods for the synthesis of verdazyls without affecting the free valence, it is possible to obtain spin-labelled compounds, so that verdazyls are likely to be useful in molecular biology, biophysics, the physical chemistry of polymers, the synthesis of spin-labelled drugs, and models of physiologically active compounds, and in the study of the mechanism of the action by EPR.

Verdazyls can be used in analytical chemistry as indicators[217]. In view of their very high stability, ready availability, and the possibility of obtaining them as 100% pure preparations, verdazyls are likely to be useful as standards in quantitative measurements by EPR (the percentage content of DPPH, for example, varies markedly with time[208]). The possibility of using verdazyls in laser engineering has been investigated[209]. Being stable over a wide range of potentials (~1 V), triphenylverdazyl may be used as a "trap" for short-lived radicals obtained in electrode reactions (DPPH, for example, is electrochemically stable only in the region of ~0.3 V).[97]

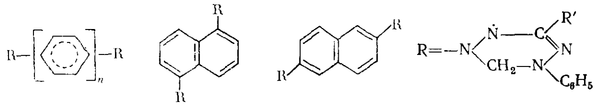
Pokhodenko et al.[210] showed recently that, in the electron transfer reaction between two stable radicals one of which is triphenylverdazyl, an e.m.f. ranging from several tenths of a volt to several volts is generated. The formation of reversible galvanic cells based on stable radicals or radical-ions[211] is of considerable theoretical and practical interest.

The use of verdazyls as dyes is promising. In contrast to DPPH, verdazyls dye fabrics uniformly, which permitted their employment for the study of the wear of knitted materials[212]. The ability of verdazyls to dye polymeric materials may prove useful in the study of the mechanical degradation of polymers by EPR.

Verdazyls react with many compounds which are sources of free radicals: peroxides, hydroperoxides, and transition metal compounds. The properties of verdazyls as free radical acceptors permit the study of cell effects in the decomposition of initiators of radical polymerisation and the dependence of the yield of radicals on the nature of the solvent. The ability of verdazyls to terminate kinetic chains by reacting with active radicals makes it possible to use them as inhibitors of autoxidation and radical polymerisation. Thus the polymerisation of styrene in the presence of triphenylverdazyl (1 : 30 000) is strongly inhibited and the autoxidation of benzaldehyde at 20°C is fully suppressed[2]. Water-soluble verdazyls inhibit the decomposition of H_2O_2 initiated by catalase or platinum black[26]. Verdazyls inhibit effectively the polymerisation not only of styrene but also of other monomers—methyl methacrylate, acrylonitrile, vinyl chloride, and vinyl acetate. In the presence of (I) polarisation is fully suppressed and after its consumption takes place at the same rate as in the absence of added inhibitor. The induction period increases linearly with increasing concentration of (I) for the same initiator concentration, which shows that, in contrast to aliphatic nitroxides, (I) does not undergo side reactions. The linear dependence of the induction period on the verdazyl concentration shows that these radicals initiate the formation of kinetic chains to only a slight extent[115]. The period corresponding to inhibition by verdazyls may be measured spectroscopically and verdazyls can thus be used to determine the rate of initiation. In contrast to hydroxylamines, leucoverdazyls do not affect the induction period but inhibit polymerisation effectively. The activities of various inhibitors of radical polymerisation have been compared in relation to the polymerisation of oligourethane-acrylate initiated by azobisisobutyronitrile. Verdazyl mono- and bi-radicals are powerful inhibitors[213,214]. Its high effectiveness, the simplicity of its synthesis, its ready availability, and the possibility of the visual monitoring of its concentration made it possible to recommend triphenylverdazyl as a promising stabiliser in the manufacture, storage, and processing of many oligomeric and monomeric compounds[214].

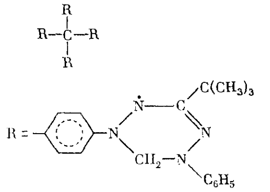
The development of research into polymers with stable radicals in the main or side chains was stimulated by the great interest in new semiconducting materials. Polymers with verdazyl radicals (molecular weight 2300–4800) as well as oligomers containing verdazyls in the polymer matrix are of interest from the standpoint of their electrical properties, radical reactions, and practical employment as antioxidants, redox indicators, and catalysts of certain oxidation-reduction reactions[36-45,115-117,215].

During the preparation of the manuscript for the press, a number of studies devoted to the chemistry of verdazyl radicals were published. New verdazyls containing heteroaromatic substituents in the 1-position of the formazan group[220,221] and triarylverdazyl radicals with perfluorophenyl substituents[222] were synthesised. New verdazyl biradicals have been obtained from the corresponding diformazans or monoverdazyls using a 1-cyano-1-methylethyl protecting group[223]:



R' = C_6H_5, or $C(CH_3)_3$.

Neugebauer et al.[224] recently obtained the tetraverdazyl (XXI), which is readily soluble in organic solvents:



4-Verdazyl[2,2]paracyclophanes have been obtained in order to study the characteristics of the distribution of spin density and interactions involving charge transfer[225]. The magnetic properties, ENDOR spectra, and characteristics of the intermolecular interactions of verdazyls with C_6H_6 and CCl_4 have been investigated[226-228].

Studies on the chemical properties of verdazyls have been developed further. It has been observed[229] that triphenylverdazyl catalyses the dark PI_3 polymerisation reaction in hexane, forms complexes with molecular oxygen[230], and decomposes peracids[231]. Triphenylverdazyl reacts reversibly with hydroquinone[232] and forms dicyanodiaziridine in the reaction with bromodicyanomethane[233]. The regeneration of verdazyls in reactions with peroxy-compounds, discovered by Yarmolyuk[125], has been investigated[234,235]. A study has been made of the influence of the composition of binary solvents on the kinetics of chemical reactions with participation of verdazyls[236-238]. The oxidation-reduction reactions of verdazyls have been investigated[239,240]. Quantum-chemical calculations on verdazyl radicals, ions, and leuco-compounds by the INDO method with total optimisation of the geometry, which made it possible to calculate their electronic and steric structures, can serve as a basis for the understanding and prediction of the chemical properties and reactivities of these species[241,242].

Spectroscopic and Quantum-chemical Studies on the Active Centres in Anionic Polymerisation

V.N.Zgonnik, E.Yu.Melenevskaya, and B.L.Erusalimskii

The mechanisms and consequences of complex formation in systems incorporating organometallic compounds are discussed on the basis of spectroscopic and quantum-chemical characteristics of alkyl, alkenyl, and aryl derivatives of lithium and certain other metals in the absence and presence of electron donors. Particular attention is devoted to "living" anionic chains. The bibliography includes 129 references.

I. INTRODUCTION

Many of the anionic polymerisation processes initiated by organometallic compounds take place with participation of "living" polymers, i.e. growing chains which retain their capacity for the propagation reaction even after the complete exhaustion of the monomer or after the attainment of a state of equilibrium in the polymer–monomer system. In order to determine the relation between the experimental effects observed in such processes and the characteristics of the growing chains active in the system, it is necessary to investigate independent physicochemical characteristics of the corresponding "living" polymers. The first information of this kind was restricted to conductimetric data for and the electronic spectra of solutions containing agents of this kind. The constants for the dissociation into free ions were determined on the basis of such data for a number of compounds and the type of the initial ion pairs, which can be either contact or solvent-separated pairs of specially introduced electron donors (ED), was established[1]. In subsequent years these characteristics were supplemented by infrared and NMR spectroscopic data, which made it possible to improve significantly the available knowledge of the structure of the anionic active centres, particularly for metal alkenyls and their complexes with electron donors. The formulation of correct conclusions concerning the structure of the active centres requires information about the low-molecular-weight organometallic compounds which initiate anionic polymerisation. A survey of the available information about the infrared and NMR spectra of the above agents is the main subject of the present review. Due attention has been devoted to the results of theoretical calculations of the electronic structures and geometries of the agents simulating anionic active centres. Both experimental and calculated characteristics of compounds of the above type are known mainly for lithium derivatives.

II. LOW-MOLECULAR-WEIGHT ORGANOMETALLIC COMPOUNDS

1. Lithium Alkyls

The compounds RLi are known to be strongly associated in hydrocarbon solutions, the size of the aggregate being determined by the structure of R.[2-4] According to modern ideas, the association is due to the formation of many-centre linkages involving the vacant *p* orbitals of the lithium atoms and the sp^3 orbitals of the carbon atoms. Depending on the degree of branching of R and the nature of the medium, hexa-, tetra-, di- and mono-meric forms of RLi may exist[4]. In non-polar media the hexamers and the tetramers predominate for straight-chain and branched groups respectively. There is a mobile equilibrium between the different forms, which has been described in terms of dissociation via dimeric forms[5] and, according to Brown[3], the fastest exchange with a low activation energy occurs when the system contains hexamers:

$$(RLi)_6 \rightleftarrows (RLi)_4 + (RLi)_2, \tag{1}$$

$$(RLi)_2 + (RLi)_6 \rightleftarrows 2\,(RLi)_4. \tag{2}$$

The C–Li bond in lithium alkyls is a polar covalent linkage[1,4]. The carbon in the α-position relative to lithium is sp^3-hybridised in lithium alkyls and sp^2-hybridised in lithium aryls, which follows from a comparison of the α-^{13}C chemical shifts in the spectra of the lithium compounds with data for the corresponding hydrocarbon. The characteristics of certain compounds RLi obtained by NMR are presented in Table 1†.

Table 1. The differences between the chemical shifts ($\Delta = \delta_{RH} - \delta_{RLi}$, p.p.m.) in the ^{13}C NMR spectra of the compounds RLi and the corresponding hydrocarbons in benzene[6].

---

† The chemical shifts in all the Tables are quoted in terms of the δ scale.

It follows from the NMR data[6,7], that n-butyl-lithium (BuLi) differs from s- and t-BuLi and isopropyl-lithium (iso-PrLi) by the absence of spin–spin splitting due to the $^{13}C{-}^{7}Li$ bond, which can be in principle accounted for by a rapid intermolecular exchange[6] via the mechanism described by Eqns. (1) and (2). On the other hand, in solutions of iso-PrLi the hexameric form is also present[8], but the natures of the NMR spectra of the compounds iso-PrLi and BuLi are different. The infrared method makes it possible to determine the fraction of the associated species $(iso\text{-}PrLi)_n$ differing in the value of n, because the stretching vibrations of the Li–C bond in the tetramer and the hexamer are characterised by absorption bands at 475 and 510 cm^{-1} respectively[9] (Fig. 1)‡.

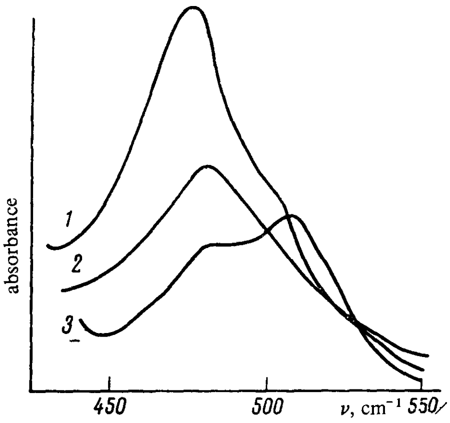

Figure 1. Infrared spectra of isopropyl-lithium in iso-octane[9]; concentration (M): 1) 0.24; 2) and 3) 1.2; temperature (°C): 1) −100; 2) 12; 3) 1.2.

The correct assignment of the ν(C–Li) absorption bands was carried out for the first time by West and Glaze[11] on the basis of the method involving the isotopic substitution of ^7Li and by ^6Li and of H by deuterium. The infrared characteristics of a number of compounds RLi are now known (Table 2). In his study of the reaction between the $CH_3^{\cdot}$ radical and metallic lithium in a solid argon matrix, Andrews[12] isolated the absorption bands due to CH_3Li in the infrared spectra. Comparison of his values with data for solid methyl-lithium[11] led him to the conclusion that the hypsochromic shift of the ν(C–Li) band in the spectrum of monomeric CH_3Li, greater than by 100 cm^{-1}, is due to the decrease of the C–Li bond length to 2.10 Å (compared with 2.28 Å in solid CH_3Li); this effect decreases the force constant. The nature of the C–Li bond vibrations in the associated species is complicated by the interaction of the vibrations of the fragments of the associated molecules.

Table 3. The charge characteristics (q) and association energies (E_a) of methyl-lithium.

Method of calculation	CNDO/1 (Ref.19)	Non-empirical method (Ref.20)	Method of calculation	CNDO/1 (Ref.19	Non-empirical method (Ref.20)
	CH_3Li			$(CH_3Li)_4$	
q_C	−0.39	−0.58	q_C	−0.26	−0.97
q_{Li}	+0.53	+0.57	q_{Li}	+0.04	+0.61
			E_a, kcal $mole^{-1}$	112.5	110.5

Quantum-chemical calculations on the CH_3Li and $(CH_3Li)_4$ molecules, carried out by the semi-empirical CNDO/1 method[19] and the non-empirical method[20], indicate a considerable energy gain on formation of aggregates. On the other hand, conclusions concerning the change in the polarity of the C–Li bond, which follow from the data of Cowley and White[19] and Guest et al.[20] do not agree (Table 3).

2. Complexes of Lithium Alkyls with Electron Donors

It follows from NMR and osmometric data[3,4] that lithium alkyls are tetrameric in polar solvents [diethyl ether, tetrahydrofuran (THF), and trimethylamine]. It has been suggested[8,21] that the hexamer is converted into the tetramer already for the molar ratio ED : $(RLi)_6 \simeq 1{-}2$. Intermolecular exchange can proceed as follows:

$$(RLi)_4.nED \rightleftharpoons 2(RLi)_2.n/2\,ED.$$

The existence of the monomeric form RLi, which follows from kinetic polymerisation data[5], could not be demonstrated with the aid of the above methods.

The NMR spectra of $(CH_3Li)_4$–polar solvent systems[3,4] indicate the occurrence of spin–spin splitting due to the $Li{-}^{13}C$ bond, which is evidence for an appreciable contribution of the covalent component to the C–Li bond. On the other hand, a significant spin–spin $^6Li{-}^7Li$ splitting is not observed, whence it follows that there is no bond between lithium atoms, i.e. that the aggregation effect is caused by the formation of Li–C–Li bridge bonds. It has

---

‡According to theoretical considerations[10], the difference between the chemical shifts of the tetramer and the hexamer should be 0.1 p.p.m. Nevertheless the ^7Li NMR method does not permit the detection of the above forms of the iso-PrLi.

been established for the BuLi–THF system in a hydrocarbon medium[8] that there is no change in the ^{7}Li chemical shift in the range of THF : BuLi ratios from 1 to 14. This can be accounted for either by the formation of the complex $(BuLi)_4.4\,THF$ when the component ratio is only unity or by the impossibility of detecting separately the chemical shifts of various intermediate aggregates owing to the rapid intermolecular exchange even at –100° C. The NMR method has also been used to characterise qualitatively the formation of BuLi complexes with dioxan, dimethoxymethane, and tetrahydropyran[22].

*Vinogradova et al.[26] used more carefully separated DMB stereoisomers than in the work of Kalnin'sh et al.,[16] which is the reason for the difference between the two sets of data.

**The above band is manifested for the ratio Li : ED = 8 with the simultaneous disappearance of the 1076 and 1110 cm^{-1} bands. The tentative composition of the corresponding complex is DMB. 2T.

***Here (A) is the monodentate complex T.4DMM and (B) is the bidentate complex T.2DMM.

The enthalpy of formation of the BuLi complex with diethyl ether (DEE) was estimated by gas–liquid chromatography (GLC)[23]; the value –5 ± 0.5 kcal mole^{-1} was obtained for the complex $(BuLi)_6.DEE$.

*See Eqns. (3) and (4).

**The quantity quoted corresponds to the case where $T.2ED \xrightarrow{2ED} T.4ED$.

Zgonnik and coworkers[16,24-26], who used the infrared spectroscopic method, showed in relation to dimethyl (DME), diethyl, and dibutyl (DBE) ethers, THF, and 2,3-dimethoxybutane (DMB) that the formation of a complex with BuLi entails bathochromic shifts of the ν(C–Li) and ν(C–O–C) bands. Systems with participation of DME and THF were studied in greatest detail[24]. It was established that the complexes are formed stepwise via n-butyl-lithium tetramers (T), differing in the degree of solvation:

$$2\,(BuLi)_6 + 3ED \overset{K_1}{\rightleftarrows} 3\,T \cdot ED,\quad T \cdot ED + ED \overset{K_2}{\rightleftarrows} T \cdot 2ED, \qquad (3)$$

$$T \cdot 2ED + ED \overset{K_3}{\rightleftarrows} T \cdot 3ED,\quad T \cdot 3ED + ED \overset{K_4}{\rightleftarrows} T \cdot 4ED. \qquad (4)$$

The values of ν(C–Li) corresponding to the products of these reactions are listed in Table 4. The first two ED molecules are linked to T very strongly, which follows from the almost complete absence of changes in the infrared spectra as the temperature is altered for complexes formed for the initial ratios THF : BuLi = 0.25 and 0.5.

The spectroscopic characteristics of a number of electron donors, both free and bound in complexes with BuLi, are listed in Table 5. The complex formation constants K_c and the enthalpies of complex formation were calculated from the absorption band intensities associated with the free and bound electron donors in some of the systems (Table 6).

The results presented in Tables 5 and 6 may be supplemented by the following comments. The preferential transformation of the *trans*, *trans*- and *trans*-conformations of the free electron donors into the *trans*,*gauche*-, and *gauche*-conformations on formation of the complexes of the electron donor with BuLi was demonstrated for DEE and MEE[27,28]. The maximum coordination saturation of lithium is rather difficult to achieve in the case of DEE and MEE; the complex corresponding to the composition T.4ED is formed to only an insignificant extent in the case of DEE even at –95° C.[28] The type of the complex of BuLi with DMM (Table 5) is determined by the temperature for a constant reactant ratio or by the DMM : BuLi ratio for a constant temperature. In particular, an increase of the BuLi concentration and a decrease of temperature promote the formation of the complex (B). The energy of the (B) ⇌ (A) transition is 12 ± 1 kcal mole^{-1}.[29]

The values of K_c could be estimated in only a limited number of cases, but the results permit the conclusion, the same as the familiar conclusions in the literature[31,32], that there is no simple relation between the physicochemical properties of the electron donors and their capacity for complex formation. Thus a number of data[16,24-29] make it possible to arrange the electron donors investigated in terms of the following activity series relative to BuLi as regards the relative amounts of the free and bound electron donors: DMB ≃ THF > DMM > DME > DEE > DBE. Since it does not agree with the variation of the ionisation potential I_p§, the steric structure of the electron donor and the number of heteroatoms may be regarded as the principal factors which determine the stability of the complexes. Data characterising the BuLi–NR_3 and BuLi–tetramethylethylenediamine (TMED) systems lead to an analogous conclusion. Thus I_p for trimethylamine (TMA) is higher than for triethylamine (TEA) (7.82 and 7.67 eV respectively[30]), but the former donor forms in the temperature range from −70° to −100°C appreciable amounts of the T.4ED complex, while the latter has been found to form only the T.ED and T.2ED complexes[30].

The complexes formed by BuLi with TMED, investigated for the first time by Langer[33,34], are known to be highly stable. In the reports quoted above, the determination of the infrared and NMR spectra of the complexes is mentioned, but no experimental results are given. The data of Zgonnik and coworkers[25], characterising the infrared spectra of the same system, indicate stepwise complex formation. Depending on the initial reactant ratio, complexes of the type T.*n*TMED, where *n* varies from 1 to 4, are formed; they are hardly dissociated and their composition is insensitive to changes in temperature between −30°C and 25°C.

The complexes of BuLi with another bidentate donor, namely DMB, whose *meso*-form has been studied[26], are much less stable. The limiting stoichiometry of the complexes in this instance also corresponds to the formula T.4ED, but, for an initial 1 : 1 reactant ratio (at 20°C in a hydrocarbon medium) there is an equilibrium between the free and bound molecules. The infrared spectra of this system, obtained in the presence of an excess of BuLi at −30°C, indicate the coexistence under the above conditions of the mono- and bi-dentate complexes. The characteristics of the $(BuLi)_4.n$ED complexes, obtained by the ^{1}H NMR method[35] at 20°C in iso-octane, are listed below (Δ is the chemical shift of the α-CH_2 group in BuLi):

ED	*n*	Δ, p.p.m.	K_C, litre mole^{-1}
DME	4	0.21	8 ± 2
DEE	3	0.14	6 ± 2
TEA	3	0.19	5 ± 2
DES	2—3	0.10	1

Comparison of the relative activities of several electron donors with different heteroatoms, including diethyl sulphide (DES), led to the following activity series: DME > DEE > DEA > DES.[35]

The formation of mixed complexes of electron donors with BuLi has been demonstrated for TMA and THF.[30] For the initial ratios BuLi : THF : TMA = 1 : 1 : 1 (in iso-octane as the solvent) and at −100°C, the complex includes approximately four times more THF than DMA; with increase of temperature, the DMA content rises somewhat.

Infrared spectroscopic data for systems with TMA, MEE, and THF also indicate the conversion of the complexes T.2ED in the range between −70° and −100°C into the complexes T.4ED (an absorption appears at 504 cm^{-1}; see Table 4). The absorption in the high-frequency region observed under these conditions (Fig. 2) led to the hypothesis[9,30] that the observed effects are due to the disproportionation of the complexes T.2ED, one of the products of which is the complex of the BuLi hexamer with ED. It is quite possible that the formation of the solvated hexamer compensates the energy gain accompanying the dissociation of the complex of the butyl-lithium tetramer.

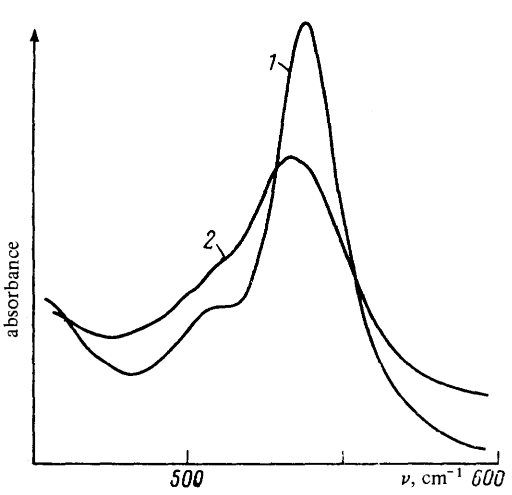

Figure 2. Infrared spectra of the 2.36 : 1 n-butyl-lithium–TMA-complex in iso-octane[30] at −17°C (curve *1*) and −100°C (curve *2*).

3. Allyl Compounds of Alkali Metals and Magnesium

The allyl derivatives of alkali metals are soluble only in electron-donating solvents or in a hydrocarbon medium containing an electron donor[36]. According to spectroscopic data (mainly NMR), under these conditions the C–Li bond in allyl-lithium (AllLi) is ionic at room temperature[36-39] and the allyl group has the delocalised structure

(I)

with free rotation about the Cα – Cβ and Cβ – Cγ bonds[36,37]. The infrared spectrum of AllLi exhibits a ν(C–C) = 1535 cm^{-1} absorption, which is characteristic of a delocalised structure with sp^2 hybridisation of the α-carbon atom[40]. Analogous data for the AllLi structure have been obtained[6] by ^{13}C NMR. According to Dolinskaya's data[36] for DME and West's data[39] for DEE and THF, the ^{1}H NMR spectra of AllLi at approximately −90°C demonstrate the presence of two types of terminal protons, which is a consequence of the complete inhibition of rotation about the above bonds. In asymmetric allyl derivatives, where the degree of delocalisation is reduced, the rotation about the

---

§THF has a smaller ionisation potential than DME, but, within the limits of the DME–DBE series, I_p decreases from 10.00 to 9.59 eV.[28]

Cβ–Cγ bond is already inhibited close to room temperature[36,39]. In a study of the vibrational spectra of the allyl compounds of lithium, sodium, and potassium, Lanpher[40] demonstrated the presence of two absorption bands corresponding to the following structures (where Mt is the metal):

and

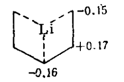
(II) (III)

[In particular, the 1525 and 1560 cm^{-1} bands correspond to the pentenylsodium structures (**II**) and (**III**) respectively]. On the other hand, only one band is characteristic of the symmetrical derivatives (for example at 1520 cm^{-1} for 2-methylallylsodium). The allyl derivatives of magnesium exist at room temperature in an ethereal medium in the form of the equilibrium system

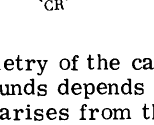
and with increase of the bulk of the substituent the fraction of the *cis*-isomer diminishes[41,42].

Among the quantum-chemical calculations for allyl compounds, the greatest interest attaches to AllLi data obtained by the non-empirical method[43]. According to these results, the symmetrical π-allyl structure with charges of −0.197*e* at the α- and γ-carbon atoms, −0.063*e* at the β-carbon atom, and +0.159*e* at the lithium atom, is energetically most favourable. Calculations for the model complex AllLi.2H₂O confirm the conclusion that the delocalised structure of allyl-lithium has the highest stability. Comparison of the AllLi dimerisation energy with the energies of formation of AllLi complexes with electron donors permit the conclusion that the formation of associated forms is favourable only in non-polar media.

The CNDO/2 semi-empirical method has been used in calculations on the $CH_2{=}CH{-}CH{=}CH{-}CH_2Li$ molecules with limited optimisation within the limits of several possible conformations[44]. The symmetrical structure illustrated below in a simplified form proved to be preferable:

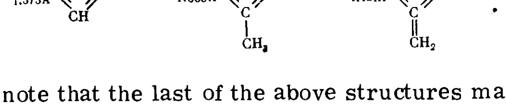


The same method has been used[45] in calculations on models of the terminal units of growing butadiene and isoprene chains associated with lithium counterions. The limiting *cis*- and *trans*-structures in their π- and σ-forms were compared. The most stable of these are structures of the type



R = H or CH₃.

The idea that the geometry of the carbanionic components of analogous compounds depends on the intrinsic structure of the alkenyls arises from the results of calculations on free allylic anions (the MINDO/3 method)[46]:



We may note that the last of the above structures may be adopted as the model of the fragment of the terminal unit in "living" buta-1,2-diene chains.

Sourisseau et al.,[38] who investigated the solid allyl compounds of lithium, sodium, and potassium by infrared spectroscopy, concluded that the allyl group has an ionic structure, which differs from its structure in π-allyl complexes of transition metals[47,48] and in covalent compounds of the type of allylmercury[49,50]. The assignments of the principal absorption bands of allyl derivatives of solid non-transition metals are listed below[38]:

Frequency, cm^{-1}	600	740	1000—1240	1400; 1460	1530	2900—3100
Assignment	δ (CCC)	r_0 (CH_2)	δ (CH); ν_s (CCC)	δ (CH_2)	ν_{as}(CCC)	ν (CH); ν (CH_2)

A set of bands in the broad range 100–600 cm^{-1} is characteristic of the C–metal bond; their multiplicity is attributed to the polymeric structure of the compounds. The force constants of the C–metal bond in the allyl compounds were found to be 0.31, 0.44, 0.55, and 0.80 mdyn $Å^{-1}$ for sodium, lithium, potassium, and magnesium derivatives respectively[38,46]. It follows from the above quantities that the bond is less stable than the C–metal bond in the analogous alkyl derivatives; thus the force constants of the C–Li bond in CH₃Li is 0.78 mdyn $Å^{-1}$.[12]

The infrared spectra of ethereal solutions of allyl compounds of lithium and magnesium contain, instead of the 600 cm^{-1} band (characteristic of the compounds in the solid state), two bands at 580 and 630 cm^{-1}, which have been attributed[38] to the effect of association. The infrared spectrum of a crotylmagnesium derivative, obtained from butadiene and magnesium in THF[51], contains bands at 1590 and 1615 cm^{-1} in the region of the ν(C=C vibrations), which the authors assigned to complexes with THF differing only in the degree of solvation (noting, however, that distillation of THF does not entail changes in the infrared spectrum of the system)[51].

The estimates of the dependence of the relative C–metal bond strengths on the nature of the substituent, carried out for alkyl and alkenyl derivatives of lithium[52], merit attention. The estimates were based on the enthalpy of alcoholysis (Δ*H*) of the etherates of various compounds RLi. The results, in the calculation of which account was taken of the degree of association of the initial compounds and of solvation effects, indicate a reduced strength of the bond in 2-propenyl lithium compared with other compounds investigated:

R	ethyl	allyl	*trans*-propenyl	2-propenyl
Δ*H*, kcal $mole^{-1}$	−7.1±1.3	4.3±1.3	5.4±0.5	20.1±2.8

III. "LIVING" POLYMERS

1. Non-polar Chains with a Lithium Counterion

In order to investigate systems simulating the active centres in the anionic polymerisation of non-polar monomers, use is frequently made of the NMR method, which makes it possible to obtain information about the structure of the terminal unit, the distribution of charges in the latter, and the type of the C–lithium bond. Low-molecular-weight adducts, formed when diene monomers (M) and s- or t-butyl-lithium interact in the proportions M : BuLi ≃ 1, have been studied as models of this kind. In order to eliminate the influence of preceding units, which complicate the NMR spectra, "living" oligomers, containing deuterated monomeric units in the main chain and a non-deuterated terminal unit, were used in a number of studies[53–56].

It follows from the chemical shifts of the α- and γ-protons of the $\sim \overset{\delta}{C}H_2-\overset{\gamma}{C}H=\overset{\beta}{C}H-\overset{\alpha}{C}H_2Li$ unit that in non-polar media most of the charge is at the α-carbon atom with a proportion of the negative charge at the γ-carbon atom. In a polar medium an upfield shift of the γ-H signal and a downfield shift of the α-H signal are observed, which indicates an increase of electron density at the γ-carbon atom. In a study of the NMR spectra of alkenyl compounds of lithium Bywater et al.[6] showed that in the THF the allyl group of allyl-lithium has the structure of a symmetrical anion with sp^2 hybridisation. It follows from the data for crotyl-lithium that the introduction of a substituent causes the breakdown of the symmetry of the anion with retention of the type of hybridisation. The chemical shifts of the α- and γ-carbon atoms in the ^{13}C spectrum of crotyl-lithium differ from the corresponding values for allyl-lithium by −14.7 and +18.7 p.p.m. An analogous effect was observed for models of "living" chains with terminal butadiene and isoprene units, which consisted of the adducts of t-BuLi with the corresponding monomers. These adducts were investigated in a non-polar medium which led to an appreciable alteration of the nature of hybridisation, namely from sp^2 to sp^3. In particular, the butadienyl derivative contains only approximately 1/3 of the charge at the γ-carbon atom relative to the charge at the γ-carbon atom of allyl-lithium.

Table 7. The ^1H NMR chemical shifts (Δ) in the model compounds RM_nLi obtained by reaction with t-BuLi.

A compilation of ^1H NMR data characterising the chemical shifts of the protons attached to the α- and γ-carbon atoms in low-molecular-weight organolithium compounds with terminal units consisting of diene monomers is presented in Tables 7 and 8. Despite the abundance of such data, there is no unanimous view in the literature concerning the type and state of the terminal unit. Nevertheless the conclusion that it has the 1,4-structure (or the 4,1-structure for isoprene) with limited rotation about the Cβ − Cγ bond, responsible for the coexistence of the *cis*- and *trans*-isomers, is fairly general. In a polar medium (in contrast to a non-polar medium) the *cis*- and *trans*-structures are in equilibrium and, as shown for butadiene[60] and isoprene[58,61] isomers, the *cis*-structure predominates at approximately −70°C.

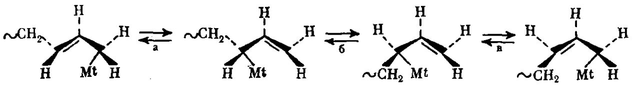
Morton and Fetters[62] assume the existence in a non-polar medium of two types of active centres of dienyl (living) chains—a localised centre (with a C–lithium σ bond), responsible for the formation of the 1,4-units, and a delocalised centre giving rise to 1,2-units. There is no direct evidence for the presence of the π-allyl structure of agents of this kind in non-polar media. Nevertheless, according to Morton and Fetters, the content of vinyl units in the chains of the corresponding diene polymers may be regarded as an indirect indication of the presence of active centres of the σ-allyl types in numbers undetectable by NMR. According to this view, the *cis–trans* isomerisation proceeds via the structure $\sim CH_2{-}\overset{3}{C}H(Li)\overset{2}{C}H{=}\overset{1}{C}H_2$ in which there is free rotation about the $C_{(2)} - C_{(3)}$ bond. Morton and Fetters base their hypothesis on the nature of the ^1H NMR spectra of oligopentadienyl-lithium (OPL) in benzene[55], attribute the chemical shift of 3.1 p.p.m to the γ-proton (Table 7), and conclude (by analogy with data for oligobutadienyl-lithium in THF) that the terminal OPL unit has a π-allyl type of structure; the chemical shift of the α-proton is not quoted. Dolinskaya[36], who found chemical shifts of 2.9 and 5.5 p.p.m. for the α- and γ-protons of *cis*-OPL in benzene respectively, concluded that a different isomerisation mechanism operates, namely that the reaction proceeds via the delocalised structure (I) with free rotation about the Cβ – Cγ bond (see above); this structure is consistent with data which she obtained[36] for the change in the chemical shifts of OPL on passing from a non-polar to a polar medium (Table 7). Glaze and coworkers[63,64] postulate the possibility of the oscillation of the metal atom between two potential minima for each geometrical isomer (equilibria *a* and *c*); isomerisation (equilibrium *b*) is significant only for magnesium derivatives at an elevated temperature:



We may note that all the results quoted for non-polar media refer to associated lithium alkenyls. The monomeric forms $RM_nLi.ED$ are apparently formed in polar media. As regards their nature, they should differ appreciably from the monomeric forms RM_nLi, which, according to generally accepted views, are the most active species in the polymerisation of unsaturated monomers in a hydrocarbon medium.

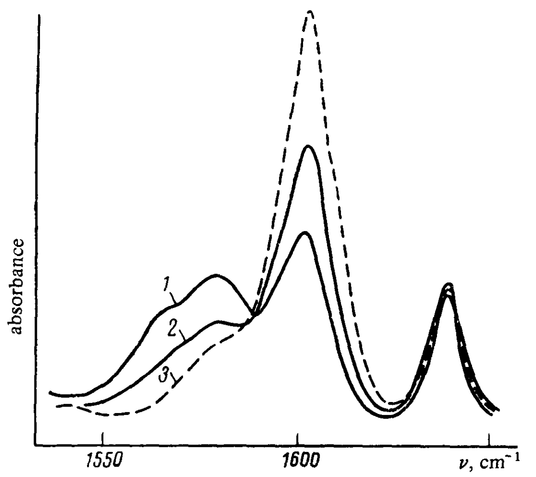


Figure 3. Infrared spectra of an artificial 1 : 1 OBL–s-BuLi mixture (curves *1* and *2*) and OBL (curve *3*) in iso-octane[17] at different temperatures (°C): 1) –31; 2) –1.5; 3) –31.

Glaze and Jones[65] were the first to use the infrared spectroscopic method in the study of compounds simulating the active centres in anionic polymerisation. The authors observed absorption bands at 1597 and 1577 cm^{-1} in the infrared spectrum of the product of the interaction of t-BuLi with butadiene and assigned them to the vibrations of the C=C bonds of the terminal units in the *cis*- and *trans*-structures respectively. These studies were developed further by Basova and coworkers[66–68] and Zgonnik and coworkers[69–71]. In particular, a detailed study of oligobutadienyl-lithium (OBL), obtained by reaction with s-BuLi, revealed a dependence of the 1602 and 1580 cm^{-1} absorption bands on the initial monomer : initiator ratio and temperature. It follows from the analysis of the infrared spectra of artificial mixtures of the initiator and OBL that the latter band refers to mixed associated species $(OBL)_3.BuLi$ (Fig. 3).

Infrared spectroscopy was then used for a more detailed investigation of OBL and was extended to the study of other "living" chains with the lithium counterion[67–76]. Zgonnik et al.[69–71] made the most complete assignment of the absorption bands in the infrared spectrum of OBL, based on the isotopic substitution of ^7Li by a ^6Li and selective deuteration of butadiene. The characteristics of the terminal unit of OBL and its deutero-analogues in the range 400–1200 cm^{-1}, presented in Table 9, demonstrate a significant contribution of the deformation vibrations of the α-CH_2 group to the 600, 775, 850, and 940 cm^{-1} bands. The isotopic shift factor for the majority of bands in the infrared spectra of the deutero-derivatives does not exceed 1.2, indicating an appreciable mixing of the vibrations of the α-CH_2 and =CH groups, which makes the out-of-plane =CH vibrations in the terminal units less characteristic. It appears that the 895 and 695 cm^{-1} bands in the spectra of OBL and OBL-d_6 respectively refer to the *trans*-structure of the terminal unit.

Table 9. The assignment of the principal absorption bands (cm^{-1}) in the infrared spectra of oligobutadienyl-lithium (OBL) and its deuterated derivatives (OBL-d_n).[71]

C—Li	α=CH_2	α-CH_2+ =CH	=CH	C—Li	α-CH_2	α=CH_2+ =CH	=CH
	OBL				OBL-d_4(1,1′, 4,4′)		
430 m. 482 m.	600 s.	775 s.	895 s.	427 m. 475 m.	525 s.	670 s.	817 m.
	OBL-d_2(2,3)				OBL-d_6		
425 m. 475 m.	582 s. 850 m.	758 s.	770 sh.	425 m. 475 m.	515 s. 766 w.	633 s.	695 s.

Note. s = strong (intense) absorption band, m. = moderately intense band, w. = weak band, sh. = shoulder.

The stretching vibration band of the double bond in the terminal unit is sensitive to the type of deuteration:

Compound	OBL-H_6	OBL-d_2 (2,3)	OBL-d_4 (1,1′, 4,4′)	OBL-d_6
$\nu_{C=C}$, cm^{-1}	1602	1568	1594	1564

It is a single band (only a slight shoulder was noted at 1580 cm^{-1})¶, which indicates the preferential existence of a structure of one type. The direction of the shift on deuteration is consistent with the NMR data and the 1,4-structure of the terminal unit.

Oligoisoprenyl-lithium (OIL)[72,73] and oligo-2,3-dimethylbutadienyl-lithium (ODMBL)[75] were investigated similarly. The frequencies (cm^{-1}) of the absorption bands of the terminal OIL and ODMBL units (in iso-octane) are listed below:

Compound	C—Li	$=C<^{H}_{C}$; $=C<^{C}_{C}$	α-CH_2	C=C	References
OIL	455,475	575	600	1600	72
OIL-d_4 (1,1′, 4,4′)	455,475	500	540	1600	73
ODMBL	445,495	560	595	1600	74,75

¶This shoulder may, in principle, refer to another structure of the terminal unit responsible for the formation of 1,2-units in the polymer; its contribution does not exceed 10%.

We may note that the low-frequency shoulder characteristic of OBL is absent from the spectra of OIL and ODMBL, indicating a more homogeneous structure of the terminal units of OIL and ODMBL, which evidently have the *trans*-4,1-structure.

Table 10. The NMR characteristics of the terminal units of the "living" chains of styrene and α-methylstyrene with a lithium counterion.

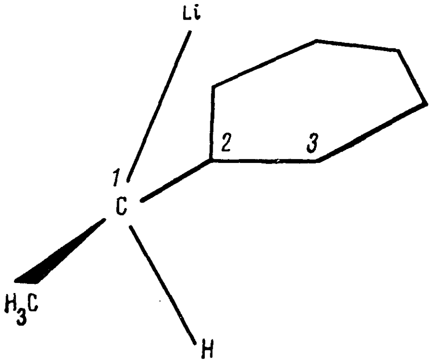

Figure 4. The optimised geometry of the model active centre $CH_3CH(Li)C_6H_5$.[80] Li–C distance (Å): 1) 2.1; 2) 2.2; 3) 2.2.

Different spectroscopic characteristics have been obtained for oligostyryl- and oligo-α-methylstyryl-lithium (OStL) and (OMStL). The ^{1}H NMR spectra led to the conclusion that at least half of the charge of the anionic component is concentrated on the benzene ring[6,77–79], the fraction of this charge increasing on passing from benzene solution to THF solution (Table 10). A paper[76] dealing with the infrared spectra of OStL lists the following characteristics of the terminal unit:

ν, cm^{-1}	505	1585	2800
assignment	δ (Li—CH)	in-plane C_6H_5 vibrations	ν(C-H) vibrations of CHLi

The appreciable difference between the intensity of the 1585 cm^{-1} absorption band of the terminal unit of OStL and the data for the internal units (by a factor of approximately 10) indicates the interaction of the terminal benzene ring with the counterion. This conclusion is consistent with the results of a quantum-chemical calculation on the $CH_3CH(Li)C_6H_5$ model compound by the CNDO/2 method[80], according to which the lithium atom in the optimised structure is significantly closer to the C_6H_5 group (Fig. 4); see also below.

Wicke and Elgert[81] arrived at a similar conclusion in a study of the ^{13}C NMR spectra of the compound  $(CH_3)_3CCH_2\underset{\displaystyle C_6H_5}{\underset{|}{C}}(CH_3)Li$, simulating the terminal unit of the growing chain of α-methylstyrene. The orientation of the lithium atom relative to the benzene ring which they propose[81] agrees in principle with the geometry illustrated in Fig. 4.

2. Complexes of the Compounds RM_nLi with Electron Donors

The results of studies on the interaction of "living" hydrocarbon chains with small amounts of electron donors in non-polar media are considered in this section. Under such conditions, monodentate donors do not cause the decomposition of associated groups of "living" chains on formation of compounds of different stoichiometries. Thus, according to isothermal distillation and conductimetric data[82], the reaction of oligobutadienyl-lithium tetramer (T) with THF in iso-octane results in the formation of the complexes T.4THF and T.8THF at room temperature. Measurements of the electrical conductivity of the second complex showed that its ionic dissociation constant is 10^{-13} mole litre^{-1}. Data for the dielectric constants of the OBL tetramer and its complexes yielded the following dipole moments:

Compound	T	T.4THF	T.8THF
μ, D	4.0	7.7	10.4

Such high constants indicate the asymmetry of the OBL tetramer, which becomes more pronounced in its complexes.

A large amount of information has been obtained in studies of the mechanism of the formation of complexes between "living" oligomers and electron donors by infrared spectroscopy[67–76,83]. For ED/Li ratios ensuring the formation of 1 : 1 complexes with DME,[69] DMM,[83] and THF,[69–71] the infrared spectra in the region of the stretching vibrations of the C=C band of the terminal units are virtually identical: the 1600 cm^{-1} absorption band is displaced in steps to 1570 cm^{-1} as the electron donor concentration is increased. Qualitatively analogous effects have been described in other studies[67,68] devoted to the formation of complexes by polybutadienyl-lithium with THF and TEA. Such a shift corresponds to transitions of the type

$$T \underset{}{\overset{ED(K_1)}{\rightleftarrows}} T.ED \overset{ED(K_2)}{\rightleftarrows} T.2ED \overset{ED(K_3)}{\rightleftarrows} T.3ED \overset{ЭД(K_4)}{\rightleftarrows} T.4ED, \qquad (5)$$

and $K_1 > K_2 > K_3 > K_4$. The bathochromic shift of the ν(C=C) band is apparently caused by the partial delocalisation of the double bond on formation of a complex by the counterion of the "living" chain with the electron donor. The 1570 cm^{-1} band may be fairly confidently assigned to the complex T.4ED. The overlapping of the bands characterising each individual complex has not so far permitted the determination of the individual constants K_1–K_4; only certain average values of the complex formation constants (K_C) have been estimated.

The spectroscopic and thermodynamic characteristics obtained for several systems of the type under consideration are listed in Table 11. We shall consider some of them in somewhat greater detail and will supplement them with data not included in Table 11. An increase of the ED :OBL ratio to 10 does not alter the nature of the infrared spectrum of DME and DMM, but does entail the appearance in the case of THF of a new band in the region of ν(C=C) (1555 cm^{-1}) and a sharp decrease of the intensity of the 450 cm^{-1} band associated with the C–Li bond[71]; these changes have been attributed to the decrease of the degree of association of OBL under the influence of the excess of THF. The decrease of temperature in the last of the systems indicated to –100°C results in the appearance of a new intense band (447 cm^{-1})[71] in the region of the stretching vibrations of the C–Li bond and of two extremely intense bands (550 and 607 cm^{-1}) in the region of the deformation vibrations of the C–H bond, instead of the previous relatively low-intensity band at 600 cm^{-1}. Such changes can be accounted for either by a rearrangement in the α-CH_2Li group due to association–dissociation steps[71] or, on the basis of data obtained by other methods (NMR[60], ultraviolet spectroscopy[85], and chemically[61]), in terms of the *cis–trans* transitions in the terminal unit.

*The characteristics of the part of the "living" chain not bound in a complex.

**Values calculated from data in Refs. 69 and 70.

***THF used as reaction medium.

****Value corresponding to the complex OIL. 2ED.

*****Data refined after the publication of the paper of Davidyan et al.[84]

The formation of complexes between THF and OIL[72,73] is somewhat less vigorous than the reaction involving OBL. The stepwise bathochromic shift of ν(C=C) reaches a limit (1570 cm^{-1}) for an equimolar reactant ratio in the complex and remains unchanged up to the ratio ED :OIL = 10 in the reaction mixture. Only when THF is used as a solvent is a shift of the 1570 cm^{-1} band to 1575 cm^{-1} observed; the previous bands, due to the C–H bond, disappear and are replaced by a single intense absorption at 690 cm^{-1}. Monomeric complexes of the type OIL. *n*ED are apparently formed in THF; other workers[86], who investigated the analogous system by ultraviolet spectroscopy, arrived at the same conclusion.

Glyme, a bidentate electron donor, has a different effect on the terminal unit of OIL[84]. For the ratio glyme :OIL = 4 at a low temperature, unassociated complexes OIL. 2ED are already formed (the absence of association was demonstrated viscometrically). However, the frequency of the absorption band of the C=C bond in the terminal unit corresponding to these complexes is higher (1590 cm^{-1}) than in the case of complexes involving THF.

We shall now compare results referring to the formation of complexes by different oligodienyl-lithium derivatives with TMED. The simplest situation is observed for OIL[73,87]. For an initial reactant ratio of unity, the ν(C=C) band is displaced to 1570 cm^{-1}, which corresponds to a 1 :1 complex, an increase of the TMED concentration and a decrease of temperature not resulting in a shift of this band. Consequently, even for the equimolar ratio of OIL and TMED, a stable complex of a definite type (apparently monomeric) is formed. A similar conclusion is reached on the basis of the ultraviolet spectra of the same system; they are characterised by a single maximum at 330 nm, which is independent of temperature and the excess of TMED. The following absorption bands are characteristic of complexes of other oligodienyl-lithium complexes with TMED in the region of ν(C=C) vibrations: 1528 and 1550 cm^{-1} for OBL[88] and 1528 and 1582 cm^{-1} for ODMBL[74,75]. The first complex is very stable and its infrared spectra (as well as ultraviolet spectra; λ_{max} = 320 nm) are insensitive to the presence of an excess of TMED and a change of temperature. When the ratio TMED :Li = 1, complexes with the 1 :1 composition are formed and are present in solution in a monomeric form[88]. ODMBL exhibits a much lower capacity for complex formation. Analysis of the infrared spectra obtained for different TMED :ODMBL ratios (from 0.27 to 4.6) shows[74,75] that complete coordination saturation of the tetramer is not attained under the given conditions: only the formation of the complexes $(ODMBL)_4$.TMED and $(ODMBL)_2$.2TMED was observed.

According to the data described above, the stability of the complexes of the compounds considered and the electron donors decreases in the sequence OBL > OIL > ODMBL, probably primarily due to the steric structure of the electron acceptors.

The spectroscopic effects observed in the OStL–ED systems differ from those described for diene derivatives. A hypsochromic shift of the 1585 cm^{-1} band to 1590 cm^{-1} is characteristic of the benzene ring[76]. This result is probably due to the breakdown of the specific interaction between lithium on the aromatic ring (see above concerning the characteristics of the terminal unit of OStL). We may note that an analogous hypsochromic shift of the ν(C=C) band was observed[89] after the introduction of diethyl ether to a hydrocarbon solution of γ-butenyl-lithium, which forms an intramolecular π-complex in the absence of an electron donor.

Genkin and Moiseeva[90] investigated the stabilities of the complexes of OBL, OIL, and OPL with TMED, DEE, and di-isopropyl ether (DIPE) by GLC. K_1 was calculated [see Eqn. (5)], since, according to the conditions employed in the method the electron donor chromatographed is present at infinite dilution in relation to the oligomers. The characteristics obtained agree with the activity series of the electron acceptors (OBL > OIL > OPL) and donors (DME > DEE > DIPE). From the large number of quantities quoted by the above workers[90], we shall select only data for complexes of lithium alkenyls with DME:

Acceptor	OBL	OIL	OPL
K_1, litre mole^{-1} (20°C)	305	211	204
$-\Delta H$, kcal mole^{-1}	8.6	7.7	7.3

The study of the products of the deactivation of "living" oligomers of the diene series confirmed the 1,4(4,1)-structure of the terminal unit and showed that the fixation of the chain structure takes place in the propagation stage only in the penultimate unit[91-93]. Apart from the nature of the monomer and the solvent, the structure of the terminal unit is influenced also by the nature of the deactivating agent[93-95]; it has been suggested[93] that the chain termination reaction proceeds under these conditions via a complex formation stage.

3. Derivatives of Sodium, Potassium, and Magnesium

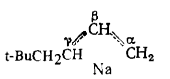
"Living" chains with a sodium counterion, with a limited solubility in hydrocarbons, have been investigated mainly in polar media. The electronic spectra indicate a much lower stability of such systems compared with the corresponding lithium derivatives[96], which is manifested in a number of irreversible reactions (the transfer of a hydride ion to the counterion[97], intramolecular proton transfer[98], the formation of alkoxides[99,100], and metallation of the solvent[101]). The *cis–trans* isomerisation of the terminal unit has also been noted[64,85]. Sodium derivatives of dienes in THF are less stable at room temperature than the corresponding derivatives of styrene[101,102], but in the region of low temperatures (–30° C), the opposite effect is observed[101,103]. These characteristics determine the temperature and time limits of the experimental study of the agents under consideration†.

Gourdenne and Sigwalt[103] showed that sodium-butadiene chains are more stable than the isoprene chains, but both undergo changes on being kept in THF (some of them reversible), which are manifested in the electronic spectra. Thus the 293 $\rightleftharpoons$ 384 → 435 and 308 $\rightleftharpoons$ 358 → 435 nm shifts of λ_{max} were observed for butadienyl and isoprenyl derivatives of sodium respectively‡. The terminal products of these reactions are inactive in relation to dienes.

The ^{1}H NMR chemical shifts (p.p.m.) in neopentylallyllithium (NPAL) and neopentylallylsodium (NPAS) are listed below (solvent—THF)[60,64]:

Compound	*cis*-Proton		*trans*-Proton		References
	α-C	γ-C	α-C	γ-C	
NPAS	1.52	2.85	—	3.55	64
NPAL	1.19	3.35	1.29	3.63	60

It follows from the data presented that NPAS is more ionic. The temperature at which the rotation about the Cβ – Cγ bond in the structure



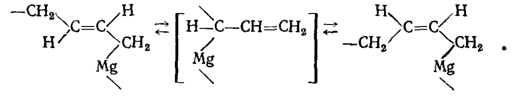
is inhibited (in terms of the NMR time scale) proved to be –20° C for NPAS and –55° C for NPAL, which indicates a higher Cα – Cβ bond order, i.e. a greater amount of ionic character of the C–Na bond compared with C–Li. The difference between the ultraviolet characteristics of NPAS and NPAL (λ_{max} = 293 and 278 nm respectively[60,63], conflicting with the hypothesis that the absorption maximum of the All–Mt contact ion pairs increases with the atomic number of the metal[104] and that absorption at longer wavelength is characteristic of more polar bonds, was explained by Glaze by the higher fraction of the *cis*-form in NPAS compared with NPAL; absorption in the region of shorter wavelengths is characteristic of the *cis*-form[100,101]. This conclusion was confirmed by the analysis of the corresponding hydrolysis products (Table 12). Garton and Bywater[85] explained the changes in the ultraviolet spectra of the polybutadienyl chains with lithium and sodium counterions after the introduction of the monomer at a low temperature (in THF) by the isomerisation of the terminal unit. The 285 and 336 nm absorption bands were assigned to the more stable *cis*-forms, while the 320 and 350 nm bands, arising after the introduction of the monomer, were assigned to the *trans*-forms of the lithium and sodium derivatives respectively.

Table 12. Structures of the hydrolysis products of the neopentylallyl derivatives of lithium, sodium, and magnesium (NPAM).

Compound	Solvent	Content of units, %			Refs.
		trans-1,4	*cis*-1,4	1,2	
NPAS	THF	27	54	20	64
NPAL	n-pentane	75	23	2	57
NPAL	DEE	68	21	11	60
NPAL	THF	49.4	36.9	13.7	
NPAM	n-pentane	42.7	19.2	38.1	63
	DEE	17.7	11.7	70.5	

The study of "living" chains with a potassium counterion is complicated by the still more intense irreversible changes which occur even at –70° C.[85] Basova and coworkers[67,68] studied polybutadienylsodium (PBS) and polybutadienylpotassium (PBP) in a hydrocarbon medium by infrared spectroscopy. In the region of the stretching vibrations of the terminal C–C bond, the following absorption bands were found (cm^{-1}): 1555 (main band) and 1535 and 1570 (shoulders) for PBS and 1570 (main band) and 1535 and 1555 (shoulders) for PBP. These characteristics indicate a greater degree of delocalisation of the above bond in PBS and PBP than in the lithium derivatives (see above). The authors attribute the 1555 cm^{-1} band in the spectrum of PBS to the presence of a certain amount of lithium alkoxide formed in the course of the synthesis[68] and interacting with the sodium counterion and assume that lithium alkoxide may not affect PBP owing to the low electron-accepting capacity of potassium[67,68].

The state of the terminal alkenyl unit with a magnesium counterion is described by a scheme[63] based on ^{1}H NMR data for a solution of neopentylallylmagnesium (NPAM) in THF at room temperature:



At a reduced temperature (~ –40° C) the attainment of equilibrium is retarded and the signals due to the *cis*- and

---

† The references to earlier studies by Medvedev and coworkers, who considered these questions, are listed by Medvedev and Gantmakher[101].

‡ Data for –40° C; the "living" polymers were obtained under the influence of sodionaphthalene.

trans-isomers, present in comparable amounts, are distinguishable. The contents of units having different structures in the hydrolysis products of an ethereal solution of NPAM were 17.7, 11.7, and 70.5% for the *trans*-1,4-, *cis*-1,4-, and 1,2-units respectively. Consequently the conclusion that the content of the *cis*-units is reduced with decrease of the amount of ionic character of the C–Mt bond has been confirmed in this instance too. On the other hand, the content of the 1,2-units in NPAL, NPAS, and NPAM is not directly related to the electronic structure of the corresponding alkenyl units (Table 12).

4. Derivatives of Polar Monomers

The formation of "living" chains of the type M_nMt, where M is a polar monomer, is usually difficult owing to their lower stability compared with the hydrocarbon chains and the side reactions, which occur differentially in the initial stage of the synthesis[107]. Side reactions can be virtually eliminated by a procedure involving the interaction of the "living" hydrocarbon chains (for example, butadiene or styrene chains) and small amounts of polar monomers. When certain conditions are observed, this ensures the introduction into the non-polar chain of several terminal units of the polar monomer. This procedure has proved particularly useful for acrylonitrile (AN) and methacrylonitrile (MAN), whose polymers are soluble only in solvents which tend to interact irreversibly with organometallic compounds (dimethylformamide, dimethyl sulphoxide, etc.). The determination of the spectroscopic and electrochemical characteristics of the chains corresponding to these monomers is possible only for macromolecules containing a fairly long non-polar block. Some of the data of Tsvetanov and coworkers[108,109] for the electronic spectra and dissociation constants (K_d) of macromolecules of the above type, consisting of a butadiene block (40–50 units) and 2–3 terminal AN units, are presented below (25° C):

Solvent	Iso-octane		THF		
Mt	Li	Na	Li	Na	K
λ_{max}, nm	330.5	337.5	342	345	351
$10^9 K_d$, mole litre^{-1}	—	—	2.4	4.0	30.0

The infrared spectra of analogous substances with a styrene main block, recorded in benzene (20° C) and THF (−40° C)[110], indicate a significant difference between the absorption band due to the nitrile group of the –CH(CN)Mt fragment and the band characteristic of the usual nitriles, including polyacrylonitrile (PAN). Thus "living" chains with Li^+, Na^+, and K^+ counterions absorb in the range 2030–2040 cm^{-1}, while PAN absorbs at 2235 cm^{-1}. The first of the above bands refers to chains containing one AN unit. An increase in the number of such units leads to a hypsochromic shift of this band (particularly 2032 → 2040 and 2042 → 2049 cm^{-1} for chains with potassium and lithium counterions respectively) and to the appearance of new bands, including a band which virtually coincides with that observed in the spectrum for the unperturbed nitrile group (2235–2040 cm^{-1}).

The conclusion concerning the strong interaction of the counterion and the polar group of the macromolecule, which follows from these results, agrees with the finding in one of the studies quoted above[109] that there is no association between the chains and the lithium counterion in a hydrocarbon medium (this conclusion is based on viscometric data), which distinguishes them from organolithium compounds with non-polar constituents. Strong intramolecular interactions apparently rule out in this instance intermolecular interactions, responsible for the formation of associated forms $(RLi)_n$, typical for lithium alkyls and lithium alkenyls. The same factor can also account for the much lower values of K_d (approximately by two orders of magnitude) compared with the analogous values for hydrocarbon chains M_nMt.[5]

Results similar to those described above have been obtained for MAN.[111] The use of oligostyryl-lithium as the initial organometallic compound made it possible to obtain soluble blocks of "living" oligomers containing up to six MAN units in the chain. The dependence of the spectroscopic characteristics of these substances on the number of MAN units is illustrated in Fig. 5.

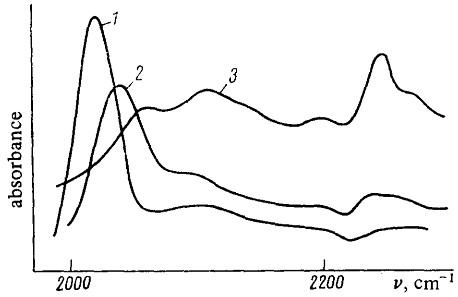


Figure 5. Infrared spectra of oligostyryl chains with terminal MAN units and a lithium counterion in benzene at 20° C.[110] Initial MAN :OStL molar ratio: 1) 1; 2) 2.2; 3) 5.5.

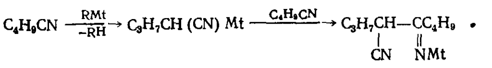
In order to achieve a correct assignment of the absorption bands and bands located in the intermediate region (between −2100 and 2200 cm^{-1}), the infrared spectra of model compounds based on valeronitrile (VN) and trimethylacetonitrile (TN) were obtained[110,111]. Oligostyryl-lithium was used as the organometallic component in these systems. When the ratio BH :RMt = 1 (with THF as the solvent), the infrared spectrum shows bands at 2030 (the most intense) and 2100 cm^{-1}. An increase of the BH :RMt ratio to three causes the disappearance of the first band and a significant increase of the intensity of the second. Treatment with ethanol of the reaction mixture obtained for the ratio BH :RMt = 3 causes the appearance of the spectroscopic characteristics of the equilibrium system[112]:

$$\underset{CN}{-CH}-\underset{NH}{C}- \rightleftarrows \underset{CN}{-C}=\underset{NH_2}{C}- .$$

This is a direct indication of the presence in the initial reaction mixture of imidonitriles, the formation of which has been described schematically as follows[110]:



$$C_4H_9CN \xrightarrow[-RH]{RMt} C_3H_7CH(CN)Mt \xrightarrow{C_4H_9CN} C_3H_7\underset{CN}{\underset{|}{CH}}-\underset{NMt}{\underset{\|}{C}}C_4H_9 . \qquad (6)$$

Among the data obtained for systems with participation of TN, these for the interaction of TN with an active reagent containing a terminal MAN unit are of interest. Steric hindrance rules out in this instance the occurrence of a type (6) reaction and limits the interaction to complex formation, as shown by the appearance of a new band in the high-frequency region (2260 cm^{-1}), the intensity of which increases with increase of the concentration of any component. We may note that a small shoulder has been noted in this region in the infrared spectrum of chains with an increased number of MAN units (Fig. 5), which may be attributed to the formation of intramolecular complexes of the counterion with a nitrile group in the polymer chain.

The results described make it possible to adopt the following assignment of the infrared bands for the "living" AN and MAN chains:

ν, cm^{-1}	2030—2050*	2100—2170	2250—2260
Group				(IV)	(V)	(VI)

In real AN anionic polymerisation processes the formation of macromolecules is ensured by substances (IV). The formation of intra- or inter-molecular complexes of type (VI), which are capable of being converted into imidonitriles (V), is favoured when the reaction is carried out in non-polar media. The sequence of steps (IV) → (VI) → (V) is responsible for the low effectiveness of initiation in AN–RMt–hydrocarbon solvent systems; the formation of imides (V) is virtually equivalent to kinetic chain termination. The occurrence of the last reaction can be readily detected from the presence of carbonyl groups in deactivated AN polymers and oligomers[114,115].

The infrared spectra of compounds simulating the anionic active centres of methyl methylacrylate (MMA) are more difficult to interpret. Lochmann and Lim[116], who synthesised the compound $(CH_3)_2C(COOCH_3)Li$, attributed the absorption of its THF solution in the region of 1676 cm^{-1} to the carbonyl group; in the spectrum of the initial methyl isobutyrate the absorption at 1730 cm^{-1} corresponds to this group. According to Panayotov and coworkers[117,118], the absorption in the range 1605–1635 cm^{-1} (in THF) is characteristic of terminal MMA–Mt units, where Mt = Li, Na, or K. Zgonnik et al.[119] obtained the infrared spectra of the products of the interaction of various compounds RLi with MMA in non-polar media. The following absorption regions, referring to terminal units, were observed: 1620–1645, 1670–1680, and 1710–1755 cm^{-1}. The last of these may be due to the formation of intra- and inter-molecular complexes analogous to those noted above for "living" AN chains [see structure (VI)].

According to Figueruelo[120], the values of K_d for "living" MMA chains with Li^+ and K^+ counterions are 0.44×10^{-9} and 0.21×10^{-9} respectively (THF, −78° C). Quantities of a similar order of magnitude have been obtained[121] for "living" chains of 2-vinylpyridine (VP): 0.83×10^{-9} (Na); 2.45×10^{-9} (K); 1.05×10^{-9} (Cs) (in THF at 23° C). The different types of dependence of K_d on the nature of the counterion for "living" chains based on AN, MMA, and VP are striking. It appears that this is caused by the difference between the relative energy contributions; due to the decomposition of the intramolecular complexes and the solvation of the counterion.

The conclusion that there are intense intramolecular interactions in organometallic compounds with polar substituents agrees well with the results of quantum-chemical calculations by the CNDO/2 method for structures simulating the anionic AN and methyl acrylate active centres, namely $CH_3CH(Li)CN$ and $CH_3CH(Li)COOCH_3$.[80] Their optimum geometry indicates a significant mutual approach of the counterion and the polar group of the active centre:

	structure (VII)				structure (VIII)		
X	C (1)	C (2)	O (3)	O (4)	C (1)	C (2)	N (3)
Li—X, Å	2.2	2.4	2.9	3.0	2.1	2.2	2.8

IV. CONCLUSION

In conclusion we shall attempt to estimate the importance of information of the above kind for the determination of the mechanism of the formation of macromolecules in anionic systems. A detailed examination of this problem, different aspects of which have been discussed in many original and review publications (see, for example, Refs. 5, 62, 101, 122–125), is outside the framework of the main topic of the present review. We shall therefore confine ourselves to several comments on polymerisation under the influence of lithium compounds.

In all the "living" dienyl chains investigated the existence of only the 1,4 (or 4,1)-structure of the terminal unit has been noted with the predominant content of the *trans*-form in non-polar media and of the *cis*-form in ethereal media. When an attempt is made to reconcile this finding with the opposite type of structure of the polymers formed in the corresponding systems (the maximum content of the *cis*-1,4-units in polybutadiene and polyisoprene is reached in polymerisation in a non-polar medium), it is necessary to take into account at least two factors. The first and possibly the most important factor is that the fixation of the structure of the elementary unit of the growing chain occurs only after the addition of the succeeding monomer molecule to the terminal unit. This result indicates a conformational rearrangement of the terminal unit (characterised by a partly delocalised electronic structure) in the propagation stage. The second factor is the different states of organolithium compounds: stable associated species $(RM_nLi)_x$ in non-polar media and monomeric forms of the complexes $RM_nLi.mED$ in media of the ethereal type. At the same time, under the polymerisation conditions usually employed, the main contribution to the propagation reaction comes from the unassociated forms of the growing chains regardless of the nature of the medium. The experimental difference between the structures of the terminal units in media of different polarities cannot therefore be regarded as a basis for inferring the structural characteristics of the active centres operating in the same media. It is quite likely that the terminal units of the monomeric forms of the "living" polydiene chains with a lithium counterion have the *cis*-structure in non-polar media; this view can be found in the literature[56,126]. Another important problem concerns the 1,2-units (or 3,4-units) in polydienes, i.e. structural units whose appearance in macromolecules is most difficult to attribute to the direct experimental characteristics of the

---

*Similar frequencies (2050–2071 cm^{-1}) were obtained by Yuchnovski[113] for lithioacetonitrile in polar solvents and in the solid state; the bands in this region were assigned to the ionic structure $(CH_2{=}C{=}N)^-Li^+$.

"living" chains. In relation to non-polar media, the solution of this problem may be based on the concentration (with respect to the growing chains) variation of the polymer structure; the content of vinyl(or isoprenyl) groups in polydienes increases with increase of the initiator concentration[56,91,127,128]. One of the possible explanations of this effect is the involvement of the associated forms of the growing chains in the progagation reaction and the increase of the relative contribution of these steps with increase of the initiator concentration[56,128]. According to Glaze et al.,[57] the reaction between the monomer and the associated species $(RM_nLi)_x$ can occur to a large extent as a result of attack on the γ-carbon atom of the terminal unit, since the α-carbon atom in the associated species is highly shielded. A natural consequence of the attack on the γ-carbon atom is the formation of 1,2- or 3,4-units. The decrease of the content of 1,4-units in polydienes on passing from non-polar to polar media and in the presence of catalytic amounts of polydentate electron donors can be explained similarly. We have in mind the partial shielding of the α-carbon atom in the solvation shell of a polar solvent surrounding the counterion, in the first instance, and the analogous effect in the formation of complexes of the active centres with electron donors containing bulky substituents or having large intrinsic dimensions, in the second. Together with steric considerations, account must be taken of the charge redistribution in the carbanionic fragment of the terminal unit on complex formation, namely the increase of the negative charge of the γ-carbon atom, which follows from NMR data[6,36,60,62].

We may note finally that the formation of intermediate complexes of the counterion with the monomer may be important for the microstructure of the polymers. In particular, the conformation of the monomer molecule in such complexes may be regarded as one of the factors determining the site of the attack on the terminal unit in the propagation stage. Unfortunately, this problem, as well as certain others among those discussed above, have not so far been studied experimentally. The quantum-chemical research technique applied to systems approaching real systems to the maximum possible extent may prove fruitful. Naturally the extent of studies in this field is still insufficient for more definite comments on this topic. Nevertheless the likely usefulness of this approach, which follows partly from the data presented in the present review, is evident from our point of view. The problem is discussed in greater detail by Eizner and Erusalimskii[129].

Organophosphorus Compounds in 1,3-Dipolar Cycloaddition

N.G.Khusainova and A.N.Pudovik

The cycloaddition of 1,3-dipoles to organophosphorus compounds containing a multiple bond is surveyed together with the reactions of phosphinylated 1,3-dipoles with various dipolarophiles, yielding five-membered heterocycles containing a phosphorus atom in either the ring or a side-chain. The Review covers also the "mixed dimerisation" of 1,3-dipoles with $\alpha\beta$-unsaturated compounds of tervalent phosphorus acting as 1,3-dipolar systems. A list of 146 references is included.

CONTENTS

I. Introduction 803

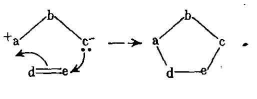
III. 1,3-Dipolar cycloaddition of phosphinylated 1,3-dipoles 808
IV. Mixed "dimerisation" of 1,3-dipoles and $\alpha\beta$-unsaturated phosphines and phosphonites 809

I. INTRODUCTION

1,3-Dipolar cycloaddition to unsaturated organophosphorus compounds forms an interesting and little studied branch of organophosphorus chemistry. The great structural variety both of 1,3-dipoles and of dipolarophiles makes this an important method for obtaining organophosphorus heterocycles that are difficult to prepare in other ways. Such addition can be defined as the interaction of a 1,3-dipole of general type $^{+}a-b-c^{-}$ with a multiple bond d=e accompanied by transfer of electrons within the cyclic transition state and by neutralisation of the formal charges[1]:



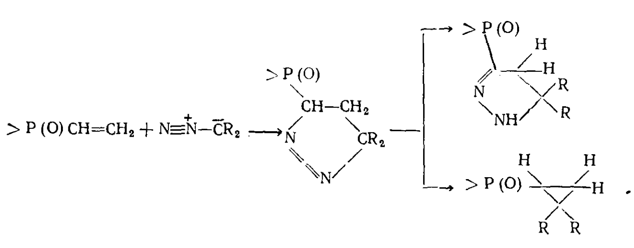
Despite the large number of investigations there is no generally accepted mechanism for 1,3-dipole cycloaddition. The majority of authors accept the single-stage mechanism first suggested by Huisgen[2,3], who regards such reactions as involving concerted but not necessarily simultaneous formation of two new σ bonds. This mechanism corresponds to a large negative entropy of activation and a moderate enthalpy of activation, a certain type of effect of substituents and solvent polarity, and *cis*-stereospecificity of addition[4,5]. Firestone[6-9] considers that a two-stage mechanism may also be possible, with intermediate formation of a diradical. A two-stage mechanism with an intermediate amphoteric compound has also been suggested[10]. In several papers the most important aspects of 1,3-dipolar cycloaddition, such as the effect of substituents, stereospecificity, regioselectivity, are discussed in terms of perturbation theory[11-14].

Considerable experimental information has now accumulated on 1,3-dipolar cycloaddition in the chemistry of organophosphorus compounds. The action of 1,3-dipoles on unsaturated compounds containing a four-coordinated phosphorus atom is a classical 3 + 2 → 5 cycloaddition. 1,3-Dipoles with phosphorus-containing substituents in a side-chain add to various dipolarophiles according to the same scheme. Reaction between $\alpha\beta$-unsaturated compounds containing tervalent phosphorus and 1,3-dipoles does not follow the usual scheme of 1,3-dipolar cycloaddition but a 3 + 3 → 6 scheme involving the phosphorus atom, with formation of six-membered heterocycles. This reaction can be regarded as mixed "dimerisation" of the 1,3-dipolar systems: under these conditions the phosphorus-containing component reacts similarly to other classical 1,3-dipoles. $\alpha\beta$-Unsaturated derivatives of three-coordinated phosphorus add to multiple bonds in various dipolarophiles according to a 3 + 2 → 5 scheme.

II. 1,3-DIPOLAR CYCLOADDITION TO ORGANOPHOSPHORUS COMPOUNDS CONTAINING MULTIPLE BONDS

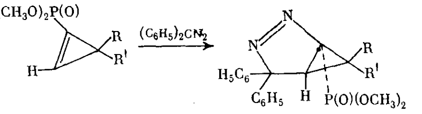
1. Phosphinylated Alkenes

Results on the addition of diazomethane to vinyl- and allyl-phosphonic esters were first published by Pudovik and his coworkers in 1964.[15] The cycloaddition of diazomethane[15-19], diphenyldiazomethane[20-25], phenyldiazomethane[26], diazopropane[26], diazoacetic ester[27,28], and 9-diazofluorene[29] to such phosphonic esters involves intermediate formation of Δ^1-pyrazolines, which either eliminate nitrogen and pass into cyclopropane derivatives or isomerise into thermodynamically stable Δ^2-pyrazolines depending on the experimental conditions:



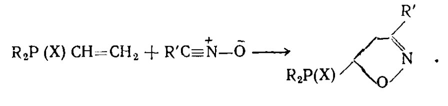
In contrast to other diazoalkanes, diazoacetic ester gives with vinylphosphonates mixtures of isomeric Δ^2-pyrazolines differing in the positions of the phosphinyl and alkoxycarbonyl groups in the ring[27]. At higher temperatures the reactions of diazoalkanes with vinyl- and allylphosphonates yield cyclopropane derivatives.

The kinetics of the cycloaddition of diphenyldiazomethane to vinylphosphonates and vinylphosphine oxides is consistent with a single-stage multicentre process with cyclic electron transfer[25]. The cycloaddition of diphenyldiazomethane at the strained double bond in phosphinylcyclopropenes leads to the formation of substituted diazabicyclo[3,1,0]hexenes[30]:



(*a*) $R=R'=CH_3$; (*b*) $R=CH_3$, $R'=C_6H_5$.

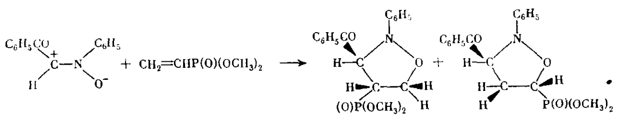
Nitrilimines, nitrile oxides, and nitrones also undergo 1,3-dipolar cycloaddition to vinylphosphonic esters and the tetramethyldiamide and to diphenylvinylphosphine oxide and sulphide[31]. Nitrilimines form 5-phosphinyl-Δ^2-pyrazolines, whereas the *N*-oxides of aceto- and benzonitrile yield 5-phosphinyl-2-isoxazolines:



The rate of addition of diphenylnitrilimine to unsaturated organophosphorus compounds increases with the electrophilicity of the ethylenic double bond. Comparison of the relative addition rate constants indicates that in the case of benzonitrile *N*-oxide the sequence of dipolarophilic activity of unsaturated organophosphorus compounds does not coincide with their activity sequence on reaction with diphenylnitrilimine. This is attributed to differences in the way in which σ bonds are formed in the transition state in these reactions[32].

In the cycloaddition of benzaldehyde *N*-phenyloxime to dimethyl vinylphosphonate the phosphinyl group occupies position 4 in the isoxazolidine ring according to Arbuzov et al.[33], in contrast to Kolokol'tseva et al.[31] Stereochemical investigation has established the *trans*-configuration for substituents in the isoxazolidine rings formed on the addition of this nitrone to vinylphosphonic and β-cyanovinylphosphonic esters, as well as to methyl β-diethoxyphosphinylacrylate[33,34].

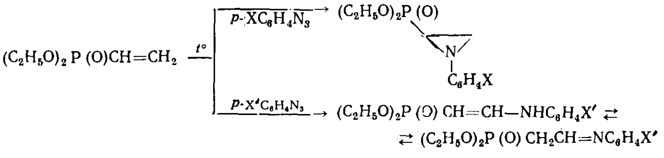
Phenylglyoxal *N*-phenylmonoxime adds to dimethyl vinylphosphonate at 20°C to form isomeric isoxazolidines corresponding to different orientations of dipole and dipolarophile[35]:



In boiling benzene only the first isomer is obtained. Cycloaddition of the nitrone to diethyl vinylphosphonate also yields only 4-diethoxyphosphinylisoxazolidine. Dimethyl allylphosphonate adds nitrones to form isoxazolodines containing a 5-phosphinyl group[35]. Potassium diethyl β-hydroxyvinylphosphonate reacts with toluene-*p*-sulphonyl azide to give a diazophosphonic ester and a potassium salt of formyltoluene-*p*-sulphonamide[36], with possible intermediate formation of a phosphorus-containing triazoline.

Aryl azides react with vinylphosphonates at room temperature[37,38] to form Δ^2-triazolines containing a phosphinyl group at position 4. To prove the orientation of addition of the azide use was made of the ability of the triazoline ring to cleave into a linear diazo-derivative in the presence of a base. Cycloaddition of *p*-nitrophenyl azide to a β-diethylaminovinylphosphonate yields a 4-phosphinyl-1,2,3-triazole as a consequence of elimination of diethylamine from the triazoline formed initially[38].

When heated (75–80°C) aryl azides react with β-cyanovinyl-, propenyl-, and vinyl-phosphonates to form aziridines[37–39]. It is interesting that, when the azide contains donor substituents, cycloaddition leads only to phosphinylaziridines, but in the presence of acceptor substituents an enamine is also formed:



$X = CH_3O$, CH_3, H, Br; $X' = Br$, NO_2.

Differential thermal analysis with quantitative measurement of gas evolution has shown that thermal reactions between phenyl azide and vinylphosphonates involve intermediate formation of Δ^2-triazolines, which under the experimental conditions break down with evolution of nitrogen and formation of aziridines.

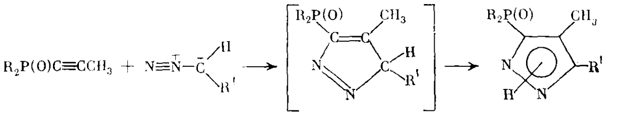
Table 1. Rate constants (10^3k_2, M^{-1} min^{-1}) for the reactions of azides *p*-$XC_6H_4N_3$ with vinylphosphonates $(C_2H_5O)_2.PO.CH:CHY$ in xylene at 115°C.

X	$Y = PO(OC_2H_5)_2$	Y=H			$Y=N(C_2H_5)_2$
	10^3k_2	10^3k_2	$E^{\neq}$, kcal $mole^{-1}$	$\Delta S^{\neq}$, e.u.	10^3k_2
NO_2	5.60	16.5	18.0	−31.1	55.5
Br	6.80	13.7	—	—	6,08
H	6.55	12.6	17.2	−33.5	1.40
CH_3	7.65	12.1	—	—	0,93
CH_3O	8.70	18.0	15.7	−36,3	0.89

Kinetic investigation of the cycloaddition of aryl azides to phosphinylated ethylenes[38] has shown (Table 1) that the reactions of a diphosphinylethylene with azides are of the "dipolarophile–acceptor, 1,3-dipole–donor" type (reactions controlled by highest occupied orbital[13,14]), whereas the reactions of azides with a β-diethylaminovinylphosphonate are of the "dipolarophile–donor, 1,3-dipole-acceptor" type. Both donor and acceptor substituents accelerate the reaction of phenyl azides with diethyl vinylphosphonate. Donor–acceptor interaction of "neutral" type probably operates in this case (reactions controlled by highest occupied and lowest unoccupied orbitals). Reactivity of the aryl azide–vinylphosphonate system is determined mainly by intermolecular donor–acceptor interactions, which stabilise the transition state and depend on the donor–acceptor properties of the reactants.

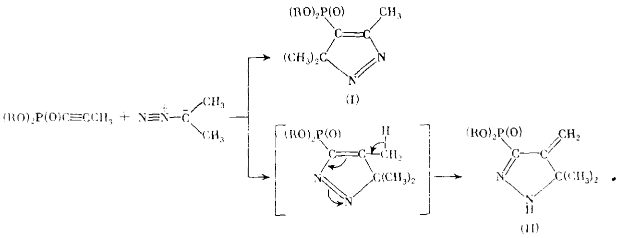
2. Phosphinylated Alkynes

In 1963 Saunders and Simpson obtained an *N*-methylated phosphinylpyrazole by the action of diazomethane on di-isopropyl ethynylphosphonate[40]. A little later the cycloaddition of diazomethane to a diphosphinylacetylene to form a diphosphinylpyrazole was accomplished[41]. With propynylphosphonates and propynylphosphine oxides diazoalkanes also form the corresponding 3(5)-phosphinylated pyrazoles[42,43]:



R = AlkO, Alk, Ar; R' = H, $CO_2C_2H_5$.

Formation of an intermediate phosphinylpyrazolenine in the 1,3-dipolar cycloaddition of diazoalkanes to phosphinylacetylenes is confirmed in the reactions of disubstituted diazo-compounds with a triple bond. The cycloaddition of 2-diazopropane to propynylphosphonates[44] yields a mixture of a 4-dialkoxyphosphinyl-3,5,5-trimethylpyrazolenine (I) and a 3-dialkoxyphosphinyl-5,5-dimethyl-4-methylene-Δ^2-pyrazoline (II) (in the proportions 60 : 40):



The first stage produces a mixture of pyrazolenines differing in the position of the phosphinyl group in the ring. The 3-dialkoxyphosphinylpyrazolenine undergoes prototropic isomerisation into the phosphinyl-Δ^2-pyrazoline. Prototropic isomerisation of a 4-phosphinylpyrazolenine is impossible.

Study of the cycloaddition of diazoacetic ester to propynylphosphonates and propynylphosphine oxides by differential thermal analysis enables[43] F-substituents to be ranged in the sequence

$$C_6H_5 \simeq C_2H_5 > C_2H_5O \sim C_3H_7O \sim C_4H_9O > Cl$$

according to their effect in raising the temperature at which the exothermic effect begins. The dipolarophilic activity of the triple bond in the above compounds obviously increases in the same sequence, owing to the diminution in the electron-accepting properties of the phosphinyl group.

Table 2. Rate constants (10^3k_2, M^{-1} min^{-1} for the cycloaddition of azides p-$XC_6H_4N_3$ to diethyl ethynylphosphonates $(C_2H_5O)_2PO.C\vdots CY$ in m-xylene at 115°C.

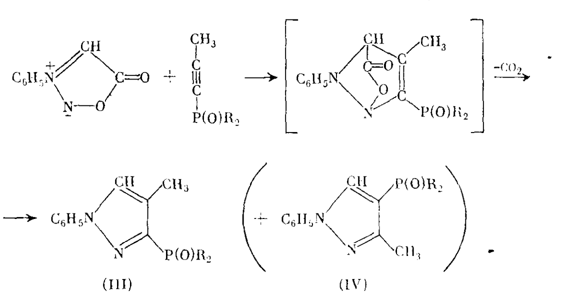
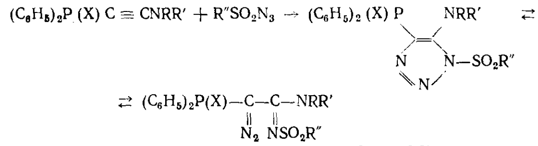
	10^3k_2	10^3k_2	10^3k_2	$E^{\neq}$, kcal mole^{-1}	$\Delta S^{\neq}$, e.u.	10^3k_2	10^3k_2
$(C_2H_5O)_2P(O)$	22.1	32.1	33.1	16.6	—32.9	36.2	43.2
Cl	4.40	6.28	7.50	17.9	—32.7	8.53	9.82
CH_3	3.47	2.20	3.10	18.7	—32.5	3.80	4.66
$N(C_2H_5)_2$	2.11	44.0	15.4	16.8	—34.2	11.6	8 56

Pyrazoles containing a phosphinyl group at the 3-position are formed by the addition of diazomethane to ethynyldiphenylphosphine and its oxide[45]. Methyl β-diphenylphosphinopropiolate forms with diazomethane a mixture of two isomeric pyrazoles corresponding to different orientations of the dipole relative to the dipolarophile[45].

The cycloaddition of N-phenylsydnone to propynylphosphonates, propynylphosphonothioates, and propynyldiphenylphosphine oxide[46] involves fixation of a dipole nitrogen atom mainly on the dipolarophile α-carbon atom [proportions of isomers (III) : (IV) = 85 : 15]:



The addition of organic azides to phosphinylethynylamines yields triazoles contaminated with diazo-compounds[47], the quantity of which depends on the nature of the substituents:

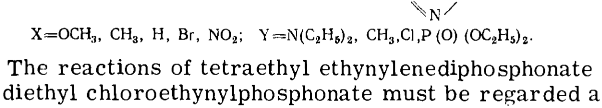


X=O, S, Se, NSO_2R''; R=CH_3, C_2H_5, C_6H_5, p-$CH_3C_6H_4$; R'=C_2H_5, C_6H_5; R''=C_6H_5, p-$CH_3C_6H_4$, $(CH_3)_3C_6H_2$, p-$NO_2C_6H_4$.

Thus, when the substituents R and R' have a high $-M$ effect, the tautomeric triazole form is absent.

The cycloaddition of aryl azides to propynylphosphonates and propynylphosphine oxides is regioselective and leads to the formation of triazoles having the phosphinyl group in the 4-position[48-51]. The structure of the adducts has been established by infrared spectroscopy, ^1H and $^1H-\{^{31}P\}$ nuclear magnetic resonance spectroscopy, and the nuclear Overhauser effect.

The reactivity of phosphinylacetylenes towards azides is increased both by donor and by acceptor substituents Y in the β position of the dipolarophile[52,53] (Table 2):



X=OCH_3, CH_3, H, Br, NO_2; Y=$N(C_2H_5)_2$, CH_3,Cl,P(O)$(OC_2H_5)_2$.

The reactions of tetraethyl ethynylenediphosphonate and of diethyl chloroethynylphosphonate must be regarded as belonging to the "dipolarophile–acceptor, 1,3-dipole–donor" type, in which interaction between the highest occupied orbital of the dipole and the lowest unoccupied orbital of the dipolarophile predominates. Those of diethyl diethylaminoethynylphosphonate with azides are of the "dipole–acceptor, dipolarophile–donor" type. Kinetic study of the reactions of diethyl propynylphosphonate with aryl azides has shown that neither electron-donor nor electron-acceptor substituents in the azide accelerate the reaction significantly.

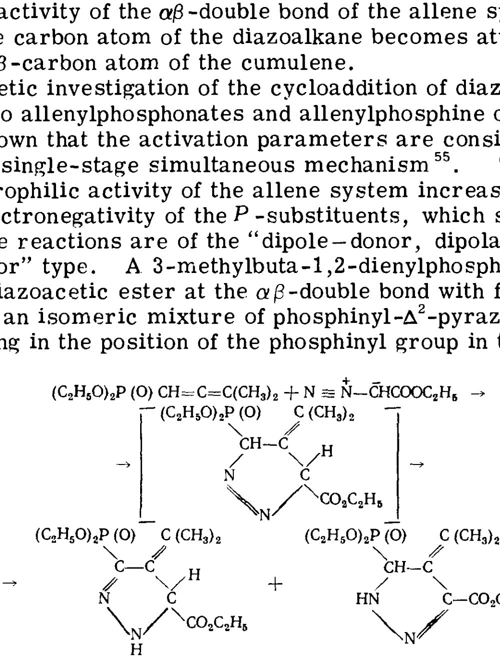
In a series of $para$-substituted phenyl azides the sensitivity of the reactivity to the activating influence of donor substituents in the phosphinylacetylenes diminishes and the sensitivity to acceptor substituents increases. This involves inversion from the "dipole–acceptor, dipolarophile–donor" type of reaction through the region of "neutral" cycloaddition to the "dipole–donor, dipolarophile–acceptor" type. Comparison of the logarithms of the rate constants for propynylphosphine oxides (measured at 115°C) with the Kabachnik σ^f constants has shown that the dipolarophilic activity of the triple bond intensifies as substituents attached to the phosphorus atom ($\rho = 0.24$, $r = 0.993$) become more electronegative. Propynylphosphonates do not conform to this correlation. The factors governing the reactivity of these dipolarophiles towards azides are evidently not described by specific phosphorus constants. The variation in the relative reactivity of these systems may be significantly influenced not only by changes in the donor–acceptor properties of the ligands but also by changes in their localisation energies.

These results taken together suggest that the reactivity of 1,3-dipoles and dipolarophiles is a consequence mainly of the highest occupied orbital–lowest unoccupied orbital model, and is consistent with a concerted reaction mechanism. The large negative entropies of activation, indicating a high degree of order in the transition state, and the moderate energies of activation agree with a single-stage multicentre mechanism. The observed slight dependence of rate of addition on solvent polarity is inconsistent with a two-stage mechanism involving an intermediate zwitterion. The weak sensitivity of the reactivity to interchange of substituents in the ligands is also evidence of the insignificant polarity of the transition state.

3. Phosphinylated Allenes

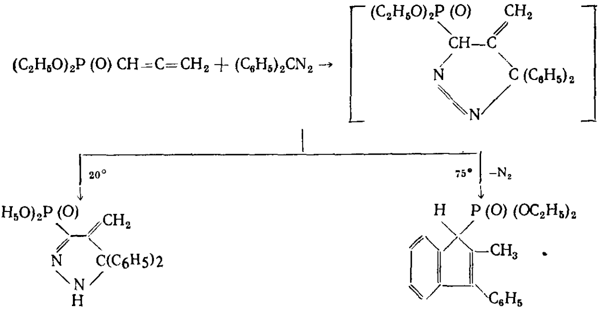
The cycloaddition of unsubstituted and monosubstituted diazoalkanes to phosphinylalenes yields phosphinylated pyrazoles[42]. The activating influence of the electron-accepting phosphinyl group is responsible for the dipolarophilic activity of the $\alpha\beta$-double bond of the allene system, and the carbon atom of the diazoalkane becomes attached to the β-carbon atom of the cumulene.

Kinetic investigation of the cycloaddition of diazoacetic ester to allenylphosphonates and allenylphosphine oxides has shown that the activation parameters are consistent with a single-stage simultaneous mechanism[55]. The dipolarophilic activity of the allene system increases with the electronegativity of the P-substituents, which suggests that the reactions are of the "dipole–donor, dipolarophile–acceptor" type. A 3-methylbuta-1,2-dienylphosphonate adds diazoacetic ester at the $\alpha\beta$-double bond with formation of an isomeric mixture of phosphinyl-Δ^2-pyrazolines differing in the position of the phosphinyl group in the ring[43]:



$(C_2H_5O)_2P(O)CH{=}C{=}C(CH_3)_2 + \overset{+}{N}{\equiv}N{-}\overset{-}{C}HCOOC_2H_5 \rightarrow$

Depending on the temperature the thermodynamically unstable Δ^1-pyrazoline formed on the cycloaddition of diphenyldiazomethane to diethyl allenylphosphonate[54] may either isomerise into the Δ^2-pyrazoline or decompose with the evolution of nitrogen and the formation of a phosphinylated indene:

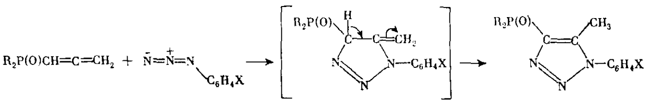


A 1-phenylpropa-1,2-dienylphosphonate with diphenyldiazomethane forms a methylenecyclopropane derivative. 2-Diazopropane reacts with allenylphosphonates at room temperature to give dialkyl 5,5-dimethyl-4-methylene-Δ^2-pyrazol-3-ylphosphonates[44]. The cycloaddition of N-phenylsydnone to allenylphosphonates and allenylphosphine oxides[56,57] produces a mixture of isomeric pyrazoles having different orientations of the dipole with respect to the dipolarophile.

Table 3. Rate constants (10^3k_2, $M^{-1}\ min^{-1}$) for the reactions of aryl azides p-$XC_6H_4N_3$ with phosphinylated allenes $R_2PO.CH:C:CH_2$.

R	X				
	NO_2	Br	H	CH_3	CH_3O
Cl	1.25	5.88	9.30	15.1	19.9
C_2H_5O	1.30	1.15	1.04	1.50	1.99
$N(CH_3)_2$	113.4	16.0	6.03	4.00	3.30

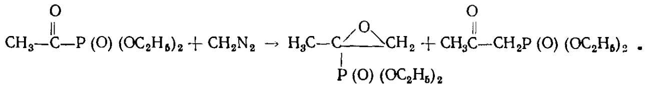
The Δ^1-triazolines having an exocyclic methylene group that are formed by the cycloaddition of aryl azides to phosphinylated cumulenes are very unstable, and are stabilised by prototropic isomerisation into triazoles[38]:



A kinetic study has been made[38] of the reactions of *para*-substituted aryl azides with phosphinylated allenes containing electron-accepting (chloro) and weakly and strongly electron-donor (ethoxy and dimethylamino) substituents attached to the phosphorus atom[38]. The reaction of allenylphosphonic dichloride is accelerated by donor and retarded by acceptor substituents in the aryl azide. Comparison of the logarithms of the reaction rate constants (Table 3) with the Hammett σ constants reveals a good linear dependence ($\rho = -0.85$, $r = 0.996$); the reaction belongs to the "dipolarophile–acceptor, 1,3-dipole–donor" type. The action of aryl azides on allenylphosphonic bisdimethylamide must be regarded as the "dipolarophile–donor, dipole–acceptor" type. Donor–acceptor interaction of "neutral" type occurs in the reactions of diethyl allenylphosphonate with aryl azides, as in those of diethyl propynylphosphonate and vinylphosphonate. The reactivity of the ligands is obviously determined by the electronic effects of the *P*-substituents, and the phosphorus atom iself participates in transmitting the effects of the substituents to the reactive centre[38].

4. α-Oxo-phosphonates

In 1963 Arbuzov et al.[58] studied the reaction of diazomethane with diethyl acetylphosphonate, from which diethyl 2-methyloxiran-2-ylphosphonate and a small quantity of diethyl acetonylphosphonate were obtained:



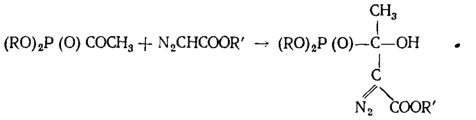
The action of diazomethane on diethyl benzoylphosphonate gives only the benzoylmethylphosphonic ester. Pudovik et al.[59] have shown that the action of diphenyldiazomethane on derivatives of acetyl- and benzoyl-phosphonic acids at high temperatures yields products of oxiran structure. The latter was confirmed by infrared spectral data and by the catalytic and thermal isomerisation of the products with rupture of a cyclic carbon–oxygen bond and formation of a phosphinyl ketone. More recently β-keto-phosphonates have been obtained[60] by the action of diazomethane and phenyldiazomethane on benzoylphosphonates under similar conditions:

$$\underset{\underset{O}{\|}}{R-C}-P(O)(OR')_2 + R''CHN_2 \rightarrow \underset{\underset{O}{\|}}{R-C}-CHR''P(O)(OR')_2$$

$R=C_6H_5$, m-ClC_6H_4, p-$CH_3OC_6H_4$; $R'=C_2H_5$, CH_3; $R''=H$, C_6H_5.

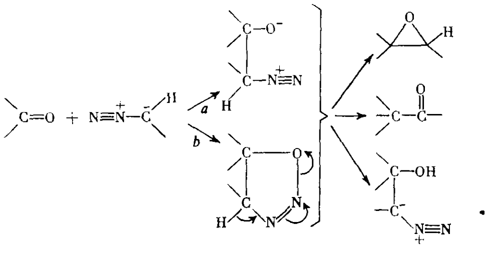
It is assumed[60] that such reactions involve migration of the phosphinyl group to form the thermodynamically stable β-keto-phosphonates. The action of diazoethane on α-oxo-phosphinyl compounds yields exclusively the corresponding β-keto-phosphinyl derivatives[61,62].

Diazoacetic esters form adducts of "aldol" type—alkyl β-dialkoxyphosphinyl-α-diazo-β-hydroxybutyrates[63,64]:



$$(RO)_2P(O)COCH_3 + N_2CHCOOR' \rightarrow (RO)_2P(O)-\overset{\overset{CH_3}{|}}{\underset{\underset{\underset{N_2 \quad COOR'}{C}}{|}}{C}}-OH$$

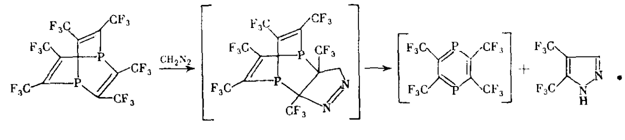
The mechanism of the reactions of diazoalkanes with α-oxo-phosphonates is represented by the general scheme[64]



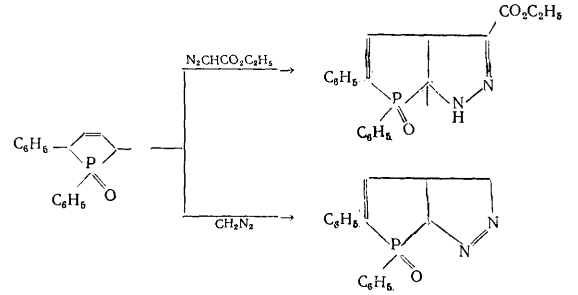
Reaction path (*a*) presupposes formation of a zwitterion in the first stage; path (*b*) involves 1,3-dipole cycloaddition, with formation of a 1,2,3-oxadiazoline derivative in the first stage. The products may be oxirans, β-keto-phosphonates, and diazohydroxyalkylphosphonates. The direction of the reaction of α-oxo-phosphonates with diazoalkanes is significantly influenced by the nature of the substituents both adjacent to the carbonyl group[58,59] and attached to the carbon atom of the diazo-component[59,61,63,64].

5. Tertiary Cyclic Phosphines and their Oxides

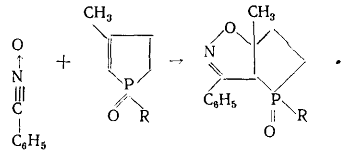
A substituted diphosphabarrelene behaves as a dipolarophile, undergoing addition at the multiple bond in diazomethane and phenyl azide[65]. However, the adducts formed by cycloaddition are unstable:



The 1,3-dipolar cycloaddition of diazoalkanes to 1,2,5-triphenylphosphole oxide yields adducts of dihydropyrazole structure[66,67]:



Δ^2-Phospholens form with oxides of aromatic nitriles derivatives of oxazaphosphabicyclo[3,3,0]octene[68]:

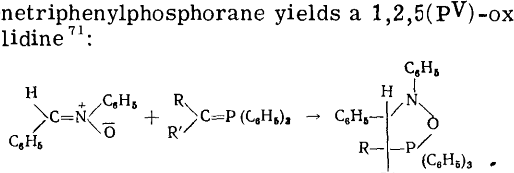


In the case of Δ^3-phospholen the sequence in which the nitrile oxide is added has no significance, because of the symmetry of the former molecule.

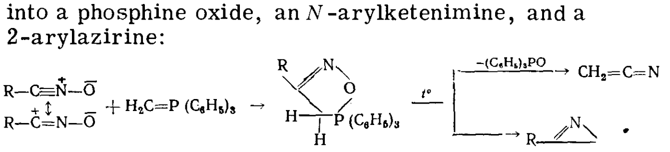
6. Alkylidenephosphoranes

The cycloaddition of 1,3-dipoles to alkylidenephosphoranes produces five-membered heterocycles containing the phosphorus atom either directly in the ring or in a side-chain. Methylene- and imino-phosphoranes have been subjected to reaction with nitrones[69–71], nitrile oxides[70,72–75], nitrilimines, and other 1,3-dipoles[70,76].

Reaction between benzaldehyde *N*-phenyloxime and an alkylidenetriphenylphosphorane yields a 1,2,5(P^V)-oxazaphospholidine[71]:



Benzonitrile oxide adds to methylenetriphenylphosphorane to form an oxazaphospholen, which breaks down at 140°C into a phosphine oxide, an *N*-arylketenimine, and a 2-arylazirine:



Huisgen and Wulff suggest[75] a multicentre single-stage addition for these reactions. The direction of cycloaddition is determined by the principle of maximum gain in energy of the σ bond, with consequent formation of an energetically favourable phosphorus–oxygen bond.

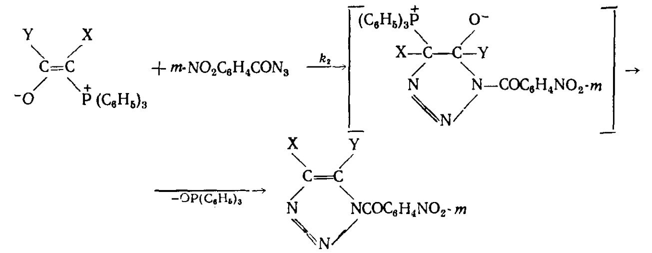
Iminophosphoranes are less active as dipolarophiles than are methylenephosphoranes. Cycloadducts of the latter with a nitrile oxide and a nitrone are quite stable and can be isolated, but with iminophosphoranes only decomposition products of the initial adducts are obtained. Thus the adduct of phenylglyoxal *N*-phenylmonoxime and phenyliminotriethylphosphorane eliminates a phosphine oxide to form N^2-benzoyl-N^1N^1-diphenylformamidine[70].

In contrast to methylene- and imino-phosphoranes, β-oxoalkylidenephosphoranes are able to react with 1,3-dipoles in the form of two resonance structures[77]

$$\underset{-O}{R-C}=CH-\overset{+}{P}(C_6H_5)_3 \leftrightarrow RCO-CH=P(C_6H_5)_3\,.$$

1,3-Dipolar cycloaddition of organic azides[77–81] to β-oxoalkylidenephosphoranes gives a mixture of products formed by incorporation into the phosphorane (*a*) at the C=C bond (triazoles and phosphine oxides) and (*b*) at the C=P bond (phosphoranes), one of which may predominate depending on the substituent in the initial phosphorane or on the conditions[77,82–84]. Benzonitrile oxides resemble azides in reacting with acylmethylenetriphenylphosphoranes to give a mixture of an isoxazole and a new phosphorane[82].

The mechanism of the reaction of azides with β-oxoalkylidenephosphoranes has been clarified by means of the kinetic investigations[77,80]

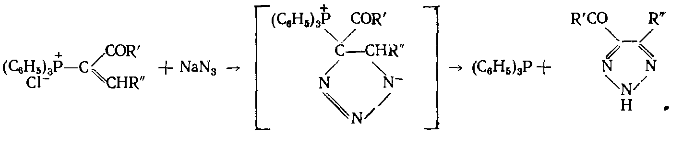


$Y=CH_3$, C_6H_5, $p\text{-}NO_2C_6H_4$.

The activation parameters are consistent with 1,3-dipolar cycloaddition. It is considered[80] that concerted formation of σ bonds takes place, but at different rates.

7. Vinylphosphonium Salts

Cycloaddition of inorganic azides[85,86] or diazoalkanes[87–90] to vinylphosphonium salts takes place at the double bond by a 3 + 2 → 5 scheme with the formation of heterocycles containing the phosphorus atom in a side-chain. Cycloaddition of sodium azide to a vinylphosphonium salt produces an unstable adduct, which splits into triphenylphosphine and a triazole:



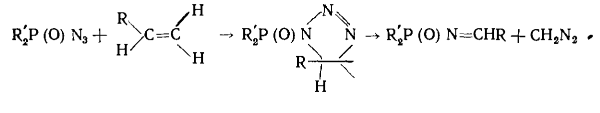
Stable 2-pyrazol-3-yltriphenylphosphonium bromides have been obtained[88] by the cycloaddition of diazoalkanes to unsubstituted vinylphosphonium salts. The action of diazo-compounds on β-acylvinylphosphonium salts gives pyrazoles and a phosphine oxide[89]. The direction of cycloaddition is controlled by the electronic and steric effects of the substituents and also by the reaction conditions.

III. 1,3-DIPOLAR CYCLOADDITION OF PHOSPHINYLATED 1,3-DIPOLES

1. 1,3-Dipoles containing Phosphinyl Substituents in a Side-chain

The cycloaddition of diazoalkanephosphonates to various unsaturated compounds yields phosphinylated pyrazoles and pyrazolines[91–104]. The dependence of the vicinal spin–spin coupling constant of phosphorus-31 and hydrogen-1 nuclei on the dihedral angle found from the nuclear magnetic resonance spectra has been used to determine the configurations of the Δ^1-pyrazolines formed by the cycloaddition of a diazoalkanephosphonate to norbornene and norbornadiene[102]. Electronic factors play an important part in the formation of configurational isomers epimeric with respect to the 3-carbon atom in the pyrazoline. The conformation has been determined for the Δ^1-pyrazolines obtained by 1,3-dipolar cycloaddition of ethyl α-diazo-β-dimethoxyphosphinyl-β-hydroxybutyrate to methyl methacrylate[104]. Reaction of this butyrate with dimethyl acetylenedicarboxylate is accompanied by decomposition of the resulting diastereomeric pyrazolenines as a consequence of rupture of phosphorus–carbon and carbon–carbon bonds[105].

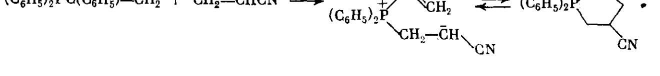
Phosphinyl azides add at multiple bonds in unsaturated compounds:



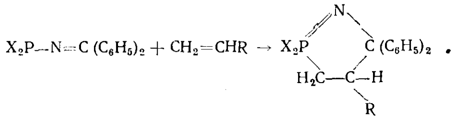
The reaction products are in one case stable triazolines[106–108], and in another *N*-phosphinylated imines and diazomethane both formed on decomposition of unstable initial adducts[109]. Diphenyl phosphorazidate reacts with enamines of cyclic ketones to form unstable triazolines, which evolve nitrogen and give products of ring contradiction[110].

2. αβ-Unsaturated Phosphines and Phosphinites

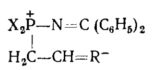
αβ-Unsaturated compounds containing a three-coordinated phosphorus atom react with such dipolarophiles as acrylates, acetylenedicarboxylic esters, and derivatives of α-keto-carboxylic acids by adding to C=C, C≡C, and C=O multiple bonds according to the classic 3 + 2 → 5 scheme. Thus 1,3-dipolar cycloaddition of diphenyl-1-phenylvinylphosphine (dipole of type $=\ddot{P}-C=C$) to acrylonitrile yields a cyclic adduct[111]:



A substituted methyleneaminophosphine adds to acrylonitrile or methyl acrylate to form a Δ^1-1,2-aza-(PV)-phospholine, the first cyclic phosphazen containing fewer than six atoms in the ring[112,113]:

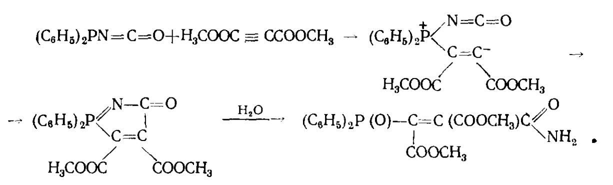


A betaine structure



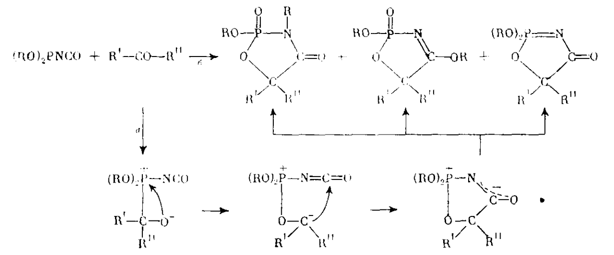
may well be formed as an intermediate stage[112,113]. Cycloaddition of diethoxymethyleneaminophosphines to acrylic esters gives derivatives of dihydroazaphospholopyridine[114].

The reaction of isocyanatodiphenylphosphine with dimethyl acetylenedicarboxylate is regarded[115] as involving an intermediate zwitterion, which cyclises into an unstable five-membered heterocycle readily hydrolysed to a phosphine oxide:

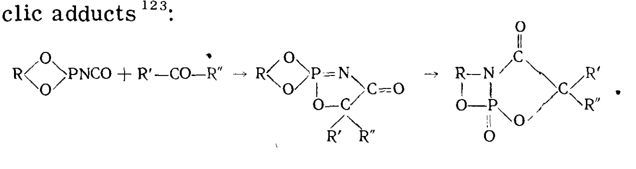


Diethyl phosphoramidinate reacts readily with acetylenedicarboxylic and maleic esters[116] to form azaphospholes and azaphospholines.

The carbonyl group also exhibits dipolarophilic activity towards phosphorisocyanatidites and methyleneaminophosphines. These esters react with esters[117,118,125,126,128] and nitriles[119,128] of α-oxo-carboxylic acids, with α-dicarbonyl compounds[120,121], and with α-oxo-phosphonates[126,127], forming mixtures of structurally isomeric substituted oxazaphospholidinones, oxazaphospholines, and oxazaphospholinones. Reaction is assumed[128] to follow path (a):

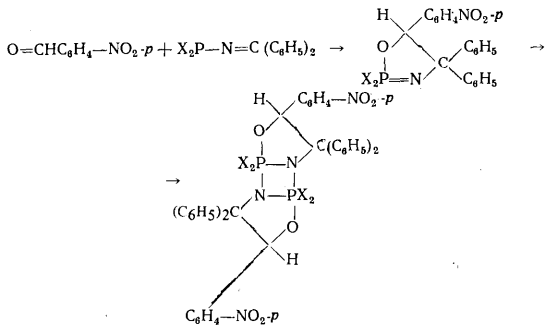


The reactions of isocyanatodiphenylphosphine and of phosphorisocyanatidous tetraethyldiamide with ethyl pyruvate go in the same direction, forming substituted oxazaphospholines, which contain a phosphimide bond[122]. Alkylene glycol esters of isocyanates of phosphorous acid form with α-oxo-carboxylic esters and phenylglyoxal 1 : 1 bicyclic adducts[123]:



Substituted bicycloheptanes are obtained by the action of carbonyl compounds on ethyl phosphorodi-isocyanatidite[124].

Cycloaddition of a substituted methyleneaminophosphine to p-nitrobenzaldehyde gives a dimeric 1 : 1 adduct[129]:



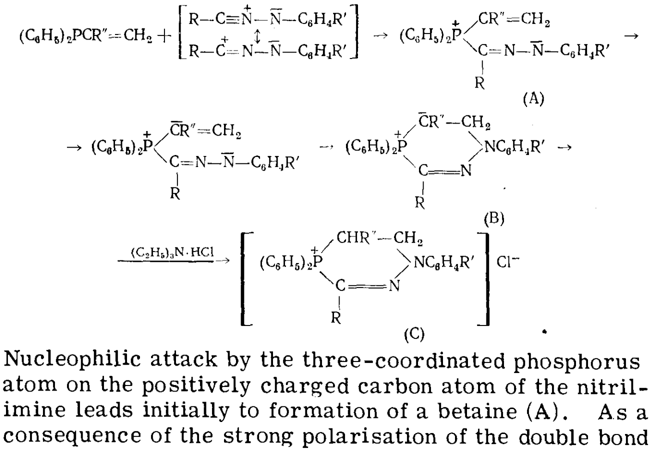
The ability of $\alpha\beta$-unsaturated compounds containing tervalent phosphorus to react as 1,3-dipolar systems is attributed[130,131] to the behaviour of the phosphorus atom as a nucleophile in virtue of its lone pair of electrons. On becoming quaternised, the phosphorus atom develops π-acceptor properties as a consequence of $d\pi - p\pi$ conjugation, activating the β position of the multiple bond. It is considered[130,131] that any system of the type $\ddot{Z}-X=Y$ can react as a 1,3-dipole, where $\ddot{Z}$ is an element having a lone pair of electrons, while X and Y are elements capable of forming π bonds.

IV. MIXED "DIMERISATION" of 1,3-DIPOLES AND $\alpha\beta$-UNSATURATED PHOSPHINES AND PHOSPHONITES

1. Ethylenic and Acetylenic Phosphines and Phosphonites

As well as reactions in which $\alpha\beta$-unsaturated compounds containing three-coordinated phosphorus behave as 1,3-dipolar systems, these substances also undergo mixed "dimerisation" with classic 1,3-dipoles.

Vinyl-, isopropenyl-, allyl, and alkynyl-phosphines react with substituted nitrilimines according to a 3 + 3 → 6 scheme involving the phosphorus atom to form (in the presence of triethylamine hydrochloride) six-membered cyclic phosphonium salts[132-134,137,138,146]:



Nucleophilic attack by the three-coordinated phosphorus atom on the positively charged carbon atom of the nitrilimine leads initially to formation of a betaine (A). As a consequence of the strong polarisation of the double bond due to the positively charged phosphorus atom, the betaine cyclises into a phosphorine (B), which is then converted into a phosphonium salt (C). The reaction of $\alpha\beta$-unsaturated ethylenic and acetylenic phosphonites with nitrilimines proceeds similarly, but the concluding stage is accompanied by an Arbuzov rearrangement[135,136,139,140].

Alkynylphosphonous tetra-alkyldiamides react with diphenylnitrilimine to form cyclic phosphonium salts, derivatives of 1,4-dihydro-4-phosphapyridazine[141]. Reaction between nitrilimines having electron-accepting groups attached to the carbon atom and β-substituted ethylenic and acetylenic dialkyl-, diamino-, and diphenylphosphines gives azomethylenephosphoranes[134,141]:

$$R_2PCH{=}CHC_6H_5 + R'{-}\overset{+}{C}{=}N{-}\overline{N}{-}C_6H_5 \rightarrow \begin{matrix} R_2\overset{+}{P}CH{=}CHC_6H_5 \\ | \\ R'C{=}N{-}\overline{N}C_6H_5 \end{matrix} \rightarrow \begin{matrix} R_2P{-}CH{=}CHC_6H_5 \\ \| \\ R'C{-}N{=}NC_6H_5 \end{matrix} .$$

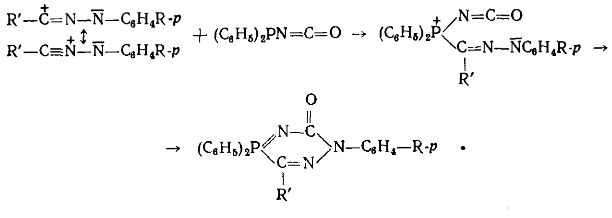
The nature (saturated or aromatic) of substituents attached to the phosphorus atom has no effect on the course of the reaction. With αβ-ethylenic phosphines and phosphonites this is determined mainly by two factors—steric hindrance by β-substituents in the unsaturated group and the nature of the substituents attached to the carbon atom of the nitrilimine. The reactions of acetylenic derivatives of tervalent phosphorus with nitrilimines, in contrast to those of ethylenic compounds, are less sensitive to steric hindrance at the β-carbon atom of the ethynyl group and to the nature of substituents attached to the nitrilimine carbon atom[137]. This difference in behaviour is attributed[137] to greater activity of the *sp*-hybridised carbon atom in reactions with nucleophilic reagents.

Kinetic investigation by the method of competing reactions has shown[141] that the reactivity of unsaturated derivatives of three-coordinated phosphorus towards nitrilimines is determined primarily by the inductive effects of the substituents and to a less extent by the $d\pi - p\pi$ conjugation. Comparison of the relative rate constants for reactions of a series of αβ-unsaturated compounds of tervalent phosphorus with diphenylnitrilimine suggests[141] a two-stage nucleophilic mechanism. The rate-determining stage is nucleophilic attack by the phosphorus atom on the electron-deficient carbon atom of the nitrilimine. Thus the rules of mixed "dimerisation" differ from those of classic 1,3-dipolar cycloaddition.

Study of the reactions of organic azides with αβ-unsaturated phosphines has shown[142] that the multiple bond is not involved, and as a result previously unknown unsaturated phosphinimines are formed.

2. Isocyanatophosphines and Methyleneaminophosphines

Three-coordinated phosphorus compounds containing an αβ-N=C bond react as 1,3-dipoles with nitrilimines, according to a 3 + 3 → 6 scheme similarly to alkenyl- and alkynyl-phosphines. Reaction between isocyanatodiphenylphosphine and a nitrilimine yields a cyclic ketoiminophosphorane independently of the nature of the substituents in the nitrilimine[143,144]:



The course of the reaction supports the above two-stage nucleophilic mechanism of interaction between αβ-unsaturated compounds of tervalent phosphorus and 1,3-dipolar systems[141]. Diphenylmethyleneaminodiphenylphosphine, in contrast to the isocyanate, reacts with *C*-ethoxycarbonyl- and *C*-acetyl-*N*-arylnitrilimines to form open-chain azomethylenephosphoranes[145].

Thus 1,3-dipolar cycloaddition of organophosphorus compounds provides a convenient method for synthesising phosphorus-containing heterocycles, which find widespread use in many branches of the national economy—as medicinals, as insecticides in agriculture, and as polymerisation initiators in chemical industry. Investigation of such reactions broadens our ideas on the influence of substituents in ligands on the dipolarophilic activity of a multiple bond, the factors determining the reactivity of dipole–dipolarophile systems, and the mechanism of cycloaddition reactions.

Organic Monothiopyrophosphates

J.Michalski, W.Reimschüssel, and R.Kaminski

The present state of the chemistry of organic monothiopyrophosphates is described. Discussion of methods of preparation is followed by consideration of physical and chemical properties. Close attention is paid to symmetrical monothiopyrophosphates and their isomerisation, as well as the properties distinguishing them from the unsymmetrical isomers. A list of 72 references is included.

I. INTRODUCTION

Isomeric monothiopyrophosphoric acids $H_4P_2O_6S$, in contrast to pyrophosphoric (diphosphoric) acid $H_4P_2O_7$, are unknown in the free state. However, their esters are known, as well as structural analogues containing a direct carbon–phosphorus bond. The present Review covers the chemistry of monothiopyrophosphoric esters, in whose molecules the sulphur atom is located either symmetrically or unsymmetrically

which we shall term symmetrical or unsymmetrical monothiopyrophosphates. Such compounds merit special attention because of the diversity of their chemical reactions and their great practical value. They are also of theoretical interest. An existing review[1] covering the development of the chemistry of organic monothiopyrophosphates has already become insufficiently exhaustive.

II. METHODS OF PREPARATION

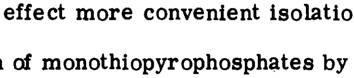
Tetraethyl thiopyrophosphate was first obtained in 1931 by A.E. and B.A. Arbuzov[2], by the addition of sulphur to the mixed anhydride of diethyl hydrogen phosphite and diethyl hydrogen phosphate:

$$(RO)_2P{-}O{-}\underset{\overset{\|}{O}}{P}(OR)_2 + S \rightarrow (RO)_2\underset{\overset{\|}{S}}{P}{-}O{-}\underset{\overset{\|}{O}}{P}(OR)_2\,,$$

R=Et (I)

An unsymmetrical structure was ascribed to compound (I).

Many fresh attempts to prepare monothiopyrophosphates began two decades later. A large group of methods developed earlier were based on the phosphorylation, usually by means of dialkyl phosphorochloridates, of inorganic and organic salts of dialkyl phosphorothionates[3-6]:



$$(RO)_2\underset{\overset{\|}{S}}{P}{-}OM + Cl{-}\underset{\overset{\|}{O}}{P}(OR)_2 \rightarrow (I) + MCl\,. \qquad (1)$$

The reactions are conducted with the sodium, potassium, and ammonium salts in aprotic solvents. The method was modified[7] to effect more convenient isolation of the final product.

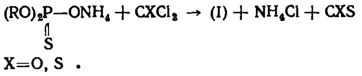
The formation of monothiopyrophosphates by the action of hydrogen sulphide on dialkyl phosphorochloridates in the presence of bases[8,9] can be regarded as a two-stage process. In the rate-determining first stage a salt of dialkyl hydrogen phosphorothionate (II) appears:

$$(RO)_2\underset{\overset{\|}{O}}{P}{-}Cl + H_2S + R'_3N \rightarrow (RO)_2\underset{\overset{\|}{O}}{P}{-}SHNR'_3 + R'_3NHCl\,.$$

(II)

In the second stage this salt (II) undergoes phosphorylation as in Eqn. (1).

Tetra-alkyl thiopyrophosphates (I) were obtained by the action of carbonyl or thiocarbonyl chloride on ammonium dialkyl phosphorothionates[1,10-12]:



$$(RO)_2\underset{\overset{\|}{S}}{P}{-}ONH_4 + CXCl_2 \rightarrow (I) + NH_4Cl + CXS$$

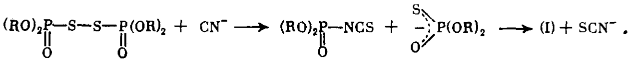
$$X{=}O, S\,.$$

The mechanism of this reaction has not yet been adequately elucidated. An analogous method is based on the thiophosphorylation of dialkyl hydrogen phosphates or their salts[9]:

$$(RO)_2\underset{\overset{\|}{S}}{P}{-}Cl + MO{-}\underset{\overset{\|}{O}}{P}(OR)_2 \rightarrow (I) + MCl\,.$$

This reaction provides indirect evidence of the unsymmetrical structure of (I).

The reaction between the diphosphoryl disulphides (III) and potassium cyanide requires separate discussion[13]. These disulphides (III) are readily formed by the oxidation of salts of dialkyl hydrogen phosphorothioates[14], so that this method has preparative value. Investigations in our laboratory[15] on the preparation and chemistry of organophosphorus thiocyanates indicate a two-stage reaction:

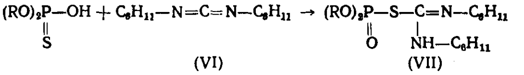


$$(RO)_2\underset{\overset{\|}{O}}{P}{-}S{-}S{-}\underset{\overset{\|}{O}}{P}(OR)_2 + CN^- \longrightarrow (RO)_2\underset{\overset{\|}{O}}{P}{-}NCS + {}^{S}_{O}{\rangle}P(OR)_2^{-} \longrightarrow (I) + SCN^-\,.$$

(III) (IV) (V)

The extremely unstable intermediate thiocyanate is converted into the isothiocyanate (IV), which then reacts with the dialkyl phosphorothioate anion (V) formed at the same time. An analogy is clearly evident between this reaction and the phosphorylation of phosphorothioic acids in conformity with Eqn. (1).

The condensation of dialkyl hydrogen phosphates with dicyclohexylcarbodi-imide (VI) [9] is the same type of reaction. It involves initial formation of the intermediate adduct (VII):[16]

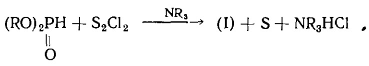


$$(RO)_2\underset{\overset{\|}{S}}{P}{-}OH + C_6H_{11}{-}N{=}C{=}N{-}C_6H_{11} \rightarrow (RO)_2\underset{\overset{\|}{O}}{P}{-}S{-}\underset{\overset{|}{NH-C_6H_{11}}}{C}{=}N{-}C_6H_{11}\,.$$

(VI) (VII)

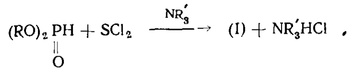
In the second stage this adduct (VII) phosphorylates another molecule of the phosphorothioate.

Two additional methods for obtaining tetra-alkyl thiopyrophosphates must be mentioned. The first is based on reaction between a dialkyl phosphite and sulphur monochloride in the presence of an amine[17-19]:



$$\underset{\overset{\|}{O}}{(RO)_2PH} + S_2Cl_2 \xrightarrow{NR_3} (I) + S + NR_3HCl\ , \qquad (2)$$

The final product is isolated from the reaction mixture by distillation. In the second method sulphur dichloride is used in the presence of a tertiary amine[18-23]:



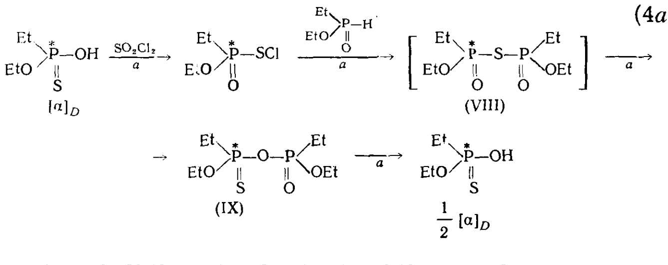
$$\underset{\overset{\|}{O}}{(RO)_2PH} + SCl_2 \xrightarrow{NR'_3} (I) + NR'_3HCl\ , \qquad (3)$$

The dichloride and the amine can be replaced by the dialkylaminosulphenyl chloride R'_2NSCl.[20,21] Present-day knowledge indicates that the primary product of reaction (2) is the diphosphoryl disulphide (III), which breaks down with formation of an unsymmetrical thiopyrophosphate[24]. Reaction (3) involves initial formation of a symmetrical thiopyrophosphate, which in the presence of the amine and at a higher temperature is converted into an unsymmetrical isomer. A special method for obtaining an unsymmetrical thiopyrophosphate, in which the PS.O.PO group of the initial product remains undisturbed, is alcoholysis of thiopyrophosphoric tetrachloride[25]:

$$\underset{\overset{\|}{S}}{Cl_2P}—O—\underset{\overset{\|}{O}}{PCl_2} + ROH \rightarrow (I) + HCl$$

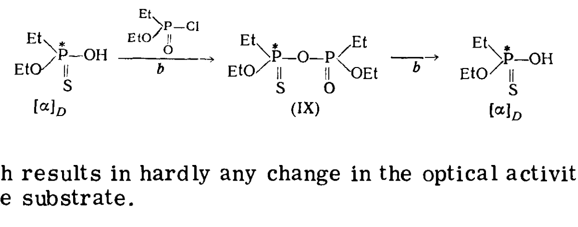
which is accompanied by alcoholysis of the P-O-P bond.

Thermochemical estimates indicate that in thiopyrophosphates the unsymmetrical skeleton is more stable than the symmetrical skeleton by ~35 kJ mole^{-1}.[26] This suggested that thiopyrophosphates containing a P-S-P group should be sufficiently stable to be isolated. In 1962 application of a stereochemical method proved[27,28] that an intermediate product containing this group is formed in the reaction between an optically active chlorothio-alkylphosphinic ester and an alkylphosphinic ester. The series of reactions



(4*a*)

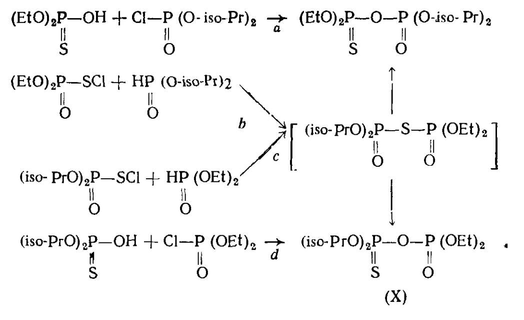
leads to half the optical activity of the initial phosphonothioic ester. Such an experimental result can be explained only by formation of the symmetrical bond system (O)P-S-P(O) in the intermediate product (VIII), which is then converted into the product (IX). This conclusion is supported by the series of reactions



(4*b*)

which results in hardly any change in the optical activity of the substrate.

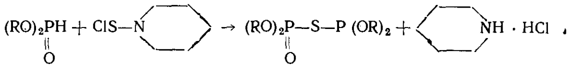
Proof of the intermediate formation of a symmetrical thiopyrophosphate was obtained by investigating the reactions of dialkyl *S*-chlorothiophosphonates with dialkyl phosphites[29]



(5)

The final product of reactions (5*b*) and (5*c*) is always an unsymmetrical thiopyrophosphate (X). This provides convincing support for the view that reactions (5*a*) and (5*d*)—the phosphorylation of dialkyl hydrogen phosphorothioates by means of dialkyl phosphorochloridates according to scheme (1)—leads directly to the formation of a P-O-P bond without intermediate formation of a product having a symmetrical skeleton.

It was subsequently established[23] that symmetrical thiopyrophosphates are formed in the reaction of a dialkyl *S*-chlorothiophosphonate with a dialkyl phosphite[23]. A general method was the reaction of dialkyl phosphites with piperidinosulphenyl chloride (XI),[23,30] yielding symmetrical thiopyrophosphates containing four identical substituents:



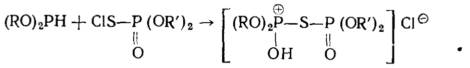
(XI)

A more general method is use of the dialkyl *S*-chlorothiophosphonate (XII),[31,32] which enables different substituents to be attached to the different phosphorus atoms:

$$\underset{\overset{\|}{O}}{(RO)_2PH} + ClS—\underset{\overset{\|}{O}}{P}(OR')_2 \rightarrow \underset{\overset{\|}{O}}{(RO)_2P}—S—\underset{\overset{\|}{O}}{P}(OR')_2 + HCl\ .$$

(XII)

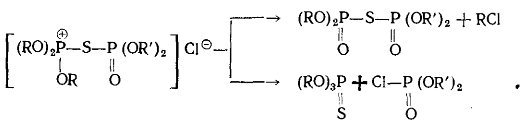
These reactions are probably of the Arbuzov type[28,30-32] with formation of an intermediate phosphonium complex:



$$\underset{\overset{\|}{O}}{(RO)_2PH} + ClS—\underset{\overset{\|}{O}}{P}(OR')_2 \rightarrow \left[(RO)_2\underset{\overset{|}{OH}}{\overset{\oplus}{P}}—S—\underset{\overset{\|}{O}}{P}(OR')_2\right]Cl^{\ominus}\ .$$

(XIII)

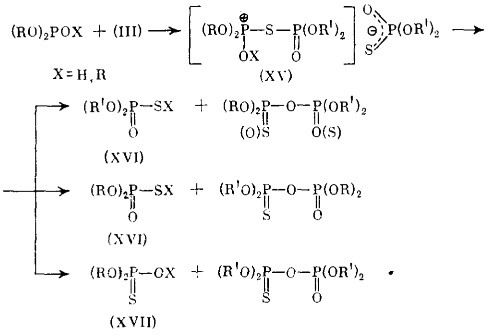
This complex (XIII) breaks down to form a symmetrical thiopyrophosphate and hydrogen chloride. The use of trialkyl phosphites (RO)$_3$P instead of dialkyl phosphites (RO)$_2$POH may change the mode of decomposition of the complex (XIV):[31]



(XIV)

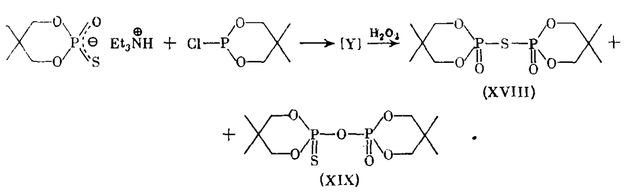
In such a case the symmetrical thiopyrophosphate is accompanied by the corresponding trialkyl phosphorothionate and dialkyl phosphorochloridate.

A special group of reactions for obtaining monothiopyrophosphates involve the diphosphoryl disulphides (III) with dialkyl[33,34] or trialkyl[35] phosphites. At present it is thought most probably that the reaction mechanism involves intermediate formation of a phosphonium complex (XV):



If in (XV) the substituent X = H, the cation of the complex (XV) is identical with the cation of the compound, and decomposition of (XV) yields a symmetrical thiopyrophosphate. If X = Alk, the cation (XV) contains three electrophilic centres—the substituent X and the two phosphorus atoms—with the occurrence of three parallel substitutions by an anion, since dialkylation of the cation (XV) is slower than deprotonation of the cation (XIII). The substitution products when X is an alkyl group are a trialkyl phosphorothioate (XVI) and two isomeric unsymmetrical thiopyrophosphates formed by isomerisation of the symmetrical skeleton. Two other reactions result from substitution by an anion at the two phosphorus atoms: substitution at the phosphonium atom P^+ yields a trialkyl phosphorothiolate (XVI) and an unsymmetrical thiopyrophosphate, whereas substitution at the phosphorus atom of the phosphinyl group leads to formation of a trialkyl phosphorothionate (XVII) and an unsymmetrical thiopyrophosphate containing four identical substituents. The action of triphenylphosphine on di(5,5-dimethyl-2-oxo-1,3,2-dioxaphosphorinan-2-yl) disulphide follows a similar course[36] to give an unsymmetrical thiopyrophosphate and a dithiopyrophosphate.

The first stable symmetrical monothiopyrophosphate to be synthesised was di-5,5-dimethyl-2-oxo-1,3,2-dioxaphosphorinan-2-yl sulphide (XVIII), obtained from an ammonium phosphorothioate and a phosphorochloridite[37]:



Three isomeric structures—essentially PO.S.P, PO.PS, and PS.O.P—can be suggested[38] for the unidentified unstable product Y obtained in the first stage. Oxidation of Y directly after formation gives a symmetrical thiopyrophosphate (XVIII), whereas oxidation of Y after storage yields an unsymmetrical thiopyrophosphate (XIX). The original attempts to obtain symmetrical thiopyrophosphates by oxidising compounds containing a P.S.P group always resulted in an unsymmetrical isomer[39,40].

Methods for obtaining thiopyrophosphates can in general be divided into two groups, comprising those leading directly to unsymmetrical products and those in which symmetrical thiopyrophosphates are formed, at least as intermediate products. The phosphorylation of dialkyl hydrogen phosphorothioates and the thiophosphorylation of dialkyl hydrogen phosphates by compounds such as dialkyl phosphorochloridates belong to the first group. The first or second substrate is often an intermediate formed in the reaction medium. In our view several published methods yielding thiopyrophosphates, whose mechanisms have not yet been fully investigated[18,41-45], can also be included in this group. The second group is based on the reactions of dialkyl phosphites with sulphenyl compounds. They involve an intermediate phosphonium complex and yield symmetrical thiopyrophosphates, but it is often impossible to isolate the latter from the reaction medium[18-22,31,46-49] owing to isomerisation. The presence of amines, acids, or ammonium salts, as well as an incorrect purification technique, results in rapid conversion of symmetrical into unsymmetrical products. These facts make clear why symmetrical thiopyrophosphates were exclusively obtained in much of the earlier work. Formally, the isomerisation of symmetrical into unsymmetrical thiopyrophosphates can be regarded as an effective method for obtaining the latter.

III. STRUCTURE AND PHYSICAL PROPERTIES

Tetra-alkyl monothiopyrophosphates are oily, non-volatile liquids, readily soluble in organic solvents but sparingly soluble in water. Several of them, e.g. derivatives of neopentyl glycol and alcohol, are crystalline.

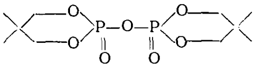
The intense biological activity of unsymmetrical thiopyrophosphates has been known for a long time: they are poisons, blocking the choline esterase system[50,51]. In view of the strong phosphorylating properties of symmetrical thiopyrophosphates, they may also be expected to possess high biological activity. Caution must be exercised in working with thiopyrophosphates.

Spectral and several other properties of monothiopyrophosphates have been reported[30-32], among which the infrared and phosphorus-31 nuclear magnetic resonance spectra are most characteristic. The infrared spectra of symmetrical thiopyrophosphates contain an absorption band in the range 520–545 cm^{-1}, corresponding to vibrations of P–S–P bonds. The characteristic band of the P=O group appears at 1270–1315 cm^{-1}, at lower wavenumbers for symmetrical thiopyrophosphates. Bands due to the P=S and P–O–P groups in unsymmetrical thiopyrophosphates are less intense, and usually appear in the region of deformation vibrations of the bonds of alkyl substituents.

As can be predicted, the signals of phosphorus nuclei in the ^{31}P n.m.r. spectrum of monothiopyrophosphates have the form, after the spin interaction of phosphorus and hydrogen nuclei has been decoupled, of pairs of separate singlets. The spectra of symmetrical thiopyrophosphates having four identical substituents contain ^{31}P n.m.r. singlet signals. The chemical shift relative to orthophosphoric acid of the phosphoryl group in symmetrical thiopyrophosphates lies between −15 and −5 ppm. In the spectra of unsymmetrical thiopyrophosphates the chemical shifts of phosphoryl and thiophosphoryl groups are respectively +12–25 and −55 to −40 ppm.[52,53]

Infrared[9,54] and Raman[55] spectra have been used to confirm unsymmetrical structures. At the present time the most convenient method of structure investigation and identification of thiopyrophosphates is ^{31}P supplemented by ^{1}H n.m.r. spectroscopy. Recently, unsymmetrical tetraethyl monothiopyrophosphate has been used to investigate the structure of organic compounds by means of the Faraday effect[56].

Table 1 lists results of the X-ray examination of the lattice structure[57] of the cyclically substituted monothiopyrophosphates (XVIII) and (XIX) together with the analogous cyclic pyrophosphate.



(XX)

Table 1. Crystallographic data for 2,2-dimethyltrimethylene pyrophosphate and monothiopyrophosphates[57].

Ester	Space group	Parameters of unit cell				X-ray density, g cm^{-3}
		No. of mol.	lattice constants, Å			
			a	*b*	*c*	
(XVIII)	***Pbca***	4	18.66	9.25	9.05	1.40
(XIX)	*Pbca*	8	27.96	9.84	11.28	1.41
(XX)	*Pbca*	8	26.90	10.00	11.13	1.39

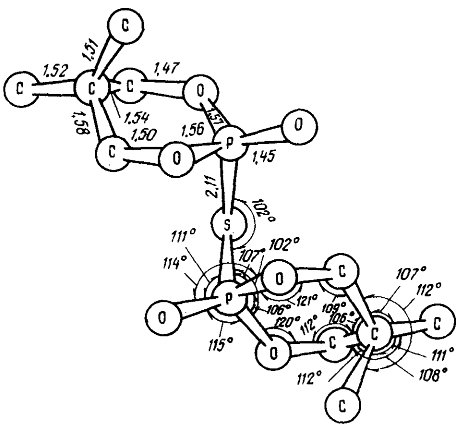


Figure 1. Structure of a molecule of symmetrical bis-2,2-dimethyltrimethylene thiopyrophosphate (XVIII) in the crystal.

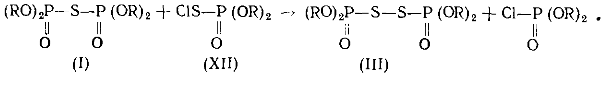
The unsymmetrical thiopyrophosphate (XIX) and the pyrophosphate form isostructural crystals in the form of rhombic bipyramids. The symmetrical thiopyrophosphate (XVIII) also has a rhombic lattice, but with different symmetry and unit cell parameters. The molecule of (XVIII), who structure in the crystal[58] is illustrated in Fig. 1, differs from the pyrophosphate[59] and the unsymmetrical thiopyrophosphate in having a twofold symmetry axis lying in the plane of the P–S–P bond system and passing through the central sulphur atom. It is characterised by long P–S bonds and relatively remote oxygen atoms in the P=O groups. The dioxaphosphan rings are flatter than the cyclohexane ring. Such flattening is exhibited by other dioxaphosphans[59, 60]. The central sulphur atom in this symmetrical molecule, like the central oxygen atom in the pyrophosphate, occurs in the crystal in an axial position[58, 59] with respect to the principal plane of the dioxaphosphan rings. In solution this molecular structure of (XVIII) is probably atypical, since the ^1H n.m.r. spectra of solutions indicate an equatorial arrangement[61] of the sulphur atom.

IV. CHEMICAL PROPERTIES

Tetra-alkyl monothiopyrophosphates contain three types of reactive centres—electrophilic phosphorus and carbon atoms and the nucleophilic sulphur atom—so that this group of compounds is characterised by three types of reactions. The chemical properties of organic monothiopyrophosphates are determined mainly by the presence around the phosphorus atoms of two strong electrophilic centres and "good" leaving groups. In this sense thiopyrophosphates resemble their oxygen analogues—pyrophosphates.

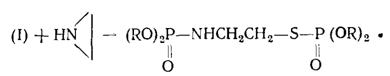
Examples of reactions in which nucleophilic properties are developed are that of an unsymmetrical thiopyrophosphate with elementary chlorine, giving a mixture of products containing the P-SCl group, and the slow reaction of a symmetrical thiopyrophosphate with the dialkyl *S*-chlorothiophosphonate (XII), yielding the diphosphoryl disulphide (III) [32]



$$\underset{(I)}{(RO)_2\overset{O}{\overset{\|}{P}}{-}S{-}\overset{O}{\overset{\|}{P}}(OR)_2} + \underset{(XII)}{ClS{-}\overset{O}{\overset{\|}{P}}(OR)_2} \rightarrow \underset{(III)}{(RO)_2\overset{O}{\overset{\|}{P}}{-}S{-}S{-}\overset{O}{\overset{\|}{P}}(OR)_2} + Cl{-}\overset{O}{\overset{\|}{P}}(OR)_2 .$$

Alkylating properties may appear at the carbon atoms of a thiopyrophosphate during nucleophilic substitution. Such reactions have not been investigated systematically, but after an unsymmetrical thiopyrophosphate has been stored or heated the corresponding phosphates, thiophosphates, and polymeric products are detected[9].

The addition of aziridine to the P–S–P chain in thiopyrophosphates, yielding diphosphorylated derivatives of 2-aminoethanethiol, has recently been described in the patent literature[62]. In the case of a symmetrical thiopyrophosphate the course of the reaction is



$$(I) + HN\!\!<\!|\; \rightarrow (RO)_2\overset{O}{\overset{\|}{P}}{-}NHCH_2CH_2{-}S{-}\overset{O}{\overset{\|}{P}}(OR)_2 .$$

The first stage probably involves nucleophilic substitution at the phosphorus atom; after this the anion of phosphorothioic acid adds to the aziridine residue.

From the difference in energy between the O–P and S–P bonds in the thiopyrophosphate skeletons[26, 63] we may predict that symmetrical isomers will react more vigorously than unsymmetrical isomers in reactions of a phosphoryl centre with nucleophilic compounds. This represents an interesting case of the presence of a leaving group, which is a "better" group not only because of the stability of the anion formed but also because the energy of the ruptured bond is less.

In symmetrical monothiopyrophosphates two phosphoryl groups are the reaction centres. Their relative reactivity depends solely on the nature of the substituents attached to the phosphorus atom. The unsymmetrical isomers contain two different groups—phosphoryl and thiophosphoryl—of which the former undergoes nucleophilic substitution more rapidly[37, 64]. Reaction on the latter centre can be observed provided that the reactivity of the former is diminished by appropriate choice of substituents; such diminution may be accomplished also by the type of nucleophilic reagent employed[65].

An unsymmetrical thiopyrophosphate undergoes hydrolysis almost exclusively at the phosphoryl centre. Kinetic data[66] for the hydrolysis of tetraethyl pyrophosphate and the corresponding unsymmetrical thiopyrophosphate indicate that the presence of the sulphur atom in the latter has relatively little effect on the reactivity of the phosphoryl centre (Table 2). Comparison of kinetic results for the hydrolysis of mono- and di-thiopyrophosphates[67, 68] confirm (Table 2) the lower reactivity of the thiophosphates found with trisubstituted phosphates and phosphorothioates[69, 70].

Table 2. Rates of hydrolysis of tetraethyl pyrophosphate, unsymmetrical thiopyrophosphate, and dithiopyrophosphate.

Compound	Aqueous solvent (dioxan, %)	Hydrolysis rate const. 10^5k, s^{-1}	Arrhenius activation parameters		Ref.
			E, kJ mole^{-1}	lg A	
$(EtO)_2\underset{\underset{O}{\|}}{P}-O-\underset{\underset{O}{\|}}{P}(OEt)_2$	0	41.0*	44.0	3.12	66
$(EtO)_2\underset{\underset{S}{\|}}{P}-O-\underset{\underset{O}{\|}}{P}(OEt)_2$	0 50	21.8 2.53	51.9 67.8	4.02 5.43	66 67
$(EtO)_2\underset{\underset{S}{\|}}{P}-O-\underset{\underset{S}{\|}}{P}(OEt)_2$	50	0.85	116.9	12.18	68

* Calculated by means of the Arrhenius equation.

Table 3. Kinetic data for the alkaline and acid hydrolysis of unsymmetrical tetraethyl monothiopyrophosphate at 25°C.[66]

Solvent	$10^5 k$	Arrhenius activation parameters	
		E, kJ mole^{-1}	lg A
Water	0.82 s^{-1}	51.9	4.02
KOH, 0.02 M	9600 M^{-1} s^{-1}	50.6	7.86
HCl, 5.78 M	1.19 s^{-1}	75.8	8.35

Hydrolysis of tetraethyl monothiopyrophosphate is considerably more rapid in alkaline than in neutral medium, while the catalytic effect of acids is insignificant. Table 3 gives some kinetic data for this process. The mechanism of the reaction is explained on the basis of specific acid–base catalysis.

The reactivities of symmetrical and unsymmetrical thiopyrophosphates have been compared[71] with respect to neutral hydrolysis in aqueous dioxan solution with the cyclic compounds (XVIII) and (XIX) as examples. The two compounds yield identical organic phosphoric and phosphorothioic acids as hydrolysis products. The rate of reaction of the symmetrical isomer exceeds that of the unsymmetrical isomer approximately hundredfold (Table 4). The reaction velocity is influenced significantly by solvation[67, 71], whose role is indicated by a difference for these isomers in the dependence of the hydrolysis rate constant on the dioxan content of the solvent (Fig. 2).

An interesting reaction is the nucleophilic substitution of a symmetrical thiopyrophosphate by the dialkyl phosphorothioate anion[32], in which an unsymmetrical isomer is formed with regeneration of the nucleophilic reagent:

$$(I) + {}^{\ominus}O-\underset{\underset{S}{\|}}{P}(OR')_2 \rightarrow (RO)_2\underset{\underset{O^{\ominus}}{|}}{P}{=}S + (RO)_2\underset{\underset{O}{\|}}{P}-O-\underset{\underset{S}{\|}}{P}(OR')_2\ .$$

Table 4. Rates of hydrolysis of symmetrical and unsymmetrical thiopyrophosphates in aqueous dioxan at 80°C.[71]

Compound	Dioxan mole fraction	$10^5 k$, s^{-1}	Arrhenius activation parameters		Compound	Dioxan mole fraction	$10^5 k$, s^{-1}	Arrhenius activation parameters	
			E, kJ mole^{-1}	lg A				E, kJ mole^{-1}	lg A
(XVIII)	0.2	103*	66.5	6.89	(XIX)	0.2	0.52	69.1	5.05
(XVIII)	0.6	17*	58.2	4.84	(XIX)	0.6	0.072	71.2	8.33

* Calculated by means of the Arrhenius equation.

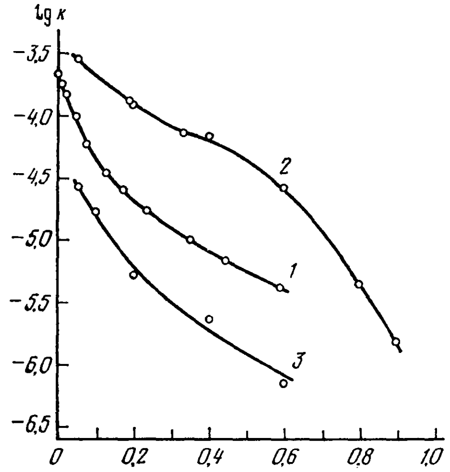


Figure 2. Dependence of hydrolysis rate constant on mole fraction of dioxan in aqueous solvent: 1) unsymmetrical tetraethyl thiopyrophosphate (80°C);[67] 2) symmetrical thiopyrophosphate (XVIII) (50°C);[71] 3) unsymmetrical thiopyrophosphate (XIX) (80°C).[71]

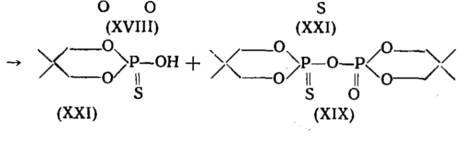
The reaction is bimolecular, but if the two reagents have the same substituents (R = R′) the reaction velocity is described by a first-order kinetic equation. Activation parameters for the reaction of the symmetrical thiopyrophosphate (XVIII) with the acid ester (XXI)[72]



have been determined as $\Delta H^{\neq} = 69$ kJ mole^{-1} and $S^{\neq} = -74$ J mole^{-1} deg^{-1}. The reaction is accelerated in the presence of amines. The above reactions most probably occur when contaminated specimens of symmetrical thiopyrophosphates are stored, and lead to spontaneous isomerisation of the latter.

The thermal isomerisation of a symmetrical thiopyrophosphate, which may proceed in parallel with the above reaction with an organic phosphorothioic acid, is unimolecular. The thermodynamic parameters of this reaction have been determined for the symmetrical (XVIII) in a polar solvent as $\Delta H^{\neq} = 128$ kJ mole^{-1} and $\Delta S^{\neq} = -16$ J mole^{-1} deg^{-1}. The transition state is probably amphoteric in structure.

Our kinetic investigations and certain qualitative results suggest that unsymmetrical are formed from symmetrical thiopyrophosphates by two independent reactions—unimolecular thermal isomerisation and bimolecular nucleophilic substitution.

Optical Isomers in Solution Investigated by Nuclear Magnetic Resonance

M.I.Kabachnik, T.A.Mastryukova, E.I.Fedin, M.S.Vaisberg, L.L.Morozov, P.V.Petrovskii, and A.E.Shipov

Work during recent years on the n.m.r. spectroscopy of solutions of optical antipodes and their mixtures with each other and with epimers is surveyed. The phenomenon of statistically controlled anisochronism of diastereomeric association (SCADA) is described. Several factors—the nature of the stereoisomers, the solvent, the temperature, etc.—affect the multiplicity of the diastereomeric anisochronism spectra. The above phenomenon is not observed in the absence of association. A theory of the phenomenon is given, and theoretical calculations are compared with experimental results. A list of 41 references is included.

I. INTRODUCTION

Aspects of the stereoselectivity of the molecular association of optical antipodes in solution have recently been attracting the attention of research workers. They are closely connected with the problem of the existence of racemic compounds in solution and in the liquid phase in general. There are a large number of papers and many reviews on this topic (for an excellent review see Ref. 1). Differences in the interactions of identical chiral molecules (e.g. S...S or R...R) or of antipodal molecules (i.e. S...R) have been studied theoretically by quantum-chemical methods [2] and in terms of the three-body problem [3]. Spatial relations were taken into account in applying statistical thermodynamics [4]. A similar treatment has been made to the classic approximation [5].

Experimental methods for studying the association of chiral molecules—measurement of density, molecular mass, viscosity, dipole moments, surface tension, heats of mixing, refractive indices of solutions, absorption spectra, etc.[1]—have not given unambiguous results. Polarimetric investigations have given more precise information. Horeau [6] was the first to show that the optical purity P of a mixture of antipodes of $\alpha\alpha$-ethylmethylsuccinic acid $HO.CO.CH_2.C(CH_3)(C_2H_5).COOH$ may vary non-linearly with the enantiomeric purity Q. Here

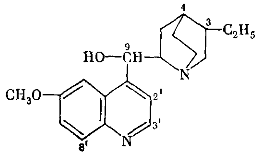
$$P = [\alpha]_\lambda^t/[\alpha_0]_\lambda^t; \quad Q = ([D]-[L])/([D]+[L])$$

where $[\alpha]_\lambda^t$ and $[\alpha_0]_\lambda^t$ are the angles of rotation of the mixture and of an optically pure specimen, while [D] and [L] are the corresponding concentrations of the antipodes in the mixture. Horeau attributed this non-linearity to different contributions by diastereomeric association complexes to the observed angle of rotation of the plane of polarisation, which served as basis for using polarimetry to investigate the interaction of antipodes in solution.

The nuclear magnetic resonance method occupies a special place in these investigations. The reason is that separate signals for diastereomeric forms can be observed in n.m.r. spectra. It has been known for a long time that the n.m.r. spectra of diastereomers may differ in the chemical shifts of signals from indicator nuclei [7,8], and this difference has been termed *diastereomeric anisochronism*. Quite recently it has become known that such anisochronism can be observed in solutions not only of diastereomeric molecules but also of diastereomeric association complexes of enantiomers, even with rapid exchange between the complexes (see below). Diastereomeric anisochronism has two independent parameters—the diastereomeric chemical shift, determined by spatial independent differences in the chemical environment of the indicator nucleus in the diastereomers, and the relative integral intensity in the diastereomeric doublets, representing the relative content of the given diastereomeric form in the solution.

We are thus concerned with the laws of diastereomeric anisochronism—the magnetic non-equivalence of nuclei in diastereomeric systems—in the narrow sense in diastereomeric molecules [7,8]; spectra of this kind are used to determine absolute configuration [9] and enantiomeric purity [10]. It includes also diastereomeric anisochronism of enantiomers in chiral solvents [11] or in achiral solvents but in the presence of chiral additives [12], which in particular may even be chiral shift reagents [12]. Finally, it includes the dynamic anisochronism of enantiomers in achiral solvents when the concentrations of the enantiomers are unequal, which is the type that will be surveyed in the present Review.

In 1969 Williams et al. [13] found that the multiplicity of the spectrum of a 1 : 1 mixture of racemic and optically active *laevo*-dihydroquinine was doubled in an achiral solvent. They felt it necessary, of course, to compare the ^1H n.m.r. spectrum (in deuterochloroform) of the racemic dihydroquinine

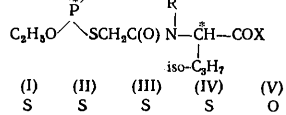


obtained on repeating Rabe's well known multistage synthesis, with the spectrum of natural (−)-dihydroquinine. The comparison showed that the signals from protons 2′, 3′, 8′, and 9 did not coincide but differed by 0.1 − 0.2 ppm. The spectrum of 1 : 1 mixture of racemic and optically active dihydroquinines showed a doubled multiplicity of these signals. The intensity ratio of the components of the doublets was 3 : 1, which corresponded to the concentration ratio of (−)- and (+)-dihydroquinines. The effect diminished on dilution and on replacement of deuterochloroform by deuteromethanol as solvent, and it decreased substantially when the hydroxy-group was acetylated. These observations were correctly interpreted[13] as evidence that, in a solution of the pure enantiomers, the racemate, and their mixtures, molecules of each individual enantiomer are situated in an identical environment, enantiomeric and diastereomeric respectively.

In a series of publications the Reviewers have reported an analogous phenomenon and a detailed study[15-20] of solutions of compounds containing two chiral centres, of the type $C_2H_5O.\overset{*}{P}O(CH_3).S.CH_2.CO.NH.\overset{*}{C}HR.COOH$. At the same time an axiomatic theory was constructed for the spectra of states of diastereomeric systems that were due to the stereospecificity of interaction of their chiral fragments[21]. One deduction from this theory was the theoretical possibility that the multiplicity of the diastereomeric anisochronism spectra of solutions of enantiomers in an achiral medium would be increased with a non-racemic concentration ratio of the antipodes. The effects studied by Williams et al.[13] indicated that the diastereomeric anisochronism observed in these cases was due to the short lifetime of association complexes of chiral molecules with rapid exchange between the complexes, i.e. with statistical control of the system. The phenomenon of the n.m.r. non-equivalence of enantiomers, occurring in such systems in an achiral medium with rapid averaging due to exchange between association complexes, has been termed *statistically controlled anisochronism of diastereomeric association* (SCADA). This is a physical aspect of statistically controlled diastereomeric association. The experimental and theoretical results of research on the former phenomenon discussed below throw light on interesting features of the latter phenomenon.

II. DIASTEREOMERIC ANISOCHRONISM IN ORGANOTHIOPHOSPHORUS DEPSIPEPTIDES

Studies of mixtures of stereoisomers of *P*-ethoxy-*P*-methylphosphinothioylthiologlycolloylvaline (I), its ethyl ester (II), the corresponding *N*-methylated derivatives (III) and (IV)



$$CH_3(C_2H_5O)\overset{*}{P}(=Y)SCH_2C(O)N(R)-\overset{*}{C}H(iso\text{-}C_3H_7)-COX$$

Compound	(I)	(II)	(III)	(IV)	(V)	(VI)
Y	S	S	S	S	O	O
R	H	H	CH_3	CH_3	H	H
X	OH	OC_2H_5	OH	OC_2H_5	OH	OC_2H_5

and a few of their simpler analogues[18,19] have revealed several intramolecular factors influencing the occurrence and variation of diastereomeric anisochronism, as well as solvation effects by molecules of a magnetically anisotropic solvent. The results were in general consistent with the views of Mislow and Raban[22], although certain facts required special treatment, e.g. the phenomenon of diastereomeric anisochronism induced by aromatic solvation[17].

In the mixtures of diastereomers investigated in solution in chloroform or benzene diasteromeric anisochronism is evident in a doubling of the multiplicity of the ^1H or ^{31}P n.m.r. spectra. In the latter spectra under conditions of wide-band suppression of spin–spin interactions with protons it is apparent as a well resolved phosphorus doublet. We therefore used $^{31}P-\{^1H\}$ n.m.r. in subsequent investigations. The impetus to a more profound study of diastereomeric anisochronism spectra in these and analogous systems was provided by observation of the unusual influence of the concentration and temperature, and also mixing[7], of solutions of the diastereomers on the $^{31}P-\{^1H\}$ n.m.r. spectra both of compounds (I)–(IV) and especially of their monothio-analogues (V) and (VI).

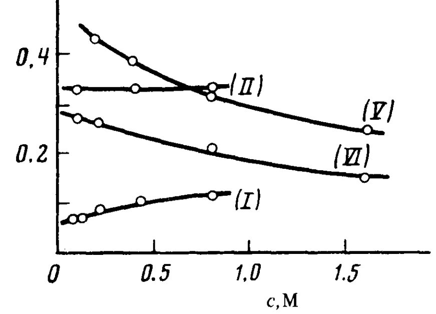


Figure 1. Concentration dependence of diastereomeric anisochronism in $^{31}P-\{^1H\}$ n.m.r. spectra of mixtures of four isomers in chloroform at 20°C (V at 25°C). The numbering of the curves corresponds to that of the compounds in the text.

The molecules of these compounds contain two asymmetric atoms—phosphorus and carbon—so that four stereoisomers—RR, SS, RS, and SR—are possible. Dilution of a chloroform solution of a specimen of the ethyl ester (II) of the dithio-derivative, which was a mixture of all four stereoisomers, had no effect at all on the diastereomeric anisochronism: the difference Δδ in the chemical shifts in the phosphorus doublet remained constant (Fig. 1). For the free acid (I) the difference diminished on dilution, which could easily be explained by the influence[23] of intermolecular hydrogen bonds on the anisochronism: dilution tends to rupture the hydrogen bonds, diminish the rigidity of the system, liberate frozen degrees of freedom, and diminish diastereomeric anisochronism by averaging.

It was found unexpectedly that dilution of solutions of the monothio-derivatives (V) and (VI) (each specimen also a mixture of four stereoisomers) produced increases in diastereomeric anisochronism, respectively strong and less marked, while the difference Δδ increased (Fig. 1). Still more complicated relations were evident with variation in temperature (Fig. 2). The dithio-derivatives (I) and (II) showed a decrease in Δδ with rise in temperature. In solutions of the monothio-derivative (V) and (VI) a rise in temperature from −60 to −45°C was accompanied by decrease in Δδ, but further rise to +50°C by a continuous increase. At about −45°C the difference Δδ became zero (or smaller than the resolving power of the instrument). Since only the absolute value was measured in such an experiment, not the sign of the difference, an alternative conclusion was that the function increased monotonically with rise in temperature from −60 to +50°C but changed sign at −45°C.[19,20]

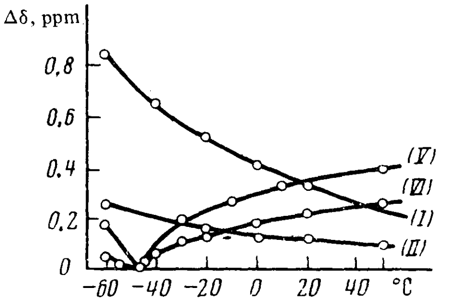

Figure 2. Temperature dependence of diastereomeric anisochronism in $^{31}P-\{^1H\}$ n.m.r. spectra of 0.4 M mixtures of four isomers in chloroform. The numbering of the curves corresponds to that of the compounds in the text.

To understand such complicated relations it is necessary to simplify the test systems consisting of mixtures of four stereoisomers (two racemic diastereomers). This was difficult with dithio-derivatives, since the phosphorus chiral centre arose at the instant of formation of the compound, but the separation of diastereomers and the resolution of racemates were quite complicated tasks. The monothio-derivative (V) provided a more favourable situation: enantiomeric (R and S) monothio-acids of phosphorus are readily available[24], as are also enantiomeric (R and S) chloroacetylvalines[25]; preparation of (V) from them leaves the centres of asymmetry unaffected, and is conducted under conditions under which no racemisation of chiral centres is observed. It thus became possible to obtain in pure form all four stereoisomers of (V)[15]—RR, SS, RS, and SR—and to investigate the $^{31}P-\{^1H\}$ n.m.r. spectra of their chloroform solutions both individually and in mixtures of various relative concentrations.

The value of Δδ calculated as the difference between the chemical shifts in the spectra of solutions of pure diastereomers of (V) taken separately was not identical with the difference in chemical shifts in solutions of mixtures of the same diastereomers at the same total concentration. In the spectra of the stereoisomers SS and SR taken separately the difference Δδ = 0.84 ppm, whereas a mixture of the same total concentration gave Δδ = 0.04 ppm, but mixing the stereoisomers SS and RS separated the signals of the doublet to Δδ = 1.05 ppm.

Furthermore, the spectrum of a mixture of all four stereoisomers in unequal concentrations contains four signals exhibiting intensity ratios equal to the corresponding concentration ratios. Finally, the temperature dependence of the spectrum of an equimolecular mixture of the four stereoisomers differs from that for the stereoisomers taken separately[20]. Fig. 3 illustrates the temperature dependence of the chemical shifts of signals due to the stereoisomers SS and SR of compound (V), together with that of $\Delta\delta = \delta_{SR} - \delta_{SS}$.

The reason for such a difference between individual stereoisomers and their mixtures with respect to the n.m.r. spectra of the solutions could only be interaction between the dissolved molecules. In solvents of low polarity, such as chloroform and tetrachloromethane, indeed, molecules of (V) are strongly associated[26]. The dithio-ester (II) is not associated at all in chloroform, and its n.m.r. spectrum exhibits no anomalous changes on dilution or change in the temperature of the solution.

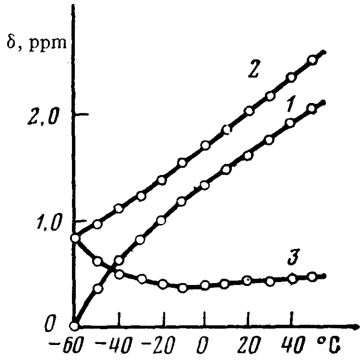

Figure 3. Temperature dependence of chemical shifts of signals from isomers of compound (V) in separate 0.4 M solutions in chloroform: 1) SS; 2) SR; 3) Δδ.

Thus the multiplicity and the frequency spacing of the signals in the diastereomeric anisochronism spectra of stereoisomers depend on association and its stereoselectivity. Hence n.m.r. spectra can be used to study the association of stereoisomers and its stereoselectivity.

III. DIASTEREOMERIC ANISOCHRONISM IN BINARY MIXTURES OF STEREOISOMERS

1. Mixtures of Enantiomers

The Reviewers investigated the n.m.r. spectra of a mixture of enantiomers of *P*-ethoxy-*P*-methylphosphinothioylthiologlycolloylvaline during 1973 and 1974.[15-18] Two fundamentally different types of association complexes of enantiomers—long and short lived—may exist with respect to the n.m.r. time scale. In the former the multiplicity of the diastereomeric anisochronism spectrum should be determined by the number of varieties of such long-lived complexes, and the intensity ratio of the signals by their relative concentrations. It would be completely fortuitous for the multiplicity to be 2 and the intensity ratio equal to the concentration ratio of the enantiomers. The other possibility—formation of short-lived association complexes with rapid exchange between them—represents the above case of statistically controlled diastereomeric association. The multiplicity of the spectrum should then be 2 (provided that the resolving power of the instrument is adequate), and the intensity ratio of the signals in an elementary doublet equal to the concentration ratio of the antipodes[16].

The $^{31}P-\{^1H\}$ n.m.r. spectrum of the enantiomers RR and SS of compound (V) in a 0.4 M solution of chloroform at −60°C contains narrow singlet signals, whose chemical shifts (homo-shifts δ_h) coincide within the limits of experimental error (±0.1 Hz). This signal will henceforward be adopted as reference point, from which other chemical shifts will be reckoned. The n.m.r. spectrum of a racemic mixture (1 : 1) of the same total concentration at the same temperature also contains a single singlet, but its position δ_r differs by 0.35 ppm (13.2 Hz) from the homo-shift δ_h. With the concentration ratio [RR] : [SS] = 7 : 3 two signals are observed, at 0.25 and 0.42 ppm, whose integral intensities are in the ratio 7 : 3. An identical spectrum is observed with the concentration ratio 3 : 7.

Similar relations are observed for the pair of antipodes RS + SR under the same conditions. At −60°C the homo-shift δ_h = 0.84 ppm, but the singlet signal of the racemic mixture is located at 0.46 ppm. Their concentration ratios 7 : 3 and 3 : 7 reveal two identical doublets at 0.38 and 0.59 ppm with the intensity ratio 3 : 7. Analogous relations are found at other temperatures. The following qualitative conclusions can be drawn from the data in Table 1.

Table 1. Chemical shifts of signals in spectra of mixtures of enantiomers of compound (V) in 0.4 M solution in chloroform (I_{rel} = relative integral intensity)*.

c_1	δ, ppm	I_{rel}	t, °C											
			−60	−50	−40	−30	−20	−10	0	10	20	30	40	50
			SS+RR											
1.00	δ_h	1	0	0	0	0	0	0	0	—	—	—	—	—
0.50	δ_r	1	0.35	0.20	0.13	0.10	0.05	0.03	0	—	—	—	—	—
0.30	δ_{SS}	0.3	0.42	0.24	0.17	0.12	0.08	0.05	0,02	—	—	—	—	—
0.30	δ_{RR}	0.7	0.25	0.13	0.09	0.06	0.03	0	0	—	—	—	—	—
			SR+RS

0.30	δ_{RS}	0.7	0.59	0.34	0.23	0.18	0.19	0.22	0,26	0.30	0.32	0,36	0.38	0.43

*The antipodes RR and RS have signals identical with those of SS or SR in a racemic mixture and in the pure state. The quantity

$$c_1 = [SS]/([SS] + [RR]) \text{ or } c_1 = [SR]/([SR] + [RS]).$$

The homo-signal of SS molecules at the given temperature has been adopted as reference signal.

1. Narrow singlet signals are observed in solutions of individual enantiomers. Since every molecule in an association complex is surrounded solely by identical molecules, and rapid exchange takes place between complexes, local fields induced at the indicator nucleus (in the present case phosphorus) are completely averaged out, regardless of the number and stability of the various complexes. Hence the signal is a narrow singlet. Since the magnetic field is achiral, the signals of antipodes, are, of course, identical.

2. In a solution of a racemic mixture the molecules of each enantiomer are surrounded both by identical and by antipodal molecules. Homo- and cross-association may be thermodynamically either equivalent or non-equivalent. With rapid exchange between complexes the statistics of exchange results in contamination of homo-interactions by cross-interactions at each enantiomer. This changes the resultant local field at the indicator nucleus of the enantiomer molecule and hence the chemical shift of the n.m.r. signal. Since the situations for the two enantiomers have a mirror-image relation, the chemical shifts of their signals are identical, and they merge into a single signal δ_r differing from δ_h. This difference, which is termed the *deviation* $D = \delta_r - \delta_h$, is a characteristic feature of SCADA.

3. When the concentration of antipodes in the solution are unequal, they exhibit different extents of contamination of homo- by cross-interactions: if homo-association predominates at one antipode, cross-association predominates at the other. The situations are not now those of mirrow-images, and a doublet appears in the spectrum, in which the intensity ratio of the components is equal to the concentration ratio of the antipodes.

In calculating the specific form of dependence of the signals of (+)- and (−)-enantiomers, i.e. δ^+ and δ^-, on the relative concentration of the enantiomers in the mixture we must take into account the statistical averaging, with rapid exchange between complexes, of the effects of homo- and cross-interactions on the shielding of the indicator nuclei in the molecules of the antipodes. If W_+^+ is the statistical weight of the contribution to δ^+ by homo-interaction, W_+^- is that of cross-interaction, and correspondingly W_-^- and W_-^+ are the statistical weights of the contributions to δ^- by homo- and cross-interactions, the chemical shifts of the signals due to (+)- and (−)-molecules are given by the formulae

$$\delta^+ = (W_+^+\delta_h + W_+^-\delta_c)/(W_+^+ + W_+^-), \tag{1}$$

$$\delta^- = (W_-^-\delta_h + W_-^+\delta_c)/(W_-^- + W_-^+) \tag{2}$$

in which δ_h is the homo-shift, identical for the two antipodes, and δ_c the cross-shift [also identical for (+)- and (−)-molecules].

The statistical weights of the contributions by homo- and cross-interactions are determined, of course, by two factors: the relative content of antipodal molecules in the mixture can be expressed as $c = [+]/([+] + [-])$; and the stability characteristics of homo- and cross-contacts can be represented by the functions of homo- and cross-interaction energies

$$\alpha_h = A_h \exp(-E_h/kT), \tag{3}$$

$$\alpha_c = A_c \exp(-E_c/kT). \tag{4}$$

The condition of rapid exchange between association complexes is indicated by the equations

$$\alpha_h = \langle\alpha_h\rangle,\ \alpha_c = \langle\alpha_c\rangle,\ \delta_h = \langle\delta_h\rangle,\ \delta_c = \langle\delta_c\rangle, \tag{5}$$

where the symbol $\langle\rangle$ denotes averaging over all types of association complexes containing the given interaction. We can then write

$$W_+^+ = \alpha_h c,\ W_+^- = \alpha_c(1-c),\ W_-^- = \alpha_h(1-c),\ W_-^+ = \alpha_c c. \tag{6}$$

Since experimental data do not yield values of the parameters α_c and α_h but only their ratio $\alpha_c/\alpha_h = m$ representing the stereospecificity of association of the antipodes, Eqns. (1) and (2) can be finally written

$$\delta^+ = [c\delta_h + m(1-c)\delta_c]/[c + m(1-c)], \tag{7}$$

$$\delta^- = [(1-c)\delta_h + mc\delta_c]/[(1-c) + mc]. \tag{8}$$

Inspection of formulae (7) and (8) indicates that both extrema and points of inflection are absent from both δ^+-c and δ^--c curves throughout the concentration range. When $c = 0$, we find that $\delta^+ = \delta_c$ and $\delta^- = \delta_h$; and when $c = 1$, that $\delta^+ = \delta_h$ and $\delta^- = \delta_c$; in both cases only one signal is observed, since δ_c cannot be observed. When $c = 0.5$, i.e. in a racemic mixture,

$$\delta^+ = \delta^- = (\delta_h + m\delta_c)/(1 + m), \tag{9}$$

and one signal is also observed, which is displaced by the deviation relative to the homo-signal. At all other concentrations two signals should be observed. Since each belongs to a definite antipode, the ratio of the integral intensities of these signals should be $c/(1 - c)$.

For both functions $\delta^+(c)$ and $\delta^-(c)$ the curvature depends on m, i.e. on the stereospecificity of homo- and cross-interactions. If $m = 1$ (i.e. $\alpha_c = \alpha_h$), the relations become linear:

$$\delta^+ = \delta_c - (\delta_c - \delta_h)\, c, \tag{10}$$

$$\delta^- = \delta_h + (\delta_c - \delta_h)\, c. \tag{11}$$

However, the main characteristics of the phenomenon are preserved: the spectrum contains one signal when c is 0, 1, or 0.5, and two signals at all other relative concentrations. This is a very important conclusion: the appearance of two signals in the n.m.r. spectrum of a mixture of unequal concentrations of antipodes is not a consequence of stereoselectivity of association (e.g. a tendency to racemate formation) but is caused by SCADA itself.

Table 2. SCADA parameters of the enantiomeric pairs SS + RR and SR + RS of compound (V) in 0.4 M solution in chloroform*.

t, °C	−60	−50	−40	−30	−20	−60	−50	−40	−30	−20
	SS+RR					SR+RS				
δ_c	0,50	0.31	0.22	0.17	0.10	0.26	−0.07	−0.18	−0.20	−0.21
α_c/α_h	2.4	1.7	1.4	1.2	1.0	1.8	1.7	1.6	1.4	1.2

*The reference signal adopted was δ_{SS} at the given temperature.

If δ_h is adopted as reference signal, Eqns.(7) and (8) permit a simple linear transformation giving the formulae

$$\frac{1}{\delta^+} = \frac{1}{\delta_c} + \frac{1}{m\delta_c}\cdot\frac{c}{1-c}, \tag{12}$$

$$\frac{1}{\delta^-} = \frac{1}{\delta_c} + \frac{1}{m\delta_c}\cdot\frac{(1-c)}{c} \tag{13}$$

which were used to treat the experimental data in Table 1. The parameters δ_c and

$$m_{SS}^{RR} = \alpha_{SS}^{RR}/\alpha_{SS}^{SS},\ m_{SR}^{RS} = \alpha_{SR}^{RS}/\alpha_{SR}^{SR}. \tag{14}$$

were found for each temperature, where the subscript denotes the stereoisomer whose signal is under consideration, and the superscript the stereoisomer that interacts with it in the association complex. Together with experimental values of δ_c these parameters give a complete description of the diastereomeric anisochronism spectra.

Table 2 gives the SCADA parameters, which were used in Eqns.(7) and (8) to calculate the curves in Fig.4. Good agreement is evident between calculation and experiment.

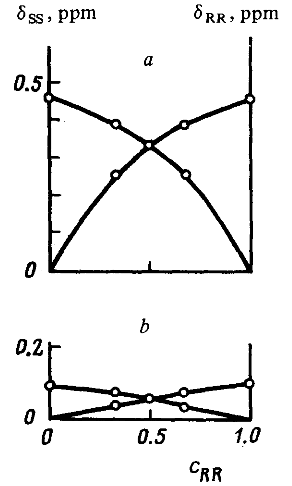

Figure 4. Dependence of chemical shifts of signals from SS and RR enantiomers of compound (V) on relative concentration of RR isomer at different temperatures: *a*) −60°C; *b*) −20°C. The curves have been obtained theoretically; the points on them represent experimental values. Each curve was reckoned from the homo-shift at the given temperature.

From the results the interesting conclusions can be drawn that for the RS + SR system the non-equivalence of shielding of the phosphorus atom in homo- and cross-complexes, i.e. $\delta_c - \delta_h$, varies comparatively slowly with rise in temperature from −60 to +50°C, while the stereoselectivity of association (the difference between m and unity) vanishes at ~0°C. In the RR + SS system both the non-equivalence of shielding and the stereoselectivity of association disappear rapidly with rise in temperature, and above 0°C the SCADA phenomenon is completely absent from the n.m.r. spectra: a single singlet signal is observed at any relative concentration of antipodes in the mixture. Thus conditions depending on the structure of the enantiomers and the thermodynamic characteristics of the system must be satisfied for SCADA to be observed in the n.m.r. spectra; otherwise the magnitude of the phenomenon in the n.m.r. will become smaller than the resolving power of the instrument. This is evidently the reason for the fewness of published examples of SCADA.

The energy difference between averaged cross- and homo-contacts in association complexes can be elucidated from the temperature dependence of α_c/α_h. Thus if

$$\alpha_c = A_c\, e^{-E_c/RT} \qquad \alpha_h = A_h\, e^{-E_h/RT},$$

we have

$$\lg(\alpha_c/\alpha_h) = \lg(A_c/A_h) + (E_h - E_c)/2.3RT.$$

A linear plot of $\lg(\alpha_c/\alpha_h)$ against $1/T$ should be observed, with a slope

$$\tan\alpha = (E_h - E_c)/2.3R,$$

whence $E_h - E_c$ can be calculated. Such linear relations are indeed found. For the pair SS + RR the difference $E_h - E_c \simeq 2$ kcal mole^{-1}, whereas the difference is ~1 kcal mole^{-1} for SR + RS. In both cases cross-interaction is appreciably more effective than homo-interaction[19,20].

A very interesting paper by Horeau and Guette[1] appeared at almost the same time as the publications by Soviet workers. As mentioned above, Horeau had earlier made a systematic study of the optical and enantiomeric purity of enantiomers. This was why he investigated the interaction of antipodes in solution and the effect of this interaction on physical constants. It has also been mentioned above that in 1969 departures from additivity were found for the angle of rotation of the plane of polarisation by solutions of a mixture of the enantiomers of α-ethyl-α-methylsuccinic acid[6]. Horeau and Guette found that such departure was still more strongly marked for solutions of the enantiomers of α-isopropyl-α-methylsuccinic acid $HO.CO.C(CH_3)(iso\text{-}C_3H_7).CH_2.COOH$ in chloroform or dichloromethane.

When discussing this result, the authors[1] refer to the work of Jurczak and Zamojski[27], who observed that the rotatory power of dimethyl malate in methanol was not a linear function of the enantiomeric composition. However, Horeau and Guette were working in non-polar solvents—chloroform and dichloromethane—and the use of methanol, ethanol, pyridine, diglyme, and acetonitrile completely depresses the non-linearity effect. Even additions of 4–6% of ethanol to chloroform were sufficient for the dependence of optical purity on enantiomeric composition to be linear. Hence it was concluded[1] that the divergence from a linear dependence of the rotatory power of a mixture of enantiomers on enantiomeric composition was due to differences in stability between diastereomeric association complexes of the antipodal molecules in the solution, so that the phenomenon could be observed only in non-ionising solvents. However, this does not extend to stable complexes, which may give deviations even in aqueous solution. Thus in the presence of ammonium molybdate $(NH_4)_6Mo_7O_{24}.4H_2O$ a solution of (+)-mandelic acid has an angle of rotation $[\alpha_0]^{22}_D = +45.6°$. For a mixture of 75% of the dextrorotatory acid and 25% of the laevorotatory acid $[\alpha]^{22}_D = -19°$. This value requires for the pure enantiomer an angle of rotation $[\alpha_E]^{22} = +38°$, instead of the observed +45.6°: i.e. non-linearity is apparent.

Table 3. Diastereomeric anisochronism in associated solutions of α-ethyl-α-methylsuccinic acid.

Substance	δ_A, Hz	$\Delta\delta_A$, Hz	δ_B, Hz	$\Delta\delta_B$, Hz	J_{AB}, Hz
Optically pure enantiomer	251,4	0	234.9	0	16.5
Mixture of antipodes	250,4	1.0	233.5	1.4	16,9
(75:25)	247,7	3,7	230,5	4.4	17.2
Racemate	248,9	2,5	231,9	3.0	17.0

However, intermolecular interactions of antipodes are most clearly indicated by results obtained by Horeau and Guette[1] in a study of the ^1H n.m.r. spectra of the above acids. These workers investigated the spectra of solutions of α-ethyl-α-methylsuccinic acid in deuterochloroform at a working frequency of 100 MHz. The protons of the methylene group give two doublets characteristic of an AB system. The magnetic non-equivalence of the two antipodes does not affect the doublet in a strong field. Table 3 gives chemical shifts and spin–spin interaction constants for the doublet in a weak field. The racemate differs appreciably in chemical shifts (by 2.5–3.0 Hz) from the optically pure enantiomers, but two signals appear in a non-equimolecular mixture of antipodes. An appreciable though smaller difference is observed for the spin–spin interaction constants. Similar results were obtained for α-isopropyl-α-methylsuccinic acid. The authors[1] interpret their findings as evidence of differences in the stability of diastereomeric interactions of enantiomers in solution.

In order to demonstrate energy differences between D...L and D...D or L...L interactions a calorimetric investigation was made[1] of solutions of enantiomers of α-ethyl(isopropyl)-α-methylsuccinic acids, and heats of mixing of antipodes at 25°C were found to be respectivelv 33.5 and 50 cal mole^{-1}. It is significant that the interaction of antipodal molecules is more advantageous energetically than is the interaction of identical molecules (this contradicts deductions made by other workers[2,3]).

Table 4. Treatment of experimental results[1,13] by means of Eqns. (12) and (13).

Enantiomers	Signal	$\delta_c - \delta_h$, Hz	α_c/α_h
Dihydroquinine	H (9)	40	1.0
α-Ethyl-α-methyl-	δ_A	−4.6	1.0
succinic acid	δ_B	−5.7	1.0

As has been shown above, diastereomeric anisochronism can be observed in solutions of enantiomers even in the absence of energy differences between homo- and cross-interactions. The appearance of an elementary diastereomeric doublet in the spectra of solutions of unequal concentrations of antipodes is due to non-equivalence of the stereochemical environment of antipodal molecules under conditions of statistical control with rapid exchange between association complexes. This non-equivalence is caused by the unequal concentration of the antipodes. It depends also, of course, on the energy parameters of association, but may arise even with equal parameters for identical and diastereomeric contacts. In this sense the conclusions of Horeau and Guette need to be refined. Equations (7) and (8) can be used to treat the experimental results for dihydroquinine[13] and α-ethyl-α-methylsuccinic acid[1]. Unfortunately, the results obtained by Williams et al.[13] are very incomplete: the authors note that the signals of aromatic protons are extremely sensitive to change in the total concentration, and coalesce on dilution. Data on the chemical shifts in the signals of 9-H protons are more reliable, their position depending mainly on the relative concentration of the antipodes. Linear plots of δ against c are obtained: i.e. stereoselectivity of association is absent. Parameters calculated by means of Eqns. (12) and (13) are listed in Table 4. Good linearity is observed also for the results of Horeau and Guette[1]. For the enantiomers of α-ethyl-α-methylsuccinic acid $m = 1$, which also supports the view that stereospecificity of association is either absent or very slight.

Thus no appreciable preference for homo- or cross-association of enantiomers is evident in solutions of dihydroquinine and of α-ethyl-α-methylsuccinic acid. In the *P*-ethoxy-*P*-methylphosphinylthiologlycolloylvalines investigated by Soviet workers cross-association, i.e. racemisation, occurs preferentially[15].

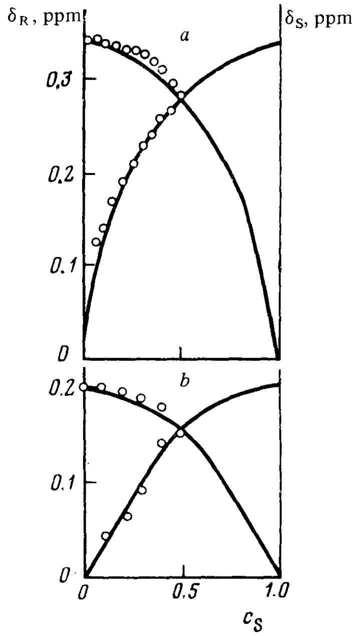

Figure 5. SCADA in deuterochloroform solution of *P*-methyl-*NP*-diphenylphosphinamide (A) at: *a*) 15°C; *b*) −26°C. The curves have been calculated theoretically; and the points represent experimental values.

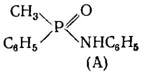
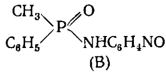
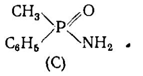
Harger[28] has investigated the ^{1}H n.m.r. spectra of amides of methylphenylphosphinic acid—the phenylamide (A), *p*-nitrophenylamide (B), and unsubstituted amide (C)



(A)

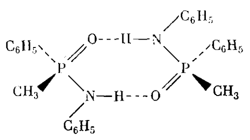


(B)

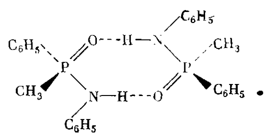


(C)

Deviation of the chemical shift for the racemic mixture of antipodes and doubling of the multiplicity of the doublet signals of *P*-methyl protons with unequal concentrations of enantiomers were observed in all cases in deuterochloroform solution. Citing Refs. 1, 13, and 15–20, Harger gives a qualitative treatment of his results that follows completely from our views. In his opinion[28] the magnetic non-equivalence of the indicator nucleus in the enantiomer molecules with statistical non-equivalence of homo- and cross-contacts and rapid exchange between complexes underlie the observed phenomenon. From infrared spectral data Harger refines the character of the diastereomeric association complexes as the dimeric



(D)



(E)

Although he gives only qualitative consideration to his results, his numerical data are susceptible to a quantitative treatment based on formulae (7) and (8). Table 5 gives values that the Reviewers have thus calculated for the SCADA parameters in the n.m.r. spectra of the phosphinamides. The curves in Fig. 5 have been calculated theoretically by the Reviewers, whereas the points have been taken from Harger's experiments[28]. It is obvious that he had investigated a typical SCADA phenomenon, with $m = \alpha_c/\alpha_h < 1$ in all cases other than the last, so that homo-association had occurred preferentially.

2. Mixtures of Epimers

Equations (1) and (2) do not involve any restrictions on the stereochemical relations of the mixture components. Equations (7) and (8), on the other hand, are applicable to mixtures only of enantiomers. If the components *i* and *j* are not antipodes but diastereomers, formulae (7) and (8) should be replaced by the more general[19,20]

$$\delta_i = \frac{\alpha_i^i c_i \delta_i^i + \alpha_i^j (1 - c_i)\, \delta_i^j}{\alpha_i^i c_i + \alpha_i^j (1 - c_i)}\,, \tag{15}$$

$$\delta_j = \frac{\alpha_j^j (1 - c_i)\, \delta_j^j + \alpha_j^i c_i \delta_j^i}{\alpha_j^j (1 - c_i) + \alpha_j^i c_i} \tag{16}$$

in which the concentrations c_i and c_j have been normalised to unity and the subscript corresponds to the isomer whose signal is under consideration, while the superscript denotes the isomer with which it interacts in the association complexes. Thus α_i^i, α_j^j and α_i^j, α_j^i are association stability characteristics; the latter two, of course, are the same for the two epimers: i.e. $\alpha_i^j = \alpha_j^i$. The chemical shifts δ_i^i and δ_j^j are homo-shifts; when $c = 1$ and $c = 0$, they equal respectively δ_i or δ_j. These shifts are unequal; furthermore $\delta_i^j \neq \delta_j^i$. In the case of enantiomers we have

$$\alpha_i^i = \alpha_j^j = \alpha_h; \quad \alpha_i^j = \alpha_j^i = \alpha_c,$$
$$\delta_i^i = \delta_j^j = \delta_h; \quad \delta_i^j = \delta_j^i = \delta_c.$$

The ^{31}P–{^{1}H} n.m.r. spectra of mixtures of epimers SS + SR and SS + RS of compound (V) were investigated. Their mirror-image mixtures RR + RS and RR + SR were enlisted only to determine the error in the measurements. Table 6 gives experimental values obtained at various relative concentrations of the epimers and of the mixture and at various temperatures. Treatment by means of formulae (15) and (16)[20] yielded all the parameters of the diastereomeric anisochronism spectra of the systems (Table 7). They are identical, of course, with the parameters of the corresponding mirror-antipodal pairs RR + RS and RR + SR. These parameters carry all the information on the influence of association on the n.m.r. spectra of binary mixtures of the diastereomers. In contrast to mixtures of enantiomers, the signals of epimers at equal concentrations naturally do not merge into one, and two signals are observed throughout the range of relative concentrations.

Table 6. Chemical shift of signals in $^{31}P-\{^1H\}$ n.m.r. spectrum of mixtures of epimers of (V) with c = 0.4 M in chloroform (I_{rel} is the relative integral intensity and $c_1 = [SS]/([SS]+[SR])$ or $c_1 = [SS]/([SS]+[RS])$

Figs. 6–9 contain theoretical curves representing the dependence of the parameters of the diastereomeric anisochronism spectrum for the mixtures of epimers SS + RS and SS + SR at various temperatures. Good agreement is evident between calculated and observed values.

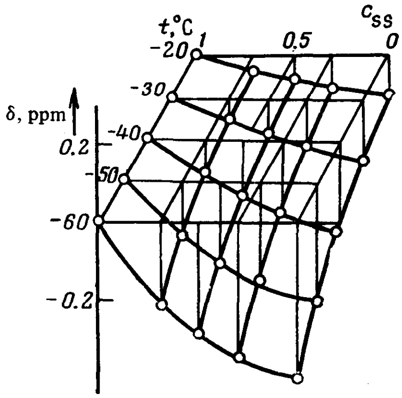

Figure 6. Dependence of chemical shifts in signals from SS isomer of (V) mixed with RS isomer in 0.4 M solution in chloroform on relative concentration at various temperatures. Each curve has been reckoned from the homoshift of the signal from SS molecules at the given temperature. The curves have been obtained theoretically, and the points represent experimental values.

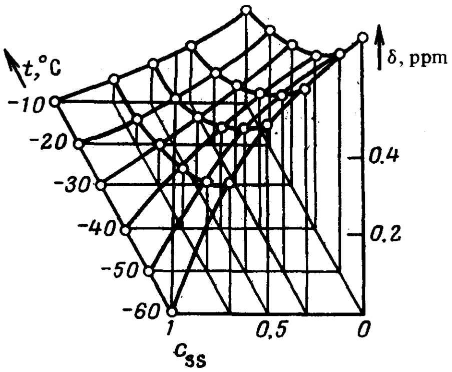

Figure 7. Dependence of chemical shifts in signals from SS isomer of (V) mixed with SR isomer in 0.4 M solution in chloroform on relative concentration at various temperatures. Each curve has been reckoned from the homoshift δSS at the given temperature. The curves have been obtained theoretically, and the points represent experimental values.

IV. DIASTEREOMERIC ANISOCHRONISM SPECTRA OF MORE COMPLICATED SYSTEMS

1. General Survey[19,20]

A general discussion of diastereomeric anisochronism spectra in terms of a plurality of theoretical ideas has shown[21] that the multiplicity of the spectra for mixtures of stereoisomers having n chiral fragments may equal the number of antipodal pairs 2^{n-1}, but cannot be less than or greater than this value. The multiplicity of such a spectrum of a mixture of stereoisomers may be increased if the asymmetrisation operators corresponding to the stereoisomers are non-degenerate and have mirror non-invariance. In achiral media with statistically controlled association, i.e. with rapid exchange between complexes, the multiplicity of the spectrum of a mixture of stereoisomers having n chiral centres may increase to 2^n, since under these conditions each stereoisomer has its own signal averaged over all association complexes of various compositions. If an achiral solvent contains a mixture of optical isomers containing N different components, the chemical shift of a nucleus in the ith component under SCADA conditions can be expressed by the formula

$$\delta_i = \left(\sum_{i=1}^{N} W_i^j \delta_i^j\right) \Big/ \sum_{j=1}^{N} W_i^j. \tag{17}$$

where δ_i^j is the chemical shift of a nucleus in the ith component in a primary interaction with the jth component and W_i^j is the statistical weight of the contribution to δ_i by this chemical shift, both parameters being averaged over all types of association complexes in which the ij interaction occurs, so that $\delta_i^j = \langle \delta_i^j \rangle$ and $W_i^j = \langle W_i^j \rangle$. As in the discussion of binary systems, it may be supposed that the statistical contribution of the interaction δ_i^j to δ_i is determined by the relative concentration

$$c_j = [j] \Big/ \sum_{j=1}^{N} [j]:$$

and the stability of the pair contacts α_i^j

$$W_i^j = \alpha_i^j c_j. \tag{18}$$

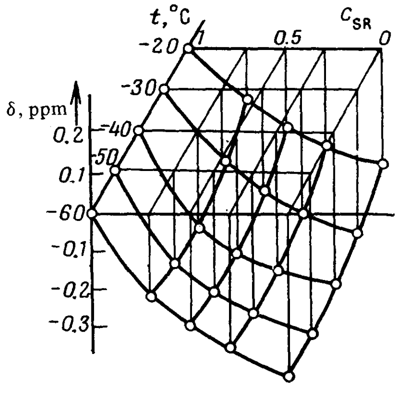

Figure 8. Dependence of chemical shifts in signals from SR isomer of (V) mixed with SS isomer in 0.4 M solution in chloroform on relative concentration of SR molecules at various temperatures. Each curve has been reckoned from the homo-shift δ_{SR} at the given temperature. The curves have been obtained theoretically, and the points represent experimental values.

Thus the chemical shift of the indicator nucleus in the ith component is given by

$$\delta_i = \left(\sum_{j=1}^{N} \alpha_i^j c_j \delta_i^j\right) \Big/ \sum_{j=1}^{N} \alpha_i^j c_j, \tag{19}$$

and the relative integral intensity of this signal by

$$I_i = [i] \Big/ \sum_{j=1}^{N} [j]. \tag{20}$$

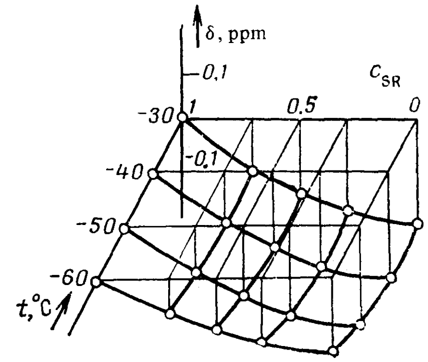

Figure 9. Dependence of chemical shifts in signals from SR isomer of (V) mixed with RR isomer [in 0.4 M solution in chloroform] on relative concentration at various temperatures. Each curve has been reckoned from the homo-shift δ_{SR} at the given temperature. The curves have been obtained theoretically, and the points represent experimental values.

The deduction of formulae (17) and (19) took into account the statistical contribution by pair contacts ij with rapid exchange between association complexes. More complicated contacts of the type ijq can in principle also be taken into consideration, when

$$\delta_i^j = \left(\sum_{q=1}^{N} W_{ij}^q \delta_{ij}^q\right) \Big/ \sum_{q=1}^{N} W_{ij}^q. \tag{21}$$

This formula covers long-range interactions, since components i and q are not in direct contact. Construction of a statistical theory for such systems of a second order of complexity gives rise to no fundamental difficulties, but the need for such complication can be ascertained only experimentally. It has been shown above that good agreement between calculated and observed chemical shifts of the diastereomeric anisochronism spectrum in binary systems is achieved with calculations based on formulae (15) and (16), or on Eqns. (7) and (8) for a mixture of enantiomers, in which only direct pair contacts are considered. We shall show below that a quaternary system can be completely analysed in terms of formula (19).

2. Four-component Systems[19,20]

For a mixture of four stereoisomers having two chiral centres we can apply Eqn. (19) to the chemical shift of phosphorus in each stereoisomer. With $N = 4$ the total number of α_i^j and δ_j^i parameters is 32, which are given in the two quadratic matrices

$$\begin{pmatrix} \alpha_{RR}^{RR}\alpha_{RR}^{SS}\alpha_{RR}^{RS}\alpha_{RR}^{SR} \\ \alpha_{SS}^{RR}\alpha_{SS}^{SS}\alpha_{SS}^{RS}\alpha_{SS}^{SR} \\ \alpha_{RS}^{RR}\alpha_{RS}^{SS}\alpha_{RS}^{RS}\alpha_{RS}^{SR} \\ \alpha_{SR}^{RR}\alpha_{SR}^{SS}\alpha_{SR}^{RS}\alpha_{SR}^{SR} \end{pmatrix} \quad \begin{pmatrix} \delta_{RR}^{RR}\delta_{RR}^{SS}\delta_{RR}^{RS}\delta_{RR}^{SR} \\ \delta_{SS}^{RR}\delta_{SS}^{SS}\delta_{SS}^{RS}\delta_{SS}^{SR} \\ \delta_{RS}^{RR}\delta_{RS}^{SS}\delta_{RS}^{RS}\delta_{RS}^{SR} \\ \delta_{SR}^{RR}\delta_{SR}^{SS}\delta_{SR}^{RS}\delta_{SR}^{SR} \end{pmatrix}$$

where the rows correspond to stereoisomers whose chemical shifts are under consideration (subscripts), and the columns to stereoisomers that interact with the former in elementary pair contacts. The right-hand matrix contains parameters describing the fields induced at the indicator nucleus in the association complexes, and the left-hand matrix parameters representing the stereospecificity of pair contacts in the complexes. With the use of these parameters formula (19) can be written for the chemical shift δ_i of each stereoisomer in the form

$$\delta_i = \frac{\alpha_i^{SS}c_{SS}\delta_i^{SS} + \alpha_i^{RR}c_{RR}\delta_i^{RR} + \alpha_i^{RS}c_{RS}\delta_i^{RS} + \alpha_i^{SR}c_{SR}\delta_i^{SR}}{\alpha_i^{SS}c_{SS} + \alpha_i^{RR}c_{RR} + \alpha_i^{RS}c_{RS} + \alpha_i^{SR}c_{SR}}, \quad (22)-(25)$$

in which the subscript i denotes respectively SS, RR, RS, and SR. When symmetry is taken into account, the number of independent parameters in these formulae is greatly diminished. Thus the parameters δ_i^j become equal when both partners in an interaction are replaced by mirror-image antipodes, and the number of such independent parameters decreases to 8. This applies also to the α_i^j parameters, but in this case we also have $\alpha_j^i = \alpha_i^j$, so that the number of these independent parameters diminishes to 6. Each set of 14 parameters corresponds, of course, to given selected conditions of the n.m.r. experiment (solvent, total concentration, temperature).

Table 8. Calculated chemical shifts of signals from stereoisomers SS and SR (or RR and RS) of (V) in a mixture of four isomers in 0.4 M solution in chloroform*.

*The homo-shift δ_{SS} at the given temperature was adopted as reference signal.

With an instrument of sufficiently high resolving power and with unequal relative concentrations of the four stereoisomers, the diastereomeric anisochronism spectrum should in general contain four signals with different chemical shifts δ_{SS}, δ_{RR}, δ_{RS}, and δ_{SR}. The relative intensities of the components of this quadruplet should be equal to the relative concentrations of the corresponding stereoisomers. If the stereoisomers are present in equal concentrations in the mixture, it is readily seen that the chemical shifts of the enantiomers RR and SS, and also of RS and SR, will become equal, their signals will coalesce, and the spectrum will contain two signals of equal intensity. This has been observed experimentally[20].

All the fourteen parameters required for the calculation had been determined earlier[20] in experiments on binary systems (Table 2 and 7). Values of $\delta_{SS} = \delta_{RR}$ and $\delta_{SR} = \delta_{RS}$ were calculated for various temperatures (Table 8). It is seen that $\Delta\delta$ actually passes through a minimum at −45°C, as illustrated by Fig. 2 (curve *V*). Agreement is observed between calculated and experimental values of $\Delta\delta$.

The molecules of quinine alkaloids contain four asymmetric carbon atoms, at positions 3, 4, 8, and 9. In natural (−)-dihydroquinine the centres at 3 and 4 have the (+) configuration, while 8 and 9 have the (−) configuration. The synthetic racemate, of course, has (±) at all centres. In general, therefore, a mixture of (−)-dihydroquinine and racemic dihydroquinine must be expected to exhibit a maximum of sixteen signals instead of the single signal of a given indicator nucleus. The fact that only two signals appear indicates that all centres of asymmetry other than one have little effect. It is most probably the chiral atom at position 9 that exerts this dominant effect.

3. Four-component Systems with Ion Exchange

An important part in experimental stereochemical investigations is played by the n.m.r. spectra of salts containing chiral cations and anions. Since Pasteur's time such salts have been used for resolving racemates. Their n.m.r. spectra have been widely applied during recent years to determine the optical purity of enantiomers, absolute configurations[9,29], etc. It is therefore important to know how the diastereomeric anisochronism spectrum of a mixture of enantiomeric or diastereomeric salts is formed, and to what extent the n.m.r. criterion is appropriate for solving the above problems.

The dependence of the chemical shifts in the n.m.r. spectra of a mixture of the salts (VII) and (VIII)

(VII) : $R^-S^+ + S^-S^+$, (VIII) : $R^-R^+ + S^-S^+$.

on the enantiomeric composition was investigated by Mikolajczyk et al.[30] Here R and S denote the absolute configurations of the cations (R^+ and S^+) and the anions (R^- and S^-). The difference $\Delta\delta$ between the chemical shifts of the *P*-methyl protons were found to vary linearly with the relative concentration of the SS isomer over the range 27−78 mole % of one of the enantiomers.

Shipov et al. investigated[31] the $^{31}P-\{^1H\}$ n.m.r. spectra of salts (IX) of enantiomeric ethyl hydrogen phosphonothionates (R and S) with 1-phenylethylamine (R and S)

(IX) : X=CH_3; (X) : X=H.

at constant total concentrations 0.5 M and 1.0 M in a 1 : 1 mixture of chloroform and deuterochloroform between −50 and −10°C. The most detailed examination was made on a 0.5 M solution at −30°C. The enantiomeric salts RR and SS were prepared by the method of Boter and Platenburg[24], and the salts RS and SR by mixing the corresponding enantiomeric acids and anions. Their absolute configurations were established from data obtained by

Mikolajczyk et al.[29] The constants of the 1-phenylethylammonium and benzylammonium ethyl phosphonothionates investigated are listed in Table 9.

Table 9. Constants for stereoisomeric salts.

Absolute configuration	$[\alpha]_D^t$	t, °C
	(IX)	
RR	+10.00°	22
SS	−9.83°	22
RS	+5.33°	20

	—	—

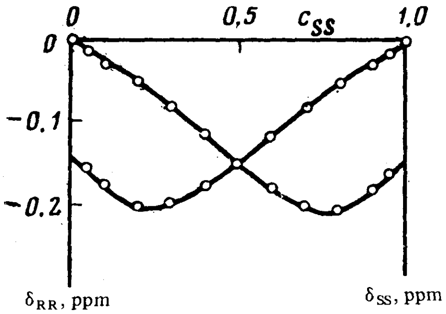

Figure 10. Dependence of δ_S and δ_R on relative content of antipodes of salt (IX) in 0.5 M solution in 1 : 1 $CHCl_3$–$CDCl_3$ at −30°C. The homo-shift δ_{SS} was adopted as reference signal.

Fig. 10 illustrates the experimental dependence of the ^{31}P n.m.r. chemical shifts of mixtures of the R^-R^+ and S^-S^+ enantiomers of the salt (IX) [20] at −30°C. A single signal is observed in the racemic mixture at −50°C, displaced by −0.27 ppm from the signal of the pure enantiomers (i.e. from the homo-shift). At all other concentrations two signals are observed. The curves differ markedly from the above cases of SCADA: they are butterfly-shaped with a minimum and an inflection, whereas typical SCADA curves with rapid exchange between association complexes do not (and cannot) contain either extrema or inflections. At −30°C the curves retain the "butterfly" character, but with narrower wings: i.e. the difference between the chemical shifts $\delta_R - \delta_S$ is smaller (Fig. 10).

Salt systems of this kind differ from the quaternary systems discussed in subsection 2 in the absence of a system of covalent bonds between the chiral centres in the stereoisomeric salts S^-S^+, R^-R^+, S^-R^+, and R^-S^+. In strongly dissociating media the chiral centres are kinetically independent; in media of low polarity they form ion-pairs or higher association complexes, between which, however, quite rapid ion exchange is possible [32].

In a solution of a mixture of the enantiomeric salts S^-S^+ and R^-R^+ in any relative concentrations, i.e. with $c^0_{SS} + c^0_{RR} = 1$, equilibrium is established between four ion-pairs:

$$S^-S^+ + R^-R^+ \overset{K}{\rightleftarrows} S^-R^+ + R^-S^+. \tag{26}$$

with the equilibrium constant

$$K = c_{SR}c_{RS}/c_{SS}c_{RR}, \tag{27}$$

where

$$c_{SR} = c_{RS};\quad c_{RR} + c_{RS} = c^0_{RR};\quad c_{SS} + c_{SR} = c^0_{SS}.$$

The chemical shifts in the n.m.r. spectra of such systems could apparently be considered in terms of additive contributions by $\delta_{R^-R^+}$ and $\delta_{R^-S^+}$ to δ_{R^-} and by $\delta_{S^-S^+}$ and $\delta_{S^-R^+}$ to δ_{S^-}. However, the $\delta - c$ relation obtained from theoretical curves calculated on the basis of this hypothesis does not resemble the experimental relation: curves for whose construction only ion exchange has been taken into account differ from the experimental curves in the absence of inflections and extrema at all values of c other than zero and unity. With salts of type (VII)–(IX) not only ion-pairs but also more complicated hydrogen-bonded complexes may be formed. The phosphonate anion is able to form only one hydrogen bond, and thereby fix an ion-pair, which therefore acts as an elementary particle in forming higher association complexes.

Thus in media of low dielectric constant the diastereomeric anisochronism spectra of stereoisomeric salts are produced under the influence of three factors—(*a*) formation of ion-pairs as stereoisomeric quasi-molecules, (*b*) ion exchange, i.e. the exchange of chiral centres between these quasi-molecules, and (*c*) association of the quasi-molecules—so that the problem of interpreting the spectra of such systems simplifies to the four-component problem of subsection 2 complicated by ion exchange [19,20]. The influence of these factors on the chemical shifts is expressed by the formulae

$$\delta_{R^-} \doteq (\Delta_{RR}c_{RR} + \Delta_{RS}c_{RS})/c^0_{RR}, \tag{28}$$

$$\delta_{S^-} = \Delta_{SS}c_{SS} + \Delta_{SR}c_{SR}/c^0_{SS}, \tag{29}$$

in which δ_{R^-} and δ_{S^-} are the chemical shifts of the indicator nucleus in R and S anions, while Δ_{RR}, Δ_{RS}, Δ_{SR}, and Δ_{SS} are those of the quasi-molecules R^-R^+, R^-S^+, S^-R^+, and S^-S^+ produced in conformity with SCADA principles, i.e. formulae (22)–(25). Thus a 33rd parameter—the equilibrium constant K—is added to the 32 parameters of a system comprising four two-centred stereoisomers given above as two quadratic matrices. In this case, too, allowance for symmetry reduces the number of δ_i^j parameters to 8, and of α_i^j to 6. The parameters δ^{SS}_{SS} and δ^{SR}_{SR} are determined directly in an experiment by measuring the chemical shift in solutions of the pure enantiomers RR (or SS) and SR (or RS).

The present problem requires knowledge of 13 independent parameters, to determine which we have used the pairs of diastereomeric salts $R^-R^+ + S^-R^+$ and $R^-R^+ + R^-S^+$. In an RR + SR mixture in solution no new species appear on ion exchange, and treatment of experimental data on the basis of formulae (28), (29), and (19) enables us to isolate the chemical-shift parameters

$$\delta^{RR}_{SR} = \delta^{SS}_{RS}\quad \delta^{SR}_{RR} = \delta^{RS}_{SS},$$

and also the constants

$$\alpha^{RR}_{SR} = \alpha^{SS}_{RS} = \alpha^{SR}_{RR} = \alpha^{RS}_{SS}.$$

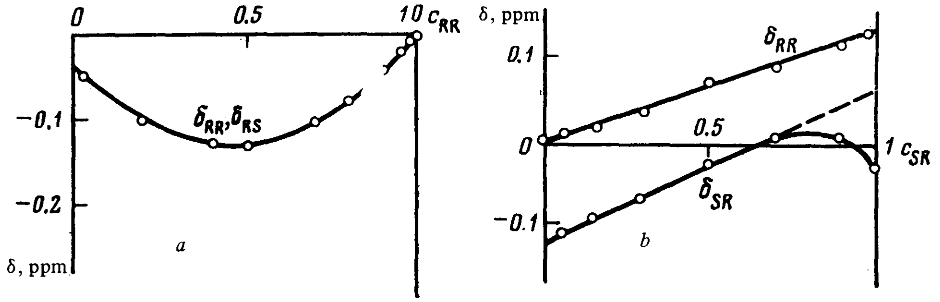

Figure 11. Dependence of chemical shifts of signals in spectra of binary salt systems (IX) on relative concentration: *a*) RR + RS; *b*) RR + SR.

If another pair of diastereomers—R^-R^+ and R^-S^+—is used, the parameters δ_{RS}^{RR} and δ_{RR}^{RS} and the equal δ_{SR}^{SS} and δ_{SS}^{SR}, as well as the parameters

$$\alpha_{RS}^{RR} = \alpha_{SR}^{SS} = \alpha_{RR}^{RS} = \alpha_{SS}^{SR}.$$

can be isolated similarly. Fig. 11 illustrates the experimental dependence of the chemical shifts of these pairs on their relative concentration†. Thus the number of unknown parameters can be reduced to two δ parameters (δ_{RR}^{SS} and δ_{RS}^{SR}) and two α parameters (α_{RR}^{SS} and α_{RS}^{SR}), together with *K*.

Comparison of theoretical and experimental δ(*c*) values with variation in the parameters α_{RR}^{SS} and α_{SR}^{RS} showed that these parameters could be taken as unity without any great error, so that the chemical shifts δ_{RR}^{SS} and δ_{RS}^{SR} and the constant *K* could be evaluated. The complete set of parameters of the system (with $K = 1.3$) is

$$\begin{array}{c} \alpha \\ \begin{array}{cccc} \mathrm{RR} & \mathrm{SS} & \mathrm{RS} & \mathrm{SR} \end{array} \\ \left(\begin{array}{cccc} 1.0 & (1.0) & 1.3 & 1.0 \\ (1.0) & 1.0 & 1.0 & 1.3 \\ 1.3 & 1.0 & 1.0 & (1.0) \\ 1.0 & 1.3 & (1.0) & 1.0 \end{array}\right) \end{array} \begin{array}{c} \\ \\ \mathrm{RR} \\ \mathrm{SS} \\ \mathrm{RS} \\ \mathrm{SR} \end{array} \begin{array}{c} \delta \\ \begin{array}{cccc} \mathrm{RR} & \mathrm{SS} & \mathrm{RS} & \mathrm{SR} \end{array} \\ \left(\begin{array}{cccc} 0 & -0.44 & -0{,}22 & +0.01 \\ -0.44 & 0 & +0{,}01 & -0{,}22 \\ -0.20 & -0{,}14 & -0.04 & -0.46 \\ -0.14 & -0{,}20 & -0{,}46 & -0.04 \end{array}\right) \end{array}$$

Fig. 10 shows the theoretical curve calculated with these values. Thus the chemical shifts observed in salt systems are due to the combined action of chemical equilibrium and SCADA. Consequently exclusion of the influence of the equilibrium factor should reveal pure SCADA. The ^{31}P n.m.r. spectra were investigated of salts of stereoisomeric R and S ethyl hydrogen phosphonothionates and benzylamine[20], in which system (X) the base is achiral. Hence the chemical shifts cannot be affected by ion exchange. In this case the experimental dependence of the chemical shifts on the relative concentration of the enantiomeric acid esters gives the usual SCADA curve with the parameters $\delta_h = 0$, $\delta_c = 0.25$, and $\alpha_c/\alpha_h = 2.4$.

The matrix elements α_i^j and δ_i^j (and *K* in the case of salt systems) carry the whole of the information on the influence of association on the n.m.r. spectra and its stereospecificity. It is better to use these parameters as physical characteristics of systems instead of the less informative quantity Δδ. The temperature variations of the matrix elements have interesting features, on whose basis we can discuss several physical aspects of the interaction of chiral molecules in the primary step of association.

The δ−*c* curves of binary systems have two parameters, $\delta_i^j - \delta_i^i$ and α_i^j/α_i^i, the first of which represents the range of variation in δ(*c*), and the second the departure of the curve from a straight line that occurs when $\alpha_c = \alpha_h$, i.e. in the absence of stereospecificity of interaction. Tables 2 and 7 show that for SS molecules the ratio $m_{SS}^j = \alpha_{SS}^j/\alpha_{SS}^{SS}$ decreases with rise in temperature. However, if in mixtures of SS with RR or with RS preference for one type of interaction is lost as the temperature rises (at the limit of disappearance of the observed effects stereospecificity is almost absent), in the SS + SR mixture interaction of SS with SR molecules becomes more preferred at low temperatures, a preference which is lost at −40°C, and with further rise in temperature homo-interaction of SS with identical SS molecules occurs in preference to interaction with SR molecules.

For SR molecules, depending on their partner in the mixture, rise in temperature may either increase (SR + SS) or lower the ratio m_{SR}^j. On the whole the great diversity of variation in *m* for different interactions indicates a non-linear variation in the energy of interaction of chiral molecules on intermolecular association depending on the interaction of individual elements of chirality. This conclusion is of fundamental importance.

The interpretation of the δ_i^j values and their temperature dependence (Tables 4 and 8) for each primary association complex is quite complicated. Without completely rejecting the influence of direct induction of additional magnetic fields at the indicator nucleus on diastereomeric anisochronism during association, nevertheless we must evidently assume that conformational changes are primarily responsible for its establishment and variation. The role of association in changing the position of the signal relative to a possible signal in an isolated molecule may consist in

---

† Divergence from the statistical SCADA rules is observed on the δ_{SR} curve in the region of c_{SR} values close to unity (Fig. 11*b*), the reason for which is not yet clear. Perhaps an inadequate rate of exchange has an influence in this concentration range, and (or) more complicated association complexes play a more important part.

fixing a conformation with a different value of δ in the primary association complex. This applies, of course, not to a single act of pair association but to interactions between partners averaged over all types of association complexes. Furthermore, the fixation of conformations having a given values of δ implies, not a rigid set of particular conformations, but a redistribution of conformational populations. More detailed investigation of these mechanisms will evidently be possible only on the development of experimental and theoretical methods for quantitative analysis of nuclear shielding in complicated molecular structures.

An interesting series of papers published during 1975 to 1977 by French workers[33-37] reported a comprehensive investigation of the association of dipeptides of alanine, valine, and norvaline of general formula

$$R(1)-C(1)O(1)-N(2)H(2)-C_{\alpha}H_{\alpha}R(2)-C(2)O(2)-N(3)H(3)-R(3).$$

Infrared spectroscopy in tetrachloromethane solution revealed the presence of a conformational equilibrium between conformers A and B. In the former the hydrogen bond H(2)...O(2) completes a five-membered ring, but in conformer B the O(1)...H(3) bond closes a seven-membered ring. Conformer A has a strong intermolecular H(3)... O(1) hydrogen bond, but B is not characterised by association. The atom C_{α} is asymmetric.

Table 10.

R (2)	R (1), R (3)	$K'/2K$
CH_3	t-C_4H_9, iso-C_3H_7	0.9
C_3H_7	t-C_4H_9, iso-C_3H_7	3.3
iso-C_3H_7	t-C_4H_9, iso-C_3H_7	8.5

In full agreement with the results of Williams et al.[13], Horeau and Guette[1], and Soviet authors[15-20], these workers[33-37] observed a doubling of the multiplicity of signals in the n.m.r. spectra in non-equivalent mixtures of antipodes. The treatment that they used[33-37] in calculating Δδ for this specific problem was based on the same principles as the above general calculation of SCADA taking exchange into account. Their equations contain four δ parameters and eight x (concentration) parameters, which were determined from infrared and ^1H n.m.r. spectra. The results for stereoselectivity of association are given in Table 10, in which K' is the cross-dimerisation ($A^D + A^L$) constant, and K the homo-dimerisation ($A^D + A^D$ or $A^L + A^L$) constant. They show that the peptide of alanine is devoid of stereoselectivity of association, whereas those of norvaline and valine form dimers with a high degree of stereoselectivity.

---o0o---

From the above considerations it is clear that SCADA, apparent in a higher multiplicity of n.m.r. spectral signals in a non-racemic mixture of optical antipodes, is a phenomenon that gives important information on association. When dissociating media (methanol, water) are used, or trifluoroacetic acid, which decomposes association complexes of chiral molecules, is added to non-polar solvents, increase in the multiplicity of n.m.r. spectra is not observed.

Investigation of intermolecular interactions of chiral molecules by other methods lies outside the scope of this Review. We will merely mention a series of studies by Wynberg et al.[38-40], in which the stereoselectivity of interaction of chiral molecules determined the reaction velocity and the proportions of products. Examples chosen were the oxidation of 5,6,7,8-tetrahydro-3,4,8-trimethyl-2-naphthyl ferricyanide, the reductive dimerisation of optically active and racemic camphor, and the reduction of camphor by lithium tetrahydroaluminate to borneol and isoborneol. Research on the spontaneous or seeded separation of racemates into antipodes is obviously of practical importance.

A prolonged "calm", during which solutions of antipodes were regarded in all cases as ideal, so that the possibility that the properties of one antipode would be affected by the presence of the other was thereby rejected *a priori*, has been followed by a period of thorough study of the stereoselectivity of interaction of antipodal molecules—a phenomenon which undoubtedly plays an important part in biological processes and in whose study the n.m.r. method is indispensable.

Chemistry of Phosphinylidene Compounds—Advances and Prospects of Development

E.E.Nifant'ev

Research in this field is surveyed, and features of individual classes of compounds having this functional group in common are compared. An attempt is made to outline possible developments in certain promising scientific directions. Attention is paid mainly to investigations made during recent years. A list of 506 references is included.

I. INTRODUCTION

The evolution of the chemistry of organophosphorus compounds has created a large region uniting many classes of compounds having a phosphinylidene functional group $OPH<$ in common. It comprises acids of tervalent phosphorus, their partial esters, thiolic esters, amides, certain anhydrides, etc., which can all be regarded as phosphinylidene derivatives. Their preparation, structure, reactions, and practical applications have now been widely investigated. Individual aspects of the results have been discussed in monographs and reviews. Thus Tsvetkov and Kabachnik published a comprehensive work[1] on the preparation and analysis of such derivatives. Other articles[2,3] were devoted to problems of alkylation. Individual classes of compounds—dialkyl phosphites[4,5], phosphonous acids and their derivatives[6], phosphinous acids[7]—have been subjects of compilations. The above reviews were written during the early and middle 1960s, and cover information that has become almost classical. Investigations made during recent years, which have been pursued especially vigorously, have not yet been summarised or examined from general points of view. The resulting need to fill the gap is intensified by certain circumstances, of which special note should be made.

1. The number of known classes and types of phosphinylidene derivatives has increased appreciably, which has permitted both comparison of the properties of a wide range of compounds having the same functional group and the first conclusions on the influence of structure of their reactivity. Moreover, it has become possible to pass from a qualitative to a quantitative treatment of the results.

2. A stereochemical principle has appeared. The first individual geometrical and optical isomers of partial phosphites, phosphonites, and phosphinous acids have been obtained. Research has begun on dynamic stereochemistry, in particular on the conformational dependence of the reactivity of phosphites.

3. Abundant preparative information has accumulated, and fundamentally new reactions of phosphinylidene compounds have been suggested. The widespread uses of several transformations discovered during the 1940-1950s has made it necessary to honour the debt to their authors and introduce the appropriate names into chemical vocabulary.

4. Physicochemical laboratories have been attracted to the study of phosphinylidene compounds. It is significant that not only structural and kinetic but also preparative problems have been solved in them, revealing unexpected possibilities for organophosphorus synthesis.

5. Methods used in the chemistry of phosphinylidene compounds have been applied to naturally occurring compounds and polymers. Original results have been obtained, indicating a promising future for these lines of investigation.

6. Work on the technology of dialkyl phosphites and related derivatives has ended in industrial realisation. Data have been obtained on the use of phosphinylidene derivatives to solve many practical problems.

The present Review has been prepared in the light of the above circumstances. It reflects (but does not always fully cite) the advances of the past decade. The Reviewer has seen his task in not only systematising and analysing published information but also assessing tendencies and the prospects for development of the most interesting lines of research. Judgments on such problems are, of course, controversial in character.

II. SYNTHESIS

Published information usually covers the preparation of phosphorous diesters, multisubstituted phosphonous esters, and oxides of secondary phosphines. During recent years, however, other related types of compounds have become accessible, including relatively unstable derivatives; in several cases stereoisomeric forms have been isolated and studied.

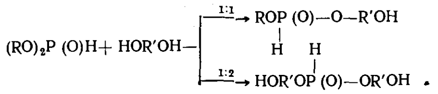
In the present Section information on the formation of phosphinylidene compounds is presented in a sequence based on chemical structure—(1) organic derivatives of phosphorous acid, (2) phosphonous acids and their derivatives, (3) phosphinous acid, (4) derivatives of hypophosphorous acid, and (5) oxides of primary phosphines and other compounds—where preparations of each class or type of compounds are separated into two groups: the first group comprises reactions in which the initial substances already contain a phosphinylidene function, and the second those in which it is formed. Where possible, data on the structure of stereoisomers are included.

1. Organic Derivatives of Phosphorous Acid

(*a*) Diesters

Dialkyl (diaryl) phosphites. The most thoroughly studied and important type of phosphinylidene derivatives comprises dialkyl and diaryl phosphites. They are widely used as intermediates in the production of pesticides[8] and complexing agents[9,10], as stabilisers for polymers[11,12], additives to oils[13,14], components of flame-proofing compositions[15], etc.

To prepare many dialkyl (diaryl) phosphites it is advisable to phosphinylate alcohols (phenols) with simple derivatives. This includes transesterification, whose advantages include high yields and mild conditions due to the absence of aggressive by-products, as well as simplicity of control. Transesterification has been used to prepare various symmetrical and unsymmetrical phosphites[16-18], phosphinylated terpenes[14], and polyfunctional systems, mainly hydroxylated phosphorous esters formed from simple dialkyl phosphites and glycols[19-21]

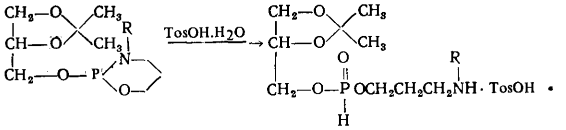


$$(RO)_2P(O)H + HOR'OH \begin{cases} \xrightarrow{1:1} ROP(O){-}O{-}R'OH \\ \qquad\quad\;\; | \\ \qquad\quad\;\; H \\ \qquad\qquad\qquad\; H \\ \qquad\qquad\qquad\; | \\ \xrightarrow{1:2} HOR'OP(O){-}OR'OH \end{cases} .$$

The products are phosphites of a new type, of interest for macromolecular chemistry. Their preparation by other routes is complicated or altogether impossible. However, transesterification has its limitations. Thus negative results have been obtained in the phosphinylation of 2-trichloromethylpropan-2-ol with simple dialkyl phosphites[22]. Because of such difficulties attention has been attracted to the alcoholysis of amides[23-25] and thiolic esters[26] of phosphorous acid, as well as the corresponding mixed anhydrides[27], which are milder reagents.

It has been proposed to obtain dialkyl phosphites of diverse structure by esterifying phosphorous acid[28,29], which is of industrial interest[30]. Similarly, monoalkyl phosphites can also be esterified[31,32]; those of more complicated structure, e.g. nucleoside phosphites, are esterified in the presence of condensing agents[33]. Phosphorous acid and monoalkyl phosphites can be alkylated to dialkyl phosphites by means of diazo-compounds[34,35], orthoesters[36], oxiran[37], and alkyl halides[38].

A large group of reactions yielding dialkyl or diaryl phosphites is based on the use of three-coordinated phosphorous derivatives. An important approach is hydrolysis of $(RO)_2PX$ systems, where X = Cl,[22,39] OAlk[†],[40-42] or NH_2.[43-45] The hydrolysis of complex phosphoramidites requires meticulous selection of conditions; thus treatment of the cyclic 2,3-isopropylideneglycerol phosphoramidite with water gives a mixture of products, but with the hydrate of toluene-*p*-sulphonic acid the required compound is formed in almost quantitative yield[44]:



In some cases a phosphorus-carbon bond may be cleaved. An example is the hydrolysis of completely esterified carborane-phosphonites[46]:

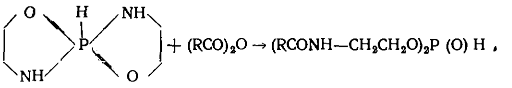
$$RCB_{10}H_{10}CP(OC_2H_5)_2 + H_2O \rightarrow (C_2H_5O)_2P(O)H + RCB_{10}H_{10}CH .$$

The preparation of acid phosphites by decomposing the neutral esters is especially valuable. Some esters, primarily those of tertiary alcohols, are degraded thermally[47]. More often, however, decomposition is effected by the use of acids—phosphorous acid[48] or dialkyl phosphorodithioates[49]— of which the latter ensure the highest rates because of the strongly nucleophilic character of the anion. An especially popular method is to dealkylate neutral phosphites with hydrogen chloride: for example[16]

$$CH_3OPCl_2 + 2C_6H_5OH \rightarrow [CH_3OP(OC_6H_5)_2 + HCl] \rightarrow (C_6H_5O)_2P(O)H + CH_3Cl .$$

A similar dealkylation completes a series of processes in the industrial production of dialkyl phosphites from phosphorus trichloride and alcohols. A continuous scheme has been suggested[50] for the process.

Much attention has been paid to the preparation of dialkyl phosphites from phosphorus sesquioxide and other anhydride systems. Direct alcoholysis of the oxide, a promising starting material for organophosphorus synthesis, leads to its complete conversion into an equimolecular mixture of mono- and di-alkyl phosphites[51]. If the reaction is conducted in boiling xylene, i.e. under conditions of azeotropic removal of water, monoalkyl phosphites are completely converted into the dialkyl esters, and a single product is formed[52]. When the technical "alcoholysate" is heated, monoalkyl phosphites disproportionate into the dialkyl esters and phosphorous acid[53]. It has been proposed to obtain dialkyl phosphites also by alcoholysis of anhydrides of alkyl dihydrogen phosphites[54,55] and by the deacylation of acyl phosphites[56,57]. An autodeacylation stage is probably involved also in passing from diaminospirophosphoran to bisacylaminoethyl phosphites[58]:



$$+ (RCO)_2O \rightarrow (RCONH{-}CH_2CH_2O)_2P(O)H ,$$

A special case of the formation of phosphorous diesters is the hydrolysis of α-oxo-phosphonates[59] and their imines[60]. It has been little studied, but is promising for the industrial production of dialkyl phosphites from white phosphorus, alcohol, and oxygen[61].

Alkylene (arylene) phosphites. Cyclic acid phosphites were first mentioned at the beginning of the century, but subsequently their study began only during recent years, when it has become possible to synthesise symmetrical and unsymmetrical 5–8-membered systems derived from glycols, dihydric phenols, and higher polyols. The most detailed investigation has been made on 1,3,2-dioxaphosphans—esters of 1,3-diols—which are of chemical and stereochemical interest, and structurally similar to certain bioregulators[62].

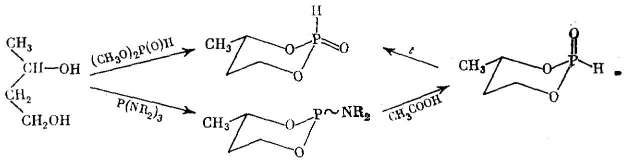
Simple and functionally substituted derivatives are usually obtained by transesterification[63-66]. Another popular approach involves modifying cyclic derivatives containing a three-coordinated phosphorus atom, by the hydrolysis of phosphorochloridites[67-71] and neutral mono- and bicyclo-phosphites[42,72], the acidolysis of phosphoramidites[63,64,66,73], or the aminolysis of pyrophosphites[74]. In several cases it is advisable to effect the preparations via thermally labile t-butyl intermediates[47,75,76].

Stereochemical factors must be taken into account in preparing substituted alkylene phosphites, owing to the possible formation of geometric isomers. A significant advance has been the development of directed methods for obtaining isomers. For example, 1-methyltrimethylene

---

[†] A reaction mechanism differing from the traditional mechanism is discussed in Ref. 42.

phosphite is formed mainly as the *cis*-isomer when obtained by transesterification, but as the *trans*-isomer when obtained by the acidolysis of 1-methyltrimethylene phosphoramidites; the latter isomer is unstable, and changes its configuration when heated[63];

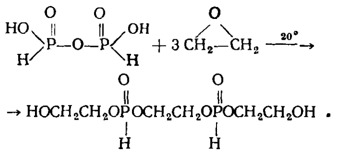


The orientation of the phosphinyl group and other structural factors in these rings have been investigated by proton nuclear magnetic resonance[63,64,66,68,69,77,78], dipole moments[63,77], infrared spectroscopy[69,79], and X-ray diffraction[80]. Moreover, several aspects of the dynamics of trimethylene phosphites—conversion of labile into stable geometric isomers[42,69,81], conformational equilibrium of symmetrical forms[79,82]—have been studied quantitatively. Geometric isomers of ethylenic phosphites do not exhibit ready interconversion[70]. Thus an appreciable difference exists between five- and six-membered cyclic phosphinylidene derivatives.

Alkylene diphosphites. These compounds, whose investigation has only just begun, have been obtained by transesterification[83]:

$$2\,(RO)_2P\,(O)\,H + HOR'OH \rightarrow RO{-}P\,(O)\,(H){-}OR'O{-}P\,(O)\,(H){-}OR\ ,$$

Opportunities for their technical use have been shown[84,85]. An unusual reaction giving an important product utilises pyrophosphorous acid and oxiran[86]:

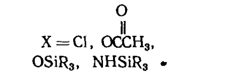


Poly(alkylene phosphites) and phosphites of polyhydroxylated polymers. It has been proposed[87-90] to obtain oligomeric and polymeric acid phosphites by the interaction of equimolecular quantities of simple dialkyl phosphites and glycols. The process develops differently according to the size of the alkylene radical: either a polyester is produced immediately or an initially formed alkylene phosphite polymerises. Unfortunately, many aspects of this promising reaction have not yet been elucidated.

A particular but important method for obtaining these polyesters is thermolysis of bis-2-chloroethyl phosphite. It is assumed that initial cyclisation to ethylene phosphite is followed by its condensation[91,92]. Polytransesterification has been extended also to triols, tetraols, and hexitols[93,94]. Several polyphosphites of hexitols have been suggested for use as additives to transformer oils[94].

Macromolecular acid phosphites of a different type are obtained by treating hydroxylated polymers with simple phosphinyl compounds. It is significant that these phosphinylating agents are more reactive than corresponding derivatives of quinquevalent phosphorus [Sic.] They have special advantages over various chlorides that are popular phosphinylating agents for lower alcohols and polyols, for their use does not liberate hydrogen chloride, which degrades or modifies many polymers. The phosphinylation of cellulose has been investigated in the greatest detail, for which purpose dialkyl phosphites[95-97], monoalkyl phosphites[96,97], and phosphorous acid[97] have been proposed. Polyphosphites, like other products of polymer-analogous reactions, are not chemically homogeneous. Amylopectin[98], lignin[99], polyallyl[100] and polyvinyl[101] alcohols, and soluble phenol–formaldehyde resins[102] undergo phosphinylation similarly to cellulose.

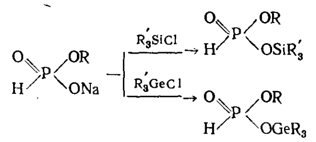
Trialkylsilyl phosphites. Silyl phosphites are definite analogues of the alkyl esters. They are usually obtained by the action of various silylating agents on phosphorous acid[103-106]:



$$(HO)_2\,P\,(O)\,H + 2R_3SiX \rightarrow (R_3SiO)_2P\,(O)\,H$$
$$X = Cl,\ O\overset{\overset{\displaystyle O}{\|}}{C}CH_3,\ OSiR_3,\ NHSiR_3\ .$$

Excess of the agent is not advisable, since neutral silyl phosphites might be formed. An interesting variant of this reaction, convenient for preparative purposes, is the interaction of phosphorous acid and a trialkylsilane in the presence of colloidal nickel[107]. Disilyl phosphites can be obtained by the alcoholysis or silanolysis of trisilyl phosphites[108], and also by the oxidation of disilyl hypophosphites[109].

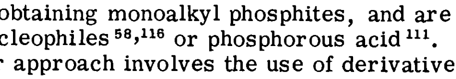
Alkyl silyl phosphites are formed by the reaction of monoalkyl phosphites with hexa-alkyldisiloxanes[110] and with trialkylchlorosilanes[105]; germanium derivatives are obtained similarly[105]:



(*b*) Monoesters

Phosphorous monoesters have been known for a long time, but their active investigation began only during recent years, probably stimulated by the discovery of interesting opportunities for their bio-organic use, as well as in solving practical problems[111]. As the first and second hydroxy-groups in phosphorous acid are esterified at different rates, a simple and convenient method has been developed for obtaining monoalkyl phosphites[28]. Phosphorous acid is poorly esterified by phenols, in contrast to alcohols[112]. The presence of a condensing agent—a carbodi-imide[113] or a sulphonyl chloride[113]—is advisable for the phosphinylation of complicated compounds (e.g. nucleosides). Phosphorous acid can be converted into monoalkyl esters by heating with alkyl halides[38] or t-butyl esters[114].

Other methods are transesterification[31,96] and the addition of hypophosphorous acid to quinones[115]:



Appropriate diesters are often used as initial compounds in obtaining monoalkyl phosphites, and are dealkylated by nucleophiles[58,116] or phosphorous acid[111].

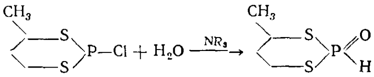
Another approach involves the use of derivatives of three-coordinated phosphorus. Thus it has been suggested that Menshutkin acid chlorides, including nucleosides, should be hydrolysed[117-119] or treated with t-butyl alcohol[120,121]. Hydrolysis has been applied also to neutral phosphites [122], phosphorodiamidites[123], and the corresponding spirophosphorans[124].

(*c*) Thiolic esters

Compounds of the type $OPH(SR)_2$ and $OPH(SR).OR$ began to be investigated only during the 1970s, when a fundamental difference from other phosphinylidene derivatives immediately became apparent. An attempt to prepare dithiolic esters by the thiolysis of tetra-alkyl phosphorodiamidites was reported; the products were neutral trithiolic esters, formed by disproportionation of the dithiolic esters [24,125]:

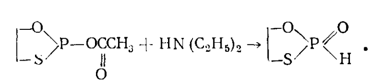
$$(R_2N)_2P(O)H + 2R'SH \rightarrow [(R'S)_2P(O)H] \rightarrow (R'S)_3P\ .$$

The required compounds are formed by the hydrolysis of dialkyl phosphorochloridodithiolites [26,125]. The clearest results are obtained with dithiols giving cyclic products[125]:



Cyclic chloridodithiolites are converted into phosphinylidene derivatives also by treatment with t-butyl alcohol[126]. Diethyl phosphorodithiolite is assumed to be formed in the hydrolysis of triethyl phosphorotrithiolite [127].

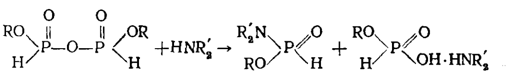
Only one phosphoromonothiolite—the ethylene ester—has been investigated. It has been prepared by hydrolysis of the corresponding chloride [128] and similar reactions, e.g. [128,129]



(*d*) Amides

Phosphinylidene compounds containing a phosphoramide bond are of very great chemical interest. Various derivatives of this class—$OPH(NR_2)_2$, $OHP(NR_2).OR'$, $OHP(NR_2).OH$—are now known. Many diamides of phosphorous acid can be obtained by transamidation [24]. However, simple derivatives are mostly prepared by hydrolysis [130] or acidolysis [130,131] of fully amidated phosphorous acid. The required compounds can be obtained from triamides and propiolactone [132], and also from silyl phosphorodiamidites and alcohols[133]. It has been suggested that cyclic amides can be obtained by hydrolysing appropriate acid chlorides [66] or by treating them with t-butyl alcohol [134]. Data have appeared on the stereochemistry of these rings [135]. Salts of phosphorodiamidous acids are formed by reducing complete amides of phosphoric acid with alkali metals [136].

Phosphoramidous esters have been obtained by transamidation of simpler compounds [23], partial alcoholysis of diamides [24], and aminolysis of anhydrides containing a phosphinylidene group [137]: for example



Another method is hydrolysis of phosphoramidochloridous [137,139] or phosphorodiamidous [23,138,139] esters, as well as alcoholysis of anhydrides of phosphoramidous acids [54].

Monoamides of phosphorous acid have been described in only one patent [140]:

$$P_4O_6 + HNR_2 \rightarrow R_2N{-}P\begin{matrix}{=}O\\ {-}H\\ {-}OH\cdot R_2NH\end{matrix}\ .$$

(*e*) Acid halides

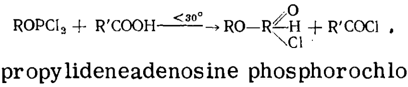
Results on the preparation of acid halides of phosphorous acid, containing a phosphinylidene group, have not yet been analysed in reviews on the phosphorus chemistry. It has evidently been assumed that these compounds are too unstable to exist. Nevertheless, such acid halides have been obtained.

Attempts have been made to prepare phosphorodichloridous acid by the action of hydrogen chloride on diamides of phosphorous acid, but the product isolated was phosphorus trichloride. The initial substance had obviously disproportionated under the reaction conditions, like other phosphinylidene compounds containing electron-accepting groups [24]:

$$(R_2N)_2P(O)H + HCl \rightarrow [Cl_2P(O)H] \rightarrow PCl_3\ .$$

Another route to an acid dichloride consists in treating phosphorus trichloride with diethyl phosphite: formation of a product was detected by n.m.r. at −40°C. [141]

A very interesting result has recently been obtained [142]:



$$ROPCl_2 + R'COOH \xrightarrow{<30^\circ} RO{-}R\begin{matrix}{=}O\\ {-}H\\ {-}Cl\end{matrix} + R'COCl\ .$$

2′, 3′-Isopropylideneadenosine phosphorochloridite has been prepared by selective hydrolysis of the corresponding Menshutkin acid chloride. The product was then oxidised and hydrolysed to 2′, 3′-isopropylideneadenylic acid [119].

Phosphorodifluoridous acid is obtained by redox reactions [143,144] and cleavage of its anhydrides by nucleophilic compounds [145,146]: for example

$$F_2PH + H_2O \rightarrow F_2P(O)H + H_2\ ,$$

$$F_2P(O)N(CH_3)_2 + 3HI \rightarrow F_2P(O)H + (CH_3)_2\overset{\oplus}{N}H_2\overset{\ominus}{I} + I_2\ .$$

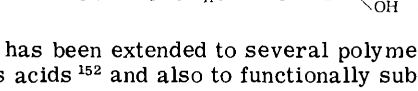
The product could be distilled (b.p. 67.7°C) and its structure proved. It disproportionates on storage [145,146]. Phosphoromonofluoridous acid and its deuteriated derivatives have been obtained by treating phosphorus trichloride with aqueous hydrofluoric acid [147]. It is easily converted into stable salts. Its methyl ester has been prepared by the reaction [146]

$$F_2P(O)H + F_2POCH_3 \rightarrow PF_3 + CH_3OP(O)FH\ .$$

2. Phosphonous Acids and their Derivatives

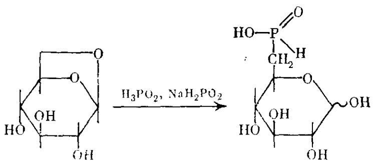
(*a*) Phosphonous acids

Phosphonous acids have been little studied as a class of compounds, but are of chemical interest and show promise for practical application. Alkylphosphonous acids are best obtained by the radical phosphinylidenation of alkenes [148-151]:



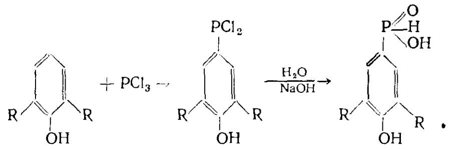
$$RCH{=}CH_2 + NaH_2PO_3 \xrightarrow[H^{\oplus}]{RO\cdot} RCH_2{-}CH_2{-}P\begin{matrix}{=}O\\ {-}H\\ {-}OH\end{matrix}$$

The method has been extended to several polymeric phosphonous acids [152] and also to functionally substituted systems[153,154]. The phosphinylidenation of hetero-unsaturated compounds—Schiff bases[155,156], hydrazones[157], oximes[158], etc.—has been studied. Certain anhydroaldopyranoses (e.g. levoglucosan) on reaction with hypophosphorous acid give 6-deoxy-6-glycophosphonous acids[153]:



The process probably involves formation and rearrangement of the hypophosphite, like the reaction of polyallyl alcohol with hypophophorous acid[159].

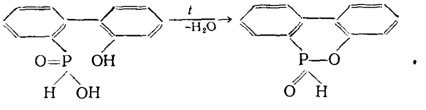
Alkyl- and aryl-phosphonous acids are often obtained by hydrolysis of their acid chlorides and other derivatives[6]. When especially pure products are required, hydrolysis must be replaced by treatment with t-butyl alcohol[160]. Acid dichlorides may yield fairly unusual acids: an example is the reaction[161]



Individual phosphonous acids are formed by the oxidation or the disproportionation of oxides of primary phosphines[162].

(*b*) Phosphonous monoesters

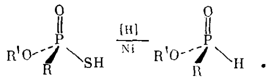
Acid phosphonites have been obtained by esterifying phosphonous acids with alcohols[28] and polyols[150,163,164]. In the latter case primary hydroxy-groups are phosphinylated preferentially. Esterification of phosphonous acids by phenols has not been reported. This reaction may well be possible under certain conditions, in view of the transformation[165-167]



For preparative purposes it is often more convenient to phosphinylate by transesterification. This process has been widely used with diols[168-170], tri- and tetra-ols,[83] carbohydrates[171], and cellulose[95].

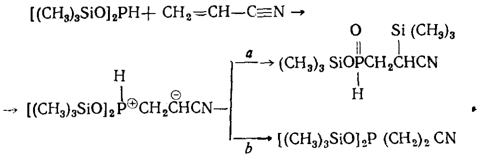
Another route starts from three-coordinated phosphorus derivatives, most frequently acid dichlorides, whose alcoholysis in the presence of amines has become widely used[172-174]. Sometimes it is convenient to treat dichlorophosphines with an equimolecular quantity of the alcohol (phenol) and t-butyl alcohol[175,176]. Acid phosphonites are formed also by the alcoholysis of phosphonous anhydrides[54,55], and the hydrolysis and acidolysis of neutral phosphonites[1] and phosphonoamidites[123,171].

In contrast to most classes of phosphinylidene compounds, acid phosphonites are often obtained from phosphorus(V) derivatives, for which purpose degradative reactions—hydrolysis of phosphonimidates[60], photochemical alcoholysis of phospholen oxides[177,178]—can be used. A very original method is the reduction of acid phosphonothioates with hydrogen over Raney nickel. This reaction can be used for the stereoselective formation of optically active compounds[179]:



Deselenation of phosphonoselenoates occurs similarly[180,181]. Optically active phosphonites can be obtained by stereospecific inclusion on cyclodextrans[182].

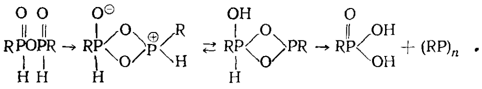
It has been proposed to obtain silicon[105,106,183], germanium[105], and antimony[184] analogues of acid phosphonites from the phosphonous acids and the corresponding hetero-organic halides. More complicated compounds of this type with additional functional groups are formed from disilyl hypophosphites and carbonyl compounds[185,186] or acrylonitrile[187]. The latter reaction apparently begins with formation of an adduct, which can then be transferred in two ways—(*a*) and (*b*):



At low temperatures the rates of reactions (*a*) and (*b*) are comparable; at high temperatures $k_a > k_b$.

(*c*) Monoamides and monohalides of phosphonous acids

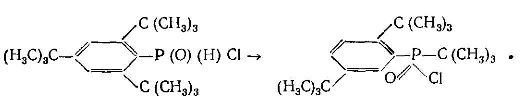
These compounds have been very little studied. The monoamides can be obtained by partial hydrolysis[171] or by acidolysis[131] of the full amides. The latter reaction is usually complicated by anhydridisation[131]; the resulting anhydride is unstable and disproportionates:



Phosphonous monofluorides have recently been obtained by a very simple process[188]:

$$RPCl_2 + HF + H_2O \xrightarrow{\text{ether}} RP(O)(F)H \ .$$

These compounds distil without decomposition. The corresponding chlorides are formed by acidolysis of alkyldichlorophosphines[189,190]. They are unstable and are readily dehydrochlorinated, which again emphasises the difference between chlorides and fluorides of phosphorus. 2,4,6-Tri-t-butylphenylphosphonochloridous acid exhibits its instability by isomerising[191]:



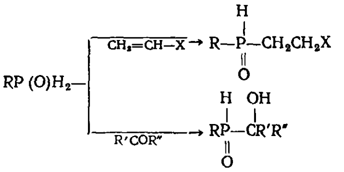
3. Phosphinous Acids

In laboratory practice it is convenient to obtain dialkyl- and diaryl-phosphinous acids from simple dialkyl phosphites and Grignard reagents[1,192,193]:

$$(C_2H_5O)_2P(O)H + 3RMgX \rightarrow R_2P\text{—}OMgX \xrightarrow{H_2O} R_2P(O)H \ .$$

Unsymmetrical phosphinous acids are formed from acid phosphonites by an analogous scheme. A stereochemically directed preparation could be achieved by using optically active phosphonites[194].

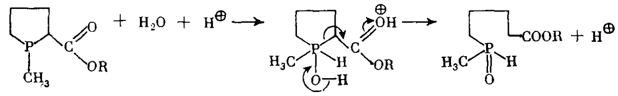
Buckler and Epstein[162] made a series of syntheses from oxides of primary phosphines together with alkenes, which might be functionally substituted, and also carbonyl compounds:



X=CN, C(O)NH$_2$.

The latter reaction has recently been extended to the preparation of phosphinous acids of the phosphan series[195].

Much research has been devoted to obtaining phosphinous acids from compounds already containing the essential molecular skeleton. Thus dimethylphosphinothious acid is hydrolysed by alkali to dimethylphosphinous acid[196]. This hydrolysis is unusual: the phosphinothioyl group in sulphides of tertiary phosphines is not converted into phosphinyl under similar conditions[196]. Thorough studies have been made of the hydrolysis of acid chlorides[60,161,197-199], anhydrides[200], esters[197,201], and amides[197] and of the thermolysis of t-butyl phosphinites[202]. The oxidation of secondary phosphines has been investigated in detail[203,204]. We can include here the acid hydrolysis of a cyclic phosphine[205]:



Other studies have been made on the preparation of phosphinous acids from phosphorus(V) derivatives. Reduction of phosphinous esters with lithium tetrahydroaluminate[194] and the desulphurisation (deselenisation) of phosphinothious (phosphinoselenous) acids with Raney nickel have been suggested; Michalski has obtained optically active products by using optically active acids[206]. Reducing processes applied to oxides of tertiary phosphines may be accompanied by rupture of a phosphorus-carbon bond[207]. α-Substituted phosphine oxides are degraded especially readily[60,208]. It is interesting that the phosphorus atom retains its configuration during their decomposition[208].

Unsymmetrical phosphinous acids have quite recently been used for fine structural investigation. Thus phenyl-s-butylphosphinous acid, which contains chiral carbon and phosphorus atoms, has been studied by n.m.r., which detected the presence of two pairs of diastereomers[209].

4. Hypophosphorous Esters and Oxides of Primary Phosphines (Phosphinyl Compounds)

Alkalyl hypophosphites were first obtained by Kabachnik et al.[210] by treating hypophosphorous acid with diazoalkanes:

$$H_2P(O)OH + RCHN_2 \rightarrow H_2P(O)OCH_2R \ .$$

These compounds have been obtained also by the action of hypophosphorous acids on orthocarbonyl compounds[211,212], neutral phosphites[213], and alcohols[214-216]. This last reaction was extended to diols[214,217] and hydroxylated polymers[101,218]. It has been shown recently that acid hypophosphites can be obtained by hydrolysis of the neutral compounds[219]. Hypophosphites, especially simple members of this group, are extremely labile and change when kept for a short time[210,213,219], but they can be stabilised by alcohols[214,219].

Monosilyl hypophosphites have been obtained by alcoholysis of the disilyl compounds and by silylation of ammonium hypophosphite with trialkylchlorosilanes[108]. Oxides of secondary phosphines can be obtained by oxidising primary phosphines with hydrogen peroxide, and also by the action of phosphine itself on carbonyl compounds[162]:

$$PH_3 + RCOR' \rightarrow [RR'C(OH)PH_2] \rightarrow RR'CHP(O)H_2 \ .$$

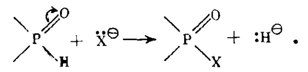
III. CHEMICAL REACTIONS

The phosphinylidene group provides a clear example of a functional group having a high and diverse reactivity. These compounds have therefore become key reagents in organophosphorus synthesis and important subjects for research on theoretical aspects of reactivity. Yet the character and the scale of development of the chemistry of phosphinylidene compounds have created the problem of a rational classification of their reactions, which are numerous and of diverse kinds. Evidently this could be most usefully based on the electronic factors determining the primary reaction step. We can then distinguish the processes indicated below.

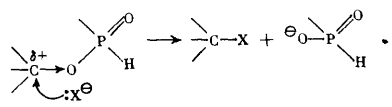
1. Acid-base equilibria and salt formation. Here we include dyadic protropy.
2. Electrophilic reactions involving an ambident anion

or the tautomeric form >P̈–OH.

3. Nucleophilic reactions occurring at the phosphorus atom bearing a partial positive charge:



Dialkyl phosphites and similar ester systems possess another centre, more open to attack by an anion:



4. Radical reactions resulting from homolysis of a phosphorus-hydrogen bond.
5. Phosphinylation, consisting in the introduction of a phosphinylidene group into the molecule of a nucleophilic compound and accompanied by loss of an anionoid group from the phosphorus. Incorporation of an amphoteric reagent at the X-P bond may be a particular case of such phosphinylation.

Unfortunately, it is not yet possible to use this scheme as a basis for the systematic arrangement of published information, since the mechanisms of many reactions have been little investigated or are altogether obscure. Furthermore, there is a large group of transformations whose initial stages are evidently related but whose subsequent stages are so different that they ultimately yield products of diverse chemical nature. Such conditions obviously justify use of a system based primarily on the mechanisms of the reactions undergone by phosphinylidene compounds but also allowing for the structure of the reaction products and other chemical circumstances. A convenient form of such an approach will be to divide the reactions into the five groups below.

1. Acid–base interactions, including tautomerism, salt formation, and complex formation.
2. Replacement of the hydrogen atom in the phosphinylidene group by a hydrocarbon radical or group.
3. Reactions not involving the phosphinylidene functional group.
4. Reactions accompanied by a decrease in the coordination number of the phosphorus atom.
5. Other reactions of phosphinylidene compounds.

This scheme does not include many widely used reactions, consisting in the replacement of groups attached to the phosphinylidene group, e.g. alcoholysis of esters, thioesters, and amides and the action of Grignard reagents on dialkyl phosphites. We have already discussed such processes in Section II, as methods for passing from one phosphinylidene compound to another.

1. Acid–Base Interactions, Salt Formation and Complex Formation

(*a*) Phosphinylidene compounds as acids and bases

Little experimental research has been done on the acidity of phosphinylidene compounds. Grayson[192] used potentiometric titration to study several arylphosphinous acids, under conditions that were not comparable for different specimens. Hammond[220] assessed the acidity of diethyl phosphite in water from results on isotope exchange‡. Moedritzer[221] showed by n.m.r. that the acidities of dibutyl phosphite and ethanol in diglyme were closely similar. These studies made in the early 1960s did not attract attention because of the disconnected and fragmentary character of the results. Systematic investigation was probably hindered by experimental difficulties and the low acidity of the compounds.

Kabachnik et al.[222] have just made a fundamental study of the acidity of dialkyl phosphites, alkyl phosphonites, and phosphinous acids by the use of transmetallation in dimethyl sulphoxide. The dissociation constants of these derivatives increase significantly in the above sequence. This work[222] is distinguished by rigorous assessment of the experimental characteristics of the proposed method and discussion of possible errors. Another recent paper[223] has described the use of potentiometric titration with sodium propoxide in propanol to study the acidity of alkylene phosphites, and has reached conclusions on the abnormally high acidity and other unexpected chemical features. Unfortunately, the account of the actual experiment is so condensed that assessment is extremely difficult. The acidity of dimethyl phosphite in its phosphorus(III) form appears unexpectedly low[225].

An unusual approach to estimating the acidity of phosphinylidene compounds is to determine J_{P-H} in the n.m.r. spectra, which depend on the *s* character of the phosphorus orbital involved in bond formation[226-228]. The acidity of dialkyl phosphites is apparent also in their interaction with trialkyl phosphites, which has been determined thermographically[229].

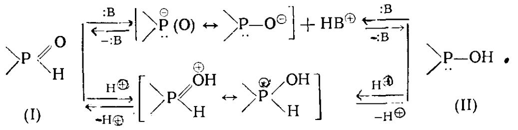
Little investigation has been made of the basicity of phosphinylidene compounds. Fluorosulphuric acid protonates dialkyl phosphites at the phosphinyl oxygen atom[230]; the process is monitored by n.m.r. Phosphinous acids are protonated considerably more readily; thus the first member of the series forms a hydrochloride stable at 50°C.[199]

Many phosphinylidene compounds form complexes with α-hydroxy-nitriles and other acidic alcohols, as is evident from the existence of azeotropes[231], and also with phenols and other compounds containing a mobile hydrogen atom[228,232-234]. The stability of the phenol complexes permits assessment of the electronic effect of substituents in the test compounds. Examination of this aspect reveals features of the various classes of phosphinylidene compounds[234]. The method enables the influence of stereochemical factors to be ascertained. Thus in six-membered cyclic phosphites the stability of complexes is determined by the orientation of the phosphoryl group. Certain judgments on the acid–base properties of dialkyl phosphites and several other phosphinylidene compounds can be based on study of the isotope effect in chemical shifts in n.m.r. spectra[40,235,236].

In connection with acid–base properties we must consider the association of phosphinylidene compounds, which depends significantly on their structure and sometimes also their stereochemistry. Dialkyl phosphites hardly associate at all[232,234]. Alkylene phosphites, in contrast, often form dimeric complexes[67,234,237,238]. It is interesting that six-membered cyclic phosphites with an equatorial phosphoryl group give more stable association complexes than do geometric isomers with an axial phosphoryl group[234]. Phosphorothiolites associate considerably more strongly than do phosphites[125].

(*b*) Tautomerism of phosphinylidene compounds

The dyadic prototropy of these derivatives, whose study constitutes one of the classic problems of organophosphorus chemistry, has been discussed in detail in several reviews and monographs[239,240]. It is catalysed by acids and bases:



Dialkyl phosphites have been the most thoroughly investigated. At equilibrium they exist almost exclusively in form (I): kinetic data on deuterium exchange indicate that the concentration of form (II) reaches ~10^{-4}%. Phosphinylidene compounds containing substituents more electronegative than alkoxyl should contain more appreciable concentrations of form (II), which probably already applies to alkylene phosphites. The infrared spectrum of 1,2-dimethylethylene phosphite contains a band due to an acidic hydroxyl[72]. Potentiometric titration indicates that the series of five- and six-membered alkylene phosphites are real prototropic systems[233]. However, the preliminary character of the above studies must be borne in mind.

Cyclic ethylene phosphorothiolite has a considerable content of form (II).[128] Dialkyl phosphorodithiolites probably contain such a large quantity of form (II) that they summetrise spontaneously into phosphorotrithiolites[24,26,125]:

$$(RS)_2P(O)H \rightleftarrows (RS)_2POH \rightarrow (RS)_3P\ .$$

---

‡Kinetic study of deuterium exchange has been used to compare the acidities of individual types of phosphinylidene compounds[194,198,224].

Bisthiocarbamoylphosphorodithiolites[241] and also phosphorodichloridous acid[24] undergo similar conversion. Phosphorodifluoridous acid is fairly stable[146]. This situation is consistent with the principles of prototropy: the aggregate electronic effect of fluorine on the polarity of the phosphorus–hydrogen bond is smaller than that of chlorine; hence the chloridous acid will have a greater content of form (II), which will undergo disproportionation.

The highest content (almost 100%) of form (II) has been found in bistrifluoromethylphosphinous acid[200]. Because of the stability of the phosphorus–carbon bond disproportionation does not take place. here. Unfortunately, synthetic investigations on fluorinated phosphinous acids are very few. Penta- and tetra-fluorinated dimethylphosphinous acids, which might be supposed to contain comparable contents of forms (I) and (II), have not yet been prepared.

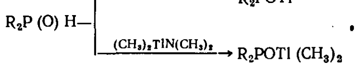
(*c*) Salt formation and complex formation

The tradition has become established in monographs and reviews on organophosphorus chemistry of not dealing separately with the preparation and properties of metal derivatives of phosphinylidene compounds, which are usually considered only as intermediate species in certain standard reactions. Interest in such derivatives, especially complexes of transition metals, has now increased sharply. Specific structural factors have been elucidated, and a catalytic effect has been detected[242-244].

The metal derivatives can be divided into salts and complexes, though the boundary is not always sharp. An alternative classification is based on the site—oxygen or phosphorus—at which the metal atoms are mainly localised. The latter scheme is adopted in the present Review.

Oxygen–metal derivatives. Alkali metals and their hydrides and alkoxides form with phosphinylidene compounds salts in which the phosphorus atom is usually three-coordinated[245]§. Salt formation is not accompanied by change in the configuration of the molecule[206,246,247]. Different phosphinylidene compounds react with metals at different rates: among the most reactive are dialkyl phosphites[206], while tetra-alkyldiamides of phosphorous acid are unreactive[248]. On treatment with Grignard reagents, however, the latter are smoothly converted into magnesium salts[193,248] having a phosphite type of structure.

Walther has prepared thallium(I) and thallium(III) derivatives of phosphinous acids[197,249,250]:



$$R_2P(O)H - \begin{cases} \xrightarrow{C_2H_5OTl} R_2POTl \\ \xrightarrow{(CH_3)_2TlN(CH_3)_2} R_2POTl(CH_3)_2 \end{cases} .$$

Titanium(IV) derivatives of these acids have been investigated¶. They were prepared not from the phosphinylidene compounds but from their ester[251] or anhydride[252] derivatives:

$$R_2POR' + TiCl_4 \rightarrow R_2P{-}OTiCl_3 .$$

Various complexes are formed by means of the phosphoryl oxygen. Thus dialkyl phosphites give interesting adducts with boron trifluoride[253].

Various physical methods have been used in a systematic investigation[254-257] of complexes with tin halides. The tendency to complex formation is determined by the structure of the ligands:

$$(RO)_2P(O)H < (RO)(R_2N)P(O)H < (R_2N)_2P(O)H \equiv R_2P(O)H .$$

Complexes of dialkyl phosphites with uranium have also been described[258]. Their structure, like that of many others, has been proved by comparing the infrared and n.m.r. spectra of the products with the corresponding spectra of the initial compounds.

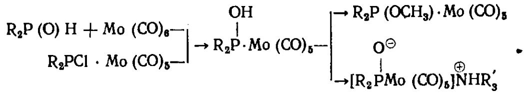
Phosphorus–metal derivatives. The *P*-mercuration of phosphinylidene compounds has been studied in detail. Biphosphinyl systems are formed by the action of mercury(II) oxide on dialkyl phosphites; if mercury halides are added to the reaction mixture, halogenomercuric derivatives separate[259,260]:

$$2(RO)_2P(O)H + HgO \rightarrow [(RO)_2P(O)]_2Hg \xrightarrow{HgX_2} 2(RO)_2P(O)HgX .$$

The structure of the products has been proved by n.m.r. and by X-ray diffraction[260,261]. Arsenation of phosphinous acids has been accomplished[249]:

$$R_2P(O)H + R'_2AsN(C_2H_5)_2 \rightarrow R_2P(O)AsR'_2 .$$

Molybdenum complexes have been obtained from the hexacarbonyl and phosphonous acids, as well as by the alkaline hydrolysis of chlorophosphine complexes of molybdenum pentacarbonyl; in these products phosphorus is attached to an acidic hydroxyl, which can be methylated with diazomethane or form salts with tertiary amines[262]:



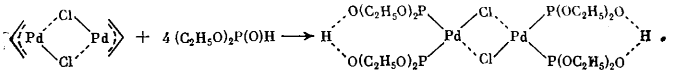
$$\left.\begin{matrix} R_2P(O)H + Mo(CO)_6 - \\ R_2PCl \cdot Mo(CO)_5 - \end{matrix}\right| \rightarrow \overset{OH}{\overset{|}{R_2P}} \cdot Mo(CO)_5 - \left|\begin{matrix} \rightarrow R_2P(OCH_3) \cdot Mo(CO)_5 \\ \rightarrow [R_2\overset{O^{\ominus}}{\overset{|}{P}}Mo(CO)_5]\overset{\oplus}{N}HR'_3 \end{matrix}\right. .$$

More complicated complexes of molybdenum with residues of dialkyl phosphites have been obtained from neutral phosphites that have undergone an Arbuzov type of rearrangement:

$$[(\pi\text{-}C_5H_5)Mo(CO)_3]_2 + P(OR)_3 \rightarrow (\pi\text{-}C_5H_5)Mo(CO)_2P(OR)_3P(O)(OR)_2 .$$

Neutral phosphonites are transformed similarly[263].

In the investigation of metal derivatives there has been a tendency during recent years to pay greater attention to elements of Group VIII. Strict structural data were first obtained by workers show showed[264] that dialkyl phosphites form complexes with simple palladium salts in which a new bond has been formed between the metal and a phosphorus atom bearing a free hydroxyl. New possibilities have since been demonstrated[243,265] for this process. Thus bis-π-allylpalladium dichloride forms a complex with diethyl phosphite in which the chloride bridges have been left undisturbed†:



The product is reduced by sodium tetrahydroborate to a mononuclear complex, which catalyses the hydrogenation of acetylenes, dienes, and aromatic nitro-compounds[243].

---

§A recent paper suggests that the bonding of sodium may be determined by the nature of the solvent. In alcohol sodium is attached to phosphorus[209].

¶Attempts to obtain complexes from dialkyl phosphites and titanium tetrachloride led to degradative reactions[254].

†The n.m.r. spectra of this and similar compounds have been studied[266].

Analogous complexes have recently been prepared from the geometric isomers of 1-methyltrimethylene phosphite. Complex formation does not affect the configuration of the phosphorus atom. The stereoisomeric complexes differ in several properties. Reduction of the primary complexes may yield new, hydride complexes, whose catalytic activity is appreciably determined by their geometry[244]. Platinum complexes are obtained similarly to those of palladium. It has been proposed to prepare them from dialkyl or diaryl phosphites, phosphinous acids[265,267,268], or phosphonites[269].

The structure of complexes obtained from cobaltocene and dialkyl phosphites has been determined by X-ray examination[270]. On treatment with an acid a complex loses one cobalt atom, which can subsequently be replaced by another metal to give a polymetallic system[270,271]. Complexes of a different type have been prepared by reaction between dimethylglyoxime derivatives of cobalt and trimethyl phosphite; the process is accompanied by demethylation of the ester and complex formation between cobalt and phosphorus[272].

It has been proposed to apply an Arbuzov type of reaction to obtain dialkyl-phosphite[273] and phosphinous[197] complexes of dicarbonylcyclopentadienyliron from the corresponding neutral esters: for example

$$(\pi\text{-}C_5H_5)\,Fe\,(CO)_2Cl + P\,(OR)_3 \rightarrow (\pi\text{-}C_5H_5)\,Fe\,(CO)_2\,[P\,(O)\,(OR)_2] + RCl\ .$$

The ruthenium complexes have the most complicated structure, and are often formed in unusual ways. Thus reaction between dodecacarbonyltriruthenium and triaryl phosphites leads initially to partial displacement of carbon monoxide; further heating of the reaction mixture is accompanied by *o*-metallation and degradation of the phosphite ligand[274,275].

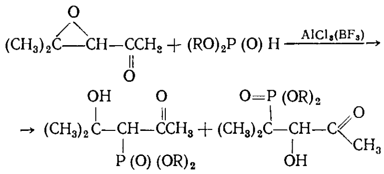
We finally note that complexes of phosphinylidene compounds are formed also by the action of diethyl phosphite on the Dewar form of tetrakistrifluoromethylthiophen, complex formation being due to isomerisation of thiophen into the usual form[276]. Complexes of dialkyl phosphites with hydrogen peroxide are also worthy of attention[277].

2. Substitution of Hydrogen Atom in Phosphinylidene Functional Group

(*a*) Electrophilic reactions

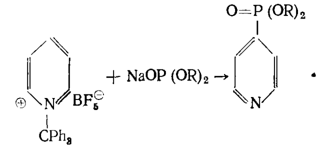
Alkylation and related processes. An important method for alkylating phosphinylidene anions is the Michaelis–Becker reaction[3]. Detailed investigation of its stereochemistry has shown that alkylation of salts of acid phosphonites[246,247] and of phosphinous acids[206] leaves the configuration at the phosphorus atom unchanged. Another group of studies of the dual reactivity of the anions has established that the direction of alkylation (at phosphorus or oxygen) may be determined by the chemical nature of the reagents[259,278] and by the solvation of the anion[279]. The influence of functional groups in the molecules on the ease of alkylation of the anions has been investigated, and in particular diaryl phosphites are found to act on α-chloro-isocyanates with remarkable ease: the reaction takes place without preliminary salt formation[280]. This has been established also for several hydroxy- and amino-benzyl systems[281–283]. Unusual conditions of alkylation apply to the use of sodium chloroacetate[284].

Special attention is merited by reactions of the Michaelis–Becker type in the presence of acid catalysts, which probably ensure regeneration of the tautomeric form of the phosphinylidene compound in which the phosphorus atom is tervalent. Moreover, these catalysts may activate also the alkylating reagents. An example is the action of dialkyl phosphites on epoxy-ketones[285]:



Study of the Michaelis–Becker reaction was initially directed mainly at the alkylating agents. In recent years investigation of the phosphorus component has developed. Thus the reaction has been extended to salts of amidic esters[286] and diamides[136,224] of phosphorous acid. Readily available magnesium salts can be used for alkylation of the latter[193], although exceptions are found[284].

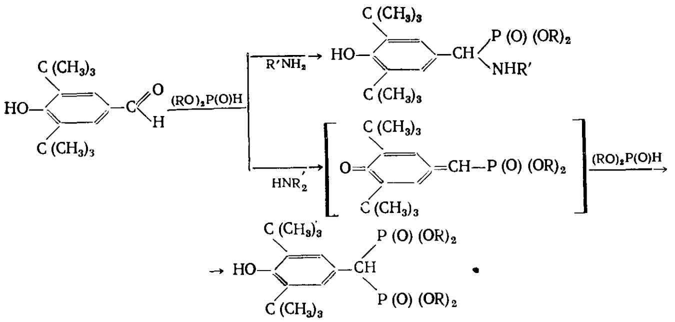
The reaction has been extended to aromatic systems. In liquid ammonia, aryl iodides react with salts of dialkyl phosphites when exposed to light of wavelength 350 nm.[287] Salts of *N*-oxides of pyridine and quinoline, as well as pyridinium salts, heteroarylate anions of dialkyl phosphites[288–290], with γ-regioselectivity observed for sterically hindered systems[290]:



The reaction between dialkyl phosphites and diazoacetic esters in the presence of copper sulphate is chemically cognate with the Michaelis–Becker reaction[34,35]. The first stage probably involves formation of a carbene, which deprotonates the phosphite, after which the classic scheme is followed.

A large number of papers have been published on α-aminoalkylation, based on a reaction discovered in the early 1950s by Kabachnik et al.[291] and described somewhat later by Fields[292]. It consists in the simultaneous or successive action of ammonia (or a primary or secondary amine) on an oxo-compound and a phosphinylidene derivative. This synthetic method, which has come to be called the Kabachnik–Fields reaction, has found widespread and diverse use. Two trends characterise its development during recent years.

The first consists in the application of many types of phosphinylidene compounds and aminoalkylating agents. Good results are obtained by working not only with dialkyl phosphites and the other usual phosphinylidene compounds but also with dialkyl phosphites containing functional groups[19,25], with polyphosphites[97], monoalkyl phosphites[31], phosphonous acids[155], phosphinous acids[293–295], phosphorous acid[296–299], hypophosphorous acid[155,300] and its esters[216], and phosphorous amides[301]. Among aminoalkylating agents that have been used are hexamethylenetetramine[302] and other cyclic amines[303], oxazolidines[304], α-amino-peroxides[305], combinations of formaldehyde with sulphonamides[306] and of indol-3-ylacetaldehyde with amines[307], etc. The reaction has been extended to hydrazinoalkylation[157]. This method has its peculiarities: thus dialkyl phosphites react with 3,5-di-t-butyl-4-hydroxybenzaldehyde and primary amines according to the general scheme, but differently with morpholine and piperidine. It is assumed that in this case a quinoid intermediate is formed, which adds a second phosphite molecule[281]:



The second trend is to use the Kabachnik–Fields reaction to solve practical problems. It has now been employed for the production of important complexones[9,10,296,297,308], pesticides[309,310], flameproofing agents[306], intermediates in the synthesis of heterocycles[391], etc. Furthermore, complicated lactam antibiotics have been synthesised from α-amino-phosphonates[303].

Definite interest attaches to the α-alkoxy- and α-alkylthio-aminoalkylation of phosphinylidene compounds[311,312]:

$$(RO)_2P(O)H + (R'X)_2CR''(NR'''_2) \rightarrow (RO)_2P(O)C\begin{cases} NR'''_2 \\ -R'' \\ XR' \end{cases}$$

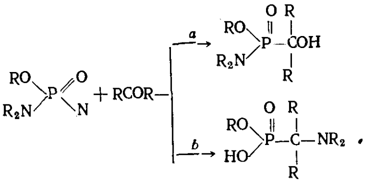
$X=O, S$.

The products react with dialkyl phosphites to give aminodiphosphonates. Phosphinous acids are immediately converted by bisdialkylaminoalkenes into aminodiphosphine oxides[311]. Acid phosphites and phosphonites react with orthoesters to form $\alpha\alpha$-dialkoxy-phosphonates and -phosphinates[313,314].

Addition to unsaturated polar compounds. The alkylation of phosphinylidene compounds by unsaturated polar compounds has proved synthetically very fruitful[2]. Conversions of this type are closely similar to the above and develop also by a carbonium mechanism.

Addition at the C=O bond. Phosphinylidene compounds undergo α-hydroxyalkylation on treatment with aldehydes and ketones. As a consequence of the work of Abramov (after whom the reaction is named) the method has been widely used. The main features‡ and the limits of applicability have now been determined, and the stereochemical direction of the reaction has been demonstrated[315]. The process usually occurs in the presence of bases, which convert the phosphinylidene compounds into the corresponding, highly nucleophilic anions. Kinetic study has shown a third-order reaction[316]. Recent results indicate[225] that addition of dimethyl phosphite at a carbonyl group in the presence of triethylamine occurs in the form $(CH_3O)_2.POH$, not as the anion $(CH_3O)_2PO^-$. Neutral phosphites as well as the usual bases can serve as catalysts[317]. Autocatalysis has been noted[201] in the addition of strongly basic phosphinylidene compounds, e.g. oxides of secondary phosphines. Bases are not employed with phosphonous acids[319]; acid catalysis probably occurs here, its role being to maintain the necessary concentration of the form of the phosphinylidene compound in which the phosphorus atom is tervalent. Acid catalysis operates also when neutral phosphinylidene compounds are used[320,321].

The Abramov reaction has been studied in greatest detail on dialkyl phosphites, partial phosphonites, and phosphinous acids[2]. Other classes of phosphinylidene compounds—diphosphites[84] and polyphosphites[88,97,322], phosphonous acids[189,300,319] and chlorides[189,323], phosphorous[324] and hypophosphorous[300] acids, alkyl dihydrogen phosphites[31,325], monoalkylphosphine oxides[162], monoalkyl hypophosphites[211,326,327], disilyl phosphites[328], phosphorodithiolites[125,128], and also diamides[241] and amidic esters[329,330] of phosphorous acid—have come to be used in recent years. With amides not only the classic reaction (*a*) but also the anomalous reaction (*b*) may occur[241,330]:



Route (*a*) is favoured by basic catalysts; reaction (*b*) occurs in their absence (further discussion of these reactions will be found below).

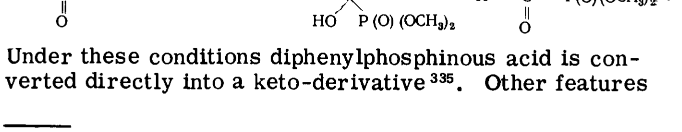
Several quantitative rules have been established for the reaction velocity: e.g. reactivity increases in the sequence

$$(RO)_2P(O)H < (RO)(R_2N)P(O)H < R_2P(O)H$$ [331].

Rates of conversion of dialkyl phosphites are hundredfold those for phosphorous acid[324].

Addition of phosphinylidene compounds to carbonyl compounds is reversible. It is often accompanied by secondary processes. α-Halogeno-carbonyl compounds with dialkyl phosphites are converted via a stage of halogenated α-hydroxy-phosphonates into enol phosphates; this reaction has been widely investigated and begun to be employed in industry[2,8]§. Rearrangement of non-halogenated hydroxy-phosphonates into phosphate systems began to be studied considerably later[2]. It is interesting that, depending on the quantity of basic catalyst present, the reaction of phosphinylidene with carbonyl compounds may or may not be accompanied by phosphonate–phosphate rearrangement[333].

Another type of rearrangement associated with the Abramov reaction is observed in the study of cyclic ketones. Thus tetraphenylcyclopentadienone and dimethyl phosphite in the presence of a tertiary amine or an alkoxide at 20°C give the hydroxycyclopentadienylphosphonate, which on further heating isomerises into a keto-phosphonate[334]:



Under these conditions diphenylphosphinous acid is converted directly into a keto-derivative[335]. Other features

---

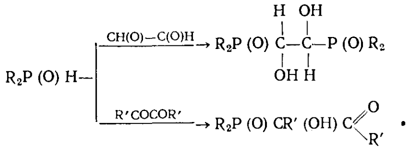
‡It must be remembered that the Abramov reaction may be accompanied by several side-processes, e.g.[318]

$$(C_6H_5)_2\dot{P}OLi + CH_3COCH_3 \rightarrow (C_6H_5)_2P(O)C(CH_3)_2CH_2COCH_3.$$

§Another type of reaction between dialkyl phosphites and α-halogenated carbonyl compounds is used in the preparation of $\alpha\beta$-epoxy-phosphonates[332].

of the reaction have been reported[336-339]. Additional complications may arise with high-temperature reactions (at 160–180°C). Thus the action of the anion of diphenylphosphinous acid on benzaldehyde and benzoylferrocene yields alkenes and their oxides[207]. Methylindanedione with dimethyl phosphite gives complicated di-indane systems[340].

The above facts do not diminish the merits of the Abramov reaction, but merely indicate how thoroughly it has been studied. During the past decade the reaction has found widespread use in the laboratory. Thus it has been applied to diverse carbonyl compounds, which has permitted development of a broad field in the chemistry of polyfunctional organophosphorus systems. Considering first the addition of phosphinylidene to dicarbonyl compounds, we note that glyoxal readily forms 1,2-diphosphinylethylene glycols with phosphinous acids, but α-diketones react differently[199]:

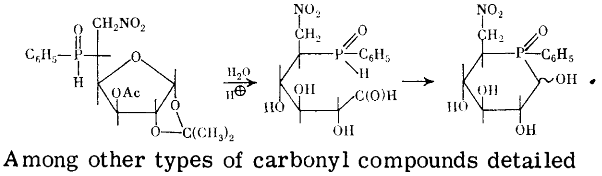


$$R_2P(O)H \xrightarrow{CH(O)-C(O)H} R_2P(O)CH(OH)-CH(OH)-P(O)R_2$$
$$R_2P(O)H \xrightarrow{R'COCOR'} R_2P(O)CR'(OH)C(=O)R' \; .$$

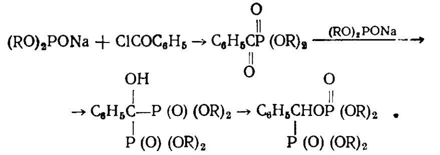
2-Methyl- and 2,2-dimethyl-indane-1,3-diones react similarly to α-diketones with dialkyl phosphites[340,341]. Several of the indane hydroxy-phosphonates obtained possess an anticonvulsant effect[341]. Pentane-2,4-dione yields 1 : 1 and 1 : 2 adducts depending on the proportions of the reactants; the latter adduct readily cyclises[342]. γ-Keto-aldehydes and γ-diketones on reaction with dialkyl phosphites and phosphinous acids give only 1,4-dihydroxytetramethylenediphosphonates (phosnin oxides).[343,344]

Reaction between dialkyl phosphites and epoxy-ketones leads to other complicated hydroxy-phosphonates[285]. Dihydroxy-phosphonates can be prepared from hydroxyketones[345]. Keto-acids and their esters have also been examined on treatment with various phosphinylidene compounds. The usual adducts are formed with temperature control[320,321], but phostones on heating[320,346]. The latter are obtained also by the action of phosphonous acids on $\alpha\beta$-unsaturated ketones[319].

During recent years the Abramov synthesis has been used in the study of carbohydrates. The reaction is applied either to the aldo-form of a monose[347-349] or to a cyclic keto-sugar[350,351]. An interesting case is the transcyclisation of an aldo-phosphonous acid[204]:

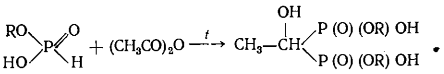


Among other types of carbonyl compounds detailed studies have been made on chlorides and anhydrides of carboxylic acids. With equimolecular proportions of the reactants and temperature control acid chlorides give α-oxo-phosphinyl derivatives on reaction with acid phosphites, phosphonites, and phosphinous acids[331,352,353]. In the presence of an excess of the phosphinylidene compound the reaction may develop further for example[352]:



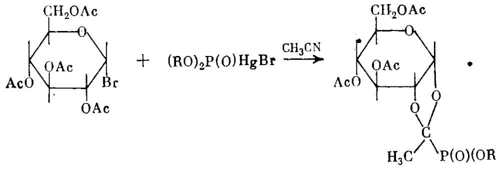
$$(RO)_2PONa + ClCOC_6H_5 \rightarrow C_6H_5C(O)P(O)(OR)_2 \xrightarrow{(RO)_2PONa}$$
$$\rightarrow C_6H_5C(OH)(P(O)(OR)_2)-P(O)(OR)_2 \rightarrow C_6H_5CH(P(O)(OR)_2)OP(O)(OR)_2 \; .$$

If excess of the acid chloride is used, it may acylate the initially formed oxo-phosphonate to a vinyl phosphonate[354]. Anhydrides of carboxylic acids react with oxides of secondary phosphines similarly to acid chlorides[355]. When anhydrides add to monoalkyl phosphites, the process develops differently, and the phosphonate–phosphate rearrangement does not occur[356][¶]:

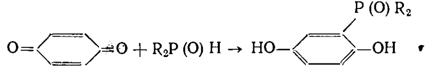


$$(RO)(HO)P(O)H + (CH_3CO)_2O \xrightarrow{t} CH_3-C(OH)H(P(O)(OR)OH)_2 \; .$$

Carboxylic esters do not usually add phosphinylidene compounds and their salts. However, Paulsen has shown[259] that tetra-*O*-acetyl-α-*D*-glucopyranosyl bromide is able to react with mercurated dialkyl phosphites:



The addition of phosphinylidene compounds to quinones has been subjected to detailed discussion. When dialkyl phosphites are used, monophosphinylated quinols are formed[358,359]. The reaction may be supposed to develop according to the classic scheme and to conclude in phosphonate–phosphate rearrangement. Hypophosphorous acid adds similarly to a quinone[115]. However, phosphinous acids behave abnormally[360,361]:



Among compounds in which the carbonyl group forms part of a cumulated system keten readily reacts with dialkyl phosphites to form α-oxo-phosphonates and their enol acetates[2]. Silylated and germylated ketens react somewhat differently with dialkyl phosphites and phosphinous acids[362]:

$$R_3ElCH{=}C{=}O + (R'O)_2P(O)H \xrightarrow{NEt_3} [R_3ElCH_2C(O)P(O)(OR')_2] \rightarrow$$
$$\rightarrow CH_2{=}C(OElR_3)P(O)(OR')_2$$
$$El = Si, Ge \; .$$

Reaction between phosphinylidene compounds and isocyanates has been studied more widely. In the presence of basic catalysts and tin derivatives dialkyl phosphites form carbamoylphosphonates[2,90,363,364]. Monoalkyl phosphites[325], acid phosphonites[365], oxides of primary phosphines[162], and magnesium[248] and silicon[366] derivatives of phosphorodiamidous acids react similarly. In the absence of bases dialkyl phosphites[367], phosphorothiolites[128], and diamides of phosphorous acid[241,248,368] may react differently, with preservation of the tervalent phosphorus atom. Under other conditions dialkyl phosphites and isocyanates give phosphoramidines[369].

Addition at the C=N bond. Phosphinylidene compounds undergo α-aminoalkylation by the action of azomethines and similar compounds. The reaction has been introduced into synthetic practice mainly by Pudovik, author of a series of experimental papers and a comprehensive

---

[¶] The action of monoalkyl phosphites on carboxylic acid anhydrides does not always produce systems in which phosphorus–carbon bonds are preserved, as is indicated by the reaction of nucleoside phosphites[357]:

$$Nucl-O-P(=O)(H)OH + (CF_3CO)_2O \rightarrow Nucl-O-P(=O)(OH)OH \; .$$

general account[2]. Investigations on the catalysis (basic and acidic) and the kinetics of the reaction have established the influence of traces of moisture on its rate and other aspects[370-372].

The addition of phosphinylidene compounds at the C=N bond has broad synthetic value. Good results are obtained not only with dialkyl phosphites, acid phosphonites, and phosphinous acid[2] but also with phosphonous acids[10], hypophosphorous acid[373], monoalkyl phosphites[325], and diamides of phosphorous acid[248,301]. Various Schiff bases have been used, including those containing functional groups[374,375], derivatives of ferrocene[376] and carbohydrates[349,377], imino-chlorides[378], acylimines[379], alkoxyimines[380], chloroacylimines[280], etc. Usually systems with additional functional groups hardly differ from simple azomethines, but in some cases complications arise. Thus salicylideneamines often give poor results on reaction with dialkyl phosphites[381], probably owing to the electronic effects of the *ortho*-hydroxyl (cf. Ref. 281).

Addition of phosphinylidene compounds to azomethines accompanied by accumulation of more than one electron-accepting group on a single carbon atom may lead to rearrangement[378,382-384]:

$$C_6H_5N{=}C\,[P(O)R_2]_2 + R_2P(O)H \rightarrow C_6H_5NHC\,[P(O)R_2]_3 \rightarrow C_6H_5\overset{\overset{\displaystyle P(O)R_2}{|}}{N}{-}CH\,[P(O)R_2]_2\,.$$

A similar rearrangement takes place also with α-amino-phosphonates, if they have first been converted into sodium or potassium (but not lithium) derivatives[385].

Interesting preparations have been based on systems containing two azomethine groups—Schiff "bisbases"[156], hydrobenzamide[386], hydrazones[387], toluene-*p*-sulphonylhydrazones[388], and azines. In the latter case acid phosphites, phosphonites, and hypophosphites form 1 : 1 and 1 : 2 adducts[387,389,390]. Individual publications on this topic, e.g. Ref. 391, are open to objection. The observed formation of α-amino-phosphonates can be explained by the benzonitrile breakdown of hydrazones obtained in the first stage:

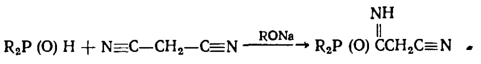
$$(C_2H_5O)_2P(O)\,CHPhNH{-}N{=}CHPh \xrightarrow{(C_2H_5O)_2PONa} \\ \rightarrow (C_2H_5O)_2P(O)\,CH(NH_2)\,Ph + PhC{\equiv}N\,.$$

Addition of phosphinylidene compounds to oximes is undoubtedly of synthetic interest. There was an indication that this reaction had been accomplished, but a later paper[392] has denied such a possibility.

Among systems containing a triple bond between carbon and nitrogen atoms aryl isocyanides react with dialkyl phosphites and phosphinous acids[380]:

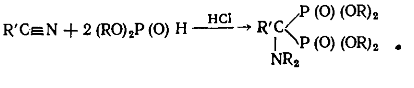
$$Ar\overset{\oplus}{N}{\equiv}\overset{\ominus}{C}{:} + {>}P(O)H \rightarrow {>}P(O)\,CH{=}NAr \xrightarrow{>P(O)H} [{>}P(O)]_2CHNHAr\,.$$

Nitriles add phosphonous acids in the presence of bases[393-396]: for example



$$R_2P(O)H + N{\equiv}C{-}CH_2{-}C{\equiv}N \xrightarrow{RONa} R_2P(O)\,\overset{\overset{\displaystyle NH}{\|}}{C}CH_2C{\equiv}N\,.$$

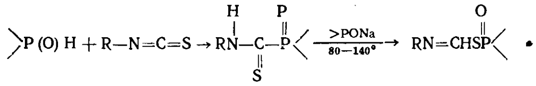
The second nitrile group is unaffected. Different assessments have been made of the possibility of the addition of dialkyl phosphites to nitriles, for a negative result[394] has been followed[397] by the positive result



$$R'C{\equiv}N + 2\,(RO)_2P(O)H \xrightarrow{HCl} R'\underset{\underset{\displaystyle NR_2}{|}}{C}\begin{matrix}{\nearrow}P(O)(OR)_2\\ {\searrow}P(O)(OR)_2\end{matrix}\,.$$

An important factor influencing the course of the reaction is acid catalysis; unfortunately, acids cause several complications, which make it difficult to assess the preparative merits of the method.

Addition at the C=S bond. Addition to isothiocyanates[2,325,398] recalls the corresponding preparation with isocyanates but differs in certain respects[366]. In several cases the addition of dialkyl phosphites and phosphinous acids to isothiocyanates concludes in rearrangement[399]:



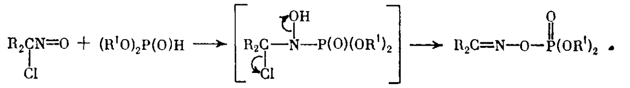
$$>P(O)H + R{-}N{=}C{=}S \rightarrow R\overset{\overset{\displaystyle H}{|}}{N}{-}\underset{\underset{\displaystyle S}{\|}}{C}{-}\overset{\overset{\displaystyle P}{\|}}{P}< \xrightarrow[80-140^\circ]{>PONa} RN{=}CHS\overset{\overset{\displaystyle O}{\|}}{P}<\,.$$

Addition to carbon disulphide[400]:

$$(RO)_2P(O)H + S{=}C{=}S \xrightarrow{NaOH} (RO)_2P(O)\,C(S)\,SNa$$

has been less investigated. The resulting salts would probably be promising for the production of organothiophosphorus compounds, including pesticides, complexing agents, oil additives, etc.

Addition at the N=O, S=O, and N=N bonds. Compounds containing these groups have been little investigated in their reactions with phosphinylidene compounds. Trifluoronitrosomethane adds to dialkyl[401] and monoalkyl[325] phosphites. If a nitroso-compound contains an α-chlorine atom, the process is more complicated[401]:



Addition at a S=O bond has been reported in the isolated examples of the reactions of dialkyl[402] and monoalkyl[325] phosphites with sulphur iminoxide. The action of dialkyl[403] and monoalkyl[325] phosphites on individual azo-compounds involves cleavage of the azo-bond.

In view of the tendency of modern chemical research to investigate complicated systems intermediate in nature between organic and inorganic we may suppose that comprehensive studies will be made in the near future on the addition of phosphinylidene compounds to unsaturated El=El′ bonds, e.g.

Addition to the C=C bond. Addition of phosphinylidene compounds at an electrophilic C=C multiple bond is a very common synthetic process[2]. During recent years especial attention has been paid to new aspects of its use. Thus the reaction has been extended to phosphinous[199,201] and phosphonous[319] acids, four-membered cyclic partial phosphonites[404], alkyl phosphorochloridites[142] and alkylphosphonous monochlorides[190], monoalkyl phosphites[325], phosphorothiolites[26], mono- and di-amides[224,286] of phosphorous acid, alkyl hypophosphites[212], and oxides of primary phosphines[162]. Rates of reaction of individual types of phosphinylidene compounds have been compared, and aspects of catalysis considered; rules already observed for addition to other electrophilic compounds are found to apply[224,405].

The range of unsaturated compounds that add phosphinylidene compounds is extremely wide—esters of unsaturated carboxylic acids[26,319]†, unsaturated heterocycles[375], nitro-compounds[406,407], fulvenes[408], allene-phosphonates[409] and other unsaturated phosphonates[410], and also 3,5-dinitrobenzoic acid[411]. Unfortunately, nitro-aromatic compounds have been little investigated in

---

†The addition of dimethyl phosphite to perfluoroacrylic esters follows an unusual course[417].

this reaction, so that the wide opportunities for arylphosphonate synthesis and analysis of phosphinylidene compounds have not yet been realised.

Attention should be directed especially at unsaturated ketones and aldehydes, which, depending on the conditions and the catalysts used, can add phosphinylidene compounds not only at the ethylenic but also at the carbonyl bond[331,340,412–416]‡. It is significant that these reactions are subject to different types of control—kinetic at the carbonyl bond, but thermodynamic at the ethylenic bond[416]. The peculiarity of the addition of phosphinous acids and phosphonites having benzyl groups attached to the phosphorus atom is noteworthy[418].

Phosphinylidene compounds add to $C{=}C{-}\ddot{X}$ systems. During recent years investigations have been made on vinyl acetate[419], glycals[420], keten acetals[313], thioketen acetals and aminals[421], and amino- and alkoxy-acetylenes[422,423]. These reactions have been examined only in general outline.

Oxidation, addition of sulphur, imination, and related processes. Oxidation. Oxidation has been studied in connection with general aspects of the reactivity of phosphinylidene compounds and extension of the possibilities of organophosphorus synthesis. Many papers and patents have been published in which these compounds are intermediates in the production of acids containing quinquevalent phosphorus, including important technical products and natural compounds.

Dialkyl phosphites are oxidised to dialkyl phosphates by treatment with nitrogen dioxide[424,425]. The reaction has been extended to alkylene polyphosphites[87] and several other types of complicated derivatives. Other suggested oxidants are aqueous potassium permanganate[426] and oxygen in the presence of copper and vanadium catalysts[427]; in the latter case oxidation is complicated by dealkylation. Simple dialkyl phosphites have been oxidised with nitric oxide[428] and with 1,3-diphenyl-1,3-dithioacetone[429].

Acid phosphonites are oxidised more readily than are the corresponding phosphites, and phosphinous acids are still more easily oxidised; oxygen[201] or hydrogen peroxide[60] can be used as oxidant. It is interesting that diferrocenylphosphinous acid is comparatively inert towards oxidation[430].

A fairly detailed study has been made of the oxidation of monoalkyl phosphites. Suggested oxidants are nitrogen dioxide[31], potassium permanganate[122], and mercury(II) chloride[117]. The oxidative phosphinylation of alcohols[431] and nucleosides[117,118,432] merits especial attention. Detailed investigations have been made on the oxidation of phosphonous acids, mainly with metal salts[433,434] but also with oxides of primary phosphines[162]. The oxidation of phosphorous amides by nitrogen dioxide involves rupture of the phosphorus–nitrogen bond[368].

Besides direct oxidation, indirect methods are often used, e.g. halogenation followed by hydrolysis. Despite the advantages of oxidation, it must be emphasised that frequently the suggested methods are not general in character. It is significant also that research is actually lacking on such current trends as catalysis on complexes, photochemistry, and in particular oxidation by singlet oxygen. Thus study of the oxidation of phosphinylidene compounds retains its urgency.

Addition of sulphur. Kabachnik et al. showed that dialkyl phosphites add sulphur in dioxan medium, and still more readily in the presence of tertiary amines[239]. Alkylene polythiophosphates[87] and cycloalkylene phosphorothioates have been prepared in this way[67,68]; retention of the configuration of the phosphorus atom has been established in the latter case. Dimethyl phosphite adds sulphur also on reaction with 1,3-diphenyl-1,3-dithioacetone[429]. Acid phosphonites also add sulphur in dioxan medium or in the presence of amines[172,435]. Retention of configuration by the phosphorus atom in this reaction has been demonstrated by the use of optically active phosphonites[180,436]. Phosphinous acids add sulphur with evolution of heat[201,430]. Phosphorous diamides[286] and amidic esters[437] react less vigorously with sulphur.

Phosphinylidene compounds add also selenium under conditions similar to the above[67,68].

Imination. The first results on this process were obtained by Kabachnik et al., who treated salts of dialkyl phosphites with diazomethane[239]:

$$(RO)_2PONa + CH_2N_2 \rightarrow (RO)_2P\langle{}^{ONa}_{N-N=CH_2} \xrightarrow{CH_3COOH} (RO)_2P(O)NH{-}N{=}CH_2 .$$

Pudovik et al.[439] have observed similar reactions between diethyl phosphite or its trialkylsilyl derivative and diazoacetic ester. The reactions of diphenyl phosphite[239] and also of trialkylsilyl derivatives of dialkyl phosphites[440] with phenyl azide can probably be included in this group. Azo-coupling occurs similarly[403,441]:

$$(RO)_2P(O)H + ArN_2^{\oplus} \rightarrow (RO)_2P(O)N{=}N{-}Ar .$$

Halogenation. Phosphorous diesters are readily converted by chlorine into phosphorochloridates. The reaction is strictly stereodirected with retention of configuration by the phosphorus atom[77,315], and has been extended to more complicated compounds, including various types of polyphosphites[85,89]. Chlorination can be effected also by sulphuryl chloride[102], chlorosuccinimide[77], and copper(II) chloride[442]. Acid phosphonites[171] and thiolic[125] and amidic[286] esters of phosphorous acid undergo similar chlorination. With monoalkyl phosphites chlorination is completed by anhydridisation; when the reaction is conducted in water, monoalkyl phosphates separate[31].

Fluorination (by means of a perchloryl fluoride)[443], bromination[33], and thiocyanation[444] of phosphinylidene compounds have been reported, but development of these processes has been slight, probably because of experimental complexity.

Todd–Atherton reaction. This reaction provides a very convenient and effective method for the oxidative phosphinylation of nucleophiles by the action of a phosphinylidene compound, tetrachloromethane (or similar halide), and a base[445]. The first stage can be written

$$\rangle P(O)H + CCl_4 + B \rightarrow \rangle P(O)Cl + HCCl_3 + HCl\cdot B .$$

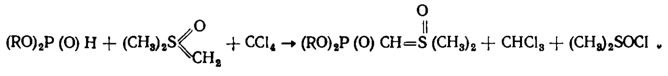
If nothing more is added to the mixture, an acid chloride is formed[240]. This process has advantages over other methods for the preparation of phosphorus acid chlorides. If, however, a nucleophile is also added to the reaction mixture, phosphinylation takes place.

The Todd–Atherton reaction has been applied not only to simple dialkyl phosphites but also to hydroxyalkyl and other functionally substituted phosphites[19,25,45,66], diphosphites[446], polyphosphites[97,102], acid phosphonites[181,447,448], diphosphinites[170], phosphonous acids[449,450], amides of

---

‡See also the comments on quinones and cyclic ketones in the above paragraphs on the C=O system.

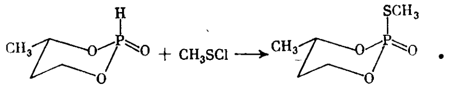
phosphorous acid[138,139,446], monoalkyl phosphites[33], and hypophosphorous acid[450] and esters[215,217]. The popularity of the reaction is due also to the wide range of nucleophiles used—alcohols and phenols[45,451], water[450], amines, which may be functionally substituted and heterocyclic[19,138,446,452], esters of amino-acids[453], hydroxylamine[454], oximes[455], silyl vinyl ethers[456], oxiran[448], etc. An unusual and interesting process is the *C*-phosphinylation of dimethylsulphoxonium methylenylide[457]:



$$(RO)_2P(O)H + (CH_3)_2S\begin{smallmatrix}\nearrow O\\ \searrow CH_2\end{smallmatrix} + CCl_4 \rightarrow (RO)_2P(O)CH{=}\overset{\overset{O}{\|}}{S}(CH_3)_2 + CHCl_3 + (CH_3)_2SOCl\ .$$

Zwierzak has recently begun to study the Todd–Atherton reaction in a two-phase system with quaternary ammonium salts as catalysts[458]. This variant of the reaction has great advantages for preparative purposes and shows promise for industrial application.

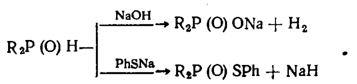
Thiolation. Phosphinylidene compounds are converted into thiolophosphoric esters by the action of organic sulphenyl chlorides, thiocyanates, and disulphides and of sulphenamides. The configuration of the phosphorus atom is preserved during thiolation: for example[459]



The reaction is of general value, and applies to acid phosphites[88,460], acid phosphonites[435], phosphinous acids[192], and monoalkyl phosphites[113]. Among the latter have been investigated nucleoside phosphites, which with diphenyl sulphide give nucleoside phosphorothiolates, of interest as reagents for producing an internucleotide bond. When disulphides are used, the composition of the reaction mixture must always be strictly controlled, the possibility of a secondary process being taken into account[461].

(*b*) Nucleophilic reactions

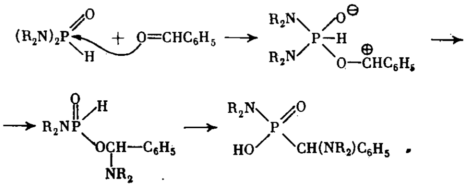
It is unlikely that a general reaction with nucleophiles will be discovered for phosphinylidene compounds. Indeed, when these compounds are esters, bifurcation occurs: both the phosphorus atom and the ester carbon atom are attacked, leading to dealkylation in the latter case. Attack on phosphorus by a nucleophile containing mobile hydrogen involves preferential displacement not of hydrogen but of an alkoxide ion: i.e. phosphinylation will occur without significant change in the nature of the phosphorus compound. When amidic or thiolic phosphinylidene compounds are used, phosphinylation of a nucleophile containing mobile hydrogen will become still more dominant. The best compounds for the investigation of nucleophilic hydrogen substitution are thus phosphinous acids[360]:



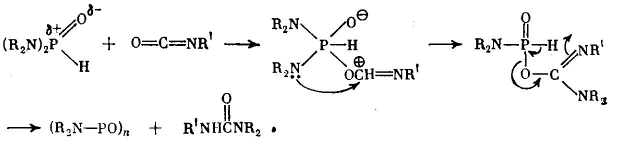
$$R_2P(O)H - \left| \begin{array}{l} \xrightarrow{NaOH} R_2P(O)ONa + H_2 \\ \xrightarrow{PhSNa} R_2P(O)SPh + NaH \end{array} \right. .$$

The reaction with alkali was subsequently extended to other compounds[462,463].

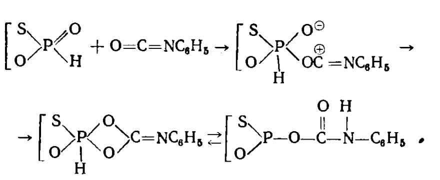
Certain complicated reactions between amides of phosphorous acid and carbonyl compounds probably begin with nucleophilic attack on the phosphorus atom: for example[241]



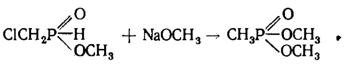
Although not all aspects of this reaction have yet been studied, an intermediate incorporation stage has already been established by nuclear magnetic resonance. The possibility of the incorporation of two molecules of the carbonyl compound has also been demonstrated[241,368]. The reaction of amides of phosphorous acid with isocyanates obviously involves a similar transformation, which has an unusual conclusion[241,248,368]:



Incorporation of carbon disulphide at a phosphorus–nitrogen bond may be supposed to develop similarly[241]. The "anomalous" action of phenyl isocyanate on ethylene phosphorothioite[128] and dimethyl phosphite[367] is more problematic, but even here the first stage probably consists in nucleophilic attack by oxygen on phosphorus:



The interaction of α-substituted phosphonous acids[464] and their partial esters[465] with nucleophiles is probably of the same type: for example



$$ClCH_2P\begin{smallmatrix}\nearrow O\\ \leftarrow H\\ \searrow OCH_3\end{smallmatrix} + NaOCH_3 \rightarrow CH_3P\begin{smallmatrix}\nearrow O\\ \leftarrow OCH_3\\ \searrow OCH_3\end{smallmatrix}\ .$$

Such reactions have no general significance: chloromethylphosphonous acid reacts with ammonia to give aminomethylphosphonous acid[466].

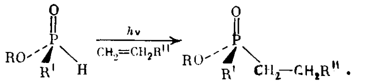
On the whole the action of nucleophiles on phosphinylidene compounds has been little investigated. Papers have been concerned mainly with the preparative aspect, while the chemistry of the processes has been discussed seldom and usually only speculatively. Nevertheless, what has been done is very valuable, since it relieves us of a certain monotony in the development of the chemistry of phosphinylidene compounds and opens up great prospects for synthetic work.

(*c*) Radical reactions

The ever increasing interest taken in radical processes in organic chemistry is evident also in the present field. The most systematic study has been made of the addition of phosphinylidene compounds to alkenes. Features and possibilities of this reaction have been surveyed in a recent monograph[467], so that here we shall consider only fundamental papers and also the most recent publications.

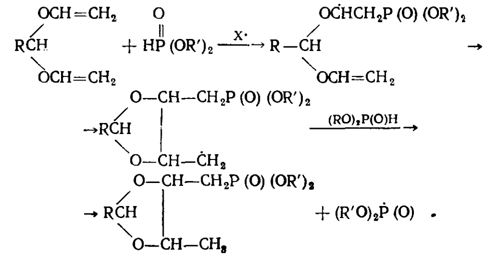
In the addition of phosphinylidene compounds to alkenes radicals can be generated by chemical[468,469], photochemical[470], or radiation-chemical[471-473] methods:

The structure of phosphoranyl radicals has been clarified in the course of a recently concluded controversy[468,469,471]. The resulting radicals are able to preserve the configuration of the initial phosphinylidene compounds, which enables optically active organophosphorus compounds to be synthesised[436]:



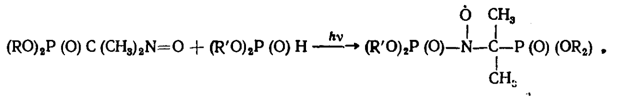
The ideas of dynamic stereochemistry have been extended to other aspects of radical addition. Thus it has been found that the conformational state of the original phosphinylidene compound governs its reactivity[468].

Synthetic investigations have been widely developed. Alkyl hypophosphites have also been brought into reaction with alkenes; under the given conditions addition occurred only once[215]. In the early work homolytic addition was applied almost exclusively to alkenes, but subsequently perfluoroalkenes[474], unsaturated heterocycles[470,475], allylic derivatives of heterochain polymers[152], etc. have been used. Diene systems exhibit noteworthy behaviour: for example[199,476]:



Cyclisation is akin to telomerisation[478] and the radical rearrangements observed in the addition of dialkyl phosphites to certain terpenes[477].

Under the conditions of radical reactions phosphinylidene compounds are able to phosphinylate aromatic compounds[479] and add to acetylene in the presence of transition-metal complexes as catalysts[480]. Homolytic addition is especially interesting in cases in which the heterolytic process cannot be accomplished, as in the recently discovered reactions with nitroso-compounds[481,482], nitro-compounds[483], and oximes[483]: for example



$$(RO)_2P(O)C(CH_3)_2N{=}O + (R'O)_2P(O)H \xrightarrow{h\nu} (R'O)_2P(O){-}\underset{\dot{O}}{N}{-}C(CH_3)_2{-}P(O)(OR_2)\ .$$

3. Reactions Not Involving the Phosphinylidene Functional Group

Phosphinylidene compounds in which the phosphorus atom is attached to electron-accepting groups are widely used in phosphinylation, e.g. in transesterification. The possibilities and peculiarities of such reactions have already been discussed in Section II. A somewhat related process is disproportionation, i.e. exchange of substituents at the central functional group. Thus unsymmetrical dialkyl phosphites give two new symmetrical esters even on storage[18], and this process may be reversed[484]:

More complicated cases of disproportionation involve the cyclisation of diphosphites[83] and the oligomerisation of alkylene phosphites[71,74]. The mechanism of disproportionation has not been investigated; it is most likely catalysed by traces of alcohols or other compounds having a mobile hydrogen atom and capable of forming labile adducts with phosphinylidene compounds.

A second type of reaction is exemplified by dealkylation of the esters, which has been studied almost exclusively on dialkyl phosphites. The kinetics and the mechanism have now been studied under conditions of acid and alkaline hydrolysis[485] and treatment with metal salts[116,486]. Dealkylation of dialkyl phosphites is used in the preparation of monoalkyl phosphites (Section II), which include products of practical importance[487]. Isolated results have appeared on the dealkylation of partial phosphonites[488], which resemble dialkyl phosphites in this respect.

4. Reactions with Decrease in Coordination of Phosphorus

Reactions in which phosphinyl (phosphinothioyl, phosphinimidyl) groups are formed are usually preferable in the chemistry of organophosphorus compounds. Especial interest therefore attaches to the opposite reactions, which have been studied in greatest detail for phosphinylidene compounds.

Treatment of phosphonous and phosphinous acids with phosphorus trichloride gives the corresponding acid chlorides[149,489]:

$$(C_6H_5)_2P(O)H + PCl_3 \rightarrow \left[(C_6H_5)_2\underset{H}{\overset{\oplus}{P}}{-}OPCl_2Cl^{\ominus}\right] \rightarrow (C_6H_5)_2PCl + [HOPCl_2]\ .$$

Alkylene phosphites react similarly with the trichloride[490], and also dialkyl phosphites and other phosphinylidene compounds with dialkyl phosphorochloridites[141,491,492]: for example

$$(RO)_2P(O)H + (R'O)_2PCl \rightleftarrows (RO)_2PCl + (R'O)_2P(O)H\ .$$

The equilibrium can be displaced by distilling off the volatile product.

The reactions usually begin with formation of pyrophosphites or other similar anhydride systems; the hydrogen chloride liberated then degrades the primary product in conformity with an Arbuzov reaction, forming either the initial or new products. If reaction occurs in the presence of a base, the anhydride can be isolated[141,491]. Anhydrides can be obtained also by several related methods[491,493]. It is very important that phosphinylidene compounds (or their salts) can be phosphinylated not only at oxygen but also at phosphorus[141,491]§: for example

$$PCl_3 + 3\,(RO)_2P(O)H \xrightarrow{C_5H_5N} P\,[P(O)(OR)_2]_3\ .$$

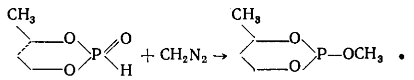
P-Phosphinylation occurs also when phosphinous acids are treated with acetic anhydride[494] or silicon tetrachloride[495]. In most cases chlorosilanes[496,497], like silylamines[133,498,499] give with phosphinylidene compounds silyl

---

§ In some cases the direction of phosphinylation is determined by steric factors[491].

phosphites. The latter are of great interest, e.g. in the chemistry of nucleic acids[497]. Phosphonous acids react similarly with silylating reagents[106,187,500]; intramolecular silylation is possible here[187].

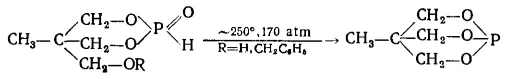
Reaction with aliphatic diazo-compounds was first studied on 1-methyltrimethylene phosphite treated with diazomethane and compounds containing mobile hydrogen as catalysts[446]:



Fresh examples of this reaction have recently been given[501] with discussion of further reactions in the system comprising cyclic phosphite and diazo-compound. The reaction of 3-hydroxy-2.2-dimethylpropyl hypophosphite with diazomethane to yield the cyclic neutral 2,2-dimethyltrimethylene hypophosphite is of fundamental interest[217].

The ready intramolecular *O*-alkylation of bis-2-chloroethyl phosphite[502]

is noteworthy. The cyclisation[42,503]

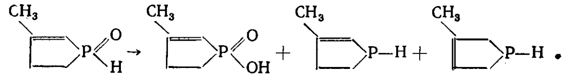


can be regarded as of the same type. One factor governing these not altogether usual transformations is evidently preferential formation of cyclic and bicyclic phosphite structures.

Several other reactions involving a decrease in the coordination number of the phosphorus atom have been considered above.

5. Other Reactions of Phosphinylidene Compounds

Investigations of the redox disproportionation of phosphinylidene compounds, begun earlier[240], have been continued during recent years. New cases of disproportionation have been found, concluding in peculiar chemical phenomena, e.g. isomerisation of one of the products[202]:

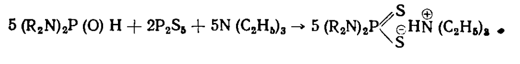


Studies have begun on the disproportionation of alkyl hypophosphites[213,327] and pyrophosphonous acids[504]. A distinguishing feature of this work is clarification of the destiny of the phosphorus intermediates; phosphenes $R\ddot{P}$ have been examined in greatest detail—the rules of their oligomerisation and other transformations.

Phosphorus pentasulphide may convert phosphinylidene compounds into phosphinothioylidene derivatives:

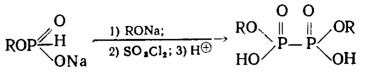
$$>P(O)H + P_2S_5 \rightarrow >P(=S)H \; .$$

The replacement of oxygen by sulphur involves no significant change in configuration of the phosphorus residue[179]. When amides of phosphorous acid are used, products containing two sulphur atoms are formed[505]:



$$5\,(R_2N)_2P(O)H + 2P_2S_5 + 5N(C_2H_5)_3 \rightarrow 5\,(R_2N)_2P(=S)S^{\ominus}\,\overset{\oplus}{H}N(C_2H_5)_3 \; .$$

An unusual reaction for phosphinylidene compounds occurs[506] when salts of monoalkyl phosphites are treated successively with an alkoxide, sulphuryl chloride, and an acid to give acid hypophosphites:



In conclusion it may be noted that the chemistry of phosphinylidene compounds, established as early as the nineteenth century, continues its successful development. One reason for such "longevity" is the appearance of fertile trends, such as steric regulation of reactions and investigation of the structure and catalytic properties of metal derivatives. At the same time the classic problems are acquiring a fresh interpretation and development by the application of modern physical methods and theoretical views. As a consequence these problems are beginning to interlock with new trends, which holds promise for further development in this field of chemistry.

Combined Inhibition of Cholinesterases by Organophosphorus Compounds

A.P.Brestkin and N.N.Godovikov

The review is devoted to studies on the combined inhibition of the catalytic activity of cholinesterases by organophosphorus compounds. This type of inhibition depends significantly on the presence of hydrophobic substituents in the organophosphorus molecule. It is suggested that there is a possibility of "concerted" or "non-concerted" sorption of the hydrophobic groups of the inhibitor on the hydrophobic regions in the vicinity of the anionic and esterase sites on the active surfaces of cholinesterases. These effects apparently determine the nature of the inhibition of cholinesterases.
The bibliography includes 44 references.

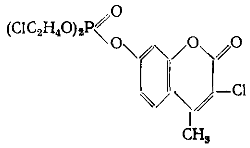
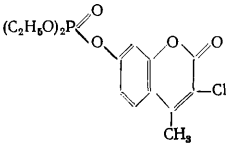
I. INTRODUCTION

The esters of phosphorus(V) acids, which exhibit a phosphorylating capacity, are known to be capable of inhibiting cholinesterases—vitally important enzymes which regulate the transmission of nerve excitation from the nerve to the innervated cell. Until recently it was believed that organophosphorus compounds are capable of only irreversible inhibition of cholinesterases by phosphorylating the serine hydroxyl, which forms part of the esterase centre in these enzymes. However, in 1969, Aldridge and Reiner[1] observed in experiments with coumarinyl phosphates (I) and (II) two types of inhibition of the catalytic activity of acetylcholinesterase (ACE) of bovine erythrocytes: (a) irreversible inhibition progressing in the course of time, and caused by the phosphorylation of the active centre of the enzyme; (b) reversible inhibition established instantaneously and non-progressive. According to the authors[1], the latter type of inhibition is associated with the interaction of the organophosphorus inhibitor (OPI) with the section of the active surface of the enzyme responsible for the inhibition of the activity of ACE by the excess of substrate.

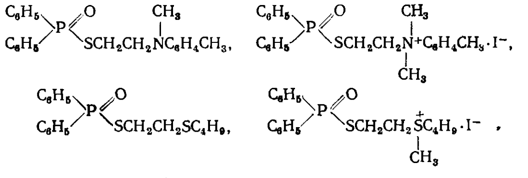


(I)



(II)

In 1971, a similar complex type of inhibition of catalytic activity was observed by Kabachnik and coworkers for another enzyme—butyrylcholinesterase (BuCE) of horse blood serum, in experiments with certain diphenylphosphinothiate esters:



Since inhibition of activity by the excess of substrate is not characteristic of BuCE, the authors[2] explained the presence of the reversible component in the enzyme inhibition by the possibility of the "non-productive" sorption of the inhibitor on the active surface of the enzyme (E), which does not entail the orientation of the inhibitor on the active surface of BuCE favourable for the phosphyrylation of the serine hydroxyl. The authors suggested that the enzyme–inhibitor complex (EI_r) formed is incapable of subsequent conversion into the phosphorylated enzyme (EIn′), in contrast to the usual Michaelis type complex (EIn): it is analogous to the enzyme–inhibitor complex obtained when cholinesterases are acted upon by reversible inhibitors, for example tetralkylammonium ions†. In other words, instead of the usual phosphorylation mechanism

$$E + In \rightleftarrows EIn \xrightarrow{k_2} EIn' ,$$

the following mechanism has been proposed for this complex and so-called combined type of inhibition[2]:

$$E + In - \begin{cases} \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} EIn \xrightarrow{k_2} EIn' \\ \overset{K_{i,r}}{\rightleftarrows} EI_r \end{cases} ,$$

where k_1, k_{-1}, and k_2 are the rate constants for the corresponding reaction stages and $K_{i,r}$ is the equilibrium dissociation constant of the "non-productive" complex EI_r.

Combined inhibition is manifested primarily by the fact that, with increase of the inhibitor concentration [In], there is a significant decrease of the experimental bimolecular rate constant for the phosphorylation of the enzyme k_{II}, which is calculated from the equation

$$k_{II} = \frac{1}{[In]\,t} \ln (v_0/v_t),$$

where v_0 is the rate of the enzymatic hydrolysis of the substrate in the absence of the inhibitor and v_t the rate (after t min) of incubation of the enzyme with the inhibitor S, the concentration of which is many times greater than

---

† The extensive experimental data available at the present time permit the hypothesis that the complex EI_r does not differ significantly from the complex EIn, and may consist of a section of the enzyme–inhibitor complex which does not enter into the enzyme phosphorylation reaction. We shall therefore henceforth regard the complex EI_r as "non-productive" and the complex EIn as "productive".

the enzyme concentration. Reversible inhibition by these compounds is manifested both in the phosphorylation of the enzyme, where it is estimated in terms of the equilibrium inhibitor constant $K_{i,r}$, and in the enzymatic hydrolysis of the substrate (acetylcholine), where it is estimated in terms of the constant $K_{i,S}$.

The most reliable parameter of the combined inhibition is the decrease of the catalytic activity of the enzyme when $t \to 0$.

In order to calculate the rate constants for the irreversible inhibition of BuCE and ACE and of the equilibrium constants $K_{i,S}$ and $K_{i,r}$, the following equations were used[2]:

$$k = \frac{1}{[\mathrm{In}]\, t}\left(\ln\frac{v_0}{v_t} - \ln\frac{v_0}{v_{0,i}}\right),$$

where k is the experimental bimolecular rate constant for the given value of t, and $v_{0,i}$ the rate of the enzymatic hydrolysis of acetylcholine in the presence of the inhibitor at zero time of the incubation with the enzyme:

$$K_{i,S} = \frac{K_m}{(K_m + [S])[v_0/(v_{0,i} - 1)]},$$

where K_m is the Michaelis constant and [S] the substrate concentration. The true bimolecular rate constant k_a, which is independent of the inhibitor concentration, and the inhibitor constant $K_{i,r}$ were determined graphically from the values of k for different [In] using the relation

$$k = \frac{k_a}{1 + K_{i,r}}.$$

A study of the kinetics of the interaction of BuCE with diphenylphosphinothioate esters[2] yielded data in good agreement with mechanism (2) and the equations which followed from it. This first study initiated a detailed investigation of the relation between the chemical nature of OPI and their ability to inhibit cholinesterases via the combined mechanism.

Preparations of butyrylcholinesterase (BuCE, CE 3.1.1.3) from horse blood serum and of acetylcholinesterase (ACE, CE 3.1.1.7) from human blood erythrocytes were used. The enzyme activities were determined from the rate of hydrolysis of acetylcholine chloride or acetylcholine iodide (AX).

The rate of hydrolysis of AC under the influence of BuCE and ACE were determined by potentiometric titration of the acetic acid formed in the reaction at a constant pH (7.5 or 7.8) using pH-meters with glass electrodes[3,4]. In the study of the inhibition of the catalytic activity of cholinesterases by purely reversible inhibitors, the inhibitor constants K_i were determined by a graphical method[5]. The results of these studies are described in the present review.

II. INTERACTION OF CHOLINESTERASES WITH DIPHENYLPHOSPHINOTHIOATE ESTERS

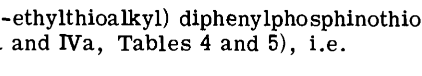
As stated above, Kabachnik and coworkers[2] investigated the inhibition of BuCE by certain diphenylphosphinothioate esters (Table 1).

The phosphinothioates investigated proved to be strong inhibitors of BuCE with a combined activity. The bimolecular irreversible inhibition rate constants obtained for them are close to the values for the analogous *OO*-diethyl *S*-alkylphosphorothioates and *O*-ethyl *S*-alkyl methylphosphonothioates[6,7]. In terms of their reversible activity, they are greatly superior to typical reversible inhibitors such as tetra-alkylammonium ions[8]. The inhibitor constants of the phosphinothioates are smaller approximately by an order of magnitude than the values of K_i for their oxygen analogues, which are also powerful but only reversible inhibitors (Table 1). Thus both phosphinothioates and their oxygen analogues are capable of forming very stable enzyme–inhibitor complexes, probably because of the presence in their composition of two or three phenyl groups, which greatly intensify the hydrophobic interaction of OPI with BuCE, the latter having comparatively large hydrophobic regions in the vicinity of both the anionic and the esterase sites[9-11].

The reversible inhibition by the phosphinothioates investigated is of a competitive type, as shown by the constancy of $K_{i,S}$ calculated by Eqn.(14) for different [In] and by the direct proportionality between $1/k$ and [In]. When [S] is reduced by a factor of 20 for a given [In], the slope remains the same (Fig.1), but the intercept *b* diminishes, i.e. the substrate exhibits a protective function in relation to the reversible inhibition of the enzyme, which is again characteristic of competitive inhibition.

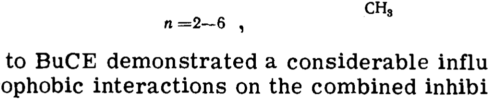
There is a definite relation between the phosphorylation rate constants k_a and the equilibrium dissociation constants of reversible enzyme–inhibitor complexes ($K_{i,S}$ and $K_{i,r}$): the higher the value of k_a, the lower the constants $K_{i,S}$ and $K_{i,r}$, i.e. the more stable are the complexes. Inhibitors with cationic groups have higher values of k_a and lower values of $K_{i,S}$ and $K_{i,r}$ than "uncharged" compounds.

The data obtained in the study of the inhibiting activity of *S*-(β-alkylthioethyl) diphenylphosphinothioates and their methiodides[12,13] (series Ia and IIa, Tables 2 and 3), i.e.



$R = CH_3—C_6H_{13}$,

as well as *S*-(ω-ethylthioalkyl) diphenylphosphinothioates[14,15] (series IIIa and IVa, Tables 4 and 5), i.e.



$n = 2—6$,

in relation to BuCE demonstrated a considerable influence of the hydrophobic interactions on the combined inhibition. It follows from Tables 2 and 3 that, with increase of the length of the alkyl group attached to sulphide or sulphonium sulphur (series Ia and IIa), a continuous increase of both irreversible (increase of k_a) and reversible (decrease of $K_{i,S}$ and $K_{i,r}$) inhibition of the catalytic activity of BuCE is observed[13]. An analogous increase of inhibition with increase of the distance between the phosphorus and sulphide or sulphonium sulphur atoms in compounds of series IIIa and VIa (Tables 4 and 5) has also been noted[15]. A characteristic feature is that, with increase of the P–S distance, the irreversible inhibition hardly changes (series IIIa, Table 5) or diminishes, particularly at the beginning as n increases from 2 to 3 (Table 5).

It follows from the results that the equilibrium constants $K_{i,S}$ and $K_{i,r}$ do indeed characterise the formation of a "non-productive" enzyme–inhibitor complex EIr, different from the Michaelis complex EIn which is rapidly converted into the phosphorylated enzyme EIn'. This has been shown most convincingly by the results of experiments on compounds in series IVa: with increase of n, there is an appreciable increase of the sorbability of the inhibitor, but at the same time the conditions for the formation of the "productive" complex are impaired owing to the increasing incompatibility of the distance between the phosphorus and sulphonium sulphur atoms in the inhibitor molecule and the distance between the esterase and anionic sites of the catalytic centre of the enzyme[15]. The influence of this incompatibility on the irreversible inhibition has been thoroughly investigated for the compounds $CH_3(C_2H_5O)P(O)S(CH_2)_nC_2H_5$ and their methosulphates[16].

Table 5. Constants for the inhibition of BuCE by the compounds $(C_6H_5)_2P(O)S(CH_2)_n\overset{+}{S}(CH_3)C_2H_5.I^-$ (series (IVa) and $(C_6H_5)_2P(O)O(CH_2)_n\overset{+}{S}(CH_3)C_2H_5.I^-$ (series IVb).[15]

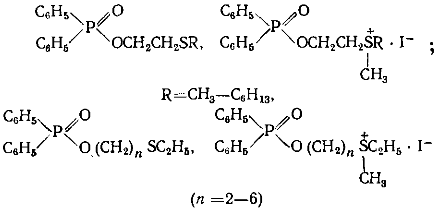
The observed enhancement of the sorbability of the inhibitors on the active surface of BuCE with increase of the size of the alkyl group attached to the sulphide or sulphonium sulphur in compounds of series Ia and IIa and with increase in the length of the polymethylene chain in compounds of series IIIa and IVa takes place owing to the improvement of the binding of the diphenylphosphinothioates to the esterase site of BuCE. Evidently it is caused by the enhanced interaction of the inhibitor with the enzyme near the anionic site. A characteristic feature is that the changes in $K_{i,S}$ and $K_{i,r}$ are in all cases correlated with the change in the K_i for the corresponding oxygen analogues[13,15]:



R=CH$_3$—C$_6$H$_{13}$,

(n =2—6)

(series Ib, IIb, IIIb, and IVb, Tables 2–5), which indicates the reliability of the results.

The study of the anticholinesterase activity of diphenylphosphinothioate thioesters[17,18] (series V, Table 6), i.e.

R=$CH_3C_6H_{13}$; iso-C_3H_7, iso-C_4H_9, or iso-C_5H_{11}

showed that these compounds inhibit cholinesterases via the combined mechanism. Both the reversible and irreversible inhibiting activities depend on the length and degree of branching of the alkylthio-group. Thus, when straight-chain alkyl substituents in the alkylthio-groups are displaced by branched substituents, a sharp decrease of both the irreversible and reversible anticholinesterase activities is observed in relation to ACE.[17] In experiments with BuCE [18] such replacement actually increases the inhibiting activity of the compounds (Table 6). Therefore compounds with straight-chain substituents inhibit ACE more strongly [k_a(ACE)/k_a(BuCE) > 1], while compounds with branched substituents inhibit BuCE more strongly [k_a(ACE)/k_a(BuCE) < 1].

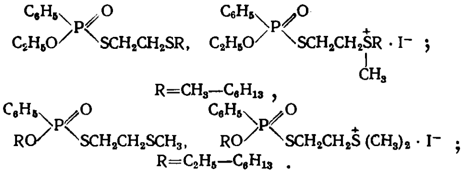
It follows from these results that the enhancement of the hydrophobic sorption of inhibitors on the active surfaces of cholinesterases via the alkylthio-groups increases the anticholinesterase activity of OPI of the types investigated only when the given effect is consistent with the hydrophobic sorption of phenyl groups on the hydrophobic regions located near the esterase site of the enzyme, i.e. when the increase of the activity of the OPI does not impair the "productive" sorption of the inhibitor on the active surface of the enzyme. If the impairment occurs, then, instead of an increase, a decrease of the anticholinesterase activity should take place owing to the "non-productive" sorption, which occurs when ACE interacts with OPI having branched alkylthio-groups[17].

On the whole the result of experiments with diphenylphosphenothioate esters confirm the existing ideas concerning the "productive" and "non-productive" sorption developed to explain the causes of the selective catalytic activity of chymotrypsin[19,20] and cholinesterases[21,22].

III. REACTIONS OF CHOLINESTERASES WITH PHENYLPHOSPHONOTHIOATE, CYCLOHEXYLPHOSPHONOTHIOATE, AND BENZYLPHOSPHONOTHIOATE THIOESTERS

In order to investigate the influence of hydrophobic sorption on the manifestation of combined inhibition by OPI, various phenylphosphonothioate esters were synthesised and their anticholinesterase activity was investigated[23,24]:



These compounds differ from those discussed above by the fact that they contain a straight-chain alkoxy-group at the phosphorus atom instead of the bulky phenyl group (Tables 7 and 8).

Table 7. Constants ($10^{-4}k_{II}$, litre mole^{-1} min^{-1}) for the inhibition of cholinesterases by the compounds $C_6H_5(C_2H_5O)P(O)SCH_2CH_2SR$ (series VI).[25]

C_2H_5	7.6	1.8	C_5H_{11}	12	6.5
C_3H_7	11	5.4	C_6H_{13}	14	3.7

The replacement of one phenyl group in compounds of series Ia and IIa by an alkoxy-group led to a sharp alteration of the nature of the inhibition of ACE and BuCE. In contrast to the analogous diphenylphosphinothioate esters, *O*-ethyl phenylphosphonothioates of both sulphide (series VI, Table 7) and sulphonium (series VII, Table 8) types cause only the irreversible inhibition of cholinesterases[25]. The $\lg(v_0/v_t)-t$ linear plots for these substances pass through the origin of coordinates. Furthermore, the values of k found are almost independent of the concentration of the inhibitors. The absence of reversible inhibition indicates a complementarity between the compounds and the active centre of the enzyme such that "non-productive" sorption is either completely absent or is so weak that it cannot be recorded with the aid of the methods described.

Thus, when the alkylthio-group, which may be sorbed on the hydrophobic region near the anionic site, became sufficiently elongated, the combined type of inhibition could not be detected either for ACE or for BuCE.

Next an attempt was made to find inhibitors of the combined type among compounds analogous to those discussed above but having alkoxy-groups of different lengths, capable of being sorbed on the hydrophobic regions near the esterase centre. *O*-Alkyl *S*-(β-methylthioethyl) phenylphosphonothioates (series VIII, Table 9) and their methiodides (series IX, Table 10) were selected as compounds of this kind[26]. In experiments with BuCE combined inhibition was observed for compounds with long alkoxy-groups (C_5H_{11}, C_6H_{13}). For compounds with short alkoxy-groups, only irreversible inhibition was observed[26]. In the experiments with ACE the reversible component was shown only for the last two compounds of the sulphide type (series VIII, Table 9). Substances of the sulphonium type (series (IX) showed only irreversible inhibition (Table 10), which permitted the conclusion that in the case of ACE an increase of the tendency of the inhibitor towards hydrophobic sorption on the active surface of the enzyme, both near the anionic and esterase sites, is not accompanied by the formation of a "non-productive" enzyme–inhibitor complex, as in the case of BuCE.[26]

In the study of the anticholinesterase activity of phenylphosphonothioate thioesters without any polar substituents in the alkylthio-group,

R=CH_3—C_6H_{13} ,

(series X, Table 11) the eliminated part of the CPI molecule was found to influence the nature of the anticholinesterase activity[27]. In contrast to *O*-ethyl *S*-(*β*-alkylthioethyl) phenylphosphonothioates and their methiodides (series VI–IX), all the compounds of this series inhibited ACE and BuCE via the combined mechanism. Evidently the absence from compounds of series X of dipolar and particularly cationic groups in the eliminated part of the molecule impairs the conditions for the correct orientation of the molecule on the active surface of the enzyme, on the one hand, and decreases the electrophilic phosphorylating capacity, on the other, which leads to a distinct combined inhibition of the catalytic activity of cholinesterases.

However, the dipolar and cationic groups in the eliminated part of the OPI molecule are by no means always able to ensure "productive" sorption. This was manifested not only for diphenylphosphinothioate esters, but also for two phenylphosphonothioate esters (Tables 9 and 10). In the first instance the orienting influence of the mercapto-group was interferred with by the two phenyl substituents, and in the second by the phenyl and alkoxy-substituents next to the C_5H_{11} and C_6H_{13} groups. In the presence of smaller alkyl groups concerted sorption of the phosphoryl component and of the mercapto-group was observed and there was no reversible component in the inhibiting activity of the CPI.

It was found that the presence of the cyclohexyl group instead of the phenyl group at the phosphorus atom in the case of compounds of the sulphide type leads to a pronounced combined inhibition of BuCE (Table 12).[30] An analogous effect for BuCE has been observed in the presence of the corresponding benzylphosphonothioate thioesters (Table 14),[31] the latter compounds being more active than derivatives of cyclohexylphosphonothioic acid[30].

The interaction of cyclohexylphosphonothioate and benzylphosphonothioate thioesters of the onium type (series XII and XIV, Tables 13 and 15) with BuCE takes place differently. In this case the only inhibitors with a combined type of activity are derivatives of cyclohexylphosphonothioic acid (Table 13).[30] Benzylphosphonothioate thioesters of the onium type cause only the irreversible inhibition of BuCE (Table 14).[31]

In experiments with ACE only irreversible inhibition was observed in all cases (Tables 13 and 15). These data and also those obtained in the study of the analogous phenylthiophosphonothioate thioesters (series VI–IX) show that the combined inhibition of the catalytic activity of cholinesterases is in most cases promoted by the presence of hydrophobic groups in the inhibitor molecule, particularly those in the phosphorylating component, and is hindered by the presence of polar groups. This is manifested most clearly in the case of ACE.

IV. INTERACTION OF CHOLINESTERASES WITH *OO*-DIALKYL *S*-ALKYL PHOSPHOROTHIOATES

Combined inhibition of cholinesterases does not occur solely when bulky hydrophobic substituents are present at the phosphorus atom. This effect is shown distinctly in those instances where there are two alkoxy-groups at the phosphorus atom. Thus *OO*-dialkyl *S*-alkyl phosphorothioates

$R = C_4H_9$ or C_6H_{13}; $R' = CH_3C_6H_{13}$
iso-C_4H_9, or iso-C_5H_{11},

with two butoxy-[32] and two hexyloxy-groups[33] (series XV and XVI, Tables 16 and 17) cause the combined inhibition of cholinesterase, the reversible component being in all cases more pronounced in the interaction with BuCE than with ACE.

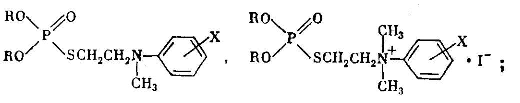
The combined inhibition of the catalytic activity of cholinesterases is apparently fairly characteristic of phosphorothioate thioesters even when there are small alkoxy-groups at the phosphorus atom. This has been shown for a series of *OO*-dialkyl *S*-[β-(*NN*-arylmethylamino)ethyl] phosphorothioates and their methiodides [34,35]:



R=C_3H_7, C_4H_9, iso-C_3H_7; X=H, *n*-, *m*-CH_3; *p*-, *m*-CH_3O, *p*-, *m*-Cl

It was found that OPI of the above type, having straight-chain alkoxy-groups at the phosphorus atom, give rise to combined inhibition [36,37]. This applies both to "uncharged" compounds (series XVII–XIII, Tables 18 and 19) and to compounds of the onium type (series XIX and XX, Tables 20 and 21). In all cases combined inhibition is shown more in relation to BuCE than to ACE.

When there are two branched isopropoxy-groups at the phosphorus atom, combined inhibition is not observed in all cases [38]. Thus the reversible component is observed in the inhibition of ACE and BuCE only by "uncharged" compounds (series XXI, Table 22). The only exception is the *p*-methoxy-derivative, which causes only the irreversible inhibition of BuCE. Only some CPI of the onium type exhibit the combined type of inhibition in relation to ACE, while BuCE is only irreversibly inhibited by these compounds [38] (series XXII, Table 23). Thus BuCE does not always tend to be more readily inhibited via the combined mechanism by *OO*-dialkyl *S*-alkyl phosphorothioate esters, in contrast to the phosphonothioate thioesters.

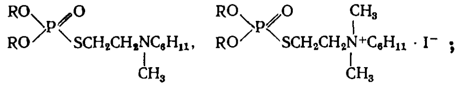
Analogous results were also obtained in experiments with *OO*-dialkyl *S*-alkyl phosphorothioate esters containing the cyclohexyl group at the nitrogen atom in the β-position relative to the thioester group [39]:



R=C_2H_5, C_3H_7, C_4H_9, or iso-C_3H_7.

Compounds with isopropoxy- or n-butoxy-groups at the phosphorus atom, exhibit the combined type of inhibition only in relation to ACE, the effect being observed with both "uncharged" compounds (series XXIII, Table 24) and with methiodides (series XXIV, Table 25). Organophosphorus inhibitors of the above types cause only the irreversible inhibition of BuCE.

The above experimental data permit the conclusion that the combined inhibition of the catalytic activity of cholinesterases is most effectively promoted by hydrophobic substituents in the phosphorylating component of the OPI molecule. However, there are also instances where substituents in the eliminated component of the OPI molecule exert a decisive influence. This has been demonstrated for the diphenylmethyl esters of various phosphorus(V) thio-acids[40]:

R=CH_3, C_2H_5, C_6H_5, C_2H_5O, or C_6H_5O; R′=C_2H_5O, C_2H_5, or C_6H_5O.

The tendency of these compounds to exhibit the combined type of inhibition in relation to ACE and BuCE is very pronounced even in those cases where there are groups with short hydrophobic substituents at the phosphorus atom. The presence of two phenoxy-groups at the phosphorus atom leads to the loss of ability by OPI to cause the irreversible inhibition of ACE, but BuCE undergoes combined inhibition under these conditions (series XXV, Table 26).

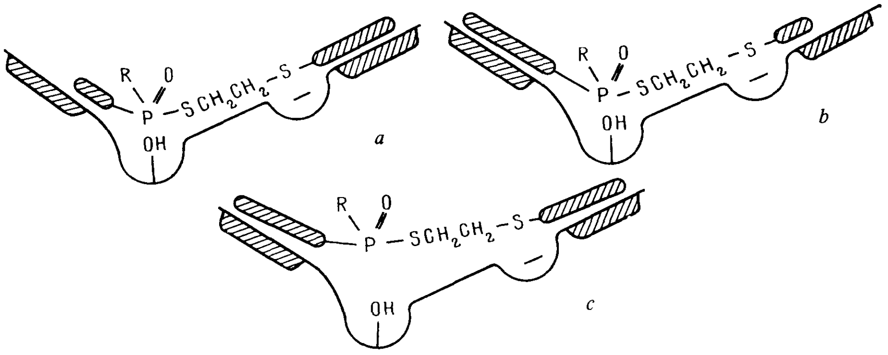
V. CONCLUSION

The results obtained show that BuCE is much more readily inhibited by substances capable of hydrophobic sorption on the active surface of the enzyme than is ACE. This conclusion had been reached earlier[9-11]. In subsequent studies it was clearly confirmed and developed further. In particular, relations were discovered between the structure of OPI with different hydrophobic substituents and their inhibiting activity in relation to ACE and BuCE.[41]

Comparison of the anticholinesterase activities of the diphenylphosphinothioates, phenylphosphonothioates, benzylphosphonothioates, and cyclohexylphosphonothioates presented in this review, as well as the methylphosphonothioates investigated earlier[7] clearly demonstrates differences between the sensitivities of ACE and BuCE to these compounds as a function of the structure of the phosphoryl component in their molecules.

S-Alkylthioethyl compounds with a methyl group at the phosphorus atom exert the strongest irreversible inhibiting activity in relation to ACE. This highly specific enzyme has apparently become adapted to acetylcholine and for this reason interacts faster with substances containing the $CH_3-P=O$ group, which simulates the $CH_3-C=O$ group of acetylcholine. Substances with a phenyl group at the phosphorus atom resemble methylphosphonothioate esters. *S*-Alkylthioethyl esters of phosphonothioic acids with benzyl and particularly cyclohexyl groups at the phosphorus atom inhibit ACE much less.

Thus substances of the type $A(C_2H_5O)P(O)SCH_2CH_2SR$ and $A(C_2H_5O)P(O)SCH_2CH_2\overset{+}{S}(CH_3).I^-$ can be arranged in the following sequence in terms of the irreversible inhibition of ACE as a function of the structure of A: $CH_3 > C_6H_5 > C_6H_5CH_2 > C_6H_{11}$.



Schematic illustration of the "compatible" (*a* and *b*) and "incompatible" (*c*) sorption of OPI on the active surfaces of cholinesterases.

A different type of behaviour is observed when the above compounds act on BuCE—the enzyme which hydrolyses butyrylcholine at the maximum rate and not acetylcholine. Sulphide derivatives of *O*-ethyl alkylphosphonothioates and of diphenylphosphinothioic acid can be arranged in the following sequence in terms of irreversible inhibition: $C_6H_5CH_2(C_2H_5O) > C_6H_5(C_2H_5O) > CH_3(C_2H_5O) > (C_6H_5)_2 > C_6H_{11}(C_2H_5O)$.

Sulphonium derivatives can be arranged in the same sequence in terms of their inhibiting activity subject to an important stipulation with regard to methylphosphonothioate esters: their positions in the series depend on the size of the alkyl group R.

The above series is valid only for $R < C_6H_{13}$. For $R > C_6H_{13}$, the inhibiting activity of methyl derivatives increases and is not inferior to that of benzyl derivatives: $(C_2H_5O)C_6H_5CH_2 \geqslant (C_2H_5O)CH_3 > (C_2H_5O)C_6H_6 > (C_6H_5)_2 > (C_2H_5O)C_6H_{11}$.

Thus in the presence of large substituents, which firmly attach the inhibitor in the vicinity of the anionic site of BuCE as a result of hydrophobic interaction, the methyl or benzyl group A at the phosphorus atom is "better" for productive sorption and subsequent phosphorylation of the enzyme than the phenyl or cyclohexyl group, while in the presence of small substituents the phenyl group A is "better" than the methyl group. The complementarity of the inhibitor molecule to the active surface of the enzyme, which ultimately determines the occurrence of "productive" sorption, in general depends on the compatibility of the ion–ion, ion–dipole, and hydrophobic interactions, as mentioned above. When these interactions are compatible, the sorbed molecule is oriented on the active centre in such a way that the phosphorus atom and the serine hydroxyl of the enzyme are in close proximity and phosphorylation may occur; this is illustrated schematically in the Figure. When the effects are "incompatible", the inhibitor molecule is arranged in such a way that the phosphorus atom and the serine hydroxyl are separated in space, phosphorylation is difficult, and the combined type of inhibition is shown clearly.

For certain structures of the inhibitors, hydrophobic sorption may promote the correct orientation of the inhibitor on the active surface of the enzyme, as a result of which the rate of irreversible inhibition increases. However, for other structures the sorption may interfere with the "correct orientation": for example, in those cases where the inhibitor molecule, fixed at two hydrophobic sites, is arranged in such a way that the phosphorus atom is separated from the serine hydroxyl of the enzyme active centre. Analogous steric hindrance may arise also when certain sulphide and sulphonium derivatives act on the enzyme, whereupon, as a result of the "incompatibility" of the sorption at the anionic site and in the corresponding hydrophobic region, the ester group of the inhibitor is incorrectly oriented relative to the esterase site of the enzyme.

Effects of this kind, which lower the rate constant for irreversible inhibition and cause the appearance of the reversible component, probably exert the most marked influence when the inhibitor molecule contains bulky hydrophobic groups, particularly those linked directly to the phosphorus atom (two phenyl groups, a cyclohexyl group, and a benzyl group).

Effects of this kind were explained previously by the absence of complementarity between the hydrophobic group of the inhibitor and the hydrophobic region located in the immediate vicinity of the esterase site of the enzyme. In the light of new experimental data, a revised treatment of the above effects is now necessary. The "hydrophobic region–esterase site" complementarity rather than with the complementarity to the hydrophobic region itself is relevant.

Thus it has been shown[9-11] that the introduction of hydrophobic groups into the eliminated or non-eliminated component of the inhibitor molecule enhances its irreversible inhibiting activity, particularly in relation to butyrylcholinesterase. On the basis of the data described, one may now claim that the introduction of bulky hydrophobic groups, particularly several such groups, may lead to the opposite effect, owing to the incompatibility of the orientation of the inhibitor molecule with the active surface of the enzyme: instead of an enhancement, a weakening of the anticholinesterase activity and the appearance of the reversible component are observed.

Thus the data described above show that the anticholinesterase activity of compounds and the nature of their inhibiting effect depend on three factors: on the electrophilic phosphorylating capacity of the inhibitor, on its tendency to undergo hydrophobic sorption on the active surface of the enzyme, and on the complementarity of the inhibitor molecule to the "hydrophobic region–esterase centre" system.

One must recall that the difference between productive and non-productive sorption apparently consists solely in the localisation of the inhibitor molecule on the active surface of the enzyme; the vigorous interactions ensuring both types of sorption are virtually identical. Accordingly, the stabilities of the "productive" (EIn) and "non-productive" (EI_r) complexes should be similar. From this point of view, the quantities $K_{i,S}$ and $K_{i,r}$ are of great interest, because they can yield information about the equilibrium constant for the formation of the Michaelis enzyme–inhibitor complex. When the above quantities are analysed, the most striking fact is that in the vast majority of instances the quantities $K_{i,S}$ and $K_{i,r}$ for BuCE are significantly smaller than for ACE. This was shown particularly clearly in experiments with *S*-alkyl diphenylphosphinothioates[18], *O*-ethyl *S*-alkyl phenylphosphonothioates[27], and *OO*-dibutyl *S*-alkyl phosphorothioates[32], in the sorption of which the hydrophobic interaction plays an extremely significant role. The hydrophobic interaction is known to be more characteristic of BuCE than of ACE. Hence it becomes understandable why BuCE forms more stable complexes than ACE on interaction with the compounds investigated. This applies to both "non-productive" and "productive" complexes.

Attention must be drawn to the fact that frequently there are differences between the quantities $K_{i,S}$ and $K_{i,r}$, characterising the reversible component of the inhibition of cholinesterases. In most instances $K_{i,S}$ is smaller almost by an order of magnitude than $K_{i,r}$, i.e. the inhibiting effect of certain compounds in the hydrolysis of acetylcholine is manifested to a greater extent than in the phosphorylation of the enzyme.

One of the possible causes of this divergence is that the reversible inhibition of the enzymatic hydrolysis of acetylcholine may be associated with the interaction of the OPI, for example via the anionic site, not only with the free enzyme but also with the acetylated enzyme. This hinders deacetylation and thereby reduces the rate of the enzymatic hydrolysis of acetylcholine and therefore affects $K_{i,S}$.[42] Such reversible interaction of the OPI with the phosphorylated enzyme cannot influence $K_{i,r}$, because the phosphorylated enzyme is the final product of the process investigated.

The second cause may be associated with the presence of the "productive" enzyme–inhibitor complex EIn in the reaction medium when the rate of the enzymatic hydrolysis of AX is determined, because there are insufficient grounds for the belief that, following the addition of AX to the reaction mixture of the enzyme and the OPI, the complex EIn is fully dissociated into the inhibitor and the enzyme, which then catalyses the hydrolysis of AX. Even under conditions where the concentration of AX is many times greater that of the OPI, part of the enzyme may be present in the form of the complex EIn if the latter is very stable. Within the narrow inhibitor concentration ranges employed in experiments, the dependence of the rate constant k for the irreversible inhibition on [In] can therefore be either comparatively weak or may not exist at all. In the latter case it is altogether impossible to determine $K_{i,r}$.

It is noteworthy that, in view of the presence of two stages in the phosphorylation process, k should depend on the incubation time t of the enzyme with the inhibitor and on the inhibitor concentration [In] even in the absence of "non-productive" sorption, provided that these parameters vary within wide limits. Methods for the calculation of the rate constants of the individual stages of the process via mechanism (1) are based on the determination of the dependence of k on t and [In].[43,44]

Thus the combined inhibition of cholinesterases by certain organophosphorus inhibitors, which is manifested clearly in experiments and about the occurrence of which there is no doubt, may be caused not only by the "non-productive" sorption of the inhibitor on the enzyme but also by the presence of an enzyme–inhibitor complex in the enzymatic hydrolysis of the substrate.

Evidently, at the level of the modern experimental technique for the investigation of the interaction of cholinesterases with OPI, where there is as yet no possibility of distinguishing experimentally the "productive" and "non-productive" enzyme–inhibitor complexes, the reversible component must be regarded as a result of the binding of the enzyme both in the complex EI_r and in the Michaelis complex EIn.

The Imide-Amide and Imide-Imide Rearrangements of Imidophosphorus Compounds

V.A.Gilyarov

Data on the imide-amide and imide-imide rearrangements of imidophosphorous compounds are surveyed, the factors influencing the ease of these rearrangements are noted, and information about their mechanisms is given.
The bibliography includes 83 references.

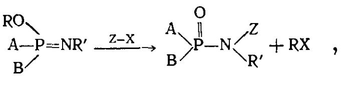
I. INTRODUCTION

Imidophosphorus compounds (IPC) containing at least one alkoxy-group at the phosphorous atom are as a rule converted into the corresponding amides on treatment with electrophiles. This reaction was observed in 1955 by Kabachnik and Gilyarov[1] and called the "imide-amide rearrangement". The centre of electrophilic attack in IPC may be not only the nitrogen atom (as in the imide-amide rearrangement) but also other atoms forming part of the conjugated system, for example, the oxygen atom of the carbonyl group in acetylimidophosphate[2] or the oxygen atom of the phosphoryl group in phosphorylimidophosphates[3], as well as the sulphur atom of thiophosphorylimidophosphates[4]. These reactions have been called the "imide-imide rearrangement"[5]. It is noteworthy that the majority of studies on the imide-amide and imide-imide rearrangements have been carried out during the last ten years.

The IPC nomenclature recommended by IUPAC[6] is used in this review, but in a number of instances, the names of compounds are quoted as given by the authors of the studies under consideration.

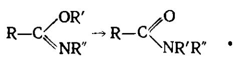
II. THE IMIDE-AMIDE REARRANGEMENT

In a general form the imide-amide rearrangement can be represented schematically as follows[7]:

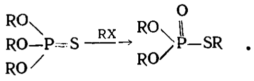


where Z-X is an electrophile and A and B are substituents at the phosphorus atom. Alkyl halides, acyl halides, phosphorus acid chlorides, chlorotrimethylsilane, or the IPC itself (in thermal isomerisation) may be used as the electrophiles. Dealkylation reactions during hydrolysis and on treatment with acids also belong to imide-amide rearrangements.

The imide-amide rearrangement of IPC may be compared with the rearrangement of alkyl imidocarboxylate esters to the corresponding amides[8]:



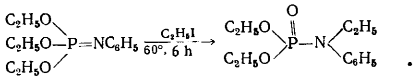
The analogy between the imide-amide rearrangement and the Pishchimuka rearrangement[9] should also be noted:



This analogy is not merely formal, being manifested also by the conditions of the rearrangement and the factors which influence its rate.

1. Rearrangement Under the Influence of Alkylating and Acylating Agents

(a) Rearrangement under the influence of alkyl halides. The first example of the imide-amide rearrangement was described by Kabachnik and Gilyarov[1] in relation to the transformation of triethyl phenylimidophosphate (I) into *O,O*-diethyl-*N*-ethylanilidophosphate (II):



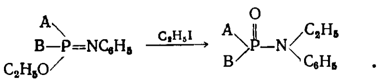
(I) (II)

A study of the reaction of trimethyl arylimidophosphates (III) on refluxing with methyl iodide showed[10,11] that electron-accepting substituents in the benzene ring hinder the isomerisation:

$$\underset{\text{(III)}}{(CH_3O)_3\,P{=}NC_6H_4X} \xrightarrow{CH_3I} \underset{\text{(IV)}}{(CH_3O)_2\,P\,(O)\,N\,(CH_3)\,C_6H_4X}\ .$$

The influence of alkyl halides on the rate of rearrangement of the imidophosphate (I) has been followed in relation to benzyl chloride and ethyl iodide. In the former case the rearrangement proceeds under more severe conditions (heating for 5 h at 130°C) than in the latter (refluxing for 6 h). Thus the same behaviour is observed as in the Pishchimuka thione-thiol rearrangement[12].

A number of workers[11,13,14] studied in detail the influence of substituents A and B in ethoxy(phenylimido)phosphorus compounds (V), having investigated the kinetics of their reactions with ethyl iodide in acetonitrile at 50°C:



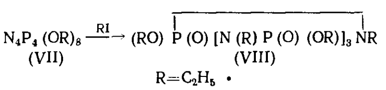
(V) (VI)

It was found that the kinetics are described satisfactorily by a pseudo-first order equation. The rate constants are given in the Table.

The rate constants for the rearrangement of phosphorus(V) acid phenylimides $AB(C_2H_5O)P{=}NC_6H_5$ under the influence of ethyl iodide.

A	B	10^3k, litre mole^{-1} min^{-1}	A	B	10^3k, litre mole^{-1} min^{-1}
C_2H_5O	C_2H_5O	0.92	C_2H_5	C_2H_5O	3.06
C_6H_5	C_2H_5O	1.14	C_2H_5	C_6H_5	4.13
CH_3	C_2H_5O	2.85	C_2H_5	C_2H_5	10.45

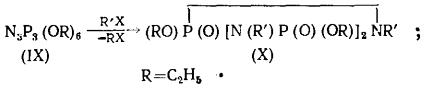
It has been established[15] that the rearrangement of triphosphatriazines and tetraphosphatetrazines is catalysed by alkyl halides. Thus tetraphosphatetrazine (VII) is converted into 2,4,6,8-tetraethoxy-1,3,5,7-tetraethyl-2,4,6,8-tetraphospha-1,3,5,7-tetrazine(VIII) on heating with ethyl iodide (4.7 h, 170°C):



$$\underset{(VII)}{N_4P_4(OR)_8} \xrightarrow{RI} \underset{(VIII)}{(RO)P(O)[N(R)P(O)(OR)]_3NR} ;$$

$R{=}C_2H_5$.

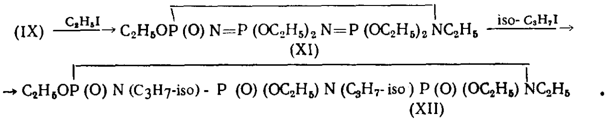
When alkyl halides were used with an alkyl group different to that in the initial triphosphatriazine (IX), compound (X), containing different substituents at the phosphorus and nitrogen atoms, was obtained[16]:



$$\underset{(IX)}{N_3P_3(OR)_6} \xrightarrow[-RX]{R'X} \underset{(X)}{(RO)P(O)[N(R')P(O)(OR)]_2NR'} ;$$

$R{=}C_2H_5$.

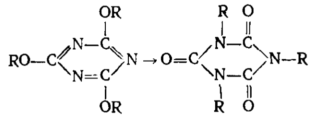
When triphosphatriazine (IX) was refluxed with ethyl iodide in the dark for a week, it was possible to obtain the partial rearrangement product (XI), which, on further heating with isopropyl iodide (35 min, 175–180°C), was converted into 1,3-di-isopropyl-2,4,6-triethoxy-5-ethyl-2,4,6-triphospha-1,3,5-triazine (XII):



$$(IX) \xrightarrow{C_2H_5I} \underset{(XI)}{C_2H_5OP(O)N{=}P(OC_2H_5)_2N{=}P(OC_2H_5)_2NC_2H_5} \xrightarrow{iso\text{-}C_3H_7I}$$

$$\rightarrow \underset{(XII)}{C_2H_5OP(O)N(C_3H_7\text{-}iso)\text{-}P(O)(OC_2H_5)N(C_3H_7\text{-}iso)P(O)(OC_2H_5)NC_2H_5} .$$

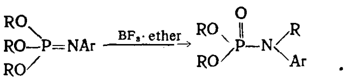
It is noteworthy that a similar rearrangement of alkyl cyanurates has been observed. Under the influence of electrophiles or on heating (180–210°C), 2,4,6-trialkoxy-1,3,5-triazines are converted into 1,3,5-trialkyl-2,4,6-trioxo-1,3,5-triazines[17] (XIII):



(XIII)

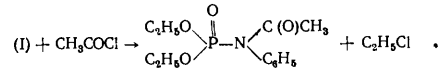
The synthesis of (IV) and (VI) via the imide–amide rearrangement is of preparative value[10,11,13]. A number of chromatographically pure N-methylanilines have been synthesised by the hydrolysis of dimethyl N-methylanilidophosphates.

(b) Rearrangement in the presence of catalytic amounts of boron trifluoride etherate. It was found[18] that the imide–amide rearrangement of arylimidophosphorus compounds takes place under mild conditions (at room temperature or on slight heating) in the presence of catalytic amounts of boron trifluoride etherate:



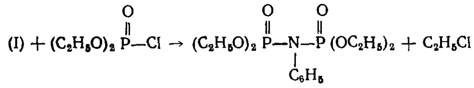
$$(RO)_3P{=}NAr \xrightarrow{BF_3\cdot ether} (RO)_2P(O)N(R)Ar .$$

(c) Rearrangement under the influence of acyl halides, phosphorus acid chlorides, and chlorotrimethylsilane. The reactions of IPC with acylating agents take place much more vigorously than with alkyl halides. Triethyl phenylimidophosphate (I) gives rise to diethyl N-acetylanilidophosphate as a result of an exothermic reaction in iso-octane[1]:



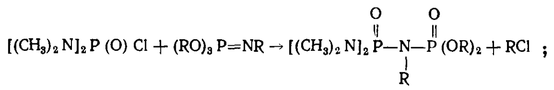
$$(I) + CH_3COCl \rightarrow (C_2H_5O)_2P(O)N(C(O)CH_3)C_6H_5 + C_2H_5Cl .$$

The reactions of dialkyl chlorophosphates and diphenyl chlorophosphinate with phenylimido- and methylimidophosphorus compounds take place vigorously, the corresponding bisphosphoryl compounds being formed[19,20], for example:



$$(I) + (C_2H_5O)_2P(O){-}Cl \rightarrow (C_2H_5O)_2P(O){-}N(C_6H_5){-}P(O)(OC_2H_5)_2 + C_2H_5Cl .$$

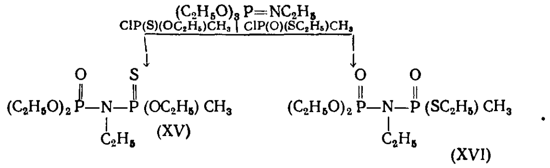
Compounds (XIV) have been synthesised similarly from tetramethyldiamidochlorophosphate[21]:



$$[(CH_3)_2N]_2P(O)Cl + (RO)_3P{=}NR \rightarrow \underset{(XIV)}{[(CH_3)_2N]_2P(O){-}N(R){-}P(O)(OR)_2} + RCl ;$$

$R{=}CH_3$ or C_2H_5 .

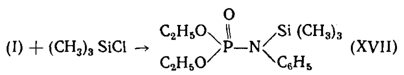
The reaction of O-ethyl methylchlorothiophsophonate and S-ethyl methylchlorothiophosphonate with triethyl ethylimidophosphate leads to the formation of compounds (XV) and (XVI)[22]:



$$(C_2H_5O)_3P{=}NC_2H_5 \text{ with } ClP(S)(OC_2H_5)CH_3 \rightarrow \underset{(XV)}{(C_2H_5O)_2P(O){-}N(C_2H_5){-}P(S)(OC_2H_5)CH_3}$$

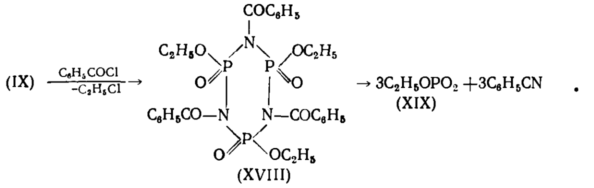
$$(C_2H_5O)_3P{=}NC_2H_5 \text{ with } ClP(O)(SC_2H_5)CH_3 \rightarrow \underset{(XVI)}{(C_2H_5O)_2P(O){-}N(C_2H_5){-}P(O)(SC_2H_5)CH_3} .$$

Thus, in all the reactions of IPC with phosphorus acid chlorides considered phosphorylation takes place at the imide nitrogen atom. This reaction has been suggested as a general method of synthesis of bisphosphoryl-N-aryl(or alkyl)imides and (phosphoryl)(thiophosphoryl)-N-aryl(or alkyl)imides. Thus bis(diphenylphosphoryl)-N-phenylimide, obtained by the method discussed, could not be synthesised by any other procedure[23]. N-Trimethylsilyl derivatives of phosphoric acid amides have been obtained by the reaction of phenylimidophosphorus compounds with chlorotrimethylsilane (4 h, 50°C), for example compound (XVII):



$$(I) + (CH_3)_3SiCl \rightarrow (C_2H_5O)_2P(O)N(Si(CH_3)_3)C_6H_5 \quad (XVII) .$$

The reactions of benzoyl chloride with 2,2,4,4,6,6-hexaethoxy-2,4,6-triphospha-1,3,5-triazine (IX) (1 h, 130–140°C) and 2,2,4,4,6,6,8,8-octaethoxy-2,4,6,8-tetraphospha-1,3,5,7-tetrazine (5 h, 140–150°C) have been investigated[15,24,25]. A mixture of products is obtained in both cases (ethyl chloride, ethyl metaphosphate, and benzonitrile). The authors suggest that the first stage of the reaction is an imide–amide rearrangement as a result of nucleophilic attack by the nitrogen atom on the carbon atom of the carbonyl group; this results in the formation of ethyl chloride and the unstable 1,3,5-tribenzoyl-2,4,6-triethoxy-2,4,6-triphospha-1,3,5-triazine (XVIII):



The intermediate (XVIII) forms on decomposition ethyl metaphosphate (XIX) and benzonitrile. Part of the latter is converted into 2,4,6-triphenyl-1,3,5-triazine under the reaction conditions.

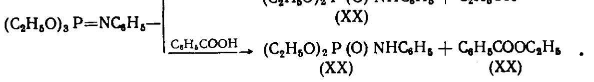
2. Rearrangement During Hydrolysis and on Treatment with Acids

When IPC with at least one alkoxy-group at the phosphorus atom are hydrolysed or treated with acids, they are dealkylated and the imidophosphates is converted into the amidophosphate, i.e. an imide–amide rearrangement takes place. Extensive experimental data on the hydrolysis of IPC have been surveyed in a monograph[26].

The general characteristics are in this case the same as on treatment with other electrophiles, namely the resistance to hydrolysis on treatment with acids increases with enhancement of the electron-accepting properties of the substituent at the nitrogen atom. Thus triethyl methylimidophosphate is readily hydrolysed by atmospheric moisture and on mixing with water heat is evolved[27]:

$$(C_2H_5O)_3\,P{=}NCH_3 \xrightarrow{H_2O} (C_2H_5O)_2\,P\,(O)\,NHCH_3 + C_2H_5OH \ .$$

The imidophosphate (I) is converted into diethyl anilidophosphate (XX) on treatment with benzoic acid in xylene at room temperature[1]:



$$(C_2H_5O)_3\,P{=}NC_6H_5 \begin{cases} \xrightarrow{H_2O} (C_2H_5O)_2\,P\,(O)\,NHC_6H_5 + C_2H_5OH \\ \qquad\qquad\quad (XX) \\ \xrightarrow{C_6H_5COOH} (C_2H_5O)_2\,P\,(O)\,NHC_6H_5 + C_6H_5COOC_2H_5 \ . \\ \qquad\qquad\quad (XX) \qquad\qquad\qquad (XX) \end{cases}$$

Triethyl diethoxyphosphorylimidophosphate is resistant to the action of formic or acetic acid on heating[27]. It has been found that the interaction of imidophosphates with dry hydrogen chloride is the best method for converting imidophosphates $(RO)_3P{=}NR'$ into amidophosphates $(RO_2)P(O)NHR'$, where R′ is an aryl[1,29], acetyl[30], halogenoacetyl[30], methanesulphonyl[28], dialkoxyphosphoryl, or dialkoxythiophosphoryl[31] group, for example[30]:

$$(C_2H_5O)_3\,P{=}NCOCF_3 \xrightarrow{HCl} (C_2H_5O)_2\,P\,(O)\,NHCOCF_3 + C_2H_5Cl \ .$$

3. Rearrangement on Heating (Thermal Isomerisation)

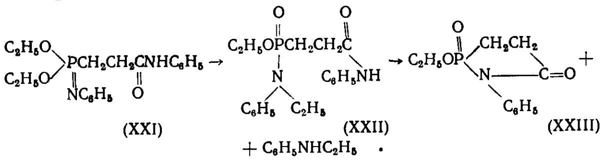
The greatest number of studies on the imide–amide rearrangement have been devoted to the thermal isomerisation of IPC. Such isomerisation was observed for the first time by Kabachnik and Gilyarov for trimethyl phenylimidophosphate[1]. On being vacuum distilled (at 150–180°, 0.1 mmHg), this substance partly isomerised to dimethyl *N*-methylanilidophosphate. It is of interest to compare this reaction with the thermal isomerisation of trimethyl thionophosphate and trimethyl thiolophosphate[32]. We shall consider the factors influencing the ease of the thermal isomerisation of IPC of the type (RO)ABP=NX; these are as follows: (a) the structure of R in the alkoxy-group; (b) the nature of the sudstituents A and B at the phosphorus atom and of the substituent X at the nitrogen atom.

The isomerisation proceeds most readily with methyl esters and is hindered as R increases in size. It has been shown[33] that thermal isomerisation of allyl diethyl phenylimidophosphate takes place at 160°C and the allyl group is the alkylating species:

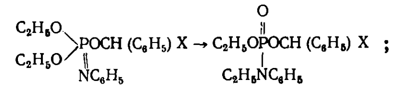
$$\underset{CH_2{=}CHCH_2O}{(C_2H_5O)_2\,\overset{|}{P}{=}NC_6H_5} \rightarrow (C_2H_5O)_2\overset{O}{\overset{\|}{P}}{-}N\begin{smallmatrix} C_6H_5 \\ CH_2CH{=}CH_2 \end{smallmatrix} \ .$$

It is of interest to note that the replacement of the ethoxy-groups at the phosphorus atom by the more electron-accepting phenoxy-groups facilitates isomerisation, which takes place even on distillation (90–120°C).[34]

Pudovik and coworkers described a number of instances of the imide–amide rearrangement. When an attempt was made to distill the imidophosphonate (XXI), the cyclic phosphonate (XXIII) was obtained[35], evidently owing to cyclisation of the product (XXII) of the imide–amide rearrangement formed initially:



The thermal isomerisation of the imidophosphates (XXIV)[36] and (XXV)[37] leads to the corresponding *N*-ethylanilidophosphates:



$$(C_2H_5O)_2\underset{NC_6H_5}{\overset{}{\underset{\|}{P}}}OCH\,(C_6H_5)\,X \rightarrow C_2H_5O\overset{O}{\overset{\|}{\underset{C_2H_5NC_6H_5}{\underset{|}{P}}}}OCH\,(C_6H_5)\,X \ ;$$

(XXIV) : X=COOR;
(XXV) : X=P (O) (OC₂H₅)₂.

It is noteworthy that the ethoxy-group is then involved in the isomerisation (when the phenyl group is present at the nitrogen atom)[35-37].

When an attempt was made to obtain trialkyl imidophosphates unsubstituted at the nitrogen atom by the interaction of trialkyl phosphites with hydrazoic acid, their thermal isomerisation products were isolated: *O,O*-dialkyl *N*-alkylamidophosphates[38,39].

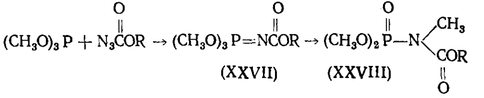
When a methyl or ethyl group is present at the nitrogen atom, heat is required for the rearrangement[40]. Thus trimethyl methylimidophosphate and *O,O*-dimethyl phenyl(methylimido)phosphonate (XXVI) isomerised to the corresponding amides in 1.5 h at 120°C:

$$\underset{(XXVI)}{(CH_3O)_2\,C_6H_5P{=}NCH_3} \rightarrow (CH_3O)\,C_6H_5\overset{O}{\overset{\|}{P}}{-}N\,(CH_3)_2 \ .$$

It was not possible to isolate the thermal isomerisation products of ethylimidophosphorus compounds[40]. The thermal isomerisation of trimethyl methylimidophosphate has been mentioned[41], but without a description of the experiment.

A considerable number of studies have been devoted to the thermal isomerisation of IPC containing electron-accepting substituents at the nitrogen atom—such as alkoxycarbonyl (ROCO), arenesulphonyl ($ArSO_2$), disubstituted phosphoryl [XYP(O)], dialkoxythiophosphoryl [$(RO_2)P(S)$], etc. groups.

Trimethyl alkoxycarbonylimidophosphates (**XXVII**) isomerise at the boiling point of ether[42]:

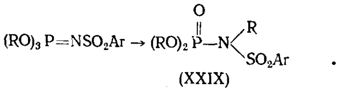


$$(CH_3O)_3P + N_3\overset{O}{\overset{\|}{C}}OR \rightarrow (CH_3O)_3P{=}N\overset{O}{\overset{\|}{C}}OR \rightarrow (CH_3O)_2\overset{O}{\overset{\|}{P}}{-}N{<}^{CH_3}_{\underset{\overset{\|}{O}}{COR}} .$$

(XXVII) (XXVIII)

This results in the formation of the corresponding dimethyl *N*-alkoxycarbonylmethylamidophosphates (**XXVIII**). The replacement of the methoxy-group at the phosphorus atom in compound (**XXVII**) by electron-donating substituents (a methyl group[43] or a dimethylamino-group[44]) increases the resistance to thermal isomerisation; the corresponding compounds may be vacuum distilled without decomposition.

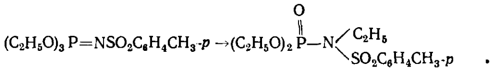
It has been shown[45] that trialkyl arenesulphonylimidophosphates isomerise on heating to esters of *N*-arenesulphonyl-*N*-arylamidophosphoric acids (**XXIX**):



$$(RO)_3P{=}NSO_2Ar \rightarrow (RO)_2\overset{O}{\overset{\|}{P}}{-}N{<}^{R}_{SO_2Ar} .$$

(XXIX)

The isomerisation of triethyl toluene-*p*-sulphonylimidophosphate (**XXX**) to diethyl *N*-toluene-*p*-sulphonyl-*N*-ethylamidophosphate (**XXXI**) during distillation (at 200°C) has been observed[46]:

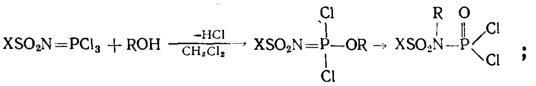


$$(C_2H_5O)_3P{=}NSO_2C_6H_4CH_3\text{-}p \rightarrow (C_2H_5O)_2\overset{O}{\overset{\|}{P}}{-}N{<}^{C_2H_5}_{SO_2C_6H_4CH_3\text{-}p} .$$

(XXX) (XXXI)

According to the authors[46], (**XXXI**) is partly converted into the initial imidophosphate (**XXX**) at 200°C, i.e. the reversible reaction (**XXX**) ⇌ (**XXXI**) takes place. However, the evidence which they present (changes in the ^1H NMR spectrum) is insufficient to sustain this claim.

The imide–amide rearrangement of *O*-alkyl dichloro-(halogenosulphonylimido)-phosphates (**XXXII**) to amidophosphates (**XXXIII**) under the influence of ether or dioxan has been observed[47,48]:

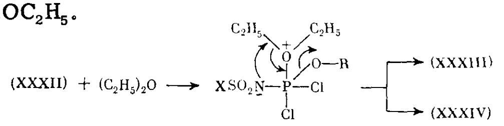


$$XSO_2N{=}PCl_3 + ROH \xrightarrow[CH_2Cl_2]{-HCl} XSO_2N{=}\underset{Cl}{\overset{Cl}{P}}{-}OR \rightarrow XSO_2\overset{R}{N}{-}\overset{O}{\overset{\|}{P}}{<}^{Cl}_{Cl} ;$$

(XXXII) (XXXIII)

$R{=}CH_3$, C_2H_5, or iso- C_3H_7, $X{=}Cl$, or F .

The imidophosphates (**XXXII**) cannot be vacuum distilled (decomposition) and, on refluxing them in ether (or dioxan) for 20 min, compounds (**XXXIII**) were obtained in high yields. Together with the main product (**XXXIII**), the catalytic isomerisation results in the formation of the *N*-ethylamide $XSO_2N(C_2H_5)P(O)Cl_2$ (**XXXIV**) and the mixed ether ROC_2H_5.



The authors[49] observed that, when *NN*-bis(alkoxydichlorophosphoranylidene)-sulphamides (**XXXV**) isomerise, the alkyl group also migrates to the nitrogen atom with formation of the amidophosphates (**XXXVI**):

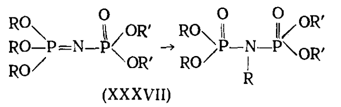
$$O_2S\,(N{=}PCl_2OR)_2 \rightarrow O_2S\,[N\,(R)\,P\,(O)\,Cl_2]_2 .$$

(XXXV) (XXXVI)

The authors[49] noted that ether influences the rate of isomerisation. The phenyl ester (**XXXV**, $R = C_6H_5$) does not isomerise even on prolonged heating.

The mode of thermal isomerisation of phosphorylimidophosphates $(RO)_3P{=}NP(O)XY$ depends on the nature of the substituents at the phosphorus atom (X and Y). When X and Y are alkoxy-groups, the alkyl group migrates exclusively to the imide nitrogen atom. When X and Y are electron-donating (alkyl) groups, the oxygen atom of the phosphoryl group is alkylated (imide–imide rearrangement). If X is an alkyl and Y an alkoxy-group, there is a possibility of the formation of products of both imide–amide and imide–imide rearrangements.

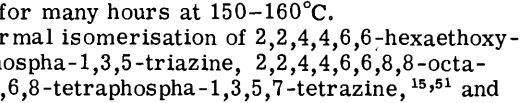
The rate of thermal isomerisation of trialkyldialkoxyphosphorylimidophosphates (**XXXVII**) depends markedly on the nature of the alkyl substituent R[50]:



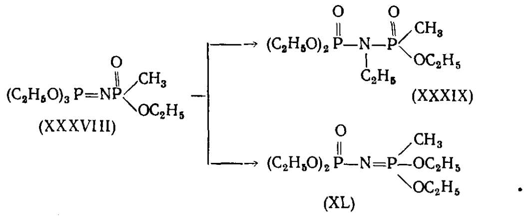
(XXXVII)

Thus trimethyl dimethoxyphosphorylimidophosphate $(CH_3O)_3P{=}NP(O)(OCH_3)_2$ partly isomerises at 50–60°C, and on vacuum distillation (100°C) the isomerisation goes to completion; triethyl dimethoxyphosphorylimidophosphate $(C_2H_5O)_3P{=}NP(O)(OCH_3)_2$ isomerises only as a result of heating for many hours at 150–160°C.

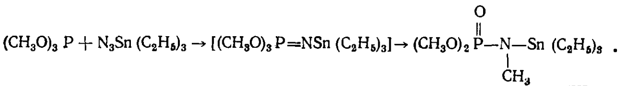
The thermal isomerisation of 2,2,4,4,6,6-hexaethoxy-2,4,6-triphospha-1,3,5-triazine, 2,2,4,4,6,6,8,8-octaethoxy-2,4,6,8-tetraphospha-1,3,5,7-tetrazine,[15,51] and 2,2,4,4,6,6,8,8-octa-(β-chloroethoxy)-2,4,6,8-tetraphospha-1,3,5,7-tetrazine (refluxing for 16 h in dichloroethane)[52] also leads to *N*-alkyl derivatives:



Two products are formed from triethyl ethoxymethylphosphorylimidophosphate (**XXXVIII**): the product of the imide–amide rearrangement (**XXXIX**) under more severe conditions (at 170°C) and the product of the imide–imide rearrangement (**XL**) under milder conditions (at 130°C)[53,54]:



The imide–imide rearrangement of compounds containing other substituents at the nitrogen atom has been little investigated. The reaction of triethylstannyl azide with trimethyl phosphite (heating, 160°C) gave the thermal isomerisation product (**XLI**)[55]:

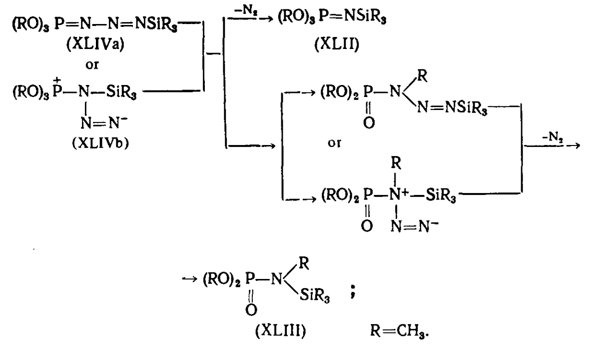


$$(CH_3O)_3P + N_3Sn\,(C_2H_5)_3 \rightarrow [(CH_3O)_3P{=}NSn\,(C_2H_5)_3] \rightarrow (CH_3O)_2\overset{O}{\overset{\|}{P}}{-}\underset{CH_3}{N}{-}Sn\,(C_2H_5)_3 .$$

(XLI)

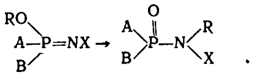
When trimethyl phosphite interacts with trimethylsilyl azide (8 h, 100–120°C), dimethyl *N*-methyl-*N*-trimethylsilylamidophosphate (**XLIII**) is formed together with trimethyl trimethylsilylimidophosphate (**XLII**).[56] Since the imidophosphate (**XLII**) is stable on heating (4 h, 190–200°C), the authors[56] suggested that the intermediate of Staudinger's reaction (cf. Ref. 57), namely the triazene

(XLIVa) or the betaine (XLIVb), undergoes the imide–amide rearrangement:

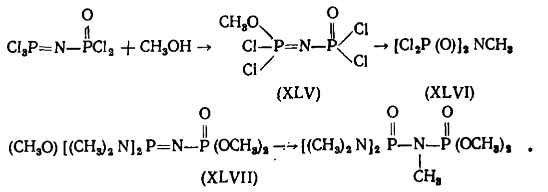


It has been shown recently[58] that, when the imidophosphate $(CF_3CH_2O)_3P{=}NSi(CH_3)_3$ is heated to 200°C, the imide–amide rearrangement does not occur and the linear polymeric product $[-N{=}P(OCH_2CF_3)_2-]_n$ is formed.

Examination of studies on the imide–amide rearrangement on heating permits a conclusion concerning the influence of the substituents at the phosphorus and nitrogen atoms on the rate of isomerisation:



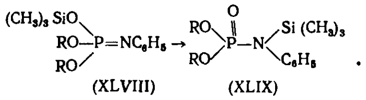
Since the IPC itself plays the role of the alkylating agent in thermal isomerisation, enhancement of the electron-accepting properties of substituents A and B facilitates the isomerisation. Thus *O*-methyl dichloro(dichlorophosphorylimido)phosphate (XLV) partly isomerises to bis(dichlorophosphoryl)-*N*-methylimide (XLVI)[59] even at room temperature. On the other hand, *O*-methyl *N*,*N*,*N'*,*N'*-tetramethyldiamido(dimethoxyphosphorylimido)phosphate (XLVII) remains unchanged after heating for 10 h at 95–100°C, decomposing under more severe conditions (5 h, 130°C)[21]:



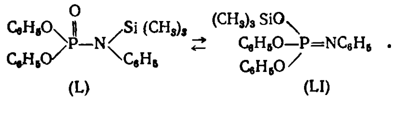
When electron-accepting substituents {arenesulphonyl ($ArSO_2$), dialkoxyphosphoryl [$(RO)_2P(O)$], and similar groups} are introduced at the nitrogen atom, the alkylation capacity of the IPC increases sharply and the thermal isomerisation is facilitated despite the fact that the electron-accepting substituents at the nitrogen atom make the IPC much less nucleophilic. The alkylating capacity of IPC with powerful electron-accepting substituents at the nitrogen atom is greatly superior to that of the corresponding phosphates and thiophosphates[4,7,10].

4. Rearrangement with Participation of the Trimethylsilyl Group

In the examples considered hitherto, the imide–amide rearrangement was irreversible with the exception of the rearrangement of compound (XXXI),[46] which we believe requires confirmation. Instances of both irreversible and reversible migration of the trimethylsilyl group in the $(CH_3)_3Si{-}O{-}P{=}N{-}$ system have been discovered in recent years. The irreversible migration has been found in phosphazines[60]. It has been shown that phosphazines, formed as intermediates in the reaction of dialkyl trimethylsilyl phosphites with methyl diazoacetate, isomerise completely to the corresponding dialkyl *N*-methoxycarbonylmethylene-*N'*-trimethylsilylhydrazidophosphates $(RO)_2P(O)N[Si(CH_3)_3]N{=}CHCOOCH_3$ even at room temperature. Dialkyl trimethylsilyl phenylimidophosphates (XLVIII), formed in the reaction of dialkyltrimethylsilyl phosphites with phenyl azide, are converted under the reaction conditions into dialkyl *N*-phenyl-*N*-trimethylsilylamidophosphates (XLIX).[61,62]



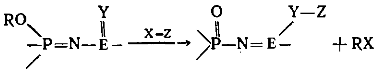
The reversible migration of the trimethylsilyl group in the $O{-}\overset{|}{\underset{|}{P}}{=}N{-}$system has been observed for compound (XLIX, R = CH_3) (on heating) and for diphenyl *N*-phenyl-*N*-trimethylsilylamidophosphate (L).[63] In the latter case the product contains 89% of (L) and 11% of form (LI) at 28°C:



At 129°C the contents of forms (L) and (LI) are 80 and 20% respectively (^1H and ^{31}P NMR data).

III. THE IMIDE-IMIDE REARRANGEMENT

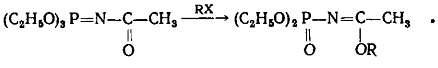
In the general case the imide–imide rearrangement can be represented schematically as follows:



where E = C or P, Y = O or S, and X–Z are electrophiles.

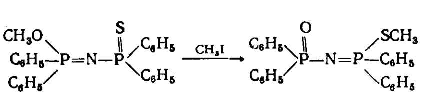
1. Rearrangement Under the Influence of Alkylating and Acylating Agents

The first example of the imide–imide rearrangement was observed by Kabachnik et al.[2] on heating triethyl acetylimidophosphate with alkyl halides (100–130°C, 4–6 h). This results in the formation of *O*-alkyl *N*-(diethoxyphosphoryl)iminoacetates, i.e. the rearrangement proceeds at the carbonyl oxygen atom:

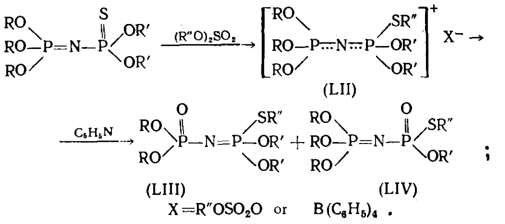


$$(C_2H_5O)_3P{=}N{-}\underset{\underset{O}{\|}}{C}{-}CH_3 \xrightarrow{RX} (C_2H_5O)_2\underset{\underset{O}{\|}}{P}{-}N{=}\underset{\underset{OR}{|}}{C}{-}CH_3 .$$

Thiophosphorylimidophosphates are alkylated usually at the thiono-sulphur atom. The reaction of *O*-methyl diphenyl(diphenylthiophosphorylimido)phosphinate with methyl iodide has been described[64]:



Khodak, Gilyarov, and Kabachnik[65,66] showed that the reaction of trialkyl dialkoxythiophosphorylimidophosphates with dialkyl sulphates proceeds via a stage involving the formation of quasi-phosphonium salts (LII), which decompose under the influence of nucleophiles with formation of the products of the imide-imide [compound (LIII)] and (or) thione-thiol [compound (LIV)] rearrangements:

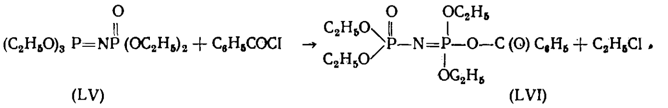


(LII)

(LIII) (LIV)

X=R″OSO$_2$O or B(C$_6$H$_5$)$_4$.

The imide-imide rearrangement proceeds via the reaction of phosphorylimidophosphates with acylating agents. Thus in the reaction of triethyl diethoxyphosphorylimidophosphate (LV) with benzoyl chloride (10 h, 60°C) the acylation is directed to the phosphoryl oxygen atom and the anhydride (LVI) is formed, its structure being confirmed by ^{31}P NMR:



(LV) (LVI)

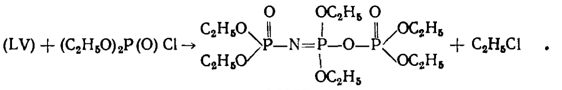
The presence of the anhydride linkage has been demonstrated by the reaction with cyclohexylamine from which cyclohexylbenzamide and the cyclohexylammonium salt of bis(diethoxyphosphoryl)imide (LVII) were isolated[18,67]:

$$\text{(LVI)} \xrightarrow{RNH_2} [(C_2H_5O)_2P(O)]_2NH \cdot RNH_2 + C_6H_5CONHR$$

(LVII)

R = cyclo-C$_6$H$_{11}$.

Diethyl phosphorochloridate reacts similarly to benzoyl chloride:

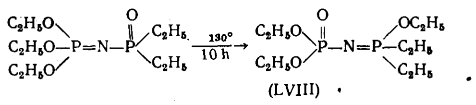


(LVIII)

O-Ethyl N,N,N′,N′-tetraethyldiamido(diethoxyphosphorylimido)phosphate $C_2H_5O[(C_2H_5)_2N]_2P{=}NP(O)(OC_2H_5)_2$ reacts with benzoyl chloride and diethyl phosphorochloridate similarly to the imidophosphate (LV).[18,67]

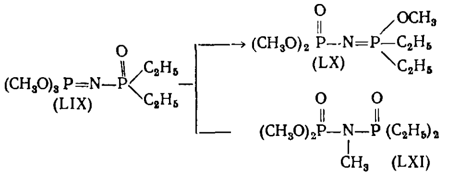
2. Thermal Isomerisation

The imide-imide rearrangement of phosphorylimidophosphates was observed for the first time[3] in the thermal isomerisation of triethyl diethylphosphorylimidophosphate and has been called by the authors the "phosphazene-phosphoxide rearrangement":



(LVIII) .

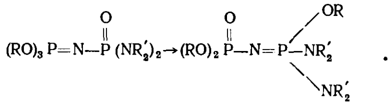
As shown in subsequent studies[53,68], the imide-imide rearrangement of phosphorylimidophosphates $(RO)_3P{=}NP(O)XY$ (X and Y are alkyl or phenyl groups) is of a general type. It proceeds readily for methoxy-derivatives. Thus even at 20°C trimethyl diethylphosphorylimidophosphate (LIX) undergoes partial isomerisation after a few days, and virtually complete isomerisation after four months, to the ester (LX); the product of the imide-amide rearrangement (LXI) is also formed as an admixture:



(LIX) (LX) (LXI)

On thermal isomerisation, trialkyl alkoxyalkylphosphorylimidophosphates give rise to products of the imide-amide or imide-imide rearrangement, depending on the reaction conditions[54,69] (see Section II, subsection 3).

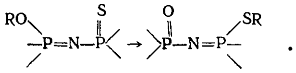
The imide-imide rearrangement with formation of the imidophosphates (LXII) is observed in the thermal isomerisation of trialkyl tetra-alkyldiamidophosphorylimidophosphates, the rate of isomerisation decreasing in the following sequence of groups R : $CH_3 > C_2H_5 > C_4H_9$:



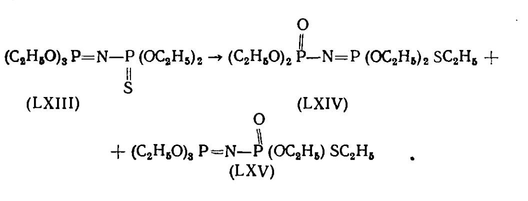
(LXII)

For example, trimethyl tetraethyldiamidophosphorylimidophosphate isomerises in 6 h at 85-90°C.[21]

In the thermal isomerisation of thiophosphorylimidophosphates mainly the thiono-sulphur atom is attacked, i.e. the imide-imide rearrangement takes place:

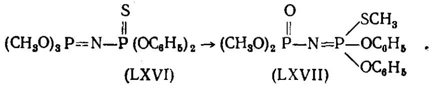


When triethyl diethoxythiophosphorylimidophosphate (LXIII) is heated (6 h, 140°C), the imidophosphates (LXIV) and (LXV) are formed[4,7]:



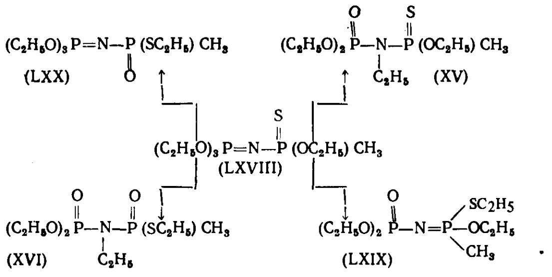
(LXIII) (LXIV) (LXV)

Attack on the sulphur atom occurs in the thermal isomerisation of trimethyl diphenoxythiophosphorylimidophosphate (LXVI) to the imidophosphate (LXVII)[70]:



(LXVI) (LXVII)

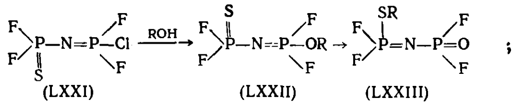
The thermal isomerisation of triethyl ethoxymethylthiophosphorylimidophosphate (LXVIII) (130°C, 10-11 h) takes place in a much more complex manner. A detailed study of this reaction[22] showed that, together with the main product O-ethyl S-ethyl (diethoxyphosphorylimido)methylphosphonate (LXIX) (77.4%), the isomers (XV), (LXX), and (XVI) are formed in small amounts (8.5, 10.4, and 3.7% respectively; GLC data):



(LXX) (XV) (LXVIII) (XVI) (LXIX)

According to earlier results[71], the thermal isomerisation of the imidophosphate (LXVIII) yields only (XV) under these conditions.

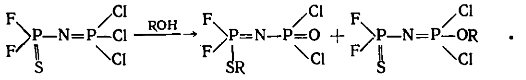
The introduction of a halogen atom at the phosphorus atom joined to the imide group in thiophosphorylimidophosphates increases sharply the rate of isomerisation. When difluorothiophosphorylimidophosphorus chloride difluoride (LXXI) reacts with methanol or ethanol[72,73], the resulting esters (LXXII) isomerise to the thioesters (LXXIII) already during the reaction:



(LXXI) (LXXII) (LXXIII)

R = CH3, or C2H5.

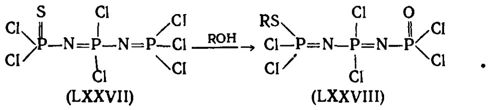
Such isomerisation is difficult for the products of the reaction of difluorothiophosphorylimidophosphorus trichloride (LXXIV) with alcohols:



(LXXIV) (LXXV) (LXXVI)

Thus the decrease of the electronegativity of the substituents at the phosphorus atom joined to the imide group (on passing from fluorine to chlorine) hinders the isomerisation.

The *S*-isomers (LXXVIII) were isolated in the reaction between (LXXVII) and methanol or ethanol (at 20°C) [75]:



(LXXVII) (LXXVIII)

Consequently the removal of the alkylating group RO to the $(-N{=}PCl_2-)$ fragment does not affect the ease of isomerisation.

3. Rearrangement with Participation of the Trimethylsilyl Group

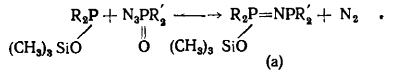
In all the instances considered hitherto the imide-imide rearrangement was irreversible.

It has been found[62,76] by $^{31}P-\{^1H\}$ NMR that the trimethylsilyl group in many phosphorylimidophosphates [(LXXIX)-(LXXXIV)] undergoes both reversible [(a)⇌(b)] and irreversible [(a)→(b)] transfers:

(LXXIX): $R{=}R'{=}OCH_3$; (LXXX): $R{=}R'{=}OC_2H_5$;
(LXXXI): $R{=}OC_2H_5$, $R'{=}OC_4H_9$-iso; (LXXXII): $R'{=}OC_2H_5$, $R'{=}N(CH_3)_2$; (LXXXIII): $R{=}OC_2H_5$, $R'{=}C_2H_5$;
(LXXXIV): $R{=}OCH_3$, $R'{=}OC_2H_5$.

A reversible transfer of the trimethylsilyl group has been observed for the imidophosphates (LXXIX)-(LXXXI) (the spectrum contains one broad signal at room temperature and an AB-quartet due to the two non-equivalent phosphorus atoms appears at a reduced temperature where exchange is inhibited). The observed changes in the spectrum as a function of temperature indicate the occurrence of slow (in terms of the NMR time scale) exchange. This made it possible to determine the lifetime τ of each isomeric form.

An irreversible transfer of the trimethylsilyl group has been observed for the imidophosphates (LXXXII)-(LXXXIV). On the basis of the scheme used for the synthesis, compounds (a) should have been formed in the absence of a rearrangement:



However, in fact the compounds obtained have a structure corresponding to form (b) according to $^{31}P-\{^1H\}$ NMR spectra, i.e. under the reaction conditions the trimethylsilyl group passes to the phosphoryl oxygen linked to the P_B atom.

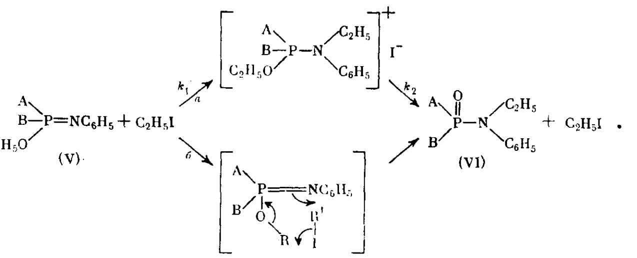
Later Riesel and coworkers[77,78] reported the reversible migration of the trimethylsilyl group in the "symmetrical" imidophosphates $[(CH_3)_3SiO]R_2P{=}NP(O)PR_2$ (R is an alkoxy or a dialkylamido-group) on the basis of ^{31}P NMR spectra.

The reversible migration of other groups (ethyl, benzoyl, or benzyl) in the imidophosphates $R_2(XO)P{=}NP.(O)R_2$ [$R = OC_2H_5$, $X = C_2H_5$ or C_6H_5CO; $R = N(C_2H_5)_2$, $X = C_6H_5CH_2$] could not be observed at temperatures between −80°C and +90°C according to $^{31}P-\{^1H\}$ NMR data[76].

IV. THE MECHANISMS OF THE IMIDE-AMIDE AND IMIDE-IMIDE REARRANGEMENTS

There have been few studies devoted to the investigation of the mechanisms of the above rearrangements. In some cases only hypotheses concerning the mechanism have been put forward.

As stated above, the kinetics of the reaction of ethoxy(phenylimido)phosphorus compounds (V) with ethyl iodide have been studied[11,13,14]. Two alternative pathways had been suggested previously to account for the mechanism of the imide-amide rearrangement[1]: (a) a two-stage pathway with an intermediate quasi-phosphonium compound (b) a single-stage pathway with a cyclic transition stage:

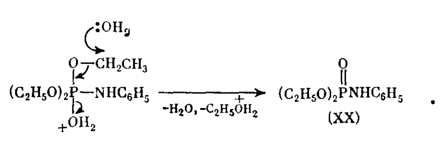


The logarithms of the rate constants listed in the Table are linearly correlated with σ^{ph} for the substituents at the phosphorus atom:

$$\lg k = 3.44 - 0.604 \sum \sigma^{ph} \ .$$

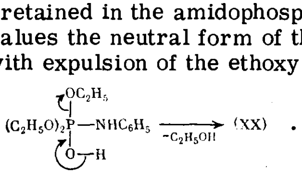
The low absolute value of the correlation parameter $\rho = 0.604$ supports a cyclic transition state, i.e. mechanism (b).

The study of the mechanism of the hydrolysis of triethyl phenylimidophosphate (I) in the presence of $H_2{}^{18}O$ at different pH (between 2 and 8) showed[79] that the content of ^{18}O in the hydrolysis products depends on pH [from 22% at low pH values (pH ~ 2) to 80% at high pH values (pH ~ 8)]. The authors[79] suggest that at low pH values the adduct of the protonated imidophosphate and water is dealkylated under the influence of another water molecule with elimination of the water molecule which had added on initially:



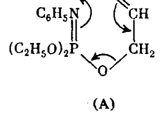
Under these conditions, all the oxygen atoms in the imidophosphate (I) are retained in the amidophosphate (XX).

At higher pH values the neutral form of the intermediate may decompose with expulsion of the ethoxy-group:

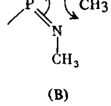


It is suggested that this entails an increase of the content of labelled oxygen in the amide (XX) formed.

The mechanism of the thermal isomerisation of aryl or alkyl imidophosphates has not been specially studied. Pudovik and coworkers[33,34] investigated the thermal isomerisation of *O*-allyl phenylimidophosphates and concluded that it is an intramolecular process with a cyclic transition state (A) (the reaction is accompanied by the inversion of the allyl group). Referring to these results, Goldwhite et al.[40] suggested that the thermal isomerisation of trimethyl methylimidophosphate also proceeds via the intramolecular mechanism (B):

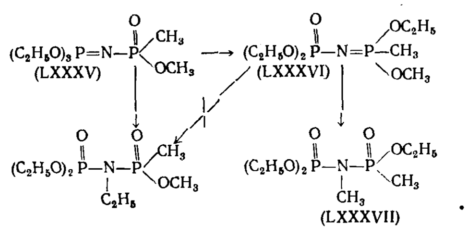


(A)



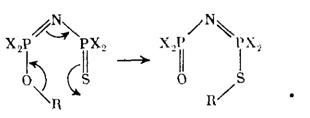
(B)

A study of the isomerisation of triethyl methoxymethylphosphorylimidophosphate (LXXXV) by ^1H NMR showed[69] that an imide–imide rearrangement takes place initially with formation of the imidophosphate (LXXXVI) and then, after further heating, it is followed by an imide–amide rearrangement; the methyl group then migrates to the nitrogen atom and compound (LXXXVII) is formed:

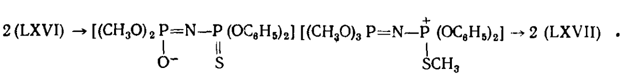


As regards the mechanism of the imide–imide rearrangement of phosphorylimidophosphates, it has been suggested that the reaction is intermolecular in the case of trialkyl dialkylphosphorylimidophosphates[68] or triethyl methoxymethylphosphorylimidophosphate (LXXXV).[69]

It has been suggested[74] that the conversion of *O*-alkyl dihalogeno(dihalogenothiophosphorylimido)phosphates into the *S*-alkyl isomers is likewise an intramolecular process and can be represented schematically as follows:

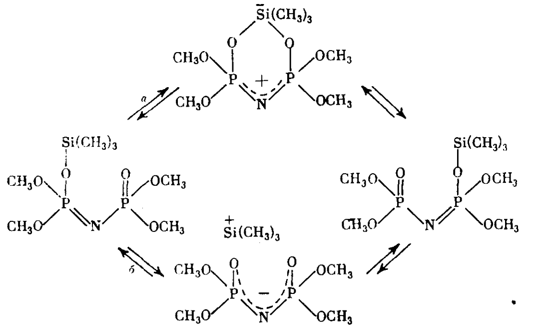


Khodak et al.[70] studied the mechanism of the imide–imide rearrangement in relation to the thermal isomerisation of trimethyl diphenoxythiophosphorylimidophosphate (LXVI). The kinetics of the isomerisation at 98°C in bromobenzene are described satisfactorily by a second-order equation [$k = (6.3 \pm 0.3) \times 10^{-5}$ litre mole^{-1} s^{-1}]. Having investigated the influence of temperature and the dielectric constant of the medium on the isomerisation rate constant, the authors[70] concluded that the mechanism involving intermolecular alkylation with a low-polarity transition state and the formation of an ion pair as a rapidly reacting intermediate is most probable for the isomerisation of the imidophosphate (LXVI) to the imidophosphate (LXVII):



$$2\,(\mathrm{LXVI}) \rightarrow [(CH_3O)_2\underset{O^-}{P}{=}N{-}\underset{S}{\overset{}{P}}(OC_6H_5)_2]\,[(CH_3O)_3P{=}N{-}\underset{SCH_3}{\overset{+}{P}}(OC_6H_5)_2] \rightarrow 2\,(\mathrm{LXVII}) \ .$$

In order to elucidate the mechanism of the migration of the trimethylsilyl group (see above), the order of the reaction of dimethyl trimethylsilyl dimethoxyphosphorylimidophosphate (LXXIX) was determined. The dependence of the lifetime of one of the tautomeric forms [the lifetimes are the same for the imidophosphate (LXXIX)] on concentration was investigated by ^1H NMR.[76] It was found that at the same temperature the lifetimes are the same in solutions at different concentrations (in chloroform). This shows that the reaction is of first order, i.e. that the imidophosphate (LXXIX) undergoes an intramolecular rearrangement. Mechanism *a* involving the formation of a cyclic intermediate, may be proposed for the rearrangement, in view of the presence of the unshared *d* orbitals of the silicon atom. Nor can one rule out the ionic mechanism *b*—the migration of the trimethylsilyl group as a cation:



Examination of the data for the imide–amide and imide–imide rearrangement permits the conclusion that the IPC containing the $R{-}O{-}\underset{|}{\overset{|}{P}}{=}N{-}$, $R{-}O{-}\underset{|}{\overset{|}{P}}{=}N{-}\overset{|}{P}{=}O$, and $R{-}O{-}\underset{|}{\overset{|}{P}}{=}N{-}\underset{|}{\overset{|}{P}}{=}S$ groups are highly reactive.

In many instances these rearrangements may be used as a method for the synthesis of new IPC and phosphorus acid amides.

The results of the study of the thermal isomerisation permit the conclusion that, owing to the high lability of the IPC, their synthesis in a pure form requires special checks (by thin-layer chromatography, infrared spectroscopy, ^{31}P NMR, and ^{1}H NMR).

Since certain types of IPC may have practical applications as drugs[90], herbicides[81,82], and defoliants[83], the importance of studies on the imide–amide and imide–imide rearrangements can be readily understood. This field of the IPC chemistry is developing vigorously; we may expect that it will yield new interesting theoretical and practical results.

Organic Phosphorus Compounds with a P-P Bond

I.F.Lutsenko and M.V.Proskurnina

Data on the methods of synthesis and reactivities of organic diphosphines with a direct P-P bond between four-coordinated phosphorus atoms as well as compounds with a P-P bond between a three-coordinated phosphorus atom and a phosphorus atom with a higher degree of coordination are surveyed and described systematically. Problems of the steric structures and the results of structural analysis, spectroscopic studies, and studies by other methods are considered.
The bibliography includes 269 references.

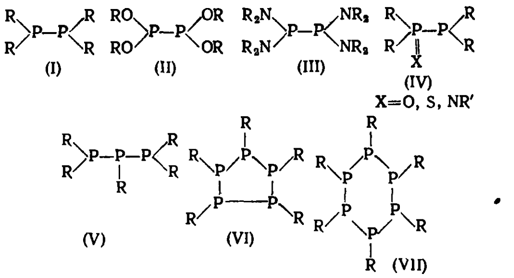
I. INTRODUCTION

Studies on organic compounds with P–P bonds have continued since 1877 when Kohler and Michaelis[1] obtained for the first time the so-called phosphobenzene[1]:

$$n\,\mathrm{PhPCl_2} + n\,\mathrm{PhPH_2} \rightarrow 2\,(\mathrm{PhP})_n + 2n\,\mathrm{HCl}.$$

Numerous classes of organophosphorus compounds (OPC) with P–P bonds are now known; these compounds can be fairly formally classified as follows: (a) in terms of the valence state of the phosphorus atoms linked to one another; (b) in terms of the number of phosphorus atoms in the chain; (c) in terms of the number of phosphorus atoms in the ring. For example, it is possible to distinguish the following types of organic compounds with P–P bonds: tetra-alkyl(aryl)-diphosphines† (I), tetra-alkoxy(aryloxy)-diphosphines (II), tetra-aminodiphosphines (III), tetra-alkyl-(aryl)diphosphine monoxides (monosulphides, monoimides), tetra-alkyl(aryl)diphosphines (IV), penta-alkyl(aryl)triphosphines (V), polyalkyl(aryl)cyclopolyphosphines (VI) and (VII), etc.



A review published in 1965 is devoted to organic diphosphines[2]. Since then the number of data on this subject has significantly increased and in the present review we shall therefore consider only compounds with a P–P bond between two phosphorus atoms at least one of which is three-coordinated; mainly studies published after the above review[3] or not included in it are analysed.

II. THE STRUCTURES OF ORGANIC DI- AND POLY-PHOSPHINES

The length of the P–P bond in organic di- and polyphosphines is ~ 2.22 Å,[4] is fairly constant, and does not deviate significantly from the value (2.24 Å) predicted by Pauling[5], which suggests either the absence of a higher degree of binding than in a simple σ bond or the presence of a constant additional binding. The latter is unlikely, since the length of the P–P bond is almost independent of the substituent, its electronegativity, or whether the molecular structure is cyclic or non-cyclic and even of the valence state of the phosphorus atom (Table 1). Thus the lengths of the P–P bond in tetramethyldiphosphine, diphosphine, and tetrakis(trifluoromethyl)diphosphine are 2.192, 2.216, and 2.160 Å respectively, while in the presence of the most electronegative substituent (fluorine) the longest P–P bond is formed (2.281 Å) (Table 1). The length of the P–P bond in diphosphine is not a simple function of the electronegativity of the groups and no evidence for the existence of $p\pi - d\pi$ conjugation can be obtained from the lengths of these bonds. However, even in difluorodiphosphine, where the greatest delocalisation should be expected, neither the bond length nor the conformation of the molecules (see below) permit the conclusion that $p\pi - d\pi$ conjugation obtains[7]. The Nyholm–Gillespie theory and semiempirical calculations predict satisfactorily the bond lengths and angles in organic phosphines[8-10] but have no predictive power as regards organic diphosphines[12,13]. On the other hand, *ab initio* calculations yield P–P bond lengths in good agreement with experiment[12,13].

Table 1. The P–P bond lengths.

Compound	P–P bond length, Å	Refs.	Compound	P–P bond length, Å	Refs.
$H_2P—PH_2$	2.218±0,004	6	$Me_2P—PMe_2 \cdot 2Fe(CO)_4$	2,231±0.007	19
$D_2P—PDH$	2.219±0,0004	15	$Ph_2P—PPh_2 \cdot 2Ni(CO)_3$	2,277±0,004	20

---

† The term "diphosphanes" has also been suggested for organic diphosphines on the basis of the analogy between these compounds and organic disilanes, distannanes, etc.[2]: however, it does not reflect the valence state of the phosphorus atoms.

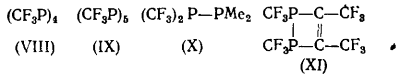
The C–H and C–P bond lengths and the C–P–C and C–H–P dihedral angles in Me_4P_2 are close to the value in Me_nPH_{4-n} (n = 1–3).[3]

The P–P bond dissociation energies in diphosphine, measured mass-spectrometrically, are 61[28] and 74[29] kcal mole^{-1} for P_2H_4, 62 kcal mole^{-1} [30] for P_2Cl_4, 71 kcal mole^{-1} [28] for P_2I_4, and 86 kcal mole^{-1} [32] for Et_4P_2, but these data are subject to large systematic errors[28]. According to data obtained by other methods, the P–P bond energy varies from 44 to 58 kcal mole^{-1} (Table 2), which is significantly less than the energies of the P–N (67–77 kcal mole^{-1}) and P–C (65–71 kcal mole^{-1}) bonds[5,38,39], but is higher than the energy of the N–N bond (in N_2F_4, for example, the latter is 20.4 ± 1.3 kcal mole^{-1} [32]).

Table 2. The P–P bond energies.

Compound	P–P bond energy, kcal mole^{-1}	Method of determination	Refs.
$H_2P—PH_2$	46.8	Thermochemical	34
P_4	51,3	Calculation	35
P_4	51,3	Thermochemical	5
P_4	44	Spectroscopic	36
$Ph_2P—PPh_2$	50	Thermochemical	37

Experimental evidence for a planar configuration of the phosphorus atoms, which might indicate the occurrence of $p\pi - d\pi$ binding, has not been obtained for phosphines having the general formula $R_2P–PR_2$ either in the gas or in the solid phase. *Ab initio* calculations by the SCF LCAO-MO method for all the possible rotational isomers of the P_2H_4 molecule also indicate the absence of $p\pi - d\pi$ binding[40]. According to photoelectron spectroscopic data for di- and poly-phosphines (VIII)–(XI), the degree of $p\pi - d\pi$ binding is very insignificant[41]:

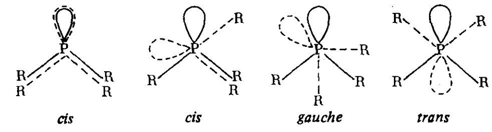


$(CF_3P)_4$ (VIII) $(CF_3P)_5$ (IX) $(CF_3)_2P—PMe_2$ (X)

$$\begin{matrix} CF_3P—C—CF_3 \\ | \quad\;\; \| \\ CF_3P—C—CF_3 \end{matrix}$$

(XI)

The substituents and the lone electron pair of the X atom in molecules having the general formula X_2Y_4*, where X = N, P, or As, have a pyramidal arrangement; in this case there is a possibility of three types of symmetry—C_2 (*cis*- and *gauche*), C_{2v} (*cis*), and C_{2h} (*trans*).[42]



Symmetry	C_{2v}	C_2	C_2	C_{2h}
Dihedral angle	0°	46°55′	93°50′	180°

The relative number of conformations, determined by their stabilities, depends in the general case on the interaction of the two lone electron pairs, on the steric repulsion between the substituents, on the electrostatic interaction, and other factors. Table 3 presents data for the conformational compositions of a series of inorganic and organic diphosphines. Evidently the *gauche*- or *trans*-conformation is the most stable. The proportion of the *trans*-conformer can be related in certain cases to the electronegativity of the substituents at the phosphorus atom: thus the contents of the *trans*-conformers of Me_4P_2 and Cl_4P_2 are respectively 40 and 95%[42–45]. This effect may be attributed wholly to the difference between the electronegativities of the Me group and the Cl atom (2.0 and 3.0 respectively), since the effective volumes of the substituents and the P–P bond lengths in these compounds are identical. This conclusion has also been confirmed by a comparison of the conformational compositions of $(CF_3)_4P_2$ and F_4P_2 (the electronegativities of the CF_3 group and the fluorine atom are 3.2 and 4 respectively); the content of the *gauche*-form of $(CF_3)_4P_2$ is much higher[46]. In this case steric hindrance is also apparently unimportant, since the P–P bond in $(CF_3)_4P_2$ is much shorter (2.16 Å) than in F_4P_2 (2.28 Å). If $(CF_3)_4P_2$ and Me_4P_2 are compared from this point of view, the latter should have the *gauche*-conformation and the former should exist as the *trans*-conformer. However, the shorter P–P bond in the perfluoro-compound prevents this and the contents of the *gauche*-conformers of $(CF_3)_4P_2$ and Me_4P_2 are 30 and 60% respectively.

Table 3. The P–P bond lengths in inorganic and organic diphosphines.

*Raman spectroscopy (Ed. of Translation).

**Extended Hückel method (Ed. of Translation).

***Photoelectron spectroscopy.

Nevertheless, mainly the *gauche*-conformation obtains for the majority of organic diphosphines, which confirms the rule of the greatest stability of the conformer with the *gauche*-disposition of the lone pairs (the *gauche*-effect)[69,70]. In the solid phase the diphosphines investigated exist in the *trans*-conformation, which may be a consequence of their packing in the crystal[69].

The conformational behaviour of diphosphines differs somewhat from that of their nitrogen analogues—hydrazine and its derivatives: the *gauche*-conformation obtains exclusively for hydrazine and tetramethylhydrazine in the gas, liquid, and solid states[71-75] and a 50% content of the *trans*-conformer has been found only for tetrafluorohydrazine in the gas and liquid states[76-78].

Photoelectron spectroscopy (PES) has been resorted to recently in order to determine the conformational compositions of organic diphosphines. On the basis of PES data, the diphosphines Me_4P_2 and $(CF_3)_4P_2$ are regarded as mixtures of *gauche*- and *trans*-conformers[54]; however, Ames and Turner[53] treat PES data for Me_4P_2 as confirmation of the existence of the latter exclusively as the *gauche*-conformer.

The barriers to rotation about the P–P bond (calculated data) are presented in Table 4; there are no experimental literature data. According to calculations by the *ab initio* SCF LCAO-MO method, the barrier to rotation in diphosphine is 3.3 kcal mole^{-1},[79] while in hydrazine the corresponding value is 11.5 kcal mole^{-1} according to the same method of calculation and experimental data. This difference between the barriers is logically consistent with the greater P–P bond length compared with $\ddot{N}$–$\ddot{N}$ and also with the greater diffuseness of the orbitals of the phosphorus atoms compared with those of the nitrogen atom[80].

Table 4. The barriers to rotation about the P–P bond (kcal mole^{-1}).[13,15,63,64].

Compound	Method of calculation

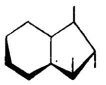
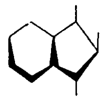
If there are two different substituents at the same phosphorus atom in the organic diphosphine $R^1(R^2)P-P(R^1)(R^2)$, then the topology of this system is analogous to that of the system with two asymmetric carbon atoms: the lone electron pair plays the role of the fourth substituent. Indeed asymmetric organic diphosphines have the *meso*- and *d*, *l*-forms, whose interconversion (22–24 kcal mole^{-1}) involves rotation about the P–P bond and inversion of the phosphorus pyramid[81,82]. The main contribution to the transition energy comes from the energy of the inversion process, which is lower in diphosphines than in trialkylphosphines. Bulky and electron-donating substituents lower the inversion barrier, the influence of electronic factors predominating as a rule. The proportions of the racemate and the *meso*-form in solution are approximately the same for sterically non-hindered substituents (R^1 = Me, R^2 = Et). When R^1 = Me and R^2 = t-Bu, the *meso*-form is absent and (XII) exists as the racemate. Indeed in the two possible rotational *gauche*-isomers the bulky R^2 groups in the *meso*-form are brought closer together and their *gauche*-steric interaction is unfavourable. According to ^1H and ^{31}P NMR data, at 130–150°C equilibrium is attained rapidly (in terms of the NMR time scale) between the two diastereoisomers[83-85].

A large number of structures have been proposed for cyclic polyphosphines. Thus all structures, ranging from dimeric to polymeric, have been discussed for phosphobenzene. It has now been established that in the crystalline state phosphobenzene exists as the pentamer or hexamer (or their mixture)[22,25,86-88]. As a rule, standard methods of synthesis lead to a mixture with the preferential formation of the pentamer, but, if the reaction between dichlorophenylphosphine and phenylphosphine is carried out in tetrahydrofuran (THF), mainly the hexamer is obtained. On crystallisation from acetonitrile, it is possible to isolate the pure pentamer, whose molecule has the structure of a flat ring where the phenyl groups are located in the plane of the ring and the deviations from the $D_{5}d$ symmetry are extremely insignificant[22]. The hexamer is polymorphic and exists in four modifications—monoclinic, orthorhombic, triclinic, and trigonal. The triclinic modification has the chair conformation with the equatorial disposition of the benzene rings[24,88]. The behaviour of phosphobenzene in solution is unusual: according to molecular weight determinations, both the pentamer and hexamer decompose to the tetramer and even the trimer; on the other hand, crystallisation from solution again leads solely to the pentamer and hexamer. In order to explain this, it is assumed that the P–P bonds readily dissociate in solution[23,89]—possibly with the intermediate formation of the phosphorus analogue of carbene, namely RP:[89]. In the solid phase rapid interconversion does not occur: thus, after two and a half years, the phosphobenzene hexamer was converted into the pentamer to the extent of only 50%.[90] Despite the large radius of the phosphorus atom, the size of the ring depends greatly on the nature of the substituent. Thus ethyl- and butyl-phosphorus consist as a rule of equal amounts of the tetramer and pentamer, but do not form hexamers[91-93]; propyl- and cyclohexyl-phosphorus are tetrameric in solution and in the solid state with the *trans*-position of the lone electron pairs[94,95]. Only the pentameric form [pentakis(pentafluorophenyl)pentaphospholane] has been found for pentafluorophenylphosphine[96].

Structural analysis of carbocyclic compounds with P–P bonds has undoubtedly revealed interesting characteristics of these substances. Hitherto the number of known compounds of this kind is comparatively small. Thus the configuration of the *trans*, *trans*-isomer has been established for 1,2,3-triphenyl-1,2,3-triphosphaindan in the crystalline state[25]:



trans, trans

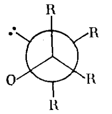


cis, trans

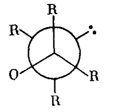
.

According to NMR data[25], phosphaindan exists as the *cis*, *trans*-isomer in solution, in good agreement with its reactivity as a ligand in the reaction with iron carbonyls[97]. 1,2,3,4-Tetraphenyl-1,2,3,4-tetraphospholane[98] exists in the stable half-chair conformation, where all the phenyl groups are axial (C_2 symmetry).

The existence of two rotational isomers, (XII) and (XIII), may be expected for organic diphosphine monoxides, but these cannot be identified on the basis of ^{31}P NMR data (the spectra of tetra-alkyldiphosphine monoxides do not change between −90° and +30° C)[99]:



(XII)



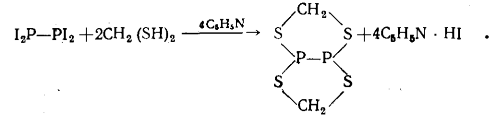
(XIII)

.

III. METHODS OF SYNTHESIS

At least two fundamentally different approaches to the synthesis of OPC with P–P bonds are possible: the first consists in the use of starting compounds already containing a P–P bond and in the second the P–P bond is formed during synthesis. In the first case it would appear convenient to employ the readily available tetra-iododiphosphine[100], but numerous attempts to use it (in reactions with alcohols, amines, alkyl halides, and organometallic compounds) have led as a rule to products with a single phosphorus atom in the molecule[101–104]. As an exception, one may mention the following reactions, which take place with extremely low yields[100,101]:

$$I_2P{-}PI_2 + 4AgCN \rightarrow (CN)_2P{-}P(CN)_2 + 4AgI \;,$$



In a study of the alkylation of phosphorus di-iodide Kirsanov and coworkers[105–109] developed a convenient method for the synthesis of symmetrical diaryldi-iododiphosphines.

Phosphorus dichloride $(PCl_2)_2$ has been hardly used in syntheses, since it is difficult to obtain[110]. There have been few examples of the use of elemental phosphorus, which already contains P–P bonds. Thus ultraviolet irradiation of a solution of elemental phosphorus in bromotrichloromethane gives satisfactory yields of (XIV) and (XV)[110]:

(XIV)

(XV)

.

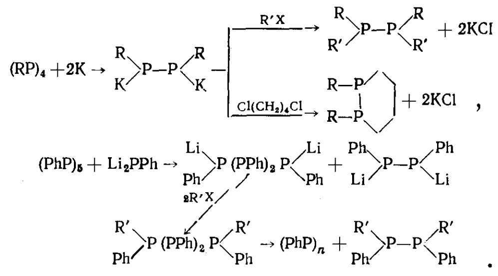
The reactions, which take place in the gas phase, are undoubtedly unsuitable for preparative purposes, but the following interesting reaction may be mentioned[111]:

$$P_4 + 4CHF_3 \rightarrow (F_3CP)_4 + 2H_2 \;.$$

The use of elemental phosphorus made it possible to obtain a very unusual molecule with a P–P bond between two two-coordinated phosphorus atoms (in the complex)[112]:

$$P_4 + 2(C_5H_5)_2Mo \cdot H_2 \xrightarrow[95^\circ]{\text{toluene}} 2(C_5H_5)_2Mo \cdot HP{=}PH \;.$$

Red phosphorus reacts smoothly with sodium in liquid ammonia to form diphosphides, which can then be alkylated by alkyl halides to form tetra-alkyldiphosphines[113,114]. The necessity to carry out experiments in liquid ammonia and the comparatively low yields (not exceeding 25%), due to the cleavage of Alk_4P_2 to sodium phosphide, limit the applicability of this reaction. On the other hand, the ability of the P–P bonds to dissociate under the influence of alkali metals and a number of other nucleophiles has been used to synthesise di- and poly-phosphines from cyclopolyphosphines, which are frequently more readily available than other compounds with P–P bonds[115–121]:



This method makes it possible to obtain a wide range of symmetrical and asymmetric organic diphosphines, as well as new compounds with a P–P bond in the ring, in 70–90% yields.

A very convenient preparative method for the synthesis of organic compounds with P–P bonds from inorganic phosphorus compounds was proposed by Kabachnik and coworkers and was subsequently developed by other investigators[122–125]:

$$RMgX + P(S)Cl_3 \rightarrow R_2P(S){-}P(S)R_2 + MgXCl \;,$$
$$R_2P(S){-}P(S)R_2 \xrightarrow{2R_3P} R_2P{-}PR_2 + 2R_3P{=}S \;.$$

Tetra-alkyldiphosphine disulphides are formed in yields greater than 60% and are reduced by metals as well as trialkylphosphines and trialkyl phosphites to tetra-alkyldiphosphines[81,82,126].

Numerous examples of the synthesis of organic diphosphines from halogenophosphines on treatment with various metals or metal phosphides via the general mechanism

$$R_2PX + M \rightarrow R_2PM \xrightarrow[-MX]{R_2PX} R_2P{-}PR_2 + MX$$

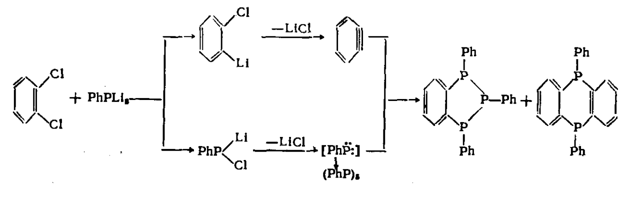
have been described in Cowley's review[3]; here we shall confine ourselves to new examples of this widely used method[63,127–129,131–135]:

$$2(C_6F_5)_2PBr + Hg \rightarrow (C_6F_5)_2P{-}P(C_6F_5)_2 + Hg_2Br_2 \;,$$
$$2F_2PI + 2Hg \rightarrow F_2P{-}PF_2 + Hg_2I_2 \;,$$
$$Ph_2PNa + ClP(NMe_2)_2 \rightarrow Ph_2P{-}P(NMe_2)_2 + NaCl \;,$$
$$(F_3C)_2P{-}SiMe_3 + IPH_2 \rightarrow (F_3C)_2P{-}PH_2 + Me_3SiI \;,$$
$$2RMgX + PCl_3 \xrightarrow[2MgXCl]{} [R_2PCl] \xrightarrow{Mg} R_2P{-}PR_2 + MgCl_2 \;,$$
$$2\,(t\text{-}Bu)_2PCl + Na \rightarrow (t\text{-}Bu)_2P{-}P(Bu\text{-}t)_2 + NaCl.$$

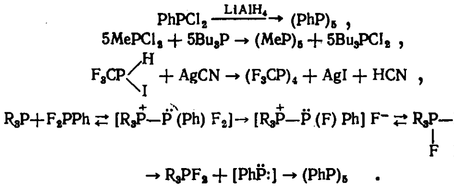
The condensation principle proved to be convenient also for the synthesis of cyclopolyphosphines using alkyldichlorophosphines in the reaction[91,134]:

$$4t\text{-}BuPCl_2 + 8Na \rightarrow (t\text{-}BuP)_4 + 8NaCl \;,$$
$$F_3CPI_2 + Hg \rightarrow (F_3CP)_4 + (F_3CP)_5 + HgI_2 \;.$$

Presumably in these and analogous instances the reaction proceeds via the phosphinidene $R\ddot{P}$:—the phosphorus analogue of carbene, which has two lone electron pairs and vacant 3*d* and 4*d* orbitals in the singlet configuration. The formation of phosphinidene is possible also in the following case[117]:



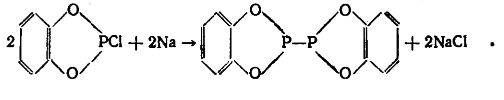
The generation of phosphinidene can apparently also be postulated in reactions of the following kind[134-137]:



$$PhPCl_2 \xrightarrow{LiAlH_4} (PhP)_5\ ,$$
$$5MePCl_2 + 5Bu_3P \rightarrow (MeP)_5 + 5Bu_3PCl_2\ ,$$
$$F_3CP(H)(I) + AgCN \rightarrow (F_3CP)_4 + AgI + HCN\ ,$$
$$R_3P + F_2PPh \rightleftarrows [R_3\overset{+}{P}-\overset{+}{P}(Ph)F_2] \rightarrow [R_3\overset{+}{P}-\ddot{P}(F)Ph]F^- \rightleftarrows R_3P(F)-\ddot{P}(F)Ph \rightarrow$$
$$\rightarrow R_3PF_2 + [Ph\ddot{P}:] \rightarrow (PhP)_5\ .$$

The esters and amides of hypodiphosphorous acid have been obtained from phosphorochloridites using sodium and potassium as well as mercury derivatives[138-141]:

$$(Me_3Si)_2Hg + 2(RO)_2PCl \rightarrow (RO)_2P-P(OR)_2 + 2Me_3SiCl + Hg\ ,$$
$$(Me_3Si)_2Hg + 2(Et_2N)_2PCl \rightarrow (Et_2N)_2P-P(NEt_2)_2 + 2Me_3SiCl + Hg\ ,$$



As will be shown below, the reactivity of organic diphosphines depends significantly on the substituents at the phosphorus atom. For this reason, the synthesis of tetra-alkoxydiphosphines, which may be assumed to undergo all the numerous reactions known in the chemistry of trialkyl phosphites, is therefore of special interest. A new approach to the synthesis of tetra-alkoxydiphosphines is based on the employment of dialkoxyphosphines—the full esters of hypophosphorous acid[142,143]. It has been shown that soft bases (dialkoxyphosphines) react with soft acids (dialkyl phosphorochloridites) to form tetra-alkoxydiphosphines[144,145]:

$$(RO)_2PH + (R'O)_2PCl \xrightarrow[90\%]{Et_3N} (RO)_2P-P(OR')_2 + Et_3N\cdot HCl\ .$$

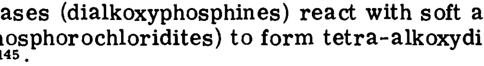
Symmetrical $(RO)_4P_2$ may be obtained (in yields up to 50%) without isolating $(RO)_2PH$:[146]

$$2(RO)_2PCl + R_3SnH \xrightarrow{Et_3N} [(RO)_2PH + (RO)_2PCl] \xrightarrow{Et_3N} (RO)_2P-P(OR)_2 + Et_3N\cdot HCl.$$

The synthesis (via the mechanism described above) of dialkoxydialkyldiphosphines—compounds with two centres of different basicity ("phosphite" and "phosphine")—is also of undoubted interest[14]:

$$(RO)_2PH + R'_2PCl \xrightarrow{R''_3N} (RO)_2P-PR_2 + R''_3N\cdot HCl\ ,$$
$$R_2PH + (R'O)_2PCl \xrightarrow{R''_3N} R_2P-P(OR')_2 + R''_3N\cdot HCl\ .$$

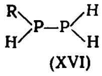
For the given type of interaction, the choice of the pair of reactants is not immaterial: the first reaction gives a yield of 70%, while that of the second is only 45%: dialkylphosphines (particularly when they are sterically hindered) react much more slowly than dialkoxyphosphines. The synthesis of trialkoxyalkyldiphosphines has been described[146]:



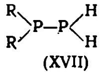
$$(RO)_2PH + R'(RO)PCl \xrightarrow{R''_3N} (RO)_2P-P(OR)R' + R''_3N\cdot HCl\ .$$

It is noteworthy that asymmetric diphosphines are as a rule difficult to obtain (the yields do not exceed 40%) owing to their disproportionation to symmetrical compounds.

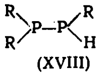
The organic diphosphines (XVII)-(XX) with PH bonds in the molecule



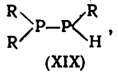
(XVI)



(XVII)



(XVIII)



(XIX)

are known only in a few instances. Among di-s-diphosphines [compounds (XIX)], 1,2-bis(trifluoromethyl)diphosphine has been described[129]; it was obtained, among other products, by the cautious hydrolysis of $(CF_3P)_4$. A seemingly general method of synthesis of diphosphines of type (XIX) was proposed in 1971:[132]

$$2PhP(H)K + BrCH_2CH_2Br \rightarrow Ph(H)P-P(H)Ph + CH_2{=}CH_2 + KBr\ .$$

However, the equilibrium

$$5\,Ph(H)P-P(H)Ph \rightleftarrows 5PhPH_2 + (PhP)_5,$$

in which a diphosphine of type (XIX) exists as a distereoisomeric mixture of the *meso*- and *dl*-forms, occurs in the temperature range between 30° and 200°C. The energy of the transition between these forms is 22-24 kcal mole^{-1}, i.e. is of the same order of magnitude as the energy of the given transition for R_4P_2.[82] It has been suggested that the intermediates $Ph\ddot{P}$: occurs in this equilibrium, particularly since the process[147]

$$5(F_3CP)_4 + 20MePH_2 \rightarrow 20F_3CPH_2 + 4(MeP)_5$$

takes place.

Above 225°C, the di-s-diphosphine $(CH_3PH)_2$ is converted into a mixture of $(CF_3P)_n$ and CF_3PH_2, but in contrast to the previous process, the reaction is irreversible[9]. A diphosphine of type (XVIII) is formed from a mixture of difluorodiphosphine or EtP_2 and an excess of PH_3 at −78°C.[148]

P-P bonds are known to be readily cleaved by amines, but the reaction may be displaced in the opposite direction in the case of the low-boiling dimethylamine[23,149]:

$$(F_3C)_2N-P(CF_3)_2 + Me_2PH \rightarrow Me_2NH + (F_3C)_2P-PMe_2\ ,$$
$$MeP(NMe_2)_2 + 2Ph_2PH \rightarrow MeP(PPh_2)_2 + 2Me_2NH\ ,$$
$$3PhP(NMe_2)_2 + 3PhPH_2 \rightarrow (PhP)_6 + 6Me_2NH\ .$$

Certain non-trivial methods of organic synthesis of diphosphines must also be mentioned. These include the electrochemical method for synthesising Ph_4P_2,[150] the condensation of Ph_2PCl with formation of a P-P bond on treatment with calcium carbide[151,152], and the reduction of di-t-butylmercury by secondary phosphines[153]. Di- and tri-phosphines with P-Si bonds have been obtained from silylated phosphines[154,155]:

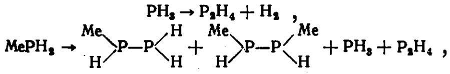
$$2Me_3Si-P(Ph)K + Br_2 \xrightarrow{THF} Me_3Si(Ph)P-P(Ph)-P(SiMe_3)Ph + 2KBr\ ,$$
$$2(Me_3Si)_2PLi + BrCH_2CH_2Br \rightarrow (Me_3Si)_2P-P(SiMe_3)_2 + 2LiBr + CH_2{=}CH_2\ .$$

A similar process occurs when lithium and potassium phosphides are acted upon by bis-(α-chlorobenzylidene)-hydrazine[156]:

$$2R_2PK + PhC(Cl){=}N-N{=}C(Cl)Ph \rightarrow 2PhC{\equiv}N + R_2P-PR_2 + 2KCl\ .$$

A new method for the synthesis of thermodynamically unstable organic compounds—in a silent electric discharge at low pressures—has been proposed recently[15]. In the series of OPC this method was used for the first time to synthesise tetrachlorodiphosphine[31] and in recent years also for the synthesis of a number of unstable diphosphines, particularly diphosphines with P-H bonds[158]:

$$PH_3 \rightarrow P_2H_4 + H_2\ ,$$



$$MePH_2 \rightarrow Me(H)P-PH_2 + Me(H)P-P(H)Me + PH_3 + P_2H_4\ ,$$
$$F_3CPH_2 \rightarrow F_3CP(H)-P(H)CF_3 + PH_3 + (F_3C)_2PH + (F_3C)_3P\ .$$

For methyldiphosphine, equilibrium with the cyclic form is established even at room temperature[159]:

$$MeP(H)PH_2 \rightleftarrows MePH_2 + \frac{1}{n}(MeP)_n\ .$$

Diphosphines with P–H bonds can also undergo further disproportionation in a silent discharge[158]:

$$F_3C(H)P{-}P(H)CF_3 \rightarrow F_3CPH_2 + (F_3C)_3P + (F_3C)_4P_2 \ .$$

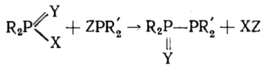
P–P bonds are formed in the thermolysis or photolysis of metal complexes with tertiary or secondary phosphines[160,161]:

$$Fe(CO)_4 \cdot HPR_2 \xrightarrow{h\nu} Fe_2(CO)_6(PR_2)_2 \ ,$$
$$W(CO)_5 \cdot HPR_2 \xrightarrow{\Delta} W_2(CO)_8(PR_2)_2 + W_2 + (CO)_7(PR_2)_2 + R_2PH \ .$$

The presence of a P–P bond in the complexes formed was established by X-ray diffraction. Many of the above complexes cannot be synthesised directly from organic diphosphines (bidentate ligands) and metal carbonyls, since dissociation of P–P bonds is frequently observed in these reactions[161–170].

Compounds with a bond between two phosphorus atoms of different valence may be synthesised by the oxidation of organic diphosphines, i.e. using compounds with P–P bonds already present. These reactions are discussed below and can be used on a preparative scale when the corresponding organic diphosphines are available.

A set of reactions, which may be described in terms of the formal general mechanism



$$R_2P{\overset{\displaystyle /\!\!/ Y}{\underset{\displaystyle \diagdown X}{}}} + ZPR'_2 \rightarrow \underset{\underset{\displaystyle Y}{\|}}{R_2P}{-}PR'_2 + XZ$$

and which give satisfactory yields in certain specific cases, have been suggested for the synthesis of diphosphine monoxides (monosulphides):

$$R_2P(O)H + R'_2PCl \xrightarrow[-HCl]{Et_3N} R_2P(O){-}PR'_2 \ (\text{Ref.}170) \ ,$$
$$R_2P(O)H + R'_2P{-}NMe_2 \xrightarrow{\leftarrow Me_2NH} R_2P(O){-}PR'_2 \ (\text{Ref.}99) \ ,$$
$$R_2PONa + R'_2PCl \xrightarrow{-NaCl} R_2P(O){-}PR_2 \ (\text{Refs. } 172{,}173) \ .$$

The interaction with dialkylphosphinous acids is complicated by the exchange reaction[174]:

$$R_2P(O)H + R'_2PCl \rightleftarrows R_2PCl + R'_2P(O)H \ ,$$

which may be suppressed by an excess of a tertiary amine. The attack by dialkylchlorophosphine on the two basic centres of the ambident anion $R_2P{-}S^-$ proceeds in the same way as on the $R_2P{-}O^-$ anion—mainly on the phosphorus atom[174]:

$$R_2PSNa + R_2PCl \xrightarrow{-NaCl} \underset{95\%}{R_2P(S){-}PR_2} + \underset{5\%}{R_2P{-}S{-}PR_2} \ .$$

In the presence of primary substituents, monosulphides are formed exclusively; they are stable and do not rearrange to thioanhydrides. In the presence of tertiary substituents it is impossible to detect the corresponding monosulphide: only thioanhydrides of phosphinous acids are always isolated, which may be a consequence of thermodynamic control, i.e. a result of the rapid rearrangement of the monosulphide to the thioanhydride. In the presence of secondary substituents, a tautomeric mixture of the corresponding monosulphides and thioanhydrides is formed. Problems associated with the rearrangement in this series will be discussed in greater detail below.

Dialkoxydialkyldiphosphine monoxides are formed in virtually quantitative yields as a result of the exothermic reaction[175]

$$R_2PONa + ClP(OR)_2 \rightarrow R_2P(O){-}P(OR)_2 \ .$$

It makes it possible to obtain 2,2-dialkoxy-1,1-dialkyl-1-oxodiphosphines; the second isomer of the monoxide—2,2-dialkoxy-1,1-dialkyl-2-oxodiphosphine—is formed from dialkylchlorophosphines and dialkyl phosphites:

$$(RO)_2P(O)H + R'_2PCl \xrightarrow{Et_3N} R'_2P{-}(O)P(OR)_2 \ ,$$

and also from tetra-alkylpyrophosphites[175]:

$$(R'O)_2P{-}O{-}P(OR')_2 + R_2PCl \xrightarrow{R'_3N} R_2P{-}(O)P(OR')_2 + (R'O)_2PCl \ :$$

The monosulphides are also readily obtainable[176]:

$$R_2P(S)H + (RO)_2PCl \xrightarrow{R_3N} R_2P(S){-}P(OR)_2 \ .$$

It is noteworthy, that dialkylphosphinous acids give rise only to mixed anhydrides of phosphonous and phosphorous acids in this reaction. 2,2-Dialkoxy-1,1-dialkyl-2-thionodiphosphines can be synthesised from the 1-sulphides[176]:

$$R_2P(S){-}P(OR)_2 \xrightarrow{\Delta} R_2P{-}P(S)(OR)_2 \ .$$

Tetra-alkoxydiphosphine monoxides are stable for several hours, while tetra-alkoxydiphosphine monosulphides are entirely stable and can be formed via a similar mechanism[177,178]:

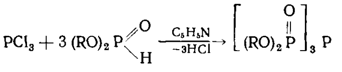
$$(RO)_2PXNa + (R'O)_2PCl \rightarrow (RO)_2P(X){-}P(OR')_2 + NaCl \ ,$$

where X = S or O.

The interaction of diphenylphosphine oxide with the mixed anhydride of acetic and diphenylphosphinous acids may be regarded as a variant of the above reactions[177]:

$$Ph_2P(O)H \xrightarrow{(MeCO)_2O} Ph_2PO(O)CMe \xrightarrow[-MeCOOH]{Ph_2P(O)H} Ph_2P(O){-}PPh_2 \ .$$

Using this scheme, it is possible to obtain compounds with three P–P bonds in the molecule in 63% yields[178]:



$$PCl_3 + 3\,(RO)_2P{\overset{\displaystyle /\!\!/ O}{\underset{\displaystyle \diagdown H}{}}} \xrightarrow[-3HCl]{C_5H_5N} \left[(RO)_2\overset{\overset{\displaystyle O}{\|}}{P}\right]_3 P \ .$$

The biphilic properties of compounds with a three-coordinated phosphorus atom suggest yet another method for the formation of a P–P bond between phosphorus atoms with different coordination [numbers?]. Indeed highly nucleophilic soft bases (trialkylphosphines, dialkylphosphines, or aminophosphines) react with electrophilic soft acids (dialkylchlorophosphines) to form crystalline adducts in which a P–P bond is formed according to NMR spectroscopic data[138,179–182]:

$$Me_3P + ClPR_2 \rightarrow [Me_3P{-}PR_2]^+Cl^- \ ,$$
$$R_2PH + R_2PCl \rightarrow [R_2P{-}P(H)R_2]^+Cl^- \ ,$$
$$R_3P{=}NPR'_2 + R''_2PCl \rightarrow [R_3P{=}N{-}P(R'_2){-}PR''_2]^+Cl^- \ .$$

The reaction is appreciably reversible in solution in methylene chloride and does not occur for weakly nucleophilic tertiary phosphines, for example, $MePh_2P$. However, the latter reacts with the more electrophilic chloride PCl_3 to form the corresponding adduct at 20°C. The adducts are usually stable up to room temperature. When two moles of dialkylchlorophosphines are used, the tertiary phosphine behaves as a "condensing" agent and tetra-alkyldiphosphines are formed in satisfactory yields[138,179,183].

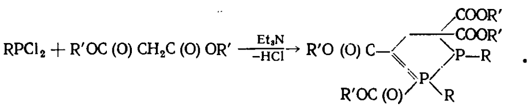
If esters of phosphonous, phosphinous, and phosphorous acids are used instead of tertiary phosphines, the Arbuzov rearrangement may occur in the system via intermediates of the type described above, which apparently have the structure of quasi-phosphonium compounds with P–P bonds[184–186]:

$$Ph_2POR + Ph_2PCl \rightarrow Ph_2P{-}P(O)Ph_2 + RCl \ ,$$
$$MeP(OMe)_2 + Ph_2PCl \rightarrow [Ph_2P{-}P(OMe)_2Me]^+Cl^- \rightarrow Ph_2P(O)(OMe)Me + MeCl \ ,$$
$$(RO)_3P + Ph_2PCl \rightarrow [(RO)_3P \rightarrow P(Cl)Ph_2] \rightarrow (RO)_2P(O){-}PPh_2 + RCl \ ,$$
$$(RO)_3P + PhPCl_2 \rightarrow PhP(Cl){-}P(O)(OR)_2 + RCl \ .$$

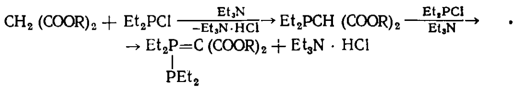
The addition of a second equivalent of chlorophosphine leads to the dissociation of the P–P bond in the resulting monoxide; thus diphosphines may be obtained in satisfactory yields for a 1 : 2 reactant ratio[184]:

$$\text{MeP(OMe)}_2 + \text{Ph}_2\text{PCl} \rightarrow \text{MeP(O)(OMe)—PPh}_2 \xrightarrow{\text{Ph}_2\text{PCl}} \text{Ph}_2\text{P—PPh}_2 + \text{Me(MeO)P(O)Cl} .$$

Ylids of a new type with a P–P bond between three- and four-coordinated phosphorus atoms have been obtained from malonic ester and a wide variety of alkyl(aryl)dichlorophosphines[187]:



Similar phosphoranes but with a linear structure are formed from malonic esters and Et_2PCl:[188]



$$\text{CH}_2(\text{COOR})_2 + \text{Et}_2\text{PCl} \xrightarrow[-\text{Et}_3\text{N}\cdot\text{HCl}]{\text{Et}_3\text{N}} \text{Et}_2\text{PCH(COOR)}_2 \xrightarrow[\text{Et}_3\text{N}]{\text{Et}_2\text{PCl}} \rightarrow \underset{\substack{|\\ \text{PEt}_2}}{\text{Et}_2\text{P}}\text{=C(COOR)}_2 + \text{Et}_3\text{N}\cdot\text{HCl} .$$

The methods of synthesis of OPC with P–P bonds are closely interrelated with certain reactions of organic diphosphines, which lead to new OPC, also with P–P bonds. Part of the synthetic data will therefore be found in the next section of this review.

IV. THE REACTIVITIES OF COMPOUNDS WITH P–P BONDS

The idea of the biphilic nature of OPC with a three-coordinated phosphorus atom is widely used in phosphorus chemistry. It can be extended to organic diphosphines, which exhibit a high reactivity in relation to both nucleophiles and electrophiles; the P–P bond is then most "vulnerable". Numerous reactions involving the dissociation of P–P bonds are known and many of these may be said to involve the heterolytic dissociation of P–P bonds, although even indirect confirmation of the reaction mechanism is by no means always presented.

The P–P bond in organic diphosphines and cyclopolyphosphines is readily cleaved by nucleophiles such as alkali metals[115,189,190], the ease of dissociation depending both on the substituents at the phosphorus atoms and on the alkali metal (K > Na > Li). Tetraphenyldiphosphine is more reactive in relation to sodium than tetra-alkyldiphosphines, which may be accounted for by the greater stability of the Ph_2P^- anion formed compared with R_2P^-. Typical nucleophiles (organolithium compounds) also dissociate P–P bonds[118,191]:

$$\text{R}_2\text{P—PR}_2 + \text{PhLi} \rightarrow \text{R}_2\text{PLi} + \text{R}_2\text{PPh} .$$

The reactivity of organic diphosphines in this interaction (for example, in relation to PhLi) is consistent with the ideas concerning the mechanism of bimolecular nucleophilic substitution at a phosphorus atom. Thus the reactivity decreases in the sequence Ph > Me > Et > n-Pr > n-Bu. The reaction results in the formation of new anion R_2P^-, the stability of which (and hence the ease of its elimination) decreases with increase of the *–I* effect of the substituents. Steric factors also play a significant role in this reaction: it does not occur at all for R = iso-Pr, t-Bu, or cyclo-C_6H_{11}.

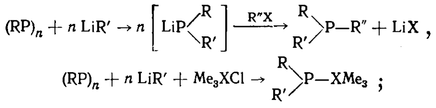
Cyclopolyphosphines are also cleaved by organolithium compounds[118,192,193]. The reaction consists of many stages, a product resulting from the dissociation of one P–P bond being formed initially:

$$(\text{EtP})_n + \text{PhLi} \rightarrow (\text{Et})(\text{Li})\text{P—(EtP)}_{n-2}\text{—P}(\text{Et})(\text{Li}) .$$

The product then reacts rapidly with phenyl-lithium to form secondary cleavage products: $EtP(Li)(PEt)_2P(Li)Et$ and Et_4P_2. The final products are lithium di- and mono-alkylphosphides and ethyldiphenylphosphine.

A detailed study of the interaction of Ph_4P_2 with phenyl-lithium[192,193] made it possible to establish the following electrophilicity series in relation to phenyl-lithium: $Li(PPh)_{n-1}PPh_2 (n \geqslant 3) > (PhP)_n (n = 3 - 5) > Li(PPh)_4Li > Ph_2P{-}PPh_2,\ Li(PPh)_3Li > (Ph)(Li)P{-}PPh_2 > Li(PPh)_2Li$.

The cleavage of P–P bonds in cyclopolyphosphines is used to synthesise linear polyphosphines (as was considered in the previous section). In addition, the availability and high reactivity of cyclopolyphosphines made it possible to develop on their basis a general method for the synthesis of chiral tertiary phosphines and also compounds with P–Ge, P–Si, and P–Sn bonds[194]:



$$(\text{RP})_n + n\,\text{LiR}' \rightarrow n\left[\text{LiP}(\text{R})(\text{R}')\right] \xrightarrow{\text{R}''\text{X}} (\text{R})(\text{R}')\text{P—R}'' + \text{LiX} ,$$

$$(\text{RP})_n + n\,\text{LiR}' + \text{Me}_3\text{XCl} \rightarrow (\text{R})(\text{R}')\text{P—XMe}_3 ;$$

X=Si, Ge, or Sn.

The interaction of organic diphosphines with alkali metal phosphides, the nucleophilic properties of which are weaker than those of organolithium compounds, takes place more slowly[193]:

$$\text{Ph}_2\text{P—PPh}_2 + \text{LiPR}_2 \rightarrow \text{Ph}_2\text{P—PR}_2 + \text{LiPPh}_2 ,$$
$$\text{Ph}_2\text{P—PR}_2 + \text{LiPR}_2 \rightarrow \text{R}_2\text{P—PR}_2 + \text{LiPPh}_2 ,$$

and may be stopped at the first stage. In the second stage attack by the R_2P^- anion is directed to the most nucleophilic centre in the molecule, which is probably associated with the ease of formation of the Ph_2P^- anion.

Cyclic polyphosphines are cleaved only by the more reactive Li_2PPh; the yield of the reactions with monolithium phosphides does not exceed 2–3%.[189–193]

Depending on the nature of the substituents at the phosphorus atom, the reactivity of organic diphosphines in relation to nucleophiles may be altered sharply: electron-accepting substituents promote the cleavage of the P–P bond. Thus water does not react at all with tetra-alkyldiphosphines[3], but reacts rigorously with tetra-alkoxydiphosphines[130]:

$$(\text{RO})_2\text{P—P(OR)}_2 + \text{H}_2\text{O} \rightarrow (\text{RO})_2\text{PH} + (\text{RO})_2\text{P(O)H} .$$

In the cold it causes quantitative dissociation of the P–P bond in diphosphines with electron-accepting substituents[3,63,179]:

$$\text{F}_2\text{P—PF}_2 + \text{H}_2\text{O} \rightarrow \text{F}_2\text{PH} + \text{F}_2\text{P—O—PF}_2 ,$$
$$\text{Me}_2\text{P—P(CF}_3)_2 + \text{H}_2\text{O} \rightarrow \text{Me}_2\text{P(O)H} + (\text{CF}_3)_2\text{PH} .$$

The reaction is accelerated sharply in the presence of an inorganic acid: the formation of $(CF_3)_2PH$ and $Me_2P(O)H$, and not $(CF_3)_2P(O)H$ and Me_2PH, as a result of the reaction may be accounted for by the initial protonation of the Me_2P group by traces of acid, the presence of which could not be as a rule avoided owing to the method used to synthesise dimethyldi(trifluoromethyl)diphosphine, and subsequent nucleophilic attack by water molecules on the phosphonium centre.

Owing to the high reactivity of the P–Cl and P–I bonds, tetraiodo- and tetrachloro-diphosphines form further hydrolysis products with dissociation of the P–P bond[195-197].

There are comparatively few data on the alcoholysis of organic diphosphines. 1,2-Dibromo-1,2-bis(trichloromethyl)diphosphine reacts with ethanol even at low temperatures to form diethyl trichloromethylphosphonite[129]. Tetra-alkoxydiphosphines undergo quantitative exothermic cleavage by ethanol[130].

Like tetra-alkyldiphosphines, cyclopolyphosphines are resistant to neutral hydrolysis but are readily cleaved by aqueous alkali: the P–C and P–P bonds in $(CF_3P)_4$ and $(CF_3P)_5$ dissociate with formation of CF_3H, H_2, and CF_3PH_2. The process is appreciably accelerated in diglyme and at low temperatures the interaction with water and alcohol leads to di-, tri-, and tetra-phosphines with linear structures[198]:

$$\begin{gathered}(F_3CP)_5 + H_2O \rightarrow H(CF_3)P{-}P(CF_3)H + F_3C(H)P{-}P(CF_3)P(H)CF_3 + \\ + H(F_3C)P(PCF_3)_2{-}P(H)CF_3 \\ (F_3CP)_4 + MeOH \rightarrow F_3C(H)P{-}P(CF_3)OMe + F_3C(H)P{-}P(H)CF_3 + \\ + (F_3C)_2POMe + H(F_3C)P{-}\underset{\underset{CF_3}{|}}{P}{-}P(CF_3)H \quad .\end{gathered}$$

The mechanism of the homolytic cleavage of the P–P bond has been discussed[199]. Isolated instances where alcoholysis goes to completion without the dissociation of the P–P bond have been reported[140].

Ammonia is relatively unreactive in relation to $(CF_3)_4P_2$: only 48% of the latter reacts after 28 days at 20° C. Chloramine proved to be somewhat more reactive in this process[200]:

$$R_2P{-}PR_2 + NH_2Cl \rightarrow R_2PCl + R_2PNH_2 \quad .$$

Secondary amines do not dissociate the P–P bond in di-iododiphosphines at 20° C, since under these conditions the reactivities of the P–P and P–I bonds apparently become comparable[131]. However, the P–P bond dissociates even on boiling in ether[201]:

$$PhP(I){-}P(I)Ph + 3HN(CH_2)_5 \rightarrow (PhP)_n + PhP[N(CH_2)_5]_2 + 2(CH_2)_5NH_2I \quad .$$

Nucleophilic attack on asymmetric alkoxydialkyldiphosphines is directed to the most electrophilic phosphite centre in the molecule[202]:

$$(\text{iso-Pr})_2P{-}P(OBu)_2 + PhNHEt \rightarrow (\text{iso-Pr})_2NH + (BuO)_2PN(Et)Ph \quad .$$

Since the less basic diphenylamine reacts much more slowly and piperidine does not react at all, the hypothesis of an optimum ratio of the nucleophilicity of the amine and its capacity for electrophilic cooperation (i.e. its acidity), whereupon the process proceeds at the maximum rate, appears to be very well-founded. The equilibrium in the reactions of tetra-alkyldiphosphines, whose electrophilic properties are fairly weak, with amines is known to be displaced in the opposite direction[3]:

$$EtPNMe_2 + R_2PH \rightarrow Et_2P{-}PR_2 + Me_2NH \quad .$$

The interaction with stronger nucleophiles (secondary phosphines) takes place non-selectively, simultaneously at the phosphite and phosphine centres[202]:

$$\begin{gathered}(\text{iso-Pr})_2P{-}P(OBu)_2 + Ph_2PH \rightarrow (\text{iso-Pr})_2P{-}PPh_2 + \\ + (BuO)_2PH + Ph_2P{-}P(OBu)_2 + (\text{iso-Pr})_2PH \\ \xrightarrow{Ph_2PH} Ph_2P{-}PPh_2 + (BuO)_2PH \quad .\end{gathered}$$

Organic diphosphines (at least those with one highly electrophilic centre) react with tertiary phosphines to form complexes—for example, the complex $(CF_3)_2P\text{-}PMe_2.Me_3P$. Secondary phosphines and arsines dissociate the P–P bond only in $(CF_3)_4P_2$:[149]

$$(CF_3)_2P{-}P(CF_3)_2 + Me_2XH \rightarrow (CF_3)_2P{-}XMe_2 + (CF_3)_2PH \ ; \quad X = \text{P or As.}$$

As described above, the P–P bond in the cyclic analogue $(CF_3)_4P_4$ is broken quantitatively under the influence of primary phosphines even at room temperature[147,203].

Organic diphosphine monoxides are much more resistant to nucleophiles than the diphosphines themselves. Thus tetra-isopropyldiphosphine monoxide requires a week for its hydrolysis by water at 20° C; the reaction with alcohol is just as slow[174]:

$$\begin{gathered}(\text{iso-Pr})_2P(O){-}P(\text{Pr-iso})_2 + H_2O \rightarrow 2\ (\text{iso-Pr})_2P(O)H \ ; \\ (\text{iso-Pr})_2P(O){-}P(\text{Pr-iso})_2 + EtOH \rightarrow (\text{iso-Pr})_2P(O)H + (\text{iso-Pr})_2POEt \ .\end{gathered}$$

The monoxides do not react with diethylamine even on heating.

Organotin hydrides, in which the amount of ionic character of the Sn–H bond is greater than in the Si–H and Ge–H bonds, cleave the P–P bond in the most electrophilic organic diphosphines at 20° C:[204]

$$\begin{gathered}(F_3C)_2P{-}P(CF_3)_2 + Me_3SnH \xrightarrow{20^\circ} Me_3Sn{-}P(CF_3)_2 + HPMe_2 \ , \\ (F_3CP)_4 + Me_3SnH \xrightarrow{20^\circ} Me_3Sn{-}P(CF_3)H + (Me_3Sn)_2PCF_3 + H_2PCF_3 \ , \\ (F_3C)_2P{-}PH_2 + R_3SnH \rightarrow R_3Sn{-}P(CF_3)_2 + PH_3 \quad .\end{gathered}$$

Trimethylgermane reacts very slowly only at 150° C and the corresponding silicon hydrides do not react even at this temperature. Under the conditions of radical interaction, it is possible to achieve the reaction also with trimethylsilane:

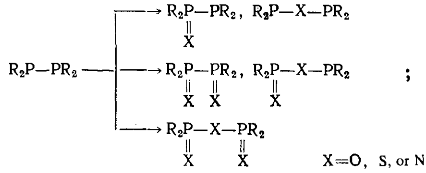
$$(F_3C)_2P{-}P(CF_3)_2 + HSiMe_3 \xrightarrow{h\nu} Me_3Si{-}P(CF_3)_2 + HP(CF_3)_2 \ .$$

Protic acids HX in aqueous media readily cleave the P–P bond[205,206]. In the presence of electron-accepting substituents at the phosphorus atom the reactivity of the compounds in reactions with protic acids is greatly reduced. Thus Ph_4P_2 reacts with hydrochloric acid more vigorously than the asymmetric dimethyldi(trifluoromethyl)-diphosphine: anhydrous protic acids do not react with $(CF_3)_4P_2$ and the reaction with $(CF_3P)_n$ (n = 4 or 5) takes place only after prolonged heating (up to 100° C in the case of sulphuric acid).[207] Carboxylic acids cleave the P–P bond in Ph_4P_2 under very severe conditions (150°–200° C) and the process is complicated by many side reactions[208]. The ability of the P–P bond to be cleaved by acids has been used in the elimination of diphosphines from phosphines[209].

The reduction of aromatic diphosphines at carbon or mercury electrodes involves the dissociation of the P–P bond[210,211]. Their reduction by $LiAlH_4$ also takes place with dissociation of the P–P bond.[212]

Being typical nucleophiles, organic diphosphines form, like tertiary phosphines, stable complexes with Lewis acids[213,214]. Thus Ph_4P_2 forms a complex with a single molecule of trialkylaluminium. The more nucleophilic Me_4P_2 forms a complex with two triethylaluminium molecules[213]. Like tertiary phosphines, Et_4P_2 forms a stable 1 : 1 complex with CuBr.[215,216]

Like tertiary phosphines, organic di- and poly-phosphines are extremely sensitive to oxidation. On oxidation, there is a possibility of the formation of the following structures:



X=O, S, or NR.

It has been shown[151,152] that the result of the oxidation of Ph_4P_2 depends on the purity of the test specimen. In all other cases only the structure of the final product was deduced as a rule:

$$P_2F_4 + O_2 \rightarrow F_2P{-}O{-}PF_2, \text{(Ref.129)}$$

$$Alk_2P{-}PAlk_2 + S \rightarrow Alk_2P{-}P(S)Alk_2 \xrightarrow[(O_2)]{S}$$

$$\rightarrow Alk_2P(S){-}P(S)Alk_2\ [Alk_2P(O){-}P(O)Alk_2], \text{(Refs.134,136,190,217,218)}$$

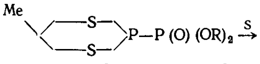
$$(t\text{-}Bu)_2P{-}P(Bu\text{-}t)_2 \xrightarrow{S} (t\text{-}Bu)_2P(S){-}P(Bu\text{-}t)_2 \rightarrow$$

$$\xrightarrow{S} (t\text{-}Bu)_2P(S){-}S{-}P(S)(Bu\text{-}t)_2, \text{(Refs.134,202)}$$

$$R_2P(O)PR_2 \xrightarrow{O_2(S)} R_2P(O){-}P(O,\ S)R_2, \text{(Ref.98)}$$

$$(RO)_2P{-}P(OR)_2 \xrightarrow{O_2} (RO)_2P{-}O{-}P(OR)_2, \text{(Ref.220)}$$

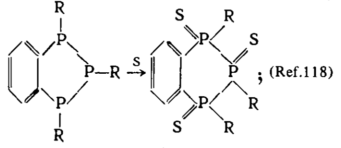
$$(RO)_2P{-}P(OR)_2 \xrightarrow{S} (RO)_2P(S){-}P(S)(OR)_2, \text{(Ref.221)}$$



$\xrightarrow{S}$ reaction does not proceed (Ref.219),

$$I_2P{-}PI_2 \xrightarrow{Se} I_2P(Se){-}PI_2 \xrightarrow{Se} I_2P(Se){-}P(Se)I_2, \text{(Ref.118)}$$

$$Ph_2P{-}P(Me){-}PPh_2 \xrightarrow{S} Ph_2P(S){-}P(Me){-}P(S)Ph_2, \text{(Ref.202)}$$

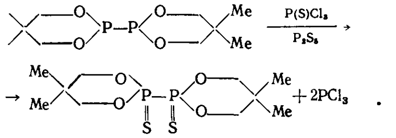


; (Ref.118)

R=Et, or Ph.

Apart from oxygen, a large number of oxidants have been used to oxidise organic diphosphines. In particular, it has been shown that diphosphine disulphides[202], $PSCl_3$, and P_2S_5[140] may be oxidised:

$$Me(Et)P{-}P(Et)Me + Me(Et)P(S){-}P(S)(Et)Me \xrightarrow[15\ h]{190^\circ} 2Me(Et)P{-}P(S)(Et)Me\ ,$$



The oxidation of tetra-alkoxydiphosphines by nitric oxide and pyridine *N*-oxide results in the formation of a mixture of products containing compounds with a single phosphorus atom and tetra-alkyl pyrophosphites. The use of dimethyl sulphoxide (DMSO) in the oxidation of tetra-alkoxydiphosphines is preparatively convenient[221]:

$$(RO)_2P{-}P(OR)_2 + Me_2S{=}O \left| \begin{array}{l} \xrightarrow{1:1} (RO)_2P{-}O{-}P(OR)_2 + Me_2S \\ \xrightarrow{1:2} (RO)_2P(O){-}O{-}P(OR)_2 + 2Me_2S \\ \xrightarrow{1:3} (RO)_2P(O){-}O{-}P(O)(OR)_2 + 3Me_2S\ . \end{array} \right.$$

It is logical to treat this reaction as one involving electrophilic attack by one of the phosphorus atoms on the oxygen atom in the DMSO molecule with subsequent rearrangement of the intermediate tetra-alkoxydiphosphine monoxide. Such rearrangement has been postulated in the study of the alkylation of tetra-alkoxydiphosphines[221] and its occurrence has been demonstrated[173]. It has been shown that tetra-alkyl pyrophosphite is a secondary product of the reaction of dialkyl phosphorochloridites with dialkyl phosphite salts and that the monoxide formed initially is stable for several hours.

In the absence of a solvent, the interaction of tetra-alkoxydiphosphines with DMSO proceeds in a different manner[221]:

$$(RO)_2P{-}P(OR)_2 + 2Me_2S{=}O \rightarrow (RO)_2P(O)CH_2SMe + (RO)_2P(O)H + Me_2S\ .$$

It appears that a definite analogy may be drawn between data for the above interaction and the reaction of DMSO with acetic anhydride (the Pummerer reaction).[222]

The oxidation of tetra-alkyldiphosphines to the corresponding *P*-imines by trimethylsilyl azide proceeds in stages[207,223]:

$$R_2P{-}PR_2 \xrightarrow[-N_2]{Me_3SiN_3} R_2P(=NSiMe_3){-}PR_2 \xrightarrow[-N_2]{Me_3SiN_3} R_2P(=NSiMe_3){-}P(=NSiMe_3)R_2\ .$$

The existence of three isomeric structures of the monoxides of asymmetric organic diphosphines was already mentioned above:

$$\underset{\substack{\| \\ X}}{R_2P}{-}PR'_2 \qquad R_2P{-}\underset{\substack{\| \\ X}}{PR'_2} \qquad R_2P{-}X{-}PR_2\ .$$

The problem of the conditions governing the formation and stability of these structures is of independent significance and its detailed elucidation made it possible to discover new rearrangements and the previously unknown phenomenon of non-prototropic tautomerism of OPC[224,225]. Thus it has been found that irreversible rearrangements take place in the following series of compounds[172]:

$$\underset{\substack{\| \\ O}}{Ph_2P}{-}PR_2 \rightarrow Ph_2P{-}P(O)R_2\ ;$$

R = iso-Pr, cyclo-C_6H_{11}, or t-Bu.

The rate of rearrangement depends on the nature of the alkyl substituent and increases in the presence of a catalyst and on heating. For R = cyclo-C_6H_{11}, the rearrangement is completed in five weeks at room temperature and in 4 h at 80° C in the presence of $MgBr_2$. Tetra-alkyldiphosphine monoxides rearrange under more severe conditions[172]:

$$Bu_2P(O){-}P(Bu\text{-}t)_2 \xrightarrow[190-200^\circ,\ 3-4\ h]{MgBr_2} (t\text{-}Bu)_2P(O){-}PBu_2\ .$$

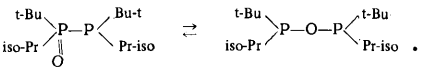
These data show that the thermodynamic stability of the isomeric monoxides of asymmetric diphosphines is determined by the nature of the substituent.

The existence of dialkylphosphinous acid anhydrides is limited by the very narrow range of suitable alkyl substituents, which is evidently associated with the steric and not electronic influence of the substituents[174,225]:

$$R_2P(O){-}PR_2 \xrightarrow[180^\circ]{MgBr_2} R_2P{-}O{-}PR_2\ ;$$

R = t-Bu.

Non-prototropic tautomerism has been observed in the following reaction[174] (we may note that the content of the anhydride increases appreciably with increase of temperature):



The accumulation of bulky substituents at the phosphorus atoms destabilises the monoxide to such an extent that its thermodynamic stability becomes comparable to that of the anhydride, since the stability of a compound with the P-O-P fragment should be less influenced by steric hindrance. Tetra-(t-butyl)diphosphine monoxide rearranges irreversibly to the anhydride of di-(t-butyl)phosphinous acid, as mentioned above.

Tetra-alkyldiphosphine monosulphides are entirely stable and usually do not rearrange on heating and under the influence of catalysts. An irreversible rearrangement occurs only for tetrahalogenodiphosphine monosulphides[117,226]:

$$F_2P(S){-}PF_2 \rightarrow F_2P{-}S{-}PF_2\ ,$$

$$I_2P(Se){-}PI_2 \rightarrow I_2P{-}Se{-}PI_2\ .$$

The rearrangement of tetra-alkyldiphosphine monosulphides[174] with secondary substituents is reversible:

$$(iso\text{-}Pr_2\ P(S){-}P(Pr\text{-}\mathit{изо})_2 \rightleftarrows (iso\text{-}Pr)_2P{-}S{-}P(Pr\text{-}iso)_2.$$

An unusual pathway in the oxidation of organic diphosphines containing phosphorus atoms of different basicities has been discovered, namely the oxidation of the less basic phosphite centre in 2,2-dibutoxy-1,1-di-isopropyldiphosphine[227,228]:

$$\text{(iso-Pr)}_2\text{P—P(OBu)}_2 + \text{HgO} \rightarrow \text{(iso-Pr)}_2\text{P—P(O)(OBu)}_2 + \text{Hg},$$
$$\text{(t-Bu)}_2\text{P—P(OBu)}_2 + \text{O=IPh} \rightarrow \text{(t-Bu)}_2\text{P—P(O)(OBu)}_2\text{PhI}.$$

In the oxidation of iodosobenzene the monoxide is formed as a result of the kinetic control of the reaction. The oxidation with mercury(II) oxide involves the following rearrangement, the general characteristics of which have been established recently[173,175]:

$$\underset{\text{(XX)}}{\text{R}_2\text{P—}\underset{\underset{\text{O}}{\|}}{\text{P}}\text{(OR)}_2} \rightarrow \underset{\text{(XXI)}}{\text{R}_2\text{P—O—P(OR)}_2} \rightarrow \underset{\text{(XXII)}}{\text{R}_2\text{P—}\underset{\underset{\text{O}}{\|}}{\text{P}}\text{(OR)}_2}.$$

(XX) (XXI) (XXII)

The monoxides (XXII) are thermodynamically the most stable in the series (XX)-(XXII) and represent the final products of the reactions in various systems containing the R_2P and $(R'O)_2P$ fragments and the oxygen atom in proportions of 1 : 1 : 1. The isomerisation of the monoxide (XX) to the mixed anhydride (XXI) may be induced both by phosphorus-containing electrophiles (above −20°C such catalytic isomerisation proceeds in the course of several minutes) and by nucleophiles, which are somewhat less effective. The rearrangement of the anhydride proceeds under more severe conditions[175]:

$$\text{(t-Bu)}_2\text{POP(OBu)}_2 \xrightarrow[120°,\ 3\text{ h}]{\text{HgBr}_2} \text{(t-Bu)}_2\text{P-P(O)(OBu)}_2.$$

As stated above, tetra-ethoxydiphosphine monoxide is stable only for several hours and readily rearranges to the pyrophosphite[176]. On the other hand, tetra-alkoxydiphosphine monosulphides are stable[176], in agreement with data for the oxidation of tetra-alkoxydiphosphine by sulphur[146]:

$$\text{(RO)}_2\text{P—P(OR)}_2 \xrightarrow{2\text{S}} \text{(RO)}_2\text{P(S)—P(S)(OR)}_2.$$

The same series of rearrangements is also characteristic of aminodiphosphines[225,229]:

$$\text{R}_2\text{P(O)—P(NR}'_2)_2 \rightarrow \text{R}_2\text{P—O—P(NR}'_2)_2 \rightarrow \text{R}_2\text{P—P(O)(NR}_2)_2.$$

The stability of the monoxide depends apparently on the extent to which the groups linked to the four-coordinated phosphorus atom can participate in the delocalisation of its partial positive charge, i.e. depends on the ratio of the inductive electron-accepting and mesomeric electron-donating properties of the substituents. This is why equilibria in the above reactions are displaced in the opposite directions:

$$\text{(Et}_2\text{N)}_2\text{P—O—P(NEt}_2)_2 \rightleftarrows \text{(Et}_2\text{N)}_2\text{P(O)—P(NEt}_2)_2,$$

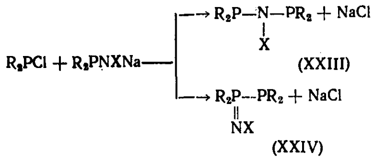
The latter equilibrium is strongly displaced to the left, which can be accounted for by the ability of the alkoxy-groups, linked directly to the four-coordinated phosphorus atom, to participate effectively in the delocalisation of the charge on the phosphorus. This is also indicated by the irreversible rearrangement of R_2P-O-$P(OR)_2$ to R_2P-$P(O)(OR)_2$ and not $R_2P(O)P(OR)_2$.[173]

Related rearrangements have been observed also for *P*-imines[230]:

$$\text{R}_2\underset{\underset{\text{NX}}{\|}}{\text{P}}\text{—PR}_2 \rightarrow \text{R}_2\text{P—}\underset{\underset{\text{X}}{|}}{\text{N}}\text{—PR}_2;$$

R = iso-Pr; X = *m*-YC_6H_4, where Y = H, OMe, Cl, Br, or CF_3.

This necessitates a re-examination of the problem of the structure of the products formed initially in the condensation of dialkylchlorophines with an amide salt[231,232]:



(XXIII)

(XXIV)

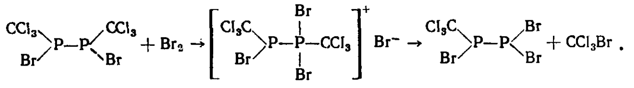
Dialkoxydialkyldiphosphine imines undergo a slow reaction, which is the opposite of the analogous rearrangement of the monoxides and monosulphides[230]:

$$\text{R}_2\text{P—}\underset{\underset{\text{NX}}{\|}}{\text{P}}\text{(OR)}_2 \rightarrow \text{R}_2\underset{\underset{\text{NX}}{\|}}{\text{P}}\text{—P(OR)}_2;$$

R = Et, X = NPh .

Cyclic polyphosphines are on the whole more resistant to oxidation than linear polyphosphines, although their reactivity also varies within wide limits. Thus $(CF_3P)_4$ and $(MeP)_4$ ignite in air[134-137], while 1,2,3-triphenyl-1,2,3-triphosphaindan is not oxidised by air in boiling toluene and alcohol[25]. Thus phenyl substituents increase sharply the resistance of the ring to oxidation and the result of the reaction of such compounds depends on the ring size[161-163]. For example, after being refluxed for 2 h in acetonitrile, $(PhP)_6$ does not react with sulphur and nickel tetracarbonyl, while the pentamer is cleaved by sulphur with formation of $(C_6H_5PS)_3$ and behaves as a ligand in relation to $Ni(CO)_4$.

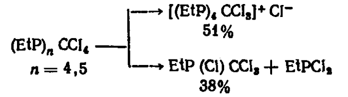
Examination of the oxidation reactions shows that organic diphosphines are extremely reactive nucleophiles. Thus their interaction with both halogens and other halogenating reagents proceeds with dissociation of the P-P bond. It may be that a quasi-phosphonium compound is formed as an intermediate, decomposing subsequently with attack by the anion either on the phosphorus atom or on the carbon atom. In the presence of strongly electronegative substituents the carbon atom is attacked under these conditions, and the P-P bond may be actually retained[111]:



Under more severe conditions, the P-P bond is cleaved even by carbon tetrachloride[234]:

$$\text{R}_2\text{P—PR}_2 + \text{CCl}_4 \underset{\text{C}_n\text{H}_{2n+2}}{\overset{\text{acetonitrile},\ 120\text{–}140°,\ 5\text{ h}}{\rightleftarrows}} \text{R}_2\text{PCl} + \text{R}_2\text{PCCl}_3.$$

The rate of reaction depends to a considerable degree on the substituents at the phosphorus atom; for example, for R = cyclo-C_6H_{11}, heating in the course of 48 h is required and the reverse reaction takes place at 180°C in solution in a hydrocarbon. If the basicity of the diphosphine is enhanced, it is possible to isolate intermediate phosphonium salts of two types: $[Me_2P-P(Me_2)(CCl_2)]^+2Cl^-$ and $[Et_2P-P(Et_2)(CCl_3)]^+Cl^-$ and in the case of cyclopentaphosphines they may be entirely stable[234]:



$$\text{(t-BuP)}_4 \xrightarrow{\text{CCl}_4} \text{reaction does not occur.}$$

In two component primary or secondary amine–carbon tetrachloride systems the interaction is of the type of the Todd–Atherton reaction[235], the yield of the salt increasing in parallel with the enhancement of the nucleophilic properties of the diphosphines and the basicity of the amines.

The reaction involving sterically hindered amines proceeds with formation of a **P–C** bond[236]:

$$(RP)_4 + 2n\,CCl_4 + 4n\,R_2NH \rightarrow n\,[RP(NR_2)_3]^+Cl^- + 2n\,CHCl_3 + n\,[H_2NR_2]^+Cl^-$$
$$R_2P{-}P(O)R_2 + 2CCl_4 + 4HNR_2 \rightarrow [R_2P(NR_2)_2]^+Cl^- + $$
$$+ R_2P(O){-}NR_2 + [R_2NH_2]^+Cl^- + 2CHCl_3\ .$$

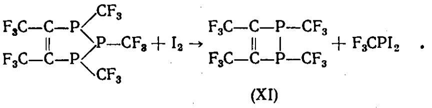
There are instances where the reactions with electrophiles are reversible; the interaction of R_4P_2 with CCl_4 described above is of this kind[202]. Equilibrium of this type may be wholly displaced towards the diphosphine if the halogenating agent is volatile[237]:

$$Cl_3Si{-}SiCl_3 + Me_2PCl \xrightarrow[-SiCl_4]{} Me_2P{-}SiCl_3 \xrightarrow{Me_2PCl} Me_2P{-}PMe_2 + SiCl_4\ .$$

This reaction is also reversible when it involves the dissociation of the low-energy **P–I** bonds[238] and is analogous to the conversion of PI_3 into P_2I_4 in ethereal solution[239]:

$$2ArPI_2 \rightleftarrows ArP(I){-}P(I)Ar + I_2\ .$$

In certain cases [structure **(XI)**] **P–P** bonds are not cleaved at all by iodine[117]:



(XI)

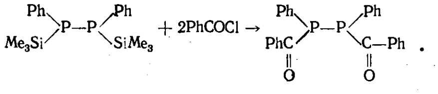
The synthetic possibilities of reactions involving the cleavage of P–P bonds are very extensive. Thus the use in this reaction of carboxylic acid chlorides made it possible to achieve for the first time the synthesis of α-ketophosphonites[240,241]; phosphorus acid chlorides have been used in the synthesis of certain asymmetric dialkoxydialkyldiphosphines[147]:

$$(RO)_2P{-}P(OR)_2 + R'{-}C(O)Cl \rightarrow (RO)_2PC(O)R' + (RO)_2PCl\ ,$$
$$(iso\text{-}Pr)_2P{-}P(OBu)_2 + (PhO)_2PCl \rightarrow (BuO)_2PCl + (iso\text{-}Pr)_2P{-}P(OPh)_2\ .$$

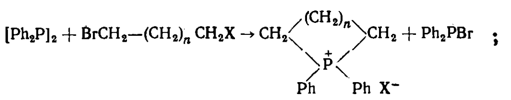
The latter reaction proceeds selectively at the phosphine centre of the dialkoxydialkyldiphosphine. The interaction of dialkoxydialkyldiphosphines with $PhPCl_2$ is unusual: as in the interaction of tetra-alkoxydiphosphines with PCl_3, the **P–P** bond undergoes oxidation-reduction cleavage and $PhPCl_2$ is reduced to $(PhP)_4$:

$$R_2P{-}P(OR)_2 + PhPCl_2 \rightarrow R_2PCl + (RO)_2PCl + (PhP)_4\ .$$

The interaction of silylated organic diphosphines with carboxylic acid chlorides leads to α-ketophosphonites containing **P–P** bonds[242]:



Alkyl halides, which are typical electrophiles, react with organic di- and poly-phosphines to form 1 : 1 phosphonium salts, which are entirely stable in the case of cyclopolyphosphines. With enhancement of the electron-donating properties of the substituents at the phosphorus atom, the rate of alkylation increases[243]. The monophosphonium salts derived from tetra-alkyldiphosphines and linear organic triphosphines are as a rule unstable, particularly for compounds with bulky substituents or in the case of 2,2-dialkoxy-1,1-dialkyldiphosphines[134,202]. Pentafluorophenylphosphine does not react with methyl iodide[243]. Cyclic monophosphonium salts may be obtained by the reaction of the readily available Ph_4P_2 with α,ω-dihalogenoalkylenes[244]:



$n = 2,\ X = ClO_4;\quad n = 3,\ 4,\ X = Br.$

The anomalous interaction of tetra-alkoxydiphosphines with methyl iodide[241] involves not only standard transformations via the mechanism of the Arbuzov rearrangement but also a rearrangement of the **P(O)–P** fragment to **P–O–P**:

$$(RO)_2P{-}P(OR)_2 + MeI \xrightarrow{-RI} [ROP(O)(Me){-}P(OR)_2] \rightarrow$$
$$\rightarrow [ROP(Me){-}O{-}P(OR)_2] \xrightarrow{MeI} Me_2P(O)OP(OR)_2\ .$$

Inorganic and organic diphosphines add to **C–C** bonds, which made it possible to draw a formal analogy between the reactivities of diphosphines and halogens[3]. In certain cases the mechanism of this addition is apparently quite unambiguous. Thus, under the conditions of a radical reaction (irradiation with ultraviolet light), F_4P_2 adds smoothly to olefins[245-247] and the ease of addition varies in the sequence ethylene > propene > but-2-ene, in agreement with the usual treatment within the framework of "steric hindrance". In this case one may speak of radical addition, since in the absence of irradiation the reaction does not occur at all at room temperature but does take place at 200°C, where F_4P_2 dissociates with formation of the PF_2 radical[247,248]. The reaction with perfluoro-olefins, which readily combine with nucleophilic intermediates, takes place slowly and with very low yields. Its stereochemistry may be inferred from the addition to cyclohexene, whereupon only the *trans*-isomer is formed[248], the ratio of compounds with axial and equatorial orientations of the PF_2 group being 6 : 4.

Tetramethyldiphosphine reacts slowly at 100°C with butadiene in the presence of azobisisobutyronitrile to form exclusively the 1,4-addition product[249]:

$$Me_2P{-}PMe_2 + CH_2{=}CH{-}CH{=}CH_2 \rightarrow Me_2P{-}CH_2{-}CH{=}CH{-}CH_2PMe_2\ .$$

In the dark the reaction does not occur even at 100°C.[250] The addition of tetra-alkyldiphosphines to a triple bond is also apparently a radical process, since it proceeds only under ultraviolet irradiation or in the presence of initiators and leads to a mixture of the *cis*- and *trans*-isomers[251]:

$$PhC{\equiv}CH + R_2P{-}PR_2 \rightarrow R_2PC(Ph){=}CHPR_2\ .$$

The tridentate ligand **(XXV)** is formed on ultraviolet irradiation at the wavelength at which F_4P_2 decomposes into F_2P radicals[252-254]:

$$F_2P{-}PF_2 + F_2PCH_2{-}CH{=}CH_2 \xrightarrow{h\nu} \underset{(XXV)}{F_2PCH_2{-}CH(PF_2){-}CH_2PF_2}\ .$$

Tetra-alkoxydiphosphines exhibit a high reactivity in reactions involving addition to multiple bonds activated in relation to nucleophilic attack[255]:

$$(RO)_2P{-}P(OR)_2 + CH_2{=}CH{-}R' \xrightarrow{20^\circ} (RO)_2PCH_2{-}CH(R')P(OR)_2\ .$$

When the electrophilicity of the double bond is reduced (methyl methacrylate), the rate of reaction falls and the completion of the reaction requires heating to 60°C. Tetra-alkoxydiphosphines do not add to butadiene even at 150°C.[130]

The optimum conditions for the homolytic dissociation of the P–P bond are known to involve irradiation (λ > 300 nm) or heating above 180°C.[256,257] The addition of tetraphenyldiphosphine to the C=O bonds of aldehydes occurs in the temperature range between 180° and 200°C, apparently via a free radical mechanism; the resulting ketophosphinites undergo a series of further transformations under the severe conditions employed[256].

It was mentioned above that the intermediate RP: (phosphinidene) is apparently a carbenoid species and cyclopolyphosphines can therefore be regarded as potential sources of phosphinidene, for example, for the synthesis of di-isopropenyl phenylphosphonites[258]:

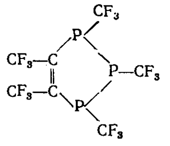
$$(PhP)_4 + 4Hg\,(CH_2COC_2H_5)_2 \rightarrow 4PhP\,[OC\,(Et){=}CH_2]_2 + 4Hg$$

or for the insertion in a non-metal–non-metal bond. The first steps in this field were made in the study of the reactions of phosphinidenes with disulphides[258] and α-diketones[259]:

$$(PhP)_5 \xrightarrow{160^\circ} 5\,[PhP{:}] \xrightarrow{Et{-}S{-}SEt} PhP\,(SEt)_2\ .$$

The formation of the intermediate PhP: in the course of addition to substituted butadienes was demonstrated mass-spectrometrically. The insertion of phosphinidene in the P–N, As–As, Si–Si, and N–N bonds was investigated subsequently[260]. The reaction of *N,N*-(dimethyl)dimethylphosphinous amide with $(CF_3P)_4$ resulted in the formation of a mixture, the main component of which was a phosphinidene complex, which was subsequently converted into the product of the insertion of phosphinidene in the P–N bond. The insertion in the As–As bond in tetramethyldiarsine took place in the same way. The interactions with tetramethylhydrazine and hexamethyldisilane could not be observed.

Mass-spectrometric data on tetra-alkyldiphosphines have been interpreted to demonstrate complete binding in these compounds[261–263], which, as stated above, is fairly controversial. In connection with the problem of the *p–d* conjugation, an attempt was made to generate radical-anions from the heterocycles (VIII), (IX), (XXII), and (XXVII):



$(MeP)_5$

(XXVI) (XXVII)

by treatment with the NaK alloy or electrochemically at −125° C.[265] It was found that (XXVII) and (VIII) do not yield radicals at all. The spin densities of the radical-anions (XI) and (XXVI) are localised at the C=C bonds and not at the phosphorus atom. This shows that the *d* orbitals do not stabilise the lowest-lying molecular orbital of the phosphorus atom, so that, among the elements of the Second Period, ready reduction to radical-anions is characteristic only of silicon in cyclopolysilanes.

Infrared and Raman spectroscopy has been used widely, particularly for the conformational analysis of diphosphines; on the other hand, for the detection of the P–P bond in compounds of a wide variety of types, ^{31}P NMR, and to a much lesser extent ^1H NMR, is the most informative method. The theoretical predictions of the chemical shifts in ^{31}P NMR spectra are still unsatisfactory, but the experimental data accumulated in this field for a wide variety of types of compounds with P–P bonds are now so extensive that identification based on analogies is entirely satisfactory. The constants for the spin–spin coupling between directly linked phosphorus atoms ($^1J_{P-P}$) lie within very broad limits (up to 1000 Hz), depending on the nature of the substituent at the phosphorus atom[265,266]; for two three-coordinated phosphorus atoms, $^1J_{P-P}$ varies in the range 100–400 Hz. The sign of the constant $^1J_{P-P}$ for organic diphosphines is known reliably in isolated instances[55] and is negative, while that of the constant $^1J_{P-N}$ is positive[267].

---oOo---

Thus the chemistry of organic di- and poly-phosphines has been developing vigorously in recent years both as regards theory (stereochemistry and conformational analysis of OPC, discovery and identification of non-prototropic tautomerism, etc.) and practical applications (tetra-alkyldiphosphines initiate the copolymerisation of chloral with isocyanates[268] and are effective phosphorylating agents in sugar chemistry[269]). There is no doubt that this comparatively inadequately investigated field of the chemistry of OPC will attract increasing attention in the coming years.

The Polarity and Structure of Unsaturated Derivatives of Four-coordinated Phosphorus

E.A.Ishmaeva

The results of studies on the steric and electronic structures of unsaturated organophosphorus compounds with a four-coordinated phosphorus atom by the dipole moment method are surveyed. The polarity of the C–P bonds is analysed and the problems of conjugation and unsaturation in organophosphorus compounds are discussed. The orientation of the double bond and the conformation of the aryl groups attached to the phosphorus atom are examined. Data are presented on the conformational analysis of unsaturated organophosphorus compounds.
The bibliography includes 108 references.

I. INTRODUCTION

Studies on steric structures with the aid of molecular dipole moment (DM) data are carried out by comparing the experimental moments with values calculated by means of an additive vector scheme[1]. The validity of the additive scheme may be regarded as firmly established; deviations from additivity indicate the occurrence of intramolecular interactions in the molecule. The determination of the absolute values and directions of bond moments is an extremely difficult problem and the reliability of the results depends in many respects on its solution. An additive computational scheme for phosphorus compounds is presented in Arshinova's review[2], who also examines the contribution of the dipole moment of the lone electron pair (LEP) of the phosphorus atom to the overall polarity of the molecule and shows that, in order to calculate the magnitude and direction of the molecular moment, even for asymmetrically substituted organophosphorus compounds (OPC), there is no need to introduce the vector of the LEP moment as an independent vector for purely mathematical reasons. For symmetrically substituted molecules, the LEP dipole moment is included implicitly in phosphorus bond moments. Any additive scheme for organic molecules is based primarily on the C–H bond moment using different DM values[1]. In the calculation of the OPC dipole moments one usually employs $m(\mathrm{H} \rightarrow \mathrm{C_{sp^3}}) = 0.28$ D, $m(\mathrm{H} \rightarrow \mathrm{C_{sp^2}}) = 0.70$ D, and $m(\mathrm{H} \rightarrow \mathrm{C_{sp}}) = 1.10$ D, determined from the line intensities in the infrared spectra[3], which makes it possible to compare the results of calculations by different investigators.

A number of reviews are devoted to the consideration of the steric structures of different OPC.[4-6] Studies on the steric and electronic structures of OPC by the method based on the Kerr effect are considered by Arshinova[2]. This review surveys and gives a systematic account of data on the polarity and structure of unsaturated OPC with a four-coordinated phosphorus atom obtained by the dipole moment method. Compounds with $\mathrm{P{-}C_{sp^2}}$ (where $\mathrm{C_{sp^2}}$ is a carbon atom in olefinic, carbonyl, and aromatic groups) and $\mathrm{P{-}C_{sp}}$ bonds are examined; whenever necessary, data obtained by other methods are invoked (infrared, Raman, ultraviolet, and NMR spectroscopy, the Kerr effect method, and electron diffraction).

II. THE POLARITY OF THE CARBON–PHOSPHORUS BOND

The considerable advances achieved in the study of the steric and electronic structures of organic molecules by electro-optical methods have been reflected also in studies on unsaturated OPC. Table 1 presents the results of investigations of phosphorus compounds with $\mathrm{P{-}C_{sp^2}}$ and $\mathrm{P{-}C_{sp}}$ bonds by the dipole moment method published up to 1978 (the numbering of the compounds in Table 1 will be used henceforth in this review). Table 2 presents the available literature data for the polarities of C–P bonds obtained for different types of OPC. It shows that the C–P bond moments are not constant; furthermore, they sometimes differ not only in absolute magnitude but also as regards direction. The majority of investigators have hitherto assumed that the $\mathrm{C_{sp^3}{-}P}$ bond moment is directed from the carbon to the phosphorus atom and that its absolute magnitude is ~0.6–0.8 D depending on the environment of the phosphorus atom. The $\mathrm{C_{sp^2}{-}P}$ bond moment is also directed to the phosphorus atom and, in conformity with the higher electronegativity of the sp^2-hybridised carbon atom, its absolute magnitude is somewhat smaller. Its direction (from C to P) has likewise been unambiguously established by comparing the dipole moments of triphenylphosphine and its *p*-substituted derivatives[12]. The sign of the $\mathrm{C_{sp}{-}P}$ bond moment is reversed, which is typical for all acetylenic compounds, including halogenoacetylenes [$m(\mathrm{Cl} \rightarrow \mathrm{C_{sp}}) = 0.66$ D].[40] The $\mathrm{P{-}C_{sp^3}}$ and $\mathrm{P{-}C_{sp^2}}$ bond moments with identical magnitudes and directions (from P to C) quoted by Mingaleva et al.[48] conflict with all other literature data. The discrepancy is probably due to the incorrect employment in the calculations of Mingaleva et al.[48] of the initial parameters: $m(\mathrm{P} \rightarrow \mathrm{O})$ was assumed to be 1.2 D, although there exist rigorous data showing that it is smaller and that it has the opposite direction[51]. Despite the fact that similar values have been obtained by Ishmaeva et al.[40] and Mingaleva et al.[48], the agreement must be regarded as fortuitous, since the two teams of investigators used different initial parameters.

Thus the following sequence has been observed for the C–P bond moments: $m(\mathrm{C_{sp^3}} \rightarrow \mathrm{P}) > m(\mathrm{C_{sp^2}} \rightarrow \mathrm{P}) > m(\mathrm{C_{sp}} \leftarrow \mathrm{P})$; the reversal of the sign of the $\mathrm{C_{sp}{-}P}$ bond moment in this series must be regarded as legitimate. The C–P bond moments calculated taking into account the dipole moments of the LEP of the phosphorus atom naturally differ from those where no account has been taken of the LEP. In this case a different sequence of C–P bond moments is observed[49]: $m(P \rightarrow C_{sp}) > m(P \rightarrow C_{sp^2}) > m(P \rightarrow C_{sp^3})$. In the calculation of the dipole moments of unsaturated OPC using the C–P bond moments with allowance for the LEP of the phosphorus atom, a new set of moments must be employed for all the remaining phosphorus bonds, also found taking into account the LEP. Since the absolute dipole moment of the phosphorus atom LEP is not known reliably (in any case it depends on the environment of the phosphorus atom) and the available literature data are contradictory, the present author suggests, in conformity with the evidence presented by Arshinova[2], that in the calculation of dipole moments of unsaturated OPC it is more useful to employ the moments of the C–P bonds and all other bonds without taking into account the LEP of the phosphorus atom.

Table 1. The experimental dipole moments of compounds of four-coordinated phosphorus containing an unsaturated carbon atom.

---

*The authors[17] evidently have in mind the group moment of the Et–P bond, so that $m(C_{sp^3}-P) = 1.11-0.28 = 0.83$ D.

**Here it is assumed that $m(H-C_{sp^2}) = 0.31$ D.

***Here $m(H-C_{sp^2}) = 0$; in all other instances the authors employed the values of m(H– C) quoted by Gribov and Popov[3].

The C_{sp^2}– P bond moments are subject to the particularly strong influence of the substituents both at the phosphorus atom and in the unsaturated group (there are very few data for C_{sp}–P bonds). An additional illustration of the foregoing considerations is provided by the experimental dipole moments of the following compounds: 2.91–2.95 D [7-9] for (I), 2.92–3.04 D [7-9] for (XXXII), and 3.13–3.18 D [17] and 3.68 D [16] for (XXXVII). With increase of the length of the π-electron system at the phosphorus atom, the experimental dipole moment increases, although calculation based on the additive scheme yields the same value for different compounds. The conjugation in buta-1,3-dienylphosphonates, buta-1,3-dienylphosphonothioates[8,52], and styrylphosphonates[53,54] (in which the C=C and P=O groups are in the *trans*-positions) has been detected by infrared and Raman spectroscopic methods. Consequently a theoretical calculation of the dipole moments of unsaturated OPC using the same value of $m(C_{sp^2}-P)$ is possible only for compounds with analogous structures. m(R–P) (where R is an unsaturated group), which is equal to the sum of the R′–C_{sp^2} and C_{sp^2}–P bond moments, the conjugation moment of the π-electron system incorporating the phosphorus atom, and the interaction moment arising when substituents (R′ = H, CH_3, etc.) are introduced into the π-electron system, may be calculated with the aid of data for model compounds for each series of unsaturated OPC:

$$m\,(\mathrm{R—P}) = m\,(\mathrm{R'—C}_{sp^2}) + m\,(\mathrm{C}_{sp^2} — \mathrm{P}) + m_{\mathrm{conjug.}} + m_{\mathrm{interact.}}$$

The conjugation moment and the intrinsic moment of the C_{sp^2}–P bond cannot be calculated separately; the instances where it is possible to isolate the interaction moments will be discussed below. Thus the C_{sp^2}–P bond moments determined are not the true moments, representing effective quantities which include the conjugation moment and frequently also the interaction moment. However, these moments may be used to estimate the conjugation effects in series of analogous compounds when only one end of the conjugated system is altered.

An additional difficulty in the study of unsaturated phosphonates is the necessity to know the magnitude and direction of the dipole moment of the irregular $P(O)(OR)_2$ group. The latter had been calculated by Mingaleva et al.[48], but was subsequently re-evaluated, for reasons stated, by Ishmaeva et al.[8] (2.30 D was obtained). The vector of the effective dipole moment of this group forms an angle of 72° with the C–P bond, which corresponds to the *gauche*-orientation (with some distortion in the direction of *cis*-orientation) of the ethyl groups in relation to the P–O bond.

Table 3. The effective values of $m(C_{sp^2}–P)$ in phosphonates[8,17].

Compound	$m(\mathrm{C}_{sp^2}\rightarrow\mathrm{P})$, D
(I)	0.56
(XXXII)	0.70
(LXXXVIII)	0.69
(XXXVII)	0.82

The determination of the magnitude and direction of the effective dipole moment of the dialkylphosphono-group made it possible to estimate the effective C_{sp^2}–P bond moments in various unsaturated phosphonates (Table 3). The high P–C_{sp^2} bond moments, with the moment directed towards the carbon atom, which are obtained on solving a quadratic equation, can apparently be excluded from consideration, since these data do not agree with the electronegativities of the C and P atoms and also conflict with ideas concerning the polarity of single bonds involving phosphorus. Table 3 shows that the C–P bond moments in unsaturated phosphonates unsubstituted in the π-electron system vary relatively little (~0.6–0.8 D).

The C_{sp^2}–P bond orders in vinylphosphine oxides and sulphides vary within wide limits (Table 4). The effective C_{sp^2}–P bond orders in compounds (III)–(VI), listed in Table 4, can be satisfactorily accounted for by steric effects and are consistent with the ideas concerning the electronic influence of phosphorus-containing substituents[55]. The variation of the C_{sp^2}–P bond moment may serve as evidence for the variation of conjugation in the π-electron system. Accordingly, one may expect a higher value of $m(C_{sp^2}–P)$ for buta-1,3-dienylphosphonate (**XXXII**) than for vinylphosphonate (I) and a higher value for styrylphosphonate (**XXXVII**) than for phenylphosphonate (**LXXXIX**), which is in fact observed (Table 3). The determination of the effective values of $m(C_{sp^2}–P)$ made it possible to estimate the moments of the interaction of the vinyl and phenyl groups with the diethylphosphono-group in esters of buta-1,3-dienyl- and styryl-phosphonic acids, which are respectively 0.14 and 0.23 D.[17] Evidently there is some electron transfer in the π-electron system, which leads to the orientation of the overall moment of the hydrocarbon groups towards the phosphorus atom. The moment of the interaction with the sulphur-containing compound (XXXIII) also proved to be close to these values (0.20 D). The interaction moment obtained for compound (XLIII) (1.12 D) indicates an appreciable involvement of the phosphorus-containing group in the direct polar conjugation of the overall chain.

Table 4. The effective values of $m(C_{sp^2}–P)$ in vinylphosphine oxides and sulphides[10-11].

Cpd.	$m\,(\mathrm{C}_{sp^2}\rightarrow\mathrm{P})$, D	Cpd.	$m\,(\mathrm{C}_{sp^2}\rightarrow\mathrm{P})$, D
(III)	0.83	(V)	0.30
(IV)	0.60	(VII)	0.40
(VI)	0.37	(VIII)	—0.09

The interaction moments may be determined also for *p*-substituted phenylphosphonates (Table 5). The values calculated for them do not agree with experiment, which is due to the interaction of the *p*-substituents in the phenyl group with the $P(O)(OR)_2$ group. The interaction moments directed along the C_{sp^2}–P bond reach values ⩾ 1 D, which indicates an appreciable involvement of the phosphorus-containing fragment in the overall conjugation chain. An excellent correlation has been found (r = 0.999) between the experimental dipole moments of *p*-substituted phenylphosphonates and the Hammett σ constants, which indicates an interaction involving conjugation. The experimental dipole moments of *p*-substituted benzoylphosphonates[21] exceed the calculated values by 0.6–0.7 D. Although it is not possible to separate the influence of the C–O and P–O groups and to calculate the interaction moments, nevertheless, the significant influence of the phosphorus-containing group in this instance may be recognised. It follows from the fact that the interaction moment in *p*-methoxyacetophenone is only 0.24 D while in *p*-chloro- and *p*-bromo-acetophenones the experimental values are actually somewhat lower than those calculated assuming additivity. This conclusion is confirmed by the results obtained in infrared and ultraviolet spectroscopic studies on benzoylphosphonates[56-64].

Thus the π-electron system in the unsaturated OPC investigated interacts with the phosphorus-containing groups. The problem of the involvement in conjugation of the tetrahedral phosphorus atom has been frequently discussed in the literature[7,16,21,24,52-54,56,65-74]. It has been suggested that the conjugation is both of the π–π and $p\pi$–$d\pi$ type, but the mechanism of the interaction of unsaturated systems with phosphorus-containing groups still cannot be regarded as accurately established. The hypothesis of the $p\pi-d\pi$ interaction in these systems, widely used by chemists, has been questioned[75], because the *d* orbitals of the phosphorus atom are fairly diffuse and energetically unsuitable and their appreciable overlapping with the orbitals of the groups attached to phosphorus is unlikely, i.e. the quantitative aspect of the problem of the role of the $p\pi-d\pi$ interaction remains controversial[6]. There is nevertheless no doubt that electron delocalisation takes place in OPC molecules containing unsaturated groups with participation of the phosphorus atom or the entire phosphorus-containing group, which the present author attempted to demonstrate by the dipole moment method.

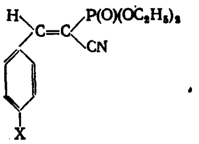
(XCII)	CH_3	3,23	3.30	—0,10
(XCVI)	Cl	2,83	2,25	1.27
(XCVII)	Br	2,81	2,26	1,22
(XCIV)	CH_3O	3.31	3,21	0,98

III. THE STERIC ORIENTATION OF THE DOUBLE BOND AT THE PHOSPHORUS ATOM

Another important task in the study of unsaturated OPC is investigation of their steric structure. There are very few electron diffraction or X-ray diffraction literature data for these compounds (see reviews[4-6]) and they are mainly concerned with compounds containing a $P-C_{sp^2}$ bond (phenyl) (see, for example, Refs. 76–80). There have been several studies on compounds with a $P-C_{sp^2}$ (olefin) bond[81-83] and acyclic OPC with a $P-C_{sp^2}$ (olefin) bond have been investigated in only one study[82] in relation to vinylphosphonic dichloride and divinylphosphinic chloride. It has been shown[82] that the main conformation of both compounds is one with the *cis*- (or nearly *cis*-) disposition of the C=C and P=O bonds, which are virtually coplanar. There is also other evidence for the preferential disposition of the C=C and P=O bonds in a single plane[52,84,85].

The dipole moment method is important and fairly reliable for the determination of the configurations of unsaturated OPC. For example, it has been established by the dipole moment method, in agreement with NMR data[86], that the benzene ring and the diethylphosphonogroup in α-cyanostyrylphosphonates are in the *trans*-positions[17] (Table 6):



Furthermore, the dipole moment method makes it possible to investigate the conformational isomerism relative to the $P-C_{sp^2}$ and other bonds involving phosphorus (P–O, P–S, P–Se, etc.). Estimation of the polarity of the $P-C_{sp^2}$ bond in styrylphosphonic acid esters made it possible to assess the conformational isomerism of α-cyanostyrylphosphonates, i.e. to examine the rotation about the $P-C_{sp^2}$ (olefin) bond[17]. The presence of the cyano-group in these compounds is responsible for the different polarities of the *s*-*cis*- and *s*-*trans*-conformers:

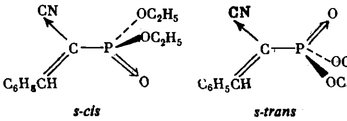


Table 6. The dipole moments of p-$XC_6H_4CH=C(CN)P.(O)(OC_2H_5)_2$.[17]

Compound	X	μ_{exp}, D	μ_{calc}, D	
			trans	*cis*
(XLV)	Cl	2.67	2,73	1,99
(XLVI)	Br	2.62	2.74	1.96
(XLVII)	NO_2	4.78	4.53	3.40

Comparison of the dipole moments calculated for the two conformers with the experimental dipole moment of diethyl-α-cyanostyrylphosphonate (XLII) indicates the preferential (approximately 80%) occurrence of the *s*-*cis*-form, i.e. the conformer with the antiparallel direction of the dipoles of the substituents (CN and P=O). The conformational isomerism in relation to the $P-C_{sp^2}$ bond in α- and β-substituted vinylphosphonates has been investigated[10,11]:

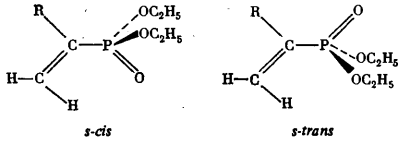

Table 7. The dipole moments of $CH_2=C(R)P(O)(OC_2H_5)_2$.[11]

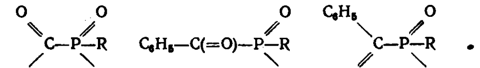
Compound	R	μ_{exp}, D	μ_{calc}, D		
			s-*trans*	*s*-*cis*	$n_{s\text{-}cis}$, %
(IX)	CH_3	2.90	2.86	3.30	10
(X)	CN	3.51	5.24	0.88	60
(XI)	Br	2,59	3.64	1.60	60

Table 7 presents the experimental and calculated dipole moments of α-substituted vinylphosphonates. The tabulated data show that the conformer with the antiparallel directions of the dipoles is more stable in all the compounds. The preferred *s*-*trans*-form of α-methylvinylphosphonic dichloride has also been detected by infrared spectroscopy[87]. The *s*-*cis*–*s*-*trans* isomerism of vinylphosphonates with an irregular substituent in the β-position and a non-uniform distribution of conformations can likewise be investigated, since the dipole moments of the two isomers are different. According to ^{1}H NMR data[13], the RO and P=O groups in β-alkoxyvinylphosphonates are in the *trans*-positions relative to the C=C bond. Comparison of the calculated and experimental dipole moments of these compounds (Table 8) shows that the conformer with the *s-trans*-disposition of the C=C and P=O bonds predominates in all the compounds[13].

Table 8. The dipole moments of $C_4H_9OCH{=}CHP(O)R_2$.[13]

Compound	R	μ_{exp}, D	μ_{calc}, D		n_s-trans, %
			s-trans	*s*-cis	
(XVII)	OC_2H_5	3.41	3.46	3.97	100
(XXII)	Cl	4.46	4.39	4.92	90
(XXI)	C_6H_5	4.36	4.18	4.70	70

The isomerism relative to the $P{-}C_{sp^2}$ (carbonyl) bond has been investigated for benzoylphosphine oxides as an example[21]. The latter are convenient subjects for the examination of rotation about the $P{-}C_{sp^2}$ bond in contrast to the unsubstituted vinyl- and buta-1,3-dienyl-phosphonates, where the polarities of the *s-cis*- and *s-trans*-conformers are independent of rotation about the bond. There is as yet no unanimous view in the literature concerning the relative positions of the C=O and P=O groups. A structure with the C=O and P=O groups in mutually perpendicular planes has been suggested[88]. According to other data[67], a planar disposition of the π-electron system and the P=O bond is the most favourable; in this case there is a possibility of two rotational isomers with the *s-cis*- and *s-trans*-dispositions of the C=O and P=O groups:



s-cis $C{=}O \perp P{=}O$ *s-trans*

Table 9 presents the experimental and calculated dipole moments of benzoyldiethylphosphine oxide (LXXI) and benzoyldiphenylphosphine oxide (LXXII).[21] If the C=O and P=O groups were located in mutually perpendicular planes, the experimental dipole moments of (LXXI) and (LXXII) would be close to 4.59 D, whereas in fact they are consistent with an equilibrium between *s-cis*- and *s-trans*-forms, where the content of the latter is approximately 90–95%. When the experimental and calculated dipole moments of benzoylphosphinates[21] are examined, the *s-trans*-conformation also proves to be preferred (approximately 90–95%), i.e. there is virtually no rotation about the $C_{sp^2}{-}P$ bond. It is noteworthy that the strong dipoles of the substituting groups in the preferred conformations (C≡N and P=O, C=O and P=O) are oriented antiparallel, which indicates a significant influence of electrostatic factors on the steric structure. There is a conformational equilibrium in benzoylphosphonates between the *s-cis*- and *s-trans*-forms, with the latter predominating slightly (~60%).[21]

The conclusion that the O=C–P=O system is not rigid has been questioned[89]. The authors[89] studied benzoylphosphonates by infrared spectroscopy and concluded that there is no rotation about the $P{-}C_{sp^2}$ bond, because the absorption band of the carbonyl group is not split. The *s-trans*-form (which predominates for benzoylphosphinates and benzoylphosphine oxides also according to dipole moment data) has been suggested as the only isomer of these compounds. If it is supposed that there is a non-planar *gauche*-disposition of the C=O and P=O groups in benzoylphosphonate (LXVIII), the dipole moment calculated for this form is found to be close to the experimental value. However, the occurrence of this form has been rejected[89].

Table 9. The dipole moments of benzoyldiethylphosphine oxide and benzoyldiphenylphosphine oxide[21].

Compound	μ_{exp}, D	μ_{calc}, D			n_s,*trans*, %
		s-cis	$C{=}O \perp P{=}O$	*s-trans*	
(LXXI)	2.28	6.25	4.59	1.73	95
(LXXII)	2.69	6.25	4.59	1.73	90

The available literature data concerning the mutual disposition of the C=O and P=O groups in benzoylphosphonates[21,88,89] are probably insufficient for a final conclusion. At any rate, the absence of the splitting of the ν(C=O) band is not adequate evidence for the rigidity of the O=C–P=O system, because the forms involved in equilibrium may have similar spectroscopic characteristics, and may be indistinguishable in the infrared spectra. Nor can one explain the difference between the calculated dipole moment (0.78 D)[21] of the *s-trans*-form of benzoylphosphonate (LXVIII) and the experimental value (3.10 D) by a deviation from additivity owing to the interactions of the carbonyl and phosphoryl groups (as was done by Laskorin et al.[89]). Experiment showed that, even in the presence of direct polar conjugation, the difference between the experimental and calculated dipole moments does not exceed 1–1.5 D. Furthermore, an analogous interaction occurs also in benzoylphosphine oxide and benzoylphosphinates, for which the results obtained by the dipole moment and infrared spectroscopic methods are virtually identical. It would be very useful to apply another independent method to this problem.

IV. THE CONFORMATION OF ARYL DERIVATIVES OF FOUR-COORDINATED PHOSPHORUS

The internal rotation of the hydrocarbon groups does not affect the magnitude and direction of the molecular dipole moment in terms of the approximation of the additive scheme. Their steric orientation may be established on the basis of molar Kerr constants (*mK*).[2] The first compound with the $C_{sp^2}{-}P^V$ bond investigated by this method was triphenylphosphine oxide[38]. The additive scheme for the anisotropy of the phosphorus bond polarisability has been analysed[2]. The available literature data show that one aryl group linked to the phosphorus atom (both tervalent and quinquevalent)[76,91] is located in the plane incorporating the axis of the CPX_2 (X = R or Hal) pyramid, i.e. is coplanar with the hybridised LEP of the phosphorus atom or with the phosphoryl group (Fig. 1).

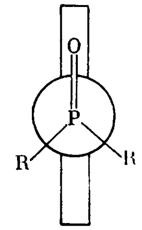


Figure 1. Conformation of dialkylarylphosphine oxides[91].

However, the aryl group in *p*-substituted arylphosphonates[23] is to a large extent displaced from the C_{sp^2}–P–O plane. Two regions of energetically favourable positions with rotation away from this plane to one side or the other ($\varphi = \pm 50°$), resembling the eclipsing of single P–O bonds (Fig. 2), have been observed for this group. It is of interest that, in the study of complexes of *O,O*-diethyl phenylphosphonite with different metals, a non-planar structure was also discovered ($\varphi = 55$–$75°$).[92] Thus the conjugation in *p*-substituted arylphosphonates[24] apparently cannot be of the π–π type and is better explained by a $p\pi$–$d\pi$ interaction. The conjugation between the phenyl and P=O groups has been confirmed by a study of the infrared spectra of cyclohexylphenylphosphine oxides.[93] The rotation about the P–C_{sp^2}(phenyl) bond in 2-oxo-(thiono)-2-phenyl-1,3,2-dioxaphosphorinanes (CII) and (CIII) and their spiro-analogues (CV) and (CVI) has been investigated[27], and it has been found that the conformer with an equatorial phenyl group predominates in these compounds (80%), the plane of the benzene ring being parallel to the LEP of the phosphorus atom or the P=O and P=S bonds. The plane of the benzene ring in the conformer with an axial phenyl group is perpendicular to the molecular symmetry plane in derivatives of both three- and four-coordinated phosphorus.

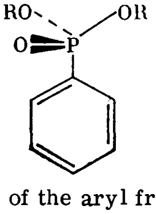

Figure 2. Orientation of the aryl fragment in *O,O*-dialkyl arylphosphonates[23].

The rotation of two aryl groups in OPC has been examined in relation to propynyl and trichloromethyl-diphenylphosphine oxides[33,40]. The angular variation of the calculated Kerr constant for compound (CLI) is very pronounced (Fig. 3), which made it possible to determine the conformation of this compound with a high accuracy. Owing to their linearity, the P=O bond and the P–C≡C group gives rise to the same steric hindrance to the rotation of substituents at the phosphorus atom; nevertheless a structure obtains in which the planes of the phenyl groups nearly eclipse the C≡C bond.

The experimental values of *mK* for diphenyltrichloromethylphosphine oxide (CXXII), trichloromethylditolylphosphine oxide (CXXIII), and di-*p*-chlorophenyltrichloromethylphosphine oxide (CXXIV)[33] correspond to the values calculated for an angle of rotation of 15°. Hence the conclusion that the conformations of the molecules investigated are close to the sterically least hindered conformation in which the plane of each aromatic ring is perpendicular to the C_{sp^2}–P–C_{sp^2} plane with a possible deviation by an angle up to 15°, which leads to the eclipsing of the phosphoryl group. The conformation established by Ishmaeva et al.[33] was explained by a balance between the energies of the steric interactions of the hydrogen atom in the *o*-position, within the pyramid formed by phosphorus bonds, with the analogous hydrogen atom in a neighbouring aryl group, on the one hand, and the trichloromethyl group, on the other. Thus the benzene rings in propynyl- and trichloromethyl-diphenylphosphine oxides are rotated by a small angle in different directions from the same initial position. However, in principle, similar results have been obtained for these compounds, i.e. the replacement of the linear propynyl group by the bulky trichloromethyl group has little influence on the conformations of the compounds.

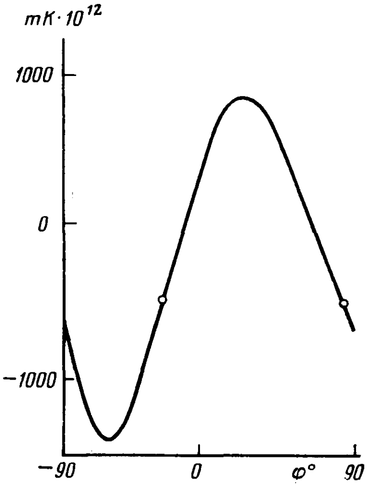

Figure 3. Conformational dependence of the Kerr constant for diphenylpropynylphosphine oxide (CLI)[40] (the circles on the curves represent experimental values).

The rotation of three aryl groups in triarylphosphine oxide molecules has been investigated[35,38,94]. Comparison of the experimental *mK* and the values calculated on the assumption of C_3 symmetry for unsubstituted triphenylphosphine oxide (CXXV) and its *p*-chloro-derivative (CXXVII), *m*-chloro-derivative (CXXIX), *p*-methyl-derivative (CXXXV), and *m*-methyl-derivative (CXXXVI)[35] led to the following angles of rotation of the benzene ring: 55°, 65°, 49°, 60°, and 52° respectively (Fig. 4). The halogen atom and the methyl group in the *p*-position lead to some flattening of the molecules compared with unsubstituted triphenylphosphine oxide. The authors[35] suggest that this may be accounted for from the standpoint of the $p_\pi - d_\pi$ conjugation of aromatic rings with the phosphorus atom. The possibility of a similar interaction has been pointed out in other studies[95,96].

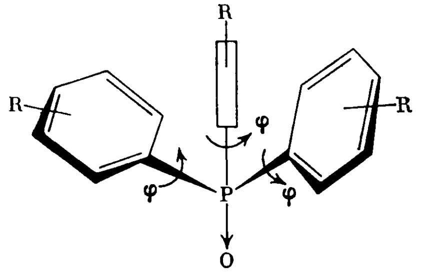

Figure 4. The conformation of triarylphosphine oxides[35].

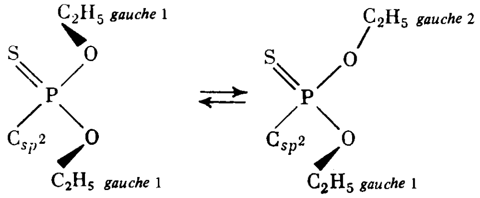
The data concerning the barriers to the rotation about the C_{sp^2}–P bonds are scanty. The rotational barriers have been estimated[87,97] from the torsional vibration frequencies of compounds (VII) and (XC): $V = 4-6$ kcal mole^{-1}.

V. CONFORMATIONAL ISOMERISM IN RELATION TO SINGLE BONDS IN UNSATURATED ORGANOPHOSPHORUS COMPOUNDS

It is now well known that, on rotation about single bonds in compounds of four-coordinated phosphorus, the *gauche*- or *trans*-form predominates[98-105], regardless of the bond (P–O, P–S, or P–Se) about which rotation takes place. Significant differences between compounds containing one, two, or three[106] irregular groups have not been observed. The same forms as in 2-alkoxy (methylthio, methylseleno)-2-oxo(thiono)-1,3,2-dioxaphosphorinanes[100,102,105] are produced in acyclic derivatives[104].

Data concerning conformational isomerism in relation to single bonds in unsaturated OPC are still very few[10,40]. However, they too indicate the preferred *gauche*- or *trans*-orientation to the alkyl and P=O or P=S group.

It has been found[10] that conformational equilibrium between two forms with the *gauche*-orientation of the alkyl and P=S groups (apparently with some distortion owing to a tendency towards the formation of the *cis*-form) obtains in diethyl vinylphosphonothioate (II):



As for diethyl ethynylphosphonate (CXLVI) and propynylphosphonate (CXLVII), the experimental dipole moments agree with the values calculated for structures with the *gauche*-disposition of the alkyl and P–O groups[39].

The study of the rotation about the C_{sp^3}–P bond in diethylpropynylphosphine oxide (CL) by the method based on the Kerr effect[40] led to the conclusion that the C–CH_3 bonds in the ethyl groups are only in the *gauche*-positions relative to the P=O group (Fig. 5). The experimental value $mK = -176 \times 10^{-12}$ for (CL) is rigorously consistent with calculations for the *gauche*$_1$, *gauche*$_1$-conformation (-180×10^{-12}) and the *gauche*$_1$, *gauche*$_2$-conformation (-178×10^{-12}). Analogous data for the structures of irregular methoxy-groups have been obtained for arylphosphonates[23]. A conformational equilibrium of the two forms of the above compounds has been demonstrated by infrared spectroscopy. These forms have been identified by the dipole moment method; the calculated and experimental data were treated by Exner's method[107], which led to the conclusion that the *gauche*-orientation of the methyl and P=O groups is preferred, with some distortion (up to 20°) towards the *cis*-form. The possibility, in principle, of such distortion has been confirmed also by quantum-chemical calculations[108].

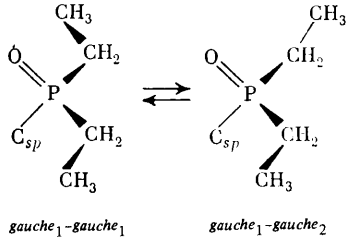


Figure 5. The orientation of the methyl groups and the P=O bond in the molecule of diethylpropynylphosphine oxide (CL).[40]

The rotation about the P–O bond in alkyl and aryl methylphenyl- and diphenyl-phosphinates[28,29] leads to conformers with the *gauche*-orientation of the alkyl or phenyl and phosphoryl groups. It is believed[28] that the increment in the refraction of the C_6H_5–P^V group (1.0 cm^3) arises owing to the conjugation of the benzene ring with the P=O group, while the second benzene ring, linked to the phosphorus atom, does not give rise to an analogous effect[28]. The *gauche*-orientation is preferred also in the esters of diphenylphosphinodithioic acid (CXI), di(*p*-chlorophenyl)phosphinodithioic acid (CXIV),[31] and di(*p*-chlorophenyl)phosphinodithioic acid (CXVI).[31]

Thus rotation about single P–O, P–S, and P–C_{sp^3} bonds in unsaturated OPC containing a four-coordinated phosphorus atom obeys rules common to organophosphorus compounds.

Summarising the discussion of the steric and electronic structures of unsaturated OPC with a four-coordinated phosphorus atom, one may note that the phosphorus atom is involved in a mesomeric type interaction. The steric orientation of the π-electron system is evidently to a large extent determined by these interactions, while the relative stabilities of the conformers involved in the equilibrium are controlled by polar factors. The presence of π-electron systems has hardly any influence on the conformations of the irregular groups attached to the phosphorus atom, which permits a comparison of the physical and chemical properties in large series of organophosphorus compounds.

New Possibilities and Chemical Applications of Raman Spectroscopy

P.P.Shorygin

The problems involved in the study and applications of Raman spectroscopy are considered, attention being mainly concentrated on resonance Raman spectroscopy. Theoretical studies are briefly surveyed and the applications of the method in the investigation of molecular structures and the mechanisms and kinetics of chemical reactions are discussed. Examples of the study of various organic, organometallic, and other compounds, polymers, haemoproteins, nucleotides, etc. are presented. The possible applications of the excitation spectra of resonance Raman lines are noted.
The bibliography includes 428 references.

I. INTRODUCTION

Raman spectroscopy is widely used in chemistry, physics, and other branches of science as one of the most important methods for the investigation of molecular structure. The set of characteristic vibration frequencies determined from the spectra together with intensity data for Raman lines yield information about the force constants of chemical bonds, molecular symmetry, the presence of definite structural groups in the molecule, and the interaction of these groups with one another. Raman spectroscopy makes it possible to determine the compositions of fairly complex products and helps to determine the structures of new compounds and to elucidate the mechanisms of chemical reactions[1-8].

However, in the first stages of the development of the method, its scope was limited to fairly severe conditions. Practical experience showed that the Raman effect may be excited by monochromatic light of any wavelength, provided that it lies in the range where the test substance is completely transparent (i.e. is remote from absorption bands). The substance scatters only a small proportion of the incident light (less than one thousandth under laboratory conditions); furthermore, almost the entire scattering is of the undisplaced (Rayleigh) type, while Raman scattering, which carries the most interesting information about molecular properties, constitutes only a few per cent of the total. Bearing in mind that less than one ten thousandth of the light scattered in all directions can be directed to the measuring apparatus (spectrometer), it is easy to imagine how small are the measured light fluxes of the individual Raman lines. In practice they can be observed only for high concentrations of the substance ($> 1\%$).

In attempts to excite the Raman effect in coloured substances in the region of absorption bands, virtually complete reabsorption occurred and the Raman lines were lost. It was suggested that under these conditions Raman scattering must be converted into fluorescence. Further theoretical studies showed that the transition to fluorescence is possible, but only in specific instances. On excitation by narrow spectral lines in the region of a fairly broad absorption band, typical Raman scattering should occur and be characterised by very high molar intensity coefficients[9].

In order to observe this effect, it was necessary to modify somewhat the usual experimental conditions; thereby it was possible to obtain distinct spectra of intensely coloured compounds. Thus, as early as 1948,[10] the Raman spectra of *p*-nitroaniline solutions were obtained with excitation in the violet part of the spectrum (within the half-width of the very intense band associated with the $\pi \rightarrow \pi^*$ electronic transition). Later the spectra of potassium *p*-nitrophenoxide were obtained with excitation at the absorption band maximum[11]. The intensity coefficients of the Raman lines were so high that the spectra were obtained without difficulty at concentrations $< 0.001\%$. The phenomenon described was called the resonance Raman effect[12].

Further studies demonstrated the possibility of observing the resonance Raman effect in chemical compounds of different classes[1]. Many objects, which previously could not be investigated by Raman spectroscopy, began to be studied with a fair degree of success. Measurements of the spectra of coloured liquid, gaseous[13-16], and solid substances were described, namely amorphous[17,18] and crystalline (semiconductors[19-24], non-conductors, various polymers[25,26], and minerals[27]) substances, monomolecular layers[28,29], chemical reaction intermediates present in solutions, free radicals[30-34], impurity centres in crystals[35-43], molecules in solid matrices[44-48], molecules in an electronically excited state[49], and compounds in natural systems (in the living tissues of plants and animals)[50-52]. One may note successful attempts at selective investigation of the structures of particular fragments of very complex molecules in whole erythrocytes[53], in the retina of a functioning eye[54], in bacteria[55,56], in viruses[57], etc. The spectra of a number of metals and metal compounds[58,59], wood charcoal, carbon black, etc. have been obtained[60]. The study of the resonance Raman effect promoted the solution of important problems of the interaction between light and matter and the elucidation of relations between principal molecular-optical phenomena[1,9].

The development of resonance Raman spectroscopy led to the establishment of an extensive branch of science within the limits of which new research fields began to be initiated; outwardly this was reflected by the appearance in Journals of new terms: "resonance Raman photochemistry",[61] "resonance Raman spectro-electrochemistry",[62-64] "internal reflection resonance Raman spectroscopy",[65] "X-ray resonance Raman spectroscopy",[66] etc.

Hitherto we spoke mainly of light scattering by molecules accompanied by excitation of molecular vibrations. The experimental observation of resonance rotational[67-69] and electronic[70] Raman light scattering by molecules, the electronic resonance Raman effect excited by X-rays in atoms[66,71,72], resonance scattering with spin-flip[4,73] and with excitation of magnons (spin waves)[74,75], excitons, and phonons (collective atomic vibrations in the crystal lattice)[76-83], and resonance-stimulated[84-87], inverse[88-90], and coherent[91-94] Raman scattering has been described in the literature in recent years. A sharp increase of the probability of Raman scattering and an increased applicability of the relevant methods to the study of molecules, crystals, and natural and technical products was noted in all cases.

Considerable progress in the experimental technique greatly extended the range of problems susceptible to solution by Raman spectroscopy. For example, the measurement of the spectra of atoms at the instant of collision in the gas phase, of individual optically active components of racemates, of flames, and of streams of exhaust gases from a reactive engine, accurate determination of the moments of inertia of molecules with revision of interatomic distances, and the study of the vibrational energy distribution of molecules formed in chemical reactions, of the distribution of electron densities in different parts of a single crystal, of the orientation of molecules in polymer blocks, etc. have become possible.

Delhaye[5] (Schmid., pp. 747 and 762) reported successful experiments involving the measurement of the Raman effect within 10^{-10} s, which gives rise to interesting prospects for the investigation of unstable species and the kinetics of rapid reactions (we may recall that at one time exposures lasting several minutes were regarded as a major achievement). A method has been developed for obtaining the images of microscopic objects at wavelengths of specified Raman lines ("micro-Ramanography"), which makes it possible to characterise the distribution of particular inclusions in homogeneous objects and to follow the chemical reactions in the latter.

Apparatus for measurements at a distance and for the investigation of remote objects under laboratory and field conditions (for the determination of flame temperatures, of the contamination of the atmosphere and water in the ocean, etc.) has been described. Ways of employing the method in astrophysics have been outlined and the parameters of Raman spectra have been used in the study of the atmosphere and in the determination of the geometrical albedos and diameters of planets on the basis of a determination of the rotational-vibrational satellites of Fraunhofer absorption lines arising in the scattering of the sun's rays by the planet's atmosphere[95-97].

The use of resonance excitation of the Raman effect has potential for a considerable improvement of the sensitivity and selectivity of the methods enumerated above.

As a result of the improvement of the experimental technique, many difficulties in the observation of the resonance Raman effect (for example, interference due to fluorescence) can be eliminated or reduced. Apparatus employing ultraviolet radiation has greatly extended the range of chemical compounds susceptible to resonance excitation. Thus nucleotides[98,99], simple amines, amides, dienes[100-103], benzene[104], etc. were investigated. Sources of monochromatic radiation with a smoothly adjustable frequency have created a considerable scope for the measurement of the excitation spectra of Raman lines, i.e. curves defining the dependence of Raman line intensities on the frequency of the exciting light $I(\nu)$. The study of excitation spectra, which may be regarded as a new and important branch of resonance Raman spectroscopy, has given rise to considerable possibilities for the investigation of molecules not only in the ground state but also in excited electronic states[9,105,106].

Below we shall briefly consider the main lines in the development of the theory of the resonance Raman effect and the chemical applications of the method. Problems closely related to those considered here have been considered in the past few years in certain specialised reviews (problems of conjugation[1], problems of the theory of the resonance Raman spectroscopy of molecules[9,107,108] and crystals[109,110], experimental investigations and technique[111], and the applications of the resonance Raman effect in biochemistry[112,113]).

II. ADVANCES IN EXPERIMENTAL TECHNIQUE

During the initial period of the study of excitation spectra, it appeared appropriate to employ three–four wavelengths in order to characterise $I(\nu)$ approximately in the region of broad absorption bands in the visible part of the spectrum. The development of tunable lasers made it possible to cover the range 3000–7000 Å with any required number of points and to obtain information about the $I(\nu)$ relation, including the regions of the fine structure of the absorption spectrum, where a series of extrema were recorded with intervals smaller than 1 cm^{-1} for varying excitation frequency ν.[114] Indirect methods for characterising the excitation spectra (employing the change in the positions of absorption bands with variation of the composition of binary systems[76,116], the solvent[115,116], the temperature of the substance[17,77], the pressure, etc. at a fixed frequency ν) have now become of secondary importance.

The use of very short exciting light pulses (10^{-11}–10^{-8} s) and the recording of secondary resonance radiation with time scanning and separate observation of synchronous glow and afterglow are of exceptional interest. The pulse technique has been used, on the one hand, to study the mechanisms of the resonance transformation of light by molecules[117] and, on the other, to investigate short-lived intermediates by the resonance Raman method[118].

Excitation in the region of absorption bands may give rise to considerable experimental difficulties from the large light losses in the specimen and the photochemical decomposition of the substance. The light losses are reduced to a minimum by optimising the concentration of solutions (this was used already in the first observations of the resonance Raman effect[11] and has been specified in detail[119,120]) or by reducing the optical path length in the absorbing medium with selection of light scattered by surface layers of the specimen in the direction opposite to that of the incident light[121]. In another version the light beam is directed through a transparent plate or layer of liquid at a low angle onto the interface with a coloured solution[27,122]; the reflected light is enriched in the spectral components of the light involved in resonance Raman scattering as a result of the interaction of the incident light with the molecules in the surface layer of the coloured substance. The distribution of surfactants in a monomolecular layer at the interface with respect to molecular orientations was characterised by a similar method[28].

The interference due to the photochemical decomposition of the substance is reduced by scanning the incident light beam over the surface of the specimen[123], by rapid rotation of the cuvette[111], or by employing a flow technique[124-127]. For a flow rate of 1–10 m s^{-1}, which is readily attainable, it is possible to obtain distinct resonance Raman spectra of relatively unstable products[128]. The kinetics of the rapid reaction between horseradish peroxidase and hydrogen peroxide have been studied in this way[129]; the resonance Raman spectra were recorded a fraction of a second after mixing the reactants and the start of the reaction and at long time intervals; by selecting a particular zone along the length of the stream it was possible to detect the formation of unstable intermediates and to characterise the kinetics of their decomposition.

The interference due to fluorescence may be eliminated by employing a series of procedures: 1. By adding quenching agents (for example, nitrobenzene)[130,131]. 2. By modulating the polarisation of the incident radiation[132] and separating the polarised Raman lines from the depolarised fluorescence. 3. By modulating the frequency of the measured secondary radiation and recording the derivative $dI/d\omega$, whereby one can isolate resonance Raman lines which are narrower than the fluorescence lines; it is more effective[133] to modulate the frequency of the incident light, so that the positions of the fluorescence bands are not modulated, (in contrast to those of the Raman lines) and the receiving device does not record them[134]. 4. By illumination with short pulses combined with synchronous recording of the secondary radiation but not the afterglow[111,135]. 5. By carrying out measurements in the anti-Stokes region (see Section IV). 6. By ensuring the maximum monochromatisation of the incident light.

III. THE RESONANCE RAMAN EFFECT WITH EXCITATION OF ATOMIC VIBRATIONS

The resonance Raman light scattering by molecules, which takes place with excitation of atomic vibrations, has been most thoroughly investigated and has found extensive applications in chemistry and physics. The resonance conditions arise when the frequency of the incident light ν is in the region of the absorption band of the substance corresponding to the $0 \rightarrow e$ electronic transition. Such bands are usually located in the visible or ultraviolet regions; for many compounds in the vapour phase they have a fine vibrational-rotational structure but are very broad for solutions (500–5000 cm^{-1}). On irradiation with quasi-monochromatic light, the secondary radiation includes that produced by the resonance Raman effect in the form of narrow lines and possibly (cf. Ref. 136) fluorescence bands, which are usually just as broad as the absorption bands[137,138]. In those cases where the fluorescence spectrum consists of narrow lines, the latter may be mixed with the Raman lines[45,139-145], hindering the interpretation of the spectrum; the broad fluorescence bands interfere with the recording of the Raman scattering.

Resonance excitation does not modify the observed vibrational frequencies ω and the contours of the Raman lines, but increases the line intensities by several orders of magnitude[9-11,144,145]. On the other hand, the quantum yield of the Raman scattering[146] changes only slightly and remains very low[126,147-150]; for aromatic nitro-compounds in solution, it amounts to about 10^{-8} and depends comparatively little on the properties of the solvent and temperature (this cannot be said of fluorescence)[137,138].

Table 1 presents as an example the parameters[137] of the usual fluorescence (including the afterglow time τ_e) and the lines due to the nitro-group in the resonance Raman spectrum of 4-dimethylamino-4′-nitrostilbene after excitation with light in the region of the maximum of the $\pi \rightarrow \pi^*$

broad absorption band (~ 23 000 cm^{-1}); I^s is the molar intensity coefficient of the Raman line[1].

In successive experiments with excitation using light corresponding to different $0 \rightarrow e$ bands of the same substance, it is possible to observe resonance-induced intensification of various sets of Raman lines[79-81,151-154], preferentially those corresponding to fully symmetrical vibrations. The similarity between the locations (and orientations) of the electronic and Raman transitions is then important[128,155,156,184]. For example an intensification of the Raman lines due to the Co–N bond in the $Co(NCS)_4^{2-}$ ions was noted when the frequency ν was in the range corresponding to the band associated with the electronic excitation of Co–N bonds and an intensification of the C–N and C–S lines was observed on excitation of the Raman effect in the region corresponding to the short-wavelength absorption band due to the electronic excitation of the ligands[157]. Ultimately, everything depends on the electronic transitions which are influenced by particular atomic vibrational modes (see Section V). The electronic transitions which make a significant contribution to the intensity of a Raman line are said to be "effective" for this line[144,158]. However, this term was subsequently frequently used with another significance—implying a "centre of gravity" of the contributions of different transitions (this interpretation is permissible for Rayleigh scattering but hardly for Raman scattering, where the contributions of different levels may have different signs!).

Table 1.

Solvent	Fluorescence		Resonance Raman effect	
	quantum yield	τ_e, s	ω, cm^{-1}	I^s
Benzene	0.7	$3 \cdot 10^{-9}$	1340	5000000
Acetone	<0.03	$<10^{-10}$	1338	6000000

The lines due to the Raman overtones ($\nu - k\omega$) under conditions remote from resonance are so weak that they are rarely susceptible to observation. However, as resonance is approached, their intensity may increase sharply—to a greater extent the higher the order of the overtone k and they may form a complete progression[9,159,160]; this is possible for those fully symmetrical atomic vibrations which modulate the electronic transition frequencies ν_e.[9,161-163] Such progressions were observed for the first time in the resonance Raman spectra of diphenylpolyenes[138] and subsequently of many other compounds[164-166]; thus fifteen overtones have been observed in the spectrum of I_3^- ions[42] and 25 in that of iodine[142,167]. If the decay of the electronic oscillator is rapid, then Rayleigh scattering continues to predominate in the resonance spectrum with a smooth decrease of intensity within a series of $k\omega$ overtones[9,156,168-172] (and with a gradual broadening due to the broadening of the rotational and isotopic structures and finite vibrational k states[42,173-177]; see, however, Howard and Andrews[178]). In other cases the smoothness of the decrease may break down[9,179-182].

The measurement of the frequencies of the resonance Raman overtones led to new possibilities for the determination of the coefficients of the mechanical anharmonicity of the vibrations[142,156,170,176] and for the revision of the frequencies and the force fields in molecules[183]; data were obtained for metal–metal[156,184], metal–halogen[160,185], etc. bonds.

The lines of the non-totally symmetric ω_{as} vibrations proved to be the most intense in the Raman spectrum only in very rare instances; this has been observed for pyrazine on excitation with light at wavelengths in the vicinity of the $n \rightarrow \pi^*$ band[186], certain metalloporphyrins on excitation with light corresponding to the long-wavelength $\pi \rightarrow \pi^*$ band[187-191], and a few other compounds[192-196]. According to Kettle et al.,[197] the high ω_{as} intensity for $Mo(CO)_6$ can be accounted for by the fact that, when the CO bond is extended, the polarisability increases along the bond and decreases at right angles to it. However, there is no doubt that the symmetry properties of the resonance level e are of primary importance. Progressions in $k\omega_{as}$ overtones have not been observed experimentally, although in principle they are not ruled out in the presence of a high anharmonicity and for large differences between the shapes of the $E(Q)$ potential energy curves for the ground and excited electronic states; in a few isolated instances it has been possible to observe a single $2\omega_{as}$ overtone in the resonance Raman spectrum[198-200].

Another characteristic feature of the resonance spectra is the possibility of the appearance of vibrational line with inverse (degree of depolarisation $\rho \rightarrow \infty$) or anomalous ($3/4 < \rho < \infty$) polarisations. These include the very intense lines of certain non-totally symmetric a_{2g} vibrations in the spectra of metalloporphyrins with D_{4h} symmetry (vibrations with turning motions of the atoms of the macroring)[190,201]; for other examples, see Refs. 202–207.

Inverse polarisation implies that the oscillating dipole induced by the electric field of the light wave along the direction of the field (x) is not modulated by the vibrations of the normal nuclear coordinate Q and does not contribute to the Raman effect, while the y-component at right angles to the field is modulated and gives rise to a Raman line. For this unusual situation to occur, the "vibronic interaction" (see Section VI) is not obligatory (cf. Refs. 208–210). We shall consider an example in a very simplified form. Two identical electronic oscillators rock slightly in the course of the intramolecular vibrations of atoms with retention of mutually perpendicular orientations[211] of the dipole moments of the $0 \rightarrow e$ transitions (see Fig. 1, the vectors M). The resultant x-component of the vibrations of the two electronic oscillators is then high but virtually unmodulated. On the other hand, the y-component is on average zero, but under certain conditions it may be actively modulated by the atomic vibrations; the extent of modulation is determined by the sum of the projections of two vectors corresponding to the change in the orientations (ΔM) and two vectors corresponding to the change in the amplitudes (δM) of the oscillations (caused by the change in the effective field). When the decay constant of the electronic oscillator is high ($\gamma_e > \omega$) or when the Raman effect is excited under conditions remote from resonance, the modulation of the orientations and amplitudes of the oscillations of the electronic oscillators takes place in phase and the sum of the four ΔM and δM vectors is close to zero; when $\gamma_e < \omega$ the phases of the modulation of the orientations and amplitudes of the oscillations do not coincide, as a result of which the annihilation of the four ΔM and δM

modulation components is disturbed; the spectrum of the y-component vibrations then contains the $\nu \pm \omega$ frequencies, i.e. Raman lines, although the ν frequency is absent.

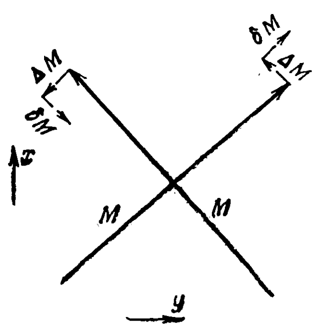

Figure 1. Evolution of the dipole moments of the transition in the course of atomic vibrations (model of a molecule with D_{4h} symmetry).

Anomalous polarisation has come to be invoked for the assignment of the resonance Raman lines to symmetry species[202,212,213], and to determine more precisely the symmetry of systems of conjugated bonds[151,190,214] and electronic transitions[204]. However, when the frequency ν changes, the quantity ρ for certain lines of porphyrins and other compounds[205,215] changes from values characteristic of fully symmetrical vibrations ($< 3/4$) to larger values ($\gg 1$), which has not so far been adequately explained and has complicated the assignment of the lines. Additional data for the $\rho(\nu)$ relation may be found in a number of studies[216-221].

Thus the resonance Raman effect is characterised by very high intensity coefficients and in certain cases also by the appearance of progressions of overtones; in a few instances there is a possibility of the appearance of anomalously polarised lines.

The resonance Raman effect may be regarded as absorption of an $h\nu$ photon and simultaneous emission of an $h(\nu \pm \omega)$ photon with an altered energy. The concept of absorption, the intermediate excited state of the molecule, and emission as successive stages of the transformation of the photon corresponds to the resonance fluorescence process and has been invoked to describe the Raman effect[222, 223] in purely conventional terms.

Typical scattering differs from the usual (relaxed) and resonance fluorescence by the following features: (1) the shift of the exciting light line in the spectrum induces the same shift of all the Raman lines (cf. Ref. 67); (2) the width of each Raman line is determined mainly by the width of the exciting line but not by the contour of the absorption band[9,224] (cf. Ref. 225); (3) there is no afterglow and no rotational depolarisation (cf. Ref. 117, where a different terminology is used).

Resonance fluorescence may be excited under the conditions of exact resonance ($\nu = \nu_{ev}$) for a very narrow absorption band (for $\gamma_e < \Gamma$, where Γ is the half-width of the incident light band). Radiationless deactivation of the intermediate excited state of the molecule[226] leads to a broadening of the absorption band, to a decrease of the intensity of the secondary resonance emission (Schmid[8], p. 286), and to its modification as far as transition to typical scattering when $\gamma_e \gg \Gamma$. Thus it creates conditions for the occurrence of scattering while at the same time it behaves as a competing process.

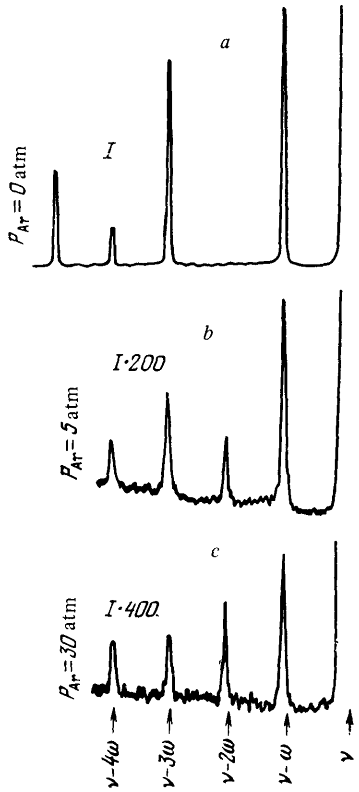

Figure 2. Spectra of the secondary emission of iodine vapour in the presence of argon; excitation by the 5017 Å line in the region of the discrete iodine absorption spectrum. With increase of argon pressure p_{Ar} from 0 to 30 atm, the intensity of the secondary emission falls sharply and there is a gradual transition of the intensity distribution in a series of overtones from that characteristic of resonance fluorescence to a smooth decrease of intensity characteristic of resonance Raman spectra[181].

The possibility, in principle, of a smooth transition from typical light scattering to resonance fluorescence with a gradual alteration of the difference $\nu_e - \nu$ and of the relations between the half-width of the incident light band Γ and the molecular parameters γ_e, ω, and the rotational frequency Ω has already been mentioned in a review[1]. Brilliant experiments, demonstrating the reality of the gradual disappearance of the dependence of the secondary emission line frequency on the frequency ν,[227] of the change in the energy distribution in the series of $0 \rightarrow k$ overtones (Fig. 2)[181], and of the evolution of the rotational structure of the lines with transformation of the Q-branch of the resonance Raman line into the R-branch of the resonance fluorescence line (Fig. 3) were carried out recently[14,181].

Certain data concerning the transformation of scattering into fluorescence as the resonance conditions are approached ($\nu = \nu_e$) for NO_2 and naphthalene and pyrazine crystals have been reported[228-230]. A resonance emission of an intermediate type, close to scattering, has been noted for solutions of diphenylpolyenes[138] and emission closer to fluorescence has been observed for ND_3 in the gas phase; in the latter case the half-width of the vibrational-rotational component of the absorption band (~ 2 cm^{-1}) was close to the half-width Γ of the incident light band[150].

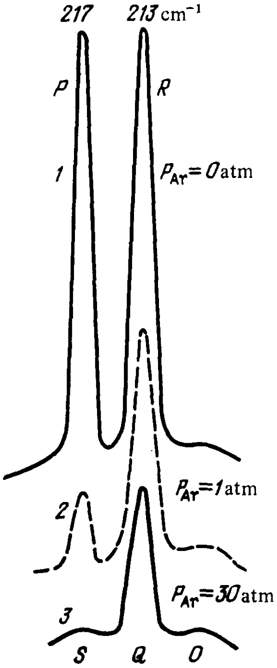

Figure 3. Modification of the rotational structure of the ~ 215 cm^{-1} iodine line with increased pressure of argon (transition from resonance fluorescence to resonance Raman spectra)[14]; the details have been omitted and the scale is arbitrary: 1) p_{Ar} = 0 atm, resonance fluorescence spectrum; 2) p_{Ar} = 1 atm, transitional spectrum; 3) p_{Ar} = 30 atm, resonance Raman spectrum.

Fig. 4 illustrates a very simplified example of the formation of the $I_{em}(\nu)$ secondary resonance emission spectrum in the region of a single $\epsilon(\nu)$ absorption band; the $I_{inc}(\nu)$ incident light line is shown continuous. The plot of the intensity of the secondary emission has two maxima; the left-hand and right-hand maxima symbolise resonance fluorescence and scattering respectively.

The problem of the boundary between scattering and fluorescence has been the subject of a lively discussion in the literature with invocation of various criteria[7,9,108,231-237].

IV. OTHER FORMS OF THE RESONANCE RAMAN EFFECT

Inverse Spectra

When light whose spectrum contains an intense ν line and a second component consisting of a broad band in a nearby region of the spectrum passes through a substance, weakening of the light flux may be observed predominantly in the region of the $\nu + \omega$ frequency (where ω is the frequency of the atomic vibrations in the molecule). This is because the "biharmonic" combination of the ν and $\nu + \omega$ components of the light field (which may be regarded as vibrations with beats at a frequency ω) may excite the atomic vibrations (along the normal coordinate Q) with a corresponding loss of light field energy provided that the derivative of the polarisability of the molecule $\partial\alpha/\partial Q \neq 0$. The components of the broad band, the frequencies of which are not equal to $\nu \pm \omega$, do not participate in such processes and are not weakened. The resulting selective (with respect to the spectrum) weakening of the light which has passed through the substance is called the "inverse Raman effect" or "inverse combination scattering" (although in essence it is not scattering). Resonance phenomena are observed for $\nu = \nu_e + \omega$ (when the intensity of the ω line increases) or when $\nu = \nu_e$ (when the intensities of all the Raman lines increase)[89,90].

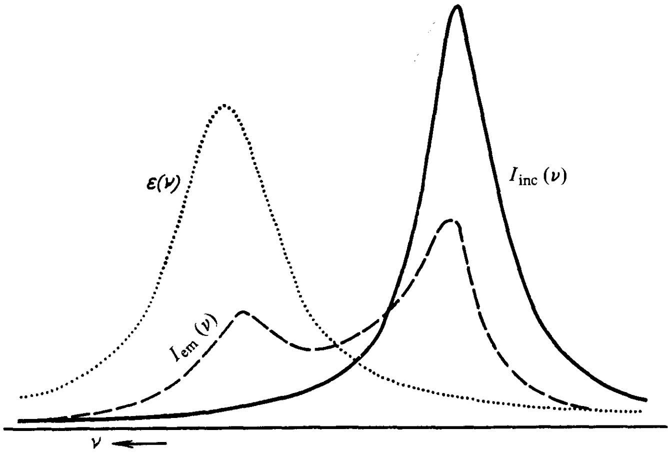

Figure 4. The $I_{em}(\nu)$ secondary emission spectrum (dashed line) with the oscillator vibrations excited in the vicinity of resonance (the simplest oscillator model); $\epsilon(\nu)$ absorption spectrum.

Coherent Active Raman Spectroscopy

When $\partial\alpha/\partial Q \neq 0$, a biharmonic light field, incorporating the ν and $\nu + \omega$ frequencies, is capable of exciting in the molecules of the given substance atomic vibrations which are concerted as regards phase over a fairly large volume of the specimen. The additional monochromatic excitation with a frequency ν^* is then actively modulated by these vibrations and gives rise to narrow directional beams due to displaced "scattering" at a frequency $\nu^* \pm \omega$ with a very large quantum yield. This phenomenon can also be regarded as a kind of refraction of light. When $\nu^* = \nu_e$, conditions are created for the resonance transformation of light, which has been demonstrated for iodine vapour[91] and solutions of β-carotene[92] and other compounds[93], (Schmid[5], p. 740). The high intensity of the anti-Stokes ($\nu + \omega$) lines make it possible to investigate the Raman spectrum in the region where the interference due to fluorescence is a minimum.

The Resonance Raman X-Ray Scattering by Metal Atoms

This has been observed under conditions where the energy $h\nu$ (reaching 9000 eV) was close to the K-electron ionisation energy[66,71,72]. Under these conditions, the absorbed photon causes the transfer of an electron from the K-shell to the conductivity band, while an electron from the L-shell fills the resulting vacancy in the K-shell, which is accompanied by the emission of a resonance Raman effect photon; the final state of the atom is determined by the presence of an additional electron in the conductivity band and of a vacancy in the L-shell.

For details about the possible applications and other forms of the resonance Raman effect, see the literature quoted in Section I. A common feature of all types of the resonance Raman effect is the high probability of the transformation of photons and the high sensitivity of the methods.

V. PRINCIPAL TRENDS IN THE DEVELOPMENT OF THE THEORY OF THE RAMAN AND RESONANCE RAMAN EFFECTS

Various aspects of the theory of the Raman effect excited under conditions close to and remote from resonance have developed vigorously in recent years. Firstly, the ideas concerning the mechanism of light scattering by molecules with excitation of vibrational and rotational states have been extended and specified in greater detail. A tendency has arisen to establish quantitative relations between the Raman line intensities and other physical and chemical properties of the molecule. Secondly, new fields and methods have been described (for example, the method of differential spectroscopy). Significant advances have been made in all these aspects of the theory.

The intensity of the mth Raman line excited by a monochromatic light flux of constant and moderate intensity can be determined from the set of all the Cartesian components of the derivative of the polarisability with respect to the normal nuclear coordinate $\partial\alpha/\partial Q \equiv \alpha'$; without going into details, one can assume that the intensity is proportional to $(\nu - \omega)^4|\alpha'|^2$. In the simplest version of the semiclassical theory[1,9,144] the quantity α' consists of contributions by all the levels (e) of the electronic excitation of the molecule:

$$\alpha' = \mathrm{const}\cdot\sum_e\left[\frac{f'_e}{z} - \frac{2f_e\nu_e\nu'_e}{z^2}\right] = \sum_e (b^*_e + a^*_e) \tag{1a}$$

or

$$\alpha' = \mathrm{const}\cdot\sum_e\left[\frac{(M^2_e)'\nu_e}{z} - \frac{M^2_e(\nu^2_e+\nu^2)\nu'_e}{z^2}\right] = \sum_e (b_e + a_e), \tag{1b}$$

where $z = \nu_e^2 - \nu^2 + i\nu\gamma_e$, ν is the frequency of the incident light, M_e, f_e, and ν_e are the matrix elements of the dipole moment, the oscillator strength, and the $0 \rightarrow e$ electronic transition frequency, and γ_e is the decay constant; each level e is regarded as an integral hole (without taking into account the vibrational-rotational structure) and the frequency ν_e corresponds to the absorption band maximum; here and henceforth a prime denotes derivatives with respect to Q. The terms b_e (or b_e^*) are determined by the modulation of the values of M_e (or f_e) by the atomic vibrations and the terms a_e (and a_e^*) are determined by the modulation of ν_e; the latter arises when electronic excitation entails a change (Δ_e) in the equilibrium interatomic distances and Q.[1] Non-totally symmetric vibrations (for which $\Delta_e = 0$) cause the modulation of the M_e (or f_e) values only (if one disregards local electronic excitations), but for overtones both mechanisms of the modulation of α are important. The intensity of the overtones[238] is determined by the highest derivatives of α with respect to Q.

A method for the determination of the mechanism of modulation, employing a more marked dependence of the Raman line intensity on the frequency ν under the conditions of the modulation of the electronic transition frequency ν_e, was proposed a long time ago[239,240]. Despite the imperfection of the experimental technique, it was then possible to show that both types of modulation, i.e. both terms, a_e and b_e, may play an important role and that, as resonance is approached, the relative importance of the a_e term increases[145,240]. Little reliable information has yet been obtained on these problems. Some workers[6,241] do not take into consideration the a_e terms [the reasons for this being stated (or not)[134] with reference to an experiment, or to intuition[242]].

Incidentally the term a_e has not been entirely correctly transformed into the expression $[1 + (\nu/\nu_e)^2][1 - (\nu/\nu_e)^2]^{-2}$ and has been used in this form[243-248] to extrapolate α' to $\nu \rightarrow 0$ (according to the authors[248,249], this leads to a "more correct" value of α').

Eqns. (1) can be regarded as the result of certain simplifications in the Kramers–Heisenberg–Weisskopf formula. The latter has also served as the basis of a number of other versions of the theory. The appreciable differences in the formulation of the fundamental expressions and the contradictory estimates of the role of different factors as well as inaccuracies and errors in individual instances may make it difficult to become acquainted with the extensive relevant literature; certain explanations are therefore useful.

The familiar Albrecht formula in its initial form[250] took into account, like the Placzek polarisability theory (despite the assertions of Chao and Lippincott[241] and Schulman and Detrano[251]), only the modulation of M_e, i.e. the factor M'_e (the term b_e). Later[252] account was taken also of the modulation of ν_e (the factor ν'_e, the term a_e) and a more complete agreement with Eqn. (1) was achieved. The origin of the dependence of M_e on Q, i.e. of the derivative $\partial M_e/\partial Q = M'_e$, was specified in greater detail on the basis of the idea that the wave functions φ of different electronic excitation levels e and s are mixed on passing from the equilibrium configuration of the molecule ($Q = 0$) to the non-equilibrium configuration ($Q \neq 0$) during atomic vibrations ("vibronic interaction"[31,222,250,252-255]). The coefficients of the mixing of the wave functions h_{es} are specific to each vibrational mode; it has been suggested[256-258] that h_{es} should be greater the larger the alteration in the frequency ω on electronic excitation.

We shall elucidate the above statement concerning the "vibronic interaction" by a simple example. We shall assume that, for the equilibrium positions of the atoms, the $0 \rightarrow e$ electronic transition is forbidden; on deformation of the molecule by the nth normal vibration (i.e. for $Q_n \neq 0$), the wave function φ_e is modified as a result of the "admixture" of the wave function of another electronic level s, the transition to which ($0 \rightarrow s$) is allowed; the oscillator strength f_e for the deformed molecule will then prove to be non-zero and during atomic vibrations the "admixture" of φ_s and the quantity f_e (and hence M_e) will be actively modulated, contributing to the intensity of the Raman line[250,264]. In the simplest case where only two electronic excitation levels e and s are involved and in the absence of the modulation of ν_e and ν_s, one must assume that $f'_e = -f'_s$; one then obtains from Eqn. (1) the multiplier

$$F_B = \frac{\nu_e \nu_s + \nu^2}{(\nu_e^2 - \nu^2)(\nu_s^2 - \nu^2)},$$

the square of which should describe, according to Ziegler and Albrecht[104,250], the $I(\nu)$ relation.

In the general case one must take into account the mixing of the φ for all the levels e and s. Thus, instead of the single quantity M'_e for a single level e in Eqn. (1), one should introduce the complete matrix of the coefficients h_{es}, which is particularly complex in the case of overtones, because it includes higher-order coefficients (cf. Refs. 222, 223, and 259). The problem has been simplified by Warshel and Dauber[260] in essence at the price of partial neglect of the mixing of the wave functions. A realistic estimate of certain coefficients h_{es} has been achieved in only isolated instances[254,257,261]. The quantities M'_e and f'_e can be determined, in principle, from the analysis of limited sections of the absorption spectrum and are known for many simple molecules[262]. Both procedures, with introduction of M'_e and the mixing coefficients h_{es}, may be useful in the study of the mechanism of the Raman effect. However, examination of the set of all the Cartesian components M'_e makes it possible to take into account not only the "vibronic interaction" and h_{es} but also the contribution of the turning motions of individual fragments of the molecule.

Formulae for specific instances of excitation before and after resonance and between two absorption bands have been obtained[241,242,263]. They correspond to neglect of the term a_e and the unjustified introduction into the initial expression of resonance denominators of the type $|\nu_e - \nu|$ instead of $(\nu_e - \nu)$ and cannot be treated as correct.

Like all other formulae where the level e is regarded as an integral whole, Eqns. (1) are suitable in the resonance region only for very high values of γ_e on excitation to the region of broad structureless absorption bands; in the presence of vibrational structure one must take into account the contribution of the individual sublevels v, which, generally speaking, can be achieved on the basis of both classical and quantum theories[9,239,264].

We shall make use of the latter and shall quote in a very simplified form the expression for the matrix element of polarisability, which facilitates the determination of the term-by-term correlations with Eqn. (1b):

$$\alpha_{0k} = \frac{2}{hc} \sum_e \left[M_e^2 \sum_v \frac{\nu_{ev} A_{0v} A_{vk}}{\nu_{ev}^2 - \nu^2 + i\nu\gamma_{ev}} + \sum_v \frac{\nu_{ev} B_{ev}}{\nu_{ev}^2 - \nu^2 + i\nu\gamma_{ev}} \right] = \sum_e (\mathrm{A}_e + \mathrm{B}_e), \tag{2}$$

where ν_{ev} is the frequency of the $00 \rightarrow ev$ vibronic transition (in cm^{-1}), A_{0v} and A_{vk} are the overlap integrals of the nuclear wave functions of the 00 and ev and of the ev and $0k$ sublevels, and $B_{ev} = \mathbf{M}_e^{0v} M_e^{vk} - M_e^2 A_{0v} A_{vk}$, where $\mathbf{M}$ (in contrast to M) have been constructed from the complete wave functions ψ and not from the purely electronic wave functions φ, the superscripts denoting the quantum numbers of the vibrational sublevels of the combining states. The quantities B_{ev} and B_e are associated with the coefficients of the expansion of M_e in a series in powers of Q or, in terms of a more drastic simplification, with h_{es} [see Krushinskii and Shorygin[264] as well as Eqn. (8) in the paper of Rousseau and Williams[117]]. The term A_e is, roughly speaking, proportional to Δ_e.

The intensity of the Raman line of the fundamental band ($k = 1$) is proportional to $|\alpha_{01}|^2$, the intensity of the first overtone ($k = 2$) is proportional to $|\alpha_{02}|^2$, etc. For the fundamental, the terms A_e and B_e corresponding to each level e approximately correspond to the terms a_e and b_e of Eqn. (1).

According to Eqn. (2), the line intensity reaches a maximum when the frequency ν coincides with any component ν_{ev} of the structured absorption band; the excitation spectrum then has a series of maxima, the intervals between which are equal to the vibration frequencies of the atoms in the electronically excited states (whereas in the Raman spectrum itself the intervals in the progression of $k\omega$ overtones are determined by the frequency ω of the atomic vibrations in the ground electronic state); for very small[265,266] shifts Δ_e (and for a small anharmonicity of the atomic vibrations in the electronically excited state), only two maxima remain in the vicinity of the frequencies ν_{e0} and ν_{e1} (for the first overtone, in the vicinity of ν_{e0} and ν_{e2}; cf. Ref. 267). In complex molecules one cannot rule out the possibility of the separation of the $I(\nu)$ maxima with frequencies ω of "foreign" modes[254,268].

Owing to the difference between the signs of A_{vk}, the contributions of the sublevels v to A_e have different signs[239], which leads to a more pronounced $I(\nu)$ relation for Raman lines compared with Rayleigh scattering, particularly in the case of overtones, where there is a possibility of a repeated alternation of signs in a series of v sublevels[9] (a similar result in the semiclassical theory is determined by the higher powers of the resonance denominators). The neglect[269,270] of the integrals A_{vk} or of the differences between their signs is unjustified.

The difference between the signs of the contributions of different electronic levels e is associated with the difference between the signs of Δ_e (and also M'_e).[239,264] For a specific frequency of the incident light, this can lead in individual instances to the "annihilation" of the contributions of different levels e with weakening or complete disappearance of the Raman line, i.e. to the appearance in the excitation spectrum of an "anti-resonance" band (see the data for naphthalene[200], CdS,[271,272] and other compounds[115,273,274]; cf. Refs. 275–277). The appearance of anti-resonance owing to the different signs of the terms A_e and B_e for a single level e has already been examined[264].

The calculation of the values of $A_{0v}A_{vk}$ for all the sublevels v is fairly complex[168,180,278-280]. In order to simplify the task, it has been suggested that the entire sum with respect to v [see Eqn. (2)] be expanded in a series[107,275,281] in powers of $\nu_e - \nu$; then[107] $\mathrm{A}_e \simeq [(\nu_e - \nu)^{-2} - \omega(\nu_e - \nu)^{-3} + \ldots]$. However, under conditions remote from resonance, this procedure leads to the same results as the more compact Eqn. (1) and in the region of resonance it gives rise to a diverging or a slowly converging series and loses its significance. The expansion[282] in powers of $\nu_{e0} - \nu$ gives rise to an even worse convergence. The above series[107] yields a more marked $I(\nu)$ relation for Raman lines with low frequencies which can actually occur only in certain special cases (approximately the same may be said about the $I \propto \omega^2$ relation obtained by Warshel and Dauber[260]).

Peticolas et al.[283] obtained a formula for the Raman intensity without summation with respect to v but with a resonance denominator of the type $(\nu_e - \nu)(\nu_e + \omega - \nu)$; in the region of a single electronic excitation level e it gives rise to two resonance points, ν_e and $\nu_e + \omega$, and therefore in the vicinity of resonance it is suitable only for a very low deformation Δ_e of the molecule on electronic excitation; the two resonance points then correspond to the frequencies ν_{e0} and ν_{e1}. The same may be said of the formulae of Kobinata[259] and Nafie et al.,[223] designed for the region of resonance, which cannot be justifiably applied to iodine molecules with their large value of Δ_e.

The employment of such formulae is more appropriate for crystals, where Δ_e is as a rule very low and a vibrational structure is not usually observed for discrete electronic levels. However, the latter led to certain other misunderstandings. The appearance of two maxima in the region of one level e (for $\nu = \nu_e$ and $\nu = \nu_e + \omega$) was interpreted as the manifestation of resonance with the incident photon ($h\nu$) and with the scattered[76,77,116,284,285] photon $h(\nu + \omega)$. In fact the usual resonance takes place, in the first instance with the purely electronic $00 \rightarrow e0$ transition, which is clearly visible in the absorption spectrum, and in the second case with the vibrational satellite corresponding to the $00 \rightarrow e1$ transition, which is very weak but which gives a high quantum yield for the Raman line. Double resonance[285-287] must be interpreted in the same spirit—as the resonance with two partly overlapping sublevels $e1$ and $s0$.

On excitation of the resonance Raman effect in the region of an absorption continuum, arising from an electronic transition to a repulsive state or a state with rapid decay, the line intensities may be determined from Eqns. (1) and (2) with the corresponding constants γ_e or by means of other[226,288-290] suitable variants, for example by integration of the contributions from all the elements of the profile of the continuum without the introduction of a decay constant (as is done in the determination of polarisability by the Kramers–Kronig method)[159,291-294]. In any case, the knowledge of the form of the $\epsilon(\nu)$ continuum is insufficient for the calculation of the resonance Raman intensity.

The above formulae describes the smooth increase of the Raman intensity as ν approaches the region of maximum absorption in the continuum and the decrease of intensity on further increase of ν. However, according to Laplante and Bandrauk[295], here there should be whole series of maxima with decrease of intensity between them down to zero. This conclusion is incorrect and arises from the use of ideas about the $E_e(Q)$ "potential energy curve" for the repulsive state without taking into account the effect of the uncertainty principle when the effective lifetime of the intermediate state τ_{eff}, which limits the time over which emission of scattered radiation with transition of the molecule to the $0k$ state can occur; this time is longer the smaller the slope of the $E_e(Q)$ curve for $Q = 0$.

Above we were concerned with the usual cases to which the adiabatic approximation is applicable. The influence of non-adiabatic conditions on the intensity of the resonance Raman effect and on the excitation spectra has been considered[107,296,297].

In order to calculate the intensities of Raman and resonance Raman lines for specific molecules by Eqns. (1) and (2), it is necessary to know a set of parameters, which can be determined, in principle, from electronic absorption spectra or calculated theoretically[9,260,298,299]. In more primitive versions of the theory semiempirical relations and simplified molecular models are introduced instead of Eqns. (1) and (2). Below we shall consider briefly the methods of calculation employed, which will be arranged in order of increasing research value and rigour.

Applequist and Quicksall[300] calculated $\partial\alpha/\partial Q$ for methyl halide molecules using the Silberstein theory, which has been known for a long time and which assumes that each atom X in the molecule is polarised directly by the electric field of the light wave and by the field of the dipoles induced by light at the neighbouring atoms Y—the "partners" in chemical bonds; this additional polarisation naturally depends on the interatomic distances $q_{\text{X-Y}}$, which is described by the increments $\partial\alpha_{\text{X}}/\partial q_{\text{X-Y}}$. The authors[300] assumed that this model elucidates the mechanism of the Raman effect to a greater extent than the model with $\partial\alpha_{\text{X-Y}}/\partial q_{\text{X-Y}}$ chemical bond increments (see below), in which the "interaction of the dipoles induced in atoms is neglected". In reality neither model (nor the concept of resonance structures[301] and Pauling's oscillations between them[302]) can claim to explain the mechanism of the Raman effect, but the model with bond increments is closer to reality (it reflects, albeit implicity, the involvement of two-centre molecular orbitals and not individual atomic orbitals).

The zeroth approximation of the valence-optical scheme assumes the additivity of the polarisabilities of individual chemical bonds—"independent" molecular fragments. Three increments of α and three increments $\partial\alpha/\partial q$, corresponding to three Cartesian components, one of which coincides with the direction of the bond, are attributed to each bond (for example, C=C, C–Cl, O–H). Strictly speaking these increments have no physical significance even in those cases where their empirical selection leads to satisfactory results for molecules which are most consistent with the additive scheme (saturated hydrocarbons under conditions remote from resonance); in connection with the proof described in an earlier review by the present author[1] (p. 707), one may also refer to new interesting data concerning the splitting of the electronic levels of alkanes[303]. At the same time the possibility of adapting the valence-optical scheme are much wider than in the case of Silberstein's model. However, its use for compounds such as TiI_4, $SnBr_4$, and other coloured compounds[176,197,304] with non-local levels e lacks any justification.

In Lippincott's scheme a purely empirical selection of $\partial\alpha/\partial q$ increments is replaced by a semiempirical calculation[305] but with limitation to a single Cartesian component per bond, which naturally greatly diminishes the possibility of adaptation. The scheme is based on a very primitive one-dimensional model—an electron in a field with two identical infinitely narrow potential wells at the sites of the two atoms forming the chemical bond; here one can imagine an electronic excitation involving a transition between states with symmetric and antisymmetric wave functions; the frequency of the transition naturally diminishes as the bond is extended and the polarisability increases. In conformity with the assumptions made, the derivative of polarisability for $\nu = 0$ in the resulting formula (see, for example, Nagarajan[305] and p. 713 in the earlier review[1]) is proportional to the chemical bond order n. The formula has been used fairly widely for approximate estimates of bond orders from Raman intensities and for converse purposes; for example, a significant degree of π bonding has been noted[243,247,249] in $TiCl_4$ and VCl_4 molecules and in CrO_4^{2-} and MoO_4^{2-} ions. Estimates of bond orders made it possible to refine the force constants[306] for PF_5 and other molecules.

Fontal and Spiro[307] recently proposed a simplified expression for single bonds: $\partial\alpha/\partial q = 0.1\chi q_0^3 n$, where χ is the electronegativity of the atoms and q_0 the equilibrium bond length. On this basis, the authors[307] reached conclusions about the bonds in bridged complexes and about the degree of covalence of certain coordinate bonds.

In the first approximation of the valence-optical (additive) scheme refinements are introduced in the form of additional empirically selected increments attributed to the influence of adjacent chemical bonds and valence angles. With the aid of a standard set of conventional increments (main and additional increments), it is possible to describe the intensities of the Raman lines for various molecules with "weakly interacting" bonds under conditions very remote from resonance. Thus, using 12 parameters of C–H and C–C bonds, determined from the Raman spectrum of cyclohexane, a satisfactory description of the spectrum of polyethylene was achieved[308]. Koenig and Bigorne[309] examined the $Ni(CO)_4$ spectrum and the additive scheme was supplemented by the separate contribution of the lone electron pair of the oxygen atom $\partial\alpha_{lp}/\partial q$.

The use of quantum-chemical LCAO-MO methods to calculate molecular wave functions and frequencies ν_e with subsequent evaluation of α_{01} or $\partial\alpha/\partial Q$ is much more promising and is of greater intellectual value than the computational procedures examined above. Quantum-chemical methods have been used for ethylene, acetylene, and certain other molecules[260,298,299,310], but in most cases only within the framework of the conventional problem of the influence of a static field[311-313].

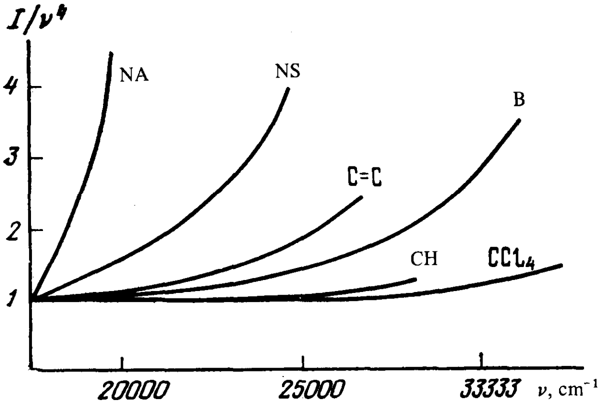

Figure 5. Deviations from proportionality between I_S and ν^4 with increase of the frequency of the exciting light ν and as resonance is approached; the values of the quantities compared are assumed to be unity at $\nu = 18000$ cm^{-1}; NA = p-nitroaniline, Raman line of the nitro-group; NS = p-nitroanisole, Raman line of the nitro-group[145]; (C=C) = line corresponding to the vibrations of the C=C bond in mono-olefins[240]; B = 992 cm^{-1} benzene line[104,314]; CH = 802 cm^{-1} cyclohexane line[314]; CCl_4 = 313 cm^{-1} carbon tetrachloride line[318,319].

VI. THE EXCITATION SPECTRA OF RESONANCE RAMAN LINES

When the spectra of colourless compounds are excited under conditions where the absorption bands are very remote from the incident light frequencies ν, the intensity of all the Raman lines increases smoothly with ν in proportion to the factor $(\nu-\omega)^4$ (see data for cyclohexane[314] and others[315-317]). It followed from the semi-classical theory that, under conditions somewhat less remote from resonance ($\nu_e - \nu < 40000$ cm^{-1}), the intensity may increase much faster owing to the simultaneous increase of α'. This was confirmed by experiments with olefins, ketones, and other compounds with single and conjugated π bonds. These experiments initiated systematic research into excitation spectra, undertaken at one time at the Karpov Physicochemical Institute[10,240]. One of the first results was the demonstration of a large contribution of the modulation of ν_e by the symmetrical vibration of the p-nitroaniline nitro-group on excitation by light corresponding to the long wavelength part of the $\pi \rightarrow \pi^*$ absorption band. Data for several compounds are presented in Fig. 5.

Further studies on p-nitroaniline[145,320,321] yielded an idea about the changes in the intensity coefficient I^S of the line due to the nitro-group over a wide range of frequencies ν [see Fig. 6, where the $\lg I^S(\nu)$ relation is presented; the continuous line corresponds to the direct experiment and its extrapolation, shown as dashed lines, were constructed on the basis of analogies with other data]. With decrease of $\nu_e - \nu$ from 20 000 to 0 cm^{-1}, the intensity I^S increases by a factor of several thousand, in approximate agreement with the contribution of α_e^*; the form of the $I(\nu)$ relation permits an estimate of the decay constant as ~ 2000 cm^{-1}.[322] We may note that, at the frequency corresponding to the same $\pi \rightarrow \pi^*$ absorption band, one may expect only slight changes in the intensity of the C–H Raman lines, which are more closely associated with the $\sigma \rightarrow \sigma^*$ bands in the far ultraviolet.

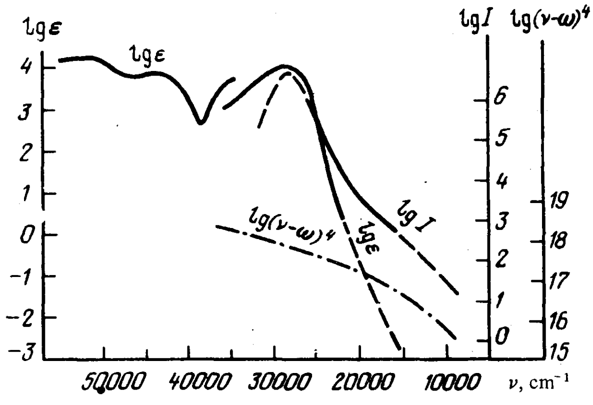

Figure 6. $\lg I(\nu)$ nitro-group line excitation spectrum and absorption spectrum of p-nitroaniline (solutions in benzene)[145,320,321].

The approximate coincidence of the $I(\nu)$ and $\epsilon(\nu)$ maxima was observed not only for p-nitroaniline but also for the majority of other compounds with broad absorption bands; but a deviation by 300–800 cm^{-1} in either direction has been observed for bromine[322,323], solutions of iodine[324,325] and dimethylaminoazobenzene[326], and in many other instances, particularly for overtones[21,142,327].

Bobovich and coworkers[328,329] believe that the $I(\nu)$ maximum must be located in the region of the $00 \rightarrow e0$ transition, i.e. at the beginning of the absorption band [experimental data, see Schmid[5], pp. 284, 340], which is possible, in principle, only in certain special cases—with partial superposition of the bands due to different electronic transitions[324,325,331], when there is marked dependence of γ_{ev} on v, for certain low values of Δ_{em}, etc. The explanation of the causes responsible for the divergence of the $I(\nu)$ and $\epsilon(\nu)$ maxima given by Michaelian et al.[276] is incorrect and has been obtained on the basis of a simple exclusion of the contribution of the short-wavelength part of the absorption band; the interpretation of Friedman et al.[322] does not differ greatly.

An example of a compound with a low decay constant ($\gamma_e < \omega$) and a distinct vibrational structure of the absorption band is provided by the diester EtOOC–(CH=CH)$_6$–COOEt. Fig. 7 illustrates the dependence of $\lg I^S/(\nu - \omega)^4$ on ν for the 1562 cm^{-1} Raman line due to the C=C vibration (the results of a direct experiment are shown by a continuous line); the curve is continued by dashed lines based on analogies with other similar compounds[138,338]. Together with experimental data, the results of calculations are presented for those cases where the intensity is determined by (1) the term b_e in Eqns. (1) of the semiclassical theory (modulation of f_e) and (2) by the formula of the quantum theory taking into account the contributions of individual sublevels ev subject to the assumptions corresponding to $f'_e = 0$ (dashed lines). The values of $\lg I^S/(\nu - \omega)^4$ for $\nu = 5000$ cm^{-1} were assumed to be unity; $\nu_e = 25\,520$ cm^{-1} and $\gamma_e = 250$ cm^{-1}.

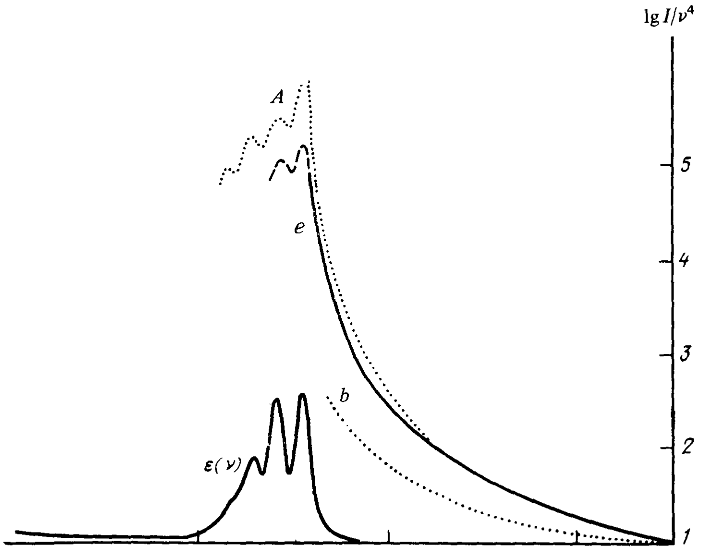

Figure 7. Relative changes in I/ν^4 for the C=C line of the diester (see text) as the region of resonance is approached; e—experimental data; A—calculated data with allowance for the term A_e only; b—ditto with allowance for the term b_e^* (modulation of f_e).

The term a_e^* of the classical theory and the A curve virtually coincide outside the region of resonance and agree with experiment much better than the term b_e and a little better than the term a_e, which shows that the contribution of the modulation of f_e is small. On excitation in the region of the components of the ev fine structure, the semiclassical theory is known to be inapplicable and the A curve, obtained within the framework of the quantum theory, agrees with experiment only qualitatively—it does not reflect the presence of several modes in the ev fine structure. Under conditions remote from resonance, either the contribution of A_e or that of the first absorption band is of secondary importance. We may note that, in the vicinity of resonance, the intensity of the diester line increases much faster than that of the p-nitroaniline line, which is due to the much smaller decay.

During recent years experimental studies have been made on the $I(\nu)$ relation for the Raman lines of many organic and inorganic compounds in the vicinity of resonance[50,243,247,317,329–336] and in the region of resonance corresponding to a structureless absorption band[56,145,148,329] [see also Schmid[5], pp. 328–337, etc.]; in the region of the band with an explicit vibrational structure studies have been made on polyene compounds[147,335–338], metalloporphyrins[202,254,261], haemoglobin derivatives[187], MnO_4^{2-},[168] and others[339–341].

Studies on certain totally symmetric vibrations of diphenylpolyenes[336], nitroaniline[277,321], $TiBr_4$,[342] MnO_4^- ions[159], and other species[160,245,276] led to the conclusion that the modulation of M_e (the term B_e) predominates. The predominance of the modulation of ν_e has been demonstrated for lines due to carotene[335,338], aminoazobenzene[326,343], diethylcyanine[344], haemoproteins on excitation with light corresponding to the Soret absorption band[187,345], nucleotides[99], SnI_4,[275,342] CrO_4^{2-} ions[36], MnO_4^{2-} ions[168], iodine[324,325], and other species[219,246,268,346] in the vicinity or in the region of resonance, as well as benzene[104], butadiene[317], and others[186,347] outside the region of resonance. On excitation with light corresponding to one absorption band, the C=C Raman line of the tetracyanoquinodimethane anion corresponds to the modulation of ν_e and, on excitation with light corresponding to another band, it corresponds to the modulation of M_e.[348] The data for phenazine, pyrazine, and PtI_6^{2-} ions indicate the modulation of ν_e by totally symmetrical vibrations and the modulation of M_e by antisymmetric modes[177,186,349]. According to Schmid et al.,[350] the asymmetric (b_{3g}) vibration line of anthracene corresponds to the frequency multiplier of the term A_e!

Unfortunately the number of experimental points[351,352] on the $I(\nu)$ curves and the information about the electronic absorption spectra and the constants γ_e employed[277,352,353] were in many cases quite inadequate and the set of electronic transitions taken into account was fairly arbitrary[160,241,245,263,276,333,342] and in addition was almost always restricted to the long-wavelength part of the spectrum. Nevertheless a more detailed analysis indicates the great importance of the range 1000–2000 Å[104,316]; thus, according to Ziegler and Albrecht[104], the most effective band for the 992 cm^{-1} Raman line of benzene is much more remote (~ 1200 Å) than the nearest intense absorption band (1830 Å).

Nevertheless, the set of all available data, including the more pronounced $I(\nu)$ relation for overtones[14,139,142] (and for the majority of lines due to 0 → 1 symmetrical vibrations compared with lines due to asymmetric modes[291]), the similarity in the sets of frequencies ω observed in resonance Raman spectra and in the fine structure of absorption bands, as well as the results of certain quantum-chemical calculations[298,299] show that the term A_e predominates in the vicinity of resonance for the majority of lines due to totally symmetrical vibrations.

As an example, we may mention the results of calculations of the intensity and scattering activity (which does not include the multiplier ν^4)[1,7,15], obtained[298] by the CNDO/C method for the Raman lines of ethylene in all three versions, which demonstrate the relative contributions of M'_e and ν'_e under conditions remote from and close to resonance (Table 2); Table 3 provides information about the contributions of the factor ν'_e for the six most important levels e, the first of which corresponds to the excitation of π electrons and the remainder correspond mainly to the excitation of σ electrons[298].

Calculation of the intensity of the C=O line of benzaldehyde[310] under conditions remote from resonance indicates the predominance of the factor M'_e for the majority of the levels e.

Table 2. Calculation of the scattering activities for the C-H (3019 cm^{-1}) and C=C (1623 cm^{-1}) ethylene lines.

ν, cm^{-1}	C–H			C=C		
	calc. with allowance for different factors			calc. with allowance for different factors

Table 3. Calculation of $\nu'_e M^2_e$ for the C-H and C=C ethylene lines.

ν_e, eV	$\nu'_e M^2_e$		ν_e, eV	$\nu'_e M^2_e$	
	C–H	C=C		C–H	C=C
6.41	0.4	−5.6	13.40	−1.6	−1.2
8.93	−2.4	−1.6	15.75	−13.6	1.6
12.50	−1.6	0.4	16.13	−1.2	−0.4

The excitation spectra of the Raman lines resemble electronic absorption spectra (see the examples quoted in the literature[24,254,329,340]), but for many complex molecules the $I(\nu)$ bands are much narrower and the excitation spectrum reveals the concealed structure of the broad absorption band formed as a result of the superposition of many components (Fig. 8).

Summarising, the following may be said. The positions of the Raman lines in resonance Raman spectra characterise the ground electronic state of the molecule; the excitation spectra of resonance Raman lines provide information about electronically excited states, which frequently cannot be secured by measuring the absorption spectrum.

The excitation spectra have been used to solve a very wide variety of problems underlying in one way or another more advanced stages associated with the study of molecular structures and chemical transformations: 1. The elucidation of the mechanism of the Raman effect (the type of modulation, the contribution of the Frölich interaction in semiconductors[22,82] etc.), and test of the validity of particular variants of the theory. 2. The separation of resonance Raman and fluorescence lines. 3. The determination of the role of various absorption bands and of their contributions to the intensities of specific Raman lines[99,317,334,354]. 4. The determination of the concealed structures of absorption bands (see Section VII). 5. The elucidation of the type, location, symmetry, and energy of electronic excitation[156,184,187,340,346,355,356]. 6. The determination of the width of the forbidden gap in the components of binary semiconductor compounds. 7. The derivation of information about the geometry of the molecule and the frequencies ω in electronically excited states[100,103,257,258,334]. 8. The estimation of the lifetime of the excited state τ_e in the case of a non-uniform broadening of the adsorption band[290] (which cannot be done on the basis of the absorption spectrum). 9. The construction of the $E_e(Q)$ potential energy curve when bands due to different electronic transitions are superimposed[289]. Other applications of the excitation spectra as well as individual examples will be given in the next section.

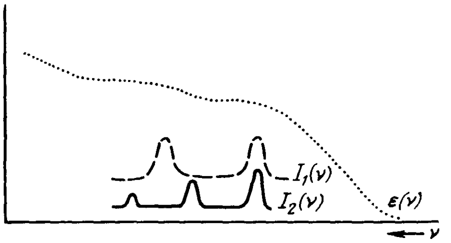

Figure 8. Excitation spectra of two Raman lines (ω_1 and ω_2) of a hypothetical complex molecule.

There is no doubt that the joint investigation of absorption and resonance Raman excitation spectra is extremely useful and improves the effectiveness of spectrochemical studies.

VII. CHEMICAL APPLICATIONS OF RESONANCE RAMAN SPECTROSCOPY

The applications of resonance Raman spectroscopy are based on determinations of the frequencies ω, the molar intensities I, the degrees of depolarisation ρ, and $I(\nu)$ line excitation spectra. The experimental data are used on the basis of theoretical generalisations and empirical relations which determine the relations between the parameters of the spectra and molecular structure.

The ways in which the information about the Raman and resonance Raman line frequencies is used are in principle the same; the most important trend in this field involves the detection of specific structural groups in the molecule and the determination of their positions as well as the characterisation of the state and rigidity of the chemical bonds. However, resonance Raman spectra give rise to the following additional possibilities: 1. An extension of the set of frequencies ω susceptible to measurement as a result of the discovery of lines forbidden by the usual selection rules (for example, inversely polarised lines). 2. The detection, identification, and investigation of the structures and chemical transformations of trace impurities[357], biologically active compounds present in very low amounts, impurity centres in crystals, etc. 3. The study of the structure of short-lived intermediates. 4. The characterisation of monomeric products in the absence of association at very low concentrations (10^{-4}–10^{-8} M[326,337]). 5. The determination of the frequencies of overtones (and the components of their isotopic structure) and of the coefficients of the anharmonicity of the interatomic potentials with the corresponding revision of the molecular force field, dissociation energy, etc. 6. The isolation of the frequencies ω and characterisation of specific chromophoric groups in complex molecules. According to Baierl et al.,[68] the moments of inertia and centrifugal deformation constants may be determined from rotational resonance Raman spectra no less accurately than from electronic absorption spectra.

The available information about the line intensity makes it possible, in principle, (1) to characterise the change in the polarisability of molecules on extension of specific chemical bonds and, on this basis, the bond order, (2) to investigate the kinetics of the reactions of unstable species and intermediates, (3) to determine quantitatively the content of microimpurities, the distribution of molecules with respect to orientation[28,61], the distribution of inhomogeneities on the surface of a solid under static conditions and in the course of chemical reactions, as well as equilibrium constants at low concentrations, (4) to demonstrate the involvement of particular atomic groups in conjugation and in the given type of electronic excitation, (5) to determine the location of the active centre responsible for the formation of an intermediate complex or the transition state, and (6) to determine, when the assignment of the resonance Raman lines is known, the type and location of electronic excitation (and conversely)[143,340,352,358].

We shall now consider in greater detail individual aspects and specific examples. In very complex molecules containing thousands of atoms the number of normal atomic vibrations is extremely large. The detection and assignment of individual lines and the derivation of useful information from the spectrum excited under conditions remote from resonance are difficult or impossible. However, when the Raman spectrum is excited in the region of the absorption band of a specific chromophoric centre, a very limited set of frequencies ω for the centre, susceptible to interpretation, is isolated. Thus, when the resonance Raman spectrum is excited with light corresponding to the long-wavelength absorption band of haemoproteins, it is possible to observe the intense lines due to the metalloporphyrin system without any interference by the protein fragments which incorporate more than 99% of the total number of atoms of the metalloprotein. The same situation arises on excitation of the lines due to the thiouracil residue of modified RNA.[98] If the molecule contains several different unconnected chromophoric centres, it is possible to excite the resonance Raman spectra of each independently. By varying the frequency of the exciting light, it has been possible to isolate consecutively the resonance spectra of systems with different numbers of conjugated double and triple bonds in polymers; thus the statistics of the distribution of conjugated systems has been characterised[359] in terms of the number of π bonds in such systems and data have been obtained on their structures and transformations as the temperature is altered.

A high intensity of the low-frequency lines due to the vibrations of bonds with a heavy atom has been noted for many compounds, the intensity increasing further on excitation with light corresponding to absorption bands associated with charge transfer along the bond[184,355,360,361]; an example is provided by the Ni–C line in the $Ni(CO)_4$ spectrum[309]. The intensification frequently extends to the lines for the atomic groups of the ligand adjoining the heavy atom. These factors have been used to assign the Raman lines (or the absorption bands corresponding to the wavelength used to excite the resonance Raman effect) and in structural studies[143,156,362,363]. Thus the enhanced intensity of the lines due to the phenolic group of tyrosine in the resonance Raman spectrum of Fe-transferrin[364] and their normal intensity for stellacyanin[365] served as a basis for inferring the structure of the region of active centres in these metalloproteins; the spectrum of stellacyanin indicates a quasi-tetrahedral coordination of copper with participation of nitrogen atoms, which can be inferred from the intensification of lines due to the amide group.

A study of the resonance Raman spectra of $NaClO_3$ crystals irradiated by a beam from an electron accelerator revealed the formation of two types of unstable ClO_3 radicals differing in their positions in the crystal lattice and in the kinetics of their decomposition; the excitation spectra showed that definite (different) regions of the ~ 5500 Å broad absorption band correspond to these types; the authors[38,39] note that, without an appreciable resonance intensification, the observation of the Raman lines would have been impossible owing to the rapid decomposition and low concentration of the radicals.

The resonance Raman lines of impurity centres (O_3^- ions) formed in chlorates on γ-irradiation have a multiplet structure and the excitation spectra of individual components of the multiplets are different. The results indicated the formation of four types of ion with different orientations; they made it possible to estimate their distribution with respect to orientations, to derive information about the mechanism of the radiolysis, and to demonstrate the formation in the first stage of ClO_3^{2-} ions, which decompose by several paths[40]. The formation of metastable O_2 molecules with a slightly reduced bond rigidity on radiolysis has been demonstrated by the same method[38,39].

The study of excitation spectra has shown that the intensity of the C=C lines of alkenes and dienes is determined mainly by the $\pi \rightarrow \pi^*$ long-wavelength absorption band (~ 1800 Å and correspondingly ~ 2200 Å[240,317]), the changes in interatomic distances in the $\pi \rightarrow \pi^*$ transition being rather significant and corresponding to $\Delta_{C=C} = 0.08$ Å and $\Delta_{C-C} = -0.055$ Å in the case of tetrachlorobutadiene[103].

The separation of the contours of broad absorption regions into zones corresponding to different vibro-electronic transitions on the basis of resonance Raman excitation spectra has frequently proved very effective[142,366,367]. Thus it has been possible to observe weak components, which are virtually indistinguishable on the basis of $\epsilon(\nu)$ curves, for example the long-wavelength electronic transition in polyenes[368-370], to detect in the broad contour of an absorption band several electronic transitions in those cases where only one had been postulated[215,355], to determine the frequency of the purely electronic $00 \rightarrow e0$ transition and other ev components[215,340,371,372] [thus a single C≡N line gave rise to seven $I(\nu)$ maxima at the wavelength corresponding to the absorption band of tetracyanoquinodimethane radical-anions, the maxima being assigned to elements of the vibrational structure[366]], to isolate absorption regions referring to very similar compounds present simultaneously in a complex product (for example to different haemoproteins, to conjugated systems of different lengths in polymers and to incompletely equivalent impurity centres in crystals) and to characterise further their structure, to determine the structure of the conductivity band of crystals which is difficult to investigate[24,35,85], and to determine the location of the lines due to dipole-forbidden exciton transitions in the absorption spectrum[285].

Thus measurements of excitation spectra assist in a more complete interpretation of the absorption spectra and hence extend the scope of structural analysis.

An exceptionally high sensitivity of the intensity to conjugation conditions has been noted also outside the region of resonance in a number of studies. Certain molecules (and ions) hardly differ as regards the frequencies ω and ultraviolet absorption spectra but have very different resonance Raman line intensities; examples are provided by tetracene[373] and triphenylmethane (Schmid[5], p. 300) anions and cations. When complexes with weak bonds are formed, the frequencies ω of the components hardly change, while I^S may increase by several orders of magnitude (complexes of tetracyanoethylene with aromatic hydrocarbons[374], etc.). A sharp increase of the Raman line intensities has been described for certain colourless compounds in contact with molecules of dyes[94 6] and with a metal[375,376], which is probably due to the breakdown of the localisation of electronic excitation.

Moschalski and Schmid (see Schmid[5], p. 46) showed, using excitation in the visible part of the spectrum, that the stretching vibration line due to the two non-conjugated C=C bonds in norbornadiene has a reduced intensity owing to the interaction of the π bonds through space; with increase of the distance between two C=C bonds in other hydrocarbons, the line intensity approaches the normal value. Evidence for conjugation has been noted in the spectra of cyanoepoxyethane[377] and π-electron systems linked by -NH- and -S- bridges (Ph-C=C-S-C=C-Ph, etc.[378]) and has been studied in detail for a large number of PhX molecules. The data obtained for the intensity of the polarised line of the benzene ring at ~ 1600 cm^{-1} have been used to determine the angle of rotation of the plane of the benzene ring in the presence of steric hindrance[336,379] and to investigate the relations with Hammett and Taft constants[1,420]. The contributions of n,π-conjugation in such systems are considered by Epshtein et al.[380] to be fairly small and masked by the influence of certain differences between the vibration modes.

The determination of resonance Raman line frequencies has been used to solve a very wide range of problems. For example, it made it possible to estimate the degree of charge transfer and the charge distribution in certain donor–acceptor complexes[381] and ions[382], having resolved controversial questions concerning their structure, to determine the rigidity of the bonds between F-centres and crystal lattice atoms[43], to establish an appreciable double bond character of the C–N linkage in the p-phenylenediamine radical-cations[30], to discover a significant redistribution of electron density from phenyl groups to the main chain in polyphenylacetylene[25], to obtain new data on the structures of iodine–amylose complexes, indicating the presence of chains comprising ~ 28 iodine atoms in which it is possible to distinguish three-atom units[383], to show that the impurity centres in natural pale-yellow fluorite crystals are O_3^- ions[37], to determine the differences between the valence states of two ruthenium atoms in a pyrazine complex[356], etc.

The mechanism of the reactions of diphenylethylene following its adsorption on silica gel has been studied recently; the appearance of new resonance Raman lines in the first stage was attributed to the formation of a carbonium ion, which is rapidly converted into a π-complex, the spectrum being modified further (see Schmid[5], p. 298).

According to certain data[384,385], it is possible to distinguish and characterise azo-quinonoid and intermediate forms of acid–base indicators (aromatic azo-compounds) and to refine ideas about the mechanisms of their reactions at varying pH and low concentrations, which correspond to the conditions under which they are applied in practice. According to Machida et al.,[384] when alkaline solutions of Methyl Orange are acidified, the azo-group is protonated and the indicator is converted into acid forms close to a quinonoid type; on the other hand, the azo-forms of analogous hydroxyphenylazo-compounds persist. The formation of Methyl Orange complexes with serum albumin modifies the colour changes of the indicator; however, the study of the spectrum disproves the conclusion that the azo-form undergoes a *trans* → *cis* transition and that a proton is transferred from the protein[386].

The resonance Raman spectra of Tropaeolin O reflect three stages in its colour changes and consecutive protonation as the pH is reduced. Saito et al.[385] determined the equilibrium position under conditions corresponding to the simultaneous presence of several forms (whose total number is 8) at all the stages of the colour changes and characterised the state of the π-electron system in each form. According to the results, the triply charged anions (judging from the spectrum, they resemble an azo-structure but with appreciable delocalisation of excess electron density) are converted into dianions, which may be present in three forms, including the quinonoid form, then into monoanions (quinonoid and azo-forms), and finally into neutral molecules which are said to exist[385] in a zwitterionic "hybrid" form similar to the quinonoid form.

The appearance of the intense 160 cm^{-1} line in the spectrum of the dimeric cations of p-phenylenediamine on excitation with light corresponding to the charge-transfer absorption band served as the basis for assigning this line to the intermolecular vibration in the dimer and for the corresponding estimate of the force constant of the bond between the dimer components (0.82×10^5 dyn cm^{-1})[387].

An exact determination of the frequencies of the overtones has been used to find the dissociation energy of I_2^- ions in a matrix (20 kcal $mole^{-1}$),[178] the heat of atomisation of O_3^- ions (153 kcal $mole^{-1}$), the electron affinity of ozone molecules (42 kcal $mole^{-1}$),[44] etc.[184]

Resonance Raman spectra are widely used to investigate metalloporphyrins and, in the words of Yamamoto et al.[388] "constitute a highly effective means for the investigation of haemoproteins". Experiments have shown that when the resonance Raman effect is excited by light corresponding to the $\pi \rightarrow \pi_1^*$ absorption band (~ 5000 Å), the lines of a number of non-totally symmetric vibrations with participation of the C–C and C–N bonds of the macroring are particularly strongly intensified; on excitation with light corresponding to the Soret band (~ 4000 Å), mainly the lines of the fully symmetrical modes, including low-frequency modes with participation of bonds involving the metal atom, are preferentially intensified[255]. Certain characteristic resonance Raman lines have been used successfully as spin indicators and indicators of the state of oxidation of the metal atom[129,360,389], of the breakdown of coplanarity of the metalloporphyrin system[188], and of the change in the quaternary structure of a protein[207]. The positions of these lines in the spectrum are associated with the conjugation conditions and the rigidity of the π bonds in the macroring[218,339,390].

We shall now present several examples. The study of the frequencies of the indicator lines led Kitagawa et al.[391] to the conclusion that there are two types of low-spin ferrohaemoproteins differing in the type of bond with the fixed (axial) ligand: with coordination of the lone electron pair of the ligand atom to the unfilled d_{z^2} orbital of the Fe atom (cytochromes) and with $d_\pi(\mathrm{Fe})-\pi^*(\mathrm{Lig})$ interaction (oxyhaemoglobin, myoglobin, nitrosohaemoglobin). The indicator line for the interaction with ligands indicates the replacement in stages of the sixth ligand in the haem groups in ferrocytochrome c_3 as the pH is raised[392]. In certain high-spin ferri-haemoproteins (chloroperoxidases) the frequencies of the indicator lines are reduced, which indicates a shift of electron density from the axial ligands to the porphyrin system accompanied by population of the anti-bonding π^* orbital and the corresponding decrease of the rigidity of the π bonds[393]. Indicators of the breakdown of coplanarity (reflecting the conjugation conditions in the metal–porphyrin system[218]) demonstrate, according to Felton et al.,[206] the displacement of the Fe atom from the plane of the four nitrogen atoms in oxidised hydroperoxidases by ~ 0.5 Å; indicators of the spin state disprove the conclusion that there is an equilibrium between states with 5/2 and 3/2 spins.

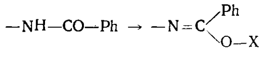
The presence of the characteristic intense 1373 cm^{-1} line confirms that protohaemin incorporates Fe^{3+} ions; the ~ 1500 cm^{-1} line is characteristic of a high-spin state of iron and of a non-planar structure of the chromophore, but in the complex with imidazole it is located in a higher position and indicates a low-spin state and a planar structure for the same oxidation state of iron[345].

The study of anomalous forms of haemoglobin[394] showed that the position of the Fe atom relative to the plane of the haem group in α-chains is not altered when iron in the β-chain is reduced and thus the quaternary T-structure is retained.

The possibility of recording the changes in the resonance Raman spectra of haemoglobin as the partial pressure of oxygen is altered has been noted[53]. It is suggested that the resonance Raman effect may serve as the basis of apparatus for clinical studies on blood (see Schmid[5], p. 212).

The study of the resonance Raman spectra of oxyhaemerythrin—an oxygen transferring agent of a non-haem type—made it possible to exclude structures with equivalent oxygen atoms from the five proposed versions of the structure; in azidomethaemerythrin all three nitrogen atoms are located in non-equivalent positions[395]. Eight models of oxyhaemocyanine, an oxygen-carrying metalloprotein from the haemolymph of molluscs, have been considered in the literature. The frequencies of the resonance Raman lines correspond to a non-planar structure in which the bound oxygen exists in the form of a peroxide ion and the copper atoms are present in the bivalent state[396–398].

Carey and Schneider[399] noted that resonance Raman spectroscopy is a very useful instrument for the investigation of the mechanisms of enzymatic catalytic reactions and may yield extensive information about the modifications of individual atomic groups on formation of intermediates when enzymes interact with coloured substrates; furthermore, the deformation of the substrate is one of the factors responsible for the increased rate of reaction. According to the authors, the intermediate formed in the reaction of papain with an ester containing the α-benzamide group has a sharply different resonance Raman spectrum compared with the initial and final products[400,401]. The spectrum indicates changes in the acetyl group and a rearrangement of the benzamide group of the substrate:



$$-NH-CO-Ph \rightarrow -N{=}C\begin{matrix}\diagup Ph \\ \diagdown O-X\end{matrix}.$$

New data on the structure of enzyme–inhibitor complexes have been obtained in a number of studies[402–404]. For example, it has been shown that the sulphonamide group in certain derivatives of sulphonamidoazobenzene in complexes with carbonic anhydrase B is ionised and that the coplanarity of the azobenzene group is significantly distorted.

Resonance Raman spectroscopy has been used to determine the types and locations of enzyme modifications. It has been established that, when carboxypeptidase reacts with arsanilic acid, the tyrosine-248 group is modified; the reaction of carboanhydrase with diazobenzenesulphonamide results in the diazotisation of the histidine residue (see Schmid[5], p. 206).

Carey et al.[406] investigated the applications of resonance Raman spectroscopy in immunochemistry, particularly for the determination of the active centres of antibodies and the structure of complexes with haptens. The resonance Raman spectra of such complexes reflect the perturbations induced by the interaction with the protein, including the changes in the state of ionisation and conformation of individual fragments. The authors investigated the lines of bound coloured haptens (dinitrophenylazonaphthalenedisulphonic acids), characterised the changes in conformation, and demonstrated a decrease of the amount of double bond character in the N–O linkage in both nitro-groups as a result of the influence of the specific charge distribution in a particular fragment of the antibody. The studies established the changes in conformation favouring contact with the active centres of antibodies isolated from mouse tumours.

Resonance scattering has been used to detect traces (⩾ 0.0001%) of polyene compounds in thermally degraded specimens of poly(vinyl chloride). On excitation of the spectrum at different frequencies, systems with different numbers of units were excited. Thus an increase of the average chain length of conjugated C=C bonds with increase of temperature and of the duration of heat treatment of the polymer has been demonstrated[357].

The spectra of the carapaces of live crayfish demonstrated the presence of astaxanthin bound to a protein[405]. Distinct lines of carotenoids were detected in the resonance Raman spectrum of the sciatic nerve of the frog[407]. The presence of β-carotene, bound in the membranes of erythrocytes (predominantly in cholesterol-depleted regions) has been demonstrated[408] and its content determined (7×10^{-4}% relative to the weight of lipids); the increase of the intensity of the characteristic lines when the membrane is acted upon by trypsin and lysolecithin is regarded as an indication of the modification of the carotene molecules as a result of the decrease of the internal strain in the surrounding regions; sharp changes in intensity with increase of temperature above 17°C indicate changes in conformation (see Schmid[5], p. 178).

In Lewis's words, resonance spectroscopy is exceptionally effective in the study of visual processes. With the aid of resonance Raman spectroscopy, Lewis investigated the transformation of rhodopsin at different stages of the dark adaptation of a functioning eye[54,414]. New data have been obtained[118,409] for the structures of intermediate products in very rapid multistage transformations of bacteriorhodopsin—a photosynthetic system which ensures proton transfer via cell membranes of halophilic bacteria. Other examples in the field of biochemistry have also been described[401,410–420].

Resonance Raman spectroscopy has been used successfully to study the mechanisms and kinetics of electrochemical processes. The advantages of the method compared with infrared spectroscopy (higher sensitivity and the possibility of employing aqueous solutions and metallic electrodes), ultraviolet spectroscopy (a greater yield of information), and EPR (the possibility of studying ions, neutral molecules, and radical-ions) have been noted[62]; the method is suitable for the investigation of organic, inorganic, and organometallic electrosynthesis[63].

The ways of using resonance Raman spectroscopy to probe the atmosphere and to determine the substances contaminating air at heights up to 10 km (Raman radars), to determine from a flying aeroplane the presence of certain coloured components in air over the surface of the sea in order to estimate its bioproductivity[421–423], etc. are being investigated. The possibility of using resonance Raman spectroscopy in the study of the atmospheres of other planets is not ruled out.

CONCLUSION

In recent years a major contribution has been made to the development of the spectroscopy of resonance light scattering by molecules and crystals. The improvement of the experimental techniques and theories and the study of correlations between the spectra and the structure of molecules and their physicochemical properties greatly extended the basis for a wide variety of applications of resonance Raman spectroscopy. According to the authors of a number of studies, "resonance Raman spectroscopy has become a powerful method for the investigation" of molecular structures[253], elementary excitations of the crystal lattice[35,424], biochemical processes[346], electronically excited molecular states[425], vibronic interaction[426] of polymers and oligomers with conjugated bonds[25], and haemoproteins[388] and has become "a powerful analytical tool"[331,337]. The method combines the high sensitivity characteristic of ultraviolet spectroscopy with the high resolution characteristic of microwave and infrared spectroscopy[28,62]; as regards the amount of information which can be derived, the method can be, in principle, superior to infrared and ultraviolet spectroscopy taken together. Despite the number of limitations of the method, many new useful data have been obtained with its aid in chemistry, physics, and spectrochemistry. The use of a more advanced technique (among others, for the measurement of the Raman line excitation spectra and for the investigation of the phenomenon by time scanning[9,117,427,428]) will promote the development of new productive research fields.

Linear Free Energy Relations as a Means of Generalising and Analysing Extraction Data

V.S.Shmidt

Data concerning the principal ways of "condensing" information about extraction equilibria are surveyed. It is shown that, together with the Law of Mass Action, equations based on linear free energy relations constitute an important means of generalising and analysing extraction data. The linear equations reviewed make it possible to describe quantitatively in an abbreviated form the influence of the structure of extractants, the nature of diluents, the nature of the anionic ligands and the cations extracted, and the phase composition on the extraction equilibria in a series of extraction systems, with the aid of relations between the extraction constants and the parameters σ, E_s, ID, H, IE, and IAP, characterising the influence of the factors indicated. Certain general characteristics of the influence of these factors on extraction equilibria and on selectivity, found with the aid of the linear correlations, are described.

The bibliography includes 125 references.

I. INTRODUCTION

During the last decades, there has been a collosal growth of information about extraction problems, which still continues. Altogether about 10 000 papers have been published[1] and in the last five years the number of annual publications has doubled[2]; at the present time not less than a thousand papers are published annually[3]. A simple list of systems for which extraction equilibria have been studied occupies hundreds of pages[1,4,5]. At the same time, despite the advances achieved in the elucidation of the general characteristics of extraction and the generalisations made, whereby many properties of extraction systems can be explained and predicted qualitatively, an adequate systematic arrangement of the available experimental data has still not been achieved.

One of the important procedures facilitating the use of the extensive information about extraction involves the publication of handbooks[6-8], and monographs with reference data[4,5]. However, the cumbersome nature of reference data involving a direct description of all the values of the partition coefficients for various systems under different conditions limits the scope of the publication of sufficiently complete handbooks of acceptable size. This makes it necessary to "condense" extraction data, i.e. to transform the accumulated information on the basis of general relations which have been discovered (particularly during the last decade). Sukhotin[9] pointed out that, as a result of the condensation of information, partial information derivable from more general information need no longer be retained in memory and can be abbreviated; at the same time the number of symbolic means used for the fixation of information is reduced without impairing the amount of information.

The aim of the present review is to consider the main results of studies devoted to the condensation and analysis of information in the field of extraction (particularly extraction equilibria) and to attempt an assessment of the possible ways towards this end, particularly the use of linear free energy relations for the further development of studies in this field.

II. THE USE OF THE LAW OF MASS ACTION AND CALCULATION OF EXTRACTION CONSTANTS—THE FIRST STAGE IN THE "CONDENSATION" AND ANALYSIS OF INFORMATION ABOUT EXTRACTION EQUILIBRIA

The most significant step towards the condensation of information in the field of extraction was made for the first time, approximately twenty years ago, by Fomin and his coworkers[10-13], who laid the foundations of a new field—the mathematical description of extraction processes based on the consideration of the latter as chemical reactions obeying the Law of Mass Action (LMA). The creation of a mathematical model of partition based on LMA makes it possible, in principle, to replace the set of partition coefficient data for each given series of the type extraction–diluent–aqueous acid (or salt) solution–compound of the extracted element at different concentrations of the components by a single quantity—the extraction constant combined with the equation of the mathematical model.

The simplest mathematical models, which are of great practical importance, but are applicable to a limited range of concentrations, have been devised in numerous fundamental studies[10-13] on the basis of LMA in the concentration form. The mathematical description of extraction equilibria on the basis of LMA made it possible to (1) determine the stoichiometry of extraction reactions by analysing the dependence of the partition coefficients on the quantitative phase composition (the "dilution" method based on equations which follow from LMA) and (2) to obtain information about complex formation, association, changes in activity coefficients, and other phenomena in solutions by analysing deviations from the distribution predicted by LMA. Numerous deviations from LMA did not lead to the abandonment of this law for the description of extraction equilibria and are regarded as a result of the influence of certain interactions in the system on the ideal distribution.

Since LMA in the concentration form does not in general hold over a wide range of concentrations (owing to failure to take into account complex formation by the components and the discrepancies between their activities and concentrations), the models derived from this form of LMA may also not hold. This made it necessary to develop models applicable over a wide range of concentrations, which take into account complex formation and deviations of the activities of components from their concentrations

The region of applicability of models is expanded in two ways: (a) by introducing into the relevant formulae, which include the thermodynamic extraction constant (independent of the concentrations of the components), the activity coefficient† of each system component and coefficients characterising the degree of binding of the components in complexes[11] or (b) the use of "apparent extraction constants" (these values are calculated from empirical equations fitted to the dependence of the constant on the ionic strength of the solution), which vary with the solution composition, without introducing the above coefficients.

The development of the first procedure depends on the development of the theory of solutions, since it requires the development of methods for the prediction and theoretical calculation of the activity coefficient of the components in relatively concentrated solutions of electrolytes. Certain advances have been made in the solution of this problem[14-16], but much work still needs to be done before the solution is sufficiently completely solved. In order to develop the second procedure, it is merely necessary to accumulate experimental data on partition over a wide range of concentrations of the components and to derive empirical equations which agree most precisely with the experimental data. Studies of this type include those[18-21] with a largely practical aim (to calculate the countercurrent distribution). Thermodynamic or at least effective constants, calculated within the framework of the first approach, would evidently be more suitable for generalisations in the chemistry of extraction equilibria.

The cumbersome nature of the computational formulae required for the determination of the activity coefficients of the components[14-16], and also the difficulty of fitting equations to the experimental data to find the "apparent extraction constants", for a long time prevented a large-scale application of these methods. For this reason, the mathematical models based on LMA have so far been designed for a relatively small number of extraction systems among those which have been investigated—for the simplest systems or systems with the greatest practical importance; extraction constants have been calculated only for several hundred systems. However, in recent years it became possible to develop mathematical models on a wider scale and to "condense" partition coefficient data to the level of extraction constant data, as a result of the employment of computers. The latter make it possible to carry out routine calculations on extraction equilibria (even on the basis of extremely cumbersome formulae), such calculations being rapid and requiring little effort[22,23].

It may be expected that improvement of mathematical partition models and the development and large-scale employment of the corresponding computer programs will lead to a more systematic "condensation" of partition data at different concentrations of the components and to their transformation into a single quantity (the extraction constant) for each series of systems of components of the same type. This tendency has been confirmed by the publication in 1974 of a handbook[24] on extraction equilibrium constants.

During the last decade, much work has been done on the higher stages in the hierarchy of studies directed towards the condensation of information in the field of extraction. Factors influencing the extraction constants when not only the concentration but also the nature of the system components is varied have been surveyed. Mathematical models describing sets of extraction constants for different series of systems, differing in the nature of the components, have been created; these models involve a smaller number of constants—parameters characterising only the nature of the components. Whereas in the first stage of the above hierarchy the LMA served as the basis for generalisations, in the next stages equations based on linear free energy relations (LFE) are most frequently used[25]. Generalisations became possible in higher stages despite the imperfection of the development of the first stage, since in many instances (when only one component is partitioned) the partition coefficients of the elements D, measured within the limits of a given series for identical quantitative phase compositions, are proportional to the extraction constants K, which permits a comparison of the values of D instead of K. Equations based on LFE have already been used for a long time in theoretical organic chemistry[26,27], whence they have been transferred to extraction chemistry.

III. LINEAR FREE ENERGY RELATIONS (LFE) AS A MEANS FOR FURTHER GENERALISATION OF EXTRACTION CONSTANT DATA

1. Earlier Applications of LFE in Chemistry

An equation based on the LFE principle was widely used for the first time in 1940 by Hammett[28] to generalise data concerning the influence of the structure of organic compounds on equilibrium constants and rates of various reactions. Hammett established that the following relation is valid for a series of different organic reactions:

$$\lg K = \lg K_0 + \rho \Sigma \sigma, \tag{1}$$

where K are equilibrium constants or rates of reactions of the same type (with a single reaction centre within the limits of the series) for different substituents in the benzene ring, σ are parameters characterising the influence of the nature of the given substituent and independent of the type of reaction series, and K_0 and ρ are quantities independent of the type of substituent and constant for the given reaction series. The quantity ρ is sometimes called[26] the sensitivity coefficient, since it shows to what extent K varies within the limits of the series under the influence of changes in σ.

A scale of parameters σ^* for substituents attached directly to the reaction centre, a scale of parameters σ_P (for substituents attached to a phosphorus atom)[30], and certain other scales for various types of inductive effects

---

† In certain cases the activity coefficients are determined experimentally[17] from extraction data.

were proposed subsequently together with the scale of parameters σ, characterising the influence of substituents on the reaction centre attached via the benzene ring. Together with the σ scales, characterising the electronic effects of substituents, scales of the parameters E_S and E_N, characterising steric effects, were also put forward[31–33].

Later equations of type (1) found applications in the quantitative description of the influence on organic reactions not only of the structure of the compounds but also of a number of other factors. Several parameters (for example E_T), characterising the influence of the nature of the solvent, were proposed[26] (equations of the type $\lg K = \lg K_0 + aE_T$). The influence of the nature of the outgoing group was estimated with the aid of nucleophilicity parameters H and equations of the type $\lg K = \lg K_0 + bH$, etc. A detailed survey of the applications of LFE in organic chemistry is given in two monographs[26,30].

Relations based on LFE have been found during the last decade also in inorganic chemistry. Thus linear correlations have been discovered between the logarithms of acid dissociation constants and the logarithms of the stability constants of the complexes formed by their anions with metal cations[34,35–41].

In essence LFE also serve as the basis of a method of comparative calculation of the physicochemical properties of inorganic compounds, which has been used in a number of studies[42–44].

2. The Application of LFE in Extraction

Since 1964–1965 the wide-scale applicability of equations of type (1) in the description and analysis of relations in organic chemistry has attracted the attention of investigators in the field of extraction. Attempts were made to extend the application of LFE to the quantitative description of the influence of various factors on extraction equilibrium constants[25,45].

The influence of the structure of the extractant. In the first place it was suggested that LFE be used to predict the extraction capacity of nucleophilic extractants, i.e. extractants (S :) which form an extractable complex with the electrophilic compound to be extracted (A)—an acid or a metal salt—as a result of a donor–acceptor interaction of the type $S\overrightarrow{:}A$.[46,47] Evidently the stability of the extracted compounds of the type $S\overrightarrow{:}A$ and the corresponding extraction constants (when the extractant is sufficiently hydrophobic) must be higher the higher the mobility of the electron pair in the functional group of the extractant molecule, i.e. the higher the basicity of the latter. For a series of extractants with the same functional group, for example, phosphate esters $(RO)_3PO$, one may expect an increase of extraction capacity with increase of the positive inductive effects of the substituents R and with decrease of the steric hindrance by these substituents in the formation of compounds of the type $(RO)_3PO\overrightarrow{:}A$. It is therefore natural to suppose that the constants for the extraction of a given substance A by a series of extractants with variable substituents and a constant functional group should be related by equations of type (1) to parameters characterising the inductive or steric effects of the substituents. This hypothesis was put forward for the first time in 1964–1965, independently in a number of studies[48–51], in relation to organophosphorus extractants and to extraction by amines[46]. They were tested experimentally initially for series of extractants where changes in substituents differing in inductive effects did not lead to significant changes in the steric hindrance in the interaction of the extractant with the compound extracted. In certain cases series were selected in which the expected changes in inductive effects would be very large and would greatly exceed the possible influence of steric effects. A satisfactory validity of the linear relations between the logarithms of extraction constants and the values of Σσ for the substituents was obtained for such series. Table 1 presents the σ parameters of the substituents used for the correlations and Table 2 lists the correlations found for the equilibrium constants of extraction reactions leading to the formation of the following extractable compounds (here and henceforth the equilibrium constants for reactions involving the formation of solvates from extractant molecules and fully dissociated inorganic compounds are considered): R_3NHNO_3 (I), $R_2SO.HNO_3$ (II); $RPO.HNO_3$ (III); $R_2N(CO)CH_3.HNO_3$ (IV); $R_3NHNO_3.HNO_3$ (V); $R_iNH_{4-i}.HCl$ (VI); $UO_2(NO_3)_2.2R_2SO$ (VII); $UO_2(NO_3)_2.2R_3PO$ (VIII); $UO_2(NO_3)_2.3[R_2P(O)O]_2CH_2$ (IX); $UO_2(NO_3)_2.R_3NHNO_3$ (X); $UO_2Cl_2.2R_3PO$ (XI); $UO_2[R_2P(O)O]_2$ (XII); $Pu(NO_3)_4.2R_3PO$ (XIII); $Pu(NO_3)_4.2(R_3NHNO_3)$ (XIV); $Ce[R_2P(O)O]_5$ (XV); $(R_3NH)_2M(NO_3)_5$ (M = Am, Cm, or Es) (XVII); $MCl_2.2R_3NHCl$ (M = Co or Zn) (XVII); $MCl_4.2R_3NHCl$ (M = Pu or Np) (XVIII); $Np(NO_3)_4.2R_3NHNO_3$ (XIX).

The values of σ are based in Refs. 26, 29, 52, and 53, those of σp are based on data in Refs. 44 and 54–56, and those of E_S^* are based on data in Ref. 52. In certain extraction studies[48] use was made of the parameters X = 2.07 + 0.5σ*; the parameters σp are related to σ* by the equation[55] σp = −0.965 + 1.97σ*. The values of E_S^* which agree with the corresponding parameters E_S [26] are underlined; values which have been tested in relation to a small number of systems are enclosed in brackets in this and subsequent Tables.

**The total number of carbon atoms in the three alkyl chains is 13.

The constants in Table 2 for approximately 400 of the extraction systems examined are expressed with the aid of 36 correlation equations. As will be shown in Section IV, the value of these equations consists not only in the abbreviation of the information, but also in the possibility of discovering new relations and predicting the extraction capacity of compounds which have not yet been investigated.

Table 2. Abbreviated expressions for the equilibrium constants for series of extraction reactions of the same type (only the nature of the substituents in the extractant molecules varies within the limits of the series).

*The notation used for the solvates (denoted by Roman numerals) and the reactions leading to their formation is explained in the text (Section III, subsection 2).

**The substituents are designated by ordinal numbers corresponding to those in Table 1; the subscript indicates the number of substituents in the molecule.

***In cases (I)-(XII) expressions are given for lg$K$, in case (XIII) an expression for ΔG is given, and in the remaining instances the expressions are for the values of lg$D$, determined under standard conditions for each series.

By analogy with organic chemistry, one may also expect the validity of linear correlations between the logarithms of extraction constants and the steric constants of substituents for series where the inductive effects of the substituents vary little. Such correlations have also been obtained in a number of studies[70]. The correlations would embrace a wider range of extractants, if they related lg$K$ simultaneously to σ^* and E_S. However, only a small proportion of the available data have been interpreted in terms of the equation lg$K = f(\sigma^*, E_S)$. This can be explained by the lack, until recently, of a sufficiently complete scale of parameters E_S and partly by the inadequate number of measured constants for extraction by extractants having different structures. An attempt to extend the E_S scale has been made recently[52]. Analysis showed that the known values of E_S for alkyl groups ranging from CH_3 to C_6H_{13} are clearly inconsistent with experimental extraction data. For example, the replacement of the alkyl group in amines of the type $(C_8H_{17})_3NR$ in the sequence CH_3, C_2H_5,..., C_6H_{13}, C_8H_{17} entails a monotonic decrease of the extraction capacity; the logarithms of extraction constants vary linearly with the number of carbon atoms in the group. The parameters E_S initially increase from CH_3 to C_4H_9 and then decrease to C_6H_{13}, after which they increase once again. This made it necessary to develop a special scale of steric parameters E_S^* obtained from extraction data. It was based on the known values of E_S for hydrogen atoms, the CH_3 and C_8H_{17} groups, and certain others (in this region the E_S^* scale coincides with the E_S scale)[52].

Table 2 shows that, for identical series of systems with different diluents, the dependence of lg$K$ on σ is expressed by different equations; for a further condensation of information, it is therefore necessary to examine the possibility of deriving LFE equations which also take into account the influence of the nature of diluents.

The influence of the nature of the diluent. A linear correlation between the logarithms of extraction constants and parameters characterising the nature of the diluent was first demonstrated[74] in 1967, but the majority of diluents for which the corresponding parameters had been determined by that time in organic chemistry[75] are soluble in water. For this reason, the authors[74] developed a new scale of parameters applicable to diluents most frequently employed in extraction. The corresponding parameters were designated by ID (an abbreviation for the influence of the diluent). The validity of the equation lg$K$ = lgK_0 + aID was demonstrated[74] for 16 series of extraction systems (the majority of the series included 20-25 diluents each). Soon the validity of LFE with account taken of the influence of the nature of the diluent was demonstrated also in another study[15]. Subsequently the applicability of LFE to the prediction of the influence of the nature of the diluent was established experimentally for a large number of systems[5]. The parameters ID are listed in Table 3; Table 4 summarises the correlations discovered for extraction reactions leading to the formation of the following extractable compounds: diheptyl sulphoxide.HNO_3 (XX); trioctylphosphine oxide.HNO_3 (XXI); (trioctylphosphine oxide)$_2$.$HClO_4$ (XXII); trioctylphosphine oxide)$_2$.$HReO_4$ (XXIII); (trioctylphosphine oxide)$_2$.$HAuCl_4$ (XXIV); $[(C_8H_{17})_3NH]_2M(NO_3)_6$ [M = Pu (a) or Th (b)] (XXV); $[(C_8H_{17})_3NH]_2Bi(NO_3)_5$ (XXVI); $[(C_{12}H_{25})_3NHNO_3]$.HNO_3 (XXVII); $[(C_8H_{17})_3NHNO_3]$.HNO_3 (XXVIII); $[(C_{12}H_{25})_3N]$.HCl (XXIX), dioctylacetamide.HNO_3 (XXXa), didecylacetamide.HNO_3 (XXXb); dilaurlyacetamide.HNO_3 (XXXc); C_8 - C_{12} dialkylacetamides.HNO_3

Table 4 shows that the dependence of lg*K* on ID, represented by an equation of type (1), has been confirmed in more than 200 systems. A characteristic feature of these systems is that elements at microconcentrations, or concentrations which were small compared with that of the extractant, were extracted; the extractant concentration was low compared with that of the diluent. Another feature was the absence of the simultaneous extraction of the acid and the metal salt, i.e. only one component was partitioned in the system; in such cases the partition coefficients of an element measured under identical conditions for a given series are proportional to the extraction constants and correlations hold also for partition coefficients measured under standard conditions. For systems where an acid is extracted appreciably together with the metal salt, there should be no correlation between the partition coefficients and the ID. In such series one may expect only correlations between lg*K* and ID.

Examination of certain equations relating lg*K* to the parameters σ of substituents (Table 2) for series differing in the nature of the diluent [(II), (III), (VII), (VIII), (XVII)] shows that the constants of the equations and the sensitivity coefficients can also be represented by linear functions of the parameters ID of the diluent. This makes it possible to reduce several equations to a single expression taking into account the influence of both the structure of the extractant and of the nature of the diluent. For example, data for the extraction of uranyl nitrate by sulphoxides of different structure in benzene, carbon tetrachloride, and chloroform [see (VII), Table 2] can be represented with a high degree of accuracy[85] by the equation $\lg K = 2.68 - 1.55\,\Sigma\sigma^* + 0.80\,ID - 0.44\,ID\Sigma\sigma^*$. It is seen from the three equations for (XXXa)-(XXXc) in Table 4 that the change in their coefficients when the structure of the amide is altered takes place in conformity with the changes in E_a^*. Calculations demonstrated the possibility of expressing data for nine systems (three amides, three diluents) by the single equation $\lg K_{HA} = 0.68 + 1.00\,\Sigma E_s^* + 0.065ID$. In the examples presented above the decrease of the number of symbols expressing the available information is insignificant, but these examples demonstrate the fundamental pathway to a further condensation of information.

*The notation for the solvates (indicated by Roman numerals) and the reactions leading to their formation is explained in the text (Section III, subsection 2).

**The diluents are designated by ordinal numbers corresponding to those in Table 3.

***In cases (XX)-(XXIV) and (XXVII)-(XXIX) the expression for lg*K* are quoted and in the remaining cases the expressions represent the values of lg*D* measured under identical conditions for each series.

Analysis of the linear relations between lg*K* and ID (Table 4) shows that they hold only for addition or double bond formation reactions which do not involve appreciable changes in the polarity of the components. In those cases where the polarity is altered appreciably, for example, in extraction via neutralisation or ion-exchange reactions, it is necessary to introduce another scale of parameters of the diluents[81], the so-called ID* scale (Table 5) in a quantitative description of experimental data. The use of this scale also made it possible to find many correlations of the type $\lg K = \lg K_0 + a\,ID^*$ (Table 6) for amine neutralisation reactions leading to the formation of the following compounds: $(C_8H_{17})_3NHCl$ (XLII); $(C_{12}H_{25})_3NHCl$ (XLIII); $(C_6H_5CH_2)_2(C_2H_{25})NHCl$ (XLIV); $(C_6H_6CH_2)\cdot(C_9H_{19})_2NHCl$ (XLV), $(C_8H_{17})_3NHBr$ (XLVI); $(C_{12}H_{25})_3NHBr$ (XLVII); $(C_8H_{17})_3NHI$ (XLVIII); $(C_{12}H_{25})_3NHI$ (XLIX); $(C_{12}H_{25})_2NHSCN$ (L); $(C_{12}H_{25})_3NHClO_4$ (LI); $(C_6H_5CH_2)\cdot(C_9H_{19})_2NHClO_4$ (LII); $(C_6H_5CH_2)_2(C_{10}H_{21})NHClO_4$ (LIII); $(C_8H_{17})_3NHNO_3$ (LIV); $(C_6H_5CH_2)_2(C_{10}H_{21})NHNO_3$ (LV); $(C_6H_5CH_2)(C_9H_{12})_2NHNO_3$ (LVI); for anion-exchange reactions leading to the formation of salts of the following type: $(C_{12}H_{25})_3NHReO_4$ (LVII); $(C_8H_{17})_3NHCl$ (LVIII, LX); $(CH_3)_2(C_{12}H_{25})NTcO_4$ (LIX); $(C_8H_{17})_3NCH_3COOH$ (LXI); for reactions involving the formation of neutral salts from alkylphosphoric acids: dioctylphosphoric acid with Er^{3+} (LXII) and Tb^{3+} (LXIII); di-2-ethylhexylphosphoric acid with Am^{3+} (LXIV), Cr^{3+} (LXV), UO_2^{2+} (LXVI), VO^{2+} (LXVII), Mn^{2+} (LXVIII), Zn^{2+} (LXIX), Cd^{2+} (LXX), Co^{2+} (LXXI), Ni^{2+} (LXXII), Ba^{2+} (LXXIII), Sr^{2+} (LXXIV), Cs^+ (LXXV), Ag^+ (LXXVI), neutral salts formed with thenoyltrifluoroacetone and solvated by tributyl phosphate (TBP), and salts with Pm^{3+} (LXXVII), Am^{3+} (LXXVIII), and Ce^{3+} (LXXIX).

12	Tetrachloroethylene	1.1	25	Nitrobenzene	4.3
13	Chlorobenzene	2.7	26	Xylene	(1.8)

Since it has been shown[14] that, for certain series of systems where there are linear relations between lg*K* and ID*, there are also linear relations between lg*K* and the solvent parameters E_T, which are known in organic chemistry, it follows that parameters of the ID* and E_T scales are presumably linear related. Indeed it has been observed[86-89] that the parameters of these scales are linked by the relation ID* = −12.4 + 0.43E_T. However, the majority of the values of ID* listed in Table 5 were derived from extraction data for diluents whose E_T parameters are unknown. The observed correlation between ID* and E_T has been confirmed only for a small number of diluents whose E_T values are known; in order to describe extraction data, it is therefore probably desirable to employ the ID* scale.

It is seen from the foregoing that two different scales of diluent parameters are required for different types of reactions, each applicable to a wide range of systems‡.

The influence of the nature of the anionic ligand. Two types of influence of anionic ligands (A) on extraction are possible as a function of the role of these anions in the formation of extractable compounds. The first type arises when the anion is a nucleophilic centre of the extractant to which the extracted compound becomes attached and hence the stability of the extracted compounds determines the nucleophilicity of the anion. The second type occurs when the anion does not form part of the extractant and enters only into the composition of the salt extracted from the aqueous phase. In this case the energy of hydration of the salt anions extracted from the aqueous phase has a decisive influence on the partition during extraction.

*The notation for the solvates (designated by Roman numerals) and the reactions leading to them is explained in the text (see Section III, subsection 2).

**The diluents are designated by ordinal numbers corresponding to those in Table 5.

***In cases (LVIII), (LIX), (LX), and (LXXV)-(LXXVIII) the expressions for values of lg*D*, measured under identical conditions for each series, are given.

In the first case one may expect that more stable complexes are formed with participation of more nucleophilic anions. Indeed it has been established[5] that acids whose anions are more nucleophilic (basic) are more effectively extracted by amine salts with a common anion via the addition reactions§ AmineHA ⇌ AmineHAHA (for example,

---

‡The validity of the observed correlations in the description of the influence of the nature of the diluent on extraction has recently been demonstrated also from the standpoint of thermodynamics[98].

§In such systems the influence of the hydration of the anions in the aqueous phase is probably a secondary factor, which does not exert a decisive influence on the partition.

HNO_3 is extracted more effectively than HCl). A scale of Edwards parameters[30] (H), characterising the nucleophilic properties of anions belonging to the class of hard bases, had been introduced earlier in organic chemistry. These parameters are related to the pK_a of the corresponding acids by the expression $H = pK_a + 1.74$, but they are more universal since they have been determined also for the strongest acids whose pK_a values lack significance. It has been suggested[99] that there is a possibility of a linear correlation between the logarithms of the extraction constants (for a series of extraction reactions where the equilibrium is determined by the nucleophilic properties of the anion) and the parameters H of the anionic ligands in the system. This hypothesis was confirmed initially[90,99] for a relatively small series of reactions of acids with their amine salts and then for a large number of reactions of acids[100]. The parameters of the nucleophilic properties of certain anions are listed in Table 7; the linear correlations between $\lg K$ and H, found for the formation of compounds of the type $(C_8H_{17})_3NHA.HA$ (LXXX), $[(C_8H_{17})_3NH].UO(A)_3$ (LXXXI), $[(C_8H_{17})_3NH]_2Pu(A)_6$ (LXXXII), and $[(C_8H_{17})_3NH]_2Np(A)_6$ (LXXXIII), are listed in Table 8.

Table 7. The H parameters.

*The notation for the solvates (designated by Roman numerals) and the reactions leading to their formation is explained in the text (see Section III, subsection 2).

**The anionic ligands A are designated by ordinal numbers corresponding to those in Table 7.

In extraction systems where the anion is not a functional group of the extractant, its influence is determined mainly by the nature of its properties in the aqueous phase. In such systems, partition is influenced mainly by the anion hydration energy. Evidently the higher the hydration energy of the extracted simple or complex anion, the smaller its capacity for extraction via an addition or anion-exchange reaction[103]. It has been shown for extraction via an addition reaction in relation to the extraction of monobasic acids by trioctylphosphine oxide (TOPO) [104] that extractability increases in the sequence $HClO_4 > HReO_4 > HNO_3 > HBr > HCl$, which corresponds to the sequence based on the decrease of the hydration energies of these acids in the aqueous phase. It was then shown in a series of investigations[105-107] and in an independent study[5] that this relation can also be expressed quantitatively in the form of a linear free energy relation. Thus linear relations have been demonstrated[5] between the logarithms of the constants for the extraction of acids via neutralisation reactions of the type Amine + H^+ + A^- $\rightleftharpoons$ AmineHA and the free energies and enthalpies of hydration of the anions A^-. Since the logarithm of the equilibrium constant for an anion exchange reaction ($\lg K_X^Y$) of the type AmineHA + X^- $\rightleftharpoons$ AmineHX + A^- is equal to the difference between the logarithms of the constants for the formation of the salts AmineHA and AmineHX by a neutralisation reaction, there are also linear relations between $\lg K_X^Y$ and the difference between the values of ΔG or ΔH for the anions undergoing exchange[5,105]. Table 9 presents the values of ΔG and ΔH for the hydration of anions[111] and Table 10 lists certain correlations between $\lg K$ and the parameters ΔG_{hydr} and ΔH_{hydr} found for neutralisation reactions leading to the formation of the salts $(C_8H_7)_3NHA$ [in nitrobenzene (LXXXIV), toluene (LXXXV), and cyclohexane (LXXXVI)], $(C_{12}H_{25})_3NHA$ (LXXXVII), (AmineLa-2)HA¶ (LXXXVIII), and (Amine-IMT)HA† (LXXXIX) and for anion-exchange reactions leading to the formation of $(CH_3)_2R_2NReO_4$ from salts of the type $(CH_3)_2R_2NA$ (XC) and of $(C_8H_{17})_{14}NA$ from $(C_8H_{17})_4NClO_4$ (XCI), from $[(C_8H_{17})_4N]_2PdCl_2$ (XCII), and from $(C_8H_{17})_4NOH$ (XCIII). The number of correlations of this type discovered is small because relatively few of the corresponding reactions have been investigated quantitatively.

Table 9. The values of ΔG and ΔH for the hydration of anions[111].

¶ LA-2 is the secondary amine N-lauryltrialkylmethylamine.

† IMT is the primary amine 1,1,1-trialkylmethylamine where the overall number of carbon atoms in the three alkyl chains is approximately 20.

In a quantitative description of the influence of the nature of the anions on extraction one must take into account the role of the anion in the given series of extraction reactions, i.e. one must distinguish the two possible types of influence of anions indicated above. For example, in the unusual case of extraction of an acid via addition to an amine salt incorporating the anion of another acid[108], the degree of extraction increases with increase of the parameter of the nucleophilic properties of the anion forming part of the extractant composition (the amine salt) and constituting its functional group; on the other hand, a change in the nature of the anion of the acid in the aqueous phase influences the extraction equilibrium in the sequence corresponding to the change in hydration energy and not the change in nucleophilic properties[109]. Only in certain specific instances are the hydration energy and the nucleophilicity correlated[110].

Table 10. Abbreviated expressions for the equilibrium constants for series of extraction reactions of the same type (only the nature of the anion is varied within the limits of each series).

***$\Delta H' = \Delta H_{A^{2-}} - 2\Delta H_{OH^-}$.[112]

****$\Delta H' = \Delta H_{PdA_4^{2-}} - \Delta H_{PdCl_4^{2-}}$.[113]

Examination of the equations listed in Table 10 [(LXXXIV)-(LXXXVI)], describing the influence of the nature of the anions on extraction via a neutralisation reaction shows that the change in the coefficient of the equations as the nature of the diluent is altered takes place in accordance with the ID* scale. Calculations showed the possibility of expressing the data for all nine systems (three anions and three diluents) indicated above [Table 10, (LXXXIV)-(LXXXVI)] by a single equation: $\lg K_{HA} = \lg K_0 + a\text{ID}^* + b\Delta G$.

The influence of the nature of the extracted cation. The influences of the nature of the cation forming part of the composition of the extracted compound on the extraction constants have been compared for a series of similar extraction systems (incorporating the same aqueous phase and forming extractable compounds with the same solvation numbers), differing only in the nature of the extractant or the diluent[62]. It was shown that, when a scale of IE ("influence of the element") parameters, proportional to the logarithms of the constants for the extraction of quadrivalent actinides by tri-n-octylammonium nitrates from nitrate solutions is constructed, a linear relation with these parameters is also found for the logarithms of the constants for the extraction of actinides by tributyl phosphate, dioctylacetamide, and certain other nucleophilic extractants. The possibility of a linear correlation of the type $\lg K = \lg K_0 + m\text{IE}$ has been confirmed by numerous examples in inorganic chemistry. A number of reaction series in which there is a correlation between lg$K$ and the nature of the element has been indicated for inorganic systems[42,43]. For example, when the nature of the element M is varied within Group II, a linear correlation is observed[43] between the free energies of series of reactions of two types: $MO + SO_3 = MO_4$ and $MO + N_2O_5 = M(NO_3)_2$. This shows that it is desirable to develop a scale of parameters IE which determine the influence of changes in the nature of the metal in series of extraction reactions.

The following values of IE have been adopted[62]: 1 for Pu(VI), ~13 for Pu(IV), ~3 for Np(IV), ~1.5 for Np(VI), 4.9 for Th(IV), and ~2.8 for U(VI). The limits of the applicability of equations of the type $\lg K = \lg K_0 + m\text{IE}$ have not yet been elucidated: the applicability of this equation has been tested for a small number of series‡.

It has been found for extraction of various elements in the form of cations by organic acids that, regardless of the type of extractant, there is a definite sequence of the capacities of the cations for extraction with formation of salts[115]; this is reflected in a sequence of pH values at which 50% extraction takes place ($pH_{1/2}$). A sequence of such capacities of the cations for extraction by acid extractants has been established[115] qualitatively: $Bi^{3+} > Te^{3+} > Ti^{3+} > Sn^{2+} > Sb^{3+} > Pb^{2+} > Ca^{3+} > Cr^{3+} > In^{3+} > Cu^{2+} > Al^{3+} > Y^{3+} \simeq Ce^{+} > Ag^{+} > Au^{3+} > Cd^{2+} > Zn^{2+} > Ga^{2+} > Ba^{2+} > Ni^{2+} > Cs^{+} > Rb^{+} > K^{+} > Ca^{2+} > Mn^{2+} > Mg^{2+} > Na^{+} > Li^{+}$. It may be that the IE parameters, which make it possible to express quantitatively the extraction constant data with the aid of LFE, can also be found for systems where extraction proceeds via a cation-exchange mechanism.

The influence of the concentrations of the components of the aqueous phase. As mentioned in Section II, the principal method adopted for taking into account the influence of the quantitative composition of the aqueous phase involved the use of LMA in combination with data for the activity coefficients, complex formation, and hydrolysis in the aqueous phase. These data may be calculated by analysing the deviations of the apparent extraction constants from the effective constant for different concentrations of the components of the aqueous phase. However, in many systems, where appreciable extraction of the elements takes place only at relatively high ligand concentrations, it is difficult to determine the effective constant by extrapolating the apparent constants to zero concentration. In this case models based on LFE may be useful for the calculation of the influence of the concentrations of the components of the aqueous phase.

---

‡ Linear relations between lg$K$ and IE have been found[62] for the extraction of Pu(IV), Pu(VI), Np(IV), Np(VI), U(VI), and Th(IV) from nitrate solutions by the following extractants: tributyl phosphate, diheptylacetamide, dilaurylacetamide, and tri-n-octylammonium nitrate.

Indeed in those cases where only one component is extracted the relation between the logarithms of the partition coefficients and the concentration of the components of the aqueous phase for a series of systems with different qualitative and quantitative compositions of the organic phase are frequently expressed by parallel lines[116,117]. The relation $\lg D = \lg D_0 + \psi\text{IAP}$, where D_0 is the partition coefficient when the aqueous phase adopted as the standard is used, D is the partition coefficient for the given aqueous phase (all other parameters being unchanged within the limits of the series), IAP the parameter characterising the influence of the aqueous phase§ of given composition and independent of the type of extraction series, and ψ the sensitivity coefficient, which is constant within the limits of each extraction series, holds for systems of this kind[118]. The employment of IAP parameters may be useful in condensing information only in those cases where a large number of systems with the same aqueous phase have been investigated. Such systems include, for example, the Co^{2+}–HCl–H_2O–organic phase or UO_2^{2+}–HCl–H_2O–organic phase systems; for each system, the number of series investigated amounts to several tens. Table 11 lists the values¶ of IAP for certain systems calculated by the present author and Shesterikov[118]; Table 12 lists the expressions for the partition coefficients using these parameters, found[118] for extraction reactions leading to the formation of solvates: $(\text{AmineH})_2\text{CoCl}_2$ (XCIV), $(\text{AmineH})_2 . \text{ZrCl}_6$ (XCV), $(\text{AmineH})_2\text{PuCl}_6$ (XCVI), $(\text{AmineH})_2\text{UO}_2\text{Cl}_2$ (XCVII), and $(\text{AmineH})_2\text{PuO}_2\text{Cl}_4$ (XCVIII). Correlations between $\lg K$ and IAP for a large number of series (about 100) have been published[118,119].

Table 11. The values of IAP characterising the influence of the aqueous phase on the partition coefficients in the Co^{2+}, M^{4+}, MO_2^{2+}–HCl–H_2O–organic phase systems*.

[HCl], M	IAP			[HCl], M	IAP		
	Co^{2+}	MO_2^{2+}	M^{4+}		Co^{2+}	MO_2^{2+}	M^{4+}
2.0	−1.16	−1.26	—	6.0	1.27	0.40	5.88
3.0	−0.63	−0.50	−4.51	7.0	1.60	0.47	7.16
4.0	0.00	0.00	0.00	8.0	1.74	0.49	8.15
5.0	0.72	0.23	3.64	9.0	1.60	0.40	8.90

* $MO_2^{2+} = UO_2^{2+}$, NpO_2^{2+}, PuO_2^{2+}, MoO_2^{2+}, or WO_2^{2+}; $M^{4+} = Th^{4+}$, U^{4+}, Np^{4+}, Pu^{4+}, Zr^{4+}, or Hf^{4+}.

It is seen from Tables 2, 4, 6, 8, 10, and 12, that the use of the above scales of parameters σ^*, E_s^*, ID, ID*, H, IE, IAP, and ΔG_{hydr} may be useful for an abbreviated formulation of the experimental data for partition in various systems with the aid of equations of type (1) and also for the prediction of the influence of various factors on extraction. Equations of type (1) hold most precisely in those cases where the reaction series do not differ greatly from one another as regards the type of the interactions which determine the partition. For such systems, comparison of the equations derived makes it possible to discover certain general characteristics, which are less apparent when one considers experimental data which have not been interpreted with the aid of LFE. When there are significant differences between the mechanisms influencing partition in various series, deviations may be observed from type (1) equations, which yield valuable evidence about the characteristics of the mechanisms of the corresponding reactions. This makes it possible to employ LFE for the analysis of the changes in the properties of extraction systems under the influence of various factors[25].

Table 12. Abbreviated expressions for the partition coefficients for series of extraction systems (only the quantitative composition of the aqueous phase is varied within the limits of each series)[118,119].

Solvate*	HCl, M	Extractant and diluent	Expressions for $\lg D$
(XCIV)	4—10	0.1 M cyclohexyldi(n-dodecyl)-amine in benzene	−0.96+1.01 IAP
(XCV)	7—10	0.1 M tri-n-octylamine in benzene	−8.32+1.0 IAP
(XCVI)	3—9	0.047 M tri-n-octylamine in xylene	0.08+0.201 IAP
(XCVII)	3—10	0.023 M tri-n-octylamine in xylene	0.76+1.17 IAP
(XCVIII	3—10	0.023 M tri-n-octylamine in xylene	1.00+2.04 IAP

* The notation for the solvates (designated by Roman numerals) and the extraction reactions leading to their formation is explained in the text (see Section III, subsection 2).

IV. ANALYSIS ON THE BASIS OF LFE OF THE CHANGES IN THE PROPERTIES OF EXTRACTION SYSTEMS UNDER THE INFLUENCE OF VARIOUS FACTORS

1. The Influence of the Structure of the Extractant

For systems where equations of type (1) hold, it is of interest to analyse (by comparing the coefficients of these equations) the influence of the structure, the solvation number, and the type of functional group on the selectivity of the extractants. Examination of the sensitivity coefficient ρ, can also be used[26] to assess the nature of the bond between the extractant and the extracted compound in the extractable complex. For individual systems where there are deviations from Eqn. (1), analysis of these deviations may be used to estimate the characteristics of the interaction of the components in the extractable complex and to elucidate the role of other factors which influence partition.

The influence of the nature of substituents on selectivity. A general characteristic feature of the equations expressing the influence of σ and E_s on $\lg K$ in extraction by nucleophilic extractants is the

---

§ IAP is the abbreviation for "influence of the aqueous phase".

¶ In constrast to all the parameters described above, the IAP parameters characterise the influence of a quantity which varies continuously and not discretely. It is therefore useful to represent the IAP scale also in the form of a function which can be fitted to the relation between IAP and [HA].

increase of the absolute sensitivity coefficients ρ and a with decrease of the capacity of the element for extraction by the given extractant with a specific functional group. Thus Table 2 [solvate (XVII)] shows that $\rho = -0.95$ for $ZnCl_2$, which is extracted by amines from hydrochloric acid solutions more effectively than $CoCl_2$, while $\rho = -1.60$ for $CoCl_2$; $a \simeq 2.2$ for $Pu(NO_3)_4$, which is extracted by amines from nitric acid solutions more effectively than $Np(NO_3)_4$ and $a \simeq 3$ for Np(IV) [Table 2, (XVIII), (XIX)]. Owing to these relations between the sensitivity coefficients, the difference between the abilities of the amines to extract cobalt(II) and zinc(II) from hydrochloric acid solutions increase with decrease of the positive inductive effects of substituents, i.e. with increase of the quantities $\Sigma\sigma^*$, and the difference between the abilities of the amines to extract plutonium(IV) and neptunium(IV) from nitric acid solutions increase with increase of steric hindrance by the substituents, i.e. with decrease of $\Sigma E^*_{\rm s}$. The following rule arises from this feature: for series of extraction systems differing only in the nature of the extracted metals but characterised by the same solvation numbers, the same composition of the extractable complex, and the same type of nucleophilic extractant, the selectivity in the extraction of the metals increases when the inductive and steric effects of the substituents change in such a way that the extraction capacity decreases, i.e. with increase of $\Sigma\sigma^*$ and with decrease of $\Sigma E^*_{\rm s}$.

This rule holds also in the extraction of tervalent transplutonic elements [Table 2, (XVI)]—for example, the extraction of americium nitrate by substituted ammonium nitrates takes place with higher partition coefficients than the extraction of curium and einsteinium and at the same time ρ for Am(III) is smaller than for Cm(III) and Es(III). This also applies to the extraction of lanthanide elements by amines from nitrate solutions. Certain deviations from the above rule indicate some unexplained features of the extraction of these elements, possibly a difference between the solvation numbers within the limits of the series [tervalent lanthanides are known[5] to be capable of extraction by amines both in the form of complexes having the composition $(AmineH)_2M(NO_3)_5$ as well as in the form of compounds of the type $(AmineH)_3M(NO_3)_6$].

The influence of the solvation number on selectivity. Other conditions being equal, an increase of the solvation number should lead to an increase of the absolute values of ρ and a. Indeed, if the formation of the disolvate is assumed to proceed via a stage in which a monosolvate is formed, then the overall equilibrium constant for the formation of the disolvate K should be equal to the product of the formation constant of the monosolvate K_1 and the constant for the formation of the disolvate from the monosolvate K_2. On the grounds of statistical considerations, one may expect that $K_2 = \frac{1}{2}K_1$, so that $K = \frac{1}{2}K_1^2$ or $\lg K = \text{const.} + 2 \lg K_1$. If $\lg K_1 = \text{const.} + \rho\Sigma\sigma^*$, then $\lg K = \lg K_0 + 2\rho\Sigma\sigma^*$, i.e. the sensitivity coefficient in Eqn. (1) for the formation of the disolvate may be approximately twice as large as for the formation of the monosolvate. Such influence of the solvation number on ρ permits the formulation of the following rule: if the extractable complexes of two elements in a given extraction system differ by their solvation numbers, then, when the nature of the substituents is altered in a way leading to an overall decrease of the extraction capacity (increase of $\Sigma\sigma^*$, decrease of $\Sigma E_{\rm S}$), the extraction selectivity falls if the element whose complex has a smaller solvation number is also distinguished by a lower capacity for extraction, and increases if the element is extracted more effectively than the element whose complex has a larger solvation number.

This rule apparently makes it possible to account for certain characteristics of the influence of the structure of amines on their selectivity in the extraction of the lanthanides. Thus it has been shown[120] that, on passing from trilauryl- or trioctyl-amine to dilaurylmethyl- or methyldioctyl-amines respectively, the partition coefficients of cerium and praseodymium in extraction from nitrate solutions increase; however, this change also entails an increase of selectivity, which is inconsistent with the rule quoted in the previous section. This discrepancy led Kopyrin et al.[120] to investigate in greater detail the stoichiometry of the extraction of the lanthanides by the above amines. It was found that, on passing from symmetrical pentylamines, forming disolvates of the type $(R_3NH)_2M(NO_3)_5$ with lanthanide nitrates, to dialkylmethylamines, the average solvation number increases owing to the extraction of part of the element in the form of a trisolvate of the type $(R_2CH_3NH)_3M(NO_3)_6$. In this case the trisolvates have a higher partition coefficient than the disolvates and, in conformity with the last rule, the partition coefficients of cerium and praseodymium increase on passing from symmetrical trialkylamines to dialkylmethylamines.

Analysis of deviations from a type (1) equation. Individual deviations from Eqn. (1) make it possible to determine the characteristics of the extraction reaction which are not taken into account in the selection of the initial data. For example, calculations showed that the use of the equation quoted in Table 2 [solvate (V)] leads to a satisfactory agreement between the calculated and experimental data for the substituents indicated in Table 2 (15 combinations), but, for certain other substituents (when the number of carbon atoms in the amine molecule is less than 18), the calculated data are somewhat higher than the experimental values, the discrepancy increasing with decrease of the number of carbon atoms[52]. This shows that, for amines, with insufficiently hydrophobic substituents, the stability of the extractable compound may no longer be regarded as the sole factor which determines the extraction constant, since the solubility of the compound in the aqueous phase also begins to have an influence, the solubility increasing with decrease of the total number of carbon atoms to values less than 18. The observed discrepancies between the experimental and calculated data can probably be used to estimate the solubility of the amine salt in the aqueous phase.

It has been shown[121,122] that the extraction capacities of certain tetra-arylmethylenediphosphine oxides in relation to americium nitrate deviate appreciably from values calculated by equations of type (1), which led the authors[122] to investigate in detail this anomalous system. Spectrophotometric study demonstrated the presence, apart from the usual P=O...Am linkages, of additional bonds between the aryl groups and the oxygen atoms of the nitrato-groups of the complex anion $Am(NO_3)_5^{2-}$ in the corresponding extractable complex.

The value of ρ and the type of bond in the extractable complex. The quantity ρ may indicate the type of bond in the complex formed on extraction (this refers primarily to the absolute value of ρ). A high absolute values of ρ is known[26] to indicate a large contribution of polar bonds to the formation of the complex, while a small absolute value indicates a predominantly homopolar nature of these bonds. The data in Table 2 show that ρ exceeds unity for the extraction of acids by amines by a neutralisation reaction, which indicates an appreciable contribution of polar bonds. In the extraction of HNO_3 by substituted ammonium nitrates via an addition reaction $\rho \simeq -0.2$, which indicates a large contribution by covalent bonds to the formation of compounds of the type [Amine.HNO_3]HNO_3. It is of interest to analyse also the sign of the coefficient ρ for series in which metals are extracted by chelate-forming extractants, for example, by alkylphosphoric acids. It was found that for these series the sign of ρ is negative, as for nucleophilic extractants of the type of phosphine oxides. This shows that the nucleophilic properties of the oxygen atoms and their ability to form electron-donor bonds with the metal cation have a decisive influence on the stability of the compounds extracted by acid phosphorus-containing extractants. The capacity of the acid for dissociation, the dependence of which on $\Sigma\sigma^*$ would involve a positive coefficient ρ, is evidently of secondary importance for extraction capacity in these systems. At the same time it is seen from Table 2 that in individual instances the sign of the sensitivity coefficient ρ for extraction by a series of acid organophosphorus extractants may be positive. Evidently in this case the role of nucleophilic interactions is small and the capacity of the acid extractant for dissociation plays a decisive role.

Comparison of the values of ρ for series of extraction reactions involving the functional groups $>S{=}O$, $>P{=}O$, or $>C{=}O$ makes it possible to estimate the change in the nature of the extractant–metal salt bonds in this series of groups.

2. The Influence of the Nature of Diluents

By analysing LFE equations, the characteristic features of the influence of the nature of the diluent on the relative strengths of various extractants and on the selectivity of extraction have been established[5,25].

The influence on the relative strengths of different extractants. Table 2 [(II), (III), (VII), (VIII), (XVII)] shows that, when electrophilic diluents (with low ID) are used, the degree of extraction via addition and complex formation reactions, which do not entail an appreciable change in the polarity of the components, diminishes, on the one hand, and the coefficients ρ in type (1) equations decrease, on the other. Because of this, the employment of diluents with low ID results in the abolition of differences between extractants of the same type having identical functional groups and variable substituents. This behaviour is also evident from a comparison of the equations presented in Table 4 [(XX), (XXI), (XXVI), (XXVIII), (XXX)]; evidently, in the extraction of HNO_3 by different extractants the coefficient of ID is lower the smaller the constant term in the equation. This leads to the mutual approach of the values of lg$K$ for extractants with different substituents and a constant functional group as ID decreases. Such behaviour is evident from a comparison of the equations for (XXXII) in Table 4 for the extraction of $ZnCl_2$ and for (XXXIX) and (XL) in Table 4 for the extraction of UO_2Cl_2 and $CoCl_2$ by extractants with different substituents. The following rule has been formulated on the basis of these observations[25]: the decrease of the parameter ID by the diluent has a levelling effect on the extracting capacities of different extractants which extract acids and metal salts via addition or complex formation reactions not involving a sharp change in the polarity of the components (i.e. those where the ID scale is applicable). Another type of behaviour is manifested in systems to which the ID* scale is applicable. Analysis of the data in Table 6 [(XLII)–(XLV) (for HCl); (XLVI), (XLVII) (for Hbr); (XLVIII), (XLIX) (for HI); (LIV), (LV) (for HNO_3)] show that the differences between the extracting capacities of extractants of different structure in such systems are apparently abolished with decrease of the solvating capacity of the diluents, i.e. with the decrease of the parameters ID*, because the coefficients of ID* in the equations for lg$K$ increase with increase of the constant in these equations. In contrast to the influence of ID, the last rule does not hold fully [for the deviations, see Table 6, (XLVI) (for HNO_3)].

The influence on extraction selectivity. The influence of ID depends on the ratio of the solvation numbers. The causes and nature of this influence are analogous to those described above for the influence of solvation numbers which the structures of the extractants are altered. With increase of the solvation number, the influence of the nature of the diluent on the partition coefficient (other conditions being equal) should be greater [cf. (XXII)–(XXIV) and (XXI), Table 4], which has a corresponding influence on the selectivity.

It is also of interest to compare the influence of the ID parameters on selectivity for identical solvation numbers of compounds of two elements being extracted. It is known that Pu(IV), Th(IV), and Bi(III) are extracted by trioctylammonium nitrate in the form of disolvates and their extractability from nitric acid solutions varies in the sequence Pu(IV) > Th(IV) > Bi(III). Comparison of (XXV) and (XXVI) in Table 4 shows that the sensitivity coefficients in the correlation equations vary in the opposite sequence. Thus the differences between the degrees of extraction of these elements will increase with decrease of ID, i.e. with the increase of the degree of specific solvation of the functional group of the extractant by the diluent.

Similar behaviour is also seen on comparing the degrees of extraction of Am(III) and Ce(III) by a substituted ammonium thiocyanate [(XLI) in Table 4], HCl and HNO_3 by their substituted ammonium salts [(XXVII) and (XXIX), Table 4], neodymium and dysprosium by a substituted ammonium nitrate [(XXXI), Table 4], and uranium(VI) and cobalt(II) by a substituted ammonium chloride [(XXXIXa), (XLa), (XXIXb), (XLb), Table 4]. Molybdenum(VI), cobalt(II), and zinc(II) are known to form the following sequence in terms of their capacity for extraction by tri-n-octylammonium chloride: Zn > Co > Mo. The sensitivity coefficients of the correlation equation increase in the opposite sequence also in the above series, which leads to an increase of selectivity with decrease of ID. One can therefore formulate the following rule: for systems where the influence of the diluent may be expressed by a dependence on ID, with identical solvation numbers of two extracted elements, the selectivity of the extraction by a given nucleophilic extractant increases with decrease of the ID parameter of the diluent, i.e. with increase of the ability of the diluent to solvate the nucleophilic functional group of the extractant.

Consider the influence of ID* on selectivity. Comparison of data for (XLII), (XLVI), and (XLVIII) as well as those for (XLIII), (XLVII), and (XLIX) in Table 6 shows that the selectivity in the extraction of hydrogen halides by trioctyl- and trilauryl amines via a neutralisation reaction decreases with increase of ID*, i.e. with increase of the solvating capacity of the diluent. Overall, an increase of ID* promotes extraction reactions leading to the formation of more polar compounds. Thus in anion-exchange by substituted ammonium salts an increase of ID* promotes the conversion of less polar substituted ammonium sulphates into more polar salts—chlorides and pertechnetates [see (LVIII) and (LIX) in Table 6] and the conversion of acetates into chlorides [see (LXI) in Table 6], but prevents the conversion of the more polar bromide into the less polar substituted ammonium chloride [see (LX)]. In extraction by acid extractants (in contrast to extraction by amines), an increase of ID* leads to a decrease of the degree of extraction. This probably indicates a lower polarity of the metal salts formed compared with that of the acid extractants. Under these conditions (for equal solvation numbers), the differences between the degrees of extraction of different elements are abolished with increase of ID* of the diluent: the absolute value of the negative sensitivity coefficient becomes smaller with decrease of the constant coefficient [see, for example, (LXIX), (LXX), and (LXXI), or (LXIV) and (LXV) in Table 6].

On the basis of the foregoing, one can formulate the following rules: (a) in anion-exchange reactions an increase of ID* greatly favours reactions leading to the formation of more polar compounds in the organic phase, i.e. an increase of ID* tends to increase the selectivity in the extraction of anions of stronger monobasic acids from a medium comprising weaker acids and the extraction of singly charged anions from a medium containing doubly-charged and multicharged anions; (b) in cation-exchange reactions an increase of ID* prevents the conversion of acids into metal salts and lowers the selectivity in the extraction of the latter[91].

3. The Influence of the Nature of the Anionic Ligand

A significant influence of the parameters H on selectivity in the extraction reactions of elements which are hard acids and have the same solvation numbers has not been observed [see, for example (LXXXII) in Table 8]. It is more likely to observe the influence of H in those cases where the formation of extractable compounds of different elements involves the addition of different numbers of anionic ligands; evidently, with increase of this number, the coefficient of the parameter H in the LFE equation [$\lg K = f(H)$] should also increase, which may lead to an alteration of the relative capacities of two such elements for extraction as the parameter H is changed.

The dependence of selectivity on H for the anionic ligand is manifested more clearly in those cases where one of the elements is a hard acid and the other is a soft acid. In this case an increase of H for the hard element leads to an increase of the degree of extraction and an increase of H for the soft element in most cases results in its decrease. For example, the degree of extraction of soft cadmium or cobalt(II) from halide media increases as the halogen is altered in the sequence $F < Cl < Br < I$, while the degree of extraction of hard zinc(II) decreases in the same sequence. (Zinc is appreciably extracted from a medium containing Cl^- anions, but is hardly extracted from a medium where iodide anions predominate[123].) On the other hand, the hard element zirconium(IV) is effectively extracted from an HF medium (at low HF concentrations), while soft cadmium(II) is hardly extracted from the same medium. One can therefore formulate the rule that, within certain limits, the parameter H has a decisive influence on the selectivity in the extraction of metal salts by substituted ammonium salts with the same anions: the extraction selectivity in relation to a pair of elements whose cations are hard and soft acids respectively may be increased by employing anions with higher values of H in those cases where the hard element is more effectively extracted or by employing anions with low values of H in those cases where the soft element is more effectively extracted.

The applicability of this rule is limited, because the sequence of the changes in the extractability of complexes of different anions for soft acids is not fully the opposite of the corresponding sequence (H scale) for hard acids. For example, the CN^- anion has a high value of H, but forms readily extractable complexes with elements whose cations are both hard and soft acids. In those cases where anions are extracted via anion-exchange reactions, the selectivity of extraction by a given extractant increases with increase of the difference between the free energies of their hydration in the aqueous phase (Table 9).

One should note certain limitations in the applicability of the rules and relations based on LFE. They are applicable in a general form to linear correlations involving the logarithms of extraction constants; they are applicable to partition coefficients only in those cases where the latter are proportional to the extraction constants, i.e. when the phase composition in terms of concentration is constant throughout the series. Such proportionality holds fully only at extractant concentrations much lower than diluent concentrations and at concentrations of the extractable compound much lower than the extractant concentrations. However, this does not diminish the generality of the method, because it is possible to extend, with the aid of the Law of Mass Action, data obtained subject to the above limitations to wider concentration ranges.

The data presented in the present review show that LFE together with LMA may be used to express in an abbreviated form large sets of experimental extraction data.

In order to be able to employ the above equations in reference compilations instead of numerous experimental data, it is extremely important to estimate the accuracy of the calculated results. In the first stages of the development of the application of LFE to extraction, investigators did not calculate quantitative parameters characterising the accuracy of the correlation (correlation coefficients, variances, average deviations). An approximate estimate shows that, for the majority of the equations quoted in the present review, the correlation coefficient is 0.9. It has now become a rule to give in extraction reports an estimate of the accuracy of the proposed correlation equations. Thus the correlation coefficient has been estimated as 0.98 in a study by Fedoezzhina et al.[58] [see (II), Table 2)] and Shmidt et al.[124] found that the average deviation of the calculated values of K from the experimental results amounted to approximately 10% when K varied by three orders of magnitude [see (XVI), Table 2]. It is necessary that in the future derivation of new correlation equations their accuracy should be estimated quantitatively in accordance with statistical requirements[125].

In essence the first steps have already been taken towards the condensation of information about extraction equilibria with the aid of LMA and LFE. Presumably in the future the need for this type of condensation will increase, which will lead to a wider employment of the methods described as well as their improvement. Equations based on LMA and LFE can also be used as instruments for discovering new characteristics of the extraction process and for the determination of the specific features of the behaviour of components in individual extraction systems.

Coordination Chemistry in Italy: The Work of the Rome School

C.Furlani

The principal directions of the development of coordination chemistry in Italy (the Rome school) are considered in their historical aspect. In the field of the theory of the structure of complex compounds research on the ligand field theory and calculations by the molecular orbital methods are being carried out in Rome. Numerous studies on the synthesis and determination of the structures of many new complexes are examined and the kinetics and mechanisms of chemical reactions of coordination compounds, mainly substitution reactions, are discussed. Much attention is devoted to the investigation of the properties of complexes with the aid of various physical methods—electronic and photoelectron spectroscopy, vibrational spectroscopy, magnetic resonance methods (EPR, NMR, NQR), and electrochemical methods (particular polarography). Studies related to the preparation of catalytically active complexes and their properties are also considered.
The bibliography includes 247 references.

I. INTRODUCTION

Coordination chemistry has been very popular in Italy for a very long time. During the period when Werner developed intensive investigations in Zurich, Miolati in Padua studied the structure of polyacids. In the next decade Cambi, Natta, and other well known chemists carried out the first studies in the field of metal complexes. Soon after the second world war Italian scientists participated in the development of all the fields of modern coordination chemistry, so that at the present time studies on the coordination compounds are prosecuted in almost every Italian university. Several particularly active scientific centres arose, the most important of which are those in Milan, Padua, Florence, and Rome. The present review gives a brief historical description of the development of the Rome centre and also the results of scientific research carried out in the last few years and being prosecuted at the present time.

The work of Professor Vincenzo Caglioti, who laid the foundations of the Rome school during the war and in the subsequent years, has had the greatest influence on the development of coordination chemistry in Rome. These studies are now being continued by Prof. Guido Sartori and many of his coworkers, working both in the Rome University and in other Italian institutes. This review will therefore survey the results of research by the chemists in the Rome school working in more or less closely related fields at the following institutes: the Institute of General and Inorganic Chemistry at the Rome University; the Laboratory of the Theory of the Electronic Structures and Spectrochemical Properties of Coordination Compounds of the National Research Council of Italy in Rome; the Institute of General and Inorganic Chemistry at the Peruggia University. In addition, mention will be made of some of the studies carried out at the Chemical Institute of the University of Trieste.

II. PRINCIPAL FIELDS OF RESEARCH

Traditionally the work of the Rome school on coordination chemistry, which began in the 1930's with early polarographic studies[1-4], embraced a wide range of fields, including almost all the aspects of the chemistry of metal compounds—from the fundamental theory to problems of industrial applications. However, studies on the electronic structures, stereochemistry, spectroscopy, and related problems have developed to the greatest extent; thermodynamics and resonance spectroscopy have been less well developed. The consideration of various aspects of this research may be divided into eight sections:

(1) theory of the coordinate bond;
(2) syntheses of new coordination compounds and determination of their structures by X-ray diffraction analyses;
(3) kinetics of substitution reactions involving metal complexes;
(4) electronic spectroscopy;
(5) vibrational spectroscopy;
(6) electrochemistry;
(7) various research methods;
(8) applied research.

This subdivision is undoubtedly extremely arbitrary, some of the relevant studies being carried out simultaneously. For example, syntheses have been frequently performed in order to obtain complexes which might confirm theoretical principles; electrochemical studies in non-aqueous solvents made it possible to characterise and synthesise complexes unstable in an aqueous medium; X-ray diffraction studies went hand-in-hand with the spectroscopy of single crystals, etc.

III. THEORY OF COORDINATION BINDING

The interest of the Rome school in research on the nature of bonds in complexes arose in the 1950's when Hartmann's work[5] demonstrated the entire importance for chemistry of the crystal field model developed by Bethe[6], Van Vleck[7], and others and laid the foundations of the modern ideas about the coordinate bond. Early contacts of Italian chemists with Hartmann's group[8-10] ensured that the ligand field theory became widely known in Italy. This led to the appearance in 1957–1964 of a large number of publications devoted to the interpretation (from the standpoint of this theory) of the structures and spectra of complexes having a definite electronic configuration, particularly the d^6 configuration in high-spin complexes of iron(II)[11,12] and the d^8 configuration in systems with high-spin and low-spin states, for example, in Lifshitz salts[13,14], metal dicyclopentadienides[15], and many tetrahedral halogenocomplexes of Series I transition metals. The development of theoretical postulates was followed by the syntheses of new complexes[16-20]. Since then the ligand field theory has been constantly used for a preliminary interpretation of the results of synthetic and spectroscopic studies by the Rome school. Furthermore, two other fields of theoretical research are being developed: the improvement of the models of the ligand field theory and attempts at a complete description of coordination compounds with the aid of the molecular orbital method.

Among the early studies, an interesting investigation was carried out—namely a detailed analysis of the magnetic susceptibility of d^2 systems[21]. This investigation was followed by an extensive review of the applications of the ligand field theory to the interpretation of the structures and spectra of complexes with a coordination number of five, published in 1968.[22] Subsequently a series of coordination compounds were synthesised and the spectra and structures of their single crystals were investigated: (see below). Numerous studies were performed on the electronic spectra of single crystals, in which the potential possibilities of the ligand field theory for the interpretation of the spectra were used more fully. They will be examined in detail in the section devoted to electronic spectroscopy. The angular overlap method, devised as a development and a revised version of the ligand field theory, was used in certain cases. This model proved to be suitable for the description of the ligand field spectra of the square-pyramidal complex $Fedtc_2Cl_2$ [23] and certain high-spin adducts of the square planar nickel(II) complex $Nidtp_2py_2$.[24] (Here and henceforth dtc = dithiocarbamate, dtp = dithiophosphate, and py = pyridine.)

Calculations on coordination compounds by the molecular orbital method were proposed at the beginning of the 1960'S as an alternative to the ligand field model (the limitations of which are now more clearly seen; its advantages for approximate estimates have also been established). A large number of more or less complex new versions of the molecular orbital method immediately arose and, although none of them can be used as yet without difficulty, they have been extremely valuable.

Theoretical studies of this kind aroused the interest of the Rome school. The problem of such studies was formulated in 1967 at the Symposium on Theoretical Inorganic Chemistry organised by the Peruggia group[25]. After that, certain models for semiempirical calculations by the molecular orbital method, for example, the "full overlap"[26], "zero differential overlap", and analogous methods[27], were developed at the Rome school and tested in practice. Particular attention in the course of this research was devoted to allowance for the effect of open shells (using the Roothaan operator technique).

Despite this, certain calculations on model molecules, such as $[TiF_6^{3-}]$, showed that semiempirical methods of this kind suffer from serious disadvantages. They are associated with difficulties in the parametrisation of empirical quantities. One can now assume that the most promising are the onn-empirical (*ab initio*) computational methods as well as simple semiempirical methods, which, although fairly approximate, are simple to use. As an example, one may quote the improvement of the Wolfsberg–Helmholtz model based on the extensive employment of the Mulliken approximation for the estimation of the contribution of each molecular integral. This model has been used successfully for a number of sulphur-containing complexes, for example $Nidtp_2$ and $Nidtc_2$.[28] As regards the intensification of attempts at the improvement of this method, one may also consider the procedure developed by Fencke where, instead of simple adjustment for self-consistency or the self-consistency of atomic charges, the requirement of the Hartree–Fock SCF is introduced and (or) one uses as a basis for molecular orbital calculations the atomic orbitals obtained by adjustment for self-consistency under the condition of perturbation of the ligand field in the complex investigated, and not the atomic orbitals of free atoms or ions[29].

IV. SYNTHESES

This section deals with the studies in the last decade which have been devoted mainly to complexes containing chalcogenide ligands. The interest in these complexes, where sulphur or selenium serve as donors, arose because of the wide variety of the electronic structures and stereochemical rearrangements and the possibility of comparing them with donor ligands containing oxygen. Thus in the case of sulphur we have a complete set of ligands: a weak field ligand and at the same time a strong π donor S^{2-}, chelating anions of the type dtc^- (R_2NCS_2), dtp^- (R_2PS_2), or dithiocarboxylates ($R-CS_2^-$) (the π-donor and spectrochemical properties of which are extremely different and depend to a large extent on the nature of R), simple neutral thioesters (R_2S), conjugated neutral ligands such as thiourea ($R'R''N-CS-NR'''R''''$) or thiocarbamate esters ($R'OCS-NR''R'''$), and, finally highly conjugated dithiolates.

A spectrochemical comparison of S^{2-}, Se^{2-}, and Te^{2-} by examining the spectra of tetrahedrally coordinated cobalt(II), introduced into the lattices of compounds of the type ZnY or CdY (Y = S, Se, or Te), proved possible for the first group of chalcogenide ligands[30]. The principal studies on chelating dithio-anions were carried out for dithiophosphate complexes. In particular, studies were made on the spectra of nickel(II) dithiophosphates (R = C_6H_5 or C_2H_5O) and their high-spin pseudo-octahedral adducts with nitrogen-containing bases and their X-ray diffraction analysis was carried out[31-34].

The addition of primary aliphatic amines to $Nidtp_2$ takes place in two stages via the formation of a five-coordinated high-spin intermediate, the spectra and reversible formation reactions of which have been studied in detail[35,36]. Other five-coordinated $Nidtp_2$ adducts have been studied by the method of the polarised spectra of single crystals[37]. The same method has been used to compare the properties of a number of phosphorus(III) compounds—dithiophosphates ($Mdtp_3$ or $Mept_3$) dissolved in $Indtp_3$ matrices containing the corresponding dithiocarbamates (In, M)dtc_3.[38] The vanadium(III) compound $Vdtp_3$, synthesised for the first time, is of special interest[39,40]. The reactions of dithiophosphate complexes with bidentate phosphorus and arsenic bases have been investigated[41,43]. As regards dithiocarbamates and related compounds, apart from a few early data on their X-ray diffraction analysis[43-45], systematic studies have been made on the analogous diselenocarbamates $Mdsec_2$, where dsec = $(C_2H_5)_2NCSe_2^-$. These compounds are largely similar to dithiocarbamates, but, in estimating their spectrochemical parameters, it is possible to make interesting quantitative comparisons of their properties.

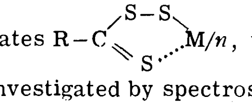
In parallel with the syntheses and spectroscopic studies[46,47], X-ray diffraction studies have also been made on copper(II),[48] nickel(II),[48,49] and zinc(II)[48] complexes. An analogous comparative study of sulphur and selenium compounds has been made for xanthates: several new metal diselenoxanthates $(ROCSe_2)_nM$ were synthesised and studied spectroscopically[50], but they proved to be less stable and less suitable for investigation than diselenocarbamates and diselenophosphates.

From the standpoint of their structures, the dithiocarbazinates ($R_1R_2N-NR_3-CS_2^-$ = dtcz) resemble dithiocarbamates, but they exhibit a greater variety of coordination stereochemistry, since they can behave as bidentate S,S- or S,N-ligands. This depends on several factors, such as the nature of the metal ion, the nature of the substituents influencing the basicity of the nitrogen atoms, and steric conditions. For example, the compounds $Nidtcz_2$ are low-spin square complexes usually forming N,S-chelates in the presence of aliphatic substituents or without substituents and S,S-chelates in the presence of aromatic substituents[51,52]. The complexes of bivalent palladium and copper exhibit similar properties, while zinc shows a greater tendency to form pseudotetrahedral S,S-chelates[53]. The pseudo-octahedral chromium(III) and cobalt(III) complexes can form either S,S- or S,N-chelates[54].

Nickel(II) complexes have been most thoroughly investigated: X-ray diffraction[55,56] and NMR studies[57,58] made it possible to elucidate their coordination stereochemistry and the conformations of the added ligands. These complexes are exceptionally reactive. They undergo deprotonation[59] and alkylation[60] very readily, form labile adducts with oxygen[61], and undergo an unusual cleavage of the N–N bond with formation of the corresponding dithiocarbamates[62].

The dithiocarbazinate esters $R_1R_2N-NR_3-CSSCH_3$ are also effective ligands, forming in the deprotonated form square inner complexes and 1 : 3 pseudo-octahedral complexes with nickel(II).[63] A number of organic reactions of these esters have been studied[63]. Systematic investigations of the corresponding thiocarbazates $R_1R_2N-NR_3-COS^-$ are being prosecuted at the present time[64] and their results will make possible numerous comparison with other compounds, including the hydrazinecarboxylate complexes $(H_2N-NH-COO)_nM$ already known in the literature[65-67].

Studies on the complexes of simple dithiocarboxylic acids R–CSSH or LH (R = alkyl or aryl) are being most vigorously prosecuted; such acids give rise to the simplest possible dithio-anions, but until 1968 they were scarcely used as ligands. Systematic studies, begun in Peruggia, showed that these ligands behave fairly strangely. Thus, although they form inner complexes with the usual stereochemistry (pseudo-octahedral $M^{III}L_3$, square $M^{II}L_2$), a greater degree of mixing of the ligand and metal orbitals (possibly associated with the low electronegativity of R compared with that of R_2N^-, RO^-, etc. in other dithio-anions) is more characteristic of their electronic structure. This is clearly seen, for example, in the electronic spectra, which frequently differ from the usual spectra corresponding to models of the ligand field theory[68]. It has been observed that low-spin nickel(II) complexes[68,69] are not monomeric but form weakly bound trimers Ni_3dtb_6†,[70,71] bridged dimers of the type Ni_2dtpa_4,[31,72] or axial dimers Ni_2dtpv_4,[69,73] or even more complex trinuclear structures of the kind found for dithioacetate[74]. Structures of the type of bridged dimers have also been observed for complexes of monothiobenzoates Ni_2mtb_4. .EtOH (pseudo-octahedral coordination of metal atoms)[75] and Co_2mtb (tetrahedral coordination of the metal)[76], while chromium gives rise to the monomer $Crmtb_3$.[77] Complexes of dithiocarboxylates are also remarkable due to the fact that they are readily transformed into complexes of perthiocarboxylates



$R-C\overset{S-S}{\underset{S}{}}M/n$, which are also being vigorously investigated by spectroscopic[78] and X-ray diffraction[79] methods. Complexes of thiourea with *N*,*N'*-substituted ligands RHN–CS–NHR′, in the case where they exist with the most preferred stereochemistry [for example octahedral stereochemistry for chromium(III)[80] or pseudotetrahedral stereochemistry for cobalt(II) and zinc[81-83]], and when there exist numerous coordination forms, possibly depending on the nature of the substituents R and R′, have been investigated in particular detail. Thus thiourea forms 1 : 4 complexes with palladium(II) and platinum(II), which do not have a simple square structure but are five-coordinated compounds $[ML_4X]^+$ (M = Pd or Pt, L = substituted thioureas, X = halogen or ClO_4) by virtue of the π-acceptor properties of the ligands[84]. On the other hand, in the presence of a molar deficiency of L or an excess of X^-, the complexes ML_2X_2 are formed[84-86]; their formation is also possible in the case of a complex equilibrium.

N,*N'*-Disubstituted selenoureas RHN–CSe–NHR′ behave in relation to palladium(II) and platinum(II) like their sulphur-containing analogues, giving rise to complexes with the same structures and stabilities, let alone the shifts in the spectra[84,87].

Thiocarbamate esters have also been studied, although they exhibit an extremely weak affinity for d^8 metal ions. Their coordination number does not usually exceed two and they are bound, whenever possible, not to the C=S group but to other electron-donating groups, for example the allyl group in PdL_aCl_2 ($L_a = CH_2 = CH-CH_2-NH-CS-OCH_3$) or the deprotonated nitrogen atom in PdL_2'' ($L'' = C_5H_5N^- - CS-OCH_3$).[88-90]

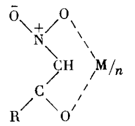
Although the complex-forming properties of thiourea in relation to nickel(II) had been known earlier, they were studied in detail by the present author. Nickel(II) complexes of *N*,*N'*-substituted thio- and seleno-ureas were investigated, which yielded evidence for the existence of different coordination forms and stability series. These series include[91-93] the octahedral chromophores $[NiS_6]$ in certain compounds of the NiL_6X_2 (X = Cl, Br, or I) series and in certain crystalline solid $NiL_6(ClO_4)_2$ specimens, tetragonal chromophores $[NiS_4...X_2]$ in solid NiL_4X_2 specimens, which are in certain cases characterised by a singlet–triplet equilibrium in the ground state, pseudotetrahedral $[NiL_2X_2]$ groups, which exist in the solid form only for fairly bulky ligands but are protonated much more readily in solution, and square $[NiS_4]$ groups, for example,

---

† Here and henceforth dtb = dithiobenzoate and dtpa = dithiophenylacetate.

in thiourea perchlorates (they also formed very readily with selenoureas[94]). Later we began to study complexes of polydentate ureas such as $H_2N-(CH_2)n-NH-CS-NHR$ and $RHN-CS-NH-(CH_2)n-NH-CS-NHR$.[95,96]

Yet another class of ligands, which has been studied in detail in the Rome laboratory, are the α-nitro-ketones $R-CO-CH_2-NO_2$ (mainly $C_6H_5-CO-CH_2-NO_2$) which give rise to chelate rings



analogous to the chelates formed by β-diketones. The greatest number of studies have been devoted to the copper complexes CuL_2 and their five- and six-coordinated adducts[97-100], for which interesting instances of conformational isomerism may be observed. Nickel(II), cobalt(II), and other transition metal complexes have also been investigated[101-104]. Unusual ligand cleavage reactions have been discovered for platinum and gold nitroketonates[105]. The properties of organic nitro-compounds as ligands are always of interest and studies on *gem*-dinitro-compounds $RCH(NO_2)_2$ have been carried out in this connection[106].

The behaviour of hydrazine as a ligand is also of interest, because this compound is a bidentate donor but does not exhibit a capacity for chelate formation. This is evident from the analysis of the spectra and structures of certain nickel(II) complexes with hydrazine and mixed ligands[107-109]. Further synthetic, structural, and spectroscopic investigations dealt with rhenium[110], titanium(II),[111] silver(II),[112] niobium(V),[113] molybdenum(III), and molybdenum(V)[114,115] complexes and transition metal complexes of phthalocyanines (known to exhibit a quasi-reversible NO absorption)[116-118].

In this section we shall also mention studies devoted to complexes of quaternary diphosphine bases and related ligands[119-121] as well as studies on equilibria in solution. Although these investigations have not been part of the main field of research of the Rome school and have not been carried out systematically, they were performed to explain the properties of the less stable compounds. Apart from the early investigations of the copper(II) complexes of aliphatic diamines with long chains[122], 1 : 1 and 1 : 2 paramagnetic adducts of the square $[NiS_4]$ complexes of amines, for example, $Nidtp_2$, have also been studied[26,35]. The stability constants of zinc(II) and cadmium tartrates and citrates in water[123], of cobalt(II) complexes of halogenophosphines in organic solvents[124,125], and of mercury(II) halides in acetonitrile[126] were investigated.

V. KINETICS AND MECHANISMS OF REACTIONS

The study of the reactivities of coordination compounds has been of continued interest at the Chemical Institute of Rome University. Attempts were made to elucidate the mechanisms of substitution in octahedral cobalt(II), rhodium(III), and iridium(III) amino-complexes. Most attention has been devoted to the behaviour of monodentate ligands—carboxylates—in hydration reactions and (or) alkaline hydrolysis in order to establish analogies between these compounds and organic esters[127-133]. Whenever possible, the kinetic data were analysed by plotting linear free energy relations in order to estimate the influence of the geometrical and electronic structures on the kinetics.

In order to discover whether the metal—oxygen or the carbon—oxygen bond is ruptured, experiments using ^{18}O were performed in the most interesting cases. It was found that in neutral or alkaline media hydration proceeds mainly via a dissociative mechanism with rupture of the metal—oxygen bond (acid catalysis takes place at low pH values). The alkaline hydrolysis proceeds either via an S_N1CB mechanism, which is typical of octahedral amino-complexes, or via a $B_{AC}2$ mechanism which is typical of organic esters. In addition, a third reaction pathway, which gives a second order dependence on OH^- and involves the dissociation of the carbon—oxygen bond, was discovered. This mechanism has no analogies in the hydrolysis of esters.

Water exchange reactions were investigated for $[Rh(NH_3)_5(H_2O)]^{3+}$ and $[Ir(NH_3)_5(H_2O)]^{3+}$ and a comparison was made with anation reactions in order to elucidate the role of the interacting groups[134-137]. It was found that, in contrast to the analogous cobalt(III) compounds, the reactions of heavier d^6 metals have an appreciably associative mechanism. This conclusion, supported by modern studies designed to determine the activation volumes in the exchange involving water[138], was unexpected, because numerous kinetic data accumulated for cobalt(III) complexes led to the conclusion that the main reaction pathway for all octahedral complexes involves a dissociative mechanism.

A study was made of the role of the leaving groups in substitution reactions involving certain monoacidic octahedral cobalt(III) and chromium(III) complexes. A linear relation was discovered between the free energies derived from the aquation constants and the values of K_a for the conjugate acids forming part of the ligand[139]. Reactions of the nitrate ion are anomalously rapid from this standpoint, although experiments with ^{18}O showed that its substitution by water proceeds via the dissociation of the metal—oxygen bond[140]. The properties of the nitrate ion as the leaving group have been the subject of special studies[141]. In the series of compounds nitratopentaminecobalt(III), nitratopentaminerhodium(III), and nitratopentamineiridium(III), the NO_3^- anion undergoes alkaline hydrolysis via the usual coupling mechanism, possibly with nucleophilic insertion of a water molecule in the case of heavier metals (S_N2CB). The entropy data show that the freedom of rotation, of which the anion is capable in the transition state, tends to diminish in the sequence $Co > Rh > Ir$.

The series of studies on the reaction mechanisms includes also research into substitution in uncharged ruthenium(II) complexes in non-aqueous solvents[142,143]; kinetic data indicate the formation of five-coordinated intermediates. A study was also made of the hydrolysis and *cis*-*trans* isomerisation in anionic aquo-complexes of ruthenium(IV), containing bidentate ligands (carboxylates)[144]. It appears that the isomerisation mechanism in these instances changes from dissociation at one end of the molecule to dissociation in water with increase of the number of atoms in the chelate ring.

Investigation of the properties of metallocenes in order to elucidate the nature and the site of the interaction of protonating agents with these molecules constitutes a relatively new field[145,146]. The important role of the cyclopentadienyl ring as the basic centre of the molecule was observed[147]. Further studies were devoted to the hydrogen—deuterium exchange in various protic media[148]. The stability constants of certain ferrocenyl carbonium ions were determined and were used to estimate the electron-donating properties of ferrocenyls.

VI. ELECTRONIC SPECTROSCOPY

The study of the electronic absorption spectra of complexes is associated both with theoretical investigations (mainly the assignment of bands in the visible region from the standpoint of the ligand field theory) and with investigations in the field of syntheses, and is part of almost all the publications mentioned in previous sections. Studies devoted to the interpretation of the electronic spectra of coordination compounds, obtained for specimens in the form of single crystals using polarised light, are of special interest for spectroscopy. This field is being developed by the Rome laboratory simultaneously with crystallographic X-ray diffraction investigations. These research techniques make it possible to employ at a deeper level the interpretative possibilities of the ligand field theory with the aid of rigorous selection rules and are widely used in the modern research by the Rome school. The following systems have been investigated: $[CuCl_4]^{2-}$ chromophores with pseudotetrahedral[149] and square planar [150] structures; square $[NiS_4]$ chromophores[151]; certain types of trigonal octahedral complexes of tervalent transition metals with bidentate sulphur-containing ligands[38-40]; the dinuclear complex $Nidtpa_4$ (where dtpa = dithiophenylacetate)[72]; pseudotetrahedral cobalt(II) complexes with various *s* and *p* donors[152]; the $[MnCl_5]^{2-}$ ion[153]; eight-coordinated tetranitrato-complexes[154]; and certain other transition metal complexes, mainly those of nickel and copper.

Another spectroscopic method, which has been developed particularly vigorously in recent years in Rome and Peruggia, involves the study of the luminescence spectra of inorganic chromophores. Both fluorescence and phosphorescence spectra yield important information for the determination of the positions and the identification of excited electronic levels and thus supplement data obtained with the aid of absorption data. Furthermore, luminescence spectra make it possible to study phenomena involving excitation via structural energy transfer and the reactivities of metal complexes. Despite its considerable advantages, emission spectroscopy is used much more rarely than absorption spectroscopy, possibly because of considerable technical difficulties and appreciable limitations in its applicability. Nevertheless this method has attracted the attention of the Rome school, which has been reflected in papers devoted to the general discussion of emission spectra[155,156], the consideration of luminescence spectra of chromium(III) complexes of sulphur-containing ligands[157] and ethylenediaminetetra-acetic acid[158], platinum(II),[159,160] platinum(IV),[161] and manganese(II) [162] complexes, as well as certain instances of energy transfer to the centres responsible for luminescence or between these centres[163].

Mention should be made in this section also of research in the photochemistry of coordination compounds [mainly chromium and chromium(III) complexes], which is directly related to the study of luminescence spectra. The formation of the same preceding state—an excited ligand field or charge-transfer state—is necessary for both processes—a photochemical reaction or luminescence. As a result, the data obtained with the aid of the two methods supplement each other and thus make it possible to describe more accurately the excited states of metal complexes. The first studies were performed jointly with two leading groups in the field of inorganic photochemisty—those of Schläfer (emeritus Professor at Frankfurt)[164] and Prof. Adamson in Los Angeles[165,166]. These studies initiated original research into the mechanisms of photochemical substitution reactions involving certain chromium(III) complexes[167,168], particularly the *trans*-disubstituted complexes $[CrA_4XY]$, in which isomerisation and (or) substitution takes place[169,170]. Among other studies[171,172], those on the mechanisms of energy transfer from certain sensitisers in reactions of chromium(III) complexes are of special interest[173,174].

VII. VIBRATIONAL SPECTROSCOPY

The method is used mainly as an auxiliary procedure in the determination of structures or in order to test theories of bonding in coordination compounds. A number of early studies were devoted to the influence of the ligand field on the bond vibration frequencies in the molecule of the complex and in the ligands. In order to account for the vibration frequency shift in coordinated water molecules[175,176] and NH_4^+,[177,178] and BH_4^- ions in crystals[179], the method of perturbation theory was used. The normal coordinates have been analysed for certain cyano-complexes[180], carbonyls[180], and other coordination compounds.

Later, interest was concentrated on empirical problems associated with developing synthetic studies. For example, infrared spectroscopic data for nitroketone[181,182], dithio- and perthio-carboxylate[183-185], and a number of other complexes[186,187] have been published together with descriptions of the syntheses of the complexes and their other structural properties. In particular, investigations on nitroketone complexes began with the study of the infrared spectra of free nitroacetone and nitroacetophenone, the band assignments in the spectra being confirmed by the isotopic shifts for certain deuterated analogues[188]. Among metal complexes, copper(II) bis(nitroacetophenonate) has been most thoroughly investigated, because the simple structure of its crystal lattice permits a more accurate calculation[189]. In further investigations of nitroacetophenonates of other bivalent transition metals, copper(II) bisnitroacetonate, and certain univalent metal dinitroacetonates, satisfactory evidence was obtained for the delocalisation of the charge over the chelate rings and the influence of substituents[190].

The dithiobenzoates ($C_6H_5-CSS^- = dtb^-$), dithiophenylacetates ($C_6H_5-CH_2-CSS^- = dtpa^-$), dithioacetates ($H_3C-CSS^- = dtac^-$), and perthiobenzoates ($C_6H_5-CS_2S^- = dtbD^-$) of certain bivalent and tervalent transition metals have been particularly thoroughly investigated. These investigations were associated with the problem of the assignment of the intense stretching vibration bands due to C–S, S–S, and other bonds in the chelate rings, for which there are contradictory literature data. Final conclusions were reached in experiments with deuteration, the observation of splittings in the spectra of crystals, and in certain instances with the aid of polarised infrared spectra of thin films[184,185].

VIII. ELECTROCHEMISTRY

As in other Italian universities, the scientists at Rome showed a deep interest in electrochemistry even before the war, particularly in polarographic studies on complexes[1,191]. Recently, the polarography of coordination compounds in an aqueous medium has been used to study the kinetics of the decomposition of $[Mn(C_2O_4)_3]^{3-}$ [192] and of complex formation in the system comprising copper(II) and polydentate amines[193-195] and in the study of the behaviour of certain organic ligands such as heterocyclic nitrogen-containing bases[196,197] or dithiocarboxylates[198] at electrodes and of the polarographic properties of molybdenum(V)[199] and molybdenum(III).[200] However, polarography in aqueous solutions is at present being displaced by other methods, which are more powerful and are more widely applicable in the chemistry of coordination compounds: on the one hand, polarography in non-aqueous solvents and, on the other, pulsed electrolysis, particularly chronopotentiometry.

Polarography in non-aqueous solvents is used to study compounds which are insoluble or undergo decomposition in water. Furthermore, it is used in investigations involving protic and aprotic systems more or less similar to water. As regards water-insoluble compounds, aromatic disulphide–mercaptan systems have been studied in benzene–methanol mixtures, while related ligands of the type of dithiocarboxylates have been studied in water, acetonitrile (AN), and propylene carbonate (PC).[198] They were reduced to polymeric thioaldehydes, which, however, undergo certain side reactions.

Among metal complexes which do not dissolve in water without decomposition, the sandwich aromatic complexes of chromium have been studied in benzene–methanol mixtures, where the Cr^0/Cr^+ redox process approaches closely polarographic reversibility and is sensitive to the influence of substituents in aromatic ligands[202-205]. The tetrahedral transition metal halide complexes $[MX_4]^{2-}$ are fully hydrolysed in water, but can be investigated either in dimethylformamide[206,207] or in acetonitrile[208]. The properties of copper(II) complexes, which react with mercury at the electrode but exhibit normal properties at a platinum microelectrode, are of special interest[207,208].

In studies on polarography, continued at the present time and associated with synthetic research, the most suitable solvents proved to be acetonitrile and propylene carbonate. Dithiocarboxylate ligands and complexes have been investigated in propylene carbonate[198], while the properties of halogenomercury complexes[209] and mixed halogenophosphinecobalt(II) complexes[210,211] have been investigated in acetonitrile. A particular advantage of acetonitrile as a solvent is that it can be used simultaneously in both polarographic and potentiometric studies (the latter with Mo or W indicator electrodes), as well as spectrophotometric measurements. The joint use of the three methods enumerated makes it possible to describe quantitatively the complex equilibrium established in the systems mentioned above, incorporating mercury and cobalt complexes[209-212].

The limited applicability of the usual polarography led investigators to employ in many instances other electrochemical methods in order to investigate electrode processes involving metal complexes. The most successful attempt was that undertaken at the Rome school to employ pulsed d.c. electrolysis or transitometry. Catalytic reduction reactions of metal complexes have been studied both experimentally {for example in the $[Ni(CN)_4]^{2-}$ system}[213] and theoretically. For this purpose, a relation was established between the transfer time and the kinetic parameters for certain complex catalytic systems[214,215] and electrolytic reduction was studied after reversing the current[216].

The dependence of the current density on the concentrations of ligands and complexes has been determined with the aid of another important parameter, measured in pulsed d.c. electrolysis (the initial reduction potential) by recording the voltage–current characteristics for a non-polarised current. The parameter is used to obtain information about the mechanisms of the electrode reactions of certain metal complexes[217], for example, the electrode reactions of cadmium(II) and zinc[218], nickel(II) and copper(II),[219,220] and iron(II) and iron(III),[221] and especially in the study of ligand and (or) proton association or dissociation reactions in the bulk of the solution before discharge at the electrode. The method suffers from limitations, particularly in the case of very high rates of charge transfer at the electrode. Despite this, it has been used in many studies and has made it possible to identify a number of interesting electrochemically active complexes, frequently different from the compounds formed at equilibrium in solution[218-221].

IX. OTHER METHODS

The magnetic resonance methods have usually been employed as auxiliary procedures in relation to the more common methods, most of which have already been described in preceding sections. From the standpoint of microwave spectroscopy, studies on nuclear quadrupole resonance (NQR) of the halogens in halogeno-complexes, for example NQR of chlorine in certain crystalline tetrachloroureas, are of special interest[222,223].

Proton magnetic resonance has been used to confirm conclusions concerning the stereochemistry and reactivity of certain sulphur-containing complexes and the corresponding ligands. Dithio-, perthio-, and mixed dithioperthio-complexes of transition metals may be identified with the aid of NMR and their interconversions may be followed[224]. The preferred conformations of certain substituted thioureas, both in the free state and as part of cobalt and zinc complexes, have been determined, which involved calculations on theoretical models of the corresponding structures[225-227]. The knowledge of conformation assisted in its turn in the elucidation of the contribution and role of hydrogen bonds, both intermolecular and intramolecular, which may be formed in metal–urea complexes in large numbers[226,227]. The conclusions reached have been confirmed by infrared spectroscopic data[82] and by X-ray diffraction[83,228]. In particular, it was shown that, for certain pseudotetrahedral dichlorobis(substituted urea)–zinc and –cobalt(II) complexes, the formation of intermolecular hydrogen bonds leads to chain polymerisation and that the resulting structures resemble to some extent the regular arrangements of polypeptide chains[83,228].

Photoelectron spectroscopy has been used on an increasing scale in research by the Rome school in recent years. The possibility of employing X-ray electronic spectroscopy in inorganic chemistry is still controversial as regards the validity of the measured ionisation energies the role of the effects of the solid phase in the determination of corrections to the results, and the factors influencing the true ionisation energy. Despite this, there is no doubt that the method has considerable potential possibilities for both analytical and structural research.

In the present author's studies attention was concentrated on certain aspects of the chemistry of complexes. X-Ray electronic spectroscopy makes it possible (to a greater extent than other methods) to determine the degrees of oxidation of two elements in certain rhodium–molybdenum heteropolyacids[229]. As regards molecular systems containing atoms in a common oxidation state, we investigated certain nickel(II) complexes of dithiocarbazin acid $H_2N-NH-CSSH$ and its derivatives as well as the corresponding free ligands. These are ambident ligands i.e. contain several potential electron donors. Since the degree of their oxidation is known, the change in electron binding energy yields information about the overall atomic charge—a quantity which is of fundamental importance for theoretical coordination chemistry, but is rarely susceptible to direct experimental determination. We were thus able to distinguish electron-donating atoms involved and not involved in complex formation and to obtain a schematic distribution of atomic charges along the complex of the complex[230]. Chromium(II) complexes, metal nitrosyls (particularly rhenium nitrosyls), and platinum acetylides have also been investigated by X-ray electronic spectroscopy.

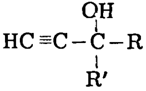
Photoelectron spectroscopy with excitation by ultraviolet light yields more detailed information about the ionisation energies of valence orbitals. A significant limitation of this method is the requirement that the molecules investigated must be in vapour phase. Despite this limitation, the method has found extensive applications in coordination chemistry, where it can yield more extensive and more detailed information about the sequence of energies and the nature of the valence orbitals than the usual methods. The systems investigated in Rome include fluorinated sulphur-containing complexes, mainly perfluorodithiocarboxylates and the corresponding ligands [231], difluorodithiophosphates[232], and particularly thio- and dithio-derivatives of metal β-diketonates, such as nickel(II) bis(dithioacetylacetonate) and similar volatile nickel(II), cobalt(II), copper(II), and zinc complexes[233]. The existence of *d* orbitals adjoining or mixed with ligand orbitals, which differs from the traditional idea of clearly defined, separate, and partly filled electron shells in transition metal complexes, has been observed in these compounds.

X. APPLIED RESEARCH

Although applied research in the Rome school has not been of the type of systematic actively developing investigations, studies have been made on certain systems which are of potential or real applied interest, mainly catalytically active complexes and models for organic catalysis.

Studies of this kind were begun at the end of the 1950's, in collaboration with research workers of Natta's group in Milan in connection with the extensive applications of the Ziegler–Natta catalysts for the polymerisation of olefins. The first attempts were directed towards the elucidation of the structures of the active products of the reactions between transition metal halides (or acetylacetonates) and aluminium alkyls. For example, the formation of labile Cr(O) compounds was established in the reaction between $Cr(acac)_3$ and $AlEt_3$.[234,235] Subsequent investigations were devoted to the determination of the catalytic activities of certain Ziegler–Natta catalysts of the polymerisation reactions of acetylenic hydrocarbons[236-240]. It was found that monosubstituted acetylenes are converted into a mixture of symmetrical and asymmetric trisubstituted benzene derivatives. The yield of aromatic trimers usually depended on the catalyst : cocatalyst ratio. However, when different monomers were employed, the maximum yield did not correspond to the same catalyst : cocatalyst ratio. Linear polymers were also sometimes investigated.

Studies have been likewise carried out on other catalytic systems in order to find simpler reaction conditions. In fact, when catalysts of the Ziegler–Natta type are used, oxygen and water must be completely absent from the system. It was found that triphenylphosphinenickel complexes act as polymerising agents even when the reaction is carried out in solvents containing water and in air[241,242]. In the course of these investigations it was observed that the complex $(n\text{-}Bu_3P)_2NiBr_2$ is a very active catalyst for the trimerisation of α-hydroxyacetylenes having the general formula $HC{\equiv}C-\overset{\displaystyle OH}{\underset{\displaystyle R'}{C}}-R$, pure 1,3,5-trisubstituted benzene derivatives being obtained in very high yields. Asymmetric isomers were not found in the reaction mixture[243].



In order to elucidate the role of transition metals in the mechanisms of catalytic reactions, a series of platinum complexes of bis(triphenylphosphines) were synthesised[244,245] and their catalytic activity was investigated in the polymerisation of phenylacetylene and 2-methylbut-3-yn-2-ol [246,247]. In the presence of platinum complexes monosubstituted alkynes were converted into linear polymers. Complexes having the general formula $[(C_6H_5)_3P]_2Pt(C{\equiv}C-R)_2$, containing the monomer linked by a σ bond to the platinum atom, were identified and isolated from the crude reaction mixture. These complexes may in fact be the active intermediates in the polymerisation reaction. There is evidence that the polymer chain grows as a result of the insertion of the monomer molecule in the Pt–C σ bond.

The Chemistry of 1,5,9-Cyclododecatriene and Syntheses Based on It

L.I.Zakharkin and V.V.Guseva

The methods of synthesis and chemical properties of 1,5,9-cyclododecatriene (the butadiene cyclotrimerisation product), which is manufactured on an industrial scale, are examined; syntheses based on this interesting compound have played a major role in the development of organic chemistry of medium and large rings.
The bibliography includes 406 references.

I. INTRODUCTION

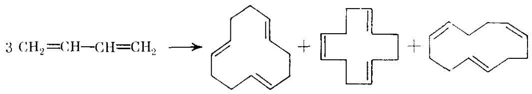
The first studies on cyclododecane and its derivatives were begun in 1926 by Ruzicka and coworkers, but the difficulty of the synthesis of these compounds and of their isolation in a pure form hindered the development of their chemistry.

In 1954, Reed reported for the first time[1] the synthesis of a cyclic butadiene trimer in the presence of bis(triphenylphosphine)nickel dicarbonyl, but it was not until Wilke's study[2] of the cyclotrimerisation of butadiene in the presence of organometallic complex catalysts that 1,5,9-cyclododecatriene (1,5,9-CDT) became readily available and vigorous development of the chemistry of this compound and its industrial use were initiated.

cis,trans,trans-1,5,9-CDT is manufactured at present on a large scale in many countries. The following products obtained from 1,5,9-CDT are of major technical importance: ω-dodecalactam—the monomer for the synthesis of nylon-12; decane-1,10-dicarboxylic acid—the monomer for the synthesis of polyamides and polyesters and a substitute of sebacic acid in the synthesis of plasticisers and lubricating oils; 1,12-diaminododecane—the monomer for the synthesis of polyamides; 1,2,5,6,9,10-hexabromocyclododecane, which is used as an additive to polymers in order to render them incombustible; cyclododecanone which is used as the initial compound for the synthesis of valuable perfumes—cyclopentadecanone (exaltone) and the lactone of ω-hydroxypentadecanoic acid (tibetolide).

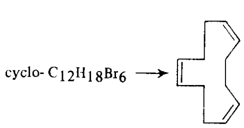
II. SYNTHESIS AND CHEMICAL REACTIONS OF 1,5,9-CYCLODODECATRIENE ISOMERS

It has now been established that the cyclotrimerisation of butadiene to 1,5,9-CDT proceeds in catalytic systems containing the following transition metals as components: titanium, chromium, nickel, and manganese. *trans,trans,trans*-1,5,9-CDT (I), *cis,trans,trans*-1,5,9-CDT (II), and *cis,cis,trans*-1,5,9-CDT (III) have been obtained in the presence of these catalysts; the ratios of the yields of these products depend on the nature of the transition metal, the ligands in the catalytic system, and the reaction conditions:



(I) (II) (III)

The fourth possible isomer—*cis,cis,cis*-1,5,9-CDT (IV)—is not formed in the catalytic trimerisation of butadiene. It has been obtained by the dehydrobromination of hexabromocyclododecane—the product of the addition of three bromine molecules to (I):[3]

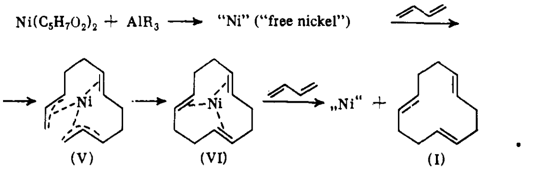


(IV)

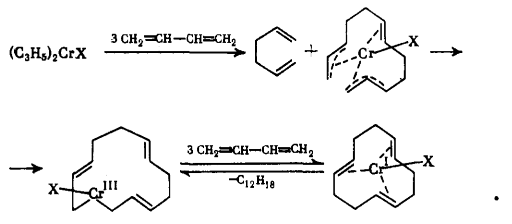
The most effective catalysts for the synthesis of 1,5,9-CDT are systems containing various titanium compounds [$TiCl_4$,[4-20] $TiBr_4$,[21] $Ti(OR)_4$,[22,23] $(RO)_2TiO$,[24] $TiCl_{4-n}(OR)_n$, $TiCl_{4-n}(OCOR)_n$,[25-28] and the complex $C_6H_6.TiCl_2.Al_2Cl_6$ [13,29,30]] in combination with reducing agents such as trialkylaluminium or aluminium alkyl halides, calcium hydride, and dialkylaluminium hydride. The reaction proceeds only in solution in aromatic hydrocarbons with formation of 1,5,9-CDT in 80–90% yield. The 1,5,9-CDT obtained is a mixture of two isomers: 3–4% of (I) and 96–97% of (II). A mixture containing 67% of (I) and 33% of (II) is formed in the catalytic system containing poly(butyl orthotitanate) and $(C_2H_5)_2AlCl$.[31]

Catalytic systems containing chromium and manganese [$(C_5H_7O_2)_2Cr$, CrO_2Cl_2 or $CrO_3 + (C_2H_5)_3Al$,[4,5,12] $CrCl_3 + (iso\text{-}C_4H_9)_3Al$,[10-12,32,33] and $(C_5H_7O_2)_2Mn + (C_2H_5)_3Al$ [34]] lead to a mixture of approximately 60% of (I) and approximately 40% of (II). A mixture consisting of 65–80% of (I), 7–9% of (II), 9–11% of (III), 7–9% of vinylcyclohexene, and 4–6% of 1,5-cyclo-octadiene is formed in the presence of nickel catalysts [$Ni(C_5H_7O_2)_2 + C_2H_5OAl(C_2H_5)_2$,[12,35,36] $NiX_2 + (iso\text{-}C_4H_9)_3Al$,[37] $(cyclo\text{-}octadiene)_2.Ni(O)$ [30,36] and cyclododecatriene.Ni(O) [35]]. The mixture composition varies with reaction temperature.

There have been numerous patents for catalytic systems containing nickel[37,38–43]. The mechanism of the reaction in the presence of nickel catalysts has been established by Wilke and coworkers[33,35,44–46]. It includes the following stages:



When $Ni(C_5H_7O_2)_2$ is reduced by an organoaluminium compound, "free" nickel is formed, which trimerises butadiene to the intermediate π-allyl complex of nickel (V); ring closure of (V) results in the formation of the π-nickel complex (VI). Treatment with butadiene leads to the displacement of 1,5,9-CDT from this complex. Complexes (V) and (VI) have been isolated and their structures have been determined by X-ray diffraction[47,48] and confirmed by certain reactions[31,35,44,45]. When complex (VI) is acted upon by *cis,cis,cis*-1,5,9-CDT (IV), *trans,trans,trans*-1,5,9-cyclododecatriene (I) is displaced from it and the complex (IV).Ni(O) is formed[45]; the latter readily reacts with carbon monoxide to give $Ni(CO)_4$ and compound (IV). A mechanism has been proposed for the trimerisation of butadiene in the presence of chromium catalysts[33] in which the valence state of chromium changes continuously from +1 to +3:



It has been shown[30,49] that in the presence of titanium catalysts the active centre for the trimerisation of butadiene is a complex in which titanium is present in the bivalent state:

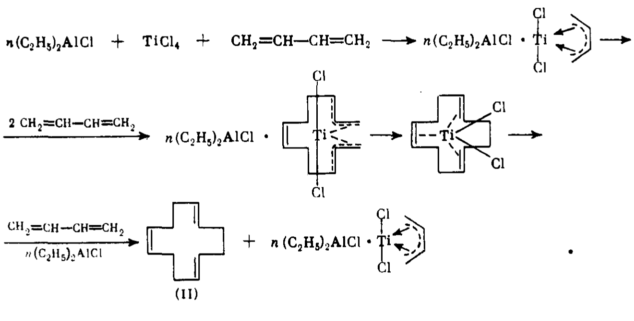


Table 1 presents the best known catalytic systems in the presence of which the trimerisation of butadiene to 1,5,9-CDT isomers takes place with a high yield.

Among the four 1,5,9-CDT isomers, the *trans,trans,trans*-isomer (I)[50] and the *cis,trans,trans*-isomer (II), which are readily obtainable in the presence of the above catalysts, have been studied in greatest detail. The presence of three non-conjugated double bonds in the 1,5,9-CDT molecule makes this system capable of undergoing many reactions. Among them the most interesting are those involving *cis–trans* isomerisation. When (II) is illuminated with ultraviolet light, a mixture of (I) and (III) is formed[51].

Table 1.

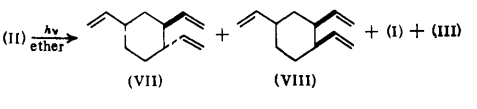
Catalytic systems	Yield of 1,5,9-CDT, %	Isomers formed (the relative percentage contents are indicated in brackets)	Refs.
$TiCl_4 + (C_2H_5)_2AlCl$	91	I (97) + II (3)	8, 9, 10
$TiCl_4 + (C_2H_5)_3Al_2Cl_3$	88	II (98) + I (2)	8, 9, 12
$CrO_2Cl_2 + (C_2H_5)_3Al$	70	I (59) + II (41)	10
$CrCl_3 + (C_2H_5)_3Al$	80	I + II	8
$CrCl_3 + (iso\text{-}C_4H_9)_3Al$	86	I (60) + II (40)	8, 9
$Ni(C_5H_7O_2)_2 + (C_2H_5)_2AlOC_2H_5$	81	I (80) + II (9) + III (11)	10
$NiX_2 + (iso\text{-}C_4H_9)_3Al$	80	I+II	37
$[(C_8H_{12})_2Ni]$	87	I+II	39

Subsequently it was shown that each of the four isomers undergoes cis–trans isomerisation giving rise to the same equilibrium mixture consisting of all four isomers (I), (II), (III), and (IV).[52] It has been established[53] that thermodynamic stability decreases in the sequence (I) > (II) > (III). Data for the photochemical isomerisation of the isomers in benzene are presented in Table 2.

Table 2. Composition of the mixture of 1,5,9-CDT isomers in photochemical isomerisation[53].

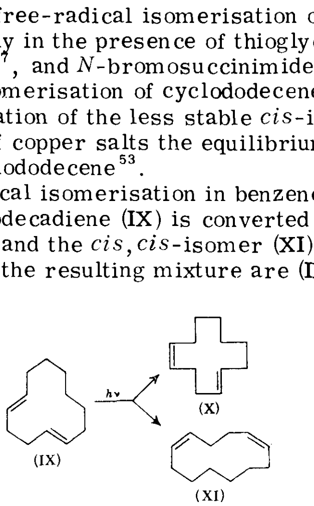
Initial olefin	Irradiation time, h	Proportions of isomers in product, %		
		(I)	(II)	(III)
(I)	17	24	43	33
(II)	17	11	55	34
(III)	100	1	21	78

Table 2 shows that (III) isomerises much more slowly than isomers (I) and (II). The proportions of the isomers also depend on the selected sensitiser. In the presence of aromatic ketones and quinones, isomer (II) predominates in the resulting mixture, while the use of aliphatic ketones leads to isomer (III). Thus the readily available isomer (II) may be easily converted into (I) and (III) on irradiation of a benzene solution containing acetophenone or acetone. After prolonged irradiation of a mixture of (I), (II), and (III), 43% of *trans,trans*-2,6-divinyl-*cis*-bicyclo[3,3,0]octane was obtained together with 1,5,9-CDT isomers[52]. When (II) in an ethereal solution is irradiated, a mixture containing 25% of (I), 29% of (III), and isomeric 1,2,4-trivinylcyclohexanes [12% of (VII) and 1% of (VIII)] is formed[54]:

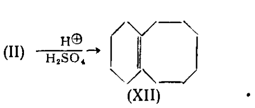


Thermal isomerisation of (II) at 450°C leads only to isomeric 1,2,4-trivinylcyclohexanes[55]. In the presence of toluene-*p*-sulphinic acid a mixture of 80–85% of (I) and 15–20% of (II) is formed from the initial (I)–(III) mixture on heating to 90° C.[53,56] Copper salts are active catalysts of the *cis–trans* isomerisation of the double bonds in (I), (II), and (III).[53] The free-radical isomerisation of (II) to (I) takes place readily in the presence of thioglycolic acid[57], benzoyl peroxide[57], and *N*-bromosuccinimide[57,58]. The photochemical isomerisation of cyclododecenes in benzene leads to the formation of the less stable *cis*-isomer[53]. In the presence of copper salts the equilibrium is also displaced to *cis*-cyclododecene[53].

On photochemical isomerisation in benzene, *trans, trans*-1,5-cyclododecadiene (IX) is converted into the *cis, trans*-isomer (X) and the *cis,cis*-isomer (XI); the ratios of the isomers in the resulting mixture are (IX) : (X) : (XI) = 17 : 55 : 28[59]:

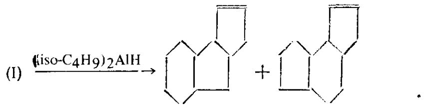


In the presence of acid reagents (II) undergoes intramolecular cyclisation, which leads to products with bicyclic and tricyclic structures. Thus a mixture of hydrocarbons in which $\Delta^{1,6}$-bicyclo[4,6,0]dodecene (XII) predominates, is formed from (II) on treatment with 80% sulphuric acid in the cold[60]:

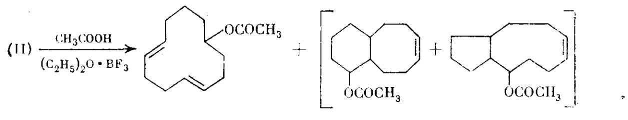


A mixture of acenaphthene and decahydroacenaphthene is formed on heating (II) with polyphosphoric acid[61].

The isomerisation of (I) takes place readily in the presence of (iso-$C_4H_9)_2$.AlH on heating to 200° C, giving an 85% yield of a mixture of tricyclo[6,4,0,$0^{3,7}$]dodec-4-ene and tricyclo[7,3,0,$0^{3,7}$]dodec-4-ene[62]:

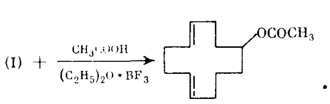


Bicyclic products were formed after the addition of acetic acid and hydrogen chloride to (II)[63]:

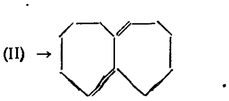


The reaction apparently proceeds both at the *cis*-double bond, giving rise to the usual addition products, and at the *trans*-double bond, giving rise to bicyclic products.

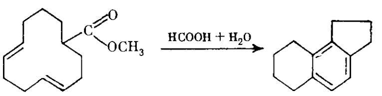
When acetic acid and hydrogen chloride react with (I), only addition products retaining the molecular skeleton are formed[63]:



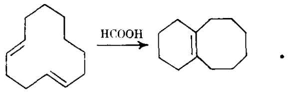
Bicyclo[5,5,0]dodeca-1,7-diene is formed from (II) in the presence of Na/Al_2O_3,[64] $Co_2(CO)_8$,[65] and the lithium derivative of ethylenediamine[66]:



When methyl *trans, trans*-4,8-cyclododecadiene-carboxylate is treated with 90% formic acid, 2,3,6,7,8,9-hexahydro-1H-benz[*e*]indene is produced[67].

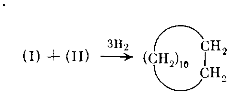


trans, trans-1,5-cyclododecadiene gives rise to bicyclo-[6,4,0]dodecene[67]:



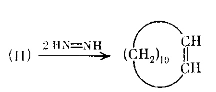
III. SYNTHESES BASED ON *cis, trans, trans*- AND *trans, trans, trans*-1,5,9-CYCLODODECATRIENES

In this section of the review we shall consider the reactions of the most readily available 1,5,9-CDT isomers—the *trans, trans, trans*-isomer (I) and the *cis, trans, trans*-isomer (II). The majority of studies on the hydrogenation of 1,5,9-CDT in cyclododecane are described in the patent literature. The two isomers (I) and (II) are quantitatively hydrogenated in the presence of platinum, palladium, and Raney nickel[68-70]:



In order to obtain large amounts of cyclododecane, (I) and (II) are hydrogenated at elevated temperatures in the presence of Ni/Al_2O_3 or Ni/Cr_2O_3.[5,68-72] Nickel, cobalt, and copper salts deposited on SiO_2 or Al_2O_3 in the presence of NaF are effective catalysts of the reduction[73,74]. The rates of hydrogenation of the two isomers are virtually the same. In the presence of these catalysts, all three double bonds are hydrogenated at virtually the same rates and one cannot therefore carry out a selective hydrogenation. When one mole of (II) is hydrogenated with two moles of hydrogen in the presence of palladium, a mixture consisting of cyclododecene, cyclododecadiene, and cyclododecanes is formed[68,75]. The hydrogenation of (I) and (II) to cyclododecane in the presence of homogeneous catalysts has been described in a number of patents: $(Ph_3As)_2(CO)RhCl$ + $AlCl_3$,[76] $Ni(C_5H_7O_2)_2$ + $LiAlH_2(OCHMeC_2H_5)_2$,[77] $Ti(OBu)_4$ + $(C_2H_5)_2AlCl$, and $Cr(C_5H_7O_2)_2$ + $(C_2H_5)_2AlCl$ + $(C_2H_5)_3Al$.[79]

The selective hydrogenation of (I) and (II) to cyclododecene, which gives rise to great possibilities for the synthesis of many products of practical importance, is of considerable interest. It has been shown that, when (II) is acted upon by di-imide, the *trans*-double bonds are reduced initially and *cis*-cyclododecene is formed in a high yield[80,81]:

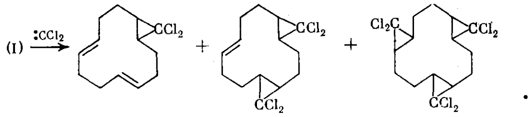


The success of the catalytic hydrogenation of (II) to cyclododecene depends primarily on the nature of the catalyst. The use of relatively inactive heterogeneous catalysts makes it possible to stop the hydrogenation at the stage corresponding to the addition of two moles of hydrogen[82-87]. Studies on a series of catalysts (Rh, Pd, and Ru on Al_2O_3)[88,89] have shown that the hydrogenation of (I) and

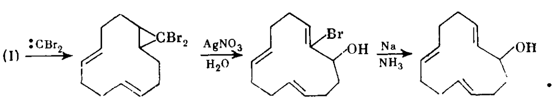
(II) to cyclododecene takes place most selectively in the presence of rhodium. The catalysts can be arranged in the following sequence in terms of decreasing yields of cyclododecene: Ph > Pd > Ru > Pt. The trichlorotripyridinerhodium +$NaBH_4$ catalytic system proved to be the most effective in the hydrogenation (II) to cyclododecene[90]. In the presence of the homogeneous catalyst $[Co(CO)_3.PR_3]_2$[83,84,91] or $(R_3P)_2(CO)_2RuCl_2$[92,93] (II) gives a high yield of a mixture of *cis*- and *trans*-cyclododecenes (96–98%) and in addition 1% of 1,5-cyclododecadiene and 0.5% of cyclododecane are formed. Hydrogenation of (II) in the presence of 7% $PtCl_2$ in a $(C_2H_5)_4NSnCl_2$ melt at 160°C and 100 atm of H_2 leads to 2% of (II), 10% of cyclododecadiene, and 87% of cyclododecene[94].

The addition of halogens and halogenocarbenes, oxidation, hydroboration, and carboxylation are other reactions involving double bonds in (I) and (II). When (I) and (II) are brominated, a mixture of dibromocyclododecadiene, tetrabromocyclododecene, and hexabromocyclododecane is formed[68,95,96]. However, it has been stated in patents[97,98] that, when one mole of (I) is brominated with two moles of Br_2 in the presence of sodium acetate, tetrabromocyclododecene is formed quantitatively. It has been shown[68] that hexabromocyclododecane obtained from (II) has a melting point of 194–195°C, while that obtained from (I) has a melting point of 177–178°C. These bromo-derivatives are different geometrical isomers. On recrystallisation from benzene, the hexabromocyclododecane obtained from (I) gives rise to the clathrate compound $(C_{12}H_{18}Br_6)_2C_6H_6$.[75] Hexabromocyclododecane has found an application as an additive to polymeric materials in order to render them incombustible.

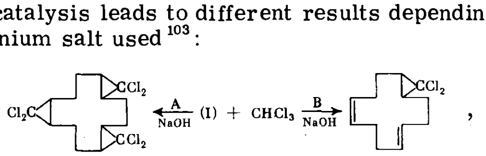
The addition of halogenocarbenes to (I) and (II) has been investigated in detail. The addition of $:CCl_2$ to (II) takes place preferentially at the *trans*-double bond[99]. When $:CHCl$[100] and $:CCl_2$[101] act on (I), a mixture of three products is formed:



Treatment of (I) with $:CBr_2$ gives a high yield of dibromobicyclotridecadiene[102], which on treatment with $AgNO_3$ in water is converted into bromohydroxycyclotridecatriene; on treatment with sodium in liquid ammonia, the latter is converted into hydroxycyclotridecatriene:



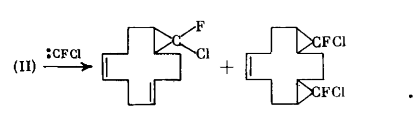
The addition of $:CCl_2$ to (II) under the conditions of phase-transfer catalysis leads to different results depending on the ammonium salt used[103]:



(XIII)

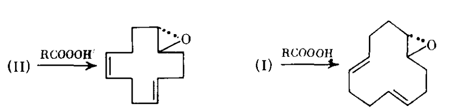
where A = cetyltrimethylammonium bromide and B = trialkyl-β-hydroxyethylammonium bromide. When the diene (XIII) is hydrogenated, the product is 13,13-dichlorobicyclo[10,1,0]tridecane, from which cyclotridecanone was obtained[104]:

The reaction of (II) with :CFCl takes place at the *trans*-double bonds with formation of two addition products[105]:



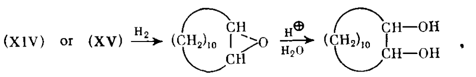
The addition of $:CHOCH_3$ to (I) entails the formation of only *trans*-13-methoxybicyclo[10,1,0]trideca-*trans*,*trans*-4,8-diene, while a mixture of diastereoisomers is formed from (II) under these conditions[106]. The reaction of $:CCl_2$ with *cis*,*trans*-1,5-cyclododecadiene takes place unambiguously, resulting in the formation of *trans*-13,13-dichlorobicyclo[10,1,0]tridec-4-ene(*cis*).[108] A study of the rates of addition of :CHCl,[100] $:CBr_2$,[107] and $:CHOCH_3$[106] to *cis*- and *trans*-cyclododecenes showed that the reaction involving the *trans*-double bond is faster.

The oxidation of (I) and (II) to epoxycyclododecadiene, further transformations of which lead to interesting and valuable products, is preparatively important. The epoxidation of (I) and (II) has been carried out with peracetic, perbenzoic, and perphthalic acids, as well as a mixture of H_2O_2 and CH_3COOH in the presence of a cation-exchange resin[5,11,68,109-114]. In the epoxidation of (II) the *trans*-double bond reacts first with formation of the epoxydiene (XIV)[68]:

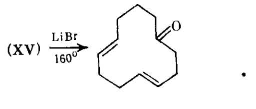


(XIV) (XV)

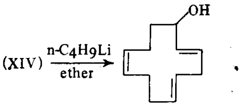
It has been established[112] that monoepoxidation of (II) results in the formation of 92% of the *trans*-epoxide and 7% of the *cis*-epoxide. The epoxidation of (I) yielded the epoxydiene (XV). The oxidation of (I) and (II) by atmospheric oxygen in the presence of boric acid or its esters leads to the formation of epoxycyclododecadiene together with 2,6,10-cyclododecatrienol[115]. The synthesis of 5,6 : 9,10-diepoxycyclododecene, 5,6 : 9,10-diepoxycyclododecane[116], 1,2 : 5,6 : 9,10-triepoxycyclododecane[117], and epoxycyclododecene[118,119] has been described in patents. The opening of the epoxy-rings of these compounds results in the formation of the corresponding diols, tetraols, and hexaols[68,74,120-122]; thus (XIV) and (XV) give rise to the corresponding *trans*-dihydroxycyclododecadienes[68]. The reduction of double bonds in (XIV) and (XV) leads to *trans*-epoxycyclododecane and subsequent opening of the epoxy-ring gives rise to *cis*-1,2-cyclododecanediol[68,123]:



In the presence of catalytic amounts of Group I and II metal halides epoxycyclododecadienes readily isomerise to the corresponding ketones[124,125]:

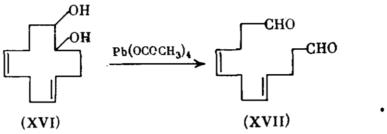


Two isomeric unsaturated ketones with different positions of the keto-group in relation to the C=C double bonds are formed from (XIV).[125] When (XIV) is acted upon by (iso-$C_4H_9)_2AlH$,[126] n-C_4H_9Li, or C_4H_9MgBr [127] isomerisation with formation of unsaturated alcohols takes place:

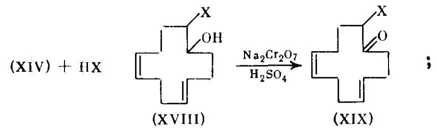


The isomerisation of the epoxide and the formation of cyclododecanone[11,75,110] together with cyclododecanol are observed in the catalytic hydrogenation of (XIV) or (XV) in the presence of nickel catalysts (Raney nickel, Ni/Al_2O_3, Ni/Cr_2O_3) at 120–150°C.

When (II) is oxidised by OsO_4 or $KMnO_4$, the reaction proceeds primarily at the *trans*-double bond with formation of the corresponding *trans*-diol and *trans,trans*-tetraol[128]. When cyclododecadienediol (XVI) was oxidised, the unsaturated dialdehyde (XVII) was obtained[129]:

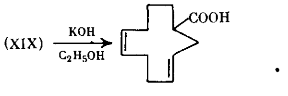


The opening of the epoxy-ring in (XIV) and (XV) takes place readily under the influence of hydrochloric and hydrobromic acids with formation of the corresponding halogenohydrins (XVIII)[114]:

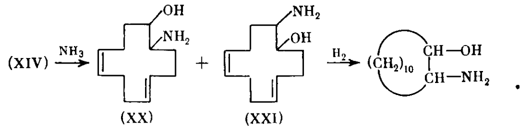


X = Cl or Br.

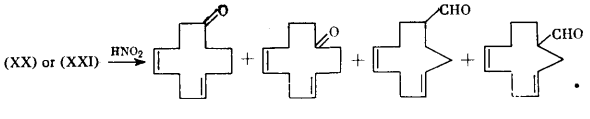
When the halogenohydrins (XVIII) are oxidised by the chromic acid mixture, it is possible to obtain high yields of the unsaturated halogeno-ketones (XIX). The halogenohydrins and the halogeno-ketones obtained from the epoxide (XIV) consist of a mixture of isomers with different positions of the OH group, the halogen atom, and the carboxy-group relative to the *cis*- and *trans*-double bonds in the ring[114]. Cycloundecadienecarboxylic acid has been obtained from the ketones (XIX) by the Favorskii reaction[114]:



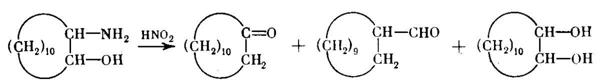
On heating with an aqueous ammonia solution, the epoxide (XIV) gives rise to a mixture of two isomeric *cis*-amino-alcohols (XX) and (XXI)[130], which form *cis*-1,2-aminocyclododecanol on hydrogenation:



When (XX) and (XXI) were deaminated, a mixture of isomeric cyclododecadienones and formylcycloundecadienes was isolated[130]:

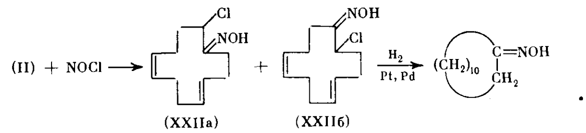


Regardless of the configuration of the initial compound, the deamination of *cis*- and *trans*-2-aminocyclododecanols leads to a mixture of cyclododecanone, formylcycloundecane and *cis*-1,2-cyclododecanediol in equal proportions[130]:

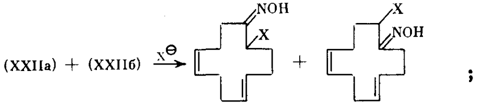


When α-aminocyclododecanecarboxylic acid is deaminated, α-hydroxycyclododecanecarboxylic acid is obtained in a quantitative yield[131].

Nitrosyl chloride readily adds to (II) at a *trans*-double bond with formation of two products (XXII, a and b)[132–140]:

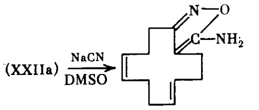


The hydrogenation of chloro-oximes at atmospheric pressure in the presence of platinum and palladium catalysts yields cyclododecanone oxime as the main product[132,133,135]. Several patents[141–144] and another communication[140] describe chlorine exchange reactions involving α-chlorocyclododecadienone oxime. When (XXIIa) and (XXIIb) are treated with nucleophiles, products resulting from the substitution of a chlorine atom are obtained in a high yield[142]:

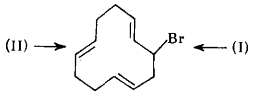


X = C_2H_5O, CH_3O, C_2H_5S, CH_3COO, or R_2N.

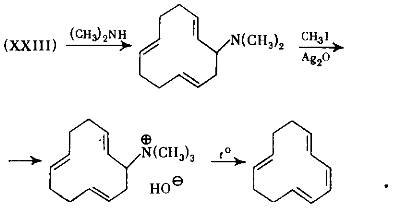
The reaction of (XXIIa) with sodium cyanide in dimethyl sulphoxide (DMSO) leads to the formation of the corresponding aminoisoxazoles[140], for example:



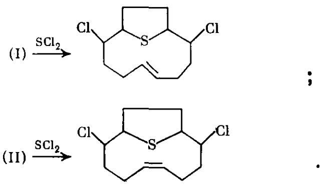
Allylic bromination of (II) by *N*-bromosuccinimide proceeds with isomerisation involving the *cis*-double bond and leads to bromocyclododecatriene (XXIII), which is also obtained on allylic bromination of (I)[58]:



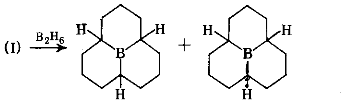
Treatment of the bromo-derivative (XXIII) with ammonia, dimethylamine, and potassium acetate gives rise to substitution products[58], for example:



Acylation of (II) via the Kondakov reaction yields a mixture of 1-acyl-2,5-9- and 1-acyl-1,5,9-cyclododecatrienes[145]. Reactions involving the addition of sulphur dichloride to (I) and (II) and leading to dichlorothiabicyclotridecenes are of interest[146,152]:

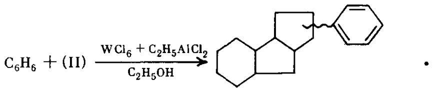


The chlorine atoms in these compounds are readily replaced by cyano- and acetoxy-groups[152]. The hydroboration of (II) gives rise to a mixture of the *cis*- and *trans*-isomers of 9*b*-boraperhydrophenalene (XXIV, a and b) together with 9*b*-boraperhydrobenzo[*ed*]azulene. The latter is converted into *cis*-9*b*-boraperhydrophenalene on heating[147,148]:



(XXIVa) (XXIVb) .

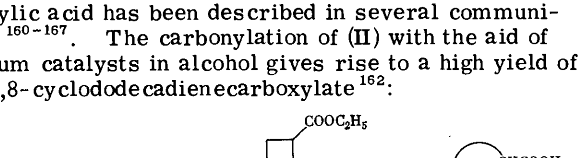
(XXIVa) readily reacts with LiH to form an addition product, which is an effective stereoselective reducing agent for cyclic ketones[149,150]. Trichlorosilane and dichloromethylsilane add to (II) preferentially at the *trans*-double bond in the presence of platinum[151]. When (II) is treated with hydrogen bromide in the presence of benzoyl peroxide, 9-halogeno-1,5-cyclododecadiene is obtained[154]. The reaction of (II) with nitrogen oxides has been described[155]. When (II) reacts with benzene in the presence of the $WCl_6 + C_2H_5AlCl_2 + C_2H_5OH$ system, phenyltricyclo$[6,4,0,0^{2,6}]$dodecane is formed[156]:



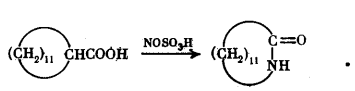
Incomplete ozonisation of (I) and (II) with subsequent cleavage of the ozonide leads to deca-3,7-diene-1,10-dicarboxylic acid and the corresponding dialdehyde[157,158]:

$$\text{(I) or (II)} \xrightarrow{O_3} HOOC(CH_2)_2CH{=}CH(CH_2)_2CH{=}CH(CH_2)_2COOH \ .$$

It has been established that ozone attacks (I) and (II) at the same rate[159]. The carbonylation of (I) and (II) under the influence of CO in the presence of metal (Ni, Co) carbonyls and palladium complexes with formation of cyclododecanecarboxylic acid has been described in several communications[160-167]. The carbonylation of (II) with the aid of palladium catalysts in alcohol gives rise to a high yield of ethyl 4,8-cyclododecadienecarboxylate[162]:

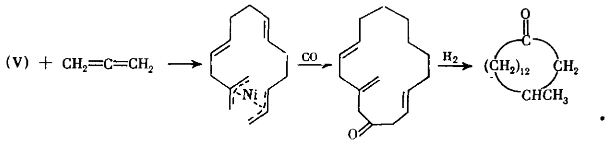


When cyclododecanecarboxylic acid is acted upon by nitrosylsulphuric acid, ω-dodecalactam is obtained in a high yield[168,169]:

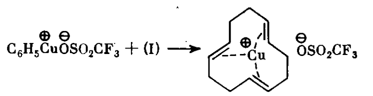


Certain other reactions of cyclododecanecarboxylic acid have been described[170,171]. (I) and (II) react on heating with maleic anhydride to form 1 : 1 adducts[172-174]. The condensation of (II) with cyclopentadiene has been described[175].

Metal complexes of (I) and (II) are known. A π-allyl complex of (V), which reacts with allene, has been described[176,177]. Subsequent reactions of the product lead to the synthesis of DL-muscone:



π-Complexes of palladium $(C_{12}H_{17-19}PdCl)_2$[178] and copper[179,180] have been obtained and a copper complex, synthesised by the reaction[181,182]



has been synthesised.

When a heptane solution of (I) is refluxed with bis(trimethylgermyl)tetracarbonylruthenium, a mixture of products with different structures is formed[183]. The reaction of (I) with dodecacarbonyltriruthenium also leads to a mixture of products having different compositions[184]:

$$\text{(I)} + Ru_3(CO)_{12} \rightarrow HRu_3(CO)_9(C_{12}H_{15}) + HRu_3(CO)_9(C_{12}H_{17}) + \\ + HRu(CO)_7(C_{24}H_{34}) + Ru_4(CO)_{10}(C_{12}H_{16}) \ .$$

Analogous complexes have been obtained for rhodium[185,186], iridium[187], nickel[40,48], and iron[188].

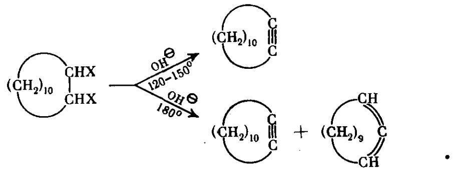
Silver nitrate forms with (I) three types of adducts in which one, two, or three *trans*-double bonds are coordinated to the silver ion[56,68,189]:

$$C_{12}H_{18}\cdot AgNO_3, \ C_{12}H_{18}\cdot 2AgNO_3, \ C_{12}H_{18}\cdot 3AgNO_3.$$

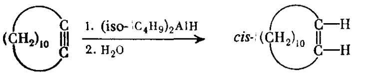
When (II) reacts with a silver ion, only the two *trans*-double bonds are coordinated, while the *cis*-double bond is unaffected[68,189].

IV. SYNTHESES BASED ON *cis*- AND *trans*-CYCLODODECENES

Several methods for the synthesis of *cis*- and *trans*-cyclododecenes (XXV) and (XXVI) are known. It was noted above that they are obtained on selective hydrogenation of (I) and (II)[83,84,91-94] in the presence of homogeneous catalysts or when (II) is acted upon by di-imide[80]. A mixture of (XXV) and (XXVI) is formed when HCl is eliminated from chlorocyclododecane in the presence of iron-containing catalysts[190]. Dehalogenation of 1,2-dichloro- or 1,2-dibromo-cyclododecane by sodionaphthalene or sodiobiphenyl gives a 90% yield of a mixture of (XXV) and (XXVI)[191]. When 1,2-dihalogenocyclododecanes are heated in the presence of alkalis at 150°C, only cyclododecyne is formed[192-194]. On raising the temperature to 180°C, a mixture of 28% of 1,2-cyclododecadiene and 72% of cyclododecyne was isolated[193]:

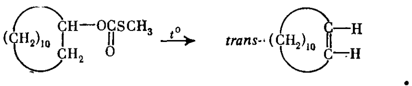


An analogous mixture was obtained after double dehydrobromination of dibromocyclododecane with alcoholic alkali[130]. When cyclododecyne is reduced by (iso-C_4H_9)$_2$.AlH, mainly 6-cyclododecene is formed[193]:



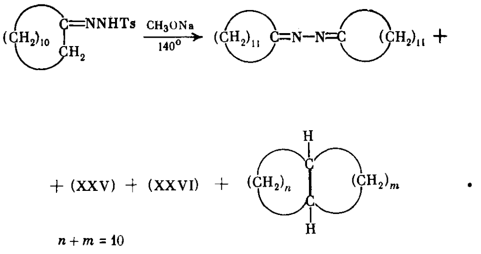
(XXV)

A mixture of 90% of *cis*- and 10% of *trans*-cyclododecyne is formed on decomposition of cyclododecenone semicarbazone by alkoxides at 180–240°C.[195,196] Pyrolysis of cyclododecyl acetate at 550°C leads to a mixture of isomers (XXV) and (XXVI) in proportions of 1 : 5.[197] When (XXV) or (XXVI) is heated in acetic acid at 80–130°C, *cis–trans* isomerisation takes place with formation of an equilibrium mixture containing approximately equal amounts of (XXV) and (XXVI)[197]. Contrary to the Chugaev rule, the decomposition of *O*-cyclododecyl *S*-methyl thiocarbonate gives rise to *trans*-cyclododecene[130]:

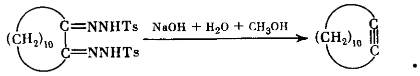


(XXVI)

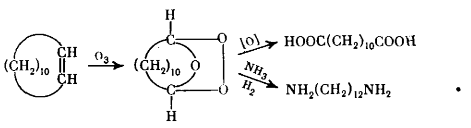
When cyclododecanol was heated to 250–270°C in the presence of toluene-*p*-sulphonic acid, a high yield of cyclododecene was obtained[198]. The reaction of cyclododecene with *N*-bromosuccinimide and subsequent dehydrobromination of the product in pyridine or quinoline result in the formation of 1,3-cyclododecadiene[199]. The dehydration of 6-hydroxy- or 6-acetoxy-cyclododecanone in the presence of $Zn_3(PO_4)_2$ and Fe_2O_3, leading to cyclododec-5-en-1-one, has been described. In the presence of alkyllithium in tetrahydrofuran (THF), cyclododecanone *N,N*-ditosylhydrazone decomposes to form a mixture of *cis*- and *trans*-cyclododecene and cyclododecanone[201]. When cyclododecanone tosylhydrazone is heated in the presence of sodium methoxide, the decomposition leads mainly (to the extent of 60%) to cyclododecanone azine[202]:



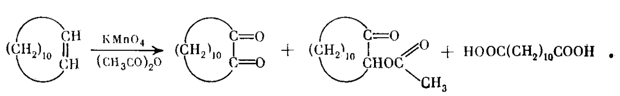
On photolysis of 1,2-cyclododecanedione bistosylhydrazone in an alkaline solution, cyclododecyne was isolated in 53% yield[203]:



Ozonisation with subsequent conversion into decane-1,10-dicarboxylic acid[204–206] and 1,12-diaminododecane[207] is an important reaction of cyclododecene:

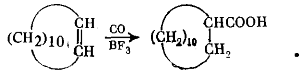


When cyclododecene is oxidised by nitric acid in the presence of ammonium vanadate, considerable amounts of nonane-1,9-dicarboxylic acid are formed together with decane-1,10-dicarboxylic acid[208]. Catalytic oxidation of cyclododecene by hydrogen peroxide in the presence of Re_2O_7 takes place with dissociation of the C=C bond and yields decane-1,10-dicarboxylic acid[209]. Oxidation with potassium permanganate in acetic anhydride leads to 1,2-cyclododecanedione (48%) and other products[210]:

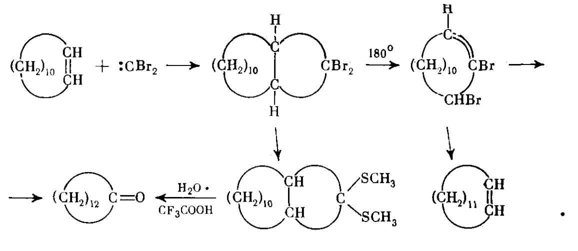


In an alkaline medium in the presence of catalytic amounts of benzyltriethylammonium chloride, *trans*-1,2-cyclododecanediol is formed in 50% yield[211].

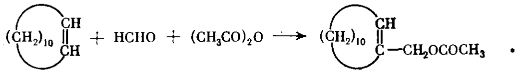
Cyclododecanecarboxylic acid has been obtained from cyclododecene by the Koch reaction[167]:



Dibromocarbene adds smoothly to cyclododecenes with formation of 13,13-dibromobicyclo[10,1,0]tridecane, from which cyclotridecanone[212,213] and cyclotridecene[212] were obtained:

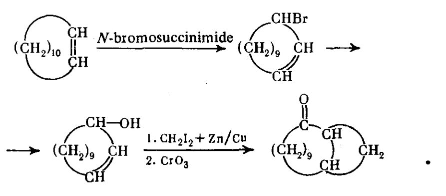


Metathesis of cyclododecene in the presence of the WCl_6 + $C_5H_5AlCl_2$ system yielded unsaturated cyclic hydrocarbons containing 24, 36, and 48 carbon atoms in the ring[214]. The condensation of cyclododecene and (II) with formaldehyde has been described[215]:

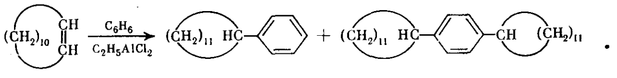


When cyclododecene reacts with paraformaldehyde, *trans*-bicyclo[10,3,0]-2-oxa-14-pentadecene is formed[216].

trans-Bicyclo[10,1,0]-2-tridecanone has been obtained from cyclododecene[217]:

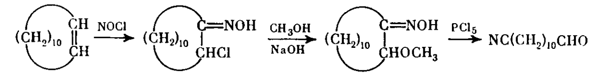


When cyclododecene is acted upon by NO in the presence of O_2, 1-nitroso-2-nitrocyclododecane is obtained. It rearranges on heating in DMF to give 2-nitrocyclododecanone oxime. 1,12-Diaminododecane and ω-nitrolauric acid were obtained from the latter[218]. Cyclododecene undergoes a Friedel–Crafts reaction with benzene and its homologues to form alkylation products[219,220]:



Pyrolysis of (XXV) and (XXVI) results in the cleavage of the ring with formation of 1,8-nonadiene and 1,11-dodecadiene and also in isomerisation involving the double bonds[221]. When cyclododecene was treated with atmospheric oxygen in t-C_4H_9OH in the presence of manganese naphthanate, 1,2,3-cyclododecanetriol was obtained[222]. Photochemical cycloaddition of the olefins (XXV) and (XXVI) to dichlorovinylene carbonate leads to three stereoisomeric carbonates of dichlorobicyclo[10,2,0]-2,3-tetradecanediols[223].

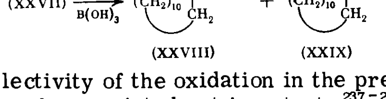
The synthesis of ω-cyanoundecanoic aldehyde from (XXV) and (XXVI) via the mechanism



is of great interest[224]. The reaction of cyclododecene with B_2H_6 yielded the corresponding tri(cyclodecyl)borane[225]. When cyclododecene was treated with nitrogen oxides and air, α-nitrocyclododecanone was obtained in a high yield[226-230]. The mechanism of the oxidation of (XXV) and (XXVI) by molybdenum peroxide has been investigated[231]. A study has been made of the kinetics of the hydrogenation of (XXV) and (XXVI) to cyclododecane in the presence of platinum and palladium blacks[232]. (XXV) and (XXVI) form π-allyl complexes with palladium chloride[233]. The structure of the complex of *trans*-cyclododecene with $AgNO_3$, having the composition (*trans*-$C_{12}H_{22})_2.AgNO_3$, has been investigated[234]. On heating with perfluorobutyne, *cis*, *trans*-1,3-cyclododecadiene gives rise to a mixture of two bicyclic products[235].

V. SYNTHESES OF CYCLODODECANE DERIVATIVES

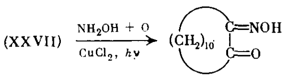
The methods of synthesis of cyclododecane derivatives are of great significance, since the preparation of the industrially important decane-1,1-dicarboxylic acid, 1,12-diaminododecane, and ω-dodecalactam is based on them. The oxidation of cyclododecane (XXVII) by atmospheric oxygen to cyclododecanol (XXVIII) and cyclododecanone (XXIX) has been studied in detail. When (XXVII) is oxidised by oxygen in the presence of boric acid or boron trioxide, a mixture of 80% of (XXVIII), 8–10% of (XXIX), and 10% of polyfunctional oxygen-containing compounds (conversion 30–35%) is formed[69,236]:



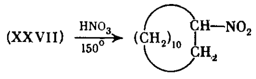
(XXVIII) (XXIX)

The high selectivity of the oxidation in the presence of boric acid has been pointed out in patents[237-239]. A greater amount of the ketone (XXIX) is formed in the presence of manganese or cobalt salts[240,241]. When (XXVII) was oxidised by oxygen in the absence of boric acid, it was found that at the beginning of the process cyclododecyl hydroperoxide, (XXIX), and (XXVIII) accumulate simultaneously[242-245]. After the attainment of the maximum, the concentration of the hydroperoxide falls owing to its thermal decomposition. This results in the formation of a mixture of 70% of (XXIX) and 30% of (XXVIII). Cyclododecane is oxidised to cyclododecyl hydroperoxide in the presence of alkali metal salts[246-248]. A study of the mechanism of the decomposition of cyclododecyl hydroperoxide showed[249] that considerable amounts of undecane and undecyl alcohol are formed in an inert medium, while in the presence of O_2 hardly any undecane is formed. The oxidation of (XXVII) by nitrogen dioxide to decane-1,10-dicarboxylic acid has been reported[250,251].

Treatment of (XXVII) by hydroxylamine and oxygen under irradiation leads to 1,2-cyclododecanedione monoxime[252]:

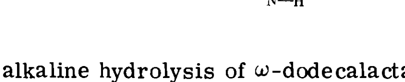


Nitrocyclododecane was obtained in the liquid-phase nitration of (XXVII) by nitric acid[168,253,254]:

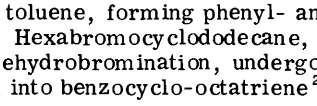


Nitrocyclododecane was also obtained on hydrogenation of 3-nitrocyclododecene[255]. When nitrocyclododecane is treated with a solution of potassium hydroxide, the potassium salt of *aci*-nitrocyclododecane is formed and is converted into *aci*-nitrocyclododecane on acidification[254,256]. This *aci*-form is stable and does not change even on recrystallisation[254]. When nitrocyclododecane was hydrogenated, aminocyclododecane and cyclododecanone oxime were obtained[254,257]. When the potassium salt of *aci*-nitrocyclododecane was treated with $H_2NOH.HCl$, cyclododecanone oxime is formed in a high yield[254].

The hydrolysis of a nitrocyclododecane salt results in the formation of cyclododecanone[254,258,259]. The conversion of nitrocyclododecane into ω-dodecalactam at a high temperature in the presence of certain metal oxides has been described[260]. Numerous studies have been devoted to the photonitrosation of (XXVII) to cyclododecanone oxime[139,153,168,261-266] and to the isomerisation of cyclododecanone oxime to ω-dodecalactam, which is the initial compound in the synthesis of polyamide-12[261,262,267-271]:

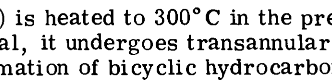


Nitrododecalactam has been obtained by treating α-nitrocyclododecanone oxime with concentrated sulphuric acid at 40-50° C:[272]



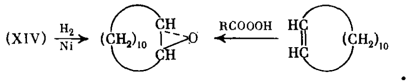
The acid or alkaline hydrolysis of ω-dodecalactam results in the formation of ω-aminododecanoic acid[11,273,274].

The photochemical chlorination of (XXVII) to monochlorocyclododecane has been investigated[75,275,276]. Monochlorocyclododecane undergoes the Friedel–Crafts reaction in benzene and toluene, forming phenyl- and tolyl-cyclododecanes[277]. Hexabromocyclododecane, obtained from (I) and (II) on dehydrobromination, undergoes an unusual transformation into benzocyclo-octatriene[278]:



When (XXVII) is heated to 300° C in the presence of platinised charcoal, it undergoes transannular dehydrocyclisation with formation of bicyclic hydrocarbons[279].

Epoxycyclododecane (XXX) has been obtained by the hydrogenation of the double bonds in epoxycyclododecadiene[68] and by the epoxidisation of cyclododecene by peracids[75,130]:



(XXX)

The *cis-* and *trans*-oxides are formed from *cis-* and *trans*-cyclododecene. Catalytic hydrogenation of (XXX) over Raney nickel[11,68,75] leads to the formation of cyclododecanol and cyclododecanone:

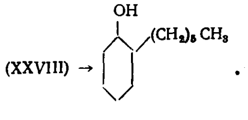
$$(XXX)\ \xrightarrow[Ni]{H_2}\ (XXVIII) + (XXIX)\,.$$

Isomerisation of the epoxide (XXX) under the influence of LiBr[125] or MgI_2[124] leads to cyclododecanone:

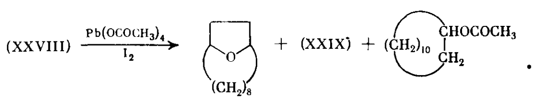
$$(XXX)\ \xrightarrow{MgI_2}\ (XXIX)\,.$$

Cyclododecanol has been obtained by hydrating cyclododecene with sulphuric acid[280] and also on hydrogenation and hydrolysis of 1-acetoxy-5,9-*trans*,*trans*-cyclododecadiene[273]. Dehydrogenation of cyclododecanol at 240–250°C under the influence of catalysts (Raney nickel, Cu/Cr, Ni/Al_2O_3, Cu/SiO_2) leads to the formation of cyclododecanone in a high yield[11,70,240,281]. The synthesis of cyclododecanone by the hydrolysis of cyclododecanone oxime has been described[258,259].

Decane-1,10-dicarboxylic acid is formed in a high yield when cyclododecanol or its mixture with cyclododecanone is acted upon by nitric acid in the presence of ammonium metavanadate[11,110,282] or V_2O_5.[283] It has been stated in patents[284,285] that the oxidation of cyclododecanol is accompanied by nitration, which resulted in the isolation of ω,ω-dinitrododecanoic acid; however, the addition of copper powder to the oxidation reaction prevents the formation of nitro-acids[285]. When cyclododecanol is treated with a mixture of $FSO_3H-SbF_5-SO_2$, it isomerises to hexylcyclohexanol[286]:



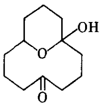
The oxidation of cyclododecanol by lead tetra-acetate in the presence of iodine gives rise to a mixture of oxygen-containing products in which 13-oxabicyclo[8,2,1]dodecane (XXXI) predominates[287]:



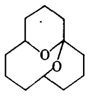
(XXXI)

Oxidation in the absence of iodine leads mainly to acetoxycyclododecane.

When cyclododecanediol is heated in the presence of Raney nickel, 2-hydroxycyclododecanone is formed[288], while catalytic oxidation in the presence of $[(C_6H_5)_3P]_3RuCl_2$ and benzaldehyde yields 1,2-cyclododecanedione[289]. Methods for the preparation of 2-alkoxy-1-alkylcyclododecanes[290] and cyclododecylamides[291], which exhibit pharmacological activity, have been described. 1-(Dialkylaminoalkyl)cyclododecyl carboxylates[292] and the esters of 1-(aminoalkyl)cyclododecanol possess bactericidal properties[293]. The oxidation of *cis*,*cis*,*trans*-1,5,9-cyclododecanetriol by the Brown method proceeds with a transannular interaction and leads to the hemiacetal (XXXII) and the acetal (XXXIII) in proportions of 43 : 57.[294]



(XXXII)



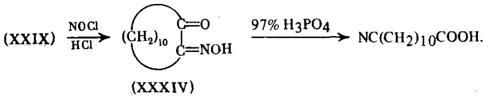
(XXXIII)

VI. SYNTHESES BASED ON CYCLODODECANONE

Numerous compounds have been synthesised on the basis of cyclododecanone (XXIX) and many interesting reactions have been carried out. As stated above, (XXIX) is obtained by the dehydrogenation of cyclododecanol (XXVIII)[11,70,240,281], the isomerisation of epoxycyclododecane (XXX)[124,125], the hydrolysis of cyclododecanone oxime[258,259], and the oxidation of cyclododecane[69,236–248] and cyclododecanol[69]. Several studies have been devoted to the synthesis of cyclododecanone oxime from (XXIX) and its conversion into ω-dodecalactam[11,70,295–297].

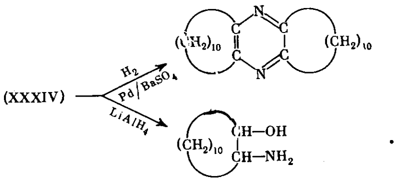
The reaction of hydroxylamine with cyclododecanone under the influence of hydroxylammonium chloride or sulphate takes place readily and in a quantitative yield in the presence of bases (ammonia, potassium or sodium carbonate)[11,70,295,296]. When industrial hydroxylammonium sulphate, containing ammonium sulphate and sodium sulphate, is used, the conversion of cyclododecanone into the oxime takes place without the addition of bases, because sulphuric acid is bound into acid ammonium and sodium salts[11,295]. The reaction with hydroxylamine is carried out in alcoholic, aqueous alcoholic, and aqueous media, a higher temperature being necessary in an aqueous medium. Cyclododecanone oxime forms a 2 : 1 complex with $SnCl_4$.[298]

The mechanism of the Beckmann rearrangement in cyclododecanone oxime has been investigated and it has been found that the process proceeds via a unimolecular mechanism[299]. α-Chlorocyclododecanone oxime is readily obtained when nitrosyl chloride adds to cyclododecene[300]. The substitution of the chlorine atom in α-chlorocyclododecanone oxime by alkoxy- and amino-groups has been described[301–304]. On treatment of (XXIX) with NOCl or $RONO_2$ in the presence of HCl or sodium alkoxide, cyclododecanedione monoxime (XXXIV) is formed in a high yield[305]; it rearranges smoothly to 11-cyanoundecanoic acid under the influence of phosphoric acid[306,307]:



(XXXIV)

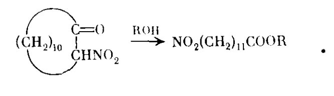
The hydrogenation of (XXXIV) yielded bis-2,3,5,6-decamethylenepyrazine[130]:



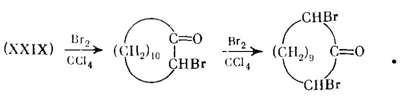
The reaction of (XXIX) with NOCl and ethanol in SO_2 leads to the cleavage of the ring via the mechanism[308]:

$$(XXIX) + NOCl + C_2H_5OH \xrightarrow{SO_2} HON{=}CH(CH_2)_{10}COOC_2H_5 .$$

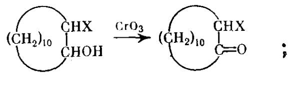
α-Nitrocyclododecanone is obtained by the hydrolysis of its oxime with hydrochloric acid[309]. The alcoholysis of α-nitrocyclododecanone results in the formation of ω-nitrododecanoate esters[310]:



When (XXIX) is brominated, monobromo- or dibromocyclododecanone[311] is obtained:

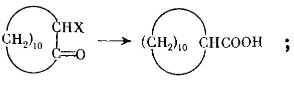


Monohalogenocyclododecanones are readily formed on oxidation of the corresponding halogenohydrins[114]:



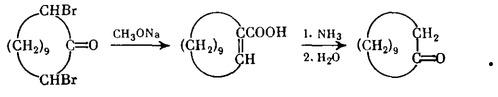
X = Cl, or Br.

The Favorskii rearrangement of α-halogenocyclododecanones under the influence of alcoholic alkali leads to the formation of cycloundecanecarboxylic acid[114]:

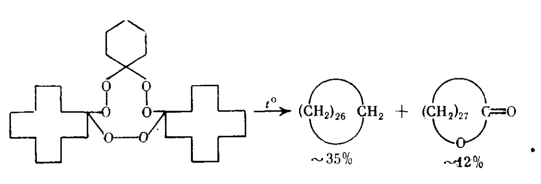


X = Cl, or Br.

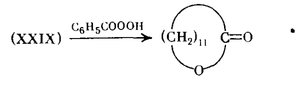
Under these conditions, α,α′-dibromocyclododecanone gives rise to cycloundecenecarboxylic acid, which has been converted into cycloundecanone[311,312]:



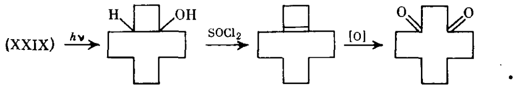
The oxidation of (XXIX) by hydrogen peroxide in the presence of SeO_2 leads to cycloundecanecarboxylic acid[313]. Cyclododecanone peroxide has been obtained by treating (XXIX) dissolved in carboxylic acids with H_2O_2.[314,315] In the presence of cyclic ketones bis(cyclododecylidene) cycloalkylidene triperoxides are formed[316] and their thermal decomposition in chlorobenzene leads to macrocyclic compounds, for example:



Perbenzoic acid[317-319], Caro's acid, and hydrogen peroxide in sulphuric acid[318] were used to oxidise (XXIX) to dodecanolide:



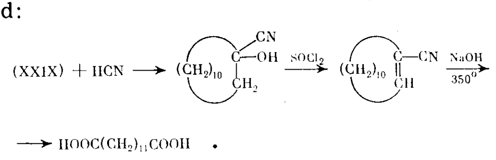
Irradiation of (XXIX) results in a transannular rearrangement with formation of bicyclo[8,2,0]dodecan-1-ol[320,321]:



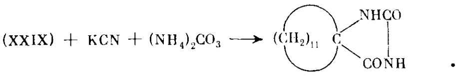
On heating cyclododecanone and cyclododecanol with alkalis to 350°C, a mixture of lauric and nonane-1,9-dicarboxylic acid is formed in 90% yield[322-324]:

$$(XXVIII) + (XXIX) \xrightarrow[350°]{KOH} CH_3(CH_2)_{10}COOH + HOOC(CH_2)_9COOH .$$

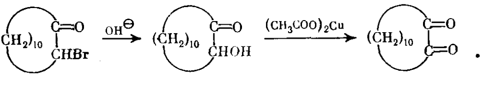
The addition of hydrocyanic acid to (XXIX) takes place readily in the presence of $(C_2H_5)_3N$ with formation of a cyanohydrin[325-327], from which cyclododecanecarboxylic acid[326], cyclotridecanone[327], and brassylic acid[325] were obtained:



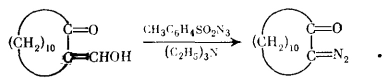
The formation of hydantoins from cyclododecanone or cyclododecenones has been described[328]:



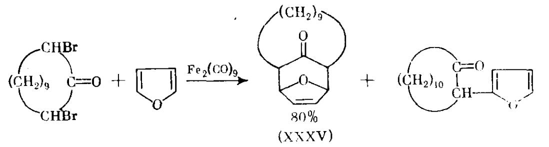
1,2-Cyclododecanedione is formed in a high yield on heating hydroxycyclododecanone with copper diacetate[329,330]:



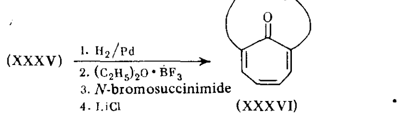
Diazocyclododecanone has been obtained by the reaction[331]:



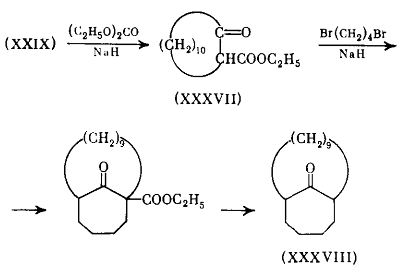
α-Halogenocyclododecanones are readily reduced to cyclododecanone in the presence of LiI and $(C_2H_5)_2O.BF_3$.[332] The reaction of α,α′-dibromocyclododecanone with furan in the presence of $Fe_2(CO)_9$ takes place in an interesting manner[333]:



(XXXV) has been converted via a series of stages into tropone (XXXVI)[334]:



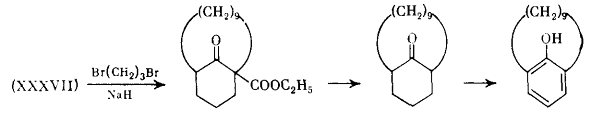
Tropone has been obtained from cyclododecanone also in accordance with another scheme via the ethoxycarbonyl derivative (XXXVII)[335]:



(XXXVII)

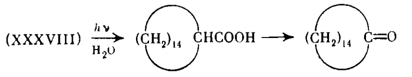
(XXXVIII)

When the ketone (XXXVIII) was brominated and debrominated, tropone was obtained[336]. Metacyclophane (XXXIX) was synthesised similarly[336]:



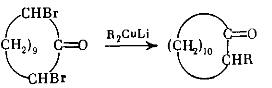
(XXXIX)

Ultraviolet irradiation of the ketone (XXXVIII) led to the formation of cyclopentadecanecarboxylic acid (XL), which was converted into cyclopentadecanone[335,337]:

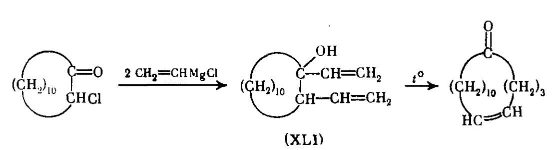


(XL)

A new method has been proposed for the alkylation of α,α'-dibromocyclododecanone with formation of α-alkylcyclododecanones[338,339]:

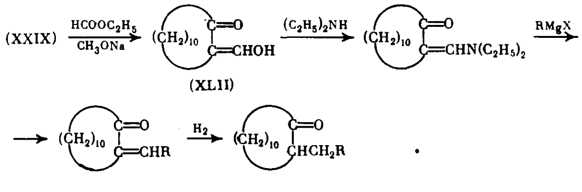


The action of a Grignard reagent on (XXIX) with formation of alkylcyclododecanols has been investigated[202]. Methylcyclododecanone has been obtained by the reaction of bromocyclododecanone with CH_3ZnI in DMSO[202]. The reaction of chlorocyclododecanone with two moles of vinylmagnesium chloride leads to the formation of (XLI), which is converted into 5-cyclohexadecenone after the Cope rearrangement[340,341]:



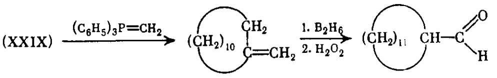
(XLI)

α-Alkylcyclododecanones have been obtained by the formylation of (XXIX) via the mechanism[342]:

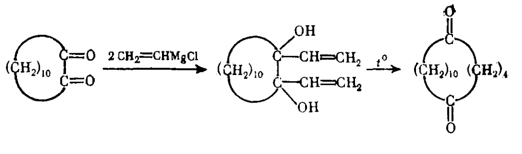


(XLII)

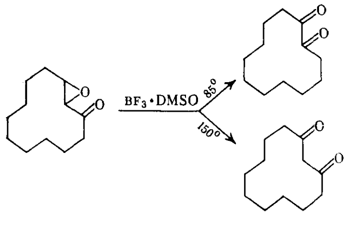
(XLII) undergoes oxidative cleavage by hydrogen peroxide, which leads to brassylic acid[325]. Formylcyclododecane was synthesised from (XXIX) as follows[202]:



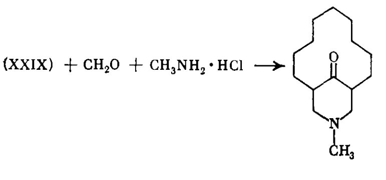
A method has been described for the synthesis of 1,6-cyclohexadecanedione by treating 1,2-cyclododecanedione with vinylmagnesium chloride and a subsequent rearrangement[343]:



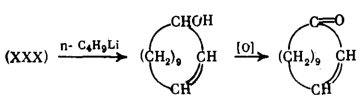
Depending on temperature, the isomerisation of 2,3-epoxycyclododecanone takes place with formation of 1,2- or 1,3-cyclododecanediones[345]:



Methods have been developed for the synthesis of [7]-metacyclophane and its bromo-derivative via the aldol condensation of 1,4-cyclododecanedione[346,347] and [7](2,6)pyridinophane derived from 1,5-cyclododecanedione[348,349]. Cyclododecanone has been made to undergo the Mannich reaction[350,351]:

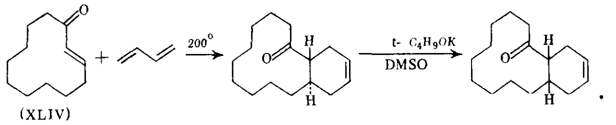


The *cis*- and *trans*-2-cyclododecenones (XLIII) and (XLIV) were obtained from epoxycyclododecane[352]:

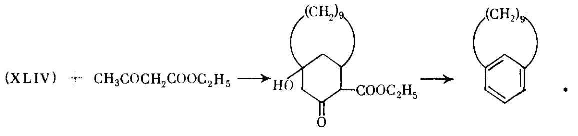


(XLIII) (*cis*-)
(XLIV) (*trans*-).

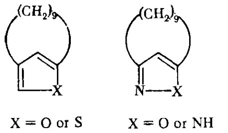
The synthesis of a mixture of *cis*- and *trans*-cyclododecenones by the bromination of cyclododecanone ethylene acetal and subsequent dehydrobromination by t-C_4H_9OK in DMSO has been proposed[353]. *cis*-Cyclododecenone (XLIII) is thermodynamically less stable than the *trans*-isomer (XLIV) and isomerises to the latter[352]. Ultraviolet irradiation of a hexane solution of (XLIV) leads to a mixture of (XLIII) and *cis*-3-cyclododecenone[352]. Diene condensation of (XLIV) with butadiene leads to *trans*-bicyclo[10,4,0]-hexadec-14(15)-en-2-one, which wholly isomerises to the *cis*-isomer on treatment with t-C_4H_9OK:[354]



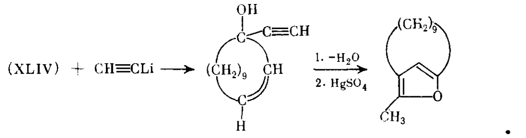
The *cis*-isomer (XLIII) does not undergo diene condensation with butadiene. [9]Metacyclophane and [9](2,4)pyridinophane have been obtained by the reaction of (XLIV) with acetoacetic or cyanoacetic ester and subsequent reactions of the adducts[355]:



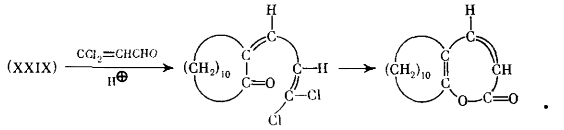
A series of [9]heterophanes have been obtained from (XLIV)[356,357]:



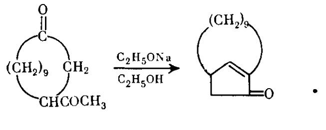
When (XLIV) reacts with hydrazine hydrate and this is followed by dehydrogenation with sulphur, [9](3,5)pyrazolophane is formed, while treatment with lithium acetylide and further cyclisation lead to 11-methyl[9](2,4)furanophane[353]:



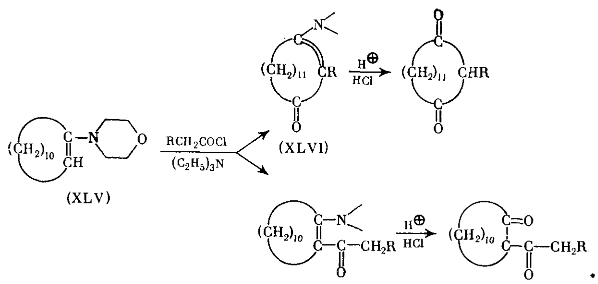
Decamethylene-α-pyrone has been obtained by the condensation of (XXIX) with dichloroacrolein and subsequent cyclisation[358]:



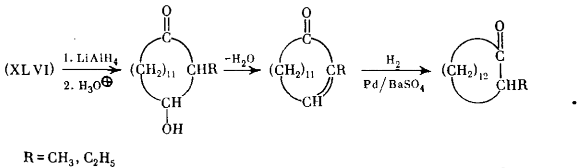
The product of the condensation of 1-methoxycyclododecene with 2-methylbut-3-yne-2-ol undergoes the Cope rearrangement to give 3,3-dimethylallenylcyclododecenone, which isomerises on ultraviolet irradiation to 4-isopropylidenecyclotetradecenone[359]. When 3-acetylcyclododecanone is acted upon by C_2H_5ONa, a bicyclic ketone is formed[360]:



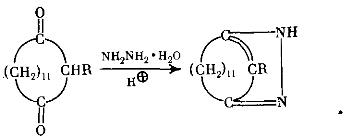
Enamines have found extensive applications in the synthesis of various cyclododecanone derivatives[361-363]. When morpholinocyclododecene (XLV) is treated with carboxylic acid chlorides in the presence of $(C_2H_5)_3N$, 2-alkyl-1,3-cyclotetradecanediones (resulting from the insertion of two carbon atoms in the ring) and acylation products are formed[364,365]:



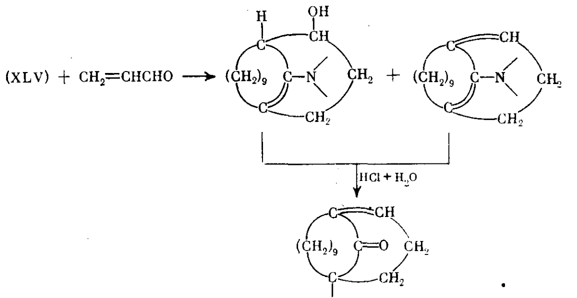
When (XLVI) was treated with lithium tetrahydroaluminate and this was followed by dehydration and hydrogenation, methyl- and ethyl-cyclotetradecanones, which have a strong musk-like scent, were obtained[366]:



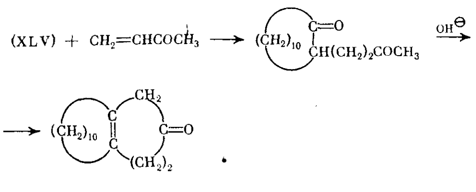
The interaction of 2-alkyl-1,3-cyclotetradecanedione with hydrazine hydrate[364] or 2,4-dinitrophenylhydrazine[366] leads to a pyrazole derivative:



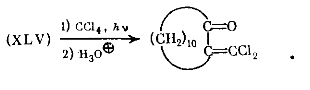
When acrolein acts on (XLV), an interesting reaction takes place[344]:



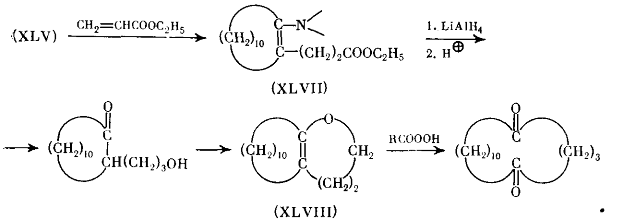
The interaction of (XLV) with methyl vinyl ketone leads to a bicyclic ketone[367]:



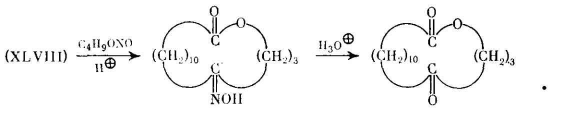
When (XLV) is irradiated with ultraviolet light in the presence of CCl_4, a dichlorovinyl ketone is formed[368]:



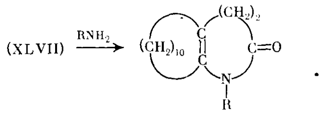
Oxopentadecanolide has been synthesised from (XLV) and ethyl acrylate via the mechanism[369]



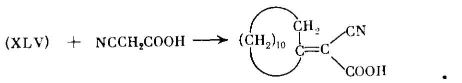
Hydrolysis of (XLVII) leads to β-(2-oxocyclododecyl)propionic acid[344,370]. Ultraviolet irradiation of this acid results in the formation of ω-formyl-4-tetradecenoic acid, whose reduction leads to ω-hydroxypentadecanoic acid[370]. Oxopentadecanolide has also been obtained from (XLVIII) by treatment with butyl nitrite and subsequent hydrolysis[371]:



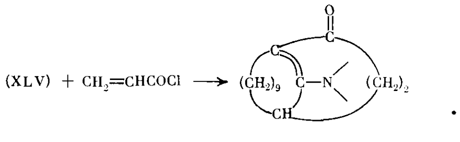
Similarly 1-acetyl-13-hydroxyimino-1-azahexadecan-2-one was obtained from 1-acetyl-2,3-decamethylene-1,4,5,6-tetrahydropyridine[372]. Treatment of the ketoester obtained from (XLVII) with alkylamines leads to the synthesis of bicyclic lactams[373]:



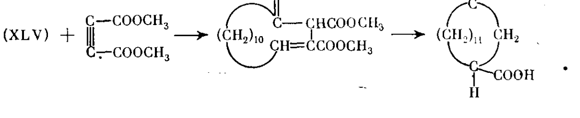
The reactions of (XLV) with a substituted cyclopropene[374] and dibromoacetone have been investigated[375]. The morpholine residue in (XLV) undergoes an exchange reaction with cyanoacetic acid[376]:



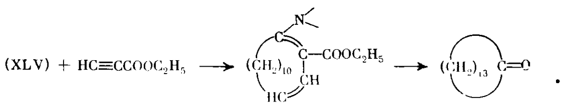
When (XLV) interacts with acryloyl chloride, a bicyclic product is formed[377]:



α-(2-Oxocyclododecyl)acetic acid has been obtained by the reaction of (XLV) with a bromoacetate ester[344]. When pyrrolidinocyclododecene condenses with an ester of acetylenedicarboxylic acid[378], ring expansion takes place with formation of a cyclotetradecenone derivative, which has been converted into 3-carboxycyclotetradecanone[376]:

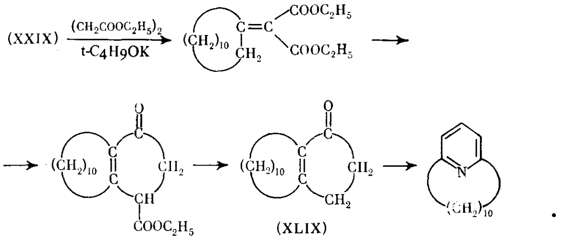


Cyclotetradecanone has been obtained by the reaction of (XLV) with ethyl propiolate[379]:

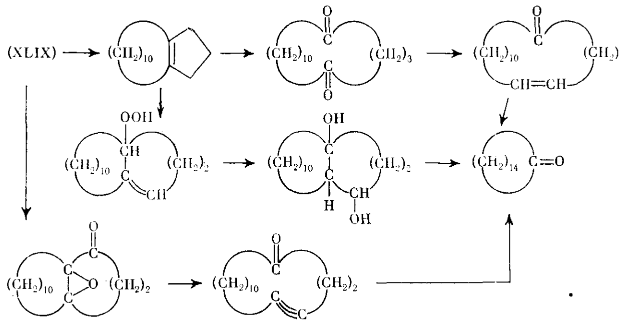


Using this reaction, it is possible to obtain the racemic muscone[380]. A series of methods of synthesis of muscone, cyclopentadecanone (exaltone), pentadecanolide (tibetolide), and methylpentadecanolide (muscolide), which are valuable perfumes, have been developed on the basis of cyclododecanone.

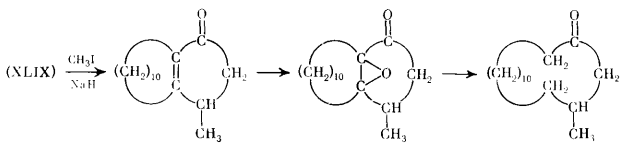
The synthesis of natural muscopyridine from cyclododecanone has been achieved by the Stobbe reaction via (XLIX)[381]:



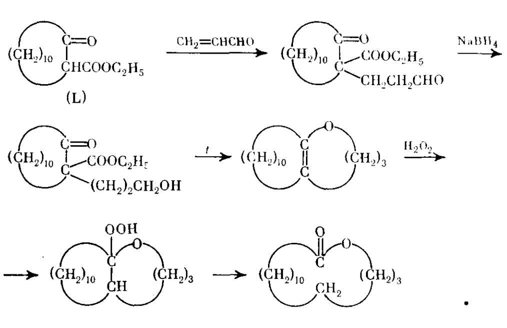
This reaction has served as the basis of a method of synthesis of cyclopentadecanone[382–385]:



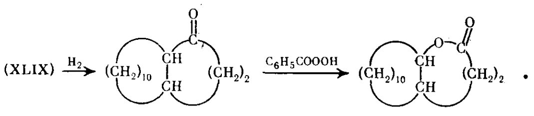
Muscone has been obtained from (XLIX) via the mechanism[383]



A convenient method of synthesis of cyclopentadecanolide via the mechanism[335,337]



has been developed. The methyl analogue of cyclopentadecanolide (muscolide) has been obtained similarly from (L) and methacrolein[328,337]. It has been reported that γ,δ-decamethylene-δ-valerolactone has a strong musk-like scent[386,387]. It has been synthesised via the mechanism



The products of the reaction of cyclododecanone with glycols[388] are components of perfumes.

During the preparation of the review for the press, studies which are of interest were published. An industrial method of synthesising compound (II) (1,5,9-CDT) by a continuous method in the presence of the $(C_2H_5)_2AlCl-TiCl_4$ catalytic system has been developed[389]. A mechanism has been proposed for the cyclisation of butadiene to (I) in the presence of $Ni(C_5H_7O_2)_2 + (C_2H_5)_3Al$.[390] Partial ozonolysis of (I), with subsequent reduction of the peroxycompounds formed by dimethyl sulphide, leads to 1,12-diformyl-*trans*,*trans*-4,8-dodecadiene[391]. Conditions have been found for the selective hydrogenation of (II) to (XXVI) in the presence of $RuCl_2(PPh_3)_3$ activated by $(C_2H_5)_3N$.[392] The reaction of (XXV) and (XXVI) with *N*-bromosuccinimide in the presence of water, methanol, or acetic acid proceeds with formation of 2-bromocyclododecanol, 2-bromo-1-methoxycyclododecane, and 1-acetoxy-2-bromocyclododecane respectively[393]. Oxidation of a mixture of (XXV) and (XXVI) by Jones reagent in the presence of mercury propionate leads to cyclododecanone[394]. It was noticed for the first time that oxidation of cyclododecane by air results in the formation of 2–3% of *trans*-epoxycyclododecane[395]. The isomerisation of epoxycyclododecane to cyclododecanone proceeds with a high yield in the presence of palladium and rhodium catalysts[396]. When epoxycyclododecane is acted upon by formaldehyde in the presence of $AlCl_3$, 13,15-dioxabicyclo[10,3,0]pentadecane and 13,15,17-trioxabicyclo[10,5,0]heptadecane are formed[397]. On ultraviolet irradiation, a mixture of 36% of methyl cycloundecanecarboxylate, 17% of *cis*- and 25% of *trans*-cyclododecenones, and 9% of *cis*-3-cyclododecenone is formed on ultraviolet irradiation of α-diazocyclododecanone[398]; the reaction involving 2-methylcyclododecanone takes place with ring cleavage and the formation of 40% of formyl-12-dodecene[399]. A synthesis of bicyclo-[10,3,0]pentadeca-1(12)-en-13-one and its methyl analogues from cyclododecanone has been proposed[400]. Formylcyclodecane has been obtained from cyclododecanone and ethoxymethylmagnesium chloride[401]. Treatment of 1,5-cyclododecadiene with *N*-bromosuccinimide and subsequent reduction of the product with $LiAlH_4$ lead to 13-oxabicyclo-[8,2,0]dodecane[402].

A method of synthesis of cyclododecanone oxime on heating cyclododecanone with ammonia in the presence of t-butyl hydroperoxide has been described in a patent[403]. A method of synthesis of 1,3- and 1,4-cyclododecanediones from a mixture of *cis*- and *trans*-3-cyclododecenones has been discovered[404]. [10]Paracyclophane has been synthesised from cyclododecene and methyl acetylenecarboxylate[405]. [9](2,4)Pyrrolophane has been synthesised in two ways: (1) by the condensation and cyclisation of 3-formylcyclododecanone with ammonia and (2) by the condensation of chlorocyclododec-2-en-1-one with di(ethoxycarbonyl)-methylamine[406].

Cyclotrimerisation of Cyano-compounds into 1,3,5-Triazines

D.Martin, M.Bauer, and V.A.Pankratov

A survey is made of papers on the cyclotrimerisation of substituted monofunctional cyanides X.C:N differing in the structure of the substituent X = H, R, Ar, >N, HO, RO, ArO, HS, RS, Hal. This reaction has been widely used in recent years both in preparative organic chemistry and in large-tonnage industrial manufactures, by virtue of the availability of the initial compounds, the high yields of 1,3,5-triazines, and the simplicity of operation. Attention is paid mainly to recent work to elucidate the influence of substituents X on the reactivity of N⋮C-containing compounds; various mechanisms of cyclotrimerisation are discussed, as well as the effects of catalysts, pressure, and other factors. Consideration is given not only to homocyclotrimerisation but also to mixed cyclotrimerisation of cyanide derivatives and the influence of the reaction conditions on the structure of the resulting 1,3,5-triazines. A list of 247 references is included.

I. INTRODUCTION

1,3,5-Triazines are important products of modern organic chemistry. They are widely used as intermediates in dye chemistry and in the paper, paint and varnish, and pharmaceutical industries, as herbicides and as monomers for the synthesis of thermostable polymers, and in several other branches of the national economy.

The most promising method for the industrial synthesis of 1,3,5-triazines is the cyclotrimerisation of compounds containing a nitrogen–carbon triple bond, since this reaction usually occurs selectively to give high yields of the final products. In industry cyclotrimerisation has been used to obtain such compounds as cyanuric acid, melamine, cyanuric chloride, etc. The cyclotrimerisation of several compounds containing an N⋮C bond was known as early as the nineteenth century, but the largest amount of research has been conducted during recent years. Attention has been concentrated mainly on studying the mechanisms of cyclotrimerisation, the synthesis of new derivatives of 1,3,5-triazine, the selection of various catalytic systems, etc. Furthermore, a long series of papers has appeared on the synthesis of highly heat-resistant and thermostable polymers from N⋮C-containing monomers.

In several of the earlier reviews and monographs[1–5] containing information on 1,3,5-triazines little attention was paid to cyclotrimerisation. Most of these surveys were published 15–20 years ago, and do not reflect advances made during recent years.

The present Review surveys published results on the cyclotrimerisation of cyanide derivatives in which the cyano-group is attached to various atoms and radicals (H, R, RO, RS, R_2N, Hal). Data on the conditions for the cyclotrimerisation of particular classes of compounds are summarised in tables. Attention is paid mainly to recent studies of mechanisms, the influence of the nature of substituents attached to cyano-groups on their electrophilic character, and the tendency to undergo this reaction. The cyclotrimerisation of compounds containing two or more functional groups to give polymers has been discussed in detail in several recent reviews[6–8], and therefore will not be considered here.

II. 1,3,5-TRIAZINE FROM HYDROGEN CYANIDE

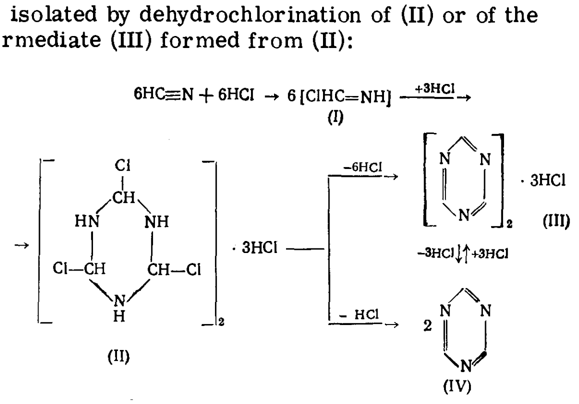
Since 1,3,5-triazine, unlike most of its derivatives, is highly reactive towards nucleophiles, it could not be identified until 1954.[9,10] This compound was obtained by Nef[11] more than a half-century ago, but it was then regarded as a dimer of hydrogen cyanide.

The mechanism of the formation of 1,3,5-triazine by the action of hydrogen chloride on hydrogen cyanide was investigated by Grundmann and Kreutzberger[12]. They suggested that initial addition of equimolecular quantities of the reactants is followed by spontaneous trimerisation of the adduct (I)† to bis-(2,4,6-trichlorohexahydro-1,3,5-triazine) trihydrochloride (II); 1,3,5-triazine (IV)

---

†Kreutzberger has since[4] attributed the structure $[HC⋮NH]^+Cl^-$ to the adduct (I).

was isolated by dehydrochlorination of (II) or of the intermediate (III) formed from (II):

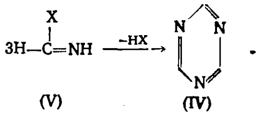


The yield of 1,3,5-triazine from the trimerisation of hydrogen cyanide in the presence of hydrogen chloride is 55-60%.[9,12,13]

Table 1. Synthesis of 1,3,5-triazine by the cyclocondensation of compounds (V).

X	Reaction conditions			Yield, wt.%	Ref.
	catalyst	T, °C	p, atm		
C_2H_5O	NaOH	—	—	10	11
HS	—	80	vacuum	20	15
H_2N	R_3N	150—250	0.02	3—72	12, 16, 17
$C_6H_5CH_2$—O	$C_6H_5N(C_2H_5)_2$	80	0.01	50	18

1,3,5-Triazine can also be obtained[10,14] by the thermal or base-catalysed (Table 1) cyclocondensation of compounds (V):

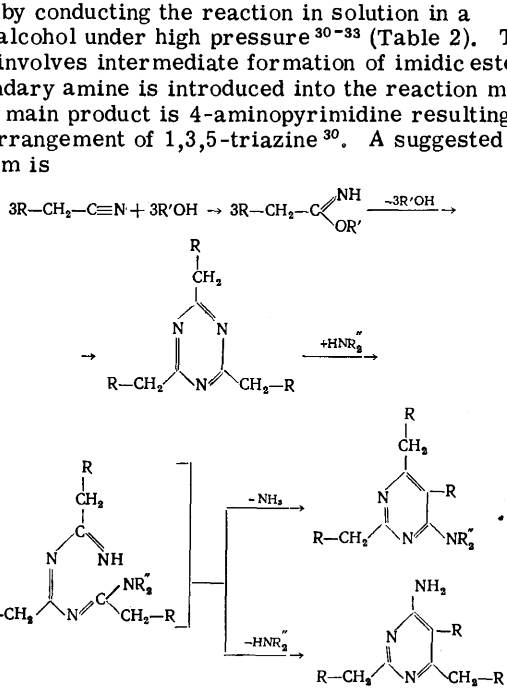


III. 2,4,6-TRIALKYL-1,3,5-TRIAZINES FROM ALKYL CYANIDES

1. 2,4,6-Trialkyl-1,3,5-triazines from Unsubstituted Alkyl Cyanides

Repeated attempts were made[19-29] to synthesise trialkyltriazines by the cyclotrimerisation of alkyl cyanides R.CN, but few successes were achieved. Thus the action of strong bases on alkyl cyanides involves deprotonation of the α-carbon-hydrogen bond followed by addition of the next cyanide molecules to form aminopyrimidine rings[19-29].

1,3,5-Triazines have been obtained from aliphatic cyanides by conducting the reaction in solution in a primary alcohol under high pressure[30-33] (Table 2). The reaction involves intermediate formation of imidic esters. If a secondary amine is introduced into the reaction mixture, the main product is 4-aminopyrimidine resulting from rearrangement of 1,3,5-triazine[30]. A suggested[32] mechanism is



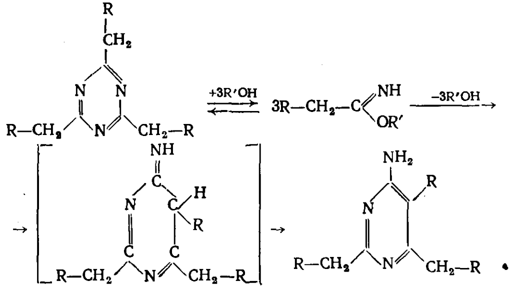
(1)

Table 2. 2,4,6-Trialkyl-1,3,5-triazines from unsubstituted alkyl cyanides RCN.

R	Reaction conditions				Yield, wt.%	Ref.
	10^3p, atm	T, °C	solvent	duration, h		
CH_3	7.9	120	methanol	10	29	32
	7.9	120	ethanol	10	6	32
	7.9	120	ethanol	24	11	32
C_2H_5	7.9	120	ethanol	24	7	32
	7—8	70	methanol	65	36	30, 31
C_3H_7	7.9	120	ethanol	24	1	32
n-C_4H_9	7—8	150	methanol	18	35	30, 31
	7—8	100	methanol	18	7	30, 31
t-C_4H_9*	10.5	130	thiolan *S*-dioxide	8	50	33
	9	160	thiolan *S*-dioxide	6	90	33
	8—9	200—210	ethanol	10—15	90	33
	8—9	200—210	propan-1-ol	10—15	70	33

*Methanol used as catalyst.

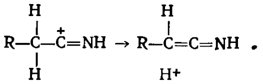
Such rearrangements have been observed[33] even in the absence of amines, under 9000 atm at 200°C. They were explained by the scheme



(2)

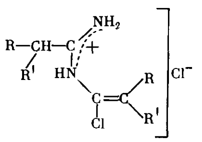
As evidence of the formation of an intermediate imidic ester 2-substituted benzimidazoles were isolated[33] on the addition of *o*-phenylenediamine to the reaction mixture. 4-Aminopyrimidines may be formed either through an intermediate stage from 1,3,5-triazines (schemes 1 and 2) or directly from the initial compounds. They were not observed[34] in the acid-catalysed formation of 1,3,5-triazines from imidic esters.

Several attempts have been made to synthesise 1,3,5-triazines by the cyclotrimerisation of unsubstituted alkyl cyanides in the presence of acids, but this has not yet been achieved. Ruske[35] explains the lack of success by the hyperconjugation effect of the alkyl radical, which diminishes the electrophilic character of the cyanide carbon atom and thus hinders addition of the next cyanide molecule:



$$R{-}\underset{H}{\overset{H}{C}}{-}\overset{+}{C}{=}NH \rightarrow R{-}\underset{H^+}{\overset{H}{C}}{=}C{=}NH\ .$$

Yanagida et al.[36] have also investigated the reaction between alkyl cyanides and hydrogen chloride, and have shown that stable hydrochlorides of *N*-substituted amidines



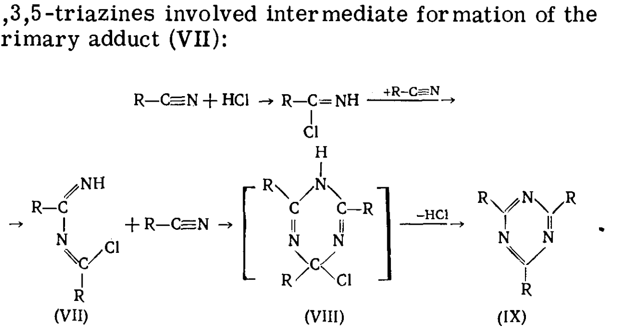
(VI)

are formed. The use of Lewis acids as catalysts for the cyclotrimerisation of acetonitrile also failed to yield the corresponding 1,3,5-triazine: 4-amino-2,6-dimethylpyrimidine was isolated[37].

2. 2,4,6-Trialkyl-1,3,5-triazines from Substituted Alkyl Cyanides

1,3,5-Triazines are formed from α-halogenated alkyl cyanides by acid catalysis, since the hyperconjugation effect of the α-carbon–hydrogen bond is counteracted by the effect of the substituent. Thus, whereas monohalogenated acetonitriles do not usually trimerise‡, and dihalogenated acetonitriles trimerise with insignificant yields§, trihalogenated acetonitriles readily yield the corresponding 2,4,6-tristrihalogenomethyl-1,3,5-triazines.

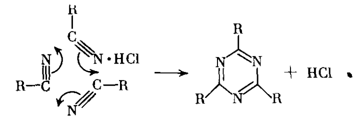
In the presence of hydrogen chloride the catalytic process leads to formation of a primary adduct[36,38,39] of the type 2RCN.3HCl. The electrophilicity of dimers of monohalogenoacetonitriles then becomes weaker in comparison with the monomer, and addition of another nitrile molecule impossible[40]. The mechanism first suggested[40] for this acid-catalysed cyclotrimerisation of $\alpha\alpha$-di- and $\alpha\alpha\alpha$-tri-halogenated alkyl cyanides to the corresponding 1,3,5-triazines involved intermediate formation of the primary adduct (VII):



(3)

This was followed[40] by cycloaddition of another cyanide molecule to give the 2,4,6-trialkyl-4-chloro-1,4-dihydro-1,3,5-triazine (VIII), which underwent spontaneous dehydrohalogenation to the 1,3,5-triazine (IX), However, treatment of $2CCl_3CN.HCl$ with acetonitrile does not yield the expected 1,3,5-triazine, although cyclotrimerisation of trichloroacetonitrile together with acetonitrile in the presence of hydrogen chloride gives the corresponding methylbistrichloromethyl-1,3,5-triazine[40].

Zil'berman[41,42] has suggested a different mechanism, in which the relatively easy formation of 1,3,5-triazines is due to a large gain in energy accompanying cyclisation, which may involve cyclic electron transfer:



On this view both free nitriles and their complexes with hydrogen halides take part in the formation of triazines.

Sulphuric acid[47], Lewis acids[47–49], and complexes of the latter with hydrogen halides[50–53] have also been used as acid catalysts, among which the complexes are the best for cyclotrimerisation. Zil'berman et al.[48] have described the preparation of 2,4,6-tristrichloromethyl-1,3,5-triazine from the complexes

$2Cl_3C{-}CN\cdot AlCl_3$; $Cl_3C{-}CN\cdot AlCl_3$; $Cl_3C{-}CN\cdot 2AlCl_3$.
(X) (XI) (XII)

at 100°C (Table 3). They showed[48] that raising the temperature to 140–150°C leads to the formation of polymers, hexachloroethane, and cyanogen in various proportions. Polymeric products are also formed from dichloroacetonitrile in the presence of aluminium trichloride at 100°C.[49]

A large number of possible catalysts have been reported for the cyclotrimerisation of fluorinated nitriles to 1,3,5-triazines, including metal oxides[54,55]

(Al_2O_3, Bi_2O_3, CaO, Ag_2O, Co_2O_3, Fe_2O_3, HgO, PbO_2, Cu_2O, BaO, Sb_2O_3, TiO_2, V_2O_3, Y_2O_3, ZnO, Mn_2O_3, Tl_2O_3)

silver salts[56]

(AgCl, AgBr, AgI, $AgClO_3$, $AgNO_3$, Ag_2SO_3, Ag_2SO_4, $AgClO_4$, $AgBF_4$

fluorides[56]

SnF_2, CdF_2, ThF_2, AgF, CoF_2, CoF_3, FeF_2, FeF_3, CrF_3, VF_5, CuF_2, ZnF_2, NaF, KF, NH_4F, NH_4BF_4, SnF_4, LiF, NiF_2);

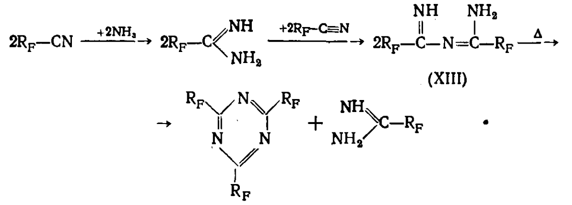
and organometallic compounds[57] [e.g. $(n\text{-}C_8H_9)_3SbO$ and $(CH_3)_3Sb(OH)_2$], as well as amine oxides[58]. Ammonia also catalyses the cyclotrimerisation of fluorinated

---

‡Yanagida et al.[36] have obtained 2,4,6-trischloromethyl-1,3,5-triazine from the adduct $2CH_2ClCN.2HCl$.

§It was assumed in the early work that dimers were formed[43–46].

nitriles $R_F.CN$¶, both at high[59] and at normal[59-62] pressures. At normal pressure the reaction is assumed to involve intermediate formation of imidoylamidines (XIII)[59,60]:



(XIII)

In the presence of alcohols at high pressures the formation of 1,3,5-triazines from fluorinated alkyl cyanides[63] and also from 1,1-dichloropropionitrile[30] may involve an imidic ester stage:

$$C_3F_7-CN + CH_3OH \xrightarrow{+NaOCH_3} C_3F_7-C\begin{matrix}{=}NH\\ {-}OCH_3\end{matrix} .$$

At 70–140 atm fluorinated alkyl cyanides trimerise even in the absence of a catalyst[62]. The uncatalysed cyclotrimerisation of pentafluoropropionitrile at normal pressure has been reported[62], providing additional

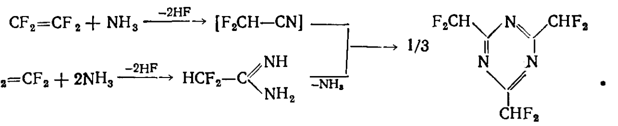
evidence of the highly electrophilic character of the nitrile group in perfluorinated alkyl cyanides.

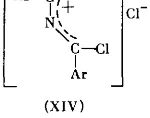
Syntheses of 1,3,5-triazines have also been described[63-67] in which halogenated nitriles are probably intermediate products. Thus the action of chlorine on acetonitrile and on propionitrile yields 2,4,6-tristrichloromethyl- and 2,4,6-trisdichloroethyl-1,3,5-triazine respectively[65-67]. A fluorinated triazine has been obtained[64] via an intermediate amidine stage:



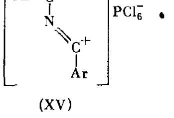
The action of chlorine or bromine on 1,2,2,2-tetrafluoroethyl cyanide gives 2,4,6-tris-1′-chloro(or bromo)tetrafluoroethyl-1,3,5-triazine[68].

IV. 2,4,6-TRIARYL-1,3,5-TRIAZINES FROM ARYL CYANIDES

2,4,6-Triphenyl-1,3,5-triazine (cyaphenine) was first isolated[81] from the reaction between benzoyl chloride and potassium cyanide. It was first obtained by the cyclotrimerisation of benzonitrile in the presence of metallic sodium in 1868.[82] Later, in 1878, a method of synthesising 2,4,6-triaryl-1,3,5-triazines was developed[83] by the acid-catalysed cyclotrimerisation of aromatic nitriles, a process which has since been widely used. Good yields of 2,4,6-triphenyl-1,3,5-triazines are obtained by using as catalyst chlorosulphuric acid[84] in the molecular proportions $HSO_3Cl : C_6H_5CN = 3 : 1$ at 0°C. Increasing this ratio or lowering the temperature diminishes the yield. Raising the temperature by 10 deg also lowers the yield of trimer as a consequence of sulphonation of the benzonitrile. Hydrogen chloride is a weak cyclotrimerisation catalyst, since it forms a stable 2 : 2 adduct with benzonitrile[39], but when a Lewis acid is also present high yields of triaryltriazines are formed[53,85]. It was assumed[53] that the mechanism of formation of triphenyltriazine in this case consisted in weakening of the nucleophilic character of the chloride ion in the adduct (XIV) by formation of the complex (XV) with the Lewis acid (phosphorus pentachloride):



(XIV)

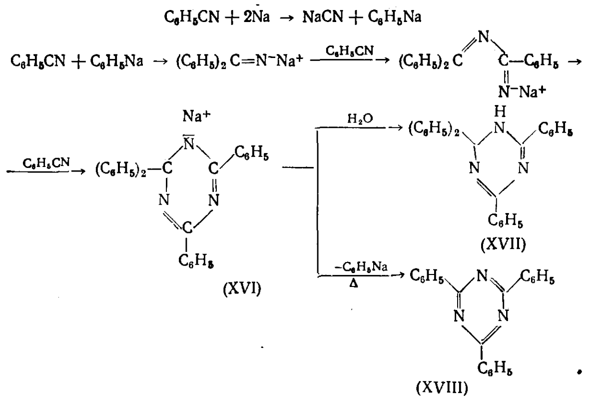


(XV)

The hexachlorophosphate (XV) reacts further with another molecule of the aryl cyanide or with an adduct (1 : 1) of the nitrile and phosphorus pentachloride to give a 1,3,5,triazine, which may also be formed[39] by the pyrolysis of (XIV).

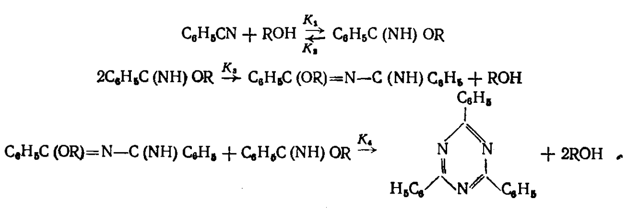
Lewis acids—aluminium, phosphorus(V), zinc, and titanium(IV) chlorides and boron trifluoride—have been used as catalysts for the cyclotrimerisation of aryl cyanides[50,53,86-91]. Their catalytic activity is considerably lower than that of corresponding mixtures of Lewis acids with various promoters—proton-containing compounds (mineral acids, water, amides, organic acids) and organic compounds containing mobile halogens—e.g. benzoyl chloride, etc.[87-89] Such a difference in catalytic activity is attributed to a change in the structure of the complexes† of the aryl cyanides with the Lewis acids[6,92-94]. When complexes of benzonitrile with Lewis acids are heated, either triphenyltriazine or a linear polymer of azomethine structure may be obtained depending on the conditions chosen (temperature, nature of complexes, additions of promoters, etc.)[87-89,92,95]. Pure Lewis acids have little catalytic effect on the cyclotrimerisation of nitriles[50], and only additions of cocatalysts (water, hydrogen chloride, etc.) produce a marked increase in their activity (see below).

The reactions involved in the trimerisation of benzonitrile in the presence of bases have been studied in detail[97-100]. The action of sodium on benzonitrile forms initially phenylsodium‡, to which three molecules of benzonitrile then add successively to give the sodium salt of 1,2-dihydro-2,2,4,6-tetraphenyl-1,3,5-triazine (XVI):



Hydrolysis of (XVI) gives the dihydro-1,3,5-triazine (XVII) in 85% yield[100]. When (XVI) was heated in a high-boiling solvent (xylene or nitrobenzene), 2,4,6-triphenyl-1,3,5-triazine (XVIII) was isolated[99]. The elimination of phenylsodium is accelerated by passing carbon or sulphur dioxide through the reaction mixture or by adding benzonitrile.

The cyclotrimerisation of aryl[30,31,33,43] and heterocyclic[33] cyanides catalysed by amines and alcohols under high pressures occurs similarly to that of alkyl cyanides described above. The trimerisation of benzonitrile in the presence of an alcohol under 2–10 kbar at 100–120°C involves initial formation of the benimidic ester[101]:



---

†For the structure of the complexes of nitriles with Lewis acids see also Ref. 96, pp. 571 and 583.

‡With organic compounds of alkali metals of the type RCH_2Na 2,4,6-triphenylpyrimidine is formed (with elimination of ammonia)[98].

Raising the pressure shifts the equilibrium towards formation of the trimer, whereas increasing the chain length and the degree of α-branching of the alcoholic radical hinders this reaction:

$CH_3OH > C_2H_5OH \approx n\text{-}C_3H_7OH \approx n\text{-}C_4H_9OH > iso\text{-}C_3H_7OH \approx s\text{-}C_4H_9OH.$

The reaction is second order with respect to the imidic ester: i.e. dimerisation (K_3) is the rate-determining stage. Polar solvents accelerate the reaction and increase the yield of trimer. The reaction is completely suppressed by acids; bases have hardly any effect. The effects of acid and basic catalysts on cyclotrimerisation are fundamentally different at high and normal pressures: in the latter case the reaction occurs in the presence of strong acids or bases. Raney nickel[102] and iron carbonyls[103] are relatively weak catalysts for the trimerisation of aryl cyanides.

Even in the absence of a catalyst aryl[30,31,104] and also heterocyclic[33] cyanides can be trimerised at high pressures. Formation of a dipolar intermediate form $R\text{-}C^{+}{=}N^{-}$ can be assumed, since in dipolar aprotic solvents[104], e.g. thiolan *S*-dioxide, trimerisation occurs under milder conditions than in the absence of a solvent[105].

*Chlorinated 1,3,5-triazines formed as byproducts.

**Phenylsodium is an active catalyst, and has been used for the cyclotrimerisation of benzonitrile.[71,80,81]

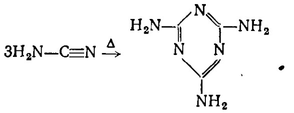
***Duration of reaction in minutes.

****Reaction conducted in an autoclave.

Steric factors also exert a strong influence on cyclotrimerisation. With *ortho*-substituted aryl cyanides, in contrast to the *meta*- and *para*-derivatives, severe conditions are required, and 1,3,5-triazines are formed from them in lower yields. 9-Cyanophenanthrene, 9-cyanoanthracene, and adamant-1-yl cyanide do not trimerise[33] even under 8000-17 000 atm at 150-240°C (Table 4).

V. 1,3,5-TRIAZINE-2,4,6-TRIAMINES (MELAMINES) FROM CYANAMIDES

Few results have been published on the cyclotrimerisation of cyanamide (XIX) to form 1,3,5-triazine-2,4,6-triamine (XX):

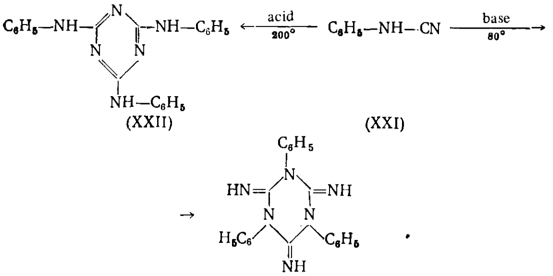


(XIX) (XX)

This synthesis is achieved either in molten cyanamide above 150°C (Ref. 1, p. 309) or by heating in a solvent of high boiling point[115].

The cyclotrimerisation of substituted cyanamides has been reported repeatedly (Ref. 1, p. 349), but until recently published results were contradictory[116-122]: in some cases the products were isomelamine derivatives[116, 117, 120], whereas in others substituted melamines of normal structure were obtained[118, 119, 121, 122]. From these results it may be concluded that 1,3,5-triazine-2,4,6-triamines are formed more readily if the substituting groups cause steric hindrance to attack on the NH group, as do tertiary alkyls[118, 119, 121], adamant-1-yl,[119] and *ortho*-substituted aryls[122].

A recent series of investigations[123-128] on the cyclotrimerisation of phenylcyanamide (XXI) has shown that either the normal triphenylmelamine (XXII) or triphenylisomelamine (XXIII) may be formed depending on the conditions:



(XXII) (XXI) (XXIII)

Thus in the melt under mild conditions (20–80°C) the cyclotrimerisation of (XXI) yields (XXIII), whereas at 200°C the normal product (XXII) is mainly formed[123]. The structure of the final product is determined also by the nature of the catalyst: in the presence of Lewis acids—tin(II), zinc, titanium(IV) chlorides, etc.—(XXII) is formed, but basic catalysts—triethylamine, pyridine, triphenylphosphine, etc.—yield the iso-form (XXIII).

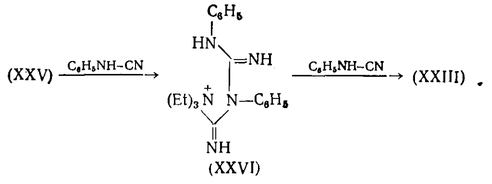
As in the catalytic cyclotrimerisation of nitriles, Lewis acids probably form with (XXI) adducts in which the electron pair of the π bond has been displaced to different extents, from molecular compounds of the type $C_6H_5.NH.C\equiv N, MX$ to ionic structures $C_6H_5.NH.C^+:N.M^-X$. Increasing the polarisation of the cyano-groups tends to accelerate the cyclotrimerisation of (XXI) to (XXII).

Catalysis by triethylamine probably involves formation of a complex with (XXI) by nucleophilic attack by the nitrogen atom of the tertiary amine on the electrophilic carbon atom of the nitrile group:

$$(\mathrm{XXI}) \xrightarrow{N(Et)_3} [C_6H_5-NH-\underset{+N(Et)_3}{C}=\bar{N}] \rightarrow [C_6H_5-\bar{N}-\underset{+N(Et)_3}{C}=NH] \;.$$

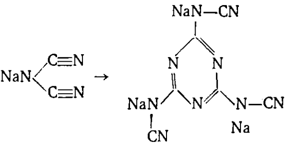
(XXIV) (XXV)

It is probable that (XXV) is more stable than the tautomeric structure (XXIV). This is supported by infrared spectroscopy, since addition of triethylamine to a toluene solution of (XXI) is accompanied by weakening in the spectrum of the mixture of the absorption band at 2230 cm^{-1} characteristic of vibrations of the N≡C bond in cyanamides,[129] with appearance of a band at 2130 cm^{-1} due to vibrations of the carbodi-imide group[129]. The complex (XXV) evidently then adds two more (XXI) molecules to form triphenylisomelamine (XXIII) via the transition state (XXVI)[125]:



(XXVI)

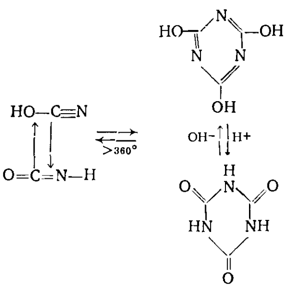
The trimerisation of disubstituted cyanamides was first described by Weith[130], who obtained hexaphenylmelamine by the action of cyanogen chloride on diphenylamine, which should involve intermediate formation of diphenylcyanamide. 2,4,6-Tripyrrol-1′-yl-1,3,5-triazine was also obtained by the action of cyanogen chloride on pyrrole.[131] Heating the sodium salt of dicyanamide gave the trisodium salt of 2,4,6-triscyanoamido-1,3,5-triazine[132]:



A kinetic study of the cyclotrimerisation of *N*-ethyl-*N*-phenylcyanamide has shown[126] that the presence of an aliphatic substituent α to the cyano-group diminishes the reactivity of the cyanamide group, so that this compound cyclotrimerises only in the presence of a cationic catalyst such as a Lewis acid to form 2,4,6-tris-(*N*-ethyl-*N*-phenylamino)-1,3,5-triazine. The presence of an isomelamine structure among the reaction products was not detected[126].

VI. CYANURIC ACID FROM CYANIC ACID

Cyanic acid exists in tautomeric equilibrium with isocyanic acid, and hence two forms of its trimers are possible—enolic (XXVII) and ketonic (XXVIII):



(XXVII)

(XXVIII)

Polymerisation of cyanic acid yields not only cyanuric acid but also cyamelide,[133-135] a polymer (or trimer) of cyanic acid in which the carbonyl bond has been opened. Cyamelide is an amorphous white powder, insoluble in water and organic solvents, and readily depolymerised when heated (especially in the presence of acids). The polymerisation of cyanic acid vapour above 150°C results in formation mainly of cyamelide, but below this temperature the chief product is cyanuric acid[135], which depolymerises at about 360°C.

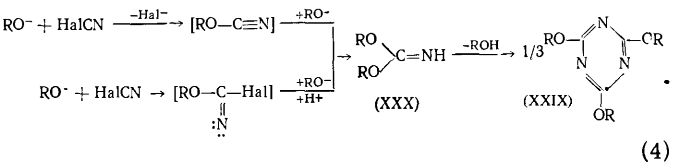
The Raman spectra show that solid cyanuric acid is present in the keto-form[136], which is confirmed by numerous investigations of the infrared spectra[137–140]. In solution the content of a particular form is determined by the pH: thus in saturated aqueous solution[141] at 20°C the content of the enolic form is 5.6%, in strongly alkaline medium the trimer is present in the enolic form, but in acid medium (pH < 6) the keto-form predominates[142–144]. An explanation of the predominance of the keto-form of cyanuric acid in neutral solution and in the solid state is that the loss of π–π conjugation is largely balanced by strong n–π conjugation, which makes this form the energetically more favourable structure.

Several syntheses of cyanuric acid other than the cyclotrimerisation of cyanic acid have been described[1,135] (see Ref. 2, p. 26). The principal industrial method is the pyrolysis of urea:

$$3NH_2CONH_2 \rightarrow (HOCN)_3 + 3NH_3 \ .$$

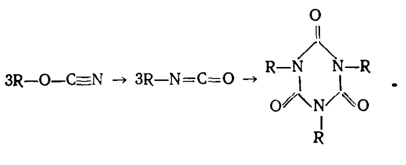
VII. 2,4,6-TRIALKOXY-1,3,5-TRIAZINES (TRIALKYL CYANURATES) FROM ALKYL CYANATES

Trialkyl cyanurates (XXIX) were first obtained in attempts to prepare alkyl cyanates from alkoxides and cyanogen halides[145–148]. A carbonimidic ester (XXX) is an intermediate product, which Nef[149] assumed to be formed directly from the anion of the chloroformidic ester, whereas other workers[150] assumed initial formation of the alkyl cyanate:



(4)

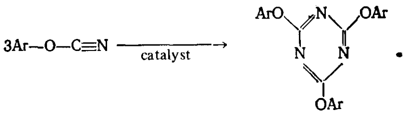
An obstacle to direct trimerisation of alkyl cyanates is the lability of the alkyl–oxygen bond, which results in side reactions. Thus the nucleophilic catalysts and anions of Brønsted acids used for trimerisation undergo alkylation[151,152], whereas Lewis acids and exposure to light of wavelength ≤250 nm promote their isomerisation into alkyl isocyanates[153]. Even on attempted distillation at normal pressure or on heating in solvents alkyl cyanates are isomerised into isocyanates[154–157], which in turn partly trimerise to form isocyanurates:



The rate of this isomerisation depends on the polarity of the solvent and on its ability to solvate cations. Solvents investigated in relation to this reaction form the sequence toluene < nitrobenzene ≈ acetonitrile < dimethylformamide ≪ dimethyl sulphoxide according to their tendency to isomerise alkyl cyanates[158]. Steric hindrance or strongly electron-accepting substituents enhance the stability of alkyl cyanates[7,158–164]. Thus 2,2,3,3-tetrafluoropropyl cyanate has been cyclotrimerised in theoretical yield to the corresponding cyanurate[159,160]. Carbaborane-containing cyanic esters $CB_{10}H_{10}CCH_2.O.C{\equiv}N$ resistant to isomerisation have been obtained[7,161–163], which also undergo selective trimerisation to the corresponding cyanurate structures[7,162,164].

VIII. 2,4,6-TRIARYLOXY-1,3,5-TRIAZINES (TRIARYL CYANURATES) FROM ARYL CYANATES

In the presence of catalysts aryl cyanates readily undergo trimerisation to 2,4,6-triaryloxy-1,3,5-triazines (Table 5):



In contrast to alkyl cyanates, aryl cyanates do not isomerise into isocyanates: resonance interaction occurs between the cyanato-oxygen atom and the aromatic ring[165] (σ_R^0 = −0.27), which stabilises the carbon–oxygen bond.

Table 5. 2,4,6-Triaryloxy-1,3,5-triazines from aryl cyanates ArOCN.

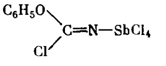
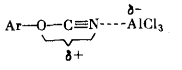
*Duration of reaction in minutes (Ed.of Translation).

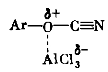
Active catalysts for the trimerisation of aryl cyanates include protic and aprotic acids[7,158,166–180] and bases[157,166–168,173,175–181], mixtures thereof[176], transition-metal complexes[176–178,182–190], and others[176]. Several hypotheses on the mechanism of catalysis of this reaction by Lewis acids [antimony(V), tin(IV) and aluminium(III) chlorides, the ether complex of boron trifluoride] were made by Martin and Weiss[172] in an infrared spectroscopic investigation of complexes of aryl cyanates with Lewis acids. But, whereas the boron trifluoride–ether complex produces no change in the structure of phenyl cyanate, antimony pentachloride forms in dichloromethane solution the complex (XXXI). From the shift in the infrared absorption band of the cyanato-group and the appearance of a few new bands in the range 1700–700 cm^{-1} it was suggested that structures such as (XXXII)–(XXXVI) might be formed. Structure (XXXVII) was assumed for the complex $ArOCN-SnCl_4$. The way in which the complexes (XXXII)–(XXXVII) are involved in trimerisation has not yet been ascertained[172].



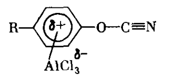
(XXXI)



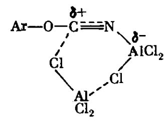
(XXXII)



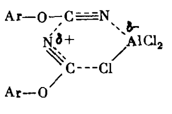
(XXXIII)



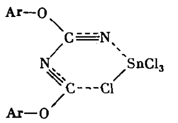
(XXXIV)



(XXXV)

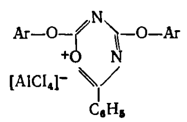


(XXXVI)



(XXXVII)

The complex of aluminium and benzoyl chlorides[174] causes especially rapid trimerisation of aryl cyanates, probably with intermediate formation of 2,4-diaryloxy-6-phenyl-3,5-diazapyrylium tetrachloroaluminate[191]



This intermediate can be isolated by replacing aluminium(III) by antimony(V) chloride.

Shevchenko et al.[170] trimerised aryl cyanates in the presence of phosphorus pentachloride, and showed that the reactions

$$ArO{-}C{\equiv}N + PCl_5 \rightarrow ArO{-}C(Cl){=}N(PCl_4) \xrightarrow{+PCl_5}$$
$$\rightarrow [ArO{-}C(Cl){=}N(PCl_3)]^+PCl_6^- \xrightarrow{+ArO-C\equiv N} [(ArOC(Cl){=}N)_2PCl_2]^+PCl_6^-$$

occurred between −20 and −40°C.

Gaseous hydrogen chloride is a very good catalyst for the trimerisation of aryl cyanates[158,173–175]. On cooling in inert solvents phenyl cyanate forms with excess of anhydrous hydrogen chloride or bromide the complex

(XXXVIII)

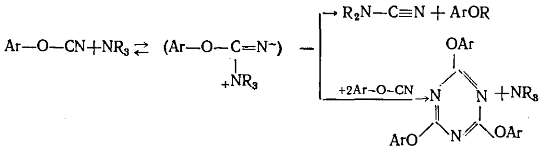
a : Hal=Cl
b : Hal=Br

which separates from solution (in almost theoretical yield). The complex (XXXVIIIa) is more stable than (XXXVIIIb), comparable in stability with the cyanamide complex $H_2NCN.2HCl$,[192] whereas the corresponding complexes of acetonitrile[173] and thiocyanates[193] decompose at room temperature§. Mesomeric interaction of the aryloxy-group with the C_{sp^2} atom obviously enhances the activity of the imino-nitrogen atom.

There are hints in the literature[176–178] that the rate of the catalytic cyclotrimerisation of aryl cyanates by Lewis acids is appreciably increased by the addition of water.

Monohydric and dihydric phenols of varying acidity have also been examined as catalysts for the trimerisation of aromatic cyanic esters. The reaction velocity increases in proportion to the decrease in the pK_a of the phenols, and appropriate correlations have been derived[176,177].

High yields of aryl cyanurates have been obtained in the presence of bases. In addition to the catalysts listed in Table 5 alkoxides[166–168], aliphatic and heterocyclic tertiary amines[166,175–178,180], and sodium hydroxide[166,175] have been used. Several suggestions have been made concerning the mechanism of trimerisation catalysed by tertiary amines[166,173,176,177,181]. Thus it has been assumed[181] that the complex (XXXIX) is formed, and then may either take part in trimerisation or break down into a cyanamide and an ether by the van Braun reaction:



(XXXIX)

Pankratov et al. have shown[195] that the substituted cyanamide is not the active catalyst in the cyclotrimerisation of aryl cyanates. With tertiary amines of type NR_3 weakening their basicity produces some decrease in rate of cyclisation[176,177]. Pyridine and isoquinoline, however, despite their weak basicity, possess catalytic activity exceeding severalfold that of the considerably more basic aliphatic tertiary amines. This phenomenon is attributed[176,177] to the greater steric accessibility of the nitrogen atom in heterocyclic amines. It is noteworthy that mixtures of trihexylamine both with diphenylpropanediol and with tin dichloride exhibit a synergistic effect when used as catalysts[176,177].

Complexes of transition metals have also been used as trimerisation catalysts[176–178,182–190]. The kinetics and the heat of cyclotrimerisation of various aryl cyanates in the presence of chromium(III) acetylacetonate have been investigated by means of a double calorimeter[182–189]. The heat of reaction, the rate, and the effective activation energy were shown to be largely determined by the nature of the solvent, and the role of specific solvation in various solvents is discussed[186]. The nature of ring substituents in phenyl cyanates also has a great influence on the heat of reaction and the kinetic parameters: electron-donor substituents diminish, whereas electron-acceptor substituents increase, the rate of cyclotrimerisation, which correlates well with the σ_R^0 constants of the substituents[187].

The trimerisation of aryl cyanates by chromium(III) acetylacetonate is autocatalytic. Investigation of the nature of the active centre has shown[185] that the presence of water accelerates cyclotrimerisation, whereas the

---

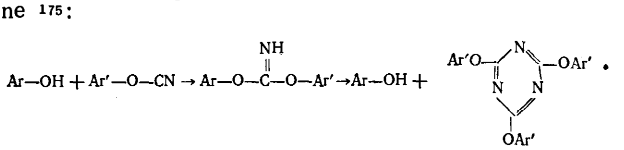
§Phenyl thiocyanate in ether does not form complexes with hydrogen chloride even at −78°C.[194]

introduction of pentane-2,4-dione considerably retards it. It was suggested that water was involved in producing the active form of the catalyst, which was in equilibrium with the main form:

$$\mathrm{Cr\,(acac)_3 + H_2O \rightleftarrows [Cr\,(acac)_2]^+OH^- + acacH}\ .$$

The 1,3,5-triazine ring is stabilised both by delocalisation of electrons to form an analogue to the π system of the benzene ring and by partial polarisation of the cyclic nitrogen–carbon bond[182,196]. The experimental heat of cyclotrimerisation of phenyl cyanate to triphenyl cyanurate was compared with the heat of reaction in the gaseous state (ΔH = −84.3 ± 1.0 and −58.2 kcal mole^{-1}). The latter value was calculated from the heats of formation of the two compounds computed additively from the contributions by the appropriate groups ($\Delta H^\circ_{\mathrm{form}}$ = 29.7 and 30.9 kcal mole^{-1}). The difference of 26 kcal mole^{-1} between experimental and theoretical heats of trimerisation was regarded as the energy of stabilisation of the 1,3,5-triazine ring (that of the benzene molecule is ~36 kcal mole^{-1}).[182,196]

Phenols add readily to aryl cyanates in the presence of bases[175] to form carbonimidic esters (XL) that decompose when heated, with separation of the more acidic phenol ($\mathrm{p}K_{\mathrm{ArOH}} < \mathrm{p}K_{\mathrm{Ar'OH}}$) and the 2,4,6-triaryloxy-1,3,5-triazine[175]:



(XL)

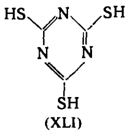
Formation of carbonimidic esters as intermediate products has been observed also in the trimerisation of aryl cyanates catalysed by alkoxides[197-201].

2,4,6-Triaryloxy-1,3,5-triazines can be formed also from aryl thiocarbamates by elimination of hydrogen sulphide followed by rapid trimerisation of the resulting aryl cyanates[169,199].

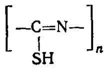
The formation of 2,4,6-triphenoxy-1,3,5-triazine from cyanogen chloride and sodium phenoxide[148,150,202] probably occurs by a similar mechanism to scheme (4).

IX. 1,3,5-TRIAZINES FROM THIOCYANIC ACID AND ITS DERIVATIVES

Thiocyanic acid exists in tautomeric equilibrium with isothiocyanic acid. In aqueous solution the equilibrium is strongly displaced towards thiocyanic acid[203], which can be trimerised to 1,3,5-triazine-2,4,6-trithiol (XLI). Only one case has yet been found[204] in which the thiocyanic acid formed in a reaction has been 23% converted into (XLI) and 77% into a linear polymer (XLII).

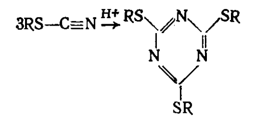


(XLI)



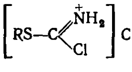
(XLII)

In contrast to alkyl cyanates, alkyl thiocyanates trimerise in the presence of acid catalysts to 2,4,6-trialkylthio-1,3,5-triazines (Ref. 1, p. 111), without formation of thio-compounds analogous to isocyanurates (Section VII)[205-207]:

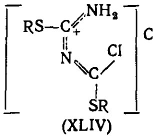


$R = CH_3,\ C_2H_5,\ C_2H_5O_2C{-}CH_2,\ CH_3{-}CO{-}CH_2$.

When heated in the absence of a catalyst, pure methyl thiocyanate does not trimerise, but isomerises into methyl isothiocyanate[205].



(XLIII)



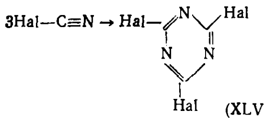
(XLIV)

Alkyl thiocyanates form adducts from hydrogen halides[39,194]. Those with two molecules of the latter (XLIII) resemble the corresponding adducts of acetonitrile[193] in being unstable at room temperature[194]. Adducts of structure (XLIV) have since been obtained[39] on the introduction of hydrogen chloride into alkyl thiocyanates (RSCN, where R = CH_3, C_2H_5, C_3H_7, C_4H_9, C_8H_{17}, $C_6H_5CH_2$); when heated, they were converted into the corresponding 1,3,5-triazines.

Trimerisation of aryl thiocyanates has not been reported: they have been used solely as "dienophiles" in mixed trimerisation (Section XI).

X. 2,4,6-TRIHALOGENO-1,3,5-TRIAZINES (CYANURIC HALIDES) FROM CYANOGEN HALIDES

Many studies have been made of the trimerisation of cyanogen halides to 2,4,6-trihalogeno-1,3,5-triazines (XLV):

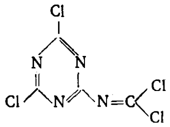


(XLV)

a) Hal = F; b) Hal = Cl; c) Hal = Br .

The more reactive the cyanogen halide, the more readily does it trimerise and polymerise: whereas liquid cyanogen fluoride is rapidly converted into (XLVa) and a polymer even at room temperature[208], trimerisation of the chloride[209-231] and the bromide[232-234] requires the presence of catalysts (acids, metal oxides or sulphides, activated carbon, zeolites, etc.). Trimerisation of cyanogen iodide has not been reported.

Together with the trimer (XLVb) have been isolated tetramers



(XLVI)

and polymers[209-212]. In some cases[209,211] the compound (XLVI) is the main product. It can be converted into (XLV) by being heated with activated carbon to 400 to 450°C.[213]

Most of the investigations on the trimerisation of cyanogen halides have been made on the chloride. Little research has been done on the mechanism of the reaction catalysed by hydrogen chloride and by Lewis acids [aluminium chloride, boron, tin(IV), and phosphorus(V) fluorides] [209–211,214–219,231,234]. Catalysis with hydrogen chloride involves initial formation of an adduct with cyanogen chloride[¶], which is then converted into a dimer. The latter reacts further either with another molecule of cyanogen chloride to give the trimer (XLVb) or with another dimer molecule to form the tetramer (XLVI).[209,210]

Good yields of (XLVb) have been obtained by using as catalysts metal sulphides and oxides,[212,220–222] activated carbon,[220–228] and also zeolites.[229,230] The catalyst poisoning that occurs with activated carbons can be diminished by introducing into them china, graphite, or quartz.[224]

Malinin et al.[216,218,223] have investigated the kinetics of the trimerisation of cyanogen chloride in the gas phase[†] on activated carbon at 280–540°C, and have found that the reverse reaction takes place above 430°C. They have suggested[218,223] a kinetic model for the range 440–540°C that takes into account the reverse reaction, the decrease in catalytic activity with time, and also the observed reaction velocities:

$$A + [K] \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} [AK] \tag{5.1}$$

$$[AK] \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} [AK^*] \tag{5.2}$$

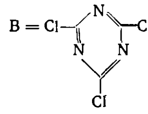
$$2[AK^*] \underset{k_{-3}}{\overset{k_3}{\rightleftarrows}} [2AK^*] + [K] \tag{5.3}$$

$$[2AK^*] + [AK^*] \underset{k_{-4}}{\overset{k_4}{\rightleftarrows}} [3AK^*] + [K] \tag{5.4}$$

$$[3AK^*] \underset{k_{-5}}{\overset{k_5}{\rightleftarrows}} B + [K] \tag{5.5}$$

$$[AK] \xrightarrow{k_6} [AK^{**}] \tag{5.6}$$

A = ClCN; B =



, [K] = Catalyst.

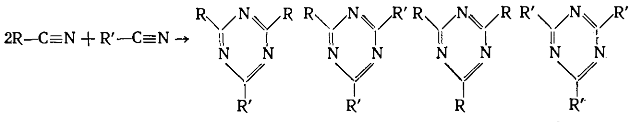
In the first stage (5.1) a molecule of cyanogen chloride is sorbed on the activated carbon, the product is activated [AK*] (5.2), and then other molecules of cyanogen chloride are added (5.3 and 5.4). After this the trimer is desorbed, and the active catalyst [K] returns to the reaction (5.5). Equation (5.6) represents the case in which cyanogen chloride does not trimerise but forms polymers $(ClCN)_n$, where $n > 3$. The trimerisation of cyanogen chloride on highly active carbons is apparently due to the presence of a graphite phase, on which cyanogen chloride molecules can be spatially oriented[229].

Wolf and Renger[229,230] have examined the influence of additions of crystalline molecular sieves on the trimerisation of cyanogen chloride. Coordination of the chloride molecules on the oxygen atoms of the catalyst facilitates their subsequent interaction to form the 1,3,5-triazine ring. The trimerisation of cyanogen chloride is a first-order reaction[229] with an activation energy of 15.2 kcal mole^{-1}.

Cyanuric halides (XLV) can be obtained not only from cyanogen halides but also directly from the halogens and hydrogen cyanide without intermediate isolation of the cyanogen halides[214,215,217,232,234].

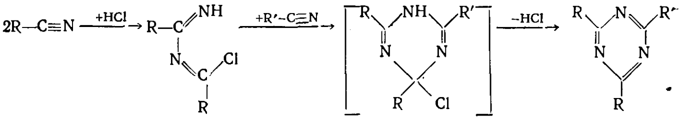
XI. MIXED CYCLOTRIMERISATION

The mixed trimerisation of two or three compounds containing a cyano-group can yield theoretically four or ten different 1,3,5-triazines. Only the former case



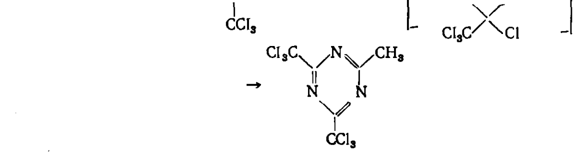
(XLVII) (XLVIII) (XLIX) (L)

has been investigated experimentally (Table 6). The catalytic activity of Brønsted and Lewis acids towards this reaction increases in the sequence from gaseous hydrogen chloride[40,50,237–243] through hydrogen chloride plus a Lewis acid to hydrogen chloride plus aluminium bromide[50,244]. In general aluminium bromide is a relatively inactive catalyst[50]. Grundmann[40] showed that catalysis by hydrogen chloride is accompanied by selective mixed trimerisation by dienophilic addition of the cyanide RCN to the adduct (LI) to form the trimer (XLVII):



(LI) (LII) (XLVII)

The intermediate complex (LII) evolves hydrogen chloride spontaneously with the formation of (XLVII). Successful selective mixed trimerisation to (XLVII) depends on the ability of the cyanides to form "dienes" (LI) and on the relative "dienophilic" activities of RCN and R'CN. When RCN forms a "diene", the products (XLVII) and (XLIX) may be expected. If the rate of addition of R'CN to the "diene" far exceeds that of RCN, the product (XLVII) is formed selectively. This occurs in the reactions of trichloroacetonitrile, catalysed by hydrogen chloride, with acetonitrile,[40,50] aryl cyanides,[40,242] and thiocyanates [50][‡] (Table 6, No. 2, 4, and 5). In the catalysed reaction between trichloroacetonitrile and acetonitrile (2 : 1) more rapid conversion is obtained[50] by using an equimolecular mixture of the ready prepared "diene" (LI) (R = CCl_3) and the equimolecular adduct of acetonitrile with hydrogen chloride instead of "free" acetonitrile:



[¶] Hydrogen fluoride acts on cyanogen halides in the absence of moisture at 200–450°C to form bistrifluoromethylamine $(CF_3)_2NH$.[235]

[†] Humphries and Nicholson[236] calculated the heat of formation of (XLVb) as 72.9 kcal mole^{-1} from the reaction 3 ClCN (gas) → $(ClCN)_3$ (liq.).

[‡] Although in acid medium thiocyanates isomerise readily into isothiocyanates[245], formation of the latter has not been observed in mixed cyclotrimerisation[243,244].

Table 6. Mixed cyclotrimerisation of cyano-compounds RCN and R'CN.

---

*Symbols: + = trimer isolated; (+) = traces of trimer found; – = compound not formed.

**Mixed trimerisation proceeded better if the reaction mixture was heated to 150–200°C after the introduction of hydrogen chloride. In all other cases the reactions were conducted in the range from –40 to 25°C.

***Reaction conducted under pressure.

****Cyclotrimerisation took place in the absence of a catalyst.

Compound (XLVII) is formed only[67,238,239] when the molecular ratio RCN:R'CN $\leqslant$ 2.

The main product (XLVII) of the reaction between cyanogen chloride and hydrogen cyanide (2 : 1) is accompanied by traces of 2,4,6-trichloro-1,3,5-triazine (XLIX),[237] which indicates competitive addition of cyanogen chloride (RCN) to (LI). In the reaction between ethyl cyanoformate or cyanogen chloride and acetonitrile (2 : 1),[40] however, this last compound (R'CN) adds preferentially to (LI) (Table 6, No. 8).

If both cyano-compounds are able to form "dienes", three types of reaction are hypothetically possible. When the rates of formation of the "diene" (LI) and of subsequent addition of "its own" nitrile with separation of (XLIX) exceed the corresponding rates for the other nitrile, the homotrimerisation products (XLIX) and (L) should be formed exclusively. In the second alternative both "dienes" prefer to react solely with the "foreign" nitrile, and only the mixed trimerisation products (XLVII) and (XLVIII) should be formed. Neither type of reaction has yet been met in practice.

The third case—formation of all four structures (XLVII)-(L)—is realised with trichloroacetonitrile and ethyl cyanoformate (2 : 1) (Table 6, No. 6). The proportions on the products ($R = CCl_3$, $R' = C_2H_5COO$) can easily be controlled by varying the reaction conditions[40]. Thus initial treatment of trichloroacetonitrile with hydrogen chloride to form the "diene" followed by introduction of the ester yields (XLVII) as the main product. When hydrogen chloride is introduced into a mixture of the two nitriles, however, the main product will be (XLVIII): i.e. the rate of "diene" formation is greater from the ester than from the nitrile.[40]

Only qualitative information is available on uncatalysed mixed cyclotrimerisation[246]. The proportions of the products suggest[246] that RCN ≪ R'CN in "dienophilicity", while RCN ≫ R'CN in tendency to diene formation (Table 6, No. 9 and 10). A few cases of mixed cyclotrimerisation have been reported also in which nitriles are apparently formed as intermediate products during the reaction[67,240,241,247].

o0o

In conclusion we must note the great theoretical and practical value of research on the cyclotrimerisation of compounds containing cyano-groups. As a consequence of the large number of investigations in this field, especially during recent years, the influence of the chemical structure of the initial cyano-compounds, the catalysts, and also several other factors has been elucidated. This in turn has permitted the directed synthesis of 1,3,5-triazines having valuable combinations of properties. For example, 1,3,5-triazines containing perfluorinated substituents are stable up to ~500°C and can be used as thermostable heat-transfer agents and lubricants.

Further fundamental research is required on the reaction mechanism. Mixed cyclotrimerisation of various cyano-containing compounds has great prospects, enabling the synthetic possibilities to be greatly extended.

At the present time several cyano-compounds—hydrocyanic acid, cyanogen chloride, cyanamide, acrylonitrile, etc.—are large-tonnage industrial products. Several 1,3,5-triazines (cyanuric chloride, melamine, cyanuric acid, and their derivatives) are produced on a large scale.

In view of the simplicity and technical importance of the cyclotrimerisation of compounds containing cyano-groups, industry may be expected in the near future to make use of many valuable new monomeric and polymeric products containing 1,3,5-triazine rings.

Functional Group Analysis of Nitrogen- and Sulphur-containing Organic Compounds

M.A.Ignatenko, V.K.Promonenkov, T.S.Godunova, and E.N.Kayushina

Data published during the last 7-9 years on problems concerning the determination of nitrogen- and sulphur-containing functional groups in organic compounds are surveyed.
The bibliography includes 281 references.

I. INTRODUCTION

Methods of functional group analysis are of indepenent important both in industry, for the analysis of various industrial mixtures, and in the study of newly synthesised compounds. During recent years, three monographs have been published[1-3] on advances in analytical chemistry in the field of functional group analysis of organic compounds. However, they deal only with studies published up to 1967. This paper represents a review of studies on the analysis of various amines, amides, hydrazines, hydrazides, oximes, nitro- and nitroso-compounds, thiols, sulphides, disulphides, sulphonic acids, etc., carried out in 1968 to 1977.

Studies on analysis in recent years have been carried out with the following main aims: (1) the improvement of known analytical methods, their application to more complex systems, and detailed investigation of reaction mechanisms; (2) automation of methods involving the use of electrometric methods for the determination of the titration end point (amperometry, potentiometry, and coulometry); (3) the application of new chemical reagents; (4) the development of new analytical methods.

II. TITRIMETRIC METHODS FOR THE DETERMINATION OF NITROGEN- AND SULPHUR-CONTAINING ORGANIC COMPOUNDS

1. Acid–Base and Oxidation–Reduction Titration Methods

(a) Determination of amines. Acid–base titration is one of the classical methods for the analysis of nitrogen-containing organic compounds, but it has not been used on a sufficiently large scale until the non-aqueous titration technique became popular[4]. At present organic bases are widely determined by acid–base titration in research and in industry[5,6]. Comparatively recently a review has been published on methods for the determination of aromatic amines[7], which shows that the most general and easiest method for determining amino-groups is non-aqueous potentiometric titration. Thus a procedure has been proposed[8,9] for the non-aqueous potentiometric titration of polyethyleneamines and pyridyl-containing carbamates using a solution of $HClO_4$ in glacial acetic acid as the titrant. Solutions of neutral salts ($CaCl_2$, LiCl, NaCl, etc.) are sometimes used in the potentiometric determination of weak bases. The effectiveness of the above salts is determined by their influence on the hydrogen ion activity and entails an increase of the width and sharpness of the potential jumps. Kreshkov et al.[10] investigated certain features of potentiometric titration in solutions of alkali and alkaline earth metal chlorides and developed methods for the determination of amines; they also studied the influence of the salt solution on the pH shift. According to the authors[10], the best salts are LiCl and $CaCl_2$. Thus *m*-, *p*-, and *o*-phenylenediamines were titrated using $CaCl_2$ solutions; comparison of titration curves in a salt solution with the corresponding curves for the same substances in water shows that the use of a salt solution greatly improves the titration conditions. The error of the method is 0.3%.

Titration in a non-aqueous medium has been used for the joint determination of higher aliphatic amines and quaternary ammonium salts[11]. The method is as follows: the quaternary ammonium salt is converted into the perchlorate or iodide and the remaining amine is determined by titration with $HClO_4$. After the titration of the amine, mercury(II) acetate is added in order to convert the quaternary ammonium perchlorate or iodide into the highly basic quaternary ammonium acetate and the undissociated HgI_2:

$$2\,(R_4\overset{+}{N}\overline{I}) + Hg\,(CH_3COO)_2 \rightarrow 2\,(R_4\overset{+}{N}CH_3COO^-) + HgI_2 \quad .$$

HgI_2 is then dissolved in an excess of the mercury(II) acetate solution and the quaternary ammonium acetate is titrated with $HClO_4$:

$$R_4\overset{+}{N}CH_3COO^- + H^+ + ClO_4^- \rightarrow CH_3COOH + R_4\overset{+}{N}ClO_4^- \quad .$$

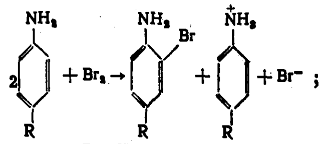
Since the basicity of all the compounds titrated is high, the final titration point is readily determined visually. For specimens with a ratio of tertiary amine to quaternary ammonium salt of 1 : 40, the results of the determination of the amine were reproducible to within 3–5% and those of the determination of the quaternary ion were reproducible to within 1–2%.

Potentiometric titration of a 0.1 *N* $HClO_4$ solution using differentiating non-aqueous solvents has been used to determine amine *N*-oxides. The methods for a quantitative determination of amine *N*-oxides are based mainly on their reduction to amines and the determination of the excess reductant. $SnCl_2$, $TiCl_3$, and HCl have been recommended as reductants[1]. However, these methods suffer from many limitations. Methods involving the direct titration of the *N*-oxides as bases are more promising[12].

Comparison of the ionisation constants of amines and *N*-oxides showed that aliphatic and saturated heterocyclic amines and their *N*-oxides with $pK = 4-5$ can be determined separately by potentiometric titration with $HClO_4$ in differentiating non-aqueous solvents. The interaction of amine *N*-oxides with protic acid solutions in dioxan, ethyl methyl ketone, and acetonitrile proceeds via a stage involving the formation of anomalous salts in which there are two molecules of the base per acid molecule. The method proposed[12] has been used to analyse mixtures of amine *N*-oxides and amides, hydrogenated aromatic heterocyclic bases, and the corresponding amines. Kwiatkowski et al.[13] used potentiometric titration in dimethyl sulphoxide (DMSO) with the aid of glass electrodes to analyse di-(n-butyl)amine, tri-(n-butyl)amine, piperidine, *N*-ethylpiperidine, allylamine, isobutylamine, diethanolamine, etc.

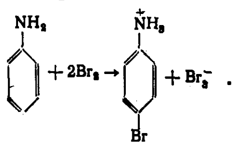
Careful studies of potentiometric titration in non-aqueous media are being continued and the influence of the titrant concentration, temperature, and amine structure is being investigated. Apart from $HClO_4$, the titrants used in the determination of amines are HCl, H_2SO_4, and toluene-*p*-sulphonic acid, dissolved in DMSO.[13] However, in many instances, particularly in the analysis of the products of synthesis, precipitates or tarry substances are formed during the titration, coat the electrodes, and interfere with a clear-cut determination of the titration end point. The high-frequency titration method, which is free from this disadvantage, was therefore used in the determination of certain aromatic amines[15]. This procedure has been used successfully for the overall and separate determination of primary and secondary amino-groups in polyethylenepolyamines and products of synthesis based on them. A TV-61 high-frequency titrator was employed; the determinations were carried out mainly by the back-titration method, since the equivalence point is then determined more clearly. A suitable solvent, ensuring the most distinct inflections in the titration curve, was selected for each compound.

The bromination method is frequently used for the quantitative determination of amines. The bromide–bromate system, which evolves bromine in an acid medium, has come to be employed as a source of bromine. However, this method requires the use of aqueous solutions which has limited its applications to the determination of amines. In recent years a number of studies have been made on titration with bromine in non-aqueous solutions[16-19]. Krause and Kratochvil[16] determined a number of aromatic amines to within 1% using propylene carbonate as the solvent. Propylene carbonate is a convenient medium for the bromination of amines, is resistant to the action of the halogen, has a high dielectric constant which increases the rate of reaction, is soluble in water, colourless, and non-toxic. The majority of amines are soluble in propylene carbonate. In many cases the bromination takes place in the presence of bases such as pyridine (in order to bind the evolved protons). Like the hydroxy-group, the amino-group activates the *ortho*- and *para*-positions in electrophilic aromatic substitution. Since primary amines are proton acceptors, the bromination of certain amines in propylene carbonate is possible without the addition of a base. In the titration of *p*-phenetidine, *p*-toluidine, and aniline the potential increases sharply when 1-2 equivalents of bromine has been added. This can be explained by the reaction

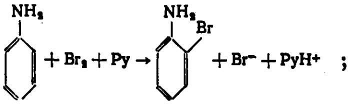


$R = CH_3$, H, or OC_2H_5.

Since the monobrominated aromatic amine is a weaker base than the non-brominated amine, the protons produced in the substitution stage apparently combine with the non-brominated amine. The protonated amine is not brominated subsequently, since the protonated amino-group hinders electrophilic substitution. The second potential jump in the absence of pyridine occurs after the addition of two moles of bromine per mole of aniline:

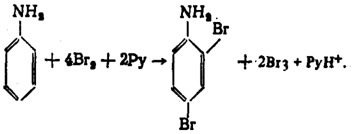


When pyridine is present in the reaction mixture, two potential jumps also occur. The first takes place after the addition of one equivalent of bromine:



Py- pyridine.

The second occurs after the addition of four moles of bromine per mole of aniline:



p-Toluidine behaves similarly to aniline. The introduction of a third bromine atom in the free *ortho*-position of aniline is apparently difficult, although after the addition of six moles of bromine a very small potential jump does appear[16].

Analysis of *m*-phenylenediamine by titration with bromine is possible both in the presence of pyridine and in its absence. The bromide–perbromide system in pyridine[17] (PBPB, $C_5H_5N.HBr.Br_2$), each molecule of which readily evolves one molecule of free bromine, may be used as the source of bromine. The greater availability of crystalline PBPB compared with the bromide–bromate solution and high reaction rates with minimal side reactions make this method more suitable in both preparative and analytical chemistry. The above system had been used previously to brominate substituted phenols and aromatic amines and aliphatic and alicyclic ketones in acetic acid[18]. The system has been used[17] to determine aniline and various monosubstituted anilines. The majority of reactions were rapid (over a period of 10–15 min); the concentration of the amine analysed was 10^{-4} M and the error of the method was $<1\%$. The end point was determined spectrophotometrically; photometric titration is possible only for colourless or slightly coloured products, which is a significant disadvantage of this method.

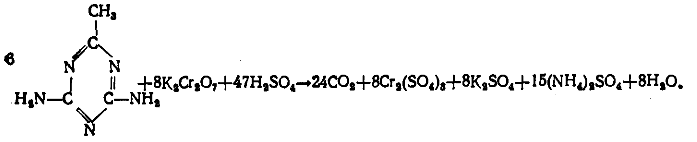
Sotsenko et al.[19] modified the bromide–bromate method for the determination of aromatic amines in various solutions. The essential feature of their procedure reduces to analysis in a specially designed diffusion apparatus with addition of a known excess of a standard bromide–bromate solution. In an acid medium the free bromine evolved brominates, for example, aniline to tribromoaniline and its excess is absorbed by a potassium iodide solution deposited on a porous material (filter paper or synthetic water-soluble paper). The titration of the iodine, evolved in an amount equivalent to that of the absorbed bromine, is carried out in the same apparatus with sodium thiosulphate solution; the time required for the analysis is 10 min at 40°C or 17 min at room temperature, and the accuracy of the determination is to within 1.5%. This method can be used to analyse dark or intensely coloured solutions. Sotsenko et al.[19] analysed *m*-toluidine, anthranilic acid, sulphanilic acid, and anilinium chloride. In the determination of semicarbazide hydrochlorides Campbell et al.[20] used successfully titration with potassium bromate in the presence of metal ions (nickel, cobalt, and manganese). Semicarbazides are determined with $KBrO_3$ in accordance with the following scheme:

$$3NH_2\underset{\overset{\|}{O}}{C}NHNH_2 + 2BrO_3^- \rightarrow 2N_2 + 3CO_2 + 3NH_3 + 2Br^- + 3H_2O \quad .$$

Iodometric titration combined with various procedures for the detection of the titration end point is widely used in the determination of organic compounds. A thermometric titration method, in which alicyclic and aliphatic amines and hydrazines are titrated with iodine in non-aqueous solutions containing alkyl vinyl ethers, which polymerise exothermically in the presence of an excess of iodine, has been described[21]; the titration end point is determined on the basis of the exothermic polymerisation reaction. This method has an accuracy to within 1% in most cases.

In the above study iodine was used both as the titrant and as the catalyst of the cationic polymerisation and ethyl vinyl ether was employed as the monomer. Among organic bases, aliphatic and alicyclic amines have been determined by this procedure, namely n-butylamine (3.6), benzylamine (3.7), piperidine (3.6), tris(hydroxymethyl)-methylamine (4.3), 2-*N*,*N*′-diethylaminopropionitrile (4.4), *N*-methylmorpholine (4.6), etc.; pyridine derivatives, namely pyridine (4.1), *α*-picoline (3.8), pyridine-2,6-dicarboxylic acid (0.09), pyridine *N*-oxide (2.2), 3-picoline *N*-oxide (2.2), etc.; aniline derivatives, namely aniline (1.3), *o*-toluidine (1.5), diphenylamine (0), triphenylamine (0), etc.; and heterocyclic nitrogen-containing compounds, namely hexamethylenetetramine (5.0), phthalazine (3.5), quinoline (0), and benzimidazole (4.0). The number of iodine atoms consumed per molecule of the test compound is indicated in brackets. It is believed[21] that the number of iodine atoms reacting with the molecule of the base may be used as a measure of the strength of the base.

The titrimetric method involving oxidation by $K_2Cr_2O_7$ has been used successfully[22] to determine acetoguanamine in the presence of melamine and guanidine; the excess oxidant was determined iodometrically:



$$+8K_2Cr_2O_7+47H_2SO_4\rightarrow 24CO_2+8Cr_2(SO_4)_3+8K_2SO_4+15(NH_4)_2SO_4+8H_2O.$$

A method of direct potentiometric titration of various amines by hypobromite, based on the hydrogen substitution reaction in the amino-group has been proposed[23]:

$$RNH_2 + 2BrO^- \rightarrow R{-}NBr_2 + 2OH^- \quad ,$$
$$R_2NH + BrO^- \rightarrow R_2{-}NBr + OH^- \quad .$$

The authors[23] tested the method on 40 different compounds.

(b) Determination of hyrazine and its derivatives. A monograph[24], which describes a comparative analysis of all the existing methods and examines in detail the reaction mechanisms and the influence of various factors on analytical results, is devoted to various methods for the determination of hydrazine and its derivatives. Malone[25] proposed an acid–base isocyanate method for the determination of mixtures of hydrazine with 1,1-dimethylhydrazine and monomethylhydrazine. The method is based on the difference between the rates of reaction of isocyanate with the corresponding hydrazines in anhydrous acetic acid solution; the rate of reaction decreases in the sequence hydrazine > monosubstituted hydrazine ≫ disubstituted hydrazine. An alcoholic HCl solution was used as the titrant, the accuracy of the method being to within 0.1 to 0.5%. A method involving direct non-aqueous titration in dimethylformamide (DMF) by strong bases has been proposed for the determination of *N*,*N*′-diacylhydrazines[26]. Tetrabutylammonium hydroxide or potassium t-butoxide were proposed as titrants in the presence of 2-nitroaniline as the indicator.

Titration with a solution of ICl in 5 *N* HCl has been used recently[27] to determine hydrazine, phenylhydrazine, *p*-nitrobenzoic hydrazide, semicarbazide, and isonicotinic acid hydrazide; the oxidation is in all cases rapid and quantitative. Amperometric titration methods for the determination of certain mono- and di-substituted hydrazines with a permanganate solution at pH 6–7 have been described[28]. The relative standard error in ten replicate experiments was 3%. Subsequently the method was improved[29], using as the medium an aqueous acetone solution in which the potentials of the onset of the oxidation of hydrazine and dimethyl hydrazine at a platinum anode differ sharply. The reaction mechanism is based on the difference between the rates of oxidation by potassium permanganate of the products of the interaction of hydrazine and dimethylhydrazine with acetone in the presence of $Na_4P_2O_7$. A solution of potassium dichromate may be used as the oxidant; the accuracy of the method is to within 0.5%.[30]

(c) Determination of amides and nitriles. A review has been devoted to the determination of amides and nitriles[31]; the authors discuss the principal methods for the determination of amides: hydrolysis (alkaline, acid, and catalytic), potentiometric and amperometric titration, reduction with $LiAlH_4$, and colorimetry. For nitriles, there are as yet no specific analytical methods, which makes it very difficult to determine them chemically in mixtures with nitrogen-containing compounds. Hydrolysis yields satisfactory results only for primary aliphatic nitriles. Reports have been published recently about new methods for the determination of organic compounds of this class, which are discussed in detail in Section IV.

(d) Determination of oximes and their derivatives. The principal methods for the determination of compounds of this class are given in a monograph[1]. The latest studies[32,33] were devoted to potentiometric non-aqueous titration of mono- and di-oximes and benzohydroxamic acids with a 0.1 *N* solution of tetrabutylammonium hydroxide. In all cases a clear-cut end point, corresponding to one mole of base for one mole of oxime, was obtained. The influence of the solvent on the change in potential at the end point has been discussed[32,33]. An attempt[34] to modify the iodometric method for the determination of hydroxylamines (Blom's method) was unsuccessful; the authors studied the oxidation reaction in detail and proposed a mechanism:

$$\begin{gathered}RCH_2NHOH \xrightarrow{I_2} RCH{=}NOH \quad ,\\ RCH{=}N{-}OH \overset{H_2O}{\rightleftarrows} RCHO + NH_2OH,\\ NH_2OH \xrightarrow{I_2} NO_2^- \quad .\end{gathered}$$

The amount of nitrite formed from hydroxylamine derivatives depends on the rate of hydrolysis of the intermediate oxime; if the latter is low, the quantitative determination of nitrite is difficult. For this reason, the method is used only for qualitative analysis.

(e) Determination of nitro-compounds, nitroso-compounds, and nitrosamines. Aromatic nitro- and nitroso-compounds are determined by reduction either with Fe^{2+} in an acid or alkaline medium[35,36] or with an excess of titanium chloride solution[37]. An interesting method, involving the aquametric determination of nitro-compounds, based on their reduction by $SnCl_2$ in anhydrous acetic acid to the amine and water and subsequent determination of the evolved water with Fischer's reagent, has been proposed[38]:

$$RNO_2 + 3SnCl_2 + 6HCl \rightarrow RNH_2 + 3SnCl_4 + 2H_2O \quad .$$

The excess $SnCl_2$ was titrated with an anhydrous solution of iodine in DMF. Thus the content of NO_2 groups was estimated simultaneously by both potentiometric and aquametric methods. The titration end point was in both cases established biamperometrically using the $I_2 \rightleftharpoons 2I^-$ system; the accuracy of the method is to within 0.5%.

It has been suggested that thiourea dioxide (TUD) be used for the determination of nitro-groups in phenols[39]. The essential feature of the method consists in the quantitative reduction of the nitro-groups to amino-groups:

The aminophenols formed were determined spectrophotometrically.

Methods for the determination of nitrosamines are described in detail in reviews[41,42], where the chemical properties, biological activities, and methods of analysis of compounds of this class are considered. A sensitive method for the determination of nitrosamines consists in their reduction by $LiAlH_4$ to hydrazine and condensation of the latter with anthracene-9-aldehyde or phenanthrene-9-aldehyde, which leads to the formation of highly fluorescent hydrazones. After their isolation, the hydrazones are identified spectrophotometrically or mass-spectrometrically[43]. Mention should also be made of a new interesting reagent used to determine various functional nitrogen-containing groups, namely 1-chloro-3-ethylpent-1-en-4-yn-3-ol (Placidyl)[44]. This reagent can be used in various solvents (C_2H_5OH, $CHCl_3$, CCl_3CCl_3) to test for ureas, primary aromatic amines, *sym*-alkylhydrazines, and indole derivatives.

(f) Determination of thiols. One of the most frequently used methods for the determination of thiols is oxidative titrimetry. Direct and back titration with iodine, accompanied by the visual or potentiometric indication of the end point, are used[45-48]. The mechanism of the oxidation of thiols to disulphides has been studied in detail comparatively recently[48] and may be represented schematically as follows:

$$\begin{array}{l}2RSH + 2H_2O \rightleftarrows RSSR + 2\overset{+}{H_3}O + 2e^- \quad ,\\ 2e^- + (I_2)_{aq} \rightleftarrows 2I^- \quad ,\\ \hline 2RSH + (I_2)_{aq} + 2H_2O \rightleftarrows RSSR + 2I^- + 2H_3O^+ \quad .\end{array}$$

In an anhydrous medium the reaction does not go to completion owing to the reverse protolytic reaction

$$2H_3^+O + 2I^- \rightleftarrows 2HI + 2H_2O \quad .$$

The reducing effect of HI predominates. The reaction involving t-butylmercaptan proceeds to the sulphenyl iodide:

$$R_3CSH + I_2 \rightleftarrows R_3CSI + HI \quad .$$

The side reaction

$$R_3CSI + RSH \rightleftarrows R_3CSSR + HI$$

is suppressed with lead(II) nitrate, which forms the mercaptide and then lead iodide:

$$(RS)_2Pb + I_2 \rightleftarrows RSSR + PbI_2 \quad .$$

It has been shown[48] that there is a tendency towards further oxidation to higher oxidation states of sulphur, so that errors in the determination of certain thiols are possible.

Together with iodine, bromine or a bromide–bromate solution are used[49-51]. They are stronger oxidants than iodine and increase the degree of oxidation of the disulphide. The titration with bromide–bromate, proposed previously for the determination of sulphides and disulphides in acetic acid, has been used to determine thiols with potentiometric indication of the end point using platinum or graphite electrodes[49]. The potential jump corresponds to the reaction

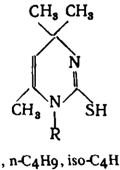
$$RSH + 3Br_2 + 7H_2O \rightleftarrows RSO_2Br + 5H_3\overset{+}{O} + 5Br^- \quad .$$

Aromatic thiols are oxidised quantitatively to sulphonyl bromides, while the reaction involving aliphatic thiols proceeds with difficulty. The sensitivity of the method is to within 5×10^{-8} M thiol. Apart from the bromide–bromate system, a study was made of the $Pb(CH_3COO)_4/Pb(CH_3COO)_2$ system[49], which has a still higher standard oxidation potential, but the oxidation of thiols to the sulphonic acids in anhydrous acetic acid was not observed. This is probably caused by the solvolysis in this medium. Only the following reaction takes place:

$$2RSH + (CH_3COO)_4Pb \rightleftarrows RSSR + (CH_3COO)_2Pb + 2CH_3COOH \quad .$$

The reaction is used in both potentiometric and visual titration with an indicator to determine primary aliphatic thiols with a long chain and aromatic and heterocyclic thiols[51].

Potassium or sodium periodate in dilute sulphuric acid has been used for the quantitative determination of primary and secondary thiols[52]. Thiocarbonyl compounds and sulphocyanamide ions interfere with the determination. The same method has been used[53] to determine 2-mercaptopyrimidines of the type



R = H, CH_3, n-C_4H_9, iso-C_4H_9, C_6H_5, 3-$NO_2C_6H_4$, or 2-NO_2-4-$CH_3C_6H_3$.

One of the oldest methods for the determination of thiols involves their oxidation with copper(II) salts. Nowadays the reaction is usually carried out in DMF with potentiometric indication of the end points, using platinum, graphite, or copper electrodes[54]. The oxidation of thiols by potassium hexacyanoferrate(III) $K_3[Fe(CN)_6]$ proceeds quantitatively only in an alkaline medium[54,55], but, since the oxidation of thiols is accelerated in air under these conditions, the determination must be carried out in an inert gas atmosphere; in the back titration ascorbic acid must be used to determine the excess $[Fe(CN)_6]^{3-}$. The accuracy of the method is to within 1.5%.

Iodine chloride and bromide and iodine and bromine cyanides are used very frequently to determine thiols[56-58]. The method is based on the oxidation of thiols to disulphides:

$$2RSH + IX \rightleftarrows RSSR + HI + HX;$$
$$X = Cl,\ Br,\ or\ CN.$$

The reaction is carried out in an aqueous or anhydrous medium with potentiometric or visual indication of the equivalence point. The somewhat unstable results obtained when iodine cyanide is used[57] are associated with the formation of hydrogen iodide, which is a powerful oxidant. Its influence can be eliminated by adding benzene, because HI is soluble in water and thiols are soluble in benzene. Bromine cyanide is more convenient than iodine cyanide, because HBr is a weaker reductant. The accuracy of the method is to within 0.25%. Thiocarbonyl compounds, sulphides, and thiocyanate ions interfere with the determination. It has been found recently[59] that, in the presence of acetic acid, thiols are readily and quantitatively oxidised to disulphides by *N*-bromosuccinimide. However, this method is inconvenient owing to the low solubility of *N*-bromosuccinimide in water and the changes in its solutions with time.

A number of methods for the determination of thiols are based on the formation of insoluble or undissociated mercaptides. These are primarily reactions with silver and mercury ions. Silver salts had been frequently used previously to determine thiols by amperometric titration[2], but, in view of the difficulty of determining the end point, potentiometric determinations have come to be used. During recent years, methods have been developed for the determination of thiols using silver electrodes[60-64] with solutions of mercury salts and silver nitrate as titrants. Apart from mercury salts, organomercury compounds, which are more selective for the thiol group, are frequently employed. *p*-Dimethylaminophenylmercury acetate and *p*-diethylaminophenylmercury acetate[65,66] have been proposed for the visual, potentiometric, and amperometric titration of thiols (the error of the method is $<1.5\%$).

Qualitative tests for the mercapto-group must also be mentioned. Thus the reaction of thiols with 2,2-dithiobis-(5-nitropyridine) leads to the appearance of a yellow colour due to the formation of 5-nitropyridine-2-thione[67]. This reaction is used for the detection of thiols in paper and thin-layer chromatography. Another sensitive test for the SH group is reaction with $Hg(CN)_2$,[68] which leads to the formation of mercury mercaptide and HCN. The evolution of the latter may be detected from the appearance of a blue colour in filter paper impregnated with a solution of tetrabase or copper ethylacetoacetate in chloroform. The minimum amount of thiols which may be determined is 1–5 μg.

(g) Determination of sulphides and disulphides. The principal methods for the determination of sulphides and disulphides have been described fairly completely in a monograph[1] and in conference proceedings[3,6]; during recent years, few studies have been published on the analysis of compounds of this class. Thus a method involving acid–base potentiometric titration with sodium hydroxide in DMF has been proposed for the analysis of bis-(2-carboxyphenyl) disulphide[69]. Potentiometric titration (using a silver sulphide electrode) by silver salts has been employed for the separate determination of thiols and disulphides in a mixture[48]. The thiol is titrated initially and then sodium sulphite is added, the latter reacting with the disulphide as follows:

$$RSSR + SO_3^{2-} \rightarrow RS^- + RSSO_3^- \quad .$$

The mercaptan produced is titrated with silver salts. The disulphide group is frequently reduced to the mercapto-group and all the analytical methods for the determination of thiols can be used. Many reagents have been proposed for the reduction of disulphides[64,70,73], but none of them are universal. Best results have been obtained for the solution $LiAlH_4$ in tetrahydrofuran (THF).

Wronski[64] proposed a new reagent—sodium aluminium bis-(2-methoxyethoxide) dihydride (70% solution in benzene):

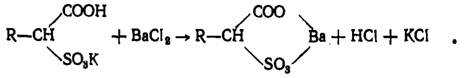
$$NaAlH_2(OCH_2CH_2OCH_3) + RSSR \rightarrow NaAl(SR)_2(OCH_2CH_2OCH_3) + H_2 \quad .$$

Decomposition with water yields thiols, hydrogen sulphide, sodium hydroxide, aluminium hydroxide, and α-methoxyethanol. The method is applicable to aliphatic and aromatic disulphides and its accuracy is to within 5%. Sulphides and disulphides are usually determined by methods based on their oxidation with periodate to the corresponding sulphoxides[71]. A solution of phenyliodoso acetate in dilute acetic acid has been proposed as the oxidant[72]:

$$RSSR + 4PhI(OCOCH_3)_2 + 4H_2O \rightarrow RSO_2SO_2R + 4PhI + 8CH_3COOH \quad .$$

The excess of phenyliodoso acetate is reduced with ascorbic acid and titrated with a solution of iodine. The method can be used also for the analysis of a mixture of thiols, sulphides, and disulphides; it is accurate, rapid, and does not require special conditions.

(h) Determination of sulphonic acids, sulphinic acids, thioureas, and dithiocarbamates. The principal method for the analysis of sulphonic acids is alkalimetry. In recent years many technological products have been analysed by this procedure, and mixtures of isomeric sulphonic acids have been determined. Thus an attempt has been made[74] at the separate determination of toluene-*o*- and toluene-*p*-sulphonic acids by high-frequency titration in non-aqueous media. Kreshkov and coworkers[75] developed a differential titration method (with the aid of KOH) for the determination of a mixture of aminobenzenesulphonic acids, the accuracy of the method being to within 2–6%. Certain substituted aromatic sulphonic acids are determined by potentiometric titration with sodium methoxide in pyridine or acetone[76], but the accuracy is low. In the determination of a mixture of isomeric sulphonic acids the latter are frequently subjected to preliminary separation on a column with cation-exchange resins[77]; the accuracy of the method is to within 1%. A specific method[78] for the determination of α-sulphocarboxylic acids is based on their ability to cyclise readily to form a six-membered ring with alkaline earth metal ions, particularly the barium ion:



$$R{-}CH(COOH)(SO_3K) + BaCl_2 \rightarrow R{-}CH(COO)(SO_3)Ba + HCl + KCl \quad .$$

Thus the determination of α-sulphocarboxylic acids can be reduced to the determination of hydrochloric acid. The titration is carried out in a 1 : 1 water–isopropyl alcohol medium with strong bases.

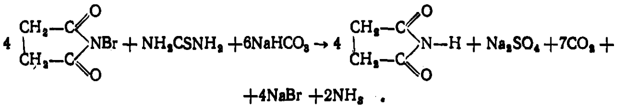
Iodometric titration has been used to determine sodium noramidopyrinemethanesulphonate[79].

A method for the quantitative determination of sulphinic acids[80,81] is based on the reaction with nitrous acid:

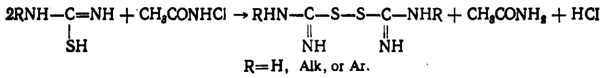
$$2RSO_2H + HONO \rightarrow (RSO_2)_2NOH + H_2O \quad .$$

The reaction is carried out in a strongly acid medium, the end point being determined potentiometrically or amperometrically; the accuracy is to within 0.8%.

Thiourea and its derivatives are readily determined by oxidative titrimetry. A method for the determination of thiourea by its direct titration with $KMnO_4$ in sulphuric acid has been described[82]; the end point is distinct and stable. Thiourea can be oxidised quantitatively to the sulphate with potassium dichromate in sulphuric acid[83]. The excess dichromate is titrated with ferrous ammonium sulphate; it is noteworthy that, under these conditions, thiocyanates are also oxidised; the accuracy of the method is to within 0.5%. It was shown subsequently that[84] the presence of copper(II) ions greatly accelerates the reaction. It has been suggested recently that *N*-bromosuccinimide be used as an oxidant for thiourea[85,86] (the reaction is carried out in the presence of sodium bicarbonate):



N-Chloroacetamide has also been proposed as a thiourea oxidant[87] (for potentiometric and visual titration):

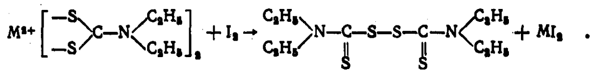


$$2RNH{-}\underset{\displaystyle SH}{\underset{|}{C}}{=}NH + CH_3CONHCl \rightarrow RHN{-}\underset{\displaystyle NH}{\underset{\|}{C}}{-}S{-}S{-}\underset{\displaystyle NH}{\underset{\|}{C}}{-}NHR + CH_3CONH_2 + HCl$$

$$R{=}H,\ \text{Alk, or Ar.}$$

Potassium iodate is used successfully to oxidise thiourea to the disulphate[70,88]. One of the old methods for the oxidation of thiourea consists in its titration by silver salts in an ammoniacal medium in the presence of dithizon[89]. This procedure is also used for the joint determination of thiourea and thiocyanates[90]. The ability of thiourea to form stable insoluble compounds with silver ions has been used to make silver halide membrane electrodes, which are employed for the potentiometric determination of thiourea[91,92].

In view of the great practical importance of dithiocarbamates (as fungicides), a review was published comparatively recently by Halls[93], which the principal method for the determination of compounds of this class are analysed. The majority of the methods are based on the decomposition of dithiocarbamates in an acid medium and the determination of carbon disulphide. Oxidative methods of determination are also discussed. The determination of water-insoluble bivalent mercury, lead, cadmium, and zinc ions as the diethyldithiocarbamates by titration with a solution of iodine and chloroform has been proposed[94]:



$$M^{2+}\left[\begin{matrix}{-}S\\{-}S\end{matrix}\!>\!C{-}N\!<\!\begin{matrix}C_2H_5\\C_2H_5\end{matrix}\right]_2 + I_2 \rightarrow \begin{matrix}C_2H_5\\C_2H_5\end{matrix}\!>\!N{-}\underset{\displaystyle S}{\underset{\|}{C}}{-}S{-}S{-}\underset{\displaystyle S}{\underset{\|}{C}}{-}N\!<\!\begin{matrix}C_2H_5\\C_2H_5\end{matrix} + MI_2 \quad .$$

The end point is determined visually or spectrophotometrically. Iodine chloride[95] and iodine and bromine cyanides[96] are also used as oxidants for dithiocarbamates; the accuracy of the method is to within 0.5%. The influence of the pH of the medium, the nature of the solvent, and the nature of extraneous ions has been investigated[95]. Methods have been proposed for the determination of dithiocarbamates with the aid of the iodine–azide reaction[97] and potentiometric titration with perchloric acid in an anhydrous medium[98]. A method involving the direct titration of dialkyl and diaryl phosphorodithioites with dimethyl- and diethyl-aminophenylmercury acetates has been developed[99]. Mention should be made of studies[5,100] in which a method has been proposed for the coulometric analysis of a technical mixture of sulphenamides and dibenzothiazolyl sulphide, based on the oxidation of solutions in acetic acid with bromine. The separate determination of the mixture components is based on their different solubilities in the organic solvent.

2. Titration with Preliminary Chemical Reactions

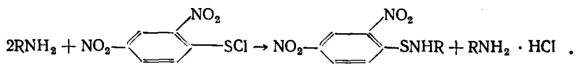
a. Determination of nitrogen-containing organic compounds. A widely used method for the determination of tertiary amines in the presence of secondary and primary amines is titration in glacial acetic acid with a solution of perchloric acid after preliminary acylation with acetic anhydride[101]. However, quantitative acylation of certain amines by acetic anhydride requires severe conditions. It has been suggested[102] that trifluoroacetic anhydride be used as the acylating agent. The acylation reaction proceeds at room temperature; the error is 0.4%. Isopropenyl acetate can be used successfully as the acylating agent[103], its acylating capacity being superior to that of keten and acetic anhydride; the compound is of interest for the acylation of readily enolised compounds; the accuracy of the method is to within 0.1–0.4%. The formaldehyde–sodium bisulphide complex reagent is frequently used in the iodometric determination of amines[104-106]; it reacts with the amino-group to form methanesulphonates, which are titrated with a solution of iodine in an aqueous acid medium. Aniline and its derivatives[104], toluidines, and xylidenes[105] have been determined by this method; its accuracy is to within 0.5%.

The cyanoethylation reaction has been used for the determination of primary and secondary amines[107]; the amines react with acrylonitrile in accordance with the equations

$$RNH_2 + CH_2{=}CHCN \rightarrow RNHCH_2CH_2CN \, ,$$
$$R_2NH + CH_2{=}CHCN \rightarrow R_2NCH_2CH_2CN \, .$$

The reaction is accelerated by catalysts (water and acids) and takes place at room temperature for the majority of amines. The excess acrylonitrile is titrated by the sulphite method.

Obtemperanskaya and Kalinina[108] suggested that 2,4-dinitrobenzenesulphenyl chloride be used for the determination of aliphatic and aromatic amines; it reacts over a period of 10–15 min with the amine in benzene solution, forming 50% of the amide and 50% of the amine hydrochloride:



The employment of pyridine greatly accelerates the reaction and improves the yield of the product. The determining factor in the reaction is the change in the pK_b of the amine; one should note that amines with $pK_b \geq 11$ do not react (diphenylamine); the error is <1%. Since the reagent is highly hygroscopic, the authors subsequently replaced it by 2-nitrobenzenesulphenyl thiocyanate[109]. The method[109] is based on the reaction of these compounds in the presence of a small amount of alkali:

$$RNH_2 + NO_2C_6H_4SSCN \xrightarrow{NaOH} NO_2C_6H_4SNHR + NaSCN + H_2O \quad .$$

The excess reagent is decomposed with an aqueous solution of alkali. The sulphenamide formed reacts with hydrochloric acid to form sulphenyl chloride, which interacts quantitatively with potassium iodide to form iodine:

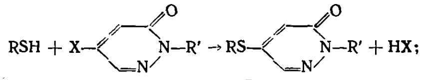
$$NO_2C_6H_4SNHR + 2HCl \rightarrow NO_2C_6H_4SCl + RNH_2 \cdot HCl \quad ,$$
$$2NO_2C_6H_4SCl + 2KI \rightarrow (NO_2C_6H_4S)_2 + I_2 + 2KCl \quad .$$

The liberated iodine is titrated with sodium thiosulphate; the accuracy of the method is to within approximately 1%. The application of these reagents in analytical chemistry has many advantages over methods based on the acylation reaction and acid–base titration.

Primary and secondary amines may be determined quantitatively by reaction with 1-(isothiocyanatomethyl)-isatin, in which crystalline urea derivatives are formed readily[110]. Phenyl isocyanate has been suggested[111] for the determination of primary and secondary amines. The thiourea derivatives formed are titrated with potassium iodate in an acid medium at room temperature.

Among the titrimetric methods for the determination of amino-compounds used at the present time, mention should be made of titration with bivalent metal (Cu^{II} and Mn^{II}) salts. For example, α-amino-acids have been determined[112] by titration with a solution of copper(II) sulphate, the maximum error being 0.3%. Aminopolycarboxylic acids are analysed by titration with Mn^{2+} salts[113-115]. A solution of N-chlorosuccinimide in the presence of Methyl Red as the indicator has been suggested for the determination of microamounts of hydrazines and their salts[116]. The end point is determined from the disappearance of the colour of the indicator. A 0.1 N solution of N-chloroacetamide has been used for the potentiometric analysis of hydrazine derivatives[117], the error of the method being ±0.8%. Potentiometric oxidative titration of oximes is carried out with $K_7Cu(HTeO_6)_2$.[118] The reagent is prepared by oxidising copper(II) to copper(III) with $K_2S_2O_8$ in KOH solution in the presence of $K_2Te_2O_7$ as the complex-forming agent.

b. Determination of organic sulphur compounds. Many methods for the determination of thiols involving phenylation by various reagents have been proposed. It has been suggested that 3-phenothiazinone in 80% acetic acid be used for the back titration of thiols[119]; the excess is titrated with sodium thiosulphate. The same reagent is suitable for the determination of thiourea and thiosemicarbazides. The titration of thiols with 4,5-dibromo-6-pyridazinone or 4,5-dichloro-6-pyridazinone in aqueous or organic media takes place quantitatively with elimination of an equivalent amount of the hydrogen halide[120]:



X = Cl or Br.

Side reactions with other nucleophiles, amines, phenols, sulphides, and alcohols were not observed. In a series of studies for the determination of thiols[121-126] new reagents have been proposed and analytical methods devised. We believe that vinyl sulphones are interesting reagents[112]. Owing to the presence of the electron-accepting sulpho-group, they readily react with nucleophiles via the terminal carbon atom attached to the double bond:

$$R{-}SO_2{-}CH{=}CH_2 + R'SH \rightarrow RSO_2CH_2CH_2SR' \quad .$$

A three-fold excess of a solution of the vinyl sulphone in dioxan is added to the thiol being analysed, the excess being titrated by the sulphite method. Aliphatic, aromatic, and heterocyclic mercaptans may be determined by this procedure. A method, which had been used earlier for the analysis of aliphatic and aromatic mercaptans and is based on nucleophilic addition to acrylonitrile, has been suggested for the quantitative determination of heterocyclic thiols[121]; the accuracy is to within 0.5%.

Arenesulphenyl halides are highly reactive in relation to thiols[123-126]; the reaction results in the formation of asymmetric disulphides:

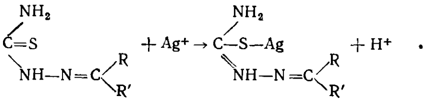
$$RSH + ClSC_6H_3(NO_2)_2 \rightarrow RSSC_6H_3(NO_2)_2 + HCl \quad .$$

It is carried out in acetic acid, the excess reagent being determined iodometrically. Aliphatic and aromatic thiols containing OH, NH_2, and COOH groups can be determined by this method In the reaction with heterocyclic thiols it is necessary to add pyridine in order to bind the hydrogen chloride. The error of the method does not exceed 1%. In the potentiometric titration of thiols with tetraethylammonium hydroxide, it is necessary to add 1-chloro-2,4-dinitrobenzene, which leads to a sharp increase of the potential jump[125].

Chloramine-T has been suggested as the oxidant for the analysis of thiosemicarbazides[127]; the reaction takes place quantitatively under the usual conditions:

$$NH_2NHCSNH_2 + 6\,[CH_3C_6H_4NCl]^- + 6H_2O \rightarrow 6CH_3C_6H_4SO_2NH_2 +$$
$$+ 6Cl^- + CO_2 + N_2 + \overset{+}{N}H_4 + H^+ + SO_4^{2-} \quad .$$

The excess chloramine-T is determined iodometrically. Thiocyanates and hydrazines interfere with the determination of thiosemicarbazides. Despite the enormous importance of thiosemicarbazones in pharmacology, until recently there were no suitable methods for their quantitative determination. Comparatively recently Campbell et al.[128] proposed a simple and rapid method for the quantitative determination of aromatic monothiosemicarbazones by the potentiometric titration of the protons liberated on formation of the complex with silver ions:



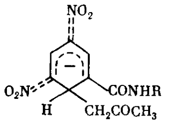
The accuracy of the method is to within 0.5%, but the procedure cannot be extended to all types of thiosemicarbazones and requires further development. The same workers[129] used copper(II) instead of silver for the determination of alkylbisthiosemicarbazones by an analogous procedure, the accuracy of which is to within 0.5%.

III. PHOTOMETRIC METHODS FOR THE DETERMINATION OF NITROGEN- AND SULPHUR-CONTAINING ORGANIC COMPOUNDS

A method widely used in recent years for the determination of nitrogen-containing organic compounds has been photometric analysis [3,24]. A number of investigators have developed new procedures for the determination of amines, amides, hydrazines, oximes, azo-compounds, etc. by colorimetric methods using various chemical reagents, which can be nitro-compounds, aromatic halogeno-derivatives, dyes, metal ions, etc. Most of these are readily available, and the analytical methods are simple and highly sensitive. There have been few studies in recent years on the photometric analysis of sulphur-containing organic compounds.

1. Photometric Analysis Using Organic Reagents

a. Determinations with nitro-compounds. Various aromatic nitro- and polynitro-derivatives, which give rise to intensely coloured solutions in acetone in the presence of strong alkalis, are fairly frequently used for the quantitative determination of nitrogen-containing compounds. The procedure is based on the Janowsky reaction, in which acetone interacts with the dinitro-compound in the enolic form, forming a quinonoid structure of the following type:



Comparatively recently Malone [130] investigated the interaction of hydrazine and amine derivatives with 20 different nitro-compounds and established that all the nitro-compounds which he proposed are suitable under certain conditions for the quantitative analysis of nitrogen-containing compounds. Bartos showed [131,132] that nitromethane, which forms red compounds in the presence of alkylamines or their quaternary bases, can be used successfully instead of acetone in reactions of polynitro-compounds (1,3,5-trinitrobenzene, picric acid). Bartos determined by this method many alkylamines and their hydrochlorides. Arylamines are less reactive and several hours are required for the appearance of the colour. The same workers [133] proposed a method for the photometric analysis of primary and secondary amines using 1-fluoro-2,4-dinitrobenzene and nitromethane in DMF. In order to obtain a more intense colour in solutions, Bartos introduced in addition potassium hydrogen borate. The addition of potassium hydrogen borate in DMF to the organic phase leads to an intense violet colour, a green-violet colour, and a green colour in the presence of primary alkylamines, secondary alkylamines, and aromatic amines respectively. The microanalysis of aromatic amines via the Janowsky reaction has been investigated [134] and its conditions have been discussed in detail.

It has been suggested that *sym*-trinitrobenzene be used for the determination of certain aromatic amines [135]. The authors regard this reaction as a charge-transfer process which leads to the formation of $\pi-\pi$ complexes absorbing in the ultraviolet or in the visible region, λ_{max} depending on the nature of the amine (primary, secondary, or tertiary). Thus aniline and toluidine (primary amines) can be readily distinguished from *N*-methylaniline (a secondary amine) and *N*,*N*-dimethyl- and *N*,*N*-diethyl-anilines (tertiary amines).

Legradi [136,137] suggested that aliphatic amines and amino-acids be determined with the aid of 2,4-dinitrobenzene in the presence of hydroxylamine hydrochloride as the catalyst. Obtemperanskaya and coworkers [138,139] also used 2,4- and 3,5-dinitrobenzenes to analyse primary and secondary aromatic and heterocyclic amines and hydrazines. The majority of aromatic primary amines and hydrazines are phenylated quantitatively at room temperature. The appearance and development of the colour of the solutions over a period of time and its stability depend on the nature of the functional substituents in the benzene ring of the amine or hydrazine. The sensitivity of the method is to within $10^{-5}-10^{6}$ M and the accuracy of the determination if to within 0.13–2.8% for aliphatic amines, 0.8–6.0% for aromatic amines, 0.5–4.7% for heterocyclic amines, and 0.6–4.0% for substituted hydrazines.

A method has been proposed for the photometric microdetermination of certain biogenic amines in the presence of amino-acids and amino-alcohols, based on the reaction with 3,5-dinitrobenzoyl chloride [140]. The sensitivity and accuracy of the method are to within 1×10^{-6} M and 2% respectively. The same workers used 2,4-dinitrobenzoyl chloride for the analysis of aromatic, aliphatic, and acyclic amines. The reaction takes place quantitatively at room temperature, its sensitivity and accuracy being to within 1.3×10^{-6} M and 0.2–2.8% respectively. Obtemperanskaya et al. [141] made a comparative assessment of 3,5-dinitrobenzoyl and 2,4-dinitrobenzoyl chlorides. The latter reagent is more sensitive and in addition can be used for a test in the qualitative analysis of aromatic, aliphatic, and acyclic amines, since it forms solutions having different colours. 1-Fluoro-2,4-dinitrobenzene can be employed successfully for the analysis of aromatic and aliphatic amines [142]. The reaction takes place quantitatively at room temperature for aliphatic amines and at 60°C for aromatic amines, its accuracy being to within 0.5–6.0%.

b. Determination using other chlorine-containing reagents. Fickentscher [143] and Tashima et al. [144] used chloranil (2,3,5,6-tetrachloro-1,4-benzoquinone) as the reagent for the photometric determination of nitrogen-containing compounds. On interaction with aromatic amines it gives rise to bluish violet solutions. Fickentscher determined by this method microamounts of dimethylamine in DMF; Tashima et al. [144] used this reagent for the analysis of methylcellosolve solutions of various aniline derivatives. The accuracy of the method is satisfactory.

Quinone dichloroimide has been proposed for the separate determination of aliphatic and aromatic amines [145]; 53 compounds have been studied by this procedure. The ability of many aromatic amines and heterocycles to react with polyhalogeno-compounds (with CBr_4 or CHI_3) and to give rise to coloured solutions under the influence of ultraviolet light served as the basis for their colorimetric analysis [146]. Apart from CBr_4 and CHI_3, di- and trichloroethylenes, hexachloroethane, and isopropyl iodide may be used; however, one should note that the method requires further development. There are several analytical procedures for hydroxylamines, including thin-layer chromatography [147,148].

Stewart and coworkers[149,150] proposed a new photometric method for the determination of microamounts of arylhydroxylamines with the aid of 9-chloroacridine. The sensitivity and accuracy of the method are to within 0.8 to 3.0 mg ml^{-1} and 1.6–3.6% respectively. Hydroxylamines can be determined by the same method in the presence of primary aromatic and aliphatic amines, amides, aromatic nitro-compounds, and phenols.

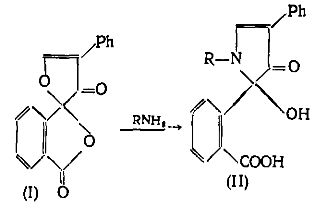
c. Determination using organic dyes. Organic bases and their salts may be determined by an extraction-photometric method using acid dyes as the reagents. The employment of dyes, whose solutions have high molar extinction coefficients, makes it possible to determine quantitatively amines in very dilute solutions. Two reviews[151,152], which discuss in detail the choice of dye and solvent, the influence of the pH of the medium, and the influence of various factors on the extraction constants of the complexes formed, have been devoted to the development of this method. A number of determinations have been made of the extraction constants[153–159]. It is recommended that Bromothymol Blue or the ethyl ether of tetrabromophenolphthalein be used for the analysis of quaternary ammonium salts[160,161]. Among all the solvents investigated, chloroform, a chloroform–alcohol mixture, or a benzene–isopentyl alcohol mixture proved to be most effective[162]. In the analysis of amines in the presence of Bromophenol Blue[163] the complexes formed were isolated and identified; the colour of the complex can be accounted for by the quinonoid structure of the dye. Bromophenol Blue, Bromocresol Purple, Bromocresol Blue, and Bromochlorophenol Blue have also been used as reagents for the determination of amines[164–167]. Korenman[164] used Bromophenol Blue for the quantitative determination of aromatic amines to within 0–6%.

Amines have been determined[165] by their extraction with chloroform using Bromocresol Purple and Bromothymol Blue. The authors established that the dyes react as singly-charged anions, which are responsible for the colour of the extracts of the amine compounds. The accuracy of the extraction-photometric analysis may be increased severalfold by adding C_1–C_4 alcohols to the reaction mixture[166] or by extraction with ternary nitrobenzene–chloroform–benzyl alcohol mixtures[167].

d. Determination of amines by the azo-coupling reaction. Azo-coupling is widely used for the determination of aromatic amines[3]. Diazotised dinitroaniline has been used[168] as a reagent for the determination of various aromatic amines; the reaction is carried out in highly acid solution and its accuracy is to within 0.5–5.9%. The method involving diazotisation with subsequent coupling to an H$^+$ acid and colorimetric determination of the resulting dye has been employed[169]; the authors determined toluidines, chloramines, and nitroanilines; the accuracy of the analysis is to within 1–1.5%. Bromonitrosol (3-bromo-2-nitroso-1-naphthol) can be used for the analysis of amines and hydrazines[170]; the reaction leads to the formation of coloured azo-compounds, which can be determined photometrically, but the accuracy of the analysis is comparatively low.

e. Other methods of colorimetric analysis. An interesting photometric method for the determination of *p*-phenylenediamine has been proposed by Corbett[171], its sensitivity and accuracy being to within 10^{-4}–10^{-5} M and 2% respectively. Aliphatic primary and secondary amines, α-amino-acids, sulphamides, hydrazines, and other compounds containing the amino-group condense in an alkaline medium with 1,2-naphthoquinone-4-sulphonic acid to form red, orange, and yellow derivatives of 1,2-naphthoquinonemonoimines[172]. The method is simple and highly sensitive, but suffers from limitations in the determination of secondary arylamines. The method involving the coulometric titration of amines is of definite interest[173]. Biphenyl radical-anions are used as the titrant. At a low rate of conversion it is possible to measure the absorption due to intensely coloured radical-cations generated from the amines in the course of the reaction; the accuracy is to within 1.7 to 3.0%.

Fluorescamine (I),[174] which forms coloured compounds (II) with amines, is an effective reagent in the colorimetric analysis of primary amines:



.

The pH of the medium and the concentration of reagent (I) are important for the reaction. The sensitivity of the method is to within between 0.01 and 0.1. M.Legradi[175,176] used successfully phenylacetonitrile in an alkaline medium and diazotised sulphanilic acid for the analysis of nitro-compounds. The method described by Mordovina et al.[177] may be used for the microdetermination of nitrobenzenes in aqueous solution. Thiourea dioxide $(NH_2)_2CSO_2$ in an alkaline medium has been suggested for the microdetermination of the nitro-groups in aromatic compounds; the sensitivity of the method is high and its accuracy is to within 1–4%.

2. Photometric Analysis Using Inorganic Reagents

Quantitative photometric analytical methods, based on reactions with simple and complex metal salts, are widely used in the analysis of nitrogen-containing organic compounds[3]. Many fundamental studies devoted to a detailed investigation of the structures of the complex formed and the determination of various factors influencing the reaction have been published in recent years. For example, a study has been made[178] of 15 different aromatic amines in the presence of 13 metal ions[178]: Cr^{3+}, Cu^{2+}, Fe^{3+}, Bi^{3+}, Ag$^+$, Ni^{2+}, etc. It was shown that, in the presence of hydrogen peroxide and alkali, coloured complexes are formed and that the colour of the solution depends on the concentration of the amine. A method based on the reaction with $Fe(NO_3)_3$ in the presence of acetyl chloride is highly sensitive in the determination of aliphatic and aromatic amines[179]. The influence of temperature, the concentration of the salt and acetyl chloride, and the pH of the medium on the formation of the complexes has been studied, and a mechanism has been proposed for the formation of the complexes; the accuracy is to within at least 3%.

Connors and Albert[180] used successfully the Hamilton reagent for the analysis of 15 aromatic amines, including α-methylbenzylamine. The reaction with the copper(II) ion in ammonia solution has been used in the determination of isomeric aminophenols in mixtures[181]; the reaction led to the formation of coloured complexes, which were extracted with 1-butanol and determined colorimetrically. Copper and nickel salts in the presence of salicylaldehyde have been used to analyse amines[182]; the reaction results in the formation of coloured complexes: yellow for aromatic amines and yellow-green for aliphatic amines. Mitsui and Fujimura[183] used this method to determine primary amines but, instead of salicylaldehyde, they employed nitrosalicylaldehyde; the accuracy of the method is to within 0.5–1.5%.

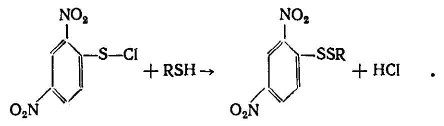
Legradi[184] developed an interesting drop method for the determination of amines and hydrazines with the aid of silver nitrate in the presence of alkalis; a drop of an ethanol solution of the amine (or hydrazine), a drop of silver nitrate solution, and a drop of 0.1 *N* NaOH are deposited on filter paper, which results in the appearance of an intense colour. This method may be used to determine *p*-, and *o*-phenylenediamines, *o*-aminophenol, anisidines, and toluidines. Sodium nitroprusside, which forms solutions with a characteristic colour, is fairly frequently used to determine amino-compounds[1,2]. Sodium nitroprusside was used comparatively recently[185] in a mixture with acetaldehyde for the quantitative determination of secondary aliphatic amines in a mixture with primary amines. The same method can be employed also for the determination of *N*-methylated amino-acids to within 3%. Marco and Mecarelli[186] used sodium nitroprusside together with ferrocyanate for the determination of guanidine and arginine derivatives. The employment of a mixed solvent containing isopropyl alcohol and water prevents the formation of insoluble deposits and gives rise to a high intensity of the colour of the solution.

Reactions involving oxidation by potassium peroxydisulphate, potassium hexacyanoferrate, potassium bromate, sodium perchlorate, etc. are frequently used in the photometric analysis of amines[187-189]. Korotkova and Noskov[189] used $K_3[Fe(CN)_6]$ as the oxidant for the determination of certain aromatic amines and, in order to establish the optimum conditions for the photometric determination, they employed the Box–Wilson mathematical experimental design method.

In conclusion, one should note that each of the methods described for the quantitative colorimetric determination of nitrogen-containing compounds has its advantages, disadvantages, and limitations. Certain methods are applicable only to the simplest representatives of compounds of the class indicated and are not applicable to more complex systems; in many instances difficulties arise in carrying out the experiment. However, sometimes the colorimetric method of analysis is the only suitable procedure among all the known methods of functional group analysis for compounds of the given class.

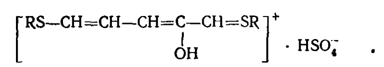
3. Photometric Analysis of Sulphur-containing Organic Compounds

Photometric methods for the determination of thiols are based on the following reactions: phenylation reactions, reactions with disulphides, and reactions with organomercury compounds. The first type includes primarily the dinitrophenylation reaction proposed[190] for the determination of aliphatic and aromatic thiols. The method proposed by the same workers[191] for the determination of thiols using 2,4-dinitrobenzoylsulphenyl chloride is based on the Janowsky and *sym*-phenylation reactions. The reaction of a thiol with an excess of the reagent by a factor of 2–3 is quantitative over a period of 3–5 min at 50°C:



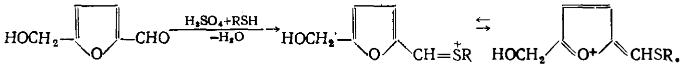
After the Janowsky reaction has been carried out, photometric measurements are made on the solutions at $\lambda = 480$ nm.

Another interesting reaction has been suggested by Unorits[192]. Furfural reacts with thiols in sulphuric acid at room temperature to form a red-violet substance ($\lambda_{max} = 505$ and 535 nm), which consists of the hydrolytically cleaved furan ring:

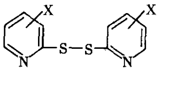


$$\left[RS{-}CH{=}CH{-}CH{=}\underset{\displaystyle OH}{\underset{|}{C}}{-}CH{=}SR\right]^{+}\cdot HSO_4^- \ .$$

In the reaction with hydroxymethylfurfural ring opening does not occur, and the colour arises as a result of the formation of cations having the following structure:

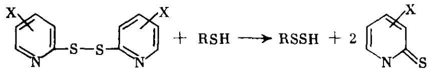


The use of heterocyclic disulphides of the type



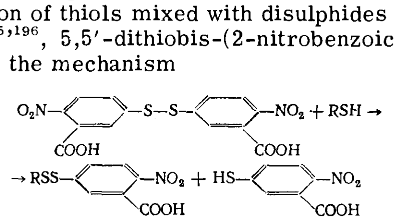
X = NO_2, NH_2, or COOH.

has been proposed for the photometric determination of thiols[193]. The reaction proceeds in accordance with the equation



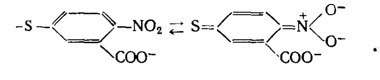
The thiopyridone formed absorbs in the range 240–430 nm. We may note that the accuracy of the method is low.

4,4′-Bisdimethylaminophenylmethanol, which forms intensely blue cations at pH 5.0, is also used as an alkylating agent[194]. The addition of a thiol causes the disappearance of the colour. This method is widely used in the analysis of proteins. Photometric methods for the determination of thiols mixed with disulphides have been described[195,196], 5,5′-dithiobis-(2-nitrobenzoic acid), reacting via the mechanism



(III)

being used as the reagent. An intense yellow colour ($\lambda_{max} = 412$ nm) arises owing to the formation of the aromatic mercaptide (III). The generation of the colour due to this mercaptide has been demonstrated by the detection of the quinonoid mesomeric structure



Reactions with organomercury compounds are widely used in photometry[64,196]. *p*-Dimethylaminophenylmercury acetate and *p*-diethylaminophenylmercury acetate are used for the extraction-photometric determination of thiols. It is suggested[64] that organomercury compounds form chelates with diphenylcarbazone which has a bright violet colour in benzene. The accuracy of the method is to within 4–8%; thioureas, sulphates, nitrates, and phosphates do not interfere with the determination. The results of the photometric method agree satisfactorily with those of titrimetric analysis where the given reagents are used as titrants.

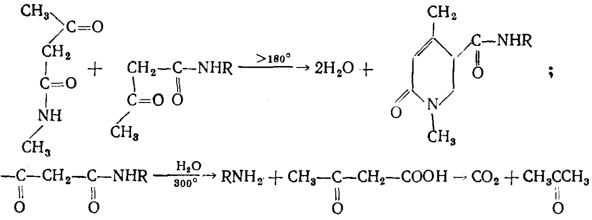
Only one paper has been published in the last six years on the photometric determination of sulphides and disulphides, involving the determination of thiuram disulphide in fungicides in the course of the analysis of industrial preparations; the method is based on the reaction with copper acetate[73]. Basic dyes of the type of rhodamine C, Acridine Orange, and Chrysandine [chrysoidine? (Ed. of Translation)] have been proposed as reagents for the determination of sulphonic acids[46,52]. Some of the main factors which determine the interaction between basic dyes and sulphonic acids are the pH of the medium and the concentration of acid. Quinone derivatives are used in the colorimetric determination of thiourea. Thus 1,4-diamino-5-nitroanthraquinone has been used in anhydrous acetic acid[200]; the measurements were made at 565 nm. Thioureas, thiosemicarbazides, monothiosemicarbazides, and isothiocyanates react with 2,3-dichloro-1,4-naphthoquinone in an ethanol solution of ammonia, forming an intense violet colour[201]. Apart from ammonia, pyridine, quinoline, ethylamine, and aniline may be used as the bases. The sensitivity of the method decreases in the sequence thiosemicarbazones > thiosemicarbazides ≫ thioureas > isothiocyanates. We believe that the method requires further development. Wronski[202] suggested a method based on the reaction of thiourea with an alkaline solution of *o*-(hydroxymercuri)benzoic acid with heating.

It has been noted that aromatic substituents increase while aliphatic substituents decrease the rate of desulphonation; tri- and tetra-substituted and cyclic thioureas are extremely resistant to this reaction. Attempts have been made[88,203] to reduce the reaction time by employing dipolar aprotic solvents—dimethylformamide and dimethyl sulphoxide. An interesting photometric method has been proposed for the determination of xanthates[204]: acetone and then the xanthate are added to a solution of nickel nitrate in acetic acid; photometric measurements are then made at 420 nm on the resulting intensely yellow solution. The error of the method is to within less than 0.5%. Dixanthates are determined with the aid of an excess of potassium thiocyanate[205]; the amount of potassium thiocyanate is determined photometrically on treatment with $(NH_4)_2SO_4.Fe(SO_4).24H_2O$ in nitric acid. A comparative assessment of all the methods for the analysis of sulphur-containing compounds permits the conclusion that the potentiometric titration procedures are the most suitable, being simplest and most accurate.

IV. OTHER METHODS

One should consider in the first place certain new analytical methods devised in recent years. A definite interest attaches to the method for the determination of aliphatic nitriles based on catalytic hydrogenation with subsequent titration in a non-aqueous medium[206]. The authors[206] devised a special apparatus for the hydrogenation of nitriles, which occurs in the presence of platinum oxide as the catalyst in acetic acid. The amines formed are determined by potentiometric titration with 0.1 *N* $HClO_4$ solution in dioxan. The standard deviations do not exceed 0.003–0.006.

Two methods for the determination of amides are noteworthy: the ion-exchange method[207] and analysis of *N*-substituted amides by the thermal cleavage method[208]. The latter procedure is based on brief (1–2 min) heating of amides at 300–400°C, amides being readily decomposed under these conditions to the amines and acids (or their decarboxylation products). The reaction products are identified chromatographically (by TLC or paper chromatography). More than one hundred compounds have been studied by this method; a mechanism has been proposed for the cleavage reaction and may be represented schematically as follows[208]:



$$CH_3-\underset{\underset{O}{\|}}{C}-CH_2-\underset{\underset{O}{\|}}{C}-NHR \xrightarrow[300^\circ]{H_2O} RNH_2 + CH_3-\underset{\underset{O}{\|}}{C}-CH_2-COOH \rightarrow CO_2 + CH_3\underset{\underset{O}{\|}}{C}CH_3 .$$

A highly sensitive colorimetric method[209], in which the amide group is oxidised with bromine, the excess bromine is decomposed by sodium formate and the products are oxidised further with iodine until the formation of a pale-blue complex (the "tri-iodine – starch" complex), may be used to determine trace amounts of various amides in aqueous solutions; photometric measurements are made on the complex at 610 nm. The accuracy of the method is to within 3.0%.

A rapid and convenient micro-gas-volumetric method for the determination of the hydrazino-group in organic and inorganic compounds by oxidation of the group with *p*-benzoquinone in 5% Na_2HPO_4 solution has been reported[210]. Hydrazine derivatives may be determined by this procedure in the presence of ammonium salts; the accuracy is to within 0.2%. A method for the quantitative determination of dimethylhydrazine in solution by classical and a.c. polarography has been developed recently[6]. The method may be used in the dimethylhydrazine concentration range 10^{-3}–10^{-6} M and the error is 4%.

A very interesting analytical method has been developed for the determination of a mixture of α-amino-alcohols (primary, secondary, and tertiary) by treatment with an excess of potassium periodate in a weakly alkaline medium[211]. The method is rapid and accurate; the presence of α-amino-acids and α-diamines does not interfere with the analysis. It should also be mentioned that, following the development of the technique of ion-selective electrodes[213,216], potentiometric methods have come to be even more widely used for the determination of various nitrogen and sulphur-containing compounds. These methods may be used to determine many substances belonging to the classes noted above[5,6,212,214,215]. The polarographic method is used on a fairly wide scale in the analysis of complex organic sulphur-containing compounds[5,198].

The experimental data presented in this review indicate the great interest of investigators in the problem of the functional group analysis of nitrogen- and sulphur-containing organic compounds. At the same time one should note that there are still too few universal methods for the chemical analysis of mixtures of compounds belonging to different classes. The problems to be solved in the immediate future apparently involve the search for new reagents and greater use of mathematical experimental design methods for the selection of optimum reaction conditions.

---o0o---

During the preparation of the manuscript for the press, a number of new publications appeared. There are several reviews devoted to general problems of functional group analysis[217-220]. Titrimetric methods for the determination of nitrogen- and sulphur-containing compounds have been described[221-225] and accounts of photometric methods have appeared[256-266]. Other analytical methods have also been described[267-281].

Packed Capillary Columns in Gas Chromatography

V.G.Berezkin, L.A.Shkolina, V.N.Lipavskii, and A.A.Serdan

Data on the preparation, properties, and applications of packed capillary columns are surveyed and analysed. The characteristics of chromatographic separation in columns of this type are discussed, the principal ways of improving the efficiency of packed capillary columns are considered, and the regions where they can be employed in practice are indicated.
The bibliography includes 85 references.

I. INTRODUCTION

One of the methods for improving the efficiency of separation in gas chromatography involves the use of small-diameter columns. The first capillary column was proposed by Golay[1] and many different useful modifications of small diameter columns, whose advantages have been demonstrated quite clearly in recent years, are now known. However, there are no reviews in the literature on packed capillary columns, which inhibits somewhat their wide-scale application.

Packed capillary columns (PCC) should be understood as columns having an internal diameter $\leqslant$ 2 mm and filled with a sorbent. This definition is arbitrary and somewhat subjective, owing to the absence of a clear-cut boundary between packed capillary columns and ordinary packed columns. According to our observations, characteristic features begin to be manifested precisely in columns whose diameter is 1–2 mm. The above definition indicates the upper limit of the diameter. Most studies have been carried out on columns having diameters less than 1 mm.

Halasz and Heine[2] obtained the first PCC by drawing on a Desty machine[3] tubes which had been filled either with an active adsorbent[2,4-8] or with an inert carrier[9], the stationary phase being deposited subsequently on the latter by the frontal method. The distribution of the sorbent is non-uniform in columns obtained by this procedure; it is partly forced into the walls of the capillary. This method can be used to obtain long columns with a comparatively high efficiency, but a carrier with an adequate mechanical strength and thermal stability is required; in most cases the carrier cannot be treated with the stationary phase beforehand. Capillary columns with regular close packing of the sorbent, obtained[10] by filling 200 cm steel tubes having internal diameters of 0.25 and 0.5 mm with glass microbeads (grain size 40 μm) and depositing on the latter the stationary liquid phase (SLP) by the frontal method, proved to be preferable. The height H of columns obtained in this way equivalent to the theoretical plate was 2 and 0.7 mm. More efficient columns ($H = 0.3$–0.39 mm) were obtained subsequently in a study[11] where metallic columns 0.5 and 1 mm in diameter and 100 cm long were filled with Chromosorb or Kieselguhr by means of a vibrator, and then the SLP was again deposited on the solid carrier in the column by the frontal method.

Capillary columns filled with the sorbent prepared beforehand have been used in gas-chromatography since 1963.[12-17] Systematic study of the characteristics of columns of this type have also been carried out in other investigations[18-25] dealing with broader aspects of their general analytical properties (in particular, a study was made for the first time of the changes in the efficiencies of columns of this type as a function of the principal experimental parameters) and their usefulness for the measurement of physicochemical characteristics was demonstrated.

In the development of sorbent-filled capillary columns, it is possible to distinguish two stages: (1) the development of methods for the preparation and application of short columns; (2) the development of methods for the preparation and application of long columns. Short columns (mainly 1–2 m long) are characterised by a high specific efficiency (the number of theoretical plates per metre of column length is approximately 2000), but their overall efficiency is small (usually not more than 2000–5000 theoretical plates). Short columns can be usefully employed for rapid analysis of relatively simple mixtures. The second stage, involving the development of long packed capillary columns (more than 10 m long) did not begin until 1971.[26] The high efficiency of these columns (columns with an efficiency equivalent to 60 000 theoretical plates have been described, but even longer columns can be prepared) makes them useful for the investigation of multicomponent mixtures and mixtures which are difficult to resolve and for the analysis of impurities.

Owing to their low diameter and the presence of the sorbent, PCC combine the advantages of classical capillary columns (capillaries whose internal walls are coated by the SLP) and ordinary packed columns. The small diameter is responsible for the significant advantages of PCC compared with columns of the usual type; these are (1) high efficiency, (2) high speed of the analysis (calculations[27] have shown that the time required for the attainment of the same degree of separation in PCC is shorter by a factor of two than in ordinary columns), (3) more stable conditions when the temperature is programmed owing to the low thermal inertia of the columns, (4) miniaturisation of the columns, i.e. the possibility of devising apparatus of small size, with a compact thermostat, in which rapid heating and cooling of the column may be achieved, and (5) low cost, i.e. there are extensive possibilities for employing scarce and expensive sorbents, since the amounts required are small. The following disadvantages of PCC compared with ordinary packed columns may be mentioned: (1) the filling technique is somewhat more difficult and prolonged and (2) it is necessary to employ detectors with a "dead" volume less than 30 μl, particularly a microkatharometer, since an ordinary katharometer cannot be used owing to its high inertia[28].

Because of the use of a sorbent in PCC, the latter have many advantages compared with classical capillary columns: (1) a high rate of separation of readily and moderately sorbed substances[27]; thus the time for separation in PCC is shorter by a factor of approximately 30 for a partition coefficient $K = 10$ and by a factor of 2.3 for $K = 50$; (2) by employing sorbents of different polarity, one can prepare columns of this type with a high selectivity for both gas–liquid and gas–solid chromatography; (3) a fairly high capacity, which makes it possible to introduce the sample without dividing the stream and thus reduces the error in the qualitative results and makes the requirements for the sensitivity of the detector less stringent (experiments with a microkatharometer are possible). Furthermore, it leads to an increase of the separating capacity of the column in the separation of weakly sorbed substances and extends the scope of capillary chromatography in the analysis of admixtures. A deficiency of PCC compared with classical capillary columns is a fairly high resistance to flow.

Comparison of PCC characteristics with those of columns of the type usually employed shows that their wide-scale application in chromatographic practice is entirely justified.

II. CHARACTERISTICS OF THE CHROMATOGRAPHIC SEPARATION PROCESS IN PACKED CAPILLARY COLUMNS

Theoretical and experimental studies designed to elucidate the dependence on column diameter of the spreading of the chromatographic band in narrow columns have been carried out for gas-liquid chromatography[27,29] and gas-adsorption chromatography[27,30,31], where the fundamental efficiency characteristics were adopted as the spreading criteria, namely the minimum height equivalent to the theoretical plate ($H_{\min}$) and the coefficient of resistance to mass transfer (C) in the Van Deemter equation[32]:

$$H = A + \frac{B}{u} + Cu,$$

where A and B are coefficients taking into account the turbulent and molecular longitudinal diffusion respectively and u is the carrier gas flow rate.

Comparative results for the efficiency of packed columns of different diameters (Table 1)[27] show that in gas-liquid chromatography (GLC), $H_{\min}$ changes insignificantly in columns 1.2, 0.8, and 0.5 mm in diameter and increases appreciably only in a column with a diameter of 3 mm. According to other workers[29], an appreciable influence of column diameter (d_c) on $H_{\min}$ was not observed either in columns having diameters of 0.75, 1.0, and 1.5 mm. The coefficient of resistance to mass transfer C, which decreases with decrease of d_c (Table 1), changes more significantly. This type of behaviour has been observed for all the substances tested and for all carrier gases.

In gas-adsorption chromatography (GAC) a change in d_c has been found to entail, as in GLC, only slight changes in $H_{\min}$, the minimum value of $H_{\min}$ being obtained for the column 0.8 mm in diameter (Table 1). With decrease of the column diameter from 3 to 0.5 mm, the coefficient C diminishes almost by a factor of 2, and, compared with the column 0.8 mm in diameter, by a factor of approximately 2.5.

Fig. 1 presents the dependence of C on the column diameter d_c.

In GLC C decreases monotonically with decrease of d_c. In GAC the curve relating C to d_c passes through a minimum. This difference can apparently be accounted for by the different grain sizes of the sorbent employed: a coarser sorbent (100–200 μm) is used in GAC than in GLC (100–160 μm), so that in a 0.5 mm diameter column (GAC) the sorbent was probably more loosely packed, which led to an increase in the degree of spreading.

Earlier studies[30,31] on GAC showed a somewhat different variation of $H_{\min}$ with d_c: in the range d_c = 1.6–0.6 mm the quantity $H_{\min}$ is directly proportional to d_c, increasing as d_c is diminished further (on passing from 0.6 to 0.3 mm).

*The optimum rates u_{opt} are quoted.

The relations obtained[27,29-31] between the efficiency of the columns and their diameters are in the main analogous. Certain discrepancies in the optimum column diameters (0.8 mm[27] and 0.6 mm[30,31]) can probably be explained by the different grain sizes of the sorbents used.

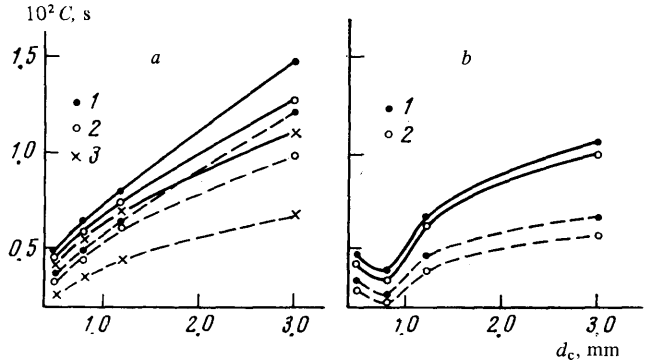

Figure 1. Dependence of the coefficient of resistance to mass transfer C on the column diameter d_c: a) sorbent—5% of squalane on Chromosorb W (100–160 μm); b) sorbent–XOB.075 Spherosil (100 – 200 μm); 1) pentane; 2) hexane; 3) octane. Continuous lines—nitrogen as carrier gas; dashed lines—helium as carrier gas.

According to the Jones equation[33]

$$H = A + \frac{B}{u} + C_g u + C_s u,$$

kinetic spreading in the chromatographic process is due to the resistance to mass transfer in the mobile (C_g) and stationary (C_s) phases. According to the Giddings theory[34], each of these factors plays a significant role in the assessment of the spreading mechanism in the column. In the study of the spreading of a chromatographic band in PCC it is therefore of interest to investigate the question of the relative role of mass transfer in the mobile and stationary phases as a function of d_c. Such studies were made for the first time for GLC[25] and their authors proposed a graphical method for the separate determination of the coefficients of external diffusion and internal diffusion resistance to mass exchange, and estimated their contributions as a function of the ratio of d_c to the grain diameter d_p. The coefficients of the external diffusion resistance to mass transfer C_g for a column 0.58 mm in diameter increase only slightly with increase of d_p. For a column with a larger diameter (0.98 mm) and for the same ratios d_c/d_p, the quantity C_g is greater by a factor of two and an increase of d_p by a factor of ten leads to an increase of C_g also by a factor of ten.

The results of a recent separate determination of C_g and C_s in GLC and GAC[27] by the method described in Grant's book[35] are presented in Table 2. Evidently both C_g and C_s diminish with decrease of d_c, the values of C_s found by two other methods (described by Perrett and Purnell[36] and Novak et al.[37]) being in good agreement. The changes observed[27] in C_s conflict with the classical concept of the independence of processes controlling the interphase mass transfer in a chromatographic column and agree with the conclusions of Novak and coworkers[37,38], who showed theoretically and experimentally that the coefficients C_s and C_g depend on each other and on the average pressure in the column. In the case considered the average pressure increases with increasing column diameter, which may be accounted for by the increase of permeability in narrow columns (for $d_p/d_c > 0.05-0.1$)[39], apparently owing to the greater influence of the wall effect.

Table 2 also shows that in gas–liquid chromatography $C_s > C_g$ for pentane in all the columns investigated, the difference diminishing on passing to substances with larger extraction coefficients. In gas-adsorption chromatography $C_g > C_s$ for a column 3 mm in diameter; for the other columns investigated the values of these quantities are comparable (when nitrogen is used as the carrier gas).

The dependence of C_g on d_c is illustrated in Fig. 2. The power exponent m in the relation $C_g \propto d_c^m$, found from the slopes of the straight lines, is 0.42 for GLC and 0.8 for GAC; this difference has been explained[27] as the influence of the form of the sorbent and the grain size on its packing in columns of different diameters.

The greater efficiency of PCC compared with packed columns having the usual diameters is apparently due to the special role of radial diffusion in the spreading of the band in PCC[30] and the nature of the packing of the sorbent in them[27]. In order to test the hypothesis of the greater smoothing role of radial diffusion in narrow columns, a comparative study has been made[40] of the efficiencies of capillary and the usual packed columns filled with a sorbent known to be inhomogeneous (mixed), which consisted of a mixture of a sorbent for GLC (i.e. of particles of the solid

carrier impregnated with the SLP) and the solid carrier without SLP. The measurements were performed on two spiral columns: a glass column 3 m long and with an internal diameter of 0.8 mm, and a metallic column 2.9 m long and with an internal diameter of 3 mm. The two columns were filled with the same sorbent, which consisted of a mixture of Chromaton N-AW without an SLP, and Chromatone N-AW with 5% of squalane in different proportions: 95 and 5, 50 and 50, and 0 and 100 wt.% respectively.

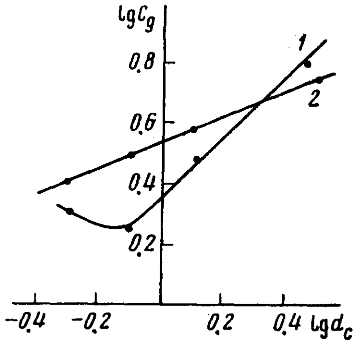

Figure 2. Dependence of the coefficient of resistance to mass transfer in the mobile phase C_g on column diameter d_c: 1) GAC; 2) GLC.

Table 3. The efficiency of columns having different diameters and filled with a mixed sorbent[40].

Sorbent, %		d_c, mm	10^2C, s			H_{min}, mm		
Chromaton + 5% of squalane	Chromaton N-AW		heptane	toluene	octane	heptane	toluene	octane
5	95	3.0	2.2	2.2	4.6	1.3	1.7	1.6
5	95	0.8	1.6	1.7	3.0	1.1	1.4	1.3
50	50	3.0	2.0	1.9	1.8	1.1	1.0	1.0
50	50	0.8	1.5	1.5	1.4	1.0	0.9	0.9
100	0	3.0	1.1	1.0	1.0	0.9	0.7	0.8
100	0	0.8	0.9	0.8	0.8	0.8	0.7	0.7

It follows from the results presented in Table 3 that, for all the substances investigated which are characterised by different partition coefficients, the values of H_{min} and C are smaller for the capillary column. They diminish (i.e. the efficiency improves) with decrease of the inhomogeneity of the sorbent. We may note that the greatest decrease of H_{min} and C is observed on passing from the packing containing 5% of the sorbent to the packing containing 50% of the sorbent, i.e. in the region of the greatest increase of the inhomogeneity of the sorbent. The experimental results are fully consistent with the idea that radial diffusion plays an important smoothing role in PCC. Indeed the time required for the diffusion of the molecules of the substance analysed in the gas phase from one wall of the column to the other may be estimated from the equation:

$$\tau = d_c^2/2D, \qquad (1)$$

where D is the diffusion coefficient of the test substance in the gas phase. If it is assumed that $D = 0.5$ cm^2 s^{-1}, then we have $\tau = 6.4 \times 10^{-3}$ s for a capillary column 0.8 mm in diameter and $\tau = 9 \times 10^{-2}$ s for an ordinary packed column 3 mm in diameter, i.e. τ is 15 times longer (the influence of the tortuosity of the path was disregarded in this calculation).

Thus, when a mixed sorbent is used, the efficiency of PCC is in all cases greater than that of large-diameter columns; the relative improvement of the efficiency characteristics of PCC increases with increasing inhomogeneity of the sorbent.

The equalisation of the chromatographic band front over the cross-section of PCC and an ordinary analytical column has been studied qualitatively[27]. The shape of the boundary of the layer of sorbent saturated by the volatile component, which reacts chemically with the sorbent to form a coloured compound, was observed. The saturated (spent) layer was obtained as a result of the reaction of hydrogen sulphide with the sorbent—Chromaton N (125–160 μm), on the surface of which 3% of lead acetate has been deposited. The reaction results in the formation of black lead sulphide. Glass tubes 3 and 0.8 mm in diameter, filled with the above sorbent, were used in the investigation. Hydrogen sulphide was injected into the carrier gas directly at the column wall and at right angles to the stream. When hydrogen sulphide was introduced, the sorbent turned black. It was observed that the boundary of the front of the saturated sorbent forms an acute angle γ with the wall at which hydrogen sulphide has been injected.

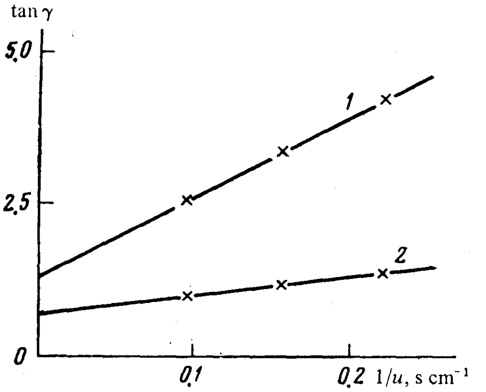

Figure 3. Dependence of the slope of the boundary of the saturated (spent) sorbent layer on the reciprocal of the linear carrier gas flow rate for columns having diameters of 0.8 mm (line *1*) and 3 mm (line *2*).

It follows from the data in Fig. 3 that, in a column 0.8 mm in diameter, the slope of the front for all the carrier gas flow rates investigated is greater than in an ordinary column 3 mm in diameter, i.e. the front of the band in PCC is steeper. This can probably be accounted for by the more regular packing of the sorbent in PCC. The time required for the diffusion in PCC of weakly sorbed molecules over a distance equal to the column diameter is $d_c/\tan\gamma \times u \simeq 4.5 \times 10^{-3}$ s, which agrees fully with the value calculated by Eqn. (1): $\tau = 6.4 \times 10^{-3}$ s.

One can apparently postulate the formation in packed columns of "domains"—regions of close-packed particles forming poorly ventilated cavities. It may be that the probability of their formation in PCC as well as their dimensions are much smaller, which should lead to a decrease of the spreading of the front. Furthermore, the effect of "remote" channels, noted by Giddings[34] as the main factor influencing the non-uniformity of the distribution of velocities with respect to the cross-sections of packed columns, should be significantly reduced in columns with small diameters, since it operates over fairly long distances, amounting to approximately $7.5d_p$, which is less than the diameters of the columns considered. Thus the non-uniform distribution of velocities with respect to the column cross-section plays a smaller role in PCC in the impairment of the efficiency characteristics than in columns having the usual diameters.

The characteristics of the separation in PCC, distinguishing them from classical capillary columns, are determined mainly by the presence of the sorbent in the former, which leads to a decrease of the phase ratio β (the ratio of the volume of the gas phase to that of the liquid phase in the column). β has a significant influence on separation. According to the equation[41]

$$R=\frac{\alpha-1}{4\alpha}\,\frac{K}{\beta+K}\,N^{1/2}$$

(R is the degree of separation, K the partition coefficient, N the number of theoretical plates, and α the relative retention volume), an increase of β should lead to an impairment of separation, which has a particularly marked effect in the separation of poorly sorbed compounds. Calculations have shown[40] that the amount of liquid phase in PCC is greater by two orders of magnitude than in classical capillary columns, and β is therefore much smaller.

The presence of the sorbent in PCC is also responsible for a different spreading mechanism than in classical capillary columns. The main characteristics of classical capillary columns are the absence of turbulent diffusion and a dependence of the coefficient of resistance to mass transfer in the gas phase mainly on dynamic diffusion. The coefficient C_s in classical capillary columns is usually greater than in PCC, since the film of the SLP on the porous sorbent is usually thinner than on the walls of capillaries. However, there have been no experimental studies of the comparative characteristics of spreading in PCC and classical capillary columns.

III. THE INFLUENCE OF THE PRINCIPAL EXPERIMENTAL PARAMETERS ON COLUMN EFFICIENCY

1. The influence of Pressure

One of the ways of increasing the overall efficiency of chromatographic columns involves increasing their length. Small PCC are promising in this respect. However, the increase in length entails an increase in the resistance of the columns, which leads to the necessity of employing increased pressures at the inlet to the column. For this reason, it is useful to examine the problem of the dependence of the efficiency of PCC on pressure.

The variation of the efficiency of the chromatographic column on various process parameters can be most fully described by the equation[29]

$$H_i=a_d\frac{D_{im}}{\bar u}+\frac{a_c'd_p}{1+a_e''(D_{im}/\bar u d_p)^{1/2}}+a_f\left(\frac{\bar u}{D_{im}}\right)^{1/2}d_p^{3/2}\left(\frac{k_i}{k_i+1}\right)^2+ \\ +a_b\frac{\bar u}{D_{ip}}d_p^2\frac{k_i}{(k_i+1)^2}, \qquad (2)$$

where H_i is the value of H for the ith component, $\bar u$ the average linear flow rate, D_{im} the diffusion coefficient for the ith component in the mobile phase, k_i the partition coefficient of the ith component, D_{ip} the overall diffusion coefficient of the ith component in a particle, and a_d, a_c', a_e'', a_f, and a_b are factors reflecting the influence of the geometry of the column on the diffusional and convective mixing, the dispersion caused by the mass exchange in the moving part of the mobile phase, and the dispersion caused by mass exchange in the particle, both in the "stagnant" component of the mobile phase and in the SLP. The diffusion coefficient in the mobile phase is related to pressure by the following equation:

$$D_{im}p=\text{const}, \qquad (3)$$

where p is the pressure.

It follows from Eqns. (2) and (3) that H decreases with increase of pressure for low linear flow rates and increases for high linear flow rates, the latter effect diminishing with decrease of d_p and k. In addition, as the pressure increases, the minimum value of H falls and shifts towards lower linear flow rates. The experimental results (Fig. 4)[27] show that this relation is characteristic of PCC in both gas–liquid and gas–adsorption chromatography. Huber et al.[29] obtained a detailed theoretical explanation of the results on the basis of Eqns. (2) and (3). With increase of pressure, the first term of Eqn. (2) diminishes, the second hardly changes in the usual range of flow rates, and the third increases. The influence of pressure on the fourth term of Eqn. (2) depends for its effect on D_{ip}, which in its turn depends on the degree of saturation of the pore space of the particles. In the simplest case the pores are completely filled by one phase, whereupon D_{ip} is proportional to the diffusion coefficient in this phase[42-45]. In gas–liquid chromatography the particles are usually saturated by the stationary liquid and the "stagnant" carrier gas. In this case the influence of pressure on D_{ip} is determined by the ratio of the volumes of the stationary liquid and gas phases in the particle and their relative geometrical distribution. With increase of pressure, the fourth term of Eqn. (2) increases and its value depends on the porosity of the particles, the accessible internal volume of which is filled by the stationary carrier gas.

According to the data of Bruner et al.,[46] $H_{\min}$ in gas–liquid PCC is independent of column length and hence of pressure (at least up to 15 m). For PCC of the gas–liquid–solid type, these workers observed, as in their first study[47], a "deepened" minimum on the curve relating H to u for comparatively long columns, i.e. with increase of the rate above u_{opt}, H initially increases, and then remains virtually unchanged. The authors suggest this effect may be caused by the mechanism of the operation of columns of this type.

The pressure gradient in the chromatographic column determines the presence of gradients of linear flow rates of the gas phase and of the diffusion coefficient in the mobile phase (owing to the high compressibility of the gas). The first three terms of Eqn. (2) remain constant, since the ratio D_{im}/u does not change. The influence of the pressure gradient on H is determined exclusively by the fourth term, describing the mass exchange in the particle. This term increases with increasing linear flow rate, which increases along the column as a function of the ratio of the inlet and outlet pressures[48]:

$$u_x = u_L \left\{\left(\frac{p_i}{p_0}\right)^2 - \left[\left(\frac{p_i}{p_0}\right)^2 - 1\right]\frac{x}{L}\right\}^{-\frac{1}{2}}, \tag{4}$$

where L is the column length, u_{L} the linear flow rate at the end of the column, x the coordinate along the length of the column, and p_{i} and p_0 are the pressures at the inlet and outlet.

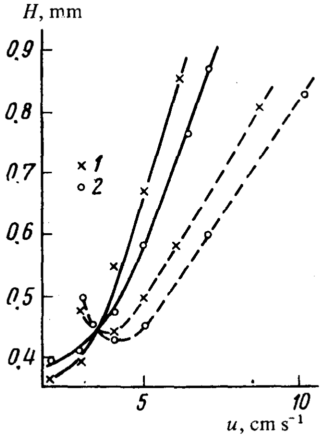

Figure 4. Dependence of H on the average linear carrier gas flow rate for short and long columns with an internal diameter of 0.8 mm, using 15% of squalane on Chromosorb P as the sorbent (100–160 μm) at 80°C: 1) hexane; 2) heptane. Continuous lines—15 m column; dashed lines—2 m column.

It follows from Eqns. (2) and (4) that H increases from the beginning to the end of the column in accordance with the expression

$$H_{ix} = \mathrm{const} + a_b \frac{u_L}{D_{ip}\left\{\left(\frac{p_i}{p_0}\right)^2 - \left[\left(\frac{p_i}{p_0}\right)^2 - 1\right]\frac{x}{L}\right\}^{1/2}} \cdot d_p^2 \frac{k_i}{(k_i+1)^2}, \tag{5}$$

where $H_{\mathrm{ix}} = H$ at the position defined by x. Eqn. (5) does not allow an exact prediction of the H_{i} gradient in the column, since D_{ip} is an unknown function of x.

Experimental results[27,29] have shown that the efficiency of PCC depends only slightly on the pressure gradient; the average pressure in the column has a much greater influence on the efficiency.

2. The Influence of the Particle Size of the Packing

The permeability of the column and to a large extent its efficiency depend on the particle size of the packing. Theoretically the permeability of an open capillary depends only on its diameter, but in practice the permeability of a capillary is smaller by 10–13% than the theoretical values r_0^2,[49] which can probably be accounted for by the roughness of the walls or fluctuations in the tube diameter. The permeability P of packed columns depends on the particle size and on the packing density[50,51]:

$$P = \frac{\psi^2 d_p^2}{180} \cdot \frac{\varepsilon_0^3}{(1-\varepsilon_0)^2},$$

where ψ is the particle inhomogeneity factor and ϵ_0 the column porosity, which does not include the internal volume of the particles. In practice the permeability of packed columns depends on the ratio of the particle diameter to the column diameter ($d_{\mathrm{p}}/d_{\mathrm{c}}$) and on the degree of roughness of the carrier. The permeability of the usual packed columns, where $d_{\mathrm{p}}/d_{\mathrm{c}} < 0.1$, is independent of the column diameter[52].

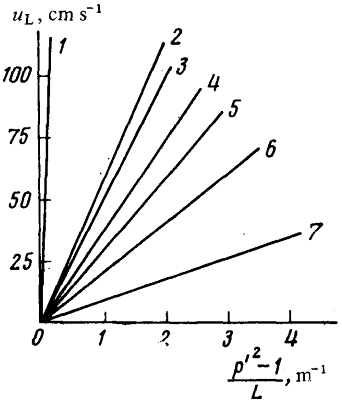

Figure 5. Dependence of the carrier gas flow rate at the outlet u_{L} on $(p^2 - 1)/L$ for columns of different types: 1) classical capillary column (internal diameter 0.25 mm); 2) and 4) PCC, $d_{\mathrm{p}} = 100 - 125$ μm, $d_{\mathrm{c}} = 0.45$ and 0.55 mm respectively with Chromosorb P as the carrier; 3) and 5) PCC, $d_{\mathrm{p}} = 140 - 160$ μm, $d_{\mathrm{c}} = 0.64$ and 1.26 mm respectively with glass beads as the carrier; 6) and 7) usual packed columns, $d_{\mathrm{p}} = 200$–250 μm and $d_{\mathrm{c}} = 4$ mm with glass beads as the carrier.

The column permeability may be determined experimentally from the slope of the plot of the linear carrier gas flow rate at the outlet of the column u_{L} against $(p'^2 - 1)/L$:

$$u_L = \frac{P p_0 (p'^2 - 1)}{2\eta L},$$

where η is the viscosity of the carrier gas, p_0 the pressure at the outlet from the column, $p' = p_{\mathrm{i}}/p_0$, and p_{i} the pressure at the inlet. Plots of this relation for different types of column are illustrated in Fig. 5.[52] Evidently the permeabilities of PCC occupy an intermediate position between those of classical capillary columns and ordinary packed columns; for a given particle size, the permeability diminishes with increase in column diameter. Cramers et al.[53] showed that a decrease of the column diameter with the same grain size of the packing requires the application of lower pressures at the inlet to the column (Fig. 6). Rijks et al.[54] recommend the ratio $d_p/d_c = 0.2-0.25$ for the optimum permeability of PCC.

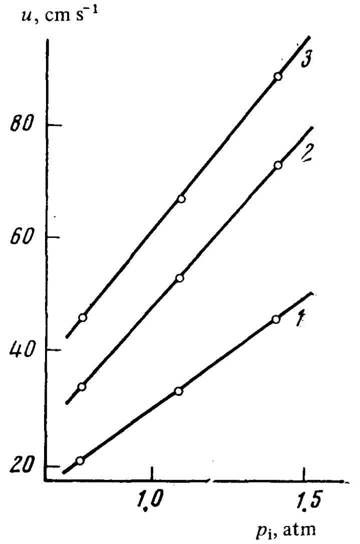

Figure 6. Dependence of u on the inlet pressure p_i for 1 m columns with different diameters (mm): 1) 1.26; 2) 0.92; 3) 0.64.

It has been shown[29] that a decrease of d_p leads to the following changes in the efficiency of PCC: (1) $\bar{H}_i$ diminishes for low values of $\bar{u}$; (2) the limiting value of $\bar{H}_i$, obtainable at high values of $\bar{u}$, diminishes for non-retained compounds; (3) the minimum value of $\bar{H}_i$ for retained compounds shifts towards lower values and its magnitude is greatly diminished; (4) the slope of the right-hand branch of the plot of $\bar{H}$ against $\bar{u}$ decreases for retained compounds. These experimental results have been explained[29] on the basis of Eqn. (2). With atmospheric pressure at the inlet the changes in $\bar{H}_i$ are induced directly by the change in d_p in Eqn. (2) and by the indirect influence of size owing to the dependence of the pressure drop on d_p (p' increases with decrease of d_p for a given value of $\bar{u}$). When the pressure at the outlet is increased, p' increases only slightly with decrease of d_p for a given value of u. In this case the changes in $\bar{H}_i$ are caused mainly by the change in d_p in Eqn. (2). The decrease in the minimum value of $\bar{H}_i$ for retained compounds and the decrease of the limiting value of $\bar{H}_i$ for high values of $\bar{u}$ for non-retained compounds, as well as the decrease of the slope of the curves relating $\bar{H}$ to $\bar{u}$ for retained compounds at high values of $\bar{u}$ are caused directly by the decrease of d_p in Eqn. (2). Thus the decrease of the particle size of the packing has a favourable influence on the column efficiency.

Generalising the results obtained, Huber et al.[29] concluded that PCC filled with a packing having particles much smaller than usual may prove to be extremely effective. The columns which they prepared (internal diameter 0.75–1.5 mm) with fine-grained packing (30–35 μm) had an efficiency equivalent to 10 000 theoretical plates per metre. In order to attain the optimum carrier gas flow rate (2.5 cm s^{-1}) in a column 1.5 m long and containing this type of sorbent, a pressure of 25 atm is necessary. It was concluded[29] that packed columns with an efficiency equivalent to 50 000 theoretical plates, which requires a length of 6 m, a pressure of 50 atm, and a volume flow rate at the outlet from the column of 5 ml min^{-1}, are realistically attainable.

Consequently there are two ways of attaining a high-efficiency of PCC: (1) by increasing the column length; (2) by employing short columns with a very fine-grained packing. We believe that the first procedure is preferable, because the use of highly efficient long PCC involves the employment of relatively low pressures at the inlet to the column. Short columns with a very fine-grained packing require an inlet pressure higher by an order of magnitude in order to achieve the same efficiency as for long PCC, which entails difficulties as regards apparatus. Furthermore, the resistance of long PCC may be appreciably reduced by employing surface-layer sorbents with large-diameter particles, since the efficiency of columns with such a sorbent is independent of particle size[55].

3. The Influence of the Nature of the Carrier Gas

According to the D'Arcy law, the pressure gradient is proportional to the viscosity of the flowing medium, so that the inlet pressure in PCC may be reduced by employing carrier gases with low viscosities. The usefulness of ammonia as the carrier gas has been demonstrated[56]. The viscosity of ammonia is a factor of 1.8 smaller than that of nitrogen and a factor of 2 less than that of helium. The density of ammonia is intermediate between those of nitrogen and helium, so that the diffusion coefficients of the components in ammonia should be higher than in nitrogen and this should lead to a higher efficiency if the spreading of the band is determined by the slow mass transfer in the mobile phase. In order to confirm these hypotheses, a study was made[56] of the dependence of column efficiency on the nature of the carrier gas. A spiral glass column 5.5 m long and with an internal diameter of 0.8 mm, filled with Chromaton N treated with 3% potassium hydroxide (160–200 μm) and impregnated with 10% Apiezon L, was used. Nitrogen, helium, and ammonia were compared as carrier gases.

Table 4. The values of H_{min} and C in packed capillary columns for different carrier gases.

Component	H_{min}, mm			10^2C, s		
	nitrogen	ammonia	helium	nitrogen	ammonia	helium
Heptane	0.82	0.85	1.0	2.0	1.5	0.8
Octane	0.65	0.70	0.84	2.4	1.7	1.2
Toluene	0.74	0.68	0.92	1.6	1.2	0.8
m-Xylene	0.66	0.63	0.82	1.7	1.4	0.9

The experimental results (Fig. 7 and Table 4) show that the employment of ammonia reduces the coefficients of resistance to mass transfer compared with chromatography in a stream of nitrogen, virtually without impairing the efficiency $H_{\min}$. Compared with helium, ammonia leads to a considerable increase of efficiency in the region of $H_{\min}$. The use of ammonia as the carrier gas in packed capillary columns is justified also because of its main advantage—a low pressure gradient. Thus, for the column used in the above investigations, with $u = 10$ cm s^{-1}, the pressure at the inlet was smaller by a factor of 1.5 compared with nitrogen (5.9 atm) when ammonia was used (3.8 atm) and smaller by a factor of 1.6 compared with helium (6.2 atm).

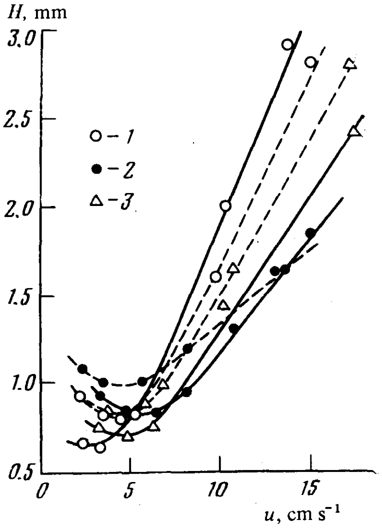

Figure 7. Dependence of H on u for different carrier gases: 1) nitrogen; 2) helium; 3) ammonia; continuous lines—octane; dashed lines—heptane.

The use of ammonia as the carrier gas to accelerate prolonged analyses has been demonstrated[56] in the separation of alkylcyclohexanols. The analysis was performed on a column 14.8 m long with an internal diameter of 0.8 mm filled with Chromosorb W containing 5% of Carbowax 20M at 160°C. Peaks of 32 compounds were detected on the chromatograms. Table 5 shows that the use of ammonia instead of nitrogen made it possible to reduce the analysis time by a factor of 1.6 without impairing the separation. For the same analysis time, a more clear-cut separation is attained and the pressure at the inlet to the column is smaller by a factor of 1.7.

The employment of ammonia as the carrier gas has the following advantages over the carrier gases usually employed (nitrogen and helium): (1) the pressure drop diminishes owing to the lower viscosity, which is important for long PCC; (2) when ammonia is used, $H_{\min}$ is smaller than in the case of helium; (3) the capacity of ammonia cylinders is larger than that of nitrogen and helium cylinders, which makes it possible to change cylinders less frequently and to employ small cylinders for mobile chromatographs; (4) the symmetry of the chromatographic bands is sometimes improved owing to the adsorption of ammonia on the active centres of the solid carrier[57].

Table 5. Results of the separation of alkylcyclohexanols using different carrier gases.

Carrier gas	P_i, atm	u, cm s^{-1}	Duration of analysis, min
Nitrogen	8.5	4.0	130
Ammonia	5.0	4.0	125
Ammonia	7.5	6.2	82

IV. THE PREPARATION AND USE OF PACKED CAPILLARY COLUMNS IN GAS CHROMATOGRAPHS

1. The Preparation of Packed Capillary Columns

Short capillary columns, (with a length up to 5 m) can be filled by hand with a sorbent prepared beforehand, either by tapping the column or by moving a mechanical vibrator down its length[58]. These procedures make it possible to obtain columns reproducible with respect to both packing density and retention characteristics. A common disadvantage is the possibility of filling with the sorbent only disassembled and short columns. The overall efficiency of short columns is low; in order to obtain highly efficient columns, it is desirable to increase their length to 10 m and more while retaining their high specific efficiency. Furthermore, the employment of these sorbents imposes a limitation on the material of the columns; for example, one cannot use glass capillaries, which have many significant advantages compared with metallic capillaries. Thus, on contact with a metallic surface, certain substances are sorbed irreversibly or decomposed[59-63]. A glass surface is chemically highly inert (the chemical inertness of glass is superior to that of diatomaceous brick). The possibility of direct observation of the filling of glass columns and of the visual changes occurring in them greatly facilitates the experiment. An important advantage of glass capillary columns is also the relatively ready availability of the apparatus[3] for the preparation of capillaries of the required length and diameter.

The methods developed recently for the preparation of long PCC, including glass ones, have extended the scope of their application in gas-chromatographic analysis. The procedure proposed by Cramers et al.[53] is as follows. A spiral tube (glass or metallic), arranged horizontally, is connected to a cylindrical container, the packing is poured into the container, and the latter is connected to the pressure supply line. The lower part of the container and almost the entire spiral tube are placed in an ultrasonic bath, the second end of the column being placed above the level of the bath. Vibration and pressure promote a continuous transfer of the packing into the column. By maintaining an approximately constant pressure drop across the filled part of the column, a homogeneous packing density throughout the column is ensured. The final pressure depends on the material of the packing employed, but it should be approximately 0.4–0.2 atm per metre of column length (the first figure refers to Chromosorb and the second to glass beads). The time required for filling is 1–2 min per metre of the column. The homogeneity of the packing particles, the scatter of which should be not more than 20 μm, is important. Dust particles are removed by vacuum screening. Depending on the density of the carrier, flotation or sedimentation may be used instead of screening to obtain a homogeneous fraction. Columns with lengths up to 15 m and internal diameters of 1.0–0.6 mm, the efficiency of which was equivalent to 3500 and 3000 theoretical plates per meter (with satisfactory reproducibility) for glass beads and Chromosorb respectively, were obtained by this method described above.

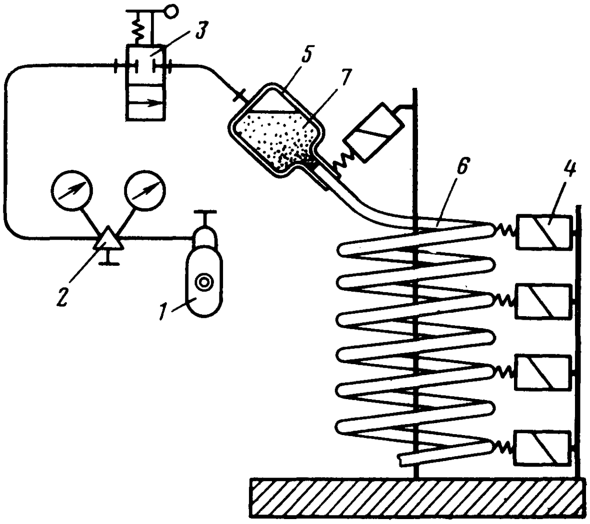

Figure 8. Schematic illustration of the device for filling capillary glass columns with the sorbent[64].

A simpler device, which does not require the use of an ultrasonic bath and is also based on the action of two factors—the vibration of the column and the pressure of an inert gas—has been developed[64]. The vibration is achieved by means of electromechanical low-frequency (50–100 Hz) vibrators placed at certain points along the length of the column. To improve the effectiveness of the stream, the pressure at the outlet from the column is applied in pulses in accordance with a specified programme†. The device (Fig. 8) consists of a compressed gas cylinder *1*, to which a valve *3*, with an electromechanical actuating device for the periodic application of pressure, is connected via a reduction valve *2*, and stands with several vibrators consisting of PE-20 electromagnetic relays *4*, with a vibration frequency of 100 Hz. A reservoir *5*, for the sorbent *7*, is attached to one of the stands, and clamps used to hold the column *6* are attached to the remaining stands. The relays are mounted along the circumference of the common base in such a way that the filled column is held by the clamps at intervals corresponding to 5–10 turns (depending on the column length).

The columns are filled as follows: a portion of the sorbent (1–2 cm^3) is poured into the reservoir *5*, the supply of gas is turned on, the automatic pressure programmer *3* is started simultaneously, and the vibrators *4* are switched on. Under the influence of the gas stream and the vibration, the sorbent is continuously transferred to the column. To ensure rapid and effective filling of the columns, the sorbent must be subjected to preliminary screening and the 100–160 and 160–200 μm fractions are used. The above device can be employed to fill spiral gas columns with various sorbents, including those which are readily charged electrically. Rapid filling by the latter is achieved by saturating an inert gas with the vapour of a polar liquid (for example ethanol); for this purpose, a porous material moistened with the liquid is placed in the reservoir with the sorbent, but does not come into contact with the latter. The device makes it possible to fill with the sorbent glass columns having lengths up to 20 m and more and with an internal diameter in the range 0.6–1.2 mm, a satisfactory reproducibility being achieved as regards both packing density and efficiency. The efficiency of the columns was equivalent to 3000 and sometimes up to 4000 theoretical plates per metre[65], which is not less than the efficiency of the columns obtained with the aid of ultrasound.

Bruner and coworkers[46,47] filled with the sorbent metallic columns having lengths up to 15 m and internal diameters in the range 0.7–0.8 mm without using a vibrator. The tube was extended in a vertical position, the lower end being fixed in such a way that the tube was subjected to a certain amount of tension. The upper end was connected to a small reservoir containing the packing, which was compacted by tapping with a rubber rod. The efficiency of the resulting columns was equivalent to 2000–2500 theoretical plates per metre of column length.

Less effective columns (1250 theoretical plates per metre) were prepared[66] by connecting individual filled sections, having lengths up to 3 m, by means of special junctions. Columns having lengths up to 12 m and an internal diameter of 1 mm were prepared.

2. Chromatographic Apparatus for Packed Capillary Columns

The use of PCC imposes a number of requirements on the apparatus owing to the following characteristic features of the analysis on such columns: low flow rates of the carrier gas, high efficiency, and high speed of analysis. In order to reduce the spreading outside the column, the volumes of the metering device, the connecting tubes, and the detector must be reduced to a minimum. Fig. 9 illustrates schematically the connection of a packed capillary column to the metering device and the detector, which makes it possible to inject the sample without dividing the stream[53]. The sample is introduced into the column via a tubular glass insert 11 cm long and with an internal diameter of 0.8 mm. One end of the insert, used to make a junction with the column, is broader and conical in shape. The column is fitted onto the cone to a depth of 2 mm. A seal is achieved with the aid of a silicone rubber washer. The exit end of the column is inserted in a stream of hydrogen and nitrogen in a flame-ionisation detector[53].

---

†An effective and comparatively rapid filling can be achieved also with a continuous application of pressure.

The volume of the metering device may be reduced by employing a metallic insert with an internal diameter of 0.8–1.0 mm. Another way of reducing spreading in the metering device involves the employment of a stream divider. The stream can be divided in proportions corresponding to a small ratio (1 : 2–1 : 5), which is required merely to increase the rate of passage of the sample through the metering device.

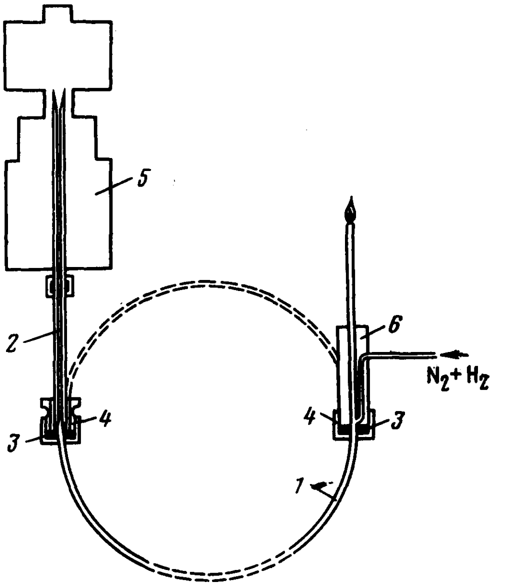

Figure 9. The connection of PCC to the gas-chromatographic system: 1) capillary column; 2) glass tube 0.8 mm in diameter; 3) silicone rubber; 4) lock-nut; 5) evaporator; 6) detector.

When PCC are used in industrial chromatographs, where samples are introduced automatically, particular attention must be devoted to the metering system. Special studies[28] on gas metering devices of membrane and plunger types in commercial chromatographs showed that, during the period of transport from the metering device to the column, the volume of the sample greatly increases and, with decrease of the initial volume of the sample, the relative increase in volume becomes more pronounced. Thus an initial sample volume of 0.15 cm^3 at a flow rate of 5 cm^3 min^{-1} increases by a factor of 8.7. To reduce the spreading, a membrane metering device, where "dead" volumes had been eliminated from the switching valves, was prepared and tested[28]. In the tests the column was replaced by a detection system, which determined the profile of the sample at the inlet to the column. The results of the test showed that, for a sample volume of 0.15 cm^3 and a carrier gas flow rate of 5 cm^3 min^{-1}, the volume of the sample increases by a factor of 5.3, i.e. is smaller by a factor of 1.5 than in a commercial metering device. A metering device of this design can be recommended for use with PCC in commercial chromatographs.

Table 6[67] presents the parameters of the sample for a metering system with switching valves. Using Klinkenberg's expression[68]

$$V_S \leqslant \frac{0.5}{N^{1/2}} V_R,$$

(where V_S is the volume of the sample at the inlet to the column, V_R the retention volume of the component, and N the number of theoretical plates) and the data in Table 6, it is possible to calculate the permissible initial volume of the sample. Thus, for a permissible sample volume of 0.8 cm^3 and a carrier gas flow rate of 0.5 litre h^{-1}, the volume of the initial sample must be not more than 0.1 cm^3.

Table 6. Parameters of the sample for a metering system incorporating switching valves without "dead" volumes.

Parameter	Carrier gas flow rate, litre h^{-1}	Volume of initial sample V_g, ml			
		0.1	0.15	0.5	1.0
Volume of sample at inlet to column, cm^3	0.1	0.55	0.6	0.75	—
	0.15	0.62	0.7	0.85	—
	0.3	0.72	0.8	1.0	1.5
	0.5	0.82	1.0	1.2	1.7
	0.8	0.92	1.15	1.4	2.0
	1.0	1.1	1.4	1.8	2.45
Ratio of given sample volume to initial volume	0.10	5.5	4.0	1.5	—
	0.15	6.2	4.7	1.7	—
	0.3	7.2	5.3	2.0	1.5
	0.5	8.2	6.7	2.4	1.7
	0.8	9.2	7.7	2.8	2.0
	1.0	11.0	9.3	3.6	2.45
Ratio of the concentrations in the sample at the maximum and in the initial sample	0.1	0.6	0.7	1.0	—
	0.15	0.55	0.65	1.0	—
	0.3	0.5	0.6	1.0	1.0
	0.5	0.42	0.45	0.9	0.95
	0.8	0.36	0.4	0.8	0.85
	1.0	0.32	0.35	0.7	0.8

The columns may be connected to the metering device in the detector either directly (Fig. 9) or via a metallic capillary. One should note that the scheme illustrated in Fig. 9 has been used in a chromatograph prepared in the laboratory. On the other hand, in commercial chromatographs such arrangement of the column is not possible and the ends of the column must be straightened before filling. This method of attachment is most effective from the standpoint of reducing the spreading outside the column and the possibility of employing columns at high temperatures (up to 260°C), but it is fairly laborious. A simpler procedure[27] involves making a connection via a metallic capillary: small sections of a metal capillary, the external diameter of which is smaller than the internal diameter of the column, are joined to the detector of the metering device (also via a silicone rubber washer). The ends of the capillaries are inserted into the inlet and outlet of the column and are glued on by means of an epoxy-resin. In this method of connection there is no need to straighten the ends of the column and the metal capillary and not the column itself is clamped by a nut, which is a much more reliable arrangement. For high-temperature analysis, it is necessary to use heat-resistant adhesives, or intermediate capillaries made of alloys (for example Kovar), forming a junction with glass, must be employed.

Flame-ionisation detectors are mainly used in conjunction with PCC. Owing to their considerable inertia, katharometers impair the quality of the separation and reduce the column efficiency. Comparative results of analyses of the products of the hydrocracking of heptane on PCC in conjunction with commercial katharometers of a polydiffusion type and with a flame-ionisation detector showed[28] that, when the latter was used, the specific efficiency of the column was equivalent to 1200 theoretical plates, while in the experiment with a katharometer the efficiency was equivalent to only 400 theoretical plates. However, the katharometer has significant advantages owing to its universality, simplicity of the apparatus involved, ease of operation, and reliability.

Studies have been made[28] on the possibility of employing a katharometer in work with PCC. The inertia of the katharometer is determined by the volume of the chamber and the inertia of the sensor elements. It has been established that the main factor determining the inertia of the katharometer is the volume of the detector chamber. A microkatharometer with a volume of the chamber of 40 μl, in which the same sensor elements as in an ordinary katharometer are employed, was therefore developed for experiments with PCC[28].

Certain requirements must also be met by the system for the recording of the results of analysis when short columns are used in rapid analysis. The limited speed of the response of the recording device is the cause of the distortion of the shape and amplitude of the chromatographic peaks, if the width of the latter is smaller than the permitted value. If the speed of the response of the recording device is T, then the minimum width σ_f of a chromatographic peak with a height h_0, which can be measured without distortion of its shape, may be determined from the relation

$$\sigma_f \geqslant \frac{h_0}{l}\frac{T}{1.65}, \tag{6}$$

where l is the length of the scale and h_0 the amplitude value of the signal. For the peak amplitude, we have correspondingly[69]

$$\sigma_a \geqslant \frac{h_0}{l}\frac{T_a}{2,22}. \tag{7}$$

The minimum permissible width of the peak at any specified height, for which the peak is measured with the specified response time of the recording device without distortion of the shape or height respectively, can also be determined from Eqns. (6) and (7). The minimum possible duration of analysis on a column with a specified efficiency can be determined from the minimum permissible peak width. The period from the instant of the injection of the sample into the column to the instant when the peak maximum emerges (t_R) is defined by the equation[28]

$$t_R = (N/5{,}54)^{1/2}\tau_{0,5}.$$

Having expressed the peak width in terms of the standard deviation σ (the peak half width at a height $h = h_{\max}e^{1/2}$), we can obtain

$$t_R = (N/5{,}54)^{1/2}\cdot\sigma\cdot 2\sqrt{2\ln 2} \simeq \sigma N^{1/2}.$$

Hence the minimum permissible elution time of the component for recording without distortion of the shape and amplitude of its peak is determined respectively by the expressions

$$t_{R_f} = \frac{h_0}{l}\frac{T}{1.65}N^{1/2}; \qquad t_{R_a} = \frac{h_0}{l}\frac{T}{2.2}N^{1/2}.$$

V. THE APPLICATIONS OF PACKED CAPILLARY COLUMNS IN GAS CHROMATOGRAPHY

1. The Separation of Complex Mixtures

The separating capacity of chromatographic columns can be increased by increasing either the sorbent selectivity or the efficiency of the columns employed. The use of selective sorbents is effective only for the separation of pairs of substances which differ in their properties; for the separation of multicomponent mixtures consisting of narrow fractions of substances whose properties differ little, highly efficient columns are necessary. The only method for the separation of multicomponent mixtures available at present is classical capillary chromatography, employed mainly for the analysis of non-polar compounds. The preparation of highly efficient capillary columns with a polar phase requires special treatment of the surface of the columns and still constitutes an art [rather than a science]. Packed columns can be filled with any sorbent and the scope of detailed studies of multicomponent mixtures of different compositions is thus extended. It is particularly useful to employ PCC for the separation of substances with small partition coefficients.

Table 7. Results of the separation of industrial mixtures of oxygen-containing compounds on capillary and ordinary packed columns.

Type of column	Sorbent	t, °C	Mixture analysed	Efficiency, N		No. of separated components
				overall	specific, per metre	
13.8 m x 0.8 mm PCC	15% PEG-400 on Chromosorb P	120	Product of oxo synthesis in Salavat [Combine]	42 000	3000	40

Highly efficient PCC have been applied successfully to the determination of the compositions of complex hydrocarbon mixtures—fractions of liquid high-temperature pyrolysis products[70] and fractions (150–180° C) of the petroleums of the Surgut deposit (Western Siberia)[27]. Analysis of the C_4–C_{13} petroleum cracking fraction on PCC by gas–liquid–solid chromatography established[47] that, in terms of the number of peaks, the resulting chromatogram is analogous to that obtained on a classical capillary column.

The separation of light hydrocarbons on a usual packed column is fairly difficult. Using the main advantage of PCC—high efficiency and the possibility of filling with any sorbent—it is possible to achieve a clear-cut separation of light hydrocarbons[53].

The separation on PCC of multicomponent mixtures incorporating polar components is of particular interest. Specimens of industrial mixtures of oxygen-containing compounds—products obtained at different stages of oxo synthesis—has been studied[27] with the aid of PCC. The results of the separation are presented in Table 7, which includes for comparison also data for the separation of certain specimens on ordinary packed columns. Table 7 shows that PCC make it possible to detect on the chromatogram a number of peaks greater by a factor of 2–4 than on ordinary packed columns.

A multicomponent mixture of hydrocarbons and C_8–C_{12} alcohols, obtained as a result of synthesis from carbon monoxide and hydrogen, was separated by PCC under isothermal conditions in combination with linear programming conditions[27]. The duration of the entire analysis was 210 min; during the first 30 min, the separation was carried out at 120°C and during the next 30 min linearly programmed heating at a rate of 2 K min^{-1} was employed up to 160°C, this being followed by isothermal conditions. The chromatogram presented in Fig. 10 shows that under these conditions a fairly clear-cut separation of 60 components is achieved, and that during linearly programmed heating there is almost no displacement of the base line.

The advantages of PCC in the separation of polar compounds have been demonstrated[71] in the analysis of C_1–C_6 alcohols, aliphatic acids, and primary amines. Highly efficient PCC have also been used to analyse complex mixtures of steroids[53], barbiturates[54], organic mixtures in water[47], and impurities contaminating air[46,47] and for the separation of the stereo-isomers of acyclic hydrocarbons[72] and structural isomers of aromatic hydrocarbons[72].

2. Analysis of Impurities

In the determination of impurities it is necessary (1) to separate them from the main component and then from one another, and (2) to carry out the determination under optimum conditions as regards sensitivity, i.e. under the conditions of maximum concentration in the centre of the zone. In order to separate the impurities from the main component, a much higher column efficiency is necessary than in the separation of zones with identical concentrations. Thus, in the separation of substances with a concentration ratio of 1000, it is necessary to employ a column with an efficiency higher by a factor of 2.8 than that of the column used to separate substances with identical concentrations[74].

In conformity with the theoretical plate theory[75,76], the maximum concentration in the zone increases with efficiency and with the weight of the sample:

$$C_{\max} = \frac{N^{1/2}}{V_R}\,\frac{q}{(2\pi)^{1/2}},$$

where q is the weight of the sample.

The simplest method of increasing the sensitivity is to increase q. However, an increase of q entails a decrease of column efficiency and an impairment of separation. For this reason, it is in many cases more useful to employ highly efficient columns.

The capillary columns proposed by Golay[1] have been and still are the most efficient chromatographic columns. However, owing to their disadvantages they have not found applications on quite such a wide scale as packed columns. In particular, one of the disadvantages of classical capillary columns is the difficulty and in many instances the

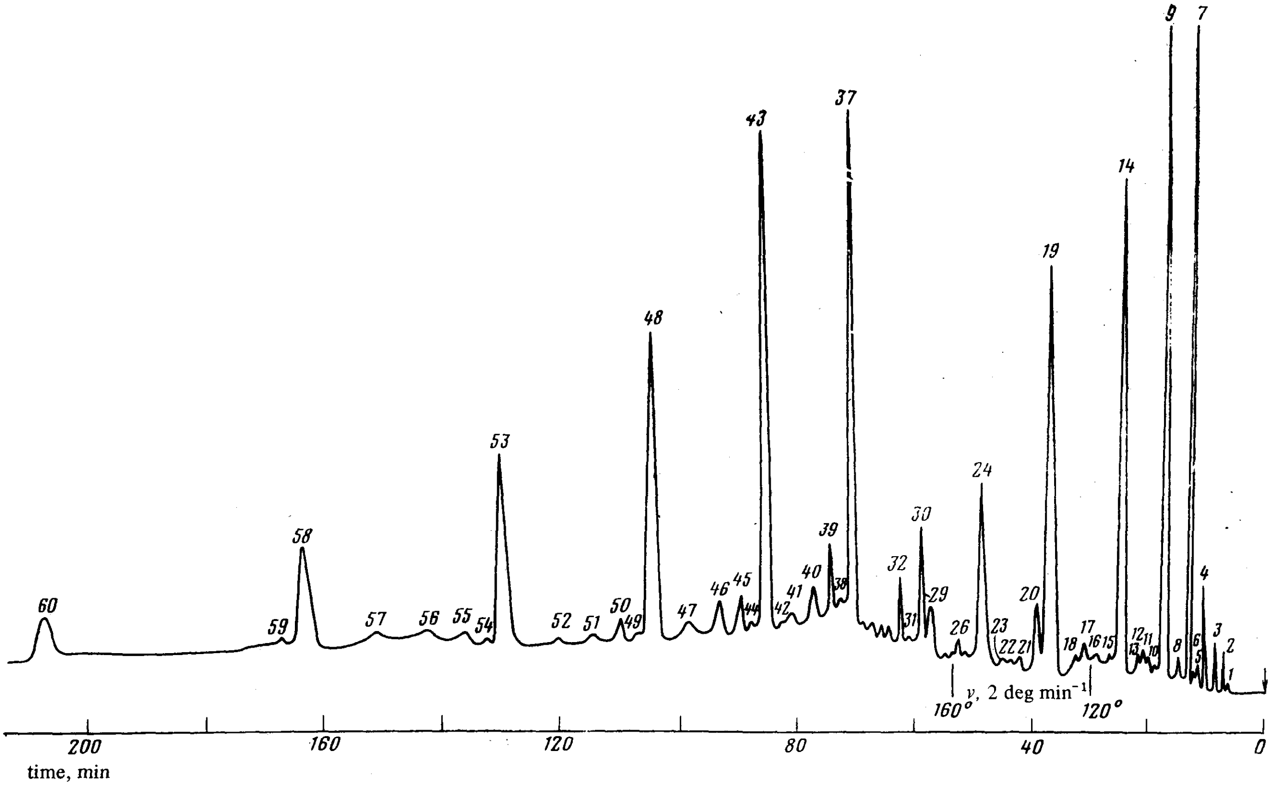

Figure 10. Chromatogram of the separation of the oxo synthesis products. 15.5 m × 0.8 mm column; sorbent—15% of 1,2,3-tris-(2-cyanoethoxy)propane on Chromosorb P.

impossibility of analysing admixtures and especially microimpurities, since, owing to the extremely small amount of charge which the columns can handle, the determination of impurities requires unduly sensitive detecting systems. Furthermore, the high phase ratio β impairs the separation, which has a particularly marked effect in the separation of weakly sorbed compounds. These disadvantages may be to a large extent eliminated by employing long PCC, the small diameter of which ensures their high efficiency, and the presence of a sorbent ensures a high capacity.

If H is increased by 10% compared with the limiting value H_c for an infinitesimally small sample, then the limiting sample size V_{lim} can be estimated from the equation[77]

$$V_{lim} \simeq 0.2 V_R / N^{1/2},$$

or, assuming that $V_R \simeq K v_l$ (K is the gas–liquid partition coefficient and v_l the volume of the SLP in the column), from the expression

$$V_{lim} \simeq 0.2 K v_l / N^{1/2}.$$

In comparing the limiting sample sizes for capillary (V^c_{lim}) and packed capillary (V^{cp}_{lim}) columns, it is useful to employ the relation

$$V^{cp}_{lim} / V^c_{lim} = v_l^{ce} / v_l^c, \tag{8}$$

where v_l^{cp} and v_l^c are the volumes of SLP in packed capillary and classical capillary columns respectively. Eqn. (8) was obtained on the assumption that the number of theoretical plates in the columns compared and the partition coefficients in the latter are similar. Since the volume of the SLP in PCC is approximately 100 times greater (see Section II) than in classical capillary columns, the sample size in PCC is one hundred times greater than in classical capillary columns. Consequently, when detectors of the same sensitivity are used, the minimum concentration of the impurity which can be determined with the aid of PCC is approximately 100 times smaller than that which can be determined by means of classical capillary columns.

Additional advantages of PCC compared with classical capillary columns are the possibility of employing mixed sorbents and the possibility of gas–adsorption chromatography in packed capillary columns.

Long PCC have been used[78] to determine impurities in 2-bromo-2-chloro-1,1,1-trifluoroethane (fluorothane). The separation of the isomeric 1-bromo-2-chloro-1,1,2-trifluoroethane impurity from the main substance constitutes a particular difficulty in this analysis. The application of PCC in the analysis of fluorothane made it possible to determine a larger number of microimpurities (almost by a factor of two). Furthermore, this ensures a higher separation factor ($R \gg 1$) for the main component and the isomer[78,79].

The use of short PCC permits the determination of microimpurities by a micromethod[13] and a high-speed method[19]. The authors of these investigations carried out an analysis (at 70° C over a period of 70 min) of microimpurities in isoprene on a 2.5 m × 1.1 mm column filled with modified (with 2% of squalane) alumina; H for 2-methylbut-1-ene amounted to 0.04 cm. Rapid analysis of the same isoprene specimen (at 30° C over a period of 7 min) was carried out on a 0.5 m × 0.6 mm column with the same adsorbent; in this case H for the same component was 0.06 cm. Fig. 11 shows that the reduction of the analysis time by a factor of 10 is entirely worthwhile, despite the slight impairment of efficiency. One should also note that rapid analysis has been achieved for a much lower temperature, which is very important in experiments with readily polymerisable substances. The content of the impurities determined in the two instances was 2 × 10^{-4} vol.%.

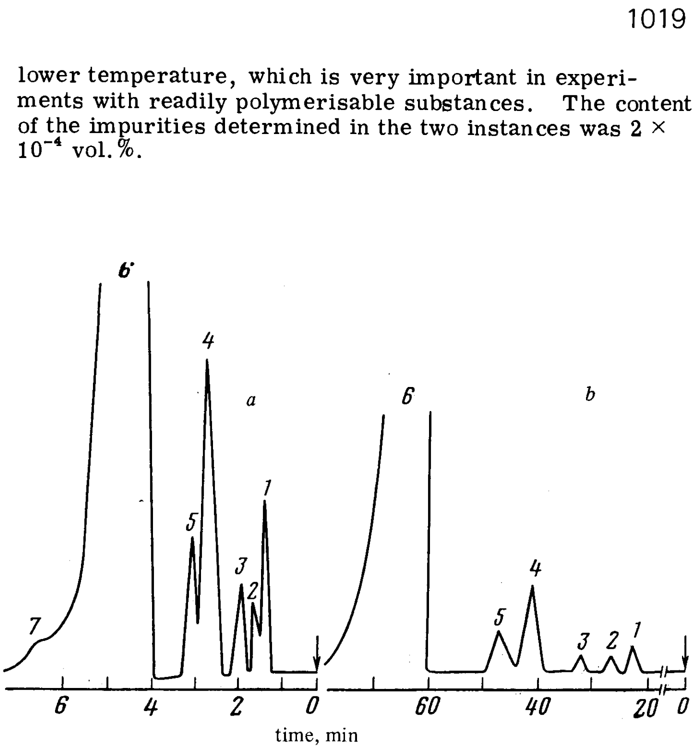

Figure 11. Chromatograms of the separation of impurities in isoprene: *a*) high-speed method; carrier gas (hydrogen) flow rate 50 cm s^{-1}; 30° C; *b*) usual analysis; carrier gas (nitrogen) flow rate 8.1 cm s^{-1}; 70° C; 1) 3-methylbut-1-ene; 2) pent-1-ene; 3) pent-2-ene; 4) 2-methylbut-1-ene; 5) 2-methylbut-2-ene; 6) isoprene; 7) butadiene.

Packed capillary columns have been used[31] to determine gaseous hydrocarbon impurities in the propane–propene fraction used to make polypropylene. The high-speed method for the determination of microimpurities has been applied in gas-adsorption chromatography on alumina modified with 3% of squalane using a programmed temperature up to 70° C. The analysis time of an artificial propane–propene fraction consisting of 13 components was 8–10 min (on a column of the usual type, it is 40 min); the volume of the sample injected was 2 cm^3. The column efficiency H for α-butene was 0.028 cm, i.e. was close to H for classical capillary columns. The minimum impurity content in the sample was 8 × 10^{-4} vol.%.

3. High Speed Analysis

When a gas chromatograph is used as a pulse generator for the regulation of chemical processes, the duration of the analytical cycle must be reduced, i.e. high speed analysis is necessary. It is also required in routine analyses, in the study of complex multicomponent systems, in kinetic measurements, etc. The duration of analysis may be reduced by means of a higher separating capacity of the column under optimum separation conditions, by increasing the flow rate at the mobile phase, and by employing shorter columns, high-speed amplifiers, and computer integrators.

Since PCC are characterised by high resolving capacity per unit length, this makes it possible to employ short separating systems. The high permeability of columns of this type permits the use of higher carrier gas flow rates, which can be ensured by moderate pressures. The stable conditions which obtain when the temperature is programmed permit an increased rate of separation by programming the temperature and pressure without an appreciable decrease of separating capacity.

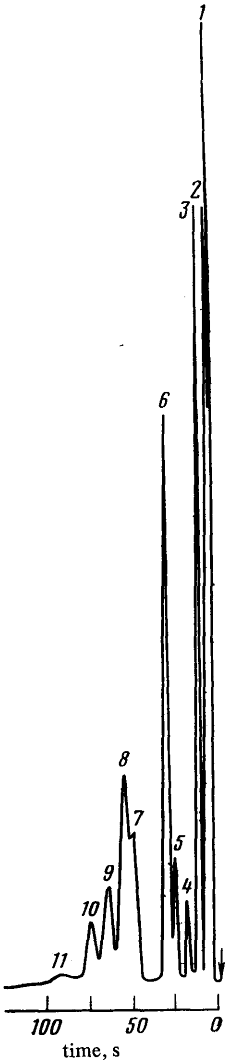

Figure 12. Chromatogram of the high-speed separation of C_1-C_4 hydrocarbons. 0.2 m × 0.58 mm column; carrier gas (hydrogen) flow rate 40 cm min^{-1}; room temperature: 1) methane; 2) ethylene; 3) propane; 4) n-butane.

Kaiser[80] suggested that the carrier gas pressure and the separation number per unit time Tz/t be used as the principal characteristics of high-speed chromatographic separation. The separation number Tz is defined by the relation

$$Tz = \frac{t_2 - t_1}{\tau_{0.5}^{(2)} + \tau_{0.5}^{(1)}} - 1,$$

where t_1 and t_2 are the uncorrected retention times of the first and second components and $\tau_{0.5}^{(2)}$ and $\tau_{0.5}^{(1)}$ are the widths of peaks at the level of half their height. The separation number can be measured with programmed temperature and pressure, so that it is preferable as a criterion to measurements based on the theoretical plate theory. Short PCC have been assessed[80] in terms of the proposed criteria when the columns were used for high-speed analyses.

Capillary columns filled with a sorbent have been employed[31] for the high-speed analysis of low-boiling C_1-C_4 hydrocarbons by gas-adsorption chromatography on modified alumina. A mixture of eleven components was separated in 90 s. An example of high-speed analysis of a mixture of light hydrocarbons over a period of 3.5 s is illustrated in Fig. 12 (column with alumina gel modified with the aid of 5% of squalane). The methane elution time was less than 1 s and the column efficiency for n-butane was $H \simeq 0.1$ cm.[31]

A further decrease of the duration of analysis is hindered by difficulties associated with the apparatus. Thus the sample injection time is almost equal to the elution time of the first component, which distorts the shape of the peak; it is impossible to measure accurately the elution times of the components with the aid of the usual stop watch (the error of the measurement is 100% and more); the unduly high volume flow rates in a flow-type detector limit stable combustion and accuracy of the measurement. High-speed analysis (1 peak in 1 s) therefore requires special automatic metering, recording, and integrating (counting) devices.

The possibility of reducing the duration of analysis by a factor of 2-5 has been demonstrated[81] in a study where capillary columns filled with Spherosil were used in gas-solid chromatography and gas-solid chromatography with a modified SLP.

4. The Use of Packed Capillary Columns in Industrial Automatic Chromatographs

Industrial automatic chromatographs are used as sensors of composition in automatic monitoring and control systems for technological processes. A specific feature of industrial chromatographs is that they are mounted directly at the sampling points in technological apparatus and operate under automatic conditions. These devices must therefore be more compact, must require a fairly small amount of carrier gas, and must be reliable. The columns in such apparatus must meet another requirement: long operating time without alteration of the characteristics of the separation process. For this reason, the number of sorbents and liquid phases suitable for industrial chromatographs is much smaller than for laboratory chromatographs. Apart from characteristics such as sensitivity and error, an important parameter of industrial chromatographs is the analysis time, which determines the possibility of obtaining information about the composition of the mixture analysed in a specified time.

Packed capillary columns satisfy all the requirements enumerated above to a much greater extent than the usual packed columns. The high specific efficiency of PCC and the possibility of carrying out analyses at a fairly high linear flow rate of the carrier gas without reducing the efficiency of the separation make it possible to reduce greatly the duration of the analysis. The small amounts of carrier gas and sorbent required permit the use of scarce and expensive carrier gases and sorbents and the small size of the columns permits the construction of a compact analyser ensuring effective temperature control and the possibility of ensuring any category of protection from explosion.

However, one should bear in mind that PCC impose definite requirements, primarily as regards the automatic metering device and the detector. Thus, when appreciable spreading of the sample occurs in the metering system, the column is overloaded, and its efficiency falls[66]. The inertia of the detector should correspond to the parameters of the peak[82], otherwise the apparent efficiency of the separation falls, and an appreciable error is introduced into the results of the measurements.

The following apparatus has been developed[81]: an automatic metering device and a low-inertia thermal conductivity detector, suitable for PCC, and on their basis, an industrial automatic "Mikrokhrom" chromatograph with an explosion-resistant device was constructed. The apparatus has been used successfully for the determination of the compositions of many industrial mixtures directly in industrial plants.

In the study of individual stages of the technological processes under development automated pilot microapparatus has been used recently. One of the most important parameters in the assessment of the results is the composition of the multicomponent mixture at the outlet from the microreactor. The most suitable analyser is a compact high-speed automatic chromatograph with a small volume of samples removed (this makes it possible to calculate the material balance without taking into account the amount of substance taken for analysis). The chromatograph with PCC meets the above requirements to the greatest extent.

The Mikrokhrom chromatograph of normal design (not the explosion-resistant design) has been used in experiments with a pilot microapparatus for catalytic hydrocracking[83]. The chromatogram of a mixture of catalytic n-heptane hydrocracking products is illustrated in Fig. 13.

5. Measurement of Physicochemical Characteristics

One of the most important applications of PCC involves the determination of physicochemical characteristics by a micromethod, i.e. using small amounts of the test substances and the sorbent (reagent). The determination of rate constants on PCC was first developed[24] for the reaction of isoprene with maleic anhydride in the liquid phase by a chromatographic pulse micromethod. The degree of conversion was determined from the change in the area under the chromatographic isoprene peaks (n-pentane was used as the internal standard). The contact times of the reactants were calculated from the retention times of the diene taking into account the "dead" time of the chromatograph. The reaction rate constants, determined at 42°, 48°, 56°, and 62°C, and the activation energy of 12.1 kcal mole^{-1} agree satisfactorily with the values obtained on a column of the usual type[84].

An advantage of PCC is the possibility of employing them (by virtue of their high efficiency) for the determination of the rate constants for rapid reactions. A special calculation showed[24] that the kinetic coefficient of sorption and desorption (internal-diffusion mass exchange) corresponding to the maximum degree of conversion is a factor of 2×10^3 greater than the rate constant (for an analytical column, the ratio is smaller by an order of magnitude). PCC can also be used to determine heats of adsorption. The heats of adsorption of α-butene on various alumina specimens have been determined[24] using a 0.5 m × 0.58 mm PCC in the temperature range from −20° to +100°C. According to literature data[85], the heat of adsorption of n-butane is 8.2 kcal mole^{-1}; values in the range 8.5–8.1 kcal mole^{-1} have been obtained on PCC. Consequently the micromethod described above for the determination of heats of adsorption is entirely reliable and accurate.

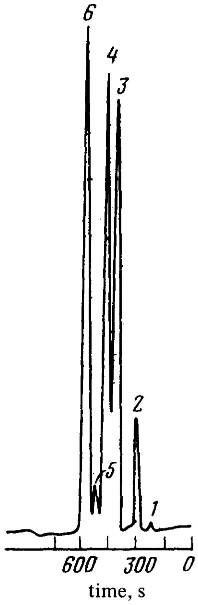

Figure 13. Chromatogram of the separation of the products of the catalytic hydrocracking of heptane. 1.2 m × 1.0 mm metallic column; sorbent—Chromosorb P (120–150 μm) impregnated with 15% of squalane; 60°C; carrier gas (nitrogen) flow rate 2.4 cm^3 min^{-1}: 1) n-hexane; 2) methylcyclopentane; 3) 2-methylhexane; 4) 3-methylhexane; 5) 3-ethylpentane; 6) n-heptane.

In conclusion we may note that PCC extend the scope of gas-chromatographic studies both in the field of analysis, particularly of multicomponent mixtures and mixtures difficult to separate, and in the measurement of physicochemical quantities. Also promising is the application of PCC in microchemistry, particularly for microseparations on a preparative scale.

Theory of Chemical Reactivity

S.Beran, P.Carsky, P.Hobza, J.Panciř, R.Polak, Z.Slanina, and R.Zahradnik

This critical review deals with the present state of the theory of chemical reactivity, based on the methods of quantum chemistry and statistical thermodynamics. Reactions in the gaseous phase and in solution are examined. The static and dynamic theories of reaction rates are analysed. Catalytic reactions are discussed briefly. The bibliography contains 272 references.

I. INTRODUCTION

The calculation of equilibrium constants and rates, based on the methods of quantum chemistry and statistical thermodynamics, is one of the most important problems of theoretical chemistry and hence is of considerable significance not only for the development of chemistry but also for its various practical applications.

For the solution of many problems in experimental chemistry it is sufficient to know the relative values of the equilibrium constants and rates in series of structurally related compounds. Nevertheless, the absolute values of these quantities for reactions taking place under different conditions is of considerable interest for present-day theoretical chemistry. Although this problem has already been solved in principle for some time, considerable difficulties are encountered in applying the theory to specific problems. In the theory of reactivity there are many problems, the solution of which requires new ideas. These ideas need not always be completely new; in some cases, the modification of old methods may lead to considerable progress. An example is provided by collision theory (in chemical reactions), the development of which has led in the last 15 years to the formulation of the present dynamic theory of reactivity.

The elementary quantum-chemical theory of reactivity, which reduced chiefly to the construction of correlations for experimental data, reached its greatest development in the nineteen-fifties [1-8] and was for the most part complete by the nineteen-sixties [4]. Even now, however, this theory is useful for chemists. In the nineteen-seventies, the development of the static theory of reactivity is taking place in the following directions [9]: a) calculations of the absolute values of equilibrium constants and rates; b) the study of the structure of the potential energy surfaces of reacting species; and c) calculations of solvation energies (this last is extremely important, since 95% of chemical reactions take place in solution).

In the second half of the nineteen-sixties, considerable efforts were directed to the study and development of the principle of the conservation of orbital symmetry,[9] which met with considerable response in organic and then inorganic chemistry. In this field, important results were obtained, which made it possible to estimate qualitatively the relative values of activation barriers and hence the possibility of a given type of reaction.

In the first part of the present review, problems at present common to the entire theory of chemical reactivity are discussed. In the second part, various theoretical studies in the field of reactivity are examined, An attempt has been made to cover completely work on the calculation of the absolute values of equilibrium constants or rates. Very little work of this kind has been published up to the present. Since the present review emphasises quantitative work, almost no attention is paid to methods for the qualitative study of reaction kinetics, except for adiabatic reactions taking place in the electronic ground state. Most attention is paid to the theory of the equilibrium and kinetics of reactions, and to various types of reaction between reagents. Some catalytic reactions are also included in the review.

II. GENERAL PROBLEMS OF THE THEORY OF CHEMICAL REACTIVITY

1. Stationary Points of Potential Energy Surfaces

Points on the potential energy surface at which the first derivatives with respect to the coordinates of all the atoms are equal to zero are called stationary points [10]. Stationary points are of particular importance in the theory of chemical reactivity. For the subsequent treatment it is convenient to divide these into three groups, on the basis of the properties of the matrix of the second derivatives of the energy with respect to the coordinates, that is the matrix of force constants. If all the eigenvalues of this matrix are positive, the point is a local minimum and corresponds to a stable conformation of the molecule. If only one eigenvalue of the force constant matrix is negative, the point is called a saddle point and corresponds to an activated complex in the sense of the theory of absolute reaction rates (see Part III). If more than one eigenvalue of the force constant matrix is negative, the corresponding stationary point is of no interest for the theory of chemical reactivity. For the description of equilibria it is necessary to consider only points of the first type, and for the description of the kinetics of processes, the points of the first and second types should be known. The determination of these points until recently presented considerable difficulties, which in practice could not be overcome for molecules containing five or more atoms.

The development of computer techniques and optimisation methods in recent years has led to the development of new algorithms for finding local minima. The method of successive optimisation of the coordinates [10], which has a low efficiency, has been replaced by more effective methods [11-25]. The rate of convergence of the calculation depends on the energy characteristics used to define the stationary points. Methods based only on energy values, in particular the simplex method [14,15], require considerable machine time; on the other hand, methods based on the use of second derivatives (of the energy with respect to the coordinates) also have a low efficiency, since the values of the second derivatives are calculated numerically from the values of the first derivatives, and this increases considerably the time required for the calculations [11-13,20,26].

The most effective methods are those which use only the first derivatives of the energy. The simplest of these, the linearly converging method of steepest descent, is less effective [20] than the quadratically converging methods of variable metrics. The Fletcher–Powell algorithm [27] has been used by Bloemer and Bruner [21], and this algorithm and those of Broyden [28], Goldfarb [29], and Hoshino [30] have been used by Pancíř [26]. The most effective method has been found to be that of Murtagh and Sargent [31], used by a number of authors [16,19,23,26]. By carrying out the optimisation of the geometry and the SCF procedure in a single iteration cycle in the CNDO/2, INDO, and MINDO/2 approximations, the time required for complete optimisation of the geometry has been decreased considerably [19].

In all cases, the determination of the stationary points of the potential energy surface is based on some initial approximation. The choice of this approximation presents no difficulty for finding local minima, since in this case the information on the structure of the molecule is usually sufficient. In the case of saddle points, the situation is more complicated (see Part III for the method for finding these points). Moreover, in the determination of saddle points it is impossible in the general case to employ methods based on the use of only the values of the energy or its first derivatives. Gardient methods are applicable only for symmetrical molecules, and then only when the eigenvector belonging to the negative eigenvalue satisfies definite symmetry conditions [16]. The calculation of the matrix of the second derivatives of the energy, which complicates the determination of stationary points, is necessary in the case of saddle points: the analysis of the eigenvalues of the force constant matrix is the only method for determining the type of stationary point, and in addition the eigenvectors give information on the direction of the reaction coordinate (see Refs. 26 and 32 for more details). Unfortunately, the time required for the optimisation of the geometry when the force constant matrix obtained by semi-empirical methods of the CNDO type are used is more than ten times the time required for the solution of this problem by the method of variable metrics [26].

2. Energy in the Hartree–Fock Method and Exact (Non-relativistic) Energy: the Problem of Allowing for Correlation Energy

Most quantum-chemical calculations are carried out in the SCF approximation. It is therefore important to know the extent to which SCF methods are suitable for the study of chemical reactivity. For this purpose, qualitative results obtained in this field, chiefly by non-empirical methods, are examined below.

One unsatisfactory feature of the SCF method is that the probability density (the combined distribution of the coordinates) of two electrons in this approximation is equal to the product of one-electron functions. This means that the motion of the electrons is regarded as taking place independently, so that no allowance is made for electron correlation. The difference between the energy obtained by exact solution and the energy from the SCF solution is called the correlation energy. The energy of the exact solution is understood to be the lowest non-relativistic energy in the Born–Oppenheimer approximation, and the energy of the SCF solution the lowest energy possible within the framework of the SCF method.

From the viewpoint of chemical reactivity, the chief disadvantage of the SCF approximation is the incorrect description of a large part of the dissociation region of the system. A classical example is the potential energy curve for the hydrogen molecule (Fig. 1). In this case it is possible to describe the dissociation correctly[33] if allowance is made for the interaction of the ground state with the doubly excited state $(1\sigma_u)^2$. In the case of the molecules C_2 and N_2, however, the correct description of the dissociation requires the use of four or ten configurations[34] respectively. Thus the solution of a problem of this type must be carried out by the method of configuration interaction or some other method taking account of correlation energy. The same unsatisfactory features of the SCF method appear in the study of activated complexes.

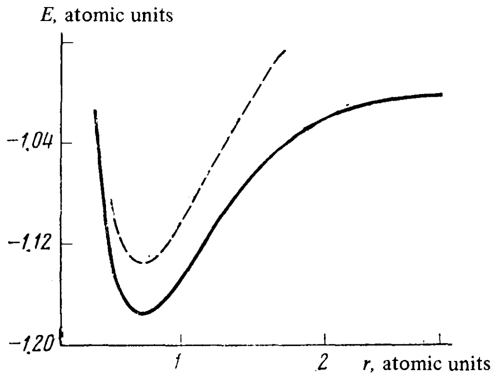

Figure 1. Potential energy curves[33] (in atomic units) for the H_2 molecule. Continuous line—exact solution, broken line—SCF approximation.

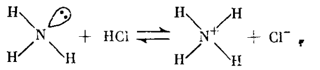
In the general case, the use of the SCF approximation to construct energy surfaces with "chemical accuracy" is fairly limited. For one type of reaction, however, the SCF approximation is satisfactory[35]. These are exothermic reactions, which, according to Polanyi[36], correspond to a potential energy surface without any barriers or activation energy. The problem of the activated complex thus diappears in this case. Moreover, for ion–molecular reactions of the type $Li^+ + H_2 \rightarrow H^+ + LiH$ the structure of the potential energy surface is determined chiefly by ion–quadrupole and ion–induced dipole interactions, which can readily be taken into account in the SCF approximation[37].

In the case of chemical equilibria, it is possible to limit the treatment to the study of fairly small regions around the minima of the energy surfaces. It has been established empirically[38,39] that the enthalpy of a reaction depends little on the correlation energy if all the reagents are systems with closed electron levels. The enthalpies of reactions, however, are not determined with an accuracy which would make it possible to carry out reliable statistical-thermodynamic calculations of the equilibrium constants. For the correlation energy to be preserved in a reaction, certain conditions must be fulfilled[40], namely: a) the number of electron pairs† should not change, and b) the relative arrangement of neighbouring electron pairs should also be preserved approximately‡.

In reactions involving molecules with filled orbitals, the first condition is often satisfied, but the second less frequently. In other words, for the preservation of correlation energy, not only in-pair interactions (in-pair correlation energy), but also between-pair interactions (between-pair correlation energy), are important. An elementary example of a reaction in which both of these conditions are fulfilled is the following[42]:



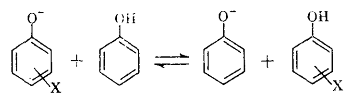
(1)

Preservation of correlation energy is also to be expected in so-called isodesmic reactions. This term was introduced by Pople and coworkers[43] for reactions in which the number of bonds of a definite formal type is preserved, but the relative arrangement of the bonds is changed. Condition (a) is always fulfilled for these reactions. Condition (b) may be fulfilled to different extents; for example, it is fulfilled to a sufficient extent in the following cases[44,45]:

(2)

$$RO^- + MeOH \rightleftharpoons MeO^- + ROH\ , \tag{3}$$

$$RCC^- + HCCH \rightleftharpoons HCC^- + RCCH\ , \tag{4}$$



(5)

The enthalpy of a reaction can often be determined indirectly; for example, for the reaction

$$NaCl \rightarrow Na + Cl \tag{6}$$

none of the above conditions is fulfilled, Since NaCl is an ionic compound, however, it is possible in the SCF approximation to study the process

$$(Na^+Cl^-) \rightarrow Na^+ + Cl^-, \tag{7}$$

---

†To keep the subsequent discussion simple, an exact definition of electron pair will not be given.

‡For example, for internal rotation in ethane. In this case the potential energy curves obtained by the SCF and PC methods are very similar[41].

for which both conditions are fulfilled, Since the correlation energies of Na, Cl, and $Na^+ + Cl^-$ are well known, this method[46] can be used to find the exact value of the enthalpy of reaction (6). Thermochemical cycles are used similarly to study so-called bond separation reactions[43]. These are isodesmic processes of the type

$$X{-}Y{-}Z + Y \rightarrow X{-}Y + Z{-}Y, \tag{8}$$

or, for example,

$$CH_3CHO + CH_4 \rightarrow C_2H_6 + H_2CO, \tag{9}$$

which are not of interest in themselves, but which can be used to obtain useful results.

A description of methods for the direct calculation of correlation energy is beyond the scope of the present review. Only a few brief points will therefore be made. Mention may be made first of the simplest method[47], in which a constant empirical value of the correlation energy is associated with each bond, and the total correlation energy is calculated as the sum of the individual contributions (just as dipole moments, heats of formation, etc. are estimated empirically in chemistry). This method can hardly give sufficiently accurate values of the correlation energy, since it does not take account of in-pair interaction. Of semi-empirical methods, mention may be made of that based on the many-electron theory of Sinanoğlu[50], in which allowance is made for the effective paired correlation energy (the EPCE method[48,49]), and the method proposed by Lie and Clementi[51], in which Wigner's equation[52] is used. The results which have been published do not yet make it possible to discuss the possibilities of these methods more fully. The results obtained by the present authors[53] for the complex $(H_2)_2$ show that the EPCE method may give useful information for the description of van der Waals interaction. An advantage of both of the above methods is their relative simplicity, but an unsatisfactory feature is the incorrect description of the dissociation limits in most cases.

Many versions of non-empirical methods exist. In some of these, however, allowance is made only for in-pair correlation energy (calculations based on the theory of geminals), or else the part played by correlation energy is overestimated, and it is usually difficult to estimate the error (the approximation of independent electron pairs, IEP [40]); other methods require a large expenditure of machine time (PC SCF methods) with allowance for a large number of configurations. A modified IEP approximation[54,55] or simple versions of the configuration interaction method[56,57] are therefore usually employed.

To conclude this section, brief mention may be made of semi-empirical SCF calculations of the CNDO and INDO types. Among those who use these methods, there is the widespread opinion that correlation effects can be taken into account by empirical parameters, so that there is no need to consider the estimation of the correlation energy. In fact, the empirical parameters are chosen in such a way that the bond energy of the molecule is reproduced for the equilibrium geometry. These semi-empirical methods, however, are based on non-empirical versions of the SCF method and therefore should exhibit all the weaknesses of this approximation, for example the incorrect description of the dissociation limits. It may be assumed, however, that the study of energy surfaces by semi-empirical methods is meaningful and that studies in this field are required, since these surfaces may give at least useful "semi-quantitative" information.

3. Calculation of Thermodynamic Functions in Statistical Thermodynamics

The quantitative estimation of the equilibrium constants and rates of chemical reactions is based on statistical thermodynamics. For the great majority of processes taking place in the gaseous phase at temperatures not exceeding 1000 K, involving normal molecules, radicals, or ions (in contrast to van der Waals complexes), the equilibrium constants (or rates) are determined chiefly by the value of ΔH_0° (or $\Delta H_0^{\neq}$). The calculation of the enthalpy change is of course a quantum-chemical problem. Thus the problem of improving the rigid rotator–harmonic oscillator (RR–HO) approximation is not the primary problem, although from the physical viewpoint it is a crude approximation. Thus the principal and very difficult problem is the calculation of the enthalpy changes by the methods of quantum chemistry. The value obtained corresponds to 0 K and does not take account of zero-point vibrational energy.

The calculation of the vibrational partition function (since it is desired to avoid the use of experimental data) can be carried out by the methods developed by Wilson and coworkers[58] and El'yashevich[59]; the zero-point energy is of course again determined. The complete partition functions can be used to calculate the values of the thermodynamic functions at any temperature. The relationships between the thermodynamic functions and the partition functions, and methods for calculating the partition functions from spectroscopic data, has been described in textbooks and monographs[60-63]. In the general case, an appreciable contribution to the total partition function is made by the translational, rotational, and in a number of cases vibrational partition functions. Analysis of the structure of the vibrational partition function shows that with increase in the temperature and decrease in the frequency of the normal vibrations, the magnitude of the contribution from the vibrational partition function increases. At temperatures not exceeding 1000 K, for systems in which there are no vibrational modes having frequencies (wavenumbers) smaller than 100 cm^{-1}, the contribution of the vibrational partition function is small. This is a favourable feature, since the purely theoretical calculation of the fequencies of the normal vibrations not only is tedious and requires considerable skill, but also is accompanied by extremely large errors.

Analysis of the literature shows that if the experimental values of ΔH_0° are used, the calculation based on the spectroscopic data and the partition functions in the rigid rotator–harmonic oscillator approximation leads to extremely reliable equilibrium constants; the error often does not exceed ±10%. The results of calculations for 33 reactions in the gaseous phase and for reactions between solids and gases have been published[64]. The error in the determination of $\lg K_p$ using the results of theoretical calculations of partition functions based on semi-empirical methods (CNDO/2, INDO, MINDO/2) has been studied[65,66]. The error introduced by the rotational partition function is independent of temperature, whereas the error due to the vibrational partition function increases with increase in temperature (by 2–3 orders of magnitude on going from 100 K to 2000 K).

In the general case, the results of the most reliable recent calculations of ΔH_0° (or $\Delta H_0^{\neq}$) indicate that the calculated values of the rotational and vibrational partition functions (based on semi-empirical quantum-chemical methods) are satisfactory. Nevertheless, it is appropriate to discuss the possibilities provided by various approximations which represent improvements on the RR–HO approximation[67].

Statistical thermodynamics provides general equations for calculating partition functions in the non-rigid rotator–anharmonic oscillator NR–ANO approximation[68]. The rotational–vibrational spectra have been studied to the extent required for the NR–ANO approximation for only a small number of molecules, however. Nevertheless, for this group of molecules it is possible to reach definite conclusions regarding the relationships between the thermodynamic functions calculated in the two approximations. For example, for the entropy of water at 1000 K, Godnev[69] gives the following data: RR–HO approximation, S^0_{1000} = 55.52 cal.mole^{-1} K^{-1}; NR–ANO approximation, S^0_{1000} = 55.598 cal. mole^{-1} K^{-1}. The calculations show that allowance for the anharmonicity and non-rigidity of the molecule introduces small corrections to the value of the logarithm of the equilibrium constant[65,70].

At the present time, for most molecules, calculations of the thermodynamic functions based on experimental data or on the methods of quantum chemistry are possible in practice only in the RR–HO approximation. Comparison of the results of calculations carried out in the RR–HO and NR–ANO approximations show that the RR–HO approximation is fully applicable, at least for rigid molecules.

It would be extremely attractive to be able to determine the molecular data appearing in the partition functions from an analysis of the potential energy surfaces. It is not very simple, however, to use the results of quantum-chemical calculations to solve problems in molecular spectroscopy. For the construction of the rotational–vibrational Hamiltonian it would be most convenient to have an analytical expression describing the potential energy surface. Even if this problem were solved, however, it is impossible to find a general analytical solution of the corresponding eigenvalue problem, and this makes the exact calculation of the partition functions impossible. With the exception of the simplest systems, energy surfaces at present cannot be represented in analytical form.

The methods of quantum chemistry can be used to find the first derivatives of the total energy, and this makes it possible to carry out the approximate calculation of the second derivatives at the stationary points (see Part II). If however it is desired to take account, albeit partly, of anharmonicity and rotational–vibrational interaction in the calculation of the thermodynamic functions, it is necessary for this purpose to find the values of the derivatives of third and fourth orders. Except for the case of diatomic molecules, the possibilities provided by present-day quantum chemistry for the solution of this problem are extremely limited[67]. At least a partial solution to this problem was proposed by Simons and coworkers[71], who introduced a new type of anharmonic potential. The results obtained up to the present indicate that it is possible to take account of anharmonicity and non-rigidity without complicating appreciably the quantum-chemical calculations, compared with the harmonic approximation.

In conclusion it may be noted again that the errors introduced into the equilibrium constant K_p in the calculation of the entropy term in the RR–HO approximation are at present much smaller than the errors in the calculation of ΔH°_0. It is therefore necessary to pay particular attention to the development of reliable methods for estimating the enthalpy term.

III. EQUILIBRIUM AND KINETICS OF REACTIONS

1. Classification of Chemical Reactions

Not only from a formal viewpoint, but also from physical considerations, it is convenient to divide reacting systems into two groups: equilibrium and kinetic. A more detailed classification of chemical processes can be carried out according to the states of aggregation of the reactants and reaction products. There are three types of homogeneous processes: reactions in the gaseous (1), liquid (2), and solid (3) phases. In addition, reactions may be heterogeneous, that is they may take place at the interface between two phases: liquid and gas (4), liquid and solid (5), and gas and solid (6).

The subsequent treatment deals chiefly with homogeneous reactions taking place in the gaseous and liquid phases, and processes of the fourth and sixth types are discussed briefly.

2. Equilibrium in the Gaseous Phase

Calculations of the equilibrium constants of reactions in gases are of considerable importance for the development of the theory of reactivity. The quantum-chemical analysis of equilibria in the gaseous phase is facilitated by two features: firstly, these processes can be sufficiently effectively studied by the methods of chemical thermodynamics, and secondly, the intermediate results of quantum-chemical calculations for many reactions can be compared with experimental data (molecular geometry, frequencies of the normal vibrations, electronic spectra, barriers to internal rotation, heats of formation, and enthalpies of reactions).

Although the basic scheme for calculating K_p in the gaseous phase is clear, its application to problems of chemical reactivity is still extremely limited. Various gaseous equilibria have been studied[72–83] on the basis of theoretical calculations of K_p with different potential functions (empirical functions, or functions found from the solution of the Schrödinger equation). Except for the case of diatomic molecules, the partition functions in the RR–HO approximation were used in all cases (see Section II.3).

In the determination of equilibrium constants by theoretical methods, the enthalpy of reaction is the most complicated characteristic to calculate. The rotational and vibrational partition functions have little influence on the accuracy of the calculation of K_p. It can be shown that an error of 3 kcal mole^{-1}, allowed in the determination of the enthalpy at low temperatures, leads to an error in the equilibrium constant which is greater by two orders of magnitude. The versions of the MO methods available at present can hardly give enthalpy values even with this clearly inadequate accuracy of ±3 kcal mole^{-1}. In 1970, the semi-empirical MINDO/2 method aroused great expectations, but it was found in the general case that this method also does not make it possible to calculate ΔH°_f with the required accuracy[84].

Nevertheless, there are a large number of reactions for which the NDO approximation can be used to carry out sufficiently accurate calculations of equilibrium constants. These calculations can be carried out directly only by the MINDO/2 method, since the CNDO/2 and INDO methods require modification[83]. (Examples can be found in papers[81,83] on the dimerisation of the radicals CH_3, NH_2, HCO, and NF_2.) In many cases the error of the determination of the enthalpy of reaction is so great that it makes it impossible to estimate equilibrium constants reliably by semi-empirical methods. At present there is no semi-empirical method which is sufficiently general and could be used to find the enthalpies of reactions with the required accuracy. The recently published MINDO/3 method[85] has not yet been thoroughly tested.

Some positive results have been obtained by semi-empirical methods. The dimerisation of NF_2 represents an equilibrium involving the isomerisation of the reagent; this feature is encountered fairly frequently, but does not usually attract attention. Tetrafluorohydrazine exists in *trans*- and *gauche*-forms

$$\begin{array}{l} 2NF_2^{\bullet} \rightleftarrows trans\text{-}N_2F_4 \qquad (10) \\ \qquad\qquad \Updownarrow \\ 2NF_2^{\bullet} \rightleftarrows gauche\text{-}N_2F_4\ . \qquad (11) \end{array}$$

The values of ΔH_0° for reactions (10) and (11) were obtained by the CNDO method[83] with modified values of the parameters; for this purpose, a number of N and F compounds having known properties were used. The optimised molecular geometries and calculated frequencies of the normal vibrations were used to calculate ΔH_T°, ΔS_T°, and the equilibrium constants of reactions (10) and (11). In the calculation of the entropy term, the existence of two optical isomers[86] of the *gauche*-form of N_2F_4 was taken into account. The values of ΔH°, ΔS°, and K_p for the equilibrium $2NF_2^{\bullet} \rightleftharpoons N_2F_4$ were calculated from Eqns. (12)–(14), in which the index "i" refers to reactions (10) and (11)[88,89]

$$K_p = \sum_{i=1}^{n} K_p^i, \qquad (12)$$

$$\Delta H^0 = \sum_{i=1}^{n} \frac{K_p^i}{K_p} \Delta H_i^0, \qquad (13)$$

$$\Delta S^0 = \sum_{i=1}^{n} \frac{K_p^i}{K_p} \left(\Delta S_i^0 + R \ln \frac{K_p}{K_p^i} \right). \qquad (14)$$

The values obtained show fairly good agreement with the experimental data.

The study of the carbon systems C_n in the vapour over graphite is of both theoretical and experimental interest. The geometry has been determined experimentally only for C_2 and C_3; for $n > 3$, a linear arrangement of the carbon atoms was first assumed[73], and for these systems the values of ΔH_0° were calculated by the simple MO method (as far as C_{17}). Later, it was established theoretically that rings are more stable than linear forms[90,91]. The study of the potential energy surfaces of several of these systems has shown, however, that the species C_n have a more complex geometric structure at the stationary points. As an illustration, Fig. 2 gives the geometry of the singlet ground state of C_4 at different stationary points of the surface. Of the seven stationary points, three are minima; the linear form corresponds to a saddle point. The thermodynamic characteristics of the reaction $4C(graphite) \rightleftharpoons C_4(gas)$ have been published[74,92].

To conclude this section, mention may be made of a systematic study[66] of the applicability of the CNDO/2, INDO, and MINDO/2 methods in the calculation of the entropy term of equilibria. It was shown that the replacement of the experimental molecular data by quantities determined by the methods of statistical thermodynamics introduces into the value of $\lg K_p$ (at temperatures below 1000 K) an error not exceeding 0.5%. This feature provides an optimistic estimate of the possibilities provided by semi-empirical methods for the calculation of K_p in the gaseous phase.

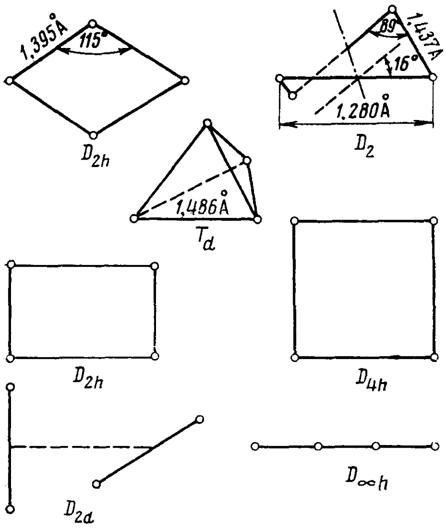


Figure 2. Configurations of the nuclei of the C_4 molecule corresponding to stationary points situated on its energy surface. For configurations in which the energy is a minimum, their symmetry groups and geometric parameters are indicated.

3. Kinetics of Reactions in the Gaseous Phase

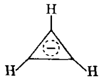
a) Static approximation

Static methods for studying chemical reactivity are based on the theory of absolute reaction rates, formulated by Eyring in the nineteen-thirties. In contrast to the case of "dynamic" methods, it is assumed that the velocity of the reacting species is so low that in the course of the reaction, energy transfer between different degrees of freedom can take place. The reaction trajectory, and hence the dependence of the geometry of the reacting species on the time measured from the start of the reaction, is replaced by the reaction coordinate, defined as the "energetically most favourable" path by which it is possible to go from the starting materials to the reaction products as a result of a continuous change in the geometry of the molecules. The change from reaction trajectory to reaction coordinate is extremely significant. The positions of the points on the reaction trajectory depend on the initial conditions—the geometries and momenta of the reacting species. Since these quantities are usually unknown (more accurately, they should be regarded as random quantities), it is necessary, in the calculation by dynamic methods, to carry out a large number of calculations for different initial conditions and to treat these results statistically. The reaction coordinate is independent of the choice of initial state of the system, and as a rule, only one reaction coordinate can be constructed for a given reaction. Thus the use of static methods leads to considerable economy in the calculations. It is necessary, however, to take account of the assumption that the reaction takes place sufficiently slowly. From this viewpoint, the extent to which the static or dynamic approximation corresponds to the conditions for the problem being studied can be estimated.

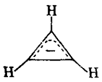
As already noted, the description of the reaction mechanism by static methods is independent of the initial conditions (the relative arrangement of the atoms and the momentum). Moreover, if various purely quantum-chemical effects, for example the tunnel effect, are neglected, it is sufficient, for the calculation of the rate constant, to know only the properties of the reacting species and the system situated on the reaction coordinate and exhibiting the highest energy. This system is called the activated complex; the difference between the energy of this complex and the energy of the original molecules is called the activation energy. If the treatment is restricted to qualitative or comparative conclusions, it is possible to estimate the reactivity of molecules by studying the properties of the starting materials. This can be done by methods using the theory of reactivity indices [7,93,94], the theory of frontier orbitals [4,96], and a whole series of methods based on perturbation theory [95,97-101]. Finally, it is possible to make qualitative estimates of the nature of a reaction without any calculations, merely on the basis of symmetry considerations, as for example in the simple version of the Woodward–Hoffman theory [9,102]. All these methods are static methods. The present review, however, will deal chiefly with methods which can be used (in principle at least) to carry out exact calculations of rate constants. These methods are based directly on the theory of absolute reaction rates.

Although accurate data on the structures of the molecules of the reacting substances are often available, there is almost no information on the structure of the activated complex. The determination of the geometry of the activated complex or of all possible activated complexes in the case where a given reaction can take place by several mechanisms is therefore a fundamental problem of the theory of absolute reaction rates. In the case of unimolecular reactions for symmetrial molecules, the study of activated complexes reduces to an analysis of the stationary points of the potential energy surfaces. This analysis can be carried out using programmes for the automatic optimisation of the geometry (see Part II).

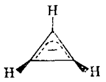
An example is provided by the calculation of the possible structures of the excited singlet state of the cyclopropenyl anion [103]. In this case the programme for optimising the geometry gave the completely symmetrical structure (I) and also structures (II)–(VI) having a lower symmetry. System (VI) is a stable isomer; structures (III)–(V) are activated complexes. Structures (I) and (II) are neither stable isomers nor activated complexes.



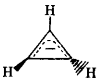
(I)



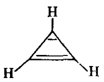
(II)



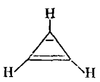
(III)



(IV)



(V)



(VI)

An analogous problem was examined by Dewar and coworkers [104-106] and Komornicki and McIver [107], who did not, however, analyse the nature of the stationary points. If even qualitative information on the structure of the activated complex is available, the correct structure of the activated complex can be obtained by optimising the geometry [108].

In most cases, there is of course no reliable information on the structure of the activated complex. If however a definite structure is taken as a basis, it is always possible that there exists another activated complex, which may correspond to a lower activated energy. In the general case, it is in practice impossible to carry out a rigorous analysis of the energy as a function of all the internal coordinates of the molecule. It may be noted that for a complete description of one of the simplest reactions of the type $AB + C \rightleftharpoons A + BC$, involving only three particles, it is necessary to take account of three internal coordinates, so that in this case it is necessary to study a surface in four-dimensional space. The problem can often be simplified by assuming that only one or two internal coordinates of the molecule (bond lengths, valency angles, or twisting angles) change in the course of the reaction, while all the other coordinates remain constant. This method has been used in many cases [109-118].

This method has two important disadvantages. Firstly, it is assumed that only a small number of coordinates change in the course of the reaction. This assumption is never fully justified in practice, and it introduces an error which cannot be calculated, even approximately. Moreover, for many reactions it is impossible to describe a mechanism involving changes in only two coordinates. Secondly, when certain coordinates are distinguished, a subjective factor is introduced into the calculation; a definite reaction mechanism, not necessarily correct, is assumed a priori.

The first of these unsatisfactory features was eliminated soon after the development of methods for the automatic optimisation of the geometry. When these methods are used, allowance is made for the fact that the activated complexes correspond to points situated on the reaction coordinates; it is assumed that in the course of the reaction the system is unstable with respect to one of the internal coordinates, the so-called critical coordinate, which may be, for example, a bond length in the case of addition or dissociation, a valency angle in isomerisation, or a torsional angle in the study of barriers to rotation. A series of calculations is then carried out, in which the critical coordinate is varied in definite steps, and the other coordinates are optimised.

This technique was used by Dewar [114-116] and McIver and Komornicki [117]. The method is undoubtedly more convenient than the methods mentioned earlier, since the multi-dimensional problem is reduced to a one-dimensional problem, and involves essentially modelling of the most favourable reaction path. The coordinate of the forward reaction determined in this way usually differs from the coordinate of the back reaction, however, and neither of them passes through the point corresponding to the activated complex [117]. This "chemical hysteresis" naturally does not agree with experiment. A more significant unsatisfactory feature is the arbitrary nature of the choice of critical coordinate. In most cases this choice is based on intuition, and the chemical hysteresis may increase considerably if the choice of critical coordinate is not successful. Moreover, many reactions cannot be described satisfactorily in terms of one critical coordinate.

These unsatisfactory features were eliminated in a study [32] based on the classical idea that the reaction coordinate is described by a point which changes along a path passing through one of the troughs of the potential energy surface. The method of calculation is analogous to that in which the critical coordinate is used. The reaction coordinate is approximated successively by a series of points x_k. It is first assumed that these points are equally separated from one another. The first approximation of the $(\mu + 1)$th point $x'_{\mu+1}$ is determined from the μth point and the direction of the gradient. The position of the $(\mu + 1)$th point is then refined until the conditions formulated in the work cited[32] are fulfilled. If c_{ik} is the ith component of the kth eigenvector, E_k the kth eigenvalue of the force constant matrix, g'_j the jth component of the gradient at the μth point, and n the number of the eigenvector parallel to the gradient, the correction r_i to the ith coordinate of the point $x'_{\mu+1}$ is given by the equation:

$$r_i = -\sum_{k \neq n} E_k^{-1} c_{ik} S_k, \tag{15}$$

where $S_k = \sum_j c_{jk} g'_j$. This method makes it possible in principle to calculate all reaction coordinates and to obtain all activated complexes; the method does not exhibit chemical hysteresis.

b) Dynamic approximation

Chemical reactions represent the sum of a whole series of elementary processes taking place between atoms and molecules, as a result of which the molecules of the reagents interact with one another for a period of time, forming so-called "collision complexes", activated complexes, or transition states. If the lifetime of this system is sufficiently long ($\tau > 10^{-12}$ s), the interaction of the particles may lead to energy exchange between separate degrees of freedom. In this case the subsequent course of the elementary reactions depends chiefly on the properties of the "collision complex", and the process can be described within the framework of the theory of absolute reaction rates. In those cases where $\tau < 10^{-12}$ s, the course of the elementary process depends on the initial state of the system, and its description requires non-stationary methods. It is to be expected that "collision complexes" having a long lifetime will be more probable for systems having a large number of degrees of freedom than for systems having a small number of degrees of freedom.

The study of the dynamics of elementary chemical reactions is almost always based on the Born–Oppenheimer approximation. This problem therefore essentially breaks down into two independent problems: a) solution of the electronic Schrödinger equation and determination of the potential energy functions, which depend on the coordinates of the nuclei; and b) determination of the dynamic behaviour of the nuclei in the known potential field.

The solution of the first problem belongs to the field of quantum chemistry. The calculation of the potential energy surfaces raises a number of specific problems. The calculation must be carried out with sufficient accuracy, and the potential energy surface should provide a correct quantitative description of all possible modes of dissociation of the system, and for this it is necessary that the total energy of the system be sufficiently well determined for all internuclear distances.

At present, calculations of the ab initio type having the required accuracy can be carried out only for relatively small systems[118] (where the number of electrons does not exceed 40), and potential energy surfaces (for the ground state or the most important lower electronic excited states) have been found only for some of the simplest systems[119-127]. Considerable attention is now being paid to the problem of constructing model potentials in analytical form[128-133].

For complex systems, calculation of the potential energy surfaces is possible only by semi-empirical or empirical methods. The use of these methods is particularly attractive in those cases where it is possible to determine the potential in analytical form. The potential energy surfaces are most frequently calculated by the LEPS method (London–Eyring–Polanyi–Sato)[134-136]; the DCM method (diatomic complexes in molecules)[137,138], proposed more than ten years ago[139], has recently been used successfully.

The study of the dependence of the dynamics of a chemical reaction on the initial conditions and the form of the potential surface is a problem in the field of the quantum theory of scattering. In the stationary theory of scattering, the wavefunction $\psi(r)$ of a system of reacting particles is determined by solving the equation

$$\psi(r) = \varphi(r) - \int G(r, r') \cdot V(r') \cdot \psi(r')\, dr' \tag{16}$$

(the Lippman–Schwinger equation[140]), where $V(r')$ is the potential energy of the interaction, $\varphi(r)$ the wavefunction of the system of independent particles, and $G(r, r')$ the corresponding Green's function. For the case of elastic scattering, when the internal structure of the reacting particles remains unchanged, the Green's function can usually be found, so that the calculation of the scattering process presents no fundamental difficulty. The situation is more complicated for inelastic collisions. In this case the calculation can generally be carried out only after a number of crude approximations. The results obtained in this field have been summarised in a number of monographs[140,141] and reviews[142,143]. (The quantum theory of scattering has also been used to study various elementary chemical reactions[144-155].)

The scattering problem, even in the case of three particles, at present does not have an exact solution. One possible way of overcoming this difficulty is to replace the quantum-chemical description of the motion of the particles by the classical description. In this case, however, it must be borne in mind that certain quantum-mechanical phenomena have no analogy in classical mechanics, for example the tunnel effect or zero-point vibrational energy. From general considerations it may be concluded that the agreement between the results obtained by the two methods should improve with increase in the kinetic energy and mass of the interacting particles, and depends on the nature of the potential surface.

The classical reaction trajectories can be found by solving Hamilton's equations of motion

$$\begin{aligned} \frac{\partial H}{\partial q_i} &= -\frac{dp_i}{dt}, \\ \frac{\partial H}{\partial p_i} &= \frac{dq_i}{dt}. \end{aligned} \tag{17}$$

where q_i represents the generalised coordinates of the reacting particles, p_i the generalised momenta, and H is Hamilton's function, which in the case of purely conservative forces has the significance of the total energy of the system. These equations form a system of first order differential equations, which (for given initial conditions) can be solved by standard methods of numerical integration. The initial conditions are naturally determined by the positions of the particles and their velocities. The vibrational and rotational states of the particles are also taken into account in the initial conditions. The values of the coordinates and momenta obtained from the solution of the system of equations (17) can be used to determine firstly the nature of the reaction and secondly the state of the reaction products. In order to use these calculations to interpret experimental data, it is necessary to find a sufficiently large number of trajectories, corresponding to different initial conditions and modelling the real conditions statistically. A detailed analysis of the problem of the collision of three particles was carried out by Karplus and coworkers[156].

The application of the method of classical trajectories to systems having a large number of particles presents no fundamental difficulties[157] if the reaction takes place under adiabatic conditions. A number of processes take place under non-adiabatic conditions, however. Typical reactions of this kind are, for example, reactions involving the transfer of charge or of electronic energy, or spin-forbidden reactions. In the case of non-adiabatic reactions, the important regions are those in which several potential surfaces are situated fairly close to one another; this leads to considerable interaction between different states. Examples of this type of interaction are non-adiabatic electron–nuclear interactions or spin–orbital coupling. Considerable attention has been and is being paid to the calculation of these effects and the probabilities of transitions between different surfaces[158–160]; from these studies it is possible to modify the method of classical trajectories in such a way that it can be used to carry out calculations for non-adiabatic reactions[161].

The method of classical trajectories is used to solve the following problems:

a) for the theoretical estimation of various experimentally observable quantities[162–164]: the total reaction cross-section (or reaction rate constant), angular distributions and energy distributions of the products, etc.;

b) to study the influence of the nature of the potential surface and the states of the reagents on the reaction cross-section[165–169];

c) for comparison with the results of calculations by other methods[170–177] (in quantum mechanics, theory of absolute reaction rates).

Finally, the method of classical trajectories has been successfully used to study a number of reactions[162–164, 178–203].

4. Equilibrium in Solution; Solvation Energy

The properties of molecules in the gaseous phase often differ from the properties in the liquid phase. This difference is due to the interaction between the molecules of the solute and solvent. Depending on the nature of the medium, it is convenient to distinguish two types of interaction—specific and non-specific[204]. In non-specific solvation, no allowance is made for the specific characteristic features of the molecules of the solvent, which is regarded as a uniform and isotropic medium, characterised by various macroscopic constants, such as the dielectric constant or refractive index. Within the framework of this model, the energy of solvation is defined by the following equation, derived by Born[205]:

$$\Delta G = -\frac{q^2}{2r_0}\left(\frac{1}{\varepsilon} - 1\right), \qquad (18)$$

where ϵ is the dielectric constant of the solvent, q the charge of the ion, and r_0 the radius of the ion. The theory of the continuous model of a solvent was developed in more detail by Onsager[206] and Kirkwood[207]. These methods, however, make it possible to estimate only the magnitude of the solvation energy. Recently, several methods have been proposed[208–212], based on specific allowance for solvent effects directly in the Hamiltonian. These methods make it possible to take account of the influence of the solvent on those properties of the molecule which can be studied by quantum-mechanical methods. The disadvantages of the continuous model of a liquid have been discussed in detail[204].

In specific solvation, allowance is made for the specific characteristic features of the molecules of the solute and solvent. Interactions of this type are studied using models consisting of the molecules of the solute and an ordered set of solvent molecules. These systems are regarded as supermolecules, and studied by the methods of quantum chemistry. In practice, this procedure involves a number of difficulties: 1) the arrangement of the solvent molecules relative to the solute molecule is not known; 2) an appropriate potential has to be chosen for calculating the energy of interaction; and 3) usually, only the primary§ solvation shell is taken into account. These difficulties can be considered in more detail.

1. The determination of the structure of the primary or secondary solvation shells is very difficult. The experimental data can be used to estimate in a number of cases[213] only the number of solvent molecules in the primary solvation shell. This problem is unlikely to be solved for polyatomic molecules in the near future. The only possibility remaining is to model the solvation shell theoretically. In principle, this can be done by three methods: a) by using the Monte Carlo method to determine the most stable structures consisting of a given number of solvent molecules; b) to optimise, by a standard method, the structure of the entire solvation shell consisting of a given number of solvent molecules; and c) to study not the entire solvation shell, but only the part interacting most strongly with the solute molecule. All three methods have advantages and disadvantages. The Monte Carlo method is most appropriate, but even for small solute molecules the use of this method involves a considerable expenditure of machine time, even on modern fast computers. The second method can give valuable information on solvation for the expenditure of much less machine time. The third method can also be used for large molecules, but it must be borne in mind that this method can be used only to study some properties of the solvated molecule, for example the spectra or the conformation.

2. In the selection of the interaction potential, the entire structure of the molecules of the solute and solvent must first be taken into account. For the calculation of the energy of interaction it is possible to use all available methods—empirical, semi-empirical, and non-empirical. Brief mention may be made of some of the most promising methods.

Ab initio methods have been used to study the structures of various models of solvation layers. Mention may be made first of all of the work of Clementi and coworkers[214], who studied the hydration of various ions (Li^+, Na^+, K^+, F^-, and Cl^-). Here, the potential was determined by calculations of the Hartree–Fock type, after which the Monte Carlo method was used. It is very difficult to compare theoretical calculations of solvation energies with

---

§The primary solvation shell consists of those solvent molecules which interact directly with the solute molecule.

experimental data. The calculated enthalpies of the complexes of the ions with 1, 2, 3, etc. water molecules show fairly good agreement, however, with mass-spectrometric data [215,216]. One method for the direct confirmation of calculations of solvation energies is by comparing the theoretical and experimental radial distribution functions. Best agreement in the case of water was obtained in a study [217] using a two-particle potential, defined in the Hartree–Fock approximation with allowance for correlation energy. For ion–H_2O complexes, unfortunately, there are no published experimental estimates of the corresponding partition functions.

The method of Clementi and coworkers [214] is fairly well founded from the physical viewpoint, but as a consequence it is used at present only for the study of the hydration of ions and small molecules. In the case of polyatomic systems, it is practically impossible to study the supermolecule either in the Hartree–Fock approximation or by the Monte Carlo method.

In a study of the hydration of the Li^+ ion, Kollman and Kuntz [218] estimated the total energy of the complexes $Li^+ + nH_2O$ ($n = 2, 4, 6$) from the $Li^+...OH_2$, $Li^+...(OH_2)...(OH_2)$, and $OH_2...OH_2$ potentials. In this way, the authors cited were able to avoid the need to examine the complex as a whole. The electrostatic model (see below) was used to take account of the H_2O molecules in the secondary and tertiary hydration shells. It was shown that the central ion influences the arrangement of the molecules in the tertiary hydration shell. The use of two-particle and three-particle potentials for a definite geometry of the solvation shell is at present the only available method for calculating the solvation energy of polyatomic systems. Complete allowance for the entire solvation shell and solvate molecule is extremely complicated, and the calculations have been carried out only for small systems.

Pullman and coworkers [219] developed a method in which only part of the solvation shell is studied. This method is based on the determination of the most stable complexes containing a small number of solvent molecules. Various properties of the solvated molecules, such as the conformation or the spectra, can be interpreted using a complex of this type. An example is provided by the results of studies of the conformations of the histamine mono- and dications by the PCILO method (see below) [220]. The isolated molecule exists in only one conformation—*gauche* in the case of the monocation and *trans* in the case of the dication. From ab initio calculations it was found that in aqueous solution the monocation can exist in both the *gauche* and *trans* forms; in the case of the dication, the *gauche*-isomer may accompany the *trans*-isomer. These results agree with experiment.

Semi-empirical methods have been used to calculate the solvation energies of ions and simple systems. In most cases the solvation layer and the central ion were regarded as a supermolecule. Good results were obtained for the hydration of ions (ion–polar molecule interaction [221-224]). The study of solvation in non-polar systems at a semi-empirical level is unlikely to succeed. It has recently been shown that the results obtained in the study of the conformation of molecules and the interactions between molecules using the semi-empirical PCILO method show good agreement with the results of calculations by ab initio methods [225]. The PCILO method is apparently the most promising method for the study of the influence of the solvent on the properties of solvated molecules.

In conclusion, brief mention may be made of a simple method for estimating the energy of interaction for polar or charged systems, based on the electrostatic approximation [226]. From the wavefunctions of two systems it is possible to estimate the energy of their electrostatic interaction and to determine their relative arrangement, corresponding to the potential energy minimum. The positions in a molecule most favourable for electrophilic attack by a point particle carrying a positive charge are often of interest. From the wavefunction (non-empirical or semi-empirical) of the corresponding molecule, the electrostatic potential at the point r_i can readily be determined from the equation:

$$V(r_i) = -\sum_{q,s} P_{qs} \cdot \int \frac{\chi_q(1)\,\chi_s(1)}{r_{i1}}\, d\tau_1 + \sum_{\alpha} \frac{Z_\alpha}{r_{\alpha i}}, \qquad (19)$$

where $\chi_q(1)$ and $\chi_s(1)$ are the AO; P_{rs} is the element of the density matrix corresponding to these AO; Z_α the charge of the nucleus of the atom α; and $r_{\alpha i}$ and r_{i1} represent respectively the distances from the point r_i to the nucleus α and to the electron. By connecting points at which the values of the potential are equal, it is possible to obtain isopotential surfaces, which give a clear description of the possible directions of electrophilic attack.

3. Kollman and Kuntz [218] used the SCF method (ab initio) to study the hydration of the Li^+ ion. It was shown that the tetrahedral structure of the primary hydration shell is energetically most favourable, and that the hydration energy is 107 kcal $mole^{-1}$. The energy of the interaction of the Li^+ ion with the water molecules of the secondary and even the tertiary hydration shells is fairly high: in the first case it is equal to 80 kcal $mole^{-1}$, and in the second case it amounts to almost 20% of the total hydration energy (the experimental value is 228 kcal $mole^{-1}$). Here it must be borne in mind that the energy of the interaction of the Li^+ ion with water is unusually high. In the case of the hydration (or solvation) of neutral molecules, it is to be expected that allowance for only the primary or secondary hydration (solvation) shells will not introduce a large error into the calculation of the energy of hydration (or solvation).

5. Kinetics of Reactions in Solution

The calculation of the rate constants of reactions in solution is an extremely complex problem [227-230]. The development of the theory of chemical reactions in the gaseous phase [231] will obviously facilitate the successful solution of this complex problem. In general, however, the methods of studying reactions in the gaseous phase can hardly be applied directly to the study of reactions in solution. It is only in the case of relatively weak interactions between the molecules of the reactants and the activated complex on the one hand and the solvent on the other hand that these methods can lead to correct semi-quantitative results.

6. Catalytic Reactions

The methods of quantum chemistry used in catalysis can be divided into two groups [232]. The first group consists of the methods of solid state physics [233-244]. For catalysis, information on the states of the electrons on the catalyst surface (surface states) are most important, since their symmetry and energy can give information on the course of the adsorption. The bulk and surface states can be studied without particular difficulty in the case of the ideal lattice of a semi-infinite crystal. Unfortunately, deviations from the ideal lattice (for example in the surface layer) and the presence of defects and chemisorbed molecules introduce considerable difficulties.

The second group consists of various methods in the quantum chemistry of molecules. The most promising methods for the solution of problems in catalysis are those which take account of all the valency electrons (semi-empirical methods of the CNDO and EHM type). The methods of this group can be used to study small systems comparatively easily, so that the catalyst is usually modelled by a system consisting of several atoms. The quality of the theoretical study of a catalytic process depends on the reliability of the quantum-chemical approximation and on the model of the catalytic reaction used.

Chemical reactions in the presence of a catalyst usually take place in several stages, the first of which is the interaction of the molecules of the original reagents with the catalyst (the formation of an adsorbate–catalyst complex, A–C). This first stage has been studied by many workers in different systems. Mention may be made of several studies[245-258] of the adsorption chiefly of diatomic molecules on the surfaces of transition metals and oxides. The authors cited obtained a model of the solid state by considering a part of a crystal consisting of several tens of atoms (three-dimensional model) or a part of the surface of the crystal (two-dimensional model), or considered only one metal atom (or one molecule of the oxide). Most calculations have been carried out by the simplest version of the EHM.

Several procedures can be used in the study of a catalytic reaction by the methods of quantum chemistry. The most fully developed of these involves the calculation of the potential energy surface for the system consisting of the atoms of the adsorbate and catalyst. Because of the complexity of the calculations, however, this approach can be used only for the simplest reactions[258-260]. For the study of systems of chemical interest, it is possible to use a simpler method involving the calculation of the electronic structure, geometry, total energy, and various other physical characteristics of A–C systems for assumed intermediate products and possible activated complexes[261,262]. The reliability of the information on the catalytic process obtained in this way depends to a considerable extent on the choice of the model for the reaction, that is on the assumptions regarding the intermediate products or activated complexes. The third and most economic method is based on the calculation of the electronic structure of the complex A–C. The reactivity of this complex is estimated using quantum-chemical indices of reactivity[263] or orbital symmetry conservation rules[264-267].

From the foregoing it follows that in the study of a catalytic reaction by the methods of quantum chemistry, the description of the catalyst presents the greatest difficulty. A model of the catalyst, taking account of its surface or bulk properties, should consist of a large number of atoms, and this complicates the calculation considerably. Moreover, in these models, allowance is made for crystal lattice defects. Another no less important problem concerns the quality of the quantum-chemical approximation. Non-empirical methods are in practice inapplicable to the solution of problems of catalysis, because of the complexity of the systems. Even without considering the problem of the parametrisation of semi-empirical methods for transition metals, the use of these methods to study the reactivity of systems containing a model of the catalyst with a large number of atoms still lies beyond the computing facilities of most laboratories. Thus at present the reactivity of a complex A–C can in most cases be studied only by means of the EHM, which suffers from a fairly large number of disadvantages. Even this method, however, can be used to study the potential energy surface or any cross-section of this surface only for the simplest catalytic reactions.

Thus the problems associated with taking explicit account of the catalyst are related to the specific features of the methods of quantum chemistry and difficulties of computation. In this connection, in the study of a catalytic reaction, the catalyst is taken into account implicitly as a perturbation of the adsorbate. The reactivity of this adsorbate can be studied by standard methods of quantum chemistry.

The results of the theoretical analysis and the experimental data, discussed in more detail elsewhere[232,268], indicate that the interaction of an adsorbate with a catalyst is accompanied by the transfer of electron density from a bonding MO of the adsorbate to a vacant MO of the catalyst, and also from a filled MO of the catalyst to an antibonding MO of the adsorbate. The degree of electron density transfer is determined by the electronic structure of the adsorbate and catalyst. When the transfer of charge is approximately the same in both directions, the state of the adsorbate is analogous to the excited state of the isolated molecule, or the superposition of several excited states. In charge transfer, the frontier orbitals of the interacting systems usually play the most important roles, so that it may be assumed that the state of the adsorbate corresponds to the first excited state. An example is provided by the interaction of a two-electron adsorbate (for example H_2) and a two-electron catalyst (this model can be used to study the interaction of the frontier orbitals of a many-electron adsorbate and a many-electron catalyst) (Fig. 3*a*). If φ^A represents a filled MO and φ^B a vacant MO of the adsorbate, and ψ^B and ψ^A represent filled and vacant MO of the catalyst respectively (the superscripts A and B characterise the symmetry of the MO), the MO of the complex A–C has the form:

$$\begin{aligned}\Phi_1^A &= c_1^A\varphi^A + c_2^A\psi^A,\\ \Phi_2^B &= c_1^B\psi^B + c_2^B\varphi^B,\\ \Phi_3^A &= c_1^A\psi^A - c_2^A\varphi^A,\\ \Phi_4^B &= c_1^B\varphi^B - c_2^B\psi^B.\end{aligned} \qquad (20)$$

$(c_2^A)^2$ then provides a measure of the transfer of electron density from the adsorbate to the catalyst (from the MO φ^A to the MO ψ^A), and $(c_2^B)^2$ the transfer of electron density from the catalyst to the adsorbate (from the MO ψ^B to the MO φ^B). The difference $(c_2^A)^2 - (c_2^B)^2$ characterises the charge on the adsorbate, and the smaller of the squares of these coefficients gives the degree of excitation of the adsorbate. If one of the coefficients is much greater than the other (see Figs. 3*b* and 3*c*), charge transfer takes place in only one direction. In extreme cases, when $c_1^A \simeq 1/\sqrt{2}$, $c_2^A \simeq 1/\sqrt{2}$ and $c_1^B \simeq 1$, $c_2^B = 0$, a radical-cation is formed, and when $c_1^B \simeq c_2^B \simeq 1/\sqrt{2}$ and $c_1^A \simeq 1$, $c_2^A \simeq 0$, a radical-anion is formed.

It may thus be expected that the reactivity and various other physical properties of the adsorbate in the complex A–C corresponds qualitatively to the properties of radical-ions or an excited state of the adsorbate. Here, the following points should be borne in mind:

a) only "part" of the electron density is transferred from the metal atom to the ligand;

b) the donor and acceptor powers of the adsorbate with respect to the metal atom are usually different, so that quantitatively, the decrease in the population of the bonding MO is different from the increase in the population of the antibonding MO;

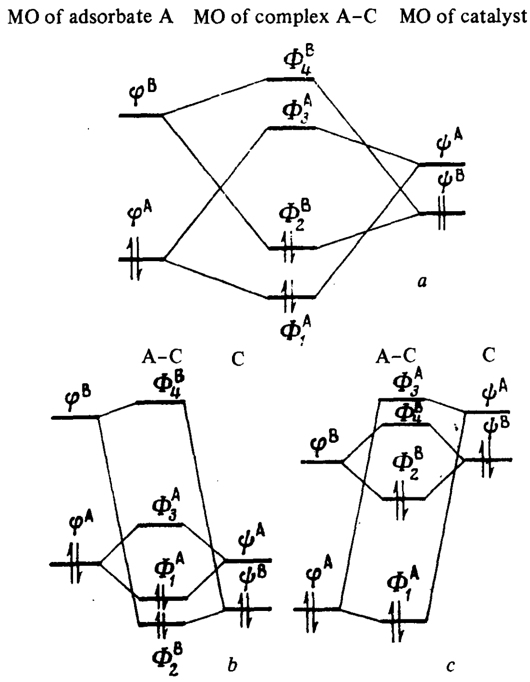


Figure 3. Interaction of the molecular orbitals of the adsorbate (A) and catalyst (C): *a*) for the formation of a partly excited state of the adsorbate ($c_2^A \simeq c_2^B$); *b*) for localisation of the positive charge on the adsorbate ($c_2^A \gg c_2^B$); *c*) for localisation of the negative charge on the adsorbate ($c_2^B \gg c_2^A$).

c) charge transfer takes place not only from the highest filled MO, but also from other orbitals, Moreover, there may be changes in the population of other vacant MO (although the frontier orbitals probably play the chief role in this process);

d) in this model, no allowance is made for the specific characteristic features of the catalyst surface.

The potential at the catalyst surface, which may lead to appreciable changes in the electronic structure of the adsorbate, is of considerable importance in heterogeneous catalytic processes. A strong electrostatic field may lead to appreciable decrease in the strength of the bonds of the adsorbate[269,270]. Moreover, allowance must be made for the fact that the magnetic moments of the atoms of the catalyst also influence the course of the reaction.

Comparison of catalytic and non-catalytic reactions.

Catalytic reactions	Non-catalytic reactions
Reactions catalysed by electron-acceptor systems (for example metal oxides)	Reactions of radical-cations and reactions taking place in the source of a mass spectrometer (cationic mass spectrometry)
Reactions catalysed by electron-donor systems (for example alkali metals)	Reactions of radical-anions and reactions taking place in the source of a mass spectrometer (anionic mass spectrometry) (Ref.271)
Reactions catalysed by systems in which the back-donation mechanism occurs (transition metal atoms and ions)	Reactions of electronically excited particles (photochemistry)
Reactions influencing the catalyst surface; the action of its force field	Reactions in an external electric or magnetic field

The mechanism of the effect of the catalyst on the adsorbate described above have analogies in other fields of chemistry (see Table). The analysis of catalytic reactions can therefore be facilitated by studying these processes, involving radical-ions (radical reactions,

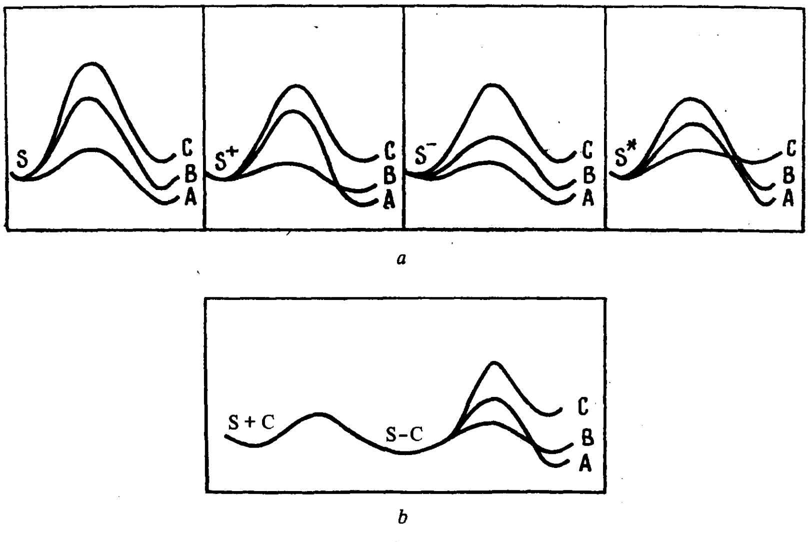

Figure 4. Section of the energy surface: *a*) for the molecule of a hypothetical substance S, for the radical-cation S^+, for the radical-anion S^-, and for the excited state S^*; *b*) for the catalytic reaction.

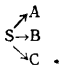
cation and anion mass spectrometry) and molecules in excited electronic states. In the theoretical study of catalytic processes, the state of the adsorbate in the A–C complex can be modelled either by an appropriate radical-ion or by an excited electronic state[232], depending on the nature of the catalyst. This procedure makes it possible to use more fully developed quantum-chemical methods than in the case where explicit account is taken of the catalyst. The quality of the results naturally depends on the extent to which the model corresponds to the actual state of the adsorbate interacting with the catalyst.

The similarity between catalytic processes on the one hand and radical or photochemical reactions on the other makes it possible to determine beforehand the appropriate type of catalyst for carrying out the reaction. Fig. 4*a* gives the cross-sections of the potential energy surface of a molecule of a hypothetical substance S, its ions S^+ and S^-, and its excited state S^*. It is assumed that the transformation of the substance S can take place according to the following scheme:



It is assumed that analogous processes are possible for other forms of the adsorbate. Comparison of the activation energies (see Fig. 4) shows that the decomposition of the substance S (S^+, S^-, or S^*) gives the products A for S and S^-, B for S^+, and C for S^*. If it is desired to use a catalyst to obtain, for example, product B, it is necessary to use a catalyst with strong electron-acceptor properties. The cross-sections of the corresponding surface for the S–C complex for a catalyst of this type are shown in Fig. 4*b*. If on the other hand the products of the catalytic transformation of the substance S are known, it is possible to determine, from the known reactivity of the radical-ions and excited states of the adsorbate, how the catalyst influences the adsorbate.

Advances in the Study of the Chichibabin Reaction

A.F.Pozharskii, A.M.Simonov, and V.N.Doron'kin

The state of research into one of the most important reactions of heterocyclic compounds—their amination by sodium amide (the Chichibabin reaction)—is described. The mechanism of the reaction, its application to specific classes of nitrogen-containing heterocycles, and certain reactions related to the Chichibabin reaction, namely amination of heterocycles by organic derivatives of metal amides, substitutional amination with elimination of hydrocarbon groups, amination of *N*-heteroaromatic cations, and hydrazination and hydroxylation, are discussed.
The bibliography includes 235 references.

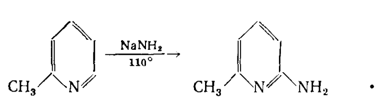
I. INTRODUCTION

In 1914 Chichibabin and Zaide reported that, when they attempted to metallate the CH_3 group of α-picoline by sodium amide in toluene, they unexpectedly observed the amination of the pyridine ring in the free α-position[1]:



Later Chichibabin and his students extended this amination method to many pyridine, quinoline, and isoquinoline derivatives. The Chichibabin reaction has had an enormous influence on the development of the entire chemistry of pyridine and has acquired great practical importance. Its application to condensed imidazole systems, achieved for the first time by Simonov and coworkers[2], proved to be particularly fruitful. A view widely expressed in textbooks and reference literature (see, for example, Surrey[9]) is that the Chichibabin reaction is most typical for pyridine and its benzologues. Nevertheless, we shall show that this is not altogether the case.

There exist two fundamental reviews on the Chichibabin reaction[3,4]. The first, published more than 30 years ago, is naturally obsolete. The second has unfortunately remained little known and since its publication many fundamental new data concerning this reaction have accumulated in the literature. In a number of other reviews the discussion is restricted to reactions of pyridine[5-7] or imidazole[8] derivatives.

The aim of the present review is to give an account of the present state of research into the Chichibabin reaction and certain related reactions, primarily processes such as hydroxylation of heterocycles by alkalies and their hydrazination by metal hydrazides. The review reflects as far as possible the entire literature on the given problem published up to 1st June, 1976.

II. REACTION MECHANISM

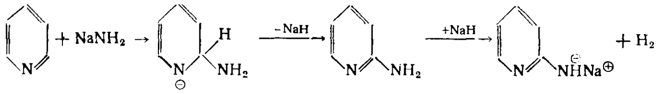
Owing to the high basicity of the amide ion, the Chichibabin reaction is usually carried out in aprotic solvents inert with respect to $NaNH_2$. Aromatic hydrocarbons, dimethylaniline, and liquid paraffin are most commonly used. Sodium amide is almost insoluble in these solvents, so that the reaction takes place under heterogeneous conditions. The only solven in which $NaNH_2$ (and to a greater extent KNH_2) is soluble proved to be liquid ammonia[10]. The Chichibabin reaction in liquid ammonia, achieved for the first time by Bergstrom[11-15], requires specific conditions: the use of sealed tubes and a long process time (up to several days); at the same time it is difficult to follow the course of the reaction. Furthermore, many heterocycles (pyridine, condensed imidazoles, etc.) are not aminated in liquid ammonia. The Chichibabin reaction can be carried out also without a solvent, in the melt, but this usually leads to less satisfactory results. In most instances the reaction begins at a comparatively high temperature (100–130°C), which is regulated in such a way that the evolution of hydrogen (a characteristic feature of amination) is uniform.

The mechanism of the Chichibabin reaction has been studied much less than those of other nucleophilic substitution reactions and is still not entirely clear. This is to a large extent due to the difficulty of studying the reaction kinetics (specificity of the conditions and occasional formation of side products). However, studies have been published recently on the reaction kinetics, based on the measurement of the rate of evolution of hydrogen[16-18].

In broad outline, the reaction involves the substitution of a hydride ion in the α- or γ-position in azaheterocycles by an amino-group. Two different mechanisms of the Chichibabin reaction have been discussed in the literature; —"addition-elimination" and "elimination-addition" (the heterocyclic aryne mechanism).

1. THE "ADDITION-ELIMINATION" MECHANISM

In 1930 Ziegler and Zeiser[19] proposed a two-stage reaction mechanism, the first stage involving the formation of an addition product I and the second its aromatisation to the 2-amino-derivative (II) as a result of the elimination of sodium hydride. It was suggested that NaH immediately reacts with the amino-group, which leads to the formation of the sodium salt of the amine (II) and the evolution of hydrogen:



(I) (II) (III) (1)

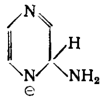
Although the main idea of this mechanism has been generally accepted[5,20,21], it has not been specified in detail and does not explain many experimental facts. Thus, as regards the addition stage, the mechanism does not provide an answer to the following questions: (1) whether sodium amide adds to the C= N bond synchronously or in stages; (2) if the addition takes place in stages, does the coordination of the $Na^{\oplus}$ ion to the pyridine nitrogen atom or the addition of $NH_2^{\ominus}$ to the carbon atom in the 2-position take place first; (3) do other intermediates, for example, radical-anions, etc., participate in the addition stage. There is similar uncertainty as regards the aromatisation stage (see below). It is not surprising that the Ziegler mechanism has no predictive power and cannot explain why some heterocycles are aminated while others, with a similar structure, are not.

Experimental facts which throw light on the mechanism of each reaction stage separately are discussed below.

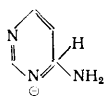
(a) The Additional Stage

The formation of the σ-complex. For a long time the formation of anionic σ-complexes (I) was accepted without proof, although analogous adducts with sodium hydrazide[22], lithium tetrahydroaluminate[23], and phenyl-lithium[24] have been described.

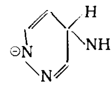
Deeply coloured adducts of certain azines and diazines with sodium and potassium amides [compounds (IV)–(VII)] were detected recently in liquid ammonia by ^1H NMR:[25,26]



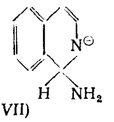
(IV)



(V)



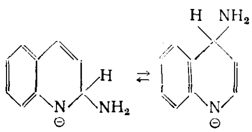
(VI)



(VII)

.

The σ-complexes (IV)–(VII) are formed almost instantaneously. Judging from their dissociation constants ($K \leq 10^{-5}$), the addition under these conditions is almost irreversible. It was not possible to isolate the complexes in a crystalline state[11–15,25,26]. Two σ-complexes, formed under kinetically [compound (VIII)] and thermodynamically [compound (IX)] controlled conditions, were discovered for quinoline



(VIII) (IX)

.

There is no doubt that σ-complexes are also formed on amination under heterogeneous conditions. Thus in the reaction involving isoquinoline the red colour characteristic of the σ-complex (VII) in liquid ammonia appears on amination in xylene and dimethylaniline. In general the appearance of a deep, frequently red, colour is a characteristic feature of the Chichibabin reaction.

Quantum-mechanical reactivity indices. Bearing in mind the nature of the Chichibabin reaction, it is logical to suppose that the carbon atom with the lowest positive charge q^+ is attacked first by the amide ion. Tables 1 and 2 present the values of q^+ for certain azines and azoles.

Quantum-mechanical calculations on the Chichibabin reaction are of dual importance. On the one hand, one can compare with their aid the reactivities of various positions within the same molecule (for example the α- and γ-positions in the pyridine and quinoline molecules) and, on the other hand, the electrophilic properties of a specific centre can be compared in different heterocycles.

Table 1. The positive charges on the carbon atoms, the basicities, and the reactivities of azines.

**An attempt was made to aminate 9-ethyl-6-dimethylaminopurine (pK_a = 3.90)[27].

The results sometimes depend significantly on the chosen method and parameters. For example, in the calculation by the Hückel molecular orbital method the highest positive charge in the isoquinoline molecule is found in the 1-position, while calculation by the CNDO/2 method shows that it occurs in the 3-position (Table 1). Comparison of experimental data and the results of the calculations leads to the following conclusions.

1. For the successful amination of the heterocyclic compound, it is necessary that the α-carbon atom in its molecule should carry a fairly large positive charge. Thus indazole, imidazole, 4,5-diphenylimidazole, and phenanthreno[9,10-*d*] imidazole†, which do not possess a sufficiently high charge, are not aminated.

2. A high positive charge by itself does not guarantee successful amination. For example, purine, imidazo-[4,5-*b*]pyridine, and imidazo[4,5-*b*]phenazine, which are not aminated, carry a positive charge which is comparable to that in the readily aminated benzo- and naphtho-imidazoles.

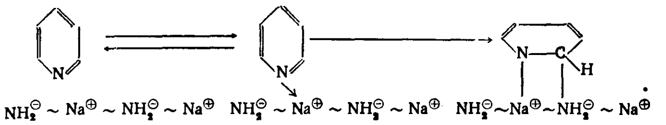
3. The site of attack by the amide ion does not always coincide with the location of the highest positive charge. For example, quinazoline is aminated in the 4-position and not the 2-position [33].

4. The employment of the energies of anionic localisation as reactivity indices is also unsatisfactory. Thus the values of L_2 and L_4 for pyridine (2.35 β and 2.37 β) and quinoline (2.24 β and 2.13 β) are non-informative and agree poorly with experiment [27,34].

The role of the basicity of the heterocycle. In principle, the Chichibabin reaction may be regarded as the interaction between the nitrogen-containing heterocycle and the amide ion, disregarding the influence of the counterion [35]. In amination in liquid ammonia, which ionises the M$-$NH$_2$ bond [10], such simplification is permissible‡, which is demonstrated, particularly, by the absence of a relation between the basicity of the heterocycle and its ability to be aminated in liquid ammonia.

On the other hand, in amination under heterogeneous conditions there is a distinct relation between the basicity of the compound and its ability to be aminated by metal amides [4,36]. Compounds whose basicity is in the range $pK_a = 5-6$ are most readily aminated; they include benzo- and naphtho-imidazoles, pyridine, isoquinoline, benzo[*f*]quinoline, and many others. Weakly basic diazines, triazines, quinoxaline, and certain imidazole systems are poorly aminated or do not react with NaNH$_2$ at all (Tables 1 and 2). The Chichibabin reaction is most sensitive to variations in basicity in the series of azoles [36-40]. Inspection of extensive experimental data shows that the lower limit of the basicity of benzimidazole derivatives which can be aminated lies in the range $pK_a = 4.2$ to 4.3. [27,36]

In order to account for the influence of basicity, it has been suggested that the pyridine nitrogen atom undergoes preliminary coordination to the sodium cation [4,36]. Such coordination not only orients the heterocycle at the NaNH$_2$ surface but also greatly increases the positive charge on the α-carbon atom, facilitating thereby the addition of the amide ion to the latter:



(X) (XI) (XII)

It has been shown by infrared spectroscopy that the sorption and coordination processes are reversible and precede the formation of the σ-complex [4,27].

If the $\gtrdot N \rightarrow NaNH_2$ coordination is regarded as the first stage of the Chichibabin reaction, then presumably more basic heterocycles should be aminated more readily. However, this happens only up to a certain limit. The point is that, with increase of basicity, the position charge on the α-carbon atom decreases synchronously. For successful amination, the optimum combination of pK_a and q_{α}^{+} is evidently necessary [4,36]. Heterocycles with $pK_a = 5-6$ evidently meet this requirement. Incidentally, there are also other exceptions, which will be discussed later. More basic heterocycles ($pK_a > 6-7$) do not enter into the Chichibabin reaction or are aminated with much difficulty. These include, in particular, imidazole [4] and 4- and 5-azaindoles [41]. The most basic of all the compounds which are successfully aminated is 4-dimethylaminopyridine ($pK_a = 9.37$), which reacts with NaNH$_2$ under extremely severe conditions and the yield of the 2-amino-derivative is low [41].

The hypothesis of the coordination of the pyridine nitrogen atom to the Na$^+$ ion helps to explain, apart from the influence of basicity, a number of other interesting features of the Chichibabin reaction, primarily the difficulty of γ-amination under heterogeneous conditions and the so-called *ortho*-dimethoxy-effect.

Characteristics of γ-amination. The possibility of γ-amination is determined mainly by two factors: the relative activities of the α- and γ-positions and the reaction conditions (homogeneous and heterogeneous). It must be emphasised that, when both positions are free, the reaction is predominantly directed to the α-atom. If the α-positions are occupied, the reaction is directed to the γ-position (the 4-position). For example, on amination in liquid ammonia, quinoline forms a mixture of 2- and 4-aminoquinolines in proportions of 6 : 1, [13] while 2-phenylquinoline [15] and quinoline-2-carboxylic acid [42] are aminated under the same conditions in the 4-position with an almost quantitative yield. Successful γ-amination under homogeneous conditions is, incidentally, not surprising, since metal amides are highly dissociated in liquid ammonia [10] and the ratio of the isomers is determined mainly by the relative reactivities of the α- and γ-carbon atoms.

On the other hand, under heterogeneous conditions, after the $\gtrdot N \rightarrow NaNH_2$ coordination, the γ-position becomes relatively inaccessible to the amide ion for geometrical reasons and the yield of the isomer is greatly reduced. Indeed, γ-amination of quinoline under heterogeneous conditions has not been observed. 2,6-Dimethylpyridine is converted into 4-amino-2,6-dimethylpyridine with a yield of only 6%. [43]

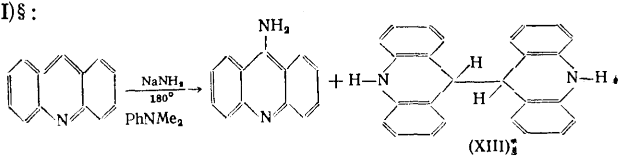
Acridine in a very convenient compounds for the study of γ-amination. In liquid ammonia 9-aminoacridine was obtained in a high yield [42], but in dimethylaniline the yield

---

† Here, and henceforth in the discussion of the ability of azoles to be aminated we have in mind the behaviour of their *N*-substituted derivatives in relation to sodium amide.

‡ However, Bergstrom showed that, even under these conditions, the nature of the cation influences the reaction. Thus quinoline is more effectively aminated in liquid ammonia with the aid of Ba(NH$_2$)$_2$ than KNH$_2$. [12-15]

fell to 31%[44] and the main product became 9,9′-biacridanyl (XIII)§:

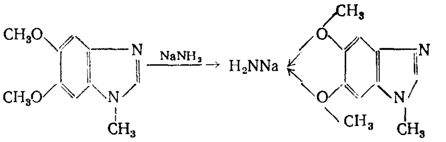


(XIII)§

Since the pK_a and q_γ^+ values for acridine favour the Chichibabin reaction (Table 1), the low yield of the amine can be accounted for only by the separation of the amide ion and the γ-position in the adsorption complex.

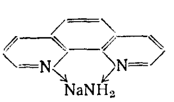
The *ortho*-dimethoxy-effect (ODE). In the study of the Chichibabin reaction involving the benzimidazole series it was observed that compounds containing methylenedioxy- or *ortho*-dimethoxy-groups cannot be aminated under a wide variety of conditions regardless of the site in the molecule containing the *ortho*-dimethoxy-group[39,46]. On the other hand, compounds with separated methoxy-groups are aminated to a satisfactory yield.

In order to account for the ODE, it has been suggested that *ortho*-dimethoxy-derivatives are sorbed on the NaNH$_2$ surface with formation of complexes of type (XIV),[39,46] which cannot be aminated further owing to their unfavourable orientation in relation to the C=N bond (ultimately one of the methoxy-groups is demethylated with formation of the corresponding phenoxide ion, which is inert with respect to NaNH$_2$ [46,47]). This explanation of the ODE has been confirmed by data for azacrown-ethers, which give rise to complexes with alkali metal ions via oxygen and not nitrogen atoms (in consequence of the ion–dipole mechanism of the interaction[48]):

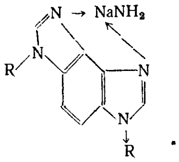


(XIV) .

The ODE has also been observed in the isoquinoline[46] and veratrol[47] series. The cause of the inertness of *o*-phenanthroline and benzo[1,2-*d* : 3,4-*d*′]di-imidazoles, which form complexes of types (XV) and (XVI) incapable of being aminated, is probably similar to the ODE:



(XV)



(XVI) .

The polarisability of the C=N bond. Bearing in mind the role of the >N → NaNH$_2$ coordination as the first stage of the Chichibabin reaction, when the latter is considered within the framework of the LCAO-MO theory, it is necessary to take into account the results of calculation not only for neutral molecules but also for heteroaromatic cations. Conversion into cations is accompanied by a sharp increase of the positive charge on the α-carbon atom (Table 3). The difference Δq_α^+ between the charges in the base and in the cation is then not the same for different heterocycles, being a minimum for pyridine and increasing on passing to its benzologues. Δq_α^+ is particularly large for the benzo- and naphtho-imidazole systems and also perimidine. The variation of Δq_α^+ on passing from one heterocyclic system to another may be attributed to the different polarisabilities of their C=N bonds in the course of the >N→NaNH$_2$ coordination (the importance of the polarisability factor in the Chichibabin reaction was first mentioned by Abramovitch et al.[49,50]). Evidently, the greater the value of Δq_α^+, the greater should be the ease, other conditions being equal, of the interaction of the heterocycle with the metal amide. Table 3 presents the Δq_α^+ calculated by the Hückel molecular orbital method for a series of heterocycles whose pK_a values lie in the region most favourable for the Chichibabin reaction. Also included are the values of $\Delta\delta_\alpha$ characterising the chemical shift of the α-CH proton in the ^{1}H NMR spectrum of the cation compared with the corresponding base. Overall, the variation of Δq_α^+ and $\Delta\delta_\alpha$ are the same.

Table 3. The effective positive charges q_2^+ and the chemical shift δ_2 of the protons of the α-carbon atom in certain heterocycles and their cations[27].

Compound	Neutral molecule		Cation		Δq_2^+	$\Delta\delta_2$, p.p.m.
	q_2^+	δ_2, p.p.m.	q_2^+	δ_2, p.p.m.		
Pyridine	+0.077	8.60	+0.241	8.98	+0.164	+0.38
Isoquinoline	+0.105	9.31	+0.329	10.07	+0.224	+0.76
Benzo[*f*]quinoline	+0.095	9.18	+0.276	9.95	+0.181	+0.77
Acridine*	+0.105	8.97	+0.288	10.15	+0.183	+1.18
Benzimidazole	+0.170	8.18	+0.443	9.61	+0.273	+1.43
Naphtho[1,2-*d*]imidazole	+0.152	8.15	+0.419	9.67	+0.267	+1,52
Perimidine	+0.256	7.41	+0.511	8.98	+0.255	+1.57

*Data for the γ-position.

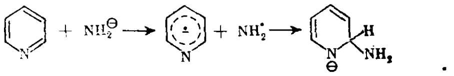
On the basis of kinetic data, heterocycles can be arranged in the following series in terms of the ease with which they enter into the Chichibabin reaction: benzimidazole > isoquinoline > perimidine > benzo[*f*]quinoline > pyridine ≫ acridine[16]. If acridine is excluded (difficulty of γ-amination), this series agrees very closely with the variation of Δq_α^+, except for the fact that isoquinoline and perimidine change places. However, it is difficult to expect that a complex process such as the Chichibabin reaction should be ideally correlated in terms of a single electronic parameter. Apar from polarisability, the basicity of the compound, the positive charge on the α-carbon atom, the ease of aromatisation of the σ-complex, and possibly certain other factors play a role.

The possibility of a radical-anion stage in the Chichibabin reaction. The view that radical stages are possible in nucleophilic substitution reactions of aromatic compounds has become established in recent years[51–56]. It has also been shown in relation to the Chichibabin reaction that it is sensitive to the action of inhibitors of free radical processes[16]. It has been

---

§ The claim[45] that only 9-aminoacridine is formed under these conditions in 72% yield was not confirmed[44].

suggested that a one-electron transfer stage probably precedes the formation of the σ-complex and takes place immediately after the sorption of the heterocycle on the $NaNH_2$ surface:

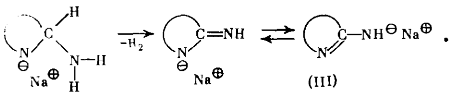


(XVII)

It must be emphasised that the introduction of the electron transfer stage does not conflict with the other considerations concerning the addition mechanism stated above and merely refines them, making it possible to explain many additional facts. In particular, certain compounds containing electron-accepting groups (NO_2, Ar–N=N, etc.) are not aminated, despite their satisfactory basicity and the large value of q_α^+. Presumably these substituents decrease with spin density in the 2-position of the radical-anion (XVII) and thereby prevent the recombination of radicals with formation of the σ-complex. On the whole, the problem of the intermediate formation of radical-anions in the Chichibabin reaction requires further study.

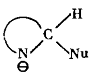
(b) The Elimination Stage

There are two main points of view concerning the mechanism of the aromatisation of the σ-complex in the Chichibabin reaction. The first, illustrated in Scheme (1), involves the loss of sodium hydride by the σ-complex. According to the Scheme (2), proposed in an early study by Bergstrom[11-15], the σ-complex is stabilised by the direct loss of an H_2 molecule as a result of the elimination of a proton from the NH_2 group and a hydride ion from the tetrahedral carbon atom:



(I) (III) (2)

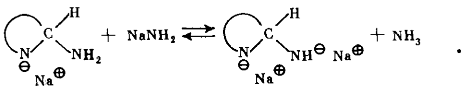
Scheme (2) is supported, in particular, by the fact that the reactions of nitrogen-containing heterocycles with anionic nucleophiles take place particularly readily when the nucleophile contains at least one hydrogen atom capable of being protonated. These include the $\overset{\ominus}{NH_2}$, $\overset{\ominus}{OH}$, and $\overset{\ominus}{NHR}$ anions. The σ-complexes (XVIII, a–c) corresponding to them



(XVIII) (a) Nu = NH_2; (b) Nu = OH;
(c) Nu = NHR;
(d) Nu = NR_2; (e) Nu = OR .

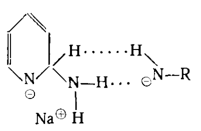
may be aromatised as a result of the loss of an H_2 molecule without preliminary elimination of sodium hydride. When the anions of secondary amines or metal alkoxides, whose σ-complexes (XVIII, d and e) cannot be stabilised in this way, are used as the nucleophiles, it is as a rule impossible to achieve the corresponding substitution reactions.

Direct elimination of hydrogen from the σ-complex is also likely to be a simplification. Clearly the mixture must contain the corresponding hydride ion and proton acceptors for this to occur. It has been suggested[12,57] that a hydride ion is eliminated from the dianionic σ-complex (XIX), formed as a result of an acid–base interaction, and not from the σ-complex (I):



(I) (XIX)

The possibility of the formation of such complexes is indirectly confirmed by ^{1}H NMR data[25,26] and by the finding that in liquid ammonia the amination reaction proceeds at an appreciable rate only in the presence of an excess of the metal amide[12]. In terms of this interpretation of the aromatisation stage, the evolution of hydrogen should occur as a result of the elimination of the hydride ion from the complex (XIX) with the aid of an ammonia molecule, i.e. in fact we are dealing here with bifunctional catalysis via a transition stage (XX). The decisive evidence in support of bifunctional catalysis is apparently the observation of the catalytic effect on the Chichibabin reaction of added sodium salts of amines and the presence of an autocatalytic section on the kinetic curves representing the variation of the rate of evolution of H_2.[16] Despite the presence in the mixture of an excess of more basic amide ions, the salts (III) catalyse the reaction, which shows that, in the transition complex (XX)



(XX)

(a), R=H, (b), R=heteroaryl.

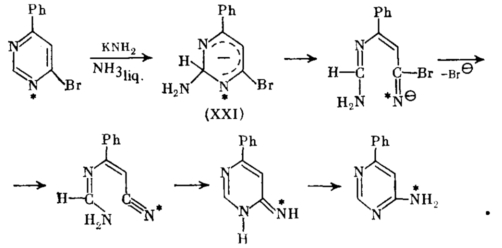
the hydride ion is eliminated with greater difficulty than the proton, i.e. not only the elimination of the proton but also the elimination of the hydride ion is catalysed. This implies that the transition state in the elimination stage is close to the σ-complex (XIX) and not the Ziegler adduct (I), as has been believed hitherto.

The hydride ion may be eliminated from the σ-complex also with the aid of a molecule of the initial compound, which entails the formation of dihydro-derivatives[16].

The foregoing considerations refer to heterogeneous amination. Successful amination in liquid ammonia takes place only in the presence of oxidants (KNO_3 is usually employed[11-15]), which convert the intermediate adduct (I) into an amine.

The behaviour of halogeno-derivatives of *N*-heterocycles in relation to metal amides. There has not been a single example in the literature hitherto of successful amination of halogenated *N*-heterocycles by the Chichibabin reaction, although such attempts have been made[4]. It is well known that halogeno-derivatives of heterocycles interact with metal amides, the halogen atom being substituted by an amino-group either via the S_N2Ar mechanism[5,6] or via the heteroaryne mechanism[58]. These reactions are usually carried out in liquid ammonia.

The so called *ANRORC* mechanism, proposed recently by Dutch chemists, throws some light on the characteristics of the behaviour of halogenated *N*-heterocycles in the Chichibabin reaction[59,60]. This mechanism is particularly characteristic of compounds of the pyrimidine series, for example:

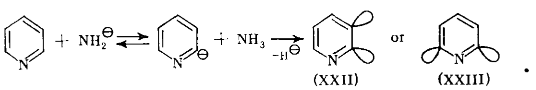


The reaction begins with the addition of an NH_2 ion to $C_{(2)}$ atom, without a halogen. The resulting σ-complexes of type (XXI) have been recently detected[61,62]. An important feature of these complexes is that they are stabilised by the elimination of a bromide ion with synchronous or stage-by-stage recyclisation and not by the loss of an $H^\ominus$ ion, which would constitute the Chichibabin reaction. As a result, the N atoms of the amide ion and the heterocycle change places. The *ANRORC* mechanism usually competes with the S_N2Ar or *EA* mechanism[59,60].

Yet another possible cause of the inability of halogenated heterocycles to be aminated by the Chichibabin reaction is the fact that their radical-anions (the possible reaction intermediates) are frequently fragmented with the loss of a halide ion[63]. Nevertheless it appears of interest to investigate the behaviour of halogenated *N*-heterocycles in relation to $NaNH_2$ in an aprotic medium. This applies particularly to compounds containing a relatively immobile halogen (for example, 3-bromopyridine).

(c) The "Elimination-Addition" Mechanism

The *EA* mechanism proposed for the Chichibabin reaction in 1963,[64,65] involving the intermediate formation of heteroarynes of type (XXII) or (XXIII), has been vigorously criticised[4,5,66,67]:

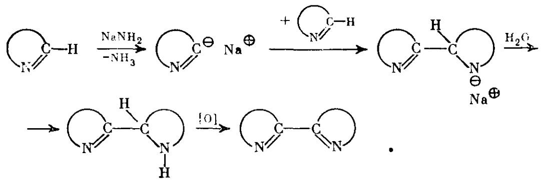


The following main evidence has been put forward:

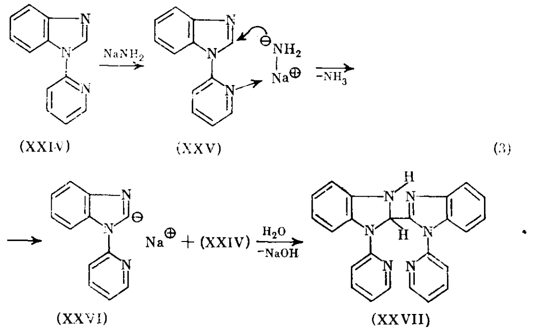
1. The absence of a kinetic isotope effect in the amination of a mixture of [2-D]pyridine and [3-D]pyridine.
2. The preferential amination of 3-substituted pyridines in the 2-position.
3. Successful amination of heterocycles which cannot form an aryne (azoles, acridine, isoquinoline). The amination of 2,5-disubstituted pyridines[68] also cannot involve the intermediate formation of 2,3- or 2,6-dihydropyridine.
4. According to calculations by the extended Hückel method, the arynes (XXII) and (XXIII) are much less stable than 3,4-dehydropyridines[69], which has been confirmed by data for the reactivities of 2- and 3-halogenopyridines[58].

2. SIDE REACTIONS

The most typical side reaction in the Chichibabin reaction amination of heterocycles is their dimerisation involving the α- or γ-positions. The formation of dimers with aromatic or hydrogenated structures has been observed for pyridine[1,3,7], quinoline[70], acridine[44], quinoxaline[71], and *N*-substituted benzimidazoles[27,38,46,72]. The yield of the dimer, which sometimes reaches 60%, depends strongly on the nature of the heterocycle and the solvent. The dimerisations mechanism is still not entirely clear. In principle, the reaction may reduce to the metallation of the α-CH bond with subsequent nucleophilic addition of the carbanion to the C=N bond of a second molecule[27]:



Another pathway involves the dimerisation of the intermediate radical-anion of type (XVII). According to the authors of the present review, both dimerisation pathways occur in different cases. For example, bearing in mind the ease of the polarographic reduction of acridine[73], the formation of 9,9′-biacridanyl (XIII) almost undoubtedly proceeds via a radical-anion mechanism. On the other hand, the formation of the dimer (XXVII) in 51% yield in xylene and in 10% yield in dimethylaniline when 1-α-pyridylbenzimidazole reacts with $NaNH_2$ probably involves the stage where the organosodium compound (XXVI) is formed, which may be favoured by intramolecular cooperation via type (XXV) coordination (such cooperative effects in the metallation of aromatic compounds have been described by, for example, Houghton[74] and Slocum and Stonemach[75]):

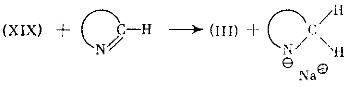


(3)

Scheme (3) is supported by the fact that 1-methyl-2-sodiobenzimidazole reacts with 1-methylbenzimidazole under the conditions of the Chichibabin reaction, giving rise to a high yield of 2,3-dihydro-1,1′-dimethyl-2,2′-bibenzimidazolyl[27]. It is noteworthy that the formation of organometallic compounds in the Chichibabin reaction should be accompanied by the evolution of gaseous ammonia. The presence of the latter in the gaseous reaction product does indeed range from 10 to 50%.[16,17] However, the main pathway leading to the formation of NH_3 is apparently the formation of the σ-complex (XIX) from the σ-complex (I). Thus up to 50% of NH_2 is evolved in the amination of 1-methylperimidine, although a dimer is not formed in the reaction at all[16].

The influence of solvents on dimerisation is indicated by the following facts. In the case of 1-alkylbenzimidazoles the formation of dimers in appreciable amounts (7–12%) is observed only in amination in dimethoxyethane or in the absence of a solvent. The amination of pyridine in hexamethylphosphoramide results in the formation of 4,4′-bipyridyl in 20% yield[7], the carbon atoms with the maximum spin density in the pyridine radical-anions being involved in the reaction[76].

The second in importance side reaction in the Chichibabin amination of heterocycles is the hydrogenation of their C=N bond, which leads to the formation of the corresponding dihydro-derivatives (XXVIII), sometimes in yields up to 25%. This reaction has been observed for phenanthridine[57], Schiff bases[20,21,77], and 1-methylperimidine. The mechanism probably involves the transfer of a hydride ion from the σ-complex (I) or, what is more likely, from the dianionic σ-complex (XIX), to the readily reduced C=N bond of the initial compound:



(XXVIII)

Other side reactions are specific to various compounds and will be considered in Section III.

3. THE INFLUENCE OF SOLVENTS

Unfortunately there are so far no quantitative data for the influence of solvents on the Chichibabin reaction. Taking into account the high polarity of the σ-complex, the ease of its formation should presumably depend on the solvating capacity and the dielectric constant of the solvent. Indeed in liquid ammonia, a solvent with proton-accepting and proton-donating activities which also has a very high dielectric constant ($\epsilon = 25.4$), the σ-complexes of many heterocycles with metal amides are formed even at $-40°$.[25,26] On the other hand, in inert solvents such as aromatic hydrocarbons ($\epsilon = 2-2.5$) σ-complexes are formed at 70–90°C and even higher temperatures. Dimethylaniline, dimethoxyethane, tetrahydrofuran, ($\epsilon = 7-7.5$), and other related solvents occupy an intermediate position between liquid ammonia and hydrocarbons. Amination in dimethylaniline takes place as a rule at a lower temperature and faster than in xylene or toluene although in isolated instances side products are formed in large amounts[37]. Reports have been published recently about the successful use of tetrahydrofuran and dimethoxyethane as solvents[27,57]. Thus phenanthridine is aminated in tetrahydrofuran even at room temperature[57].

Amination without a solvent has been described for 1-alkylbenzimidazoles[27], pyrazine[78], pyridine[79], anabasine[80], *N*-methylanabasine, and nicotine[80], the yields of the amino-derivative in the last two cases being even higher than in the presence of a solvent.

III. INTERACTION OF NITROGEN-CONTAINING HETEROCYCLES WITH METAL AMIDES

All the heterocycles which have been made to undergo the Chichibabin reaction hitherto contained a pyridine nitrogen atom. The role of the latter consists in the activation of the ring with respect to nucleophilic substitution by analogy with the function of the nitro-group in aromatic compounds. Indeed the σ constants of the nitro- and aza-groups are extremely similar[81]. Heterocycles with a single nitrogen atom of the pyridine type are aminated most effectively: pyridine, quinoline, isoquinoline, phenanthridine, and benzoquinolines. When several aza-groups are introduced into the molecule, the situation becomes more complex and treatment with $NaNH_2$ can lead to either amination (naphthyridines, pyrazines) or to side reactions (quinoxaline, triazine). Systems with excess π electrons, containing only a pyrrole nitrogen atom (indoles, indolizine, etc.), do not undergo the Chichibabin reaction. The only heterocycle with excess π electrons, which it has been possible to introduce into the reaction is perimidine, but its molecule contains a pyridine nitrogen atom in addition to a pyrrole nitrogen atom.

Azoles, another class of compounds with heteroatoms of both types, behave in different ways in relation to metal amides. Non-condensed azoles (imidazole, pyrazole) are usually not aminated, although there are exceptions (thiazole). The situation changes in benzazoles and naphthazoles as a result of the depletion of the heterocyclic ring in electrons and the compounds show a tendency towards amination (benzimidazole, naphthimidazoles), although this is not always the case (indazole and benzoselenazole are not aminated).

The pre-rearrangement of the N=CH group by $NaNH_2$ in a manner favouring amination is apparently so pronounced that the group is sometimes aminated even when it is not incorporated in a ring. Thus Schiff bases have been made to undergo the Chichibabin reaction[20,21,77].

The foregoing may create the impression that the presence of a pyridine nitrogen atom is a necessary condition for amination. However, such a claim must be approached with caution. In an early study Sachs showed that under severe conditions even compounds such as naphthalene, naphthylamines, and naphtholes may be aminated by sodium amide[82], hydrogen being evolved in the reaction (i.e. the latter proceeds as nucleophilic substitution). Later other non-heterocyclic compounds (mesobenzanthrone[83,84] and nitrobenzene[85]) were aminated, although the yields of amines in these instances are low. Evidently the problem of the possible amination of heterocycles without an aza-group requires further study.

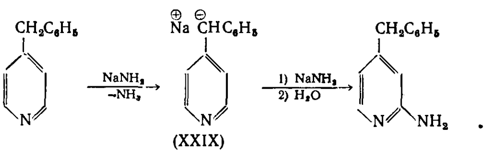
1. AZINES

(a) Pyridines

Pyridine and its 2- and 4-substituted derivatives. Despite the widely held view, pyridine is one of the most slowly aminated heterocycles. In contrast to diazines, quinoline, and isoquinoline, it does not, for example, react with KNH_2 in liquid ammonia even after prolonged treatment[25]. The amination of pyridine requires heating for many hours at 105–130°C (the yield of 2-aminopyridine is 70–85%).[1,79,86-88] Small amounts of bipyridyls, 2,2′-dipyridylamine, and 4-aminopyridine are formed as side products[1,3]. 2,6-Diaminopyridine may be obtained in 55% yield at 170–180°C [1] and 2,4,6-triaminopyridine may be formed in a low yield at 200°C and in the presence of a large excess of $NaNH_2$.[42] The relative difficulty of aminating pyridine can be accounted for by the comparatively low positive charge on the α-carbon atom and also by the low polarisability of the C=N bond (Tables 1 and 3).

2-Alkylpyridines ($R = CH_3$ [1,86-91] or n-C_3H_7 [3]) are aminated in the free α-position; if the latter is occupied, γ-amination takes place to a small extent[43]. 2,4,6-Trisubstituted pyridines do not enter into the Chichibabin reaction[1] and 2-t-butylpyridine is not aminated even under severe conditions[92]. The bulky t-butyl group apparently prevents, owing to steric considerations, the sorption of the compound on the $NaNH_2$ surface. The phenyl group has less stringent requirements and 2-phenylpyridine yields 6-amino-2-phenylpyridine (in dimethylaniline at 130–140°C) in 87% yield together with a small amount of the 4,6-diamino-derivative[93,94].

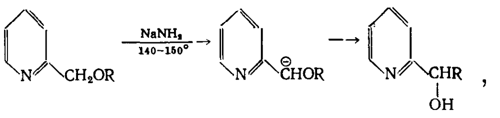
4-Alkylpyridines (R = CH_3,[95] C_2H_5,[96] n-C_3H_7,[97] or n-C_5H_{11}[98]) are converted into 2-amino-derivatives in 60 to 76% yields; 2,6-diamino-derivatives are not then formed. The high yields of amines in the amination of α- and γ-picolines show that in aprotic solvents the CH_3 group does not ionise (such ionisation takes place only in liquid ammonia[99]). On the other hand, 4-benzylpyridine initially forms the carbonium ion (XXIX), which is aminated with difficulty[98]:



(XXIX)

The difficulty of amination owing to analogous ionisation increases also for amino- and hydroxy-pyridines. Thus γ-pyridone is aminated only at 250°C in liquid paraffin, forming 2,6-diamino-4-hydroxypyridine in 69–75% yield[100]. α-Pyridone is aminated to 2-amino-6-hydroxypyridine[88]. The reaction of 2-aminopyridine with $NaNH_2$ at 120–130°C is accompanied by vigorous evolution of ammonia and the resulting salt (III) is aminated further to 2,6-diaminopyridine only at 160–180°C (in 71–79% yield)[41,87]. 4-Aminopyridine could not be introduced into the Chichibabin reaction[41]. The data for the amination of 3-aminopyridines are contradictory[41,101].

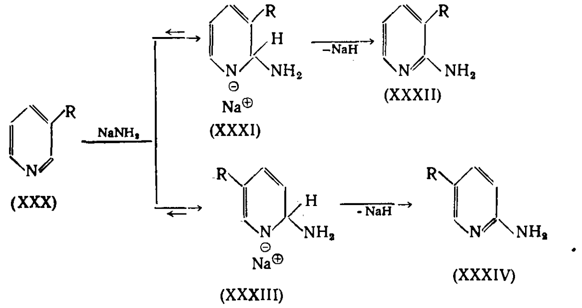
In certain cases the treatment of pyridine with $NaNH_2$ is accompanied by rearrangements or the elimination of substituents. Thus 2- and 4-alkoxymethylpyridines undergo the Wittig rearrangement[102]:



where R = C_2H_5, $C_6H_5CH_2$, etc. On treatment with $NaNH_2$, 2-dimethylaminopyridine gives a 30% yield of 2,6-diaminopyridine, the dimethylamino-group being substituted initially[41,103]. 4-Dimethylaminopyridine is aminated in the 2-position without the elimination of the substituent, but 4-diethylaminopyridine undergoes dealkylation, resulting in the formation of the sodium salt of 4-ethylaminopyridine, which is inert in relation to further treatment with $NaNH_2$.[41]

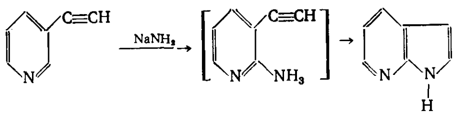
Pyridine-4-carboxylic acid and its amide are converted into 2,6-diaminopyridine on amination[104].

Substituted pyridines. One of the interesting features of the Chichibabin reaction is the preferential amination of 3-substituted pyridines (XXX) in the 2-position (Table 4).



(XXX) (XXXI) (XXXII) (XXXIII) (XXXIV)

As expected, 3-alkyl-groups deactivate the ring with respect to the amide ion, but the 2-position is deactivated more than the 2-position[5,50]. This feature of the amination reaction has been successfully used in the synthesis of 7-azaindole from 3-ethynylpyridine[111]:



When compounds with bulky groups in the 3-position are aminated, the yield of the 6-amino-derivatives becomes equal to that of the 2-isomer or even exceeds it (Table 4).

Table 4. Amination of 3-substituted pyridines (XXX).

R	Reaction products (the ratios of the isomers are indicated in brackets)	Overall yield, %	References

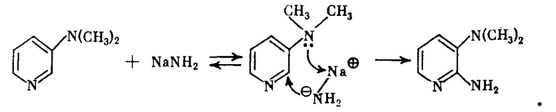
An analogous directing effect obtains in the interaction of 3-alkylpyridines with methyl-[125] and phenyl-lithium[126,127]. The nature of this phenomenon has been frequently discussed. No clear correspondence has been discovered between the position to which the nucleophile is directed and any reactivity index[128], which is not surprising, since steric and solvation effects and the possible interaction of the 3-substituent and the nucleophile in the transition state are ignored in calculations of this kind. The preferential formation of the 2-amino-derivative is believed to be associated with the fact that the corresponding σ-complex (XXXI) loses a hydride ion faster than the σ-complex (XXXIII).[5,50,126] This explanation is satisfactory if the rate of reaction is limited by the aromatisation stage. However, as already stated, a kinetic isotope effect has not been observed in the Chichibabin reaction[66].

The most attractive explanation is the hypothesis that the nucleophile is directed to the 2-position by London forces or the ion–dipole interaction of the nucleophile with the 3-substituent in the transition complex[5,50,129]. Such interaction should be particularly appreciable for 3-dimethylaminopyridine. Indeed, this compound is aminated exclusively in the 2-position[41]:



Other pyridines. The few studies on the amination of bipyridyls have shown that the latter react with $NaNH_2$ with much difficulty, forming amino-derivatives in low yields. Data for the amination of bipyridyls and disubstituted pyridines are presented in Table 5.

Table 5. Amination of disubstituted pyridines and bipyridyls.

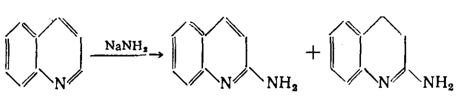
*There is no information about the yields.

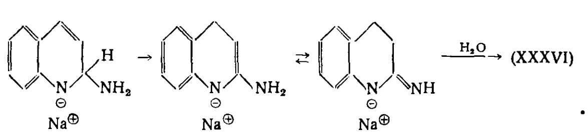
(b) Condensed Systems Containing a Pyridine Ring

In aprotic solvents quinoline is ineffectively aminated: the yield of 2-aminoquinoline (XXXV), which is difficult to purify, does not exceed 32% in toluene[1,70] and xylene[79]. In dimethylaniline the yield of (XXXV) falls to 7% and the main product becomes, somewhat unexpectedly, 2-amino-3,4-dihydroquinoline (XXXVI) (yield 24%):[137]



(XXXV) (XXXVI)

The formation of (XXXVI) can be represented schematically as follows:



This reaction occurs also for certain quinoline derivatives[138,139]. The highest yield of 2-aminoquinoline (53–69%) may be reached by amination by barium or potassium amides in liquid ammonia[13]: in the latter case 4-aminoquinoline is also formed in 10% yield.

As already mentioned, quinoline forms two σ-complexes in liquid ammonia—the 2-amino-1,2-dihydroquinolinide anion (VIII) and the 4-amino-1,4-dihydroquinolinide anion (IX).[26] Despite the fact that the latter is thermodynamically more stable, quinoline is nevertheless aminated mainly in the 2-position. A possible explanation of this finding is that (VIII) is aromatised faster (in liquid ammonia, to which the above considerations refer, the aromatisation stage is undoubtedly rate-limiting).

The results of the amination of various quinoline derivatives are presented in Table 6, which shows, in particular, that quinolines are much more readily aminated in the γ-position than pyridines.

2- and 4-Methylquinolines are not aminated in liquid ammonia owing to the ionisation of the methyl groups[14,142]. However, 4-methylquinoline is aminated in dimethylaniline (Table 6). In contrast to pyridine derivatives, quinolinecarboxylic acids and their amides are aminated without the elimination of the substituent. Hydroxy- and amino-quinolines are not aminated even under severe conditions[14].

Table 6. Amination of monosubstituted quinolines.

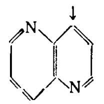
*2-Amino-8-methyl-3,4-dihydroquinoline was also isolated (1%).[128]

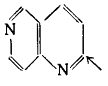
Isoquinoline is one of the most readily aminated heterocycles; the amino-group enters exclusively the 1-position. The yield of 1-aminoisoquinoline is quantitative in dimethylaniline[44], 87% in liquid ammonia[12,13], and 38% in toluene[143]. Isoquinoline-4-carboxylic acid[144], 5,6,7,8-tetrahydroisoquinoline[145], and 7-methoxyisoquinoline[146] are also satisfactorily aminated.

5,6- and 7,8-benzoquinolines give rise to high yields of 2-amino-derivatives both in liquid ammonia[15] and in dimethylaniline[147]. Phenanthridine is readily aminated in the 6-position in dimethylaniline[148,149], xylene[148], tetrahydrofuran[57], and liquid ammonia[42], but the amount of hydrogen evolved is less than the theoretical amount, which can be explained by the formation of 5,6-dihydrophenanthridine as a side product (yield 20%).[57] The amination of acridine was discussed above (Section II, 1a).

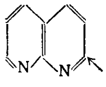
The amination of several compounds in which the pyridine ring is condensed to a further heteroatomic system has been described. These include the naphthyridines (XXXVII)–(XL),[150,151] β-carboline (XLI),[152] imidazo[4,5-*c*]-pyridine (XLII),[153] pyrido[4,5-*b*]-pyridazine (XLIII),[154] and imidazo[4,5-*f*]quinoline (XLIV) [147] (the arrow indicates the site where the amino-group enters):



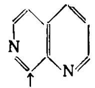
(XXXVII)



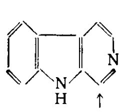
(XXXVIII)



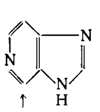
(XXXIX)



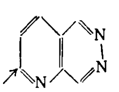
(XL)



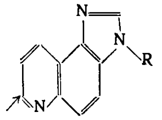
(XLI)



(XLII)

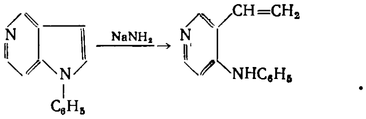


(XLIII)



(XLIV)

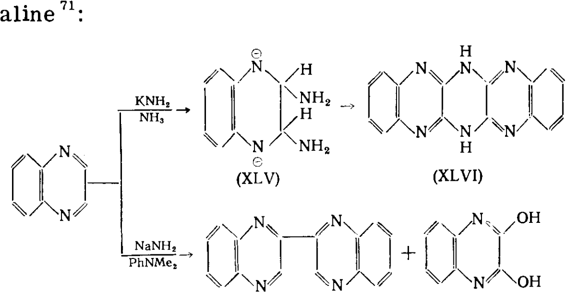
It was not possible to aminate 7-azaindolines[41], 7-azaindole[155], 1-methylimidazo[4,5-*b*]pyridine[156,157], 1-benzyl-4-azaindole, and 1-phenyl-5-azaindole[41]. It is of interest that the last compound is converted into 4-phenylamino-3-vinylpyridine on treatment with sodium amide[41], i.e. formally two-electron reductive cleavage of the C–N ring bond takes place:



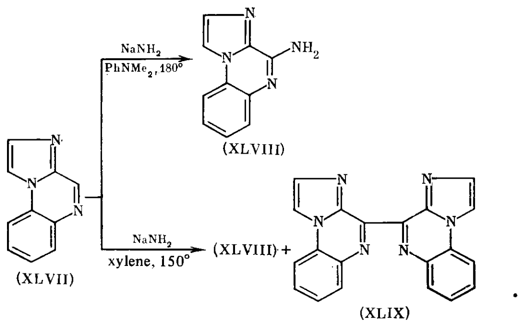
(c) Diazines and Triazines

Pyridazine does not undergo the Chichibabin reaction[154], although it does form the σ-complex (XVI) in liquid ammonia[25]. There has been only one report of the amination of pyrimidine derivatives: when 4-methylpyrimidine was treated with $NaNH_2$ in decalin, 2-amino-4-methyl- and 2,6-diamino-4-methyl-pyrimidines were isolated (the yields are not indicated)[158]. Pyrazine is aminated by sodium amide without a solvent, forming 2-aminopyrazine in a low yield (8–17%);[78] the available data on the amination of pyrazine in liquid ammonia are contradictory[159,160]. Amino-derivatives of 2,5-dimethylpyrazine are formed in 10% yield in xylene[161] and 35% yield in dimethylaniline[162]. 2,5-Di-s-butylpyrazine has been converted into an amine in 60–65% yield[163].

The reactions of quinoxaline with alkali amides take place in a complex manner and without the evolution of hydrogen. In liquid ammonia the only identified product of the reaction with two equivalents of potassium amide was fluorubine (XLVI).[160] It is apparently formed as a result of the reaction of the σ-complex (XLV) [164] with a molecule of the initial compound. In dimethylaniline the reaction of quinoxaline with sodium amide at 210–225°C gives rise to 2,2′-biquinoxalinyl and 2,3-dihydroxyquinoxaline[71]:



The only quinoxaline derivatives aminated under the conditions of the Chichibabin reaction proved to be imidazo[1,2-*a*]quinoxaline (XLVII): the amine (XLVIII) was isolated in 44% yield in dimethylaniline, while in xylene its yield fell to 11% and the main product became the dimer (XLIX):[72]

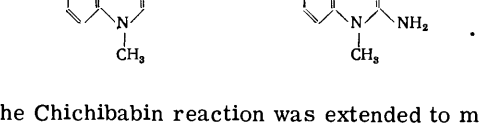


Quinazoline is aminated to 4-aminoquinazoline in dimethylaniline[33]. 4-Mercaptoquinazoline and 4-mercapto-6,7-benzoquinazoline are aminated with elimination of the mercapto-group and the formation of 2,4-diamino-derivatives[165]. Analogous results were observed also for 5,6-benzoquinazoline and its mercapto-derivatives[165].

Among triazines, the 1,3,5-isomer reacts with $NaNH_2$ and is cleaved to sodium cyanide in xylene at 160°C.[166] Pteridine, which is soluble in liquid ammonia, combines with ammonia covalently, but decompose when acted upon by KNH_2.[167]

2. IMIDAZOLE SYSTEMS

In 1951 Simonov and Uglov[2] demonstrated the possibility of the amination of the imidazole ring in the 2-position in relation to 5-methoxy-5-methylbenzimidazole:



After this, the Chichibabin reaction was extended to many benzimidazole derivatives and a series of imidazole systems[4,8]. One should note that imidazoles with a free amino-group are not aminated, since they are converted into the *N*-anion, which is inert in relation to sodium amide.

The possibility of the amination of imidazole derivatives is determined mainly by three structural factors: (1) the nature of the ring condensed to the imidazole ring; (2) the structure of the substituent at the pyrrole nitrogen atom; (3) the influence of the substituents in the aromatic ring.

The nature of the ring condensed with the imidazole ring. Whereas *N*-derivatives of benzimidazole, the isomeric naphthimidazoles, and 6,7,8,9-tetrahydronaphtho[1,2-*d*]imidazole are readily aminated in the 2-position (Table 7), *N*-substituted imidazoles, 4,5-diphenylimidazoles, and 5,6,7,8-tetrahydrobenzimidazoles do not undergo the Chichibabin reaction[168]. Thus, successful amination of the imidazole ring requires that it should be condensed to an aromatic ring. The role of the latter probably consists in creating a fairly large positive charge on the α-carbon atom as a result of the delocalisation of the π electrons (Table 2). The inability of phenanthro[9,10-*d*]imidazole to be aminated can be accounted for by the low aromaticity of the central benzene ring[168].

Table 7. Amination of naphthimidazoles, permidines, and aceperimidines.

*The yield varies as a function of the solvent.

It is of interest that imidazoles which are not aminated readily undergo the azo-coupling reaction in an alkaline medium involving the μ-carbon atom, while imidazoles capable of being aminated do not react with diazonium salts; this difference served at one time as a test for ability to be aminated. This finding clearly demonstrates the differences between the charges in the μ-positions of the two types of azoles. However, there are also exceptions. *N*-derivatives of imidazo[4,5-*b*] phenazine[39], imidazo[4,5-*b*]pyridine[156], and purine[27] are inert both to diazonium salts (high q_{α}^{+}) and sodium amide (low basicity).

The influence of the *N*-substituent. The nature of the substituent at the nitrogen atom has a significant influence on the amination of imidazoles and in certain cases completely alters the mode of reaction.

Benzimidazoles containing straight-chain alkyl substituents are readily aminated at 105–120°C (Table 8). Secondary *N*-alkyl groups hinder the reaction only slightly[17]. 1-*t*-Butylbenzimidazole is aminated with a low yield[175].

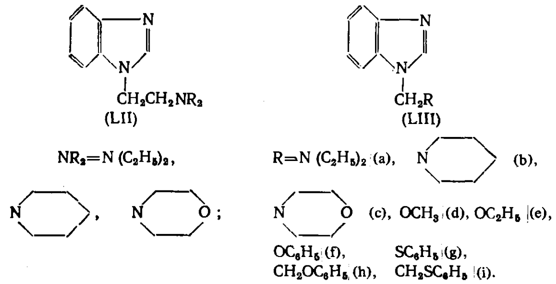
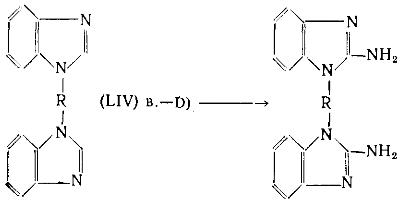
1-β-Dialkylaminoethylbenzimidazoles (LII) are aminated with greater difficulty than 1-alkylbenzimidazoles. One of the possible explanations involves competing coordination of the nitrogen atom of the substituent to the sodium cation, which should hinder the reaction. Under the conditions of the Chichibabin reaction, 1-diethylaminomethylbenzimidazole (LIIIa) gives rise to benzimidazole and 1-piperidino- and 1-morpholino-methylbenzimidazoles (LIII, b and c) are converted into 1-aminomethylbenzimidazole[182]. Compounds (LIII, d–i) do not form amino-derivatives[36,182].



1-β-Pyridylethylbenzimidazoles do not react with $NaNH_2$ at 110–140°C, decomposing at a higher temperature with formation of benzimidazole and a tar [38].

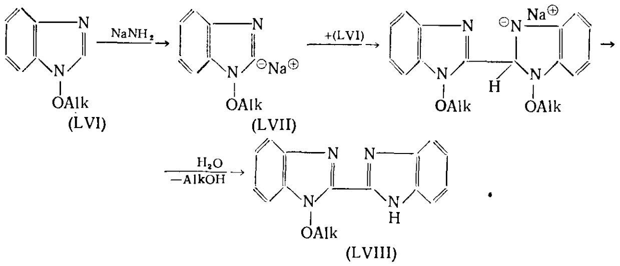
Depending on the length of the hydrocarbon chain, di-(1-benzimidazolyl)alkanes (LIV) behave in different ways in the Chichibabin reaction. Thus compounds (LIV, a, b, and f) are not aminated even at 180°C, while compounds (LIV, c–e) form the diamines (LV).[183] The reason for the difference between the reactivities is not altogether clear.



(LIV)
$R=CH_2$ (a), $(CH_2)_2$ (b), $(CH_2)_3$ (c), $(CH_2)_4$ (d), $(CH_2)_5$ (e), $CH_2C_6H_4CH_2$ (f);

(LV)
$R=(CH_2)_3$, $(CH_2)_4$, or $(CH_2)_5$.

The weakly basic 1-alkoxybenzimidazoles (LVI) are converted into the "dimers" (LVIII) when acted upon by sodium amide, probably via the intermediate carbanion (LVII):[184]



Thus the ease and mode of reaction of 1-substituted benzimidazoles with sodium amide greatly depend on the presence of a heteroatom in the substituent.

1-Benzylbenzimidazole and its derivatives with electron-donating substituents in the benzyl group are readily aminated (Table 8), with the exception of 1-*p*-hydroxybenzylbenzimidazole, which forms the less reactive *O*-anion, and 1-(3,4-dimethoxybenzyl)benzimidazole, which is converted into benzimidazole [46]. The formation of a dimer (7%) was observed in the amination of 1-*p*-methoxybenzylbenzimidazole [46]. Different 1-arylbenzimidazoles without electron-accepting substituents are also effectively aminated (Table 8). 1-γ-Pyridylbenzimidazole is inert with respect to $NaNH_2$, whereas 1-α-pyridylbenzimidazole is converted into the dimer (XXVII) under the same conditions[38] (Section II, 2).

The influence of substituents in the benzene ring of benzimidazole. When electron-accepting substituents (COOH, COOR, $CONH_2$, NO_2, N_3 PhN = N, F, Br, or Cl) are present in the benzene ring of benzimidazole, amination is impossible [8,39,185,186]. This is probably due to one of the following causes or their combination: (1) a decrease of the basicity of the nitrogen atom ($pK_a \leqslant 4.8$); the tendency of these groups to form non-aminated complexes with $NaNH_2$; (3) a change in the distribution of spin density in intermediate radical-anion which is unfavourable for amination.

Benzimidazoles with electron-donating groups in the benzene ring are readily aminated (Table 9), the substituents decreasing the rate of reaction in accordance with their electron-donating properties: 5,6-Me_2 < 5-MeO < 5-Me < 5-H.[17] 5-Hydroxy-, 5,6-dimethoxy-, and 5,6-methylenedioxy-benzimidazoles are not aminated [39,46] (Section I, 1a). 5-Amino-1-methylbenzimidazole is aminated under severe conditions [39].

Table 9. Amination of benzimidazoles substituted in the benzene ring

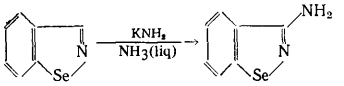
3. PERIMIDINES

Perimidines (L) are *peri*-isomeris of naphthimidazoles, but differ from the latter by the size of the heterocycle and a number of important physicochemical properties. Thus, together with a considerable deficiency of π electrons, a large excess of π electrons is also characteristic of perimidines [190], so that one may say that they are the only compounds with an excess of π electrons which enter into the Chichibabin reaction. The successful amination of perimidines is due to the strong polarisation of the C=N bond as a result of which a large positive charge is concentrated on the μ-carbon atom, where amination takes place, while a negative charge is created at the pyridine nitrogen atom (perimidines are much more basic than naphthimidazoles; see Table 2). Furthermore, the C=N bond in perimidines is highly polarisable (Table 3). *N*-Substituted aceperimidines (LI) undergo the Chichibabin reaction with much difficulty than perimidines. Data for the amination of perimidines and aceperimidines are presented in Table 7.

4. OTHER HETEROCYCLIC SYSTEMS

Thiazoles, selenazoles, and oxazoles. The Chichibabin reaction involving thiazoles and benzothiazoles proceeds in a complex manner and is of no practical importance. Sodium amide converts 4-methylthiazole into the 2-amino-derivative only after prolonged heating at 150°C.[191] Benzothiazole is aminated at 140°C but 2,2′-bibenzothiazolyl and bis-(2-aminophenyl) disulphide are formed together with 2-aminobenzothiazole [192].

When benzoselenazole was acted upon by $NaNH_2$, only bis-(2-aminophenyl) diselenide was isolated[193]. The amination of benzoisoselenazole with KNH_2 in liquid ammonia leads to the 3-amino-derivative, but its yield is low (36%):[194]



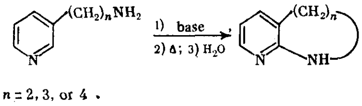
4-Methylselenazole[195] and isoxazoles[196] undergo ring opening without the formation of an amine.

Pyrazoles and indazoles. The positive charge on the α-carbon atoms of pyrazoles and indazoles are insufficient for amination. For this reason and also because of the lability of the nitrogen–nitrogen single bond, they are converted into ring-opening products and recyclisation products on being treated with methyl amides (see the relevant reviews[197,198]).

IV. REACTIONS RELATED TO THE CHICHIBABIN REACTION

Alkyl- and aryl-amination of heterocycles. The amination of nitrogen-containing heterocycles by organic derivatives of sodium amide is the closest analogue of the Chichibabin reaction. The possibility, in principle, of the phenylamination of pyridine in the 2-position by sodium anilide was demonstrated a long time ago[1]. However, owing to its low yields, the reaction is of no practical importance; furthermore, quinoline does not react with sodium anilide[22], while isoquinoline[13] and pyridine[199] do not react with sodium *N*-methylanilide. The alkylamination of heterocycles takes place successfully, but it has been little studied. Quinoline, acted upon by lithium methylamide, is known to form 2-methylaminoquinoline[200]. Alkali metal dialkylamides react only weakly with *N*-heterocycles or convert them into a tar[11,13,200].

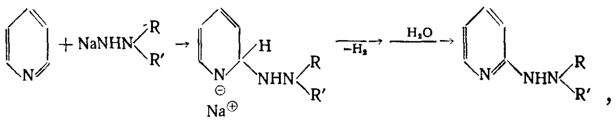
Bergstrom and coworkers achieved the alkylamination of pyridine and quinoline in the 2-position with the aid of aliphatic and alicyclic amines and the KNH_2-NaNH_2 eutectic in the presence of KNO_3.[201] The yield of reaction products reaches 60%. Kovacs and Vajda modified this method, having replaced the metal amide eutectic by metallic sodium[202–205]. Although it is natural to suppose that the aminating agent in these cases is sodium alkylamide, this is apparently not the case[204]. It has been suggested that the reaction proceeds via the intermediate formation of the pyridine radical-anion (as a result of electron transfer from sodium), which has been confirmed by the formation of 2,2′- and 4,4′-bipyridyls as side products and also by the available data on the mechanism of the interaction of sodium and pyridine[206]. An interesting variety of the reaction is intramolecular alkylamination of 3-ω-aminoalkylpyridines in the presence of strong bases (n-C_4H_9Li, Na, NaH, or $NaNH_2$) in dioxan or toluene[5,207,208]



$n = 2, 3,$ or 4 .

It must be emphasised that the reaction takes place in this case exclusively in the 2-position of the pyridine ring.

Hydrazination by metal hydrazides. The sodium salts of hydrazine, *N*-methylhydrazine, and *N*,*N*-dimethylhydrazine react very readily with pyridine, quinoline, 5,6- and 7,8-benzoquinolines, and their methyl derivatives with formation of the corresponding α-hydrazino-derivatives (LX):[209,210]



(LIX) (LX)

R, R′=H, or CH_3 .

The yields of products from pyridine and α-piccoline do not exceed 30%, those from quinoline do not exceed 45%, but in other cases the yields reach 70–80%.

In this reaction, which also proceeds with elimination of a hydride ion, a deeply coloured σ-complex (LIX) is formed initially[22,210], losing an H_2 molecule on heating and forming the corresponding hydrazine. A distinctive feature of the hydrazination reaction is the enhanced stability of the 1,4-adducts formed from pyridine and 2-methylquinoline: they are not aromatised even on heating[210]. It may be that their formation is the cause of the relatively low yield of 2-hydrazino-derivatives of pyridine and quinoline. Indeed, if the 4-position is occupied (γ-picoline, 4-methylquinoline, isoquinoline), α-hydrazination takes place with a satisfactory yield.

The adducts of acridine and phenanthradine with sodium hydrazide and dimethylhydrazide are anomalously stabilised. Instead of hydrogen, they split off on heating NH_3 and $(CH_3)_2NH$ molecules respectively, which results in the formation of 9-aminoacridine and 6-aminophenanthridine[22]. When quinazoline is acted upon by sodium hydrazide, hydrazination and amination take place simultaneously and 4-amino-2-hydrazinoquinazoline is formed[211]. Under these conditions, quinoxaline undergoes ring opening and pyrimidine undergoes ring contraction with formation of *o*-phenylenediamine and pyrazole respectively[211]. Yet another side reaction, which is observed, in particular, when pyridine is acted upon by sodium hydrazide, is the formation of hydrazo-compounds[210].

There is evidence for the possibility of direct hydrazination of benzoxazole and benzoselenazole[22]. Sodium phenylhydrazide could not be introduced into the reaction with heterocyclic compounds[209].

Hydroxylation of heterocycles. Direct hydroxylation of *N*-heterocycles is, as it were, the oxygen analogue of the Chichibabin reaction and is also accompanied by the evolution of hydrogen. The successful hydroxylation of both six- and five-membered heterocycles has now been achieved. α-Oxo-derivatives of pyridines[213–216], quinolines[215–218], benzoquinolines[218], isoquinoline[218], and phenanthridine were obtained by this method[219]. The hydroxylation of 1-substituted imidazoles and perimidines (Table 10), achieved for the first time by Pozharskii and coworkers[221], is of special preparative importance, because the *N*-monosubstituted imidazolidinones and perimidones, formed at the same time, are difficult to obtain by another procedure. It has been shown for compound (LXVI) and (LXVII) that, in the presence of two atoms active in relation to the nucleophile in the molecule of the *N*-heterocycle, both can be hydroxylated[183,220].

The hydroxylation can be carried out by fusing the heterocyclic compound with a large excess of anhydrous powdered alkali [KOH and, more rarely, NaOH and

$Ba(OH)_2$]. Owing to the weak nucleophilic properties of the $OH^{\ominus}$ ion, the process proceeds at an extremely high temperature (usually above 200°C), but is nevertheless characterised by a surprisingly high selectivity and, as a rule, high yields (particularly for imidazoles and perimidines). The only known instance of γ-hydroxylation is the formation of acridinone in 40% yield on hydroxylation of acridine with KOH at 300°C.[44] The ease of hydroxylation depends mainly on the positive charge of the α-carbon atom (Table 2).[221] Thus 1-methyl-4,5-diphenylimidazole is hydroxylated at 370–400°C, while 1-substituted perimidines are hydroxylated at a temperature as low as 200°C.

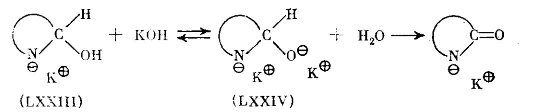
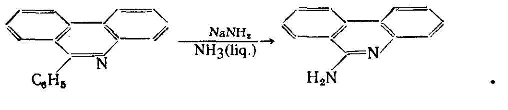
Much less is known about the side reactions in the hydroxylation process than for the Chichibabin reaction. Thus, on being fused with KOH, 1-phenylbenzimidazole gives rise to 1,1′-diphenyl-2,2′-bibenzimidazolyl together with 1-phenylbenzimidazolidinone[221]. On treatment with KOH, 1-methoxymethyl-, 1-isopropyl-, and 1-t-butylbenzimidazoles are converted into benzimidazole and other decomposition products, i.e. the elimination of the *N*-substituent is observed.

The hydroxylation mechanism probably resembles the mechanism of the Chichibabin reaction, although it has not been specially studied. We have reason to believe that the dianionic σ-complex (LXXIV) is formed as an intermediate: before the evolution of hydrogen, water is usually distilled off, which displaces the equilibrium (LXXIII) ⇌ (LXXIV) to the right:



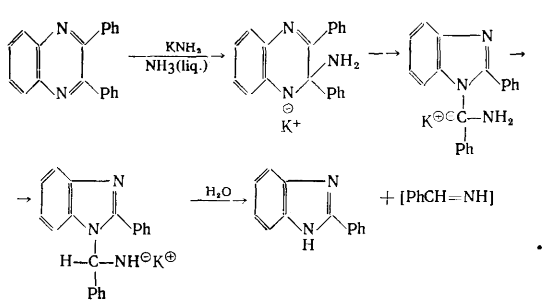
Direct alkoxylation of *N*-heterocycles by metal alkoxides could not be achieved[221].

Amination and hydroxylation with elimination of a carbanion. In our discussion of the Chichibabin reaction involving pyridine and quinolines we quoted a number of reactions in which the leaving groups were NMe_2, SO_3H, a halogen, etc. and not a hydride ion. However, all the groups are readily eliminated. In this respect the reactions of *N*-heterocycle derivatives, in which their amination by metal amide is accompanied by the elimination of a hydrocarbon substituent, are much closer to the Chichibabin reaction. Thus it has been shown that 6-phenylphenanthridine is aminated by sodium amide in liquid ammonia with replacement of the phenyl group by the NH_2 group[226]:



Similarly, 1-methyl-2-phenylbenzimidazole is converted into 2-amino-1-methylbenzimidazole (in 55% yield) on fusion with $NaNH_2$ and into 1-methylbenzimidazolidinone (in 60% yield) on fusion with KOH. This reaction is less characteristic of 2-alkylbenzimidazoles[227,228]. There is little doubt that the phenyl group is eliminated in the form of the carbanion, since benzene is produced in the reaction. It is of interest to note that 2-phenylquinoline and 2-phenylpyridine are aminated at the vacant sites (the 4- and 6-positions respectively). An attempt should be made to discover what result is obtained when these compounds are fused with $NaNH_2$ without a solvent.

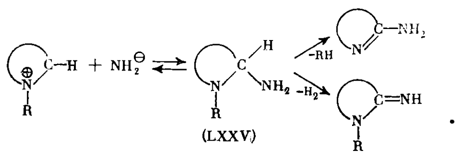
An unusual rearrangement, leading to 2-phenylbenzimidazole, was observed when 2,3-diphenylquinoxaline was acted upon by KNH_2 in liquid ammonia[229]. It has been suggested that the first stage of the process is also the formation of a σ-complex, which then undergoes ring contraction with elimination of one of the phenyl groups as benzylideneamine:



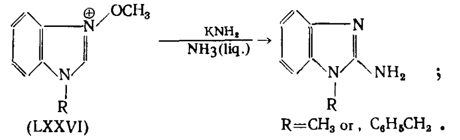
It has been shown recently that the CF$_3$ group in α-trifluoromethyl derivatives of pyridine, quinoline, and isoquinoline is readily substituted by an amino-group on treatment with KNH$_2$ in liquid ammonia[230]. The mechanism of this reaction has been studied[231].

Amination of heteroaromatic cations by metal amides. N-Heteroaromatic cations are known to react with nucleophiles much more readily than neutral molecules, which is frequently used for synthetic purposes. In relation to the Chichibabin reaction, this problem is of fundamental importance in connection with the hypothesis that the pyridine nitrogen atom is coordinated to the Na$^{\oplus}$ ion, as a result of which the heteroatom is partly converted into the onium state. The first data on the interaction of N-heterocyclic cations with metal amides were obtained only recently[232]¶.

If other possible reactions (for example, reactions involving ring opening) are disregarded, adducts of type (LXXV) can be, in principle, stabilised either by the formation of an amine (with elimination of RH) or an imine (with elimination of H$_2$):

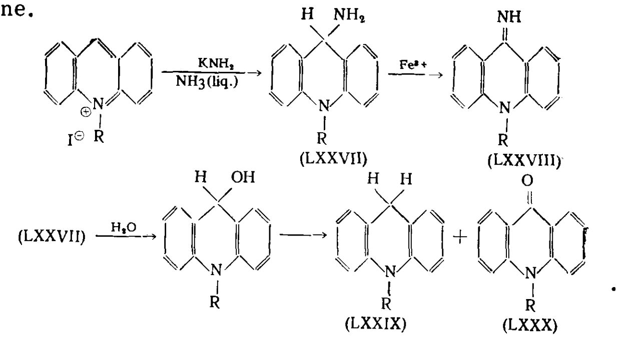


When the first pathway is followed, the N-substituent must be readily eliminated after the addition of the NH$_2^{\ominus}$ anion. It was shown that the N-methoxy-group possesses this ability. Thus, when the salt (LXXVI) is acted upon by KNH$_2$, 1-substituted 2-aminobenzimidazoles are formed in high yields[232]:



The problem of the action of metal amides on the N-oxides of nitrogen-containing heterocycles is very interesting, because the N-oxide group can also activate the addition of a nucleophile and then can be eliminated[184]. Surprisingly, there is so far no information in the literature about the behaviour of N-oxides in relation to metal amides.

The second pathway in the aromatisation of adducts of type (LXXV) constitutes in essence the direct imination reaction. Only one example of such a reaction is known: when the N-methylacridinium cation is acted upon by KNH$_2$ in the presence of Fe(NO$_3$)$_3$, N-methyl-9-acridinone imine (LXXVIII) is formed in 35% yield with approximately the same amount of N-methylacridan (LXXIX) and N-methylacridinone (LXXX).[232] It was not possible to select more effective oxidants in order to increase the yield of the imine.



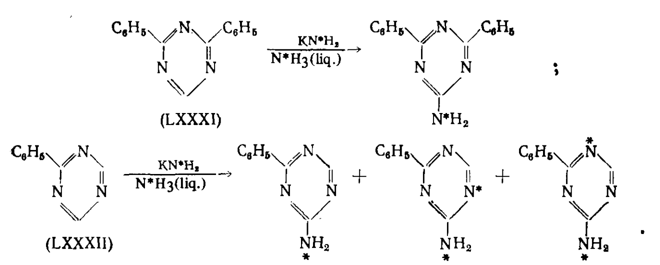
When metal amides act on 1,3-dialkylbenzimidazolium, naphthimidazolium, 4,5-diphenylimidazolium, and perimidinium salts, mainly the corresponding pseudobases or 2-oxo-derivatives are formed[232]. Thus, despite the possibility, in principle, of the amination and imination of N-heterocycles via their quaternary salts, synthetic methods of general importance have not in essence been developed as yet in this field. The difficulties are to a large extent associated with the selection of solvents, because metal amides are soluble only in liquid ammonia and quaternary ammonium salts are soluble in solvents in which experiments with metal amides are impossible.

Thus there have been significant advances in recent years in the study of all the aspects of the Chichibabin reaction. As regards its mechanism, the formation of σ-complexes has been demonstrated†, the phenomenon of

---

¶ Certain N-heteroaromatic cations[164,233] and bases[167] (pteridine) undergo covalent amination in liquid ammonia even in the absence of amide ions.

† Two papers by Dutch chemists, which report the successful amination in liquid ammonia of diphenyl-1,3,5-triazine (LXXXI) and phenyl-1,3-triazine (LXXXII), have been published recently[234,235]. The reaction is slow (up to 72 h) and requires a large excess of KNH$_2$ (by a factor of 40–50), but the yield of the amine is fairly high (72%):



The formation of hydride σ-complexes as intermediates was noted in both cases. According to the authors, (LXXXI) is aminated exclusively via the addition-elimination mechanism, while the amination of (LXXXII) takes place to an extent of 55% via the *ANRORC* mechanism and to an extent of 45% via the ***AE*** mechanism (demonstrated with the aid of tracer atoms). However, we are dealing in essence, not with a new mechanism of the Chichibabin reaction, but with an unusual behaviour of the σ-complex, capable of ring–chain tautomerism, as a result of which the label enters the ring. On the other hand, the addition and elimination stages themselves probably proceed in the usual way.

bifunctional catalysis in the aromatisation stage has been observed, a study has been made of the influence of substituents on the rate of amination, and the important role of the $>$N → NaNH$_2$ coordination as the initial reaction stage has been elucidated; in connection with the last item, the role of the basicity of the heterocycle, the *ortho*-dimethoxy-effect, the difficulty of γ-amination, etc. have been explained. An important factor is the determination of the relative activities of various types of heteroaromatic systems in the Chichibabin reaction. The applications of the reaction have been extended to perimidine derivatives (the first type of heterocyclic systems with an excess of π electrons which are aminated on treatment with NaNH$_2$) and quinazoline derivatives as well as condensed imidazole systems. It has been possible to introduce into the reaction *N*-heteroaromatic cations, to achieve substitutional amination with elimination of carbanions, and to extend significantly the scope of direct hydroxylation and hydrazination of heterocycles.

At the same time many problems still await solution. Thus the role of radical-anions as intermediates in the amination reaction is still not clear; the problem of the rate-limiting stage of the reaction in an aprotic medium requires elucidation. The search for new types of solvents (apart from liquid ammonia), capable of dissolving even to a slight extent sodium amide, is urgently required; the introduction of crown-ethers as additives appears to be an attractive possibility. One may expect new advances in extending the scope of the Chichibabin reaction to the *N*-oxides of nitrogen-containing heterocycles and new types of heteroaromatic systems.

Janovsky σ-Complexes

S.S.Gitis and A.Ya.Kaminskii

The methods of preparation, structure, and properties of the coloured products formed in the Janovsky reaction of aromatic polynitro-compounds with acetone and other ketones in an alkaline medium as well as the analogous complexes with other compounds containing mobile hydrogen atoms are examined and the existing ideas about the mechanism of the Janovsky reaction and further transformations of the σ-complexes are discussed.
The bibliography includes 218 references

I. INTRODUCTION

In 1976 90 years had elapsed since the discovery by the Czech chemist Jaroslav Janovsky of the reaction between *m*-dinitrobenzene and acetone in an alkaline medium. This interaction, which is accompanied by the appearance of a deep colour, has come to be known as the Janovsky colour reaction. It was subsequently extended to various aromatic polynitro-derivatives and ketones. Many investigators have now established that in the majority of cases the colour is due to the formation of σ-complexes—the products of the addition of the nucleophile to the substrate. A number of reviews have been devoted to the structure and properties of anionic σ-complexes[1-6] in which the σ-complexes with acetone and other carbanions are only rarely mentioned. The aim of the present review is to fill the gap in this field. The σ-complexes of aromatic polynitro-compounds with various carbanions can be quite justifiably called "Janovsky σ-complexes". The authors of recently published reviews of the complexes of ketones with polynitro-compounds[7,8] consider mainly the subsequent cyclisation reaction of the Janovsky σ-complexes, which they discovered and investigated (in the present review studies on the structure and properties of the so-called bicyclic complexes are not included).

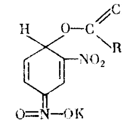
In 1886 Janovsky and Erb[9,10] established that the addition of an alcoholic solution of potassium hydroxide to an acetone solution of *m*-dinitrobenzene (*m*-DNB) causes the appearance of a violet colour. Subsequently, Janovsky[11], Wilgerodt[12], and many other investigators extended this sensitive colour reaction to many ketones and aldehydes[13-19] and also various polynitro-compounds[13,17,20-25]. A series of empirical rules were derived[14,23-25] and it was shown that not only *meta*- but also *ortho*- and *para*-dinitrobenzenes[26] as well as many mononitro-compounds containing an electron-accepting substituent in the *meta*-position with respect to the nitro-group[27,28] tend to undergo the Janovsky reaction.

Apart from alkalis, weak bases such as sodium carbonate or iodide may be used to establish an alkaline medium[29].

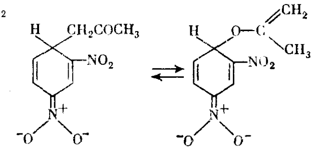
II. INTERACTION OF AROMATIC NITRO-COMPOUNDS WITH ACETONE IN THE PRESENCE OF ALKALI

1. σ-Complexes of *m*-Dinitrobenzene and Its Derivatives

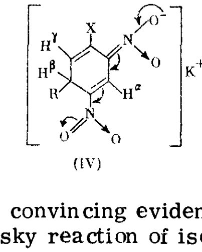
The study of the absorption spectra[23,25,30-36] of solutions of the coloured products of the Janovsky reaction enabled a number of workers[23,25,30] to put forward a hypothesis concerning their structure. Baernstein[30] suggested that the reaction involves the addition of the enolic form of the ketone to the *aci*-form of the nitro-compound with formation of product (I). Canbäck[23,25] believed that real covalent C–C or C–O bonds are not formed in coloured products of types (II) and (III) and that the linkage between *m*-DNB and the acetone residue is one between a dipole and an anion. Subsequently evidence was adduced in support of both the enolic form (III)[21,22,26,36] and the keto-form (II)[14,37,38].



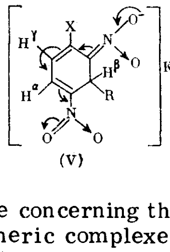
(I)



(II) (III)



(IV)



(V)

The first convincing evidence concerning the formation in the Janovsky reaction of isomeric complexes (IV) and (V), differing in the site of addition of the acetone residue, was presented by Gitis and coworkers[39-41]. Having observed the absence of a colour in the case of 2,4-dinitromesitylene, they investigated a large number of model compounds in which the substituent X prevents the addition of the acetone residue R to the carbon atom linked to the substituent. When the 3- and 5-positions in the molecule of a 1-X-2,4-dinitro-compound are vacant, both complexes, (IV) and (V), are formed in all cases and the absorption spectra show two maxima. If the 3-position is occupied by a substituent, complex (IV) is formed and the spectrum shows only the short-wavelength absorption maximum (λ_{max} = 550–570 nm). The introduction of a substituent into the 5-position leads to the formation of complex (V) only, which gives rise to the long-wavelength absorption maximum (λ_{max} = 600–690 nm). This product is less stable and cannot be detected for certain *m*-DNB derivatives containing an electron-donating substituent X.

The conclusions reached about the structure of the coloured Janovsky complexes[39,40] were confirmed by studies of the influence of substituents on the positions of both absorption maxima (Table 1) using correlation analysis[41-43]. Analogous conclusions concerning the correspondence of the absorption maxima to definite coloured reaction products were arrived at somewhat later by Pollitt and Saunders[43,44], who believe[43] that the hypsochromic shift of the two absorption maxima, caused by the majority of substituents, is due to the displacement of the nitro-groups from the plane of the ring. According to their view[44], direct attack by the HO^- ion on the polynitro-compound is possible together with the formation of Janovsky complexes in dimethylformamide and the assignment of the bands in the absorption spectra is difficult, particularly for electronegative substituents.

Thus, using model compounds, various investigators came close to the determination of the structure of the products of the above reaction with the aid of electronic absorption spectra. The final answers to a number of questions concerning the detailed structure of the coloured complexes were obtained as a result of their isolation in a free form and their investigation by ^{1}H NMR and infrared spectroscopy.

The first attempts[14,15,36,38] to isolate these products were unsuccessful—in all cases the decomposition products of the Janovsky complexes and not the complexes themselves were obtained. The first successful synthesis of this kind was achieved by Akatsuka, who was able to obtain the dark-violet products of the addition of acetone and acetophenone to 3,5-dinitrobenzenesulphonic acid[45] and 3,5-dinitrobenzoic acid[46] in the presence of K_2CO_3. The reaction products were identified by elemental analysis, paper chromatography, and their conversion into *S*-benzylthiuronium salts[47], which made it possible to attribute to them structure (VI):

a) Ethanol (lg ε = 4.076 in tetrahydrofuran); *b*) DMSO; *c*) DMF; *d*) $(n\text{-}C_4H_9)_4\overset{+}{N}$ cation; *e*) it has been shown[40,44] that the formation of a colour in the presence of these substituents is due to the elimination of a hydrogen atom from the amino-group and the formation of the 2,4-dinitrophenylanilinium ion; *f*) double maximum; *g*) acetone + 10% of methanol.

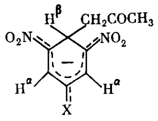
Gitis and Kaminskii[48] developed a spectrophotometrically monitored synthesis of classical Janovsky complexes from *m*-DNB, 1,3,5-trinitrobenzene (TNB), and then 2,4-dinitroanisole[49]. It was established[48,50] that they are σ-complexes of type (VII), where the acetone residue adds in the keto-form to a ring carbon atom with formation of a covalent C–C bond. This is confirmed by the presence in the infrared spectra of the ν(C=O) band at 1710 cm^{-1}, whose position and intensity are close to those of the ν(C=O) band of 2,4-dinitrophenylacetone. Furthermore, a small amount of 2,4-dinitrophenylacetone was detected together with the initial *m*-DNB in the products of the acid decomposition of complex (VII).[50] By treating an acetone solution of *m*-DNB with solid KOH, Kimura et al.[51] also isolated the Janovsky complex (VII), whose structure was demonstrated by elemental analysis and by comparison with the specially prepared potassium salt of 2,4-dinitrophenylacetone (VIII).

Contrary to generally accepted ideas, Ryzhova and coworkers[52–54] suggest that the products of the interaction of *m*-, *o*-, and *p*-dinitrobenzenes, which they obtained in the presence of KOH by reaction with acetone, acetophenone, cyclohexane (cyclohexanone?), and ethyl methyl ketone and which have the 1 : 1 and 1 : 2 compositions, are donor–acceptor complexes of type (IX), formed as a result of the local interaction of the ketone with the nitro-group. However, the evidence presented by these workers[54] in support of structure (IX) cannot be regarded as convincing; it conflicts with all the available data concerning the structure of Janovsky complexes.

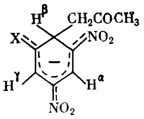
The ^{1}H NMR spectrum of a Janovsky σ-complex of *m*-DNB was studied for the first time by Fyfe and Foster[55], who obtained this complex by adding solid sodium methoxide to a solution of *m*-DNB in a 1 : 1 mixture of acetone and dimethyl sulphoxide (DMSO). The structure of the σ-complex (VII) was confirmed by its characteristic chemical shifts and spin–spin coupling constants: $\delta = 8.32$ (H^α), 4.17 (H^β), 5.38 (H^γ), and 6.6 p.p.m. (H^ω); $J_{\alpha,\omega} = 1.9$ and $J_{\gamma,\omega} = 10.2$ Hz. The $H^{\epsilon(1)}$ and $H^{\epsilon(2)}$ methylene protons are non-equivalent owing to the lack of symmetry of the $C_{(1)}$ atom. As a result of the spin–spin coupling with H^γ, $H^{\epsilon(1)}$ and $H^{\epsilon(2)}$, the signal due to the H^β nucleus is therefore a quintet; $J_{\beta,\gamma} = J_{\beta,\epsilon(1)} = 5.0$ and $J_{\beta,\epsilon(2)} = 10.0$ Hz. This assignment of the signals is confirmed by the ^{1}H NMR spectrum of the analogous complex obtained from hexadeuteroacetone. In the reaction solutions investigated no isomers of type (V, X = H) were detected. The σ-complex (VII) was isolated in a free form[56] by treating an acetone solution of *m*-DNB with potassium hydroxide and subsequent precipitation with benzene. The infrared spectrum of the complex showed absorption bands at 1719 cm^{-1} (C=O), 1290 cm^{-1} (*sym*.NO_2^-), and 1610 cm^{-1} (C=C).

The electrochemical reduction of the σ-complex (VII) at the potential of the first reversible reduction wave (~ 1.0 V) in acetone in the presence of $(n\text{-}Bu)_4NClO_4$ as the supporting electrolyte made it possible to obtain for the first time[57] its radical-dianion, which was detected by ESR. The large difference between the splittings due to the ^{14}N nuclei confirms the non-equivalence of the nitro-groups and the quinonoid structure of the complex.

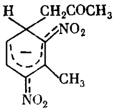
The structure and properties of the σ-complexes of acetone with various *m*-DNB derivatives have been studied in detail by ^{1}H NMR and infrared spectroscopy. Initially these complexes were investigated in reaction solutions and then most of them were isolated in a free form. Thus Foreman and Foster[58] showed that, when acetone solutions of 1-X-3,5-dinitrobenzenes (X = COOMe and COO$^-$) are treated with triethylamine or sodium methoxide, the σ-complex (X) is formed initially, but after several days is converted into a 7 : 1 equilibrium mixture of isomers (X) and (XI):



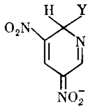
(X)



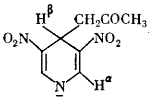
(XI)



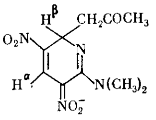
(XII)



(XIII)



(XIV)



(XV)

Y = OCH_3 (a) or
CH_2COCH_3 (b) ,

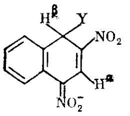
This is consistent with the results obtained for X = CF_3 and CN.[59] The exchange interaction of σ-complexes containing other substituents with the free radicals formed in the reaction mixture leads to a broadening of the signal and, when diethylamine is used[59], the exchange altogether precludes the measurement of the ^{1}H NMR spectrum.

Such broadening does not occur in the study of the ^{1}H NMR spectra of complexes isolated in a free form. Because of this, Gitis and coworkers were able to investigate a large number of σ-complexes of *m*-DNB derivatives, obtained by the spectrophotometrically monitored synthesis which they developed previously[48]. Analysis of the electronic, ^{1}H NMR, and infrared spectra of the σ-complexes of a series of 1-X-3,5-dinitrobenzenes (X = Me, OMe, COOEt, or CF_3 [60,61] and X = COOMe, $CONC_5H_{10}$, $CONMe_2$, or $CONH_2$ [62]) also confirmed (Table 2) that they are a mixture of isomers (X) and (XI), with the latter predominating; the stability of the complexes increases with enhancement of the electron-accepting properties of the substituent. The σ-complexes of a series of 1-alkyl-2,4-dinitrobenzenes[63–65] (alkyl = Me, Et, iso-Pr, or t-Bu) and a series of 1-X-2,4-dinitrobenzenes[60,65] (X = OMe, COOMe, SEt, or SCN) were obtained by a similar procedure. In the latter case the formation of two isomeric complexes of types (IV) and (V), differing in the site of addition of the acetone residue (R = CH_2COCH_3), established previously on the basis of electronic absorption spectra[39,40], was finally demonstrated with the aid of ^{1}H NMR and infrared spectra. Complex (IV) is more stable owing to the presence in the *para*-position with respect to the rehybridised carbon atom of a powerful electron acceptor (the nitro-group). The type (V) isomer with X = OMe is extremely unstable and, when X = H or alkyl, it cannot be obtained in a free form at all. Enhancement of the electron-accepting properties of the substituent increases the stability of this complex; for X = COOMe, it was isolated[60] in a mixture with isomer (IV). It is noteworthy that, for sulphur-containing substituents (X = SCN or SEt), the opposite behaviour is observed: isomer (V) becomes more stable than isomer (IV).

It has recently been possible to isolate in a free form[66] extremely labile σ-complexes of 1-halogeno-2,4-dinitrobenzenes (halogen = F, Cl, Br, or I), which, according to ^{1}H NMR, infrared, and electronic spectroscopic data, are also mixtures of isomers of types (V) and (IV) with the latter predominating (with the exception of the fluorine-containing complex). The synthesis of a series of σ-complexes from *m*-DNB derivatives showed that the spectra contain new maxima in the near ultraviolet in addition to the absorption maxima in the visible region known previously[40–42] (Table 1). On the basis of the successful[67] chromatographic separation of isomers (X) and (XI) with X = COOEt and the resolution of the overlapping bands into their components, the short-wavelength maximum in the ultraviolet region was assigned to isomers of type (V) (λ_{max} between 338 and 350 nm for different substituents X) and type (X) (λ_{max} = 360–408 nm), while the long-wavelength maximum was assigned to isomers of type (IV) (λ_{max} = 354–396 nm) and type (XI) (λ_{max} = 360–424 nm) (Table 1). The resolution of the bands using the characteristics of the complexes isolated made it possible to observe[68] in the spectra of the reaction solutions an absorption maximum for 2,4-dinitroanisole (λ_{max} = 625 nm) corresponding to the unstable isomer (V, X = OMe) and a maximum at 515 nm for 2,6-dinitrotoluene corresponding to a product of the transformation of the σ-complex (XII).

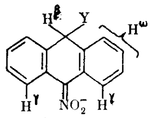
A number of studies[58–68] showed that the presence of electron-accepting groups in the molecule of the *m*-DNB derivative increases the stability and hence the yield of the σ-complexes formed. Both isomers of the σ-complexes derived from 1-X-3,5-dinitrobenzenes, (X) and (XI), are much more stable than the corresponding isomers (V) and (IV) obtained from 1-X-2,4-dinitrobenzenes. The σ-complexes of 3,5-dinitropyridine with acetone[69], formed as a mixture of isomers (XIIIb) and (XIV) with the latter predominating (λ_{max} = 519 nm) following the addition of acetone to a solution of the alkoxide complex (XIIIa) in DMSO, are still more stable. On the other hand, solvolysis by acetone of the methoxide complex of 2-dimethylamino-3,5-dinitropyridine results in the formation[69] of a single acetone σ-complex, probably having structure (XV), with characteristic signals at δ = 8.14 and 5.1 p.p.m. for H^{α} and H^{β} respectively[69].

Stabilisation of the same type owing to the electron-accepting properties of condensed aromatic rings enabled Foster and coworkers[70] to obtain fairly readily the σ-complexes of 1,3-dinitronaphthalene (XVIa) and 9-nitroanthracene (XVIIa) by treating their acetone solutions with triethylamine. The structures of these σ-complexes were demonstrated on the basis of the ^{1}H NMR spectra of their solutions [(XVIa): δH^{α} = 8.76 p.p.m., δH^{β} = 4.81 p.p.m., $J_{\alpha,\beta} \simeq$ 1 Hz; (XVIIa): δH^{β} = 4.29 p.p.m., δH^{γ} = 8.72 p.p.m., δH^{ω} = 7.16 p.p.m.].



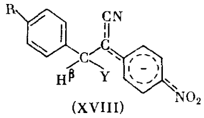
(XVI)

Y = CH$_2$COCH$_3$ (a) or CH$_2$NO$_2$ (b);



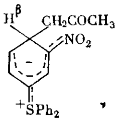
(XVII)

Y = CH$_2$COCH$_3$ (a) or CH(CN)$_2$ (b);



(XVIII)

Y = CH$_2$COCH$_3$ (a) or OCH$_3$ (b)



(XIX)

When acetone solutions of 4′-substituted α-cyano-4-nitrostilbenes (R = NO$_2$ or Me) were treated with sodium methoxide, the corresponding σ-complexes (XVIII) were obtained[71]. The observed absorption maxima (λ_1 = 543 nm, λ_2 = 576 nm) correspond to products of the addition of the acetone residue to the double bond (XVIIIa), which in the authors view are formed from the alkoxide addition products (XVIIIb). The ^{1}H NMR spectra of the reaction solutions indicate the presence of a single adduct of type (XVIII) regardless of the *cis*- or *trans*-structure of the initial 4-nitrostilbene.

Table 2. ^{1}H NMR spectra of the Janovsky σ-complexes obtained from *m*-DNB and its derivatives (R = CH$_2$COCH$_3$) in [D$_6$] dimethyl sulphoxide.

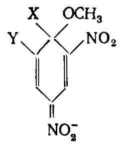
a) usually δ(CH$_2$) = 3.10–3.20 p.p.m., δ(CH$_3$) = 2.05–2.15 p.p.m., and $J_{\beta CH_2} \simeq$ 5.0 Hz for the added acetone residue; *b*) δH^{ω} = 6.57 p.p.m., $J_{\alpha,\omega}$ = 1.9 Hz, $J_{\gamma,\omega}$ = 10.2 Hz, and $J_{\beta,\omega}$ = 1.0 Hz; *c*) in a 1 : 1 acetone–DMSO mixture; *d*) in DMSO; *e*) all the signals are the same for the (n-C$_4$H$_9$)$\overset{+}{N}$ K$^+$ cations; *f*) complexes with acetonitrile (R = CH$_2$CN), λ_{max}(CH$_3$CN) = 590 nm (IV) and 618 nm (V); *g*) δ(CH$_2$) = 2.37–2.50 p.p.m., δ(CH$_3$) = 2.02–2.14 p.p.m., J_{β,CH_2} = 6.0–4.0 Hz (XI), and J_{β,CH_2} = 5.6–5.0 Hz (X) for the added acetone residue; *h*) in [D$_6$] acetone; *i*) signals due to the C$_2$H$_5$ group in isomers [δ(CH$_2$) = 4.13 p.p.m. and δ(CH$_3$) = 1.21 p.p.m. for (XI); δ(CH$_2$) = 4.11 p.p.m. and δ(CH$_3$) = 1.19 p.p.m. for (X)]; *j*) complex with C$_2$H$_5$COC$_2$H$_5$, $J_{\beta,CH_2} \simeq$ 4.0 Hz; *k*) complexes with cyclohexanone; *l*) J_{β,CH_2} = 1.5 Hz (XI) and 7.0 Hz (X), λ_{max} = 640 nm (X) and 540 nm (XI); *m*) J_{β,CH_2} = 6.5–6.0 Hz, λ_{max} = 625 nm (X); *n*) J_{β,CH_2} = 2.0 Hz, λ_{max} = 550 nm.

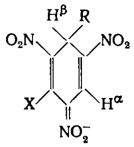
The formation of Janovsky σ-complexes from mononitrobenzenes was demonstrated by Reutov and coworkers[72] who obtained a solution of the σ-complex (XIX) (λ_{max} = 490 nm; lg $\epsilon \simeq 4.25$) by adding an alcoholic solution of KOH to an acetone solution of *m*-nitrophenyldiphenylsulphonium fluoroborate. Its structure was demonstrated with the aid of ^{1}H NMR spectra (δH^β = 5.80 p.p.m., δH_{Ar} = 8.0–7.4 p.p.m.) and also by synthesising the same product by the reaction of the initial substrate with $CH_3COCH_2.HgCl$ in the presence of Bu_4NI.

2. Janovsky σ-Complexes of 1,3,5-Trinitrobenzene and Its Derivatives

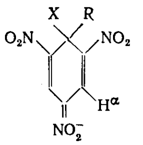
In studies of the structure of the coloured products of the interaction of *sym*-TNB and its derivatives with acetone in an alkaline medium many workers compared their absorption spectra with those of Meisenheimer σ-complexes, for which a structure of type (XX, Y = NO_2, X = OMe) was regarded as generally accepted[1-6]:



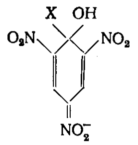
(XX)



(XXI)



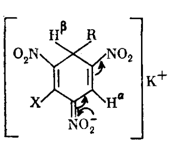
(XXII)



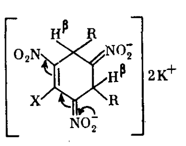
(XXIII)

Thus Kimura[73] suggested that the bands observed for 1-X-2,4,6-trinitrobenzenes in an acetone–methanol mixture in the presence of alkali (λ_1 = 450 nm and λ_2 = 520–530 nm) are due to the products (XXI)–(XXIII) (R is the acetone residue). When X = H, Cl, Me, OMe, OEt, or NEt_2, structure (XXI) is characteristic of the complexes and, when X = OPh, COOH, or COOEt, the latter has structure (XXII). Having established the similarity of the absorption spectra of picryl chloride[74,75] and tetryl in water, methanol, and acetone in the presence of alkali, Abe concluded[75-77] that in both cases the colour is due to product [XXIII, X = Cl or $N(NO_2)Me$]. Pollitt and Saunders[44] suggested that, of the three bands (462, 570, and 518 nm) observed for *sym*-TNB, the first two correspond to a 1 : 1 complex and the third is due to side products. Spectroscopic determination of the composition of the complex of 2,4,6-trinitrobenzoic acid (TH) with acetone (HA) (1 : 2) enabled Neufer et al.[78] to ascribe to it the structure $TH.A^- + H_2A^+$.

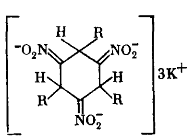
Detailed spectrophotometric studies[39,79] showed that, of the three structures (XXIV), (XXV), and (XXVI) proposed[39] for the products derived from *sym*-TNB, only one is actually formed, namely (XXIV, X = H). It is fairly stable and has two maxima in the visible region (at 462 and 568 nm) with an intensity ratio of 2 : 1. On the other hand, in the presence of a large excess of alkali[80] additional maxima appear at 430 and 518 nm, corresponding to the formation of the product of the addition of a hydroxide ion to a molecule of the trinitro-derivative (XXIII, X = H). When potassium methoxide is used as the alkaline agent, the complex (XX, X = H, Y = NO_2) is formed together with (XXI, X = H).



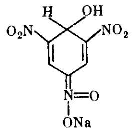
(XXIV)



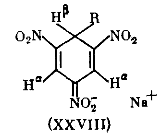
(XXV)



(XXVI)



(XXVII)



(XXVIII)

R = $CH_2^\epsilon COCH_3^\eta$ (a) or $CH_2COC_6H_5$ (b)

Owing to the greater stability of the σ-complexes obtained from *sym*-TNB compared with the complexes of *m*-DNB, studies on their synthesis have been more successful. Thus, by allowing an acetone solution of *sym*-TNB to react with NaOH, Giua[81] isolated a red-brown crystalline product. The author believed that in this case an NaOH molecule adds on and the compound has the structure (XXVII). However, the data available at present suggest that in reality he isolated for the first time the Janovsky σ-complex of *sym*-TNB (XXVIIIa). By allowing solid sodium bicarbonate to react with an acetone solution of *sym*-TNB, Kimura[82] obtained a σ-complex, to which he attributed the structure (XXVIIIa) on the basis of analysis and determination of the molecular weight. He obtained the analogous acetophenone complex (XXVIIIb) from an alcoholic solution[51]. By carrying out the reaction in an indifferent solvent, Gitis[26] obtained products of the addition of two and three molecules of the sodium derivative of acetone to di- and tri-nitro-compounds in the form of amorphous brown powders, which are rapidly converted into a tar in air. By treating acetone solutions of *sym*-TNB and some of its derivatives with concentrated aqueous ammonia and subsequently evaporating the solvent *in vacuo*, Abe[75] isolated dark-red crystalline substances and suggested that they are products of the addition of ammonium hydroxide to polynitro-compounds (XXIII). A stable σ-complex of *sym*-TNB with acetone was isolated as a result of a spectrophotometrically monitored synthesis[48]; it was shown[48,50] that it has the structure (XXVIIIa), in which the acetone residue in the keto-form is attached to a ring carbon atom.

Foster and Fyfe[83] established that, when the methoxide complex of *sym*-TNB (XX, X = H, Y = NO_2) is dissolved in acetone, the methoxy-group is replaced by the conjugate base of the solvent with formation of the corresponding Janovsky complex (XXVIIIa). The signal of the H^β proton in its ^{1}H NMR spectrum at 5.18 p.p.m. is split into a triplet (J = 9 Hz) owing to the interaction with neighbouring methylene protons; the signal due to the ring protons H^α at 8.47 p.p.m. consists of a doublet (J = 1 Hz). A similar substitution occurs when an acetone solution of *sym*-TNB is acted upon by sodium methoxide. If the substitution is carried out in hexadeuteroacetone, a broad unresolved band at 5.18 p.p.m. is observed for H^β, which indicates the formation of the σ-complex (XXVIII, R = CD_2COCD_3). When trimethyl- or triethyl-amine was added to an acetone solution of *sym*-TNB, the σ-complex (XXVIIIa) was isolated in a free state[84]. This made it possible to assign the signals of the attached acetone residue (δH^ϵ = 2.65 p.p.m., J = 5 Hz; δH^η = 2.15 p.p.m.) and the cation $H\overset{+}{N}Me_3$ (δ = 2.85 p.p.m.) in the ^{1}H NMR spectra. The positions of the signals in the ^{1}H NMR spectrum and of the absorption maxima in the electronic spectra (λ_1 = 557–572 nm and λ_2 = 460–465 nm) as well as their intensities change somewhat as a function of the nature of the cation (Table 3). Similarly the interaction of *sym*-TNB with diethylamine and other secondary amines[85] leads to the formation of σ-complexes of type (**XXVIII**) with the $H_2\overset{+}{N}R_2$ cation. However, the authors showed that in this case the reaction is accompanied by the formation of a whole series of side and intermediate products.

In the reaction of the organomercury derivatives of acetone $(CH_3COCH_2)_2Hg$ and $CH_3COCH_2.HgX$ with *sym*-TNB in the presence of NaI in DMSO Beletskaya et al.[86] detected by ^{1}H NMR the formation of the σ-complex (**XXVIIIa**) in a high yield via the mechanism

$$CH_3COCH_2HgX + sym\text{-}TNB + 2NaI \rightarrow (XXVIIIa) + HgIX \cdot NaI \ . \qquad (1)$$

The resulting complex is stable in solution for a long time and its ^{1}H NMR spectra agree with those described in the literature[83,84]. The σ-complex (**XXVIIIa**) was obtained by a similar procedure as a result of the interaction of the organotin derivative of acetone $CH_3COCH_2.Sn(CH_3)_3$ with *sym*-TNB in DMSO, as shown by the ^{1}H NMR spectrum[88].

In the study of the structure of Janovsky σ-complexes obtained from *sym*-TNB derivatives one of the fundamental controversial problems is the site of addition of the acetone residue: to an unsubstituted ring carbon atom in polynitrobenzene or to a carbon atom attached to a substituent. Thus, as a result of the study of the interaction of substituted 1-X-2,4,6-trinitrobenzenes (X = OEt, OPh, Cl, or NMe_2) with acetone in the presence of amines, Foster et al.[70] showed that, in contrast to Kimura's ideas[73], the acetone residue adds to an unsubstituted ring carbon atom with formation of compound (**XXI**). According to their data, an acetone solution of picryl chloride and triethylamine gives rise to an ^{1}H NMR spectrum corresponding to structure (**XXI**, X = Cl) and not (**XXII**, X = Cl) (triplet with δ = 5.2 p.p.m. and J = 6 Hz).

Kimura et al.[89] isolated by thin-layer chromatography the products formed when acetone solutions of 2,4,6-trinitroanisole and phenyl 2,4,6-trinitrophenyl ether are acted upon by sodium methoxide. The structure of the σ-complex (**XXI**, X = OCH_3) was demonstrated by ^{1}H NMR (Table 3) and by the fact that its decomposition in an acid medium yielded 3-acetonyl-2,4,6-trinitroanisole. The same workers[90] investigated analogous σ-complexes of picryl chloride and sodium 2,4,6-trinitrobenzenesulphonate. They believe that the Janovsky reaction results in both cases in the formation of the σ-complexes (**XXI**, X = Cl or $NaSO_3$) and, when X = $NaSO_3$, also a small amount of (**XXII**).

The problem of the site of addition of the acetone residue to 1-X-2,4,6-trinitrobenzenes was finally solved in a series of studies[91,92]. It was shown[90] that, when the σ-complex of *sym*-TNB with KOH (XXIII, X = H) is acted upon by acetone, the HO^- ion is displaced by the acetone residue. This is indicated by the change in the electronic spectra [the maxima at 440 and 520 nm are converted into the maxima at 470 and 574 nm corresponding to the σ-complex (**XXI**)] and by the identification of complex (**XXI**) by ^{1}H NMR and infrared spectra. The products of the addition of acetone to 1-X-2,4,6-trinitrobenzenes (X = Me, OMe, COOH, COOMe, COO^-, Cl, or SMe) were isolated in a free state[92] and their structure, like that of the σ-complexes (**XXI**), was confirmed by elemental analysis, ^{1}H NMR, and infrared spectra (Table 3). Thus the acetone residue always adds to an unsubstituted carbon atom regardless of the electron-donating or electron-accepting nature of the substituent. According to the authors[92], the steric hindrance to the incorporation in the ring of the fairly bulky CH_2COCH_3 substituent plays the main role here. The C–CH_2 bond formed in this process is stronger than the C–O bond in the Meisenheimer complexes (**XX**), which prevents the isomerisation of the Janovsky σ-complexes (**XXI**) to complexes (**XXII**). Both these factors are more significant than the stabilisation of the σ-complex (**XX**) or (**XXII**) caused by the energy gain as a result of the weakening of the steric interactions of the substituent X with neighbouring nitro-groups in the course of the formation of the complex. Even in the presence of the electron-accepting substituent COOMe the appearance of an additional positive charge on the $C_{(1)}$ atom does not alter the general features of the addition process. As a result, when *sym*-TNB derivatives interact with acetone, the formation of σ-complexes of type (**XXI**) becomes preferred both kinetically and thermodynamically.

2,4,6-Trinitrobenzoic acid and its potassium salt undergo extremely rapid decarboxylation and it is possible to obtain[92] only the σ-complex (XXVIIIa) of *sym*-TNB and acetone. The study of the ultraviolet spectra of all the σ-complexes in methanol revealed a third maximum in the range 240–260 nm, which probably corresponds to the $\pi-\pi^*$ charge transfer within the cyclohexadiene system (Table 3).

Recent studies[93] of the infrared spectra of the σ-complexes of polynitro-compounds with acetone and alkoxides permitted an unambiguous assignment of the most intense bands in the range 1100–1300 cm^{-1} to the symmetrical stretching vibrations of the negatively charged nitro-group $[\nu_s(NO_2^-)]$. Moderately intense bands near 1500 cm^{-1} apparently correspond to the $\nu_{as}(NO_2^-)$ vibrations. Conclusions concerning the assignment of these bands to the ν_s and ν_{as} frequencies of the NO_2^- group have been confirmed[94] by polarisation Raman spectra.

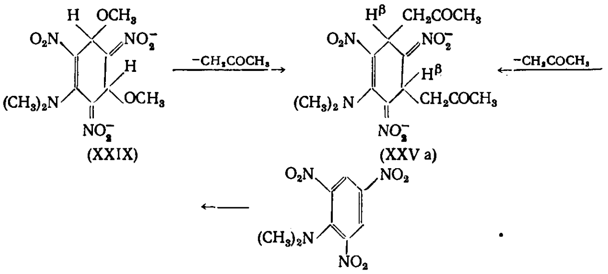
It has also been shown[95] that the Janovsky σ-complexes as well as the Meisenheimer complexes (XX) exhibit a fluorescence at reduced temperatures (77 K) characterised by a single long-wavelength band in the ranges 15 700–16 400 cm^{-1} [compound (XXVIIIa)] and 15 630–17 010 cm^{-1} [compound (VII)]; the intensity of the luminescence of the *sym*-TNB complex (XXVIIIa) is much higher and the spectrum of its polycrystalline form shows a splitting of the band into the two maxima.

The structure of the Janovsky σ-complex of *sym*-TNB (XXVIIIa) has also been demonstrated by X-ray diffraction studies[96], the results of which are presented in the Figure. It was shown that the ring is non-planar–the $C_{(1)}$ and $C_{(4)}$ atoms deviate from the plane of the $C_{(2)}$, $C_{(3)}$, $C_{(5)}$, and $C_{(6)}$ atoms by 0.30 and 0.11 Å respectively and are in the *cis*-position. The $C_{(1)}-C_{(2)}$ and $C_{(1)}-C_{(6)}$ bonds are single (1.54 Å), while the $C_{(2)}-C_{(3)}$ and $C_{(5)}-C_{(6)}$ bonds are predominantly double (see Figure), which demonstrates the overall quinonoid structure of this salt. The acetone residue is located in the plane perpendicular to that of the quinonoid part of the molecule. It is therefore more accurate to represent Janovsky σ-complexes by quinonoid structures of type (XXVIII) and (VII), despite the fact that in the majority of latest studies structures of type (XI) and (X) are quoted to take into account the delocalisation of the charge of the anion between the nitro-groups and the ring.

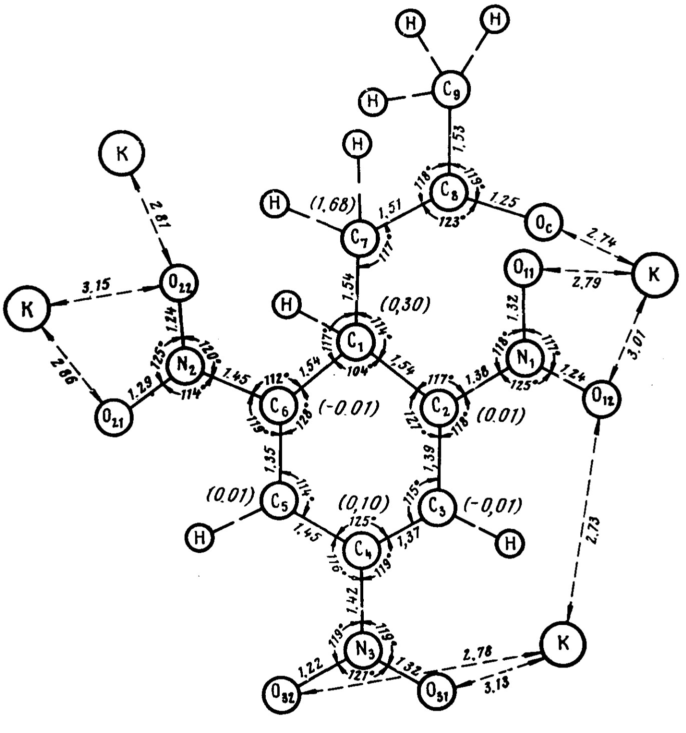
Thus application of the ^{1}H NMR method combined with electronic and infrared spectroscopic data as well as X-ray diffraction analysis finally established the structure of Janovsky complexes. They are products of the addition of acetone in the keto-form to an unsubstituted carbon atom of an aromatic ring with formation of a C–C bond; structures (IV), (V), (X), and (XI) are formed from *m*-DNB and its derivatives, while *sym*-TNB gives rise to structures (XXIV) and (XXVIII). The data obtained at the present time for the electronic and ^{1}H NMR spectra of these complexes are presented in Tables 1–3.

3. Multicharged Janovsky Complexes

In many cases the interaction of polynitro-compounds with acetone in an alkaline medium has been found to entail the formation of doubly and triply charged complexes, either as a result of the addition to the substrate of several acetone residues or as a result of the ionisation of substituents in the aromatic nitro-compound. Thus Foster et al. reported[70] that, when the σ-complex (XXIX) is dissolved in acetone, it is solvolysed with formation of the complex (XXVa, X = NMe$_2$), which is also formed when an acetone solution of *N,N*-dimethylpicramide is treated with a large excess of triethylamine. The product was identified by ^{1}H NMR (δH^β = 4.7 p.p.m.).



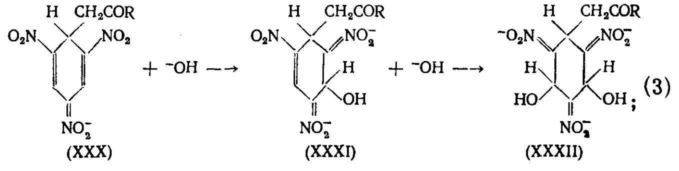
(2)



The geometry of the molecule of the σ-complex of *sym*-TNB with acetone (XXVIIIa). The distances (in Å) between the atoms of the anion and the $C_2C_3C_5C_6$ plane are given in brackets.

A dianionic complex of *sym*-TNB and acetone of type (XXV) was also obtained[97] in the presence of an excess of tetraethylammonium hydroxide. Its structure was demonstrated by electronic (λ_{max} = 516 nm) and infrared spectra [ν(C=O) = 1700 cm^{-1}, $\nu(NO_2^-)$ = 1110 cm^{-1}] as well as the splitting constants for the ESR spectrum of the radical-trianion obtained by its electrochemical reduction. It is suggested that this product has a non-planar structure.

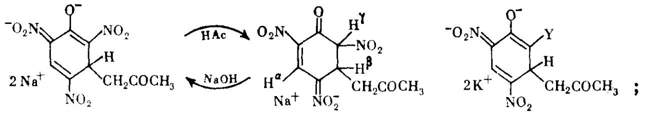
The first doubly charged mono-complexes of type (VI) were isolated a long time ago by Akatsuka[45,46]. In a series of studies[98-100] involving the investigation of the absorption spectra and of the structures of the acid decomposition products, a general mechanism was proposed for the reactions occurring following the addition of NaOH to solutions of the σ-complexes (XXXa) in water[98] and (XXXb) in dimethylformamide (DMF).[99]



(XXX) (XXXI) (XXXII) (3)

$R = CH_3$ (a) or C_6H_5 (b).

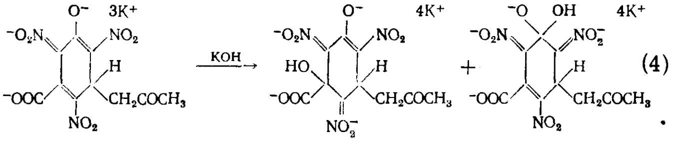
An analogous mechanism has been proposed for the conversion of the σ-complex of *sym*-TNB and cyclohexanone and a dianionic complex of type (XXXI) was isolated in a free form. The σ-complex (XXIVa) was subsequently obtained[100] (and identified) in similar reactions with picric acid. The complex is converted in an acid medium[101] into the complex (XXXIII), from which it can be regenerated by treatment with an excess of alkali.



(XXIVa) (XXXIII) (XXXIV)

$Y = COOCH_3$ (a) or COO^- (b).

On treating an acetone solution of 3,5-dinitrosalicylic acid with an alcoholic solution of KOH, Kovar[102-104] isolated the product (XXXIVb); the absorption spectrum of this complex is analogous to that of the corresponding methyl ester (XXXIVa), which was identified by ^{1}H NMR. The structure of the coloured crystalline σ-complexes (XXIVa) and (XXXVa), obtained similarly from picric and 3-hydroxy-2,4,6-trinitrobenzoic acids, was demonstrated by their chemical reactions and ^{1}H NMR. When one mole of 3-hydroxy-2,4,6-trinitrobenzoic acid is mixed with three moles of KOH in acetone, the σ-complex (XXXV) is formed; it was isolated in a free state and identified on the basis of its ^{1}H NMR and infrared spectra[104,105]. This product is converted into quadruply charged complexes (XXXVI) and (XXXVII) via the mechanism

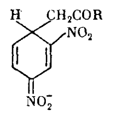


(XXXV) (XXXVI) (XXXVII) (4)

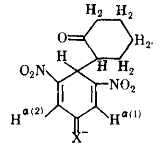
III. PRODUCTS OF THE ADDITION OF OTHER COMPOUNDS WITH MOBILE HYDROGEN ATOMS TO AROMATIC POLYNITRO-DERIVATIVES

By allowing *m*-DNB to interact with acetophenone in an alkaline medium, King and Newall[106] obtained a labile coloured product, whose decomposition with acid yields 2,4-dinitrobenzyl phenyl ketone, which indicates the addition of acetophenone in the keto-form to *m*-DNB. Pollitt and Saunders[44] showed that the characteristics of the formation of σ-complexes of types (IV) and (V) and of the blocking effect of substituents observed for acetone are largely retained in the reactions of *m*-DNB and its derivatives with cyclohexanone, diethyl malonate, cyclopentadiene, and di-n-butyl phosphite in DMF in the presence of NaOH. The relative yield of complexes of type (IV) then increases for cyclopentanone and cyclohexanone, while the reaction with di-n-butyl phosphite yields mainly complex (V). The σ-complexes of *m*-DNB and the ketones CH_3COR ($R = Me$, Et, n-Pr, n-Bu, iso-Bu, n-C_5H_{11}, and n-C_7H_{15}), obtained by Bronshtein et al.,[107] have been shown by correlation analysis of the oscillator strengths to be the addition products (XXXVIII). When ethyl methyl ketone was allowed to interact with *m*-DNB, 2,4-dinitroanisole, and *sym*-TNB in the presence of KOH, the σ-complexes (XXXVIII, $R = Et$), (IV, $X = OMe$, $R = CH_2COC_2H_5$), and (XXX, $R = Et$), in which the ketone residue is attached to an unsubstituted ring carbon atom, were isolated in a free state[108]. It has been shown by ^{1}H NMR[59] that the reaction of 3,5-dinitrobenzonitrile with diethyl ketone in DMSO in the presence of triethylamine leads to the formation of two isomeric σ-complexes of types (X) and (XI, $X = CN$) (Table 2).

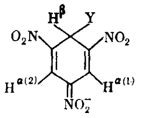
The products of the interaction of *sym*-TNB with various ketones have now been more fully investigated. The products of the addition of cyclohexanone to *sym*-TNB have been isolated[109] in the form of alkali and alkaline earth metal salts, for which the structure (XXXIX, $X = NO_2$) has been postulated.



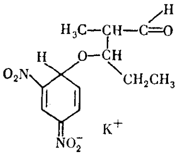
(XXXVIII)



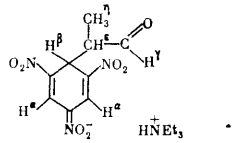
(XXXIX)



(XL)



(XLI)



(XLII)

Foster and Fyfe[84] investigated for the first time by ^{1}H NMR the products, obtained in a free form, of the interaction of *sym*-TNB with ethyl methyl ketone, diethyl ketone, and isopropyl methyl ketone in the presence of triethylamine. Elemental analysis and the electronic spectra correspond in all cases to type (XL) products of the addition of one ketone molecule to *sym*-TNB. The positions of the signals in the ^{1}H NMR spectrum, their relative intensities, and the spin–spin interaction constants in Table 4 established that compound (XLa) is formed in the case of diethyl ketone; only compound (XLb) has been isolated for isopropyl methyl ketone, while the reaction with ethyl methyl ketone results in the formation of both isomers, (XLc) and (XLd), in proportions of 4 : 1. In the study of acetonylacetone the authors were unable to isolate the σ-complex in a free form, while the study of ^{1}H NMR spectra in solution showed that the reaction entails the formation of a mixture of two isomers, (XLe) and (XLf), in proportions of 3 : 1. The splitting of the signals due to the $H^{\alpha(1)}$ and $H^{\alpha(2)}$ protons, caused by the asymmetry of the $C_{(1)}$ ring atom, has been observed[110] in the ^1H NMR spectra of a number of σ-complexes of *sym*-TNB with bulky substituents Y[compound (XL, g–j)] (Table 4). The authors believe that the temperature variation of the splitting confirms the view that it is due to the hindered rotation about the C–C bond between the rings in σ-complexes of type (XL). An analogous phenomenon has recently been observed[111] for the σ-complexes (XXXIX) of 1-X-3,5-dinitrobenzenes with cyclohexanone (Table 2).

Table 4. Electronic and ^1H NMR spectra of the σ-complexes of 1,3,5-trinitrobenzene with various nucleophiles containing a mobile hydrogen atom.

a) M = methanol, DMSO = dimethyl sulphoxide, Al = acetonitrile, E = ethanol, An = acetone, P = pyridine, D = dioxan; b) $J_{\alpha,P}$ = 21 Hz, $\delta(CH_2)$ = 4.5 p.p.m., $\delta(CH_3)$ = 1.53 p.p.m.; c) X = $N(CH_3)_2$; d) inflection; e) $\delta(CH_3)$ = 1.14 p.p.m.; f) X = OCH_3, δH = 3.4 p.p.m.; δ = 3.8(2H), 2.2(3H), and 1.1(3H) for R; g) R = H$^\gamma$, δH$^\gamma$ = 5.38 p.p.m., δH$^\omega$ = 6.59 p.p.m.; $J_{\omega,\gamma}$ = 10.2 Hz, $J_{\alpha,\gamma}$ = 1.9 Hz, $J_{\beta,\omega}$ = 5.0 Hz; h) λ_3 = 262 nm, lgε_3 = 4.18, $\delta[\overset{+}{N}(CH_3)_4]$ = 3.12 p.p.m.; i) $\delta(OCH_3)$ = 3.76 p.p.m.; j) λ_3 = 256 nm, lgε = 4.04, $\delta(CH_3)$ = 2.58 p.p.m.; k) $J_{\varepsilon,\gamma}$ = 6.6 Hz, $J_{\varepsilon,\omega}$ = 0.8 Hz, $J_{\gamma,\omega}$ = 1.18 Hz; l) $J_{\varepsilon,\gamma}$ = 6.4 Hz, $J_{\varepsilon,\omega}$ = 1.1 Hz, $J_{\gamma,\omega}$ = 5.3 Hz.

Thus the Janovsky reaction with various ketones exhibits the characteristics described above for acetone. Furthermore, in many instances isomers are formed due to the presence of several reaction centres in complex ketones. The non-equivalence of the $H^{\alpha(1)}$ and $H^{\alpha(2)}$ protons has been observed for ketones with bulky substituents.

Very much less attention has been devoted to the interaction of polynitro-compounds with aldehydes. A spectrophotometric study of this reaction for a series of aldehydes showed[112] that the first stage is aldol condensation of the aldehydes, after which the polynitro-compound combines with the aldol alkoxide to form a σ-complex of type (XLI). Having isolated the product of the interaction of propionaldehyde with *m*-DNB, Gitis and Kaminskii[113] concluded somewhat later that this involves the addition of the aldol—the product of the condensation of four molecules of the initial aldehyde—to *m*-DNB. After treating *sym*-TNB with triethylamine in propionaldehyde, Strauss[114] isolated a crystalline product, to which he proposed structure (XLII) on the basis of elemental analysis and infrared [ν(C=O) = 1720 cm^{-1}] and visible (λ_{max} = 470 and 566 nm in methanol) spectra. This structure was also confirmed by the ^{1}H NMR spectrum. Thus in this case the aldehyde reacts like ketones, which may be due, on the one hand, to the greater reactivity of *sym*-TNB compared with *m*-DNB and, on the other, to the smaller capacity of diethylamine (compared with KOH) to induce aldol condensation.

The interaction of *m*-DNB with ethyl malonate, phenylacetate, and cyanoacetate in the presence of aqueous KOH yielded coloured solutions whose absorption maxima are in the same part of the spectrum as for the products of the reaction with acetone (515 ± 15 nm). On this basis, the authors[23-25,31] believe that the structures of the complexes are the same in all cases.

However, there are few reliable data on the structures of such products. In an early study Jackson and Gazzolo[115] isolated the products of the addition of the sodium derivatives of malonic and acetoacetic esters to *sym*-TNB and 2,4,6-trinitroanisole in proportions of 3 : 1. Their insignificant stability indicates, according to the authors, an addition reaction with formation of a C–O bond and not a C–C bond. The products of the addition of two molecules of sodium derivatives of acetophenone, benzyl cyanide, and malonic and cyanoacetic esters to *m*-DNB have been obtained[14]. Shein and Ivanova[116] showed that the σ-complex isolated by Baudet[117] in the reaction of equivalent amounts of 1-fluoro-2,4-dinitrobenzene with malonic ester in the presence of triethylamine is a mixture of the initial 1-fluoro-2,4-dinitrobenzene, diethyl 2,4-dinitrophenylmalonate, and ethyl α,α-bis(2,4-dinitrophenyl)acetate. By treating[118] 9-nitroanthracene with the sodium derivatives of malonic ester, methylmalonic ester, nitropropane, etc. in DMSO, intensely coloured solutions, evidently containing the σ-complexes [XVIIb, Y = $CH(CO_2Et)_2$, $C(CH_3)(CO_2Et)_2$, $C(CH_3)_2NO_2$, $CH(CN)_2$, etc.], were obtained; after acidification, they are converted quantitatively into the corresponding derivatives of dihydroanthracene.

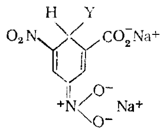
The only study where the structure of coloured products of this type was demonstrated unambiguously is that of Strauss[119], who treated a tetrahydrofuran solution of 2,4,6-trinitroanisole with an excess of acetoacetic ester in the presence of potassium butoxide and isolated the 1 : 1 adduct [XXII, X = OMe, R = $CH(COCH_3)COOEt$]. Its structure was established by elemental analysis and ^1H NMR (Table 4); on treatment with an acid, the OMe group is split off and ethyl α-picrylacetoacetate is formed.

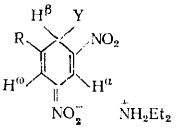
After surveying the entire data accumulated at the time, Foster and Mackie[37] concluded, following Canbäck[23-25], that not only carbonyl compounds but also many other substances with a fairly mobile hydrogen atom can react successfully with polynitro-compounds. Indeed, instances of the employment of uric acid and a number of amino-acids[18], laevulose, glucose, and other sugars[22,23], instead of acetone, in the colour reaction have been described. On the other hand, if the ion of the conjugate base is extremely stable, no colour is produced[37]. Many dialkyl and alkyl aryl ketones and derivatives of fluorene, indene, phenanthrene, etc. give rise to an intense violet colour on reaction with o-dinitrobenzene or 2,2′-dinitrobiphenyl in DMF in the presence of tetrabutylammonium hydroxide[120-123]. In many instances a colour appears on interaction of *m*-DNB and its derivatives with DMF in the presence of alkali[121,124].

Numerous studies have been made on the interaction of *sym*-TNB and *m*-DNB with compounds having a mobile hydrogen atom. Saunders and Stark[125] suggested that coloured products (XLIIIa) or (XLIIIb) are formed in the reaction of 3,5-dinitrobenzoic with dialkyl phosphites. Alkylphosphine oxides in the presence of 30% NaOH[126], methylenediphosphonates[125], di-isopropyl ethynylphosphonate[127], alkyltriphenylphosphonium salts[120], and quaternary α- and γ-picolinium salts[128] give rise to a similar colour reaction. It has been shown recently[129] that trialkyl phosphites, phosphorimidites, phosphonites, phosphinites, and dialkyl phosphorofluoridites (but not triphenyl phosphite) react readily with *sym*-TNB in DMSO to form σ-complexes of type (XL), which are converted in solution into the corresponding phosphoryl compounds ($Ar\overset{+}{P}OR'R''$). Some of the σ-complexes [XL, Y = $\overset{+}{P}(OMe)_3$, $\overset{+}{P}(OEt)_3$, $\overset{+}{P}(OEt)_2Ph$, or $\overset{+}{P}(NMe_2)_3$] have been identified with the aid of ^1H NMR and electronic spectra (Table 4). It is believed[129] that phosphorylation of *sym*-TNB and its halogeno-derivatives by phosphorus(III) compounds proceeds via the intermediate formation of σ-complexes of type (XXII, X = H, F, or Cl, R = $\overset{+}{P}R_3$), whose stability is to a large extent determined by the ease of elimination of the substituted group and by the nature of the solvent.

Urbanskii[130] was the first to measure the absorption spectra of the products of the reaction of nitromethane and other nitroalkanes with *m*-DNB and *sym*-TNB in methanol in the presence of NaOH. Subsequently treatment with triethylamine led to the isolation[131] in a free form of σ-complexes of type (XL) after the reaction of *sym*-TNB and *N*,*N*-dimethyl-2,4,6-trinitroaniline with a series of nitroalkanes (Table 4). Their electronic and ^1H NMR spectra are close to the characteristics of the corresponding acetone complexes (Table 3) as well as the σ-complex of *m*-DNB and nitromethane (XLIV, R = H, Y = CH_2NO_2), which has been investigated in solution (Table 4). Furthermore, the formation in reaction solutions of σ-complexes of nitromethane with 1,3-dinitronaphthalene (XVIb) and with 3,5-dinitropyridine has been detected with the aid of electronic and ^1H NMR spectra[131]; in the latter case a mixture of isomers analogous to (XIIIb) and (XIV) is formed.

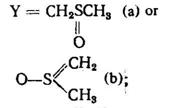
A study of the reaction of *m*-DNB and a series of 1-R-3,5-dinitrobenzenes (R = H, $CONH_2$, CO_2Et, CO_2Na, etc.) with DMSO led to the conclusion[132,133] that the coloured products have a structure analogous to that of the products of the reaction with acetone and that DMSO may add in the "keto-form" (XLIVa) or in the "enolic" form (XLIVb). In the interaction of $-CH_2SOCH_3$ with *sym*-TNB in DMSO Foster and coworkers[134,135] detected by ^1H NMR the σ-complex (XLIVa) (Table 4), which, however, is rapidly converted into (XXIII, X = H). Soon the σ-complex (XLIVa) was isolated in a free form[136] and its structure was demonstrated; the stretching vibration of the S=O bond is observed in the infrared spectra at 1035 cm⁻¹ and that of the $S-CH_3$ groups occurs at 1320 and 1410 cm⁻¹. The same workers[146] isolated type (XL) products of the interaction of *sym*-TNB with DMF or dimethylacetamide, a detailed study of which showed (Table 4) that the addition of a nucleophile takes place also with formation of a C–C bond. It was noted that in acetone and acetonitrile the added DMSO, DMF, etc. anions are displaced by the more active anions $-CH_2CN$ and $-CH_2COCH_3$. Certain products of the addition of CH_3CN to polynitro-compounds, namely σ-complexes of type (XXI, X = H or COOH, R = CH_2CN) as well as (IV) and (V) with X = H or OMe and R = CH_2CN (Table 2) were investigated recently[137] with the aid of electronic, ^1H NMR, and infrared spectra. As in the reactions with acetone and nitromethane, the addition of acetonitrile leads to the formation of a C–C linkage.





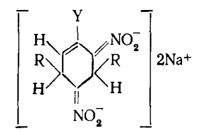
$Y = \overset{O}{\overset{\|}{P}}(OR)_2$ (a) or $OP(OR)_2$ (b)

(XLIII)



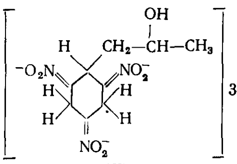
$Y = CH_2SCH_3$ (a) or $\overset{O}{\overset{\|}{}}\!-\!S(CH_2)(CH_3)$ (b);

(XLIV)



R = H (a) or Alk (b).

(XLV)

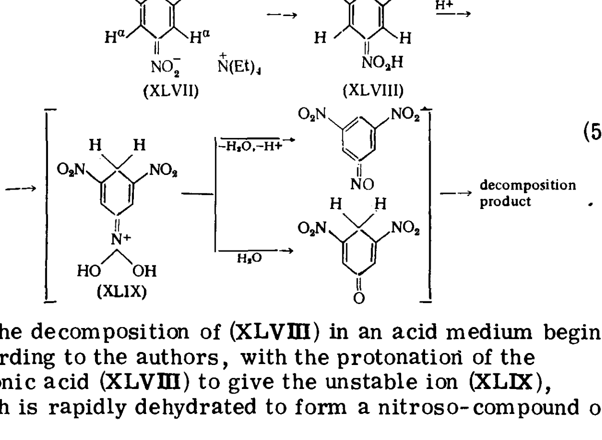


(XLVI)

When a solution of *sym*-TNB in acrylonitrile was treated with triethylamine, an extremely unstable 1 : 1 : 1 addition product was isolated[138] after subsequent precipitation with ether. Having analysed its ^{1}H NMR spectra, the authors gave preference to the second of the two possible structures of the zwitter-ions [XL, Y = $-CH(CN)CH_2\overset{+}{N}Et_3$] and [XL, Y = $-C(CH_3)(CN)\overset{+}{N}Et_3$] (Table 4).

In a study of the reduction of *m*-DNB, *sym*-TNB, and its derivatives with sodium tetrahydroborate to the corresponding polynitrocyclohexanes Severin and coworkers[139, 140] suggested the formation of intermediates involving the addition of one (IV or V, R = H, X = H, Cl, Br, Me, COOH, or CH = CHC_6H_5) and then two (XLVa) and three (XXVI, R = H) hydride ions to the initial nitro-compounds. Certain products of type (XLV) were obtained in the form of crystalline salts[141], which proved to be stable in the case of 2,4- and 3,5-dinitroanisoles and labile in the case of *m*-DNB. The structure of the complexes (XLV, Y = OMe, R = H) was demonstrated by their conversion into azabicyclononene derivatives as a result of aminoalkylation. The possibility of the formation of the trianionic complex (XLVI) after the reduction of the σ-complex (XXVIIIa) derived from *sym*-TNB with sodium tetrahydroborate was demonstrated[142]. Although the product (XLVI) was not isolated in a free form, its structure was confirmed by the finding that, on being oxidised with bromine, it is converted into 2-methyl-4,6-dinitrocoumaran.

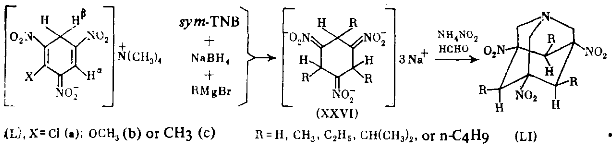
When *sym*-TNB was mixed with tetraethylammonium tetrahydroborate in acetonitrile in an atmosphere of nitrogen, purple crystals of the σ-complex (XLVII) were isolated[143]. Treatment of this complex with sulphuric acid made it possible to obtain[144] the nitronic acid (XLVIII), which is stable only in dilute solutions. Its absorption maximum in chloroform is at 370 nm, while in ethanol two maxima, characteristic of the usual σ-complexes of type (XXVIII), are observed.



(5)

The decomposition of (XLVIII) in an acid medium begins, according to the authors, with the protonation of the nitronic acid (XLVIII) to give the unstable ion (XLIX), which is rapidly dehydrated to form a nitroso-compound or is hydrolysed to cyclohexadienone. To confirm this mechanism, the authors isolated and demonstrated the structures of the decomposition products [3,5-dinitroaniline, *N*-(3,5-dinitrophenyl)hydroxylamine, 3,3′,5,5′-tetranitroazoxybenzene, 3,3′,5,5′-tetranitrohydrazobenzene, bis-(3,5-dinitrophenyl)amine, and 3,5-dinitrophenol]. The hydride complex (XLVII) was also isolated[145] after treating an acetonitrile solution of *sym*-TNB with tetramethylammonium octahydroborate in an inert atmosphere. The hydride complexes of 1-X-2,4,6-trinitrobenzenes (L) were obtained similarly[145]; when X = Cl or OMe, the complexes are isolated in a mixture with (XLVII), the complex (L) being obtained in a pure form only for X = Me†.

The interaction of *sym*-TNB and *m*-DNB with Grignard compounds in the presence of sodium tetrahydroborate, which results in the formation of 1,3,5-trialkyl-2,4,6-trinitrocyclohexanes and dialkyldinitrocyclohexanes respectively, proceeds, according to Severin and coworkers[146,147], via intermediate complexes of type (XLV) and (XXVI) with R = Me, Et, etc. The authors were unable to isolate these products and to investigate their structures, while aminomethylation of (XLVI, R = Me) and (XXVI, R = Me) by formaldehyde and ammonium nitrate makes it possible to obtain[148] a series of trinitroaza-adamantanes (LI), whose structure has been convincingly demonstrated by a number of methods.



(6)

(L), X = Cl (a); OCH_3 (b) or CH_3 (c) R = H, CH_3, C_2H_5, $CH(CH_3)_2$, or n-C_4H_9 (LI) .

The products of the addition of aliphatic and aromatic hydrocarbons, with fairly mobile hydrogen atoms, to *sym*-TNB were obtained by a number of workers, who either used specific reagents or selected appropriate reaction conditions. Thus, on treating *sym*-TNB in acetone and in an inert atmosphere with tetramethylammonium (or tetraphenylarsonium) tetra-alkylborates, Taylor[149] obtained the σ-complexes (XL, Y = Me or Bu) (Table 4).

Electrochemical reduction of *sym*-TNB in acetone at a controlled potential, corresponding to the transfer of two electrons, led to the isolation[150] of the "paired" σ-complex (LII)—the product of the interaction of two *sym*-TNB molecules with one another—which has two absorption maxima (at 432 and 510 nm), characteristic of σ-complexes of type (XXVIII). Its ^{1}H NMR spectrum has only two singlets—due to the four H^α protons (δ = 8.01 p.p.m.) and two H^β protons (δ = 5.37 p.p.m.); its infrared spectrum is analogous to that of (XXVIIIa), but there is no ν(C=O) band.

Foster and Mackie[37] observed that solutions of 2,4-dinitrotoluene in alkaline ethanol absorb at ~ 520 nm, which they attributed to the complex (LIII, Y = H). Here 2,4-dinitrotoluene behaves both as an electron acceptor and as a substance with mobile hydrogen atoms. On the other

---

† It has been shown recently[218] that hydride σ-complexes of type (XLVII) can be readily isolated after the interaction of *sym*-TNB with dihydro-derivatives of nitrogen-containing heterocycles: 1,3-dimethylbenzimidazoline, 1,3-dimethylnaphtho[2,3-*d*]imidazoline, 1,3-dimethyl-2,3-dihydropyrimidine, and 1-benzyl-1,4-dihydronicotinamide. A σ-complex of *sym*-TNB with the model coenzyme NADH was also detected, which may be important in biochemistry for the investigation of the mechanism of oxidation-reduction reactions.

hand, Pollitt and Saunders[44] believe that the long-wavelength maximum (at 648 nm), arising when a solution of 2,4-dinitrotoluene in DMF is treated with NaOH, corresponds to the 2,4-dinitrobenzyl anion and not the complex (**LIII**, Y = H). This is confirmed by the results of quantum-chemical calculations[151] of its structure and electronic spectra. A study of the kinetics of the rapid reaction of 2,4,6-trinitrotoluene with alkoxides in an alcoholic medium demonstrated the possibility of the formation of the products (LIII, Y = NO_2) with calculated absorption maxima at ~ 450 and ~ 550 nm. However, a compound of this type could not be isolated in a free form and it was investigated in detail much later[153,154]. When 2,4,6-trinitrotoluene is added to a solution of *sym*-TNB in DMSO in the presence of KOH, new maxima, corresponding to the σ-complex [XL, Y = 2,4,6-$(NO_2)_3C_6H_2CH_2$], appear at 465 and 580 nm, instead of the absorption spectrum of the σ-complex with the OH^- ion (**XXIII**, X = H) formed initially (λ_{max} = 440 and 518 nm).

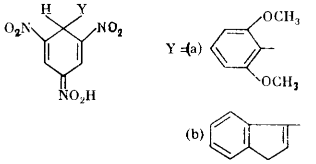
(LV)



(LVI)

σ-Complexes of *sym*-TNB with 2,4-dinitrotoluene, 4,6-dinitro-*m*-xylene, and 2,4,6-trinitro-*m*-xylene were obtained similarly (Table 4). In the last two cases treatment with alkali in a polar medium may result in the ionisation of the second methyl group, which entails the formation of the σ-complexes (LIV, a and b) in the interaction with *sym*-TNB. These compounds were also isolated in a free form and identified with the aid of electronic and ^1H NMR spectra. Electronic absorption spectra make it possible to detect similar reactions with *sym*-TNB and other alkyl derivatives of *m*-DNB or *p*-nitrotoluene[154]. Thus it has been established that, under the influence of alkali in aprotic solvents, *sym*-TNB and *m*-DNB derivatives containing methyl groups may behave not only as electron acceptors but also as nucleophiles as a result of the dissociation of a hydrogen atom in the methyl group.

Shein and coworkers[155,156] showed by ^1H NMR that, when the σ-complex of *sym*-TNB with potassium methoxide (XX, Y = NO_2, X = OMe) is treated with haloforms in DMSO in the presence of NaOMe, the stable σ-complexes (XL, Y = CCl_3, CBr_3, or CI_3) are formed, and isolated the first two in a free form (Table 4). Similar reactions occur when weaker bases are used: piperidine, diethylamine, and triethylamine. An interesting case of the formation of a σ-complex with a C–C and not a C–O bond has been described[157]. In accordance with the ambident nature of the phenoxide ion, its slow interaction with *sym*-TNB in a 4 : 1 DMSO–MeOH mixture leads to the σ-complex (LV), which then rearranges to (XLk, Y = *p*-HOC_6H_4). The latter was isolated in a free form (Table 4) and proved to be fairly stable even in weakly acid media.

The use of organometallic compounds as a source of carbanions is of considerable interest. A very novel method has been proposed by Beletskaya and coworkers[86,87], who treated *sym*-TNB with a series of organomercury compounds of the type R_2Hg and RHgX in DMSO in the presence of NaI and obtained a series of new σ-complexes [XL, Y = CHPhCOOEt, $B_{10}H_{10}C_2H$, C_6F_5, $(CF_3)_2CH$, CN, or CCl_3, X = Br], which were identified by ^1H NMR in the reaction solutions (Table 4). σ-Complexes of type (XL) were obtained similarly[88] by employing organotin compounds $RSnMe_3$ (where R = C_6F_5, fluorenyl, cyclopentadienyl, or indenyl, but not alkyl or phenyl) (Table 4). In certain cases a mixture of isomers is formed, for which a complete analysis of ^1H NMR spectra is difficult. The same workers recently synthesised[158] σ-complexes of a new type in which the tetrahedral carbon atom is linked to Si, Ge, and Sn. The compounds R_2EM (R_2E = Me_3Sn, Ar_3Sn, Et_3Ge, or Me_3Si, M = K or Li) were added to a solution of *sym*-TNB in tetrahydrofuran at temperatures down to −30°C in an inert atmosphere. All the σ-complexes obtained have characteristic electronic spectra (λ_1 = 435–440 nm, and λ_2 = 494–500 nm) and ^1H NMR spectra (δH^α = 8.30–8.40 p.p.m., δH^β = 6.10–6.30 p.p.m., 2 : 1 ratio), which confirms their structure. On treatment with acetone, they are converted into the corresponding Janovsky σ-complex (XXVIII).

Wennerström and coworkers[159] showed that, when phenylcopper reacts with *sym*-TNB in pyridine or quinoline at room temperature, an intensely coloured compound is formed. They identified it as a σ-complex on the basis of the characteristic absorption in the visible spectrum (λ_{max} = 444 and 522 nm). For the more stable 2,6-dimethoxyphenylcopper, it was possible to obtain a fairly stable crystalline complex (XLl), which was isolated as the pyridinium salt after acidifying the reaction mass with acetic acid (Table 4). Similar reactions occur, albeit more slowly, with 2,4,6-trimethoxy- and 2,6-dimethoxyphenyl silver[160]. In the latter case acidification of the σ-complex (XLl) with dilute H_2SO_4 made it possible to isolate in a free form 4-(2,6-dimethoxyphenyl)-3,5-dinitrocyclohexa-2,5-dienenitronic acid (LVIa). Its structure was demonstrated with the aid of infrared and ^1H NMR spectra; the ^1H NMR spectrum in DMSO virtually coincides with the spectrum of the corresponding σ-complex (XLl). In a polar medium (pyridine, ethanol) the nitronic acid fully dissociates with formation of the anion (λ_{max} = 470 and 590 nm), in a non-polar medium ($CHCl_3$) the undissociated form predominates (λ_{max} = 360 nm), while in acetone the two forms are in equilibrium and the spectrum shows all three maxima. Analogous results were obtained[161] in a study of the interaction of *sym*-TNB in pyridine with phenylethynylcopper and phenylethenylsilver and with hexylcopper. The formation of coloured σ-complexes (XL, Y = C≡C–Ar) was detected with the aid of electronic spectra (λ_{max} = 442 and 530 nm) and confirmed by the structure of the acid decomposition products isolated, among which the main component is 2,4,6-trinitrotolane.

The interaction of *sym*-TNB with cyclopentadiene[162,163] in pyridine in the presence of silver oxide leads to two isomeric σ-complexes (XL, Y = 1,3- or 1,4-cyclopentadienyl) in approximately equal amounts (Table 4). When *sym*-TNB is acted upon by indene under analogous conditions, the σ-complex with pyridine (XL, Y = ) is formed initially (λ_{max} = 437 and 520 nm) and is then gradually converted into the σ-complex (XLm), which has been isolated in 87% yield and identified (Table 4). On treatment with H_2SO_4, this complex is converted into 4-(3-indenyl)-3,5-dinitrocyclohexa-2,5-dienenitronic acid (LVIb), which is reconverted under the influence of NaOH into the "indenyl" σ-complex (XLm). The σ-complexes of *sym*-TNB with 2-furyl-, and 2-thienyl-copper (Table 4) have been isolated in a free form at a reduced temperature[164]. The reaction of *sym*-TNB with cyclopentadienylmanganese silver tricarbonyl in pyridine similarly leads to the formation[165] of the corresponding σ-complex (XLn) (Table 4).

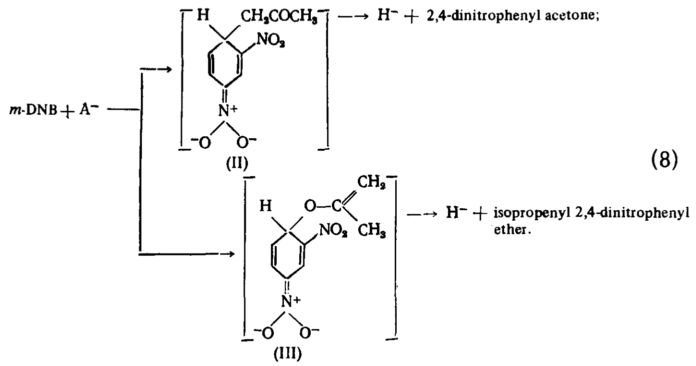
Thus the interaction of polynitro-derivatives of aromatic hydrocarbons with various compounds containing mobile hydrogen atoms yields Janovsky σ-complexes in an alkaline medium, in which a C–C bond is formed between a tetrahedral ring carbon atom and a carbon atom of the nucleophile. Under these conditions, their further reduction or acid decomposition in many instances lead to new pathways towards the formation of previously unobtainable aromatic and alicyclic compounds.

IV. KINETICS AND MECHANISM OF THE JANOVSKY REACTION

1. The Formation of σ-Complexes

In his review Canbäck[166] examined the mechanisms proposed[14,15,36] for the Janovsky reaction and showed that none is sufficiently convincing. He suggested for the first time[23] that the interaction of *m*-DNB with acetone in an alkaline medium be regarded as nucleophilic substitution of a hydrogen atom in the aromatic ring by the acetone residue in one of its tautomeric forms [Eqn. (7)] with formation of 2,4-dinitrophenylacetone or isopropenyl 2,4-dinitrophenyl ether [(Eqn. (8)]:

$$CH_3COCH_3 + {}^-OH \rightleftarrows [\underbrace{CH_3-\overset{\overset{\displaystyle O}{\|}}{C}-\bar{C}H_2 \leftrightarrow CH_3-\overset{\overset{\displaystyle O^-}{|}}{C}=CH_2}_{(A^-)}] + H_2O \qquad (7)$$

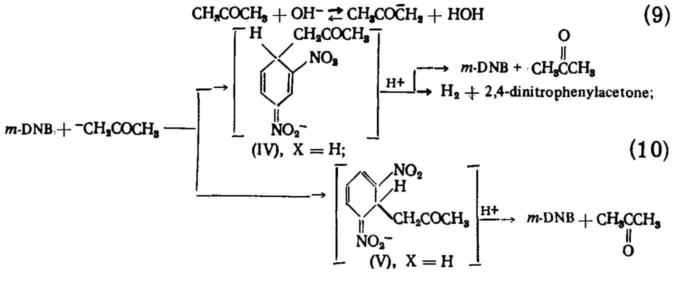


(8)

However, all attempts to isolate the final reaction product proved to be unsuccessful.

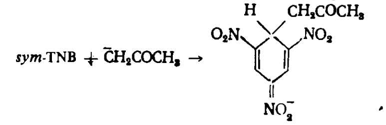
In a number of studies[23,26,120,166] dealing with the mechanism of the Janovsky reaction an analogy is drawn with the mechanism of the formation of type (XX) Meisenheimer σ-complexes[1,6]. In their survey of these ideas, Gitis and Kaninskii[48,50] proposed a mechanism for the formation of Janovsky reaction products and their decomposition in an acid medium:

$$CH_3COCH_3 + OH^- \rightleftarrows CH_2CO\bar{C}H_3 + HOH \qquad (9)$$



It is based on the observation that the acetone residue adds in the keto-form to polynitro-compounds[50] and on the identification of the above decomposition products[48,50]; it may be regarded as the first general mechanism of the Janovsky reaction supported by experimental data. These ideas were confirmed by Foster and Fyfe[84], who, having obtained the Janovsky σ-complex by the interaction of *sym*-TNB with acetone in the presence of tertiary amines, assumed that the amine reacts as a base, after which *sym*-TNB is attacked by the acetone carbanion

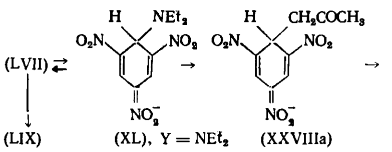
$$NEt_3 + CH_3COCH_3 \rightleftarrows \overset{+}{N}HEt_3 + \bar{C}H_2COCH_3 \qquad (11)$$



(XXVIIIa) (12)

However, the same workers showed[85] that in the presence of diethylamine (DEA) the above reaction proceeds via a more complex pathway. After the addition of DEA to an acetone solution of *sym*-TNB, ^1H NMR spectra revealed the successive formation of (XL, Y = NEt_2) and then (XXVIIIa), which are converted after a long time into a 1 : 1 mixture of *N*,*N*-diethyl-4-nitroaniline and an aliphatic dinitro-ketone (LVIII). It was established that these compounds are formed directly from (XXVIIIa) in acetone and, when deuterated acetone was used, *N*,*N*-diethyl-4-nitro-[2,6-D]aniline was obtained. A cyclic complex (LIX), which the authors believe is formed either directly from *sym*-TNB or from (LVII) but not via (XXVIIIa), was also isolated from the reaction mixture. On this basis, the authors[85] proposed a general reaction mechanism, which, however, did not receive further experimental confirmation or theoretical justification:

$$sym\text{-TNB} + 2NHEt_2 \rightleftarrows \text{(LVII) (charge-transfer complex)}, \qquad (13)$$



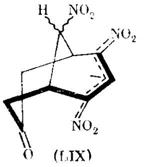
$$\rightarrow N,N\text{-diethyl-}p\text{-nitroaniline} + \underset{\text{(LVIII)}}{CH_3COCH_2-CH(CH_2NO_2)_2}\ . \qquad (14)$$

Studies on the kinetics of the reactions of polynitro-compounds with ketones in an alkaline medium have been published comparatively recently. Caldin and coworkers[167] investigated for the first time by the stopped flow method the kinetics of the reaction of *sym*-TNB with DEA in acetone at low temperatures (down to −85°C). In order to account for the observed third order of the reaction (first with respect to *sym*-TNB and second with respect to DEA), they suggested that equilibrium is established rapidly initially, possibly involving the dimerisation of the amine, which is then followed by the rate-determining bimolecular reaction via the mechanism

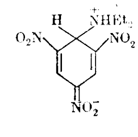
$$2\text{DEA} + \text{TNB} \rightleftharpoons (\text{DEA})_2 + \text{TNB} \rightleftharpoons Z \rightleftharpoons \text{TNB}.(\text{DEA})_2. \qquad (15)$$

(Z is an intermediate complex).

According to the results of a study[168] of the same reaction by the stopped flow method at room temperature, it proceeds in two consecutive stages, the first of which is rapid and reversible (TNB + DEA ⇌ K) and is of first order with respect to both components. The increase of the concentration of the complex K is found from the increase of absorption at 429 nm. The authors believe that the complex K differs from the charge-transfer complexes Z proposed by Caldin[167] and (LVII) in the mechanism (13) of Foster and Fyfe[55]. The first order with respect to DEA agrees either with the structure of the σ-complex (XL, Y = NEt$_2$) ($H_2\overset{+}{N}Et_2$ cation) or the zwitterionic complex (LX) formed via the direct interaction between *sym*-TNB and DEA.



(LIX)



(LX)

The second, slow stage involves further interaction of the complex K with associated acetone and DEA species, leading to the formation of a complex whose rate of accumulation was determined from its absorption at 516 nm. It is now clear from the work of Strauss[169,170] and Kohashi[98,99] that the final product isolated is the cyclic complex (LIX); similar complexes are formed particularly readily when secondary amines are used as alkaline agents[99,170]. It therefore becomes clear that in all the instances described, involving the use of diethylamine, the authors investigated different processes, predominating under the particular experimental conditions. Caldin[167] probably investigated the kinetics of the first, faster stage of the Janovsky reaction involving both the preliminary formation of the charge-transfer complex (LVII) [mechanism (13)] or Z [mechanism (15)] and the Janovsky complex (XXVIIIa). Although the interaction of *sym*-TNB with acetone in the presence of DEA is not considered in mechanism (15) proposed by the authors, evidently the final product, the rate of formation of which was measured, is in reality a Janovsky σ-complex of type (XXVIIIa). The observed considerable difference between the activation parameters and the orders with respect to DEA of the first rapid stage of the reaction in the studies of Caldin[167] and Osugi[168] is apparently caused by the different contributions of the charge-transfer complex and complex (XXVIIIa) to the measured rate of reaction. At higher temperatures Osugi and Sasaki[168] measured also the rate of the cyclisation reaction (which is not discussed in the present review), leading to the formation of bicyclic compounds of type (LIX) from compound (XXVIIIa) formed initially. The products of the further transformation of the Janovsky σ-complex (XXVIIIa) in an alkaline medium were investigated by Fyfe and Foster[55] [see mechanism (14)].

Features of another type were observed in a study of the kinetics of the interaction of *sym*-TNB and its derivatives with acetone[171] and cyclohexanone[172] in the presence of sodium methoxide. Thus the reaction of *sym*-TNB involves the initial formation of the methoxide σ-complex (XX) together with the Janovsky complex (XXVIIIa). The observed dependence of the initial rate of reaction on the concentration of *sym*-TNB shows that the stage involving attack by the acetonate ion via mechanism (16)–(18) is rate-limiting, and not the acetone deprotonation stage:

$$sym\text{-TNB} + CH_3O^- \xrightarrow{k_1} (\text{XX}),\ X = H,\ Y = NO_2\ , \qquad (16)$$

$$CH_3COCH_3 + CH_3O^- \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \bar{C}H_2COCH_3 + CH_3OH\ , \qquad (17)$$

$$sym\text{-TNB} + \bar{C}H_2COCH_3 \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} (\text{XXVIIIa})\ . \qquad (18)$$

Comparison of the activation parameters of the Janovsky σ-complexes (XXVIIIa) and (XXXIX, X = NO$_2$)[171,172] with the known characteristics of the Meisenheimer σ-complexes (XX)[174,175] shows that the former are more stable.

According to Kimura et al.,[90] the type (XXI, R = X = OMe) σ-complex of 2,4,6-trinitroanisole and methoxide formed initially in an acetone–methanol medium is not solvolysed by acetone to (XXIV, X = OMe), as happens at high concentrations of the complex[83]; this requires an additional amount of methoxide. The change in the rate of generation of the colour as a function of the order in which sodium methoxide and 2,4,6-trinitroanisole are added is associated with the formation of diacetone alcohol from acetone via mechanisms (19) and (20); diacetone alcohol was detected chromatographically in a mixture of acetone and sodium methoxide. Thus the overall mechanism of the complex reactions occurring in the reaction system may be represented by Eqns. (17) and (19)–(21):

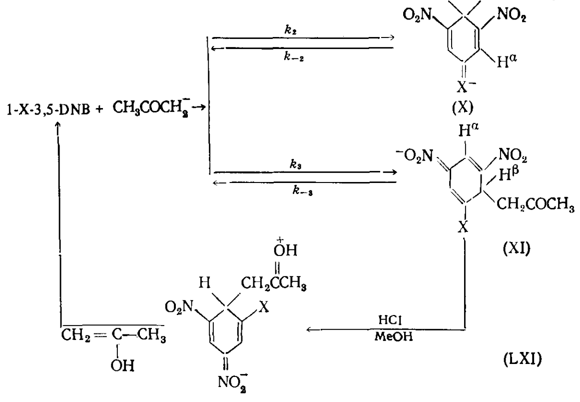
$$CH_3CO\bar{C}H_2 + CH_3COCH_3 \rightarrow CH_3COCH_2\text{–}C(CH_3)_2O^-\ , \qquad (19)$$

$$CH_3COCH_2C(CH_3)_2O^- + CH_3OH \rightarrow CH_3COCH_2C(CH_3)_2OH + CH_3O^-\ , \qquad (20)$$

$$2,4,6\text{-trinitroanisole} + \bar{C}H_2COCH_3 \rightarrow (\text{XXIV}),\ X = OMe,\ R = CH_2COCH_3\ . \qquad (21)$$

The kinetics of the interaction of *m*-DNB and its derivatives with acetone in an alkaline medium have been studied to an even lesser extent. Gitis and coworkers[175] showed that in aqueous acetone (15% H$_2$O) complexes of type (VII) are formed via a first-order reaction with respect to *m*-DNB and the alkaline agent. The reaction is faster when the alkaline agent and not *m*-DNB is added last to the solution, which is due to the consumption of alkali in side reactions with acetone. The authors believe that the results support mechanisms (9) and (10).

The kinetics of the formation of complexes by 1-X-3,5-dinitrobenzenes in a mixture with methanol and acetone[62] (X = COCH$_3$, CONMe$_2$, CONC$_5$H$_{10}$, or CONH$_2$) and cyclohexanone[111] (X = CN, COOMe, or CONC$_5$H$_{10}$) in the presence of sodium methoxide have been investigated. The authors believe that the reaction proceeds in two stages, the first of which [a reaction of type (17)] is much faster; this ensures a constant ratio of the concentrations of the MeO$^-$ ion and the ketone anion and the first order of the reaction with respect to these components. The rates of formation of both complexes are much higher than the rates of their decomposition and of the isomerisation of the symmetrical isomer (X) to the asymmetric isomer (XI). The latter is independent of the concentration of the methoxide, but increases with the methanol content, which indicates[62] isomerisation via the decomposition of (XI) to the initial nitro-compound:



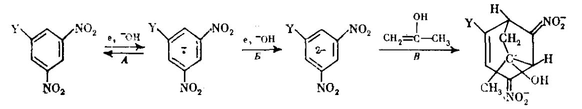
(22)

The quantities k_2 and k_3 increase with decrease of methanol concentration in solution and with increase of the electronegativity of the substituent X. The rate of formation of cyclohexanone complexes (XXXIX)[111] is 50 times greater than the rate of formation of acetone complexes[62]. According to the authors, this is due to the greater acidity of cyclohexanone (the concentration of its anion should be higher by three orders of magnitude). The weakening of nucleophilic properties and steric hindrance to a large extent diminish this effect. The authors[111] believe that acidification of the reaction mixture with HCl solution in methanol leads to the conversion of (XI) into the σ-complex (LXI) protonated at the carbonyl group, which then decomposes to the initial nitro-compound and the enolic form of acetone [reaction (22)].

Thus the kinetic data available at present do not permit unambiguous conclusions about the mechanism of the Janovsky reaction. As a rule, the conditions of the kinetic measurements (mixtures of acetone and other solvents, unusual alkaline agents such as DEA, MeO^-, etc.) are very markedly different from the conditions of the Janovsky reaction and the findings must be used with caution for the interpretation of its mechanism.

One should note that the majority of workers[62,90,167,168,171,175] treat the results of kinetic measurements within the framework of the traditional mechanisms (9)–(10) and (16)–(18). On the other hand, a number of facts have been discovered which do not fit within the framework of these ideas and require a detailed study of the elementary steps. This is, in the first place, the detection of the radical-anions of nitro-compounds in typical activated nucleophilic substitution reactions[176-182], so that a radical chain mechanism has been proposed for these processes[183-188]. The formation of oxygen in the Janovsky reaction, which has been detected polarographically both when an acetone solution of *m*-DNB is acted upon by KOH[189] and in the conversion of the "paired" complex (LII) into the σ-complex (XXVIII) in the presence of acetone and KOH[150], cannot be accounted for by mechanisms of types (9), (10), and (12). This suggests that the Janovsky reaction includes a stage involving electron transfer from the OH^- ion, the electron-donating properties of which are well known[190]. It appears that the evolution of oxygen is due to the decomposition in acetone of the hydrogen peroxide formed from the $\dot{O}H$ radicals after the electron transfer step. Quantitative formation of H_2O_2 in this process has been recently demonstrated experimentally[191,192]. Having observed the broadening of the proton signals of *sym*-TNB and the positive polarisation of the H^{β} protons of the σ-complex (XXVIII), Beletskaya and coworkers[86,87] do not rule out the possibility of the formation of intermediate radical species in the Janovsky reaction.

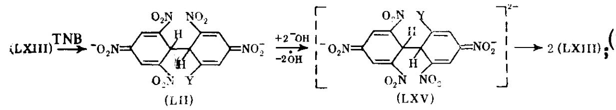
The role of electron transfer and the involvement of individual intermediate species in the elementary steps of the Janovsky reaction have been elucidated with the aid of electrochemical modelling. Polarographic reduction of *m*-DNB derivatives in DMF and acetone[189,193] showed that the reversible electron transfer at the potential of the first half-wave leads to the appearance of the radical-anions (LXII). It is seen from the results[194] of coulometric measurements in a circulation cell[195] that one electron is consumed in the reduction of *m*-DNB to (LXII, Y = H), while the addition of the second electron leads to the formation of the dianion (LXIII, Y = H), which interacts with acetone and gives rise to a doubly charged bicyclic complex with the postulated structure (LXIV, Y = H):



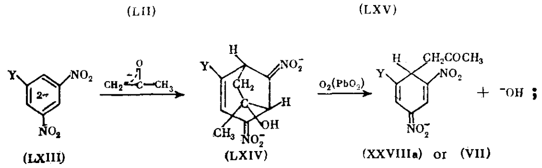
(23)

Coulometric measurements[194] have also shown that the formation of the corresponding intermediate complexes in the reaction of *sym*-TNB—the tentative bicyclic complex (LXIV, Y = NO_2) and the "paired" complex (LII)—also involves the consumption of two electrons; (LII) is then irreversibly reduced and gives rise to two (LXIII, Y = NO_2) species. The bicyclic complex (LXIV), formed on rapid interaction of the dianion (LXIII) with acetone, is fairly stable in an inert atmosphere. Under the influence of oxygen, (LXIV) is converted into the corresponding σ-complexes. Electrolysis at a controlled cathodic potential[194] made it possible to obtain the σ-complexes (VII) and (XXVIIIa), agreeing in terms of all characteristics with the complexes synthesised chemically[50,58].

The set of data obtained suggest[189,193,194] that the Janovsky reaction includes the same stages as the electrochemical reduction of aromatic polynitro-compounds in acetone with the sole difference that the electron donor in the former case is the hydroxide ion. In a general form the mechanism of this reaction may be supplemented, apart from Eqn. (23), by processes (24)–(26). The radical-anions (LXII) are generated in the first stage, some being converted under the influence of oxygen into the initial reactant and others being reduced by OH^- ions to the dianions (LXIII).



(24)



(25)

$$2\,{}^{-}OH \longrightarrow 2\,\dot{O}H \longrightarrow H_2O_2 \longrightarrow H_2O + {}^{1}\!/_{2}\,O_2 \ . \qquad (26)$$

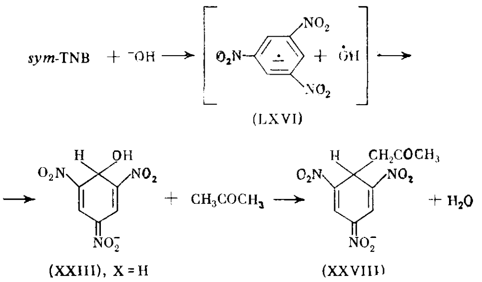
Owing to their high reactivity, they immediately undergo further transformations, attacking the double bond of the enolic form of acetone with formation of the bicyclic complexes (LXIV) via reaction (23). In the presence of an excess of a strong electron acceptor (*sym*-TNB) the interaction of the latter with the dianion (**LXIII**, Y = NO_2) leading to the paired complex (**LII**), is more likely. Under the influence of alkali, the latter is reduced (by the addition of two electrons) to (LXV), which dissociates into two dianions (**LXIII**) via mechanism (24). The compound (LXIV, Y = H or NO_2) formed subsequently is oxidised by oxygen and converted into the final product of the Janovsky reaction, namely the σ-complex (**VII**) or (XXVIIIa) respectively.

The majority of the intermediates indicated in mechanisms (23)–(25) have been identified in solutions in the course of electrochemical simulation or isolated in a free form. The structure of the bicyclic complexes (LXIV) was not demonstrated unambiguously[189,194], since, owing to their low stability, they cannot be isolated from the reaction solutions. The available experimental data show that they are doubly charged species; the absorption bands at 688 and 510 nm in the spectra of the reaction solutions have been assigned to (LXIV, Y = H) and (LXIV, Y = NO_2) respectively, the wavelengths being close to the maxima of the absorption bands of the bicyclic σ-complexes (LIX) obtained by Strauss[169,170] from *sym*-TNB. Mechanisms (23) and (25) explain the evolution of oxygen in the Janovsky reaction (26) and confirm the presence of the stage involving electron transfer from the OH^- ion in accordance with Eqn. (23) and subsequent dimerisation of $\dot{O}H$ radicals via mechanism (26).

When alkali is used as the electron donor in acetone solutions, it is not possible to detect the radical-anions of the initial nitro-compounds, because they are "quenched" by the oxygen evolved. This reaction stage was detected[196] by EPR when an acetone solution of *m*-DNB was treated with sodium thiophenoxide as the alkaline agent. Further reactions of the radical-anion formed from *m*-DNB lead, as in the Janovsky reaction with KOH, to the σ-complex (**VII**) as the final product. When potassium 2,4,6-tri-t-butylphenoxide, which has a low oxidation potential (−0.305 V relative to the saturated calomel electrode in DMF), is used as the electron donor in the reaction of acetone with *m*-DNB and *sym*-TNB in a 20 : 1 DMF–acetone mixture in an inert atmosphere, it is possible to detect by EPR the tri-t-butylphenoxy-radical, which is formed from the initial phenoxide as a result of electron transfer. Thus it proved possible in this experiment to detect directly for the first time species formed from the electron donor after the one-electron transfer step. As for the thiophenoxide, the final reaction products in this case are the σ-complexes (**VII**) and (**XXVIIIa**), which have been identified on the basis of their absorption spectra.

Data for the chemical simulation of this process constitute convincing confirmation of the involvement of the *m*-DNB dianion in the intermediate stage of the Janovsky reaction[197,198]. Using the method of homogeneous electron transfer from the dipotassium salt of the cyclo-octatetraene dianion (**LXIII**, Y = H) were obtained in quantitative yields. Experimental data showed that (LXII, Y = H) does not react Experimental data showed that (**LXII**, YH) does not react with acetone, a stable EPR signal, identical with that of the radical-anion formed by the electrochemical reduction of *m*-DNB[193] being observed under these conditions. On the other hand, when the *m*-DNB dianion (**LXIII**, Y = H) is treated with acetone, an unstable compound is formed and on contact with oxygen is rapidly converted into the Janovsky σ-complex (**VII**). The latter is formed as a result of the direct interaction of the dianion with acetone, since the σ-complex (**VII**) was not obtained on treating with acetone the *m*-DNB dianion subjected to a preliminary treatment with oxygen. Thus, of the two charged *m*-DNB species, only the dianion (**LXIII**, Y = H) interacts with acetone in the absence of alkali and forms the Janovsky complex (**VII**). Furthermore the product of the interaction of the *m*-DNB dianion with acetone has been converted into the σ-complex (**VII**) in the complete absence of oxygen but in the presence of another electron acceptor—lead dioxide[197]—which constitutes yet another demonstration of the presence of the stage involving the oxidation of the bicyclic product (LXIV) into the final σ-complex and of the overall reaction mechanism (23)–(26).

It has also been suggested[199] that the Janovsky reaction may proceed via the hydroxylated σ-complex (**XXIII**, X = H), the formation of which is preceded by electron transfer, the radical-anion of the polynitro-compound reacting with the $\dot{O}H$ radical in the cage (LXVI). Under the influence of a large excess of the ketone, this is followed by the displacement of the OH group by the acetone residue and the formation of the Janovsky σ-complex (**XXVIIIa**):



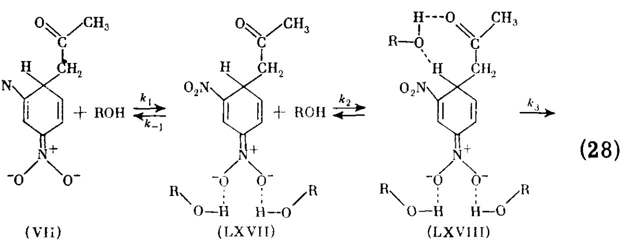
(27)

These conclusions are based on the fact that, when alkali is added to a solution of *sym*-DNB and an aromatic compound with activated methyl groups in DMSO, the σ-complex of *sym*-TNB with the OH^- anion of type (**XXIII**) is formed initially and then gradually converted into a complex of type (XL) with the above nucleophiles[153,154]. It has also been shown[91,136] that acetone and acetonitrile displace the OH group from σ-complexes of type (**XXIII**), forming more stable complexes of types (**XXVIII**) and (**VII**). A mechanism similar to mechanism (27) was then extended[175] to *m*-DNB in view of the observation that the reaction is of first order with respect to both alkali and *m*-DNB. However, it is noteworthy that the first order of the reaction with respect to KOH is also possible for mechanism (23) if stage (23*A*) or (23*B*) is rate-limiting. On the other hand, the identification of the radical-anions of the polynitro-compounds in the reaction solutions by EPR[176,183,196,200] shows that they emerge from the cage and can participate in other processes, differing from the pathway indicated by mechanism (27).

2. Decomposition of σ-Complexes by Proton-Donating Agents

The overall mechanism of the Janovsky reaction [Eqns. (9) and (10)] shows that the σ-complexes formed in an acid medium decompose to the initial nitro-compounds[48,50]. Whereas the decomposition of the *sym*-TNB complex (**XXVIIIa**) under these conditions requires a fairly concentrated acid, the *m*-DNB σ-complex (**VII**) undergoes slow decomposition[201–205] even in aprotic polar solvents (acetone, DMSO, DMF, etc.). The addition of other polar aprotic solvents (DMSO, DMF, etc.) to the acetone solution does not affect the rate of decomposition of the σ-complex (**VII**), while the introduction of an alcohol or water sharply increases it[201]. When the content of the proton-donating additive in the mixture is small (up to 4–6 M), the reaction is of first order with respect to both ROH and the complex undergoing decomposition, the second-order rate constants being proportional to the acidity of the alcohols employed.

The addition of large amounts of an alcohol (or water) to acetone leads to a deviation from the linear relation between lg*k* and N_{ROH}, which is due to the manifestation of the specific solvation of the complex by the alcohol or water. According to the authors[202], it occurs as a result of the formation of hydrogen bonds involving the nitro-groups, as in (LXVII), and the typical mechanism of the decomposition of σ-complexes of type (VII) by polar proton-donating solvents may be represented by the following scheme:



(VII) (LXVII) (LXVIII)

$$\longrightarrow m\text{-DNB} + \mathrm{ROH} + \mathrm{CH_3COCH_3}\ . \qquad (28)$$

One should note that the second nitro-group can also participate in the formation of hydrogen bonds with the solvent. The decomposition is then a second-order reaction, whose rate is determined by the rate of formation of the intermediate complex (LXVIII) ($k_3 \gg k_2$). Together with *m*-DNB, a certain amount of 2,4-dinitrophenylacetone was detected [Eqn. (30)].

At high concentrations of the proton-donating solvent the influence of structure formation in the solvent is superimposed on this process, apart from the solvation effect[202]. The decrease of the rate of decomposition of the σ-complex (VII) for a water mole fraction greater than 0.7 is associated with formation under these conditions of the three-dimensional structure of the framework characteristic of water, which greatly reduces the concentration of "free" H_2O molecules attacking the σ-complex in accordance with mechanism (28).

A change in the composition of the mixed solvent influences not only the rate of decomposition of the σ-complex (VII) but also its optical characteristics ($\lambda_{\max}$ and $\epsilon_{\max}$). It has been shown by ^{1}H NMR[202] that this does not entail the substitution of the acetone residue in (VII) by the conjugate base of the solvent with formation of complexes of the type (XX, X = Y = H).

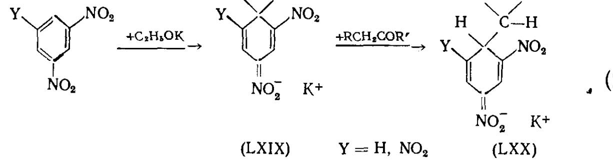
The stability of the σ-complexes of *m*-DNB derivatives increases as the electron-accepting properties of the substituent X are enhanced and the change in the first-rate constant is largely determined by the entropy factor[203,204]. A linear correlation is observed between the values of σ_X for the substituent and the logarithms of the decomposition rate constants[204] for isomers (IV) and (V); the sensitivity constant ρ for the latter isomer is twice as high as for the former. The authors believe that the cyclohexadiene system of the σ-complexes (IV) and (V) has a capacity for transmission of electronic effects close to that of an aromatic structure. Both in the decomposition by water in acetone[203,204] and in the reversible acid-catalysed decomposition in an acetone–methanol medium[62], the rate of decomposition of "symmetrical" isomers of types (V) and (X) is much higher than for the "asymmetric" isomers (IV) and (XI). The decrease of the concentration of methanol and the increase of the electronegativity of X under these conditions lead to an insignificant diminution of the constants k_{-2} and k_{-3} for the decomposition of isomers (X) and (XI) [mechanism (22)], which the authors[62] attribute to a decrease of the degree of solvation of the anion by methanol. On passing from the "acetone" complex (XI, X = $\mathrm{CONC_5H_{10}}$)[62] to the analogous cyclohexanone complex[109], the stability of the σ-complex increases appreciably; it is believed that this is due to an additional energetically preferred interaction of the piperidine and cyclohexane rings.

When alkali is added[205] to an aqueous acetone solution of the σ-complex (VII), its decomposition is accelerated sharply. The first order of the reaction with respect to the initial compound and alkali and the dependence of lg K_{act} on the concentration of the alkaline agent suggested that the main step in the alkaline decomposition is attack by the OH^- ion on the σ-complex (VII).

Thus in the presence of proton-donating solvents, and in an acid medium, Janovsky σ-complexes decompose mainly to the initial compounds owing to solvation by the proton-donating component. On the other hand, the mechanism of the alkaline decomposition of type (VII) complexes still remains unelucidated.

3. Oxidation of σ-Complexes

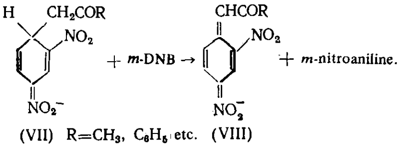
Detailed studies of the behaviour of type (VII) σ-complexes in the reaction system showed that, in the presence of an excess of the polynitro-compound, (VII) may be oxidised. This has been established in connection with the study of the mechanism of the Zimmermann reaction[206], which has been suggested for the analysis of ketosteroids with the aid of *m*-DNB (solvent—alcohol). Foreman et al.[110] initially proposed a reaction mechanism where the polynitro-compound reacts with the alkoxide in the first stage and gives rise to the complex (LXIX), while in the second stage the alcohol is displaced by the ketone with formation of a coloured salt, which has the general structure (LXX):



(LXIX) Y = H, NO₂ (LXX) (29)

However, it was found that in fact the type (LXX) σ-complex is oxidised by the excess of the nitro-compound under the reaction conditions.

The possibility of such oxidation was first suggested by Isidate and Skaguchi[207], who proposed the reaction mechanism



(VII) R=CH₃, C₆H₅ etc. (VIII) (30)

This course of the reaction in the presence of an excess of the nitro-compound was then demonstrated by numerous investigations[114,208-212]. Mechanism (30) has also been confirmed[209] by the similarity of the absorption spectra of the products of the interaction of acetone or acetophenone with *m*-DNB under the conditions of the Zimmermann reaction and the spectra of 2,4-dinitrophenylacetone or 2,4-dinitrobenzyl ketone in an alkaline medium, which had been noted earlier[38]. The results of spectrophotometric studies on the Janovsky and Zimmermann reactions are presented in a short review[210].

The agreement of the products of the Zimmermann reaction with structure (VIII) has been demonstrated convincingly by Kimura and coworkers[51,56], who isolated this compound in a free form, determined its structure, and demonstrated its difference from the Janovsky σ-complexes. The authors proposed a general mechanism (31) for the reaction of *m*-DNB in an alkaline medium, which is similar to mechanism (30):

$$m\text{-DNB} + \text{acetone} \xrightarrow{^{-}\text{OH}} (\text{VII}) \xrightarrow{\text{oxidation}} (\text{VIII}) \xrightarrow{^{-}\text{OH}} \text{unidentified products.} \qquad (31)$$

The polarographic reduction potentials of *m*-DNB (−0.62 V), the Janovsky complex (−0.68 V) and the Zimmermann complex (−0.63 V) which they measured[56] (at pH 13) hardly confirm the earlier view[206-209] that *m*-DNB can oxidise (VII) to (VIII). The authors[213] suggest that the oxidation stage is not rate-limiting in the Zimmermann reaction.

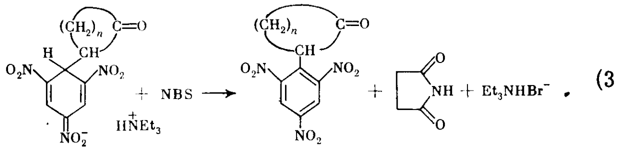
The study of the electrochemical mechanism of the oxidation[214] of Janovsky σ-complexes derived from *m*-DNB and *sym*-TNB showed that they are irreversibly oxidised in a single two-electron stage. Electrochemical oxidation and oxidation by manganese(III) acetate convert the σ-complex (VII) into 2,4-dinitrophenylacetone. The comparatively high oxidation potential of the σ-complex (VII) obtained ($E_{1/2} = +0.330$ V) shows that a fairly strong oxidant is necessary for the occurrence of the Zimmermann reaction.

Recent quantum-chemical calculations[151] showed that the benzenoid structure, in which the negative charge is distributed principally between the methylene carbon atom (−0.320) and the ring (−0.276), is largely retained in the anion (VIII) of 2,4-dinitrophenylacetone.

Thus it can be regarded as established that the Zimmermann reaction involving *m*-DNB and its derivatives consists in further oxidation of the Janovsky σ-complex by the excess of the nitro-compound with formation of more stable type (VIII) products. The insignificant amount of 2,4-dinitrophenylacetone formed in the decomposition of type (VII) σ-complexes by proton-donating agents [mechanisms (9) and (10)] is apparently due to oxidation by the excess of the *m*-DNB produced. On the other hand, the quantitative yield of the initial *sym*-TNB in the decomposition of its type (XXVIII) σ-complexes shows that reaction (30) does not occur here. This is evidently due to the greater stability of (XXVIIIa), whose oxidation requires a stronger oxidant, in conformity with its higher oxidation potential[214] ($E_{1/2} = +0.825$ V). Indeed, it has been shown for the oxidation of a number of σ-complexes (XL) by copper(II) oxide[159], chromium oxide[160], *p*-benzoquinone[164], tropylium tetrafluoroborate, and the bromine-pyridine adduct[165] that *sym*-TNB derivatives containing the corresponding aromatic or alicyclic groups in the 1-position are formed in high yields.

There are also other instances of the oxidation of σ-complexes by *sym*-TNB with retention of the added nucleophile. These include the conversion of the trianionic complex (XLVI) on oxidation with bromine into 2-methyl-4,6-dinitrocoumaran[142]. Wennerström and coworkers[162,164] oxidised a mixture of the isomers of (XL, Y = cyclopentadienyl) under mild conditions with *p*-benzoquinone or hydrogen peroxide in an acid medium to a mixture of 2,4,6-trinitrophenylcyclopentadienes and they also oxidised the σ-complex (XLm) or the corresponding nitronic acid (LVIb) to indenyl-2,4,6-trinitrobenzene.

The oxidation of the σ-complexes (LXXI), obtained in an earlier study[119], by *N*-bromosuccinamide in methanol at 0°C has been described[215]:



(LXXI) (LXXII) (32)

This led to the isolation of the ketones (LXXII) in a high yield. The reaction is of a general type and the complexes obtained from cyclopropyl methyl ketone and acetophenone are also readily oxidised to the corresponding trinitrophenyl ketones. The oxidation of asymmetric ketones, capable of giving rise to carbanions of different types, yields a mixture of products.

Many oxidants have been investigated by Kursanov and coworkers[216], who obtained 2,4,6-trinitrophenylacetone in 93% yield by oxidising the σ-complex (**XXVIIIa**) with tropylium tetrafluoroborate:

(33)

The authors showed that both two-electron (lead tetraacetate, hypohalogenites, and halogens) and one-electron (Fenton's reagent, silver nitrate, and ferric chloride) oxidants may be used, the rate and yield of the reaction depending on the standard potential of the oxidant. 1-Trihalogenomethyl-2,4,6-trinitrobenzenes have been obtained similarly from the σ-complexes (XL, Y = CCl_3, CBr_3, or CI_3) by oxidation with chlorine or bromine in t-butyl alcohol and pyridine.

I. Introduction 1084
II. Mechanism of reactions of aldehydes and carboxylic acids with hydrogen azide 1084
III. Applications of reaction 1091

I. INTRODUCTION

In 1923 Schmidt, on investigating the reaction of hydrogen azide with various organic compounds, discovered that carbonyl compounds undergo rearrangement in the presence of acid catalysts[1]. Thus aldehydes are converted into formamides and nitriles, ketones into amides, and carboxylic acids into amines:

$$RCHO + HN_3 \xrightarrow{H+} RCN + RNHCHO \tag{1}$$

$$RCOR' + HN_3 \xrightarrow{H+} RCONHR' + RNHCOR' \tag{2}$$

$$RCOOH + HN_3 \xrightarrow{H+} RNH_2 \tag{3}$$

Some years later Braun and Österlin used this reaction to obtain aliphatic[2], alicylic[3], and aromatic[4] amines from carboxylic acids. Since that time the Schmidt reaction has found widespread application as a convenient method for obtaining *N*-substituted amides, amines, nitriles, and several other compounds.

Since the conversion of carboxylic acids into amines occurs with retention of optical activity[3,5], and is not accompanied by *cis-trans* isomerisation[6-8], it has been used as a convenient model in solving several important theoretical problems associated with the stereochemistry of molecular rearrangements[5,6]. The reaction of carboxylic acids with hydrogen azide has been employed to investigate the structure of alkaloids[9-11] and as an analytical method in studying the mechanism of the solvolysis of alkyl bromides[12].

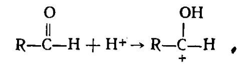
During recent years the Schmidt reaction has still been the subject of numerous investigations. Experimental results obtained up to 1962 were summarised by Wolff[13] and by Smith[14]. Surveys have recently appeared[15,16] on the Schmidt reaction with ketones. The present Review examines fresh results on the reactions of aldehydes and carboxylic acids with hydrogen azide, paying attention mainly to their mechanism and applications.

II. MECHANISM OF REACTIONS OF ALDEHYDES AND CARBOXYLIC ACIDS WITH HYDROGEN AZIDE

The action of hydrogen azide on aldehydes and carboxylic acids is an acid-catalysed reaction. Protic acids—sulphuric and polyphosphoric (in most cases the former)—are used as catalysts. In discussing the mechanism of these reactions we must obviously consider first of all the behaviour of the reactants in aqueous sulphuric acid.

1. Behaviour of Aldehydes, Carboxylic Acids, and Hydrogen Azide in Aqueous Sulphuric Acid

Aldehydes are weak organic bases and are protonated in aqueous sulphuric acid, with the proton adding to the carbonyl oxygen[17]:



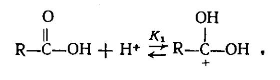
$$R{-}\overset{\overset{O}{\|}}{C}{-}H + H^+ \rightarrow R{-}\overset{\overset{OH}{|}}{\underset{+}{C}}{-}H \ , \tag{4}$$

A considerable number of studies have been made on the protonation of aldehydes, but in most cases aromatic aldehydes were investigated, since aliphatic aldehydes are unstable in aqueous mineral acids. The sole method for assessing the basicity of aliphatic aldehydes is therefore to measure the spectral shifts due to the hydrogen bond. On the basis of data at present available it may be postulated that pK_a values for the simplest aliphatic aldehydes lie between −7 and −8 H_0 units.

Protonation has been studied in greatest detail on substituted benzaldehydes. Basicity data were first obtained during the mid-1950s, when Schubert et al.[18], and later Yates and Stewart[19], made pK_a determinations on a large number of substituted benzaldehydes. It was postulated that these compounds were Hammett bases. Their basicity constants correlated well with the σ^+ constants of the substituents. The basicity of benzaldehyde of aqueous sulphuric acid has more recently been reinvestigated by several workers[20], who have concluded that protonation of this aldehyde is described better by the acidity function H_A than by H_0.

As previous determinations of the basicity constants of aldehydes had used out-of-date values for the acidity function of aqueous sulphuric acid, and in some cases employed insufficiently rigorous methods for processing the experimental results, a fresh study has recently been made[21,22] of the basicity of a series of substituted benzaldehydes. These compounds are protonated similarly to Hammett bases, except in the case of *p*-methoxybenzaldehyde, whose divergence is obviously due to specific solvation of the methoxy-group. Benzaldehyde and 1′-deuterobenzaldehyde in sulphuric and deuterosulphuric acids have almost identical basicities[23], and a similar situation is observed with the corresponding 2,4,6-trimethylbenzaldehydes[18]. The slight differences in the basicity constants are not due to variation in the acid–base properties of these compounds, since they lie within the limits of accuracy with which the ionisation ratios have been determined.

Like aldehydes, carboxylic acids are weak organic bases, and are protonated in aqueous sulphuric acid, with the proton adding to the carbonyl oxygen atom:



$$R{-}\overset{\overset{O}{\|}}{C}{-}OH + H^+ \overset{K_1}{\rightleftarrows} R{-}\overset{\overset{OH}{|}}{\underset{+}{C}}{-}OH \ . \tag{5}$$

The basicity of carboxylic acids has been investigated in some detail[17], for study of the mechanisms of acid-catalysed reactions involving carboxylic acids, including the Schmidt reaction, is impossible in the absence of knowledge of their equilibrium constants in mineral acids. Depending on the acidity of the medium, furthermore, protonated carboxylic acids may undergo secondary ionisation to form acylium ions[24,25]

$$R-\overset{\overset{\displaystyle OH}{|}}{\underset{+}{C}}-OH + H^+ \overset{K_2}{\rightleftarrows} R-\overset{+}{C}O + H_3\overset{+}{O} \qquad (6)$$

which provide a convenient model in studies of the properties and the structure of carbonium ions[26,27].

The basicity of aliphatic carboxylic acids has been investigated by ultraviolet, infrared, and nuclear magnetic resonance spectroscopy. Some workers assumed that these acids are Hammett bases[28,29]. During recent years, however, this view has been criticised, and it is suggested that such acids as acetic are protonated by a so called hydration mechanism[30,31].

The protonation of aromatic carboxylic acids has been widely investigated. The early work showed that substituted benzoic acids are Hammett bases[32,33]. Later results indicated[34–37] that the protonation of benzoic acids is not described by the acidity function H_0. Such deviations have been observed in the protonation of salicylic[37], 2,2′-diphenic[34], and *o*-benzoylbenzoic[35] acids. For the latter acids this might be due to secondary ionisation of the protonated compound and formation of an acylium ion. Vinnik et al. [38] pointed out the difficulties arising in the interpretation of experimental results on the protonation of such acids. Ultraviolet and n.m.r. spectroscopy have recently been used to study the basicity of a series of mono-, di-, and tri-substituted benzoic acids in aqueous sulphuric acid[39]. It was concluded that, despite some inconsistency in available data, there are grounds for supposing that substituted benzoic acids are protonated similarly to Hammett bases. With benzoic acid a temperature dependence of protonation and the basicity have been studied in deuterosulphuric acid[39].

With increase in the concentration of sulphuric acid, as already noted, protonated carboxylic acids may undergo dehydration with formation of acylium ions. Investigation by n.m.r. spectroscopy of the behaviour of a series of aliphatic carboxylic acids in concentrated sulphuric acid or oleum showed[26] that e.g. with acetic acid reaction (6) is observed in 15% oleum, but a still more acid medium is required for propionic and isobutyric acids. Data on the formation of aromatic acylium ions, obtained in a study of the cryoscopic properties of solutions of benzoic acids in concentrated sulphuric acid[24,40], showed that formation of acylium ions is favoured by the presence of two electron-donor *ortho*-substituents in the benzene ring. This is obviously because such substituents stabilise the acylium ion and destabilise the protonated form of benzoic acid. For 2,4,6-trimethylbenzoic acid attempts were made[25,41] to estimate the equilibrium (6) constant, by means of the acidity functions H_0 and I_0 respectively. It was shown subsequently, however, that such processes should be described by the acidity function H_R.[42,43] Indeed, in the case of 2,4,6-trimethylbenzoic acid formation of the acylium ion is well described[39] by this last acidity function, with $pK_a = -19.87$.

It must be emphasised that published data obtained by different workers on the basicity of particular carbonyl compounds are often difficult to compare, for inadequate methods of calculating ionisation ratios are used in processing the experimental results. Yet it has been noted repeatedly[33,44] that this stage is extremely important in studying the basicity of organic bases. Certain difficulties arise also in discussing the basicity constants of aldehydes and carboxylic acids obtained by different physicochemical methods, especially nuclear magnetic resonance. The reasons have been examined by several workers[17,39,45]. Finally, it is obviously a simplification to describe the protonation of aldehydes and carboxylic acids by means of the Brønsted equations (4) and (5).

It has recently been suggested that carbonyl compounds are protonated by a "dehydration" mechanism[46]:

$$\begin{gathered} B\cdot b\ H_2O + H^+\cdot x\,H_2O \rightleftarrows B\ \cdots\ H^+\cdot n\,H_2O + (b+x-n)\,H_2O \\ B\ \cdots\ H^+\cdot nH_2O \rightleftarrows B\ \cdots\ H^+\cdot(n-1)\,H_2O + H_2O \\ \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\ B\ \cdots\ H^+\cdot H_2O \rightleftarrows \overset{+}{B}H + H_2O \end{gathered} \qquad (7)$$

where B is the base (aldehyde or carboxylic acid). The occurrence of such processes in the protonation of weak organic bases has been established quite convincingly by laser Raman spectroscopy[47,48]. This view is supported also by kinetic data on certain acid-catalysed reactions[46], including the Schmidt reaction[49]. However, the lack of constants of the equilibria (7) presents certain difficulties in interpreting the kinetic results.

Table 1. Basicity of hydrogen azide determined by various methods.

Method	$-pK_a(H_2N_3^+)$	Ref.
Partition in $CHCl_3$–H_2SO_4	6.9	51
Vapour pressure (Henry's law)	7.02	52
Ultraviolet spectroscopy	7.19	55
Kinetic data	5.4	53
	6.6	54

Hydrogen azide is protonated in aqueous sulphuric acid

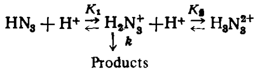
$$HN_3 + H^+ \rightleftarrows H_2\overset{+}{N}_3 \qquad (8)$$

$$H_2\overset{+}{N}_3 + H^+ \rightleftarrows H_3N_3^{2+} \qquad (9)$$

a possibility first pointed out by Hantzsch[50]. More recently Bak and Praestgaard[51] found by a partition method that the basicity of hydrogen azide is $pK_a(H_2N_3^+) = -6.9$. Almost the same value has been obtained (−7.02) by measuring the vapour pressure over solutions of perchloric acid[52], and kinetic methods yield similar results[53,54]. It has been postulated in all cases that hydrogen azide is a Hammett base. Study of its basicity by ultraviolet spectroscopy has shown[55] that its protonation is actually described by the acidity function H_0. Table 1 gives values obtained by different methods for the basicity of hydrogen azide. The approximate value obtained by Hantzsch[50] for singly protonated hydrogen azide was $pK_a(H_3N_3^{2+}) \approx -10.2$. Recent kinetic determinations[54,55] give limits of −9.60 and −9.99 H_0 units. The basicity of deuterium azide in a D_2O–D_2SO_4 mixture obtained by ultraviolet spectroscopy[56] differs from the value for hydrogen azide: $pK_a(D_2N_3^+) = -7.56$.

In studying the mechanism of the Schmidt reaction it must be borne in mind that hydrogen azide decomposes in aqueous mineral acids[57]. In 73.8–98.7% sulphuric acid at

60°C the decomposition is an acid-catalysed process[55], the activated species being $H_2N_3^+$. The mechanism of this reaction can be represented as



$$HN_3 + H^+ \overset{K_1}{\rightleftarrows} \underset{\underset{\text{Products}}{\downarrow k}}{H_2N_3^+} + H^+ \overset{K_2}{\rightleftarrows} H_3N_3^{2+} \qquad (10)$$

where K_1 and K_2 are the basicity constants of HN_3 and $H_2N_3^+$ respectively, and k is the true rate constant. The effective rate constant is then related to the true rate constant by the formula

$$k_{\text{eff}} = \frac{k}{K_1/h_0 + h_+/K_2 + 1},$$

or

$$k_{\text{eff}} = k \cdot A, \qquad (11)$$

in which

$$A = (K_1/h_0 + h_+/K_2 + 1)^{-1}.$$

The equation to the regression line for the dependence (11) is

$$\lg k_{\text{eff}} = (0.85 \pm 0.05) \lg A - (2.18 \pm 0.02)$$
$$r = 0.98; \; n = 14; \; s = 0.05 \; . \qquad (12)$$

Kinetic results obtained in 73.8–89.6% sulphuric acid, in which the activity of water is quite high, were treated by Bunnett's method[58] in conformity with the equation

$$\lg k_{\text{eff}} - \lg \frac{h_0}{h_0 + K_1} = \omega \lg a_{H_2O} + c. \qquad (13)$$

The equation to the regression line is

$$\lg k_{\text{eff}} - \lg \frac{h_0}{h_0 + K_1} = (0.13 \pm 0.03) \lg a_{H_2O} + (1.80 \pm 0.06)$$
$$r = 0.91; \; n = 7; \; s = 0.02.$$

The value of $\omega < 1$ indicates that water is not involved in forming the activated complex.

Table 2. Activation energy of decomposition of hydrogen azide.

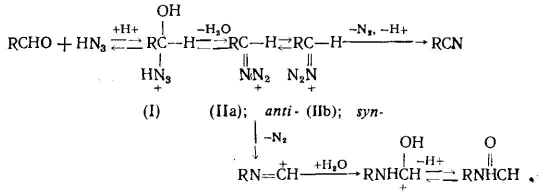
H_2SO_4, %	75.9	86.3	96.3
E_a, kcal mole^{-1}	31.2	23.2	19.8

Additional information on the mechanism of the decomposition of hydrogen azide has been obtained from a study of the kinetics at different temperatures. Table 2 shows that the activation energy does not remain constant with variation in the concentration of sulphuric acid. This is obviously due to partial change in the reaction mechanism on passing from the dilute to the concentrated acid. It may be postulated that non-protonated hydrogen azide also decomposes, although the rate is considerably smaller than that of the main reaction. Some departure from unity in the slope of the relation (12) is obviously due to the same causes. Kinetic study shows[56] that the decomposition of deuterium azide in $D_2O + D_2SO_4$ has the same mechanism as that of hydrogen azide ($k_D/k_H \simeq 4$).

The acid–base equilibria preceding the reaction of aldehydes and carboxylic acids with hydrogen azide must be borne in mind when studying its mechanism. The basicity constants of carbonyl compounds and hydrogen azide required for calculation of the reaction rate constants should be determined under comparable conditions.

2. Mechanism of Reaction of Aldehydes with Hydrogen Azide

It was assumed earlier that the Schmidt reaction had the same mechanism for aldehydes and for ketones. Thus McEwen et al.[59] and later Smith and Antoniades[60] supposed that, by analogy with ketones, aldehydes react in the protonated form with hydrogen azide; the resulting protonated azidoalkanol (I) loses water to give the iminodiazonium ion (II), which is subsequently converted into the reaction products:



(14)

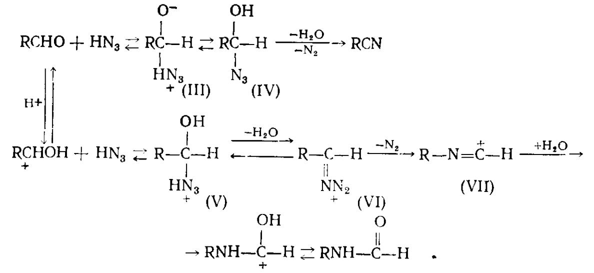
It is generally accepted for unsymmetrical ketones[15] that the iminodiazonium ion can exist as *syn* and *anti* isomers. The more bulky substituent, located in the *anti* position with respect to the diazo-group, migrates to the nitrogen atom to form an iminocarbonium ion. This important postulate will explain the preferential formation of one of the isomeric amides in the Schmidt reaction with ketones. Hence the corresponding formamide should be the sole reaction product in the case of aldehydes. In fact, however, nitriles are formed together with formamides when aldehydes react with hydrogen azide[61]. In order to explain this inconsistency it was suggested[59] that formation of the nitrile form the *syn*-iminodiazonium ion (IIb) involves detachment of a proton by the action of such a base as water or the hydrogen sulphate ion.

Subsequent detailed kinetic study of the reaction of aldehydes with hydrogen azide established that this postulate was incorrect. Furthermore, fresh results were obtained showing that the Schmidt reaction had different mechanisms with ketones and with aldehydes: ketones react in the protonated form, whereas aldehydes react in both protonated and non-protonated forms[62]. This explains the formation of two products — a nitrile and a formamide — in proportions depending on the acidity of the medium[63]: the proportion of formamide in the product increases with acidity, and the nitrile is favoured by diminished acidity. For example, the only product of the reaction of benzaldehyde with hydrogen azide in 71.2% sulphuric acid, in which the protonated form of the aldehyde is almost completely absent, is benzonitrile, but in the 87.4% acid only formanilide is produced. The ratio of the reaction products changes precisely in the range of sulphuric acid concentrations in which the acid–base equilibrium of benzaldehyde is observed. This enables the ratio to be calculated by means of the equation

$$\lg F = \mathrm{p}K_a - H_0, \qquad (15)$$

where $F = [\text{Fo}]/[\text{H}]$ is the ratio of the final concentrations of formamide and nitrile, $\mathrm{p}K_a$ relates to the conjugate acid of the aldehyde, and H_0 is the Hammett acidity function. Hence the formation of nitriles and formamides form aldehydes and hydrogen azide can be regarded as two parallel reactions involving respectively non-protonated and protonated forms of the aldehyde.

Thus the mechanism of the reaction of aldehydes with hydrogen azide can be represented



$$\mathrm{RCHO + HN_3 \rightleftarrows R\overset{O^-}{\underset{\overset{+}{H}N_3}{C}}{-}H \rightleftarrows R\overset{OH}{\underset{N_3}{C}}{-}H \xrightarrow[-N_2]{-H_2O} RCN}$$

$$\mathrm{R\underset{+}{C}HOH + HN_3 \rightleftarrows R{-}\overset{OH}{\underset{\overset{+}{H}N_3}{C}}{-}H \underset{}{\overset{-H_2O}{\rightleftarrows}} R{-}\underset{\overset{+}{N}N_2}{\overset{}{C}}{-}H \xrightarrow{-N_2} R{-}N{=}\overset{+}{C}{-}H \xrightarrow{+H_2O} RNH{-}\overset{OH}{\underset{+}{C}}{-}H \rightleftarrows RNH{-}\overset{O}{\overset{\|}{C}}{-}H} \quad (16)$$

Interaction of the non-protonated aldehyde with the azide forms the ambipolar ion (III), which isomerises into the azidoalkanol (IV). The latter is converted into the nitrile by dehydration and the elimination of nitrogen.

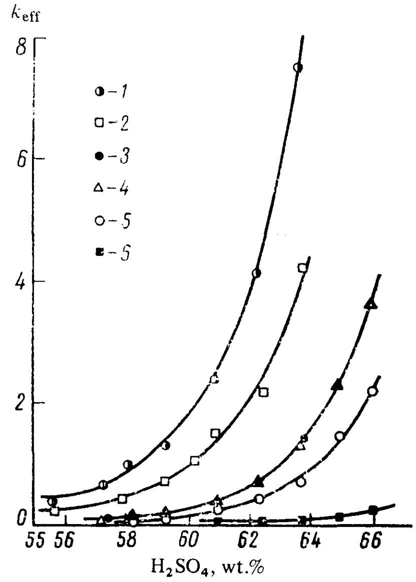


Figure 1. Influence of concentration of sulphuric acid on effective rate constants of the reaction of hydrogen azide with benzaldehydes containing various substituents:
1) *p*-methyl; *2*) none; *3*) *p*-chloro; *4*) *p*-bromo;
5) *m*-chloro; *6*) *m*-nitro.

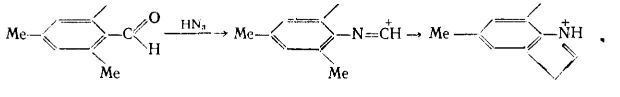
Such a reaction mechanism is quite consistent with the kinetic results. Kinetic study of the action of a series of substituted benzaldehydes[49] on hydrogen azide is moderately concentrated aqueous sulphuric acid, in which the non-protonated form of the aldehyde is reactive, has established a monotonic increase in reaction velocity with acid concentration (Fig. 1). This is because the aldehyde reacts as a complex with a hydrated proton. When weak organic bases (aldehydes) dissolve in aqueous mineral acids, such complexes $B\ldots H^+.nH_2O$ are supposed[46] to be formed (scheme 7). As the mineral acid becomes more concentrated, these complexes undergo dehydration to the protonated base. This involves a gradual advance by the proton from the "initial position of attack" [46] to the aldehydic oxygen atom, which tends to increase the reactivity of the complex. It thus becomes clear why the rate of reaction of the non-protonated aldehyde with hydrogen azide increases with the sulphuric acid concentration.

True rate constants for each type of complex cannot be calculated because of the absence of values for the equilibrium (7) constants. This leads to some difficulties in determining the limiting stage, since the ρ–σ method cannot be used for these purposes. However, existing data suggest that addition of hydrogen azide to the non-protonated aldehyde is the rate-determining stage. This is supported by a study[23] of the kinetic isotope effect in the reaction of benzaldehyde with hydrogen azide and by activation parameters (Table 3) †, which are typical of nucleophilic addition at a carbonyl group. The opposite kinetic isotope effect is observed for the reaction of benzaldehyde with hydrogen azide in D_2SO_4 in comparison with H_2SO_4: $k_D/k_H \simeq 4$. Yet no kinetic isotope effect is observed when benzaldehyde is replaced by 1′-deuterobenzaldehyde in sulphuric acid[23].

Table 3. Activation parameters for reaction of benzaldehyde with hydrogen azide.

$[H_2SO_4]$, %	E_a, kcal mole^{-1}	$H^{\neq}$, kcal mole^{-1}	$\Delta S^{\neq}$, e.u.
53.1	14.6	14.0	−12.8
55.6	15.6	14.9	−9.1
57.9	15.3	14.7	−8.1

According to Eqn. (16) the first stage in concentrated aqueous sulphuric acid is addition of hydrogen azide to the protonated aldehyde to form the protonated 1-azido-alkanol (V). Dehydration of (V) gives the iminodiazonium ion (VI), which eliminates nitrogen and undergoes rearrangement to the iminocarbonium ion (VII). The action of water on this ion (VII) yields the formamide. Existence of an iminocarbonium ion as an intermediate species is confirmed by the formation of "anomalous products" with certain aldehydes. Thus the reaction between 2,4,6-trimethylbenzaldehyde and hydrogen azide yields not only 2,4,6-trimethylformanilide but also the cation of 5,7-dimethylindole[22] as a result of intramolecular attack by the iminocarbonium ion on the carbon of an adjacent methyl group:



(17)

The kinetics of the reaction of aldehydes with hydrogen azide in concentrated aqueous sulphuric acid has been studied in detail. For a series of substituted benzaldehydes[62,64] the steady-state principle is applicable to the reaction, since intermediate products accumulate neither before nor

---

† The slight increase in entropy of activation is fully consistent with the postulate that aldehydes react as complexes having different degrees of hydration.

after the rate-determining stage. The relation between the true rate constant k' and the effective constant k_{eff} is then

$$k_{\mathrm{eff}} = \frac{k' \cdot h_0}{(K_1 + h_0)\,(1 + h_0/K_2 + h_0 \cdot h_+/K_2 \cdot K_3)} \tag{18}$$

or

$$\lg k_{\mathrm{eff}} = \lg A + \lg k', \tag{19}$$

where

$$A = h_0/[(K_1 + h_0) \cdot (1 + h_0/K_2 + h_0 \cdot h_+/K_2 \cdot K_3)],$$

h_0 and h_+ are the Hammett acidity of the medium and the acidity for singly charged cations, K_1 is the basicity constant of the aldehyde, and K_2 and K_3 are those of hydrogen azide and of its monoprotonated form. Thus for benzaldehyde in 90.5–97.8% sulphuric acid good correlation is observed between $\lg k_{\mathrm{eff}}$ and $\lg A$ (formula 19). The equation to the regression line is

$$\lg k_{\mathrm{eff}} = (0.99 \pm 0.05) \lg A + (5.05 \pm 0.09)$$

$$r = 0.99;\ n = 8;\ s = 0.05.$$

The action of hydrogen azide on aldehydes is a multistage process, so that the true rate constant k' calculated by means of Eqn. (18) can be assigned to any of these stages—addition of hydrogen azide to the aldehyde, dehydration, or rearrangement.

Table 4. Rate constants of reactions of substituted benzaldehydes RC_6H_4CHO with hydrogen azide in H_2SO_4 (at 20° C).

R	$[H_2SO_4]$, %	$10^{-3}k_{\mathrm{eff}}$, $M^{-1}\ \mathrm{min}^{-1}$	$\lg k'$	R	$[H_2SO_4]$, %	$10^{-3}k_{\mathrm{eff}}$, $M^{-1}\ \mathrm{min}^{-1}$	$\lg k'$
p-CH_3	89.0	0.101	—	p-Br	94.5	0.176	5.63
p-CH_3	90.2	0.044	4.10	p-Br	97.6	0.032	
p-CH_3	92.8	0.019	—				
H	96.3	0.021	5.05	m-Cl	96.7	0.407	6.60
H	97.8	0.008		m-Cl	98.3	0.121	
p-Cl	90.0	0.601		m-NO_2	95.8	3.640	
p-Cl	92.7	0.458	5.52	m-NO_2	97.6	2.890	7.63
p-Cl	95.8	0.086					

The method of ρ–σ analysis has been successfully applied to ascertain the rate-determining stage[64]. Thus the true rate constants of substituted benzaldehydes (Table 4) correlate with the substituent constants σ^+. The equation to the regression line is

$$\lg k' = (3.515 \pm 0.091)\,\sigma^+ + (5.126 \pm 0.032),$$

$$r = 0.99;\ n = 6;\ s = 0.02.$$

From the absolute magnitude and the sign of the reaction constant ρ the limiting stage in the reaction of benzaldehydes, as with ketones[65], is addition of non-protonated hydrogen azide to the protonated aldehyde.

3. Mechanism of Reaction of Carboxylic Acids with Hydrogen Azide

The mechanism of the reaction of carboxylic acids with hydrogen azide was not discussed at all in the early work. The first attempt is evidently that by Briggs and Lyttleton[66], who tried to formulate a mechanism on the basis of a study of a series of substituted benzoic acids. A little later Newman and Gildenhorn[67] suggested a mechanism for the acid-catalysed reaction. They considered that the carboxylic acid reacts either in a protonated form or as an acylium ion; in either case the final products are the corresponding amine and carbon dioxide.

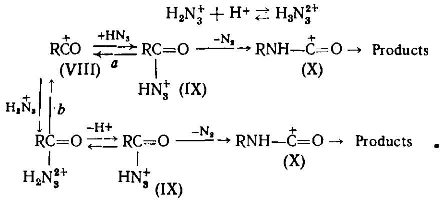
In a subsequent study of the Schmidt reaction with various carboxylic acids and also a detailed kinetic study fresh data were obtained largely supplementing and refining these views. Taking into account the protolytic equilibria preceding the main process, we can represent the mechanism of the reaction with carboxylic acids as

$$RCOOH + H^+ \rightleftarrows [RCO_2H_2]^+ \tag{20}$$

$$[RCO_2H_2]^+ + H^+ \rightleftarrows R\overset{+}{C}O + H_3O^+ \tag{21}$$

$$HN_3 + H^+ \rightleftarrows H_2N_3^+ \tag{22}$$

$$H_2N_3^+ + H^+ \rightleftarrows H_3N_3^{2+} \tag{23}$$



(24)

Such a mechanism is fully consistent with kinetic studies[57,68–70].

Table 5. Kinetics of reaction of 2,4,6-trimethylbenzoic acid with hydrogen azide in H_2SO_4 (at 15° C).

9	90.5	9.00	2.09	19	100.0	11.84	0.28
10	91.0	9.10	2.08				

Important results have been obtained for the reaction of 2,4,6-trimethylbenzoic acid with hydrogen azide in 77.2 to 100% sulphuric acid (Table 5 and Fig. 2).[70] The dependence of the logarithm of the effective reaction rate constant on the acidity function of the medium H_0 exhibits a characteristic break in the range 88.9–95.1% sulphuric acid (Fig. 2). The reaction velocity successively increases, decreases, and again increases in this acidity range, in which the content of the acylium ion increases sharply[39], while the proportion of free hydrogen azide decreases[55]. The explanation for such a complicated dependence of $\lg k_{\mathrm{eff}}$ on H_0 is that both free and protonated forms of hydrogen azide react with the acylium ion of 2,4,6-trimethylbenzoic acid.

The kinetic equation describing this process is

$$k_{\text{eff}}\frac{K_2}{h_R}\left(1+\frac{K_1}{h_0}+\frac{h_R}{K_2}\right)\left(1+\frac{K_3}{h_0}+\frac{h_+}{K_4}\right)=K'k'\frac{K_3}{h_0}+K''k'' \qquad (25)$$

or

$$k_{\text{eff}}D=K'k'\,\frac{K_3}{h_0}+K''k'', \qquad (26)$$

where K_1, K_3, and K_4 are the basicity constants of the carboxylic acid, hydrogen azide, and monoprotonated hydrogen azide, K_2 is the equilibrium constant for protonated acid and acylium ion, k' and k'' are the true rate constants of reactions (*a*) and (*b*) respectively (scheme 24), K' and K'' are the equilibrium constants of the stages preceding the rate-determining stage, h_0, h_R, and h_+ are the Hammet acidity of the medium and the acidities for triarylmethanols and singly charged cations, and

$$D=\frac{K_2}{h_R}\left(1+\frac{K_1}{h_0}+\frac{h_R}{K_2}\right)\left(1+\frac{K_3}{h_0}+\frac{h_+}{K_4}\right).$$

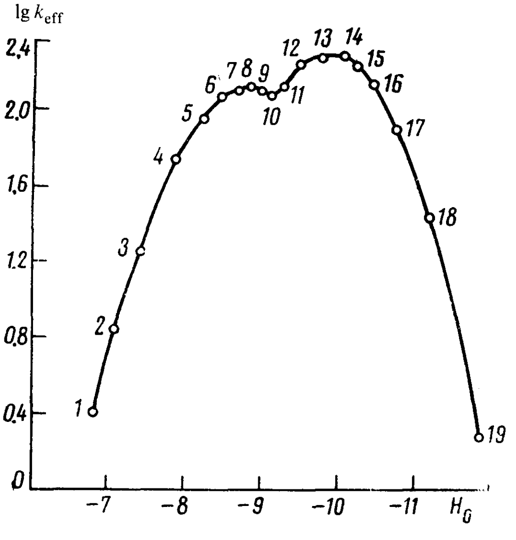

Figure 2. Dependence of effective rate constant for reaction of 2,4,6-trimethylbenzoic acid with hydrogen azide on the acidity function (for numbering of points see Table 5).

Under the boundary conditions with $h_0 \ll K_4$ or $h_0 \gg K_3$ (path *a* or *b*) Eqn. (25) becomes

$$\lg k_{\text{eff}}=\lg K'k'+\lg B \qquad (27)$$

$$\lg k_{\text{eff}}=\lg K''k''+\lg C, \qquad (28)$$

where

$$B=\frac{K_3h_R}{K_2h_0\,(1+K_1/h_0+h_R/K_2)\,(1+K_3/h_0+h_+/K_4)}$$

$$C=\frac{h_R}{K_2\,(1+K_1/h_0+h_R/K_2)\,(1+K_3/h_0+h_+/K_4)}\,.$$

Statistical treatment of the experimental results gave equations to the regression line for relations (27), (26), and (28) — experiments 1–6, 7–13, and 14–19 respectively (Table 5):

$$\lg k_{\text{eff}}=(4.26\pm 0.08)+(0.51\pm 0.17)\lg B, \qquad (29)$$
$$r=0.99;\ n=6;\ \alpha=0.975;\ f=12;$$

$$\lg k_{\text{eff}}\,D=(1.23\pm 0.35)\cdot 10^6\frac{K_3}{h_0}+(5.66\pm 35)\cdot 10^2; \qquad (30)$$
$$r=0.99;\ n=7;\ s=3.4\cdot 10^3;$$

$$\lg k_{\text{eff}}=(3.98\pm 0.06)+(1.39\pm 0.04)\lg C; \qquad (31)$$
$$r=0.97;\ n=6;\ \alpha=0.95;\ f=12.$$

Good correlation of $\lg k_{\text{eff}}$ with $\lg B$ and with $\lg C$ is observed (Eqns. 29 and 31), which confirms the mechanism of the reaction of carboxylic acids with hydrogen azide (scheme 24). However, the slopes of these relations differ from unity. For this reason Eqns. (29)–(31) cannot be used to calculate the true rate constants k' and k''. Thus the reactive species is the acylium ion (VIII). In moderately concentrated sulphuric acid the first stage involves addition of free hydrogen azide to this ion (path *a*). At high acidities the protonated form reacts with the acylium ion (path *b*). In media of intermediate acidity the reaction occurs by a mixed mechanism. Independently of the reaction path (*a*) or (*b*) the first stage involves formation of the protonated acyl azide (IX). Elimination of nitrogen and rearrangement convert (IX) into the protonated isocyanate (X), which then reacts with water to give the reaction products.

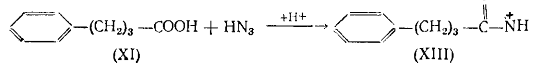
Unfortunately, existing data do not permit an assessment of the mode of rearrangement of the acyl azide (IX) — whether in one stage

$$R{-}\overset{\overset{\displaystyle O}{\|}}{C}{-}NH{-}\overset{+}{N}_2 \xrightarrow{-N_2} R{-}NH{-}\overset{+}{C}{=}O \qquad (32)$$

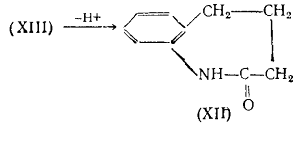
or in two stages

$$R{-}\overset{\overset{\displaystyle O}{\|}}{C}{-}NH{-}\overset{+}{N}_2 \xrightarrow{-N_2} R{-}\overset{\overset{\displaystyle O}{\|}}{C}{-}\overset{+}{N}H \rightarrow R{-}NH{-}\overset{+}{C}{=}O\ . \qquad (33)$$

For example, the action of hydrogen azide on γ-phenylbutyric acid (XI) in the presence of sulphuric acid forms not only the corresponding amine but also the lactam (XII) [71], presumably by intramolecular attack by the positively charged nitrogen on an *ortho* carbon atom of the benzene ring in the intermediate ion (XIII):



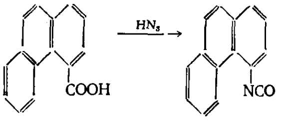
(34)



(35)

This suggests that rearrangement of the azide (IX) takes place in two stages. On the other hand, the lactam (XII) could be formed by a concerted mechanism with simultaneous detachment of nitrogen and electrophilic attack on the *ortho* carbon atom. Since there is no direct evidence in support of either mechanism, it is difficult to decide by which route (32 or 33) rearrangement of the protonated acyl azide takes place. Nevertheless, preference must be given to the synchronous mechanism by analogy with the Curtius reaction of the same type[72]. This suggestion is supported by the retention of configuration in the reaction of carboxylic acids with hydrogen azide[5–8, 73, 74].

Intermediate formation of an isocyanate from a carboxylic acid and hydrogen azide was demonstrated by Rutherford and Newman[75], who isolated the corresponding isocyanate in the reaction of phenanthrene-4-carboxylic acid:



(36)

The reaction of a carboxylic acid with hydrogen azide involves several stages, and the problem of which is rate-determining is important for an understanding of the overall mechanism. Kinetic results obtained[76] for a series of substituted benzoic acids in 99.9% sulphuric acid (Table 6) have been used to define the limiting stage. At this acid concentration ($H_0 = -11$) almost all the azide is present in the protonated form[55], and the reaction follows path (*b*) of scheme (24). The kinetics can then be represented by the equations

$$A^+ + B^+ \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} C^{2+} \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} C^+ \xrightarrow{k_3} D^+, \qquad (37)$$

$$[c] \qquad [d] \qquad [e]$$

where A^+ is the acylium ion, B^+ is the protonated hydrogen azide, C^{2+} and C^+ are the doubly and singly protonated acyl azide respectively, and D^+ is the protonated isocyanate. The effective rate constant k_{eff} is then related to the true rate constant k'' by Eqn. (28). Since no data are available on the acidity function H_R for sulphuric acid at concentration exceeding 99.9%,[39,43] equilibrium constants K_2 cannot be evaluated for substituted benzoic acids (except in the case of 2,4,6-trimethylbenzoic acid[39]). Hence formula (28) cannot be used to calculate the true rate constants for these compounds. This leads to difficulties when the Hammett equation is used to investigate the reaction mechanism. Nevertheless, under certain conditions effective rate constants can be used to correlate kinetic data for the action of hydrogen azide on substituted benzoic acids.

Table 6. Second-order rate constants for reaction of substituted benzoic acids RC_6H_4COOH with hydrogen azide in 99.9% H_2SO_4 (at 60° C).

Cpd.	R	k_{eff}, $M^{-1}\,min^{-1}$	Cpd.	R	k_{eff}, $M^{-1}\,min^{-1}$
1	H	12.59	5	*m*-F	2.34
2	*p*-Cl	8.32	6	*m*-NO_2	0.32
3	*p*-Br	8.32	7	*p*-NO_2	0.24
4	*m*-Br	3.31			

For scheme (37) either (*c*) or (*e*) can theoretically be the rate-determining stage, and they are indistinguishable kinetically. Only the protolytic equilibrium (*d*) is definitely not the limiting stage. If the rate constants k_1, k_{-1}, and k_3 are mutually comparable, the Hammett equation is quite inapplicable[77]. Provided that $k_1 \gg k_3$ or $k_3 \gg k_{-1}$, a correlation should be observed between $\lg k_{eff}$ and the substituent constants[78]. Combining the Hammett equation with the relation (28), we then obtain

$$\rho\sigma = \lg\frac{k_{eff}}{k_{0\,eff}} + \lg\frac{K_2}{K_{02}} + \lg\frac{(1 + K_1/h_0 + h_R/K_2)}{(1 - K_{01}/h_0 + h_R/K_{02})}. \qquad (38)$$

The last term on the right-hand side of (38) can be neglected, since in 99.9% sulphuric acid $K_1 \ll h_0$ and $K_2 \gg h_R$. If the rate constants of the reactions of substituted benzoic acids with hydrogen azide and the equilibrium constants K_2 correlate with the same substituent constants σ^+, we then have

$$\lg\frac{k_{eff}}{k_{0\,eff}} = (\rho_1 - \rho_2)\,\sigma^+. \qquad (39)$$

A correlation is indeed observed between $\lg k_{eff}$ and σ^+ (Fig. 3), and the equation to the regression line is

$$\lg k_{eff} = -(2.33 \pm 0.15)\,\sigma^+ + (1.21 \pm 0.07), \qquad (40)$$

$$r = 0.99;\ n = 7;\ s = 0.11.$$

However, the constant obtained in this way is an effective value, and it is difficult to assess the reaction mechanism from its sign and absolute magnitude.

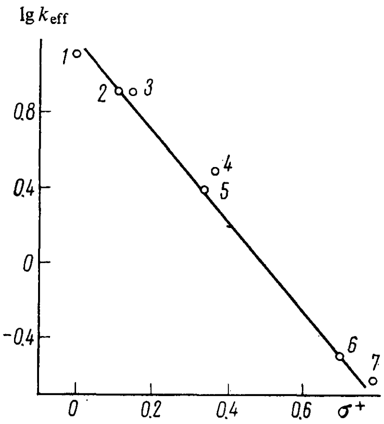


Figure 3. Dependence of effective reaction rate constants for benzoic acids on substituent constants σ^+ (for numbering of points see Table 6).

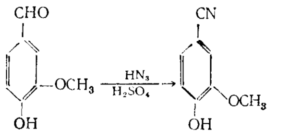
The correlation (40) indicates that the rate constants k_1, k_{-1}, and k_3 are not comparable, and that the rate of the reaction of substituted benzoic acids with hydrogen azide is increased by the presence of electron-donor substituents. Yet the opposite pattern is found for the analogous reactions of ketones and aldehydes, when addition of hydrogen azide to the protonated carbonyl compound is the rate-determining stage[64,65]. Furthermore, the tendency of substituted phenyl groups to migrate in reactions involving rearrangement of the carbon skeleton increases in the presence of electron-donor substituents[79,80]. These results obviously indicate that the rearrangement (*e*) is the rate-determining stage in the reaction of benzoic acids with hydrogen azide. The same conclusion was reached by Rabinowitz et al.[81], who found an approximately 15% decrease in reaction velocity when the carbonyl carbon-12 atom in carboxylic acids was replaced by carbon-14. This is supported by the absence of a kinetic isotope effect for the reaction of benzoic acids[70] in D_2O–D_2SO_4 relative to the H_2O–H_2SO_4 system of the same composition (79.3%): k^D_{eff} and k^H_{eff} are respectively 0.027 and 0.035 $M^{-1}\,min^{-1}$. Some difference between these constants is obviously due to differences in the value of D_0 and H_0 [82,83] and in the basicity constants of hydrogen azide in deuterosulphuric[56] and sulphuric[55] acids. The opposite kinetic isotope effect is found for the reaction of ketones and aldehydes with hydrogen azide: k^D/k^H = 4-6.[23,84]

III. APPLICATIONS OF REACTION

The reaction of aldehydes with hydrogen azide-provides a simple method for obtaining formamides and nitriles. However, several manuals of organic synthesis[85] state that it is difficult to control the proportions of the products. Actually, the factors governing the ratio of formamide to nitrile have become known only after the reaction mechanism has been finally established. This reaction can now be expected to be an effective method for obtaining various formamides and nitriles. It is noteworthy that the Schmidt reaction enables nitriles to be obtained from readily available compounds in a single stage, with sulphuric acid as catalyst. This method has advantages over others, since in most cases metal cyanides are used to obtain nitriles, or else the reaction occurs in several stages.

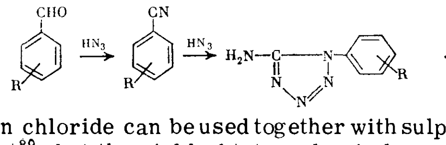
With acetaldehyde hydrogen azide forms acetonitrile[86]. This is apparently the only example of the application of the Schmidt reaction to aliphatic aldehydes. Such a situation is obviously due to their instability in aqueous sulphuric acid.

Aromatic aldehydes have been studied in greater detail. Thus McEwen et al.[59] investigated the action of hydrogen azide on a series of substituted benzaldehydes in the presence of sulphuric acid. They showed that the yields of formamides and nitriles can vary within wide limits depending on the acid concentration. From 4-hydroxy-3-methoxybenzaldehyde[87] the corresponding nitrile was obtained in 70% yield:



(41)

With excess of hydrogen azide and substituted benzaldehydes in the presence of concentrated sulphuric acid 5-amino-1-aryltetrazoles are formed[88,89]:



(42)

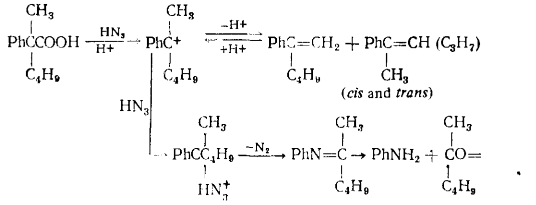
In this case tin chloride can be used together with sulphuric acid as catalyst[89], but the yield of tetrazoles is lower.

Since the early work of Schmidt the reaction of carboxylic acids with hydrogen azide has been widely used as a convenient method for obtaining various amines. This is due to the advantage of the Schmidt reaction over other processes for obtaining amines, e.g. the related Curtius and Hofmann rearrangements, as it occurs in a single stage. Other advantages are its simplicity, the availability of the initial reactants, and the quite mild conditions. The catalysts may be sulphuric acid[4,70,73], polyphosphoric acid[90,91], and mixtures of sulphuric and trichloroacetic acids[92,93] and of trifluoroacetic acid and anhydride[75]. In most cases sulphuric acid is used. Hydrogen azide is used as a solution in an inert solvent[74,94] (chloroform, benzene) or is generated *in situ* by adding sodium azide to the reaction mixture[95-97]. The latter procedure eliminates contact with the explosive and toxic hydrogen azide without lowering the yield of products. Aliphatic[98-100], alicyclic[3,74,94,101], bicyclic[102], and aromatic[4,103-106] acids react with hydrogen azide. The presence of a heteroatom (boron, nitrogen, oxygen) in the acid molecule[9,10,101,107] does not hinder the normal course of the reaction.

Aliphatic carboxylic acids of normal structure are converted into good yields of the corresponding amines[98]. However, acids containing alkyl or aryl substituents in the α position undergo secondary reactions. For example, αα-dimethylpropionic ("trimethylacetic") acid[108] forms a mixture of several products:

$$(CH_3)_3CCOOH \xrightarrow[H_2SO_4]{HN_3} CH_3NH_2 + CH_3\overset{\overset{O}{\|}}{C}CH_3 + NH_3 + CO + CO_2\ ,$$

A similar pattern is observed with 2-methyl-2-phenylhexanoic acid[91,109]. These departures from the "normal" reaction are due to decarboxylation of the initial acid to the corresponding carbocation and its subsequent reactions:



(43)

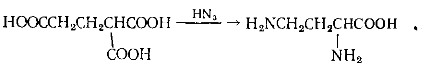
In aliphatic dicarboxylic acids only one carboxyl reacts if it is separated from the other by less than two carbon atoms[99]:

$$HOOCCH_2COOH \xrightarrow{HN_3} H_2NCH_2COOH\ . \qquad (44)$$

In the case of amino-dicarboxylic acids hydrogen azide reacts with the carboxyl that is more remote from the amino-group[99]:

$$HOOC(CH_2)_n\underset{\underset{NH_2}{|}}{C}HCOOH \xrightarrow{HN_3} H_2N(CH_2)_n\underset{\underset{NH_2}{|}}{C}HCOOH\ . \qquad (45)$$

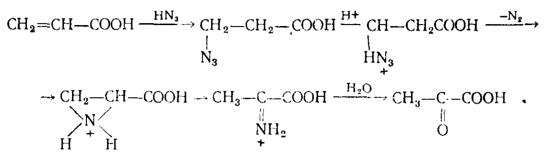
Similarly, tricarboxylic acids yield diamino-carboxylic acids[100]:



$$HOOCCH_2CH_2\underset{\underset{COOH}{|}}{C}HCOOH \xrightarrow{HN_3} H_2NCH_2CH_2\underset{\underset{NH_2}{|}}{C}HCOOH\ . \qquad (46)$$

Tetracarboxylic acids are converted into the corresponding tetramines[110].

Unsaturated aliphatic acids such as acrylic undergo a complicated reaction yielding pyruvic acid[111]:

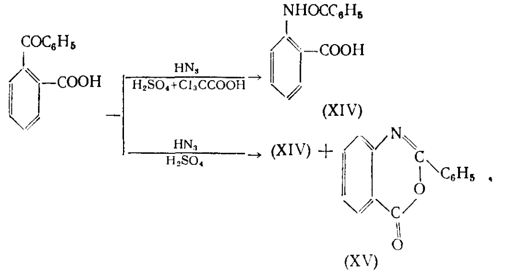


(47)

As already noted, alicyclic and bicyclic mono- and dicarboxylic acids react with hydrogen azide to form the corresponding amines, unaccompanied by *cis–trans* isomerisation. Thus the Schmidt reaction has been used to obtain *cis*- and *trans*-cyclobutane-1,2-diamines[74] and *cis*-cyclohexane-1,2-diamine[6,7].

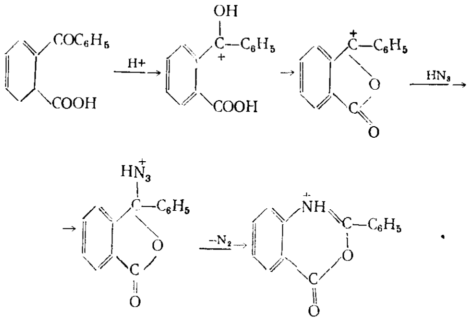
The Schmidt reaction with aromatic carboxylic acids has been especially widely studied. Thus substituted benzoic acids[4,103-106] are converted by hydrogen azide in the corresponding anilines in good yields. If electron-accepting substituents are present in the benzoic acids, 100% sulphuric acid[105] or even oleum[103,106] must be used as catalyst.

Interesting results were obtained with *o*-benzoylbenzoic acid[92,93]. If a mixture of sulphuric and trichloroacetic acids is used as catalyst, benzanilide (XIV) is formed, but with concentrated sulphuric acid as catalyst this is accompanied by oxazine (XV):



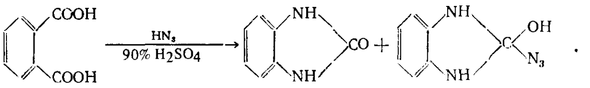
(48)

Oxazine results from cyclisation and ring expansion:



(49)

Aromatic dicarboxylic acids have been less studied than benzoic acids. In the presence of concentrated sulphuric acid phthalic acid gives an 80% yield of anthranilic acid with traces of *o*-phenylenediamine[4]. If 90% sulphuric acid is used, a mixture of two products—benzimidazolinone and 2-azido-2-hydroxybenzimidazoline—is formed[112]:



(50)

The information given in the present Review on the reactions of aldehydes and carboxylic acids with hydrogen azide indicates the considerable progress made in this field. Future research will undoubtedly bring interesting knowledge on the mechanism of acid-catalysed rearrangements and reveal fresh opportunities for the application of these reactions to organic synthesis.

Poly(arylene Sulphides)—Preparation, Structure, and Properties

V.A.Sergeev, V.K.Shitikov, and V.I.Nedel'kin

Chemical aspects of the synthesis, structure, and properties of oligo- and poly-(arylene sulphides) are surveyed. The Review concludes with several fields of application and a list of 252 references.

CONTENTS

I. Introduction 1095

II. Methods of preparation of poly(arylene sulphides) 1095

III. Practical applications 1106

I. INTRODUCTION

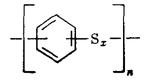
The advantageous properties of polymers like polyphenylenes are difficult to realise practically in ready-made materials and articles, mainly because such polymers are insoluble and infusible right up to their thermal decomposition temperatures. As a consequence, vigorous research has been undertaken on the synthesis of modified polymers of this type. A great deal of experimental information has now accumulated on the synthesis and the properties of oligo- and poly-phenylenes containing functional groups[1], whose fields of practical application are continuously expanding. Polyheteroarylenes, containing in the main chain aromatic rings and various heteroatoms, e.g. oxygen[2] or sulphur[3], are being increasingly utilised in industry. Recent years have seen an especially marked increase in the number of studies aimed at developing methods of preparation, investigating the properties, and applying poly(arylene sulphides), which are distinguished by high resistance to thermal oxidation and several specific properties.

Although poly(arylene sulphides) were first synthesised in 1866, by the action of alkali-metal sulphides on bis-diazonium salts of benzidine[4], systematic investigations on their synthesis and more thorough study of their structure and properties in 1948, after Macallum's discovery[5] of a new process for obtaining poly(arylene sulphides) by the high-temperature polycondensation of polyhalogenated benzenes in the presence of mixtures of sulphur and alkali-metal carbonates.

Methods for obtaining oligo- and poly-(phenylene sulphides) of linear structure

have been elaborated in the greatest detail, and their properties have been investigated most thoroughly. The enhanced heat-resistance and thermal stability of such polymers is due primarily to the comparatively high energy of rupture of the phenyl–sulphur bond (72.7 kcal mole^{-1})[6] and to their physical structure, largely determined by the strong intermolecular interaction of the polymer chains and the formation of a crystalline structure[7]. Furthermore, the presence of sulphur atoms between aromatic rings not only ensures that the polymeric molecule shall be flexible and highly resistant to thermal oxidation but also is responsible for the cross-linking of poly(phenylene sulphides) at 300–350°C.[8,9]

The term *poly(arylene sulphides)* is met more often than other names, in both Soviet and foreign literature, in relation to simple aromatic "polythioethers" or polysulphides. The Reviewers consider this name most rational and able to represent quite adequately the various chemical structures of most oligomers and polymers of simple aromatic polysulphides. For example, the name *poly(phenylene sulphides)* applies to polymers in which the repeating monomer unit is



where $x = 1$. The aromatic rings in such polymers may be combined by sulphur atoms in the relative positions 1,2, 1,3, and 1,4 (poly-(*o*-phenylene sulphide), poly-(*m*-phenylene sulphide), and poly-(*p*-phenylene sulphide) respectively). When $x \geqslant 2$, poly(phenylene disulphides), poly(phenylene trisulphides), poly(phenylene tetrasulphides), and poly(phenylene polysulphides) are formed.

The same principles underly the nomenclature of poly(arylene sulphides) having a branched structure or substituents in the aromatic ring. The only difference is that the substituents and their positions are indicated before the name of the chief arylene ring. For example, a polymer based on the monomer unit

is termed *poly-(2,6-dimethyl-1,4-phenylene sulphide)*.

The present Review surveys almost all known methods for obtaining poly(arylene sulphides) of diverse structure. It gives their principal characteristic properties and several fields of application.

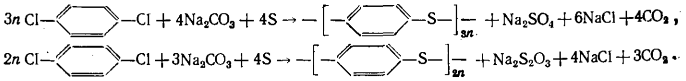
II. METHODS OF PREPARATION OF POLY(ARYLENE SULPHIDES)

1. Polycondensation of Polyhalogenated Aromatic Compounds with a Mixture of Sulphur and Various Derivatives of Alkali and Alkaline-earth Metals

One of the best known and simplest methods for obtaining poly(phenylene sulphides) is based on the high-temperature (275–360°C) polycondensation of polyhalogenated benzenes in the presence of mixtures of sulphur and alkali-metal carbonates, first accomplished in 1948 by Macallum[5]. In his view only after a first stage of formation of alkali-metal sulphides

$$3M_2CO_3 + (2n + 2)\,S \rightarrow 2M_2S_n + M_2S_2O_3 + 3CO_2$$
$$4M_2CO_3 + 4S \rightarrow 3M_2S + M_2SO_4 + 4CO_2$$

did polycondensation occur with the halogenobenzenes. With *p*-dichlorobenzene mixed with sulphur and sodium carbonate we can represent the process by the equations



The poly-(*p*-phenylene sulphides) thus obtained are slightly coloured powders, sparingly soluble in the usual organic solvents and softening at 250–300°C. Macallum assumed[10] that the first stage was far slower than the second, so that the reaction mass always contained a small quantity of elementary sulphur, which assists polycondensation of halogenobenzenes with metal sulphides. Indeed, it was found experimentally[5] that a slight excess of elementary sulphur not only played a part in building up the polymer chain but also catalysed the process to high degrees of conversion of the initial halogenobenzenes. In the absence of excess of sulphur halogenated aromatic compounds and alkali-metal sulphides either do not interact at all or undergo polycondensation only slowly even at high temperatures.

However, the quantity of combined sulphur depends mainly on the initial molecular ratio of the dihalogenobenzene and sulphur[10], so that the monomer unit in the resulting poly-(*p*-phenylene sulphides) can be represented by the general formula

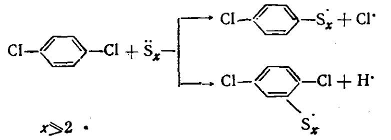
Thus the polycondensation of *p*-dichlorobenzene and sulphur taken in the molecular proportions 1.0 : 1.5 yielded solid poly-(*p*-phenylene sulphides) of m.p. 215–240°C, whose monomer unit corresponded to the above general formula with $x = 1$. When the molecular ratio was increased from 1.5 to 2–3 the melting point fell to 55–80°C, while the sulphur content corresponded to $x = 2$–5. Copolymers obtained from a mixture of *p*-di- and 1,2,4-tri-chlorobenzenes in the presence of sulphur and sodium carbonate had the analogous structure

$$-[C_6H_4S_x]\cdot[-C_6H_3S_y]_n-$$

with $x = 1.15$–1.25, $y = 1.72$–1.87, and $n = 0.04$–0.25. From the above results it was concluded[10] that the main polymer molecule consisted of aromatic rings linked both by monosulphide and by polysulphide groups.

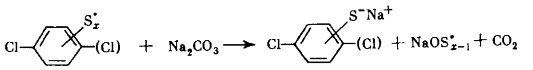
Later investigations have shown[11] that the polycondensation of dihalogenobenzenes can be accomplished also in the presence of a mixture of sulphur and an alkaline-earth metal or its carbonate, borate, or oxide. The formation of poly-(*p*-phenylene sulphides) is catalysed by *N*-halogenated derivatives, e.g. *N*-bromosuccinimide, *N*-bromoacetamide, etc. (5% based on the initial monomers)[12]. Aromatic compounds containing activated halogen atoms, e.g. di-*p*-chlorophenyl sulphide or sulphone, have been used[13] as activators of polycondensation: in their presence up to 80% yields have been obtained of poly(arylene sulphides) of molecular mass 237 000 (calculated from the chlorine content).

Lenz and Carrington[14] suggested an alternative mechanism, in which the first stage involves reaction between the halogenated aromatic compound and a sulphur biradical formed during heating:

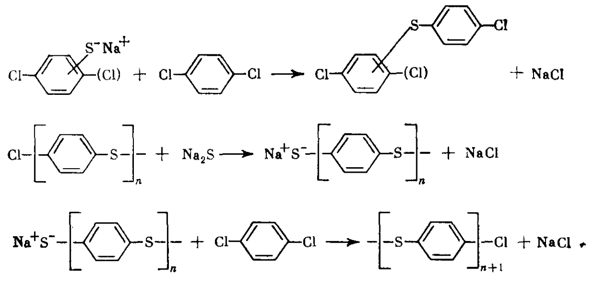


$x \geqslant 2$.

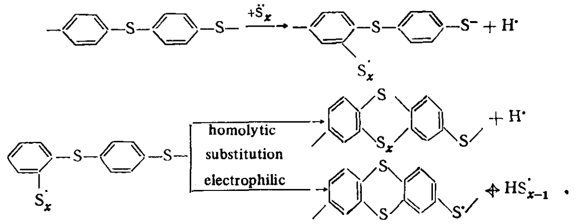
The polysulphide substituents in the aromatic ring then react with sodium carbonate to form benzenethiolate ions:



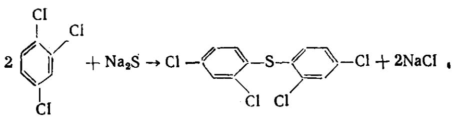
Nucleophilic substitution occurs with the dihalogenoarenes to give primary oligomeric or secondary polymeric products:



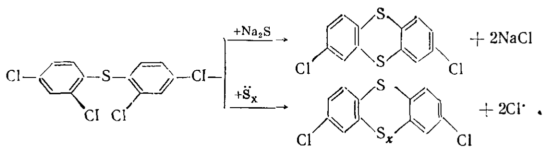
According to the above scheme sulphur biradicals are able to replace not only halogen but also hydrogen atoms in the aromatic ring, which may promote the formation both of branched and of "cross-linked" poly(arylene sulphides). Indeed, infrared spectroscopy established[15] that the polymer obtained from *p*-dichlorobenzene had a branched or partly cross-linked structure. Some ordering (detected by X-ray diffraction) was attributed[15] to the presence of linear segments comprising 6 or 7 monomer units between side-chains, able to form zones with some ordering of the spatial arrangement of the polymer chains. The increase in the sulphur content of the polymer above that calculated for a $C_6H_4.S$ monomer unit was explained[15] by intramolecular cyclisation, which may result in sulphur-containing rings:



Study of the simultaneous polycondensation of *p*-di- and 1,2,4-tri-chlorobenzenes revealed[15,16] not only that the rate of nucleophilic substitution of the latter exceeds that of the former more than fourfold but also that the 1-chlorine atom in the trichlorobenzene is the most reactive of the three in nucleophilic substitution. Therefore the first stage involves preferential formation of a dimer from 1,2,4-trichlorobenzene:



Subsequent nucleophilic or radical substitution of one of the *ortho*-chlorine atoms forms phenylthio-groups or polysulphide links, which are readily converted by intramolecular cyclisation into thianthren units:



Hence, owing to intramolecular cyclisation, 1,2,4-trichlorobenzene is actually difunctional on polycondensation in the presence of sulphur and alkali-metal carbonates. The change in functionality during copolycondensation and the considerable differences in activity between the initial monomers have a significant influence on the direction of the process and on the properties of the resulting poly(phenylene sulphides).

Table 1. Properties of homopolymer from *p*-dichlorobenzene and of copolymer from *p*-di- and 1,2,4-tri-chlorobenzenes.

Property	Homopolymer*	Copolymer**
1	2	3
Degree of conversion (from Cl⁻ in aq. extract), %	99.0	99.0
Yield of toluene-soluble polymer, %	8.3	5.8

Chlorine content, %	1.60±0.1	1.70±0.1
Yield of polymer soluble in diphenyl ether, %	63.5	77.5
Softening point, °C	193—204	171—177
Sulphur content, %	33.2±0.3	31.6±0.3
Chlorine content, %	0.50±0.1	0.6±0.1
Yield of insoluble polymer, %	20.6	11.6
Total yield, %	94.2	94.9

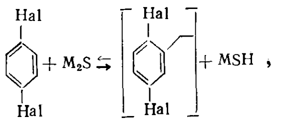
*Molecular proportions $C_6H_4Cl_2 : S : Na_2CO_3 = 1 : 1.73 : 1.73$ at 300°C for 20 h.

**Molecular proportions $C_6H_4Cl_2 : C_6H_3Cl_3 : S : Na_2CO_3 = 1 : 0.1 : 1.84 : 1.84$ at 300°C for 24 h.

Table 1 compares the characteristics of the homopolymer obtained from *p*-dichlorobenzene with those of the copolymer obtained from the same monomer together with 10 mole % of 1,2,4-trichlorobenzene[15]. It is evident that polycondensation gives high yields of poly(phenylene sulphides), and higher yields of soluble fractions in the case of the copolymer. However, the strength characteristics of the copolymers are somewhat inferior to those of the homopolymers. In order to improve the durability of copolymers it was suggested[16] that copolycondensation with sulphur and sodium carbonate should be conducted in the presence of alkylated aromatic hydrocarbons, e.g. toluene, xylene, methylnaphthalenes, etc., which were considered to inhibit or completely to eliminate formation of thianthren groups in the copolymer structure.

Intramolecular cyclisation can be observed especially distinctly in the high-temperature polycondensation of *o*- and *m*-dihalogenobenzenes in the presence of a mixture of sulphur with oxides or sulphides of alkali or alkaline-earth metals. . Thus under these conditions up to 75% yields of thianthren were obtained from *o*-dichlorobenzene[10], but from *m*-dichlorobenzene an insoluble product was formed and a substance was isolated (molecular mass 1120) that contained 31.5% of sulphur and was free from chlorine[17]. It was considered[17] that the polycondensation of *o*- and *m*-dihalogenobenzenes may give high yields of cyclic *ortho*- or *meta*-substituted oligomers (tetramers, pentamers, heptamers, nonamers, decamers, etc.).

The evolution of hydrogen sulphide under these conditions of the Macallum polycondensation of dihalogenobenzenes was attributed to side-reactions with the metal sulphide[14]:



$$2MSH \rightleftarrows M_2S + H_2S$$

This process results in formation of polymers having a branched and cross-linked structure.

Monohalogenated aromatic compounds containing various substituents in the aromatic ring can also be used for high-temperature polycondensation with sulphur and sodium carbonate[18,19]. Thus various poly(phenylene sulphides) have been obtained by heating *para*-halogenated phenols, toluene, aniline, or benzoic acid with a mixture of sulphur and sodium carbonate (molecular proportions 1 : 1.73 : 1.73) at 160–340°C for 18 h. The degree of conversion of the monomers, calculated from the quantity of chloride ions in an aqueous extract, depends on their structure and on the temperature of polycondensation; the yield of the reaction products reaches 80% or more. Experimental results are given together with the polymer structure established on the basis of infrared, ultraviolet, and nuclear magnetic resonance spectral data[18]. For comparison polymers were obtained from *p*-dichlorobenzene under the same conditions. Poly(phenylene sulphides) obtained from *para*-chlorinated phenol and aniline contain hydroxy- and amino-groups respectively, whereas the carboxyl and methyl groups of *para*-chlorinated benzoic acid and toluene undergo various changes during polycondensation. On the assumption of first- or second-order kinetics for polycondensation, with simultaneous solution of the Arrhenius and Hammett equations, it was found that the overall rate depended mainly on polar effects and on the slowest stage, i.e. electrophilic attack by the sulphur atom on the monomer. Raising the temperature of polycondensation increases the yield of polymers having a branched and cross-linked structure.

Scanning calorimetry and thermogravimetric analysis indicate[19] that poly(phenylene sulphides) containing various substituents in the aromatic ring have softening and decomposition points of 90–263 and 270–320°C respectively. The degradation of such polymers has first-order kinetics; activation energies in an atmosphere of nitrogen are 7–30 kcal mole^{-1}, the lowest values applying to poly(phenylene sulphides) containing amino- and hydroxy-groups.

According to a patent[20] soluble poly(phenylene sulphides) resistant to thermal oxidation at high temperatures can be obtained from a mixture of *para*-chlorinated triphenyl-1,3,5-triazines with *p*-dichlorobenzene. When such monomers undergo polycondensation in the presence of a mixture of sulphur with carbonates, sulphides, or oxides of alkali or alkaline-earth metals at 270–360°C, triazine-containing poly(phenylene sulphides) are obtained that undergo losses in mass of 3.3% and 5.3% when heated at 300°C for 100 h and at 400°C for 20 h respectively.

Aromatic polysulphide polymers of molecular mass M_n = 2500–10 000) and general formula $[ArS_x]_n$, where $x = 2-5$, which form predominantly white powders soluble in oxolan and with m.p. $\geqslant$100°C, have been obtained by the polycondensation of disulphonic, disulphinic, dithiosulphonic, and dithiosulphinic acids, and also their salts, esters, anhydrides, chlorides, and amides, with alkali-metal polysulphides formed by the action of powdered sulphur on aqueous solutions of alkali-metal sulphides[21]. Water or a lower alcohol was used as solvent, and polycondensation was effected in the presence of gaseous hydrogen together with sulphides or polysulphides of elements of the iron subgroup, as well as the finely powdered metals, under 7–350 kg cm^{-2} in an autoclave at 150–200°C.

2. Polycondensation of Polyhalogenated Aromatic Compounds with Alkali-metal Sulphides

Despite the apparent simplicity and the availability of the initial compounds, the high-temperature polycondensation of polyhalogenoarenes in the presence of a mixture of sulphur and a carbonate, sulphide, or oxide of an alkali or an alkaline-earth metal has not found wide industrial application owing to the experimental difficulties involved in isolating the poly(phenylene sulphide) from the melt containing a large quantity of impurities of low molecular weight and owing to the strongly branched and partly cross-linked character of the products. These disadvantages are to some extent avoided when polyhalogenated aromatic compounds undergo polycondensation with alkali-metal sulphides in polar organic solvents of high boiling point[22,23].

Polycondensation of polyhalogenated aromatic compounds with alkali-metal sulphides is at present the only industrial method of obtaining poly(arylene sulphides)[24], but information on this process is extremely limited. Polycondensation is continued in an inert atmosphere at 125–450°C for 17–20 h; *N*-methylpyrrolid-2-one, hexamethylphosphoramide, tetramethylurea, etc. can be used as solvents. Poly(phenylene sulphides) of highest molecular mass are obtained in *N*-methylpyrrolidone solution[22]. At moderate temperatures and pressures maximum rates can be achieved[25] by gradually adding increasing quantities of the arylene halide to the alkali-metal sulphide and varying the duration of polycondensation. The anhydrous sulphide (mainly sodium sulphide) is generally used, or else water of crystallisation is evaporated from a hydrate by preheating the reaction mass to 160°C.[22,26] Alternatively, sodium sulphide can be obtained directly in the reaction vessel by treating sodium hydroxide with hydrogen sulphide[27,28] or industrial waste gases containing it[29].

Isolation of the poly(arylene sulphides) from the reaction mixture apparently presents some difficulty. For this purpose it is proposed to treat the mixture with water vapour[30] or liquid ammonia[31] under pressure, evaporate off the solvent under adiabatic conditions[32–35], or apply filtration followed by treatment of the polymer with water and organic solvents[36]. The extractants used are acyclic or alicyclic hydrocarbons[37], dichloroethane, or benzene[38].

Yields up to 85% of poly(arylene sulphides) have been obtained in this way. The products were pale grey powders, soluble in high-boiling organic solvents, e.g. polyphenols, above 235°C.[39] Poly(arylene sulphides) obtained from *p*-dihalogenobenzenes and sodium sulphide in *N*-methylpyrrolid-2-one solution have molecular masses around (5–14) $\times 10^3$. Such products probably separate from solution during polycondensation, and play no part in further growth of the polymer chain.

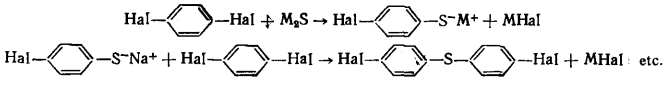
Table 2. Dependence of viscosity of poly(arylene sulphides) (melt at 303°C) on initial molecular ratio of *p*-dichlorobenzene to sodium sulphide.

Ratio	Viscosity, P	Ratio	Viscosity, P
1:1	37.3	1.04:1	4.8
1.02:1	6.4	1.05:1	7.1

The molecular mass is also influenced by the properties of the initial components[22]. Table 2 gives the viscosities of the poly(arylene sulphide) melts obtained with different initial molecular ratios of *p*-dichlorobenzene and sodium sulphide[22]. The use of purified initial compounds, including sodium sulphide with an impurity content not exceeding 1–2%, is therefore of interest[28,41]. An equimolecular mixture of purified *p*-dichlorobenzene and sodium sulphide gave poly(phenylene sulphides) having a lower melt index and a higher viscosity. With a 2 : 1 molecular ratio of sodium sulphide oligo(phenylene sulphides) were obtained having molecular mass 510 and softening point 125–130°C.[27] Benzenethiol separated as a byproduct in yield almost equal to that of the oligomers. If, however, a threefold excess of functional groups in the halogeno-derivative was used relative to the sodium sulphide, a product of low molecular mass was obtained[42], with a mean degree of polycondensation of 2.

Thus the above results show that equimolecular proportions of the initial components are necessary to obtain poly(arylene sulphides) of maximum molecular mass. Furthermore, there are data indicating that two measures must be taken to increase the rate of the process and the molecular mass of the products: (i) polycondensation of sodium sulphide with dihalogenated unsaturated cyclic hydrocarbons, preferably aromatic, in the presence of trihalogenobenzenes[22,28] or 3–33 wt.% of activators (a mixture of oligo(phenylene sulphides) extracted from products of a similar reaction with benzene, toluene, or *N*-methylpyrrolidone at 80–150, 110–150, or 135–150°C respectively)[43,44]; and (ii) the temperature must be raised at a specified rate during polycondensation[45].

According to infrared and n.m.r. spectral data and X-ray diffraction poly(arylene sulphides) obtained by the polycondensation of dihalogenated aromatic compounds with alkali-metal sulphides have a linear structure, in contrast to the branched polymers obtained in the presence of sulphur and alkali-metal carbonates. It follows that a mechanism of nucleophilic substitution is responsible for the appearance of the former when the process occurs in a polar organic solvent[40]:



Various halogenated aromatic compounds can be used for polycondensation with sodium sulphide in order to obtain poly(arylene sulphides) having modified properties.

Thus the copolycondensation with sodium sulphide of *p*- and *m*-dichlorobenzenes in various proportions by weight gives poly(phenylene sulphides) that are soluble in oxolan[46], a few characteristics of which are listed in Table 3. It is significant that increase in the proportion of *p*-dichlorobenzene in the reaction mixture increases the viscosity and raises the glass point of the resulting polymers. Unfortunately, however, the patent literature contains no evidence of their structure[46].

Table 3. Properties of copolymers from *p*- and *m*-dichlorobenzenes.

Isomer, %		Properties of copolymers		
para	*meta*	η	glass point, °C	solubility in oxolan, g/100 g
75	25	0.11	68	insol.
50	50	0.09	49	>20
25	75	0.05	47	42
0	100	0.01	15	<0.5

Polycondensation of a mixture of poly-(*m*- and *p*-phenylene sulphides) with sodium sulphide yields block copolymers[47] containing, according to infrared spectroscopy, *meta*- and *para*-substituted aromatic groups in proportions varying between the limits 3 : 1 and 1 : 3 for fractions of the block copolymer respectively soluble and insoluble in *N*-methylpyrrolidone.

Polymethylated and branched poly(phenylene sulphides) have been obtained respectively from dibromodurene and from a mixture of *p*-dibromobenzene and 1,3,5-tri-*p*-bromophenylbenzene in the molecular proportions 20 : 1.[40] The good solubility of the products in dimethylformamide is attributed[40] to disorder resulting from the introduction of substituents or a branching agent respectively into the polymer molecule. In contrast to the poly(phenylene sulphide) obtained from *p*-dibromobenzene and melting at 280°C, the copolymer from the 20 : 1 mixture with 1,3,5-tri-*p*-bromophenylbenzene softened at around 235°C.

Poly(arylene sulphides) containing reactive groups can be obtained by the polycondensation with alkali-metal sulphides of halogenated aromatic compounds containing various functional groups. Thus 2,5-dichloroaniline yields amino-containing polymers, which become infusible and insoluble on treatment with dicarboxylic acids[43], but the corresponding products of the simultaneous polycondensation of *p*-dichlorobenzene and *o*-chloroaniline melt at 283–286°C and have a viscosity of 52 P at 303°C.[22] Poly(arylene sulphides) from 2,4-dichlorotoluene soften below 100°C and are readily soluble in benzene, while those from 2,5-dichlorobenzenesulphonic acid are readily soluble in water[22].

The polycondensation of *p*-dichlorobenzene with sodium sulphide in the presence of copper cyanide gives oligo-(phenylene sulphides) of molecular mass 500–5000, containing terminal nitrile groups[48], which may subsequently be involved in thermal or catalytic cross-linking.

Polycondensation of dichlorodinitrobenzene with sodium tetrasulphide at 70 and 110°C gives oligo(phenylene tetrasulphides) containing amino- and nitro-groups[49], the maximum yield of polymer (>90%) being obtained with the reactants in the molecular proportions 1 : 2. This is attributed mainly to secondary processes, in particular reduction of nitro- to amino-groups:

$$C_6H_2Cl_2(NO_2)_2 + 2Na_2S_4 + 2H_2O \rightarrow C_6H_2Cl_2(NH_2)_2 + 2Na_2S_2O_3 + 4S\ .$$

Since the content of so called free sulphur in the polymer is only 0.78%, while the total sulphur content is ~44.2%, it is thought[49] that all the sulphur atoms are present in the main chain of the macromolecule, while the terminal groups may be chlorine atoms or hydroxyls (analysis indicates that the latter amount to 1.93%). Apparently, therefore, the structure of the oligomer can be represented by the formula

$$Cl\,(NH_2)_2\,C_6H_2S_4\text{—}\ldots\text{—}C_6H_2\,(NH_2)_2\,OH.$$

The maximum molecular mass is ~850 (determined cryoscopically in benzene). The resulting oligomers had softening points of 47–63°C and were readily soluble in benzene, acetone, carbon disulphide, and mineral acids.

Another monomer that has been used is di-*p*-chlorophenyl sulphone, whose chlorine atoms are activated by the electron-accepting sulphonyl group[50–52]. In dimethyl sulphoxide solution at 170°C a theoretical yield was obtained of polymers having a reduced viscosity of 0.15 in a 1% solution in this solvent at 25°C. Polycondensation of the initial sulphone with sodium sulphide can be effected also in aqueous solution or in a mixture of an organic solvent with water at 150–400°C.

Poly(quinone sulphides) of molecular mass ~3000 have been obtained by the polycondensation of tetrachloro-*p*-benzoquinone with sodium sulphide in toluene solution at 0°C.[53] They are solid powders apparently having a linear structure, with softening points of 320°C and above.

Quite recently poly(arylene sulphides) have been obtained by heating polyhalogenated aromatic compounds with thiourea and oxides (or carbonates) of alkali and alkaline-earth metals in *N*-methylpyrrolidone solution under pressure[54]. The procedure is to heat thiourea with the metal oxide (or carbonate) in *N*-methylpyrrolidone solution, and then add to the mixture the polyhalogenated aromatic compound, which probably reacts with an already formed sulphide. Yields of 41–94% are obtained of polymers that soften at 249–273°C and have reduced viscosities of 0.01–0.07.

The thiourea can be replaced by thiocarbonates of general formula R_2CS_3 (where R represents an alkali metal or a hydrocarbon radical)[55–57], thiosulphates, thiocarboxylic acids[57–59], thiols, thiolates, or sulphides containing an activating substituent in an α or β position (e.g. α-mercaptopropionic acid)[57,60], carbon disulphide and carbonyl sulphide[61], thioamides of general formula $R'(CS.NR_2)_x$ (where R is hydrogen or a radical of valency 1–4), *N*-methylpyrrolidine-2-thione[62], thiocarbamates (e.g. sodium dimethyldithiocarbamate)[63], and also phosphorus pentasulphide[64] in hexamethylphosphoramide solution.

Yields of poly(phenylene sulphides) from the polycondensation of dihalogenated aromatic compounds with alkali-metal hydrogen sulphides are only 24–45%.[65] To increase the yield the polycondensation is conducted in the presence of alkali-metal *N*-substituted ω-amino-carboxylates[66]. Similar compounds have been used also in the polycondensation of dihalogenated aromatic compounds with carbon disulphide[67]. Furthermore, up to 94% yields of poly(phenylene sulphides) are obtained from dihalogenated aromatic compounds and alkali-metal hydrogen sulphides in the presence of alkaline-earth metal hydroxides or alkali-metal carbonates[68] or of sodium hydroxide and salts of aliphatic alcohols and acids[69].

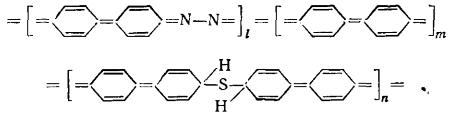
3. Decomposition of Diazonium Salts

Poly(arylene sulphides) were first obtained by Griess[4] in 1866, by the decomposition of aromatic diazonium salts in the presence of an alkali-metal sulphide. An equation has been suggested for this reaction only comparatively recently[70]:

$$n\overline{\mathrm{Hal}}\overset{+}{\mathrm{N}}_2\mathrm{Ar}\overset{+}{\mathrm{N}}_2\overline{\mathrm{Hal}} + nM_2S \rightarrow -[-\mathrm{ArS}-]_n- + 2n\mathrm{MHal} + 2nN_2 .$$

Later work has shown that decomposition takes place also in the presence of hydrogen sulphide[17] or thiourea[7] and water at 0–5°C. The products (obtained in almost theoretical yield) are brown powders, partly soluble in carbon disulphide, dioxan, and dimethylformamide. The soluble fraction of the poly(arylene sulphides) softens at 70–80°C, but the insoluble fraction does not soften below the thermal decomposition point.

Since cryoscopic determination in diphenylamine solution and calculation from the chlorine content give molecular masses of 460–1400 and 5000–10000 respectively for the soluble fraction, it is assumed[72] that chlorine atoms are present in the polymer molecule not only as terminal groups. Elementary analysis and the ultraviolet spectra indicate[70] that the polymer chain contains quinoid structures, azo-groups, and sulphur in semiquinoid groupings:



The presence of azo-groups is confirmed also by the evolution of gaseous nitrogen when the soluble fraction is heated to 150–200°C, with formation of an infusible and insoluble product.

The formation of azo-groups in the polymer molecule may result from the decomposition of aromatic diazonium salts by a radical mechanism:

$$\overset{+}{\mathrm{N}}_2\mathrm{Ar}\overset{+}{\mathrm{N}}_2 \xrightarrow{\mathrm{HS}^-} {}^{\cdot}\mathrm{N}_2\mathrm{Ar}^{\cdot} + \ddot{\mathrm{Ar}} + {}^{\cdot}\mathrm{N}_2\mathrm{ArN}_2^{\cdot} + \ddot{\mathrm{S}} \rightarrow -[-\mathrm{ArN}_2-]_l-[-\mathrm{Ar}-]_m-[-\mathrm{ArS}-]_n-$$

However, this reaction can take place also by a mechanism of nucleophilic substitution[73, 74]. In the homopolycondensation of *p*-mercaptobenzenediazonium chloride in aqueous solution at pH 7, for example, an insoluble solid product is obtained, whose colour is apparently due to the presence of azo-groups in the polymer chain[74]. The overall equation for the reaction can be written

$$2n\overset{+}{\mathrm{H}}\overline{\mathrm{S}}\mathrm{C}_6\mathrm{H}_4\overset{+}{\mathrm{N}}_2\overset{-}{\mathrm{Cl}} \rightarrow -[-\mathrm{S}-\mathrm{C}_6\mathrm{H}_4-\mathrm{S}-\mathrm{N}{=}\mathrm{NC}_6\mathrm{H}_4-]_n- + nN_2 + n\mathrm{HCl}$$

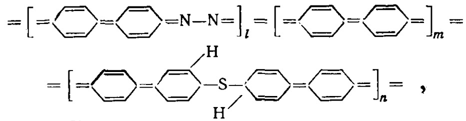
with growth of the polymer chain due to interaction of the zwitterions

$$2\overline{S}C_6H_4N_2^+ \rightarrow -S-C_6H_4SC_6H_4N_2^+ + N_2 .$$

The infrared spectra of the product contain absorption bands due to diazo-sulphide groups, as well as *para*- and *meta*-disubstituted and 1,2,4-trisubstituted benzene rings, which may be centres of chain branching and cross-linking. Even after heat-treatment 150–200°C, with evolution of nitrogen and predominant formation of poly-(*p*-phenylene sulphide) structures, nitrogen could not be completely eliminated from the polymer.

4. Polycondensation of *p*-Halogenobenzenethiolates

The homopolycondensation of metal salts of *para*-halogenated thiophenols is now one of the most promising and quite widely investigated methods for obtaining poly(arylene sulphides). This reaction was first described in 1960 by Lenz et al.[15], and can be represented by the general scheme



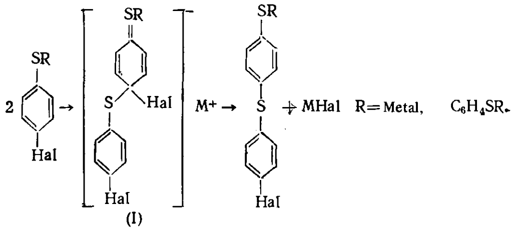
Various copper salts and amines can be used as catalysts, in amounts from 0.01 mole % to equimolecular relative to the initial thiolate[75, 76].

Good yields of poly(arylene sulphides) having high reduced viscosities are obtained by the homopolycondensation of *para*-halogenated thiols in the presence of catalytic quantities of dihalogenobenzenes[77]. Either soluble or infusible and insoluble polymers are obtained depending on the conditions. If the *para*-halogenated thiolate undergoes polycondensation in the mass at temperatures 10–20 deg below the melting point of the initial thiolate, for example, linear polymers are obtained; at higher temperatures infusible and insoluble products are formed under these conditions.

The rate of polycondensation in solution exceeds that in the solid state[78] by factors of 50–100. Depending on the organic solvent used—pyridine, quinoline, dimethylformamide, dimethyl sulphoxide—the process can be carried out over a wide temperature range[75]. Poly(arylene sulphides) obtained by the polycondensation of *para*-halogenated thiolates in solution had a softening point of 280°C, and according to X-ray diffraction a linear structure.

The initial *p*-halogenobenzenethiolate can be obtained *in situ* by the action of an alkali-metal hydride or carbonate on the thiol[79, 80]. An alternative is the cleavage of dihalogenated aromatic disulphides in the presence of copper powder[81]:

In a suggested[82] mechanism the resonance structure (I) formed in the first stage is responsible for the appearance of an inorganic salt and a dimer (a *p*-halogenophenyl *p'*-mercaptophenyl sulphide), the latter able to undergo further reactions leading to poly-(*p*-arylene sulphides):



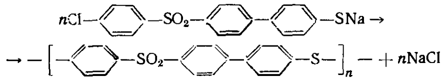
(I)

The activities of halogen atoms in the polycondensation of sodium *p*-halogenobenzenethiolates in pyridine diminish in the sequence I > Br > F ≈ Cl; and those of alkali metals in the polycondensation of a *p*-bromobenzenethiolate diminish in the sequence Li > Na > K.[82] Furthermore, the activities of iodine and bromine are little affected by the change from monomer to polymer, whereas those of chlorine and fluorine as terminal groups of the polymer molecule exceed those in the initial *p*-halogenobenzenethiolate. The nature of the halogen affects also the occurrence of secondary branching and cross-linking reactions, the probability of which decreases in the sequence I > F > Br > Cl. Such reactions disturb the balance of functional groups in the reaction mixture and lower the molecular mass of the resulting polymers. However, when monomers at least 99.6% pure are used, the occurrence of side-reactions is insignificant.

In order to obtain oligo(arylene sulphides) in which the molecular chains terminate only in chlorine atoms copper *p*-chlorobenzenethiolate was subjected to polycondensation in the presence of *p*-dichlorobenzene or di-*p*-chlorophenyl sulphide[76]. Oligomers of analogous structure have been obtained also by the copolycondensation of di-*m*(or *p*)-bromophenyl disulphide and *m*- or *p*-dibromobenzene in the presence of copper powder[83,84]. The molecular mass of the resulting oligomers varies from 186 to 2300 depending on the initial ratio of bisbromophenyl disulphide and dibromobenzene. The polycondensation of *p*-halogenobenzenethiolates in the presence of a monofunctional compound, e.g. bromobenzene or copper benzenethiolate, gives oligo(phenylene sulphides) of low molecular mass containing terminal phenyl groups[85].

Poly(arylene sulphides) containing groups other than sulphide between aromatic rings are obtained by the polycondensation of *p*-halogenobenzenethiolates containing the appropriate group in the initial structure. Thus sodium *p*-*p'*-bromophenoxybenzenethiolate in hexamethylphosphoramide solution gives poly-(*p*-phenoxyphenyl sulphides) (yield reaching 95%) having softening points of 176–188°C and a reduced viscosity of 0.09 (in the above solvent at 30°C)[79].

Linear polymers containing sulphonyl groups in the main chain have been obtained similarly from sodium 4'-*p*-chlorophenylsulphonylbiphenyl-4-thiolate[86,87]:



X-Ray diffraction indicates that the resulting polymer has a high degree of crystallinity, and it softens at ~330°C. The polycondensation of *p*-*p'*-halogenophenylsulphonylbenzenethiol and *p*-halogeno-*p'*-mercaptodiphenyl ketone in dimethylformamide solution at 140°C gives polymers of analogous structure, containing carbonyl and sulphonyl groups between two benzene rings, which are soluble in dimethylformamide, *N*-methylpyrrolidone, and sulphuric acid[88]. The reduced viscosity of their solution in dimethylformamide is 0.3.

The polycondensation of sodium and potassium 4-bromo-2-methylbenzenethiolates and 4-bromo-2,6-dimethylthiolates in dimethylformamide solution yields poly(arylene sulphides) containing methyl groups attached to the polymer chain[75]. The properties of these polymers depend on the structure of the macromolecules. Thus a polymer obtained from sodium 4-bromo-2,6-dimethylbenzenethiolate had molecular mass 740 and softening point 160–180°C, while the corresponding characteristics of poly-(2-methyl-1,4-phenylene sulphide) were 1500 and 60–100°C. The reactivity of the initial *para*-halogenated thiolate diminishes with increase in the number of substituents (methyl groups) in the benzene ring[75].

Perfluorinated poly(phenylene sulphides) have been obtained in high yield by the polycondensation of sodium pentafluorobenzenethiolate in pyridine at 50–200°C.[89-92] Completely halogenated polymers have been obtained also by the polycondensation of pentachloro- and pentabromobenzenethiolates[91,93]. Halogenated poly(phenylene sulphides) are insoluble, dark-coloured powders, which can be used to obtain materials having semiconducting properties.

5. Polycondensation of Benzenedithiolates with Dihalogenated Aromatic Compounds

The preparation of poly(arylene sulphides) by the polycondensation of benzenedithiolates with dihalogenated aromatic compounds, which is also of practical interest, was described by Kreuchunas[94] in 1958. When sodium benzene-*p*-dithiolate and di-*p*-chlorophenyl sulphone were boiled in ethanolic solution for 4 h, poly(arylene sulphides) of not very high molecular mass were obtained.

It was proposed[95,96] that the molecular mass could be increased by carrying out the polycondensation in polar organic solvents of high boiling point, e.g. dimethyl sulphoxide, dimethylformamide, dimethylacetamide, etc., and by using dihalogenated aromatic compounds in which the halogen atoms were activated by bivalent electron-deficient groups located between aromatic rings containing halogen in the *para* position, and also by univalent electron-accepting groups present in the dihalogenobenzene as substituents. The poly(arylene sulphides) obtained in this way had specific viscosity 0.32 (in *N*-methylpyrrolidone at 20°C).

The viscosity of the poly(phenylene sulphides) obtained from benzene-*m*-dithiol and *p*-dibromobenzene in dimethylformamide in the presence of potassium carbonate initially increases[80] on polycondensation, after which it falls as the duration of the process lengthens to 96 h.

Table 4. Dependence of properties of poly(arylene sulphides) on structure of monomer unit.

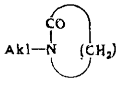
Polymer	Dihalogenoarene	Softening temp., °C	Viscosity, dl g^{-1}*
	*m*-dibromobenzene	100—120	0.1
	*p*-dibromobenzene	110—140	0.15
	4,4'-dibromobiphenyl	160—190	—
	*m*-dibromobenzene + 4,4'-dibromobiphenyl (1 : 1)	85—100	0.11
	1,4-dibromonaphthalene	155—195	—
	di-*p*-bromophenyl ether	55—70	0.07

---

* Viscosities determined for a 0.5% solution in hexamethylphosphoramide at 30°C.

Table 4 lists properties of various poly(arylene sulphides) obtained by polycondensation of benzene-*m*-dithiol with dibrominated aromatic compounds in dimethylformamide[80]. The softening points obviously depend on the structure of the macromolecules: introduction of an oxygen atom into the main chain lowers the softening temperature considerably, but biphenylylene units raise it.

However, optimum production of fibre-forming poly(arylene sulphides) of high molecular weight is achieved by the polycondensation of 25–40 wt.% of dithiolates and bis-*p*-chlorophenyl sulphone in *N*-methylpyrrolidone at 140–160°C for 4–5 h.[97,98] Dihalogenated aromatic compounds in which the halogen atoms are inactive can also be used, e.g. *p*-dichloro- or *p*-dibromo-benzene[99], but a catalyst is then necessary—a copper compound, e.g. cupric oxide, copper acetate, a halide, etc., or *N*-bromosuccinimide (0.06–3 wt.%)—and temperatures of 200–210°C are required. In order to diminish the quantity of byproducts, whose formation is due to the high-temperature (above 140°C) decomposition and oxidation of *N*-methylpyrrolidone, cyclic lactams of general formula



$m = 5-11$,

e.g. *N*-methylcaprolactam, have also been used[100].

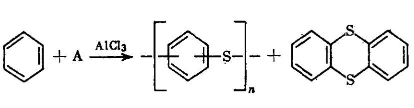
Aromatic dithiolates are usually prepared directly in the apparatus for their polycondensation with dihalogenated aromatic compounds. For this purpose the dithiol is treated with aqueous alkali[99,101], or an alkali-metal carbonate is gradually added to a solution of the dithiol in dimethylformamide[80,96,102]. The hydrogen halide evolved is removed by means of ammonia, diethylamine, morpholine, etc. introduced directly into the reaction space. This increases the rate of polycondensation and yields poly(arylene sulphides) of higher molecular mass[100].

Poly(arylene sulphides) containing functional groups have also been obtained from dithiolates and polyhalogenated aromatic compounds. Thus the reactions of aromatic dithiols with perchlorinated aromatic compounds in the presence of bases gives fusible and soluble poly(arylene sulphides) containing perchlorinated aromatic groups in the main chain[103,104]. After pressure moulding at 400°C such polymers lose their solubility in benzene.

The copolycondensation of benzene-*m*-dithiol with *p*-dibromobenzene and 2,4- or 3,5-dichlorobenzonitrile yields poly(phenylene sulphides) containing nitrile groups[80,105,106], but the action of excess of the dithiol on the dibromobenzene gives polymers having terminal mercapto-groups, treatment of which with *p*-bromobenzonitrile in dimethylformamide containing potassium carbonate gives poly(phenylene sulphides) with terminal nitrile groups. Polymers containing in the main chain sulphur, oxygen, and also various other groupings between the benzene rings are obtained by the copolycondensation of aromatic dithiols with a mixture of two dihalogenated aromatic compounds[107]. Analogous copolymers have been obtained also by using a mixture of aromatic dithiol and diol with the dihalogenated compounds[108]. Another alternative is the polycondensation of *p*-mercaptophenol with the dihalide[100,109].

6. Reaction of Aromatic Compounds and their Derivatives with Sulphur or its Chlorides

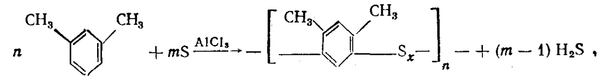
The reaction of benzene with sulphur when heated in the presence of aluminium chloride was first effected in 1888 by Friedel and Crafts[110], when relatively simple compounds—hydrogen sulphide, benzenethiol, diphenyl sulphide and disulphide, thianthren, isothianthren, etc.—were isolated. It was shown somewhat later[111,112] that under these conditions an amorphous polymer having a softening point of ~295°C can be obtained in yields up to 80%. Elementary analysis indicates that the monomer unit in the polymer is C_6H_4S, so that formation of the poly(phenylene sulphide) can be represented by the general scheme[113]



A = S, S_2Cl_2, SCl_2 ,

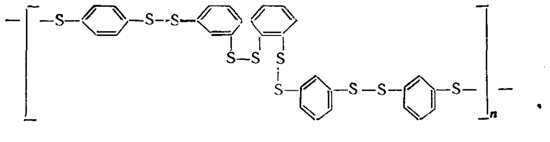
The quantity of byproducts formed—thianthren and diphenyl sulphide—depends on the initial content of aluminium chloride, increase in which increases formation of the sulphide and diminishes that of thianthren[114]. Complexes of aluminium chloride with these two compounds were also isolated[115]. The reaction between aromatic hydrocarbons and sulphur has therefore been carried out[116] in the presence of sulphuric acid under increased pressure at 220–300°C. Poly(arylene sulphides) obtained in this way from benzene, naphthalene, and anthracene softened at ~100°C. Since their sulphur content varied from 10% to 90%, it was supposed[115] that the sulphidation of aromatic rings under these conditions yields polymers containing polysulphide groups $[ArS_x]_n$.

Benzene derivatives can also be used for reaction with sulphur. Thus resinous products useful for medicinal purposes were obtained from xylene and sulphur in the presence of aluminium chloride at 80–90°C.[117] It has since been established[118] that under these conditions only *m*-xylene forms polymeric products, probably by the mechanism



The formation of polymers having a regular structure is attributed[118] to the influence of substituents in the benzene ring. With increase in the content of sulphur or the concentration of aluminium chloride in the initial mixture the quantity of combined sulphur in the polymeric product increases to a limiting maximum of 11.1%. Polymers containing >8% of sulphur solids of molecular mass 1000 and softening point 40°C. Later investigation has shown[119] that the aromatic rings in the polymer from *m*-xylene are interlinked mainly by disulphide groups.

Gaseous hydrogen chloride is evolved from the action of sulphur on chlorinated benzenes (e.g. chlorobenzene or dichlorobenzenes) at 225–350°C (and also at high pressures)[120]. The solid products are oligo(phenylene sulphides) containing 40–80 wt.% of sulphur, softening at ~100°C, and soluble in carbon disulphide. When they are decomposed by metallic sodium in liquid ammonia[121], a mixture of isomeric dithiolobenzenes is isolated in 35% yield, comprising 50% of the *para* isomer with 25% each of the *ortho* and *meta* isomers. It is thus confirmed[121] that the oligomers contain all three types of substituted aromatic rings interlinked by disulphide groups:



Black sulphur-containing polymers with improved electrical conductivity and electron-exchange properties, infusible and insoluble in organic solvents, have been obtained by the polycondensation of sulphur with chloranil, 1,4-naphthaquinone, anthraquinone, or 1,5-dihydroxyanthraquinone in the molecular proportions 4–12:1 at 280–400°C.[122] The polymer chains contain not only monosulphide-linked quinoid but also thianthren groups, and may be joined by polysulphide cross-links. Excess of sulphur increases the likelihood of polysulphide bonds.

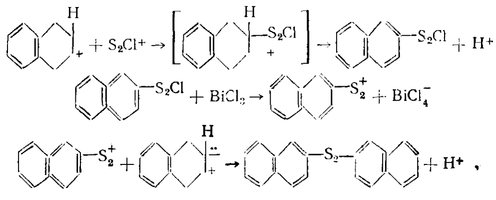
The structure of the products formed from aromatic hydrocarbons with sulphur and especially sulphur chlorides is significantly influenced by the nature of the catalyst. The reaction of benzene with sulphur dichloride in the presence of aluminium chloride yields thianthren as main product[123]. In the presence of sulphuric acid, however, sulphur dichloride acts on benzene, toluene, or xylene to give polymeric products as powders readily soluble in xylene[124].

The action of sulphur chlorides on diphenyl ether and sulphide in the presence of aluminium or its salts yields cyclic compounds—phenoxatin and thianthren respectively[125,126]—intramolecular cyclisation probably being due to formation of complexes of aluminium or its salts with the initial heteroatomic products, containing oxygen and sulphur respectively. In order to obtain linear compounds of high molecular weight the reaction between diphenyl ether and sulphur chloride has been conducted in the presence of iron powder or anhydrous iron(III) chloride in chloroform solution at room temperature[125-127]. The resulting polymers (obtained in quantitative yield) had a reduced viscosity of 0.1 (in 1% solution in hexamethylphosphoramide) and a softened point at 147–156°C. Elementary analysis, X-ray diffraction, and n.m.r. spectra indicated that polymers formed from diphenyl ether and sulphur dichloride are crystalline and contain only monosulphide links between aromatic rings, whereas those obtained from the ether and sulphur monochloride are amorphous and contain not only monosulphide but also up to 15% of disulphide groups. However, it has been reported[128] that polymers obtained from diphenyl sulphide and sulphur dichloride, partly soluble solids softening at 125°C, also contain up to 10% of disulphide groups.

Poly(arylene sulphides) of diverse structure and molecular mass up to 2000 have also been obtained[129] by the polycondensation of aromatic hydrocarbons with sulphur chlorides in chloroform solution in the presence of various metals (bismuth, tin, or antimony) at ~60°C. Chlorides of the metals are probably formed in the first stage, and the overall reaction of naphthalene with sulphur dichloride in the presence of bismuth can be written

$$3S_2Cl_2 + 2Bi \rightarrow 2BiCl_3 + 3S_2$$

$$BiCl_3 + S_2Cl_2 \rightarrow [BiCl_3 \cdot S_2Cl_2] \rightarrow BiCl_4^- + S_2Cl^+$$



Further growth of the polymer molecule probably involves di-2-naphthyl disulphide formed from chlorodisulphanyl ions, polarised naphthalene, and bismuth chloride, which appear as intermediate products. However, infrared spectral data, elementary analysis, measurements of molecular mass, and the separation of elementary sulphur on prolonged storage indicate that the products are oligomers, whose molecules comprise seven or eight ββ'-disubstituted naphthalene groups, interlinked not only by disulphide but also by polysulphide bonds. The formation of such groups can be explained by the participation in intermediate reactions of polysulphur chlorides resulting from decomposition of sulphur monochloride:

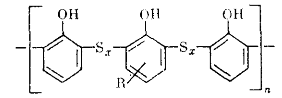
$$2S_2Cl_2 \rightarrow SCl_2 + S_3Cl_2$$

$$2S_nCl_2 \rightarrow S_{n-1}Cl_2 + S_{n+1}Cl_2\ .$$

Oligomers obtained from anthracene or phenanthrene under the same conditions contain respectively ββ'-substituted anthracene or 2,3- and 6,7-substituted phenanthrene groups, as well as di- and poly-sulphide groups. The yield of oligomers is 49–63% depending on the nature of the catalyst[129].

Poly(arylene sulphides) of molecular mass up to 3×10^6 are obtained[130] by reaction between various aromatic compounds and sulphur halides at a constant pH in the presence of up to 35% of an activator (an alkali or a carboxylic acid or ester). The polymer thus obtained from anthracene and sulphur chloride is a powder having a softening point of ~90°C.

Poly-(2-hydroxy-1,3-phenylene polysulphides) of general formula



where R = Alk and $x = 1-7$, are synthesised by the polycondensation of *p*-alkylphenols or their substituted derivatives with sulphur monochloride or dichloride[131,132], or of phenolic compounds with sulphur in the presence of a basic catalyst (e.g. sodium hydroxide) at 120–200°C.[133]

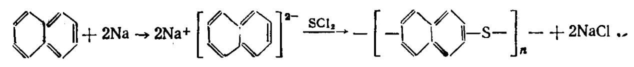
Table 5. Properties of methylated poly(arylene sulphides).

Arene	Monomer unit	Yield, %	Softening temp., °C	Mol. wt.	Cl, %
p-Xylene		60	270—285	1500	7.75
2,2',5,5'-Tetramethyl diphenylmethane		55	240—250	1300	11.88
1,2,4,5-Tetramethylbenzene		70	291	950	6.5

Methylated poly(arylene sulphides) have been obtained by the action of sulphur dichloride on methylated aromatic compounds in the presence of iron powder[128]. Table 5 gives several characteristics of such polymers. The products had a regular structure and contained up to almost 12% of chlorine. An interesting feature of this reaction is that, whereas *p*-xylene and sulphur dichloride gave methylated poly(phenylene sulphides) under these conditions, the polycondensation of *p*-xylene with sulphur in the presence of aluminium chloride does not yield polymeric products[118]. Oil-soluble chlorinated poly(phenylene sulphides) are obtained by the polycondensation of tri-, tetra-, and penta-chlorobenzenes with sulphur monochloride in the presence of aluminium chloride[134,135].

Such polymers soften above 85°C, the viscosity of the melt is 0.256 P (at 131°C), and they contain up to 50% of chlorine.

Furthermore, a process has been elaborated[136] for the preparation of poly(arylene sulphides) in high yields by the reaction of dipotassium diphenylbutane, disodium diphenylmethane, disodium naphthalene, and other dimetallated aromatic derivatives with sulphur halides in inert solvents (oxolan, n-hexane, etc.) at temperatures from −75 to +75°C. The reaction of disodium naphthalene with sulphur dichloride can be represented in general as



The products have softening points of ~175°C, and can be used as thermostable adhesives.

An examination of thermodynamic aspects of the formation of sulphur polymers by heating has shown[137] that polymeric phenylene polysulphides can be obtained from chlorinated aromatic compounds and polymeric sulphur.

7. Homopolycondensation of Aromatic Sulphenyl Chlorides and their Copolycondensation with Aromatic Hydrocarbons or Thiols

The first descriptions have appeared[138–140] of the preparation of poly-(*p*-phenoxyphenylene sulphides) by the copolycondensation of diphenyl and di-*p*-chlorothiophenyl ethers in the presence of metal powders or salts in an inert atmosphere away from the light at room temperature:

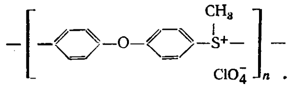
The resulting polymers dissolve readily in aromatic hydrocarbons and polar organic solvents. Table 6 gives data on the influence of the nature of the catalyst on the yield and certain properties of the products. Elementary analysis and n.m.r. spectra indicate that the polymer molecule contains *para*-substituted aromatic rings joined together by mono- and di-sulphide groups, the latter amounting to 9–10%. The formation of disulphide links is attributed[138–140] to reaction between the sulphenyl chloride groups, which is supported by the evolution of gaseous chlorine. The mechanism of polycondensation has been studied also on model compounds.

Table 6. Dependence of properties of polymers on nature of catalyst.

Catalyst	Yield, %	Softening temp., °C	Viscosity, dl g⁻¹*
Fe	75	160—170	0.12
$FeCl_3$	75	156—189	0.10
$SnCl_4$	68	153—173	0.07
$AlCl_3$	38	140—175	0.08

* Viscosities determined for 1% solutions in hexamethylphosphoramide at 30°C.

Polymers containing aromatic rings linked by sulphide groups are obtained[140] by the homopolycondensation of benzenesulphenyl and *p*-phenoxybenzenesulphenyl chlorides in chloroform solution in the presence of metal powders or Lewis acids. The poly-(*p*-phenoxyphenylene sulphide) was obtained in 53% yield and softened at 134–145°C. Poly(alkyl- and aryl-*p*-phenoxyphenylsulphonium) salts, with decomposition points of 165–275°C and reduced viscositities of 0.06–0.55, have been obtained[141] by the homopolycondensation of alkyl and aryl *p*-phenoxyphenyl sulphides in a mixture of 70% of perchloric acid and phosphoryl chloride in argon at 25°C for 20 h followed by heating at 50–60°C. The structure of the polymer obtained from the methyl sulphide corresponds to the formula



Such a polymer is soluble in formic acid and in aprotic polar solvents. On dealkylation by boiling in pyridine it is converted into a poly(*p*-phenoxyphenylene sulphide) of softening point ~188°C and reduced viscosity 0.27.

Table 7. Dependence of properties of polymers on structure of initial monomers.

R	R′	Molecular mass*	Sulphur, %	
			expt.	calc.
		(insol.)	29.3	29.6
		(2–4) x 10³	27,6	27.8
		(insol.)	28.5	28.7
		(2–4) x 10³	31.2	34.6
		(insol.)	35.1	36.0

*Determined by osmometry.

Poly(arylene sulphides) have been obtained in yields up to 90% also by the polycondensation of aromatic disulphenyl chlorides with aromatic dithiols in oxolan solution at 20°C:[142]

$$n\text{ClS—R—SCl} + n\text{HS—R}'\text{—SH} \xrightarrow[-\text{HCl}]{} \text{— [—S—R—S—S—R}'\text{—S—]}_n \text{ —} ,$$

Table 7 shows that poly(arylene disulphides) containing biphenylylene groups are insoluble in the usual organic solvents, in contrast to those containing *m*-phenylene or diphenylmethane groups, and are readily soluble in oxolan and chloroform. The structure of the polymeric disulphides has been confirmed by infrared and n.m.r. spectra and by X-ray diffraction[143]. Redistribution of monomer units by interaction of the disulphide bond with the chlorothio-group does not take place, and the polymers have a regular structure.

8. Preparation of Poly(arylene Disulphides) by the Oxidation of Dithiols

In 1909 Zincke and Frohnberg[144] oxidised benzene-*p*-dithiol with various oxidants (e.g. air, iron chlorides, peroxides, sulphuric and nitric acids) in acetic acid, and isolated as main product an amorphous yellow powder, insoluble in the usual organic solvents. Analysis suggested a polymer having the monomer unit $[C_6H_4.S_2]_n$. Treatment with copper powder and heating in order to cleave the disulphide bonds gave an oil, from which a cyclic dimer, *pp'*-diphenylene bisdisulphide, was obtained[145]. When benzene-*p*-dithiol was oxidised with chlorine or bromine under the same conditions, the precipitated product passed after some time back into solution, from which benzene-*p*-disulphonyl chloride or bromide respectively was then isolated[144].

However, the oxidation of benzene-*p*-dithiol with ethanolic iodine gives an approximately 75% yield of a solid product that is partly soluble in organic solvents and softens at 198–202°C.[128] Elementary analysis (sulphur content 46.12%) and X-ray diffraction indicate that it is a linear poly-(*p*-phenylene disulphide).

Biphenyl-4,4'-diol is oxidised more slowly by air than by alkaline solutions[146], to give a cyclic tetraphenylene tetrasulphide

$$\begin{array}{ccc} C_6H_4\text{—}S\text{—}S\text{—}C_6H_4 \\ | \qquad\qquad\qquad | \\ C_6H_4\text{—}S\text{—}S\text{—}C_6H_4 \end{array}$$

as an insoluble amorphous product.

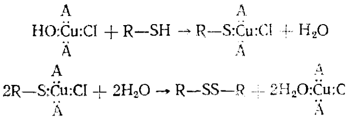
Aliphatic sulphoxides have also been used as oxidants. The oxidation of dithiols when solutions in dimethyl sulphoxide are heated at 95–170°C can be represented by the general scheme[147]

$$n\text{HS—R—SH} + nR'_2SO \rightarrow \text{H—}[\text{—S—R—S—}]_n\text{—H} + nH_2O + nR'_2S \ .$$

More detailed investigation of the action of various oxidants on aromatic dithiols has established[148] that iodine and hydrogen peroxide tend to increase not only the rate of formation but also the yield of poly(arylene disulphides), while the use of catalysts (e.g. a mixture of a copper salt and an amine, acid, or alkali) dissolved in an inorganic solvent (e.g. water) at temperatures of 0 to 38°C promotes the formation of poly(arylene disulphides) of higher molecular mass. An intermediate complex is probably formed in the inorganic solvent, according to the general scheme (for a mixture of copper(I) chloride and an amine A)

$$2A + CuCl + H_2O \rightarrow H_2O{:}\overset{A}{\underset{A}{\ddot{C}u}}{:}Cl + {}^1/_4O_2 \xrightarrow{-{}^1/_2H_2O} HO{:}\overset{A}{\underset{A}{\ddot{C}u}}{:}Cl \ .$$

Its reaction with a mercapto-group can then be written



$$HO{:}\overset{A}{\underset{A}{\ddot{C}u}}{:}Cl + R\text{—}SH \rightarrow R\text{—}S{:}\overset{A}{\underset{A}{\ddot{C}u}}{:}Cl + H_2O$$

$$2R\text{—}S{:}\overset{A}{\underset{A}{\ddot{C}u}}{:}Cl + 2H_2O \rightarrow R\text{—}SS\text{—}R + 2H_2O{:}\overset{A}{\underset{A}{\ddot{C}u}}{:}Cl \ ,$$

This reaction results in regeneration of the amine complex of the copper salt and formation of organic disulphides. It is noteworthy that the polycondensation of dithiols also occurs in conformity with the mechanism suggested for the oxidation of thiols.

Table 8 gives the structural formulae of the initial dithiols subjected to oxidation together with characteristics of the poly(arylene disulphides) obtained in quantitative yield. The polymer from 4-methylbenzene-1,2-dithiol dissolves readily in chloroform, whereas that from naphthalene-1,5-dithiol is insoluble in the usual organic solvents.

9. Polytransarylation of Aromatic Sulphides

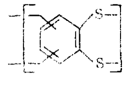
A process suggested comparatively recently[149] for obtaining poly(arylene sulphides) by the polycondensation of aromatic sulphides is to heat them in the presence of Friedel–Crafts catalysts to 160–350°C. Either insoluble or solvent-soluble products can be obtained depending on the conditions. Thus when diphenyl sulphide is heated with 6 mole % of aluminium chloride at 200°C for 4 h, benzene distils off and an 85.2% yield is obtained of a powder containing 85.6% of a benzene-soluble product of molecular mass 450 (determined cryoscopically in benzene) and softening temperature 110–120°C. Elementary analysis indicates a 37.53% sulphur content, exceeding by 8% the content for the monomer unit $[C_6H_4.S]_n$. Furthermore, preparative thin-layer chromatography has revealed thianthren among the reaction products[150].

Table 8. Structure of polymers obtained from initial dithiols.

Dithiol	Monomer unit	Softening point, °C
		~190
		~118
		>250

From the results it is considered[150] that the mechanism of the polycondensation of diphenyl sulphide is analogous to that of the well known transarylation of diarylalkanes[151] and that polycondensation is accompanied by formation of an intermediate complex of diphenyl sulphide with aluminium chloride. The appearance of cyclic products is attributed to the greater activity of the *ortho* position in the aromatic ring relative to the sulphur substituent. Cyclic compounds containing *ortho* substituents had been isolated earlier in the transarylation of diarylalkanes[152].

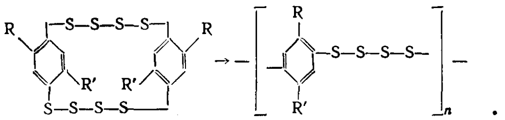
Since products of the transarylation of diphenyl sulphide contain neither thiol nor disulphide groups according to the infrared spectra and chemical analysis, the structure of the oligomers may contain predominantly polythianthren groupings.



The presence of such structures among the reaction products is confirmed by mass spectrometry and also by the polymerlike conversion of these products into the corresponding sulphones followed by analysis of thermal decomposition products of the polymer analogues.

10. Polymerisation of Cyclic Sulphides

Poly(arylene tetrasulphides) have been obtained by the thermal polymerisation of cyclic diarylene bistetrasulphides in the mass or in solution in a stream of an inert gas at 150–220°C:[153-155]



R=R'=OC_2H_5 (I); R=R'=OCH_3 (II); R=OCH_3, R'=Cl (III).

Table 9 gives conditions of preparation, reduced viscosity, and molecular mass for a few poly(arylene tetrasulphides). The products are stable under normal conditions and possess satisfactory adhesion to metals.

Table 9. Reaction conditions and properties of poly(arylene tetrasulphides).

Monomer	Conditions	Reduced viscosity, 0.4 g/100 ml $CHCl_3$	Mol. wt. (number-av.)
(I)	in mass, 195°C, 1 h	0.21	15 781

11. Polycondensation of Dihalogenated Aromatic Compounds with Alkali Metals

Application of the Wurtz–Fittig reaction to di-*o*(and *p*)-chlorophenyl sulphides with metallic sodium has recently[156] yielded soluble poly-(*o*(and *p*)-diphenyl sulphides), respectively plastic at room temperature and solids passing into a state of viscous flow at 170–200°C.

III. PRACTICAL APPLICATIONS

A previous review[3] has examined in sufficient detail the properties of various poly(arylene sulphides), the changes undergone under processing conditions, and the properties of articles made from them. Below, therefore, we give only general information on properties and practical applications, noting primarily the main lines of development in the light of recent work.

Poly(arylene sulphides) are distinguished by high thermal[8,92,95,157-163], thermo-oxidative[15,113,157-159,164,165] and chemical[17,157,162,166-168] stability, fire resistance[157,166,187-192], non-toxicity[24,183,193,194], and several other specific properties[24,103,164,195-201]. They can be readily oxidised by various oxidants (hydrogen peroxide[95-97,162,202-206], nitric acid[207], etc.) to poly(arylene sulphoxides or sulphones), a process that should be applied to the ready-made materials and articles[208]. Heat-treatment has been used to diminish the fluidity and raise the softening point[184,192,209-214]: thus heating at 320°C for 300 h raised the working range of a poly(arylene sulphide) to higher temperatures (from 100 to 200°C and above)[211]. The maximum operating temperature at which films retain their strength for a long time (>10 weeks) has been regarded[157,158,164,166,187,214] as 260°C, but the temperature of prolonged operation of the polymer has been restricted[188] to 180°C.

Poly(arylene sulphides) surpass polysulphones and polyimides in many physicochemical indices[164]. They are used as adhesives for glass-fibre laminates[164,166,180,182,215-223], which have better mechanical strength at 204°C than has polyethylene at room temperature[166].

Poly(arylene sulphides) provide good electrically insulating materials[187-189,224-228]. Thus the dielectric constant of poly(phenylene sulphide) has been given as 3.1 (10^6 Hz), the dielectric loss angle as 0.0007 (10^6 Hz), the dielectric strength as 23.8 kV mm^{-1}, and the bulk resistance as 10^{16} ohms cm.[157,166]

Great attention has been paid to studying the properties of films based on poly(phenylene sulphides)[7,157,162,164,166,168,171,172,184,187-189,229-244], which show good adhesion to various supports[24,82,164,195-199].

Compositions of poly(arylene sulphides) with various fillers can be processed into articles by injection moulding, extrusion, pressure moulding, etc.[214,215,223,229,245-251]. Articles made of such compositions can be ground, milled, drilled, welded ultrasonically, metallised with chromium and other metals, and also threaded[252]. This explains the widespread use of poly(arylene sulphides) and articles made from them in mechanical and electrical engineering, aircraft construction, chemical industry, and other technologies.

Application of Photoelectron Spectroscopy in the Study of Catalysis and Adsorption

Kh.M.Minachev, G.V.Antoshin, and E.S.Shpiro

Problems associated with the application of photoelectron spectroscopy (PES) in the study of catalysis and adsorption are examined, the physical principles of PES and the experimental technique are briefly described, and an account is given of the results of the application of the method to the study of metallic, alloy, oxide, deposited, and zeolite catalysts. It is shown that the method can be used successfully to investigate the valence and physical states and the surface concentrations of elements in catalysts, the nature of the adsorption complexes, and the mechanism of surface reactions.
The bibliography includes 332 references.

I. INTRODUCTION

Since the 1970s, X-ray photoelectron spectroscopy (XPES) has been widely used in chemical research. The method is based on the phenomenon of the photo-electric effect. The energy distribution of the inner and valence electrons of the test substance is analysed in the spectra excited by monochromatic X-rays. The practical application of the method became possible when a group of Swedish workers headed by Siegbahn developed in the middle 1950s apparatus which made possible the analysis of photoelectrons with a high resolution and sensitivity. Their studies showed that XPES is extremely sensitive to changes in the electronic structures of substances which occur on chemical reaction[1,2]. During the same years, Vilesov et al.[3] developed the practical principles of the application of ultraviolet photoelectron spectroscopy (UPES) in the study of gases. At the present time both these methods have been constructively combined and are used successfully to investigate the gaseous and solid states.

Because of the universality of the information obtained with the aid of XPES, the method has been used to solve various physical and chemical problems. During a short period, more than a thousand studies on complex and organoelemental compounds[4-8] and the electronic structures of solids[8-11] were carried out. Recently a tendency has arisen towards a more vigorous employment of XPES and UPES in the study of surface phenomena: adsorption, catalytic, corrosion, oxidation, etc. processes. In view of a number of its characteristic features, this field of application of the method appears to be the most promising.

1. The photoelectron spectra excited by X-rays record electrons leaving the specimen without loss of energy in non-elastic collisions with lattice elements. Theoretical calculations[12] and numerous experimental studies[13-15] have

shown that the depth of the surface layer from which electrons are emitted for $E_{\mathrm{kin}} \simeq 1000$ eV in most cases does not exceed 20–30 Å. In ultraviolet or synchrotron excitation of the spectra and in the measurement of low-angle photoemission the depth of the analysed layer may be equivalent to several atomic layers[16-18].

2. The energies of the lines and the structure of the spectra of the inner levels characterise the valence state of the elements and the nature of their interaction with the immediate environment; the valence bands characterise the band structure of the solid.

3. The spectra of the inner and valence levels of adsorbates serve as a basis for the determination of the type and geometry of the adsorption bond.

4. The PES method permits a quantitative analysis of the composition of the surface and the adsorption layer.

5. The method is applicable to the study of all the elements in the Periodic System.

There are many reviews devoted to problems of the study of the surfaces of solids[19-27], including heterogeneous catalysts[22-28]. Problems of the study of adsorption on clean surfaces have been repeatedly and most fully discussed[24,27,29-37], but the majority of the reviews have been published abroad and do not deal with studies carried out recently in the USSR. Furthermore, owing to the vigorous development of this field of study, even reviews published in recent years cannot claim to give a complete survey and do not include recently published fundamentally new results, acquaintance with which would promote a rapid adoption of the method in practical catalytic research.

Within the framework of the present review, the authors have considered the results of studies on heterogeneous catalysts, as well as adsorption and catalysis by methods of photoelectron spectroscopy.

II. PHYSICAL PRINCIPLES OF THE METHOD OF PHOTOELECTRON SPECTROSCOPY

Bearing in mind that the physical principles of the PES method and the problems concerned with the interpretation of the spectra have been described in detail in a number of monographs and reviews[1,4,11,22,23,25,30], we shall confine ourselves to a very brief consideration of the main principles of the analysis of the spectra. The binding energy of an electron emitted from a conducting solid is defined by the equation

$$h\nu = E_{\mathrm{kin}} + E_{\mathrm{b}}^{\mathrm{F}} + \varphi_{\mathrm{sp}}, \tag{1}$$

where $h\nu$ is the energy of the quantum (the emission energies of the Al$K\alpha$ and Mg$K\alpha$ lines are 1486.6 and 1254.6 eV and the energies of the He I and He II lines are 21.2 and 40.8 eV respectively), E_{kin} is the experimental kinetic energy of the electrons, $E_{\mathrm{b}}^{\mathrm{F}}$ is the electron binding energy relative to the Fermi level of the material of the spectrometer, and φ_{sp} is the electron work function of the material of the spectrometer. For non-conducting specimens, the determination of E_{b} is complicated for two reasons: (a) an effective electrical contact with the spectrometer is absent; (b) the specimen is charged under the influence of the radiation. (The charging is taken into account using external and internal standards[38-41]; various devices have been suggested to compensate the charge[42,43].)

The determination of the change in E_{b} for the inner levels (chemical shifts) constitutes the main source of information about the change in the valence state of elements, the nature of the chemical bond, coordination, etc. ΔE_{b} is described by the formula[1,5,11,44-46]

$$\Delta E_{\mathrm{b}} = \Delta E(q) + \Delta V + E_{\mathrm{rel.}}, \tag{2}$$

where $\Delta E(q)$ is the change in bond energy caused by the change in the charge of the free ion, ΔV the change in the crystal field potential near the atom investigated, and E_{rel} the relaxation energy of the system caused by the formation of a vacancy at an inner level. The second and third terms of Eqn. (2) in general have the opposite sign to the first term. Allowance for only the first term in Eqn. (2) leads to larger calculated shifts compared with experimental values[1,5,11,44,45]. At the same time there is a correlation between the effective charge on the ion in the compounds and E_{b}.[5,8]

The chemical shift in the spectra of adsorbed molecules is defined by the expression

$$\Delta E = E_{\mathrm{ads}} - E_{\mathrm{gas}} = \Delta E_{\mathrm{b}} + \varphi_{\mathrm{sp}} + \Delta E_{\mathrm{rel}}, \tag{3}$$

where ΔE and ΔE_{rel} are the overall change in the energy of the level and the change in relaxation energy when the molecule passes from the gas phase to the adsorbed state (the "interatomic" relaxation is of decisive importance in chemisorption[46]).

The following method for separating the chemical and relaxation shifts in the spectra of adsorbed molecules has now been adopted. It is suggested that the changes in relaxation energy for non-bonding orbitals, bonding orbitals, and the inner levels are approximately equal. ΔE_{rel} can be determined by studying the physical adsorption of condensation of molecules on inert carriers.

The spectra of the inner levels frequently consist of a set of lines and not singlets, which is due to the multiplet splitting of the inner levels[5,8,47-49], the emission of Auger electrons[1,5,11], and many-electron processes[5,8,48,50-59], arising owing to the instability of the photoionised state of the atom. The mechanism of the formation of satellite lines owing to many-electron processes has not been fully elucidated. Some workers attribute their appearance to the intra-atomic transitions from the valence band to the conduction band[50-53] or to monopole transitions with charge transfer[54-56]. According to other workers, the satellites arise owing to the interaction of the emitted and outer unpaired electrons, leading to the inversion of the spin of the latter[57,58]. The parameters of the satellite structure change when the valence state[54-56], the spin density[57,58], the coordination of the atom[54-56], etc. are altered.

The intensity of the peak in the photoelectron spectrum is described by the formula[1,5,8,60]

$$I_i = FGS_i\sigma_i\lambda_i(E_i)N_i, \tag{4}$$

where F is the intensity of the photo flux, G the fraction of the overall electron flux measured by the spectrometer (it depends on the geometry of the specimen), S_i the sensitivity of the analyser and the detector, σ_i the atomic photoionisation cross-section of the ith level, $\lambda_i(E_i)$ the average path traversed by electrons (with $E_{\mathrm{kin}} = E_i$) without undergoing non-elastic collisions in the specimen, and N_i the number of electrons emitted from the ith level of the element investigated. In practice, when the concentrations of elements are determined, one measures the relative intensities[1,5,8,12,61-64]. For two elements, the intensity ratio can be expressed thus:

$$I_1/I_2 = T_{1,2}\frac{\sigma_1}{\sigma_2}\frac{N_1}{N_2}, \qquad T_{1,2} = \frac{S_1(E_1)\cdot\lambda_1(E_1)}{S_2(E_2)\cdot\lambda_2(E_2)}. \tag{5}$$

There are now fairly reliable calculated and experimental data for σ_i[61-64] and λ_i[13-15,36,60]; the problem of the quantitative analysis of "thick" homogeneous specimens is therefore solved successfully. However, analysis of heterogeneous systems requires allowance for many additional factors (see Section III).

Studies on the angular distribution of photoelectrons[16, 17, 32, 33, 65, 66], which it is hoped will increase the surface sensitivity of PES and will make possible the investigation of the geometry of adsorption bonds, have begun recently.

Table 1 presents certain parameters of standard and modernised commercial spectrometers, which illustrate the technical scope of the PES method[87]. Certain types of unique laboratory apparatus have additional possibilities: additional monochromatisation of the X-rays makes it possible to obtain the line width (~ 0.2 eV)[68]; the employment of a synchrotron as the source of radiation makes it possible to alter continuously the energy of the quanta from 5 to 450 eV and to investigate systematically the dependence of the intensity on $h\nu$.[18] Table 1 shows that the analytical possibilities of XPES are small; however, when surfaces are investigated, this method is irreplacable. The employment of combined apparatus, involving several methods (UEPS–AES–LEED, XPES–APES–UPES, and UPES–SIMS–LEED†) has incontrovertible advantages in combined studies of surfaces, but the intrinsic possibilities of each method are then restricted.

Table 1. Parameters of electronic spectrometers*.

Name of firm and instrument	Limiting resolution on X-ray excitation, eV	Sources of excitation of spectra	Limiting sensitivity w.r.t. Au(4*f*) line, counts s^{-1}	Limiting vacuum, mmHg	Devices for treatment of specimens

*The average sensitivity with respect to elements is 0.1–1.0 wt.%; the minimum amount of adsorbate on the surface is 0.05–0.1 of a monolayer.

The method of preparation of the catalyst specimens and their treatment and the procedures used in the measurement of the spectra have been examined in a number of reviews[23, 25, 26]. One should note that the most effective elimination of impurities from the surface and dehydration are achieved when the catalysts are treated *in situ*. After the reaction the catalyst studied must be transferred to the spectrometer without any external influences on the specimen. Unfortunately these self-evident requirements were not fulfilled in all experimental studies.

III. RESULTS OF THE STUDY OF CATALYSIS AND ADSORPTION BY PHOTOELECTRON SPECTROSCOPY

1. Metals and Alloys

It has been shown[9-11, 69-79] that the stretching vibration band spectra reproduce fairly effectively the principal characteristics of the distribution of the density of the states of valence electrons in metals and alloys. Studies on many transition (Mn, Fe, Co, Ni, Cu) and noble (Ag, Pd, Au, Rh, Ir, and Pt) metals and their alloys[11, 69, 72] led to the conclusion that the d-states of both components in non-ordered binary alloys to a large extent retain the localisation characteristic of the pure metal; when an alloy is formed, the inner levels of the metals undergo only a slight perturbation[11]. Studies have been made recently to investigate the band structure of metals and alloys, using monochromatised sources of X-rays and UPE spectroscopy[11, 76, 77, 79].

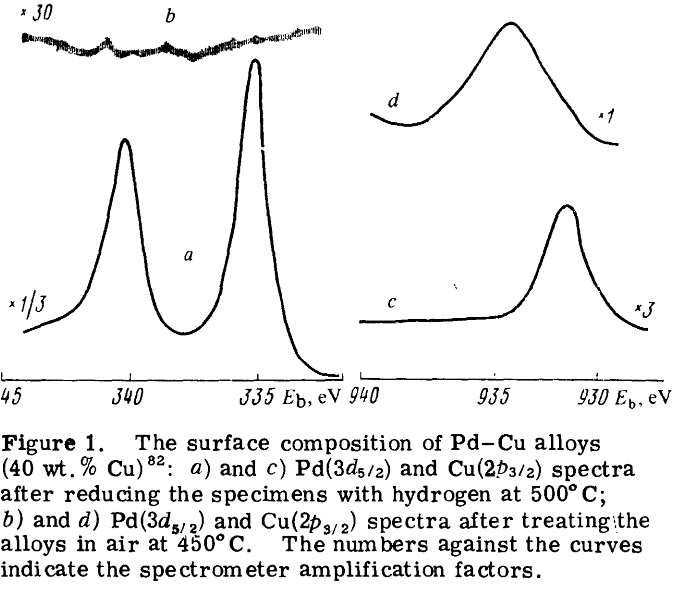

Figure 1. The surface composition of Pd–Cu alloys (40 wt.% Cu)[82]: *a*) and *c*) Pd($3d_{5/2}$) and Cu($2p_{3/2}$) spectra after reducing the specimens with hydrogen at 500°C; *b*) and *d*) Pd($3d_{5/2}$) and Cu($2p_{3/2}$) spectra after treating the alloys in air at 450°C. The numbers against the curves indicate the spectrometer amplification factors.

The composition of the surface layer of alloys in many instances differs from the bulk-phase composition: on treatment with hydrogen, the surfaces of Pt–Sn, Pt_3–Sn,[80] Ni–Al,[81] and Pd–Al[82] alloys become enriched in the second component. On treatment of the Pd–Cu (40 wt.% Cu) alloy with hydrogen at 400°C, the surface concentration of copper also increases (Fig. 1)[82]. The most marked changes in the surface layer occur in the oxidative regeneration of Pd–Cu catalysts. The spectra show that the surface layer is coated by a CuO film whose thickness exceeds 50 Å according to approximate calculations[82]. By employing synchrotron radiation or Auger electron spectroscopy, it is possible to analyse the composition of alloys in depth, starting from a monolayer and continuing up to several tens of atomic layers[80, 83].

†AES = Auger-electron spectroscopy, LEED = low-energy electron diffraction, and SIMS = secondary ion mass spectrometry.

2. Simple Oxides

Studies devoted to oxides can be divided by convention into three groups: (1) the study of thin oxide films; (2) the study of bulky oxide specimens; (3) the study of two- and multi-component oxide catalysts. Table 2 presents the principal results of studies on oxide films and bulky oxide specimens.

Table 2. Results of the study of oxides by the PES method.

Element	Main results	Changes in spectra; method of determination	References
	Thin oxide films		
Ti	formation of monolayer oxide film observed for exposures to O_2 not less than 7–10 L*	change in the form of valence bands	84
Fe	Fe_3O_4 structure studied	ditto	85
Ni	formation of NiO demonstrated in oxidation of Ni foil	shift in the $Ni(2p_{3/2})$ spectrum	86
Ni	structural differences observed in thin oxide films	position of $3d$ levels of Ni	87
Pt	formation of PtO and higher oxides demonstrated in oxidation of sputtered Pt	shifts in $Pt(4f)$ spectrum	88
Pt, Au	thin films obtained by anodic oxidation investigated	shifts in spectra of $4f$ levels of Pt and Au	89
Mo	formation of F-centres in substoichiometric amorphous MoO_3 films demonstrated; oxygen vacancies found in surface MoO_3 layer	peak near Fermi level; $O(1s)$ peak with E_b = 532.2 eV	90,91
Pb	formation of orthorhombic and tetragonal PbO demonstrated	$Pb(4f)$ and $O(1s)$ spectra	92–94
r.e.	formation of lanthanide (from Tb to Lu-) oxide films demonstrated	shifts in spectra of inner levels	95
Si	stoichiometry and structure of thermally grown SiO_2 films investigated	analysis of $Si(2p)$, $Si(2s)$, and $O(1s)$ spectra	96
–	stability of oxide films in vacuum heat treatment investigated	spectra of inner levels	97
	Bulk-phase oxide specimens		
V	reduction of V_2O_5 to V_4O_9 and V_6O_{11} observed	appearance of $3d$ states in valence band	98
Mn	reduction of α-MnO_2 and β-MnO_2 investigated; only one oxidation state of Mn found in Mn_3O_4	changes in the spectra of the $2p$ level of Mn	99
Fe	the occurrence of reaction $Fe_2O_3 \xrightarrow{CO,\ 300\text{–}460°C} Fe_3O_4$ demonstrated	–1.0 eV shift of $Fe(2p)$ line	100
Co	the reaction $Co(CO_3)_2 \xrightarrow{250°C,\ vacuum} Co_2O_3$ (surface layer contains only Co^{3+} ions) investigated	no satellite in $Co(2p_{3/2})$ spectrum	101
Co	Co_3O_4 surface layer found to contain Co^{3+} and Co^{2+} ions	spectra of inner levels and stretching vibration bands	102
Co	Co^{2+} and Co^{3+} ions identified in Co oxides	$2p_{1/2}$ – $2p_{3/2}$ spin–orbital splitting of Co levels	103
Co	quantitative determination of degree of reduction of Co in $Co_2O_3 \rightarrow Co_3O_4 \rightarrow CoO$ transitions	intensity ratio $I_{cat}/[I_{cat} + I_{Co}.(2p_{1/2})]$	104
Ni	formation of Ni_2O_3 on Ni and NiO surfaces observed	the shift of $Ni(2p_{3/2})$ level is + 1.5 eV in the transition $Ni^{2+} \rightarrow Ni^{3+}$	54
Ni	the formation of $Ni\text{–}O_{ads}$ and $NiO\text{–}O_{ads}$ on bombardment with O_2^+ ions demonstrated	$Ni(2p_{3/2})$ and $O(1s)$ spectra	54,105
Cu	$CuO \rightarrow Cu_2O \rightarrow Cu$ reduction investigated	satellite disappears from $Cu(2p_{3/2})$ spectrum in the $Cu^{2+} \rightarrow Cu^+$ transition	55, 106–108
Ag	$Ag \rightarrow Ag_2O \rightarrow AgO$ oxidation investigated	negative shift observed in $Ag(3d)$ spectrum	109
Pb	Pb in two oxidation states not detected in Pb_3O_4	$Pb(4f)$ spectra	110
Pb	surface composition of Pb_3O_4 found to correspond to $2PbO.PbO_2$	$Pb(4f)$ and $O(1s)$ spectra	92
Cr	$CrO_3 \rightarrow Cr_2O_3$ reduction observed	shift of $2p$ level of Cr	111
Mo	quantitative analysis of MoO_3–MoO_2 mixture	analysis of intensities in $Mo(3d)$ and $O(1s)$ spectra	112
Mo	reduction process $MoO_3 \xrightarrow{400°C,\ H_2} Mo^{6+}, Mo^{5+}, Mo^{4+}$ observed	shifts in $Mo(3d)$ spectra	113,114
Mo	reduction process $Mo^{6+}(MoO_3) \xrightarrow{400°C,\ H_2} Mo^{n+}$ $(n < 4)$ observed	ditto	115
Mo	reduction process $Mo^{6+}(MoO_3) \xrightarrow{400°C,\ H_2} Mo^0$ observed	"	116
Ru	RuO_3 and $RuOCO_3$ detected on the surfaces of RuO_2 and hydrated specimens respectively	analysis of $Ru(3d)$, $O(1s)$, and $C(1s)$ spectra	117
W	$WO_3 \rightarrow WO_2$ reduction observed	analysis of $W(4f)$ spectra	118,119
Re	surfaces of the oxides Re_2O_7, ReO_3, and ReO_2 investigated	analysis of $Re(4f)$ spectra	120
Re	distribution of the density of states in the valence band of ReO_3 investigated	analysis of valence band	121
Al	differences observed in the energies of levels of different modifications of aluminium oxide and hydroxide	analysis of $Al(2p)$ and $O(1s)$ spectra	122
Al	correlation found between E_b for $2p$ level of Al and Al–O distance in aluminosilicates	analysis of $Al(2p)$ spectra	123
–	correlation established between E_b for $O(1s)$ and $1/r$ for M–O bond in 50 oxides	analysis of $O(1s)$ spectrum	124,125
Co, Ni	decrease of E_b for $O(1s)$ with increasing oxidation state of the cation in oxides observed	analysis of $O(1s)$ spectra	126
Fe, Zn	three types of oxygen observed in oxide minerals	analysis of $O(1s)$ spectra	127
–	dependence of shifts of inner levels of metals on the nature of their bond with oxygen in oxides investigated	analysis of $O(1s)$spectra and inner levels of metals	47

*1 L (1 Langmuir) = 10^{-6} mmHg s^{-1}.

Generalising the experimental data, one may conclude that the most significant information has been obtained about the state of transition metals in the surface layer of oxides. Further studies are probably required to identify the different forms of surface oxygen, using methods sensitive to the nature of the surface oxygen, such as, for example, EPR, optical spectroscopy, etc.

3. Complex Oxides

Regions of homogeneity (solid solutions or chemical compounds) and heterogeneity are as a rule present in two-component variable-composition oxide catalysts. The study of the state of the components in such catalysts and the estimation of surface concentrations are therefore of considerable interest. Quantitative analysis of CuO–MgO, CoO–MgO, CuO–ZnO, and CoO–ZnO systems has been carried out [128,129]. It follows from Fig. 2*a* that in the region of solid solutions in the CuO–MgO system, there is a linear relation between the intensity ratio and the atomic ratio of the components in the bulk of the catalyst. The agreement between the slopes of the experimental and calibration (not shown in Fig. 2) lines indicates the similarity of the surface and bulk-phase compositions [128]. On passing to the heterophase system, the straight line shows a break. Enrichment of the surface in the region of solid solutions has not been observed for CoO–MgO specimens, whereas in CoO–ZnO the surface concentration of cobalt is somewhat higher than the bulk-phase value. No changes in the spectra of the inner levels of the metals after the alteration of the concentrations of the components have been observed [128,129]. It has also been noted [130] that the E_b for the $2p_{3/2}$ levels of cobalt, copper and nickel in the $M_xMg_{1-x}O$ systems do not change, but the ratio of the intensities of the satellite and the peak and the half-widths of the Co^{2+} and Cu^{2+} levels in the catalyst are smaller than in CoO and CuO respectively. In contrast to the above studies, an increase of E_b for the $2p_{3/2}$ level of cobalt by 0.5–0.6 eV has been observed[131] at the 11.3% CoO–MgO concentration, which was accompanied, according to magnetic susceptibility measurements, by an increase of the magnetic moment of cobalt ions. The authors believe that this is caused by the absorption of oxygen in a paramagnetic form, which results in electron transfer from Co^{2+} to O_2.

In $Li_xNi_{1-x}O$ catalysts ($0 \leq x \leq 0.3$) the addition of lithium leads only to a change in the profile of the $Ni(2p_{3/2})$ and O(1*s*) lines[132]. More significant changes in the spectra were observed for $NiO–Al_2O_3$ specimens (Fig. 2*b*). In catalysts with a high NiO content (97.5 and 95%) E_b for $Ni(2p_{3/2})$ is close to the value observed in NiO. However, the shoulder in the spectrum characterising the multiplet splitting is absent for these specimens. With decrease of the NiO concentration to 40 mole %, E_b increases by 1.6 eV and becomes close to the value for the $NiAl_2O_4$ spinel. In the region of solid solutions (0–15 mole % NiO), there is a further increase of E_b, apparently characterising the increase of the effective charge of Ni ions. As in the study of Boreskov and Zhdan[128], the dependence of the line intensity ratio on concentration was obtained in the form of a broken straight line with the break point in the region of the transition to the heterophase system (Fig. 2*b*). A change in the slope of the straight line may be caused by the change in the surface concentrations of the components or the ratio of the particle sizes.

Catalysts obtained by the joint treatment of the La_2O_3–Cr_2O_3 oxides at 750°C have been investigated[133]. For the ratio $La_2O_3 : Cr_2O_3 = 3:1$, chromium is almost completely oxidised to Cr^{6+}, while for the 1 : 1 ratio approximately 50% of chromium remains in the form of Cr^{3+}. The $Mg_{1-x}Cu_x.Al_2O_4$ three-component system has been studied by a number of methods: XPES, secondary ion mass spectrometry (SIMS), EPR, and others[134]. It follows from SIMS data that, after heat treatment at 900°C in air, the system has only the spinel structure. In the spectra of specimens with a low copper content, the O(2*p*) signal is split into two peaks and, with increase in the copper content, the higher energy peak remains unchanged either as regards energy or intensity, while the intensity of the lower energy peak increases and it is displaced towards lower values of E_b. The set of data obtained led to the conclusion that an increase of the copper content results in a delocalisation of the copper electrons, which is the cause of the decrease of the activity of the catalyst in the oxychlorination of ethylene.

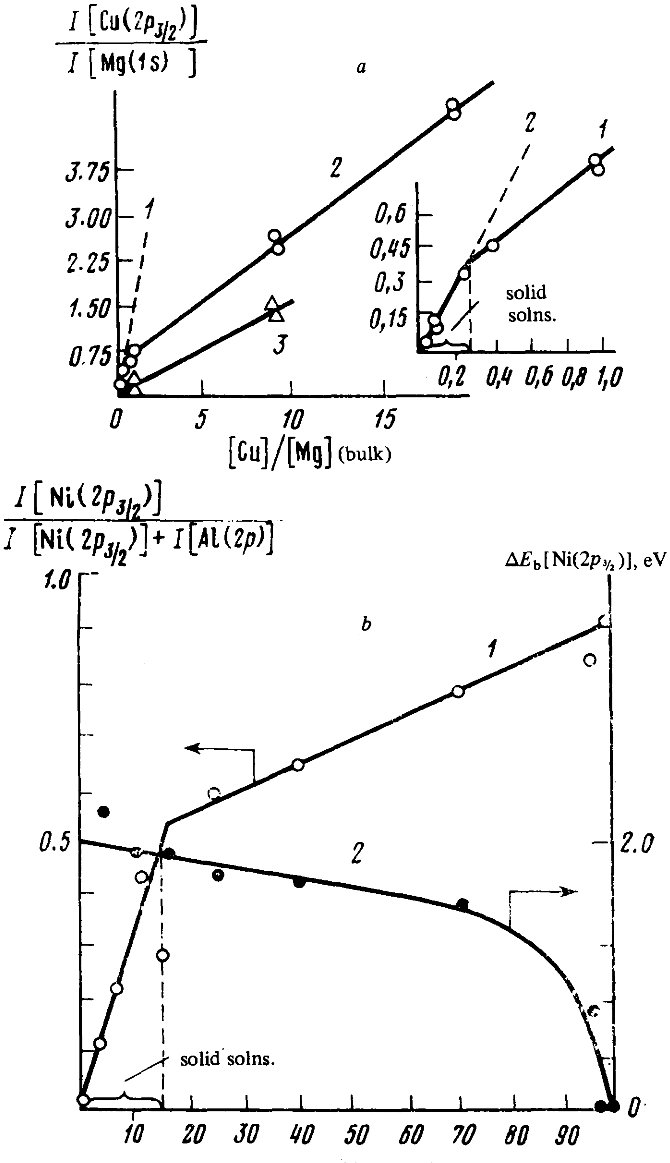

Figure 2. Dependence of the spectroscopic characteristics of the elements (the intensity ratios and the inner level bond energies) on the composition of oxide catalysts: *a*) CuO–MgO[128] [1) and 2) catalysts (curves *1* and *2* represent the solid solution and heterogeneous regions respectively); 3) mechanical mixture]; *b*) $NiO–Al_2O_3$ [1) dependence of the intensity ratio on composition; 2) dependence of the $Ni(2p_{3/2})$ line shift (relative to the NiO line) on composition].

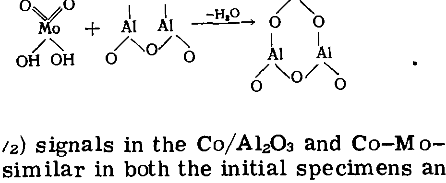
4. Deposited Catalysts

In the study of catalysis on deposited catalysts, information about the nature of the interaction of the active components with one another and with the carrier, about the surface compounds, and about the valence state and concentration of the deposited component is of significant interest for investigators. Depending on the state of the deposited component in the active form, deposited catalysts may be divided into two groups: oxides on carriers and metals on carriers.

(a) Oxides on carriers. Starting with the study of Miller et al.[135], investigators drew attention to the fact that the spectra of deposited cations giving rise to oxides or oxide compounds after heat treatment differ from those of the cations in the corresponding individual compounds. The lines due to the elements in the spectra of catalysts are appreciably broadened and in certain cases chemical shifts are also observed. The magnitude of the observed effects depends on the type of cation and carrier and the method of preparation and treatment of the specimen. The usual scheme followed in the study of such catalysts therefore involves a comparison of the spectra of the catalysts, after various types of treatment or catalysis, with the spectra of the individual oxides, and with those of the postulated bulk-phase analogues of the surface phases and the estimation of the relative surface concentrations.

The most important results were obtained in a study of molybdenum catalysts, which have practical importance. These include in the first place data obtained in the investigation of the alumina–cobalt–molybdenum catalyst for the elimination of sulphur from petroleum, the binary deposited Co/Al_2O_3 and MoO_3/Al_2O_3 catalysts, and the non-deposited cobalt and molybdenum sulphide catalysts, which to some extent simulate the structure of the Co–Mo–Al_2O_3 surface layer, after various types of treatment, or the hydrodesulphurisation reaction in hydrocarbons. In a study of MoO_3/Al_2O_3 Miller et al.[135] observed for the first time a broadening of the Mo(3*d*) line, which was attributed to a donor–acceptor interaction of MoO_3 with the carrier. Other workers reached the same conclusion[114,115,136]. When (3% MoO_3)/Al_2O_3 was reduced, Mo^{6+}, Mo^{5+}, and Mo^{4+} ions were detected[114], oxidation in air resulting in a decrease in the concentration of Mo^{5+} ions, while that of Mo^{4+} ions remained unchanged. The reduction of Mo^{6+} ions in MoO_3/Al_2O_3 proceeds with much more difficulty than in the MoO_3/SiO_2 catalyst owing to the stronger interaction of molybdenum with Al_2O_3. The intense interaction of molybdenum with the carrier persists also in the ternary system[115,136–138]. This is indicated particularly by the finding that the reduction of MoO_3 at 400–500°C in hydrogen leads to the formation of metallic molybdenum, while only Mo^{5+} and Mo^{4+} ions are formed in the Co–Mo–Al_2O_3 system[115,136,138], and, even after prolonged treatment in hydrogen[138] at 500°C, approximately 25% Mo^{6+} remains unreduced. A study of the reduction kinetics showed[138] that Mo^{5+} ions behave as intermediate species in the $Mo^{6+} \rightarrow Mo^{4+}$ transition; the Mo^{5+} concentration on the surface exceeded by a factor of 5 that observed by EPR. The similarity of the Mo(3*d*) bond energies in Co–Mo–Al_2O_3, $Al_2(MoO_4)_3$, and MoO_3 precludes a conclusion in favour or against the formation of aluminium molybdate on the surface. It is noteworthy that XPES data do not appear to conflict with the reaction mechanism adopted in the literature[138].



The Co($2p_{3/2}$) signals in the Co/Al_2O_3 and Co–Mo–Al_2O_3 catalysts are similar in both the initial specimens and after heat treatment at 600°C and apparently correspond to Co^{2+} ions[136,138,139]. We may note that the peaks with E_b = 781.4 and 780.5 eV for Co($2p_{3/2}$) were assigned to cobalt in Co_2AlO_4 and CoO respectively, while the satellite peak with E_b = 784.9 eV was erroneously assigned to Co^{2+} ions coordinated to H_2O molecules. The decrease of the spin–orbit splitting of the $2p_{1/2}$ and $2p_{3/2}$ cobalt sublevels[103] after the heat treatment of (5–10% Co)/Al_2O_3 led to the hypothesis that the cobalt on the surface exists in the tervalent state, although X-ray diffraction revealed the presence of the $CoAl_2O_4$ phase. Analysis of the satellite structure of the spectra of the variable-composition Co–Mo–Al_2O_3 system[140] (0.5–0.6% Co, 2–10% Mo) led to the conclusion that at low concentrations the tetrahedral centres in Al_2O_3 are occupied solely by Co^{2+} ions, while after the formation of the monolayer the Co_3O_4 phase appears. Although, in view of some discrepancy between the results, one cannot postulate an unambiguous form of the surface compound of cobalt and alumina, it is evident that such a complex exists. This is also indicated by the difficulty of reducing Co^{2+} by hydrogen in deposited catalysts.

The problem of the interaction of cobalt and molybdenum in the cobalt–molybdenum–alumina catalyst is no less complex. The authors[141] believe that, with increase of the cobalt concentration to 1% (to give a ratio Mo : Co $\leq$ 4), a phase designated as Mo_4Co is formed on the surface. When the ternary system is heat-treated in air at 600°C, the ratios of the integral intensities of the Co and Al, Mo and Al, and Co and Mo pairs of signals change, which indicates an enrichment of the surface in molybdenum ions and a decrease of the surface concentration of cobalt ions[136]. Reduction of the specimen leads to the opposite effect[115,136]. A smaller cobalt and molybdenum signal intensity ratio in Co–Mo–Al_2O_3 compared with CoO/Al_2O_3 for the same bulk-phase CoO concentrations may be attributed to the fact that cobalt ions are located in deeper layers of the catalyst than molybdenum ions[115,136]. Thus the different conditions for the reduction of cobalt and molybdenum ions and the variation of their surface concentrations when different types of treatment are employed, as well as the differences between the energies in the $CoMoO_4$ and Co–Mo–Al_2O_3 spectra, show that cobalt and molybdenum interact mainly on the carrier. At the same time, according to some data, molybdenum ions prevent the penetration of cobalt ions into the lattice and the formation of a phase resembling a bulk-phase spinel[136].

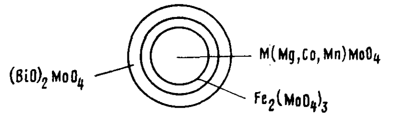
It has been found that the state of cobalt and molybdenum changes significantly in the interaction of the catalyst with model mixtures: thiophen–H_2,[138,142] H_2S–H_2,[138,139] and CS_2–H_2.[143] A general conclusion arrived at in these studies is that cobalt and molybdenum are vigorously, although not completely, converted into sulphides. As regards the identification of the surface sulphides, reliable data on E_b for the electrons of cobalt and molybdenum in sulphides of different composition are necessary. It has been found[143–145] that in contrast to the oxides MoO_2 and MoO_3 the transition from the lowest to the highest molybdenum sulphide entails a negative shift of the Mo(3*d*) line. Furthermore, two S(2*p*) components (with an intensity ratio of 1 : 2), having E_b = 162.9 (S^0) and 161.8 eV (S^{2-}) were observed in MoO_3. This shows that MoS_3 is formed by the association of subcrystalline MoS_2 and amorphous sulphur. A similar conclusion was reached in another study, where Co–Mo–Al_2O_3 deposited catalysts were investigated. Reliable information[146,147] for the Co–S systems was not obtained in the above investigations, because specimens with low cobalt contents were studied [Co/(Co + Mo) < 0.1].

The NiO–WO_3–Al_2O_3 catalyst, which is an analogue of the cobalt–molybdenum–alumina catalyst, has been studied in detail[148]. In the oxide form of the specimen nickel is present as Ni_2O_3 and $NiAl_2O_4$, while W forms a stable complex with γ-Al_2O_3. Nickel is comparatively readily reduced in H_2 to zerovalent nickel, while tungsten remains in the form of W^{6+}. Treatment with thiophen–H_2 and particularly H_2S–H_2 mixtures leads to the formation of sulphides: WS_2 and Ni_3S_2 and NiS. Since the ratio of the nickel and aluminium signal intensities increases under these conditions, it is suggested that nickel sulphides are dispersed on the alumina surface and possibly on the surface of WS_2. We may note that, in contrast to $Co-MoO_3-Al_2O_3$, the $NiO-WO_3-Al_2O_3$ system is almost completely converted into sulphides under these conditions.

Thus XPES yielded information about the state and distribution of molybdenum and cobalt (or nickel and tungsten) ions in the structures of oxide and reduced catalysts and catalysts converted into sulphides. The model of the sulphur-elimination catalyst put forward in a number of studies [149–151], where the ions of the active component exists in the form of a monolayer and those of the promoting agent enter the tetrahedral Al_2O_3 centres, is in general confirmed by these results. At the same time, no evidence has been obtained for the presence of Mo^{3+} (W^{3+}), which are believed [149] to enter into the composition of the active centre, and no data supporting the formation of so-called "incorporated" structure have been obtained [149–151].

The influence of the nature of the additives on the structure of the $V_2O_5-MoO_3$ catalyst has been studied [152,153]. In the NaH_2PO_4 concentration range between 0 and 5% the ratio of the surface concentrations [V]/[Mo] changes by a factor of 4, while the bulk-phase ratio remains constant [152]. When the oxides of various elements were added to the $V_2O_5-MoO_3$ solid solution, a change in the degree of reduction of vanadium ($V^{4+} \rightarrow V^{5+}$) and in the [V]/[Mo] (surf.) ratio was observed. After the introduction of promoting additives into the $CoMoO_4$ α-phase, the bond energies in the cobalt and molybdenum spectra change little [154]. However, when V_2O_5 was deposited on the $CoMoO_4 + MoO_3$ surface using the layer-by-layer method, then the values of E_b for the $Co(2p_{3/2})$ level (+0.6 eV) of [Co]/[Mo] (surf.) increased with the concentration of the additive [154]. This is due to the formation of a $V_2O_5-MoO_3$ solid solution, having the same structure as $CoMoO_4$, and the increase of the charge on cobalt.

An interesting attempt at a layer-by-layer analysis of MCM catalysts (bismuth and iron molybdates with added magnesium, cobalt, and manganese) was undertaken [155]. The iron signal was not detected in the spectrum of the surface layer of the initial specimen. However, after bombardment with Ar^+ ions the surface was depleted in molybdenum and bismuth ions [under certain conditions, the intense $Bi(4f_{7/2})$ peak fully disappeared], whereupon the $Fe(2p_{3/2})$ signal appeared and its intensity increased. On the basis of these results, the following three-layer model was proposed for MCM catalysts:



It is not clear whether the possibility of the migration of the components on the surface during the bombardment with Ar^+ has been taken into account in the above study. The interaction of Bi_2MoO_6 with H_2 led to the reduction of Mo^{6+} to Mo^{4+} [156] and the UPE spectra indicated the formation of two types of donor levels above the valence band; in the last stages of the reduction process some of the bismuth was converted into Bi^{3+}.

Among deposited metal carbonyl catalysts, the $Mo(CO)_6/\gamma-Al_2O_3$ catalyst heated *in vacuo* at 400°C was investigated; molybdenum in the $0 < n < 6$ state was detected in the catalyst [157]. It has already been stated that many deposited oxides react vigorously with the Al_2O_3 surface. In addition it has been shown [158] that heat treatment of catalysts containing zinc and nickel nitrates on the $\gamma-Al_2O_3$ surface leads to an increase of the binding energy in the spectra of the metals by 1 eV relative to the oxides and to a decrease of the $Al(2p)$ binding energy by 0.7 eV. The similarity of the E_b values in the spectra of deposited cations and the corresponding aluminates led to the hypothesis that the latter are formed on the surface of the carrier. A similar conclusion was reached for CuO/Al_2O_3 [159] and WO_3/Al_2O_3. [160] It is believed [103] that the strength of the interaction of CoO with the carrier increases in the sequence $SiO_2 < \gamma-Al_2O_3 < La_2O_3$, $LaCoO_3$ being formed in the last system.

The surface composition of alumina–chromium oxide catalysts (ACC) depends on the nature of the aluminium compound chosen as the carrier [161]. The ratios of the intensities of the $Cr(2p)$ and $Al(2s)$ lines for the catalysts obtained by impregnating bayerite, boehmite, and $\gamma-Al_2O_3$ with the same amount of CrO_3 and heat-treated at 700°C are similar, while the ratio for hydrargillite is higher by a factor of 2. With certain assumptions, the ratio $I(Cr)/I[(Cr) + (Al)]$ may serve as a measure of the specific surface of Cr_2O_3 in ACC. [161] The state of the chromium ions in ACC depends on the chromium content [162]: at low concentrations Cr^{6+} ions were detected in the heat-treated specimens, and, as the chromium concentration increased, the Cr^{3+} phase appeared. The change in the splittings of the $Cr(2p_{1/2})$ and $Cr(2p_{3/2})$ lines and their shift (−1.7 eV) relative to the Cr^{6+} spectrum show that almost the entire chromium is reduced under mild conditions to Cr^{5+}. In the above study and elsewhere [112,163] attention was drawn to the possibility of the photochemical reduction of Cr^{6+} on the surface of carriers. Data [113,164] for the change in the surface composition of CrO_3/SiO_2 catalysts conflict with one another. A sharp decrease in the ratio of the $Cr(2p)$ and $Si(2p)$ signal intensities has been observed [112] as a function of the heat treatment temperature and was explained by the agglomeration of chromium into large Cr_2O_3 particles. On the other hand, the sharp increase of the Cr and Si signal intensity ratio was attributed to the formation of a dispersed $\alpha-Cr_2O_3$ phase on the SiO_2 surface [164]. According to our data, the ratio of the $Cr(2p_{3/2})$ and $Si(2s)$ signal intensities in the non-heat-treated (5% CrO_3)/SiO_2 specimen is higher by a factor of 2 than in the specimen heat-treated at 550°C. In addition, it has been shown [164] that the reduction of CrO_3/SiO_2 to cobalt *in situ* leads to a negative shift of the $Cr(2p_{3/2})$ line by 0.7 eV, which can be explained by the formation of Cr^{2+}. An AlF_3 surface complex on $\gamma-Al_2O$ has been observed [165]. This result as well as data for the interaction of HF with alumina [166] may be of interest for the study of catalysts in which the carrier is fluorinated Al_2O_3.

(b) Deposited metal and "grafted" catalysts. The principal trend in the application of the method to these systems involves the study of the interaction of metal clusters with the carrier, of the degree of reduction of metals, and of the nature of their distribution on the surface. As an example, Fig. 3 presents certain data for the Re/SiO_2 and $Re/\gamma-Al_2O_3$ catalysts [120]. The spectra of the catalysts obtained by impregnating $\gamma-Al_2O_3$ with NH_4ReO_4 and $HReO_4$ solutions differ greatly from those of Re_2O_7 or NH_4ReO_4. An appreciable broadening of the $Re(4f)$ lines and a positive shift are observed for the catalyst. To a lesser extent, this is also seen for the Re/SiO_4 specimens. The reduction of the catalysts in a stream of H_2 at 500°C leads to the appearance of a spectrum which also differs from that of the compact metal. We may note that, according to the results of chemical analysis, rhenium is almost completely reduced to the zerovalent state. The positive shift in the Re($4f_{7/2}$) spectrum relative to the Re^0 spectrum changes as a function of the type of compound used for impregnation: $KReO_4(0) <$ NH_4ReO_4 (0.3 eV) $<$ $HReO_4$ (0.5 eV) $<$ $Ba(ReO_4)_2$ (1.1 eV). The main effect for all the Re/SiO_2 specimens consists in a broadening of the lines. The differences between the spectra of the deposited and compact metal are apparently due to the donor–acceptor interaction between the highly dispersed rhenium particles and the carrier. The broadening of the lines may indicate an energetic inhomogeneity of the rhenium atoms on the surface.

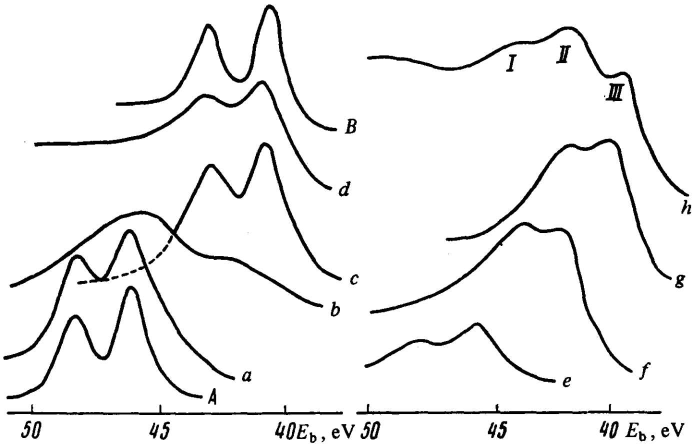


Figure 3. Re($4f$) photoelectron spectra of deposited Re/γ-Al_2O_3 and Re/SiO_2 catalysts[120]: *a*) initial Re/SiO_2; *b*) Re/SiO_2, 300°C, H_2, 10 mmHg; *d*) Re/SiO_2, 200°C, $C_6H_6 + H_2$, 30 atm; *e*) initial Re/γ-Al_2O_3; *f*) Re/γ-Al_2O_3, 500°C, H_2, 10 mmHg; *g*) Re/γ-Al_2O_3, 650°C, H_2, 10 mmHg; *h*) Re/γ-Al_2O_3, 200°C, $C_6H_6 + H_2$, 300 atm; A = NH_4ReO_4; B = Re(metal), 480°C, H_2, 10 mmHg. The I, II doublet characterises Re^{n+} (n = 3 or 4) and the II, III doublet characterises Re^0.

The differences between the spectroscopic characteristics of the deposited and bulk-phase metals have been pointed out in a number of studies: for Ir[167-169], Pt,[170-173] Pt–Ge,[173] Pt–(Mo, W, Re),[174-176] W,[178] Rh,[179] and Pd.[45] The chemical shift of the Ir($4f$) line[169] relative to Ir^0 changes as a function of the nature of the carrier: ZnO (0.3 eV) $<$ SiO_2 (0.9 eV) $<$ α-Al_2O_3 (1.0 eV) $<$ TiO_2 (1.2 eV) $<$ δ-Al_2O_3 (1.8 eV) $\leqslant$ aluminosilicate. The appearance of the shift is caused, according to the authors[169], by the equalisation of the positions of the Fermi level on the surfaces of different oxides. The broadening of the Pt($4f$) line and the appearance of an additional peak near the Fermi level has been interpreted[170] as a consequence of the interaction of Pt clusters (whose size is d = 12–20 Å) with silica gel. Similarly, a broadening of the Pd($3d$) line and a small positive shift relative to the Pd^0 spectrum have been observed for Pd/Al_2O_3.[45] In addition there is a decrease of the density of states in the vicinity of the Fermi level. Calculation with the aid of the extended Hückel method showed that the interaction of the palladium atom with the γ-Al_2O_3 surface may lead to similar changes in the spectra. According to an alternative explanation, the effects observed in the spectra of deposited metals are due to the anomalous electronic properties of the metallic clusters. The most interesting attempt to follow the changes in the spectrum in the valence region for different surface coverages by metal atoms was undertaken by Mason and coworkers[171,180] and Hamilton[181]. For low surface coverages of graphite by silver, the spectra of the valence bands show that the *sp* band of silver atoms is unfilled and that there is a small peak with $\Delta E\Phi = -2$ eV. Calculation by the CNDO method showed that such states are characteristic of Ag_1–Ag_4/C_{16} clusters[180]. With increase of the degree of surface coverage, the spectrum characteristic of metallic silver gradually appears.

The nature of the clusters and their interaction with carriers can in principle be inferred from XPE spectra. However, it is first necessary to solve a number of complex problems: (1) one must find a method of separating chemical relaxation shifts and shifts caused by the matrix effect. The difficulty is that the charging of the inhomogeneous surface of the specimen can also cause a broadening and distortion of the lines. More direct results can be obtained by studying the UPE and XPE spectra of the valence bands. (2) One must find a method of isolating the components responsible for the alteration of the electronic properties of the clusters and for the interaction with the support. For this purpose, it is necessary to study the clusters on inert carriers and to compare the experimental data with calculation. In view of the foregoing, studies on "grafted" catalysts, particularly on organic carriers, on which it is possible to obtain clusters with rigorously specified dimensions, appear promising. At the present time there have been few investigations, in which only metals grafted via π-allyl complexes to the silica gel surface were investigated[174-178]. In the presence of low-valence molybdenum, tungsten, and rhenium ions, the electron density of platinum diminishes[174-178]. The enhancement of the interaction of tungsten grafted to the SiO_2 surface relative to the standard specimen obtained by impregnation is indicated by the results of Shul'ga et al.[178]

It has been suggested[172] that, after the impregnation of alumina with H_2PtCl_6 and reduction, some of the platinum atoms are coordinated to chloride ions and Al_2O_3, i.e. are formally in the quadrivalent state. The state of a rhodium complex deposited on a polymer has been characterised[182]: E_b for Rh($3d$) in the catalyst was close to the value for the initial complex $RhCl_2[P(o\text{-tolyl})_3]_2$. A change in the valence state of rhodium was not observed after prolonged exposure of the specimen to air. After treating SiO_2 with hydrogen at 800°C in the presence of metals (Ni, Pt, Ta, and W) but without physical contact with them, the Si–OH groups were reduced to Si–H groups, which, judging from the XPES data, is due to transfer of traces of metals to the surface[183].

In a heterophase system the expression for the intensity ratio may be represented as follows[184]:

$$\frac{I_M}{I_C} = \frac{I_M^\infty}{I_C^\infty}\,\frac{f\,[1 - e^{-c/\lambda_M(E_M)}]}{1 - f\,[1 - e^{-c/\lambda_M(E_M)}]}\,, \tag{6}$$

where I_M^∞ and I_C^∞ are the signal intensities in the spectra of infinitely thick metal and carrier specimens, f is the fraction of the surface occupied by the metal, c the size of the metal crystallites, and λ_M the mean free path of electrons with a kinetic energy E_M. Thus, together with concentration, the surface coverage by the metal and the size of its crystallites influence the intensity ratio. Evidently in the two extreme cases (where $c \ll \lambda$ and $c \gg \lambda$) with homogeneous coverage, a linear relation should be observed between I_M/I_C and the metal concentration. Indeed, a direct correlation has been noted[184,185] between the ratio I(Pt)/I(Si) and the characteristics of the platinum surface, namely the volume of absorbed H_2 and the ratio of the number of Pt atoms, i.e. [Pt], to the specific surface of the carrier S_{sp}. For highly disperse systems (Pt/SiO_2 and Na/Al_2O_3), the composition determined with the aid of XPES is close to that of the bulk phase. For specimens with a lower degree of dispersion, a direct relation is observed only when I(Pt)/I(Si) is plotted against [Pt]/cS_{sp} (Fig. 4).

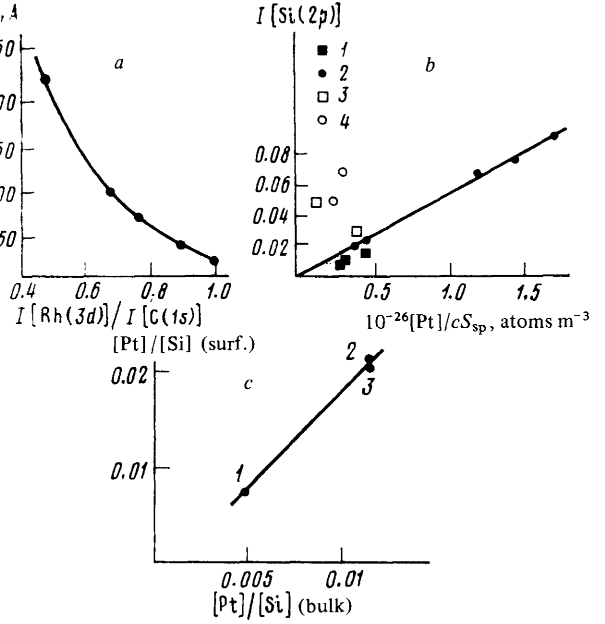

Figure 4. The influence of the particle size of the metal and of its surface concentration on the metal : carrier signal intensity ratio in the spectra of catalysts with deposited metals: *a*) dependence of the ratio $I[\mathrm{Rh}(3d)]/I[\mathrm{C}(1s)]$ on the particle size of Rh^0 in the catalyst [(12 wt.% Rh)/C];[186] *b*) dependence of the intensity ratio $I[\mathrm{Pt}(4f)]/I[\mathrm{Si}(2p)]$ on the surface concentration of platinum [see Eqn. (6)] in Pt/SiO_2 catalysts[184,185] [1) and 2) specimens prepared by ion exchange; 3) and 4) specimens prepared by impregnation]; *c*) dependence of the surface concentration of platinum {determined by analysing the $I[\mathrm{Pt}(4f)]/I[\mathrm{Si}(2p)]$ ratio} on the total amount of platinum in Pt/SiO_2 specimens [1) (1.2 wt.% Pt)/SiO_2, ion-exchange method; 2) (3.5 wt.% Pt)/SiO_2, ion-exchange method; 3) (3.5 wt.% Pt)/SiO_2, impregnation method].

According to the results of Shul'ga and coworkers[178], a linear relation between I(W)/I(Si) and the tungsten content is characteristic both of specimens obtained by impregnation and of "grafted" catalysts. However, the increase of the slope for specimens of the latter kind indicated a higher degree of surface coverage by tungstate (higher by a factor of 20 than for the "impregnated" specimens). According to our results, the ratio [Pt]/[Si](surf.) (Fig. 4) found from the XPE spectra exceeds the average bulk-phase value. Subsequent heat treatment and reduction of the specimen led to a decrease of the ratio of the Pt and Si signal intensities. One of the causes of this is the increase in the size of the metal particles.

Similar phenomena in the spectra have been observed in other studies[120,172,173,186,187]. Thus, with increase of the size of the Rh^0 crystallites in the (12% Rh)/C catalyst from 20 to 235 Å (λ = 18 Å), the intensity ratio $I[\mathrm{Rh}(3d)]/I[\mathrm{C}(1s)]$ decreases by a factor of two[186] (Fig. 4). With increase in the size of the platinum crystallites from 10 to 25 Å in the (1.2% Pt)/SiO_2 ion-exchange specimens, a decrease of the Pt and Si signal intensity ratio by a factor of 1.8 was observed, and a slight decrease of the degree of dispersion of the metal (from 50 to 60 Å) in Pt/SiO_2 specimens obtained by impregnation resulted in an appreciable decrease of the intensity ratio (by a factor of 3). These data show that the change in intensities is caused not only by the change in the degree of dispersion, but also by a redistribution of the metal atoms on the surface. In consequence of the inhomogeneous distribution of the metal in the "impregnated" specimens, there is a possibility of a transition of metal atoms from pores more accessible to analysis to less accessible regions[184,185]. Clearly the ratio of the metal and carrier signal intensities may depend, other conditions being equal, on the porosity of the carrier, which has in fact been observed experimentally[188,189].

5. Zeolite Catalysts

The study of the state of elements in the surface layers of zeolites may be of considerable interest for the selection of conditions in the formation and operation of zeolite catalysts. Such information is important also because certain catalytic reactions apparently occur only in surface layers of zeolite crystals.

(a) Zeolites not containing transition metals. Fig. 5 presents the dependence of the ratio I(Al)/I(Si) on the zeolite modulus obtained in a number of studies[23,190-193]. In all cases the relation is linear. However, the calculations of [Al]/[Si](surf.) carried out in these studies indicates a discrepancy between the experimental results. According to some data[23,193], within the limits of experimental accuracy and the assumptions made, the compositions of the surface and bulk-phase of A, X and Y zeolites and mordenite are similar. Systematic elimination of aluminium from the surface of zeolites of these types has been pointed out[190-192]. The ratio [Al]/[Si](surf.) increased when the zeolite structure was disrupted[197]. The lower Al and Si signal intensity ratio found by Tempere and Delafosse[190] cannot be explained by the shielding of the Al^{3+} ions by water or by other cations, because changes in these factors do not alter the intensities[196]. The discrepancies between the experimental data are probably due to the non-equivalence of the specimens used in different investigations[23,190-193]. Comparison of the Ca and Si signal intensity ratios for (NaCaA) and Na/Si(HNaY) (Fig. 5) with the degrees of exchange of the corresponding cations shows that non-transition metal ions are apparently uniformly distributed in the zeolite structure. With increase of the SiO_2/Al_2O_3 ratio, the energies of the Al lines do not change and are similar to those in

Al_2O_3, while the Si(2p) line shifts by 0.7 eV and the energy of the Si(2p) bond approaches the value observed in SiO_2.[191] These data conflict with those[123] for natural aluminosilicates where a correlation was found between the shift of the Al(2p) line and the average Al–O distance.

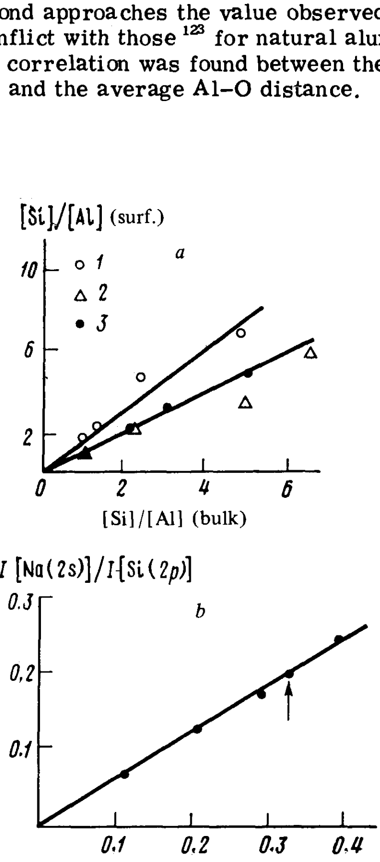

Figure 5. Composition of the surface layer of zeolites. a) dependence of the ratio of the numbers of silicon and aluminium atoms in the surface layers of zeolites (XPES data) on the ratio of the total numbers of these atoms in the zeolites [1) data of Temperet et al.[191]; 2) data of Finster and Lorens[193]; 3) present authors' data]; b) dependence of the intensity ratio I[Na(2s)]/I[Si(2p)] on [Na]/[Si] in the "bulk" of partly "decationated" type Y zeolites. For the specimen marked with an arrow, [Na]/[Si](bulk) = 0.32 [Na]/[Si](surf.) = 0.39.

With increase of the degree of exchange of Na^+ for Ca^{2+} from 20 to 80%, a positive shift (0.5 eV) of the Ca(2p) line is observed, apparently characterising the increase of the effective charge on calcium[40]. Comparison of the positions of the Na, K, Ca, and Mg lines in the spectra of zeolites and compounds with different types of chemical bonds permits the conclusion that the cations form predominantly ionic bonds with the zeolite skeleton[23,40]. A similar conclusion was reached in other studies[194,195] for magnesium ions in MgNaX and MgNaY.

According to some data[192,196], the adsorption of pyridine on the HY zeolite at 150°C led to the reduction of surface silicon ions to the elemental state. This result is not altogether understandable from the standpoint of the thermodynamics of the reduction of silicon and apparently requires further confirmation. The adsorption of pyridine at room temperature can be used as a test for quantitative estimates of the fraction of Brønsted and Lewis acid centres[192,196]. The splitting E[N(1s)] – E[Si(2p)] is 297.4 and 298.3 eV after adsorption on Lewis centres and 299.5 and 300.1 eV after adsorption on Brønsted centres[192]. A study of the adsorption of aniline on the HY zeolite was also undertaken[197].

(b) Zeolites containing transition metals. Systematic studies on individual and polycationic forms of zeolites have been made[23,40,198-205]. Since some of the results obtained have already been published in a review[200], we shall confine ourselves to an examination of certain examples.

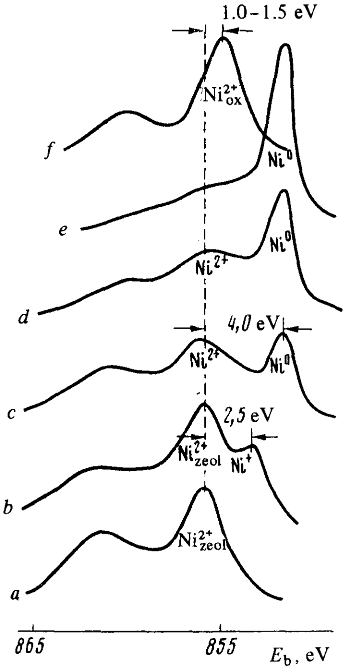

Figure 6. Variation of the valence and physical states of nickel for different methods of treatment of the NiNaY zeolite: a) dehydration, 400°C, air + 500°C, helium; b) 400°C, 10 mmHg CO; c) 350°C, 10 mmHg H_2; d) 400°C; 10 mmHg H_2; e) 450°C, 1 atm H_2 (the spectrum is shown in terms of a 1 : 3 scale); f) 450°C; H_2 + 500°C, air.

Comparison of the parameters of the spectra of Cr, Fe, Co, Ni, and Cu (the positions of the lines and of the satellite structures) in zeolites and in compounds with different types of bonds showed that the amount of ionic character of the cation–zeolite skeleton bond is close to that in fluorides or chlorides[40,203]. The capacity of cations for reduction depends on the nature of the transition metal[40,198-203], the type of structure[40,201], the degree of exchange[40,200,201], and the cationic composition[40,201-203]. As an example of the possible changes in the state of the elements in zeolites, we shall consider the spectra of Ni(2$p_{3/2}$) in NiNaY, treated under different conditions (Fig. 6). Spectrum a is due to Ni^{2+} ions. After dehydration, the lines characterising the distribution of the ions in regions with different crystal field symmetries are broadened somewhat. The new line in the spectrum with $\Delta E = -4$ eV, appearing after the reduction of the specimen with hydrogen, corresponds to zerovalent nickel. With increased temperature of the heat treatment in hydrogen, the degree of reduction of zerovalent nickel increases, and at high temperatures the ratio of the integral Ni and Si signal intensities increases relative to the initial value. The latter observation demonstrates the diffusion of zerovalent nickel atoms on the outer surface. On treatment in carbon monoxide, a line occupying a position intermediate between those of the Ni^{2+} and Ni^0 lines is observed. It has been attributed to the formation of the Ni^+ ion[204].

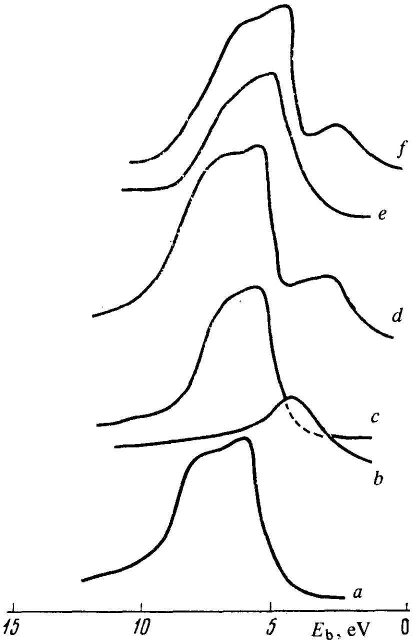

Figure 7. The interaction of metallic silver and copper in zeolites[203]; spectra: *a*) 0.14 AgNaY, 500°C, H_2; *b*) 0.26 CuNaY; 500°C, H_2; *c*) initial 0.25Ag.0.31CuNaY specimen; *d*) 0.25Ag.0.31CuNaY, 350°C, vacuum; *e*) 0.25Ag.0.31CuNaY, 500°C, H_2; *f*) result of the addition of spectra *a* and *b*.

Finally, after the oxidation of reduced Ni-zeolites, the position of the spectral line is close to that observed in the NiO spectrum[198]. This indicates the formation of the oxide phase on the outer surface. Thus XPES makes it possible to obtain information about several valence and phase states of metals in zeolites. Interesting results were obtained in the study of polycationic forms (Ag–Cu, Cu–Ni, Co–Ni, Cr–Ni)[203-205]. In all cases the capacity of cations for reduction and migration changes in relation to individual forms. This is due to the interaction of transition metals with one another. Fig. 7 illustrates the spectra of the valence bands of silver and copper in individual and polycationic forms[203]. Their comparison with one another, and also with the spectrum obtained by adding together curves *a* and *b*, shows that zerovalent silver and copper interact with one another, forming alloys on the outer surface or bimetallic clusters[202,203].

Despite the fact that quantitative analysis in zeolites containing transition metals involves a number of difficulties, one may reach certain important conclusions on the basis of the changes in signal intensities concerning the distribution of transition metals between the outer surface and the bulk of the crystals. The changes in the $Cu(2p_{3/2})$, $Ni(2p_{3/2})$, and $Si(2s)$ lines occurring in the oxidation-reduction treatment of Ni–Cu-zeolites have been investigated[205]. After treatment with hydrogen, the increase of the Cu and Si and of the Ni and Si signal intensity ratios indicates the migration of zerovalent copper and nickel onto the outer surface, while magnetic susceptibility measurements indicate the formation of an Ni–Cu alloy[205]. Oxidative treatment of these specimens causes a decrease of the intensity ratio of the Cu and Si lines, although the absolute magnitude of the $Si(2s)$ signal also diminishes by a factor of two. The decrease of the intensity of the $Si(2s)$ line may be caused by the increased shielding of the surface by metals as a result of their dispersion and hence should lead to an increase of the Cu and Si signal intensity ratio. Since the opposite behaviour is observed, presumably part of the copper diffuses after oxidation to the bulk of the zeolite crystal, which has indeed been confirmed by the appearance of an EPR signal due to isolated Cu^{2+} cations[205]. As for catalysts with deposited metals, the metal distributed in the zeolite may interact with the lattice. It has been stated[206] that E_b for Pt and Pd in zerovalent palladium and platinum clusters, trapped within zeolite cavities, is greater by approximately 1.0 eV than for metallic palladium and platinum, which has been attributed to the transfer of electron density from the metal atoms to the elements of the skeleton and also by a smaller relaxation energy.

In addition, a study has been made of the reduction $Eu^{3+} \rightarrow Eu^{2+}$ in the Eu-form of the zeolite, which is accompanied by an unusually large shift of the 3*d* line of europium (−7.6 eV).[23] The photochemical reduction of nickel in nickel-containing zeolites has been observed[207]. Under the conditions adopted in the measurement of spectra[199-203], this was not observed, although such effects were noted for silver, palladium, and copper cations.

(c) Other catalysts. The surface composition of rhenium heptasulphide has been studied[208,209]: the presence of sulphur in two states (S^{2-} and S^{6+}) was noted. It was shown that the hydrogenating activity of catalysts varies as a function of the ratio of sulphate and sulphide ions. When pyrolytic graphite, with silver sputtered onto the surface of the basal planes as the catalyst, was oxidised[210], no shifts of the Ag(3*d*) lines were observed. The decrease of the intensity of the Ag(3*d*) signal was explained by the agglomeration and evaporation of (Ag). It was noted that, when WC is formed, the density of states near the Fermi level becomes close to that for platinum[211]. This explained the similarity of the catalytic properties of WC and Pt in many reactions.

6. The Surface Compositions and Catalytic Properties of Heterogeneous Catalysts

Together with direct study of the catalytic reactions by the PES method (see below), there are also other procedures for the determination of the relation between the catalytic properties of heterogeneous catalysts and the state of their surfaces.

(a) The influence of the state of the elements on the activities and selectivities of catalysts. An industrial silver catalyst for the synthesis of epoxyethane has been studied[212,213] before and after γ-irradiation. It was shown that irradiation leads to an increase of the concentration of calcium ions on the surface, which entails an increase of the activity of the catalyst. With increase of the oxide/metal ratio in Rh/C catalysts, an increase of their hydrogenating capacity was noted[214]. Comparison of XPES data obtained in the reduction of Ni-, Co-, Ni–Co, Ni–Cu-, Ni–Cr, and Cu-zeolites and the activities of the catalysts in the reactions of carbon monoxide with nitric oxide and molecular oxygen led to the conclusion that the reduction of transition metal ions to the metals entails an appreciable increase of activity[215]. The same conclusion was arrived at for the reaction of carbon monoxide with nitric oxide on NiO, Co_2O_3, and Fe_2O_3.[216] The highest activity among copper(II) oxide catalysts is shown by that containing Cu^+. After the addition of platinum, the catalytic activity of the perovskites $La_{0.7}Pb_{0.3}.MnO_3$ in the oxidation of cobalt increases by a factor of 100. The increase of activity exceeds the effect expected for the homogeneous redistribution of platinum, whose activity corresponds to that of metallic platinum on A_2O_3. XPES data show that platinum is localised in the perovskite lattice in the form of Pt^{4+}.[217]

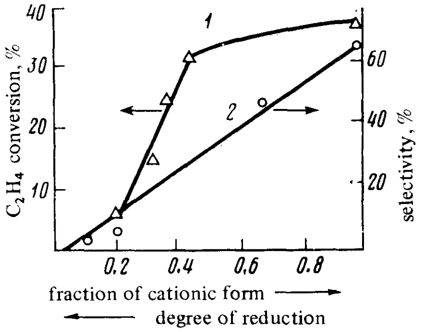

Figure 8. The influence of the state of transition elements on the activity and selectivity of zeolites in hydrocarbon conversion reactions: 1) variation of the degree of conversion of C_2H_4 on PdCaNaY[220] with the degree of reduction of palladium; 2) variation of the selectivity of NiNaY in the synthesis of s-butylbenzene with the degree of reduction of nickel[219].

Comparison of data for the catalysis of the oxidative dehydrogenation of paraffins in the presence of mixtures of nickel and tin oxides promoted by phosphorus and potassium and the results of physicochemical experiments (EPR, XPES)[218] led to the hypothesis that the lattice oxygen is involved in the reaction. The changes in the state of vanadium and of the ratio [V]/[Mo](surf.) in V_2O_5–MoO_3 catalysts promoted by Na_2HPO_4 are correlated with the changes in catalytic activity in the oxidation of furan to maleic anhydride[152]. In the case of $CoMoO_4$ modified by oxides the decisive factor determining the activity in the oxidation of propene and acrolein is the nature of the additive and not the ratio [Co]/[Mo](surf.)[155]. With increase of the fraction of Mo^{4+} bound to sulphur and oxygen in the overall amount of molybdenum in the Co–Mo–Al_2O_3 catalyst, an increase of the yield of CH_4 in the reaction involving the hydrodesulphurisation of CS_2 is observed[143].

The study of Ni- and Pd-zeolites[219,220] showed that the main factor determining the selectivity in the alkylation of benzene by ethylene to s-butylbenzene and the dimerisation of ethylene is the state of nickel and palladium respectively. In both cases cations are active in catalysis and a qualitative parallel relation between the fraction of the cationic form and the catalytic activity is observed (Fig. 8). The data examined show that in many instances a relation has been found between the state of the elements on the surface and the activity. It is also clear that, in order to obtain more far-reaching relations, additional data on the reaction mechanisms are required.

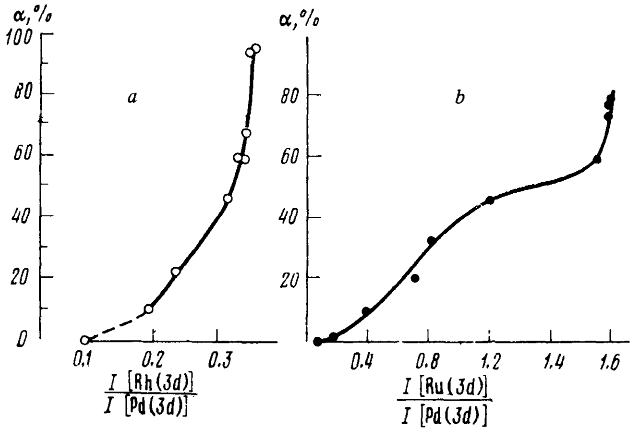

Figure 9. Correlation between the changes in the surface state of palladium alloys and their activity (α is the yield of C_6H_6) in the dehydrogenation of cyclohexane: *a*) Pd–Rh (10% Rh)[221]; *b*) Pd–Ru (10% Ru)[222].

(b) Modification of the surface of the catalysts under the influence of the reaction medium. Modification of the surface layer of catalysts in the reaction medium is characteristic of many specimens and reactions. The surface composition of binary alloys of palladium with rhodium (5 and 10%) and ruthenium (10%) changes only slightly when the catalysts are treated in H_2 and O_2.[82] At the same time the interaction of these alloys with hydrocarbons under the conditions of the dehydrogenation of cyclohexane to benzene leads to an appreciable enrichment of the surface in rhodium or ruthenium. Fig. 9 shows that there is a parallel variation of the catalytic activities of these alloys and of the surface composition[221,222]. It was shown, on the basis of these data and adsorption measurements, that the active surface is formed as a result of the segregation of the second component on the surface and the increase of the roughness of the latter[222]. A study of the initial and spent Pt–Rh catalysts for the oxidation of NH_3 showed that their deactivation is due to the segregation of rhodium on the surface in the form of Rh_2O_3 and Rh^0, which takes place as a result of the volatilisation of oxidised platinum. The activation of the Rh/Al_2O_3 catalyst in the tricyclomerisation of ethylene was accompanied by a positive shift of the Rh(3*d*) line by 0.6–0.8 eV. This was caused by the appearance of a positive charge on rhodium as a result of its interaction with hydrocarbons. Treatment with the $C_6H_6 + H_2$ mixture leads to partial reduction of rhenium in Re/Al_2O_3 catalysts and to the appearance of catalytic activity[126] (Fig. 3). On the other hand, the reduction in ethylene of the zeolite palladium and of its reaction products deactivates the catalyst[220]. The reduction of palladium in the Pd/SiO_2 catalyst in the hydrogenation of hex-1-ene has been pointed out[224].

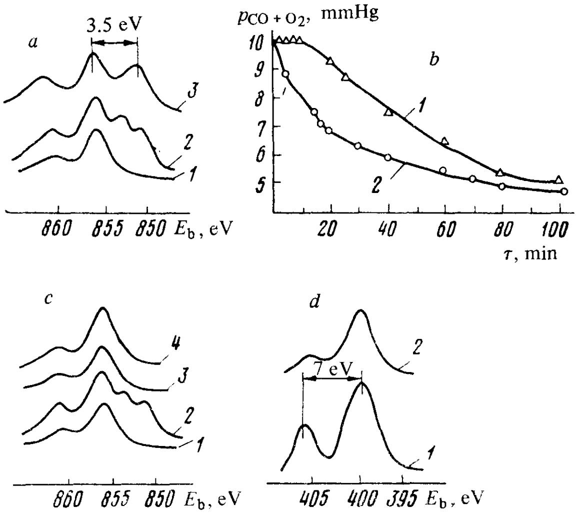

Figure 10. The influence of the state of transition elements on the catalytic activity of zeolites in the oxidation of CO by oxygen and the reduction of NO by carbon monoxide[215]: *a*) lines of $Ni(2p_{3/2})$ in NiNaY [1) dehydrated specimen; 2) specimen treated with CO at 400°C; 3) specimen treated with CO + O_2 at 400°C]; *b*) kinetics of the oxidation of CO on NiNaY at 400°C [1) first experiment; 2) second and subsequent experiments]; *c*) lines of $Ni(2p_{3/2})$ in CuNiNaY [1) dehydrated specimen; 2) specimen treated in CO at 400°C; 3) after subsequent treatment with NO at 400°C; 4) specimen treated in NO + CO at 400°C]; *d*) N(1*s*) lines [1) heat treatment of CuNiNaY in NO + CO at 400°C; 2) heat treatment in NO at 400°C].

Fig. 10 illustrates the changes in the XPE spectra and of the catalytic activity of NiY in the oxidation of carbon monoxide[215]. The interaction of the zeolite with the CO + O_2 mixture under the conditions of the catalysis leads to the reduction of Ni^{2+} to the metallic and possibly the univalent states. The period of the activation of the given specimen is apparently associated with this process. The concentration of Cr^{2+} in Cr/SiO_2 catalysts subjected to preliminary reduction in CO diminishes on subsequent interaction with NO at 300°C.[164] When the specimen is maintained in the NO + CO mixture, Cr^{2+} is reformed. The activity of the complex $ReCl(NO)(Py)_2$ in the hydrogenation of pyridine or cyclohexene was four times greater than that of Re_3Cl_9.[225] According to XPES and infrared spectroscopic data, this is due to the fact that part of the rhenium in the complex retains its coordinate linkage with NO, while the surface layer of the chloride is completely reduced to zerovalent rhenium.

Thus XPES data show that changes in the surface layer under the influence of reaction medium, which may lead to both activation and deactivation of the specimens, are characteristic of catalysts of different types.

The products formed on the surface during the reactions may be investigated with the aid of XPES. The consecutive aldehyde → acid → $CO_2 + H_2O$ transformations on the selective MoO_3, MoO_2, and $CoMoO_4$ oxidation catalysts were investigated at 77–773 K.[226] The interaction of NO with CoO and NiO [227] leads to the appearance of the N(1*s*) peak, whose position indicates electron transfer from the oxide to NO. In the adsorption of nitrogen on Fe_2O_3, the Fe(3*p*) bond energy did not change, while the positive shift of the spectrum of iron in Fe_3O_4 indicated the oxidation of the surface[228]. The two forms of adsorption of NO have been observed to a lesser extent on the surfaces of nickel-containing zeolites after their interaction with NO or NO + CO at 220–550°C.[215] The higher- and lower-energy peaks characterise the formation of the nitrosyl and nitrate complexes respectively. The deactivation of zeolites at low temperatures in the reduction of NO is probably due to the formation of stable nitrate complexes[215] (Fig. 10).

Results obtained by UPE and XPE spectroscopy led to conclusions concerning the mechanisms of the decomposition of HCOOH and the adsorption of pyridine on metallophthalocyanines[229]. The adsorption of pyridine is not accompanied by a change in the charge on iron, while HCOOH dissociates heterolytically with adsorption of the formate ion on the central atom and of the proton on the bridging nitrogen atom in the porphyrin ring.

7. Results of Adsorption Studies

As mentioned above, there is an extensive literature on the application of PES to the study of adsorption[24,25,29–37]. Two international conferences have been devoted to problems associated with the interpretation of the spectra of adsorbates[32,33]. Taking this into account, we decided to give only a brief account in the present review (retaining as far as possible the complete bibliography) of the principal research trends. New results of studies on the adsorption of hydrocarbons and catalytic reactions at low pressure of reactants are described in greater detail.

(a) Adsorption on metals. The study of the interaction of simple gases with metallic surfaces is the main field of application of PES to adsorption. In these systems there is in fact a possibility of obtaining polycrystalline and single-crystal atomically pure surfaces and of deriving the maximum information with the aid of other physicochemical methods.

The interaction of CO with tungsten[230–238], molybdenum[30,232–234,239–241], platinum[232,242–250], ruthenium[248,251–255], palladium[256,257], nickel[232,233,241,249,258–262], iridium[263,264], iron[166,265], copper[232,241,266,267], titanium[268], and cobalt[269] has been studied vigorously. Several forms of adsorption of CO on polycrystalline tungsten have been observed[230,231,238]: The α-form with bonding close to that in carbonyls, which disappears in the temperature range 300–640 K, the dissociative form, and the weakly adsorbed "virgin" state. In molecular adsorption on tungsten, and on other metals, the chemisorption linkage is formed by the $5d$ orbitals with the lone electron pair. A correlation has been observed[232] between E_b for the O(1s) level and the heats of adsorption on five metals, which indicated a contribution of the πd component to the chemisorption linkage. For the strongest adsorption (Ni, Pt, Pd, Ru, Fe), ΔE_b = 2 eV, and for the weakest adsorption (γ = CO/Mo) ΔE_b = −3.2 eV. According to the authors[232], there is a CO dissociation threshold at room temperature: ΔH_{ads} = 260 kJ mole^{-1}. Apart from tungsten (β-form), dissociative adsorption has been observed on molybdenum (β-form)[240], iron[265], nickel[233,261], titanium[268], and copper[266].

Polycrystalline tungsten and platinum do not catalyse the dissociation of NO at temperatures up to 100° C[30,270-272]. Ruthenium[248], iridium[273], nickel[262,274], and iron[275-277] are more active in the dissociation of NO. NO dissociates on the (1010) faces of ruthenium even at 100 K (NO exposure = 1.5 L). The peaks of nitride nitrogen and atomic oxygen in the spectrum of NO adsorbed on the (111) face of iridium are observed at 323–373 K; it has been suggested that oxygen blocks the active centres for the decomposition of NO.[273]

Numerous studies have been devoted to the interaction of O_2 with metal surfaces, and, together with adsorption on reconstructed surfaces, the oxidation of surface layers was investigated, from the initiation of the oxides until the formation of oxide phases. These processes may constitute the individual stages of the reactions with participation of oxygen.

The interaction of O_2 with the surfaces of polycrystalline tungsten[231,265] and the (111), (110), and (100) tungsten faces[238,274,278-280], polycrystalline molybdenum[30,240], platinum[243,248,281], palladium[256], iridium [(100)[263] and (111)[282]], ruthenium [(10$\bar{1}$0) and (001)][253,279,283], polycrystalline nickel[30,232,284-286], nickel (100)[287], polycrystalline silver[288,289], the (100) face of silver[278], polycrystalline copper[266,289-291], the (110)[292] and (100)[293] faces of copper, polycrystalline gold[289], sputtered iron[267,286,294,295], zinc[296], and tin[297], and magnesium, aluminium, chromium, manganese[238], lanthanide[299], cerium[84], titanium[84], and cobalt[269] films.

It has been stated in a report[300], and in a number of reviews[30,32,33,36,37] that the adsorption of oxygen on a number of metals (V, Mn, Fe, Co, Ni, Cu, Ag, Zn, Mo, W, Ru, Ir, Au, and Na) at room temperature leads to the appearance of the O(1s) peak with E_b = 530 ± 0.5 eV (in UPE spectra there is a maximum with $E_b \simeq$ 6 eV). This may indicate a similarity of the structures of the adsorption complexes of oxygen, which are believed[33] to be of "the oxide-like" type. However, it is more likely that the agreement is merely formal and does not reflect the constancy of the charge on oxygen but is caused by the different contributions of the Madelung and relaxation terms to ΔE_b.

At the same time other forms of adsorbed oxygen were also observed: O(1s) signals with 531.4–532.0 eV (Ni, Co, Mn) and 533 eV (Pt) corresponding to them. The adsorption of O_2 on nickel at 300 K and $\theta < 1$ led to the appearance of two O(1s) peaks, one of which was assigned to adsorbed oxygen and the other to oxygen which penetrated underneath the surface of the crystal (531.4 eV). Three types of oxygen were observed in another study[285] in the range 77–500 K ($\theta < 1$) on nickel. Finally, the transition from adsorption to the generation of the NiO phase and the formation of the bulk-phase oxide were observed in the range $0.5 \leqslant \theta \leqslant 2.0$. The exposure and temperature required for the bulk-phase oxidation are determined by the nature and reactivity of the metal. Thus, an O_2 exposure of 2 L is sufficient for the formation of a ~ 10 Å cerium oxide film at room temperature[84] (Fig. 11). The first oxidised layer on titanium, magnesium, aluminium, and chromium becomes protective and prevents the formation of the bulk-phase oxide[84,293]. A kinetic study of the oxidation of iron[295] showed that the oxidation process proceeds in two stages—rapid oxidation with formation of four oxide layers, and a slow stage with formation of ten atomic oxide layers. Evidently studies in this field are extremely informative. Table 3 gives a brief compilation of the results of studies on the adsorption of other inorganic molecules: CO_2, NO_2, N_2, H_2O, and H_2.

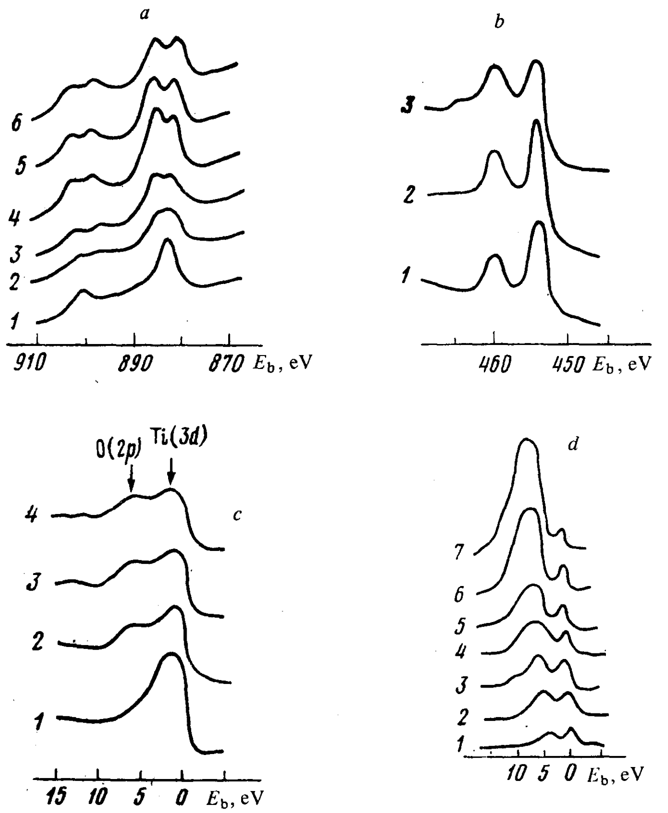

Figure 11. Adsorption of O_2 and surface oxidation of metals[84]: a) adsorption of O_2 on cerium, Ce(3d) lines [1) 0L; 2) 2L; 3) 10L; 4) 40L; 5) 100L; 6) 1000L]; b) adsorption of O_2 on titanium, Ti(2p) lines [1) 0L; 2) 1000L; 3) 3000L]; c) adsorption of O_2 on titanium, XPE spectra of the (Al $K\alpha$) valence band [1) 0L; 2) 300L; 3) 1000L; 4) 3000L]; d) adsorption of O_2 on titanium, UPE spectra, He(II) [1) 0L; 2) 1L; 3) 3L; 4) 10L; 5) 30L; 6) 100L; 7) 300L].

Until recently the number of PES studies dealing with the adsorption of hydrocarbons on metals was very limited. This was due to the experimental difficulties and the difficulties in the interpretation of the spectra. At the same time, this application of the method is of significant interest for organic catalysis. Studies which yielded extremely interesting data about the nature of the chemical bond between a number of hydrocarbons and metal surfaces have been carried out recently.

Table 3. Results of the study of the adsorption of certain inorganic molecules on metals.

Adsorbate	Adsorbent	Principal results	References
CO_2	Mo	the reaction CO_2 (gas) $\rightarrow CO_{ads} + O_{ads} \rightarrow C_{ads} + O_{ads}$ observed in the temperature range 77–298 K	240
CO_2	Au	monolayer and multilayer adsorption observed at 77 K	244
CO_2	Ni	reversible adsorption observed	262
CO_2	Pt	physical adsorption observed at 77 K	243,245
N_2	W	γ-state (weakly ads.) $\xrightarrow{300\ K}$ β-form (strongly ads.) transition observed	278
N_2	W (100)	two states of nitrogen observed	301,302
N_2	Ni	molecular adsorption found at 80 K	262,292
N_2	Fe (100)	two states of nitrogen found at 298 K	303,304
NO_2	Ni	molecular and dissociative adsorption found (77–400 K)	292,303 277
NO_2	Fe	dissociative adsorption observed at 298 K	292,303
N_2O	Ni	multilayer condensation with subsequent dissociation of N_2O observed at 80 K	
H_2O	Mo, Au	molecular and dissociative adsorption found	238,240
H_2O	Pt	molecular adsorption observed at 160 K	281
H_2O	Mg	formation of OH groups at 77 K followed by formation of MgO found	298
H_2O	Al, Cr, Mn	conditions for the formation of oxides and hydroxides investigated	298
H_2O	r.e.	the formation of oxides and hydroxides observed	299
H_2*	W	two adsorption states found on the (100) and (110) faces	302,305

---

*The adsorption of H_2 was also investigated on Ir(100)[268], Pd(110)[256], Ni(111)[306], Fe, Cu[266], and Ti[307].

One of the first studies dealt with the condensation and adsorption of ethylene, acetylene, and benzene on nickel [(111) face of a single crystal] and it was shown[31,308] that E_b and the intensity of the peak of the valence σ orbital depend on the type of hybridisation of carbon atoms and are consistent with LCAO-MO SCF calculations. Physical adsorption entails a relaxation shift of the σ and π orbitals relative to E_b in the gas phase. In chemisorption the energies of the π orbitals approach those of σ-orbitals, which indicates the formation of a πd-bond at right angles to the surface; there is no rehybridisation of the σ-bond. Data for C_2H_4/Ni have been used[309] to calculate the structure of the adsorption complex. It has been shown by the method of $X\alpha$-scattered waves that UPES data support the formation of a π-complex of ethylene adsorbed on two nickel atoms, the Ni–Ni bond being perpendicular to the plane of the molecule. It has been noted that UPES data do not make it possible to distinguish this structure from that of the σ-complex in which the Ni–Ni bond is parallel to the C_2H_4 plane. The latter complex may be intermediate in the catalytic process in view of the weaker C–C bond. We may note that the model proposed cannot be regarded as rigorously proved because of the assumptions made in calculations and in the separation of chemical and relaxation shifts.

In studies on the adsorption of ethylene and acetylene on copper and iron[266,310] no correlation was observed between the heats of adsorption and the shifts of the signals due to the π-levels. The importance of taking into account the interaction within the adsorption layer was pointed out in an investigation of the adsorption of ethylene on Pt (100), although it is not clear how this is reflected in the spectra[247]. Interesting results were obtained in a study of the interaction of ethylene and acetylene with the Ir(100) and α-Fe(100) surfaces by a combined method: LEED, UPES, and Auger spectroscopy[311,312]. According to the changes in the spectra, the formation of a πd-bond ("back-donation") is accompanied by perturbation of low-lying σ-orbitals, which are not directly involved in the bond. Such perturbation results in distortion (extension and twisting) of the bonds in the chemisorbed molecules, with subsequent bond dissociation and formation of fragments (Fig. 12). Depending on the reactivity of the metals and on the state of the surface (clean, carbon-coated, oxidised) the fragmentation process can occur at different temperatures. Thus, no distortion in the structure of the C_2H_2 molecule was observed on nickel and copper, on Ir(100) the acetylene molecule is stretched and twisted at 298 K[311], while on α-iron at 123 K it fragments with formation of CH_n (n = 1 or 2) radicals and possibly $CCH_2^{\cdot}$.[312] The bond distortion effect in C_2H_2 diminishes on passing from the clean to the carbon-coated surface and is scarcely observed on the oxidised surface[312]. C_2H_4 behaves significantly differently: on α-iron the molecule fragments with formation of $CH_2^{\cdot}$ (Fig. 12). This hypothesis is supported by data for the adsorption of H_2 on the carbon-coated surface of α-iron (Fig. 12); the spectra are close to the corresponding C_2H_4 spectra. In contrast to α-iron, on iridium and nickel at $T < 300$ K, ethylene undergoes preferential dehydrogenation with formation of acetylene[308,312] (Fig. 12). At a higher temperature (600° C) a spectral band characteristic of the σ-band of pyrolytic graphite arises in the Ni(100) spectrum, which indicates the cracking of C_2H_4.[313] The mechanism of the formation of carbon on the W(100) surface in the decomposition of butadiene at 1000 K has been investigated[301].

When halogenoalkenes interact with the Pt(100) and Pt(111) surfaces, both dissociative adsorption (vinyl fluoride and chloride), accompanied by the elimination of the halogen, and non-dissociative adsorption ($CH \equiv C-CF_3$, $CH_2=CH-CF_3$, CF_2CFCl) are observed[314,315]. The degree of dissociation of vinyl fluoride, determined from the ratio $I[F(1s)]/I[C(1/s)]$ depends on the crystal face index [80% for the (111) face and 40% for the (100) face] and is inhibited in the presence of CO on the surface. The adsorption and decomposition of methanol and formaldehyde on tungsten[316] and palladium[317] and of CH_3OCH_3, $(CH_3)CHO$ and $(CH_3)_2CO$ on palladium[317] were investigated. On tungsten, for coverages corresponding to saturation, methanol and formaldehyde form molecular complexes and at low coverages the β-CO state arises already in the early stages of adsorption[316]. At 120 K on palladium, the bond between the adsorption complex and the surface is formed via an atomic orbital of oxygen, which has a lone electron pair, while at 300 K the decomposition of the molecules begins and chemisorbed CO appears. The d-band of palladium is involved in the formation of the bond, which entails a decrease in the intensity of the spectrum on adsorption. Using the chemical shifts, an attempt was made to estimate the strength of the adsorbate–adsorbent interaction and E for the chemisorption bond within the framework of Mulliken's theory of donor–acceptor complexes[317]. Catalytic decomposition of HCOOH on copper, nickel, and gold, at 80–295 K leads to a change in the UPE spectra and a shift of the 1s level of O by 2 eV, which is associated with the formation of a formate ion[318]. With increase of temperature, the formate ion decomposes and the H_2 and CO_2 formed are desorbed into the gas phase. The activation energies found from these data are close to those obtained in the catalytic experiment. Comparison of the catalytic activities in the sequence Au < Fe < Ag < Ni < Cu < Pt in the decomposition of HCOOH and the densities of states in the vicinity of the Fermi level in these metals led to the conclusion that there is no correlation between the above quantities[37,318].

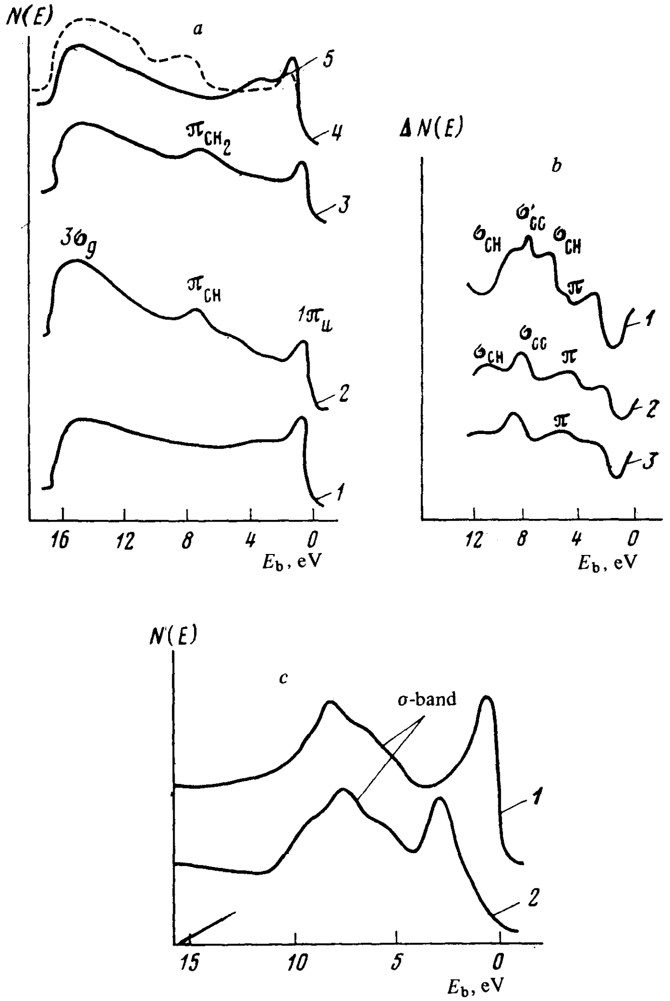

Figure 12. Adsorption of ethylene and acetylene on metals: *a*) C_2H_2, C_2H_4, and H_2 on α-Fe(100)[312], UPE spectra, He(I) [1) clean surface; 2) 123 K, C_2H_2 (6*L*); 3) 123 K, C_2H_4 (6*L*); 4) carbon-coated surface of α-Fe(100); 5) adsorption of H_2 on the carbon-coated surface of α-Fe(100)]; *b*) adsorption of C_2H_4 on nickel, differential He(I) spectra[308] [1) C_2H_4 1.2*L*, 100 K; 2) C_2H_4 1.2*L*, heating to 300 K; 3) C_2H_2 1.2*L* (100–300 K)]; *c*) high-temperature adsorption of C_2H_4 on Ni(110), He(II) UPE spectra[313] [1) C_2H_4, 780*L*, 873 K, $C_2H_4 \rightarrow 2H_2 + 2C$(graphite); 2) spectrum of pyrolytic graphite cleaved *in vacuo*] [*N*(*E*) is the intensity and Δ*N*(*E*) the differential intensity].

Of the other studies which have been made, we shall mention the investigation of the layer-by-layer condensation of CB_4 [246] and the chemisorption of C_2N_2 on platinum[319]. In the latter case interaction with transfer of a *d* electron of the metal to the unoccupied $2\pi^*$ orbital of the adsorbate was postulated. There are data for the adsorption of NH_3 on W(100),[320] of iodoaniline on gold[321], and of H_2S and SO_2 on nickel[259,282].

The spectra of C_2H_6, C_6H_6, CH_3OH, C_2H_5OH, H_2CO, H_2O, and NH_3 in the gaseous state and condensed at 77 K on MoS_2 [322] confirm the hypothesis that the relaxation shifts are equivalent in different systems. In general, the same conclusion may be arrived at by examining the physical adsorption of Xe on W(111)[274] and nickel[323], for which the spectra of the inner and valence levels exhibit identical shifts relative to the gas phase (1.1–1.3 eV for nickel). However, in a study of the excited HeI line in the spectrum of the 5*p* level of Xe on the (100) face of tungsten[324] a marked broadening of the signal due to the $5p_{3/2}$ sublevel was observed and interpreted as a consequence of the splitting of the $5p_{3/2}$ xenon sublevel under the influence of the crystal field. Thus even in physical adsorption the system of adsorbate levels may undergo non-identical perturbations.

(b) Catalytic reactions on metal surfaces. The methods for the measurement of XPE and UPE spectra make it possible to investigate surface reactions under two sets of conditions: (1) with the reaction mixture passed over the catalyst and scanning of the spectra. Since the pressure of the reactants is very low ($< 10^{-7}$ mmHg), coverages sufficient for the recording of the spectra (approximately 0.05 of a monolayer) cannot always be attained; (2) reactions in the adsorption layer; in this case it is possible to achieve a higher surface concentration of one of the components. Evidently the interactions of many adsorbates with the surface, leading to a chemical alteration of the adsorbate (for example, the decomposition of NO and CH_3OH, the dehydrogenation of C_2H_4, etc.) can be regarded as reactions in the adsorption layer. However, mainly qualitative data concerning the structures of the adsorption complexes were obtained in the studies quoted above. Furthermore, there have been investigations where the reaction kinetics were studied by PES, and definite conclusions about the reaction mechanisms were reached. This applies to the investigations of reactions of molecular hydrogen with molecular oxygen[281,325,326], of carbon monoxide with molecular oxygen[253,259,264,327,328], of carbon monoxide with molecular hydrogen and nitric oxide[256,329], and of hydrogen sulphide with molecular oxygen[265].

The first attempt to investigate the reaction of H_2 with $O_{2(ads)}$/Pt directly during the scanning of the XPE spectra was apparently made in Norton's study[281]. After the adsorption of oxygen at 120 K $\{E_b[O(1s)] = 530.2$ eV$\}$, a stream of H_2 (10^{-7} mmHg) was passed through the system and the specimen was subjected to linear heating. An O(1*s*) peak with $E_b = 533$ eV (evidently $H_2O_{(ads)}$) appeared at 140 K, indicating the onset of the reaction, which terminated at 150 K. The line with $E_b = 533$ eV disappeared at 170 K and water was desorbed. The kinetics of this reaction were studied and an equation describing the reduction of $O_{2(ads)}$ was derived. In contrast to this reaction, the oxidation of adsorbed H_2 was much slower, which was explained by the poisoning of the active centres by hydrogen. According to some results[325,326] the probability of the interaction of an H_2 molecule with an $O_{2(ads)}$ molecule, leading to reaction at $\theta = 0.5$ at room temperature on platinum, is approximately 0.7, which is ten times greater than the value found by Norton. The authors[325,326] believe that this discrepancy is caused by the inaccuracy of the measurement of pressure in Norton's study[281].

The adsorption of CO on the Ru(001) surface covered by oxygen entails a change in the O(1*s*) lines, indicating the joint adsorption of CO and O_2 and then a displacement of O_2 from the surface (15–20% of the initial coverage[257]). It is suggested that part of the CO reacts with O_2 even at low temperatures. The oxidation of CO on Ir(111) was studied directly during the recording of the spectra[328]. The results obtained with the aid of XPES show that the reaction proceeds via the Langmuir–Hinshelwood mechanism. According to data obtained with the aid of LEED, flash desorption, and UPE spectroscopy, the oxidation of carbon monoxide on Ir(111) can proceed via the Eley–Rideal mechanism[264].

The interaction of carbon monoxide with molecular hydrogen on the Ni(111) surface was studied at relatively low temperatures (< 400 K). According to LEED data, a (2×2) structure of the adsorbate is produced[323], although the interaction of CO with H_2 is still insignificant and does not lead to a change in the energy of the valence orbitals. At low coverages, H_2 is present in the β_1-state, passing to the β_2-state as the degree of coverage increases. The formation of reaction complexes on the surface and of the products in the gas phase was not observed under these conditions. The interaction of H_2S with O_2 adsorbed on lead is a typical instance of a surface reaction leading to a change in the state of the elements of the support[265]. The observed changes in the positions and intensities of the O(1*s*) and S(2*p*) lines constitute the basis for the hypothesis that the reaction $PbO_{surf} + H_2{}_{gas} \rightarrow PbS_{solid} + H_2O_{gas}$ takes place.

(c) Other adsorbents. The interaction of oxygen with the basal and prismatic faces of graphite was begun by Thomas and coworkers[330,331]. In the study of catalysts having semiconducting or insulating properties certain difficulties are encountered due to the charging of the surface, the possibility of a more ready modification of the properties of the surface under the influence of radiation compared with metals, etc. One can only mention one of the first attempts to study adsorption on clean catalyst surfaces. Almy et al.[332] obtained the spectra of partly dehydrated α-Al_2O_3 (0001) and of the surface after the adsorption of H_2O, excited with the aid of He(I) lines. The specimen was subjected to preliminary cleaning in O_2 and, according to Auger spectroscopic data, its surface was free from impurities. There is an appreciable difference between the spectra of the clean surface and the surface coated by H_2O. Calculation by the method of X_α-scattered waves agreed satisfactorily with the experimental spectrum. A cluster model was chosen, according to which H_2O molecules are strongly bound to the α-Al_2O_3 surface. The number of UPE studies on powdered non-conducting specimens has been extremely limited[118,156]. Studies by the XPES method, but not under "clean surface" conditions, were examined above.

---o0o---

The studies carried out hitherto demonstrate the high efficiency of the PES method in the study of catalytic and adsorption problems. The method makes it possible to obtain unique information about the structures of the surface layers of catalysts and about the nature of adsorption complexes. There is no doubt that, as the theory of the method is developed further and experimental technique is improved, the range of problems soluble by PES in this field will be extended. The wide-scale application of PES in the study of catalytic problems will assist in deepening our knowledge about the nature of the catalytic activity of solids.

Methods of Mathematical Treatment of the Results of Physicochemical Studies on Complex Compounds

E.S.Shcherbakova, I.P.Gol'dshtein, and E.N.Gur'yanova

The general principles of the determination of the equilibrium constants and the physicochemical parameters of complexes under the conditions of their dissociation are examined. The possibilities of approximate computational methods and direct analytical procedures for the solution of systems of the corresponding equations are analysed. Various methods involving the simultaneous determination of the equilibrium constants and physicochemical parameters of complexes, based on the statistical principle of maximum probability, are compared. The ways of the most rational employment of computer techniques in the study of involved complex-formation reactions by various physical methods are discussed.
The bibliography includes 226 references.

I. INTRODUCTION

The problem of coordination interaction has been attracting much attention by investigators working in different fields because this type of intermolecular interaction plays a major role in many physical, chemical, and biological phenomena. The range of energies of coordination interactions is extremely wide, starting with the formation of weak self-associated species in liquids and vapours and extending as far as the formation of fairly stable complexes (various molecular complexes, hydrogen-bonded complexes, complexes of ions with various ligands, etc.).

The advances made in recent years in the study of the nature of the coordinate bond and the characteristics of the formation and the properties of complex compounds have been to a large extent due not only to the employment of modern physical research methods but also to improvement of the mathematical procedures used in the interpretation of the experimental results[1-11]. Many physical research methods such as spectrophotometry, NMR, measurements of dipole moments, calorimetry, etc. require that the experiment be carried out in the liquid phase, in solution, or in the vapour phase, i.e. under conditions where there is a possibility of the dissociation of the complexes into the initial components. Any measured property of the solution or vapour is then an overall characteristic of the equilibrium mixture of the initial components and the complexes formed in the system. In order to determine particular parameters of the complexes, it is necessary to know the composition of the equilibrium mixture and hence the stability constants of the complexes. The latter can be determined in an individual experiment, for example, by measuring the colligative properties of the solutions, i.e. properties which depend only on the concentrations of the components of the equilibrium mixture and are independent of the physical characteristics of these molecules. However, even when the equilibrium constants for multistage complex-formation reactions are known, the calculation of equilibrium concentrations is an extremely complex task, since it requires the simultaneous solution of a system of non-linear equations corresponding to the Law of Mass Action and the material balance equations.

The development of a mathematical description of the chemistry of equilibrium processes leads to the possibility of determining the equilibrium constants and the physicochemical parameters of the complexes formed in a given experiment. Methods which permit the determination of the parameters of the complexes without isolating the latter in a pure state are of special interest. The formulation of the experiment under these conditions reduces to the measurement of a physicochemical property of the solution or vapour as a function of the overall concentration of the initial components, mixed in various molar proportions [titration and isomolar series (continuous variations) methods]. In the vast majority of cases the simultaneous determination of the physical parameters and stability constants of complexes in a single experiment is virtually impossible without the use of a computer.

Thus the realisation of the potential possibilities of even extremely informative and accurate physical methods, which require that the experiment be carried out in the liquid or gas phases, depends to a large extent on the reliability of the method of mathematical treatment of the results of the measurements.

The first studies on these lines were carried out towards the end of the 1940s and the beginning of the 1950s, i.e. at a time when computer technology had not developed sufficiently. Different versions of analytical and graphical extrapolations based on approximate equations were widely used. It is noteworthy that, in the analysis of data obtained by these methods, no account is frequently taken of the degree of approximation of the equations employed and attempts are actually made to solve approximate equations by means of a computer. Clearly such a procedure cannot be regarded as rational. Further development of computer technology led to a rigorous solution of the problem under consideration.

In this review an attempt is made to analyse the present state of methods for the mathematical treatment of the results of physicochemical studies of complex formation reactions, to demonstrate the advantages and disadvantages of many computational methods used, and to discover the most rational ways of employing computers for a rigorous solution of the problem of the simultaneous determination of the equilibrium constants and physical parameters of complexes.

II. GENERAL PRINCIPLES OF THE DETERMINATION OF THE PARAMETERS OF DISSOCIATING COMPLEXES

The methods for the treatment of the results of physicochemical experiments designed to determine the parameters of complexes are based on the following relations: (1) the equation relating the measured property of the solution to the parameters of the components of the equilibrium mixture and their concentrations; (2) the Law of Mass Action equation; (3) the material balance equation.

An experimentally measured physicochemical property of a system containing an equilibrium mixture of the initial components and the complexes formed is a function of the parameters of all the components of the mixture and their equilibrium concentrations. The measured property X can be represented by the following additive function with a degree of approximation which is adequate for many methods[12]:

$$X = X_z + L\left(x_A C_A + x_B C_B + \ldots + \sum_{i=1}^{n} x_i C_i\right), \qquad (II.1)$$

where x_A, x_B, ..., x_i are the parameters of the initial compounds A, B, ..., and the ith complex respectively, c_A, c_B, ..., c_i are their equilibrium molar concentrations, n is the number of complexes in the mixture, L is a constant whose magnitude and dimensions depend on the physical method used and the experimental conditions, and X_Z is the corresponding property of the medium (solvent).

For example, in spectrophotometry the measured property of the solution is the optical density D at a given wavelength λ. Eqn. (II.1) then assumes the form of Eqn. (II.2). In order to synthesise the formulation of this and subsequent equations, we shall assume that the system contains only two initial components A and B:

$$D = l\left(\varepsilon_A C_A + \varepsilon_B C_B + \sum_{i=1}^{n} \varepsilon_i C_i\right) + D_z, \qquad (II.2)$$

where l is the optical pathlength, ϵ_A, ϵ_B, and ϵ_i are the molar extinction coefficients of A, B, and the ith complex, and D_Z is the optical density of the solvent.

In the determination of the dipole moments of complexes by the Debye method the measured dielectric constants ϵ and the densities d of the solution may be represented by the following functions[12]:

$$\begin{aligned} \varepsilon &= \alpha_A C_A + \alpha_B C_B + \sum_{i=1}^{n} \alpha_i C_i + \varepsilon_z, \\ d &= \gamma_A C_A + \gamma_B C_B + \sum_{i=1}^{n} \gamma_i C_i + d_z, \end{aligned} \qquad (II.3)$$

where α_A, α_B, α_i and γ_A, γ_B, and γ_i are parameters linked to the dipole moments of the corresponding molecules by the expressions

$$P_{i,\infty} = \frac{\varepsilon_S - 1}{\varepsilon_S + 1} \cdot \frac{1}{d_S}\left(M_i - 1000\gamma_i + \frac{3000}{(\varepsilon_S + 2)^2}\alpha_i\right)$$

$$\mu_i = 0.01283\sqrt{(P_{i,\infty} - P_A - P_E)\,T} \quad .$$

Here $P_{i,\infty}$ is the molar polarisation of the substance at infinite dilution, P_A, and P_E are the atomic and electronic polarisations (it is usually assumed that $P_A + P_E = R_i$, R_i being the molar refraction of the substance for the sodium D line), and T is the absolute temperature.

In high-resolution NMR spectroscopy (under the conditions of rapid exchange) one usually measures the chemical shift of the averaged signal δ, whose position depends on the contributions of all the components of the equilibrium mixture containing the resonating nucleus. If the molecules of A and B incorporate respectively y and z atoms with the resonating nucleus, then Eqn. (II.1) becomes[13,14]

$$\delta = \frac{1}{yC_{A_0} + zC_{B_0}}\left(y\delta_A C_A + z\delta_B C_B + \sum_{i=1}^{n} \delta_i C_i\right), \qquad (II.4)$$

where δ_A, δ_B, and δ_i are the chemical shifts of the signals due to the nuclei in the corresponding molecules.

In calorimetric measurements the amount of heat Q evolved as a result of the complex formation reaction is related to the enthalpies of formation ΔH_i of the complexes from the components as follows[6-10]:

$$Q = v\sum_{i=1}^{n} \Delta H_i C_i, \qquad (II.5)$$

where v is the volume of the solution (litres). It is readily seen that Eqn. (II.5) is also a special case of Eqn. (II.1) in which $x_A = x_B = 0$, $x_i = \Delta H_i$, $L = v$, and $X_Z = 0$.

The quantities x_A, x_B, and some of the x_i may be zero not only in calorimetric measurements but also in studies by other physicochemical methods. For example, in spectrophotometry zero values are assumed by the parameters of those substances which have no absorption bands in the experimental frequency range; in NMR spectroscopy the characteristics of the molecules without resonating nuclei are zero.

Methods based on the measurement of colligative properties of the system are used frequently to determine the equilibrium constants. These properties are independent of the physical parameters of the molecules present in the equilibrium mixture, which makes it possible to assume that $x_A = x_B = x_i = \ldots = x_n = 1$. In this case Eqn. (II.1) becomes

$$X = L\left(C_A + C_B + \sum_{i=1}^{n} C_i\right) + X_z. \qquad (II.6)$$

This simplified form of the general equation (II.1) may be used to interpret data obtained by cryoscopic, ebullioscopic, tensimetric, gas–liquid chromatographic, etc. methods.

The concentrations of the components of the equilibrium mixture are related to the equilibrium constants of the complex formation reactions by the Law of Mass Action equations. Assuming that the test solutions or the gas mixture are ideal (the activity or fugacity coefficients are unity), the equilibrium constant of the reaction

$$pA + qB \overset{K}{\rightleftarrows} A_pB_q, \qquad (II.7)$$

can be formulated in the following form:

$$K = [A_pB_q]/[A]^p \cdot [B]^q \, . \qquad (II.8)$$

If the assumption of ideality is invalid, the concentrations in Eqn. (II.8) must be replaced by the activities. K depends on the way in which the concentration is expressed. At concentrations expressed on the molar scale, Eqn. (II.8) becomes

$$K=\frac{C_{A_pB_q}}{(C_A)^p\,(C_B)^q}\quad\text{or}\quad C_{A_pB_q}=K\,(C_A)^p\,(C_B)^q\,. \tag{II.9}$$

The complex A_pB_q with $p > 1$ and(or) $q > 1$ is as a rule formed in stages. The equilibrium mixture can then contain complexes having different compositions. Furthermore if the initial molecules A and B show a tendency towards self-association, then the mixture may contain also associated species of the type A_m and B_n.[9] The stepwise formation of the complex AB_n can be represented schematically thus:

$$\begin{gathered}A+B\overset{K_1}{\rightleftarrows}AB,\ C_1=K_1C_AC_B;\\ AB+B\overset{K_2}{\rightleftarrows}AB_2,\ C_2=K_2C_1C_B=K_1K_2C_AC_B^2;\\ \cdots\cdots\cdots\cdots\cdots\cdots\\ AB_{n-1}+B\overset{K_n}{\rightleftarrows}AB_n,\ C_n=K_nC_{n-1}C_B=K_1K_2\,\ldots\,K_nC_AC_B^n.\end{gathered} \tag{II.10}$$

The mechanism of the same reaction can be formulated as follows:

$$\begin{gathered}A+B\overset{\beta_1}{\rightleftarrows}AB,\ C_1=\beta_1C_AC_B;\\ A+2B\overset{\beta_2}{\rightleftarrows}AB_2,\ C_2=\beta_2C_AC_B^2;\\ \cdots\cdots\cdots\cdots\\ A+nB\overset{\beta_n}{\rightleftarrows}AB_n\ C_n=\beta_nC_AC_B^n\ .\end{gathered} \tag{II.11}$$

Thus we have for the stepwise formation of complexes AB_i

$$c_i=K_iC_{i-1}C_B=K_1K_2\,\ldots\,K_ic_Ac_B^i=\beta_i\,c_A\,c_B^i, \tag{II.12}$$

where $\beta_i=\prod_{l=1}^{i}K_l$ is the overall stability constant of the complex AB_i.

The mechanism of the involved reaction whereby the complex A_mB_n is formed can be formulated, for example, as follows when account is taken of the self-association of component A:

$$\begin{gathered}A+A\overset{K_1}{\rightleftarrows}A_2,\ C_1=K_1C_A^2;\\ A+B\overset{K_2}{\rightleftarrows}AB,\ C_2=K_2C_AC_B;\\ AB+A\overset{K_3}{\rightleftarrows}A_2B,\ C_3=K_3C_AC_2=K_2K_3C_A^2C_B;\\ AB+B\overset{K_4}{\rightleftarrows}AB_2,\ C_4=K_4C_2C_B=K_2K_4C_AC_B^2;\\ AB_2+A\overset{K_5}{\rightleftarrows}A_2B_2,\ C_5=K_5C_4C_B=K_2K_4K_5C_A^2C_B^2;\\ A_2B_2+B\overset{K_6}{\rightleftarrows}A_2B_3,\quad C_6=K_{65}C_5C_B=K_2K_4K_5K_6C_A^2C_B^3.\\ \cdots\cdots\cdots\cdots\cdots\cdots\end{gathered}$$

In the general case the equilibrium concentration of the complex formed in the ith stage of any involved reaction is a function of the equilibrium constant of the ith and preceding reaction stages and the equilibrium concentrations of the corresponding complexes in the mixture:

$$C_i=f_i\,(C_A,\ C_B,\ \ldots,\ C_1,\ \ldots,\ C_{i-1},\ K_i)=\varphi_i\,(C_A,\ C_B,\ \ldots,\ K_1,\ \ldots,\ K_i). \tag{II.13}$$

The form of the functions f_i and φ_i depends on the stoichiometry of the reaction investigated.

The most general and convenient method of representing the mechanisms of involved chemical reactions is based on their formulation with the aid of numerical matrices of stoichiometric coefficients. The most general method of such formulation has been proposed by Temkin[15] and Aris[16]. The equation for the ith stage of the reaction

$$pA+qB+\ldots\rightleftarrows p'E+q'D+\ldots$$

can be formulated in the following way by transferring all the terms to the left-hand side:

$$\sum_{l=1}^{m+s}\alpha_{il}A_l=0,\ i=1,2,\ \ldots,\ n,$$

where m is the number of reaction products, s the number of reactants, n the number of stages, and α_{il} the stoichiometric coefficient of the component A_l in the ith reaction stage, which can be any integer (positive, negative, or zero).

The stoichiometric mechanism of an n-stage reaction is a matrix of integers:

$$\|\alpha_{il}\|;\ i=1,\ \ldots,\ n;\ l=1,\ \ldots,\ m+s. \tag{II.14}$$

The number of columns in this matrix is equal to the number of all the substances involved in the reaction and the number of rows is equal to the number of reaction stages. If any of the reaction components does not participate in the ith stage, the corresponding element in the ith row of the matrix (II.14) is assumed equal to zero. A matrix of type (II.14) is used in the interpretation of data on the kinetics of involved chemical reactions[17-19].

An abbreviated version of the matrix (II.14) rather than the matrix itself is usually employed for complex formation reactions. If each reaction stage is formulated in terms of the dissociation of the complex into its components:

$$A_{p_i}B_{q_i}D_{r_i}\ \ldots\ \overset{\beta_i}{\rightleftarrows}p_iA+q_iB+r_iD+\ \ldots,$$

then part of the matrix (II.14), which is made up of the stoichiometric coefficients of the complexes, will always be an $n\times n$ unit matrix. Tobias and coworkers[20] and Sillén and coworkers[21-23] do not write out this unit matrix and formulate the reaction scheme solely in terms of the matrix of the stoichiometric coefficients of the initial components A, B, D, ...:

$$\|p_iq_ir_i\ \ldots\ \|=\|p_{il}\|\ i=1,\ \ldots,\ n;\ l=1,\ \ldots,\ s. \tag{II.15}$$

A matrix of type (II.15) has been widely used in calculations of the equilibria of involved complex-formation reactions in two-component[24-29] and multicomponent[30-42] systems.

The matrix (II.15) makes it possible to formulate the equation of the Law of Mass Action in a general form[20-23]:

$$c_i=\beta_i\,(C_A)^{p_i}(C_B)^{q_i}(C_D)^{r_i}\ \ldots\ . \tag{II.16}$$

We may note that the formulation of stoichiometric schemes for involved complex-formation reactions in terms of matrices of type (II.15) makes it possible to calculate only the overall equilibrium constants β_1, β_2, ..., β_n corresponding to, for example, scheme (II.10). Another method of the matrix formulation of a stoichiometric scheme for a multistage reaction has been proposed[13,43]. It permits the determination of both the overall equilibrium constants and the constants for each stage. It is assumed that each reaction stage involves the formation of a single complex from two reactants:

$$m_{i1}D_{m_{i2}}+m_{i3}D_{m_{i4}}\overset{K_i}{\rightleftarrows}m_{i5}D\,m_{i6}, \tag{II.17}$$

where m_{i1}, m_{i3}, and m_{i5} are the stoichiometric coefficients of the ith reaction, m_{i2}, m_{i4}, and m_{i6} are the numbers of substances D participating in the given stage, which may be the components A, B, ... and the complexes formed in preceding stages. The substances are numbered as follows: the numbers 1, 2, ..., s are assigned to the initial components A, B, ... and the numbers $i+s$ are assigned to the complexes formed in the ith stage. The scheme for an ***n***-stage reaction is formulated by means of a matrix of the following form:

$$M = \| m_{i1} m_{i2} m_{i3} m_{i4} m_{i5} m_{i6} \|,\ i = 1,\ \dots,\ n, \qquad \text{(II.18)}$$

where the number of rows is equal to the number of reaction stages and the number of columns is six.

The equation of the Law of Mass Action can be written in the following form using the elements of the matrix (II.18):

$$C_i = C_{m_{i6}} = [K_i (C_{m_{i2}})^{m_{i1}} (Cm_{i4})^{m_{i3}}]^{1/m_{i5}}, \qquad \text{(II.19)}$$

where C_{mi_2}, C_{mi_4}, and C_{mi_6} are the equilibrium concentrations of the corresponding substances.

It is noteworthy that, when matrices of types (II.15) and (II.18) are used, a stoichiometric reaction scheme can be usefully set up in such a way that the complex of the given composition is formed solely in one reaction stage. This makes it possible to obtain a system of independent Law of Mass Action equations[15-19].

For a complex formation reaction with participation of s initial components A, B, ..., one can formulate s material balance equations with respect to each component separately:

$$\begin{aligned} C_{A_0} &= C_A + \sum_{i=1}^{n} p_i C_i, \\ C_{B_0} &= C_B + \sum_{i=1}^{n} q_i C_i\ , \end{aligned} \qquad \text{(II.20)}$$

where C_{A_0} and C_{B_0} are the overall concentrations of substances A, B, ... Equations for the calculation of p_i and q_i from the matrix (II.18) have been published[13,43].

Simultaneous solution of Eqns. (II.1), (II.13), and (II.20) permits the simultaneous calculation of the stability constants K_1, ..., K_n of the complexes formed and the required parameters x_1, ..., x_n.

If the reaction investigated has n stages and s initial components are involved in the interaction, then one can write $n + s + 1$ equations for each jth experiment and the total number of equations for N experiments is $N(n + s + 1)$. The unknowns which must be determined using the above system of equations are as follows: C_A, C_B, ...; C_1, ..., C_n; K_1, ..., K_n; x_1, ..., x_n. The total number of unknowns is $(n + s)N + 2n$. By comparing the number of equations with the number of unknowns, it is easy to determine the minimum number of experiments N necessary to solve the problem formulated:

$$N \geqslant 2n. \qquad \text{(II.21)}$$

Thus even the study of complex-formation reactions with not unduly complicated stoichiometric ($n \geqslant 2$) necessitates the solution of a system of non-linear equations with a fairly large number of unknowns.

There exist various approaches to the solution of the problem of the determination of the parameters of the complexes from the results of a physicochemical experiment. In terms of mathematical procedures, they can be divided into three groups.

1. Approximate methods involving linear graphical extrapolation or a simplified analytical calculation.
2. Methods based on the exact solution of the system of equations.
3. Methods involving the search for the parameters on the basis of the statistical principle of maximum probability.

These methods of calculation will be discussed below.

Any physicochemical method permitting the determination of equilibrium constants over a temperature range can be used to determine the thermodynamic parameters of the complex formation process: $\Delta G°$, $\Delta H°$, and $\Delta S°$. The free energy $\Delta G°$, enthalpy $\Delta H°$, and entropy $\Delta S°$ of a given reaction under standard conditions are related to the equilibrium constants K as follows:

$$\Delta G^0 = -RT \ln K = \Delta H^0 - T\Delta S^0. \qquad \text{(II.22)}$$

$\Delta H°$ and $\Delta S°$ are usually calculated from the relation between $\ln K$ and $1/T$ as the linear coefficients of Eqn. (II.22) written in the following form[2,5,6,44,45]:

$$\ln K = -\Delta H^0/RT + \Delta S^0/R. \qquad \text{(II.23)}$$

In principle it is not obligatory to calculate initially the equilibrium constants for each given temperature and then evaluate $\Delta H°$ and $\Delta S°$ from Eqn. (II.23).[46] As suggested by the present authors[47], $\Delta H°$ and $\Delta S°$ may be adopted as the required parameters and Eqns. (II.1), (II.13), (II.20), and (III.23) may be solved simultaneously.

In order to determine the enthalpies and entropies of formation of complexes from the temperature variation of the equilibrium constants, one usually begins with the hypothesis that $\Delta H°$ and $\Delta S°$ are independent of temperature. This assumption is more or less valid when $\Delta H°$ and $\Delta S°$ are determined from data obtained over a comparatively narrow temperature range and close to standard conditions[48]. However, in studies over a wide temperature range, where the heat capacity of the system may change significantly, one must take into account the possible temperature dependence of $\Delta H°$ and $\Delta S°$.[49-51] This applies particularly to tensimetric measurements, which are carried out, as a rule, at a high temperature (200° to 600°C) over a range of the order of 100-200 K.[51-53] The values of ΔH°_{T} and ΔS°_{T} obtained from such measurements are difficult to adjust to standard conditions owing to the lack of data for the heat capacities of the complexes.

III. APPROXIMATE METHODS FOR THE CALCULATION OF THE PARAMETERS OF COMPLEXES BASED ON A LINEAR GRAPHICAL EXTRAPOLATION

In order to simplify the solution of the system of non-linear equations (II.1), (II.13), and (II.20), one frequently uses particular approximations or limitations are imposed on the experimental conditions. This makes it possible to convert the equations into a form convenient for the graphical determination of the required parameters.

For a single-stage complex-formation reaction, where only one complex A_pB_q is formed in solution [Eqn. (II.7)], the equilibrium concentration C_C and the stability constant of the latter can be expressed[1,6] in the following form on the basis of Eqns. (II.1), (II.9), and (II.20):

$$C_c = \Delta X/\Delta x, \qquad \text{(III.1)}$$

where

$$\Delta X = X - X_z - L(x_A C_{A_0} + x_B C_{B_0}) \text{ and } \Delta x = L(x_c - p x_A - q x_B).$$

The above symbols (ΔX and Δx) will be used also in subsequent equations.

$$K = C_c/(C_{A_0} - pC_c)^p (C_{B_0} - qC_c)^q. \qquad \text{(III.2)}$$

For 1 : 1 complexes ($p = q = 1$), the following expression may be obtained on the basis of Eqns. (III.1) and (III.2):[6]

$$\frac{1}{K} = \frac{C_{A_0}C_{B_0}}{\Delta X}\Delta x - (C_{A_0} + C_{B_0}) + \frac{\Delta X}{\Delta x}. \qquad \text{(III.3)}$$

For highly dissociated complexes, where $C_C = \Delta X/\Delta x \ll (C_{A_0} + C_{B_0})$, the last term in Eqn. (III.3) may be neglected, which yields

$$\frac{1}{K} = \frac{C_{A_0}C_{B_0}}{\Delta X}\Delta x - (C_{A_0} + C_{B_0}). \qquad \text{(III.4)}$$

After certain rearrangements, it is easy to obtain the following relations from the simplified Eqn. (III.4):[6]

$$C_{A_0}C_{B_0}/\Delta X = (C_{A_0} + C_{B_0})/\Delta x + 1/K\Delta x, \qquad \text{(III.5)}$$

$$C_{A_0}C_{B_0}/\Delta X (C_{A_0} + C_{B_0}) = 1/K\Delta x (C_{A_0} + C_{B_0}) + 1/\Delta x. \qquad \text{(III.6)}$$

Equations of type (III.5) and (III.6) are used widely for the graphical determination of the parameters of highly dissociated molecular complexes[1,2,5,6,54-81]. According to Eqn. (III.5), based on experimental data, the plot of $C_{A_0}C_{B_0}/\Delta x$ against $(C_{A_0} + C_{B_0})$ should be a straight line whose slope is $1/\Delta x$ and the intercept on the ordinate axis is $1/K\Delta x$ (Fig. 1). Hence it is possible to obtain the values of K and Δx and to calculate $x_C = \Delta x/L + x_A + x_B$ for known values of x_A and x_B [see Eqn. (III.1)] with $p = q = 1$. The same parameters may be obtained when the experimental data are represented by a plot of $C_{A_0}C_{B_0}/\Delta X(C_{A_0} + C_{B_0})$ against $1/(C_{A_0} + C_{B_0})$. According to Eqn. (III.6), the plot should be a straight line which makes an intercept on the ordinate axis equal to $1/\Delta x$ and has a slope equal to $1/K\Delta x$.

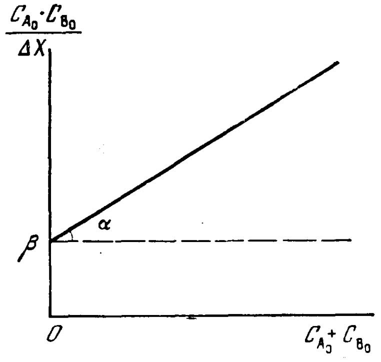

Figure 1. Determination of the parameters x_C and K from a linear plot corresponding to Eqn. (III.5); $\tan\alpha = 1/\Delta x_C$; $\beta = 1/K\Delta x_C$.

This method for the simultaneous determination of the stability contants and the physical parameters of 1 : 1 complexes was proposed for the first time by Benesi and Hildebrand[54] for the interpretation of spectrophotometric data. Apart from the condition $C_C \ll (C_{A_0} + C_{B_0})$, a further two conditions are imposed on the formulation of the experiment: firstly, there must be a large excess of one of the components, i.e. $C_{A_0} + C_{B_0} \simeq C_{B_0}$ and, secondly, the experiment must be carried out at a wavelength where only the complex absorbs. Under these conditions, one can obtain the following expression from Eqns. (III.4), (III.1), and (III.5):

$$C_{A_0}l/D = 1/K\varepsilon_C C_{B_0} + 1/\varepsilon_C. \qquad \text{(III.7)}$$

Under the same conditions, Eqns. (III.6) readily yield Scott's equation[55]:

$$C_{B_0}C_{A_0}l/D = C_{B_0}/\varepsilon_C + 1/K\varepsilon_C. \qquad \text{(III.8)}$$

Subject to the condition C_{A_0} = const., Foster and coworkers[5,56] obtain the equation

$$D/C_{B_0} = -KD + KC_{A_0}\varepsilon_C. \qquad \text{(III.9}$$

from the Benesi–Hildebrand equation. According to Eqn. (III.9), K and ϵ_C may be determined from a linear plot of D/C_{B_0} against D, whose slope is $-K$ and whose intercept on the ordinate axis is $KC_{A_0}\epsilon_C$.

Together with its various modifications, the Benesi–Hildebrand method has been used widely in the interpretation of not only spectrophotometric data[5,6,54-72] but also of results obtained by other physical methods: NMR[5,6,72-79] calorimetry[5,6,8,9], dielectric measurements[6,8], etc.

Graphical methods for the simultaneous determination of K and x_C, based on equations of type (III.5)–(III.9), suffer from significant disadvantages, which have been widely discussed in the literature[5,6,8,9,58-73,81]. These are primarily the restriction of their application solely to systems where one 1 : 1 complex AB is formed, i.e. where $p = q = 1$. With increase of p and q, the degree of Eqn. (III.2) increases, which makes it virtually impossible to convert it into a form permitting the construction of linear plots.

Furthermore, the use of equations of type (III.5)–(III.9) yields satisfactory results only subject to the condition $C_C \ll (C_{A_0} + C_{B_0})$. However, in order to test the validity of this condition, it is necessary to know at least the order of magnitude of K; such information is as a rule lacking in the study of new types of complexes. Significant errors in the determination of K and x_C may arise owing to the possible formation in the test system of complexes having compositions other than 1 : 1.

Certain methods of improving the accuracy of the required parameters of the complexes A and B when the use of Eqns. (III.5)–(III.9) leads to large errors for one reason or another have been proposed in a number of studies[82,83]; sometimes attempts were made to employ a computer in order to introduce appropriate corrections[84-86]. For example, in a study of fairly stable 1 : 1 complexes, Tamres and coworkers[82] suggested the use of linear regression models and an iterative procedure in order to refine with the aid of a computer the parameters K and x_C obtained from approximate relations. Such ways of developing computational methods involving the use of approximate equations with subsequent refinement of the parameters obtained are apparently irrational. If the approximations adopted do not satisfy the experimental conditions, it is necessary to employ more rigorous computational methods.

In order to determine the compositions and parameters of complexes A_pB_q which are relatively little dissociated in solution [reaction (II.7)], graphical extrapolation of linear sections of curves obtained by the molar ratios (titration) or continuous variations (isomolar series[1,2,6,]

[12,87,88]) methods is used widely. One then begins with the assumption that the linear sections of $X - C_{B_0}/C_{A_0}$ titration curves (with C_{A_0} = const.; see Fig. 2) or $X-C$ isomolar series curves, where $C = C_{A_0}/(C_{A_0} + C_{B_0})$ (with C = const.; see Fig. 3), correspond to complete binding, i.e. a complete displacement of equilibrium (II.7). This eliminates the necessity for the employment of the non-linear Law of Mass Action equation (II.9) in order to estimate the equilibrium concentrations of the mixture components, which are related solely by the material balance equations (II.20). The composition of the complex and its parameter x_C can be found by extrapolating the linear sections of the experimental curve on the basis of the so-called point of "equivalence"[6] (see Figs. 2 and 3). Knowing x_C it is possible to calculate by Eqns. (II.1) and (III.2) the equilibrium constant for the given reaction from data referring to the part of the experimental curve where the complex dissociates into components (sections KL in Figs. 2 and 3).

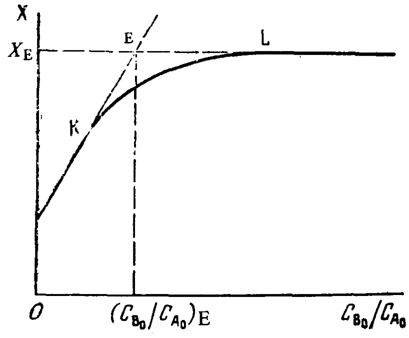

Figure 2. Determination of the composition and parameters of complexes A_pB_q by the titration method. At the equivalence point E we have $(C_{A_0}/C_{B_0})_E = p/q$ and $x_C = (X_E - X_z)p/L(C_{A_0})_E = (X_E - X_z)q/L(C_{B_0})_E$. Along the section KL of the experimental curve, the complex dissociates into components.

A common disadvantage of the method based on linear graphical extrapolation is the absence of a reliable criterion which would make it possible to infer that the condition of the formation in the system of only one complex, which has been adopted in this procedure, does indeed hold. The linearity of sections of the curve, frequently adopted as evidence for the validity of the assumptions made, cannot be regarded as a sufficiently reliable criterion, because, owing to the scatter of experimental points on the graphs, one cannot always detect the curvature which might be a sign of the formation of more than one complex in the system[6,84,85].

If several complexes having different compositions are formed simultaneously in the system, the problem of the determination of their parameters becaomes extremely more complex. The conversion of the computational equations into a form suitable for linear graphical extrapolation or calculation by hand then requires even more drastic approximations than those quoted above for single-stage reactions. In the interpretation of the results of the study of multistage complex-formation reactions it is frequently assumed that, under particular experimental conditions, the solution or vapour contains mainly only one of the complexes formed[1,2,6,12,89-99]. However, this hypothesis can be valid only in relation to complexes with limiting compositions, i.e. complexes containing the maximum or minimum number of the molecules of A and B. The latter is sometimes achieved in the presence of a large excess of the corresponding initial component.

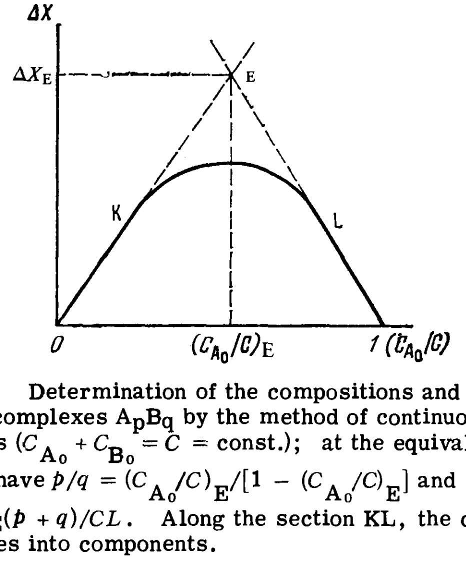

Figure 3. Determination of the compositions and parameters of complexes A_pB_q by the method of continuous variations ($C_{A_0} + C_{B_0} = C$ = const.); at the equivalence point we have $p/q = (C_{A_0}/C)_E/[1 - (C_{A_0}/C)_E]$ and $x_C = \Delta X_E(p + q)/CL$. Along the section KL, the complex dissociates into components.

The available approximate methods for the interpretation of the results of the study of multistage complex-formation reactions are as a rule extremely cumbersome and insufficiently reliable[1,2,6,12,89-95]. We believe that the use of a computer in order to simplify and refine approximate methods of calculation[90,91,98,99] is undesirable, because computer technology permits a rigorous solution of the problems under consideration.

IV. METHODS FOR THE DIRECT SOLUTION OF THE SYSTEM OF EQUATIONS RELATING THE PARAMETERS OF COMPLEXES TO EXPERIMENTAL DATA

Owing to the approximations adopted in the derivation of the corresponding equations, the linear graphical extrapolation methods discussed in the previous section are applicable solely in the study of either comparatively weak or extremely strong complexes. The interpretation of the results of the physicochemical study of complexes of the most common type, i.e. with moderate stabilities, requires the use of more rigorous computational methods.

For single-stage complex-formation reactions, methods for the solution of the system of four equations, comprising Eqns. (II.1), (II.9) and two equations (II.20) without the introduction of any approximations, have been examined[100–118]. Simultaneous solution of these four equations eliminates the equilibrium concentrations of mixture components, which depend on the experimental conditions (c_A, c_B, c_C), and yields only one equation [Eqn. (IV.1)], which contains two unknowns (x_C and K) and the experimental data (X, C_{A_0}, and C_{B_0}):

$$K=\frac{\Delta X/\Delta x}{(C_{A_0}-p\Delta X/\Delta x)^p\,(C_{B_0}-\Delta X/\Delta x)^q}\,. \qquad \text{(IV.1)}$$

In principle, the solution of two equations (IV.1) for two experimental points makes it possible to find the parameters x_C and K.[100] However, the possible experimental errors necessitate the determination of the parameters x_C and K on the basis of data referring to a number of experimental points significantly larger than two. It is necessary to solve a system of non-linear equations (IV.1) for all the pairs of experimental points[100–105]. This method of solution is extremely cumbersome and in practice is possible only with the aid of a computer[100,102]. For the simplest case with $p = q = 1$, methods have been proposed[106–116] for the determination of the parameters x_C and K which replace the procedure involving the solution of a system of non-linear equations (IV.1). Having specified an arbitrary set of values of one of the parameters to be determined, the second parameter is determined from experimental data. Eqns. (IV.1) are then written in a form convenient for the calculation of one parameter from the specified values of the other:

$$K=\frac{\Delta X/\Delta x}{(C_{A_0}\Delta x-\Delta X)\,(C_{B_0}\Delta x-\Delta X)}\,, \qquad \text{(IV.2)}$$

$$x_K=x_A+x_B+\frac{\Delta X}{2L}/(R-\sqrt{R^2-4C_{A_0}C_{B_0}}), \qquad \text{(IV.3)}$$

where $R = C_{A_0} + C_{B_0} + 1/K$.

The solution of the problem is found by studying the relation $K = f(x_C)$ or $x_C = f'(K)$, or $K = \varphi(C_{A_0}, c_{B_0})$, or $x_C = \varphi'(C_{A_0}, C_{B_0})$. Bearing in mind that the system must have a unique solution for x_C and K, these parameters can be found graphically from the coordinates of the points of intersection of the lines of the $K = f(x_C)$ or $x_C = f'(K)$ series, plotted for each experimental point[106].

Since the equilibrium constants and the physical parameters of the complexes are independent of the experimental conditions, K and x_C may be found by varying arbitrarily one of the parameters until a value is obtained for which the second parameter remains constant regardless of the initial concentrations C_{A_0} and C_{B_0}.[114–116] The last pair of values of x_C and K is a solution of the problem.

Olofson and coworkers[117,118] proposed a method for the solution of Eqn. (IV.1) with $p = q = 1$ on a computer. Eqn. (IV.1) is written as follows:

$$\frac{C_{A_0}C_{B_0}}{\Delta X}\,\Delta x-(C_{A_0}+C_{B_0}+1/K)+\frac{\Delta X}{\Delta x}=\varphi_j=0. \qquad \text{(IV.4)}$$

Values of x_C and K for which the functions φ_j become zero are solutions of Eqn. (IV.4). Owing to experimental errors, the required parameters are found from the pair of values of x_C and K corresponding to the minimum in the function $\sum_{j=1}^{N}|\varphi_j|$, where j and N are the ordinal number of the experiment and the total number of experiments respectively. For complexes A_pB_q with compositions more complex than 1 : 1, the use of such procedures in order to solve equations of type (IV.4) involves considerable difficulties owing to the increasing degree of Eqn. (IV.1).

A method has been proposed[119] for the solution of Eqns. (IV.1) for complexes A_pB_q with any values of p and q by means of the following equation:

$$x_C=px_A+qx_B+\frac{\Delta X}{2LC_{A_0}}\,\frac{a\pm\sqrt{a^2-4bC_{A_0}\Delta X'\,(q\Delta X-C_{B_0}\Delta X')}}{q\Delta X-C_{B_0}\Delta X}\,, \qquad \text{(IV.5)}$$

$$\text{where } a=[p(p-1)C_{B_0}+q(q-1)C_{A_0}]\,\Delta X'+pq\Delta X,$$
$$b=pq(p+q+1),\ \Delta X'=(\partial X/\partial C_{B_0})_{C_{A_0}}-x_BL.$$

Eqn. (IV.5) was obtained by differentiating Eqn. (IV.1) with respect to C_{B_0} subject to the condition $(\partial K/\partial C_{B_0})_{C_{A_0}=\text{const.}}=0$. The derivative $(\partial X/\partial C_{B_0})_{C_{A_0}}$ in Eqn. (IV.5) may be found from the experimental dependence of X on C_{B_0} by any of the known methods for the determination of a derivative with respect to a specified function. Knowing x_C, it is easy to calculate K from Eqn. (IV.1). Such calculations may be performed also by hand, but this requires a considerable amount of time. A program has been devised[43] for calculations by Eqn. (IV.5) on a Minsk-22 (or Minsk-32) computer. The derivatives $(\partial X/\partial C_{B_0})_{C_{A_0}}$ are then calculated by fitting a second-degree polynomial to sections of the experimental $X - C_{B_0}$ curve[43,120]. The use of a computer greatly reduces the time required for calculation.

In the general case of an n-stage complex-formation reaction, the number of equations is $n + 3$: one equation (II.1), n equations (II.9), and two equations (II.20). When the equilibrium concentrations of the mixture components (C_A, C_B, ..., C_1, ..., C_n) are eliminated by the simultaneous solution of these equations, then in principle it is possible to obtain one equation relating the parameters of the complexes x_1, ..., x_n, K_1, ..., K_n to be determined to the experimental X, C_{A_0}, C_{B_0} data. Simultaneous solution of the system of equations for $2n$ experiments makes it possible to find all $2n$ unknowns.

However, with increase of the number of reaction stages and of the complexity of the composition of the complexes formed, there is an increase not only of the number of equations to be solved simultaneously but also of their degree. As a result of this, the rearrangements associated with the elimination of equilibrium concentrations from Eqns. (II.1), (II.9), and (II.20) become much more laborious. Even in the simplest case involving the simultaneous formation of only two complexes, having 1 : 1 and 1 : 2 compositions, the solution of a system of not less than four cubic equations is necessary[100,124,125]. There are no literature data concerning the use of such procedures for the interpretation of the results of studies on complex-formation reactions involving more than three stages[100,121–125].

Thus the procedure involving the direct solution of a system of non-linear equations, particularly in the study of multistage complex-formation reactions (even with the aid of a computer), appears to be relatively unsuitable, primarily because of its extremely cumbersome nature. For a rigorous determination of the parameters of the complexes from physicochemical experimental data, it is apparently more rational to employ computational methods based on the statistical principle of maximum probability.

V. METHODS OF CALCULATION BASED ON THE STATISTICAL PRINCIPLE OF MAXIMUM PROBABILITY

Methods of computer calculations based on the principle of maximum probability[126] consist in seeking a set of parameters x_1, ..., x_n, K_1, ..., K_n to be determined which gives the best description of the experimental data, i.e. the dependence of the measured property of the solution (or vapour) X on the initial concentrations C_{A_0}, C_{B_0}, ... In essence, all these methods reduce to seeking a minimum in the function reflecting the deviation of the experimental quantities X_{exp} from the values X_{calc} calculated by Eqns. (II.1), (II.13), and (II.20) using arbitrarily specified and varied values of the required parameters[127]. The principle of least squares, which is most widely used in such calculations, yields fairly reliable results[12–14,20–47,128–203].

Methods of calculation in accordance with the principle of least squares involve the seeking of a minimum in the function

$$F=\sum_{j=1}^{N}(X_{\text{exp}\,j}-X_{\text{calc}\,j})^2. \tag{V.1}$$

The calculation of the quantity F [Eqn. (V.1)] from the specified set of parameters $x_1, \ldots, x_n, K_1, \ldots, K_n$ consists of three stages.

1. Starting with the specified equilibrium constants $K_1, \ldots, K_n$ and the experimental values of C_{A_0j} and C_{B_0j}, one calculates the equilibrium concentrations of all the mixture components $C_A, C_B, \ldots, C_1, \ldots, C_n$ by the simultaneous solution of the system of non-linear Law of Mass Action equations (II.13), (II.15), or (II.19) and the material balance equations (II.20).
2. Using the values of $C_A, C_B, \ldots, C_1, \ldots, C_n$ obtained and the specified set of physical parameters of the complexes $x_1, \ldots, x_n$, the values of $x_{\text{calc}\,j}$ are calculated from the linear equations (II.2)–(II.6) or (II.1).
3. Having determined the $X_{\text{calc}\,j}$ for all the N experiments and using the corresponding values of $X_{\text{exp}\,j}$, one calculates F by Eqn. (V.1).

By varying the arbitrarily specified set of parameters $x_1, \ldots, x_n, K_1, \ldots, K_n$, one finds a minimum in the function F. As a first approximation, one can use parameters obtained with the aid of approximate methods of calculation. The set to which corresponds a minimum in F is regarded as a probable set of parameters $x_1, \ldots, x_n, K_1, \ldots, K_n$ to be determined.

In order to find the minimum in the function F of $2n$ variables, various methods for seeking an extremum in a function are used[17,204–212]. In particular, in the study of single-stage processes, the simplest method of "trial and error" is sometimes employed[141,142,177,179,195]. The method of successive sorting of variables and the method of "descents along coordinates" are frequently used[147,157,174–176,189]. At the same time, various types of iterative procedures are widely employed to seek the minimum in the function F: gradient methods[33–36,134], Newton's method and its versions (the Newton–Raphson method[14,21–25,37–39] and the Gauss–Newton method[20,27,30–32,40,152,160]), and the Davidson–Fletcher–Powell (DFP) method[41,165].

The function F [Eqn. (V.1)] is "pit-like"[210–212], i.e. near the minimum it is represented by an extended narrow "pit". For this reason, in seeking the minimum in F one frequently employs special so-called "pit mapping" methods[13,43,47,156]. The possibilities and disadvantages of various methods used in seeking the minimum in F are compared in the Table.

The derivatives $\partial F/\partial x_i$ and $\partial F/\partial K_i$ required in the search for the minimum in F are usually calculated by the approximate finite difference method[17,204]. A method involving a rigorous analytical calculation of these derivatives with the aid of Jacobi matrices has been proposed[13,43]. The minimum in F may be sought both with respect to all $2n$ variables[155–157,161,176,195] and with respect to n variables $K_1, \ldots, K_n$.[12–14,22,25,141,147,165–170,185,189]

The fact that the parameters $x_1, \ldots, x_n$ enter into Eqns. (II.1)–(II.6) as coefficients of the equilibrium concentrations of the complexes $c_1, \ldots, c_n$ makes it possible to reduce the number of variables with respect to which the search is made from $2n$ to n. This leads to the possibility of calculating, by the method of least squares which is applicable to linear equations[213], the parameters $x_1, \ldots, x_n$ giving the best description of the experimental data for a specified set of $K_1, \ldots, K_n$.[10,13]

Comparison of the methods for seeking the minimum in F.

No.	Method	Advantages of method	Disadvantages of method
1	Construction of networks of schematic maps (tabulation)	Method is complete and accurate	Requires much computer time
2	Newton–Raphson method	Method requires little computer time	Method does not distinguish saddle points and minima. The quadratic approximation method can be both positively and negatively defined. The region of convergence is small
3	Gauss–Newton method	Method locates only minima. The quadratic approximation matrix is always positively defined. The region of convergence is larger than in method 2	Method requires more computer time than method 2.
4	Davidon–Fletcher–Powell (DFP) method	Method locates only minima. The region of convergence is larger than in methods 2 and 3	Method requires approximately 25% more computer time than method 2. Its computation algorithm is more complex
5	"Pit mapping" method	Method locates only minima. The region of convergence is larger and the "ravine" direction is better defined than in methods 2, 3, and 4. The method requires a smaller amount of computer memory	Method requires more computer time. Near the minimum its execution is slower than that of methods 2, 3, and 4

The required parameters $x_1, \ldots, x_n$ and $K_1, \ldots, K_n$ may differ significantly in magnitude, which complicates the search for the minimum in F and frequently requires a special scaling procedure, which is extremely difficult for the K_i.[129–131] In addition, in seeking $F_{\min}$ some of the values of $K_1, \ldots, K_n$ may fall within the region of negative values, which has no physical significance and this also complicates the search for $F_{\min}$ and requires the use of a special computational algorithm[129,130]. The use of the $\ln K_i$ instead of the K_i as the mapping variables makes it possible to overcome these difficulties[10,12,13,20,23].

In the calculation of the equilibrium concentrations $C_A, C_B, \ldots, C_1, \ldots, C_n$ from the specified $K_1, \ldots, K_n$ the system of equations consisting of n non-linear Law of Mass Action equations and s material balance equations (see Section II) is reduced by simultaneous solution to s equations with s unknown $C_A, C_B, \ldots$ On solving the resulting system of s non-linear equations by one or other iterative procedure[214–216], the values of $C_A, C_B, \ldots$ are found; Newton–Raphson procedure, which is fastest, is most frequently employed for this purpose[22,27,43,215]. It has been suggested in a number of studies[12,22,43] that a satisfactory initial approximation to C_A, C_B, ... required for the iterative method be calculated on a computer for each *j*th experiment by means of special algorithms. On the basis of the values of C_A, C_B, ... obtained, the equilibrium concentrations of the complexes C_1, C_2, ..., C_n are calculated with the aid of the Law of Mass Action equations. The algorithms proposed in the literature for the calculation of equilibrium concentrations are frequently based on the employment of Law of Mass Action equations (II.13) in which the functions f_i or φ_i assume different forms depending on the stoichiometry of each stage of the given reaction. This approach requires the development of individual programs for different types of complex-formation reactions [141-146,153-155,161,173-190,202].

A unique program, applicable to any involved complex-formation reaction, can be devised by resorting to the matrix formulation of the reaction stoichiometry and correspondingly to the Law of Mass Action equations expressed in form (II.15) [14,20-42,156,165,166] or (II.18). [13,43,47,168-170,191,194]

Complexes are studied by various physical methods, so that procedures for the interpretation of experimental results in terms of the principle of least squares and on the basis of specific equations of type (II.2)–(II.6), applicable only to each specific physical method separately, have been developed extensively. Methods have been described for the interpretation of the results of calorimetric [25,28,33,38,161-173], spectrophotometric [22,141-160],

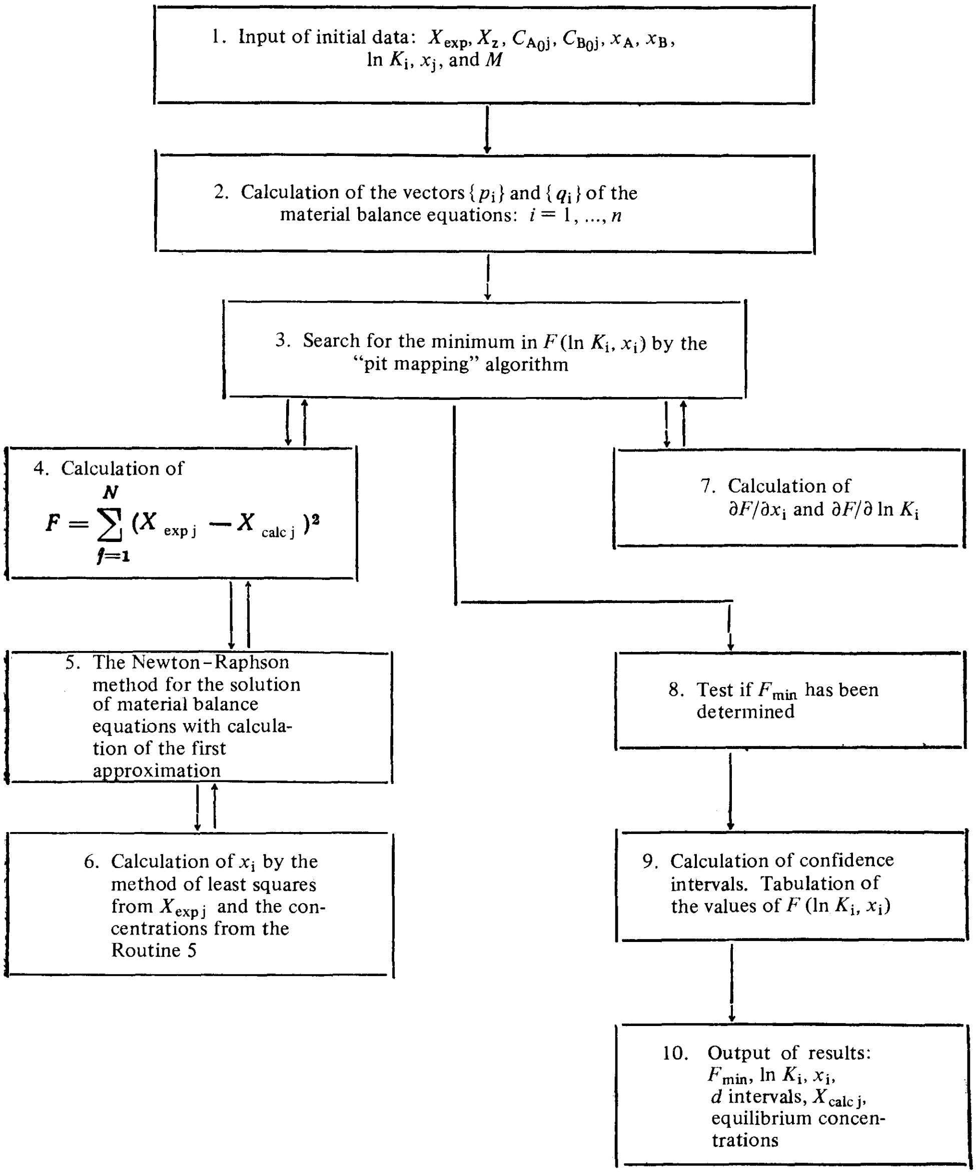

Figure 4. Flow diagram of the computer program for the calculation of the parameters of complexes.

NMR,[14,174-191] dielectric constant[12,192-196], potentiometric[20-23,26-36,39-42,128-140], tensimetric[197-201], and cryoscopic[24,202] measurements. Thus, when several methods are used, a whole library of programs is required. It appears more rational to develop general programs applicable to any research technique.

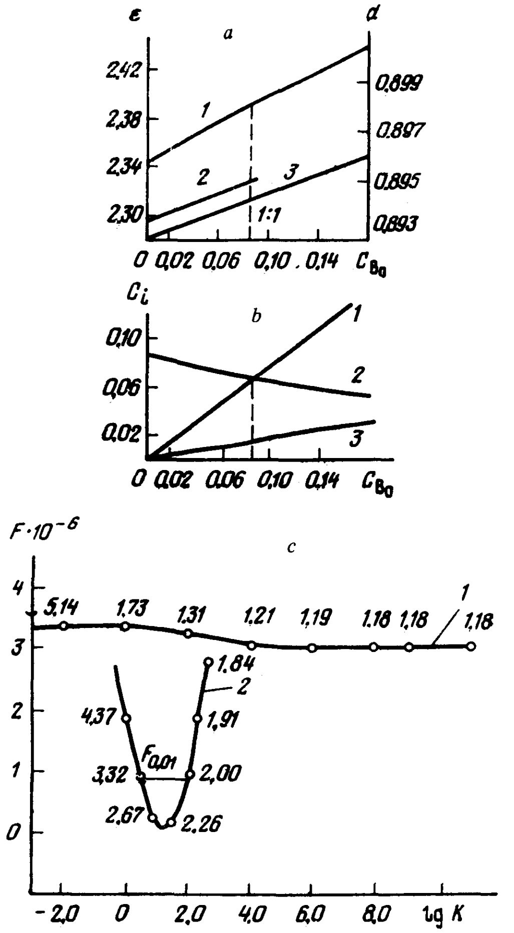

Figure 5. *a*) Experimental $\epsilon - C_{B_0}$ (curves *1* and *2*) and $d - C_{B_0}$ (curve *3*) plots; $B = (C_6H_5)_2S$ [C_{A_0}: 1) and 3) 0.085; 2) 0.028]; *b*) equilibrium concentration distribution diagram [1) $(C_6H_5)_2S$; 2) $TeCl_4$; 3) $TeCl_4.(C_6H_6)_2S$; $C_{A_0} = 0.085$]; *c*) $F = \ln K$ tabulation graphs for a dielectric constant study of the reaction $TeCl_4 + (C_6H_5)_2S \overset{K}{\rightleftharpoons} TeCl_4.(C_6H_5)_2S$ in benzene [C_{A_0}: 1) 0.028; 2) 0.085]; $\ln K = 1.25 \pm 0.75$; $\alpha = 2.4 \pm 0.4$; the numerals opposite the points in the figure represent the values of α; $F_{0.01}$ is the F level for $p = 0.01$.

Such a program, consisting of individual routines, each of which can be used when necessary and can be supplemented by other routines, was proposed for the first time by Sillén and Ingri[22-25,129-131]. A more general and convenient program has been proposed by the present authors[13,43]. The program is based on the general functional relation (II.1), which, as shown above (Section II), is applicable with adequate approximation to the majority of physical methods which are most informative and most widely used in the study of complexes.

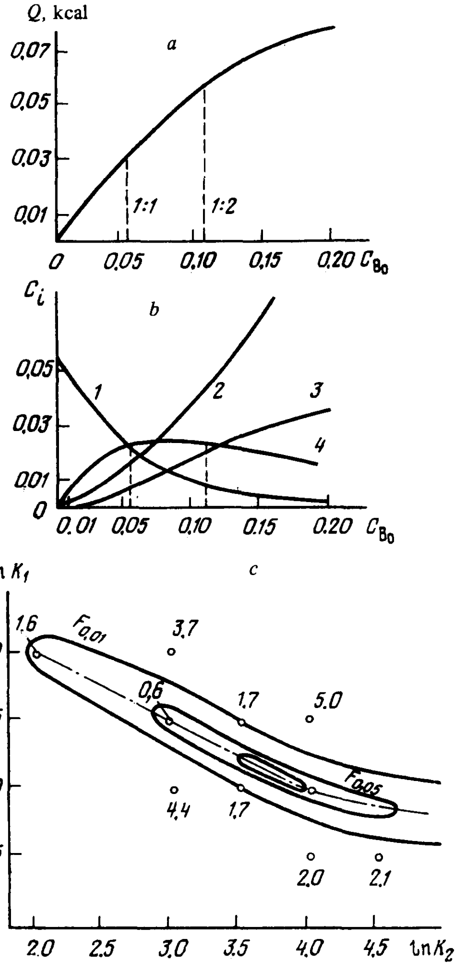

Figure 6. *a*) Experimental $Q - C_{B_0}$ curve; B = $(iso\text{-}C_4H_9)_2SO_2$; *b*) equilibrium concentration distribution diagram ($C_{A_0} = 0.055$) [1) $SnCl_4$; 2) $(iso\text{-}C_4H_9)_2SO_2$; 3) $SnCl_4.2(iso\text{-}C_4H_9)_2SO_2$; 4) $SnCl_4.(iso\text{-}C_4H_9)_2SO_2$; *c*) 10^{-6} F tabulation plot in the $\ln K_1 - \ln K_2$ plane for a calorimetric study of the reactions $SnCl_4 + (iso\text{-}C_4H_9)_2SO_2 \overset{K_1}{\rightleftharpoons} SnCl_4.(iso\text{-}C_4H_9)_2.SO_2$ and $SnCl_4.(iso\text{-}C_4H_9)_2SO_2 + (iso\text{-}C_4H_9)_2SO_2 \overset{K_2}{\rightleftharpoons} SnCl_4.2(iso\text{-}C_4H_9)_2SO_2$ in benzene; F_p are the F levels for $p = 0.01$ and 0.05.

A general computational algorithm was developed on the basis of the general equation for the measured property [Eqn. (II.1)], the matrix formulation of the stoichiometric reaction scheme [Eqn. (II.18)], and the "pit mapping" procedure for seeking the minimum in the function F.

It makes it possible to employ a single program in order to interpret the results of studies on various types of complex-formation reactions by ultraviolet and NMR spectroscopic methods, dielectric measurements, and calorimetric, cryoscopic, and any other methods for which the measured property obeys the rule of additivity of contributions. A brief flow diagram of the program is illustrated in Fig. 4. Together with the parameters $x_1, \ldots, x_n, K_1, \ldots, K_n$ to be determined, the program generates the minimum in F ($F_{\min}$), the values of X_{calc}, and the equilibrium concentrations of the components corresponding to all the points on the experimental curve. The values of $C_A, C_B, \ldots, C_1, \ldots, C_n$ at each point on the experimental $X = f(C_{A_0}, C_{B_0})$ curve can be used to plot diagrams illustrating the distribution of the equilibrium concentrations (Figs. 5*b*, 6*e*, and 7*b*). The values of $X_{\text{calc}\,j}$ make it possible to compare clearly (graphically) the experimental results with the calculation (Figs. 5*a*, 6*a*, and 7*a*). $F_{\min}$ is used to estimate the reliability of the results obtained.

The determination of the parameters $x_1, \ldots, x_n, K_1, \ldots, K_n$ by seeking the minimum in F is not the final stage of the calculation. A necessary condition for the solution of problems on the basis of the statistical principle of maximum probability is the estimation of the reliability of the results. This is particularly important when the functions X are non-linear [Eqn. (II.1)] and when F [Eqn. (V.1)] can have several minima and only one of these must correspond to a unique solution of the problem. Various procedures have been described in the literature[13,33,43,129,161,164] for describing the reliability of the parameters of the complexes obtained. It has been suggested[13,43] that the Fischer statistic be used:

$$\sigma^2/\sigma^2_{\exp} \leqslant F_{\nu_1,\nu_2,p}, \qquad (V.2)$$

where σ and $\sigma_{\exp}$ are the variances of the calculation and the experiment respectively, ν_1 and ν_2 are the numbers of degrees of freedom in the numerator and denominator of Eqn. (V.2), and p is the level of significance of the statistic. This statistic is fairly well founded only for linear problems[126,217-220], but, owing to the lack of other statistics, it is usually employed also for non-linear relations.

The quantity σ may be calculated from $F_{\min}$:

$$\sigma^2 = F_{\min}/(N - 2n). \qquad (V.3)$$

On the basis of Eqns. (V.2) and (V.3), we obtain the condition for the reliability of the results:

$$F_{\min} \leqslant F_{\nu_1,\nu_2,p}\sigma^2_{\exp}(N - 2n),$$

or

$$\tau = F_{\min}/[F_{\nu_1,\nu_2,p}\sigma^2_{\exp}(N - 2n)] \leqslant 1. \qquad (V.4)$$

The validity of condition (V.4) shows that the proposed stoichiometric reaction scheme and the parameters $x_1, \ldots, x_n, K_1, \ldots, K_n$ obtained correspond to the true values with a probability close to $1 - p$, where p is the chosen level of significance (usually $p = 0.01$, 0.05, and 0.5). When the reaction stoichiometry has been incorrectly formulated, the condition (V.4) is not as a rule fulfilled[43,47,168-170,194,221]. Thus the above criterion of reliability can be used to establish the stoichiometry of the reaction investigated.

The confidence limits serve as an indication of accuracy. The determination of confidence limits for $x_1, \ldots, x_n$ and $K_1, \ldots, K_n$ is a fairly complex task. In a number of studies[27,33,36,129,155-157,163] the confidence limits are determined using the information matrix[126,217-220], which is constructed on the basis of the quadratic approximation to the function F at the minimum.

A more rigorous procedure for estimating the confidence limits for the parameters to be determined involves the construction of confidence regions using the Fischer statistics[13,43]. The confidence region (*d* region) is made up of all the sets of parameters satisfying the condition

$$F(x_1, \ldots, x_n, K_1, \ldots, K_n) \leqslant F_{\nu_1,\nu_2,p}\sigma^2_{\exp}(N - 2n). \qquad (V.5)$$

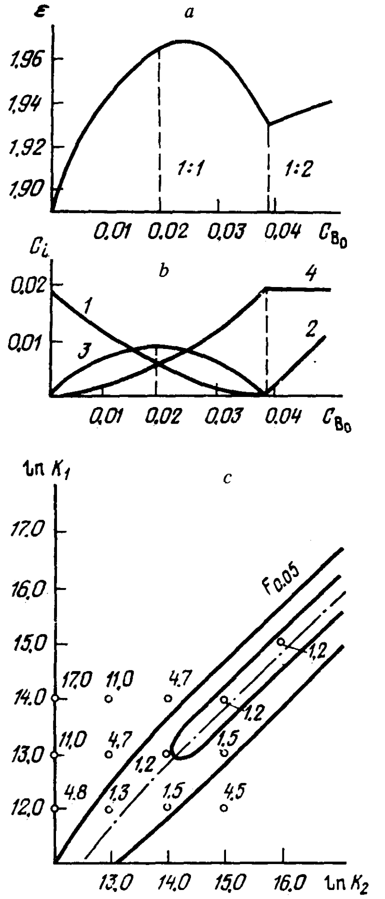

Figure 7. *a*) Experimental $\epsilon - C_{B_0}$ curve; $B = (C_4H_9)_3PO$; *b*) equilibrium concentration distribution diagram (C_{A_0} = 0.019) [1) $SnCl_4$; 2) $(C_4H_9)_3PO$; 3) $SnCl_4.(C_4H_9)_3PO$; 4) $SnCl_4.2(C_4H_9)_3PO$]; *c*) 10^{-5} F tabulation graph in the $\ln K_1 - \ln K_2$ plane for a dielectric constant study of the reactions $SnCl_4 + (C_4H_9)_3PO \overset{K_1}{\rightleftharpoons} SnCl_4.(C_4H_9)_3PO$ and $SnCl_4.(C_4H_9)_3PO_4 + (C_4H_9)_3PO \overset{K_2}{\rightleftharpoons} SnCl_4.2(C_4H_9)_3.PO$ in hexane; $F_{0.05}$ is the F level for $p = 0.05$.

The true values of the parameters are located with a probability $\sim(1 - p)$ within the limits of this region. The standard deviations for the parameters found (the set corresponding to $F_{\min}$) are obtained from the largest and smallest values of each of the required parameters in the *d* region.

d regions can be constructed by a tabulation procedure, i.e. one involving the calculation of F for a series of values of the required parameters varying within the specified region in specified steps. For $n \leq 2$, it is possible to construct tabulation graphs (Figs. 5*c*, 6*c*, and 7*c*) and find the confidence regions by plotting lines corresponding to constant values of F for each of the selected levels of significance. The same procedure can be used to investigate the behaviour of the functions F in the particular region of variation of the mapping variables[13,43,221]. It is noteworthy that the dimensions of the confidence regions and correspondingly of the confidence limits for the parameters obtained are greater the less sensitive the function F to changes in the mapping variables[43,221-225]. The sensitivity of F to mapping variables depends on the amount of information yielded by the experiment[43,225] and, in particular, on the choice of the initial concentrations C_{A_0} and C_{B_0} (see, for example, Fig. 5*c*, curves I and II, and Figs. 6*c* and 7*c*).

Thus the reliability of the results depends both on the reliability of the method of calculation and on the correct formulation of the experiment. Mathematical experimental design methods[223-226] make it possible, in principle, to select the optimum conditions for the experiment. In problems of the determination of the stoichiometric scheme and of the physicochemical parameters of complexes, a successive design is most suitable. It can be achieved in two ways: (1) design for refining the values of the required parameters for a known stoichiometry; (2) design for refining and selecting stoichiometric reaction schemes[224]. It is noteworthy that in problems of the type under consideration mathematical experimental design has not yet found sufficiently extensive applications[224,226].

In the study of two-component systems mathematical treatment of the first series of titration curves and analysis of equilibrium concentration distribution diagrams as a rule make it possible to select the concentration conditions for yet another one or two series of experiments and to obtain fairly reliable results by treating all the experimental data together[43,169,170,221,225].

An effective criterion of the reliability of the physicochemical parameters determined is a satisfactory agreement between the stoichiometric schemes for complex-formation reactions and equilibrium constants for individual stages obtained in the mathematical treatment of the results of studies of the same reactions by several physical methods[6,13,43,155,169,170].

In conclusion it must be emphasised that the development of methods for the mathematical and statistical treatment of experimental results greatly extends the scope of physicochemical studies of complex-formation reactions. In particular the study of multistage reactions and multicomponent systems became possible only after the development of the corresponding computational methods.
