Kinetic Models in Heterogeneous Catalysis

S.L.Kiperman

The role and importance of chemical kinetics in heterogeneous catalysis at the present stage of development are examined and the concept of kinetic models, in the exact, reliable, complete, and well-founded form, as well as the usefulness of combined kinetic investigations for the determination of these models are discussed. The effectiveness of combining different methods for devising informative models of this kind, examples of which are quoted, is demonstrated. The problems involved in setting up non-steady-state kinetic models, which are some of the most important in chemical kinetics, are briefly described. The optimum characteristics of kinetic models and the relation between the properties of the latter and the characteristics of reaction selectivities are analysed. The kinetic aspects of tests of the activities and selectivities of catalysts of complex reactions are mentioned in conclusion.

The bibliography includes 202 references.

I. INTRODUCTION

The principal trend in theoretical research into heterogeneous catalysis is the determination of a relation between the properties of the surface layer of catalysts and the characteristics of the processes which they accelerate. Progress in this direction requires a profound understanding of the time course of catalytic processes, which determines the status of chemical kinetics in heterogeneous catalysis and gives rise to the idea of its "kinetic foundation".

Although the creation of such foundation was begun by the early investigations of Langmuir, Hinshelwood, and Schwab, the role and importance of the kinetics of heterogeneous catalytic reactions became evident only comparatively recently, this being promoted by the factors listed below:

(1) The spread of accurate kinetic experimental techniques[1-3], which make it possible to obtain reliable data without the distorting influence of factors which were previously not taken into account.

(2) The development of a theory of complex reactions[4-6] whereby one can approach an understanding of the kinetics without undue simplifications.

(3) The extension of the theory of macrokinetics to permit the estimation of transport parameters in the course of reactions and the inclusion of real process conditions[7,8].

(4) The employment of computer techniques and the increase in the scope of the mathematical analysis of kinetics and kinetic problems[9-11]. The operation of these factors clearly established the role of chemical kinetics as a science and the possibility of its theoretical employment to establish one of the necessary procedures for the elucidation of the mechanisms of catalytic reactions as well as its practical employment in one of the stages of the incorporation of the technology of catalytic processes in industry and its improvement. Table 1 gives a brief compilation of processes for which reactors have been simulated in recent years and the optimum conditions analysed on the basis of kinetic data[12-40]. In Boudart's review[41], a greater importance is already attributed to the practical aspects of the employment of kinetics than to its theoretical aspects. However, both aspects of the problem are so closely interrelated and inseparable that preference should not be given to either.

Table 1. Examples of processes for which modelling and optimisation have been carried out using kinetic data.

The central task of kinetics in heterogeneous catalysis at the present stage is the creation of kinetic models of various catalytic processes and a comparison and generalisation of these models. This task is particularly urgent in the light of the fact that further development of catalysis at the present time can apparently involve primarily the elucidation and accumulation of special and general relations rather than the creation of new universal theories.

On the basis of the foregoing, we shall consider the problem of kinetic models in heterogeneous catalysis and the extent to which it can be described by these models. Ways for the effective creation of kinetic models and certain problems associated with the properties of the models and the characteristics of catalytic processes will be discussed.

II. CHARACTERISTICS OF KINETIC MODELS

A quantitative characteristic of a process in the form of a mathematical description of its velocities (in the presence of a given catalyst) in the different directions realised under specified conditions, based on multistage mechanisms reflecting the general characteristics of the reaction, and carrying the necessary information about the catalyst and about significant non-steady-state changes as a function of different factors, will be regarded as a kinetic model. Multistage mechanisms (proved or hypothetical) indicate the sequence and stoichiometry of the transformations of the intermediate compounds. The availability of data for the ratios of the rates of the stages under the conditions investigated permit simplifications in the complete mathematical description of the rate of the process. In considering a kinetic model, we can speak of its form, implying by this a mathematical description of the rate of the process and the factors influencing it (including factors causing a change in the activity of the catalyst) and of the content of the model, i.e. the characteristic features which give rise to the given form.

Such traetment of the concept of the kinetic model differs significantly from the concept of reaction mechanism—the comprehensive qualitative characteristic of its internal features in the presence of the given catalyst under the specified conditions, reflecting the nature of the intermediate species produced at the elementary stages as well as their coupling. In the kinetic model, the principal factor is tested and detailed information about the changes in the rate of the process, while in the concept of reaction mechanism the main factor is detailed information about the nature, properties, and interconversions of the intermediates. The simplest step in the change of the chemical state of the system, involving the overcoming of not more than one energy barrier corresponding to the formation and decomposition of a single activated complex, must be regarded as an elementary stage.

In its broad sense, the kinetic model serves as a most important process characteristic, which may be tabulated for a given catalyst under specified conditions. The model must therefore be exact, reliable, complete, and well-founded. The accuracy of the kinetic model is determined primarily by the accuracy of the experimental methods used to establish it. Gradient-free methods[1-3], which make it possible to obtain accurate kinetic data under steady-state conditions, are nowadays generally accepted for this purpose. They can be supplemented by non-steady-state methods for the elucidation of the influence of the reaction system on the catalyst, the characteristics of its activation, and the changes in the activity and behaviour of the catalyst under non-steady-state conditions[42,43]. The reliability of the model depends not only on the experiment but also on its treatment and interpretation, taking into account all the factors influencing the kinetics, and

Table 2. The ambiguity of certain kinetic equations and process mechanisms.

Reaction	Kinetic equation	Multistage mechanism	Remarks
Hydrochlorination of acetylene on $HgCl_2$ (Ref.53)	$r = k \frac{P_{C_2H_2} P_{HCl}}{1 + k'P_{C_2H_2} + k''P_{HCl}}$ $r = k \frac{1 + k' (1 + k'' P_{HCl}) P_{C_2H_2} P_{HCl}}{(1 + k_1 P_{HCl}) (1 + \frac{k_2 P_{C_2H_2}}{1 + k_3 P_{HCl}} + k_4 P_{HCl})}$	—	Both equations describe kinetic data equally well
Hydrogenation reaction $A + H_2 = AH_2$ (Ref.54)	$r = k P_A^{1-m} P_{H_2}$	I. 1) $A = A_{ads}$; 2) $A_{ads} + H_2 = AH_2$(slow) II. 1) $H_2 = 2H_{ads}$; 2) $2H_{ads} + A = AH_2$(slow) III. 1) $A + H_2 + [K] = A[K] \cdot H_2$ (slow) 2) $A[K] \cdot H_2 = AH_2 + [K]$	All three mechanisms lead to the same kinetic equation
Conversion of methane by water vapour (Ref.55)	$r = k \frac{P_{CH_4} P_{H_2O} \gamma}{P_{H_2O} + k_1 P_{H_2} + k_2 P_{H_2}^2 + k_3 P_{H_2}^3}$ (γ = correction for effect of reverse reaction)	"Oxidative mechanism" 1) $CH_4 = CH_{2ads} + H_2$ 2) $CH_{22ads} + H_2O = CHOH_{ads} + H_2$ 3) $CHOH_{ads} = CO_{ads} + H_2$ 4) $CO_{ads} = CO$ "Dehydrogenation mechanism" 1) $CH_4 = CH_{2ads} + H_2$ 2) $CH_{2ads} = C_{ads} + H_2$ 3) $C_{ads} + H_2O = CO_{ads} + H_2$ 4) $CO_{ads} = CO$	The same kinetic equation corresponds to both mechanisms

on the choice of the most adequate and unambiguous mathematical description of the process. Numerous methods involving the use of computers and experimental design have been developed for this purpose[10,11,44-51]. The completeness of the model depends on the width of the range of variation of the process conditions under which it is investigated and on the allowance for all possible pathways contributing to the observed features. Secondary pathways are frequently significant under these conditions (even when their contribution to the overall rate of the process is slight; see, for example, Spivak et al.[52]); also important is allowance for non-steady-state transitions (including those due to changes in the catalyst activity), the influence of the reaction mixture on the composition of the surface layer, the blocking of the surface by coke or other substances, etc. Depending on the purpose of the models, their completeness may be various. Finally, in order to prove the validity of kinetic models it is desirable that other physicochemical methods as well as kinetic methods should be used in devising them. This is because the application of kinetic experimental techniques and kinetic computational procedures alone can frequently lead to ambiguous models, examples of which are illustrated in Table 2. The examples[53-55] show that kinetic data, even those obtained by exact methods over a wide range of variation of conditions, can be described equally well by different fairly complex equations. On the other hand, various mechanisms and hence various multistage schemes can correspond to the same simple or complex kinetic equation.

Although numerous new physical methods, which can be used successfully (although still insufficiently) in catalysis for the elucidation of the nature of the intermediate species (see, for example, McCarroll[56]) have become available in recent years, the results obtained with their aid but without kinetic justification can also prove to be ambiguous. An example is provided by the decomposition of formic acid. The conclusion had been reached previously on the basis of infrared spectroscopic and adsorption studies[57,58] that the dehydrogenation of formic acid in the presence of nickel proceeds via the formation and slow decomposition of a surface formate. In a later study[59] it was shown (by combining the same measurements with kinetic data) that the rate of reaction decreases with increasing concentration of the surface formate. This introduces significant corrections to the earlier mechanism (the reaction proceeds on the part of the surface which is not blocked by the formate, apparently via the formation and decomposition of carboxylate complexes).

Conclusions reached solely on the basis of kinetic studies, even as regards the slow stage of the process, can be equally unreliable. Thus a study of the kinetics of the hydrogenation of cyclohexene in the presence of nickel and calculations of the absolute reaction rate led to the conclusion[60] that the process proceeds via a slow surface interaction of the two components. However, the present author's investigations[61,62] (where isotope exchange in cyclohexene and cyclohexane was studied in addition to reaction kinetics, measurements were made of the kinetic isotope effects, and the rates of the individual stages were compared using the ^{14}C label) showed that the process proceeds via the slow formation of a surface compound of cyclohexene followed by its rapid interaction with hydrogen†.

Thus in the general case, the kinetic model must not be justified by kinetic data alone, while, on the other hand, the corresponding reaction mechanism and the corresponding multistage schemes cannot be reliably established solely by means of the pyhsicochemical methods designed for this purpose without combining them with kinetic measurements. Hence the kinetic foundation

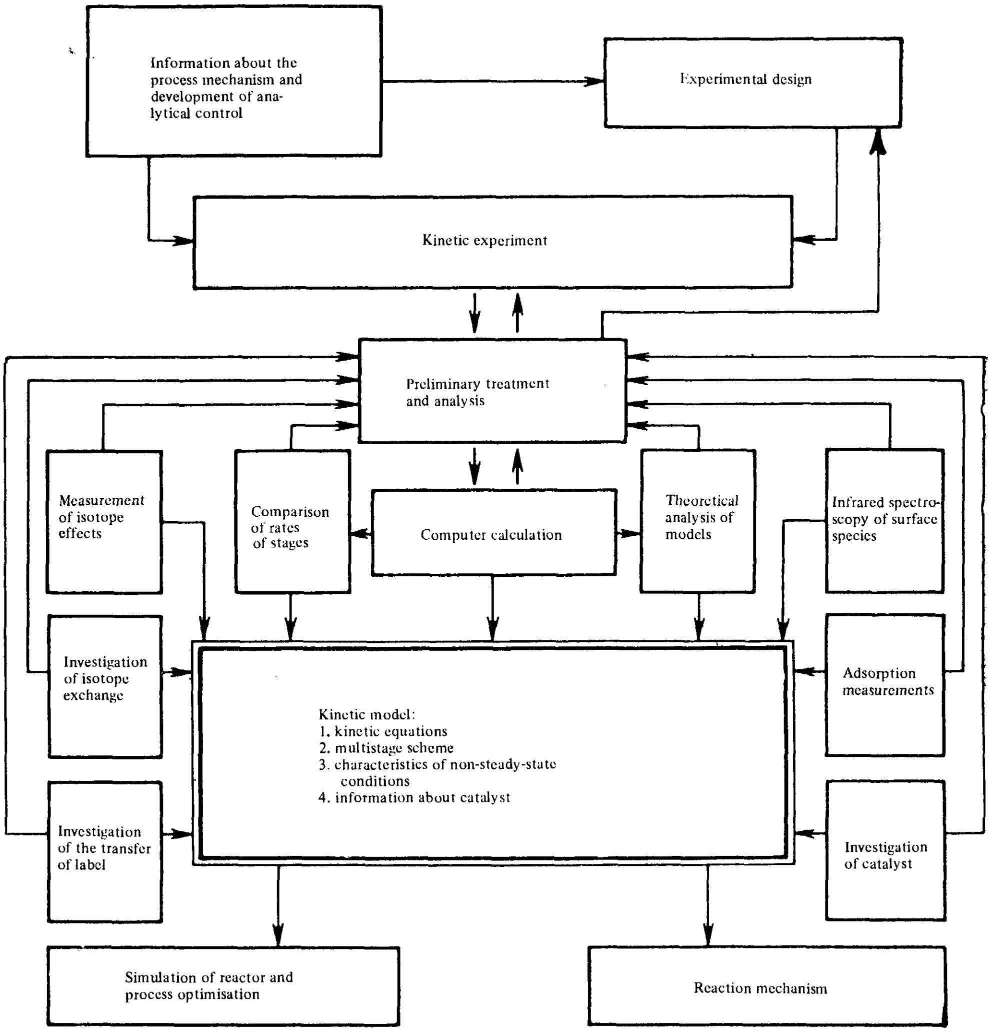
---

†The present authors data were obtained at higher temperatures than those of Erkelens and Ejkema[60], but, since the slow chemical adsorption stage cannot become rapid on decreasing the temperature, it is hardly likely that another stage becomes rate-limiting.

requires a physicochemical support and for this reason it is desirable to carry out complex kinetic studies in which accurate kinetic and other physicochemical measurements are combined‡.

Scheme 1

Formulation of complex kinetic studies



Such combination of procedures (particularly when kinetic, isotope, adsorption, and spectroscopic methods are used, especially under the conditions of the reaction investigated) may be effective in obtaining information about kinetic models. Measurements of kinetic isotope effects and the study of isotope exchange in the reaction components yield particularly valuable information about the role of the possible stages and intermediate species. On the other hand, spectroscopic studies yield more information when they are combined with kinetic measurements, which also reduces the risk of adopting as the main ones the intermediate forms of the "blind end" compounds responsible for secondary reaction pathways (see above). Scheme 1 illustrates the formulation of complex kinetic studies. Kinetic models devised in this way can be justified and can be made to yield much information by making sure that the model corresponds to the specified set of results. Evidently, such models are preferable to those obtained on the basis of kinetic measurements alone.

Only a few kinetic models obtained on the basis of complex investigations are described in the literature. Some of them, described in recent publications, may be mentioned. The kinetics of the isomerisation of but-1-ene and but-2-ene in the presence of a magnesium oxide catalyst have been investigated[63] at 26°C. At the same time, a study was made of the adsorption of the reaction components and the infrared spectra of the surface species and the ESR spectra of the catalyst were obtained. The results were described by a first-order kinetic equation which was derived on the basis of a multistage mechanism

---

‡Here and henceforth we shall use the term "complex kinetic studies" emphasising thereby that kinetic measurements are the fundamental feature.

presupposing the physical adsorption of the initial substance with its slow conversion into the *cis*- and *trans*-isomers of but-2-ene simultaneously and their desorption.

A kinetic model for the dehydrogenation of isobutane to isobutene in the presence of an alumina–chromium oxide catalyst was obtained[64,65] in the temperature range 380 to 575°C. Apart from kinetic measurements, a study was made of the transfer of the radioactive carbon and deuterium labels[64] and a comparison was made of the rate of the process with the rate of the para-ortho conversion of hydrogen in order to determine the ratio of the rates of the stages[65]. A first-order kinetic equation satisfying the mechanism in which the slow stage is the formation of the surface compound C_4H_{10ads} was obtained in both investigations.

The kinetics of the hydrogenolysis of cyclopropane in the presence of a nickel catalyst at 60°C have been investigated[66] and at the same time a study was made of the adsorption of the components and of their isotope exchange with deuterium. The rate of reaction r with formation of propane as well as ethane and methane was described by the kinetic equation

$$r = k\frac{P_1}{1 + k'P_1}, \tag{1}$$

where P_1 is the partial pressure of the initial substance and k and k' are constants. The author justifies it by a scheme according to which a C–C bond in the adsorbed cyclopropane is dissociated on the surface with formation of adsorbed propene. The latter either combines with hydrogen (to form a surface propyl and then propane) or undergoes further hydrogenolysis to ethyl and methyl fragments.

In a study of the kinetics of the reaction of carbon monoxide and nitric oxide in the presence of copper(II) oxide at 135–200°C, i.e.

$$2CO + 2NO = 2CO_2 + N_2 \quad , \tag{2}$$

London and Bell[67] also obtained the infrared spectra of the surface species and studied the catalyst. They derived the kinetic equation

$$r = k\frac{P_{NO}}{(1 + k_1P_{NO} + k_2P_{N_2O})(1 + k_3P_{CO})}, \tag{3}$$

which corresponds to a scheme presupposing the following transformations:

$$NO_{gas} \rightarrow NO_{ads} \rightarrow (N_{ads} + O_{ads}) \xrightarrow{+NO} \rightarrow N_2O_{gas} \rightarrow NNO_{ads} \rightarrow O_{ads} + N_2 \xrightarrow{CO} CO_2.$$

Earlier, Apel'baum and Temkin[68] combined a careful kinetic study of the hydrogenation of ethylene on palladium with the use of the catalyst in the form of a membrane permeable to hydrogen. This enabled them to describe the kinetic data in terms of a scheme involving the interaction of the adsorbed ethylene with gaseous hydrogen followed by the slow interaction of the surface ethyl radical with adsorbed atomic hydrogen (Twigg's mechanism).

Many models devised by the present author and his coworkers for different classes of gas-reactions will be briefly considered below mainly from the standpoint of the information obtained for the construction of models from a combination of exact kinetic studies in gradient-free systems with other physicochemical methods. Kinetic equations were derived for the resulting multistage mechanisms using hypotheses concerning processes on inhomogeneous catalytic surfaces[1].

III. KINETIC MODELS OF CERTAIN REACTIONS OBTAINED BY COMPLEX INVESTIGATIONS

1. Hydrogenation Reactions

(a) Selective Hydrogenation of Diolefins. The investigations were based on the hydrogenation of isoprene to isopentenes in the presence of a palladium–lead catalyst at 58–118°C.[69-71]. The rate of reaction r is described by the equation

$$r = kP_1^{0{,}5}P_{H_2}, \tag{4}$$

where P_1 and P_{H_2} are the partial pressure of the substance hydrogenated and hydrogen respectively. This equation is valid for the formation of each isopentene isomer separately, so that products with different structures arise from intermediate species without a subsequent bond redistribution. This is confirmed by the finding that, when isoprene reacts with deuterium, the degree of isotope exchange in the resulting isopentenes is slight {there is only a small amount of substituted $[D_1]$ and $[D_3]$ derivatives apart from the main addition $[D_2]$ product}. In this case kinetic isotope effects amount to 1.5–1.6, which indicates the involvement of hydrogen in the slow stages. The degree of isotope exchange in the initial isoprene is also low: hence it follows that the formation of the semi-hydrogenated form cannot be rapid.

Infrared spectroscopic study of the surface compounds produced in the reaction showed that the semihydrogenated form generated is strongly retained by the main part of the surface and only a small proportion (20–30%) is converted into the hydrogenation product under the reaction conditions. Experiments on the thermal desorption of hydrogen showed that it is strongly retained by the catalyst, passing into the gas phase only at high temperatures than those used in the reaction. However, this did not permit the conclusion that only the gas-phase hydrogen reacts, but it did indicate the probable nature of the relevant pathway. The combination of results led to scheme 2.

Scheme 2

Stage	Stoichiometric numbers of stages via different pathways		
	I	II	III
1. $C_5H_{8gas} = C_5H_{8ads}$	1	1	1
2. $C_5H_{8ads} = C_5H_{7ads} + H_{ads}$(slow)	0	0	1
3. $C_5H_{8ads} + H_{2gas} = C_5H_{9ads} + H_{ads}$(slow)	1	1	0
4. $C_5H_{9ads} + H_{2gas} = C_5H_{10gas} + H_{ads}$(slow)	0	1	0
5. $C_5H_{7ads} + H_{2gas} = C_5H_{9ads}$	0	0	1
6. $C_5H_{9ads} + H_{ads} = C_5H_{10gas}$(slow)	1	0	1
7. $2H_{ads} = H_{2gas}$	0	1	0

The reaction proceeds mainly via pathways I and II, with rapid formation of a surface isoprene compound and its slow interaction with gaseous or surface hydrogen. Pathway III takes into account isotope exchange.

A kinetic equation agreeing with experimental Eqn. (4) follows from Scheme 2. The combination of Eqn. (4) and scheme 2 constitutes the kinetic model of the process.

(b) Selective hydrogenation of acetylenic compounds. Reactions of this class were studied in relation to the hydrogenation of ethynyldimethylmethanol to dimethylvinylmethanol in the presence of a palladium–lead catalyst at 143–258°C [13,72,73]:

$$(CH_3)_2C(OH)C{\equiv}CH + H_2 = (CH_3)_2C(OH)CH{=}CH_2 \ . \tag{5}$$

The hydroxy-group is unaffected during the reaction, so that the starting compound is henceforth designated by RC≡CH, where R = $(CH_3)_2C(OH)$. The rate of the process is described by the kinetic equation

$$r = k\frac{P_1 P_{H_2}}{(P_1 + k'P_{H_2}^{0,5})^{-2,1}}\quad . \tag{6}$$

The specific features of this equation are reflected by the maximum in the "conversion curves"[48] relating r to the degree of conversion x. The kinetic isotope effect in the replacement of H_2 by D_2 amounts to 1.8–1.9, which indicates the involvement of hydrogen in the slow stages.

The study of the interaction of the initial alcohol with deuterium by mass-spectrometric, infrared spectroscopic, and NMR methods yielded interesting information. It was found that substitution in the hydroxyl and in the methyl group does not take place at all and the degree of exchange of α-hydrogen in the initial alcohol does not exceed 14%, being more pronounced in the resulting dimethylvinylmethanol but occurring without the involvement of the gas phase, i.e. solely as a result of the redistribution of H and D among the reaction components. Thus it follows from the isotope exchange data that the hydroxy-group in the alcohol is not subject to the influence of the surface, apparently because it is remote from the latter owing to the rigidity of the molecule. The absence of isotope exchange between the gas phase and dimethylvinylmethanol, whose molecules should no longer be rigid, shows that the latter is not retained by the surface in the presence of the initial alcohol, passing immediately to the gas phase. The small contribution of the isotope exchange involving the acetylenic alcohol shows that its interaction with hydrogen is not the rapid reaction stage.

Combination of the results leads to Scheme 3 in which the first pathway predominates:

Scheme 3

Stage	Stoichiometric numbers of stages via different pathways		
	I	II	III
1. $HC = CR_{gas} = HC = CR_{ads}$	1	1	1
2. $H_{2gas} = 2H_{ads}$	1	0	0
3. $HC = CR_{ads} + 2H_{ads} = H_2C = CHR_{gas}$(slow)	1	0	0
4. $HC = CR_{ads} + H_{2gas} = H_2C = CHR_{gas}$(slow)	0	1	0
5. $HC = CR_{ads} + H_{2gas} = HC = CHR_{ads} + H_{ads}$(slow)	0	0	1
6. $HC = CHR_{ads} + H_{ads} = H_2C = CHR_{gas}$(slow)	0	0	1

This scheme leads to a kinetic equation agreeing with experimental Eqn. (6). Evidently the kinetic models of the two reactions considered above differ significantly in the presence of the same catalyst.

(c) Hydrogenation of Aromatic Hydrocarbons. Kinetic models have been obtained[74-80] for the hydrogenation of benzene and toluene in the presence of a nickel oxide–zinc oxide catalyst at temperatures up to 270°C, mainly in the region where the processes are reversible. The rates of both reactions pass through a maximum at 180–190°C and the region where the reactions are reversible corresponds to the descending sections of the r–T curves, the decrease of the reaction rate with increasing temperatures being unrelated to the approach to equilibrium and being caused by the process mechanism. The kinetics of the two reactions in the region of reversibility are described by the equation

$$r = kP_1^{0,5}P_{H_2}^{3}\gamma, \tag{7}$$

where γ is the multiplier taking into account the influence of the reverse reaction[81]. Kinetic equations for the forward[82] and reverse[83-85] processes have been obtained separately for the hydrogenation of benzene, the equation for the reverse reactions being

$$r = kP_{C_6H_{12}}P_{C_6H_6}^{-0,5}. \tag{8}$$

In the region of low conversions at low pressures $P_{C_6H_{12}}$ (up to 0.1 atm) another equation is valid for the rate of dehydrogenation of cyclohexane:

$$r = kP_{C_6H_{12}}^{0,5}, \tag{9}$$

with increase of the partial pressure of C_6H_{12}, it is converted into a zero-order equation.

Comparison of the rates of hydrogenation of [^{14}C] benzene, cyclohexene, and cyclohexadiene (separately or jointly)[61] showed that, over the entire range of conversions, benzene reacts much more slowly, so that the transformations of C_6H_8 and C_6H_{10} in the hydrogenation of benzene cannot constitute the slow stage. Under these conditions, the rate of hydrogenation of cyclohexene in the presence of an excess of hydrogen is expressed by the equation

$$r = kP_{C_6H_{10}}P_{C_6H_{12}}^{-0,5}. \tag{10}$$

Comparison with the rate of the para-ortho conversion of hydrogen

$$para\text{-}H_2 = ortho\text{-}H_2 \tag{11}$$

under analogous conditions yields information about the contribution of the rates of adsorption and desorption of hydrogen to the overall rate of the process. It was found that the rates of hydrogenation of benzene and dehydrogenation of cyclohexane are much lower than the rate of reaction (11); consequently the adsorption and desorption of hydrogen cannot be the slow stages in the given process.

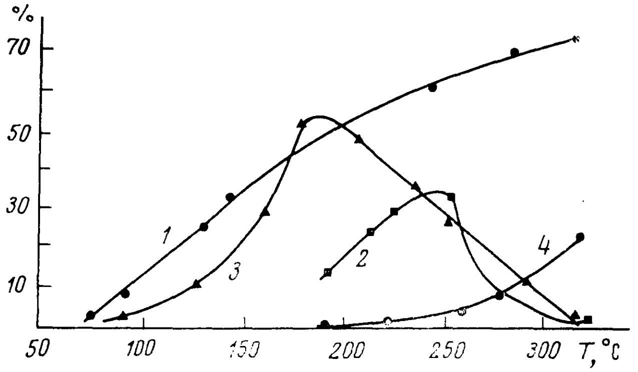


Figure 1. Temperature dependence of the degree of conversion in hydrogen–deuterium isotope exchange processes in benzene (curve *1*) and cyclohexane (curve *2*), the hydrogenation of benzene (curve *3*), and the dehydrogenation of cyclohexane (curve *4*) in the presence of a nickel oxide–zinc oxide catalyst.

Figs. 1–3 present the temperature variation of the rate of isotope exchange (proportional to the degree of conversion) between hydrogen and deuterium in the initial substances and in the products of the given reactions. Evidently, the rate of isotope exchange in benzene and toluene increases monotonically with temperature and greatly exceeds the rate of hydrogenation. On the other hand, the rate of dehydrogenation increases with temperature, while that of isotope exchange passes through a maximum, although in the region of the reversibility of the reaction it exceeds the rate of dehydrogenation. The rates of hydrogenation and dehydrogenation of cyclohexane are much higher than the rate of isotope exchange, which is extremely low.

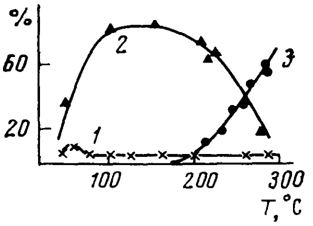

Figure 2. Temperature dependence of the degree of conversion in hydrogen–deuterium isotope exchange processes in cyclohexene (curve *1*), the hydrogenation of cyclohexene (curve *2*), and its dehydrogenation (curve *3*) in the presence of a nickel oxide–zinc oxide catalyst.

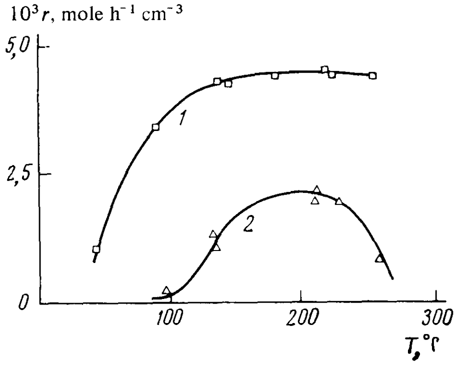

Figure 3. Temperature dependence of the rate of the hydrogen–deuterium isotope exchange in toluene (curve *1*) and the hydrogenation of toluene (curve *2*) in the presence of a nickel oxide–zinc oxide catalyst.

The exchange in toluene proceeds most readily when the methyl group is involved; the nature of the isotope distribution in the methylcyclohexane shows that the latter is not retained by the catalyst surface. Comparison of the rates of the ortho-para conversion of hydrogen on the clean catalyst surface and on the surface with adsorbed cyclohexane or cyclohexene[86] confirms the dissociative mechanism of the adsorption of cyclohexane. The study of the adsorption of benzene[87], the infrared spectra of the surface compounds, and ferromagnetic resonance[88,89] as well as quantum-chemical calculations[90] led to the conclusion that the benzene molecules assume a planar orientation with the probable formation of π-complexes. These results made it possible to rule out the possibility of slow adsorption and desorption stages in the hydrogenation of benzene and cyclohexane.

Measurements of the kinetic isotope effects β confirmed these conclusions. Table 3 lists the values of β obtained, expressed as the ratios k_H/k_D of the rate constants for the reactions before and after the substitution of protium by deuterium (the values of β may be distorted slightly owing to isotope exchange during the reaction).

Table 3. Kinetic isotope effects β in the substitution of H by D in the hydrogenation of benzene, cyclohexene, and toluene and in the dehydrogenation of cyclohexene.

*A mixture of different deuterocyclohexanes.

Appreciable effects in the hydrogenation of benzene and toluene involving the replacement of protium by deuterium in the hydrocarbon and in the hydrogen molecule indicate the involvement of the two components in the slow stages. It is remarkable that the effects observed here are the opposite of those usually found (the rate of the process increases following substitution by the heavy isotope instead of decreasing in accordance with the postulate of the elementary theory of isotope effects[91–93]; on the other hand, the effects in the reverse reaction are normal). The present author explained this finding on the basis of the multistage nature of the process and the relative bond strengths in the initial substances and in the activated complexes[94].

The stoichiometric number ν of the rate-limiting stage[1,4,5] was calculated from the values of β for the forward and reverse reactions by Boreskov's method[95]. It proved to be unity, which rules out the possibility that the reaction proceeds via slow stages characterised by other stoichiometric numbers (for example, the absorption of hydrogen or a process proceeding via the disproportionation of intermediates[1,96]). Table 3 shows that there is no isotope effect in the hydrogenation of cyclohexene; consequently, hydrogen is not involved in the slow stage. The slow stage can only be the formation of a surface cyclohexene compound, which is also confirmed by isotope exchange data (see above).

Comparison of the rates of hydrogenation and isotope exchange for benzene and its alkyl derivatives showed that the rate of hydrogenation decreases steadily, while that of isotope exchange remains at approximately the same level. On the other hand, in cycloalkanes it depends significantly on the nature of the substitution[79,97].

A scheme for the hydrogenation of benzene and toluene, providing for the rapid formation of a surface π-complex of the hydrocarbon on the part of the surface weakly retaining molecularly adsorbed hydrogen, which does not hinder the adsorption of the hydrocarbon, was put forward on the basis of the complete set of results. Subsequently, there is slow interaction between the hydrocarbon and the surrounding molecules of the weakly bound hydrogen, which leads to the formation of a coordination complex retaining the features of a surface π-complex. This reaction stage virtually constitutes a rearrangement of the surface bonds. The complex formed undergoes rapid isomerisation as far as the cycloalkane (possibly also via other intermediate stages), as shown in Scheme 4.

Scheme 4

1. $H_2 = (H_2)_{ads}$
2. $C_nH_{2n-6} + (Ni) = C_nH_{2n-6}(Ni)$
3. $C_nH_{2n-6}(Ni) + 3(H_2)_{ads} = [C_nH_{2n-6}(Ni)] \cdot 3H_3$ (slow)
4. $[C_nH_{2n-6}(Ni)] \cdot 3H_2 = [C_nH_{2n-4}(Ni)] \cdot 2H_2$ (rapid isomerisation)
5. $[C_nH_{2n-4}(Ni)] \cdot 2H_2 = [C_nH_{2n-2}(Ni)] \cdot H_2$ (rapid isomerisation)
6. $[C_nH_{2n-2}(Ni)] \cdot H_2 = C_nH_{2n\,gas} + (Ni)$.

The isotope exchange in benzene and toluene under the conditions of their hydrogenation also proceeds via the formation of a π-complex, which is converted, in conformity with the dissociative π-complex substitution mechanism[98], into a σ-bonded intermediate compound with elimination of a hydrogen atom (H_{ads}).

Scheme 4 leads to kinetic equations agreeing with the experimental Eqns. (7)–(9). Analysis shows that the decrease of the reaction rate after the temperature maximum and the formally negative apparent activation energies obtained are due to the high heats of formation of the surface compounds (their estimate[99] for benzene gave values in the range 25–35 kcal mole^{-1}).

In the region of irreversibility, the rate of hydrogenation of benzene is described by other relations: the equation

$$r = kP_{H_2}^{0.5} \tag{12}$$

holds at 90–135°C, while the equation

$$r = kP_1P_{H_2} \tag{12a}$$

is valid in the range 150–180°C. Here the process mechanism changes significantly and the rate of reaction is apparently determined by the rate of formation of the intermediate compounds $C_6H_7(Ni)$ and $C_6H_8(Ni)$ respectively.

The following kinetic equation is valid for the reaction in the presence of a nickel oxide–chromium oxide catalyst under the same conditions[100]:

$$r = kP_1^nP_{H_2}^m;\quad m = 1.5 - 1.2;\quad n = 0 - 0.5. \tag{13}$$

According to the authors[100], this corresponds to reaction via six slow stages involving consecutive addition of hydrogen and follows from a more general complex equation.

Thus the examples presented show that the kinetic models for the hydrogenation of organic compounds of different classes are distinguished by high specificity and a wide variety.

2. Isotope Exchange Reactions Involving Hydrocarbons

A kinetic model has been obtained[101-103] for isotope exchange reactions between hydrogen and deuterium in cyclohexane in the presence of nickel and platinum at low temperatures (up to 80°C). Previously, exact kinetic models for isotope exchange in hydrocarbons had been altogether absent from the literature. It was found that in the presence of nickel catalysts there is a possibility of two exchange mechanisms depending on the surface concentration of deuterium. In the presence of an excess of the latter, products with low degrees of substitution are formed, while in the presence of its deficiency mainly highly deuterated products are generated. The intermediate species responsible for isotope exchange in cyclohexane and benzene and for the hydrogenation of benzene were found to be different, i.e. the exchange in cyclohexane does not proceed via aromatic intermediates. In contrast to isotope exchange, the hydrogenation of benzene on nickel hardly occurs in the absence of hydrogen (deuterium) in the gas phase, i.e. the process requires the presence of weakly bound hydrogen (this can also be regarded as confirmation of the hydrogenation mechanism proposed above[4]). The rate of isotope exchange

$$C_6H_{12} + yD_2 = C_6H_{12-y}D_y + yHD,\quad y = 1, 2, \ldots, 12, \tag{14}$$

at low pressures and temperatures is described by the kinetic equation

$$r = k\frac{P_1P_{D_2}^{0.5}}{(k_1P_1 + k_2P_{D_2}^{0.5})^2}, \tag{15}$$

which holds both for the overall exchange and for the initial rates of formation of each product with different constants k. This is illustrated in Fig. 4, which shows that the rate of accumulation of each product constitutes a constant fraction of the rate of consumption of C_6H_{12}. Calculation of the isotope distribution in the products by a stochastic method yields values agreeing with experimental data only if simultaneous (and not consecutive) formation of all the substitution products in the initial stages of the processes is postulated (see Fig. 5).

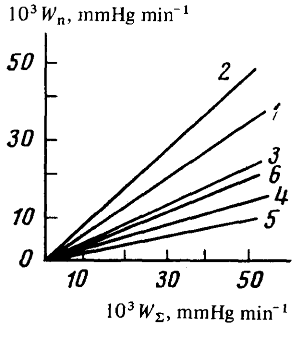

Figure 4. Dependence of the rates of accumulation W_n of different $[D_n]$ deuterocyclohexanes on the rate W_Σ of consumption of $[D_0]$ cyclohexane at 30°C in the presence of platinum: 1)–6) curves for the accumulation of $[D_1]$–$[D_6]$-cyclohexanes respectively.

The proposed scheme (Scheme 5) provides for the formation of all the products via the successive abstraction of hydrogen from the surface fragment on interaction with surface D atoms (for simplicity, it covers only the range y = 1–6). The formation of each product is described by the corresponding stoichiometric reaction pathway.

Scheme 5 also explains the different types of isotope distribution in the exchange products on nickel and platinum. This is due to the different ratios of the rates of reaction via pathway I and the remaining pathways, depending on the rates of stages 4 and 14.

Scheme 5*

18. $C_6H_7D_{4ads} + D_{ads} = \underline{C_6H_7D_5}$	0	0	0	0	1	0
19. $C_6H_6D_{5ads} + D_{ads} = \underline{C_6H_6D_6}$	0	0	0	0	0	1

---

*Compounds evolved into the gas phase are underlined; stages 3–19 are assumed to be slow. Pathways VII–XII have been omitted for brevity as well as the subsequent stages 20, 21,...

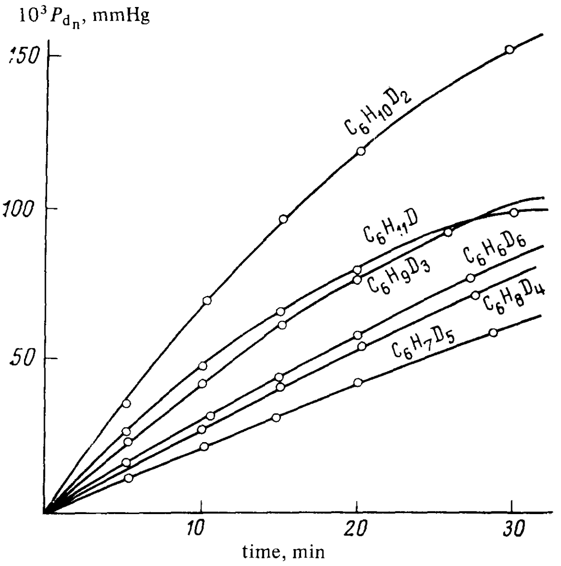

Figure 5. Time dependence of the distribution of isotopes in the products of the exchange between cyclohexane and deuterium at 30°C in the presence of nickel. The curves were calculated from the probable distribution based on the initial rates of formation of $[D_n]$cyclohexanes and the circles represent the experimental partial pressures of different $[D_n]$ cyclohexanes.

The model obtained actually relates for the first time the kinetics of the exchange in hydrocarbons to the nature of the isotope distribution and the mechanism of these multipathway reactions.

3. Dehydrogenation Reactions

The dehydrogenation of isopropyl alchol to acetone in the presence of nickel has been investigated in detail[104–106] in the region corresponding to the reversibility of the reaction (130–200°C):

$$iso\text{-}C_3H_7OH = CH_3COCH_3 + H_2. \quad (16)$$

Although this reaction has been frequently used by various investigators as a model, there were virtually no accurate kinetic literature data for this process. The kinetics of the reaction proved to be extremely unusual. The reaction is inhibited by one of the products (acetone), but is appreciably accelerated by the other (hydrogen), the rate of the process, measured in accordance with a single-parameter scheme[50], being proportional to the alcohol concentration. Fig. 6 compares the rates of dehydrogenation and isotope exchange in the alcohol and acetone.

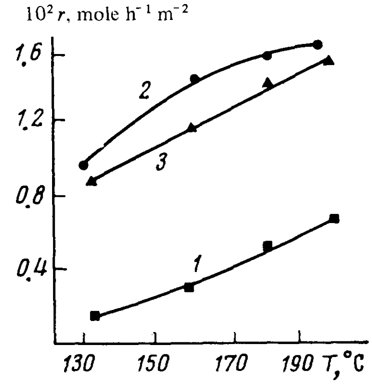

Figure 6. Temperature dependence of the rates of dehydrogenation of isopropyl alcohol (curve *1*) and the hydrogen–deuterium isotope exchange in isopropyl alcohol (curve *2*) and acetone (curve *3*) in the presence of nickel.

The rate of the overall isotope exchange in the alcohol exceeds approximately by a factor of three the rate of dehydrogenation, which is approximately the same as the rate of isotope exchange involving the hydrogen of the hydroxy-group. The nature of the isotope distribution in the exchange products (according to infrared and NMR spectra) and the results of the measurements of the kinetic isotope effects quoted below show that there is no intermediate enol rearrangement in this instance. Table 4 lists the kinetic isotope effects β for the replacement of protium by deuterium in the forward and reverse processes of the acetone hydrogenation reaction:

$$CH_3COCH_3 + H_2 = iso\text{-}C_3H_7OH; \quad (17)$$

here β is defined as the ratio of the rates of reactions involving compounds with the light (r_H) and heavy (r_D) isotopes under the same initial conditions and for the same composition of the reaction mixture:

$$\beta = r_H/r_D. \quad (18)$$

Table 4 shows that there is virtually no isotope effect in the substitution of protium by deuterium in the alkyl group of the alcohol, but it is appreciable for substitution in the hydroxy-group. This can be regarded as proof that the hydrogen of the hydroxy-group is involved in the slow stage (confirming the isotope exchange data) and that the adsorption and desorption stages are rapid.

Table 4. Kinetic isotope effects β in the dehydrogenation of isopropyl alcohol and the hydrogenation of acetone on nickel at 200°C.

Reaction	β	Reaction	β
$C_3H_7OH=C_3H_6O+H_2$ $C_3H_7OD=C_3H_6O+HD$	3.4	$C_3H_6O+H_2=C_3H_7OH$ $C_3D_6O+H_2=C_3D_6HOH$	1.0
$C_3H_7OH=C_3H_6O+H_2$ $C_3D_7OH=C_3D_6O+HD$	1.1	$C_3H_6O+H_2=C_3H_7OH$ $C_3H_6O+D_2=C_3H_6DOD$	0.8
$C_3H_7OH=C_3H_6O+H_2$ $C_3D_7OD=C_3D_6O+D_2$	4.3	$C_3H_6O+H_2=C_3H_7OH$ $C_3D_6O+D_2=C_3D_7OD$	0.8
		$C_3H_7OH=C_3H_6O+H_2$ (in excess of H_2) $C_3H_7OH=C_3H_6O+H_2$ (in excess of D_2)	3.5

The marked isotope effect in the replacement of the excess hydrogen by deuterium in the dehydrogenation of isopropyl alcohol confirms the involvement of hydrogen, in conformity with kinetic data. The observed low values of the isotope effects ($\beta < 1$) in reaction (17) are due to its specific features, which are analogous to those mentioned above for the hydrogenation of aromatic hydrocarbons. Comparison of the rate of reaction (16) with that of reaction (11) under the same conditions also demonstrated the impossibility of slow hydrogen desorption and adsorption stages.

The set of the above data corresponds to the following two-pathway scheme (Scheme 6), which provides for the simultaneous occurrence of the process via the slow abstraction of the hydrogen of the hydroxy-group directly from the adsorbed alcohol, which predominates at high concentrations of surface hydrogen:

Scheme 6

Stage	Stoichiometric numbers of the stages via different pathways	
	I	II
1. $H_2 = 2H_{ads}$	1	0
2. $CH_3CH(OH)CH_{3gas} = CH_3CH(OH)CH_{3ads}$	1	0
3. $CH_3CH(OH)CH_{3ads} = CH_3CH(O)CH_{3ads} + H_{ads}$(slow)	1	0
4. $CH_3CH(OH)CH_{3gas} + H_{ads} = CH_3CH(O)CH_{3ads} + H_2$(slow)	0	1
5. $CH_3CH(O)CH_{3ads} = CH_3COCH_{3ads} + H_{ads}$	1	1
6. $CH_3COCH_{3ads} = CH_3COCH_{3gas}$	1	1

With increase of the concentration of surface hydrogen, hydrogenation proceeds mainly as a result of the slow interaction of the gaseous alcohol with the surface hydrogen.

The kinetic equation giving the best (compared with all the other equations which have been tested) description of the experimental data follows from the scheme:

$$r = k\frac{P_1(1 + k^*P_{H_2}^{0,5})\,\gamma}{1 + k_1P_{ac} + k_2P_{ac}P_{H_2}^{0,5} + k_3P_{H_2}^{0,5}}, \tag{19}$$

where P_{ac} is the partial pressure of acetone and γ a correction for the influence of the reverse reaction (the unity in the denominator may not be neglected only for the description of the initial stage of the reaction for very low values of P_{ac}). Evidently the accelerating effect of hydrogen can be naturally accounted for within the framework of this scheme: it can be retained by the surface either during reduction or in the course of the reaction. A similar behaviour has been observed in the dehydrogenation of cyclohexane[107-109] and isopentenes[110] on palladium.

The above results also make it possible to characterise the kinetic model for the hydrogenation of acetone[111]. It corresponds to the reverse of Scheme 6 and the equation

$$r = k\frac{P_{ac}P_{H_2}(1 + k^*P_{H_2}^{0,5})\,\gamma}{1 + k_1P_{ac} + k_2P_{ac}P_{H_2}^{0,5} + k_3P_{H_2}^{0,5}}. \tag{20}$$

In the region corresponding to irreversibility, the rate of reaction (17) at lower temperatures (up to 90°C) is described by another equation according to Babkova et al.[112]:

$$r = k\frac{P_{ac}P_{H_2}}{(1 + k_1P_{ac} + k_2P_{ac}P_{H_2}^{0,5} + k_3P_{al})(1 + k'P_{H_2}^{0,5})}, \tag{21}$$

while in the presence of a copper catalyst it is described by the equation

$$r = k\frac{P_{ac}^2P_{H_2}}{(1 + k_1P_{ac} + k_2P_{ac}P_{H_2}^{0,5} + k_3P_{al})^2} \tag{22}$$

(P_{al} is the partial pressure of the alcohol).

Thus the complex kinetic investigation of the dehydrogenation of isopropyl alcohol in the presence of nickel in the region of reversibility made it possible to obtain concordant results and to elucidate the complex pattern of the reaction, which had been previously regarded as extremely simple. Conclusions concerning the characteristics of this process cannot, however, be extended to other dehydrogenation reactions. Thus quite different results were obtained[113-115] in a complex investigation of the selective dehydrogenation of cyclohexanol to cyclohexanone in the presence of a copper–magnesium catalyst at 210–270°C:

$$C_6H_{11}OH = C_6H_{10}O + H_2\ . \tag{23}$$

This shows that there are differences between the kinetic models. The rate of reaction (23) no longer depends on the concentration of hydrogen and there is no proportionality between the rate of the process and the concentration of the starting material, but inhibition by the ketone is also observed. The results of the measurements of the kinetic isotope effects for the forward and reverse processes are listed in Table 5.

Table 5. Kinetic isotope effects β in the dehydrogenation and hydrogenation of cyclohexanol at 240°C.

Reaction	β
$C_6H_{11}OH=C_6H_{10}O+H_2$ $C_6H_{11}OD=C_6H_{10}O+HD$ $C_6H_{11}OD=C_6H_9DO+H_2$	1.0
$C_6H_{11}OH=C_6H_{10}O+H_2$ (in excess of H_2) $C_6H_{11}OH=C_6H_{10}O+H_2$ (in excess of D_2)	1.0
$C_6H_{10}O+H_2=C_6H_{11}OH$ $C_6H_{10}O+D_2=C_6H_{10}DOD$	1.3

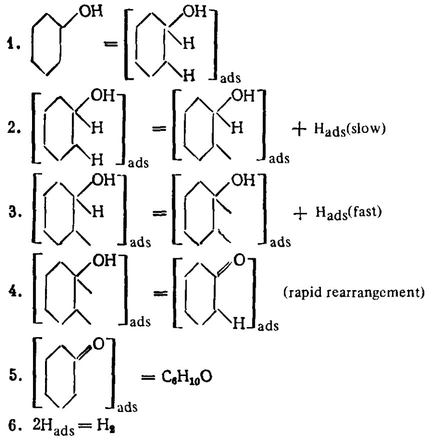
Evidently there is no isotope effect in the substitution of the hydrogen in the hydroxy-group and when the reaction is carried out in an atmosphere of deuterium, but it does operate in the reverse reaction. Experiments on isotope exchange showed that the rate of exchange of the hydroxyl hydrogen is higher than the rate of the reaction itself.

The rate of reaction (23) corresponds to Scheme 7 and the following kinetic equation:

$$r = k\frac{P_1\gamma}{(P_1 + k'P_{\text{ket}})^m}, \quad m = 0.5 - 0.6, \tag{24}$$

where P_{ket} is the partial pressure of cyclohexanone. Scheme 7 presupposes the occurrence of the reaction via the slow abstraction of β-hydrogen and rapid enol rearrangement.

Scheme 7



Thus a change in the structure of the molecule and the use of a different metallic catalyst have a significant influence on the form and properties of the kinetic model, while the general character of the reaction remains the same. The kinetic models for the dehydrogenation of hydrocarbons have a completely different form[116-118]. This shows yet again that dehydrogenation processes cannot be embraced by a general kinetic model, as suggested previously by some workers.

4. Extensive Oxidation of Microadmixtures of Organic Substances

These reactions were investigated in relation to the oxidation of microadmixtures of n-pentane, benzene, and their mixtures[119,120] in the presence of an aluminium-platinum [alumina-platinum?] catalyst and platinum foil at 100–350°C over a wide range of conditions. The rate of extensive oxidation of benzene is expressed by the equation

$$r = \frac{kP_1P_{O_2}^{0{,}5}}{(1 + k_1P_1 + k_2P_1P_{O_2}^{0{,}5} + k_3P_{H_2O}P_{O_2}^{-0{,}5})^2}; \tag{25}$$

at fairly high oxygen concentrations ($P_{O_2} \geqslant 0.1$ atm), we have

$$r = kP_1/(1 + k'P_1)^2. \tag{26}$$

At 130°C and above, a heterogeneous-homogeneous process mechanism operates to some extent (this was demonstrated by the inhibiting effect of the packing in a reactor with a vibrofluidised catalyst bed[121] and directly by the method involving separate calorimetric measurements[122]), which leads to the appearance of additional terms in Eqns. (25) and (26). This is a fairly rare instance; the homogeneous propagation of the oxidation reactions of organic compounds (which is in general not observed very frequently) usually occurs only at 400–600°C[123,124]. Above 240°C, the reaction passes to the external-diffusion region. When benzene is replaced by deuterobenzene, there is no kinetic isotope effect, so that the slow stages of the process apparently do not entail the dissociation of C–H bonds. The mechanism of the process presupposes its simultaneous occurrence via four independent pathways: the purely heterogeneous pathway (via successive oxidative cracking on the surface of platinum coated with oxygen with slow stages involving the conversion of aromatic bonds into ordinary bonds), the heterogeneous-homogeneous pathway (with transfer of the intermediate oxygen complexes of benzene into the gas phase and their subsequent interaction with molecular oxygen) and two "empty" pathways involving the deactivation of radical-like compounds in the gas phase.

The characteristics of the extensive oxidation of n-pentane are quite different; there is no homogeneous propagation of the reaction and the kinetic isotope effects show that the slow stages involve the dissociation of C–H bonds, the rate of the process being described by the equation

$$r = kP_1, \tag{27}$$

which corresponds to a scheme presupposing slow dissociative adsorption of pentane on the oxidised surface of platinum.

When both hydrocarbons are oxidised simultaneously, pentane does not affect the oxidation of benzene; at low concentrations, benzene does not affect the oxidation of pentane up to a certain critical concentration beyond which benzene causes a sharp inhibition of the pentane oxidation reaction. The rate of oxidation of pentane in the presence of benzene is characterised by the equation

$$r = k\frac{P_1}{(1 + k'P_{C_6H_6})^2}, \tag{28}$$

corresponding to kinetic models involving separate oxidation processes.

The above examples show that accurate complex investigations lead to exceptionally varied and specific kinetic models for different classes of reactions and catalysts.

IV. NON-STEADY-STATE KINETIC MODELS

The kinetic models discussed above characterise steady-state or quasi-steady-state reactions. The concentrations of the intermediates formed and decomposed during the process then remain constant under specified conditions, corresponding to the given constant concentrations of the reactants, and when the latter are altered, there is sufficient time for new concentrations of the intermediates corresponding to them to be established. Steady-state conditions can frequently break down, so that the catalytic reactions proceed as non-steady-state processes. Such breakdown is caused, particularly, by the activation of the catalyst in the initial stages of the reactions, by the gradual blocking of the surface by side products, by the influence of the reaction system, by the changes associated with transitions to other conditions, and by other factors causing oscillations or steady alterations in the activity of the catalysts[125-127].

Analysis demonstrates the possibility of the occurrence of more than one steady state of the process in the kinetic region, depending on its mechanism and the nature of the kinetic model[128-132]. The necessary condition for this is the presence of stages involving interaction between different intermediates[128-132,164-166]. A multiplicity of steady states has been observed experimentally, for example, in the reaction of carbon monoxide with hydrogen in the presence of nickel[141].

The attainment of a steady state requires a certain relaxation time of the rate of reaction[126,133,167,168]. In conformity with Frank-Kamenetskii's conditions[169], it must be much shorter than the reaction time and must depend on the conditions of the process, its mechanism, and the ratios of the rates in different stages (Belousov[170] refers to the relaxation time as the duration of the intrinsically non-steady state). Temkin[126,167,168] showed that the relaxation time constitutes in the general case a fraction of the "reaction turnover time", which is the reciprocal of the "reaction turnover number"[41] (i.e. the number of molecules which have reacted per unit time referred to the number of active sites on the catalyst surface).

The relaxation time characterises the time required for the attainment of the steady state, determined by the specific features of the multistage nature of the process and its mechanism, but not by other influences caused by the effect of the reaction system on the catalyst and secondary factors. Relaxation in consequence of such "secondary influences"[126,168] may be much more prolonged than the reaction itself and the process as a whole then takes place under non-steady-state conditions. Such a situation arises, for example, in the oxidation of ethylene in the presence of silver[171] owing to the modifying effect of the oxygen penetrating into the surface layer of the catalyst.

Experimental studies on processes under non-steady-state conditions, both in order to determine the relaxation time as a function of various factors and to elucidate other characteristics, can therefore serve as an effective means for devising kinetic models required for a more complete understanding of catalytic processes. Certain approaches of this kind have been described in the literature, for example, in Refs. 42, 43, 133–139, and 172–175. Thus the determination of the ignition limits in the synthesis of alcohols on transition of the latter from the kinetic region to the external-diffusion region has been used to describe the rate of this process[133]. The study of decay phenomena as a function of various factors in the transition of the ammonia oxidation reaction on a non-platinum catalyst from the external-diffusion to the kinetic region made it possible to derive a kinetic equation for the reaction[139]. Non-steady-state effects in the ammonia and sulphur dioxide oxidation reactions have been investigated[174,175] by the electrothermographic method. The parameters of the non-steady-state kinetic models for the oxidation of carbon monoxide on platinum and lanthanum trioxide have been determined and the models have been analysed[128,176,177]. The kinetics of the oxidation of hydrogen in the presence of nickel under the conditions of stable auto-oscillations of the system, having a chemical mechanism, have been investigated by Slin'ko and coworkers[142,178,179].

Non-steady-state kinetic models have also been obtained for the hydrochlorination of acetylene[143], the oxidation of propene, and its oxidative ammonolysis[144]. For a model of this kind, Gel'bshtein and coworkers[144] reported to the earlier idea[180] of a surface "reaction layer" of the catalyst, where oxygen ionises and is transferred from centres of one type to those of another. They believe[144] that the thickness of this layer determines the occurrence of the process under particular conditions. When the layer is thin, the characteristics of the steady-state and non-steady-state course of the reaction are the same. Many non-steady-state kinetic models have been devised for the description of the dehydrogenation of hydrocarbons, taking into account the blocking of the catalyst by coke[116,117,145-147,181-183] (although not all such models have been adequately justified). The earlier models for the dehydrogenation of hydrocarbons containing four carbon atoms in the presence of alumina–chromium oxide catalysts have been reviewed[184].

A kinetic model (unsupported by multistage mechanisms), taking into account the rates of conversion of butane into butenes (r_1) and of butenes into butadiene (r_2), of the cracking of butane (r_3), and of coke formation from both hydrocarbons (r_4 and r_5) has been proposed for the single-stage dehydrogenation of butane in the presence of an alumina–chromium oxide catalyst in the temperature range 570–630°C [145]:

$$r_1 = k_1(1 - c/c_{\max})P_1\gamma/M^2, \tag{29}$$

$$r_2 = k_2(1 - c/c_{\max})^2 P_{C_4H_8}\gamma/M^2, \tag{30}$$

$$r_3 = k_3(1 - c/c_{\max})P_1/M, \tag{31}$$

$$r_4 = k_4P_{C_4H_8}/M^2, \tag{32}$$

$$r_5 = k_5P_{C_4H_6}/M^2, \tag{33}$$

where M depends on the concentrations of all the reactants and the rate of the main reactions depends on the area of the coke-free surface (c and $c_{\max}$ are the concentration of coke at any instant and the concentration corresponding to monolayer coverage).

The dependence of the rate of the process on the amount of coke and the influence of the oxygen concentration ω in the surface layer of the catalyst, which varies owing to the slow diffusion of oxygen during preliminary treatment and during the reaction itself, have been refined[148]:

$$r_1 = k_1\omega\,e^{-uc}P_1\gamma/(1 + k'P_1)^2, \tag{34}$$

$$r_3 = k_3P_1, \tag{35}$$

$$r_4 = k_4P_{C_4H_8}, \tag{36}$$

$$r_5 = k_5\omega P_{C_4H_8}/P_{H_2}. \tag{37}$$

Under the experimental conditions (535–585°C), the conversion of butenes into butadiene is reversible and the changes in ω are defined by equations for diffusion in a solid. A similar exponential dependence of the rate of the process on coke concentration characterises the kinetic models for the dehydrogenation of butane and isopentane in the presence of another alumina–chromium oxide catalyst[147,148]. A kinetic equation analogous to Eqn. (29) with $M = 1$, to which a linear decrease of the rate of reaction with increasing coke concentration corresponds, is valid for the dehydrogenation of isobutane to isobutene in the presence of an alumina–chromium oxide catalyst[146].

A study of the kinetics of the dehydrogenation of isopentenes to isoprene in the presence of a zinc–chromium [zinc oxide–chromium oxide?] catalyst[116-118,186] at 540 to

620°C using ^{14}C and deuterium led to the derivation of the equation

$$r = k^{*} \frac{P_1\gamma}{(P_1 + k'P_{C_5H_8})^{0,5}}, \tag{38}$$

where the constant k^* depends in the general case on the change in the free energy of the system ΔG_X for the given degree of conversion x, which affects the free energy of the catalyst surface (taken into account by the factor a), and also on the amount of coke:

$$k^{*} = k\,(1 - lc/c_{\max})\,e^{-a\Delta G_x/RT} \tag{39}$$

(where l is a variable multiplier close to zero, reaching unity for $c = c_{\max}$) and $a \simeq 1$. This equation corresponds to the scheme taking into account the slow abstraction of hydrogen from the most reactive isomer (2-methylbut-2-ene) accompanied by the attainment of isomerisation equilibrium. The changes in free energy have a marked influence on the rate of the process, causing considerable alterations in the latter for a small increase in the degree of conversion.

The same reaction in the presence of a nickel–phosphate catalyst is described by a more complex kinetic model[181-183] characterising the rate of dehydrogenation (r_1), the formation of light hydrocarbons from isopentenes (r_2), and coke formation (r_3) in the temperature range 580–680°C and also the rate of regeneration of the catalyst (r_6):

$$r_1 = k_1 \frac{P_1\gamma}{c^{2/3} + k'P_{C_5H_8}}, \tag{40}$$

$$r_2 = k_2 \frac{P_1}{c^{2/3} + k'P_{C_5H_8}}, \tag{41}$$

$$r_3 = \frac{k_3P_1 + k_3^{*}P_{C_5H_8}}{c^{2/3} + k'P_{C_5H_8}} + \frac{k_3'P_1 + k_3''P_{C_5H_8}}{(c^{2/3} + k'P_{C_5H_8})^{0,5}}\,c^{2/3}\,e^{-\alpha c}, \tag{42}$$

$$r_6 = k_6 \frac{P_{O_2}c^{2/3}}{P_{O_2} + k_6'c^{2/3}}. \tag{43}$$

These equations follow from the general multistage mechanism (i.e. are not empirical), which presupposes that the reaction proceeds via reversible isomerisation stages, slow successive elimination of hydrogen from the adsorbed isopentenes, their cleavage, and coke formation on the free surface as well as the surface already occupied by coke. The experimental kinetic isotope effects obtained[183] agree with this mechanism.

The kinetics of cracking reactions under non-steady-state conditions, due to the decrease of the activity of the catalyst caused by the blocking of the active surface sites, have been considered by Wojciechowski (see his review[187]) on the basis of ideas which he developed. These refer only to the simplest instances of previously postulated mechanisms and lead to time-dependent non-autonomous models. The requirement that the model be independent of time is extremely important for its practical employment[140]. Models describing the decrease of activity have also been discussed in a number of other studies (see, for example, Refs. 188–192). Non-steady-state changes may arise as a consequence of the rearrangement of the active sites on the catalyst surface during the reaction and the formation of surface phases. The kinetics of such processes have been examined in a general form[193].

The formal kinetic descriptions of the reaction under steady- and non-steady-state conditions can naturally be significantly different. Certain simplest cases of such changes and transitions from one set of conditions to another have been discussed[170,194]. However, apart from the intrinsic non-steady state (see above), only the non-steady chemical state, in which the chemical composition of the catalyst is brought into correspondence with that of the gas phase after the attainment of adsorption equilibrium, has been examined in these investigations. This limitation rules out a general approach to this problem.

If the processes corresponding to the attainment of a steady state during the relaxation of the rate of reaction are considered for a fixed number of active sites on the catalyst surface, all the "extraneous" non-steady-state processes caused by the influence of some other factors (the influence of the reaction system, etc.) are as a rule associated with changes in the number or quality of active regions. The mechanism of such changes is in most cases insufficiently clear and a mathematical description taking them into account in kinetic models is much more complex than the description of the steady-state cases. A further development of experimental techniques and approaches to the interpretation and description of the results is therefore necessary for the investigation of the kinetics of non-steady-state processes. This is significant also owing to the practical importance of non-steady-state conditions, particular examples of which may arise in processes with a pseudofluodised catalyst bed or with a moving bed. The possibility of non-steady-state changes and the effectiveness of such, perhaps even brief non-steady-state conditions, which have proved to be more suitable than steady-state conditions[127,128], result in an extremely urgent need for studies designed to obtain and interpret non-steady-state kinetic models.

At the same time, since the bulk of catalytic industrial processes are nowadays carried out under steady-state conditions, further research on processes under steady-state conditions and establishment of steady-state kinetic models are equally necessary. Both types of research should naturally supplement one another, clearly under conditions where non-steady-state effects are real, currently important, and useful. The search for such non-steady-state effects can also prove extremely useful, which in no way diminishes the importance and the amount of information derivable from steady-state models which can lead to the process mechanism by a more direct and productive procedure.

The problems of non-steady-state kinetics may be the subject of a separate review.

V. OPTIMUM KINETIC MODELS

Each kinetic model must reflect real specific properties of the reaction–catalyst system investigated under the given conditions. If the kinetic equation for the reaction via one of the pathways is considered in a general form, it can be represented[48] as a product of the initial velocity r_0 ("reaction level") and a function of the degree of conversion $\Phi(x)$ (normalised to unity), which determines the form of the kinetic model:

$$r = r_0\Phi(x). \tag{44}$$

The level r_0 depends on the initial conditions, the amount of the catalyst, its activity and adsorption capacity, and the specific form of the kinetic equation, to which the function $\Phi(x)$ is extremely sensitive (see Fig. 7). Fig. 7 shows that changes in r relative to r_0, which are determined by the changes in $\Phi(x)$ during the process, from $x = 0$ to $x \simeq 1$, will be smallest for a zero-order reaction.

For other kinetic relations, there is a steady decrease of the reaction rate, which is more marked for higher-order reactions and when the reaction is strongly inhibited by its products. Relations with extrema are also possible, but these need not be discussed here, since they do not alter our conclusions.

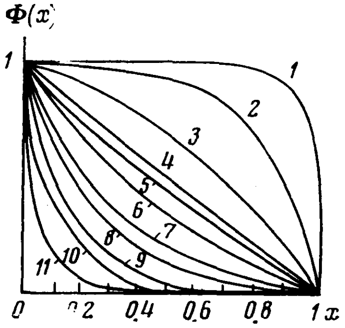


Figure 7. Dependence of the form of $\Phi(x)$ on the degree of conversion for different kinetic equations $r = kP_1^n/P_{prod}^m$: 1) $m = 0$, $n = 0$; 2) $n = 0.3$; 3) $n = 0.5$; 4) $n = 1$; 5) $n = 1.5$; 6) $n = 2$; 7) $n = 3$; 8) $m = n = 0.5$; 9) $m = 0.5$, $n = 2$; 10) $n = 0.5$, $m = 1$; 11) $n = m = 1$.

Thus the form of the kinetic model, specified by the kinetic equation, describes the nature of the changes in the rate of the process, throughout its course, under steady-state conditions. From this standpoint, one may speak of the optimum form of the kinetic model, reflecting the most convenient type of changes in the rate of the reaction throughout the latter. Since high or the maximum possible conversions (for the given selectivity) are of greatest interest for practical use, the minimum decrease of the rate of reaction compared with its initial value as the degree of conversion increases is the most convenient. The form of the kinetic model characterising the smallest changes in the reaction rate with increasing degree of conversion, other conditions being equal, may be regarded as the optimum form. It is clear from the foregoing that the form describing a zero-order reaction or other similar relations, in which the decrease of the rate of reaction during the process is a minimum compared with the relations corresponding to other kinetic equations possible for the given system, is the optimum form[149].

However, the fact that the model has the optimum form does not yet show that the model as a whole is optimum, which depends on the superposition of various factors. If we again restrict ourselves to a single stoichiometric reaction pathway, then, for the specified activity of the catalyst and the optimum form of the kinetic model, the latter is optimum as a whole when the level r_0 is higher than that corresponding to other kinetic models.

Thus the model which adequately describes the changes in the reaction rate during the process, which are the smallest possible compared with the initial level r_0 (r_0 being greater than other possible values obtained for other models under the specified conditions and for the specified catalyst activity), may be regarded as the optimum model. The optimum properties treated in this way depend on the internal characteristics of the process, which determine the given kinetic model. Consequently one may be dealing with kinetically optimum reaction mechanisms from which follow optimum kinetic models. The kinetically optimum reaction mechanism (which depends on the reaction conditions and the catalyst properties) will then be one ensuring that the optimum kinetic model arises from it, i.e. the most convenient form of the model and the most convenient initial process velocity. Hence it follows that, in selecting the catalyst, it is useful to take into account whether or not it can ensure a rate of the process whose value and the changes in the latter correspond to the optimum or nearly optimum kinetic model.

Analysis of the kinetic relations arising from various possible multistage process mechanisms and the relative rates of the stages may indicate which models are optimum or nearly optimum for the specified activation energy under the given conditions, together with approximate estimates of the rate constants for the elementary stages by the transition state method. Such analysis of the optimum properties of the models may constitute one of the stages in the selection of catalysts accompanied by the consideration of the possible properties and composition which would ensure the required kinetically optimum mechanism.

An estimate[149] has shown that the most convenient form of the model, i.e. the most nearly zero-order reaction, corresponds in most instances also to the highest level r_0 for the specified activation energy, provided that the reaction proceeds via slow stages involving surface interaction or desorption (the activation entropy is zero or higher). The initial velocities for different forms of the models proved to be extremely different and the replacement of a zero-order equation by other equations alters the level r_0 so much that the influence of the decrease in the latter on the rate of reaction may be compensated only by an improbably large decrease of activation energy.

Table 6. The degree of approach to an optimum by the kinetic models for certain reactions[149].

Reaction	Model characteristics	Remarks
Isomerisation of cyclohexene to methylcyclopentane on CaY zeolite (0.5% Pt); 268–320°C; 13–17 atm (Ref.150)	Zero-order equation corresponding to rapid formation of C_6H_{10ads} and its slow conversion into $C_5H_9CH_{3ads}$	Nearly optimum model
Hydrogenation of benzene on nickel; 90–150°C; 1 atm (Refs. 74,100)	The observed equation $r = kP_{H_2}^{0.5}$ is closer to a zero-order equation than other possible expressions; it corresponds to the slow conversion of C_6H_{6ads} into C_6H_{7ads} (Ref.151)	Model closer to an optimum under the given conditions than other models
Oxidation of hydrogen on oxide catalysts (Sn, Mo, W, Cd, Mn, V, Co, Cr, Cu, and Ni oxides) (Refs.152,153)	The rate of the process is described by a first-order equation with respect to hydrogen and corresponds to an oxidation-reduction mechanism or other multistage mechanisms.	Model closer to an optimum than the model corresponding to single-stage mechanisms.

Table 6 presents the results of the analysis[149] of certain simple models as regards their optimum properties, using literature data[74,100,150–153].

The kinetic models listed in Table 6 may be closer to the optimum model than others for the same reaction under different conditions or in the presence of other catalysts. For example[149], if the isomerisation of cyclohexene proceeded in a single stage (i.e. in accordance with another model), its rate would be described by a first-order equation (and not a zero-order equation as in the model described above), with values of r smaller by several orders of magnitude (for the same experimental activation energy and under the same conditions). Consequently the model with the optimum form also corresponds to the highest initial velocity of the reaction.

It has been shown for the hydrogenation of benzene[48,74] that the rate of the process under the given conditions, characterised by the model in Table 6, is higher than when the process is described by other kinetic equations: $r = kP_1P_{H_2}$ or $r = kP_1^{0.5}P_{H_2}^3$.

Analysis[149] also leads to the conclusion that the rate of the reaction corresponding, for example, to the Parravano mechanism[195] (the slow stage involves the adsorption of hydrogen and its subsequent rapid interaction with benzene in the gas phase) would be described by a more complex kinetic relation and would be lower approximately by 8 orders of magnitude than for the model in Table 6. If Kagan's mechanism[96] were valid (slow formation of cyclohexadiene with subsequent rapid disproportionation), the kinetic equation for such a model would be complex with a sharper decrease of the rate of reaction compared with the initial value and the rates r under the specified conditions for the given activation energy would be in order of magnitude lower than for the model in Table 6[149].

According to the results of Goncharuk and Golodets[152], the rate of oxidation of hydrogen in the presence of tungsten trioxide under conditions such that a first-order equation (which is closer to the optimum expression than the other observed kinetic relations) does not hold, proves to be an order of magnitude lower than in the presence of the same catalyst when the equation does hold. Comparison of the activation entropies for oxidation reactions carried out by Boreskov[154] also showed that the entropy is much higher for the oxidation-reduction mechanism than for a single-stage reaction. The form of the kinetic model is also much less favourable[149] for the single-stage mechanism. According to Popovskii et al.[153], the rate of oxidation of hydrogen in the presence of chromium trioxide at 226°C, where a kinetic equation with a fractional order holds ($r = k_0e^{-20\,000/\mathrm{RT}}P_{H_2}^{0.6}$), is approximately the same as in the presence of V_2O_5 at a much higher temperature (440°C), where a first-order kinetic equation $r = k_0e^{-21\,000/\mathrm{RT}}P_{H_2}$ is valid (evidently the activation energies are similar in the two cases and cannot be the cause of the discrepancy between the values of r at comparable temperatures). Consequently, for the form of the kinetic model closer to the optimum, which obtains in the presence of chromium oxide, the initial reaction rate is much higher than in the presence of V_2O_5, where the form of the model is further removed from the optimum.

The turnover number of the reaction[41] can serve as a quantitative characteristic of its initial level, because it refers, as a rule, to a degree of conversion of zero. Maatman[197] calculated the turnover numbers for different reactions and catalysts assuming in many instances that the reactions proceed in accordance with a zero-order equation and an activation entropy close to zero. If his values were sufficiently well-founded, the greatest turnover number would correspond precisely to the optimum model. Thus, according to his calculations[197], the turnover number for the cracking of cumene on a "decationated" zeolite is higher by many orders of magnitude than on an aluminosilicate catalyst. Thus Maatman's results show that, despite the optimum form of the kinetic models in the two instances, they differ sharply as regards the level of the reaction and therefore the first model must be regarded as optimum. Unfortunately, Maatman's calculations are not based on accurate kinetic data and accurate information about the reaction mechanism.

The above examples demonstrate the usefulness of the analysis of the optimum properties of kinetic models. In the selection of catalysts it is therefore useful to carry out an analysis in order to determine which kinetic models could describe the reaction in the presence of the selected catalyst and which additives (if the possible mechanism of their action is considered) could lead to other models closer to the optimum. Naturally such an approach is extremely simplified and one-sided, but, when the appropriate information is available, it can be very useful. Kol'tsov, Beskov, and the present author[196] considered in general terms the optimum process conditions which may be predicted from the form of kinetic models (references to preceding communications are given in this paper).

VI. KINETIC MODELS AND REACTION SELECTIVITIES

The selectivity is one of the most important kinetic factors characterising the course of complex reactions and determining their practical employment. It can be expressed as the ratio of the sum of the reaction rates via pathways leading to the formation of the desired product to the sum of the rates of all the transformation of the initial substances under identical conditions[156] ("differential selectivity"[155]). This ratio characterises the true process selectivity. Since the desired product can undergo secondary transformations, it is necessary to consider the apparent selectivity[156,157] taking into account the rate of accumulation of the desired product W_j as the algebraic sum of the rates of reaction via all the pathways leading to its formation and decomposition (for the given composition of the reaction mixture):

$$\begin{gathered} S = W_j/W_1, \\ P_1^0,\ P_2^0,\ \ldots = \text{const},\ x = \text{const};\ T = \text{const}, \end{gathered} \tag{45}$$

where W_1 is the overall rate of the transformations of the starting material. This expression for a reaction in a gradient-free system[1] is identical with the expression for the integral selectivity—the ratio of the amount of the desired product to the overall amount of all the products.

The changes in selectivity during the process evidently depend on its nature, which is determined by the properties of the kinetic model and the rates of reaction via different pathways. These changes, caused by the form of the dependence of the reaction rates on the degree of conversion which follows from the given kinetic model, may be different for different selectivities.

Such instances reflect a parallel process mechanism (where the desired product does not undergo further transformations on being separated from the catalyst), or a consecutive mechanism (the desired product is partly returned to the surface and is converted into side products), or a parallel-consecutive mechanism (a combination of the first two mechanisms). The expression for the selectivity covering these instances follows from Eqns. (44) and (45)[156,157,198]:

$$S = \left(1 - \eta\frac{\Phi_{\mathrm{III}}(x_{\mathrm{III}})}{\Phi_{\mathrm{I}}(x_{\mathrm{I}})}\right) \Bigg/ \left(1 + \alpha\frac{\Phi_{\mathrm{II}}(x_{\mathrm{II}})}{\Phi_{\mathrm{I}}(x_{\mathrm{I}})}\right). \tag{46}$$

Here subscripts I, II, and III indicate the pathways leading to the formation of the desired product and the parallel and consecutive formation of side products, $\alpha = r_0^{\mathrm{II}}/r_0^{\mathrm{I}} = \text{const}$.

(i.e. the initial reaction rates via parallel pathways do not vary during the process), but $\eta = r_0^{\mathrm{III}}/r_0^{\mathrm{I}} \neq \mathrm{const.}$ (i.e. the initial rate of reaction via pathway III changes continuously owing to the changes in the concentration of the desired product); $\eta = 0$ for the parallel mechanism and $\alpha = 0$ for the consecutive mechanism.

Eqn. (46) indicates a direct relation between the form of the kinetic model and the changes in selectivity. From this it follows that the constancy of the selectivity during the process is possible only under certain conditions: (a) when the reaction proceeds in accordance with a zero-order equation via all the pathways (an unlikely case); (b) $\alpha \ll 1$ and $\eta \ll 1$ (i.e. reaction via the main pathway I predominates throughout the process) whereupon $S \simeq 1$; (c) when the process proceeds via a parallel mechanism, the kinetic equations for both pathways are identical, and there is no inhibition by the products.

Consequently the independence of the selectivity of the degree of conversion over a fairly wide range of the latter when S is appreciably different from unity may correspond only to a fully defined type of the kinetic model for the process. This is illustrated, for example, by the isotope exchange reaction in cyclohexane, discussed above, when its rates via all the parallel pathways are described by identical kinetic equations (Fig. 4). The properties of the kinetic model, characterised by identical kinetic equations in the absence of inhibition of the reaction via all the pathways by its products, determine the constancy of the ratios of the reaction rates via these pathways throughout the process. The latter is equivalent to the constancy of reaction selectivity for variable degrees of conversion [this should in its turn indicate the parallel formation of all the products, confirming the multistage mechanism (5)]. Evidently, the selectivity in the given instance serves as an additional factor whereby one can test and confirm the proposed kinetic model, which determines the observed characteristics of the selectivity (see also Butovskii et al.[182]).

An increase of selectivity during the processes is possible if the reaction via the required pathway is inhibited by its products to a lesser extent than via the remaining parallel pathways (for example, in the oxidation of cyclopentadiene[158]) or when the desired product is formed via several pathways and the formation of other products is inhibited by the initial substance. The latter case is observed in the oxidative ammonolysis of xylenes[159]. For example, isophthalonitrile is formed in this reaction from *m*-xylene in accordance with a second-order equation and the formation of extensive oxidation products is inhibited by the initial xylene, such products being obtained only from the initial xylene and the intermediate tolunitrile but not from the desired product (isophthalonitrile). One may therefore expect an increase of selectivity with increasing degree of conversion; this is in fact observed, which indicates the validity of the chosen kinetic model. Eqn.(46) shows that in other instances the selectivity should decrease during the process in conformity with numerous data[157].

Thus the properties of kinetic models determine to a significant extent the magnitude and nature of the changes in selectivity, which may be used in the analysis of kinetic relations.

Analysis of the changes in selectivity for processes described by different kinetic power equations is described in a book[199]. Golodets and coworkers[200-202] obtained and analysed expressions for the selectivity corresponding to the kinetic equations for certain oxidation reactions. The expressions can also be used in the analysis of kinetic models.

VII. ESTIMATION OF THE ACTIVITIES OF CATALYSTS OF COMPLEX REACTIONS

The problems associated with the tests, estimations, and comparison of the activities of catalysts are purely kinetic, since the only objective criterion of catalytic activity is the rate of reaction under the specified conditions and for the given composition of the reaction mixture[155,156,160,161]. For complex processes occurring via different pathways, the rate of accumulation of the desired product[156], i.e. the algebraic sum of the rates of reaction via independent pathways leading to its formation and decomposition, can serve as a criterion of the activity of catalysts. Since the rate of reaction depends on the degree of conversion, information about the rates of accumulation of the desired product for different compositions of the reaction mixture and for different conversions at the limits of the ranges of variation of the specified process parameters is desirable if sufficiently complete characteristics of the catalytic activity are to be obtained.

For objective tests and comparison of catalytic activities, exact measurements of the rate of reaction in the presence of distorting transport effects (and when internal-diffusion inhibition cannot be eliminated also with allowance for the latter) are necessary. It is useful to carry out such tests in gradient-free apparatus. The results of the tests can be expressed by "conversion curves"[48] relating the rate of reaction to the degree of conversion under specified initial process conditions.

The problem of tests of the activity of catalysts used under non-steady-state conditions is naturally more complicated. It requires the determination of the relation between the activity of the catalyst and various factors, particularly the duration of the continuous process, which depends in its turn on the concentration of impurities, the changes in the state of the catalyst as a consequence of the influence of the reaction system, etc. In this case it may be useful to combine tests in gradient-free apparatus with non-steady-state methods providing for the simultaneous monitoring of the state of the catalyst and the changes in the latter. Such methods are urgently required in preliminary studies and subsequent development [of the process?].

Exact tests and an objective estimate of catalytic activity and selectivity are evidently by no means easy and for complex reaction systems, for example for petroleum processing reactions, the problem is far from solution, although there are publications in this field[162,163]. However, despite the difficulties which must be faced in its solution (particularly in the case of tests of catalysts in non-steady-state processes), the magnitude of the problem is in no way comparable to the problem of devising kinetic models which requires a much greater expenditure of time and effort.

Despite this, further development of new effective and rapid methods for the testing of catalysts of complex reactions and the estimation of their activity and selectivity constitutes one of the most important problems of chemical kinetics in heterogeneous catalysis.

o0o

In conclusion one may note that further development of the theory and practice of heterogeneous catalysis will depend to a considerable extent on the strength of its kinetic foundation. It is based on informative kinetic models for various catalytic processes. The valuable information which can be derived from these models should help in understanding the essential features of catalytic activity and should extend the practical employment of catalysis. In order to set up such models, it is useful to carry out complex kinetic investigations. Although the methods for devising kinetic models and their analysis have been adequately developed, they require new approaches and further expansion, particularly for non-steady-state processes. The possibilities arising from complete, reliable, exact, and well-founded kinetic models, some of which were described above, make the task of their formulation and general treatment exceptionally important and necessary.

Oxidation-reduction Reactions of Free Radicals

I.V.Khudyakov and V.A.Kuz'min

The results of experimental studies on the oxidation-reduction reactions of free radicals with organic donors and acceptors and transition metal compounds involving one-electron transfer are surveyed. Attention is concentrated on studies performed in recent years (up to 1976 inclusive) in which the reactions of short-lived radicals have been investigated by pulse radiolysis, stopped flow, ESR, polarographic, and flash photolysis methods. The relation between the structures and reactivities of radicals in such porcesses and the methods for the measurement of their oxidation-reduction potentials are examined. Data on the formation of complexes of radicals with metal compounds are presented.

The bibliography includes 171 references.

VI. Reactions of radicals with metal compounds 32

I. INTRODUCTION

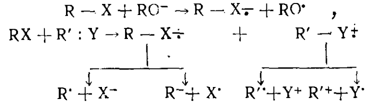
Various radical reactions proceed in the presence of metal compounds and electron donors and acceptors. Many of them are of biological importance and take place in living organisms. Free radicals, which have a high electron affinity, behave in most cases as vigorous oxidants. However, there are data suggesting that free radicals are in a certain sense amphoteric, i.e. are capable both of capturing an electron to form the carbanion and of transferring the unpaired electron to a sufficiently strong acceptor with formation of the corresponding cation[1]. Radical-ions are strongly involved in oxidation-reduction reactions, behaving as electron donors or acceptors (reactions with organic halides, initiation of polymerisation, exchange reactions, etc.).

There has been an increase of interest in recent years in the oxidation-reduction and complex-formation reactions of radicals in connection with the elucidation of the detailed mechanisms and kinetics of many homogeneous-catalytic processes, particularly liquid-phase oxidation reactions†. Emanuel' and coworkers[2-5] demonstrated the inhibiting or catalytic (depending on the conditions) effect of transition metal compounds on liquid-phase chain oxidation reactions of hydrocarbons.

The interaction of radicals with metal compounds, which are oxidation-reduction or complex-formation processes, has been postulated for a fairly long time. However, only in the last five-ten years numerous experimental data, demonstrating convincingly the occurrence of radical reactions of this class, have been obtained as a consequence of the development of the relevant experimental techniques. This review deals with the results of studies on oxidation-reduction and complex-formation reactions of radicals obtained mainly by the direct recording of the structure of the radicals and of the rates of their destruction. Attention has been concentrated on the reactions of short-lived radicals in the liquid phase.

II. ONE-ELECTRON OXIDATION (REDUCTION) OF RADICALS BY ORGANIC COMPOUNDS

It has been suggested that electron transfer is the elementary step in many organic reactions[1,6]. Numerous experimental data confirming this hypothesis have accumulated in recent years. Examples of the one-electron reduction reactions of organic compounds (R−X) are provided by the reactions with alkali metals, organic anions, or other organic electron donors (R′−Y):



$$R-X+Na\rightarrow R-X\overset{\cdot}{-}+Na^{+},$$
$$R-X+RO^{-}\rightarrow R-X\overset{\cdot}{-}+RO^{\cdot},$$
$$RX+R':Y\rightarrow R-X\dot{\div}\quad+\quad R'-Y\dot{+}$$
$$R-X\dot{\div}\rightarrow R^{\cdot}+X^{-}\ \text{or}\ R^{-}+X^{\cdot};\qquad R'-Y\dot{+}\rightarrow R'^{\cdot}+Y^{+}\ \text{or}\ R'^{+}+Y^{\cdot}$$

In certain cases several electrons can apparently be transferred in a single stage in oxidation-reduction reactions[7]. This hypothesis is based on the general postulate that a many-electron process taking place in one stage requires a smaller expenditure of energy than the overall energy required for the consecutive transfer of several electrons.

One-electron reduction (oxidation) reactions of molecules inevitably lead to the formation of radicals (radical-ions), which may be reduced (oxidised) in the presence of the same donors (acceptors). It has been convincingly demonstrated in many instances that the oxidation of organic compounds leads to the formation of radicals

---

† The 1st All-Union Symposium on "Oxidation-Reduction Reactions of Free Radicals", organised by the Scientific Councils for Chemical Kinetics and Structure of the USSR Academy of Sciences and the Ukrainian SSR Academy of Science jointly with the Pisarzhevskii Institute of Physical Chemistry of the Ukrainian SSR Academy of Sciences (Chairman of Organising Committee—Corresponding Member of the Ukrainian SSR Academy of Sciences V.D. Pokhodenko) was held in Kiev during October, 1976 [see G.A.Kovtun and I. I. Moiseev, Koord. Khim., 3, 4439 (1977)]).

which are then also oxidised. Thus under certain conditions phenols are oxidised via the reactions‡ [8]

$$\mathrm{PhOH} \xrightarrow{-e} \mathrm{PhO}^{\cdot} + \mathrm{H}^{+} \quad ,$$
$$\mathrm{PhO}^{\cdot} \xrightarrow{-e} \mathrm{PhO}^{+} \quad .$$
$$\mathrm{PhO}^{+} + \mathrm{PhOH} - \text{products} + \mathrm{H}^{+} \cdot$$

The oxidation of BPh_4^- proceeds as follows[9]:

$$\mathrm{BPh}_4^- \xrightarrow{-e} \mathrm{BPh}_4^{\cdot} \xrightarrow{-e} \mathrm{BPh}_4^+ \quad ,$$
$$\mathrm{BPh}_4^+ \rightarrow \mathrm{PhPh} + \mathrm{BPh}_2^+ \xrightarrow{\mathrm{H_2O}} \mathrm{Ph_2BOH} + \mathrm{H}^+ \quad .$$

The problem of the quantitative estimation of the ability of unstable radicals to be oxidised or reduced arises in this connection.

Owing to the development of pulse techniques for the investigation of fast reactions and particularly the wide availability of pulse radiolysis apparatus, it is now possible to measure fairly accurately the rate constants for electron transfer reactions involving radicals. Such reactions are important both for chemical kinetics and the chemistry of free radicals, on the one hand, and for testing the postulates of the electron transfer theory, on the other.

1. The Electron Transfer Theory

During the last three decades, electron transfer reactions (oxidation-reduction reactions) between metal complexes have been investigated vigorously. It has now become usual to divide them into reactions of the inner-sphere and outer-sphere types (see, for example, Refs. 10 and 11). The inner-sphere electron transfer between reactants X and Y can be represented as follows in a general form:

$$\mathrm{X} + \mathrm{L} + \mathrm{Y} \rightleftarrows \mathrm{XL} + \mathrm{Y} \quad ,$$
$$\mathrm{XL} + \mathrm{Y} \rightleftarrows \mathrm{XLY} \quad ,$$
$$\mathrm{XLY} \rightleftarrows {}^{-}\mathrm{XLY}^{+} \quad ,$$
$${}^{-}\mathrm{XLY}^{+} \rightleftarrows \mathrm{X}^{-} + \mathrm{LY}^{+} \quad ,$$
$$\mathrm{X}^{-} + \mathrm{LY}^{+} \rightleftarrows \mathrm{X}^{-} + \mathrm{L} + \mathrm{Y}^{+} \quad ,$$

where L is the third species, constituting a binding ligand (usually an anion).

In inner-sphere electron transfer reactions the transition state is formed in such a way that the L species plays the role of a "bridge" between two metal centres, ensuring a pathway for electron transfer. There is then a possibility of the simultaneous dissociation (or formation) of a bond between the inner orbitals of the metal ion (usually between the d orbitals). An alternative electron transfer mechanism does not require the presence of a binding ligand and the formation (dissociation) of new bonds and is referred to as the outer-sphere mechanism§.

In certain cases (see, for example, Thornton and Laurence[13]) one distinguishes reactions in the inner sphere where the rate-limiting stage is either substitution:

$$\mathrm{M}^{n+}\mathrm{X}_m + \mathrm{L} \xrightarrow{\text{slow}} \mathrm{M}^{n+}\mathrm{X}_{m-1}\mathrm{L} \xrightarrow{\text{fast}} \mathrm{M}^{(n+1)+}\mathrm{X}_{m-1}\mathrm{L}^-$$

or electron transfer:

$$\mathrm{M}^{n+}\mathrm{X}_m + \mathrm{L} \xrightarrow{\text{fast}} \mathrm{M}^{n+}\mathrm{X}_{m-1}\mathrm{L} \xrightarrow{\text{slow}} \mathrm{M}^{(n+1)+}\mathrm{X}_{m-1}\mathrm{L}^- \quad .$$

The ideas developed for electron transfer between metal complexes have been applied to electron transfer reactions between metal complexes and organic compounds and between organic molecules.

Criteria have been put forward for the determination of the electron transfer mechanism[12,14]. It is extremely likely that the reaction is of the outer-sphere type if the observed rate is higher than the rate at which ligands are substituted in the species being reduced (oxidised). There are also indirect methods for the determination of the electron transfer mechanism[14]. The necessity to know the electron transfer mechanism is due to the fact that a change in the structure of the metal ion or ligand leads to different types of influence on the rate of electron transfer depending on the reaction mechanism.

From the theoretical standpoint, the mechanism of outer-sphere electron transfer reactions is simpler and the theory of such reactions is developing successfully[15,16] The Marcus theory[17-21] is widely used nowadays for the analysis of experimental data for electron transfer in the outer sphere. According to this theory, the rate constant for the reaction determining the rate of the outer-sphere electron transfer,

$$A^m + B^n \underset{k_{ba}}{\overset{k_{ab}}{\rightleftarrows}} A^{m-1} + B^{n+1} \quad ,$$

is given by the following equation:

$$k_{ab} = Z_{ab} \exp(-\Delta G^*/RT), \tag{1}$$

where Z_{ab} is the frequency factor (~10^{11} litre mole^{-1} s^{-1}) and ΔG^* the free energy of activation. The following relation holds for ΔG^*:

$$\Delta G^* = W + \frac{1}{4}\lambda + \frac{1}{2}\Delta G^0_{ab} + \frac{1}{4\lambda}(\Delta G^0_{ab})^2, \tag{2}$$

where W is the Coulombic term expressing the difference between the amounts of work which must be expended to join and separate reactants A^m and B^n, λ the free energy of the rearrangement of the polarised solvent associated with the change in the nature of the spatial distribution of charges on electron transfer, and ΔG^0 the standard free energy of reaction. In electron transfer reactions between radicals and organic molecules one of the reactants is in most instances uncharged and W may be regarded as zero. Eqn. (2) then simplifies:

$$\Delta G^* = \frac{1}{4}\lambda(1 + \Delta G^0_{ab}/\lambda)^2.$$

For the oxidation (reduction) of radical-ions by the initial molecules, we have

$$\Delta G^0_{ab} = 0 \quad \text{and} \quad \Delta G^* = \frac{1}{4}\lambda. \tag{3}$$

If the rate of reaction approaches the diffusional rate, the following expression is used for the observed constant k_{ab}:

$$k_{ab} = k_{\text{diff}}\ k_{\text{act}}/(k_{\text{act}} + k_{\text{diff}}), \tag{4}$$

where k_{act} is the reaction rate constant according to Eqn. (1). If it is assumed that the contribution to the parameter λ is due solely to the reorientation of the solvent molecules, one can estimate the reaction radius r_{ab} by means of the equation[17-21]

$$\lambda_0 = \left(\frac{1}{2r_a} + \frac{1}{2r_b} - \frac{1}{r_{ab}}\right)\left(\frac{1}{D_O} - \frac{1}{D_s}\right)(\Delta ze)^2, \tag{5}$$

where Δz is the number of electrons transferred, r_a and r_b are the polarisation radii of the reactants, D_O is the optical dielectric constant of the solvent (the square of the

---

§ It has been suggested[12] that the first mechanism be called the "bonded mechanism" and the second the "non-bonded mechanism" in order to avoid confusion in terminology in connection with the inner-sphere and outer-sphere association of species. However, the generally accepted terminology will be used in the present review.

refractive index), and D_S is the static dielectric constant. It is usually assumed that[22]

$$r_a = r_b = \frac{1}{2} r_{ab}.$$

2. Reactions of Radicals with Nitro-compounds and Other Oxidants

Free radicals are known to react with various electron acceptors—quinones, dyes, nitro-compounds, etc. The study of the reactions of radicals with organic nitro-compounds is of undoubted interest for the elucidation of the mechanism of the radiation-initiated processes in chemical and biological systems. It is suggested that compounds with a sufficiently high electron affinity, particularly aromatic and heterocyclic nitro-compounds, are radiation stabilisers even at low concentrations as a result of secondary reactions involving radicals formed in the biological "targets"[23,26]. The reactions of organic radicals with nitrobenzene, nitromentane, etc. have been investigated by pulse radiolysis and ESR combined with pulse irradiation or the $Ti^{4+}-H_2O_2$ flow system[29-32]. It has been shown that such interactions may involve both addition and electron transfer reactions, the relative contributions of which depend on the nature of the organic radical, the nitro-compound, and the pH of the medium. For example, aliphatic hydroxy-radicals are ionised in an alkaline medium and electron transfer predominates; in neutral solutions, addition to the aromatic ring or the nitro-group is observed together with electron transfer[24].

It has been shown by ESR that α-hydroxy- and α-alkoxy-radicals give up an electron to suitable acceptors[28-30,32]. Alkyl radicals, β-hydroxy-radicals, $OH^{\cdot}$, and $NH_2^{\cdot}$ react with electron acceptors mainly via the addition mechanism[29,33-35].

In the general case radicals participate in oxidation reactions and reactions involving addition to the acceptor. The change in the relative contributions of these reactions as a function of the radical structure can be accounted for by the change in the electron-donating capacity of the radical. It is believed that the electron-donating capacity is characterised by the stability of the carbonium ions obtained from the radicals, which increases in the sequence[30]

$$^{+}CH_2OH < CH_3\overset{+}{C}HOH < (CH_3)_2\overset{+}{C}OH \quad .$$

The tendency towards electron transfer then varies in the sequence[24]

$$(CH_3)_2\dot{C}O^- > CH_3\dot{C}HCO^- > \dot{C}H_2O^- > (CH_3)_2\dot{C}OH > CH_3\dot{C}HOH > \dot{C}H_2OH \quad .$$

The reducing capacity of radicals diminishes in the sequence[25,37]

$$CO_2^{\overline{\cdot}} > (CH_3)_2\dot{C}OH > CH_3\dot{C}HOH > \dot{C}H_2OH \quad .$$

Various organic radicals may be oxidised by hydrogen peroxide and other peroxides[53]. For example:

$$\dot{C}O_2H + (CH_3)_3COOR \rightarrow H^+ + CO_2 + (CH_3)_3C\dot{O} + RO^- \quad .$$

$[R = H$ or $C(CH_3)_3]$. It has been suggested that oxygen may oxidise certain organic radicals via one-electron transfer[53]:

$$R^{\cdot} + O_2 \rightarrow R^+ + O_2^{\overline{\cdot}} \quad .$$

The one-electron oxidation of radicals by oxygen competes with the addition reaction—the formation of a peroxy-radical[53]:

$$R^{\cdot} + O_2 \rightarrow RO_2^{\cdot} \quad .$$

The radical-anions of aromatic compounds and certain quinones also react with oxygen via electron transfer[66,87]:

$$R^{\overline{\cdot}} + O_2 \rightarrow R + O_2^{\overline{\cdot}} \quad .$$

It has been established that the ability of radicals to transfer an electron to O_2 and H_2O_2 varies in the sequence[53]

$$^{\cdot}CO_2H > (CH_3)_2\dot{C}OH > \dot{C}H_2OH > \dot{C}H_2C\,(CH_3)_2OH,$$
$$\dot{C}H_2CH\,(CH_3)\,OH \quad .$$

$CO_2^{\overline{\cdot}}$, a strong reductant, is involved in reductive elimination reactions with various alkyl halides RX:[54]

$$CO_2^{\overline{\cdot}} + RX \rightarrow CO_2 + R^{\cdot} + X^- \quad .$$

One-electron reactions in which $CO_3^{\overline{\cdot}}$ is oxidised by duroquinone, benzoquinone, and 2-methylnaphthoquinone have been discovered[162,167]:

$$\begin{tikzcd}[column sep=small] CO_3^{\overline{\cdot}} + Q \arrow[r] & CO_3 \arrow[dl] \arrow[dr] & + Q^{\overline{\cdot}} \\ CO_2 & + & 1/2O_2 \quad . \end{tikzcd}$$

The kinetics of electron transfer reactions between radicals and electron acceptors have been investigated mainly by pulse radiolysis. The course of the reaction can then be followed from the accumulation of the acceptor radicals, which usually absorb light in a spectral region convenient for recording. A study has been made[23] of the oxidation of the radicals obtained from alcohols by aromatic nitro-compounds. The rate constants for the radical oxidation adduct formation reactions increase with increase of the oxidation-reduction potential of the acceptor. This behaviour appears to be fairly general (see end of Section III). However, when the differences between the oxidation-reduction potentials of the acceptors E^0 are fairly small (for example, amounting to several hundredths or tenths of a volt) and the reaction kinetics approach diffusion kinetics, there may be no correlation (see also the end of Section IV, subsection 1). A relation between the rate constants for electron transfer from $O_2^{\overline{\cdot}}$, $\dot{C}H_2OH$, and $\dot{C}H_2O$ to quinones with a similar structure, on the one hand, and E^0 for the acceptor, on the other, has not been observed in a number of studies[38-40,47].

Many radicals which are important from the biological point of view react with vitamin K_3.[41] The reactions have been investigated by pulse radiolysis. Under the experimental conditions (low doses and low radical concentrations) the rate constants for the reactions of the majority of radicals with vitamin K_3 are $k \geqslant 2 \times 10^8$ litre mole^{-1} s^{-1}¶. More than 90% of the initial radical concentration is then consumed by reaction with the vitamin. Certain radicals are hardly involved in the electron transfer reaction ($k \ll 1 \times 10^8$ litre mole^{-1} s^{-1}) and participate either in the addition to the vitamin or react with one another. The cause of this may also consist in the formation of several types of radicals with different values of E^{01} under the influence of the electron pulse[41].

It has been established that certain oxidation-reduction reactions of aromatic radicals are reversible[22,66,72,157,166]. The semiquinone radical-anions $Q^{\overline{\cdot}}$ are reversibly oxidised by nitroimidazoles S and quinones[72,157]:

$$Q^{\overline{\cdot}} + S \rightleftarrows Q + S^{\overline{\cdot}} \quad ,$$

$$Q_i^{\overline{\cdot}} + Q_j \rightleftarrows Q_i + Q_j^{\overline{\cdot}} \quad .$$

Different radicals of pyridine derivatives, including the product of the one-electron reduction of nicotinamide-adenine dinucleotide ($NAD^{\cdot}$) participate in reversible

---

¶ The constants obtained at room temperature are quoted in this review.

reactions involving electron transfer from flavin-adenine dinucleotide (FAD):[160]

$$\mathrm{NAD^{\cdot} + FAD \rightleftharpoons NAD^{+} + FAD^{\cdot -}}$$

The kinetics of numerous electron transfer reactions with participation of free radicals, investigated mainly by pulse radiolysis, have been analysed[22]. It has been established that the experimental data obey the Marcus theory; a satisfastory correlation has been found between $\lg k_{ab}$ and ΔG^{0}_{ab} with $\lambda \simeq 18$ kcal mole^{-1}.[22] Three groups of reactions with participation of radical-anions were examined:

$$\mathrm{O_2^{\cdot -} + Q \rightleftarrows O_2 + Q^{\cdot -}}$$

$$\mathrm{RNO_2^{\cdot -} + DQ \rightleftarrows DQ^{\cdot -} + RNO_2}$$

$$\mathrm{Q^{\cdot -} + Q^{\cdot -} \rightleftarrows Q + Q^{2-}} \text{ (disproportionation of semiquinones),}$$

where Q are 1,4-quinones, $\mathrm{RNO_2^{\cdot -}}$ are aromatic radical-anions, and DQ is duroquinone.

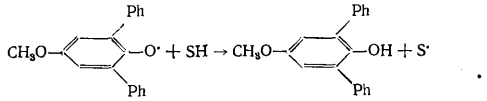
Using Eqn.(5), $r_{ab} \simeq 10$ Å, which is the distance between the centres of the reactants in the transition state for which electron transfer takes place in the given reactions, was obtained.

3. Radical Reduction Reactions

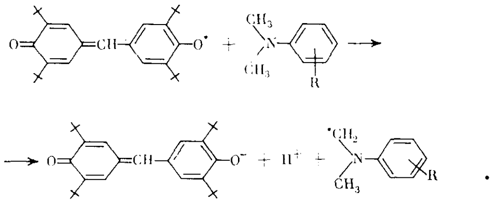
The simplest example of radical reduction reactions is the abstraction of a hydrogen atom from a suitable substrate:

$$\mathrm{R_1^{\cdot} + R_2H \rightarrow R_1H + R_2^{\cdot}} \quad . \qquad (6)$$

Reactions of type (6) have been investigated in detail in studies on liquid-phase chain oxidation reactions of hydrocarbons[2]. Reaction (6) with $\mathrm{R_1^{\cdot} = OH^{\cdot}}$ constitutes a common method for the generation of various free radicals (see Section VI, Subsection 1)†. Phenoxy-radicals are capable of being reduced to phenols by oxidising solvents containing mobile hydrogen atoms, for example[42]:



It has been shown[43-46] that stable phenoxy-radicals oxidise organic compounds without mobile H atoms via electron transfer:



(7)

Galvinoxy- and indophenoxy-radicals are reduced to the corresponding phenoxide ions by reaction with $\mathrm{OH^-}$ and

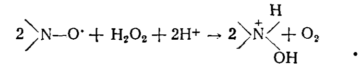
.[85,103]

The inorganic radical species $\mathrm{SO_4^{\cdot -}}$, $\mathrm{CO_3^{\cdot -}}$, $\mathrm{\dot{C}O_3H}$, and $\mathrm{Br_2^{\cdot -}}$ oxidise disulphides[137], and $\mathrm{Br_2^{\cdot -}}$, $\mathrm{CO_3^{\cdot -}}$, and $\mathrm{(SCN)_2^{\cdot -}}$ oxidise tryptophan[163]. These reactions proceed via one-electron transfer. The quenching of the triplet state of pyrene in micelles by the radical-anion $\mathrm{Br_2^{\cdot -}}$ involves the same mechanism[171]:

$$\mathrm{{}^{3}P_{\mathit{mic}} + Br_2^{\cdot -} \rightarrow P^{+}_{\mathit{mic}} + 2Br^{-}} \quad .$$

The radical obtained when e^{-}_{aq} interacts with $\mathrm{SF_6}$ (tentatively identified as $\mathrm{SF_5^{\cdot}}$) is an extremely powerful oxidant, more active than $\mathrm{SO_4^{\cdot -}}$ and $\mathrm{Cl^{\cdot}}$ [159]. It can be used for the effective generation of other free radicals.

In an acid medium nitroxy-radicals are powerful oxidants. The 2,2,6,6-tetramethylpiperidinyloxy-radical oxidises $\mathrm{H_2O_2}$.[84] The overall reaction equation is

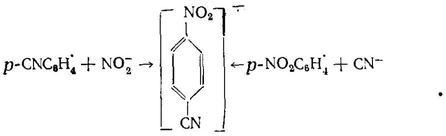


$$2\,{>}\mathrm{N{-}O^{\cdot} + H_2O_2 + 2H^{+} \rightarrow 2\,{>}\overset{+}{N}(H)(OH) + O_2} \quad .$$

In the presence of various anions, active free radicals participate in competing reactions[48]:

$$\mathrm{R^{\cdot} + A^{-}} \begin{cases} \xrightarrow{a} \mathrm{[R-A]^{\cdot -}} & (8a) \\ \xrightarrow{b} \mathrm{R^{-} + A^{\cdot}} \quad . & (8b) \end{cases}$$

The relative contributions of reactions (8a) and (8b) depend on many factors—the stability of the radical-anion $\mathrm{[R{-}A]^{\cdot -}}$ and the ease of the oxidation of $\mathrm{A^-}$ and the reduction of $\mathrm{R^{\cdot}}$. The unsubstituted phenyl radical adds to $\mathrm{NO_2^-}$ or to $\mathrm{(CH_3)_2C{=}NO_2^-}$, forming the $\mathrm{[R{-}A]^{\cdot -}}$ species, which have been detected by ESR. *p*-Nitrophenol or *p*-cyanophenyl radicals possess powerful electron-accepting properties and, in the presence of a readily oxidisable species $\mathrm{A^-}$, reaction (8b) takes place. The $\mathrm{NO_2^-}$ and $\mathrm{CN^-}$ species, which are more resistant to oxidation, react with these radicals via reaction (8a):



Many organic synthetic reactions involve the competing processes (8a) and (8b) as the intermediate stage[48].

The equilibrium

$$\mathrm{[R-A]^{\cdot -} \rightleftarrows R^{-} + A} \qquad (9)$$

may be postulated. Electron transfer then takes place with the preliminary formation of $\mathrm{[R{-}A]^{\cdot -}}$, i.e. via reactions (8a) and (9).

4. Oxidation (Reduction) of Radical-anions by the Initial Compounds

The kinetics of electron exchange reactions between organic molecules and the corresponding radical-anions and radical-cations are usually investigated by ESR; the radicals are then generated by various methods, for example by electrochemical reduction (oxidation)[49-51].

The reactions of phenothiazine, 10-methylphenothiazine, phenoxazine, and phenoxanthine radical-cations have been investigated[51]. Much attention has been devoted to the radical-anions derived from compounds such as benzonitrile, phthalonitrile, terephthalonitrile, pyromellitonitrile, 4-cyanopyridine, and a number of others. The ability of the initial neutral molecules to accept an electron is characterised by the rate constant for the reaction

$$\mathrm{R^{\cdot -} + R \xrightarrow{k_{10}} R + R^{\cdot -}} \qquad (10)$$

and the ability to give up an electron is characterised by the constant k_{11}:

$$\mathrm{R^{\cdot +} + R \xrightarrow{k_{11}} R + R^{\cdot +}} \quad . \qquad (11)$$

---

† In many instances (for example, when $\mathrm{R_2H}$ is an aromatic compound) the formation of $\mathrm{H_2O}$ and $\mathrm{R_2^{\cdot}}$ is preceded by the formation of the adduct $\mathrm{HOR_2H}$.

The above assumption is equivalent to the hypothesis that there is a correlation between the values of $\lg k_{10(11)}$ and certain quantities which may be either calculated or measured. The ability of the molecule to accept an electron is associated with its electron affinity, which in the simplest molecular orbital method is believed to be equal to $-E$, E being the energy of the lowest vacant orbital of the initial molecule. The quantity $\lg k_{10}$ should also be correlated with the electrochemical reduction half-wave potentials $E_{1/2}$. Analogous correlations are to be expected between the values of $\lg k_{11}$, the energies of the highest occupied molecular orbitals (HOMO) of R, and the corresponding oxidation potentials.

Entirely satisfactory correlations have been found between $\lg k_{11}$ and E_{HOMO} and between $\lg k_{11}$ and $E_{1/2}$.[51] Such correlations show that the energy required to remove an electron from the initial molecule may have a decisive influence on k_{11}. An analogous correlation has been obtained for reaction (10) between $\lg k_{10}$ and $E_{1/2}$. Solvation apparently plays an important role for radical-anions and it is not surprising that the values of $\lg k_{10}$ are better correlated with experimental high-wave potentials $E_{1/2}$.[51]

In the electron exchange between a quinone and the corresponding semiquinone, i.e.

$$Q^{\overline{\cdot}} + Q \rightleftarrows Q + Q^{\overline{\cdot}}$$

no correlation was observed between the rate of electron exchange and the reduction potential of the quinone[157], with no change in geometry in the course of the reaction; the authors[157] believe that the correlations observed[51] between $\lg k_{10}$ and $E_{1/2}$ reflect certain geometrical changes following electron transfer from radical-anions to the initial molecule.

The change in the geometry of the species during the reaction can have a significant influence on the rate constant for electron transfer. For example, the rate constant for the reaction involving cyclo-octatetraene

$$R^{\overline{\cdot}} + R^{2-} \rightarrow R^{2-} + R^{\overline{\cdot}} \tag{12}$$

is $k_{12} \simeq 10^9$ litre mole^{-1} s^{-1}, while $k_{10} \simeq 10^5$ litre mole^{-1} s^{-1} or less[52]. The difference is probably caused by the fact that the $R^{\overline{\cdot}}$ and R^{2-} species derived from the given molecule are planar while R is non-planar[52].

It is possible to estimate theoretically the rate constant for the electron exchange between the initial molecule and the radical-ion in water. Using Eqns.(1) and (3) and the value $\lambda \simeq 18$ kcal mole^{-1},[22] one obtains $k_{10(11)} \simeq 5 \times 10^7$ litre mole^{-1} s^{-1}. Indeed, $k_{10} = 1 \times 10^7$ litre mole^{-1} s^{-1} has been found for the radical-anion $(CH_3)_2CO^{\overline{\cdot}}$.[22] $k = 1 \times 10^8$ litre mole^{-1} s^{-1} for the exchange between the phenoxy-radical and the phenoxide ion[22]. The exchange reaction between the nitromethane radical-anion and nitromethane has a rate constant $k_{10} < 3 \times 10^5$ litre mole^{-1} s^{-1}.[22] Such a low value of k_{10} is probably due to the significant geometrical changes accompanying the radical-anion–molecule transition. The upper limit to the values of k_{11} for the reaction

$$H^+ + H \rightleftarrows H + H^+$$

is 5×10^5 litre mole^{-1} s^{-1}. The low value of k_{11} is associated with the extremely high solvation energy of H^+.[22]

5. The Influence of the Solvent on Electron Transfer Reactions

Reactions (10) and (11) take place between species which are dipoles and between an ion and a dipole. In a solution with a macroscopic dielectric constant D the interaction energy between an ion and a dipole is expressed as follows:

$$E_{13} = ze\mu \cdot \cos(\theta/Dr^2), \tag{13}$$

where μ is the permanent dipole moment and ze the ionic charge; the orientations of the ion and the dipole are illustrated in Fig.1; $E_{13} = E_{\max}$ when $\theta = 0$. The interaction energy between two dipoles reaches a maximum when they are arranged "head-to-tail" along a straight line:

$$E_{14} = -\frac{2\mu_1\mu_2}{Dr^3} \quad . \tag{14}$$

The maximum interaction energy between a dipole-anion and a dipole is then given by the expression

$$E_{15} = -\mu_1\left(e + \frac{2\mu_2}{r}\right)\Big/Dr^2 \quad . \tag{15}$$

For example, $E_{15} = 1.0$ kcal mole^{-1} is obtained for $\mu_1 = \mu_2 = 4D$, $r = 4$ Å, and $D = 35$, and we have $E_{13} = \frac{2}{3}E_{15}$.[51]

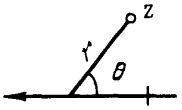


Figure 1. The mutual orientation of the ion and the dipole.

One may assume that the rate constant for electron transfer is given by the equation

$$k = Ae^{-(E_a + E_{15}/RT)} , \tag{16}$$

where A is independent of the solvent and E_a incorporates all other factors contributing to the activation energy which are independent of the solvent[51]. One can then write $k = Z'e^{-E_{15}/RT}$ $(Z' = Ae^{-Ea})$ or

$$\ln k = \ln Z' + \mu_1(e + 2\mu_2/r)/RTDr^2. \tag{17}$$

Eqn.(17) predicts a decrease of the rate constant with increase of the dielectric constant of the solvent. Such a tendency has been observed for reactions (10) and (11) in many solvents, with the exception of dioxan[51]. However, one must bear in mind that dioxan has a very low dielectric constant ($D = 2$); the formation of bound ion pairs in such a solvent may play a significant role and may affect the constant.

If the values of $\mu(R)$ and $\mu(R^{\overline{\cdot}})$ are known‡, it is possible to obtain from the experimental relations (17) the distance r between the reactants for which electron transfer takes place. Thus $r \simeq 4$ Å has been obtained for the benzonitrile radical-anion[51].

A study of the unimolecular reaction

$$^{\overline{\cdot}}NfCH_2 - C_6H_{10} - CH_2Nf \rightleftarrows NfCH_2 - C_6H_{10} - CH_2Nf^{\overline{\cdot}}$$

(Nf = α-naphthyl; the $NfCH_2$ substituents are in the 1,4-positions in cyclohexane) established that electron transfer requires the mutual approach of the naphthalene rings to a distance not greater than 7–9 Å.[50] The authors believe

---

‡ It is sometimes assumed that $\mu(R^{\overline{\cdot}}) = \mu(R)$.[51]

that electron transfer does not require a close approach of the reactants, in contrast to the reactions involving the formation of excimers, exciplexes, and charge-transfer complexes.

The electron exchange reaction between benzoquinone (duroquinone) and the corresponding semiquinone (durosemiquinone) involves a radius of 5–6 Å; the molecular radii of the species are smaller approximately by 1.5 Å. Presumably a monomolecular solvation shell remains around the reacting species at the instant of electron transfer[157].

The Marcus theory may be tested by studying the influence of the solvent on $k_{10(11)}$. Since in many instances the values of $k_{10(11)}$ are comparable to those of k_{diff}, it is useful to employ Eqn.(4). It follows from Eqns.(3) and (5) that $\lg k_{10(11)}$ should increase with decrease of the parameter $D_{\text{o}}^{-1} - D_{\text{s}}^{-1}$. However, the experimental values of $\lg k_{\text{obs}}$ and $\lg k_{\text{ab}}$ decrease as the above parameter diminishes[51]. In the Marcus theory Z is independent of the solvent. Nevertheless, there is a satisfactory linear correlation between $\lg k_{\text{obs}} - \lg k_{\text{diff}}$ and $D_{\text{o}}^{-1} - D_{\text{s}}^{-1}$; the corresponding plot has a negative slope[51]. Thus in many cases agreement between experiment and the Marcus theory requires the introduction of additional parameters, in particular, one must assume that the frequency factor depends on the solvent.

The influence of the solvent on the kinetics of reaction (10) has been investigated[49] using the radical-anion derived from *N*-(n-butyl)phthalimide as $\text{R}^{\overline{\cdot}}$. It was observed that k_{10} depends little on the solvent (hexamethylphosphoramide, 1,2-dimethoxyethane, dimethylformamide, acetonitrile, and propionitrile) despite the marked differences between the solvent viscosities and it was found that $k_{10} \simeq 3 \times 10^8$ litre mole^{-1} s^{-1}, which is less than k_{diff} for all the solvents and is close to its value for hexamethylphosphoramide. The activation energies E_{10} are higher by approximately 1 kcal mole^{-1} than the corresponding activation energies for the viscous flow of the solvents. The comparatively high values of E_{10} imply that the ions are surrounded by weakly oriented solvent molecules, which undergo a rearrangement in the transition state. The reaction is slower in 1,2-dimethoxyethane than in the other solvents; E_{10} is greater than the activation energy for the viscous flow of this solvent by 1.6 kcal mole^{-1}, which can be accounted for by the formation of ion pairs in this ether[49]. The above effect can be observed in other solvents when the concentration of the supporting electrolyte is increased[49].

The polarity of the medium has a significant influence on the kinetics of the one-electron reduction of the galvinoxy- and indophenoxy-radicals by substituted amines [reaction (7)].[43] The rate of reaction increases with increase of the polarity of the medium, so that the dipole moment of the activated complex in the transition state is greater than the sum of the dipole moments of the reactants. The experimental values of k_7 are described satisfactorily by the relation[43]

$$\lg k_7 = \lg k_0 - \frac{A}{T} \cdot \frac{D-1}{2D+1},$$

where A is the constant.

The influence of solvent (water–alcohol) composition on the kinetics of the following reactions has been investigated by pulse radiolysis[55]:

$$\text{CH}_3\text{CHO}^{\overline{\cdot}} + \text{C}_6\text{H}_5\text{NO}_2 \rightarrow \text{CH}_3\text{CHO} + \text{C}_6\text{H}_5\text{NO}_2^{\overline{\cdot}} \quad ,$$

$$\text{CH}_3\text{C}_6\text{H}_5\text{CO}^{\overline{\cdot}} + \text{C}_6\text{H}_5\text{NO}_2 \rightarrow \text{CH}_3\text{C}_6\text{H}_5\text{CO} + \text{C}_6\text{H}_5\text{NO}_2^{\overline{\cdot}} \quad ,$$

$$\text{CH}_3\text{CHO}^{\overline{\cdot}} + (\text{C}_6\text{H}_5)_2\text{CO} \rightarrow \text{CH}_3\text{CHO} + (\text{C}_6\text{H}_5)_2\text{CO}^{\overline{\cdot}} \quad ,$$

$$\text{CH}_3\text{C}_6\text{H}_5\text{CO}^{\overline{\cdot}} + (\text{C}_6\text{H}_5)_2\text{CO} \rightarrow \text{CH}_3\text{C}_6\text{H}_5\text{CO} + (\text{C}_6\text{H}_5)_2\text{CO}^{\overline{\cdot}} \quad .$$

The rate constants for these reactions in water vary from 8×10^8 to 3×10^9 litre mole^{-1} s^{-1}, which is close to the value of k_{diff}.[56] The solvent was found to have a stronger influence on slow reactions than on fast reactions. There is no regularity in the influence of the solvent on the rate of reactions with the same functional groups and the kinetic parameters of reactions vary in a complex manner with the composition of the binary mixtures[55]. The observed relations cannot be accounted for with the aid of the Marcus theory. In this and other electron transfer theories the activation energy required for the reaction refers solely to the ion–solvent interaction, the solvent being regarded as a continuum[15,17,19]. It appears that a deeper understanding of the influence of the solvent on the rate of electron transfer requires allowance for the microscopic properties of the solvent surrounding the reaction species[55].

III. OXIDATION–REDUCTION POTENTIALS OF FREE RADICALS

The knowledge of the one-electron oxidation-reduction potentials of radicals (E^{01} at pH 7.0 and approximately 25°C) could serve as a basis for the prediction of the directions and rates of the oxidation-reduction reactions of these species. Waters and Mackinnon[58] noted the important role of the oxidation-reduction potentials in the elucidation of the directions of radical reactions. They suggested that free radicals and the corresponding cations or anions form pairs of reversible oxidation-reduction systems, i.e.

$$\text{R}^{\cdot} \rightleftarrows \text{R}^{+} + \text{e}; \quad \text{R}^{\cdot} + \text{e} \rightleftarrows (\text{R:})^{-}$$

to which correspond two different oxidation-reduction potentials $E_{(-\text{e})}$ and $E_{(+\text{e})}$. A simple procedure was proposed for the estimation of $E_{(-\text{e})}$. The radicals which are involved in the chain oxidation of the initial compound RH by Fenton's reagent take part in the reaction[58]

$$\text{R}^{\cdot} + \text{Fe}^{3+} \rightarrow \text{R}^{+} + \text{Fe}^{2+}; \quad \text{R}^{+} + \text{H}_2\text{O} \rightarrow \text{ROH} + \text{H}^{+} .$$

Consequently $E_{(-\text{e})} < 0.74$ V for these radicals. (The potential of the $\text{Fe}^{2+}|\text{Fe}^{3+}$ pair is +0.74 V at pH 0.[58])

The ability of the radical to be oxidised has been studied in connection with investigations of the mechanism of the Kolbe electrosynthesis[59,60]. During this process, the oxidation of the carboxylate ion at the anode

$$\text{RCOO}^{-} \rightarrow \text{R}^{\cdot} + \text{CO}_2 + \text{e}^{-}$$

is followed by further oxidation of $\text{R}^{\overline{\cdot}}$ to the carbonium ion:

$$\text{R}^{\cdot} \rightarrow \text{R}^{+} + \text{e}^{-}, \tag{18}$$

provided that the ionisation potential I of the radical is less than 8 eV.[59] A linear relation has been observed between I (determined by the electron impact method) and the potential of the electrode at which reaction (18) takes place[59]. (One should also note that there is a linear correlation between the values of I for radicals, determined by the electron impact method, and the energies of the highest occupied molecular orbitals[59].)

In many cases the values of E^{01} can be calculated from known thermodynamic quantities. $E^{01}(\text{CO}_2|\text{CO}_2^{\overline{\cdot}}) = -1.8$ V [170] and $E^{01}(\text{O}_2|\text{O}_2^{\overline{\cdot}}) = -0.16$ V [150] were evaluated in in this way.

The experimental determination of the values of E^{01} for short-lived free radicals involves certain difficulties associated with the necessity to generate radicals and to measure the values of E^{01} rapidly before the radicals are destroyed.

The potentials E^{01} for the reactions of short-lived radicals with electron acceptors and donors have been determined[39,61-64], using mainly dyes and quinonoid compounds as acceptors. The study of the interaction of dyes with radicals is of special interest, since various photochemical and radiation-chemical one-electron reduction reactions of dyes yield substrate radicals capable of reacting with the dye molecules. The proposed method is based on the investigation of the ability of the free radicals $^{\cdot}RH$ to participate in electron transfer reactions with various acceptors A, whose oxidation-reduction potentials are known:

$$^{\cdot}RH + A \rightleftarrows R + A^{\cdot-} + H^+ \quad . \tag{19}$$

Depending on the pH of the aqueous solution, the radical species $^{\cdot}RH$ or $A^{\cdot-}$ were found to exist either in the acid or basic form:

$$^{\cdot}RH \rightleftarrows R^{\cdot-} + H^+ \quad ,$$
$$^{\cdot}AH \rightleftarrows A^{\cdot-} + H^+ \quad .$$

The studies were performed by pulse radiolysis and kinetic spectrophotometry. The course of reaction (19) was monitored by following the formation of $A^{\cdot-}$ (or the protonated form $^{\cdot}AH$) or the "decolorisation" of the acceptor (usually a dye in such cases).

It was observed that the plot of the efficiency of electron transfer, expressed as a percentage, against E^0 for the acceptors (donors) is a curve analogous to a titration curve (Fig. 2*a*). The value of E^0 corresponding to 50% electron transfer was used to calculate E^{01} for the radical[39,52-64]. Thus one-electron potentials were obtained by means of a comparison with the known two-electron potentials, which is not entirely correct. If a correlation is observed between the two-electron potentials and any parameter associated with the one-electron transfer (such as the rate of electron transfer or the energy of the lowest vacant orbital), this implies in essence that in the given instance there is a correlation between the one- and two-electron potentials[164].

Furthermore, in the calculation of E^{01} it was implicitly assumed that equilibrium (19) can be attained and the Nernst equation was used. However, additional experiments showed that there is insufficient time for the attainment of equilibrium (19) during the experimental time interval. For example, the oxidation of the lactic acid radical,

$$CH_3\dot{C}(OH)COO^- + A \rightarrow CH_3COCOO^- + A^{\cdot-} + H^+$$

leads to the formation of pyruvate ions, but the observed rate of formation of the radicals $A^{\cdot-}$ is independent of $[CH_3COCOO^-]$. Thus there is insufficient time for the attainment of equilibrium and the reverse reaction is very slow ($k_{-10} \leqslant 10^6$ litre mole^{-1} s^{-1}) compared with the observed value $k_{19} = 3.0 \times 10^9$ litre mole^{-1} s^{-1}.[64] An analogous situation was observed also for the other radicals investigated, so that Eqn. (19) is inapplicable. One must therefore consider only the reaction

$$^{\cdot}RH + A \rightarrow R + A^{\cdot-} + H^+ \quad . \tag{20}$$

"Titration" curves (Fig. 2*a*) are obtained as a result of competition between radicals (20) and (21) (mechanism I):

$$^{\cdot}RH + {}^{\cdot}RH \rightarrow \text{products} \quad . \tag{21}$$

and (or) between reactions (20) and (22) (mechanism II)

$$^{\cdot}RH + A \rightarrow {}^{\cdot}RHA \ (\text{addition of radical}) \quad . \tag{22}$$

For the majority of radicals investigated, mechanism I does not apparently play a significant role, since it has been found that under the experimental conditions the efficiency of the formation of $A^{\cdot-}$ (expressed as a percentage) is independent of the ratio $[A]/[^{\cdot}RH]$ in the range of the latter 15–100.

We shall now consider in greater detail mechanism II involving competition between oxidation [reaction (20)] and addition [reaction (22)] reactions. The following expressions can be formulated[23,64]:

$$-\frac{d[^{\cdot}RH]}{dt} = \frac{d[A^{\cdot-}]}{dt} + \frac{d[^{\cdot}RHA]}{dt} = (k_{20} + k_{22})[^{\cdot}RH]\cdot[A] \quad . \tag{23}$$

Taking into account the relation

$$\frac{d[A^{\cdot-}]}{dt} = k_{20}[^{\cdot}RH]\ [A], \tag{24}$$

we obtain

$$-\frac{d[^{\cdot}RH]}{dt} = \frac{k_{20} + k_{22}}{k_{20}}\frac{d[A^{\cdot-}]}{dt}. \tag{25}$$

Integration with respect to time from zero to t gives

$$[^{\cdot}RH] = [^{\cdot}RH]_0 - \frac{k_{20} + k_{22}}{k_{20}}[A^{\cdot-}] \tag{26}$$

or substituting the resulting expression for $[^{\cdot}RH]$ in Eqn. (24), we obtain the relation

$$\frac{d[A^{\cdot-}]}{dt} = k_{20}[^{\cdot}RH]_0[A] - (k_{20} + k_{22})[A][A^{\cdot-}]. \tag{27}$$

Provided that reaction (20) has reached completion $\{d[A^-]/dt = 0\}$, it is possible to obtain from Eqn. (27)

$$\frac{[A^{\cdot-}]}{[^{\cdot}RH]_0} = \frac{k_{20}}{k_{20} + k_{22}} = \frac{[R]}{[^{\cdot}RH]_0}. \tag{28}$$

The quantity $[R]/[^{\cdot}RH]_0$ is called the "percentage electron transfer". Consequently, we finally obtain the following expression for the reaction rate constant[23]:

$$k_{20} = k_{\text{obs}} \cdot (\text{percent electron transfer}), \tag{29}$$

where $k_{\text{obs}} = k_{20} + k_{22}$. Fig. 2 presents relations between k_{20} and the oxidation-reduction potentials E^0 of the acceptors used for the one-electron oxidation of the lactic acid radical and the dependence of the percentage electron transfer on E^0 at the same instant after the electron pulse. The constants k_{obs} and the percentage electron transfer were also independent of the ratio $[A]/[RH^{\cdot}]$ in the range 15–100. Examination of Fig. 2 and Eqn. (29) permits the following conclusions:

1. The reaction of the radical with acceptors involving 100% electron transfer (the upper plateau in Fig. 2*a*) is very close to a diffusion-controlled process. In this case $k_{20} = k_{\text{obs}}$ and $k_{22} \ll k_{20}$, i.e. reaction (22) is unimportant.
2. For reactions with 0% electron transfer (the lower plateau in Fig. 2*a*), we have $k_{20} \ll 10^7$ litre mole^{-1} s^{-1}.

In the intermediate region the efficiency of electron transfer depends on the ratio k_{20}/k_{22}. It is believed[64] that k_{20} depends strongly on E^0 for the acceptor, while k_{22} varies comparatively little over a narrow range of ΔE^0 values (here one must apparently assume that the chemical nature of the acceptor also changes little). Consequently, the observed changes in the "titration" curve reflect mainly the changes in k_{20} and in the observed efficiency of the electron transfer reaction (20) as a function of E^0 for the acceptor.

Thus the method proposed[62,63] does not yield the true oxidation-reduction potentials of free radicals. The potentials corresponding to 50% electron transfer on the "titration" curves must be regarded as "kinetic" potentials E_k^{01} based on two-electron oxidation-reduction potentials of the acceptor (donor)[64]. The values of E_k^{01} are fairly close to those of E^{01}.[61-64] The differences between the numerical values are due to the fact that corrections based on the Nern equation are not used in the determination of E_k^{01}. $E^{01} < E_k^{01}$ for the oxidation of free radicals and $E^{01} > E_k^{01}$ for their reduction. The E_k^{01} scale is of definite practical value for the prediction of the rates of radical reactions. It has been found for a large class of radicals that the values of E_k^0 explain correctly the course of one-electron reactions between these radicals and the electron donors and acceptors[39,62,64,65].

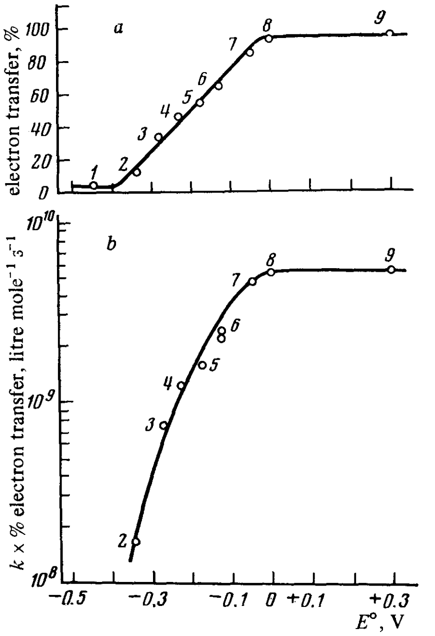

Figure 2. The one-electron oxidation of the $CH_3\dot{C}(OH)CO_2^-$ radical by different acceptors A in aqueous solution[64]: *a*) dependence of the percentage electron transfer on E^0 of the acceptor; *b*) variation of the observed rate constant for the destruction of the radical multiplied by the percentage electron transfer. The same acceptors are designated by identical numerals; the data were obtained after the elapse of the same time interval from the pulse.

The oxidation-reduction potentials of radicals make it possible to account for the relation between the ratio of the rate constants for the oxidation and addition reactions, on the one hand, and the radical structure, on the other (see Section II). Measurements of E^{01} and E_k^{01} [39,62-64] have shown that the basic forms of all the radicals investigated are stronger reductants than the acid forms. For example, $E_k^{01}[CH_3\dot{C}(OH)COOH] > E_k^{01}[CH_3\dot{C}(OH)COO^-] > E_k^{01}[CH_3\dot{C}(O^-)COO^-]$, the corresponding values being +0.16, −0.20, and −0.34 V respectively.

Electron transfer reactions may require considerable activation energies. Despite the favourable relation between the thermodynamic potentials E^{01} of the radical (provided that it is known accurately) and the acceptor (donor), the reaction cannot proceed in this case at a rate sufficient to be able to compete with other radical destruction pathways, for example, reaction (21). The kinetic potentials characterise the ability of the radical to reduce the acceptor (or to oxidise the donor) in kinetic competition with other reactions[64].

For simple aliphatic radicals and the radicals of pyrimidine basis which have been investigated[62-64], reaction (20) is not reversible[64], but the radical-anions derived from quinones and aromatic and heterocyclic nitro-compounds as well as $O_2^{\overline{\cdot}}$ participate in reversible reactions with quinones Q (see the end of Section II, subsection 2):

$$X^{\overline{\cdot}} + Q \rightleftarrows X + Q^{\overline{\cdot}} \quad . \tag{30}$$

The true one-electron potentials at pH 7.0 have been determined for these radical-anions by pulse radiolysis[36,164-166]. These quantities have been designated by E_7^1.

Equilibrium (30) is established fairly rapidly; the destruction of radicals via the $X^{\overline{\cdot}} + X^{\overline{\cdot}}$ and $Q^{\overline{\cdot}} + Q^{\overline{\cdot}}$ reactions is much slower[36,164-166]. It has been shown that the observed spectral changes are caused solely by electron transfer. The observed first-order reaction rate constant (relaxation to the equilibrium value) is given by the relation

$$k_{obs} = k_{30}[Q] + k_{-30}[X].$$

In order to measure the one-electron potential $E_7^1(X|X^{\overline{\cdot}})$, the values of $K_{30} = \{[Q^{\overline{\cdot}}][X]/[X^{\overline{\cdot}}][Q]\}$ were obtained, Q being the reference quinone whose one-electron potential is known§. In order to calculate K_{30}, the concentrations of all the reactants under equilibrium conditions were determined, whereupon $E_7^1(X|X^{\overline{\cdot}}) = E_7^1(Q|Q^{\overline{\cdot}}) - 0.059 \lg K_{30}$.[164]

$E_7^1(O_2|O_2^{\overline{\cdot}}) = -0.155$ V was obtained by this method[164], in agreement with the calculated value[150] (see above). The values $E_7^2(O_2^{\overline{\cdot}}|O_2^{2-}) = 0.865$ V, $E_7^2(DQ^{\overline{\cdot}}|DQ^{2-}) = 0.355$ V, $E_7^1(MQ|MQ^{\overline{\cdot}}) = -0.203$ V, and $E_7^1(BQ|BQ^{\overline{\cdot}}) = 0.1$ V were also obtained (MQ = 2-methyl-1,4-naphthoquinone and BQ = 1,4-benzoquinone) together with the one-electron potentials of many other quinones and nitro-compounds[36,164-166].

It is believed that mainly the nitro-group is involved in electron transfer from the nitro-compound RNO_2 and from the radical-anions of nitro-compounds[165]. It is therefore reasonable to seek a relation between the spin density at the nitro-group and the one-electron potentials of the radicals. The correlation $E^{01}(RNO_2|RNO_2^{\overline{\cdot}}) = 0.315 - 0.054a_{NO_2}^{N}$ (volts) has been found[165]. Thus the lower the spin density at the nitro-group, the smaller the absolute value of the negative one-electron potential. Consequently, the one-electron oxidation-reduction potentials of the radical-anions of nitro-compounds can be obtained from ESR spectra, provided that certain precautions are observed[36].

The radical-anions $RNO_2^{\overline{\cdot}}$, for which $E_7^1(RNO_2|RNO_2^{\overline{\cdot}}) < E_7^1(DQ|DQ^{\overline{\cdot}})$, react effectively with DQ, whereupon the constants k_{30} vary in the range $3 \times 10^8 - 1 \times 10^8$ litre mole^{-1} s^{-1}.[36] On average, k_{30} increases as E_7^1 decreases[36].

---

§ The value $E_7^1(DQ|DQ^{\overline{\cdot}}) = -0.235$ V was obtained for the first time for duroquinone (DQ) in a study by Meisel and Czapski[164].

Strictly speaking, one should not expect a clear-cut correlation between the rate of electron transfer and the difference between the one-electron potentials $\Delta E\frac{1}{2}$ or the two-electron potential E^0 of the acceptor (donor). The rate of electron transfer is influenced by various factors, but in the majority of cases there is a tendency towards its increase with increasing ΔE^1 or E^0 for the acceptor within certain limits. Indeed, $\Delta E \simeq -\Delta G^\circ$ and $\Delta G^* \simeq \Delta G^0$ [see Eqns.(1) and (2)].

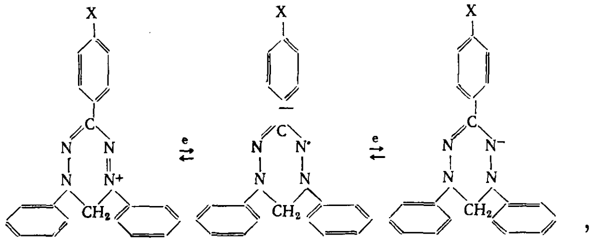
Electron transfer takes place in the acceptor molecule which has a higher (more positive) potential. Many of the so called "cascade" electron transfer processes can be accounted for on the basis of the differences between the oxidation-reduction potentials of donors and acceptors. An interesting example of the cascade electron transfer "initiated" by the electron pulse is the system containing isopropyl alcohol, acetone, acetophenone (AP), benzophenone (BP), and *p*-nitroacetophenone (PNAP):[24]

.

Under the experimental conditions, [AP] > [BP] > [PNAP]. It has been shown by kinetic absorption spectroscopy that the process does indeed proceed in the above sequence[24].

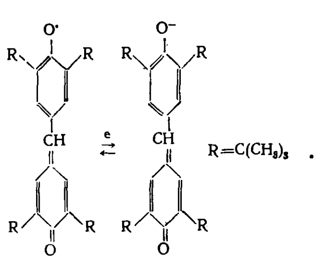
IV. THE POLAROGRAPHY OF FREE RADICALS

Certain stable radicals, for example *C*-phenyl-substituted triphenylverdazyls, are capable of undergoing reversible oxidation or reduction at a dropping mercury electrode[67], which results in one oxidation wave and one reduction wave:



where X = H, Cl, NO_2, CH_3, or OCH_3.

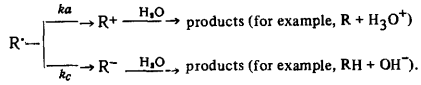
The polarographic reduction of the galvinoxy-radical is also reversible with $E_{1/2}$ = 0.07 V:[68]



.

The polarographic detection of short-lived radicals obtained as a result of an electron pulse has been used in a number of studies[70,71,154]. Such experiments yield oscillograms reflecting the time-dependence of the current. The variation of the concentration of radicals in the bulk of the solution can be investigated in the usual way—by kinetic spectrophotometry. The cathodic and anodic currents give rise to positive and negative signals respectively. The polarograms thus obtained consist of irreversible waves and cannot therefore be used to determine the oxidation-reduction potentials, but they yield valuable information about the behaviour of radicals at the mercury electrode and can be used to identify new radicals formed in the experiments on pulse radiolysis.

In contrast to stable molecules, which can give rise either to an anodic or a cathodic wave (mercury electrode in water, potentials between +0.2 and −1.9 V relative to the calomel electrode), short-lived free radicals usually give rise to both waves in the above potential range. Experiments have shown that the radicals are usually oxidised and reduced at comparable rates in a definite potential range[70]. The oxidation and reduction of radicals may be regarded as competing processes in accordance with the following scheme:



$$R^\cdot \xrightarrow{ka} R^+ \xrightarrow{H_2O} \text{products (for example, } R + H_3O^+)$$
$$R^\cdot \xrightarrow[kc]{} R^- \xrightarrow{H_2O} \text{products (for example, } RH + OH^-).$$

The majority of the waves obtained are completely irreversible, since the oxidation or reduction products of many radicals (such as carbonium ions or carbanions) rapidly react with water before the reverse reaction can take place at the electrode.

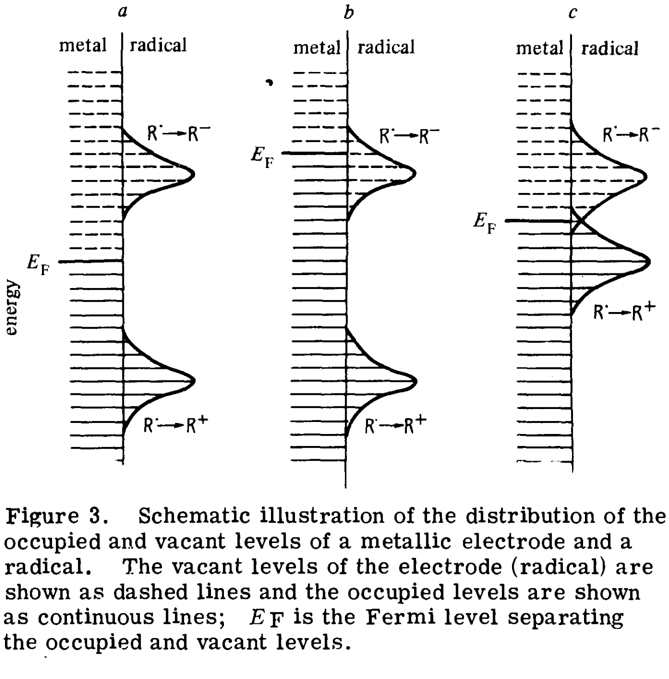


Figure 3. Schematic illustration of the distribution of the occupied and vacant levels of a metallic electrode and a radical. The vacant levels of the electrode (radical) are shown as dashed lines and the occupied levels are shown as continuous lines; E_F is the Fermi level separating the occupied and vacant levels.

The oxidation and reduction of radicals at the electrode can be considered in terms of the scheme illustrated in Fig. 3.[70] Electron transfer can take place only between levels with identical electrode energies in the following system: $R^\cdot \rightarrow R^-$ (reduction) or $R^\cdot \rightarrow R^+$ (oxidation). Thus, according to this scheme, there is neither oxidation nor reduction of $R^\cdot$ in case *a*. With increase of the electrode potential, the energy of the occupied levels increases. Fig. 3*b* illustrates the situation where the reduction of $R^\cdot$ should occur. (The situation where $R^\cdot$ is oxidised may be represented analogously—for this to occur, the value of E_{ph} must be fairly low.) In the case represented in Fig. 3*c* both oxidation and reduction can take place at comparable rates.

A polarographic study of $CO_3^{\overline{\cdot}}$ confirmed the ability of this radical-anion to participate in both oxidation and reduction reactions; it has been established that $E^1(CO_3^{\overline{\cdot}}|CO_3^{2-}) > E^1(CO_3|CO_3^{\overline{\cdot}})$.[158] The study of the polarograms of radicals has made possible definite conclusions about their structures[70].

V. THE $R^{\cdot} + R^{\cdot} \rightarrow$ PRODUCTS REACTION: RECOMBINATION, DISPROPORTIONATION, OR ELECTRON TRANSFER?

It was shown above (Sections II–IV) that free radicals are capable of being both reduced and oxidised in reactions with stable species. Presumably, when two radicals differing in their oxidation-reduction potentials react, electron transfer will again occur. This hypothesis was put forward by Hayon and coworkers[62] on the basis of a study of the oxidation-reduction potentials of short-lived radicals. Indeed, if the radical $^{\cdot}R_2H$ in the reaction

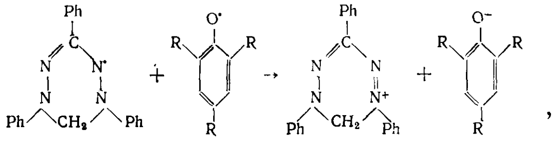
$$^{\cdot}R_1H + {}^{\cdot}R_2H \rightarrow R_1 + R_2H_2$$

has a more positive potential, then, according to the ideas developed above (Section III), one may expect electron transfer from $^{\cdot}R_1H$ to $^{\cdot}R_2H$.[62] The final reaction products will be the same as in the generally accepted mechanism of radical disproportionation (via H atom transfer).

Pokhodenko and coworkers[73–75] observed one-electron transfer in reactions between many stable free radicals:

$$R_1^{\cdot} + R_2^{\overline{\cdot}} \rightarrow R_1^{+} + R_2^{-} \quad , \qquad (31)$$

where, for example, $R_1^{\cdot}$ = triphenylverdazyl and $R_2^{\cdot}$ = 2,4,6-tri-t-butylphenoxyl, galvinoxyl, indophenoxyl, etc. The radical of Wurster's blue oxidises certain triphenylverdazyl radicals and is itself oxidised to the corresponding doubly-charged cation by nitroxy-, phenoxy-, and a number of other stable radicals[75]. The reaction products were identified on the basis of their absorption spectra and the reaction kinetics were followed from the time variation of the intensity of the ESR signal of one of the radicals. It was shown that the reaction



$R{=}C(CH_3)_3$, (32)

in chlorobenzene is described by the second-order kinetic equation: $k_{32} = 8 \times 10^8 \exp(-16\,300 \pm 500)/RT)$ litre mole^{-1} s^{-1}.[73]

Evidently a significant charge separation takes place in the transition states of reactions (31) and (32), so that k_{32} increases with increasing polarity of the medium[73]. The generation of an e.m.f. in electron transfer reactions between two stable free radicals has also been observed[74].

The radical-anions of sulphoanthraquinones ($AQ^{\overline{\cdot}}$) react with the 4-hydroxy-2,2,6,6-tetramethylpyridino-1-oxy-radical ($RNO^{\cdot}$) via electron transfer[57]:

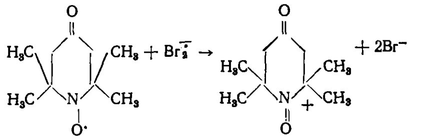
$$AQ^{\overline{\cdot}} + RNO^{\cdot} \rightarrow AQ + RNO^{\overline{\cdot}} \quad .$$

Reaction (32) has a high activation energy and is comparatively slow at room temperature. It is of interest to elucidate the possibility of the occurrence of electron transfer steps in rapid reactions of short-lived radicals with stable radicals or with one another. The stable nitroxy-radical 2,2,6,6-tetramethyl-4-oxopiperidino-1-oxyl (TAN) ($AP^{\cdot}$) reacts with a wide variety of organic and inorganic radicals[76,155]. The rate constants for these reactions are close to the diffusional values. It is not clear whether these reactions involve addition or electron transfer or whether both pathways are involved in competition[76,155]:

$$R^{\cdot} + AP^{\cdot} \rightarrow R - AP \quad , \qquad (33)$$

$$R^{\cdot} + AP^{\cdot} \rightarrow R^{+} + AP^{-} \; (R^{-} + AP^{+}) \quad . \qquad (34)$$

However, it can be regarded as proved that the fast reaction



(35)

involves electron transfer with $k_{35} = 1.6 \times 10^9$ litre mole^{-1} s^{-1}.[76] Indirect evidence has been obtained[73] that the reaction between the active acetyl radical and the triphenylverdazyl radical also involves electron transfer:

$$>N^{\cdot} + CH_3COO^{\cdot} \rightarrow \; >N^{+} + CH_3COO^{-} \quad .$$

The fast reaction of the radical-anion of anthraquinone-2,6-disulphonic acid ($A^{\overline{\cdot}}$) with the $NO_3^{\cdot}$ radical proceeds via the same mechanism[77]:

$$A^{\overline{\cdot}} + NO_3^{\cdot} \rightarrow A + NO_3^{-} \quad , \qquad (36)$$

$$k_{36} = 1.0 \cdot 10^8 \text{ litre mole}^{-1} \text{ s}^{-1}.$$

There is at present no convincing evidence showing that the reactions of uncharged short-lived radicals with one another involve electron transfer. However, hypotheses of this kind have been put forward in a number of studies[62,69,70,148,154]. Radicals capable of being both reduced and oxidised with equal case should have overlapping levels[70] (Fig. 3*c*, Section IV). It can be assumed that such radicals may be destroyed as a result of the formation of ion pairs on collision in solution[70]:

$$R^{\cdot} + R^{\cdot} \rightarrow R^{+} + R^{-} \quad .$$

This process should probably be regarded as involved in competition with the usual radical destruction reactions—recombination and disproportionation via the transfer of a hydrogen atom. For example, the destruction of hydroxycyclohexadienyl radicals can be represented as follows[154]:

$$\begin{array}{l} ^{\cdot}C_6H_6OH + {}^{\cdot}C_6H_6OH \rightarrow \underset{\displaystyle C_6H_5OH + H^{+}}{\underset{\downarrow}{C_6H_6OH^{+}}} + \underset{\displaystyle C_6H_6 + OH^{-}}{\underset{\downarrow}{C_6H_6OH^{-}}} \quad . \end{array} \qquad (37)$$

The detection among the products of reactions between two $R^{\cdot}$ species of compounds whose formation via recombination or disproportions cannot be postulated [for example, C_6H_6 in reaction (37)] would constitute evidence in support of one-electron transfer. The solvent may influence the rate of reaction between two $R^{\cdot}$ species in the manner predicted by the electron transfer theory; such data must be regarded as indirect evidence for electron transfer.

It is well known that alkyl radicals recombine with formation of a new chemical bond between carbon atoms having an unpaired electron:

$$RCH_2CH_2^{\cdot} + R'CH_2CH_2^{\cdot} \rightarrow R\,(CH_2)_4R' \qquad (38)$$

(in the special case where $R = R'$). The rates of the majority of these reactions are limited by diffusion and their activation energies are close to zero[78]. If one of the radicals has an H atom in the β-position relative to the radical centre, there is a possibility of a competing disproportionation reaction[78]:

$$RCH_2CH_2^{\cdot} + R'CH_2CH_2^{\cdot} \rightarrow RCH_2CH_3 + R'CH{=}CH_2 \quad . \qquad (39)$$

Reaction (39) is also diffusion-controlled[78]. The recombination (disproportionation) of such radicals via electron transfer is apparently impossible. In contrast to reactions (38) and (39), the electron transfer reaction

$$RCH_2CH_2^{\cdot} + R'CH_2CH_2^{\cdot} \rightarrow RCH_2CH_2^{+} + R'CH_2CH_2^{-} - \begin{cases} \rightarrow R(CH_2)_4R' \\ \rightarrow RCH_2CH_3 + R'CH{=}CH_2 \end{cases} \qquad (40)$$

requires an activation energy ΔG^* [Eqn.(1)] and in addition the formation of a carbonium ion and a carbanion is a highly endothermic process.

On the other hand, many long-lived or stable radicals with different E^1 values cannot participate in recombination (disproportionation) reactions and are converted into diamagnetic products via electron transfer [reaction (31)]. One can probably postulate that there exists an "intermediate" class of radicals for which ΔG^* [Eqn.(1)] is comparable to $\Delta G^{\neq}$ for recombination (disproportionation) reactions and the radical destruction reaction is in fact reaction (40) involved in competition with reactions (38) and (39).

The reaction

$$R^{\cdot} + R^{\cdot} \rightarrow \text{products} \qquad (41)$$

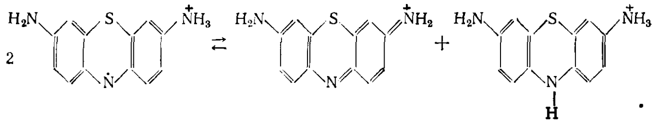
is one of the fundamental processes in the chemistry of short-lived radicals. If it is indeed found that certain radical destruction reactions proceed via electron transfer (the rate-limiting stage), then the kinetics and mechanisms of these reactions in different solvents have to be described in terms of the concepts developed for electron transfer reactions (Section II).

Reaction (41) involves electron transfer if the $R^{\cdot}$ species are radical-ions. Examples of these reactions are the disproportionation of the radical-anions of quinones (Q) or aromatic molecules (Ar):

$$Q^{\overline{\cdot}} + Q^{\overline{\cdot}} \rightleftarrows Q^{2-} + Q \quad ,$$

$$Ar^{\overline{\cdot}},\ M^+ + Ar^{\overline{\cdot}},\ M^+ \rightleftarrows Ar^{2-},\ 2M^+ + Ar \quad .$$

Radical-cations also disproportionate in solutions, for example[79]:



Rapid electron transfer reactions between radical-cations and radical-anions,

$$R_1^{\overline{\cdot}} + R_2^{\overset{+}{\cdot}} \rightarrow R_1^{\cdot} + R_2 + h\nu \quad ,$$

are frequently accompanied by chemiluminescence.

It is noteworthy that rotational diffusion, leading to the mutual orientation of the reactants in the solvent cage required for the occurrence of their reaction, should apparently play a smaller role in bimolecular reactions involving the destruction of radical-ions than in the reactions where uncharged radicals are destroyed[78,79]. This can be understood if account is taken of the fact that the electron transfer takes place over fairly long distances (see Section II, subsection 5).

VI. REACTIONS OF RADICALS WITH METAL COMPOUNDS

Different classes of organic compounds can undergo chemical transformations via a free-radical mechanism in the presence of transition metal compounds. Examples of such processes are the decomposition of peroxides, the halogenation of aliphatic compounds, the amination of aromatic compounds, certain cyclisation reactions, and other processes catalysed by transition metal compounds. Many photochemical reactions of complex compounds lead to the formation of free radicals, which are then involved in dark reactions with metal compounds. In a general form, one can postulate that the interaction of a radical with a metal compound proceeds via one (or several simultaneously) of the following pathways[80,168]:

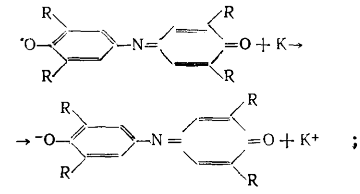
$$R^{\cdot} + M^{n+}L_m - \begin{cases} \rightarrow RH + L'M^{n+}L_{m-1} & \text{(abstraction of hydrogen),} \\ \rightarrow RL + M^{n-1}L_{m-1} & \text{(ligand transfer),} \\ \rightarrow R^{\pm} + M^{(n\mp1)+}L_m\ (M^{n+}L^{\mp}L_{m-1}) & \text{(electron transfer),} \\ \rightarrow {}^{\cdot}RM^{n+}L_{m-1} + L & \text{(ligand substitution),} \\ \rightarrow R^{\cdot}\ldots M^{n+}L_m & \text{(formation of charge-transfer complexes).} \end{cases}$$

Examples of these reactions and the rules that they obey are discussed below.

The influence of transition metal compounds on many organic reactions with radical mechanisms is discussed in a number of reviews[11,81,101,168] and a monograph[82]. Since the publication of the review[83] devoted to the kinetics of the reactions of radicals with metal compounds, many new data have become available.

1. Oxidation-reduction Reactions of Radicals with Metals and Their Compounds

Alkali metals, which are powerful reductants, are capable of reducing various organic species, including free radicals. The indophenoxy- and galvinoxy-radicals react with metallic potassium and are converted into the corresponding phenoxide anions[85,103]:

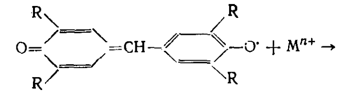


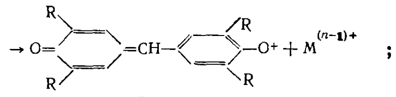
R = C (CH₃)₃ .

Aromatic radical-anions are reduced to the corresponding dianions[87]:

$$Ar^{\overline{\cdot}},\ K^+ + K \rightarrow Ar^{2-},\ 2K^+ .$$

Apart from electron-accepting properties, stable phenoxy-radicals can exhibit the properties of electron donors. 2,4,6-Tri-t-butylphenoxy-, galvinoxy, and indophenoxy-radicals undergo one-electron oxidation in the presence of Lewis acids $MHal_n$ ($M = Sb^V$, Nb^V, Ti^{IV}, Sn^{IV}, or Al^{III}; Hal = Cl or Br), as well as $VOCl_3$ and $AgClO_4$ in various solvents. For example:





$$R = C(CH_3)_3 \ . \qquad (42)$$

The occurrence of reactions of this kind has been demonstrated convincingly by ESR, NMR, spectrophotometric, and polarographic methods[88,89]. The stability of the diamagnetic salts obtained in reactions (42) depends on the structure of the radicals being oxidised, the nature of the oxidant, and the medium. The rate of reaction (42) is described by a second-order kinetic equation: $k_{42} \simeq 10-10^3$ litre $mole^{-1}$ s^{-1} for different $NHal_n$. The study of the interaction of 2,2,6,6-tetramethyl-4-oxopiperidino-1-oxy-radical and DPPH with Group III metal halides showed that the nitroxy-radicals form a complex with $MHal_3$ while DPPH is oxidised to the corresponding cation[89-91]. The results permit the conclusion that the electron-donating properties of the radicals in many respects determine the kinetic parameters of the reaction of stable radicals with $MHal_3$. When the galvinoxy-radical is converted into DPPH, the activation energy of the type (42) reaction increases, owing to the weaker electron-donating properties of DPPH ($E_{1/2} > 0.5$ V) compared with the galvinoxy-radical ($E_{1/2} = 0.38$ V). The nitroxy-radical has a higher oxidation potential ($E_{1/2} \simeq 0.9$ V) and the reaction stops in this instance at the stage involving the formation of the complex[89-91].

A classical example of the manifestation of the electron-donating capacity of free radicals is the reduction of heavy metal salts by the triphenylmethyl radical[92]:

$$Ph_3C^{\cdot} + AgClO_4 \rightarrow Ph_3C^{+}ClO_4^{-} + Ag \ .$$

The oxidation of organic compounds via a radical process in the presence of metal ions has been investigated in the course of eight decades with the aid of Fenton's reagent; this involves the following fundamental processes[93]:

$$H_2O_2 + Fe^{2+} \rightarrow Fe^{3+} + OH^- + OH^{\cdot} \ , \qquad (43)$$

$$HO^{\cdot} + Fe^{2+} \rightarrow Fe^{3+} + OH^- \ , \qquad (44)$$

$$HO^{\cdot} + RH \rightarrow H_2O + R^{\cdot} \ . \qquad (45)$$

The radicals formed participate in the destruction reaction

$$R^{\cdot} + R^{\cdot} \rightarrow \text{products}, \qquad (46)$$

and can regenerate Fe^{2+} or be reduced, oxidising Fe^{2+} at the same time:

$$R^{\cdot} + Fe^{3+} \rightarrow Fe^{2+} + \text{products} \qquad (47)$$

$$R^{\cdot} + Fe^{2+} \xrightarrow{+H^+} Fe^{3+} + RH \ . \qquad (48)$$

Apart from Fenton's reagent, other $H_2O_2 + M^{n+}$ systems are used to generate radicals (see subsection 3 of this section).

In later investigations organic radicals were generated in different systems by pulse radiolysis or by a flow technique, the radicals being identified on the basis of their ESR spectra[95]. Here the active reactant is $OH^{\cdot}$, obtained in the radiolysis of water (pulse radiolysis[66]) or on decomposition of H_2O_2 (using a flow technique).

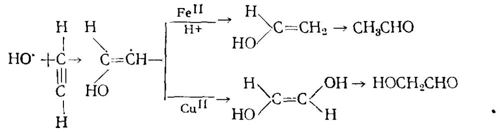
The data accumulated make it possible to classify radicals in terms of their capacity to participate in oxidation-reduction reactions. The radicals forming comparatively stable carbonium ions oxidise iron(III) effectively and quantitatively [reaction (47)]. They include radicals containing an OH or OR group, amide nitrogen, and tertiary alkyl substituents in the α-position. Primary and secondary alkyl radicals are inert in relation to iron(III), while allyl and benzyl radicals occupy an intermediate position. All these species effectively oxidise copper(II).[93]

Conjugated carbonyl radicals and related radicals giving rise to comparatively stable anions are inert with respect to oxidation by copper(II) or iron(III). They are readily reduced by iron(II) [reaction (48)], for example[96]:

$$R-\dot{C}(OH)-CCl_3 + Fe^{II} \rightarrow R-\bar{C}(OH)-CCl_3 + Fe^{III} \ .$$

Furthermore, iron(II) reduces the radicals derived from carboxylic acids with a free valence in the α-position, for example $R(R')\mathring{C}CO_2H$, $\dot{C}H_2CO_2H$, and $\dot{C}H(CO_2H)_2$.[97]

Radicals derived from alcohols and carboxylic acids show the opposite tendencies in their capacity to oxidise or reduce iron ions. It has been shown[97] that the ability of hydroxyacid radicals $\dot{R}(OH)CO_2H$ to participate in oxidation-reduction reactions with iron ions is determined by the OH group and not the CO_2H group. Vinyl radicals, obtained as a result of attack by hydroxy-radicals on acetylene, are unique in the sense that they are capable of being both oxidised by copper (II) [but not by iron(III)] and of being reduced by iron(II).[93] Thus acetylene is converted by Fenton's reagent into acetaldehyde in the absence of copper(II) and into hydroxyacetaldehyde in the presence of copper(II):



The oxidation of iron(II) proceeds selectively and the efficiency of the oxidation varies in parallel with the stabilities of the carbonium ions obtained[93].

The iron(III)–EDTA system oxidises different radicals obtained on radiolysis of alcohols, aldehydes, ketones, and dicarboxylic acids[98]. The principal factor influencing the ability of the radical to be oxidised is its structure. Radicals with an unpaired electron in the α-position relative to the functional group as well as radicals without functional groups which would prevent the attainment of the necessary mutual orientation of iron(III) and the reaction centre of the radical are oxidised by iron(III). The oxidation can be very rapid; for example, $k_{47} > 4 \times 10^8$ litre $mole^{-1}$ s^{-1} has been estimated for $\dot{C}H_2OH$.[93] In contrast to this, the ligand exchange reactions of iron(III) have rate constants $k < 10^4$ litre $mole^{-1}$ s^{-1}. These two findings thus agree with an outer-sphere electron transfer mechanism involving the formation of a product of the carbonium ion type:

$$R^{\cdot} + Fe^{III} \rightleftarrows R^{+} + Fe^{II} \ . \qquad (49)$$

Primary and secondary alkyl radicals are not oxidised, probably because in this case equilibrium (49) is displaced to the left[96,99].

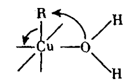
The reduction of many organic radicals by iron(II) is also a very rapid process with $k \geqslant 10^7$ litre $mole^{-1}$ s^{-1} [100] and proceeds more effectively the greater the stability of the resulting carbanion, which also indicates an outer-sphere electron transfer mechanism[93]:

$$Fe^{II} + R^{\cdot} \rightleftarrows Fe^{III} + R^{-} \ .$$

Iron(II) is oxidised by disulphide radical-cations[137]:

$$Fe^{II} + RSSR^{\dot{+}} \rightarrow Fe^{III} + RSSR \ .$$

As stated above, reaction (47) is reversible for primary and secondary alkyl radicals. One can therefore postulate that copper(II), the weakest oxidising agent, cannot oxidise these radicals via an outer-sphere mechanism. It has been shown[93,101] that the radicals are oxidised with formation of an intermediate organocopper compound, which decomposes into hydroxylated products and copper(I):



Oxidation with the aid of copper(II) is usually slower than oxidation by iron(III).[93] The oxidation rate constants for alkyl radicals are $k \simeq 10^6-10^8$ litre mole^{-1} s^{-1},[102] and ligand substitution in the coordination sphere of copper then proceeds fairly rapidly (the bimolecular rate constants are $k \simeq 10^9-10^{10}$ litre mole^{-1} s^{-1}). Consequently the rate-limiting stage in these inner-sphere reactions is electron transfer (see Section II, subsection 1).

It is noteworthy that copper(II) is in general highly reactive in relation to free radicals[11,53,66,94,101,102,104]. Copper(I) compounds can be readily oxidised to copper(II) in their turn. These properties apparently constitute the explanation of the wide-scale employment of copper compounds as catalysts in reactions involving free radicals. Cu^{2+} ions effectively oxidise certain aromatic radicals—chloranil radical-anions ($CQ^{\overline{\cdot}}$), anthraquinone-2,6-disulphonic acid radical-anions ($AQ^{\overline{\cdot}}$), and 2-hydroxy-1-naphthoxy-radicals [Nf(OH)O$^{\cdot}$]:

$$CQ^{\overline{\cdot}} + Cu^{2+} \rightarrow CQ + Cu^{+};\ k = 1{,}0\cdot 10^{9}\ \text{litre mole}^{-1}\ \text{s}^{-1}$$

(in a 9:1 mixture of propanol and water by volume)[80],

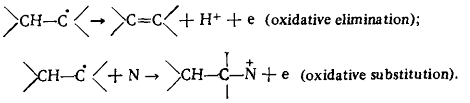
$$AQ^{\overline{\cdot}} + Cu^{2+} \rightarrow AQ + Cu^{+};\ k = 1{,}0\cdot 10^{6}\ \text{litre mole}^{-1}\ \text{s}^{-1}$$

(in water)[140],

$$\text{Nf (OH)O}^{\cdot} + Cu^{2+} \rightarrow \text{products};\ k = (3{,}2 \pm 0{,}6)\cdot 10^{6}\ \text{litre mole}^{-1}\ \text{s}^{-1}$$

(in water)[141].

The oxidation of alkyl radicals by many transition metal compounds in solution leads to the formation of olefins and alkyl derivatives[102]. The following mechanisms may be postulated for these reactions:



$$>CH-\dot{C}< \rightarrow >C=C< + H^+ + e\ \text{(oxidative elimination)};$$

$$>CH-\dot{C}< + N \rightarrow >CH-\underset{|}{\overset{|}{C}}-\overset{+}{N} + e\ \text{(oxidative substitution)}.$$

Here N is a nucleophile (HOAc, HOR, CH_3CN, ArH, etc.);

$$M^{n+}(OAc^-)_n + e \rightarrow M^{(n-1)+}(OAc^-)_n\ \text{(reduction of metal compound)}.$$

The rates of oxidation of n-butyl, isopropyl, and neopentyl radicals by a copper(II) carboxylate have been determined in acetonitrile–acetic acid mixtures[102]. The neopentyl radical is oxidised much more slowly than the other alkyl radicals. An alkylcopper compound is also postulated as an intermediate[102]:

$$(CH_3)_3C\dot{C}H_2 + Cu^{II} \rightleftarrows [(CH_3)_3CCH_2Cu]\ ,$$
$$[(CH_3)_3CCH_2Cu] \rightarrow Cu^{I} + (CH_3)_3CCH_2^{+}\ .$$

Whereas iron(II) ions are capable of reducing only radicals forming comparatively stable anions, titanium(III) ions reduce a wide variety of radicals—alkyl and hydroxyalkyl radicals, radicals derived from carboxylic acids, etc.[97] The reaction

$$Ti^{III} + \dot{C}H\,(COOH)_2 \rightarrow \text{products}\ (Ti^{IV}) \qquad (50)$$

was investigated by ESR combined with radiolysis *in situ*: $k_{50} = 8 \times 10^6$ litre mole^{-1} s^{-1}.[97] The authors[97] believe that the mechanism of this reaction is similar to that adopted for the reduction of hydrogen atoms by iron(II), which includes the formation of a metal hydride intermediate:

$$Fe^{II} + H^{\cdot} \rightarrow Fe^{II} - H^{\cdot}\ ,$$
$$Fe^{II} - H^{\cdot} + H^{+} \rightarrow Fe^{III} + H_2\ .$$

This mechanism can be adopted for the reduction of radicals with an unpaired electron at the carbon atom:

$$R^{\cdot} + M^{n+} \rightarrow M^{n+} - R\ ,$$
$$M^{n+} - R + H^{+} \rightarrow M^{(n+1)+} + RH\ .$$

These are apparently inner-sphere reactions[97,105].

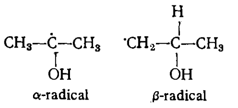
Titanium(III) ions oxidise formic acid radicals[106]:

$$^{\cdot}CO_2H + Ti^{III} - Ti^{II} + CO_2 + H^{+} \qquad (51)$$

with $k_{51} \simeq 5 \times 10^6$ litre mole^{-1} s^{-1}. One may claim (see Section III) that the rate constant for the interaction of the radical-anion with titanium(III) is still greater. Comparison of the rate of substitution by ligands in the coordination sphere of titanium(III) with the rate of reaction (51) suggests that the reaction with titanium(III) proceeds via an outer-sphere mechanism[106].

Europium(III) ions also oxidise $^{\cdot}CO_2H$ and $CO_2^{\overline{\cdot}}$; the rate constant is $k > 7 \times 10^6$ litre mole^{-1} s^{-1}. The reaction does not proceed with ytterbium(III), chromium(III), and scandium(III). It follows from a comparison of the standard oxidation-reduction potentials that chromium(III) is most readily reducible. However, the outer-sphere conversion of chromium(III) into chromium(II) requires a large reorganisation energy in view of the presence of tetragonal distortions in the high-spin chromium(II) complex. The inner-sphere reaction is ruled out in view of the inertness of chromium(III) in relation to substitution[106].

The ability of radicals to participate in oxidation-reduction reactions with metal compounds depends significantly on the structure of the radicals. For example, the α-radical of isopropyl alcohol is oxidised by titanium(IV), iron(III), and chromium(III) more effectively than the β-radical[107]:



$$CH_3-\underset{OH}{\dot{C}}-CH_3 \qquad {}^{\cdot}CH_2-\underset{OH}{\overset{H}{C}}-CH_3$$

because the carbonium ion corresponding to the α-radical is more stable (see Section II, subsection 2).

The inorganic radical-anions $Cl_2^{\overline{\cdot}}$ and $Br_2^{\overline{\cdot}}$ oxidise Fe^{2+}, Co^{2+}, and Mn^{2+} ions[13,108,109]. The reactions were investigated by flash photolysis. The reaction

$$Cl_2^{\overline{\cdot}} + Fe^{2+} \rightarrow Fe^{3+} + 2Cl^{-} \qquad (52)$$

proceeds via an outer-sphere mechanism with $k_{52} = (1.0 \pm 0.2) \times 10^7$ litre mole^{-1} s^{-1}. The inner-sphere reaction

$$Cl_2^{\overline{\cdot}} + Fe^{2+} \rightarrow FeCl^{2+} + Cl^{-} \qquad (53)$$

has a smaller rate constant: $k_{53} = (4.0 \pm 0.6) \times 10^6$ litre mole^{-1} s^{-1}.[13]

The oxidation of $Cl_2^{\overline{\cdot}}$ and $Br_2^{\overline{\cdot}}$ by Mn^{2+} ions takes place with formation of an intermediate complex, which then decomposes into products[109]. The rate-limiting stage in this inner-sphere reaction is electron transfer. The oxidation of Fe^{2+} by the $Br_2^{\overline{\cdot}}$ radical-anion and of Co^{2+} by $Cl_2^{\overline{\cdot}}$ also proceeds via an inner-sphere mechanism, the rate-limiting stage being the substitution reaction[13,108]. The second-order rate constants have been obtained for all the inner-sphere reactions: $k = 10^6$ litre mole^{-1} s^{-1} [13,108,109].

The $N_3^{\overset{\cdot}{-}}$ radical-anion oxidises Fe^{2+} via an inner-sphere mechanism

$$N_3^{\cdot} + Fe^{2+} \rightarrow Fe^{III} + N_3^-$$

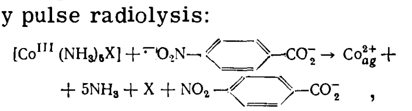
with $k > 1.7 \times 10^9$ litre mole^{-1} s^{-1}.[156]

The reduction of $OH^{\cdot}$ by Fe^{2+} ions has been investigated by pulse radiolysis[110] and it has been established that the reaction proceeds as an outer-sphere electron transfer:

$$OH^{\cdot} + Fe^{2+}(H_2O)_6 \rightarrow Fe^{3+}(H_2O)_6, OH^- \xrightarrow{H^+} Fe^{3+}(H_2O)_6 + H_2O \qquad (54)$$

with $k_{54} = (2.3 \pm 0.2) \times 10^8$ litre mole^{-1} s^{-1}.[110] The corresponding reaction of $OD^{\cdot}$ radicals in D_2O is characterised by the rate constant $k_{54} = (9.4 \pm 0.8) \times 10^7$ litre mole^{-1} s^{-1}. The difference between the rates of these reactions is due to the difference between the free energies of hydration of the ions in the solvents[110]. Many other oxidation-reduction reactions of the $OH^{\cdot}$ radical have been examined[83,169].

The reaction between pentammine(ligand)cobalt(III) complexes and the *p*-nitrobenzoate radical-anion has been investigated by pulse radiolysis:



(55)

where X = NH_3, $PhCO_2^-$, *p*-$O_2NC_6H_4CO_2^-$, Br^-, pyridine, or *m*-$H_2NCOC_5H_4N$. The reaction proceeds via an outer-sphere mechanism in all cases with $k_{55} \simeq 10^6-10^7$ litre mole^{-1} s^{-1}. The reactants initially form an outer-sphere ion pair (they approach one another to a distance equal to the reaction radius) and then electron transfer takes place:

$$\begin{aligned}&[Co^{III}(NH_3)_5X] + {}^-O_2CC_6H_4NO_2^{\overset{\cdot}{-}}\text{-}n \rightleftarrows \\ &\rightleftarrows [Co^{III}(NH_3)_5X, {}^-O_2CC_6H_4NO_2^{\overset{\cdot}{-}}\text{-}n] \xrightarrow{k_{56}} \\ &\rightarrow Co^{2+}_{aq} + 5NH_3 + p\text{-}O_2NC_6H_4CO_2^- + X \quad . \qquad (56)\end{aligned}$$

The intramolecular electron transfer reaction

$$[Co^{III}(NH_3)_5(O_2CC_6H_4NO_2\text{-}n)]^+ \rightarrow Co^{2+}_{aq} + 5NH_3 + p\text{-}O_2NC_6H_4CO_2^- \qquad (57)$$

was found to have $k_{57} = 2.6 \times 10^3$ s^{-1} with $k_{57} < k_{56}$, i.e. the intramolecular transfer is slower. The most probable explanation of this is that the carboxylate ion exhibits a comparatively low "electron permeability"[111].

The rate constants for reactions with participation of *m*- and *o*-nitrobenzoate radical-anions, analogous to reaction (57), are 1.5×10^2 and 4.0×10^5 s^{-1} respectively[112,166]. The increase of the rate of reaction by several orders of magnitude for the ortho-isomer is probably due to the overlapping of the orbitals of the nitro- and carboxy-groups, which generates an effective pathway for electron transfer. The study of the distribution of spin density in the radical helps to interpret the kinetic data[166].

The strong reductant $CO_2^{\overset{\cdot}{-}}$ is oxidised by various cobalt(III) complexes[111]:

$$CO_2^{\overset{\cdot}{-}} + Co^{III}(NH_3)_5X^{2+} \rightarrow CO_2 + \text{reduced complex.} \qquad (58)$$

The reaction has been investigated by pulse radiolysis combined with the method of competition kinetics: $k_{58} = 10^7-10^9$ litre mole^{-1} s^{-1}. The complexes investigated can be divided into two groups: (1) highly reactive complexes whose reactions involve direct attack on the ligand and electron transfer to an available orbital localised at the ligand; (2) complexes exhibiting a moderate reactivity in which ligand orbitals of lower energies are saturated and the available antibonding orbitals have high energies. As in the study of Land and Swallow[113] (see below), no direct correlation was observed between k_{58} and the overall charge of one of the reactants (in the present instance the complex). k_{58} is more influenced by the properties of the complex as a whole than by the properties of any one free ligand X. Nor was a correlation observed between the rate constants for electron transfer from the $CO_2^{\overset{\cdot}{-}}$ and $^{\cdot}CH_2OH$ radical species to the $Co^{III}.(NH_3)_5X^{2+}$ complexes [reaction (58)] and E^0 for the complex. This can be explained by the comparatively low values of E^0 for such complexes (see Section II, subsection 2), which corresponds to a small difference between their free energies. One can then expect that other factors affect the rate constant for the electron transfer reaction[38].

The ions of metals in unusual valence states inhibit or catalyse various chemical reactions. Reactions of Ni^+ ions with radicals have been investigated[114]. The Ni^+ ions and organic radicals were generated by an electron pulse, the intermediates being detected on the basis of the absorption spectra and conductimetrically. It was found that Ni^+ is capable of reducing various radicals extremely effectively and of forming intermediate complexes:

$$Ni^+ + {}^{\cdot}CH_2C(CH_3)_2OH \rightarrow Ni^{2+} + CH_2=C(CH_3)_2 + OH^- ,$$
$$Ni^+ + CO_2^{\overset{\cdot}{-}} \rightarrow NiCO_2 ,$$
$$Ni^+ + {}^{\cdot}CH_2OH \rightarrow NiCH_2OH^+ ,$$
$$Ni^+ + \dot{C}(CH_3)_2OH \rightarrow NiC(CH_3)_2OH^+ .$$

The complexes interact with water:

$$NiCH_2OH^+ + H_2O \rightarrow Ni^{2+} + CH_3OH + OH^-$$

or with another Ni^+ ion, forming metallic nickel

$$Ni^+ + NiC(CH_3)_2OH^+ \rightarrow Ni^{2+} + Ni + (CH_3)_2\dot{C}OH .$$

Pb^{2+} ions oxidise via a one-electron transfer mechanism hydroxyalkyl radicals and the $CO_2^{\overset{\cdot}{-}}$ radical-anion[161]:

$$Pb^{2+} + CO_2^{\overset{\cdot}{-}} \rightarrow Pb^+ + CO_2 ,$$
$$Pb^{2+} + (CH_3)_2\dot{C}OH \rightarrow Pb^+ + (CH_3)_2CO + H^+ .$$

Pb^+ ions may be reduced to metallic lead in reactions with hydroxyalkyl radicals[161]:

$$Pb^+ + (CH_3)_2\dot{C}OH \rightarrow Pb\dot{C}(CH_3)_2OH^+ \rightarrow Pb + H^+ + (CH_3)_2CO .$$

The reaction proceeds via the formation of an intermediate radical-ion complex.

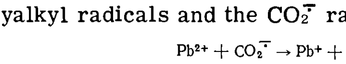
Pb^+ ions are oxidised by the radicals obtained on radiolysis of solutions in t-butyl alcohol and cyclopentane[161]:

$$Pb^+ + {}^{\cdot}CH_2(CH_3)_2COH \rightarrow Pb^{2+} + OH^- + CH_2=C(CH_3)_2 ,$$
$$Pb^+ + C_5H_9^{\cdot} \xrightarrow{H_2O} Pb^{2+} + C_5H_{10} + OH^- .$$

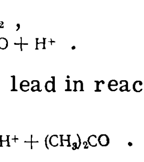
Cytochrome *c* effectively oxidises various radicals:

$$Fe^{III}\ \text{cyt}\ c + R^{n+} \rightarrow R^{(n+1)+} + Fe^{II}\ \text{cyt}\ c \quad . \qquad (59)$$

$k_{59} = 2.4 \times 10^8$ litre mole^{-1} s^{-1} for lactic acid radicals[115], $k_{59} = 5 \times 10^8$ litre mole^{-1} s^{-1} for $CO_2^{\overset{\cdot}{-}}$ radical-anions[116], and $k_{59} = 1.8 \times 10^8$ litre mole^{-1} s^{-1} for radicals derived from ethanol[115]. The oxidation of pyridine radicals by cytochrome *c* has been studied by pulse radiolysis[113]. The radicals were obtained by the one-electron reduction of the following bypyridylium and pyridylium compounds:

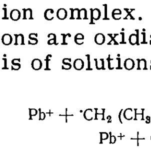


(I)



(II)

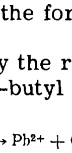
(III)



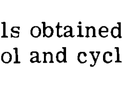
(IV)

NAD^+

(V)



(VI)



(VII)

The resulting rate constants can be divided into two groups. It was found that $k_{59} = (1.8 \pm 0.4) \times 10^8$ litre mole^{-1} s^{-1} for the radical species derived from the bipyridylium salts (I)–(IV) and $k_{59} = (8 \pm 1) \times 10^8$ litre mole^{-1} s^{-1} for the radical species obtained from compounds (V)–(VII).[113] The difference between the values of k_{59} for these groups of radical species may be accounted for by the presence of the positive charge in the radical species from compounds (I)–(IV), which should retard the reaction with the positively charged cytochrome *c*, but this effect is weakened owing to the high ionic strength of the solution. The main reason for the difference may be that the oxidation-reduction potentials of compounds (I) to (IV) are in the range between −0.3 and −0.55 V,[117] while those of compounds (V)–(VII) are in the range between −0.9 and −1.1 V.[113] The reaction apparently proceeds via attack on the part of the porphyrin ring remote from Fe(III), which is confirmed by the high values of k_{59} and resembles the reaction with an organic acceptor rather than with a simple metal complex[41,113].

2. Complexes of Radicals with Transition Metal Compounds

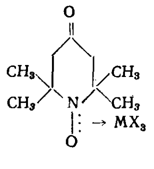
The oxidation-reduction reactions between radicals and metal compounds involving inner- or outer-sphere mechanisms terminate with the decomposition of the intermediate complex or the collision complex into the final products. However, in both cases complexes of the charge-transfer type, association complexes, or coordination compounds with radical ligands may be formed when no oxidation-reduction reactions are observed. Apart from the chemical affinity between the radical and the metal compound, paramagnetic interactions may play an important role in the formation of such complexes, because many metal ions have unfilled or partly filled orbitals, Complexes of radicals and metal compounds (ions) are of great interest, because complex formation alters greatly the reactivity of the radicals. In many cases this entails a relative stabilisation of the radical.

Depending on the degree of charge transfer, the structures of the complexes can be conventionally described by the following formulae:

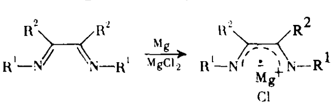
$$R^{\cdot}M^{n+};\quad R^{+}M^{(n-1)+};\quad R^{\overset{\cdot}{-}}M^{(n+1)+}.$$

The metal in complexes of this kind is frequently in an unusual valence stage. The radical ligand has an unpaired electron which is highly delocalised. Under these conditions, the splitting of the ESR spectral lines of the radical, caused by the interaction of the unpaired electron with the paramagnetic metal nucleus, is observed in many instances[66,101]. Despite this, the radical retains its nature in many complexes, which has been confirmed by ESR studies[101].

Stable aliphatic nitroxy-radicals form in solution complexes with aluminium(III) and gallium(III) halides[90,91]. The existence of complexes of the 2,2,6,6-tetramethyl-4-oxopiperidino-1-oxy-radical with the above compound has been demonstrated by ESR. The most probable structure of the complexes is shown below:

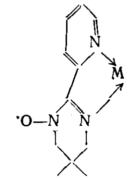


Here the vacant orbital of the Lewis acid interacts with the 3-π-electron fragment N...O, which leads to a slight distortion of the planar configuration of the complex at the nitrogen atom and to an increase of a_N compared with the initial nitroxy-radical[91]. Stable radicals capable of forming complexes with ions having filled electron shells (d^0 or d^{10}) may be obtained by the one-electron reduction of molecules containing the fragments shown below:



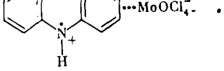
These may be *αα′*-bipyridyl, *o*-phenanthroline, etc. The ESR spectra of a number of such complexes of glyoxal-bis-*N*-t-butylimine (R_1 = t-butyl and R_2 = H) have been recorded[118]. The ESR data have shown that the unpaired electron is delocalised over the entire complex MLCl, including the halogens.

Paramagnetic ligands capable of delocalising the unpaired electron over diamagnetic metal atoms are extremely rare. Complexes of this kind are of interest for the investigation of metal–ligand bonds as well as spin labels linked to the metal ion in proteins. When such labels are employed, spin density is transferred from the radical ligand via the metal to the remaining part of the ligand environment. The stable pyridyliminonitroxy-radical forms complexes with various diamagnetic metal ions[119]:

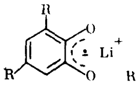


M=Zn^{II}, Cd^{II}, or Hg^{II}.

In certain cases complexes of radicals with metal compounds may be isolated in a crystalline state[120]. The tetrachloro-oxomolybdate of the phenothiazinium radical-cation, isolated in the solid state, gives rise to an ESR spectrum with a single broad signal (g = 1.98), while the ESR spectrum of the complex in solution consists of two superimposed singlets with different g-factors[120]:

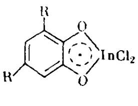


The ions of Groups I–III metals form complex with *o*-quinone radical-anions[121–125]. ESR data have shown that the majority of the complexes remain π-radicals and the degree of transfer of spin density to the metal ion is low[124]. The nature of the oxygen–metal bond has a marked influence on the distribution of the unpaired electron density in the *o*-semiquinone and on the hyperfine interaction with the paramagnetic nucleus of the central atom. Complexes with alkali metal ions, for example, complex (VIII), can be regarded as contact ion pairs:

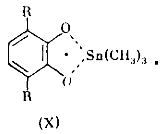


(VIII)

R = C(CH₃)₃

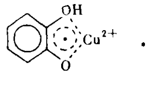


(IX)



(X)

Complexes formed with thallium(I) or indium(III) ions [for example, compound (IX)] are apparently chelates[123]. Significantly higher constants for the hyperfine interaction with metal nuclei compared with contact ion pairs have been obtained from the ESR spectra of the chelates[123]. The ESR spectrum of the tin-containing radical (X), which can be usefully regarded as an organoelemental radical rather than a complex, has been measured[128]. Thus the ESR data for radical complexes make it possible to investigate the nature of the oxygen–metal bond. The complexes of neutral semiquinone radicals having a chelate unit have been recorded by flash photolysis[86]:



The complexes of short-lived radicals with transition metal compounds are destroyed via second-order reactions, like the radicals themselves, but the rate constants are significantly lower than those for the destruction of free radicals. Complexes of the *p*-benzoquinone radical-anion ($Q^{\overline{\cdot}}$) with Cu^{n+} ions have been detected[104]. The rate constants for the reactions

$$Q^{\overline{\cdot}} + Q^{\overline{\cdot}} \xrightarrow{2H^+} Q + QH_2 \qquad (60)$$

$$Q^{\overline{\cdot}}Cu^+ + Q^{\overline{\cdot}}Cu^+ \rightarrow \text{products.} \qquad (61)$$

are $k_{60} = 1.2 \times 10^8$ litre $mole^{-1}$ s^{-1} and $k_{61} = 1.6 \times 10^7$ litre $mole^{-1}$ s^{-1} (in water).

The complex $Pb\dot{C}(CH_3)_2OH^+$, formed by the Pb^+ ion with the α-radicals derived from isopropyl alcohol, has a much longer life in solution than the initial radical[161]. However, the ion pairs involving radical-anions are destroyed faster than the initial radicals. The rate constants for the reactions

$$T^{\overline{\cdot}} + T^{\overline{\cdot}} \rightleftarrows T^{2-} + T \quad , \qquad (62)$$

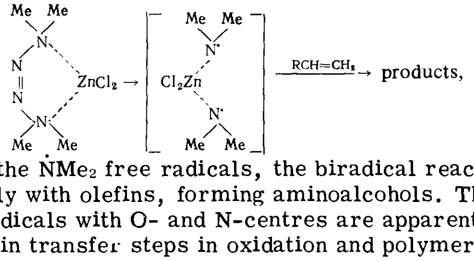
$$T^{\overline{\cdot}}, Na^+ + T^{\overline{\cdot}}, Na^+ \rightleftarrows T^{2-}, 2Na^+ + T \qquad (63)$$

of the tetraphenylethylene (T) radical-anions in tetrahydrofuran (THF) have been estimated: $k_{62} < 10^3$ and $k_{63} < 8 \times 10^6$ litre $mole^{-1}$ s^{-1}.[129] In this case the Coulombic repulsion of the similarly charged species [reaction (62)] has a decisive influence on the kinetics[129]. The rate constant $k_{64} = 1 \times 10^7$ litre $mole^{-1}$ s^{-1} has been obtained for the reaction between the ion pair and the radical:

$$T^{\overline{\cdot}}, Na^+ + T^{\overline{\cdot}} \rightleftarrows T^{2-}, Na^+ + T \ . \qquad (64)$$

Reaction (63) is slower than reaction (64), since two Na^+ ions are desolvated simultaneously in the transition state of reaction (63).[129]

As stated above, the reactivity of the radicals changes markedly on formation of complexes. Evidence has been obtained[130] for the existence of a biradical complex formed on thermal decomposition of the complex of tetramethyl-2-tetrazene with $ZnCl_2$:



In contrast to the $\dot{N}Me_2$ free radicals, the biradical reacts very selectively with olefins, forming aminoalcohols. The coordinated radicals with O- and N-centres are apparently inactive in chain transfer steps in oxidation and polymerisation reactions, which is important in connection with the problem of the inhibiting activity of phenols, aromatic amines, and related compounds[131,132].

The ability of transition metal ions to catalyse the recombination of methyl radicals is explained by the formation of an intermediate species—the complex of the alkyl radical with the metal ion, which is stable in relation to the abstraction of a hydrogen atom and participates only in the reaction with the analogous complex[133]:

$$\dot{C}H_3 + M^{n+} \rightleftarrows {}^{\cdot}CH_3M^{n+} \quad ,$$

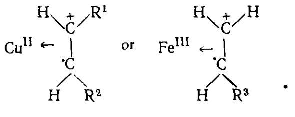
$$2\dot{C}H_3M^{n+} \rightarrow C_2H_6 + 2M^{n+} \quad .$$

Studies by pulse radiolysis have shown that $OH^{\cdot}$ forms a complex with benzoatopentamminecobalt(III),[134] adding to the ligand—the benzoate anion:

$$(NH_3)_5\, Co^{III}\, (O_2CC_6H_5OH)$$

The complex is destroyed via a second-order reaction: $k = 9.3 \times 10^7$ litre $mole^{-1}$ s^{-1}, which is significantly less than the rate constants for the reactions of $OH^{\cdot}$ radicals and their adducts with benzoic acid and benzoate ion (1.2×10^8 and 4.4×10^8 litre $mole^{-1}$ s^{-1} respectively)[134].

When s-butyl-lithium was oxidised with the aid of di-isopropyl salicylate or copper(II) or iron(III) acetylacetonate, ESR spectra were recorded[126]. The absence of splitting by the copper nucleus and the low constants for the hyperfine splitting by protons enabled the authors to attribute the following structure to the complexes:



The unpaired electron is localised in an orbital of the carbon atom[126].

Hyperfine splitting by the silver nucleus has been observed in the ESR spectra of many silver(I)–olefin radical complexes ($g = 2.0017$) formed when polycrystalline silver complexes of olefins are subjected to γ-irradiation[127]. Analogous complexes with a radical ligand have been obtained on irradiating compounds of silver perchlorates with cyclohexa-1,3-diene or cyclohexa-1,4-diene. The constants for hyperfine splitting by the protons in the complex

are virtually the same as in the spectrum of the free cyclohexadienyl radical, which indicates a weak interaction between the hydrocarbon radical and the nucleus of the metal ion[127].

The formation of a complex by the benzyl radical and chromium(II) has been reported[135]:

$$Ph\dot{C}H_2 + Cr^{II} \rightleftarrows Ph\dot{C}H_2Cr^{II} \quad .$$

Complexes of related aromatic radicals—semiquinone and phenoxy-radicals—have been discussed in a review[66].

Many complexes of radicals and transition metal ions (compounds) have structures resembling very closely those of ion pairs formed by aromatic radical-anions and alkali metal ions. The difference consists in the absence of electrostatic attraction which holds together ion pairs[101].

The study of the interaction of peroxy-radicals $R\dot{O}_2$ with transition metal compounds is of interest in connection with the investigation of homogeneous-catalytic liquid-phase oxidation of hydrocarbons. The existence of complexes formed by peroxy-radicals $R\dot{O}_2$ with vanadyl, cobalt, and manganese acetylacetonates and naphthenates has been suggested[136–138]. The studies were performed by the ESR method, solutions of the hydroperoxide ROOH and $M^{n+}L_m$ being mixed. The authors believe that the formation of the complex stabilises $R\dot{O}_2$. However, it is not stated[136-138] whether ROOH has been completely consumed at the time when the ESR spectra of the stabilised $RO_2^{\cdot}$ were observed. If ROOH were present in solution, then fairly high $RO_2^{\cdot}$ concentrations might have been observed for a long time simply owing to the decomposition of the hydroperoxide[139], which throws doubt on the conclusions reached by the authors[136-138].

3. Interactions of the Hydroperoxy-radicals with Metal Ions

Under certain conditions, hydroperoxy-radicals capable of interacting with metal ions are formed in systems of the type of Fenton's reagent. In the presence of an excess of H_2O_2, $HO_2^{\cdot}$ radicals are formed by the reaction[142]

$$Ce^{4+} + H_2O_2 \rightarrow Ce^{3+} + H^+ + HO_2^{\cdot} \qquad (65)$$

or via the reactions[142-144]

$$M^{n+} + H_2O_2 \rightarrow M^{(n+1)+} + OH^- + OH^{\cdot} \;, \qquad (66)$$

$$OH^{\cdot} + H_2O_2 \rightarrow H_2O + HO_2^{\cdot} \;, \qquad (67)$$

$$M^{n+} = Ti^{3+},\; Fe^{2+},\; V^{4+}, \text{ or } Cr^{2+}.$$

The interaction of the hydroperoxy-radical with metal ions was studied on stopped flow apparatus with two mixing chambers: the $HO_2^{\cdot}$ radical was formed in the first chamber via reaction (65) and, when the latter had reached completion, the solution was mixed with the solution of the metal ions in the second chamber. The changes in the system were followed on the basis of the ESR spectra.

The method of flash photolysis with detection of intermediates by ESR is convenient for kinetic measurements. $HO_2^{\cdot}$ radicals are then generated via reaction (67) and

$$H_2O_2 + h\nu \rightarrow 2OH^{\cdot}$$

in a cell located in the cavity of the ESR spectrometer. It is also possible to investigate the reactions of $HO_2^{\cdot}$ radicals by the method of steady-state radiolysis in combination with a flow system and ESR.

The existence of complexes of $HO_2^{\cdot}$ with a number of transition metal ions, such as Ti^{4+}, Zr^{4+}, Ce^{3+}, V^{5+}, Th^{4+}, U^{6+}, Mo^{6+}, etc. has been established[142,145-151]:

$$M + HO_2^{\cdot} \rightleftarrows M{-}HO_2^{\cdot} \quad . \qquad (68)$$

The complexes may be formed not only via reaction (68) but in many instances also as a result of the interaction of the $HO_2^{\cdot}$ or $OH^{\cdot}$ radicals with the $M{-}H_2O_2$ complex[142]:

$$M{-}H_2O_2 + HO_2^{\cdot} \rightarrow M{-}HO_2^{\cdot} + H_2O_2 \quad ,$$

$$M{-}H_2O_2 + OH^{\cdot} \rightarrow M{-}HO_2^{\cdot} + H_2O \quad .$$

In the presence of ions of two metals, M and M′, ESR spectra due to two species have been recorded: $M{-}HO_2^{\cdot}$ and $M'{-}HO_2^{\cdot}$. The occurrence of the reversible reaction[142]

$$M{-}HO_2^{\cdot} + M' \rightleftarrows M'{-}HO_2^{\cdot} + M \qquad (69)$$

was demonstrated. This may be a bimolecular reaction [Eqn. (69)] or it may proceed via the association of the complex $M{-}HO_2^{\cdot}$ [the reverse process in reaction (68)] followed by the formation of the complex with the M′ ion. Reaction (69) involving many pairs of ions has been observed: $U^{6+}{-}Th^{4+}$, $Th^{4+}{-}Zr^{4+}$, $Zr^{4+}{-}U^{6+}$, $Th^{4+}{-}Ti^{4+}$, $U^{6+}{-}Ti^{4+}$, $V^{5+}{-}Ti^{4+}$.[142] Kinetic studies have shown that the exchange reaction between Cu^{2+} and Th^{4+} ions is more likely to proceed via the direct transfer of $HO_2^{\cdot}$ than via a dissociation-association mechanism[145]:

$$Cu^{2+} + [Th{-}HO_2]^{4+} \rightleftarrows [Cu{-}HO_2^{\cdot}]^{2+} + Th^{4+} \;, \qquad (70)$$

where $K_{70} = 3 \times 10^2$.

Apart from the $M{-}HO_2^{\cdot}$ complexes, more involved $M{-}HO_2{-}M'$ complexes may exist[145]. The $HO_2^{\cdot}$ radical disproportionates in solution:

$$HO_2^{\cdot} + HO_2^{\cdot} \rightarrow H_2O_2 + O_2 \qquad (71)$$

with $k_{71} = 6.7 \times 10^5$ litre $mole^{-1}$ s^{-1}.[152] Under the experimental conditions, the lifetime of the $HO_2^{\cdot}{-}M$ complexes is significantly longer than that of $HO_2^{\cdot}$. This is one of the reasons why the ESR spectra of many such complexes have been recorded. The Zr^{4+}, Th^{4+}, and U^{6+} complexes are destroyed via first-order reactions for higher values of [M]. The lifetime of such complexes varies from several tenths of a second to several seconds[142]. The lifetime of the $Nb^{5+}{-}HO_2^{\cdot}$ and $La^{3+}{-}HO_2^{\cdot}$ complexes is significantly shorter, which gives rise to certain difficulties in their detection[146].

Apart from their involvement in complex-formation reactions, the $HO_2^{\cdot}$ and $O_2^{\overline{\cdot}}$ radical species participate in oxidation-reduction reactions. Thus Cu^{2+} oxidises the $HO_2^{\cdot}$ radical[152]:

$$Cu^{2+} + HO_2^{\cdot} \rightarrow Cu^+ + H^+ + O_2 \qquad (72)$$

with $k_{72} \simeq 1 \times 10^8$ litre $mole^{-1}$ s^{-1}. Reaction (72) also proceeds via the formation of a complex[145]:

$$Cu^{2+} + HO_2^{\cdot} \rightleftarrows [Cu{-}HO_2^{\cdot}]^{2+} \;, \qquad (73)$$

$$[Cu{-}HO_2^{\cdot}]^{2+} \rightarrow Cu^+ + H^+ + O_2 \qquad (74)$$

[$K_{73} = (5.1 \pm 1.0) \times 10^7$ litre $mole^{-1}$, and $k_{74} = 30 \pm 5$ s^{-1}] and reaction (74) determines the rate of oxidation for higher values of $[Cu^{2+}]$.

The oxidation of $O_2^{\overline{\cdot}}$ by Cu^{2+} ions also proceeds with formation of an intermediate complex[149,151,152]:

$$Cu^{2+} + O_2^{\overline{\cdot}} \rightarrow [CuO_2]^+ \rightarrow Cu^+ + O_2 \qquad (75)$$

with $k_{75} = (1.7 \pm 0.3) \times 10^9$ litre $mole^{-1}$ s^{-1}¶ [150,151].

It has been found that the complex of $O_2^{\overline{\cdot}}$ and Cu^{2+} exists and that its lifetime is shorter than that of the complex with $HO_2^{\cdot}$.[145,152] This is quite reasonable, since $O_2^{\overline{\cdot}}$ is a stronger reducing agent than $HO_2^{\cdot}$: $E^0_C(O_2|O_2^{\overline{\cdot}}) < E^0_C|HO_2^{\cdot})$ [39] (see Section III). Cu^+ ions reduce $HO_2^{\cdot}$ and $O_2^{\overline{\cdot}}$:[152]

$$Cu^+ + O_2^{\overline{\cdot}} \xrightarrow{2H_2O} Cu^{2+} + H_2O_2 + 2OH^- \;, \qquad (76)$$

$$Cu^+ + HO_2^{\cdot} \xrightarrow{H^+} Cu^{2+} + H_2O_2 \qquad (77)$$

with $k_{76} > 10^9$ litre $mole^{-1}$ s^{-1} and $k_{77} \simeq 10^{10}$ litre $mole^{-1}$ s^{-1}.

In contrast to Cu^{2+} ions, Fe^{3+} ions oxidise $O_2^{\overline{\cdot}}$ via an outer-sphere mechanism:

$$Fe(H_2O)_6^{3+} + O_2^{\overline{\cdot}} \rightarrow Fe(H_2O)_6^{3+},\; O_2^{\overline{\cdot}} \rightarrow Fe^{2+} + O_2 \qquad (78)$$

with $k_{78} = (8 \pm 2) \times 10^8$ litre $mole^{-1}$ s^{-1}.[49,150]

Titanium(IV) and vanadium(V) ions form fairly stable complexes with $O_2^{\overline{\cdot}}$.[149] Analysis of the results of ESR studies of these complexes and the interpretation of the structures of the complexes with the aid of the molecular orbital method have shown that the molecular oxygen in the coordination spheres of these metal ions should have a singlet ground state[149]. This conclusion makes it possible to explain the relative stability of the radical complexes with respect to electron transfer within the inner-sphere. The highest molecular orbitals of $O_2^{\overline{\cdot}}$ are designated by π^* (HOMO) and $\bar{\pi}^*$. The energetically most favourable direct electron transfer $\pi^* \rightarrow t_{2g}$ with formation of singlet oxygen in the coordination sphere is forbidden by symmetry considerations. Electron transfer

---

¶ According to Rabani et al.[152], $k_{75} = 8 \times 10^9$ litre $mole^{-1}$ s^{-1}.

from the π orbital to the t_{2g} orbital requires a large activation energy, since it leads to the formation of oxygen in the excited triplet state[149].

The high rate of electron transfer within the inner sphere in the $Cu^{2+}O_2^{\bar{\cdot}}$ complex is apparently caused by the σ-coordination of oxygen[149].

The kinetics and mechanism of the formation and destruction of radical complexes in the titanium(IV)–H_2O_2–cerium(IV) system have been investigated in detail[147] by ESR. The accumulation of the radical $Ti^{IV}O_2^{\bar{\cdot}}$ complex in this system proceeds via the reactions

$$Ti^{IV}(O_2^{2-}) + Ce^{IV} \underset{k_b}{\overset{k_a}{\rightleftarrows}} Ti^{IV}(O_2^{2-})Ce^{IV} \xrightarrow{k_{79}} Ti^{IV}(O_2^{\bar{\cdot}}) + Ce^{III}, \qquad (79)$$

$$k_a = 5 \cdot 10^4 \text{litre mole s}^{-1}, \quad k_b = 130 \text{ s}^{-1}, \quad k_{79} = 75 \text{ s}^{-1}.$$

The $Ti^{IV}O_2^{\bar{\cdot}}$ complex is destroyed via the reactions:

$$Ti^{IV}O_2^{\bar{\cdot}} + Ce^{IV} \rightleftarrows Ti^{IV}(O_2^{\bar{\cdot}})Ce^{IV} \xrightarrow{k_{80}} Ti^{IV} + Ce^{III} + O_2, \qquad (80)$$

$$Ti^{IV}O_2^{\bar{\cdot}} + H^+ \rightleftarrows HO_2^{\cdot} + Ti^{IV}, \qquad (81)$$

$$Ti^{IV}O_2^{\bar{\cdot}} + Ti^{IV}O_2^{\bar{\cdot}} \rightarrow \text{products}, \qquad (82)$$

$$Ti^{IV}O_2^{\bar{\cdot}} + HO_2^{\cdot} \rightarrow \text{products} \qquad (83)$$

$$k_{80} = 7 \text{ s}^{-1}, \quad k_{81} = 2 \text{ litre mole}^{-1}\text{ s}^{-1}, k_{82} \leqslant 500 \text{ litre mole}^{-1}\text{ s}^{-1},$$
$$k_{83} > 2{,}8 \cdot 10^5 \text{ litre mole}^{-1}\text{ s}^{-1}, \quad k_{-81} > 2{,}8 \cdot 10^3 \text{ litre mole}^{-1}\text{ s}^{-1}.$$

The reversible formation of copper(II) complexes of $O_2^{\bar{\cdot}}$ has also been observed in an organic medium[153]. In the oxidation of methanol in an alkaline medium and of cumene, it was observed that the catalytic effect of the copper complexes of *o*-phenanthroline (*o*-P) is due to the formation of the complex $Cu^I(o\text{-}P)_2$ in the system, which coordinates oxygen, forming a copper(II) complex:

$$Cu^I(o\text{-}P)_2 + O_2 \rightleftarrows Cu^{II}(o\text{-}P)_2O_2^{\bar{\cdot}}$$

---o0o---

Thus many reactions involving free radicals proceed via one-electron transfer. Fairly extensive experimental data on the oxidation-reduction reactions of radicals have now accumulated, which makes it possible to establish certain structural-kinetic rules. Kinetic data are very important for the theory of electron transfer and for its further development.

The vast majority of free radicals are short-lived in liquid solutions, which necessitated the use of flow or pulse techniques in order to obtain reliable information about reactions involving them. The use of the pulse radiolysis method proved to be extremely promising for the measurement or estimation of one-electron potentials of free radicals. The knowledge of such potentials permits in the majority of instances a correct prediction of the direction and rate of the oxidation-reduction reaction.

The study of one-electron transfer reactions involving cytochromes, oxygen, quinones, flavins, and pyridine bases is of interest for the elucidation of the detailed mechanism of electron transport in biological systems.

Transition metal compounds are widely used as catalysts in radical reactions. The reactions of macroradicals with transition metal complexes play an important role in radical polymerisation and in the stabilisation of polymers. Different metal complexes or salts can have a significant influence on the kinetics and mechanisms of radical oxidation and reduction reactions of organic compounds.

The study of the influence of the magnetic field on the kinetics of oxidation-reduction reactions of radicals with transition metal compounds having different electronic configurations may promote a further development of the theory of magnetic effects in radical reactions.

The study of coordination compounds with radical ligands constitutes a new field in the chemistry of complex compounds. On formation of the complex with a transition metal compound, the reactivity of the radical changes; in most cases short-lived radicals become more stable on forming a complex.

The oxidation-reduction reactions of free radicals can have a wide variety of practical applications. The electron transfer reactions between certain stable free radicals generate an e.m.f. The one-oxidation of $CO_3^{\bar{\cdot}}$ constitutes the basis of the reduction of oxygen by the action of visible light on the duroquinone–carbonate ion system and thus provides a valuable means of utilising solar energy.

The Photonics of Porphyrin Molecules

I.I.Dilung and E.I.Kapinus

The review deals with the properties and behaviour of porphyrin molecules in an excited state. Modern data on the electronic structure of metalloporphyrins and their luminescence-spectroscopic properties are presented. The problems of the photonics of metalloporphyrins, which are of great importance for the understanding of the initial stages in photosynthesis and for the control of the latter, are discussed in detail.

The bibliography includes 124 references.

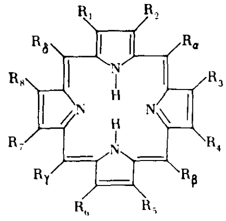
III. The luminescence spectroscopic properties of metalloporphyrins 46
IV. The photochemistry of metalloporphyrins 48

I. INTRODUCTION

Porphyrins belong to one of the most thoroughly investigated classes of organic compounds, owing to their enormous role in biological processes. Several fundamental monographs and reviews devoted to the structure and coordination chemistry of metalloporphyrin[1-5] as well as their reactivity[6] were published in recent years. There are no reviews in the modern chemical literature in which the properties and behaviour of porphyrin molecules in an excited state are discussed. A monograph[2], which is partly devoted to the luminescence of porphyrins, is an exception. However, during the period which has elapsed since its publication, new extensive information has accumulated on the photophysical properties of metalloporphyrins. Furthermore, the photonics of porphyrins is of primary importance for the understanding of the essential features of the processes underlying the initiation of the electron transport chain in photosynthesis and for the control of these processes as well as for the simulation of natural systems suitable for the transformation of light energy into a chemical form. The aim of the present article is to fill the existing gap in the literature and to survey the experimental data on the photonics of porphyrins obtained mainly during the last decade.

Porphyrins are derivatives of porphin–a cyclic system formed by four pyrrole rings linked by methine bridges:



porphyrin
(R = H throughout)

we have etioporphyrin (I; $R_1 = R_3 = R_5 = R_7 = CH_3$, $R_2 = R_4 = R_6 = R_8 = C_2H_5$, $R\alpha = R\beta = R\gamma = R\delta = H$), mesoporphyrin (IX; $R_1 = R_3 = R_5 = R_8 = CH_3$, $R_2 = R_4 = C_2H_5$, $R_6 = R_7 = CH_2CH_2COOH$, $R\alpha = R\beta = R\gamma = R\delta = H$); haematoporphyrin (IX; $R_1 = R_3 = R_5 = R_8 = CH_3$, $R_2 = R_4 = CH_2CH_2OH$, $R_6 = R_7 = CH_2CH_2COOH$, $R\alpha = R\beta = R\gamma = R\delta = H$), octaethylporphin ($R_1 = R_2 = R_3 = R_4 = R_5 = R_6 = R_7 = R_8 = C_2H_5$, $R\alpha = R\beta = R\gamma = R\delta = H$), and tetraphenylporphin ($R_1 = R_2 = R_3 = R_4 = R_5 = R_6 = R_7 = R_8 = H$, $R\alpha = R\beta = R\gamma = R\delta = C_6H_5$). Hydrogenation of the double bond in the pyrrole ring leads to chlorins, the most important representative of which is chlorophyll, while hydrogenation of two double bonds result in the formation of bacteriochlorins, the natural representatives of which transform light energy in bacterial photosynthesis. When methine bridges are replaced by tertiary nitrogen atoms, azaporphyrins are obtained. Structures consisting of four isoindole units linked by methine bridges are called benzoporphyrins. When the methine bridges in tetrabenzoporphin are substituted by nitrogen atoms, tetrabenzo-tetra-azaporphin or phthalocyanine is obtained.

Porphyrins are amphoteric compounds capable of combining two protons via the lone electron pairs of the unsubstituted nitrogen atoms or can exhibit acid properties, giving up two central protons in an alkaline medium. The substitution of the protons by a doubly charged cation results in the formation of chelate complexes—metalloporphyrins. The metal atom in these compounds is linked to the four nitrogen atoms by equivalent chemical bonds. As a result of complex formation, the molecule acquires a fourfold symmetry axis.

II. THE ELECTRONIC STRUCTURE OF METALLOPORPHYRIN MOLECULES

All porphyrins have similar electronic spectra, a characteristic feature of which is the presence in the visible region of four absorption bands and of an intense band, the so called Soret band, at the boundary between the ultraviolet and visible regions. The positions and relative intensities of the absorption bands depend on the nature of the substituents. Fundamental studies have now been carried out on the interpretation of the absorption spectra of porphyrins[2]. It has come to be assumed that the long-wavelength bands in the spectra of both porphyrins themselves and of their metallo-derivatives are due to transitions in the branched π-electron system of the bonds in the tetrapyrrole macroring. This is suggested by the results of quantum-chemical calculations and experimental data. Polarisation measurements[7-9] have shown that the electric dipole moment of the electronic transition lies in the plane of the porphyrin molecule. The weak influence of the solvent on the position of the absorption band is also evidence for the $\pi \rightarrow \pi^*$ type of the lowest excited states. A purely phenomenological approach confirms this conclusion. Indeed the $n \rightarrow \pi^*$ transitions in nitrogen-containing heterocycles occur in the region of approximately 310 nm.[10] If account is taken of the presence of an intramolecular hydrogen bond in the porphyrin molecules, the above absorption should occur at still higher frequencies. The formation of metalloporphyrins is accompanied by significant changes in the spectrum. In the vast majority of cases, the four-band spectrum in the visible region is converted into a two-band spectrum without an appreciable change in the position of the Soret band—the latter merely becomes appreciably narrower.

The positions of the absorption bands of metalloporphyrins depend little on the nature of the central metal atom: the wavelengths of the longest-wavelength maximum varies within the range of 30 nm. A correlation has been observed between the position of this band and the stability of the complex. Thus the stability decreases and λ_{max} increases in the sequence[11-13]

$$\mathrm{Pd} > \mathrm{Pt} > \mathrm{Ni} > \mathrm{Co} > \mathrm{Ag} > \mathrm{Cu} > \mathrm{Zn} > \mathrm{Mg} > \mathrm{Cd} > \mathrm{Ba}\ .$$

It has been noted that, within the limits of the same subgroup in the Periodic System, the stability of the complexes decreases with increase of the atomic number of the central metal atom[11]. The hypsochromic shift of the absorption bands observed as the stability of metalloporphyrins increases, is evidence for the dominant role of σ bonds in complex formation, compared with π-dative bonds, i.e. for a weak interaction of the central metal atom with the π-electron system of the ligand[12]. The electronegativity of the ions increases in the above sequence with increase of the stability of the complexes[14]. A linear relation has been established between the electronegativity of the central ion and the first oxidation potential for a series of metallo-derivatives of porphyrins and chlorins[15,16]. Such correlation is associated primarily with the decrease of the energy of the highest occupied level on enhancement of the electron-accepting properties of the central atom; this should entail also a decrease of the energy of the lowest vacant level. As a result of the latter, smaller reduction potentials of the complex correspond to higher oxidation potentials and conversely. This conclusion is fully consistent with experiment[6].

The similarity of the electronic spectra of the majority of metalloporphyrins and their weak dependence on the nature of the central metal atom are apparently additional confirmation of the fact that the absorption of all the metalloporphyrins is due to the same chromophore. It is noteworthy that the "simplification" of the spectra of porphyrins on formation of metallo-derivatives, noted above, is attributed to the increase of molecular symmetry from D_{2h} to D_{4h}.[17]

The interpretation of the spectra of metalloporphyrins is based on Gouterman's four-orbital model[18,19]†. In this model the optical properties of the metalloporphyrins are accounted for by the electronic transitions from the two highest occupied orbitals to the lowest vacant orbitals taking into account the configuration interaction. The lowest vacant orbitals e_{gx} and e_{gy} of metalloporphyrins are degenerate, while the highest occupied orbitals a_{1u} and a_{2u} are almost degenerate. The $(a_{1u}e_g)$ and $(a_{2u}e_g)$ configurations interact in pairs, giving rise to states in which almost equal dipole moments of the transitions weaken or enhance one another. This leads to the occurrence of a weak Q transition and a very intense B transition corresponding to an absorption band in the visible region and to the Soret band. The longest-wavelength absorption band and the Soret band in the spectra of metalloporphyrins are associated with purely electronic transitions; the second band in the visible region has a vibronic origin[17]. The four-orbital model has been confirmed satisfactorily by the results of numerous spectroscopic studies[2]. The four main transitions in the visible spectra of free porphyrins are interpreted as the daughter transitions Q_x and Q_y and two vibrational transitions. The B_x and B_y transitions are in the region of the Soret band. It is significant that the intensities of the Q_x and Q_y bands are extremely sensitive to substituents, while the intensities of the vibronic bands are almost independent of the nature and positions of the side groups. This factor constitutes a theoretical basis for the classification of porphyrins in terms of spectral types.

The interpretation of the electronic spectra of porphyrins and their metallo-derivatives within the framework of the four-orbital model agrees satisfactorily with the results of studies on magnetic circular dichroism (MCD) and magnetic optical rotatory dispersion (MORD). The magnetic optical activity of tetrapyrrole pigments has been investigated in fair detail[22-36]. Stephens et al.[24] analysed the MORD data[22,23] and confirmed that the visible bands in the spectra of Zn-haematoporphyrin and Mg-phthalocyanine correspond to the vibrational components of the ${}^1A_{1g} \rightarrow {}^1E_u$ transition, while the Soret band corresponds to the second ${}^1A_{1g} \rightarrow {}^1E_u$ transition. It has been found from MCD data that the longest-wavelength bands in the spectra of free porphyrins are due to two electronic transitions, the moments of which are mutually perpendicular and lie in the plane of the molecule. Comparison of the magnetic moments obtained by Stephens et al.[24] with the values calculated by Simpson[27] and Gouterman[19] showed that the four-orbital model leads to data in good agreement with experiment. The interpretation of the absorption spectra of chlorins proposed by Gouterman[19] has also been confirmed by MCD data[24].

Experiment has shown that the set of configurations of the four-orbital model is in many cases quite sufficient for calculations of the spectra of metalloporphyrins. For example the Q state of chlorophyll consists to the extent of 97% of the configurations of the four-orbital model[28]. However, the influence of new configurations introduced into the calculation varies from porphyrin to porphyrin[28], so that in the studies carried out in recent years account is taken of a large number of singly excited configurations. As an example, one may quote the calculation for porphyrin and its zinc complex carried out by the Pariser–Parr–Pople method taking into account all singly excited configurations[29,30]. The electronic structure of the metallo-derivatives is characterised by the occurrence of three low-lying electronic transitions[29]. The first apparently corresponds to the longest-wavelength band and the second and third to the Soret band and its shoulder respectively. Differences from the results obtained on the basis of the four-orbital scheme are observed for porphyrins. According to one calculation[29], three electronic transitions correspond to the Soret band. Bands I and III have been interpreted as purely electronic, and the authors assumed that the third transition in the visible region can refer either to band IV or to the Soret band. The calculated charges on the atoms and the bond orders indicate the presence in the Zn-porphin of two equivalent conjugation chains—inner and outer (Fig. 1*b*). Of the two conjugation chains of free porphin (Fig. 1*a*), that which passes through unsubstituted nitrogen atoms makes the greatest contribution to the charges and bond orders. The conjugation

---

† The latter is based on earlier investigations[20,21].

chains served for a long time as models for the early quantum-chemical calculations on porphyrins[31,32].

It has been observed recently that the absorption spectra of metalloporphyrins containing certain ions with powerful electron-accepting properties have an anomalous form. These include derivatives of the dimethyl ester of mesoporphyrin (IX) with $Fe^{III}Cl$, $Bi^{III}OH$, $Mn^{III}Cl$, $As^{III}Cl$, and Hg^{II}, of aetioporphyrin with $Sb^{III}Cl$,[32] and of octaethylporphin with $Mn^{III}OPh$ (OPh is the phenoxy-residue)[34].

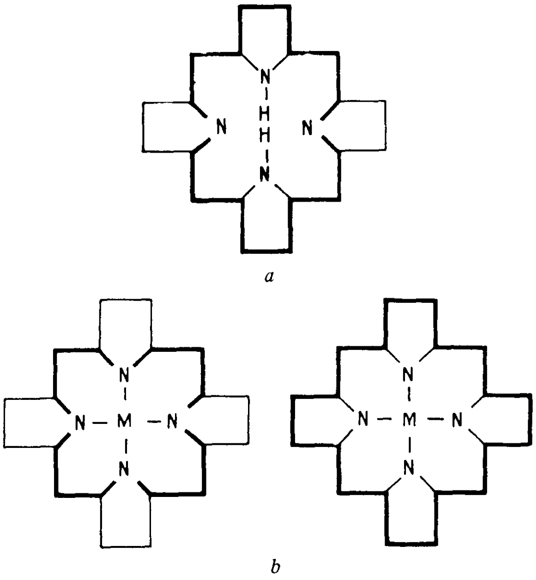


Figure 1. Conjugation chains of porphin (*a*) and metalloporphin (*b*)[29].

In order to be able to understand the nature of the excitation and to elucidate the mechanism of the deactivation of the excitation energy, it is necessary to know the electronic structure of the molecule. For the majority of metalloporphyrins, it has sofar been possible to obtain data for the electronic levels of the central metal atom from quantum-mechanical calculations but not on the basis of spectroscopic studies. Calculations of the energy levels of porphyrins and their metallo-derivatives can nowadays be carried out only by semiempirical methods. The majority of the calculations have been performed by the extended Hückel method (EHM). The series of theoretical studies by Gouterman and coworkers, devoted to the investigation of metalloporphyrins containing Group II–VIII elements (mainly those of the Third Period), are of interest in this sense[35-41].

Fig. 2 illustrates the energy level diagram for metalloporphyrins quoted by Zerner and Gouterman[35]. In the zinc complex the *d* orbitals are located fairly low in the above scheme and are almost completely mixed with the orbitals of the tetrapyrrole ring. The highest occupied orbital is b_{1g}, which is a σ orbital. Cu-porphyrin has a similar electronic structure. In the molecule of this complex the b_{1g} orbital is also below the vacant $e_g(\pi)$ orbital of the porphyrin, but possesses a more distinct $d_{x^2-y^2}$ character than in the zinc derivative. Other *d* orbitals with lower energies resemble the corresponding orbitals of the zinc complex. The b_{1g} orbitals of Ni- and Co-porphyrins are vacant. They lie below the vacant $e_g(\pi)$ orbital or porphin and are almost pure $d_{x^2-y^2}$ orbitals of the metals. The remaining *d* orbitals are occupied and are located between the highest occupied $a_{2u}(\pi)$ levels and the vacant $e_g(\pi)$ levels of the tetrapyrrole ring; the splitting of the *d* levels is approximately 0.05 eV. A distinctive feature of the iron and manganese complexes of porphyrins is the presence of low-lying vacant d_{z^2} and $d(\pi)$ orbitals. The vacant *d* level between the occupied and vacant levels of the tetrapyrrole chromophore creates the necessary conditions for the corresponding intramolecular electronic transitions. Indeed the anomalous absorption spectra of certain iron(III) and manganese(III) complexes of porphyrins, described above, have been attributed to $\pi \rightarrow d(\pi)$ transitions in a number of recent studies[42-44]. We may note that the idea of the interpretation of the absorption bands of Fe-porphyrins as charge-transfer bands was put forward as early as 1957 by Dain and Ashkinazi[45] on the basis of the photochemical behaviour of these compounds.

The quantum-mechanical calculations on metalloporphyrins can be tested by comparison with the results of experiments on the reduction and oxidation of metalloporphyrins. It is then necessary to take into account the fact that, when the pigment molecule is reduced, the electron is localised either at the central ion or occupies a vacant $e_g(\pi)$ orbital of the conjugated bond system. On the other hand, in the oxidation reaction the electron can also be split off either from the central ion or from the organic component of the molecule. The site where the electron is added or abstracted should apparently be determined by the relative positions of the energy levels of the ligand and the metal (within the framework of the simple molecular orbital model).

The available data for the oxidation-reduction reactions of the majority of metalloporphyrins are summarised below:

1. Metal ions which remain stable in the electrochemical oxidation or reduction of metalloporphyrins:
   (a) univalent—alkali metals;
   (b) divalent—alkaline earth metals, Pd, Cu, Zn, and Cd;
   (c) trivalent—Sb, Sc, Al, Ga, In, and Tl;
   (d) tetravalent—Si, Ge, Sn, TiO, and VO.
2. Oxidation-reduction reactions involving the metal atom:
   (a) $M(I) \rightleftharpoons M(II)$—Co;
   (b) $M(II) \rightleftharpoons M(III)$—Mn, Fe, Co, Cr, Ag, and Ni;
   (c) $M(II) \rightleftharpoons M(IV)$—Pb;
   (d) $M(III) \rightleftharpoons M(IV)$—Cr and Fe;
   (e) $M(IV) \rightleftharpoons M(V)$—MoO.

Evidently experiments agree satisfactorily on the whole with calculated data (Fig. 2). The VO, copper, and zinc complexes of porphyrins are exceptions. Indeed, when they undergo electrochemical oxidation, an electron is abstracted from the tetrapyrrole ligand despite the fact that the highest occupied orbital in the molecules of these substances is the $d_{x^2-y^2}$ orbital. In this case explanations based on the EHM calculations for the initial molecules alone are clearly inadequate. The data for the electrochemical reduction have been confirmed by the results obtained in the study of the reduction of metalloporphyrins by electron donors such as alkali metals and anthracene, naphthalene, pyridine, benzophenone, etc. radical-anions[46,47].

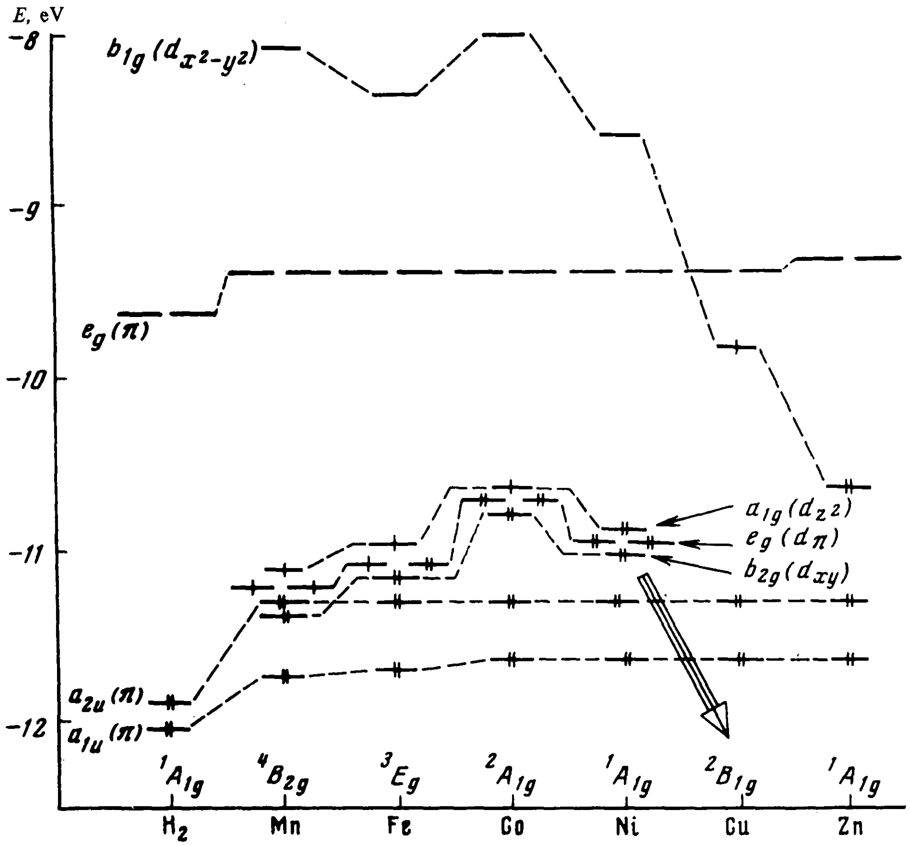

Figure 2. The energy levels of metalloporphyrins[35].

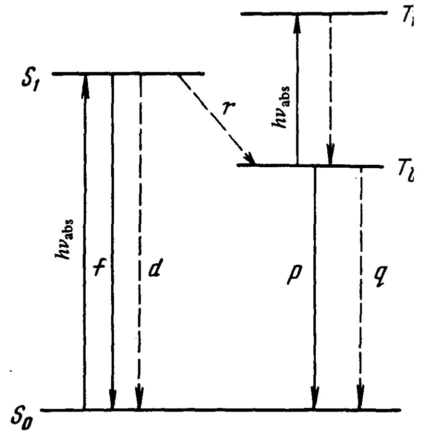

Figure 3. A typical energy level diagram for an organic molecule.

It is of interest that in the case of porphyrins containing transition metal ions oxidation-reduction reactions may lead to compounds with the metal atom in an unusual oxidation state. Thus it is suggested that the electrochemical reduction of Co-sulphophthalocyanine involves the transition of the central metal atom to the zero-valent and univalent states in the primary stages[48]. Evidently in all cases the number of electrons which can add to the central metal atom is determined by the number of vacant levels below the $e_g(\pi)$ electronic level. The compounds formed are of interest from the standpoint of isoelectronic complexes. Such a compound was obtained for the first time by Watt and Davis[49] on reduction of Cu-phthalocyanine by metallic sodium in liquid ammonia. They identified a compound having the composition K_2CuPhc, in which the copper ion has the electronic configuration $3d^{10}4p_1$.

Metalloporphyrins derived from transition metals can combine with up to four electrons in each doubly degenerate $e_g(\pi)$ orbital; the properties of the anions have been thoroughly investigated. Since these data are important for the understanding of the photochemical reduction reactions of metalloporphyrins, they will be considered in detail below.

III. THE LUMINESCENCE SPECTROSCOPIC PROPERTIES OF METALLOPORPHYRINS

The main electronic transitions associated with the step involving light absorption by porphyrin molecules are shown in the simplified diagram in Fig. 3. The probabilities of these processes are determined by the nature of the substituents in the ring and at the central metal atom. We shall consider here only the influence of the metal atom on the photophysical processes in metalloporphyrins.

The Table lists the main luminescence spectroscopic parameters of certain metalloporphyrins. Evidently metalloporphyrins can be divided into three groups in terms of their luminescence properties: (a) complexes of porphyrins with non-transition metals; (b) complexes of porphyrins with the majority of transition metals; (c) complexes of porphyrins with platinum-group metals and also with copper(II) and VO(II).

The luminescence spectroscopic characteristics of metalloporphyrins (φ = quantum yield; τ = phosphorescence and fluorescence lifetime; γ = interconversion quantum yield).

*Tetraphenylporphin.

**Octaethylporphin.

(a) Metalloporphyrins containing non-transition metals fluoresce and phosphoresce. It has been shown for various porphyrins that the sum of the fluorescence and intercombination transition quantum yields for these compounds is approximately unity[52,58,59]. Hence it follows that the main pathways to the deactivation of excited porphyrin molecules are fluorescence and transition to a triplet state, while the probability of the radiationless transition from the excited singlet state to the ground state is apparently low. The nature of the axial ligands apparently has virtually no influence on the luminescence properties of porphyrins containing trivalent and tetravalent metal atoms[53,60]. The tabulated data show that, with increase of the atomic number of the central metal atom, the intensity of the fluorescence falls while that of the phosphorescence increases. This finding can be explained by the influence of the heavy inner atom which increases the probability of the intercombination transitions[60]. Indeed, when the central metal atom is replaced by one of a heavier element, all three rate constants r, p, and q for intercombination transitions increase. It is of interest that the central metal atom has the greatest influence on r and the smallest on q. The probability q of intercombination degradation in free porphyrin molecules is greater than in their magnesium and zinc derivatives. This is associated with the involvement of the vibrations of the N–H bonds in the radiationless deactivation of the lowest triplet state of porphyrins[61,62].

(b) Metalloporphyrins containing the transition elements manganese(II), manganese(III), iron(II), iron(III), cobalt(II), cobalt(III), nickel(II), etc. do not fluoresce or phosphoresce. The existence of excited triplet states of these pigments could not be observed either by the usual pulse technique[63] or with the aid of laser photolysis used recently[64,65]. Thus excited states with lifetimes exceeding 10^{-9} s were not observed for these compounds.

(c) Metalloporphyrins containing platinum metals, copper(II), and VO(II) do not fluoresce but phosphoresce intensely. The phosphorescence and intercombination transition quantum yields for many complexes of this group are unity. It is remarkable that the lifetimes of the excited triplet states of the compounds under consideration are much shorter than those of derivatives with non-transition metals. Thus measurements of the lifetimes of the triplets carried out by the laser technique for the copper derivatives yielded $\tau \simeq 9 \times 10^{-4}$ s at 77 K and 1.5×10^{-7} s at room temperature.[65] The presence of the above ions also greatly reduces the lifetime of the excited singlet state. The lifetime of this state has been estimated[66] for the copper and vanadium complexes of porphyrins from the width of the quasi-lines in Shpol'skii's spectra. It proved to be 3×10^{-14} s, while the rate of the intercombination transition was found to be approximately 10^{-13} s^{-1}.

The problem of the mechanism of the deactivation of the excited states of metalloporphyrin molecules containing transition metal atoms is complex. It is simplest to postulate that the influence of the central metal atom tends to increase the rates of the intercombination transitions $S^* \rightarrow T$ and $T \rightarrow S_0$. However, this hypothesis does not show which perturbations cause the very marked increase in the probabilities of the above processes. Presumably the magnetic effects of the ions are insignificant; thus the diamagnetic nickel complexes of porphyrins neither fluoresce nor phosphoresce, while the copper derivatives, containing the paramagnetic copper ion, exhibit an intense phosphorescence. Analysis of the tabulated data shows that the enhancement of the spin–orbital interaction on passing from light to heavier elements also plays a secondary role in the deactivation of the excited states of porphyrin complexes with transition metals. Thus the zinc and cadmium derivatives fluoresce, while metalloporphyrins containing the lighter elements (Fe, Mn, Ni, and Co) do not luminesce at all. The influence of transition metal ions is apparently specific.

As shown in the previous Section, the formation of complexes by porphyrins with metal ions result in the addition of the d levels of the central metal atom to the existing system of the singlet and triplet levels. Depending on the nature of the metal atom, two variants of the relative positions of these two systems of levels are possible (Fig. 4). In the first case (Fig. 4a) the vacant d orbitals are distributed above the vacant $e_g(\pi)$ level of the ligand. Conditions for the transfer of an excited electron to the d levels of the metal do not then exist and the porphyrin is characterised by radiative transitions from the singlet and triplet states. In the second variant (Fig. 4b), the electron may pass from the excited S and T levels to the corresponding vacant levels of the metal. Such transitions should be more probable than the $S(T) \rightarrow S_0$ transitions because of the smaller difference between the energies of the d and π^* states.

The ideas about the specific influence of the central ion on the photonics of metalloporphyrins have been formulated in a general form and developed[45,67] on the basis of the study of the photochemical oxidation and reduction reactions of chlorophyll derivatives containing variable-valence metals. The photochemical activity of complexes containing variable-valence metal ions can be accounted for by the intramolecular electron transfer from the ligand to the central ion. The proposed mechanism of the deactivation of the excited states of metalloporphyrins containing transition metal ions has also received direct experimental confirmation. Thus the effect of a powerful laser pulse on the iron, manganese, and the nickel complexes of porphyrins has been studied[64,65]. The authors were unable to record the absorption for the metastable level of these compounds, but did observe a decrease in the intensity of the absorption band unambiguously related to the "simplification" of the initial state. This finding can be explained in terms of the mechanism of the deactivation of the excited states considered here. In the light of ideas about the interaction of the *d* orbitals of metals with the excited orbitals of the π-electron system, one can explain certain types of "anomalous" behaviour of many metalloporphyrins containing transition metals (Cu, Pd, Pt, and VO).

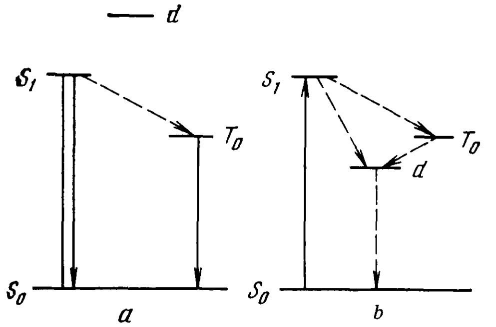

Figure 4. The electronic transitions in metalloporphyrins: *a*) a transition to atomic levels is impossible; *b*) there is no fluorescence and phosphorescence as a consequence of radiationless transitions of excited electrons to low-lying *d* levels.

The nickel complexes of porphyrins do not fluoresce although their vacant orbitals lie below the $e_g(\pi)$ level. This can be explained[68] by the finding that the distance between the d_{z^2} and $d_{x^2-y^2}$ levels is small (Fig. 2) and there is therefore a possibility of the transition of a single paired electron to the $d_{x^2-y^2}$ orbital. Conditions are thereby created for the migration of the excited π electron to the incompletely filled metal orbital.

The situation is different for the luminescence of porphyrins containing platinum-group, copper, and vanadyl ions. In these compounds there are vacant *d* levels located below the excited $\pi\pi^*$ orbitals of the ligand. Furthermore, they are characterised by an intense phosphorescence. The phosphorescence spectra of the copper and VO derivatives of porphyrins consist of two bands[69]. According to Gouterman and coworkers[69,70], the short-wavelength band is associated with the electronic transition from a "triplet-doublet" state, and the less intense band is due to a transition from the quartet state arising as a result of the splitting of the triplet level of the ligand on interaction with the *d* orbitals of the central metal atom. The small energy difference ΔE between the *d* and $\pi\pi^*$ levels constitutes a condition for such interaction. In complexes with much greater ΔE values intramolecular electron transfer is probably responsible for the quenching of the luminescence. The temperature dependence of the luminescence intensity shows that the existence of two phosphorescence bands of Cu-porphyrins is associated with the occurrence of two electronic transitions[69]. When the solution temperature is reduced from 77 to 10 K, the duration of the luminescence increases (by an order of magnitude) and the intensity of the short-wavelength emission band diminishes markedly. This effect of temperature can probably be explained by the fact that the triplet-doublet level is populated partly owing to the thermal activation of the electrons in the doublet level.

The deactivation of the excited states of metalloporphyrins by intramolecular energy transfer to the central metal atom has been observed in the ytterbium complex of tetrabenzoporphyrin[71], in the photochemical excitation of which a weak glow associated with transitions in the metal atom was observed. It is of interest that in this case the electronic excitation energy is degraded already after the step involving energy transfer to the Yb^{3+} ion.

IV. THE PHOTOCHEMISTRY OF METALLOPORPHYRINS

According to modern ideas, chlorophyll undergoes oxidation-reduction reactions following the initiation of the electron transport chain during photosynthesis. The electron phototransport reactions are therefore of greatest interest for investigation. The photochemical properties of natural porphyrins—chlorophyll and bacteriochlorophyll—have of course been investigated most thoroughly. In 1948 Krasnovskii discovered the phenomenon of the reversible photochemical reduction of chlorophyll[72], which initiated the extensive and systematic study of the photonics of tetrapyrrole pigments.

It follows from the analysis described in the previous section that the electronic structure of the central metal atom determines the photophysical properties of porphyrin compounds. In consequence of this, the metal atom must influence also the reactivity of the excited molecule.

Electron phototransport with participation of porphyrins apparently has the same features as those of the photochemical reactions of other classes of organic compounds. According to a generally accepted view, any oxidation-reduction reaction in solution includes three stages: the formation of complexes, electron transfer within the reaction complex, and decomposition of the latter. Intermediate complexes may be formed from molecules either in the ground state or in an excited state:

$$P + A \rightarrow P^{+}A^{-} \xrightarrow{h\nu} [P^{+}A^{-}]^{*} \longrightarrow \left| \begin{array}{l} \longrightarrow P + A \\ \longrightarrow P^{\dot{+}} + A^{\dot{-}} \end{array} \right. , \qquad (1)$$

$$P \xrightarrow{h\nu} P^{*} \quad P^{*} + A \rightarrow [P^{+}A^{-}]^{*} \longrightarrow \left| \begin{array}{l} \longrightarrow P + A \\ \longrightarrow P^{\dot{+}} + A^{\dot{-}} \end{array} \right. , \qquad (2)$$

where P is the porphyrin and A the electron acceptor.

The occurrence of the reaction via the first or second pathway is determined by the oxidation-reduction properties of the reacting molecules and the characteristics of their excited states. For the reaction to proceed via mechanism (**2**), the following condition must be fulfilled:

$$\frac{1}{\tau_0} \ll k_{\text{diff}}\,[A],$$

where τ_0 is the lifetime of the excited state, k_{diff} the rate constant for the diffusion of molecules (in non-viscous liquids at room temperature, $k_{\text{diff}} \simeq 10^{10}$ litre mole^{-1} s^{-1}), and [A] is the concentration of the reactant. Metalloporphyrins containing transition metals do not satisfy the condition formulated above ($\tau_0 \ll 10^{-9}$ s). Electron phototransport in such cases apparently takes place only when the complexes formed under dark conditions are acted upon by light. Thus Fe(III)-phaeophorbide is reduced only when the introduction of an electron donor into the solution causes a change in the absorption spectrum of the initial pigment, indicating the formation of a complex[73].

The introduction of electron donors and acceptors into solutions of fluorescent metalloporphyrins is accompanied by a decrease of the fluorescence quantum yield. In general the quenching of the fluorescence is a complex phenomenon and can be due to various factors. Dilung and Chernyuk[75,76] concluded on the basis of the correlation between the degree of quenching of the fluorescence of pigments of the chlorophyll series and the redox potentials of the fluorophore and the quenching agents (aromatic nitro-compounds and hydrazine derivatives) that the quenching of the fluorescence is based on electron transfer. Subsequently this was confirmed in the quenching of the fluorescence of Mg-phthalocyanine and ethylchlorophyllide[77,78], tetraphenylporphin and its zinc derivative[79], and pyrochlorophyll[80] by nitro-compounds and of the fluorescence of chlorophyll by quinones[81,82]. The study of the quenching of the fluorescence can provide an answer to the question whether electrons are transferred via mechanism (1) or (2). It was stated above that the choice between these mechanisms is determined primarily by the donor–acceptor properties of the interacting molecules. One should therefore probably only consider whether or not a particular type of interaction predominates.

The study of the quenching of the fluorescence of Zn-phthalocyanine by aromatic amines has shown that the degree of quenching is greater than might have been expected from the complex-formation constant in the ground state[83]. This is probably evidence for the simultaneous occurrence of the competing processes (1) and (2), which are responsible for the quenching. Similarly it has been concluded[84] that the quenching of the fluorescence of mesoporphyrin (IX) by *m*-dinitrobenzene is due to the complex formation reaction between them, both in the ground and excited states, but the role of the latter is significantly greater. The study of the dependence of the lifetime of the excited singlet states of porphyrin molecules on the concentration of *m*-dinitrobenzene[85] and the dependence of the constants for the quenching of the fluorescence of chlorophyll and its analogues by benzoquinone on solvent viscosity[86] also provided grounds for the conclusion that there is competition between the two types of quenching; it has been shown that the dynamic mechanism (2) makes the main contribution. It is interesting that, even in the case of a powerful acceptor such as 1,3,5-trinitrobenzene, the quenching effect is not wholly due to the formation of a charge-transfer complex in the ground state[85].

On interaction with electron acceptors, porphyrin molecules exhibit powerful π-donor properties. This is indicated primarily by the high formation constants of the charge-transfer complexes[88]. The charge-transfer bands of complexes with powerful electron acceptors such as 7,7,8,8-tetracyanoquinodimethane, 1,2,4,5-tetracyanobenzene, and tetracyanoethylene (TCE) are in the infrared and are observed only at low temperatures[89]. It is of interest that the position of the charge-transfer band depends only slightly on the nature of the central metal atom. This is apparently a consequence of its weak interaction with the π-electron system of the ligand. On the other hand, the powerful influence of the lateral substituents of the tetrapyrrole ligand on complex formation is incomprehensible. It follows from the available data[89] that the absorption band arising when Zn-aetioporphyrin reacts with TCE is located at 1070 nm, while that due to the reaction of Zn-tetraphenylporphin with the same acceptor is at 900 nm.

There are data showing that in the case of metalloporphyrins containing transition metal atoms electrons may be transferred from the *d* levels of the metal. Thus a study has been made[90] of the interaction of Co-tetraphenylporphin with tetracyanoethylene and it has been shown that the system contains complexes of two types: $[\text{Co(II)TPP}]^{+}.[\text{TCE}]^{-}$ and $[\text{Co}^{+}\text{(III)TPP}].[\text{TCE}]^{-}$. When the second complex is formed, an electron is transferred from the *d* orbital of the cobalt atom to TCE.

The electron transfer schemes show that the primary products arise in a single solvent "cage". This creates favourable conditions for their recombination. There is no doubt that the usually observed low quantum yields of photochemical processes are associated with this factor[91]. However, when there is a possibility of reactions which eliminate one of the radical-ions from the system, the photochemical oxidation quantum yield increases. An elegant procedure was used by Bobrovskii and Kholmogorov[92]. In the oxidation of chlorophyll and Zn-aetioporphyrin they used tetranitromethane as the electron acceptor, which decomposes, following the addition of an electron, into NO_2 and $\bar{C}(NO_2)_3$.

The properties of excited complexes formed by porphyrin molecules with electron acceptors and donors are of undoubted interest. The hypothesis of the existence of chlorophyll exciplexes was put forward for the first time by Dain and Dilung[93] in connection with the analysis of the results of the quenching of the pigment fluorescence by aromatic nitro-compounds. The formation of exciplexes was postulated as an intermediate stage in the photochemical oxidation of chlorophyll. However, this was not confirmed by experimental data.

In the presence of electron acceptors the intensity of the fluorescence spectra of tetrapyrrole pigments as a rule decreases in parallel with increase of the concentration of the acceptor without the appearance of new emission bands[94]. On the other hand, the interaction of chlorophyll with electron donors (amines and pyridine derivatives) leads to a shift of the fluorescence band without an appreciable change in the absorption spectrum[95]. The authors attribute this finding to the interaction of the excited chlorophyll molecules with electron donors, leading to the formation of fluorescent exciplexes.

Data[66] for the formation of ternary exciplexes, including, apart from chlorophyll, electron donors (amines, pyridine bases, and esters) and acceptors (nitro-compounds) merit attention. The conclusion that ternary exciplexes are formed was reached on the basis of changes in the fluorescence spectra of the pigment in the presence of the above compounds. Later similar ternary exciplexes were observed for tetraphenylporphin and its zinc derivative[79]. It is significant that the formation of ternary exciplexes facilitates electron phototransfer from the porphyrin compound to the acceptor. This is confirmed by the fact that the formation of exciplexes is accompanied by a significant increase of the fluorescence quenching constants[96] and by an increase of the photopotentials and photoconductivity[97]. The authors regard the ternary exciplexes as analogues of D → M → A complexes, which, according to Shilov's ideas[98], play the role of a transition state in dark heterolytic reactions.

The ESR spectra of both radical-cations and radical-anions of the majority of tetrapyrrole pigments consist of narrow lines without any signs of a hyperfine structure[99-101]. This indicates a high degree of delocalisation of the charge in the π-electron system of the tetrapyrrole ligand. Indeed, with increase of the extent of the π-electron system on passing from porphyrins to phthalocyanines, the ESR spectra of both radical-cations and radical-anions become narrower still[100]. The radical-anion forms of tetrapyrrole pigments are highly reactive. The radical-cations are powerful oxidants, while the radical-anions exhibit a considerable tendency towards protonation reactions. Their short lifetime in solution is due to this factor.[102]

The high reactivity of the radical-ion forms of pyrrole macrorings is responsible for their involvement in sensitisation processes. Krasnovskii[104,105] and Evstigneev[103] investigated the interaction of the primary photochemically reduced forms of chlorophyll and other photosensitising pigments with electron acceptors (Methyl Red, Acid Orange, Safranine T, riboflavin, etc.). The mechanism of the involvement of the radical-anions of tetrapyrrole heterocycles in photosensitised oxidation-reduction processes was proved by these investigations. Direct evidence for the involvement of the primary oxidised form of chlorophyll in the sensitisation of oxidation-reduction reactions has been published[106]. In a study of the sensitising action of chlorophyll and phaeophytin on the photochemical oxidation of the leuco-bases of triphenylmethane dyes (Malachite Green and parafuchsin) by nitro-compounds a correlation was found between the yield of the process and the oxidation potentials of the nitro-compounds. On this basis, it was concluded that the primary sensitisation reaction involves the photochemical oxidation of the pigment.

It was mentioned earlier that, depending on the relative positions of the vacant energy levels of the metal atom and the ligand, either the tetrapyrrole ligand or the central metal atom is reduced. This was also shown for the photochemical reduction of metalloporphyrins containing titanium-subgroup[107] and also manganese(III), iron(III), and cobalt(III) ions[108]. The elimination of an electron from the tetrapyrrole ligand or its addition to the latter leads to profound spectroscopic changes associated with the alteration of the chromophoric system of the molecule. Changes in the valence state of the central metal atom as a rule entail merely a displacement of the absorption bands and a redistribution of their intensities.

Irradiation of Mn(III)-, Fe(III)-, and Co(III)-porphyrins in the presence of reductants leads to the reduction of the central metal atom[108].

Iron(III) and manganese(III) derivatives of phaeophytin and phaeophorbide are of considerable interest from the standpoint of models of the second photosynthetic system. It has been shown[109,110] that these compounds are reduced by hydroxide ions on irradiation with visible light. In order to interpret these results, the concept of the so called intramolecular sensitisation of the photochemical oxidation and reduction processes was put forward[45]. According to this hypothesis, when the π-electron system of the porphyrin skeleton is excited, an electron is transferred to the vacant *d* orbital of the metal. The charge deficiency is made good by an electron of the electron donor present in the system.

It is of interest that metalloporphyrins are photochemically inactive in relation to divalent transition metals. Thus irradiation of copper(II), manganese(II), cobalt(II), and iron(II) complexes in the presence of reducing agents does not lead to changes in the absorption spectra. Furthermore, these complexes are readily hydrogenated by hydrogen at the instant of their isolation[111]. Their photochemical stability is probably associated with the short lifetime of the excited states.

The complexes of porphyrins containing central atoms of non-transition elements readily undergo photochemical reduction.

The photochemical reduction of porphyrin molecules is a multistage reaction including several dark and photochemical stages. It was already shown in the early studies that the primary reaction products are radical-anions[112]. Investigation of the interaction of porphyrin molecules with electron donors showed that porphyrins combine with an electron whilst in the triplet state[113].

As mentioned above, the radical-anions of tetrapyrrole systems exhibit a high proton affinity. A mechanism for their protonation reactions has been put forward[114]. The first stable product of the protonation reaction of metalloporphyrins is a substance with an intense absorption band in the range 435–465 nm. On the basis of NMR spectra, the structure of dipyrromethene (PH_2) was attributed to it[115]. It was suggested that it is formed as a result of the disproportionation of the monohydro-derivative ($PH^{\cdot}$) arising in the first hydrogenation stage:

$$P^{-} + H^{+} \rightarrow PH^{\cdot},$$
$$2PH^{\cdot} \rightarrow PH_2 + P^{-\cdot}.$$

Next, PH_2 may interact with the bases[114,116]:

$$PH_2 + OH^{-} \rightarrow PH^{-} + H_2O\ .$$

The PH^- spectrum is characterised by absorption bands in the range 435–465 and in the region of 800 nm.[114] On interaction with atmospheric oxygen, PH^- and PH_2 regenerate the initial metalloporphyrin.

The products of the protonation of the radical-anions of metalloporphyrins described above (PH^- and PH_2) are obtained in the majority of cases together with chlorins and bacteriochlorins on photochemical reduction of metalloporphyrins in solution.

There is no unanimous view in the literature concerning the relation between these porphyrin hydrogenation products. The majority of workers believe that chlorins are obtained from the products PH^- and PH_2 as a result of dark isomerisation[117-120]. On the other hand, others[121] postulate the formation of chlorins independently of the formation of PH^- and PH_2. It has been suggested[119] that the isomerisation is a photochemical reaction.

The isomerisation of the "reversible product" of the reduction of PH_2 to chlorin[119] under the influence of an acid was demonstrated recently. The stronger the acid, the higher the rate of reaction[122]. The study of the transformations of chlorin and PH^- revealed that, on keeping a solution of Zn-chlorin in t-butyl alcohol for 37 h at 130°C in the presence of KOH, the chlorin is completely converted into the "reversible product".[123]

In this connection the results of a study of the photochemical reduction by hydrazine-hydrate of porphyrin compounds containing atoms of aluminium-subgroup elements are of special interest[124]: by employing light at different wavelengths, it was shown that the conversion of the primary hydrogenated species into a product of the chlorin type takes place in the course of a multiphoton reaction. Under the influence of light corresponding to the long-wavelength maximum of the metalloporphyrin (TPP.InBr) at 600 nm, a product is formed with absorption bands at 450 and 800 nm, i.e. apparently PH^-. It is converted into chlorin under the simultaneous influence of light with $\lambda > 700$ nm and 510 nm. The rate of formation of chlorin from PH^- under these conditions is proportional to the intensity of the light raised to the power 1.5. Thus, apart from the photochemical stages in the formation of primary hydrogenated forms (PH^- and PH_2), further transformations of the "reversible products" are also photochemical:

$$P \xrightarrow{h\nu_1} PH^- \underset{\text{dark}}{\overset{h\nu_2}{\rightleftarrows}} z \xrightarrow{h\nu_3} \text{Chl.}$$

The multiphoton mechanism of the photochemical reduction of porphyrins was also demonstrated for the remaining pigments containing aluminium-subgroup elements as well as zirconium and hafnium[107].

Electron Diffraction Studies on Stereochemically Non-rigid Molecules

V.P.Spiridonov, A.A.Ishchenko, and E.Z.Zasorin

Electron diffraction data for the structures and potential energy functions of molecules with a certain type of intramolecular motion—high-amplitude motion—are analysed in detail and the fundamental characteristics of such motion and the conditions for its experimental observation are formulated. Important structural-chemical consequences of high-amplitude motion and the urgent need for a comprehensive investigation of stereochemically non-rigid molecules are demonstrated.
The bibliography includes 201 references.

I. INTRODUCTION

Owing to the comparative simplicity of the experimental technique and methods and the possibility of investigating complex molecules (including non-polar molecules), modern gas-phase electron diffraction is of primary importance for the analysis of molecular structures. The main information which can be derived by electron diffraction concerns the geometrical parameters characterising the steric structure as well as the mean square amplitudes of the vibrations of pairs of nuclei. The application of this method in the study of organic and inorganic molecules led to the accumulation of extensive experimental data on molecular structures in the gas phase (see, for example, the compilation in Ref. 1 as well as the relevant reviews[2-10]).

A special type of intramolecular motion of nuclei—the so called high-amplitude motion—has been detected by electron diffraction only in a comparatively small number of molecules; however, it is difficult to overestimate the importance of detailed investigation of this phenomenon for many branches of modern chemistry.

The high-amplitude motion of nuclei is characterised by low frequencies (usually below 100 cm^{-1}) and is reflected specifically in the structure, dipole moments, and other molecular properties. This is manifested in the study of spectra, thermodynamic properties, the behaviour of molecules in electric fields, and other experimental research. Investigations in recent years have provided many examples of the manifestation of complex intramolecular motions of nuclei in compounds of different classes. In this connection, the problem has been assuming increasing current chemical importance in the interpretation of data derived by a wide variety of experimental methods, in the theoretical study of the geometrical and electronic structures of polyatomic molecules, in the calculations of thermodynamic functions of substances, etc.

This review deals with a limited topic—the electron diffraction study of molecules with a complex motion of nuclei (high-amplitude vibrations)†; studies of internal rotation have been excluded, to some extent arbitrarily, because there already exists an independent and exhaustive literature on this problem (see, for example, the review of Bastiansen et al.[15] and the monograph of Orville-Thomas[16]).

II. THE GENERAL CHARACTERISTICS OF THE HIGH-AMPLITUDE MOTION AND THE CONDITIONS FOR ITS EXPERIMENTAL OBSERVATION

It is difficult to define rigorously the concept of "high-amplitude motion" because the nuclear shifts in molecules do not vary continuously. The convention has been adopted that one speaks of the high-amplitude motion of nuclei in those cases where the nuclear shifts are much larger than in the usual motion in "quasi-rigid" molecules, where the nuclei execute small oscillations about the corresponding equilibrium positions[17-19]. Large nuclear shifts arise when periodic internal rearrangements of individual atoms or whole molecular fragments take place in the molecule. The transition of the system of nuclei from one steric configuration to another—the so called hindered motion—constitutes in fact high-amplitude

---

† Among the experimental methods for the investigation of processes involving intramolecular motion, NMR also plays an important role. In particular, extensive information has been obtained by this method about the high-amplitude motion of nuclei in the condensed phase (see the relevant reviews[11-14]).

motion and the molecules where such transitions occur are referred to as stereochemically non-rigid‡.

In principle any molecules with identical nuclei can have several steric configurations differing from one another as a result of nuclear transpositions, provided that these transpositions are not equivalent to the rotation of the molecules as a whole. In addition, each non-planar molecules can have left- and right-hand configurations whose interconversion requires inversion. Thus the motion of nuclei in the majority of molecules is generally speaking characterised by potential functions (in the general case potential surfaces) with two (or more) minima corresponding to different steric configurations of the nuclei and separated by potential barriers.

We shall now consider the conditions under which high-amplitude motion is possible in principle and can be observed experimentally.

(a) If the potential function minima are fairly deep (i.e. the barriers between the minima are high), one may assume that a definite steric configuration of the nuclei corresponds to each potential energy minimum.

A quantitative criterion of the fundamental distinguishability of a particular configuration of the nuclear system is (Bersuker[30], p.192):

$$\tau \gg T\ , \qquad (1)$$

$$\Delta E \gg 2\hbar\omega, \qquad (1a)$$

where τ is the "lifetime" of the configuration corresponding to the potential minimum, T the period of the vibrations at the minimum, ΔE the depth of the minimum, and ω the vibration frequency at the minimum. When condition (1) or (1a) is fulfilled, the configuration of the nuclei corresponding to the given minimum is fairly long-lived, quasi-stationary, and in principle can be distinguished experimentally. For an approximate description of the nuclei in the configuration corresponding to the potential energy minimum, the thoroughly developed model of quasi-rigid molecules is applicable[17-19].

In the case under consideration the equilibrium configuration corresponding to the potential minimum is a characteristic of the steric arrangement of the nuclei. The transitions of the system fron one minimum to another can occur as a result of tunnelling through the potential barrier, but such transitions are not always observed experimentally.

If the thermal energy of the molecules kT is greater than the height of the potential barrier, there is an appreciable increase of the population of the upper (above the barrier) vibrational levels. In order to characterise the geometrical configuration of the molecule in these states, it is necessary to know values averaged with respect to the vibrations, which differ appreciably from the equilibrium values corresponding to the potential minima. A typical example of such a case is provided by the ammonia molecule for which there exists two equilibrium nuclear configurations arising when the nitrogen atom is reflected in the plane containing the hydrogen atoms. The vibrational and rotational spectra of the molecules as well as electron diffraction data can be interpreted satisfactorily on the hypothesis of a quasi-rigid pyramidal molecular model, while tunnelling is revealed by the inversion-induced splitting of the vibrational levels in the spectra.

If all the potential barriers separating energetically equivalent configurations are very high (virtually impossible to overcome), one can ignore the existence of all the potential minima except one. The molecular state at this minimum will be stationary and the transitions of systems from one minimum to another will hardly occur.

(b) If the minima in the potential function are shallow (the barriers between the minima are low), i.e. Eqn.(1a) does not hold, then the nuclear system does not possess a definite symmetry and is not characterised by a stable stationary configuration corresponding to the potential minimum. The equilibrium configuration loses the significance of a characteristic of the steric arrangement of the nuclei. In this case individual configurations corresponding to various minima of this type are in principle indistinguishable and the system merely executes periodic virtually unhindered transitions from one configuration to another (or others), i.e. high-amplitude motion arises. As an illustration, one may quote the cyclopentane molecule. In this molecule the motion of the ring nuclei during vibrations can be described as continuous transitions between ten configurations with C_2 symmetry and ten configurations with C_s symmetry ("pseudorotation" of the ring; see Section V below), none of which is a stable equilibrium configuration of the ring.

It is seen from the above examples that in reality one encounters most frequently cases where the total potential energy function possesses at the same time very high barriers, separating the minima from one another, the transitions between which cannot be neglected, and one (or a few) relatively low barriers. For this reason, as a rule only part of the molecule is stereochemically non-rigid in the above sense and the nuclear system executes high-amplitude motion only along one or several but not all vibrational coordinates. Thorson and Nakagawa[31] introduced the concept of quasi-symmetry for molecules with high-amplitude nuclear motion. For example, molecules characterised by a continuous reversible transition from a bent to a linear configuration and conversely are regarded as quasi-linear (quasi-linearity relative to the deformation angle; the molecule is quasi-rigid relative to the other vibrational coordinates).

We shall analyse in greater detail the conditions under which high-amplitude motion may be observed experimentally. Evidently the characteristic time of the experimental method employed should play an important role in this. Indeed, individual nuclear configurations, corresponding to the potential minimum, will be experimentally indistinguishable when the characteristic time τ' of the given experimental method (the time of the effective interaction between the molecular system investigated and the external perturbation) is greater than the lifetime τ of the individual configurations (see Bersuker[30], p.190), i.e.

$$\tau' > \tau, \qquad (2)$$

In this case there is sufficient time during the measurement for the system to undergo repeated transitions from one set of configurations to another, and an average pattern is recorded experimentally. It is easily seen that the fulfilment of condition (2) is facilitated by low values of τ, i.e. low energy barriers between individual configurations.

On the other hand, when

$$\tau' < \tau, \qquad (3)$$

---

‡ The term "stereochemically non-rigid molecules" was introduced by Muetterties[20-27]. In the NMR system other terms are also widely used in the description of the high-amplitude intramolecular motion, for example, "fluctuating molecules"[11], "degenerate intramolecular rearrangement"[13,28], "autoisomerisation"[29], etc.

then a separate configuration is manifested in the measurement with a lifetime τ (provided that it is distinguishable in principle; see above). The times τ' are different for different experimental methods (see Table) and the results of the measurements therefore depend primarily on the method employed [the rule governing the relation with the means of observation (see Bersuker[30], p. 191)].

The characteristic times τ' of certain physicochemical methods[20]*.

Deflection of molecular beams in electric field	10^{-6}

*The characteristic time of the electron diffraction experiment quoted was obtained by the authors of the review and differs from the value (10^{-20} s) in the literature[13,20].

On the other hand, since the lifetime depends on the vibrational state v at the minimum potential ($\tau = \tau_V$), the fulfilment of conditions (2) and (3) is also determined by the conditions of the measurements, for example, temperature [the rule governing the relation with the conditions of measurement; (see Bersuker[30], p. 190]. Thus the values of τ_V are high at low temperatures and condition (3) may hold for the given τ', i.e. a separate configuration with a lifetime τ_V is observed experimentally. At higher temperatures, higher vibrational levels begin to be populated and τ_V diminishes, which promotes the transition to condition (2) and an average pattern reflecting the high-amplitude motion is manifested experimentally.

The knowledge of the potential function describing the motion of the nuclei in the molecule can yield the complete characteristics of the behaviour of the nuclei, including their high-amplitude motion. However, a rigorous quantum-mechanical solution of the problem of the derivation of such a potential function in the general case is impossible because of the difficulties in the solution of the Schrödinger equation for the electronic states of complex molecules, which cannot as yet be overcome. Additional difficulties in the solution of this problem can be due to the possible deviations from the adiabatic approximation, since there is reason to believe that the vibronic interaction, which has a particularly marked effect when the electronic states are degenerate (the Renner and Jahn–Teller effects) or pseudodegenerate (the Jahn–Teller pseudoeffect), plays a major role in complex intramolecular motion of nuclei. These problems have been examined in detail by Renner[32], Jahn and Teller[33], van Vleck[34], Öpik and Pryce[35], Liehr[36], Longuet-Higgins[37,38], Bersuker[30,39–43], and many other workers (for further details, see the relevant monographs[30,44,45] and reviews[38,43]). Despite these difficulties, useful information about the potential energy functions may be obtained by LCAO-MO calculations[30,46].

The most promising approach to a quantitative description of the motion of nuclei in the case under consideration consists at present in separating the high-amplitude motion from other types of nuclear motion, specifying a definite type of potential function, and solving the corresponding Schrödinger equation for the vibrational and rotational states of the molecule. However, even this more specific problem is complicated, since the thoroughly developed procedure for calculations in terms of normal coordinates and the standard expansion of the potential energy function in terms of these coordinates is of only limited applicability in this instance. A promising approach involves the use of more general curvilinear coordinates with a corresponding increase in the complexity of the expression for the kinetic energy operator and generalisation of the concept of reduced mass. However, these methods have so far been used only in the study of three-, four-, and five-atomic molecules and molecules with pseudorotation in the rings (see, for example, Refs. 47–53). Still more complicated cases, where it is impossible to separate high-amplitude motion from other types of nuclear motion, have not so far been considered.

The application of electron diffraction to the study of stereochemically non-rigid molecules yielded in all cases a qualitative pattern of nuclear motion and sometimes also complete quantitative information about the parameters of the potential functions of such motion. Quantitative data have in fact been obtained only in relatively simple cases where the potential function depends on only one vibrational coordinate (the one-dimensional vibrational problem). In this case there is a complete analogy with internal rotation. This made it possible to employ in the structural analysis of stereochemically non-rigid molecules the classical form of the probability density function, proposed previously[54,55] in relation to internal rotation. The parameters of the potential energy function are determined in most cases by the method of least squares. Either calculated and experimental scattering intensities (radial distribution functions)[56–58], or calculated and experimental vibration amplitudes, or the internuclear distance contraction effects[59] were then compared.

Since the contribution to the intensity of the scattering of electrons by pairs of nuclei executing high-amplitude motion decays rapidly with increase in the scattering angle, it is sometimes useful and effective to analyse low-angle scattering[60–62].

III. QUASI-LINEAR MOLECULES

The motion of nuclei in quasi-linear molecules is one of the simplest cases of high-amplitude motion, because the only vibrational coordinate describing this motion is the change in the deformation angle α. The dependence of potential energy of the quasi-linear molecule on α is illustrated in Fig. 1. One must note that α varies in the region of positive values ($0 < \alpha < \pi/2$), because the configurations corresponding to the potential minima illustrated in Fig. 1 can be derived from one another by the appropriate rotation of the molecule as a whole. The vibrational potential therefore has actually only one minimum, two minima arising on the curve in Fig. 1 when one considers the section of the potential surface taking into account both the deformation vibration and the rotation of the molecule as a whole. This type of situation holds for any planar molecules (see Herzberg[17], pp. 39, 239).

The carbon suboxide molecule C_3O_2 [O(1) = C(2) = C(3) = C(4) = O(5)] is the most thoroughly investigated of the quasi-linear molecules. In the first modern electron diffraction study on the C_3O_2 molecule §[63] unusually high values of the so called "contraction effect" (see Cyvin[64], Chapter XIV) and the vibration amplitudes of pairs of nuclei, the distances between which vary during the deformation vibration, were already observed. The measured quantities did not agree with the theoretical calculations in terms of the approximation of low-amplitude harmonic vibrations[65]. In their experiments at different temperatures (237, 290, and 508 K) the authors[63] attempted to determine the temperatures of the C_3O_2 vapour flowing from the nozzle on the basis of the measured vibration amplitudes and contraction effects. Despite the failure of this attempt, the conclusion that the ν_7 deformation vibration of the C=C=C fragment is not described by a harmonic function must be regarded as an important result of this study[63]. The equation proposed[63] for the potential is (Fig. 1)

$$V(q) = Aq^4 + Bq^2, \tag{4}$$

where A and B are constants and q represents half the deviation of the C=C=C angle for the linear value:

$$q = \frac{180° - \angle\,(\mathrm{C{=}C{=}C})}{2}.$$

According to the authors' estimate, the barrier for the linear configuration is in the range 40–255 $\mathrm{cm^{-1}}$.

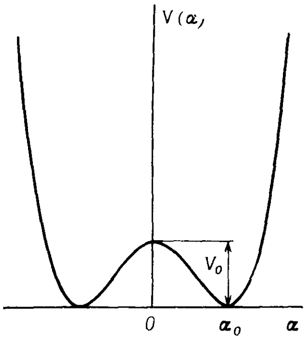

Figure 1. The potential function for the deformation vibration of quasi-linear molecules.

The C_3O_2 molecule was thoroughly reinvestigated by electron diffraction in another study[59], attention being concentrated on the potential function of the deformation vibration of the C=C=C fragment. Using this function, as defined by Eqn. (4), Tanimoto et al.[59] obtained the following expression by analysing the experimental data

$$V(Q_7) = (24 \pm 5)\,Q_7^4 - (100 \pm 31)\,Q_7^2, \tag{5}$$

where $Q_7 = (\sin\alpha)/0.145$ is the vibrational coordinate of the deformation of the C=C=C fragment (α has the same significance as q in the previous notation). The positions of the potential minima correspond to $\alpha_0 = \pm 12°$ and the height of the potential barrier at $\alpha = 0$ is $100 \pm 47\ \mathrm{cm^{-1}}$, the electron diffraction data proving virtually insensitive to the presence or absence of this barrier.

Using Eqn. (5) for the potential of the deformation vibration of the C=C=C fragment and the harmonic approximation for other types of vibration, the authors[59] obtained a satisfactory agreement between the calculated and experimental mean square vibration amplitudes and contraction effects. The vibrational-rotational ν_7 band was also calculated by Eqn. (5) and its maximum proved to be at 70 $\mathrm{cm^{-1}}$, which differs slightly from the experimental value $63 \pm 2\ \mathrm{cm^{-1}}$.[66,67]

The deformation vibration of the C=C=C fragment has been examined theoretically[68] on the basis of spectroscopic and electron diffraction data. Using the method of Thorson and Nakagawa[31], Clark and Seip[68] established by solving the Schrödinger equation for the vibrational and rotational states of the molecule that a potential function of the type

$$V(r) = 2400r^2 + \frac{14000}{2.2 + r^2}, \tag{6}$$

where $r = \alpha r[\mathrm{C(3){=}O(5)}]$ with minima at $\alpha_0 = \pm 10.8°$ and a barrier 50.6 $\mathrm{cm^{-1}}$ high at $\alpha = 0$, describes satisfactorily both spectroscopic and electron diffraction data. Calculation of the position of the absorption band maximum corresponding to the ν_7 vibration by Eqn. (6) yields a value in the range 65–69 $\mathrm{cm^{-1}}$, in good agreement with the experimental value $\nu_7 = 63 \pm 2\ \mathrm{cm^{-1}}$.[66,67] The parameters of the calculated peak of the radial distribution curve, corresponding to the distance between the oxygen atoms, agree just as well with the results of the electron diffraction experiment at 237 and 508 K.

It has also been concluded[68] that electron diffraction data are not unduly sensitive to the detailed form of the potential describing the ν_7 vibration. The potential function (6) and equations of the type

$$\left.\begin{aligned} &V(r) = \text{const}, \ \text{when} \ |\alpha| < 10.8° \ \text{and} \\ &V(r) = 2400r^2 + \frac{14000}{2.2 + r^2}, \ \text{when} \ |\alpha| \geqslant 10.8° \end{aligned}\right\} \tag{7}$$

describe with almost equal accuracy the experimental peak of the radial distribution curve corresponding to the distance between the oxygen atoms.

Another important result obtained in the above investigation[68] was that the use of the classical probability density function

$$P(\alpha) = N e^{-\frac{V(\alpha)}{kT}}$$

leads to virtually the same parameters of the peak on the radial distribution curve corresponding to the distance between oxygen atoms as the quantum-mechanical expression based on the use of 93 vibrational-rotational wave functions in combination with the Boltzmann distribution.

Numerous spectroscopic studies on the carbon suboxide molecule[66,67,69–74] demonstrated a complex structure of the absorption spectra. The absorption bands were assigned and the fine structure and the complex shape of the bands as well as the presence of numerous "hot" bands were explained by experimenters on the basis of potentials of types (4)–(6) for the ν_7 vibration. The problem of the C_3O_2 molecular structure therefore appeared to be solved in broad outline.

[§] We shall not consider the earlier electron diffraction studies (see, for example, the compilation in Ref. 1).

However, a high-resolution infrared spectrum (0.3 cm^{-1}) was obtained in 1973 in the range 20–80 cm^{-1} as well as the Raman spectra of the C_3O_2 molecule in the vapour phase and in the crystalline state[75]. Analysis of the set of experimental data obtained enabled the authors[75] to suggest that the absorption frequency observed in the region of 61 cm^{-1} may be assigned to the $0,0 \rightarrow 2,2$ vibrational-rotational transition. The frequency ν_7 was found to be 22 cm^{-1} in contrast to the results of all previous studies. The new value of ν_7, obtained in the most accurate of the known investigations[75], throws doubt on the validity of the interpretation of the previous spectroscopic and electron diffraction data. It may be that one must resort to the concept of a strong vibronic interaction in the C_3O_2 molecule (the Jahn–Teller pseudoeffect) in order to eliminate the discrepancy observed between electron diffraction and spectroscopic data. At any rate, it appears desirable to repeat the electron diffraction and spectroscopic studies of the carbon suboxide molecule, the correct interpretation of which may serve as a key to the interpretation of the experimental data for many other molecules of different classes.

Among the electron diffraction studies where the experimental data were also interpreted from the standpoint of the quasi-linear model, mention should be made of the investigation of silyl isocyanate ($H_3Si-N=C=O$) and silyl thioisocyanate ($H_3Si-N=C=S$) molecules[76] as well as indium subselenide and subtelluride[77,78]. The usual harmonic approximation for the potential function of the deformation vibration of the silyl thioisocyanate skeleton agrees with experimental data, while for the silyl isocyanate molecule agreement with experiment is achieved using a potential of the type

$$V(\alpha) = -300\alpha^2 + 1090\alpha^4 \tag{8}$$

with minima at $\alpha_0 = \pm 28°$ and a barrier 20 cm^{-1} high at $\alpha = 0$.

An electron diffraction study of the high-temperature indium subselenide and subtelluride vapours[77,78] established that the deformation vibrations are described by the potential functions

$$V(\alpha) = 12816\alpha^4 - 3280\alpha^2 (In_2Se), \tag{9}$$

$$V(\alpha) = 18080\alpha^4 - 3376\alpha^2 (In_2Te). \tag{10}$$

The first function has minima at $\alpha_0 = \pm 21°$ and a barrier 210 cm^{-1} high at $\alpha = 0$. Analogous data were obtained also for the second function: $\alpha_0 = \pm 18°$ and a barrier 157 cm^{-1} high.

IV. BICYCLIC MOLECULES

Electron diffraction studies on bicyclo[2,2,2]octane[57] and triethylenediamine[79] showed that these molecules have a "quasi-D_{3h}" symmetry, i.e. there is a possibility of high-amplitude torsional vibrations about the C_3 axis (see Fig. 2). These vibrations are described satisfactorily by a potential function of the type

$$V(\Phi) = k_2\Phi^2 + k_4\Phi^4, \tag{11}$$

where Φ for the bicyclo[2,2,2]octane molecule is the dihedral angle between the C(1)C(2)C(3) and C(2)C(3)C(4) planes—the so called torsional angle. The potential for the triethylenediamine molecule has a similar form. The energy barriers in the torsional vibrations were found to be 35 cm^{-1} [57] and 30 cm^{-1} [79] for bicyclo[2,2,2]octane and triethylenediamine respectively, and the mean square values of the angle Φ are 12.8° and 11.0° respectively.

The electron diffraction data agree well with the results of X-ray diffraction studies on the same molecules[80,81]. The substitution of one hydrogen atom in bicyclo[2,2,2]-octane and triethylenediamine by a chlorine atom increases the barriers to 46.8 and 66.8 cm^{-1}, while the equilibrium angles Φ_e are respectively 16.2 and 16.4° according to the results of microwave studies on the above molecules[82,83].

V. ORGANIC MOLECULES WITH FIVE-MEMBERED RINGS AND INORGANIC HALIDES

1. Pseudorotation in Five-membered Rings of Organic Molecules

The concept of "pseudorotation" was introduced for the first time by Pitzer and coworkers[84–86] in order to account for the high entropy of gaseous cyclopentane. According to this concept, there is a continuous migration ("rotation") of the maximum deformation of the plane of the ring along the latter in the cyclopentane molecule and not simply out-of-plane vibrations. These vibrations represent the motion of the atomic nuclei without a significant contribution to the rotational moment of the molecule. The pseudorotation of five-membered rings is a more complex intramolecular motion than the deformation of linear molecules or torsional vibrations in bicyclic systems described above. This motion can be described by two vibrational coordinates, the phase Φ and the amplitude q of the pseudorotation linked by the expression

$$Z_j = \sqrt{\frac{2}{5}}\, q \cdot \cos\left[2\left(\frac{\pi}{5} j + \Phi\right)\right], \qquad (12)$$

where q is the deviation of the nucleus of the carbon atom from the plane (two-dimensional vibrational problem).

If it is assumed that the change in the coordinate q is described by the harmonic potential function

$$V(q) = \frac{k}{2}(q - q_0)^2 \qquad (13)$$

and that pseudorotation takes place virtually freely, it is possible to separate the motions along the two coordinates. Pitzer and coworkers[85] established on the basis of this approximation that $q_0 = 0.472$ Å for this molecule.

Further thermodynamic studies on cyclopentane[87-89] as well as semiempirical quantum-mechanical calculations of the energy of this compound[90-92] confirmed Pitzer's dynamic model. However, direct experimental confirmation of pseudorotation in cyclopentane was obtained for the first time in a study of the infrared spectrum of this compound[93]. The same workers[93] determined $q_0 = 0.479$ Å, which agrees well with the thermodynamic value found previously by Pitzer and coworkers[84-86].

According to modern ideas about the structure of five-membered rings, pseudorotation may be regarded as the superposition of two types of motion: the out-of-plane ring vibrations where one of the atoms is displaced from the plane (the "envelope" conformation with C_s symmetry) and torsional ring vibrations where two atoms are displaced simultaneously from the plane (the "half-chair" conformation with C_2 symmetry)[47,94] (Fig. 3). Pseudorotation can therefore be described as continuous transitions between configurations with C_2 and C_s symmetries (in all, ten configurations for each type of symmetry in a single pseudorotation cycle).

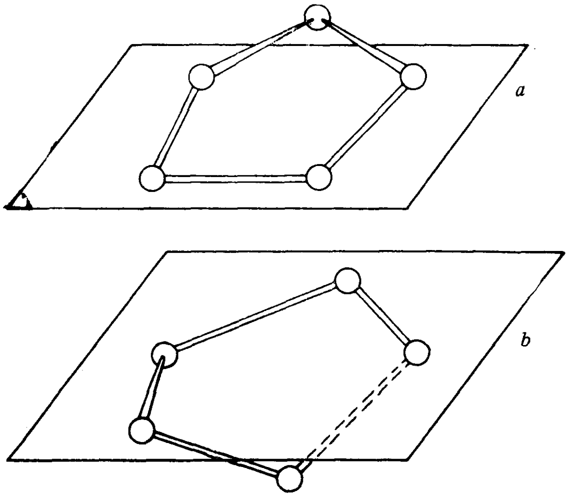

Figure 3. Conformations of five-membered cyclic molecules: *a*) "envelope" type (C_s symmetry); *b*) "half-chair" type (C_2 symmetry).

An electron diffraction study on cyclopentane[95] agreed fully with thermodynamic[84-86] and spectroscopic[93] studies and confirmed Pitzer's ideas concerning the complex motion of the nuclei in the molecule. However, the authors of the electron diffraction study[95] used a somewhat different dynamic model, where a vector S_j ($j = 1, 2, \ldots, 5$), defining the instantaneous position of a ring carbon atom, was introduced. During pseudorotation, each carbon atom moves in the vertical plane, passing through the given atom and the centre of the ring, the distance between the carbon atom and the centre of the ring being constant. Pseudorotation is also described by the two vibrational coordinates q and Φ, but in the given model the marked dependence of the C–C bond lengths on the displacement Z_j is eliminated. It was found that $q_g = 0.427$ for the effective displacement of the carbon atom from the plane (the subscript g denotes a value averaged with respect to temperature under the conditions of the electron diffraction experiment), which is somewhat less than the value obtained previously by Pitzer and coworkers[84-86] and in a spectroscopic study[93]. The equilibrium value $q_e = 0.438$ Å was also calculated[95] for the adopted anharmonicity constant of the out-of-plane vibrations $a = 2.0$ Å^{-1}. The difference between the values of q obtained in the electron diffraction[95] and spectroscopic[93] studies can be explained by the fact that the molecular parameters determined spectroscopically and by electron diffraction have a different physical significance (see, for example, Kuchitsu and Cyvin[6]).

Ab initio quantum-mechanical calculations on the cyclopentane molecule[96] confirmed the conclusion that the motion which depends on the angle Φ is virtually free and that $q_e = 0.43$ and 0.48 Å agrees well with the value determined by the electron diffraction method[95]. According to the authors' estimate[96], the height of the barrier separating the two configurations is in the range 4–8 kcal mole^{-1}.

Molecules containing a double bond [sic! a heteroatom?] in the five-membered ring have also been studied by electron diffraction: tetrahydrofuran[97-99], and 3-bromotetrahydrofuran[100]. In the first study[97], devoted to tetrahydrofuran and carried out at an earlier stage of the development of the electron diffraction method, only the planar model of the molecule was considered. A later investigation[98] established that the molecule has a non-planar structure. However, a satisfactory agreement between the theoretical and experimental intensity curves was not obtained for the individual models with C_s and C_2 symmetry (Fig. 3). Best agreement was achieved when the "envelope" and "half-chair" conformations were superimposed: $\alpha_1 C_s + \alpha_2 C_2$ (here α_1 and α_2 are the percentage contents of the forms with C_s and C_2 symmetry respectively) with $\alpha_1 \simeq \alpha_2$. This finding was interpreted[98] as evidence for the virtually free pseudorotation, the difference between the energies of the two conformers (C_s and C_2) being small and amounting to 0–3 kcal mole^{-1}.

A model of the pseudorotation of the five-membered ring, analogous to that used[95] for cyclopentane, was resorted to in an electron diffraction study[99] undertaken to interpret the experimental data for the tetrahydrofuran molecule. In this case too the model eliminates a marked dependence of the C–C and C–O bond lengths on the vibrational coordinates q and Φ. The average value of q_g was found to be 0.38 ± 0.02 Å, which is somewhat less than the spectroscopic value $q_0 = 0.470 \pm 0.025$ Å.[101]

Nevertheless one should note that the results of electron diffraction studies do not permit the conclusion whether or not the molecule is statically distorted or whether pseudorotation takes place in it. However, it has been established spectroscopically[48] that the C_2 form is energetically more favourable, while the C_s form has an energy higher by 1277 cm^{-1}.

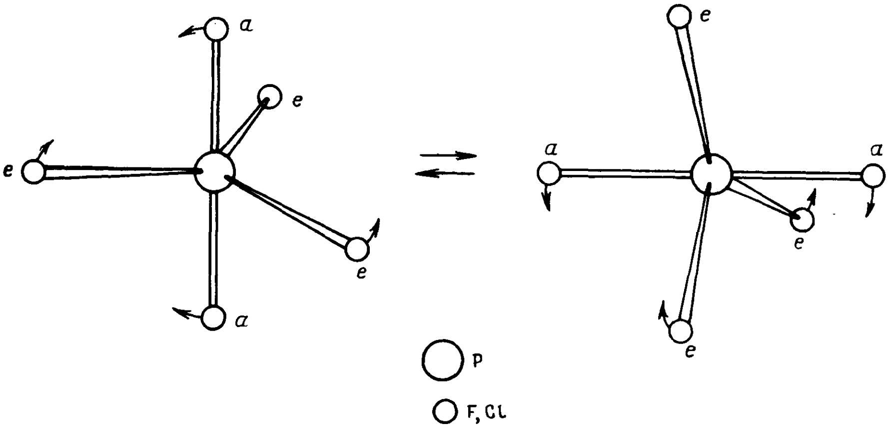

Figure 4. Schematic representation of the pseudorotation in the molecules of the phosphorus pentahalides PF_5 and PCl_5.

Apart from the electron diffraction determination of the molecular structure of 3-bromotetrahydrofuran, Smith et al.[100] also calculated the energies of its conformations by the Westheimer–Hendrickson method. They showed that the best agreement between the theoretical and experimental intensities is achieved on the hypothesis of almost free pseudorotation of the ring. The small energy differences between different conformations (of the order of 0.5 kcal mole^{-1}), found by conformational analysis, confirmed the results obtained by electron diffraction.

The electron diffraction data for other molecules with five-membered rings showed that the replacement of the oxygen atom by S, SiH_2, Se, CO, and GeH_2 leads to a greater stability of the C_2 form, the heteroatom or atomic group being displaced from the plane of the ring by approximately 20° during the vibrations[102]. The energy difference between the C_2 and C_s forms increases in the above sequence according to spectroscopic data[103-105].

2. Pseudorotation in Inorganic Halides

Pseudorotation in inorganic halides is a three-dimensional analogue of the high-amplitude intramolecular motion in five-membered cyclic organic molecules. Using these molecules as an example, it is possible to demonstrate that the characteristic duration of the experiment, which is different for different physicochemical methods used to study this problem (see Table), is significant for the observation of high-amplitude intramolecular motion.

An electron diffraction study of the PF_5 [106,107] and PCl_5 [107] molecules established that halogen atoms occupy two different positions—axial (*a*) and equatorial (*e*). The molecular model is described by the D_{3h} symmetry point group and the bond lengths $P-X(a) > P-X(e)$ (X = F or Cl). However, the NMR spectrum of PF_5 [108] indicates the complete equivalence of the fluorine atoms in the (*a*) and (*e*) positions, which served as the basis for the hypothesis of intramolecular exchange of fluorine atoms[14,109,110]. Analogous results have been obtained for the PCl_5 molecule[111-113]. The discrepancy between the electron diffraction and NMR measurements can be accounted for by the fact that the characteristic time of the NMR experiment (see Table) is apparently significantly longer than the time required for the exchange of fluorine atoms. Only the average picture of the intramolecular motion is therefore observed in this instance. On the other hand, it may be that the characteristic time of the electron diffraction experiment (see Table) is shorter than the exchange time of the halogen atoms. Because of this, at each instant the electron diffraction method records only the "instantaneous" picture of the scattering process in which halogen atoms occupy only the two most probable positions relative to the phosphorus atom, i.e. (*a*) and (*e*). For the same reason, the electron diffraction method cannot distinguish the possibilities involving the intramolecular motion in PF_5 and PCl_5 molecules as a result of which halogen atoms change places, on the one hand, or the static non-equivalence of the positions of these atoms, on the other.

Berry[109] and other workers[21-23,25,114-116] put forward the hypothesis that the exchange of axial and equatorial halogen atoms in phosphorus halides is a three-dimensional analogue of the pseudorotation in the five-membered rings of organic molecules (Fig. 4). Analysis of the Raman spectra of the PF_5 molecule in the gas phase made it possible to determine the pseudorotation barrier as 5.7 kcal mole^{-1}.[117]

As in phosphorus pentahalides, pseudorotation is observed in the heptafluorides of rhenium (ReF_7) and iodine (IF_7). The first electron diffraction study of the IF_7 molecule, carried out[118] using a visual method for estimating the electron scattering intensities, established that the nuclear configuration in this molecule is close to that of a pentagonal bipyramid (D_{5h} symmetry) in which five fluorine atoms are located in the equatorial plane, two fluorine atoms are on the axis, and the iodine atom is in the centre. According to LaVilla and Bauer[118], the fluorine atoms in the equatorial plane, which form a five-membered ring, are involved in a pseudorotatory motion, analogous to that described above for atoms in the rings of organic molecules.

The electron diffraction study of the IF_7 [119,120] and ReF_7 [119,121] molecules was repeated by Bartell and coworkers. Analysis of the results made it possible to establish reliably that the geometry of these molecules corresponds to the D_{5h} symmetry only approximately. Comparison of the theoretical intensity curve corresponding to the proposed model having D_{5h} symmetry with the experimental curve showed that the mean square vibration amplitudes for the non-bonded fluorine atoms

[$l_g(F_e\ldots F_e) = 0.254$ Å and $l_g(F_a\ldots F_e) = 0.236$ Å were obtained for ReF_7] are unduly high compared with the usually observed amplitudes for non-bonded pairs of atoms [cf. ReF_6 molecule[122]: $l_g(F_e\ldots F_e) \simeq l_g(F_a\ldots F_e) = 0.091$ Å].

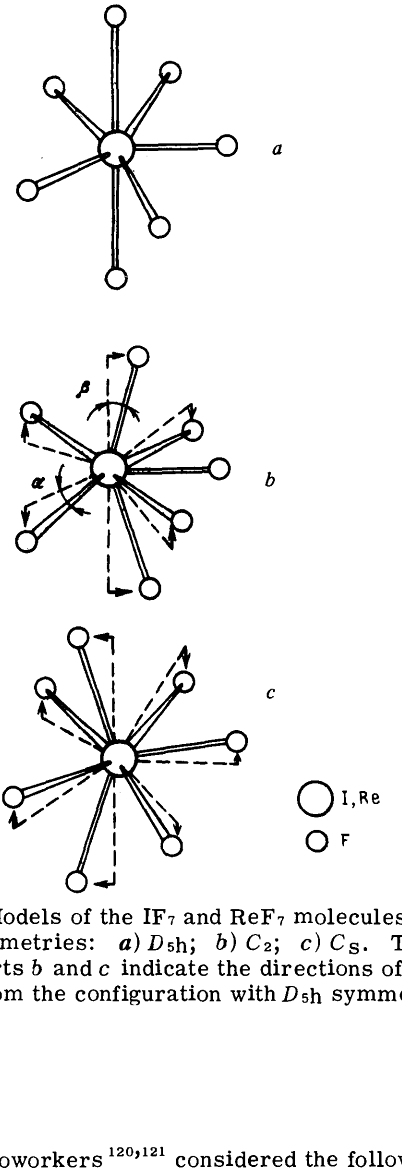

Figure 5. Models of the IF_7 and ReF_7 molecules with different symmetries: *a*) D_{5h}; *b*) C_2; *c*) C_s. The arrows in parts *b* and *c* indicate the directions of the deviations from the configuration with D_{5h} symmetry.

Bartell and coworkers[120,121] considered the following two alternative types of models of the IF_7 and ReF_7 molecules. In the first type static deformation is postulated—the displacement of fluorine atoms from the plane of the five-membered ring—described by the relation

$$\alpha_j = \alpha^0 \cos\left[2\left(\frac{2}{5}\pi j + \Phi_e\right)\right], \qquad (14)$$

$$j = 1, 2, \ldots, 5\ ,$$

where α^0 is the maximum angular deviation of fluorine atoms from the equatorial plane and Φ_e is the phase of the displacement of the same atoms. For $j = n\pi/10$ (n is an integer), we obtain a molecular model with C_s symmetry, while $j = (2n + 1)\pi/10$ yields a model with C_2 symmetry.

The angular displacement of the axial fluorine atoms is described by an analogous relation:

$$\beta_i = \beta^0 \cos\left[2\left(\frac{2}{5}\pi i + \Phi_a\right)\right], \qquad (15)$$

where β^0 is the maximum angular displacement of fluorine atoms from the C_5 axis, and Φ_a the phase of the displacement of the same atoms. From symmetry considerations, we have $\Phi_a = 4\Phi_e$. It was found that $\alpha^0 = 7.51$ and $\beta^0 = 4.55°$ for IF_7 and $\alpha^0 = 8.78$ and $\beta^0 = 7.65°$ for ReF_7. The molecular models are illustrated in Fig. 5. It is noteworthy that, both for models with C_s and C_2 symmetries and for their superposition $\alpha_1 C_s + \alpha_2 C_2$ with different statistical weighting factors α_1 and α_2, the factors governing the discrepancies between theoretical and experimental intensity curves proved to be fairly close, so that it was impossible to select any one of these models or their superposition.

The authors[120,121] put forward a dynamic pseudorotation model as the second possible interpretation of the experimental data for the ReF_7 and IF_7 molecules. It can be described as a continuous transition from the configuration with C_2 symmetry to one with C_s symmetry (Fig. 5). The motion of fluorine atoms in the equatorial plane is analogous to that on pseudorotation in the cyclopentane molecule. As a consequence of the strong interaction of vibrations of the e_2'' and e_1' type, the motion of the fluorine atoms in the equatorial plane is correlated with the motion of the axial atoms. Such interaction can be represented as the maximum "avoidance" of the fluorine atoms in the equatorial position involved in free pseudorotation by the axial fluorine atoms in the coordination sphere of the central atom.

Thus the electron diffraction method made it possible to establish unambiguously in this case also whether or not the observed distortion of the ReF_7 and IF_7 molecules is static, or whether a dynamic pseudorotation model is valid. However, the use of other experimental methods supports the dynamic model.

The effective dipole moment of the ReF_7 molecule, which increases as the temperature is reduced, has been observed by the method involving the deflection of the molecular beam in a homogeneous electric field[123]. A similar but less pronounced effect was found in the same study[123] also for the IF_7 molecule. These data, which disprove the quasi-rigid structure and demonstrate the temperature dependence of the results of the dipole moment measurements, support the dynamic stereochemically non-rigid molecular model. Furthermore, NMR studies of $Re^{19}F_7$ and $I^{19}F_7$ melts[124] indicate the complete equivalence to fluorine atoms in these compounds. Apart from the pseudorotation of the five-membered ring in these molecules, one may therefore also expect the occurrence of an intramolecular rearrangement leading to the exchange of the equatorial and axial fluorine atoms.

The study of the infrared and Raman spectra of IF_7[125,126] and ReF_7[125,127] supported a molecular model with D_{5h} symmetry. However, this does not conflict with the dynamic molecular model under consideration because an average pseudorotation pattern was apparently manifested in the spectroscopic experiment owing to the fact that its characteristic time (see Table) exceeds the time required for the intramolecular exchange.

Pseudorotation of a still more complex type may be postulated in the xenon hexafluoride molecule. The problem of the structure of this molecule has been discussed in a number of studies[128–131]. However, on the basis of theoretical analysis alone it was impossible to reach a conclusion about the molecular structure of XeF_6. X-Ray diffraction study did not permit the solution of the problem, because the compound does not form single crystals[132]. Spectroscopic investigations[133,134] likewise did not allow definite structural conclusions. The XeF_6 molecule was studied by electron diffraction several times[135–139]. A particularly detailed and thorough investigation was carried out by Bartell and Gavin[138,139] and their results are therefore described below.

The main conclusion which they reached[138,139] is that the molecular structure of XeF_6 in the gas phase cannot be described from the standpoint of a quasi-rigid model with O_h symmetry. Analysis of a wide variety of molecular models (O_h, C_{2v}, C_{3v}, D_{3d}, and C_s) and their linear combinations enabled them to establish that two alternative models may be reconciled with experimental data: (1) a static distortion model (with C_{2v}, C_{3v}, and C_s symmetry); (2) a dynamic model. According to the latter, the deformation vibrations with t_{1u} and t_{2g} symmetry in the XeF_6 molecule interact which leads to the correlation of the motions of the axial and equatorial fluorine atoms and to a distortion of the octahedron to give configurations with C_{2v}, C_{3v}, or C_{4v} symmetry. According to the authors[138,139], motion of this type can explain the virtual absence of an electrical dipole moment of the molecule[140,141] (the dipole moment measurements were performed by the method involving the deflection of a molecular beam by an inhomogeneous electric field), the unusual shapes, and anomalous half-widths of infrared absorption bands[130], as well as entropy data[142].

The nature of the dynamic distortions in the XeF_6 molecule can be clearly described by assuming that it resembles in some way three-dimensional pseudorotation in which fluorine atoms deviate from the octahedral positions by 5–10° as if striving to avoid certain regions in the coordination sphere of the Xe atom. In conformity with the Gillespie–Nyholm theory[143,144] (the theory of the repulsion of the electron pairs in the valence shell), the authors[138,139] identified these regions with the position of the lone electron pair of the Xe central atom, which migrates continuously in its coordination sphere from the position on the diagonal of the square formed by the equatorial fluorine atoms to the centres of the faces of the octahedra formed by one axial and two equatorial fluorine atoms (Fig. 6).

It is noteworthy that, although the idea of a stereochemically active lone electron pair does in general explain correctly the type of distortions in the molecule, nevertheless the theory of the repulsion of the electron pairs in the valence shell predicts much more pronounced distortions of the octahedron than are observed experimentally.

Claassen et al.[145] investigated the infrared, ultraviolet, and Raman spectra of XeF_6 in a matrix and in the gas phase, the Raman spectra and the spectra in the visible and ultraviolet regions being studied as a function of temperature. The authors suggest that, under the experimental conditions, the XeF_6 molecules exist in three electronic states ("electronic isomers"[148]): $^3A_{2u}$ (D_{3h} symmetry), ^3A_u or ^3B_u (C_{2v} symmetry), and A_{1g} (O_h symmetry). They showed[145] that all the spectra which they observed may be interpreted on the hypothesis of three "electronic isomers" of the XeF_6 molecule between which thermodynamic equilibrium is established in the course of approximately 10 min at 100°C. Evidently a reinterpretation of the electron diffraction data from the standpoint of the existence of the XeF_6 molecule in different electronic states is of undoubted interest. The interpretation of the molecular structure of XeF_6 in such a case requires in essence that one resorts to the Jahn–Teller pseudoeffect, since conditions under which the pseudoeffect is manifested may exist in the molecule[146–149].

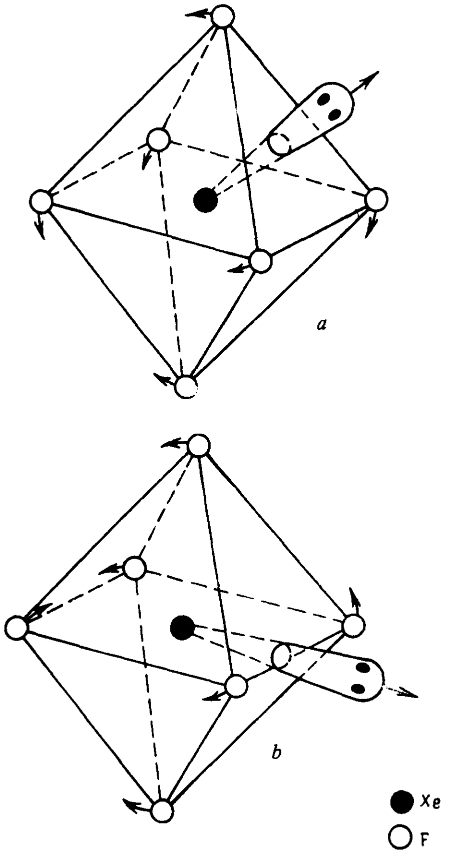

Figure 6. A model of the XeF_6 molecule. The possible positions of the lone electron pair on a face (*a*) and edge (*b*) of the octahedron and the directions of the distortions of the latter caused by the electron pair are shown.

The dynamic pseudorotation in the ReF_7, IF_7, and XeF_6 molecules described above should presumably be characterised by low frequencies. The following frequencies in the above molecules may be estimated from the electron diffraction data: 4.4 cm^{-1} (ReF_7); 5 cm^{-1} (IF_7); 10 cm^{-1} (XeF_6). Consequently the contribution of the pseudorotation to the thermodynamic functions of the given substances should be very considerable.

VI. JAHN–TELLER MOLECULES¶

Vanadium tetrachloride. The electron diffraction study of the VCl_4 molecule[150,151] was undertaken in order to determine its possible Jahn–Teller distortions, predicted on the basis of studies of the spectra of this compound[152–155] as well as theoretical calculations[45,156–160]. It was impossible to observe significant deviations of the VCl_4 structure from a regular tetrahedron[150,151], although, according to Morino and Uehara[150], the tetrahedron may deviate by 0.05 Å in the direction of the ν_2 stretching vibration. However, the greater amplitude of the vibrations of the Cl...Cl pair of nuclei in the VCl_4 molecule compared with $TiCl_4$ as well as certain other features of the structure and the vibrational spectrum of VCl_4 support, according to the authors[150], the operation of this effect. It appears that the Jahn–Teller distortions of the VCl_4 geometry are small and their measurement corresponds to the limit of the power of the modern electron diffraction method.

Vanadium hexacarbonyl. The molecules of vanadium and chromium hexacarbonyls have been investigated by electron diffraction[161]. Analysis of the experimental data established that the mean square vibration amplitudes of the vanadium atom in the $V(CO)_6$ molecule relative to the environment consisting of carbonyl groups are much higher than the corresponding values for the $Cr(CO)_6$ molecule. This was explained by the Jahn–Teller effect in the $V(CO)_6$ molecule. Schmidling[161] tested two types of models corresponding to the Jahn–Teller distortions of the nuclear configuration—of the E_g type (D_{4h} symmetry) and the T_{2g} type (D_{3d} symmetry). Best agreement was achieved for the model with D_{3d} symmetry and the deviation of the CO group in the direction towards the threefold axis was found to be 5.3°.

Rhenium hexafluoride. An electron diffraction study of the ReF_6 molecule established[122] that its geometrical configuration is described by the symmetry point group O_h. However, a spectroscopic study by Brand et al.[162] indicated the possibility of a Jahn–Teller distortion of this molecule, the displacement of the fluorine atom leading to trigonal (t_{2g} symmetry) distortions of the octahedron to the extent of 0.046 Å. The energy of the Jahn–Teller distortions was found to be 74 cm^{-1}. It is at present apparently difficult to explain the cause of the difference between the conclusions reached in the spectroscopic[162] and electron diffraction[122] studies. Nevertheless one may point out that Jacob and Bartell[122] observed a discrepancy between the theoretical and experimental intensities, which they were able to account for satisfactorily by the effects due to three-atom intramolecular scattering.

VII. BIS(CYCLOPENTADIENYL)BERYLLIUM

According to electron diffraction studies[163,164], the two cyclopentadiene rings in the $(C_5H_5)_2Be$ molecule are parallel to one another and mutually staggered, the distance between them being 3.375 ± 0.010 Å. The Be atom is located on a fivefold symmetry axis, which is the same as the two cyclopentadienyl groups, and can occupy two alternative positions at a distance $h_1 = 1.472 \pm 0.06$ Å from one ring and $h_2 = 1.903 \pm 0.008$ Å from the other.

It may be that the structural characteristics of this compound, observed in the electron diffraction experiment, are due to the manifestation of the Jahn–Teller pseudoeffect and that the beryllium atom oscillates between the cyclopentadiene rings along the fivefold symmetry axis. The potential curve describing such motion has two minima corresponding to different distances of the beryllium atom from the planes of the cyclopentadiene rings. This interpretation of the electron diffraction data[163,164] makes it possible to determine the "lifetime" of each configuration, which is 10^{-12}–10^{-13} s according to Ionov and Ionova[165], and the most probable barrier to the transition between the two configurations is in the range 1.4–2.9 kcal $mole^{-1}$.

VIII. MOLECULES OF OXYACID SALTS AND CERTAIN COMPLEX HALIDES

Electron diffraction studies on a number of alkali metal and thallium(I) metaborates[166–168], sulphates[169–171], chromates[169], perrhenates[172,173], molybdates[171,174], and nitrates[175–178] as well as complex compounds of the type $M^{I}M^{II}Hal_4$ [179–181] and M^{I} $^{II}Hal_3$ [182] (Hal = halogen and M^{I}, M^{II}, and M^{III} are Group I–III metals) yielded experimental data which have many characteristic features in common. In particular, it was observed that the electron diffraction patterns of these compounds contain only a limited amount of information about the position of the metal atom relative to the acid residue in molecules of the oxyacid salts and relative to the $M^{III}Hal_4$ (or $M^{II}Hal_3$) fragment in the complex compounds, revealed mainly in the region of low scattering angles. This situation is observed for both light and heavy atoms and cannot be explained simply by their low scattering capacity. A similar phenomenon has been called the "elution" effect[183]. It appears that it can be explained in many instances by an increase of the mean square vibration amplitudes of certain pairs of nuclei as a consequence of the increase in the populations of the excited vibrational levels of the molecule[183]. This appears to be a quite natural consequence of the influence of the high experimental temperature, particularly when the molecule executes low-frequency vibrations.

However, the above explanation, which is valid within the framework of the quasi-rigid molecular model, is inadequate for the salts of oxyacids and the complex compounds, because it is difficult to account for the above features of the experimental data simply by an increase in the populations of the excited vibrational levels. It appears much more natural to postulate a continuous change in molecular configuration as a result of the displacement of the metal atom relative to the quasi-rigid fragment (the acid residue, $M^{III}Hal_4$, or $M^{II}Hal_3$). Such a dynamic stereochemically non-rigid molecular model is apparently a general characteristic feature of the structures of many oxyacid salts and complex halides and

---

¶ The classification of different types of high-amplitude motion employed in the present review is to a large extent arbitrary and is a result of the author's endeavour to reflect the main ideas, terminology, and explanations of the observed effects in the literature quoted. However, as already mentioned to some extent, the results of many of the studies of stereochemically non-rigid molecules discussed in Sections II–V may be accounted for on the hypothesis of a Jahn–Teller pseudoeffect in the molecules and the latter may be regarded as being of the Jahn–Teller type. This also applies to the exposition below.

possibly also other classes of compounds. We shall now consider the results of the electron diffraction studies in greater detail.

The electron diffraction patterns of alkali metal metaborates[166–168] in general correspond to the symmetrical linear BO_2 fragment and the low contribution to the overall scattering by the metal atom hinders the determination of its position. In electron diffraction studies on caesium[169,171], potassium[169], and thallium(I)[170,171] sulphates, potassium chromate[169], and thallium(I) nitrate[177,178], agreement between the experimental and theoretical density curves within the framework of a single quasi-rigid model can be achieved only for anomalously high vibration amplitudes of the metal atom relative to the oxygen atoms of the acid residue (l_g = 0.15–0.25 Å). The fragment of the acid residue then has a structure close to that of a regular tetrahedron for salts of the type M_2EO_4 (E = S or Cr; M = K, Cs, or Tl) or of an equilateral triangle in the case of thallium(I) nitrate (the non-equivalence of the angles at the central atom has been estimated[166–177] as ±5°, while the possible non-equivalence of the bond lengths does not exceed 0.1 Å). An electron diffraction study of the $TlNO_3$ molecule established[177] that best agreement between the theoretical and the experimental intensity curves is attained for a superposition of models of this molecule having different symmetries ($\alpha_1 C_s + \alpha_2 C_{2v} + \alpha_3 C_{3v}$) with the greatest contribution by the model with C_{2v} symmetry (α_2 = 71%).

Thus, in conformity with electron diffraction data, in the oxyacid salts quoted above there is a high symmetry of the acid residue in combination with a high mobility of the metal atom. This picture of the structures of many oxyacid salts has been confirmed by spectroscopic data. Thus studies of the infrared spectra of the vapours of the metaborates of certain elements[184–186] failed to detect the vibration frequency of the metal atom relative to the BO_2 fragment and the observed frequencies in the range 600 to 1940 cm^{-1} are due to the vibrations of the BO_2 group and were found to be almost independent of the metal atom to which the group is attached. Similar results, indicating a weak dependence of the NO_3 and SO_4 vibrations on the nature of the metal atom, were obtained also in studies of the infrared spectra of univalent metal nitrates in a matrix[187] and in the gas phase[188] and of univalent metal sulphates[189].

Virtually analogous results were obtained in electron diffraction studies on the $NaAlF_4$,[179] $KAlCl_4$,[180] $KYCl_4$, and $TlInCl_4$[181] molecules. It was established that the $MHal_4$ fragments in these compounds have a configuration close to that of a regular tetrahedron [within the limits of the errors in the measurements of the angles, which have been estimated[179–181] as ±5°, and the possible non-equivalence of the M^{III}–Hal bond lengths (<0.1 Å)]. The univalent metal atoms are located on a line perpendicular to one of the edges of the tetrahedron. An electron diffraction study of M^IBeF_3 molecules (M^I = Na or K)[182] showed that the BeF_3 fragment has a configuration close to that of an equilaterial triangle and that the metal atom is located within the plane of the triangle on a line perpendicular to one of its sides. A characteristic feature of the studies on complex salts of both types is anomalously high vibration amplitudes of the metal atom relative to the quasi-rigid $M^{III}Hal_4$ or $M^{II}Hal_3$ fragment (for example, 0.19 Å in $TlInCl_4$[181]). This makes it possible to treat the observed configurations as the most probable and the molecular structures of these compounds should be described with the aid of a dynamic stereochemically non-rigid molecular model, fully analogous to the model discussed above in relation to oxyacid salts.

The results of *ab initio* quantum-chemical calculations on the LiNC molecule by Clementi and coworkers[190,191], *ab initio* calculations on the $LiBO_2$ molecule[102], calculations by the LCAO-MO semiempirical method on the $LiNO_3$ and $TlNO_3$ molecules[193], as well as calculations on the dependence of the electrostatic energy of the interaction between the cation and anion on the spatial position of the metal ion for $CsNO_3$ and $TlReO_4$ molecules, carried out[194] using an ionic model (Fig. 7), are of undoubted interest in connection with the problem under consideration.

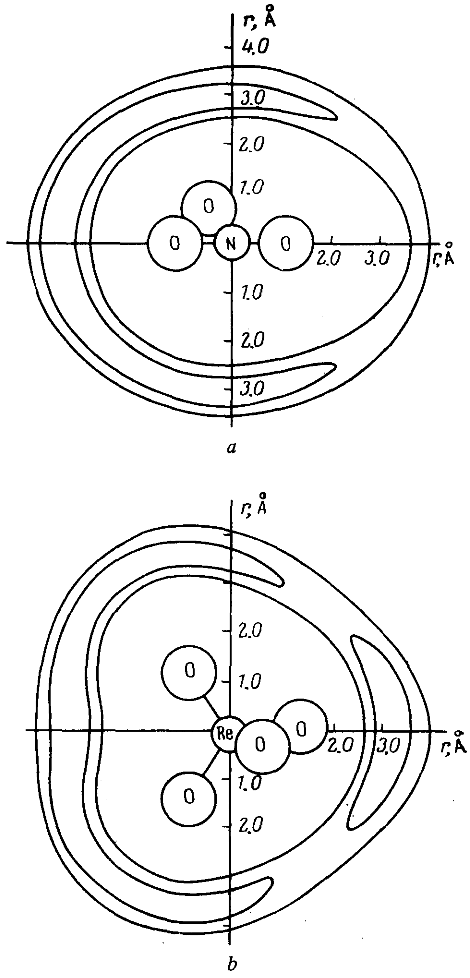

Figure 7. A map of the potential energy surface for the motion of the metal atom relative to the acid residue: *a*) $CsNO_3$; *b*) $TlReO_4$.

The electronic structure of the LiNC molecule has been calculated[191] for different positions of the metal atom relative to the NC fragment. The calculated maps of the energy surfaces for the motion of the Li atom showed that there is virtually no energy barrier between the Li–C≡N and Li–N≡C configurations. On thermal excitation (energy about 0.3 eV), the Li atom rotates freely about the NC group.

Virtually analogous results were obtained also in quantum-chemical calculations on $LiBO_2$ [192] and $TlNO_3$ [193] molecules.

Thus the results of quantum-chemical calculations have fully confirmed the conclusions reached in electron diffraction studies concerning the stereochemical non-rigidity of the molecules of many oxyacid salts.

This exhausts, for the present, the list of electron diffraction studies in which experimental data were clearly interpreted from the standpoint of the stereochemically non-rigid molecular model. However, one cannot rule out the possibility that experimental studies on many organic and inorganic compounds, in the explanation of the results of which a quasi-rigid molecular model has been used, can also be interpreted from the standpoint of the stereochemically non-rigid molecular model.

IX. CONCLUSION

The extensive experimental electron diffraction data available at the present time have shown, in agreement with the results derived by other physicochemical methods, that complex nuclear motions are executed in molecules of different classes, namely high-amplitude motions. They lead to important chemical consequences.

In the first place this concerns the classical ideas about the geometrical configurations of molecules and their symmetry. The classical structural theory is based in essence on the coordinates of the minima in a multidimensional potential energy surface, whose set forms a fixed geometrical configuration with a definite point symmetry, and not on physically determined spatial positions of the nuclei in the molecule. Therefore, if a nucleus in the molecule executes a high-amplitude motion, then under certain conditions (see Section II) the positions of the potential energy minima lose the significance of the spatial characteristics of the nuclear system and the molecular structure cannot be described, in principle, by a time-invariant geometrical configuration with fixed positions of the nuclei (and its point symmetry). In this case only the solution of the corresponding wave equation for the motion of the nuclei (if necessary, taking into account non-adiabatic corrections) and the determination of the probability density function for the distribution of the nuclei yields an adequate (although not unduly clear) picture of the structure. With the aid of this function, it is possible, in principle, to calculate the probability of any location of the nuclei. In this connection one must mention Liehr's study [36], where the quasi-rigid molecular model was subjected to a serious criticism and an attempt was made to develop a more general approach to the description of nuclear subsystems, including the construction of the complete potential energy surface.

The next problem which must be considered concerns the nature of the chemical bond in stereochemically non-rigid molecules. We shall examine it in relation to salts of oxyacids and complexes. It was shown above that in molecules of these compounds there is virtually free rotation of the metal atom about the acid residue or the $M^{III}Hal_4$ and $M^{II}Hal_3$ fragments. This shows that the theory of the chemical bond, in particular the theory of directional valence, is unsuitable for the description of the electronic structures of these molecules.

A specific feature of the chemical bond involving the metal atom in the compounds under consideration is its delocalisation in the molecule—its dynamic, distributed nature. This is not a bond between any pair of atoms, but a bond formed by the metal atom with the acid residue (or the $M^{III}Hal_4$ and $M^{II}Hal_3$ fragments) as a whole. In order to stress this feature of the bond, Clementi [191] suggested that it be called a polytopic bond and that the molecules containing such bonds should also be referred to as "polytopic" molecules. The nature of the polytopic bond is apparently close to that of the bond in ionic crystals, where there is also no appreciable bond directionality.

Another characteristic feature of the chemical bond under consideration consists in the relatively weak distorting influence of the metal atom on the acid residue (or $M^{III}Hal_4$ and $M^{II}Hal_3$ fragments), which is a consequence of the migration of the metal atom. However, according to thermodynamic studies (see, for example, Cubicciotti [195]), there are no grounds for the assumption that this bond is energetically weak and that the corresponding molecule is thermally unstable.

We may note that the experimental and theoretical studies which have been carried out have in essence merely posed the problem of polytopic bonds and that the multiplicity of questions which have arisen still require an answer. For example, the elucidation of the role of vibronic interactions in high-amplitude motions may be regarded as a problem of this kind. If the vibronic interaction is intense, the electronic spectra of molecules cannot be treated separately from nuclear motion, which leads to the necessity for a radical revision of the ideas about the nature of the chemical bond.

The accumulation of experimental data on stereochemically non-rigid molecules is important also for many other chemical problems. Thus tunnelling effects play an appreciable role in the kinetics of chemical reactions, particularly at low temperatures. The problem was formulated for the first time by Bourgin in 1929 [196] and was analysed in detail theoretically in a number of other studies [197–200]. Pearson [201] attempted to regard the activation energies of uni- and bi-molecular reactions on the basis of the analysis of the orbital symmetries of the electronic states of the molecules involved in the reaction and the influence of close excited electronic states. This approach is extremely important for the understanding of the mechanisms of intramolecular rearrangements.

Structure of Amorphous Polymers

V.P.Lebedev

A critical survey is made of experimental results obtained by the application of direct structural methods—X-ray, electron, and neutron diffraction, electron microscopy, and several other physical methods—to amorphous linear polymers. A list of 162 references is included.

CONTENTS

I. Introduction 69

III. Classical structure analysis of amorphous polymers 70
IV. Results of electron microscopy 73
V. Other physical methods of investigation 77

I. INTRODUCTION

For many years research workers have paid steady attention to the structure of polymers at a supermolecular level. Special progress has been made in studying the structure of crystallising polymers—the folding of polymeric molecules, detected originally in thin films[1] and in single crystals[2-4]—which was very reliably transferred also to crystallites present in blocks and in the fibres of most polymers[5-7]. A wide range of supermolecular crystalline structures has been discovered and studied in detail[5-7], and a systematic classification has been developed[8].

Less attention has been paid to the structure of amorphous polymers, firstly because of the opinion that polymers in the amorphous state were structureless, and secondly because application of the usual structural methods

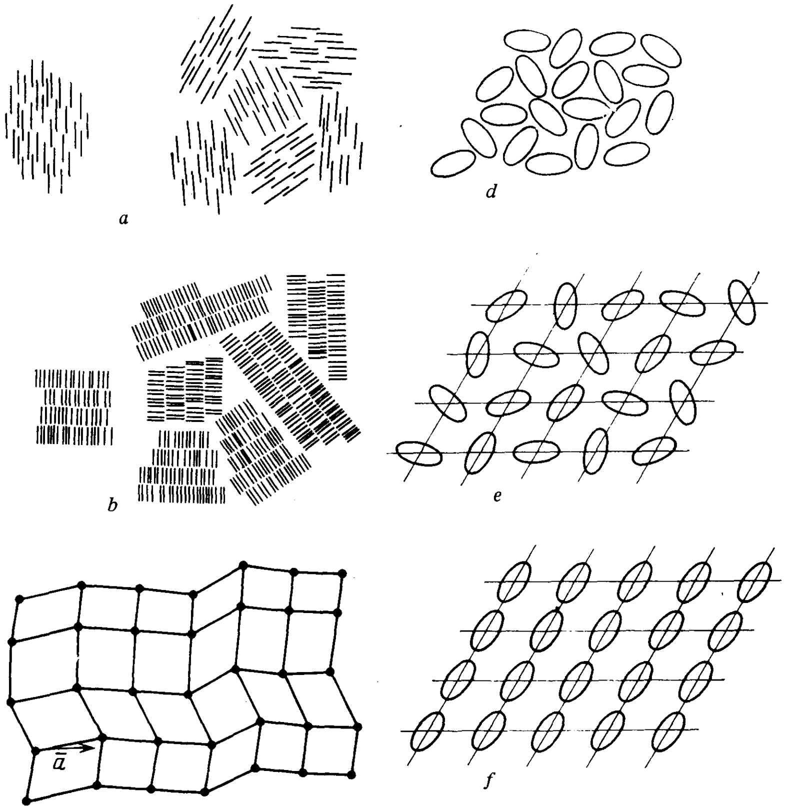

Figure 1. Schemes of packing of rod-shaped molecules: *a*) nematic structure; *b*) smectic structure (according to Friedel); *c*) ideal paracrystalline lattice (according to Hosemann); *d*) liquid packing of cross-sections of macromolecules; *e*) gasocrystalline; *f*) crystalline (according to Kitaigorodskii).

to amorphous substances yielded little information. Systematic study of the structure of amorphous polymers was initiated in 1957 by the work of Kargin et al.,[9] whose underlying idea, as expressed by one of the authors 17 years later[10], was that the structure of a polymer in the amorphous state should be similar to its structure in the crystalline state. Although the bundle model of the structure of amorphous polymers, in the form in which it was presented in that[9] and other publications of these workers[11,12], is now regarded as unsatisfactory, the actual concept of a high degree of structural order permeates the majority of current models of the amorphous state.

The present Review traces the main trends and results in the experimental study of the structure of amorphous polymers, and the extent of agreement with the most generally accepted current models of the amorphous state.

II. NOMENCLATURE OF STRUCTURES OF DIFFERENT DEGREES OF ORDER

A multitude of organic compounds exist in Nature that, over a certain temperature range, are intermediate between liquids and crystals with respect to the degree of molecular order and hence physical properties[13,14]. They comprise elongated molecules, and for this reason are able to form molecular aggregates with different degrees of ordering. The structure and the properties of liquid crystals have now been investigated for more than half a century, so that almost the whole terminology used to describe non-crystalline packages of macromolecules was developed for liquid crystals.

All types of intermediate ordering were generally termed "mesophases" (from *mesos*—intermediate and *phasis*—phase) or "mesomorphs", the "mesomorphic" state. In 1933 Rinne suggested for one- and two-dimensional mesophases, in contrast to a three-dimensional crystalline phase, the term "paracrystal", thereby emphasising that the majority of liquid crystals are *para*-substituted benzene derivatives. Somewhat earlier, in 1922, Friedel had independently suggested the term "nematic mesophase" (from *nematos*—fibrous, filamentous) for a unidimentional mesophase, and "smectic" for a two-dimensional mesophase. These structures are shown diagrammatically in Fig. 1*a*, *b*.

These terms already came to be applied in the same sense to analysing polymer structures in the early papers of the 1930s.[15] The term "paracrystal" was then made more specific by Hosemann in 1950 in his paracrystalline model of the structure of polymers as a whole, including regions of all degrees of order[16,17]. This worker postulated the presence of a three-dimensional lattice in the arrangement of atoms in a polymer, with all three parameters of the unit cell not constant but conforming to some coordination statistics (Fig. 1*c*). The type of statistics and the consequent lattice disturbances are determined by the degree of molecular order—from liquid to monocrystalline—in different polymers or in different portions of the same polymer.

In 1959 Kitaigorodskii proposed[18] the new term "gasocrystalline" structure for certain highly ordered nematic and smectic forms. If the axes of the long molecules are located at the points of a regular (crystalline) two-dimensional hexagonal lattice and the molecules perform random ("gaseous") rotations about their axes, a model of the gasocrystalline state is obtained (Fig. 1*e*). This structure will exhibit a nematic or a smectic character according as neighbouring molecules undergo random or coordinated displacements respectively.

In 1963 Vainshtein[19] discussed in the greatest detail possible types of aggregates of chain molecules. The simplest and most natural organisation of chain molecules into three-dimensional aggregates, also satisfying the principle of densest packing[20], was taken to be a parallel arrangement with a varying degree of order and with the parallelism maintained in varying degree. Having placed the chain molecule with its axis passing through a branch point of one of the five possible ideal two-dimensional networks (Fig. 2*a*, *b*), this author then examined every type of disturbance of the initial position of this molecule, various combinations of which are summarised by the scheme in Fig. 2*c*. Thus the structure of a given polymer can be regarded as established when the type of aggregation of chain molecules to which the given structure corresponds has been found experimentally and the quantitative characteristics of the disturbances involved have been determined. Later in the monograph[19] theoretical consideration was given to the character of the X-ray diffraction from all types of aggregates of chain molecules, the results being illustrated by optical diffractograms from models or X-ray diffraction patterns of model materials.

III. CLASSICAL STRUCTURE ANALYSIS OF AMORPHOUS POLYMERS

Application of X-ray diffraction to the study of natural and synthetic polymers began immediately on the appearance of industrial equipment for structural analysis. Most of the polymers known at that time were amorphous, so that greater attention was then paid to their structure than at the present time, with the abundance of well crystallised polymers, more suitable for study by means of X-rays.

Firstly the X-ray patterns of monomers and corresponding polymers were compared[15]. The greatest differences were observed with polymers having large side-chains—poly(methyl acrylate), poly(vinyl acetate)—polystyrene, polycarbonate, polyindene—whose patterns exhibited two halos within a certain range of angles, whereas the corresponding monomers showed only one of them. The additional halo, always having the greater periodicity, was termed a "polymerisation ring". The reason for its appearance became clear when it was observed to contract on to the equator in the case of an oriented specimen (Fig. 3*c*). In the uniaxial stretching of a polymer the axes of the macromolecules are oriented preferentially in the direction of stretching, and therefore the equatorial reflection may be governed merely by the interchain distance. At the same time a good correlation was noted between the length of the side-chain and the periodicity of the equatorial reflection[21]. The fact that a "polymerisation ring"—or "intermolecular interference", as it came to be called later—is observed even in an isotropic specimen shows that the polymer molecules in a block are not randomly entangled but are arranged in parallel in microregions, each randomly oriented relative to its neighbour. In the terminology of liquid crystals such polymers have a nematic mesomorphous structure.

These ideas were developed as early as 1936, when Katz published his review[15], but they were forgotten during the postwar years, when the centre of gravity of structural investigations was transferred to well-crystallised stereoregular polymers. Experimental results gradually began to accumulate afresh: in 1950 Pritshk[22] demonstrated four

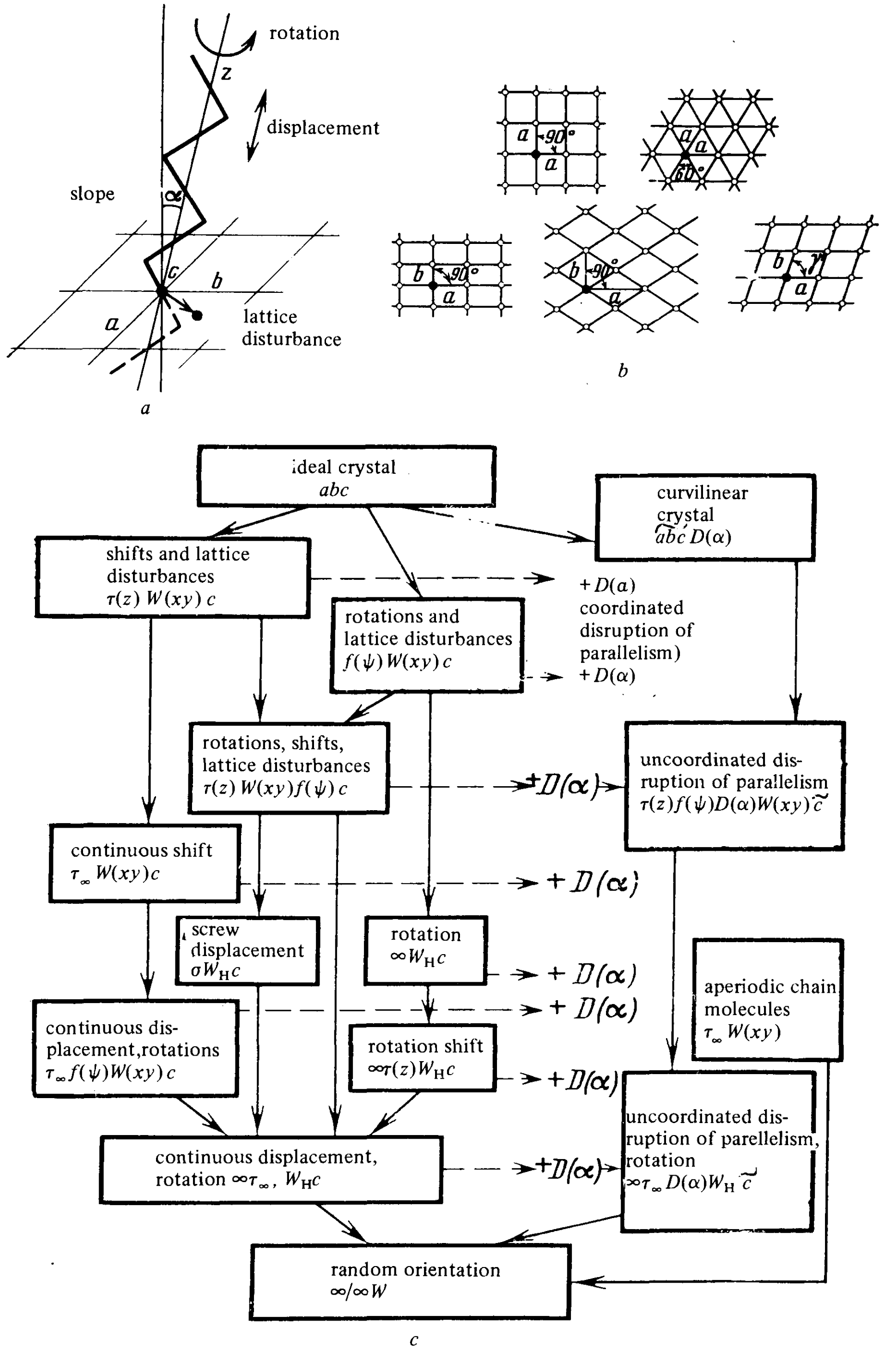

Figure 2. Packing of chain molecules (according to Vainshtein): *a*) types of disturbance of ideal packing; *b*) five regular two-dimensional networks; *c*) types of aggregation of chain molecules.

types of X-ray patterns obtainable with nylon-6, which he attributed to various combinations of liquid-amorphous, nematic, smectic, and crystalline structures; in 1951 Krimm and Tobolsky[23] reproduced the texture of atactic polystyrene discovered by Katz and Fuller during the 1930s; and in 1959 Kitaigorodskii[20] directed attention to polyacrylonitrile as the clearest example of a polymer having a gasocrystalline structure[18] (Fig. 3*a*). A nematic type of structure was noted in molten and amorphised specimens of poly(vinyl chloride)[24,25], poly(vinylidene chloride)[26], their copolymers, and chlorinated poly(vinyl chloride)[25]. The smectic state of isotactic polypropylene was revealed by X-ray diffraction and dilatometrically[26,27]. The accumulation of experimental data was accompanied by attempts to systematise mesomorphous polymeric structures. For example, Ruscher distinguished seven different types of ordering of chain molecules[28]—amorphous, nematic, smectic, nematic–hexagonal, smectic–hexagonal, defect-crystalline, and ideally crystalline structures.

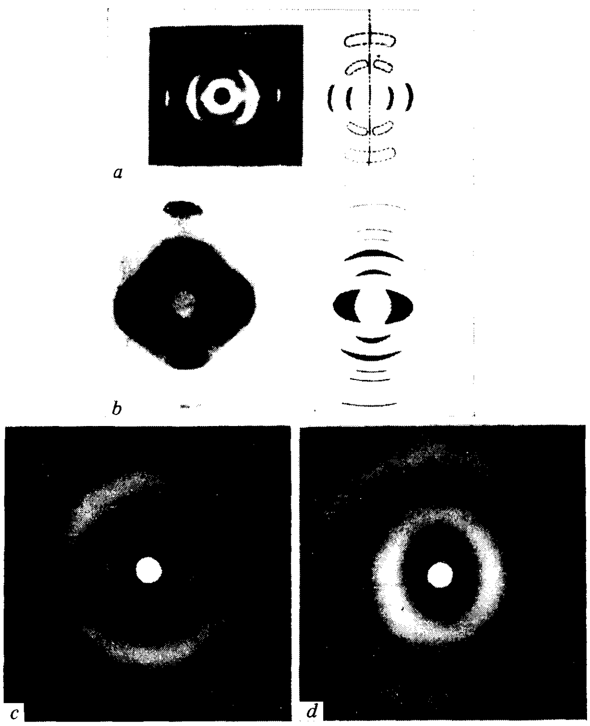

Figure 3. Effects of ordering on X-ray patterns of oriented amorphous polymers: *a*) two-dimensional long-range order[17] (gasocrystalline structure[18]) in polyacrylonitrile; *b*) one-dimensional long-range order in poly(ethylene terephthalate)[40]; *c*) interchain short-range order in polystyrene; *d*) as (*c*) in poly(methyl methacrylate).

As noted above, a rigorous and full classification of possible types of packing of chain molecules was given by Vainshtein[19]. Since the beginning of the 1970s increasing numbers of publications have appeared on the application to polymers of the analysis of radial distribution curves of electron density based on the dependence of the X-ray intensity on the scattering angle (or based on the potential distribution in the scattering of electrons). A comparatively large amount of structural information—interatomic distances in molecules, number of closest neighbours (coordination number), their mean distance, etc.—is given by radial distribution curves in the case of amorphous substances of low molecular weight[29]. For example, the examination of short-range order in cycloalkanes enables the molecular conformation (chair and boat forms of cyclohexane over different temperature ranges, the W form of cyclo-octane) and a coordination number of ~ 11.5 to be established[29] from the observed intramolecular distances. The molecules of n-alkanes, however, were packed in the liquid like cylinders of rotation, with a mean distance of 5.6 Å between their axes[29] and ~ 6 nearest neighbours.

The greatest difficulties in analysing radial distribution curves are encountered in separating the contributions of intramolecular and intermolecular interference. This is probably why such analysis was first applied to atactic polystyrene[30] and its *para*-halogenated derivatives[31], for with this polymer, as we have already seen[15,23], the effects of intra- and inter-molecular interference are quite sharply separated even on the initial scattering curves. The statistical mean intrachain short-range order was found to be the same as in isotactic polystyrene, which has since been confirmed independently by nuclear magnetic resonance[31]. Among intermolecular distances, benzene rings in neighbouring chains were 5 Å apart, and their axes 9–11 Å apart.

This method has been used to investigate a large number of molten crystalline polymers—polyethylene[33,34], polychlorotrifluoroethylene, poly(ethylene sebacate), gutta-percha[34], natural rubbers from various sources[35,36], polyacrylonitrile[36], and polycarbonate[37]—by Ovchinnikov and his coworkers, who employed the set of interchain distances in the crystal lattices of the polymers to separate the maxima observed on the radial distribution difference curves into intramolecular and intermolecular. The general deduction for all the polymers was that the character of the short-range order in the melt corresponded to their structure in the crystalline state: i.e. a parallel arrangement of chain segments and their packing in the basal plane analogous to crystals (square, rectangular, hexagonal) are present also in molten crystalline polymers. In several cases transitions are observed from one type of packing to another: in molten polyethylene a change from rectangular (rhombic) to hexagonal packing was observed at 175–200°C,[36] and in polybutadiene one pseudohexagonal packing passed into another at ~ 75°C.[36] The number of intermolecular maxima on the difference radial distribution curve was regarded as a relative measure of the degree of perfection of the short-range order and the size of the ordered regions. Most frequently there were two, corresponding to regions of diameter ~ 25–30 Å, but sometimes three (polyacrylonitrile[36]) or one (gutta-percha[34]). Other workers[38] have obtained a similar result by this method for polycarbonate [bisphenol A polycarbonate]: the size of ordered regions for an amorphous specimen prepared by injection moulding, and also after annealing below the glass point (at 120°C for 3 h), was 20–30 Å, but after prolonged annealing above this point (at 190°C for 122 h) the size had increased to 50–60 Å.

Nevertheless, the ambiguity inherent in the separation of contributions by intramolecular and intermolecular scattering to the maxima on the radial distribution curves makes a different interpretation of the experimental results possible. Thus Fischer et al.[39] have attempted to assign all the maxima on the radial distribution curves of polyethylene to intrachain distances.

The difficulties in interpreting the X-ray patterns of amorphous polymers made theoretical consideration of this question necessary. A general solution of the problem of the diffraction of X-rays on amorphous polymers has not yet been found, but certain limiting or simple cases can be examined theoretically, and hence the main features of the X-ray patterns actually obtained from amorphous polymers can be predicted and explained[19].

The first noteworthy result is the character of the diffraction pattern to be expected with non-parallel packing of the chain molecules. The pattern of scattering should be saw-tooth in character: at scattering angles corresponding to the repeat period of the chain a sharp jump in intensity should be observed, followed by a slow fall. This applies even to 8 units in a linear chain segment. Such a pattern of scattering does not correspond to the experimental X-ray photographs. Further consideration of the diffraction from an individual curved macromolecule showed[19] that the periodicity should appear with oriented preparations as a single meridional reflection, but with isotropic specimens as a ring at the same angle of scattering. The effective chain segment with respect to diffraction is then 6–7 units long. A second effect in diffraction from a single curved chain is gaseous or liquid intramolecular scattering. If large side-groups are absent, this scattering should be apparent as a uniformly decaying background. If the monomer unit has a complicated structure, the intramolecular scattering will be characterised by diffuse maxima, as with molecular gases and liquids.

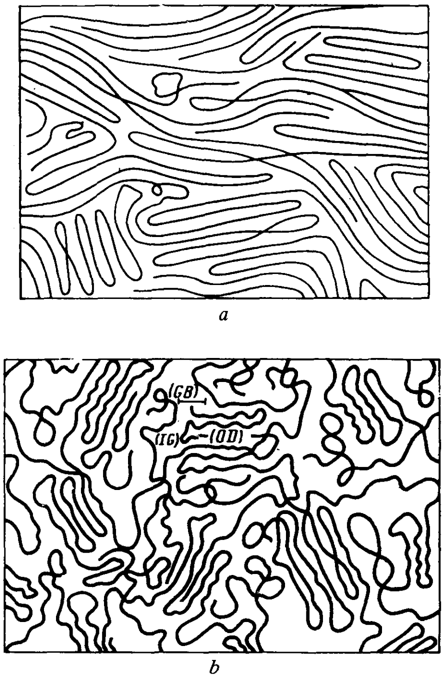

Figure 4. Diagrammatic representations of structure of amorphous linear polymers: *a*) Vainshtein model[19]; *b*) Jeh–Geil model[103,107].

Parallel packing, as far as possible, is also advantageous in aggregates of curved chains[19]: portions with skew contacts between neighbouring molecules make hardly any contribution to the overall interference pattern, whereas portions with an approximately parallel arrangement of chains will give a new diffraction effect, consisting in the appearance of an interference spot on the equator of an oriented specimen (or an additional ring, in comparison with the scattering from a single chain, with an isotropic specimen). The presence of displacements and rotations of chains does not prevent the appearance of an equatorial reflection, and the spread in interchain distances merely results in blurring of this reflection. Qualitative estimates of the size of the interference region give 20–40 Å.

Thus three types of diffraction effects must be expected on the X-ray patterns from amorphous polymers (they can be reliably separated only in the case of oriented specimens)[19]—(i) a maximum (or maxima) on the meridian resulting from chemical periodicity in the chain molecule, (ii) a maximum on the equator as a consequence of interchain interference of roughly parallel chain segments, and (iii) a diffuse background of intramolecular scattering, with "liquid" maxima when the monomer unit is complicated in structure—all of which are in some measure apparent on the X-ray patterns of amorphous polymers, especially clearly with amorphous biopolymers (see Figs. 217 and 218 in the monograph[19]) but less distinctly with synthetic polymers owing to the considerably greater non-uniformity of molecular mass, branching, stereoregularity, and other characteristics. Examples of amorphous textures with meridional reflections are incompletely crystallised oriented poly(ethylene terephthalate)[40] (Fig. 3*b*) and fibres of certain polyamino-acids[41]; amorphous textures with equatorial reflections are exhibited by polystyrene[15,23], poly(vinyl acetate)[15], and poly(vinyl chloride)[26]. If intramolecular and intermolecular interferences greatly overlap, the X-ray patterns exhibit a tendency for one ring (usually the inner ring) to contract to an equator, and the other ring to a meridian, which occurs e.g. with a polycarbonate[42] and with poly(methyl methacrylate)[45] (Fig. 3*d*).

Thus the present-day possibilities of the theory and practice of classical structural analysis enable amorphous polymers to be regarded[19] as comprising (Fig. 4*a*) regions of 20–40 Å with roughly parallel packing of segments of macromolecules. A given molecule may pass through several regions or (if strongly bent) may enter the same region several times. "Skew" contacts are present between molecules in intermediate zones. Models in which the structure of an amorphous polymer is represented by bundles of macromolecules in which good or approximate parallelism of the molecules extends to a considerable length—or conversely by disordered microtangles each formed by a single molecule—cannot explain the observed character of the X-ray patterns[19]. The possibility of the chain folding is not excluded in the model illustrated by Fig. 4*a*, although it is not considered a decisive cause of the formation of regions with a parallel arrangement of chain segments.

IV. RESULTS OF ELECTRON MICROSCOPY

When considering the results of electron-microscopic investigations, we must bear in mind that electron beams interact with an object according to laws different from those governing the scattering of light[44]. A source of error in interpreting electron micrographs lies in so called artefacts, a term which is usually taken to imply peculiarities of the image that are due not to the structure of the object but to the method of preparing the specimen. Several typical examples of artefacts can be found in monographs on the technique of electron microscopy[44], and others will be noted below in connection with the results of the electron-microscopic study of the structure of amorphous polymers.

All publications concerned with the present topic can be arbitrarily divided, according to their specific purpose, into three groups. The first group comprises studies whose principal or subsidiary aim was to detect individual macromolecules on the electron micrographs. As early as 1940 Husemann and Ruska had reported[45] the presence of spherical particles of diameter 150–300 Å in specimens of iodinated glycogen, in good agreement with the calculated diameter of 240 Å for a molecular coil of the given molecular mass and macroscopic density. Spherical domains, roughly comparable with a single macromolecule, were later detected on micrographs of thin films from solutions of polystyrene[46–48], poly(methyl methacrylate)[46–48], and natural rubber[49].

The range of objects was expanded by using replicas from "brittle" fractures and ultrathin sections from block specimens. These methods have revealed, for example, two scales of dimensions in the observed structures—molecular of diameter 40–80 Å in poly(methyl methacrylate)[50] and 150–200 Å in melamine–formaldehyde resins[51] as well as in polyacrylonitrile[52]; and micellar of diameter 200–800 Å in poly(methyl methacrylate)[50,53], 700–900 Å in phenol–formaldehyde[42] and melamine–formaldehyde[51] resins [and in phenolic, dioctyl phthalate, epoxy, leached epoxy, and silicone resins[54]], and 200–840 A in polyacrylonitrile[53]—but recently the method of replicas from "brittle" fractures has been severely criticised[55–57]. Thus even at the temperature of liquid nitrogen cleavage is non-brittle: because of local heating the polymer may undergo deformation under conditions of either forced elasticity, rubberlike elasticity, or viscous flow. Furthermore, experimental facts have been found[58] contradicting the initial assumption that a cleavage fracture bends the supermolecular structures. Thus the morphology recorded on replicas represents the actual process of fracture of the material, not the three-dimensional structure of the polymer.

With regard to the spherical particles observed in thin films mainly the interpretation of the results has changed. Thus Schoon et al.,[59,60] who investigated thin films (~ 100 Å) of polystyrene, poly(methyl methacrylate), butadiene–styrene copolymers, and also silicone replicas from these films, using several methods for comparing both films and replicas, and plasticising the polymers with various solvents, showed that two scales of spherical structures are actually observed, but no exact correspondence with the dimensions of individual molecules was established. They determined particle-size distribution curves from micrographs of narrow fractions of the polymers, and demonstrated that the first scale of particle diameters (47–62 Å for $M = (1-7) \times 10^5$ in polystyrene, 40–60 Å for $M = (2-70) \times 10^5$ in poly(methyl methacrylate), and 70 Å for $M = 10^5$ in the copolymer) are substantially smaller than the dimensions of a molecular coil of a polymer of the same molecular mass having the given macroscopic density. The second scale of particle diameters, representing aggregates of particles of the first range, exceed the calculated diameter of a single molecule by factors of 2–9. We shall return to the present interpretation of these results when discussing the third group of publications.

Observation of individual molecules under an electron microscope requires more complicated and rigorous procedures. For example, Richardson[61,62] used the vacuum sputtering of very dilute (~ 10^{-4}%) solutions of polymers—polystyrene, polyacrylonitrile, poly(methyl methacrylate), poly(vinyl acetate), etc.—in mixtures of a solvent with a precipitant in certain proportions. With very high molecular masses ($\gtrsim 10^6$), when the application of traditional methods is very difficult, electron microscopy is able, with a correct approach to problems of preparation, to cope successfully with the measurement of both the molecular mass and its distribution[63].

The second and largest group of publications on the electron-microscopic study of the structure of amorphous polymers is the product of research workers of Kargin's school, and has been the subject of several detailed reviews[11,64–68]. These studies were directed mainly at detecting experimentally the spontaneous ordering of micromolecules even in the case of non-crystallising polymers.

For this purpose a search was originally made for model substances differing in chain flexibility, and type of inter- and intra-molecular interaction (sometimes of exotic character), such as arsenic polymers (salvarsan)[68], polyacrylic acid[69], fluorinated and silicone rubbers[70], copolymers of the diethyl ether complex of vinylphosphinic acid with acrylic acid[71], etc. Application to such compounds of the usual preparation techniques (mostly film formation from dilute solutions) revealed two main types of organisation—globules, containing more than one coiled macromolecule, and fibrils (bundles of extended macromolecules). In several cases the latter were able to aggregate further to form regular polyhedra (methyl methacrylate–acrylate copolymer[68]) and well developed dendrites (copolymer of diethyl ether complex of vinylphosphinic acid and acrylic acid[71]). The so called "banded structures" were recognised as the most typical secondary formation, with such methods of preparation, from bundles of chains in any amorphous polymer.

The next stage was to study the structure of polymer solutions[67]. This complicated task involved the use or redevelopment of special techniques, such as one-step replicas from fractures of vitrified solutions[73], dissolving the polymer in a solvent at a temperature above its critical point (propane, colophony, ammonia) and "firing" the solution in a vacuum on to a support[74], thermal attachment[75,76]. Application of these methods to polymers differing in chain flexibility—e.g. in the sequence polystyrene, polyacrylonitrile, acetylcellulose, poly-(γ-benzyl glutamate)—showed that flexible molecules (polystyrene) do not form fibrils, whereas with rigid chains, as in poly-(γ-benzyl glutamate), the spontaneous aggregation of macromolecules in solution can be attacked only by special procedures. In the case of polymers having chains of intermediate rigidity (polyacrylonitrile and acetylcellulose) either globular particles (containing several dozen macromolecules) or fibrillar formations may appear depending on the ratio of solvent to precipitant.

It must be admitted that the structural studies of the Kargin school were treated with reserve by foreign workers[5,77], who remarked that "more detailed photomicrographs and electron micrographs of globules and bundles were absolutely essential" as proof of the results[5]. A tendency to reinterpret electron-microscopic data from several previous studies has recently begun to appear even in papers by Soviet investigators [sic][60]. It has been suggested[58], for example, that the "banded structures", which had been considered one of the main structural forms in amorphous polymers[65], should be regarded as artefacts of the preparative processes, since no diffraction data have yet been obtained that would support their presence in the bulk of a polymer. The appearance of images of such morphology on photomicrographs is attributed to wrinkling of the preparations under the influence of surface tension[58]. No confirmation has yet been obtained in other laboratories of the observation of large faceted structures in amorphous polyacrylic acid[68] and its copolymers with the ether complex of vinylphosphinic acid[71], as also the detection of spherulites by Utsuo and Stein in industrial poly(vinyl chloride)[78] and by Natov[79] in atactic poly(methyl methacrylate) with 3% of poly(ethylene adipate). The absence from these papers of diffraction data casts doubt on the reality of such structures in amorphous polymers. Cases are known in which the authors themselves find a simpler explanation for the observations: thus the coarse crystalline formations in annealed gels of poly(vinyl chloride) with dioctyl phthalate[80] proved to be crystals of phthalic acid, a degradation product of the plasticiser[81].

In order to eliminate the influence of the surface relief of films, fractures, and cross-sections, which is an indication of the preparative processes rather than the structure of the material, several methods were proposed and have been used to etch the surface layers[56,82-88]. Although application of the "mildest" of them[83-86] to crystalline materials has little effect on the character of the images obtained[56], a radical change in the pattern is observed in several cases with amorphous polymers. Instead of the spherulitic formations often detected on replicas from fractures in amorphous polymers, e.g. polyurethane rubber[56] or poly(methyl methacrylate)[89] (arising, as is now understood, from the mutual intersection of the propagation fronts of fracture cracks), a globular morphology is observed in both cases after surface layers of the cleavage have vaporised in the gas-discharge plasma[56,90]. Still more surprising and unexpected is the transition from the clearly defined fibrillar morphology of replicas from cleavage planes of highly oriented specimens of poly(methyl methacrylate)[91] to the globular morphology of replicas from etched surfaces of cleavage planes in analogous specimens[90].

In the search for objective criteria of the correctness of an interpretation of electron-micrographs obtained from crystallisable polymers it was proposed that optical diffraction patterns should be compared with small-angle X-ray patterns[92] or with diffractograms obtained from block specimens in polarised light[60]. The diffuse character of small-angle X-ray patterns and optical diffractograms from amorphous polymers makes wide application of this test to amorphous preparations difficult, although it may prove useful in several cases. Fig. 5 gives electron-microscopic and optical diffraction results obtained by various workers for uniaxially oriented specimens of atactic poly(methyl methacrylate). The replicas of oriented films after being etched in the gas discharge exhibit globular formations and their aggregates of dimensions 200–2000 Å (*a* and *b*) with a somewhat distorted form when specimens are stretched at temperatures above the glass point[90]. The axial ratio of such particles was always appreciably smaller than the macroscopic degree of stretch if preparation was undertaken after removal of the stretching force, but corresponded to it when the load was maintained. The attempt to compare the Fraunhofer diffraction from a photomicrograph with the X-ray pattern of oriented poly(methyl methacrylate) at large scattering angles[58] (*c*) contradicts the very idea of the method of analysis of photomicrographs and is pointless. On the other hand, the "rhomboid" pattern obtained when polarised light is scattered by the specimen[93] (*f*), analogous to the scattering pattern for a set of anisotropic cylinders[93] (*e*), corresponds more closely to the fibrillar morphology found on replicas of unetched fractures (*d*). Results obtained[94] for isotropic and oriented amorphous films of poly(ethylene terephthalate) subjected to oxygen etching contrast with those for etched oriented poly(methyl methacrylate). An unoriented preparation reveals only globular formations of diameter 300–400 Å, but oriented specimens (amorphous texture[40]) exhibit elongated structural units 100–200 Å wide and up to 1 μm long.

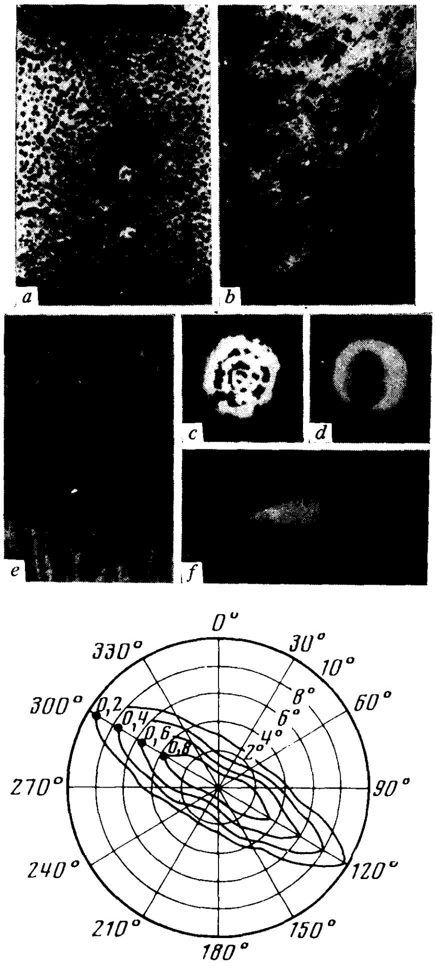

Figure 5. Morphology and diffraction of oriented poly(methyl methacrylate): *a*) electron-micrograph of replica from cleavage plane of 400% drawn polymer after ionic etching (magnification × 7000)[56,90]; *b*) as (*a*) × 70 000; *c*) Fraunhofer diffractogram from micrograph (*a*)[58]; *d*) X-ray large-angle diffraction pattern of block specimen[58,90]; *e*) micrograph of replica from cleavage plane without etching[91]; *f*) diffractogram obtained with polarised H_V light for polymer specimen stretched by 700%; *g*) theoretical intensity distribution of polarised light scattered by a set of anisotropic cylinders[8,93].

Hence the inclusion of ionic etching in the preparation of electron-microscopic objects eliminated the artefacts of the "brittle" cleavage method and of film formation from dilute solutions, but at the same time introduced new artefacts, probably due to uncontrolled heating of the surface layer[95] and to the inadequately studied mechanism of polymer degradation under ion bombardment[96]. At the present time this method shows great promise for investigation of the phase morphology of multicomponent polymer systems, such as polymer and filler[97,98], mixtures of polymers[99,100], cross-linked systems[101], etc.

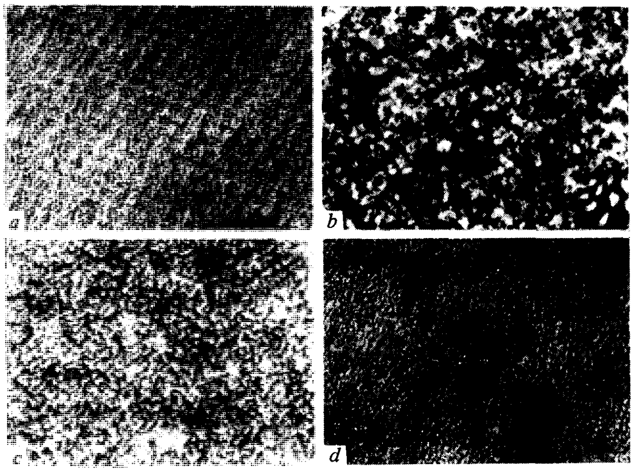

Figure 6. Granular (nodular, domainal) morphology of films of amorphous linear polymers: *a*) bright-field electron-micrograph of biaxially oriented (2 × 2 ×) amorphous film of poly(ethylene terephthalate) (shadowed with platinum plus carbon)[104]; *b*) dark-field micrograph of film of natural rubber[108]; *c*) bright-field micrograph of poly(methyl methacrylate) film (contrast enhancement with UO_2)[60]; *d*) as (*c*) (phase contrast)[115].

We have thus approached the third group of publications, reported the most complete utilisation of the current arsenal of aids to electron microscopy on preparations varying widely in their previous thermophysical history. Chronologically the first paper in this series was that by Frank et al.,[102] in which ionic etching revealed the granular structure of polycarbonate films. Grains of diameter < 100 Å were observed in films quenched in ice-water from a state of rubberlike elasticity (160°C); they could be enlarged reversibly to 200–900 Å by annealing at 110°C (glass point 150°C), and brought back to the previous size by being quenched again. The reversible character of the changes during the anneal–quench cycles, and the abrupt change in mechanical losses for an unannealed specimen in the region of 100°C, evident on the temperature curve of $\tan\delta_{\mathrm{mech}}$, indicated the structural nature of this phenomenon.

Efforts by research workers of the Geil school soon detected granular structures (nodal, nodular, domainal) in amorphous specimens of poly(ethylene terephthalate)[103-104] (Fig. 6*a*), polycarbonate[105], polystyrene[106], and natural rubber[107,108]. Usually the granular structure (grain size 60–100 Å) was revealed simply by shadowing the films, so that artefacts were tested for by such well known procedures as iodination[104], contrast intensification with osmium tetroxide[108], various types of heat-treatment[103-111], uni- and bi-axial orientation[105,103,108], analysis of crystalline morphology developed from controlled variation of the nodular structure[103-105,108], and also chemical etching[109,110].

The application to amorphous polymers of dark-field microscopy[103,106,107]—a standard method applied to crystalline substances[44], including crystalline polymers[87,104,108]—represented a fresh advance in their electron microscopy. By tilting the illuminating system of the microscope to an angle corresponding to the Bragg angle of the inner amorphous halo of the polymer it is possible to obtain an image of the object by means of those electrons that are responsible for the appearance on the electron-micrograph of the segment of the diffuse ring that has passed through the aperture diaphragm. But it is known that inner halos on diffraction patterns of amorphous polymers are due mainly to intermolecular interference of parallel chain segments. As a consequence we might expect that bright spots would appear on the dark background of the micrographs, these representing ordered regions in which the axes of the macromolecules were perpendicular to the radius of the chosen segment of the diffraction maximum[109]. Dark-field micrographs of thin films (< 500 Å[109]) of poly(ethylene terephthalate)[103], polystyrene, and natural rubber[108] (Fig. 6*b*) exhibit discrete bright spots respectively 75, 27 ± 13, and 20 Å (30 Å[109]) in size. Bright-field (unshadowed) micrographs of poly(ethylene terephthalate) films revealed a nodular structure of the same dimensions[103,109], those of polystyrene showed little contrast, and with films of natural rubber aggregates of grains of diameter 100–150 Å were probably observed after shadowing with platinum[108]. A more definite tendency for grains to aggregate into superdomains was traced by another novel method—decoration with gold—in poly(ethylene terephthalate) during uniaxial and biaxial orientation[104]: the primary grains of 60–100 Å were aggregated into coarser superdomains of minimum size 300–500 Å, which behaved as individual entities during orientation. We can now recall the studies by Schoon[59,60] discussed already, in which the application of various methods for intensifying contrast also revealed in polystyrene, poly(methyl methacrylate), and butadiene–styrene copolymer films grains and their aggregates respectively 40–70 and 200–900 Å in size (Fig. 6*c*).

The granular morphology of amorphous films has been observed many times on bright-field micrographs even without any intensification of contrast—in the films of collodion[44,109] and polyvinyl formal resin[109] used as supports, in thin films of poly(ethylene terephthalate)[103] and poly(methyl methacrylate)[111], and also in thin amorphous inorganic specimens of silicon dioxide[112,113] and germanium dioxide[114]. In general it was clear that phase contrast is not the final factor in establishing such a morphology on the micrographs, and such effects have usually been regarded rather as undesirable phenomena[44,109].

A recent publication[115] traces in greater detail the influence of phase contrast on formation of the electron-microscopic image in work with amorphous subjects in the range of limiting magnifications. The authors consider[115] that phase contrast can and must be converted from an interfering factor into an effective new procedure in electron microscopy applied to polymeric subjects, as it was[116] when the structure of inorganic materials was examined at limiting resolutions. The main conclusion from the experimental work[115] was that phase contrast is able to reveal in amorphous poly(methyl methacrylate) films (100–150 Å thick) grain-like structures of diameter 15–30 Å and their linear aggregation with a periodicity of 15–40 Å extending for 100–200 Å (Fig. 6*d*).

Such an abundance of well founded electron-microscopic data on nodal structures in amorphous polymers led to the model of the latter described in detail by Yeh[107], shown diagrammatically in Fig. 4*b* with his lettering. The actual grains observed on bright-field micrographs are usually $G = 40–100$ Å in size. The central portion of the grain $OD = 20–40$ Å comprises more or less parallel and almost equidistant chain segments, and is revealed in dark-field electron microscopy. The boundary regions of the grains, 10–20 Å thick, include folds, chain ends, and individual bent chains. The intergranular regions, of size 10–50 Å, consist of intermediate portions of chains of individual molecules (probably oligomeric) and free space. The refinement of this model by Klement and Geil[104] involves merely introducing a supergranular structure (supernodes, superdomains), within which intergranular bonds are assumed to be denser than those between grains in different superdomains; however, these authors do not indicate the reason for such differentiation of intergranular bonds. It was assumed[107] that the grains should have directional properties; polymer chains may enter and leave the ends of grains, so that the latter should be linked as in a string of beads. Nevertheless, the possibility that they could be linked into a three-dimensional lattice is not denied.

The "electron-microscopic" and "diffraction" structural models of the amorphous state of polymers (suggested independently though not simultaneously) are clearly very similar (Figs. 4*b* and 4*a*). Such similarity is evidently due to the use of essentially the same experimental diffraction evidence of order in the arrangement of chain segments in the amorphous state. The contribution of electron microscopy to further development of the model was to detect boundaries between regions of nematic order and disorder, and to establish more detailed size characteristics independently of diffraction estimates. The authors of the electron-microscopic model could cite no experimental evidence for the underlying hypothesis that macromolecules had a predominantly folded conformation in the ordered regions. They considered that the hypothetical chain folding in grains was supported by the facts that the crystallisation of poly(ethylene terephthalate) involves the conversion of grains of size 75 Å into isometric crystallites of size 140 Å, in which the chains probably have a folded conformation[104], that polycoumarin grains of size 60–110 Å coalesce during prolonged annealing at the glass point to form platelike crystals, chain folding in which has been proved by electron diffraction[105], and that the nodal morphology of natural rubber films of size 100–150 Å is transformed on cooling into a lamellar morphology with plates 55 Å thick in the direction of the chain[106].

V. OTHER PHYSICAL METHODS OF INVESTIGATION

The low degree of order in the arrangement of segments of macromolecules in amorphous polymers and the small size of the ordered regions make it necessary to use the widest possible range of physical methods to study structural details of the amorphous state. Definite progress has already been made in this direction, and several interesting facts have been discovered concerning the supermolecular organisation of amorphous polymers. Simple density measurements on an amorphous polymer, e.g. poly(methyl methacrylate)[117,118], showing a decrease on quenching from the rubberlike elastic state and a continuous increase during annealing below the glass point, have already indicated the occurrence and the reversibility of ordering in the amorphous state, while the proportionality of the density of oriented specimens of the same polymer to the double refraction[118] indicates quite clearly the character of the ordering.

However, this method is not always sufficiently sensitive: in the case of polystyrene, for example, the density remains constant after it has been stretched 50 times[119], although the double refraction and the infrared dichroism definitely record a certain degree of molecular orientation[120]. It is noteworthy that oriented amorphous preparations have seldom been chosen as subjects for structural investigations. The above examples may be supplemented by the observation of a long period (150–250 Å) on the equator of the small-angle X-ray diffraction pattern of slightly oriented poly(vinyl acetate)[121]. Furthermore, application of X-ray diffraction and physicomechanical study of oriented amorphous fibres of polyaminoacids has shown[41] that the modulus of elasticity calculated from the change in the repeat distance along the chain under the influence of tension is several times larger than the macroscopic value for the specimen as a whole. By analogy with the corresponding phenomenon in crystalline polymers, which has been studied thoroughly, this result may indicate an alternation along the texture axis of regions differing in degree of order.

More comprehensive information has been obtained for isotropic specimens. Thermographic study has shown that ordering processes, unconnected with crystallisation, the effects of which appear separately[125–127], occur in the amorphous phase of poly(ethylene terephthalate)[117], poly(vinyl chloride), and copolymers of the latter[122–124] during annealing. Interesting attempts have been made to apply nuclear magnetic resonance to polyethylene in concentrated solutions and in the melt[128]. The distortion of the form of the resonance line observed in the spectra of these preparations were interpreted as due to the superposition of two components, narrow and wide, which they assigned to disordered and ordered regions respectively. The amorphous phase of polyethylene was similarly divided into two components on analysis of the n.m.r. spectrum obtained by rotation at the "magic" angle[129], although the numerical ratios found[129] for the two components differ from the values obtained by other workers[128]. The development of order in amorphous polymers is apparent in the infrared spectra[130]: the splitting of the carbonyl vibrational band is similar in character when amorphous poly(methyl methacrylate) is precipitated from solution or from a polymerisation product and when poly-ε-caprolactone is crystallised from the melt. The type of splitting indicates the presence of mutually oriented molecular structures in poly(methyl methacrylate).

The scattering of light has recently been used to examine the structure of amorphous polymers. With poly(methyl methacrylate)[39], polystyrene[131], and polycarbonate[39] the observed intensity of vertically polarised scattering exceeded the calculated value, which may be due to the presence of scattering centres of 1000–2000 Å.[39] The intensity of this scattering increases with rise in temperature, but the monotonic character of the dependence does not change on passing through the glass point[131], as might have been expected from the electron-microscopic observations[102,109]. The horizontally polarised component of the scattered light was independent both of temperature and of angle of scattering[39,131]. This was regarded[39,131] as implying that the internal structure of the scattering centres is isotropic: i.e. the method of light scattering reveals no anisotropy in the molecular packing at dimensions exceeding 1000 Å.

Another approach to solving the problem of the scattering of light on poly(methyl methacrylate) is to replace the latter by a model consisting of spheres having different refractive indices[132]. The histograms ultimately obtained (which showed the relative contents of hypothetical spheres having various refractive indices) were even sensitive to annealing and quenching of the specimen. Nevertheless, attempts to confer a real physical meaning on absolute values of the density calculated from the refractive indices obtained are hardly soundly based. Indeed, the values found[132]—a content of ~ 40% of spheres of density $\rho_{calc} = 1.29$ g cm^{-3}—appear very high in comparison with $\rho_{amorph} = 1.19$ and $\rho_{cryst} = 1.22$–1.23 g cm^{-3},[5] especially in view of results obtained by application of small-angle X-ray scattering to amorphous materials.

Theory indicates[133] that the intensity of the scattering of X-rays at very small angles by a material exhibiting density fluctuations extending over the range 10–10^4 Å is directly proportional to the square of the density difference between "particle" and medium and to the number of inhomogeneities, and is related exponentially to their radius of gyration. For a long time, therefore, it was expected that papers would appear on the application of such scattering to the study of amorphous polymers, in order to obtain experimental estimates of the density difference between domains and interdomainal space. The very low intensity of small-angle scattering by amorphous polymers was already emphasised in the first few papers[117,134]. Within the limits of the moderate resolving power of the apparatus used ($2\theta \geqslant 8.5'$) the experimental curves for poly(ethylene terephthalate) were well reproduced by Guinier's approximation[133] with a radius of gyration of the inhomogeneous regions of 15–20 Å.[134,135] This was half the radius of domains found from electron-microscopic measurements[56,109]. It was noted that annealing at a temperature below the glass point tends to increase the product of the number of scattering centres and the square of the density difference. A study by small-angle X-ray scattering of the crystallisation of the same polymer has revealed[136] a decrease in density of uncrystallised regions from 1.337 to 1.31 g cm^{-3} (by 1.5%) with increase in the degree of crystallinity to its maximum value.

Lin and Kramer[137] were probably the first to attempt to estimate the density difference between domains and interdomainal space directly from absolute measurements of the intensity of small-angle X-ray scattering: for polycarbonate they found the radius of gyration of inhomogeneities to be 130 Å, and the density difference to be 1.6–1.8% (it is noteworthy that $\rho_{cryst} - \rho_{amorph} = 21\%$). Polycarbonate was soon examined with small-angle apparatus of ultrahigh resolution[138] ($2\theta_{min} = 10''$). The intensity of scattering at moderately small angles ($2\theta > 20'$) was almost constant, and consistent with the theoretical scattering on density fluctuations in a homogeneous liquid. At angles approaching the smallest possible with the given apparatus the intensity of scattering increased sharply, and could not be described in Guinier coordinates by a single radius of gyration. Hence it is not possible to calculate both the density difference and the concentration of scattering centres from the experimental data. If the density of the domains is taken to be ρ_{cryst}, their dimensions will lie in the range 50–3000 Å, while the volume fraction is ~ 0.04%. This most likely comprises dust particles, catalyst residues, etc. If, however, the volume fraction and the dimensions are taken from electron-microscopic data (~ 50% and 50–100 Å respectively), the density of the domains should be very close to that of the matrix. Similar results have been obtained for poly(methyl methacrylate)[39] and for polyglycol ethers[101]. Thus the results of small-angle X-ray scattering indicate a very insignificant difference ($\leqslant 1.5\%$) in the density of inhomogeneities in the structure of amorphous polymers.

A new page in research on the structure of amorphous polymers was opened by Krigbaum and Goodwin[139], who used small-angle scattering by specially prepared specimens to determine the size of single macromolecules in the block state. They studied the scattering of X-rays by a 5% solid solution in ordinary polystyrene of polystyrene molecules weighted at the ends with silver atoms. The calculated root mean square distance between the silver atoms, i.e. between the ends of the chain, was 269 Å, which exceeded by 24% the unperturbed dimensions of macromolecules of the given molecular mass (217 Å for $M = 87\,000$) according to Flory[140].

Polymer*	$10^{-3}M_w$	R_w(bl), Å	$R_w(\theta)_{calc}$[135], Å	$\frac{R_w(bl)-R_w(\theta)}{R_w(\theta)}$, %	$\frac{R_w(bl)}{M_w^{1/2}}$

* ps = polystyrene; pmma = poly(methyl methacrylate); pe = polyethylene.

The small-angle scattering of neutrons by solid solutions comprising a low concentration of deuterated molecules dissolved in the usual substance, or conversely, has become more widely used during recent years. Most of the investigations have been made on polystyrene[141-145], as well as on poly(methyl methacrylate)[146-148] and molten polyethylene[39]. The radius of gyration of the macromolecules in the block R_w(bl) was in all cases comparable with values for solutions in a θ solvent $R_w(\theta)$, but nevertheless usually exceeded it on the average by 20%, as is evident from the Table. The latter shows clearly for polystyrene the proportionality of the size of macromolecules in the block to the square root of the molecular mass: $R_w(bl) = \frac{1}{3}M_w^{1/2}$. A similar dependence has been found also for poly(methyl methacrylate)[148].

The possibility of obtaining quantitative information on the dimensions of macromolecules in the block, demonstrated in the above publications, is undoubtedly one of the greatest achievements of polymer science during recent years. Nevertheless, the conclusions reached by the authors and sustained by such authorities as Fischer[39] and Flory[162], on the correspondence of the conformation of macromolecules in the block and in solution, which were based merely on the correspondence of their external dimensions, are too categorical in the Reviewer's opinion.

In the search for ways of resolving the apparent contradiction between many facts on the development of order in the packing of macromolecules and their coiled form several authors sought to deepen the analogy between amorphous and crystalline structures: it was suggested that macromolecules are folded in vitreous polymers. This hypothesis was probably first put forward by Robertson[149], the immediate occasion being his comparison of experimental density ratios for several polymers in crystalline and amorphous states with those calculated for various angles between neighbouring chain segments. The best agreement was observed if divergence of the segments from parallelism did not exceed 5–15° for different polymers. However, Robertson's calculations on the density of packing of molecules with skew contacts have recently been subjected to serious criticism. According to Fischer et al.[39] the density of packing of polyethylene calculated on the assumption of a random distribution of angles of contact between neighbouring segments is 0.687, whereas experimental values for the molten and vitreous states are respectively 0.625 and 0.645.

Despite the controversial character of the initial premise, the hypothesis of chain folding in the amorphous state gained wide popularity. Details were filled in by Privalko et al.,[150] who suggested a formula for calculating the length of a fold from experimental values of the molecular mass, the steric factor of restricted internal rotation, and the cross-section of the molecules. An active search is being made for experimental evidence of the folding of chains in the amorphous state. Thus small-angle meridional reflections have been observed in several crystallisable polymers even when, according to large-angle X-ray diffraction, crystallisation has not yet taken place[151]. Petermann and Gleiter[152] observed that, if a single crystal of polyethylene in which the axes of folded chains are parallel to the electron beam is melted directly in the electron microscope, the diffuse ring of period 2.55 Å is absent from the resulting electron-diffraction pattern. This means that even after fusion the axes of the macromolecules retain their previous orientation perpendicular to the plane of the specimen, and hence have a folded conformation as before. In the study of polyethylene it was also observed[153] that increase in molecular mass is accompanied by a sharp increase in diamagnetic susceptibility in the region of transition from alkane crystals having straightened chains to polyethylene crystals with a folded conformation, reaching and even somewhat exceeding the values corresponding to liquid alkanes. It was then found that in the same region the diamagnetic susceptibility of molten polyethylene also increases, to a value typical of gaseous alkanes. Comparison of experimental data on the optical anisotropy of macromolecules, the root mean square distances between the ends of a chain, and several other similar characteristics of polyethylene with values calculated for models of chains containing straightened segments of various lengths showed[154] that most satisfactory agreement is obtained with lengths of 10–20 monomer units. Investigation of the dependence of the density and the surface tension of narrow polyoxyethylene fractions on molecular mass revealed a minimum in the range of values of this last factor (~ 3000) at which chain folding began on crystallisation. Similar types of relations were obtained with non-crystallising oligomers of diethylene glycol adipate[155,156].

In concluding this survey of experimental results of the application of structural methods to amorphous polymers we must also remark that the repeatedly noted ambiguity and sometimes even inconsistency of the direct structural information, the very wide range of highly specialised methods of investigation and the consequent great dispersion of literature sources among the pages of several dozen different periodicals, and several other similar factors led to the appearance of a number of models of the amorphous state arising from the need for a logical explanation of anomalies in the macroscopic properties of polymers—the molecular-domain model to describe rheological phenomena and mechanical breakdown[157], the folded-fibrillar model to explain anomalies in the recovery from forced elastic deformation[158], its cluster modification[159], the dislocation model for viscous flow[160], the associative model to explain dynamic mechanical data[161], etc. A distinguishing feature of such models is unnecessary detail, structural evidence for which is at present completely lacking.

---o0o---

Several important characteristics of the structure of amorphous polymers have been reliably established by the broad application of the traditional and the most recent resources of physical experiment to its analysis.

Firstly mention must be made of determination of the dimensions of individual macromolecules in isotropic block specimens (root mean square distance between ends of chain and weight-average radius of gyration) from data on the small-angle scattering mainly of neutrons. The principal result of these investigations is that the size of macromolecules is proportional to the square root of their molecular mass, and exceeds the size of a Gaussian coil by ~ 20%.

The next important conclusion, based on the diffraction of X-rays and electrons at large scattering angles, is that segments of chains are folded roughly in parallel in microregions of dimensions 20–50 Å. The scattering of X-rays at small angles indicates further that the density of such microregions differs very little from that of portions with skew contacts between chain segments (by 1.5% or less).

Despite the slight differences in density, these inhomogeneities in the packing of macromolecules could be visualised by the correct application of various procedures in electron microscopy (contrast enhancement, etching, dark-field technique, phase contrast effects).

The hypothesis of chain folding in the formation of ordered microregions in amorphous polymers has gained great popularity. It is based on certain theoretical arguments and several experimental analogies with the phenomena of chain folding in single crystals of polymers. Nevertheless, it must be borne in mind that all experimental results relating to chain folding have been obtained for the amorphous state of crystallisable polymers.

Of the large number of schematic models of the structure of amorphous polymers in the unoriented state (on the scale up to ~ 100–200 Å) those of Vainshtein and of Yeh and Geil, which differ merely in whether folding of macromolecules is essential, correspond most completely to the above characteristics.

Structural data at present available for dimensions of the next scale (200–9000 Å) are few and contradictory. Reliable data on the structure of the oriented state of amorphous polymers are almost completely lacking, and it is here that important advances in our knowledge of the fine structure of amorphous polymers must be expected in the very near future.

The Porous Structure of Polymers and the Mechanism of Sorption

A.A.Tager and M.V.Tsilipotkina

A survey is made of the behaviour of polymeric sorbents and the role of the porous structure of polymers in the mechanism of sorption and in the thermodynamic affinity of solvents for the polymer. The list of references contains 301 items.

CONTENTS

I. Introduction 83
II. Porous structure of materials and its estimation 83
III. Characteristics of polymeric sorbents 84
IV. Classification of polymeric sorbents and the porous structure of polymers 86
V. Relations between parameters of the porous structure of polymers, their free volume, and the packing coefficient 88
VI. Mechanism of the sorption of simple substances by polymers 89

I. INTRODUCTION

The properties of polymeric materials depend not only on the chemical structure and the dimensions of the macromolecules but also on the structure of the material, by which is usually understood the relative arrangement of macromolecules in space, their conformations, and also the internal structure of the units forming the macroscopic polymeric material and the nature of the interrelationship between them[1,2]. Furthermore, the concept of structure must include also looseness or emptiness, which are present in any material owing to the distances both between molecules and between coarser, supermolecular structures. In crystal chemistry these voids are indicated quantitatively by the packing coefficient[3,4]; the term "free volume" is usually applied to liquids[5]; and for porous solids various parameters of the porous structure are calculated[6].

A vast literature, summarised in several monographs[1,7,8], has been devoted to the structure especially of crystalline polymeric materials. These publications do not pay due attention to problems of the looseness of molecular packing and the porous structure of polymers, but are concerned mainly with the degree of ordering of the macromolecules and various morphological formations. Yet many papers have paid special attention to problems of the density of packing and the porous structure of polymers, but the regularities reported in them have not hitherto been summarised. Without knowledge of the porous structure of polymers and the density of their molecular packing it is impossible to describe the polymer structure, in particular of amorphous polymers, to understand the mechanism of the sorption of simple substances on polymers, or in general to comprehend the mechanism of the interaction of polymers with solvents.

The problem of the mechanism of sorption on polymers is of immense practical importance in connection with the expanding application of polymers as sorbents (ion-exchange resins and their frameworks, sorbents for gel-permeation chromatography)[9-11] and membranes (in particular for reverse osmosis[12-14]), as well as in connection with the sorption of simple substances by fibres, artificial leather[15,16], etc. Sorption effects play a large part in the permeability of polymers to gases and vapours[17,18]. Many processes in which polymers undergo chemical modification (e.g. the acetylation of cellulose, etc.) depend on the size of the pores, which act as transport arteries for penetration of the modifying agents to the reaction centres[19]. In this case an insufficiently developed porous structure may result in a non-uniform fibre of low quality. The mechanical and thermophysical properties of polymers are governed by their porous structure and the density of packing of the macromolecules[20,21]. It is therefore necessary to have a clear idea of the laws of the formation of the porous structure of polymers, and on the other hand also those of the production of monolithic polymers. The Reviewers have now made the first attempt to summarise all the information that has been published on this subject.

II. POROUS STRUCTURE OF MATERIALS AND ITS ESTIMATION

The concept of "porosity" and "pore" arose from consideration of the structure of solid mineral sorbents and catalysts. According to Dubinin's definition "pores are voids in solids ..."[22]; "porosity is a property of solids due to their structure and apparent in the presence of empty spaces—pores between individual grains, layers, crystallites, and other units of the coarse structure of a solid"[23]. The two definitions emphasise that the concept of porosity is applicable to solids, and that a pore is a space not between molecules but between supermolecular structures.

Table 1.

Method	Pore sizes, cm
Sorption	$10^{-7}-10^{-5}$
Chromatographic	$10^{-7}-10^{-5}$
Mercury porometry	$10^{-7}-10^{-3}$
Electron microscopy	$10^{-6}-10^{-4}$
Optical microscopy	$> 10^{-4}$
X-Ray diffraction	$10^{-8}-10^{-5}$

The porosity of solvents is usually assessed quantitatively by means of several parameters—specific surface S_{sp}, total pore volume W_0, pore radius r—and by means of differential distribution curves of pore volume with respect to radius. Methods of determination developed for mineral sorbents[24-26] are applied also to polymers. Each method covers a definite range of pore sizes (Table 1).

The most direct visual method is electron microscopy, which makes it possible to assess not only the dimensions but also the shape of the pores[27-29]; it is applied also to polymers[30-42]. X-Ray diffraction enables the effective radii of the finest pores to be determined[43,44]; in recent years this method has been widely applied to investigate ultramicrocracks in polymers[21,45], which are essentially micropores.

The sorption method was historically the first for evaluating the porous structure of sorbents, and has become classic. It consists essentially in studying the sorption of various substances from liquid and vapour media on solids and then using the resulting sorption isotherms to calculate the specific surface, the total pore volume, the pore radius, and the differential distribution curves. There exist many variants of this method and ways of calculating the parameters of the porous structure. The most common are the Brunauer–Emmett–Teller (BET) method for calculating specific surface[46,47] and the Dubinin–Radushkevich equation for calculating the total pore volume[48]. Despite the widespread use of the sorption method, it has several limitations, as indicated below.

1. It cannot estimate voids having $r < 7$ Å, since the quantity of substance sorbed by them is below the limits of sensitivity of the method.

2. Values of W_0, calculated by means of the Dubinin–Radushekvich equation or directly from the maximum quantity of substance sorbed[49], do not represent the true total pore volume, but indicate essentially the limiting volume of adsorption space, which, of course, depends on the size of the sorbed molecules: the larger the molecules the less accessible are the fine pores of the sorbent and hence the smaller the value obtained for W_0. In order to estimate the dimensions of the finer pores, therefore, use must be made of the sorption of substances having small molecules (nitrogen or argon); this is performed at temperatures at which their vapours condense (low-temperature sorption). In most cases the "porosity for nitrogen" of mineral sorbents exceeds the "porosity for benzene".[50] However, some workers[51,52] refer to quite marked changes in pore volume accompanying the cooling of certain mineral sorbents to temperatures (around −200°C) at which the sorption of nitrogen or argon is conducted, which may lead to incorrect results.

3. The parameters of the porous structure depend on the chemical surface structure of the sorbent, which in turn affects the area, occurring in the BET equation, occupied by a sorbate molecule in the adsorption layer and the degree of wetting of the surface by the liquid, i.e. the process of capillary condensation. Poor surface wetting hinders this process and leads to underestimates of the parameters[53].

4. Calculations based on the Thomson–Kelvin equation do not give true pore radii but essentially the radii of concave menisei of liquid condensed in the pores. A correction for the thickness of the adsorption layer must be made to obtain true pore radii[54,55].

5. The sorption method does not enable the size of very large pores to be estimated, in which capillary condensation is difficult because of the considerable distance between the walls.

The porous structure of solids can be investigated over a wide range of pore sizes by the method of mercury porometry, which enables pore radii to be measured from 30 to some 10^5 Å:[26,56-58] the larger pores (10^4–10^5 Å) are filled with mercury under pressures of ~ 1 atm; high pressures reaching 2500–4000 atm are used to fill the finer pores. The pore radii are calculated by means of the equation

$$r = -\frac{2\sigma \cdot \cos\theta}{p}, \tag{1}$$

where σ is the surface tension of mercury at the experimental temperature, θ the angle of wetting, and p (in kgf cm^{-2}) the pressure. This method has recently begun to be widely used to examine the porous structure of polymeric materials—fibres[59-69], network copolymers, and ion-exchange resins based on them[34,70-75].

Difficulties arise also with mercury porometry, connected with the choice of numerical values for σ and θ, which depend on the nature and the purity of the surface, and may vary with pressure[26,60,76,77]. As a result of incorrect estimates for σ and θ, as well as their possible variation during an experiment, the error in the determination of pore size may reach 30–40%.[26,77] Furthermore, the high pressures applied may disrupt the structure of the sorbent[26,51,65,76-80]. Therefore this cannot be regarded as an absolute method for determining pore size[75,77].

III. CHARACTERISTICS OF POLYMERIC SORBENTS

All that has been stated above concerning the limitations on the sorption method and mercury porometry are fully applicable also to polymeric sorbents, which also possess specific features due to the properties and structure of the polymers. In the determination of the pore structure of polymers it must be borne in mind that they exist not only in the solid but also in the rubberlike-elastic state, so that the question naturally arises of whether the idea of pores and porosity is appropriate to such a state. From the definition of these concepts (Section II) it follows that pores are voids in a solid that do not change with time[81]. This concept is fully applicable to solid polymers (vitreous and crystalline) but inapplicable to polymers in a state of rubberlike elasticity. In this last case the "voids" or "holes" have a fluctuating character (just as in liquids): i.e. they change their forms and dimensions continuously under the influence of thermal motion. However, the permanent cavities produced in polymeric materials under special conditions, e.g. in foam rubbers, can be termed pores, and the articles themselves are porous.

Furthermore, the structure of polymeric sorbents is considerably more labile and far more sensitive to sorbent–sorbate interaction, temperature, and external pressure than is the structure of classic mineral sorbents (active carbons, silica gels, etc.). This faces the investigator with the problem of the conditions under which a particular method can be used to assess porous structure, and also the conditions of preparation of polymeric sorbents.

Any substance of high molecular weight swells on interaction with liquids and vapours of low molecular weight. Swelling is not simply the absorption of these substances by the pores of the former: it necessarily involves changes in the volume of the specimen and in its structure[82]. Hence the structure of a swollen polymer differs fundamentally, especially at high relative vapour pressures, from its original structure. Since a swollen polymer is not a solid, the "holes" or free volume it contains are fluctuating in character and are not pores. Therefore the terms used in the literature—"porosity of polymers in the hydrated state"[10], "pseudoporosity"[83], "latent porosity"[84-86]—are devoid of physical meaning.

Structural lability of a polymer develops also when the temperature is varied, which often leads to incorrect results in the investigation of the low-temperature sorption of nitrogen or argon vapour[87-94]. If the coefficient of thermal expansion of a sorbent is $\alpha \simeq 10^{-6}$ deg^{-1}, the specific volume may change by only 0.002–0.003 cm^3 g^{-1} when the temperature is lowered from 25 to −195°C, and this will hardly be apparent in its overall porosity. In such cases the porosity with respect to nitrogen, determined at −195°C, will exceed the porosity with respect to benzene, determined at 25°C, as was to be expected, and the method of low-temperature sorption is applicable. With many polymers, however, the coefficient of expansion is larger by factors of $10-10^2$. For example, polystyrene and its copolymers have $\alpha = (1.8-2.7) \times 10^{-4}$ deg^{-1}, and for cellulose $\alpha = 4 \times 10^{-4}$ deg^{-1};[93,94] hence the volume of these compounds should decrease by 0.1 cm^3 g^{-1} when they are cooled by ~ 200 deg. If the pore volume of the polymer is of the same order, the porosity will almost disappear on cooling. In such cases the parameters of the porous structure determined with respect to nitrogen may be smaller than those with respect to organic compounds. This is illustrated by Table 2, which shows that, for specimens of well developed porosity (No. 4 and 5), such volume changes are insignificant, and the specific surface with respect to nitrogen is considerably larger than that with respect to methanol[94]. It is obviously for this reason that results obtained by Ruzička and Kudlaček[95] for the sorption of argon vapour on viscose tyre cord agreed with those obtained by Paul and Bartsch[96] for high-strength viscose rayon fibre by mercury porometry. In the case of polymers having relatively undeveloped porosity, however, the low-temperature sorption of nitrogen or argon vapour must be applied with great caution[94].

Table 2. Parameters of the porous structure of polymers determined from the sorption of nitrogen and organic vapours[94].

No.	Polymer	S_{sp}, m^2 g^{-1}		W_0, cm^3 g^{-1}	
		N_2	CH_3OH	N_2	CH_3OH
1	Polystyrene	—	—	0.001	0.030
2	Copolymer of styrene + 4% *p*-dvb*	~0	5.1	~0	0.030
3	Copolymer of styrene + 20% *p*-dvb	~0	17.2	~0	0.070
4	Copolymer of styrene + 60% *p*-dvb**	278.4	88.4	—	0.460
5	Polymer based on 100% *p*-dvb**	423.8	94.2	—	0.440

* dvb = divinylbenzene.

** Synthesised in n-heptane.

The structural lability of polymers and polymeric sorbents is evident also in mercury-porometric measurements, since the high pressures used may develop forced elastic deformations in the specimen. In uniformly porous polymers, with all the pores filled with mercury at almost the same pressure, the pore walls may be compressed under multilateral pressure. When pores of different sizes are present, they are filled with mercury at different pressures, and the wall between a full pore and a still unfilled pore may be deformed by unilateral pressure, closing the pore. The possibility of the reversible compression of polymers during porometric measurements was mentioned in Ref. 65, but with some polymers no significant change in porosity occurs when they are tested in a porometer[75].

The peculiarities of polymeric sorbents also lead to certain demands on their preparation, mainly the need to remove from the pores various impurities of low molecular weight. With active carbons and other mineral sorbents this is usually achieved by prolonged heating in a vacuum at 300–400°C. Such heat-treatment is excluded with polymers because of their possible degradation or other chemical changes. But the removal of moisture or organic compounds by drying polymers even at lower temperatures (but above their glass points) is also hardly applicable because of shrinkage phenomena due to the plasticising action of low-molecular liquids that are present. Thus the vaporisation of water from moistened cellulose leads to its compaction[19].

Polymeric sorbents can be subjected to lyophilic or freeze drying, first applied to biological materials. This method consists in the rapid cooling of moistened polymer specimens to the boiling point of liquid nitrogen, which leads to the sublimation of liquids present in the specimen. An advantage of lyophilic drying is the almost complete elimination of the effect of the capillary forces present in ordinary drying[97-102].

The best method for drying a polymer is inclusion, which consists in successive displacement of the liquid by treatment with various increasingly volatile miscible liquids which possess gradually diminishing affinity for the polymer. The last liquid should have as low a surface tension as possible. As a result, the polymer passes into a vitreous state, and its pores contain a readily vaporisable liquid interacting only slightly with the polymer. After removal of this liquid the polymer has more or less retained its original structure[19,67,68,98,99,103-105]. The classic example of this method is the inclusion of moistened cellulose: water is displaced by repeated treatments with methanol, and then with pentane, which is evaporated off[19].

Unfortunately, these characteristics of polymeric sorbents were ignored in many determinations of the porosity parameters, so that the results are unreliable[87,89,106,107]. For example, the specific surface of cellulose was calculated from the water-vapour sorption isotherms as 100–200 m^2 g^{-1},[87,106] values which are far too high, since cellulose swells strongly in water. If the sorbates used cause a given polymer to swell to different extents, different values of the specific surface will, of course, be obtained for the same specimen[107].

The incorrectness of such results was first pointed out by the Reviewers[108,109], who suggested the same approach as for mineral sorbents, i.e. to maintain the sorbent as far as possible rigid, retaining its structure unchanged during sorption. The appropriate sorbates were said to be "inert", a not altogether fortunate term, since absolutely inert sorbates and sorbents do not exist, as Hill showed[110-112]. Any sorbent—even if mineral—undergoes some perturbation under the influence of a sorbate, which is apparent in a change in state of the surface atoms[113-115] or even in a slight "subswelling" of the sorbent[116-119]. Henceforward, however, we shall employ the term "inert" to imply sorbates in which a polymer hardly swells at all.

Polymeric sorbents may undergo considerable disturbances under the influence of a sorbate. In order to obtain correct values for the parameters of their porous structure it is necessary to select for each polymer a sorbate that will not cause its bulk swelling (the perturbation of a polymeric sorbent by the sorbate should not exceed that of a mineral sorbent).

During recent years comprehensive experimental information has been obtained on the sorption of "inert" vapours (i.e. those that do not cause swelling) on very many polymers[49,93,94,108,109,120-141]. Parameters of their porous structure have been calculated (by generally accepted methods) from the sorption isotherms. The BET and Dubinin–Radushkevich equations are applicable over the same ranges of relative vapour pressures as for mineral sorbents[108,120,130].

IV. CLASSIFICATION OF POLYMERIC SORBENTS AND THE POROUS STRUCTURE OF POLYMERS

The first few classifications of mineral and polymeric sorbents were based on the form of sorption isotherm, which was related to the type of surface coverage of the adsorbents by the adsorbate molecules. In particular, such a classification was proposed by Brunauer, Deming, Deming, and Teller (the BDDT classification), in which all published sorption isotherms were divided into five types differing in the character of the surface coverage[6,24]. A similar approach to the classification of polymeric sorbents was suggested by Rogers, who separated all known sorption isotherms on polymers into the four types[142] illustrated in Fig. 1. The first type of isotherms correspond to a linear relation between the concentration of the sorbed substance and the pressure, which characterises the absorption of a gas in conformity with Henry's law. The second type involve systems in which only a monolayer is adsorbed on the polymer surface. Isotherms of the third type are obtained for multimolecular adsorption when the energy of interaction between sorbent and sorbate molecules exceeds the intermolecular interaction energy in the sorbate. The fourth type corresponds to multimolecular adsorption when the former interaction energy is very much smaller.

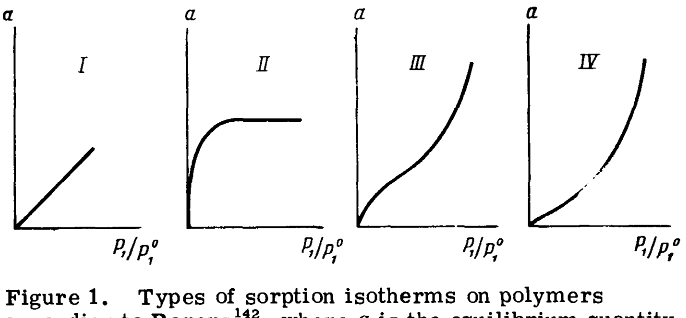

Figure 1. Types of sorption isotherms on polymers according to Rogers[142], where a is the equilibrium quantity sorbed in millimoles per gram of sorbent, and p_1/p_1^0 the relative vapour pressure.

Theories relating adsorption processes solely with surface state[24] were accompanied by the development of ideas on the role of sorbent porosity in adsorption processes, and classification of mineral sorbents were proposed according to pore size and shape. Thus there exist globular, slitlike, cylindrical, and bottle-shaped pores, as well as pores between round rods[116]. Pores are divided into closed, blind, and open pores[51,143]: the third group comprises pores, channels, and capillaries that are connected with one another and with the sorbent surface, serving as transport arteries for mass transfer; closed pores are mutually isolated and have no outlet to the surface; and blind pores are connected with the surface but are not interconnected. No unambiguous evidence has been published of the presence of one kind of pore or another. In most cases this must be judged from gas-permeability data[144,145]. The most fertile classifications of sorbents are those of Dubinin[6,22,146] and of Kiselev[147], which can be applied even to polymeric sorbents.

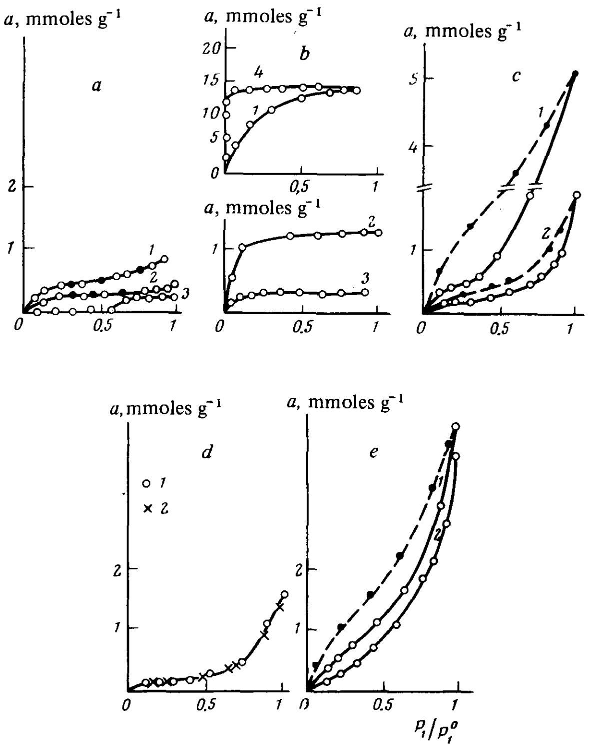

Figure 2. Sorption isotherms for vapours of "inert" liquids on different classes of polymeric sorbents, where the solid circles and broken curves denote desorption results. (*a*) Non-porous: 1) n-hexane on polyvinyl alcohol[108]; 2) benzene on polyvinylidene chloride[121]; 3) methanol on polyethylene[121]. (*b*) Microporous: 1) nitrogen on a macroscopically cross-linked isoporous polymeric sorbent based on polystyrene and *p*-bischloromethylbenzene; 2) water on polystyrene[148]; 3) n-hexane on cellulose[108]; 4) nitrogen on activated carbon[123]. (*c*) Sorbents containing continuous pores: 1) copolymer of styrene with *p*-divinylbenzene (in n-decane)[131]; 2) methanol on a polyarylate (DKh-1 brand)[237]. (*d*) Macroporous: 1) Styroflex film; 2) polystyrene film. (*e*) Mixed type: 1) copolymer of styrene with technical divinylbenzene (in n-heptane)[125]; methanol on a polyarylate (F-1 brand)[237].

Analysis of > 200 sorption isotherms for "inert" vapours on various polymers[49,93,108,109,120-141,148] enables them to be separated into the four main types illustrated in Fig. 2. The first type—non-porous sorbents (Fig. 2*a*)—are characterised by sigmoid isotherms without sorption hysteresis and with a small quantity of maximally absorbed sorbate. Such isotherms are observed with several crystalline polymers (polyvinyl alcohol, polyvinylidene chloride) and certain densely packed vitreous polymers (block poly(methyl methacrylate) and polystyrene). At low relative vapour pressures crystalline polyethylene sorbs hardly any vapour of the "inert" methanol, and insignificant sorption is observed only at higher relative vapour pressures. Such polymers are characterised by almost zero total pore volume W_0 and very small specific surfaces (~ 1–7 m^2 g^{-1}).

The second type comprises microporous polymeric sorbents having pore radii up to 16 Å. Such fine pores cannot be penetrated by large sorbate molecules and many small molecules. Microporous sorbents are characterised by Γ-shaped isotherms (Fig. 2*b*), the plateau on which results not from surface saturation with sorbate molecules but from the inaccessibility of the fine pores to the penetration of many molecules. The concept of specific surface has no physical meaning for microporous polymeric sorbents[22,149-154], but the total pore volume may reach 0.5 cm^3 g^{-1}. Fig. 2*b* indicates that the initial portion of the sorption isotherms is considerably less steep on the polymeric sorbents than e.g. on microporous carbons[123,155] or zeolites[156-159]. This is understandable, since a large number of fine pores in the latter sorbents result from the removal of hydrogen chloride or water.

Polymeric sorbents of the third type have continuous pores with radii from 16 to 1000–2000 Å. Such polymers are characterised by sigmoid isotherms and large sorption hysteresis (Fig. 2*c*). They are able to absorb large quantities of a sorbate, their total pore volume reaching $W_0 \simeq 0.8$ cm^3 g^{-1} and their specific surface ~ 700–900 m^2 g^{-1}.

Macroporous polymeric sorbents, having pore radii exceeding 1000–2000 Å, constitute the fourth type. According to Dubinin's hypothesis, sorption takes place on them in the same way as on non-porous sorbents, since the internal surface of such large cavities acts as an external surface. Indeed, Fig. 2*d* shows that the sorption isotherms for methanol on a non-porous Styroflex film and on a specially prepared macroporous specimen of polystyrene are completely identical.

It is often impossible to assign real polymers to a definite class of sorbents, and in particular it is a complicated task to obtain uniformly fine-pored sorbents, often termed "isoporous". The latter are obtained not by polymerisation or polycondensation but by the cross-linking of existing polymers[136,160-163]. The large majority of amorphous polymers are sorbents of structurally mixed type. They are characterised by slightly sigmoid isotherms (Fig. 2*e*) and possess pores of the most diverse dimensions, as is evident from Fig. 3. Such sorbents often exhibit no correlation between pore volume and specific surface. Thus, when large pores predominate, the pore volume may be large but the specific surface small; and conversely, in the presence of a large number of small pores, the sorbent has a large specific surface and a small pore volume[49,129,135].

Pore radii of the order of 10^2–10^4 Å indicate that the large cavities in the polymer are formed not between molecules but between coarse supermolecular structures, while the pore walls may be very densely packed. This suggests that amorphous polymers are structurally inhomogeneous, as is sometimes observed even with crystalline polymers. In isotactic polystyrene, for example, large pores are found situated between crystallites[122].

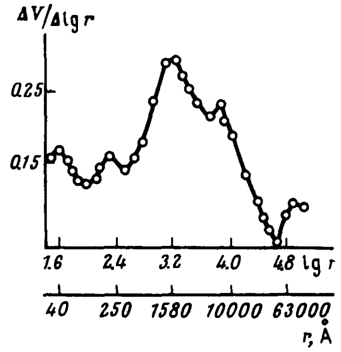

Figure 3. Differential curve of the distribution of pore volume with respect to radius for F-1 polyarylate, where ΔV is the volume of mercury filling pores of certain radii.

Porosity is not a property of a given substance but depends on its previous history. It is usually produced during preparation of the specimen. Several methods are available for obtaining porous polymers, and are used during synthesis and the moulding of articles. They usually involve heat-treatment of the material accompanied by removal of volatile products[123,161-170], with the introduction of special blowing agents[10,171], saturation of the polymers by gases under a high pressure which is subsequently released[172], or the introduction into monomers of suspensions of organic or inorganic solids which are later removed[173,174]. One process for obtaining porous polymers is synthesis in the presence of a solvent, whose removal leaves quite large cavities in the polymer. Very porous three-dimensional polymers can be synthesised in so called inert solvents, i.e. substances that are not involved in the polymerisation. Porous cross-linked copolymers (e.g. of styrene with divinylbenzene), employed in chromatography and also used as frameworks for macroporous ion-exchange resins, are produced in this way[9,10,31,32,83-86,136,174-180]. Shrinkage stresses arising on removal of the solvent then play an important part. They lead to shrinkage deformations and to contraction of the structural framework, i.e. to shrinkage of the whole material.

This phenomenon was investigated in detail by Rebinder[181], Ostrikov et al.[182-190], Vlodavets et al.[191-193], etc. The shrinkage stresses may result in contraction of the material by factors of 8–10[194], with the pore walls coming together and in some cases completely closing the pores[181,185,191]. The magnitude of the shrinkage stresses depends on the surface tension of the liquid[67,98,103-105,185,194-198], the nature of the sorbent, and the shrinkage capacity of the latter[199]. With perfectly rigid materials (porous silicate glasses, ceramics) shrinkage phenomena are almost completely absent. Elastic polymers exhibit the largest shrinkage. Hence the polymer framework should be as inelastic as possible to obtain a highly porous structure during removal of the inert solvent, as has been demonstrated experimentally for the cross-linked frameworks of styrene–divinylbenzene copolymers[200]. This is achieved by introducing a large number of cross-links during synthesis and selecting as inert solvent a "poor" solvent that does not plasticise the polymers. Cross-linked copolymers of highly developed porosity are therefore obtained in the presence of large quantities of thermodynamically "bad" solvents and with a large quantity of the cross-linking agent in the reaction mixture[31,32,34,49,70–72,84–86,124,125,131,136,173,174,176,180,201–224].

Analogous effects are observed also in the synthesis of linear polymers, as has been shown for a series of polyarylates[133,135]. Thus polymers of desired porosity can be obtained by varying the conditions of the synthesis. A porous structure can be conferred on polymers also by varying the conditions under which they are moulded, as has been demonstrated for fibres[64,67,68,225–228] and films[129,132,229–237].

V. RELATIONS BETWEEN PARAMETERS OF THE POROUS STRUCTURE OF POLYMERS, THEIR FREE VOLUME, AND THE PACKING COEFFICIENT

As already mentioned, besides the term "porosity" there exist other concepts connected with "empty" spaces in materials—the free volume and the packing coefficient—the problem of whose relationship has been discussed previously[238].

The term "packing coefficient" was first applied by Kitaigorodskii to crystals[3,4], but subsequently began to be used for amorphous solids and liquids, and also to describe the molecular packing of polymers[239–243]. This coefficient is the ratio of the actual volume of the molecules in 1 g or 1 mole of the substance to its specific (or molar) volume at the given temperature:

$$K = \frac{V_W}{V_T}. \tag{2}$$

The intrinsic volume of molecules is calculated from the intermolecular distances and the lengths of the chemical bonds between the atoms, obtained by X-ray diffraction[4,240]. For most low-molecular and polymeric crystals the packing coefficient lies in the range $K = 0.68–0.8$,[3] and for monolithic amorphous polymers it fluctuates between 0.662 and 0.723.[240]

The free volume is usually understood to be the volume not occupied by the mass of the given substance, but different authors calculated it differently. Thus Frenkel'[5] understood by free volume the excess volume of a specimen at a given temperature in comparison with its volume at the absolute zero:

$$V_F = V_T - V_0. \tag{3}$$

Hildebrand and Bondi termed the quantity V_F calculated by means of Eqn. (3) the expansion volume, and proposed that the free or empty volume V_E should be calculated by means of the formula[244,245]

$$V_E = V_T - V_W, \tag{4}$$

in which V_T is the volume of the body at the given temperature and V_W is the actual volume of its molecules.

The empty volume and the packing coefficient are related by the simple formula

$$1 - K = V_E/V_T, \tag{5}$$

from which it follows that in crystals, even with the densest packing of their atoms and molecules, the free or empty volume constitutes 20–32% of the total volume. Yet sorption experiments show that typical crystalline solids are non-porous sorbents. Hence 20–32% of the volume of crystalline solids represents "ultramicroscopic voids" inaccessible to even the smallest gas molecules, e.g. hydrogen[246]. Diffusion in the lattice of such crystals as sodium chloride, etc. is possible only when they contain defects or at high temperatures[246].

As already mentioned, crystalline polymers are in most cases also non-porous solvents, for which calculations show that V_E fluctuates within the range 0.2–0.3 cm^3 g^{-1}.[237,238] If Eqn. (4) is formally used to calculate V_E for a porous polymer, the very high values of 2–4 cm^3 g^{-1} are obtained. This empty volume obviously includes the whole total pore volume. Thus the free or empty volume of a porous polymer always exceeds its total pore volume. However, the quantity W_0 calculated from sorption data does not represent the total pore volume, since it depends on the relation between the size of the pores and that of the sorbate molecules (Section II). This led to introduction of the concept of the maximum pore volume $W_0^{\max}$, representing the volume of all the pores into which molecules of any size can penetrate[238].

A hypothetical case can be imagined in which a polymer contains pores of various sizes, while the pore walls are packed as in an ideal crystal, so that

$$W_0^{\max} = V_T - V_{\text{id.cr}} \,. \tag{6}$$

This recalls an equation often used to calculate the total porosity[25,98,105] or the so called porosity factor[31]

$$P = 1/\rho_{\text{app}} - 1/\rho_{\text{tr}}, \tag{7}$$

in which ρ_{app} and ρ_{tr} are the apparent and true densities of the material respectively[31]. The former density is determined pyknometrically with a liquid that does not wet the material and hence does not penetrate its pores (most often mercury), or is calculated from geometrical considerations[25,247]. The true density is also determined pyknometrically but with a liquid that wets the polymer and hence is able to penetrate its pores. For non-porous materials $\rho_{\text{app}} = \rho_{\text{tr}}$. For porous materials, even if microporous, these quantities may differ markedly. Therefore the method used to determine the density of a polymer must always be indicated.

Table 3 lists some typical values for the parameters V_E and $W_0^{\max}$ and for the packing coefficients. It includes apparent polymer densities, which for polyisobutylene, polyethylene, and poly(vinyl acetate) are identical with the true densities. For the first four polymers in Table 3 we see that $W_0^{\max} \simeq 0$, so that the empty volume V_E is the volume of ultramicroscopic cavities, which fluctuates from 0.26 to 0.35 cm^3 g^{-1}. However, these polymers differ in their density of packing, which is especially clearly shown in the values of V_E expressed in cm^3 mole^{-1} monomer unit: its value is least for crystalline polyethylene, which has the highest packing coefficient. A less densely packed polymer is polyisobutylene, for which $K = 0.678$; it is followed by polystyrene and poly(vinyl acetate). These data show that polystyrene is a loosely packed polymer, as follows also from heats of dissolution[248,249]. It is interesting that these last two polymers have almost the same packing coefficients, and the values for all amorphous polymers are very closely similar[240]. The empty volume V_E calculated in cm^3 mole^{-1} is probably a more sensitive measure of density of packing.

Polyarylates possess very high values of W_0^{max}, V_E (cm^3 g^{-1}), and V_E (cm^3 mole^{-1}). The porosity of these polymers is a consequence of their synthesis in solvents. Values of K calculated formally by means of Eqn. (2) for such polymers are far smaller than for non-porous polymers. Such low packing coefficients indicate not a low density of molecular packing but a loose packing of supermolecular structures. Consequently porosity and density of molecular packing are inadequate concepts.

Table 3. Densities, free volumes, maximum pore volumes, and packing coefficients of polymers[237,238,240].

No.	Polymer	ρ_{app}, g cm^{-3}	V_E, cm^3 g^{-1}	V_E, cm^3 mole^{-1}	W_0^{max}, cm^3 g^{-1}	K_{pol}
1	Polyethylene (100% cryst.)	1.00	0.26	7.2	~0	0.740
2	Poly(vinyl acetate)	1.189	0.28	24.1	~0	0.665
3	Polystyrene	1.05	0.32	33.3	0.06	0.666
4	Polyisobutylene	0.912	0.35	10.6	0	0.678
5	Polyarylate based on phenolphthalein and isophthalic acid—F-1 (synthesised in chlorinated biphenyl)	0.90	0.82	367.3	0.58	0.477
6	Polyarylate based on phenolphthalein and terephthalic acid—F-2 (in acetone)	0.77	0.74	355	0.49	0.426

VI. MECHANISM OF THE SORPTION OF SIMPLE SUBSTANCES BY POLYMERS

The absorption of one substance by another, e.g. of a liquid by another or of gases by liquids, is in general termed sorption. More often, however, this term implies the absorption of molecules of gases, vapours, or liquids or of ions by solids, which can occur by two mechanisms[24]. (1) The substance is absorbed only on the surface, whether external or internal. Such a process is termed adsorption. It is divided into physical adsorption, when the adsorbate interacts with the adsorbent by van der Waals forces, and chemisorption, when chemical reactions occur between them. (2) Molecules of the sorbate penetrate inside the solid, entering the force field existing between its atoms, ions, or molecules throughout. Here, too, two processes may occur: the gas or vapour can either dissolve in the solid or form a chemical compound with it. For the most part adsorption and dissolution occur simultaneously, and are combined under the general term sorption.

The mechanism of the sorption of low-molecular substances on polymers is complicated and depends on many factors, including the phase constitution and the physical state of the polymer, its porous structure, its chemical structure, the flexibility of the chains, intermolecular interaction, and the thermodynamic affinity of the polymer for the sorbate. Depending on the magnitude of this last factor the polymer may be perturbed to different extents and the mechanism of sorption may be different.

1. Mechanism of the Sorption of "Inert" Sorbates on Polymers

If the polymer does not swell in the sorbate vapour, the mechanism of sorption does not differ fundamentally from that on mineral sorbents. Thus physical adsorption takes place on non-porous crystalline or elastic polymers (we ignore chemical interaction between polymer and sorbate).

Interacting centres of a microporous sorbent are distributed throughout its volume. With such sorbents, therefore, a mechanism of bulk filling of pores can be regarded as "dissolution" of the gas or "inert" vapour in the bulk of the specimen[22,154,250-252]. The mechanism operating with sorbents containing continuous pores involves coverage of the pore walls layer by layer, coalescence of the multilayers, and capillary condensation. Coalescence does not take place in macroporous sorbents owing to the distance between the pore walls, so that capillary condensation is absent, and only physical adsorption is observed.

Information on the mechanism of adsorption will be given by heats of adsorption, which has been discussed in detail by Kiselev et al. for hydrocarbons on graphitised carbon black, a typical non-porous adsorbent[253-256]. They showed that at low surface coverage the hydrocarbon molecules are oriented parallel to the surface. A similar conclusion has been reached by Ostrovskii et al.[257,258] in an investigation of the heats of adsorption of hydrocarbons on poly-p-divinylbenzene. This work showed that the BET theory of multimolecular adsorption does not apply to polymeric sorbents, which was attributed to surface non-uniformity. Analysis of possible reasons for such inhomogeneity indicated that the inconsistency with the BET theory might be due to swelling of the polymer, which will be considered in greater detail in the following subsection.

2. Mechanism of the Sorption of Non-inert Vapours on Polymers

Any substances in which polymers swell will be regarded as non-inert liquids and their vapours. Sorption of the vapours is most typical in the case of polymers. Numerous papers have appeared on the sorption of the most diverse vapours on various polymers—Long[259-267], Park[268-270], Gregor[271,272], Kargin et al.,[273-281] Tager et al.,[282-288] Lipatov et al.,[289] Papkov and Fainberg[15], and others. Inspection of the immense amount of information existing on the sorption of various substances on different polymers enables certain generalisations to be made and several mechanisms of sorption of non-inert substances typical of polymers to be distinguished. Thus with dense packing of macromolecules porosity is absent and physical adsorption is impossible. The sorption of non-inert vapours on densely packed polymers (elastic or vitreous, linear and cross-linked) must be regarded as true dissolution of the vapour in the polymer "matrix". However, dissolution has different mechanisms according as the temperature is above or below the glass point.

The mechanism of the dissolution of vapours in the elastomeric polymers (above the glass point) is fluctuational: i.e. the process consists in sorbate molecules and monomer units or segments of the polymer chain changing places. Because of the great flexibility of the chain these interchanges are possible from the very first portions of gas or vapour absorbed: i.e. disturbance of the sorbent and essentially mutual dissolution of the components begin at the lowest values of p_1. Typical sorption isotherms on elastic polymers are always concave [? convex] to the abscissae axis throughout the range of relative vapour pressures (Fig. 4a). The worse is the solvent thermodynamically, the lower is the sorption isotherm situated, and a non-solvent remains almost unabsorbed by the elastomers. The overall process depends on the affinity of the solvent for the polymer and on the flexibility of the polymer chain. With the same flexibility the sorption of a given substance on different elastomers is described by a single curve[277].

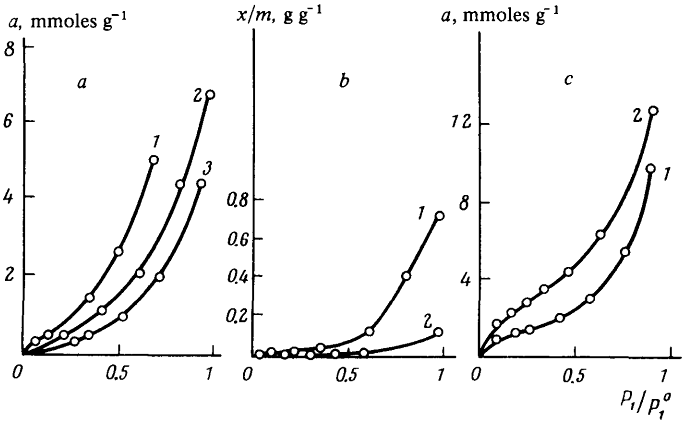

Figure 4. Types of sorption isotherms for vapours of non-inert liquids on polymers, where x/m is the equilibrium quantity sorbed expressed in grams: (*a*) 1) n-hexane on natural rubber[276]; 2) toluene on polyisobutylene[284]; 3) benzene on nitrile rubber (SKN-18)[282]; (*b*) 1) dioxan on polyurethane[287]; 2) ethanol on polyvinyl alcohol[276]; (*c*) 1) benzene on porous polystyrene[288]; chloroform on a polyarylate[237].

At temperatures below the glass point segmental motion of the chain is almost completely absent, so that interchanges between vapour molecules and chain units are difficult. The mechanism of dissolution of the vapour consists in the penetration of its molecules into existing cavities, of which there are few in densely packed polymers. The process is facilitated by the mobility of side-groups, but this effect is apparently insignificant, since at low pressures p_1 the quantity of substance dissolved lies beyond the sensitivity of the sorption method. Sorption begins to be appreciable at definite values of p_1, at which a fluctuational mechanism of swelling and dissolution of the polymer becomes possible. The sorption isotherms therefore have the form illustrated in Fig. 4*b* [278,287].

A more complicated mechanism of sorption of non-inert vapours is observed with porous vitreous polymers. The sorption isotherms are sigmoid with an initial section convex towards the ordinate (Fig. 4*c*). This portion corresponds to the vitreous state of the system[288]; the point of inflexion on the curve lies in the range of sorbate concentrations in the polymer at which the system passes, at the experimental temperature (25°C), from the vitreous state into one of rubberlike elasticity.

At higher relative vapour pressures the shape of the isotherm resembles that for elastomers: i.e. the mechanism of the absorption of a vapour by a polymer is analogous to the mechanism of sorption on rubberlike polymers. Sorption isotherms of this type have been obtained with cross-linked copolymers[271,272], polyamides[276], cellulose nitrate and acetate[290], and polystyrene[291]. Analysis of such sigmoid isotherms led to the conclusion[106,112,276,291,292] that the initial convex portion of the isotherm represents physical adsorption, and the concave portion corresponds to dissolution of the polymer, the main argument being that the former obeys the BET equation, and the latter the Flory equation.

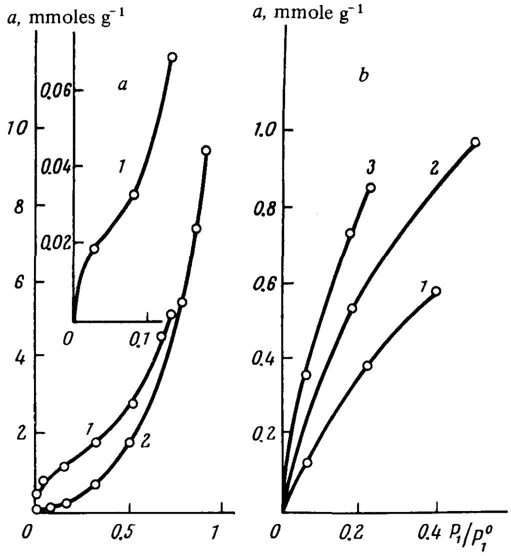

Figure 5. Sorption isotherms for the vapours of different liquids on specimens of polystyrene[288]. (*a*) Benzene vapour on polystyrene: 1) porous; 2) non-porous. (*b*) Initial portions of sorption isotherms on porous polystyrene for the vapours of: 1) methanol; 2) cyclohexane; 3) benzene.

A recent study of the sorption of various vapours on polymeric sorbents of the same chemical nature but differing in porosity has shown[288] that the height of the convex upwards section is greater the greater the porosity of the polymer, and for the same porosity the greater the thermodynamic affinity of the sorbate for the polymer (Fig. 5). This indicates the simultaneous occurrence of the processes—physical adsorption of the sorbate in the pores of the polymer and swelling of the rest of the polymer, i.e. of the pore "walls" or the polymer "matrix"—which cannot be separated. However, their simultaneous occurrence leads to very important conclusions.

Firstly, the specific surface of the polymer itself cannot be calculated when sorbates in which the polymer swells are used: i.e. the BET equation is not applicable to such a case.

Secondly, since physical adsorption is superimposed on swelling, the parameters of the thermodynamic affinity of the solvent for the polymer calculated from the sorption isotherms should depend on the porous structure of the polymer. In fact, different values of the chemical-potential difference for the solvent calculated by means of the equation

$$\Delta\mu_1 = RT \ln p_1/p_1^0, \qquad (8)$$

should be obtained for the same degree of absorption of the sorbate. When the corresponding difference $\Delta\mu_2$ for the polymer is calculated by means of the Gibbs–Duhem equation, different values are also obtained for specimens differing in porosity.

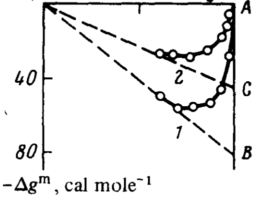

Figure 6. Dependence of Δg^m on apparent mole fraction x_2^* of the polymer (x_1^* is the apparent mole fraction of the solvent) for cyclohexane on polystyrene[288]: 1) porous; 2) non-porous.

Fig. 6 illustrates the mean free energies of mixing calculated by means of the formula

$$\Delta g^m = x_1^*\Delta\mu_1 + x_2^*\Delta\mu_2$$

as a function of the apparent mole fractions of the components. It is evident that they also depend on the porosity of the polymer. The difference between the free energies of interaction of the sorbate with porous and non-porous polymers is obviously the work required to form the pores, which can be calculated from the equations[288]

1 mole of units of non-porous polymer + solvent = soln. I - ΔG_{np}
1 mole of units of porous polymer + solvent = soln. II - ΔG_{por} ,

where ΔG_{por} and ΔG_{np} are the respective free energies of mixing of a large quantity of solvent with 1 mole of monomer units. Hence

non-porous polymer → porous polymer + $\Delta G_{por} - \Delta G_{np}$.

The difference $\Delta G_{por} - \Delta G_{np}$ represents the change in free energy accompanying transfer from the non-porous to the porous sorbent: i.e. it is the work of pore formation A_{por}. Values of ΔG_{por} and ΔG_{np} can be calculated from the dependence of Δg^m on x_2^*.[293] In Fig. 6 the intercept $AB = \Delta G_{por}$ (in calories per mole of monomer units in the polymer), while $AC = \Delta G_{np}$. The difference between them is the work of pore formation:

$$BC = AB - AC = \Delta G_{por} - \Delta G_{np} = A_{por} .$$

Values of A_{por} are independent of the nature of the sorbate, but increase with the porosity of the specimen[288].

The porous structure of a polymer influences also the magnitude and sign of the parameter χ_1 calculated by means of the Flory–Huggins equation[294]

$$\ln p_1/p_1^0 = \ln(1-\varphi_2) + \varphi_2 + \chi_1\varphi_2^2, \tag{9}$$

in which φ_2 is the volume fraction of the polymer. The concentration dependence of χ_1 is different for porous and non-porous specimens of a polymer (Fig. 7). For the latter the parameter increases with polymer concentration[294,295]. For a porous polymer χ_1 is a decreasing function of concentration at small dilutions, and the concentration dependence reaches negative values (curve *2*). Similar curves have been observed by Moore[290] for solutions of cellulose ethers, probably as a consequence of the sigmoid isotherms and the loose packing of these polymers. The above results indicate that Eqn. (9) holds only for the second stage of sorption, when the porous structure of the polymer has broken down and only swelling develops. If adsorption on the surface and sorption in the mass (swelling) take place simultaneously, the Flory–Huggins equation (9) cannot be applied.

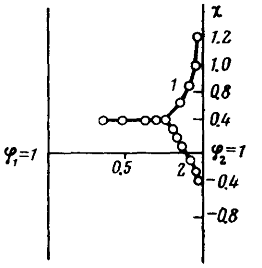

Figure 7. Concentration dependence of χ_1 (where φ_1 and φ_2 are the volume fractions of solvent and polymer respectively) for benzene on polystyrene[288]: 1) non-porous; 2) porous.

3. Role of the Porous Structure of Polymers in Sorption from Liquid Media and Vapours

An interesting phenomenon observed in the study of sorption processes is the Schroeder effect[296], according to which the quantity of a given substance absorbed by a polymer from a liquid medium always exceeds the quantity absorbed from the vapour state. It was first observed for the gelatin–water system. Analogous results were later obtained by other investigators[297–299] for the systems formed by agar-agar with water, unvulcanised and vulcanised rubber with organic liquids (alcohols, tetrachloromethane) and their vapours, and also liquid mixtures of benzene with alcohol and the mixed vapours sorbed on vulcanised rubber. The nature of the effect still remains an open question[299]. Schroeder himself[296] and the other investigators[297–299] attributed it to experimental error—fluctuations of temperature, the impossibility of achieving absolute saturation of the vapour, disregard of surface tension, a slower rate of sorption from liquid and vapour media, etc.

A more recent paper[300] has suggested, in addition to the above reasons, that the phenomenon may be due also to the presence of pores, which are filled with a liquid but not with a vapour. This hypothesis has been tested experimentally on several porous and non-porous polymers with both inert and non-inert liquids and their vapours[301]. It was found that with non-inert liquids, when the polymer swells, the Schroeder effect is not observed: i.e. the same equilibrium quantity of a substance is sorbed from liquid and vapour media. A difference is present only in the kinetics: liquids are sorbed more rapidly than are vapours (Fig. 8*a*, *b*). In the sorption of "inert" substances on porous polymers differences are observed not only in the kinetics but also in the equilibrium quantities sorbed (Fig. 8*c*): liquids are sorbed in far greater quantities than are their vapours.

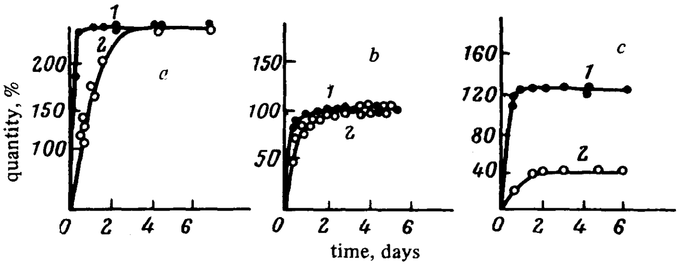

Figure 8. Rate curves for absorption by polymers from: 1) liquids; 2) vapours[301]: *a*) "non-inert" benzene on non-porous copolymer of styrene with 6% of divinylbenzene; *b*) "non-inert" benzene on macroporous copolymer of styrene with 20% of divinylbenzene; *c*) "inert" methanol on macroporous copolymer of styrene with 20% of divinylbenzene.

This last phenomenon is attributed to different mechanisms by which pores are filled. A liquid fills all the pores, including large pores, whose dimensions make them accessible to its molecules. But a vapour is sorbed by a more complicated mechanism, involving a series of successive stages—adsorption from the vapour on the pore walls with formation of multimolecular layers, coalescence of the latter with appearance of a concave meniscus, and then condensation of the vapour. Since the vapour pressure is lower the smaller the radius of curvature of a concave surface, capillary condensation occurs preferentially in fine pores (of continuous type). In coarse pores, as remarked in Section VI, 1, coalescence of multilayers and hence capillary condensation do not occur owing to the distance between the pore walls. Such pores may therefore remain unfilled by the "liquefied" vapour.

Thus development of the Schroeder effect depends both on the porous structure of the polymer and on the thermodynamic affinity of the low-molecular substance for the polymer. The absorption of substances that cause swelling involves a redistribution and partial disappearance of pores. Therefore the equilibrium quantity sorbed does not depend on whether it has been sorbed from the liquid or from the vapour.

Thermodynamic Properties of Alkaline Earth Titanates, Zirconates, and Hafnates

L.A.Reznitskii and A.S.Guzei

We shall review the problems arising during the critical analysis (aimed at selecting recommended values) of the thermodynamic constants of the alkaline-earth titanates, zirconates, and hafnates—a very important class of ferroelectric perovskites, widely used in radio electronics. Recommended values of the following standard thermodynamic quantities are given, with a statement of the uncertainty limits: the specific heat $C_{p,298}$, the enthalpy change $H_{298}-H_0$, the entropy S_{298}, the heat of formation $\Delta H_{f,298}$, the free energy of formation $\Delta G_{f,298}$, and the temperature and heat of phase transformation. The effect of impurities on the thermal constants of the phase transformations is discussed. The relationship between the thermodynamic characteristics and the crystal structure of perovskites is considered, with special reference to the effect of orthorhombic distortion of the ideal lattice on the entropy of the perovskite. In addition to thermodynamic methods we shall consider also other physical methods used to identify phase transformation temperatures, Curie points, and the temperature of the transition from the ferroelectric to the paraelectric state. Physical methods are especially important when the energy changes associated with the phase transformations are very small and cannot be detected by measurements of specific heat. 289 references.

I. Introduction 99
II. Low-temperature specific heat and entropy 100
III. High-temperature specific heat and phase transformations 105
IV. Enthalpy and free energy of formation 111
V. Discussion of the thermodynamic characteristics of perovskites 113

I. INTRODUCTION

Most of the thermodynamic data for rare-earth titanates, zirconates, and hafnates were obtained during the past 20 or 30 years. In this review we shall critically discuss the data published up to 1976 and we shall make a systematic choice of recommended values of the thermodynmic characteristics of these compounds.

In every case the standard entropy and enthalpy at 298.15 K was recalculated from the experimental data by the method described in Refs. 1 and 2. In these calculations independent interpolations of the specific heat were made at 5 K intervals for the range 5–100 K and at 10 K intervals for the range 100–300 K. Particular attention was paid to the relationship between thermodynamic characteristics and crystal structure. Most of the recommended data are compared with the most recent tabulations[3,4].

We have established a relationship between the thermodynamic formation quantities of the perovskites and the changes in the oxygen co-ordination polyhedron surrounding the cations. We have calculated the energy of the alkaline-earth cations Ca, Sr, Ba in the perovskite oxygen icosahedron, and also the energy of the transition of the zirconium and hafnium ions to an octahedral co-ordination of oxygen ions from the thermodynamically stable modifications of ZrO_2 and HfO_2. We have shown that the heat of formation of the perovskites from the simple oxides is directly proportional to the sum of the energies of the cation transitions involved in the formation of the perovskite structure. We have established a relationship between the uncritical Goldschmidt factor and the entropy change during the formation of perovskites from simple oxides.

II. LOW-TEMPERATURE SPECIFIC HEAT AND ENTROPY

1. Magnesium Titanates

$MgO{\cdot}TiO_2$. Shomate[5] measured the low-temperature specific heat of a $MgTiO_3$ sample containing 0.8% of $MgSiO_3$ in the temperature range 52.6–296.2 K. His values for the specific heat and the entropy at 298 K are 21.93 and 17.8 ± 0.1 cal $mole^{-1}$ K^{-1}, using the Debye and the Einstein function $D(365/T) + E(383/T) + 3E(711/T)$ for extrapolation to 0 K. An independent calculation using the same data[5] gave $S_{k,298} = 17.8230$ e.u. The value $S_{k,298} = 17.82 \pm 0.10$ e.u. (which is also adopted in Refs. 3 and 4) is therefore recommended. The enthalpy calculated from these results is $H_{298} - H_0 = 3239.2$ cal $mole^{-1}$, in good agreement with the tabulated value[3,4] 3240 cal $mole^{-1}$. The rounded-off value, with an uncertainty of ±20 cal $mole^{-1}$, is recommended. The standard specific heat of $MgTiO_3$ at 298 K is taken[3,4] to be 21.960 cal $mole^{-1}$: this value differs somewhat from that given by Shomate[5], but no explanation is given. Extrapolation of high-temperature enthalpy measurements[6] gives $C_{p,298} = 21.92$ cal $mole^{-1}K^{-1}$. The recommended value is $C_{p,298} = 21.96 \pm 0.03$ cal $mole^{-1}K^{-1}$.

$MgO{\cdot}2TiO_2$. The low-temperature specific heat of $MgTi_2O_5$ (99.5% purity) was measured by Todd[7] in the temperature range 52.5–296.4 K. Extrapolation to 0 K was carried out with the Debye and Einstein functions $D(264/T) + 4E(420/T) + 3E(906/T)$. The standard entropy of $MgTi_2O_5$ was rounded off to $S_{k,298} = 30.4 \pm 0.2$ e.u., although direct calculation gives 30.41 e.u. An independent calculation from the same results[7] gave $S_{k,298} = 30.415$ e.u. Ref. 4 gives the value 30.42 e.u., which agrees even better with the independent calculation. The JANAF tables[3] give a tentative value of $S_{k,298} = 32.41 \pm 1.5$ e.u. by allowing for the cation disorder at 0 K and for congruent melting of the compound $MgTi_2O_5$.

The correction for non-zero entropy at 0 K requires a detailed consideration of the crystal structure of $MgTi_2O_5$ and of the disposition of the cations in the polyhedra. Magnesium dititanate is stable with respect to $MgTiO_3$ and TiO_2 only at high temperatures, decomposing into geikielite and rutile at low temperatures. This effect arises from the possibility of disorder in the positions of the Mg^{2+} and Ti^{4+} ions in the crystallographically non-equivalent sites of $MgTi_2O_5$. If we assume that all the Mg^{2+} and Ti^{4+} ions are randomly located we must add $\Delta S = 3R \ln 2 = 3.79$ e.u. to $S = 30.41$ e.u. This gives us the best entropy value $S_{k,298} = 34.2$ e.u., which we shall use in the following calculations as well as the JANAF value[3]. If we assume that all the Mg^{2+} ions and one-half the Ti^{4+} ions are randomly positioned we obtain $S_{k,298} = 30.4 + 2.75 = 33.15$ e.u. X-Ray diffraction analysis of $MgTi_2O_5$ quenched from 1500°C indicates a distribution corresponding to the formula $(Mg_{0.684}Ti_{0.316})_{4C}{\cdot}(Mg_{0.316}{\cdot}Ti_{1.684})_{8t}O_5$, i.e. a disorder factor $x = 0.316$ ($x = 0$ for the normal cation distribution, $x = 2/3$ for a fully disordered distribution, and $x = 1$ for an inverted cation distribution).

Todd[7] obtained $C_{p,298} = 35.15$ cal $mole^{-1}$ K^{-1} for the standard specific heat of $MgTi_2O_5$. This value is adopted in Ref. 4: it is consistent with high-temperature enthalpy measurements[8] but it differs from the JANAF value[3] of 35.10. We recommend the value $C_{p,298} = 35.15 \pm 0.05$ cal $mole^{-1}$ K^{-1}.

Todd did not calculate the enthalpy of magnesium dititanate. A calculation from his results gives $H_{298} - H_0 = 5361$ cal $mole^{-1}$. The values 5363 and 5428 cal $mole^{-1}$ are given in Ref. 3 and 4 respectively: the latter value is inconsistent with the independent calculation of the entropy. We recommend the value $H_{298} - H_0 = 5360 \pm 40$ cal $mole^{-1}$.

$2Mg{\cdot}TiO_2$. The low-temperature specific heat of Mg_2TiO_4 ([MgTi]MgO_4 spinel, of 99.5% purity) was measured by Todd[7] in the temperature range 52.38–296.5 K. The results were extrapolated to 0 K by using the Debye and Einstein functions $D(305/T) + 3E(447/T) + 3E(823/T)$. He obtained a standard entropy of $S_{k,298} = 24.76 \pm 0.15$ e.u., which is exactly confirmed by an independent calculation using his results. Ref. 4 gives $S_{k,298} = 26.13$ e.u., and Ref. 3 gives 27.51 ± 1.5 e.u. The difference arises from different estimates of the configurational entropy due to disorder. Magnesium orthotitanate is an inverted spinel, with the magnesium ions in tetrahedral (A) and in octahedral (B) positions. The cation distribution can be expressed as Mg[MgTi]O_4, where the square bracket denotes the ions octahedrally surrounded by oxygen ions. Therefore the entropy obtained from specific heat data must be corrected by adding the ordering entropy of the cations in B positions ($2R \ln 2 = 2.75$ e.u.), which gives $S_{k,298} = 27.51$ e.u. This is the value which we recommend. We note that an intermediate value is quoted in Ref. 4, with an ordering correction of $R \ln 2 = 1.38$ e.u.

The standard specific heat quoted by Todd is $C_{p,k,298} = 30.76$ cal $mole^{-1}$ K^{-1}, with a probable error of ±0.02 cal $mole^{-1}$ K^{-1}. This value is consistent with high-temperature measurements of enthalpy[8], and differs only slightly from the value (30.75) adopted in Ref. 4.

The enthalpy of the orthotitanate was not computed by Todd. A calculation based on his results gives $H_{298} - H_0 = 4502$ cal $mole^{-1}$, which is identical to the value quoted i Refs. 3 and 4. We recommend the rounded-off value $H_{298} - H_0 = 4500 \pm 30$ cal $mole^{-1}$.

2. Calcium Titanates

$CaO{\cdot}TiO_2$. The low-temperature specific heat of $CaTiO_3$ (purity better than 99%) was measured by Shomate[5] in the range 52.5–296.3 K. Extrapolation to 0 K was made by using the sum $D(256/T) + 2E(375/T) + 2E(768/T)$. Shomate calculated $S_{k,298} = 22.38$ e.u. for the standard entropy of $CaTiO_3$, in very good agreement with an independent calculation based on his results and also with the JANAF value[4]. We recommend this value, with an uncertainty of ±0.10 e.u.

The standard specific heat of $CaTiO_3$ at 298 K was found[5] to be 23.34 cal $mole^{-1}$ K^{-1}. The same value is quoted in Refs. 4 and 9. Extrapolation from high-temperature measurements of enthalpy[6] gives 23.35 cal $mole^{-1}K^{-1}$. We recommend the value $C_p = 23.34 \pm 0.05$ cal $mole^{-1}K^{-1}$, the rather wide uncertainty reflecting the absence of corrections for impurities in the sample[5].

Shomate did not calculate the standard enthalpy of $CaTiO_3$. A calculation based on his results gives $H_{298} - H_0 = 3800.7$ cal $mole^{-1}$. We recommend the rounded-off value 3800 ± 20 cal $mole^{-1}$.

$3CaO{\cdot}2TiO_2$. The low-temperature specific heat of $Ca_3Ti_2O_7$ was measured by King[10] in the range 52.6 to 296.9 K. Chemical analysis of his sample gave 48.61% TiO_2 (theoretical value 48.71%). Extrapolation to 0 K was by the sum of functions $D(158/T) + 5E(333/T) + 5E(652/T) + E(781/T)$. The standard entropy recommended by King is $S_{k,298} = 56.1 \pm 0.4$ e.u., with which we concur. This value coincides, after rounding off, with the value (56.057 e.u.) obtained by an independent calculation from the same results[10]. It is also adopted in Ref. 4.

King's measurements[10] give $C_{p,298} = 57.20$ cal $mole^{-1}K^{-1}$ for the standard specific heat of $Ca_3Ti_2O_7$, with an uncertainty of ±0.05 cal $mole^{-1}$ K^{-1}. The enthalpy of the compound was not calculated by King, and is not given in Ref. 4. A calculation based on King's results gives $H_{298} - H_0 = 9418.6$ cal mole^{-1}. We recommend the rounded-off value $H_{298} - H_0 = 9420 \pm 70$ cal mole^{-1}.

3. Strontium Titanates

$SrO \cdot TiO_2$. $SrTiO_3$ undergoes four clearly defined low-temperature phase transformations of the second kind: at 0.06, 35, 65, and 107 K.

1) The transition from the high-temperature cubic structure to a tetragonal structure in the temperature range 100–110 K has been noted in more than 50 investigations.

The first report of this transition was made in 1956 by Gränicher[11], who noted anisotropy of the dielectric constant below 100 K, and subsequently by Müller[12], who observed tetragonal domains in $SrTiO_3$ crystals doped with Fe^{3+} by ESR measurements below 100 K. According to the ESR results[12-21] the low-temperature phase is tetragonal, with a c/a ratio of 1.0003 at 77 K. After a number of unsuccessful attempts[13,20,25] this structural change was demonstrated directly by X-ray diffraction[22-24]. However it was pointed out[26] that neither the axial ratio nor its temperature dependence[23] agrees with the ESR results. It was shown that the main contribution to the change in the pseudo-cubic structure with $c/a = 1.00008$ is a rotation of neighbouring oxygen octahedra around the original cubic axis[23]. The angle of rotation φ is treated as an ordering parameter for this phase transformation of the second kind. This conclusion was confirmed by neutron diffraction work[26-31]. The cubic structure of the $SrTiO_3$ perovskite is assigned O_h symmetry, and the low-temperature tetragonal structure D_{4h} symmetry[20,32,33]. The phase transformation is accompanied by marked changes in elastic constants[34-53], Rayleigh[38] and Raman spectra[32,33,54-59], double refraction[22,24], and by a decrease in the amplitude of the ^{87}Sr[60] NMR spectrum, increased thermal diffusivity and thermal conductivity[61], and a slight broadening of the ESR spectra of crystals containing magnetic impurities[12,13,15-21]. The high-temperature $SrTiO_3$ cubic structure is shown to be imperfect by the anisotropy of its electrical properties[11,62-66] and of the thermal stress[67,68]. The transition temperature varies with sample purity, pressure, and degree of reduction[46,47,69].

The mechanism of the transformation is discussed in almost all the above-mentioned papers. The most detailed analysis is given by Reshchikova[70], who assigns this $O_h \rightleftharpoons D_{4h}$ phase transition (accompanied by a fourfold increase in volume of the unit cell) to the displacement type of transition, arising from the presence of soft modes of lattice vibration in the cubic phase with a non-zero wave vector, which become "frozen" during the phase transition. Another group of papers deals with the mechanism of the transformation and with the structure of the equilibrium phases without attempting to specify the exact temperature of the transition[71-84]. Some workers failed to observe any anomalies in the electrical[85,86] and optical properties[87] in the transition region. Luthi and Moran[47] have discussed the reasons for this discrepancy.

The specific heat of $SrTiO_3$ has been measured directly in the transition region[61,66,69,88]. Garnier[69] found that the transition region extends over 2 K, and that T_{tr} is lowered by almost 1 K if the sample is annealed. The transition is also more gradual with an annealed sample. These effects are ascribed to a 0.05% decrease in the concentration of oxygen. Subsequently Salamon and Garnier[61] observed a change in specific heat at 110 K on a sample supplied by Sakudo and Unoki[65], and they also noted a 2% change in thermal diffusivity and a 1% change in thermal conductivity at the same temperature.

In most of these papers the anomalous changes in property are presented graphically, and the T_{tr} values are obtained by interpolation. Values indicated by the work of different authors range from 99.5 K[31] to 112 K.[34,35]. Averaging all the data on the temperature of this transformation gives 107.2 K. However we can identify a group of papers[17,26,30,47,48,61,67,69,88] in which special attention is paid to the precise measurements of T_{tr}, by a variety of methods. Averaging these results gives $T_{tr} = 106.9$ K. The difference between the two averages is less than the width of the transition region (2 K). Therefore we recommend the rounded-off value $T_{tr} = 107 \pm 3$ K. The quoted uncertainty encompasses most of the experimental data and corresponds to the scatter of results obtained with different samples.

2) The second low-temperature transition in $SrTiO_3$ is most clearly shown by measurements of the thermal hysteresis of $1/\epsilon$ (62 K[89], 65 K[65]), of double refraction (50 K[22], 60 K[24]), of X-ray diffraction (50 K[22], 55–65 K[23]), and of Raman (67 K[32]) and ESR spectra (65 K[21,90]). Below 65 K $SrTiO_3$ has a rhombic structure[23,32,65], of the D_{2h} type, with $a:b:c = 0.9998:1:1.0002$. Transition from the antiferromagnetic to the paramagnetic state has been demonstrated[91] experimentally: this could be due to conversion of the domain configuration in the sample from c-plate to a-plate[65].

By giving greater weight to the wider-ranging investigations[21,65,90] we select $T_{tr} = 65 \pm 5$ K as the recommended value. It should be noted that the existence of this transition is still controversial. It is not confirmed by spectroscopic measurements[33] or by studies of acoustic properties[49].

3) The Curie temperature has been obtained from measurements of the temperature dependence of dielectric constant[11,86,89,92-95], of neutron diffraction[96], of acoustic[34,45] and i.r. absorption[71], and of electrostriction[32,45,64,92-97]. The calculated values of T_C range from 28 K[96] to 50 K.[92] The transition has been observed experimentally only in three laboratories: Lytle[23] obtained $T_C = 35$ K from X-ray diffraction measurements, O'Shea and coworkers[32] observed a change in the Raman spectra at 34 K, and Sorge and Hegenbarth[98] obtained $T_C = 36$ K from measurements of elastic constants. From these results we recommend the value $T_C = 35 \pm 2$ K, in good agreement with the value (36.3 K) obtained by averaging all the above calculated and experimental results.

The only work which explicitly denies all phase transformations below 105 K is an acoustic investigation[49] at temperatures in the region 4–130 K. Bogdanov and coworkers[24] identified three temperature regions in which the double refraction of $SrTiO_3$ obeys different laws: 110–60, 60–20, and 20–4.2 K. The latter region has a maximum at 10 K, confirming a previous report[23]. We should stress that this observation has been repeated only once[22], again by measurements of X-ray diffraction and of double refraction. Hence the information on thermal characteristics in the region 4–20 K is insufficient for a recommended value to be selected. The limit of 20 K, which is only approximate, was taken from Ref. 24, where the parameter being measured was practically linear in the region 15–50 K. The results of Kirkpatrick and Müller[14] therefore would appear to confirm the existence of a phase transformation.

4) The superconductivity of $SrTiO_3$ was first observed by Schooley and coworkers[99]. In three monocrystalline samples, reduced in different ways, the temperature of the superconducting transition was found to be 0.1, 0.25, and 0.28 K. A subsequent series of investigations[100-104] established that superconductivity is present in $SrTiO_3$ samples doped with Nb as well as in reduced samples. The T_{tr} value depends on the concentration of charge carriers n_c in the region 8×10^{18}–5×10^{20} cm^{-3}. T_{tr} increases at first with n_c, reaching a maximum at intermediate values of n_c, and then decreases. The n_c values were measured by the Hall effect, and T_{tr} from the magnetic susceptibility and electrical resistivity of the samples. With reduced samples the T_{tr} maximum was found at 0.3 K, with Nb-doped samples at 0.4 K. The lowest value of T_{tr} was 0.06 K.[101] For many samples the width of the transition region was 0.1 K. The transition to the superconducting state has been observed also by measurements of low-temperature specific heat[105,106].

We choose as the recommended value of the transition temperature $T_{tr} = 0.06$ K, i.e. the value obtained[101] for a $SrTiO_3$ sample with the smallest deviation from stoichiometry, the smallest degree of reduction, and the lowest concentration of charge carriers ($n_c = 8 \times 10^{18}$ cm^{-3}). Allowing for the observed width of the transition region we estimate the uncertainty as ± 0.03 K. We note that the highest value ($T_{tr} = 0.3$ K) was obtained for $n_c = 7 \times 10^{19}$ cm^{-3}.

Todd and Lorenson[107] measured the low-temperature specific heat of $SrTiO_3$ over the widest temperature range (55–296 K). No anomalies could be detected in their plot of specific heat against temperature. Below 51 K the specific heat was determined by using the sum $D(182/T) + 2E(319/T) + 2E(776/T)$. For 298 K the authors obtained $C_p = 23.51$ cal mole K^{-1} and $S^0 = 26.0 \pm 0.2$ e.u. The C_p value coincides with the extrapolation from measurements of enthalpy at high temperature[108]. The good agreement with Refs. 107 and 108 is pointed out by Narayanan and Vedam[109], who obtained calculated values of C_V for the region 55–1800 K. Thus we can choose $C_{p,\,k,298} = 23.51 \pm 0.02$ cal mole^{-1} K^{-1} as the recommended value.

The specific heat has been measured in the region of the transition to the superconducting state[105,106,110] with $SrTiO_3$ samples containing different charge carrier concentrations. The temperature dependence of C_p obtained in this work over the narrow range 0.5–4.0 K, and also the value $\Delta S_{tr} = 0.12$ mJ mole^{-1} K^{-1},[105] are not suitable for calculating the entropy and enthalpy of stoichiometric $SrTiO_3$.

Many workers have found[50,61,66,68-70,88] that the change in specific heat in the region of the phase transition at 107 K is also negligibly small, amounting to 0.5–1.3% of the lattice contribution. These values are smaller than the error in the calculation of $H_{298} - H_0$ and S°_{298} introduced by the extrapolation to the low-temperature region.

From Todd and Lorenson's results[107] we calculate $H_{298} - H_0 = 4120$ cal mole^{-1} and $S_{298} = 25.98$ e.u. The latter value agrees well with that obtained by the authors[107]: the discrepancy is very small, and can be ascribed to differences in the computational methods. Hence we can adopt $S_{298} = 26.0 \pm 0.2$ e.u. as the recommended value. The quoted uncertainty undoubtedly allows for the entropies of the low-temperature phase transitions, which are accompanied by very small changes in C_p. To the same degree of confidence we can recommend the value $H_{298} - H_0 = 4120 \pm 40$ cal mole^{-1} for the enthalpy of $SrTiO_3$, which was not calculated by Todd and Lorenson[107].

$2SrO \cdot TiO_2$. The low-temperature specific heat of Sr_2TiO_4 was measured by Todd and Lorenson[111] in the temperature range 53.6–296.7 K on a sample of 99.5% purity. Extrapolation to 0 K was done by using the sum of functions $D(162/T) + 3E(280/T)$ and $3E(664/T)$. The standard entropy obtained[111] (38.01 e.u.) agrees exactly with an independent calculation based on their experimental results (38.013 e.u.). We choose $S_{k,298} = 38.0 \pm 0.3$ e.u. as the recommended value: the same value is tabulated in Ref. 4.

Todd and Lorenson's value[111] for the standard specific heat of Sr_2TiO_4 is $C_{p,298} = 34.34$ cal mole^{-1} K^{-1}, which agrees with the extrapolation from high-temperature measurements of enthalpy on the same sample[108], and is tabulated in Ref. 4. We adopt this as the recommended value, with an uncertainty of ±0.03 cal mole^{-1} K^{-1}.

The standard enthalpy of Sr_2TiO_4 has not been calculated before. Using the results of Ref. 111 we calculate $H_{298} - H_0 = 6060 \pm 60$ cal mole^{-1}, which we proposed as our recommended value.

4. Barium Titanates

$BaO \cdot TiO_2$. Barium titanate has five polymorphic modifications: trigonal $\xrightarrow{80°C}$ rhombic $\xrightarrow{5°C}$ tetragonal $\xrightarrow{120°C}$ cubic $\xrightarrow{1250°C}$ hexagonal, all three low-temperature modifications being pseudo-cubic because the differences in the positions of the ions are not large. We shall discuss these transitions individually.

1) The ferroelectric $BaTiO_3$ transition. Most of the work on the properties of $BaTiO_3$ has been done near 120°C (the temperature of the transition from the non-ferroelectric to the ferroelectric phase). The thermodynamic theory of this transition was developed by Ginzburg[112,113] and elaborated by other workers[114-116]. Ginzburg discusses two variants of the theory, corresponding to observed facts. According to the first variant the phase transition near 120°C should be treated as a transition of the second kind but approaching a transition of the first kind; according to the second variant it should be treated as a transition of the first kind but approaching the second kind. Some workers[114,117-127,278] have treated it as a transition of the first kind, others[108,112,115,116,128-136] as a transition of the second kind. In view of the strong discrepancies between the experimental results of different workers (for example, on the temperature dependence of the spontaneous polarisation, the constant in the Curie–Weiss law, the discontinuity in specific heat, the temperature of the transition, and its hysteresis), and in view of the strong dependence of the results on the method of preparation and on the purity of the samples, we can conclude that different types of transition were observed by different workers.

The method most commonly used to determine the transition temperature was dictated by the most outstanding feature of barium titanate: the temperature dependence of the dielectric constant, which was studied on ceramic[117-120,122,126,129,137-165] and on single-crystal samples[118,123,126,127,134,135,159-161,167-173] in different fields[138]. In parallel with this work, several authors carried out X-ray structural[124,130,142,146,152,164,166,167,174-183], crystallographic[118,142,166,184], thermochemical[108,122,123,128,133,144,148,151,153,154,185-187,279,280,281], differential thermal[121,125,175,186,188-190], and dilatometric studies[124,130,144,147,151,153,164,174,177], and measured the tangent of the loss angle[143,154,173], the spontaneous polarisability[126,167,191], the refractive index and the double refraction[118,167,169,176,179,182,192,193,283], the

ESR spectra[194], the acoustic properties[123,165,278], the ferromagnetic hysteresis[119,156], the thermal diffusivity[195], and the variation of the electric properties[114,136,166,170] and of the transition temperature[126,196,197] with pressure and with field, applied in different crystallographic directions.

Many of the reported values[133,138,140,141,148,155,177] of T_{tr} are clearly unacceptable and will not be considered further. This is specially true of values in the region of 80°C, which are reported as probably too low as a result of the presence of impurities in the samples. This transition appears to be particularly sensitive to heat treatment conditions[155] as well as to the purity of the sample, since some of the other transitions (e.g. in Ref. 148) agree well with data obtained elsewhere. The lowest values of T_{tr} are ascribed[144,175] to the impurity effect of the binders added to improve the sintering properties of the samples. One paper[149] stands alone in suggesting that the ferroelectric properties of barium titanate are due entirely to the presence of impurities: unlike every other sample previously examined in that laboratory[137,138,140,141], a sample of $BaTiO_3$ prepared from chemically pure compounds was found to have a dielectric permeability which was not only constant over a wide temperature range but also relatively small. Thus the pure sample of $BaTiO_3$ was a dielectric, but not a ferroelectric. We stress that this conclusion[149] has not been confirmed by the extensive subsequent work on a wide variety of sample types.

Hysteresis of the transition temperature has been observed repeatedly[117,119–121,124,125,142,151,153,154,169,176,177]: the hysteresis is more marked for the cubic than for the tetragonal modification[176]. The existence of a temperature region of coexistence of two phases, of width (10–11 K) depending on the thermal history of the sample[151,177], is well established, but Harwood[146] points out that this region extends over 1–2 K for monocrystalline samples and ~10 K for polycrystalline samples. Roi[117] observed an even wider transition region (104–128°C) for a ceramic sample. He suggests that a transition region of finite width should be present only in polycrystalline samples, in which the simultaneous transition in all the microcrystals of the ceramic is prevented by internal stresses. The widest reported transition region (110–135°C) was observed in a ceramic sample[153]. Meyerhofer[169] found hysteresis (4.3 K) in single-crystal $BaTiO_3$, and pointed out various possible types of transition kinetics as a function of the applied field. Cross[119] observed different transition temperatures in different parts of a polycrystalline sample.

The effect of impurities on the transition temperature has been shown by several workers[171,182,283], T_{tr} decreasing with increase in impurity concentration. Variations in T_{tr} have also been noted by other workers[126,128,144,151,155,281]. The dependence of T_{tr} on experimental conditions has been clearly demonstrated[144,146,151,154].

No regularity has been observed in the behaviour of the transition temperature on changing from ceramic to monocrystalline samples. For example, Shirane and Takeda[153] obtained T_{tr} = 127 and 115°C for a ceramic and a monocrystalline sample, whereas Samara[126] obtained 112.5°C for a ceramic sample and 118.0, 120.0, 111.0, and 122.5°C for a series of four monocrystalline samples.

Many workers[117,134,137,147,150,152,157,158,160–162,170,181,184,185,191,194,196,279,280,283] were not interested in locating the temperature of the transition, and did not quote its numerical value. In these cases we have made an estimate of the transition temperature by noting the extremum of the anomaly presented graphically by each author. The average of 98 reported values of T_{tr} and of our estimates, but rejecting some unacceptable values, is T_{tr} = 119.2 °C. By taking only the values obtained in special measurements of T_{tr},[108,114,118–130,135,136,138,139,142–146,151,153–156,159,163–169,171–176,178–180,182,183,186–193,195,197,198] and giving double statistical weight to the values obtained in investigations involving two or more methods[118,122,123,146,151,153,164,169], we obtain the average value T_{tr} = 119.6 °C. This is close to the transition temperature usually quoted by physicists (" in the neighbourhood of 120 °C").

Values of $T_{tr} \leqslant$ 115°C were probably obtained with relatively impure or imperfect samples, or may have been due to unsatisfactory measurement methods. We stress that higher values of T_{tr} correspond to smaller amounts of impurity. The mean of the values chosen by this criterion[108,114,118–130,135,136,138,139,142–146,153–155,159,163–169,171–174,178–180,182,183,187–190,192,193,195,197,198] is T_{tr} = 121.5°C. We take this as the recommended value for the transition temperature, with an uncertainty of ± 5 K which allows for the thermal hysteresis of the transition as well as the error in the measurements.

The heat of the ferroelectric transition has been obtained by direct calorimetric measurements[121–123,153,154,279], by DTA,[190] and from measurements of the temperature dependence of the thermal expansion coefficient in conjunction with the Clausius–Clapeyron equation[125–127,162,188,191]. The anomalous temperature dependence of the specific heat in the region of the transition has also been investigated[133,136,140,141,144,146,151,187,280], but these workers did not attempt to calculate ΔH_{tr} as they considered the method insufficiently accurate[151]. An estimate of ΔH_{tr} can nevertheless be made from the published graphs of C_p against temperature or from the maximum values of ΔC_p. The mean of 24 values obtained in this way is ΔH_{tr} = 53.5 cal mole^{-1}. By averaging only the direct thermochemical determinations of ΔH_{tr} [121–123,153,154,190,279] we obtain 48.1 cal mole^{-1}, and by averaging only the values obtained from the Clausius–Clapeyron equation we obtain 46.8 cal mole^{-1}. The last two values agree reasonably well. Estimates of ΔH_{tr} made from plots of C_p are very inaccurate (from 15 to 100 cal mole^{-1}) and should be rejected. We also reject the value given by Roberts[121] (ΔH_{tr} = 15 cal mole^{-1}) as the lower limit of the latent heat of the transformation, estimated from measurements of the temperature change which occurs when the transition is induced by applying an electric field under adiabatic conditions. Averaging the other 13 values gives ΔH_{tr} = 47.4 cal mole^{-1}. We choose as the recommended value ΔH_{tr} = 47.5 ± 3 cal mole^{-1}, where the quoted uncertainty describes the error in the calorimetric measurements. Using T_{tr} = 394.65 K we obtain ΔS_{tr} = 0.12 e.u. for the entropy of the transformation.

2) Low-temperature transitions of $BaTiO_3$. The temperatures of these transitions were determined by measurements of specific heat[107,122,123,153,154], by microscopic[166], X-ray diffraction[131,166,176,178,179,199–201], and dilatometric studies[135,153,177], and by measurements of dielectric constant[123,129,135–137,148,153,155,164,166,167,170,173,185,202–205], of piezoelectric[166], acoustic[148,159], optical[131,173,176,179,193,201,203,206,283], and magnetic properties[205,207], as well as by studies of NMR [194] and luminescence spectra[208]. Some workers[153,159,166,176,204,205] used monocrystalline samples. Some[203,208] examined only the low-temperature transition at −80°C, others[122,129,136,137,164,170,177,194] ignored it and studied the transition at a higher temperature in the region of 10°C. Much of the work is devoted to physical investigations, with the aim of explaining the anomalies in the physical properties. Little effort was devoted to determining exactly the temperature of the transition.

Many workers treat the transition as a phase transformation of the first kind[117] in spite of the λ-shaped plot of C_p against temperature. The lack of a definite latent heat compels us to treat the thermodynamic characteristics of these transitions as phase transformations of the second kind. A review[135] of the anomalous properties of $BaTiO_3$ identifies the low-temperature transition temperature with the Curie point.

By averaging all the data on the two transition temperatures we obtain $T_{tr} = -75.5$ and 4.58°C. Some of the values[153,154] were assigned a double statistical weight because they were obtained by several methods, and two values[107] ($T_{tr} = -71.55 \pm 0.2$ and 11.75 ± 0.2°C) were given triple weight because this was the only investigation aimed at absolute measurements of the specific heat of $BaTiO_3$. Our averaging did not include values which had not been directly quoted by the authors but estimated by us from published property-temperature plots[129,136,137,167,170,185,194,202,204,207,208]. We quote that the dilatometric measurements[177] failed to detect any anomaly between −10 and 20°C. Averaging the values obtained by calorimetric measurements[107,123,153,154] specially aimed at determining the transition temperature gives −72.75 and 11.43°C, whereas averaging all the other values gives −76.9 and 1.47°C. The discrepancy between the two sets of data is specially large for the transition at the higher temperature. Accepting only the calorimetric measurements, we recommend the values $T_{tr} = 11.4 \pm 5$°C = 284.55 ± 5 K and $T_{tr} = -73 \pm 5$°C = 200.15 ± 5 K. The quoted uncertainty allows for the thermal hysteresis of the transitions and for the scatter of the physical measurements.

The enthalpies of these transitions have been calculated[107,123,153,154] from the anomalies in the temperature dependence of the specific heat. The most careful calorimetric study of $BaTiO_3$, in the range from 53 to 103 K, was reported by Todd and Lorenson[107]. In the range 278–293 K they obtained $\Delta H_{tr} = 26$ cal mole^{-1}, and in the range 196–206 K $\Delta H_{tr} = 12$ cal mole^{-1}. An independent treatment of their results by the method described in Refs. 1 and 2 gives $\Delta H_{tr} = 22.635$ (278–293 K) and 13.03 cal mole^{-1} (180–210 K). The former value agrees well with Ref. 153, less well with Ref. 107, and badly with Refs. 123 and 144. Rejecting the latter two values and averaging the others we arrive at the recommended value $\Delta H_{tr} = 23.5 \pm 4$ cal mole^{-1} for the heat of the transition in the region of 278–293 K. The quoted uncertainty corresponds to the estimate made in Ref. 153. For the region 180–210 K we recommend $\Delta H_{tr} = 13 \pm 1$ cal mole^{-1} by averaging the values most consistent[107,154] with our calculation and rejecting an unacceptable value[153].

Low-temperature measurements[154] of C_p show considerable scatter and discontinuities, and they cannot easily be fitted to a "normal" curve. Results[282] for the range 2–37 K are presented only graphically. Hence we shall use only the data from Ref. 107 to calculate the enthalpy and entropy of $BaTiO_3$, together with the suggested[107] sum of functions $D(198/T) + 2E(351/T) + 2E(669/T)$ for extrapolating to the low-temperature region. Our calculation based on the data of Ref. 107 gives $S_{k,298} = 25.79$ e.u., and therefore we recommend the value $S_{k,298} = 25.8 \pm 0.2$ e.u. obtained in Ref. 107. The enthalpy of $BaTiO_3$ was not calculated[107]. From the published results[107] we calculate $H_{298} - H_0 = 4230$ cal mole^{-1}, and we recommend this value with error limits of ±40 cal mole^{-1}.

The standard specific heat at 298 K was found[107] to be 24.49 cal mole^{-1} K^{-1}. A different set of data[154] gives 24.31 cal mole^{-1} K^{-1} by interpolation. Extrapolation from high-temperature measurements of enthalpy[108] gives a value identical to that of Ref. 107. Hence we choose $C_{p,k,298} = 24.49 \pm 0.02$ cal mole^{-1} K^{-1} as the recommended value.

Blunt and Love[209] observed a dielectric loss peak at 70 K with a ceramic sample of $BaTiO_3$, but no anomaly in the dielectric constant. A large increase in coercive force at temperatures below 20 K was reported[210] for a multidomain sample. However a special investigation[203] failed to confirm these observations. Neither the dielectric constant nor the ferromagnetic hysteresis had any anomalies in the region from 4.2 to 180 K. Hence we are unable to recommend any values for transitions in this temperature range.

$2BaO \cdot TiO_2$. The low-temperature specific heat of Ba_2TiO_4 has been measured[111] in the temperature range 54–307 K with a sample of 99.2% purity. Extrapolation to 0 K was by the sum of functions $D(104/T) + 3E(207/T) + 2E(523/T) + E(858/T)$. The recommended[111] standard entropy $S_{k,298} = 47.0 \pm 0.5$ e.u. agrees very well with the value (46.92 e.u.) obtained by an independent recalculation.

Extrapolation of the high-temperature enthalpy measurements[108] on the same Ba_2TiO_4 sample gives a standard specific heat of $C_{p,k,298} = 35.647$ cal mole^{-1} K^{-1}. Unlike the corresponding results for $BaTiO_3$, $SrTiO_3$, and Sr_2TiO_4 this value differs significantly from the directly measured[111] value $C_{p,298} = 36.48$ cal mole^{-1} K^{-1}. We choose the latter as the recommended value, with an uncertainty of ±0.1 cal mole^{-1} K^{-1} to allow for this discrepancy and for the inadequate purity of the sample.

The standard enthalpy of Ba_2TiO_4 has not been calculated previously. We obtain $H_{298} - H_0 = 6842.8$ cal mole^{-1} by using the data of Ref. 111, and we propose the rounded-off value 6840 ± 60 cal mole^{-1} as the recommended value.

5. Mixed Barium and Strontium Titanates

$BaTiO_3 - SrTiO_3$. Todd and Lorenson[107] measured the specific heat of $Ba_{0.543}Sr_{0.457}TiO_3$ in the range 53–298 K. They obtained $C_{p,k,298} = 23.98$, which we accept as the recommended value with an uncertainty of ±0.02 cal mole^{-1} K^{-1}. The sum of functions $D(192/T) + 2E(399/T) + 2E(676/T)$ was used to extrapolate the results below 51 K. The entropy value obtained[107], $S_{k,298} = 27.4 \pm 0.2$ e.u., is recommended. This value includes an enthalpy of mixing of 1.37 e.u. An independent calculation based on the same data[107] gave good agreement when the C_p values at 45, 50, and 51 K were obtained by graphical interpolation, but not when they were computed using the functional sum. The authors[107] did not calculate the standard enthalpy. Our calculation, using their experimental data, gave $H_{298} - H_0 = 4210$ cal mole^{-1}: we recommend this value, with an uncertainty of ±40 cal mole^{-1}.

Calculation by a linear combination of the enthalpies of $BaTiO_3$ and $SrTiO_3$ gives $H_{298} - H_0 = 4180$ cal mole^{-1}, which agrees with the recommended value within the error limits. The temperature plot of the specific heat of $Ba_{0.543}Sr_{0.457}TiO_3$ does not show the two transition effects observed in $BaTiO_3$ in this temperature region. Measurements of dielectric constant[211] on various mixed titanates suggest the possibility of a transition at 248 K, the dielectric constant peak observed in $BaTiO_3$ at 393 K shifting gradually towards lower temperatures as the mole fraction of strontium titanate in solid solution increases. A special series of measurements[107] in the region 232–262 K failed to reveal any anomaly in C_p. The authors[107] point out that the temperature coefficient of the specific heat for the solid solution above 248 K is lower than expected, and this could be interpreted as anomalous behaviour. A very small anomaly was noted[279] in the plot of C_p against temperature for a sample of $Ba_{0.5}Sr_{0.5}TiO_3$ in the region 100–400 K. However no numerical values are quoted[279], and we are unable to make an estimate of the transition temperature.

$BaSrTiO_4$. The low-temperature specific heat of the $BaSrTiO_4$ solid solution was measured by Todd and Lorenson[111] in the range 53–296.5 K. The results were extrapolated to 0 K by using the sum $D(116/T) + 3E(239/T) + 3E(646/T)$. The calculated[111] value $S_{298} = 45.79$ e.u. coincides with our independent calculation based on the same data (45.795 e.u.). We therefore recommend the value $S_{k,298} = 45.8 \pm 0.4$ e.u., which includes the term $S_0 = 2.75$ e.u. calculated[111] on the assumption of a fully disordered distribution of Ba and Sr cations in the crystal lattice of the solid solution of their titanates.

For the standard specific heat we recommend the reported[111] value $C_{p,k,298} = 34.95$ with an uncertainty of ± 0.1 cal mole^{-1} K^{-1} (corresponding to the uncertainty previously suggested for Ba_2TiO_4).

From the published data[111] we calculate a standard enthalpy of 6477.9 cal mole^{-1}, and we recommend the rounded-off value $H_{298} - H_0 = 6480 \pm 60$ cal mole^{-1}. By assuming linearly additive enthalpies for these solid solutions we obtain $H_{298} - H_0 = 6450$ cal mole^{-1} for $BaSrTiO_4$, which agrees with the adopted value within the error limits.

6. Calcium, Strontium, and Barium Zirconates

$CaO \cdot ZrO_2$. King and Weller[212] measured the specific heat of $CaZrO_3$ in the range 52.81–296.10 K. The extrapolation to 0 K was done by using the sum of functions $D(233/T) + 2E(355/T) + 2E(722/T)$. The reported[212] value $C_{p,k,298} = 23.88$ is recommended, with an uncertainty of ± 0.02 cal mole^{-1}. The calculated[212] $S_{k,298}$ value was 23.92 e.u. (the value tabulated in Ref. 4). An independent calculation, using the same data[212], gave 23.915 e.u. The value recommended by the authors[212] is 23.9 ± 0.2 e.u. A calculation of the standard enthalpy of $CaZrO_3$ from King and Weller's results[212] gives 3991.5 cal mole^{-1}: we recommend the rounded-off value $H_{298} - H_0 = 3990 \pm 40$ cal mole^{-1}.

$SrO \cdot ZrO_2$. The same authors[212] measured the specific heat of $SrZrO_3$ in the range 53.4–295.8 K, extrapolating their results to 0 K by the sum of functions $D(177/T) + 2E(308/T) + 2E(678/T)$. We recommend their value[212] $C_{p,k,298} = 24.71$, with an uncertainty of ± 0.02 cal mole^{-1} K^{-1}. This value is adopted in Ref. 4. The reported[212] value of $S_{k,298}$ is 27.52 e.u.: our independent recalculation gives 27.533 e.u. The recommended value[212] is $S_{k,298} = 27.5 \pm 0.2$ e.u. (the value quoted in Ref. 4). The standard enthalpy calculated from the same results[212] is 4362.2 cal mole^{-1}: we recommend the rounded-off value $H_{298} - H_0 = 4360 \pm 40$ cal mole^{-1}.

$BaO \cdot ZrO_2$. King and Weller[212] also measured the specific heat of $BaZrO_3$ in the range 53.6–296.1 K, extrapolating their results to 0 K by using the sum of functions $D(144/T) + 2E(273/T) + 2E(692/T)$. They obtained[212] $C_{p,k,298} = 24.31$ cal mole^{-1} K^{-1}, which we recommend (with an uncertainty of ± 0.02). Their calculated value[212] of $S_{k,298}$ is 29.83 e.u., which agrees well with our independent recalculation (29.835 e.u.). We recommend the value $S_{k,298} = 29.8 \pm 0.2$ e.u. The same values of specific heat and entropy are adopted in Ref. 4. For the enthalpy of $BaZrO_3$ we recommend the value $H_{298} - H_0 = 4515 \pm 40$ cal mole^{-1}, calculated from King and Weller's results[212].

III. HIGH-TEMPERATURE SPECIFIC HEAT AND PHASE TRANSFORMATIONS

1. Magnesium Titanates

The high-temperature enthalpies of $MgTiO_3$ have been measured by drop calorimetry ("method of mixtures") in the range 298–1720 K,[6] those of $MgTi_2O_5$ and Mg_2TiO_4 in the range 298–1800 K.[8] The results are described by the equations

Compound	Equation (cal mole^{-1})	Precision
$MgTiO_3$	$H_T - H_{298} = 28.29\,T + 1.64 \cdot 10^{-3}T^2 + 6.530 \cdot 10^5/T - 10\,771$	0.4%
$MgTi_2O_5$	$H_T - H_{298} = 40.68\,T + 4.60 \cdot 10^{-3}T^2 + 7.35 \cdot 10^5/T - 15\,003$	0.3%
Mg_2TiO_4	$H_T - H_{298} = 35.96\,T + 4.27 \cdot 10^{-3}T^2 + 6.89 \cdot 10^5/T - 13\,412$	0.3%

No solid-state transformation have been detected in the magnesium titanates.

Table 1. Melting points of magnesium titanates.

1750±10*	1680±10*	1690±10	219, 220

*Incongruent melting.

Melting-point data for the magnesium titanates, obtained in studies of the $MgO-TiO_2$ phase diagram, are given in Table 1 in chronological order. The incongruent melting of $2MgO \cdot TiO_2$ and $MgO \cdot TiO_2$ was recognised in all the work after 1956.

For Mg_2TiO_4 we reject the result of Ref. 250, which is clearly too high, and that of Ref. 214, which assumes congruent melting: unsatisfactory methods were used in these investigations, especially in the MgO-rich region. In both cases the phase diagram was constructed from measurements with an optical pyrometer, relying on visual observation of melting. The difficulty of visually determining the melting point further complicated the problem (common to all these investigations) caused by the partial reduction of TiO_2 in spite of the presence of an oxidising atmosphere. The precision of these measurements depends on the viscosity of the melt (which is very high in the presence of an excess of MgO), on the composition of the melt, on the presence of a eutectic or a compound, and also on the skill of the experimenter. We note that the melting of $MgTiO_3$ was not even detected in Ref. 250. The mean of the other three values given in Table 1, obtained by a quenching method and with a hot-stage microscope, is $T_f = 1750$°C, which can be taken as the recommended value (with an uncertainty of ±15 K) for the incongruent melting point of Mg_2TiO_4 (equilibrium solid phase MgO). We note that Circular 500,[9] quoting Ref. 250, gives 1835°C as the recommended value.

For $MgTiO_3$ we can average all the data in Table 1 (rejecting Ref. 214) and we obtain $T_f = 1660$°C, which we propose as the recommended value of the incongruent melting point with error limits of ±20 K. Simple averaging is used because there is no reason to assign greater statistical weight to any of the results. The composition of the liquid phase is not specified—the equilibrium solid phase is $2MgO{\cdot}TiO_2$. The JANAF tables[3] give $T_f = 1953 \pm 20$ K, but the value obtained in Ref. 214 is also mentioned. Because of the subsequent, careful work by the quenching method we cannot agree with the JANAF recommendation[3].

By averaging all the values in Table 1 for $MgO{\cdot}TiO_2$ we obtain $T_f = 1670$°C which we propose as the recommended value, with an uncertainty of ±20 K, which includes almost all the experimental values. Circular 500,[9] quoting Ref. 250, gives $T_f = 1680$°C, and the JANAF tables[3], quoting Refs. 215–217, give $T_f = 1690 \pm 20$°C. We prefer to average all the experimental results, for the reasons given above under $MgTiO_3$.

The enthalpies of melting of $MgTiO_3$ and $MgTi_2O_5$ are given[3] as 21.6 and 35 kcal mole^{-1} by analogy with data on sodium titanates and calcium titanate silicates. In the absence of direct experimental determinations we cannot accept these as recommended values. We note that premelting effects, arising from disordering of the solid phase at temperatures below the melting point, could have a significant influence on the true enthalpy of melting.

2. Calcium Titanates

Naylor and Cook[6] measured the high-temperature enthalpy of $CaTiO_3$ in a drop calorimeter for the temperature range 298–1794 K. A phase transformation, with a heat of 550 cal mole^{-1}, was detected at 1530 K. The following enthalpy values were obtained for α- and β-$CaTiO_3$ respectively: $H_T - H_{298} = 30.47T + 0.68 \times 10^{-3}T^2 + 6.690 \times 10^5/T - 11\,389$ cal mole^{-1} (298–1530 K, 0.6%) and $H_T - H_{298} = 32.03T - 11\,197$ cal mole^{-1} (1530 to 1800 K, 0.2%). We can accept the quoted[6] values $T_{tr} = 1530$ K and $\Delta H_{tr} = 0.550$ kcal mole^{-1} as recommended values, with error limits of ±5 K and ±0.010 kcal respectively. The entropy of the transformations, according to these data, is 0.36 e.u. These characteristics of the $CaTiO_3$ transition are quoted in Ref. 9, whereas Ref. 3 does not list any phase transformation in calcium titanates.

The results of the most important thermal investigations of the CaO–TiO_2 system are compared in Table 2; the dashes denote absence of data from certain laboratories on certain compositions. Explicit statements concerning the presence or absence of a particular compound are also listed in Table 2.

Work prior to 1954 was largely fragmentary, and aimed mainly at establishing the presence of various compounds and their formation during heat treatment[222–223,225–228], or at estimating the melting points of various titanates[221,224,225] by visual observations of drop formation during melting. Work reported since 1954 is more complex, including critical analyses of previously published data and attempts to explain or eliminate inconsistencies.

The first X-ray structural study of the whole of the $CaO{\cdot}TiO_2$ system[229] was reported in 1954. Other measurement techniques used in that work included the quenching method, visual observation of the melting of specially prepared pellets in an oxy-hydrogen flame, and differential thermal analysis (up to 1720°C) coupled with microstructural analysis of the samples. Only two compounds were identified: their melting points are given in Table 2. Similar results were obtained[230] by the cone softening method, the compositions being identified by X-ray diffraction. It was noted that the compound $3CaO{\cdot}2TiO_2$ does not readily form below 1500°C, which explains the failure to detect this compound in some investigations (e.g. Ref. 225). Some workers[229] interpreted the diffraction patterns of intermediate compositions by assuming dissolution of CaO in the solid titanates. Others[230] deny this hypothesis, and assign more complex diffraction patterns to the stoichiometric titanate.

*Incongruent melting, equilibrium solid phase $CaTiO_3$.
**The numbers denote: 1) visual observation, 2) heat treatment, 3) quenching method, 4) visual observation of drop formation, 5) observation of drop formation in a H_2–O_2 flame, 6) X-ray diffraction analysis, 7) petrological study, 8) hot stage microscopy.

More recently Roth[231] extended previous work[230] by analysing the diffraction patterns of mixtures[229] in this system and comparing them with data for the SrO–TiO_2 system. He concluded that an additional compound is formed, of composition $4CaO{\cdot}3TiO_2$, rather than solid solutions. Roth demonstrated the thermodynamic stability of this compound by special X-ray studies of samples annealed at, or quenched from, 1550–1745°C. Relative measurements of the melting points of $3CaO{\cdot}2TiO_2$ and $4CaO{\cdot}3TiO_2$ gave incongruent melting points of 1740 and 1755°C respectively. These results were confirmed by visual observations of melting in different atmospheres and by the quenching method. Roth used these results to correct previously published phase diagrams[229,230].

Imlach and Glasser[232], in their study of the CaO–TiO_2–Al_2O_3 phase diagram, re-checked the work of Roth[231] and concluded that the compound $4CaO{\cdot}3TiO_2$ does not exist. Their X-ray work showed that slightly different diffraction patterns are obtained by varying the heat treatment procedure, suggesting a definite homogeneity region for the compound $3CaO{\cdot}2TiO_2$. Their ternary phase diagram[232] uses values identical to those of Ref. 229 for the binary CaO–TiO_2 system.

Jongejan and Wilkins[233] published a critical analysis of the phase diagrams and the experimental methods previously reported[229-232], and they pointed out that liquidus temperatures cannot be accurately determined by the visual method because of the difficulty of discerning the disappearance of the last crystals, particularly since the dendritic CaO crystals tend to float in the melt. They constructed a phase diagram[233] from observations in a hot-stage microscope. In addition to the congruently melting $CaTiO_3$ they detected $4CaO\cdot3TiO_2$, which melts incongruently at 1870°C (equilibrium solid phase $CaTiO_3$). The possibility that this temperature could apply merely to a solid-state transformation of $CaTiO_3$ is admitted[233], but a specially detailed study of the liquidus line in the TiO_2-rich region confirmed the existence of the compound $4CaO\cdot3TiO_2$. The incongruently melting compound $3CaO\cdot2TiO_2$ was also assumed to be present, but the solidus line was not accurately studied in this region and a break in the liquidus line was not detected. The composition ordinate for this compound and the liquidus line in the same region are shown as broken lines in the phase diagram. These results[233] were confirmed in a later paper[234].

The existence of the compound $CaO\cdot TiO_2$ is indicated by all the data on the $CaO-TiO_2$ system listed in Table 2. Among the melting-point data for this compound those from Refs. 221 and 225 are clearly unacceptable; this is not surprising in view of the inaccurate methods used. By averaging the remaining values we obtain $T_f = 1957$°C. Our recommended value is rounded off to $T_f = 1960 \pm 30$°C, the suggested uncertainty including most of the experimental data and reflecting the low precision of work at these very high temperatures.

The reported[222] existence of the compound $2CaO\cdot3TiO_2$ should be treated as unconfirmed.

Information on the CaO-rich part of the $CaO-TiO_2$ phase diagram is even more complex and contradictory.

The compound $4CaO\cdot TiO_2$ was not detected in any of the investigations which included this composition. The titanates $2CaO\cdot TiO_2$ and $3CaO\cdot TiO_2$ are indicated in one phase diagram[224], but melting points are not quoted, and the values in Table 2 were simply read off the diagram. All the other workers (see Table 2) deny the existence of these titanates. We must conclude that it would be premature to attempt a recommendation on their melting points.

Most of the structural studies which have been reported point to the existence of the compound $3CaO\cdot2TiO_2$, melting incongruently at a well defined temperature[229-231]. The temperature reported[233] as the melting point of the eutectic with CaO (1740°C) may have been a misinterpretation of the incongruent melting of $3CaO\cdot2TiO_2$. Basing our choice on the work of Roth[231], who made a special comparative study of the melting points of the neighbouring compositions $4CaO\cdot3TiO_2$ and $3CaO\cdot2TiO_2$ by several methods, we propose $T_f = 1740 \pm 15$°C as the recommended value for the incongruent melting point of $3CaO\cdot2TiO_2$. The suggested error limits include the other reported values[229,230]. The equilibrium solid phase is taken to be $CaTiO_3$, as shown by the following arguments.

The existence of the compound $4CaO\cdot3TiO_2$, discussed in three publications, is more controversial. Some deny it[232] on the basis of a special X-ray study and of the results[229] of De Vries and coworkers. On the other hand Roth[231] convincingly proves its existence by combining the same results[229] with those of his own investigations. However the break in the liquidus line[233] cannot be ascribed unequivocally to incongruent melting of a compound of the same composition. Furthermore the incongruent melting point of $4CaO\cdot3TiO_2$ quoted in Ref. 233 differs by more than 100 K from that quoted in Ref. 231, even though the latter phase diagram[231] agrees in other respects with those of other workers. We should add that the liquidus line of Ref. 233 does not show a break for the compound $3CaO\cdot2TiO_2$, in direct contradiction to other reports[229-232]. The authors[233] also cannot explain the serious discrepancy in their melting point for the eutectic composition rich in CaO. Because of all these inconsistencies we must conclude that the proof[233] of the existence of the compound $4CaO\cdot3TiO_2$ is not entirely convincing. Equally, there are no grounds for accepting the results of Ref. 231 in preference to the more recent results of Ref. 232. We must therefore await more definite confirmation of the existence of the compound $4CaO\cdot3TiO_2$, and more precise measurements of its phase characteristics.

Borisenko and Shirokova[235] observed a polymorphic transition at 765°C in their study of the compound $3CaO\cdot2TiO_2$ by a complex thermal analysis method. The thermal effect was small, and no volume change was detected. A structural study by X-ray ionisation analysis at 700 and 800°C revealed only a small change in the degree of tetragonal distortion of the lattice in this temperature range. An alternative explanation of the reported effect is possible, based on kinetic arguments. For example, a slight dependence of crystal structure on heat treatment conditions has been noted[232]. This transition is not confirmed by any of the other investigations by X-ray diffraction or thermal anslysis, and therefore we cannot include the transition temperature quoted in Ref. 235 in our list of recommended values.

3. Strontium Titanates

$SrO\cdot TiO_2$. No solid-state transformations have been observed in the measurement[108] of the enthalpy change $H_T - H_{298}$ for $SrTiO_3$. In the region 298–1800 K the results are described by the expression[108] $H_T - H_{298} = 28.23T + 0.88 \times 10^{-3}T^2 + 4.66 \times 10^5/T - 10\,058$ (cal mole^{-1}). The melting point of $SrTiO_3$ has been measured only in one laboratory[236,237], using a combination of thermal, X-ray diffraction, and microscopic methods[237], and found to be $T_f = 2040 \pm 20$°C. This must be taken as the recommended value in preference to the estimated values 2100°C [109] and 1910°C.[238]

Sr_2TiO_4. The high-temperature specific heat of Sr_2TiO_4 also was measured[108] in the range 384–1831 K. Between 298 and 1800 K the experimental results are described with 0.4% precision by the expression $H_T - H_{298} = 38.45T + 1.92 \times 10^{-3}T^2 + 4.67 \times 10^5/T - 13\,201$ (cal mole^{-1}).

An earlier[236] phase diagram for the $SrO-TiO_2$ system shows a maximum in the liquidus curve corresponding to the composition Sr_2TiO_4 ($T_f = 1800 \pm 20$°C). A more detailed investigation by the same authors[237] produced a revised phase diagram for the $SrO-TiO_2$ system in the composition range 33–100 mole % TiO_2. The left-hand boundary of this diagram corresponds to Sr_2TiO_4, with $T_f = 1860 \pm 20$°C, but the authors[237] do not discuss the type of melting or the discrepancy with their previous result. A polymorphic $\alpha-\beta$ transformation with $T_{tr} = 1600 \pm 10$°C is also reported[237] for Sr_2TiO_4.

A microstructural study[238] of the $SrO-TiO_2$ system has confirmed the stability of Sr_2TiO_4 up to T_f. A sample quenched from 1860°C showed signs of melting and traces of SrO. A polymorphic transformation was observed between 1500 and 1550°C. The structure of the samples was studied after a first anneal at 1600°C and a second anneal at 1500°C for 75 h or at 1550°C for 10 h. The first sample had the low-temperature structure, the second had the high-temperature structure. This work achieved a closer approach to equilibrium than that of Ref. 237, in spite of the large temperature step. Hence we take $T_{tr} = 1525 \pm 20°C$ as the recommended value. We note a slight discrepancy with the high-temperature enthalpy measurements of Coughlin and Orr[108], who did not attempt to detect polymorphic transformations. Since our adopted T_{tr} value lies at the boundary of the temperature range covered in Ref. 108 it is not surprising that equilibrium was not achieved in that work. Alternatively, the transition could have been masked by the interpolation procedure used in the drop calorimeter technique.

The results of Refs. 237 and 238 for the melting point of Sr_2TiO_4 are satisfactorily consistent, but those of Ref. 236 are unconfirmed. Therefore we take $T_f = 1860 \pm 20°C$ as the recommended value.

$Sr_3Ti_2O_7$. Drys and Trzebiatowski[237] detected, in addition to strontium meta- and orthotitanate, the compound $Sr_3Ti_2O_7$, which decomposes into solid strontium meta- and orthotitanate at 1640 ± 10°C. The decomposition temperature was determined by X-ray diffraction analysis of samples annealed at 1630, 1640, 1650, and 1660°C. The first two samples consisted of $Sr_3Ti_2O_7$, the last two of a two-phase mixture of $SrTiO_3 + Sr_2TiO_4$. The existence of $Sr_3Ti_2O_7$ was confirmed by microstructural studies[238], but the decomposition temperature was found in the range 1550–1600°C. A sample heat treated at 1600°C and again annealed for 10 h at 1550°C contained only $Sr_3Ti_2O_7$, whereas a sample annealed at 1600°C showed the presence of metatitanate and of the high-temperature form of Sr_2TiO_4. The work of Ref. 238 was done under conditions more closely approaching equilibrium. We therefore accept these results, and we give $T_{tr} = 1580 \pm 20°C$ as the recommended value for the decomposition temperature of $Sr_3Ti_2O_7$ into $SrTiO_3$ and β-Sr_2TiO_4.

Sr_3TiO_5. Cocco and Massazza[238] found yet another compound in this system: $3SrO{\cdot}TiO_2$, stable in the region of 1560–1760°C. Thus, a sample annealed at 1550°C contained Sr_2TiO_4 and SrO, a sample annealed at 1600 or 1750°C contained only the phase Sr_3TiO_5, and a sample annealed at 1770°C again consisted of SrO and Sr_2TiO_4. The transformation temperatures quoted by the authors[238], T_{tr} = 1560 and 1760°C, are recommended with an uncertainty of ±20 K. We note that this region of compositions was not examined in Ref. 237.

4. Barium Titanates

$BaTiO_3$. The high-temperature enthalpy of $BaTiO_3$ was measured[108] in the range 400–1800 K: $H_T - H_{298} = 29.03T + 1.02 \times 10^{-3}T^2 + 4.58 \times 10^5/T - 10\,282$ cal mole^{-1} (0.3% precision).

The melting point of $BaTiO_3$ is generally agreed[180,183,239–243] to lie in the range 1610–1620°C. There is only one substantially different value: T_f = 1700°C, reported in Ref. 244 and quoted in Refs. 108 and 135. The shortcomings of the method[244] are discussed in Ref. 241. By averaging all the values except that of Ref. 244 we obtain the recommended value $T_f = 1616 \pm 5°C$.

The high-temperature transition of $BaTiO_3$ from the perovskite to the hexagonal structure has been studied by microscopic[180,183,239], thermal[180,183,239,240,243], X-ray diffraction[183,240,243], and kinetic methods[245]. The dependence of the transition temperature on impurity concentration and on heat-treatment atmosphere was investigated by Glaister and Kay[242]. With two exceptions[239,245], giving a transition temperature of 1450°C, all the other workers give T_{tr} = 1460°C. The discrepancy arises from the different temperature intervals chosen for the heat treatment experiments (50 K in Ref. 239). We recommend the value $T_{tr} = 1460 \pm 5°C$. It should be noted that a series of enthalpy measurements up to 1800 K [108] failed to reveal any thermal effect in the neighbourhood of T_{tr}.

$BaTi_2O_5$, $BaTi_3O_7$, $BaTi_4O_9$. The liquidus diagram of the $BaO–TiO_2$ system was first reported in 1951 by Statton[244], who used an optical pyrometer to study the melting of various compositions on a molybdenum strip in a vacuum. The diagram shows clear peaks for $BaTi_2O_5$ (1675°C), $BaTi_4O_9$ (1640°C), and also for $BaTiO_3$ and Ba_2TiO_4, but the graphical presentation is not accompanied by numerical tabulations. Corrections had to be applied for the interaction of BaO with Mo, which affected the results. All the compounds were identified by X-ray diffraction.

Trzebiatowski and coworkers[239] constructed the phase diagram of this system in the composition region 33 to 100 mole % TiO_2. They used visual and differential thermal analysis methods, combined with microscopic and X-ray studies of the quenched samples. They quote 1315 and 1465°C respectively for the congruent melting points of $BaTi_2O_5$ and $BaTi_4O_9$, but congruent melting is not clearly shown in their diagram. Furthermore the presence of the compound $BaTi_3O_7$ is suggested both by the liquidus curve in the region of ~75 mole % TiO_2 and by the diffraction pattern of this composition.

Rase and Roy[240] made a careful study of the phase composition of the $BaO–TiO_2$ system at high temperatures, and analysed the results of previous work in great detail. From their study of quenched samples, and their visual and thermographic observations of melting on a platinum strip, they obtained the phase diagram of the system and they established methods of preparing the compounds in polycrystalline or monocrystalline forms, as well as their stability conditions. The existence of $BaTi_2O_5$ and $BaTi_4O_9$ was confirmed, but these compounds were found to melt incongruently at 1322 and 1428°C respectively. The equilibrium solid phases are reported to be $BaTiO_3$ and TiO_2 respectively. The same workers[240] also convincingly identified the compound $BaTi_3O_7$, with T_f = 1357°C (equilibrium solid phase $BaTi_4O_9$). We take this as the recommended value, with error limits of ±10 K.

Shchepochkina[241] critically discussed the experimental shortcomings of Statton's work[244] and obtained more precise values of the phase transition temperatures in the $BaO–TiO_2$ system by a method relying on the softening of rod tips. For $BaTiO_3$ she obtained T_f = 1615°C, which is very close to our recommended value of 1616°C, and for the congruent melting of $BaTi_2O_5$ and $BaTi_4O_9$ she obtained 1385 and 1445°C respectively.

Judging by the general standard of the work, both in quality and in quantity, we accept the result of Rase and Roy[240], and we conclude that the melting of barium dititanate and tetratitanate is incongruent. Statton's results[244] are clearly inconsistent with later work, probably because of the serious compositional changes aggravated by the use of a vacuum and by the incongruent melting of the samples. Comparison of the T_f values for $BaTiO_3$, given as 1610°C in Ref. 239 and 1618°C in Ref. 240, with the recommended value of 1616°C suggest the possibility of a large systematic error in Ref. 239. We note that Statton obtained an unacceptable value (T_f = 1700°C) even for $BaTiO_3$. By averaging the results of Refs. 239, 241, and 240, but giving the latter a doubtful statistical weight, we arrive at the rounded-off temperatures 1340 ± 20 and 1440 ± 15°C for the incongruent melting of $BaTi_2O_5$ and $BaTi_4O_9$, which are recommended. The different uncertainty limits reflect the reproducibility of the two sets of results.

Ba_2TiO_4. The incongruent melting point of the orthotitanate in Statton's liquidus diagram[244] is 1692°C. T_f values of 1820, 1860, and 1880°C are obtained in Refs. 239, 240, and 241 respectively. The experimental details of the procedures used are discussed above. Rase and Roy[240] consider Ba_2TiO_4 to be too reactive towards platinum at its melting point for a reliable identification of the type of melting. The increase in the T_f value from Ref. 244 to Ref. 241 does not line up with the results of those same workers for $BaTiO_3$ and other titanates, and it is difficult to select any particular value as the preferred one, especially in view of the experimental difficulties and of the very high value of T_f. However Statton's value[244] is probably unacceptable. By averaging the other values, giving double weight to Rase and Roy's[240], we arrive at the recommended value T_f = 1855 ± 20°C.

The high-temperature enthalpy of Ba_2TiO_4 has been measured[108] in the range 398–1831 K by a drop calorimeter method. No solid-phase transitions were noted. The experimental results are described with a precision of 0.6% by the expression $H_T - H_{298} = 43.00T + 0.80 \times 10^{-3}T^2 + 6.96 \times 10^5/T - 15\,226$ (cal mole^{-1}).

5. Magnesium Zirconate

The existence of the compounds $MgO \cdot ZrO_2$ and $2MgO \cdot 3ZrO_2$ has been suggested by a structural study[263] of the $MgO-ZrO_2$ system. The liquidus line of the $MgO-ZrO_2$ system given in Ref. 254 on the basis of a visual thermal study differs from that of Ref. 263: the compound $2MgO \cdot 2ZrO_2$ is not found on the liquidus line, and the compound $MgZrO_3$ has a congruent melting point. The melting point is not quoted, but it can be estimated from the published diagram as T_f = 2130°C. Circular 500,[9] quoting Ref. 254, gives T_f = 2120°C. Von Wartenberg[250], referring to his previous work[254,264], gives T_f = 2150°C. We note that the melting of magnesium zirconate was not studied in Ref. 264.

All these values originate from the same laboratory. Our recommended value is obtained by averaging them: T_f = 2130 ± 20°C. The suggested uncertainty allows for the likely error in the various estimates.

6. Calcium Zirconates

$CaZrO_3$. The values reported by different authors for the congruent melting point of $CaZrO_3$ are in good agreement: 2350°C,[246,247] 2325°C,[248] and 2370°C.[249] We take their mean as the recommended value: T_f = 2350 ± 20°C.

The high-temperature enthalpy of $CaZrO_3$, measured[251] in a drop calorimeter, was found to be $H_T - H_{298} = 30.41T + 0.62 \times 10^{-3}T^2 - 3.46 \times 10^5/T - 10\,290$ cal mole^{-1} (0.8%) for the range 491–1066 K. No phase transformations were observed in this temperature region.

X-ray structural analysis[252] revealed two modifications of $CaZrO_3$: a low-temperature form, stable below 1200°C, and a high-temperature form, stable above 1250°C. The transition was found to be gradual[252], occurring in the range 1100–1250°C on heating and in the range 1100–900°C on cooling the sample. The authors conclude[252] from published data that the lattice parameter of this compound depends on the temperature at which the sample was synthesised. These results are semi-quantitative and cannot be used as a basis for a recommendation on this phase transformation.

$CaZr_4O_9$. Garvie[253] carried out an X-ray structural analysis of the $CaO-ZrO_2$ system along the 1305, 1400, 1500, 1600, 1700, and 1765°C isotherms in the region rich in CaO. The variation of lattice parameter with composition revealed a sharp boundary to the formation of cubic solid solutions of CaO in ZrO_2 at 20 mole % CaO, corresponding to the compound $CaZr_4O_9$. The change in lattice parameter of this composition at ~1650°C is interpreted by Garvie as a phase transition giving a different defect structure. The existence region of $CaZr_4O_9$ in the phase diagram lies above 1270°C: below this temperature the co-existing phases are ZrO_2 and $CaZrO_3$. The recommended temperatures for the equilibrium formation and for the phase transformation of $CaZr_4O_9$ are 1270 ± 30 and 1650 ± 30°C respectively.

7. Strontium Zirconates

$SrZrO_3$. The congruence of the melting of $SrZrO_3$ was shown in Ref. 254, but the authors found the melting point inaccessible and estimated it as above 2600°C.

Berezhnoi and Belik[255] quote T_f = 2750°C for $SrZrO_3$ without disclosing the method of measurement. The same value was obtained by Travers and Foex[249], who used a solar furnace to study the $SrO-ZrO_2$ phase diagram. Noguchi and coworkers[256] also used a solar furnace in their work on the liquidus curve of the $SrO-ZrO_2$ system, and obtained T_f = 2646 ± 20°C for $SrZrO_3$.

Both these phase diagrams[249,256] indicate congruent melting of the compound $SrZrO_3$. However the melting point given in Ref. 256 is inconsistent with those of Ref. 255 and with the independent measurements of Ref. 249, and therefore we take as our recommended value T_f = 2750 ± 20°C. We note that Carlsson's review[259] gives the melting point of $SrZrO_3$ as approximately 2800°C.

Berezhnoi and coworkers[260] calculated the enthalpy and entropy of melting of $SrZrO_3$ from the phase diagram of the $SrO-ZrO_2$ system: 16.7 kcal mole^{-1} and 5.5 e.u. We recommend their ΔH_f value with an uncertainty of ±2 kcal mole^{-1}. The corresponding value of the entropy of melting is ΔS_f = 5.52 e.u.

Carlsson[259] investigated the high-temperature solid-phase transitions of $SrZrO_3$. Differential thermal analysis at 550–950°C gave two endotherms corresponding to transitions at 730 and 860°C. These measurements are found to be poorly reproducible. The transition temperature is assumed to be the point at which the heating curve begins to deviate from its normal shape. The presence of different crystal structures at 600, 820, 1000, and 1200°C was confirmed by high-temperature X-ray diffraction. A rhombic modification was found to exist from room temperature up to 700°C, when it converts into a pseudo-tetragonal form with $c/a < 1$. Above 830°C another pseudo-tetragonal modification is formed, with $c/a < 1$, and at 1170°C the structure becomes cubic. Carlsson quotes the temperatures of the first two transitions, from DTA results, as 730 ± 25 and 860 ± 25°C, stressing the satisfactory agreement with the X-ray results. The temperature dependence of the lattice parameters was studied for the high-temperature transition with T_{tr} = 1170°C. The plot of dielectric constant against temperature has a peak at ~700 and 850°C. The transformation at 1170°C is thought to be either ferroelectric–paraelectric or antiferroelectric–paraelectric, the latter being the more likely. The temperature dependence of electrical resistance of $SrZrO_3$ has no anomaly at 1170°C, though the compound behaves as a semiconductor above 1000°C.

Peaks at 762, 846, and 1095°C have been reported[261] on the DTA curve of $SrZrO_3$ (the quoted temperatures corresponding to the peak maxima, unlike those of Carlsson[259]). The same reference shows breaks at 745, 1060 (very weak), and 1480°C in the temperature dependence of electrical resistance.

The T_{tr} value of the low-temperature transition[261] agrees well with Carlsson's value[259] in view of the different methods of identifying the transition point on the DTA curve. Therefore we choose T_{tr} = 730 ± 25°C as the recommended value. The two sets of data for the second transition are also in very good agreement: we choose T_{tr} = 860 ± 25°C. For the last transition we average the DTA value[261] and the value obtained[259] from the temperature dependence of the lattice parameters, and we obtain T_{tr} = 1135 ± 35°C as the recommended value.

Further confirmation is needed of the possible transition at 1480°C [261] suggested by the electrical resistance curve, because it occurs at the very limit of the temperature range of the experiment, and it has not so far been detected by any other method.

The high-temperature enthalpy of $SrZrO_3$ has been measured by drop calorimetry[284] at temperatures in the range 562–2318 K. The results are described with 0.3% precision by the expression $H_T - H_{298} = 147.072T - 2.077 \times 10^{-3}T^2 + 4.148 \times 10^6/T - 57\,277$ (J mole^{-1}). Other workers[285] used the same method in the range 298–1620 K and obtained the following expression (1% precision): $H_T - H_{298} = 29.79T + 0.70 \times 10^{-3}T^2 + 4.89 \times 10^5/T - 10\,584$ (cal mole^{-1}). Neither of these investigations detected the polymorphic transformations of $SrZrO_3$, obviously because of the rather large temperature step between the measurements (80–120°C). Furthermore the accuracy of these results is in doubt, the former[284] being higher than the latter[285] by 5.7–7.1% in the range 700–1600 K. We should also note that existing information on the polymorphic transformations of $SrZrO_3$ is completely ignored in both these publications[284,285].

Sr_2ZrO_4, $Sr_3Zr_2O_7$, $Sr_4Zr_3O_{10}$. Noguchi and coworkers[256] studied the liquidus diagram of the $SrO–ZrO_2$ system with a solar furnace. The phase composition of the samples was checked by chemical analysis and by X-ray diffraction after quenching. The evaporation rate of some of the samples was also measured. Three compounds were found in the system in addition to $SrZrO_3$: Sr_2ZrO_4, $Sr_3Zr_2O_7$, and $Sr_4Zr_3O_{10}$. The congruent melting points of Sr_2ZrO_4 and $Sr_4Zr_3O_{10}$ are given as 2325 and 2674°C respectively. We take the latter value as the recommended T_f for $Sr_4Zr_3O_{10}$, with an uncertainty of ±20 K.

Travers and Foex[249] also studied the $SrO-ZrO_2$ phase diagram by differential thermal analysis, using a solar furnace. Special attention was paid to the compound $SrZrO_3$. The compound $Sr_4Zr_3O_{10}$ is not shown on their phase diagram, and Sr_2ZrO_4 and $Sr_3Zr_2O_7$ are stated to melt incongruently. T_f = 2250°C is quoted for $Sr_3Zr_2O_7$, and the melting of Sr_2ZrO_4 is shown as a broken line on the diagram, from which we estimate T_f = 2220°C. It is stressed[249] that all the compounds were identified by X-ray diffraction.

Evidence on the type of melting of Sr_2ZrO_4 is contradictory[249,256], and therefore we cannot give a ruling on this problem. However the direct experimental determination[256] should be the more reliable. We therefore recommend, after rounding off, T_f = 2300 ± 30°C for the melting point of Sr_2ZrO_4.

The compound $Sr_3Zr_2O_7$ was first identified[262] after heating the corresponding mixture at 1700°C. Noguchi and coworkers[256] obtained the same diffraction pattern after a similar preparation. However a 2 hour anneal at 1800 and 1900°C followed by air quenching gave only the diffraction lines of $Sr_4Zr_3O_{10}$, with small amounts of $SrZrO_3$ and SrO. The stability region of $Sr_3Zr_2O_7$ therefore appears to extend only up to 1700°C.[256] This region is shown as a broken line in the phase diagram[256], $Sr_3Zr_2O_7$ decomposing into Sr_2ZrO_4 and $Sr_4Zr_3O_{10}$ at 1700°C. We note that this decomposition is not inconsistent with the incongruent melting of the composition $Sr_3Zr_2O_7$ observed[249] at 2250°C (equilibrium solid phase $SrZrO_3$), since those workers[249] did not observe the compound $Sr_4Zr_3O_{10}$. The stability of $Sr_3Zr_2O_7$ is not discussed[249], but it is pointed out that the diffraction pattern of a sample quenched from a melt of this composition does not contain lines of the compound $Sr_3Zr_2O_7$.

Since the tentative result of Ref. 256 appears to reconcile the inconsistency of the other data we take T_{tr} = 1700 ± 50°C as the recommended temperature for the decomposition of $Sr_3Zr_2O_7$ into $SrZrO_4$ and $Sr_4Zr_3O_{10}$.

8. Barium Zirconate

$BaZrO_3$. The congruent melting of $BaZrO_3$ has been demonstrated in a study[254] of the $BaO–ZrO_2$ system. From the published phase diagram[254] the melting point of $BaZrO_3$ is estimated as T_f = 2860°C. Circular 500,[9] referring to this work[254], gives T_f = 2700°C. By averaging these two estimates we arrive at the recommended value T_f = 2690 ± 20°C.

In 1976 Levitskii and coworkers[285] measured the high-temperature enthalpy of $BaZrO_3$ in the range 298–1606 K using a drop calorimeter. The normal temperature step of 80–120 K was decreased to 10–30 K in the region of the C_p anomaly. Temperatures of 758 ± 1 K and 1175 ± 1 K were obtained for the $\alpha \rightarrow \beta$ and $\beta \rightarrow \gamma$-$BaZrO_3$ polymorphic transformations. The experimental results are described by the expressions

Compound	Equation (cal mole^{-1})	Temperature, K
α-$BaZrO_3$	$H_T - H_{298} = 25.63\,T + 3.12 \cdot 10^{-3}T^2 + 2.82 \cdot 10^5/T - 8865$	298—758
β-$BaZrO_3$	$H_T - H_{298} = 27.77\,T + 0.09 \cdot 10^{-3}T^2 - 8272$	758—1175
γ-$BaZrO_3$	$H_T - H_{298} = 24.75\,T + 2.21 \cdot 10^{-3}T^2 - 7576$	1175—1606

Tentative values of the heats of these phase transitions, defined as the difference between the enthalpies of the two forms at $T = T_{tr}$, are quoted as $\Delta H_{758}(\alpha \rightarrow \beta) = 0$ and $\Delta H_{1175}(\beta \rightarrow \gamma) = 330$ cal mole^{-1}. The authors conclude[285] that the $\alpha \rightarrow \beta$ transformation is a phase transition of the second kind. We take the published[285] characteristics of these transitions as recommended values. The entropy of the $\beta \rightarrow \gamma$ transition is $\Delta S = 0.28$ cal mole^{-1} K^{-1}.

9. Strontium Hafnate

$SrHfO_3$. Berezhnoi and Belik[255] state that $SrHfO_3$ melts at 3163 K without mentioning the method of measurement. We take this as the recommended value, with an uncertainty of ±30 K.

Berezhnoi and coworkers[260] studied solid solutions of $SrZrO_3$ and $SrHfO_3$, and they calculated the heat and entropy of melting of $SrZrO_3$ from the phase diagram of the $SrO-ZrO_2$ system. They took $\Delta S_f = 5.5$ e.u. for the fusion of $SrHfO_3$ (equal to the value for $SrZrO_3$). Using their previous value[255] of T_f they calculated $\Delta H_f = 17.5$ kcal mole^{-1} for $SrHfO_3$. Assuming an error of ±1 e.u. in the estimate of ΔS_f we obtain an uncertainty of ±3 kcal mole^{-1} for ΔH_f. We propose these as the recommended values for ΔH_f, and 5.53 e.u. for the entropy of melting.

The high-temperature enthalpy of $SrHfO_3$ in the temperature range 675–2337 K was measured by Fomichev and coworkers[284] at 100 K intervals by the drop calorimetric method. Their results are described by the expression $H_T - H_{298} = 109.509T + 13.266 \times 10^{-3}T^2 - 1.260 \times 10^6/T - 27516$ (J mole^{-1}). No polymorphic transformations were observed in this work.

IV. ENTHALPY AND FREE ENERGY OF FORMATION

Kelley and coworkers[265] measured the enthalpy of formation of these compounds in a solution calorimeter (73.7°C, mixture of hydrochloric and hydrofluoric acid). Samples of mechanical mixtures of the oxides and of the compounds, contained in gelatin capsules, were introduced into the calorimeter at an initial temperature of 25°C. The heat of formation of the compound from its oxides at 25°C was obtained from the difference between the thermal effects accompanying the dissolution of the two samples. The thermochemical cycle for the hypothetical compound $MO \cdot TiO_2$, where M is an alkaline earth metal, is illustrated by the scheme

TiO_2 (cr.; 25°) + 4 H^+ (sol.; 73,7°) $\rightarrow$ Ti^{4+} (sol.; 73,7°) + $2H_2O$ (sol.; 73,7°) (ΔH_1)
MO (cr., 25°) + $2H^+$ (sol; 73,7°) $\rightarrow$ M^{2+} (sol.; 73,7°) + $2H_2O$ (sol.; 73,7°) (ΔH_2)
$MO \cdot TiO_2$ (cr., 25°) + $6H^+$ (sol.; 73,7°) $\rightarrow$ M^{2+} (sol.; 73,7°) + Ti^{4+} (sol.; 73,7°) + $3H_2O$ (sol.; 73,7°) (ΔH_3).

The heat of formation of $MO \cdot TiO_2$ from the oxides at 25°C is $\Delta H = \Delta H_1 + \Delta H_2 - \Delta H_3$. The composition of the acid mixture was 10.05 wt.% HCl + 10.05 wt.% HF. The experimental results were corrected for the heat of dissolution of the capsule in the acid. The error of the measurement of the heat of formation of the compound from the oxides was 0.3–0.5 kcal mole^{-1}.

Feodos'ev and coworkers used the method of combustion in a bomb calorimeter under standard conditions. A mixture of the alkaline earth carbonate MCO_3 and of the dioxide M_1O_2 (where M_1 = Ti, Zr, Hf) was pelleted with powdered graphite, used as an initiator in the proportion of 1 : 5. The reaction was

$$MCO_3 + M_1O_2 = MM_1O_3 + CO_2.$$

The heat of formation of MM_1O_3 from the elements was calculated by using the known heats of formation of the carbonates and of the oxides. The experimental results were corrected for the heat of formation of the nitric acid found among the combustion products, which were tested for completeness of the reaction and examined by X-ray diffraction. The unburned graphite was determined calorimetrically. The results for the titanates were in good agreement with those of Kelley and coworkers. The error of the measurements of heat of combustion was 0.3 to 0.8 kcal.

The original calorimetric results have been recalculated in this review by using the heats of formation of the oxides, carbonates, and CO_2 previously chosen during the compilation of Ref. 2.

1. Magnesium Titanates

$MgTiO_3$. Kelley and coworkers[265] obtained $\Delta H = -6.35 \pm 0.25$ kcal by solution calorimetry for the heat of formation of $MgTiO_3$ from MgO and TiO_2. Panfilov and Feodos'ev[266] measured in a bomb calorimeter the heat of combustion of air-dry MgO and TiO_2 mixed with graphite:

$$MgO \cdot x\,H_2O \cdot y\,CO_2 + TiO_2 = MgTiO_3 + x\,H_2O + y\,CO_2$$

and also the heat of combustion of MgO mixed with graphite:

$$MgO \cdot x\,H_2O \cdot y\,CO_2 = MgO + x\,H_2O + y\,CO_2.$$

Chemical and phase analyses of the combustion products were carried out[266]: the TiO_2 was determined as the insoluble residue after two extractions in boiling hydrochloric acid (1 h). The molar amounts of MgO and TiO_2 entering into the reaction were equal. $\Delta H = -5.5 \pm 0.1$ kcal was found[266] for the heat of formation of $MgTiO_3$ from the oxides. The discrepancy between the two results[265,266] exceeds the quoted experimental errors. In our choice of a recommended value we gave preference to Kelley's results[265], because they were obtained with a very pure sample of MgO (99.8%) containing small amounts of CaO, SiO_2, Fe_2O_3, and alkaline earths. The composition of the magnesium oxide used in Ref. 266 is more indeterminate. Using $\Delta H_f(MgO) = -143.76$ and $\Delta H_f(TiO_2$, rutile$) = -225.59$ kcal mole^{-1} we obtain $\Delta H_f(MgTiO_3) = -375.7$ kcal mole^{-1} from Kelley's result[265]. By combining this value with recommended entropy data we arrive at $\Delta G_f = -354.6$ kcal mole^{-1}. The error in ΔH_f and ΔG_f is less than 0.3 kcal mole^{-1}.

Mg_2TiO_4. The heat of formation of magnesium orthotitanate (spinel) from the oxides is given[265] as $\Delta H = -4.1 \pm 0.25$ kcal mole^{-1}. Using the heats of formation of the oxides assumed above we obtain $\Delta H_f = -517.2$ and $\Delta G_f = -493.8$ kcal mole^{-1} for Mg_2TiO_4, with an uncertainty not exceeding 0.5 kcal mole^{-1}.

$MgTi_2O_5$. Kelley[265] obtained $\Delta H = -4.45 \pm 0.25$ kcal mole^{-1} for the formation of the dititanate from the oxides. From this value we calculate $\Delta H_f = -599.2$ and $\Delta G_f = -566.2$ kcal mole^{-1} for $MgTi_2O_5$ by using the value $S(MgTi_2O_5) = 34.19$ e.u., or $\Delta G_f = -565.7$ kcal mole^{-1} by using the value $S(MgTi_2O_5) = 32.4$ e.u. (see Chapter II). The uncertainty in ΔH_f and ΔG_f is less than 0.7 kcal mole^{-1}.

2. Calcium Titanates

$CaTiO_3$. Kelley and coworkers[265] obtained $\Delta H = -19.35 \pm 0.25$ kcal for the reaction $CaO + TiO_2$(rutile) = $CaTiO_3$(perovskite). Panfilov and Feodos'ev[266] found $\Delta H = 22.5 \pm 0.2$ kcal for $CaCO_3 + TiO_2$(rutile) = $CaTiO_3 + CO_2$. The extent of the combustion reaction was 99%. Calculation from Kelley's result gives $\Delta H_f(CaTiO_3$, perovskite$) = -396.7$ kcal mole^{-1}, whereas from Ref. 266 we obtain $\Delta H_f = -397.6$ kcal mole^{-1}. The uncertainty of both values is ~0.5 kcal mole^{-1}. The value obtained by solution calorimetry is the more reliable because the reaction was quantitative, and we choose it as the recommended value. By combining this with entropy data we obtain $\Delta G_f = -376.3$ kcal mole^{-1}.

$\Delta G_f(CaTiO_3)$ data have been obtained by the e.m.f. method with a solid electrolyte. The e.m.f. of the cell O_2, Pt | CaO ‖ CaF_2 ‖ $CaTiO_3$, TiO_2 | Pt, O_2 has been measured[267] at 873 K. From the result we calculate $\Delta G_{298} = -19.11$ kcal for the potential-determining reaction $CaO + TiO_2 = CaTiO_3$, and $\Delta H = -18.86$ kcal, which gives $\Delta H_{f,298} = -396.2$ kcal mole^{-1}. E.m.f. measurements are reported also[268] for the galvanic cell Pt, $CaTiO_3$, CaO, $TiO_{0.5}$ ‖ $ThO_2 + La_2O_3$ ‖ M, MO, Pt, where M = Fe or Nb, in the range 1180–1290 K. From the results the authors calculated $\Delta H_f(CaTiO_3) = -398$ kcal mole^{-1} for the reaction $0.667CaO + 0.667TiO_{0.5} + MO = 0.667CaTiO_3 + M$ by using published values of the thermodynamic functions. This value is probably inaccurate because many data, covering a wide range of temperature, were used in the calculation.

Ca_2TiO_4. The functions ΔH_f and $S(Ca_2TiO_4)$ have been evaluated by the comparative calculation method[286]. The data used for the calculation are mutually inconsistent, and the work is of doubtful value.

$Ca_3Ti_2O_7$. Measurements[269] of the heat of dissolution of a mixture of oxides and of $Ca_3Ti_2O_7$ have given $\Delta H_f(Ca_3.Ti_2O_7) = -943.8$ kcal mole^{-1}. By using the chosen value of $S_{298}(Ca_3Ti_2O_7)$ we obtain $\Delta G_{f,298} = -896.1$ kcal mole^{-1}. The error in ΔH and ΔG is less than 1 kcal.

3. Strontium Titanates

We have previously reviewed[274] the thermodynamic properties of $SrTiO_3$, and chosen the values $\Delta H_{f,298} = -402.2$ kcal mole^{-1} and $\Delta G_{f,298} = -382.3$ kcal mole^{-1}, with an uncertainty not greater than 0.5 kcal mole^{-1}.

Sr_2TiO_4. Kelley[265] obtained -37.85 ± 0.25 kcal for $\Delta H_f(Sr_2TiO_4)$ from the oxides, which gives $\Delta H_{f,298}(Sr_2.TiO_4) = -552.2$ kcal mole^{-1}. Using $S_{298} = 38.0$ e.u. we arrive at $\Delta G_{f,298} = -524.6$ kcal mole^{-1}. The error in ΔH and ΔG is less than 2 kcal mole^{-1}.

4. Barium Titanates

The thermodynamic properties of $BaTiO_3$ have already been reviewed[274]. The values $\Delta H_{f,298} = -395.2$ kcal mole^{-1} and $\Delta G_{f,298} = -374.3$ kcal mole^{-1} were recommended, with an error of less than 0.5 kcal mole^{-1}.

Ba_2TiO_4. Kelley's value[265] of the heat of formation from the oxides is $\Delta H = -45.7 \pm 0.3$ kcal. Using the accepted values of ΔH_f for BaO and TiO_2 gives $\Delta H_{f,298}(Ba_2.TiO_4) = -533.3$ kcal mole^{-1} and $\Delta G_{f,298} = -507.0$ kcal mole^{-1}. The error is less than 2 kcal mole^{-1}.

$0.543BaTiO_3 \cdot 0.457SrTiO_3$. The same reference[265] gives $\Delta H_{f,298} = -397.9$ kcal mole^{-1} for this solid solution. Using the S_{298} value recommended here leads to $\Delta G_{f,298} = -377.7$ kcal mole^{-1}; the error of ΔH and ΔG is less than 2 kcal mole^{-1}.

$BaSrTiO_4$. The value -540.2 kcal mole^{-1} is recommended[265] for $\Delta H_{f,298}(BaSrTiO_4)$ from the elements. With the S_{298} value recommended here we obtain $\Delta G_{f,298} = -514.2$ kcal mole^{-1}, with an error not greater than 2 kcal mole^{-1}.

5. Calcium Zirconate

The function $\Delta H_f(CaZrO_3)$ has been determined[270] from the heat of combustion of a pelleted mixture of $CaCO_3$, ZrO_2, and graphite. An enthalpy change of $\Delta H = 35.2 \pm 0.2$ kcal was obtained for the reaction $CaCO_3 + ZrO_2 = CaZrO_3 + CO_2$, which took place in 85% yield. By combining this result with $\Delta H_f(CaCO_3) = -288.46$ kcal mole^{-1}, $\Delta H_f(CO_2) = -94.05$ kcal mole^{-1}, and $\Delta H_f(ZrO_2) = -263.04$ kcal mole^{-1} the value $\Delta H_f(CaZrO_3) = -422.3$ kcal mole^{-1} was obtained. The uncertainty, due mainly to the failure of the calorimetric reaction to go to completion, is less than 2 kcal mole^{-1}.

The heat of combustion of a mixture of CaO + Zr in a bomb under an oxygen pressure of 25 atm has been measured[287]. The value $\Delta H_f(CaZrO_3) = -400.3$ kcal mole^{-1} was obtained[287], and good agreement with the result of Ref. 270 (−398 kcal mole^{-1}) was claimed. However the value − 398 kcal mole^{-1} quoted in Ref. 270 is not ΔH_f but $\Delta G_f(CaZrO_3)$, and therefore the claim is groundless.

6. Strontium Zirconate

The function $\Delta H_f(SrZrO_3)$ has been determined[270] from the combustion of a mixture of $SrCO_3$, ZrO_2, and graphite (95% yield). The heat of this reaction was found to be $\Delta H = 38.2 \pm 0.2$ kcal. Using the value $\Delta H_{f,298}(SrCO_3) = -294.5$ kcal mole^{-1}, the standard enthalpy $\Delta H_{f,298}(SrZrO_3) = -425.3$ kcal mole^{-1} was calculated. Khekimov and coworkers[271] measured the e.m.f. of the galvanic cell O_2, Pt | SrO, SrF_2 ‖ CaF_2 ‖ $SrZrO_3$, ZrO_2, SrF_2 | Pt, O_2, in which the potential-determining reaction is $SrO + ZrO_2 = SrZrO_3$, in the temperature range 1180–1370 K. The heat of formation of $SrZrO_3$ from the oxides was calculated as $\Delta H = -18.6 \pm 1.5$ kcal, corresponding to $\Delta H_f(SrZrO_3) = -426$ kcal mole^{-1} (from the elements), in good agreement with the thermochemical value. However the thermodynamic functions of $SrZrO_3$ used in this calculation[271] were not the experimental values but estimated values, taken to be equal to the corresponding functions for $SrTiO_3$. Hence we shall ignore this result in choosing the recommended value of $\Delta H_f(SrZrO_3)$, and we give $\Delta H_{f,298} = -425.3$ kcal mole^{-1} and $\Delta G_{f,298} = -405.0$ kcal mole^{-1} for $SrZrO_3$, with an uncertainty of less than 1 kcal.

7. Barium Zirconate

The heat of the reaction $BaCO_3 + ZrO_2 = BaZrO_3 + CO_2$ has been measured[273] under the same conditions as the heat of combustion of $SrCO_3$. The result, combined with the accepted ΔH_f and entropy values of the oxides, leads to $\Delta H_{f,298} = -425.3 \pm 2$ kcal mole^{-1} and $\Delta G_{f,298} = -405.0 \pm 2$ kcal mole^{-1}. The heats of the reactions $Ba_3Al_2O_6 + 2ZrO_2 = BaAl_2O_4 + 2BaZrO_3$ and $ZrO_2 + BaF_2 + CaO = BaZrO_3 + CaF_2$ have been measured[288] by the e.m.f. method at 980–1120 K with a fluoride ion electrolyte. The calculated value[288] $\Delta H_f(BaZrO_3) = -423.4 \pm 2.6$ kcal mole^{-1} agrees very well with the thermochemical value.

The heats of formation of $CaHfO_3$ and $SrHfO_3$ have not been measured. Estimated values[289] of $\Delta H f$ for the hafnates, calculated by the equation $\Delta H_f(MHfO_3) = 1.001\ \Delta H_f(MSiO_3) - 34.2$ (kcal $mole^{-1}$), agree within 1% with the experimental value[272] in the case of $BaHfO_3$.

8. Barium Hafnate

The measured[272] heat of combustion of a mixture of $BaCO_3$, HfO_2, and graphite gave $\Delta H = 32.3 \pm 0.8$ kcal for the reaction $BaCO_3 + HfO_2 = BaHfO_3 + CO_2$ (97% yield). BaO was not detected among the reaction products, showing that $BaCO_3$ is stable under the conditions of the calorimetric experiment. The enthalpy $\Delta Hf_{,298}(BaHfO_3) = -431.5$ kcal $mole^{-1}$ is calculated from the result[272]. Taking $\Delta S_f(BaZrO_3) \simeq \Delta S_f(BaHfO_3) = -68$ e.u. for the formation from the elements we calculate $\Delta Gf_{,298}(BaHfO_3) = -411$ kcal $mole^{-1}$. The uncertainty of ΔH and ΔG is less than 2 kcal $mole^{-1}$.

The thermodynamic constants chosen in this review are summarised in Table 3.

Table 3. Recommended values of $\Delta H_{f,298}$, $\Delta G_{f,298}$, $H_{298} - H_0$, S_{298}, and $C_{p,298}$ for the alkaline-earth titanates, zirconates, and hafnates.

V. DISCUSSION OF THE THERMODYNAMIC CHARACTERISTICS OF PEROVSKITES

The great majority of the compounds discussed here have the perovskite ABO_3 structure, where A is an alkaline earth element, and B is an element of the titanium subgroup. $MgTiO_3$ alone belongs to another structure type: ilmenite. All the other metatitanates are perovskites. According to Goldschmidt the transition from one structure to the other is determined by the tolerance factor $t = [R(A) + R(O)]\sqrt{2}[R(B) + R(O)]$, where $R(A)$, $R(B)$, and $R(O)$ are the ionic radii of the elements and of oxygen. Within the perovskite structure two types of co-ordination of the oxygen polyhedra are possible: the icosahedron, with a co-ordination number (c.n.) of 12, and the octahedron, with a c.n. of 6. The large ion of the alkaline earth element is surrounded by an icosahedron, the B^{4+} ion by an octahedron. The perovskite structure is stable for $0.8 < t < 1.0$, and for $t = 1$ it becomes ideal, with the closest contact between the A and B ions and the oxygen ions. For other values of t the ideal structure becomes distorted. The ilmenite structure, stable for $t < 0.8$, is characterised by an octahedral co-ordination of the O^{2-} ions around the cations. The case of $t < 1$ corresponds to free permutation of the type A cations in the co-ordination polyhedron, and the case of $t > 1$ corresponds to free permutation of the type B cations[277].

We shall examine the thermodynamics of the formation of an icosahedron (c.n. 12) around a large cation. There are compounds of the ABO_3 type which can exist in both polymorphic modifications (ilmenite and perovskite): for example, $CdTiO_3$. The energy relationships which determine the metal–oxygen bond in the octahedron and the icosahedron can be formulated. According to both theoretical and experimental crystal chemistry, compounds of a given type tend to have a definite metal–oxygen distance which is constant for a given c.n. It may be possible to calculate the energetics of the co-ordination polyhedra by using the heat of atomisation ΔH_a of the oxides $(MO_i)_c$ for the cases c.n. = 6 and c.n. = 12.

By definition, $\Delta H_a[(MO_i)_c] = \Delta H_a(M) + i/2D(O_2) - \Delta H_f[(MO_i)_c]$, where $\Delta H_a(M)$ is the heat of sublimation of the metal, $D(O_2)$ is the dissociation energy of O_2, and $\Delta H_f[(MO_i)_c]$ is the heat of formation of the oxide MO_i with a co-ordination number of 6 or 12. Consider the ratio $E_c = \Delta H_a[(MO_i)_c]/k$, where k is the co-ordination number, which characterises the energy of a single bond in the co-ordination polyhedron, and the quantity $A_c = E_c/R_c$, where R_c is the characteristic M–O distance in this polyhedron. It is convenient to express the thermochemical quantities in kcal, and the distances in Å. Characteristic distances are systematically reviewed in Ref. 275, and the thermochemical quantities are given in this review and in Ref. 2. In the oxides MgO, CaO, SrO, BaO, and CdO the cations under standard conditions are in an octahedral co-ordination of O^{2-} ions, with a c.n. of 6. In TiO_2(rutile) the Ti^{4+} ion also has a co-ordination number of 6, but Zr^{4+} and Hf^{4+} in their MO_2 compounds[276] have the very rare c.n. 7. When metatitanates are formed from the oxides the c.n. of M^{2+} can change, but the co-ordination polyhedron of Ti remains the same. When metazirconates and metahafnates are formed the oxygen polyhedra of both cations can change.

According to the published thermochemical data for Mg, Mn, Fe, Co, Ni, and Cd titanates the heat of formation of the ilmenites from their oxides is almost constant: $\Delta \overline{H} = -6 \pm 0.8$ kcal. In the case of $CdTiO_3$ we know ΔH_f for both the perovskite and the ilmenite modification: perovskite is the less stable by 3.6 kcal. The following thermochemical cycle can be used to evaluate the preference energy of the ion for the icosahedral co-ordination:

$$\begin{array}{l} (CdO)_{[6]} + TiO_2 = Cd_{[6]}TiO_3 - 6.6\ \text{kcal (ilmenite)} \\ (CdO)_{[6]} + TiO_2 = Cd_{[12]}TiO_3 - 3.0\ \text{kcal (perovskite)} \\ \hline (CdO)_{[6]}TiO_3 = (CdO)_{[12]}TiO_3 + 3.6\ \text{kcal} \end{array}$$

The subscripts [6] and [12] denote the c.n. of the Cd^{2+} ion. To this approximation the preference energy of Cd^{2+} for the icosahedral co-ordination is 3.6 kcal g-ion^{-1}.

The preference energy of the other ions can be estimated by assuming a ΔH_f of -6 kcal $mole^{-1}$ for the formation of the hypothetical ilmenite $ATiO_3$ from the oxides without change in the c.n. of the A ion, i.e. by taking the average of the heats of formation of the known ilmenites. With this assumption the preference energy of the ions for the icosahedral co-ordination of the perovskites is given by the expression $\epsilon = \Delta H_f + 6$ (kcal), where ΔH_f is the heat of formation from the oxides in the standard state. By using the ΔH_f values for the oxides and the titanates we obtain the following preference energies ϵ for some doubly charged cations:

Cation	Ca^{2+}	Sr^{2+}	Ba^{2+}	Cd^{2+}
ϵ, kcal g-ion^{-1}	—13.3	—26.4	—32.6	+3.6

From these ϵ values we can calculate $\Delta H_a(MO)_{12}$ in the hypothetical co-ordination with a c.n. of 12, and hence we can evaluate the quantity E_{12} which characterises the energy of a single M–O bond in the icosahedron and compare it with E_6 for the oxide in the standard state (Table 4).

Table 4. Heats of atomisation and energies of a single M–O bond in the octahedron and the icosahedron.

Cation in $MTiO_3$	ΔH_a $(MO)_6$ kcal mole^{-1}	ΔH_a $(MO)_{12}$, kcal mole^{-1}	E_6, kcal mole^{-1}	E_{12}, kcal mole^{-1}	A_6/A_{12}	R_{12}/R_6
Ca^{2+}	253.9	267.2	42.32	22.27	2.177	1.146
Sr^{2+}	243.0	269.4	40.50	22.45	1 997	1.107
Ba^{2+}	234.3	266.9	39.05	22.24	1.909	1.087

The transition of the alkaline-earth ion to the icosahedral configuration produces a remarkable levelling of the single-bond energy: the mean value is 22.32 ± 0.09 kcal per bond, i.e. within ±0.4%, as compared with a spread of 8% in the E_6 values.

The formation of Ca, Sr, and Ba metazirconates and metahafnates produces a change in the c.n. of both cations, and the heats of formation from the oxides are much lower than those for the corresponding titanates. This is evidently due to the expenditure of energy in transferring the Zr^{4+} and Hf^{4+} ions from polyhedra with a c.n. of 7 in the oxides to octahedra in the perovskites. Assuming a constant preference energy for the Ca^{2+}, Sr^{2+}, and Ba^{2+} ions to the icosahedral co-ordination from the original octahedra we can determine the energy of the transition of Zr^{4+} and Hf^{4+} to the octahedral co-ordination from the configuration with a c.n. of 7, which is characteristic of their dioxides. We assume that the heats of formation of the zirconates and hafnates from AO and the hypothetical oxide MO_2 with a c.n. of 6 are equal to the ΔH_f value of the corresponding titanates, which are formed without change in the c.n. of the B^{4+} ion. For $CaZrO_3$ (for example) we arrive at the following thermochemical cycle:

$$CaO + (ZrO_2)_{[6]} = CaZr_{[6]}O_3 \quad -19.3 \text{ kcal}$$

$$CaO + (ZrO_2)_{[7]} = CaZr_{[6]}O_3 \quad -7.5 \text{ kcal}$$

$$(ZrO_2)_{[7]} = (ZrO_2)_{[6]} \quad +11.8 \text{ kcal}$$

A similar calculation gives the energies of the transitions of the Zr^{4+} and Hf^{4+} ions in other compounds:

Cation in perovskite	Ca^{2+}	Sr^{2+}	Ba^{2+}
$\epsilon(Zr^{4+})$, kcal g-ion^{-1}	11.8	14.8	7.3
$\epsilon(Hf^{4+})$, kcal g-ion^{-1}	11.7	13.7	5.2

In spite of the significant difference between the $\epsilon(B^{4+})$ values, which is not surprising in view of the approximations made in the calculation, we think it legitimate to average these values, which gives $\epsilon(Zr^{4+}) = 11$ kcal g-ion^{-1} and $\epsilon(Hf^{4+}) = 10$ kcal g-ion^{-1} with a possible error of ±3 kcal g-ion^{-1}.

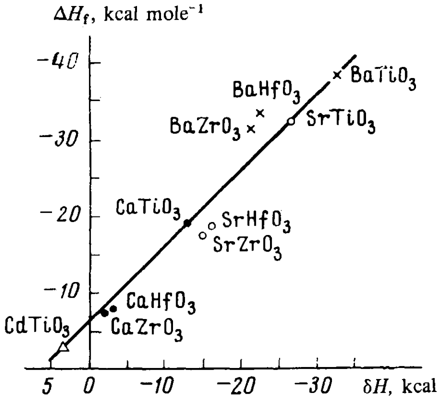

Figure 1. Heat of formation of perovskites from the oxides (ΔH_f) against energy of cation transitions (δH).

Table 5. Thermochemical and crystal chemical properties of perovskites.

Perovskite	ΔH_f, kcal mole^{-1}	ΔS_f, e.u.	t	Perovskite	ΔH_f, kcal mole^{-1}	ΔS_f, e.u.	t
	from the oxides				from the oxides		
$CaTiO_3$	—19.3	1.25	0.968	$SrHfO_3$	—18.7	—	0.938
$CaZrO_3$	—7.5	2.76	0.917	$BaTiO_3$	—38.6	—3.47	1.056
$CaHfO_3$	—7.7	—	0.922	$BaZrO_3$	—31.3	0.52	1.001
$SrTiO_3$	—32.4	0.72	0.985	$BaHfO_3$	—33.4	—	1.006
$SrZrO_3$	—17.6	2.21	0.934	$CdTiO_3$	3.6	1.75	0.954

Thus we may conclude that the heat of formation of the perovskite ABO_3 from the oxides depends on the energy of the cation transitions resulting from the change in the co-ordination of the oxygen ions surrounding the metal cation. The linear variation of ΔH_f with the quantity δ (the sum of the energies of the cation transitions accompanying the formation of the perovskite) is illustrated in Fig. 1.

In addition to the enthalpy of formation from the oxides, the entropy change is another important thermodynamic parameter of perovskites. ΔH_f, ΔS_f, and t values for a number of compounds are listed in Table 5. In most cases $t < 1$, denoting free ordering of the large cations in the icosahedra. The titanates should be treated separately from the zirconates, because there is no change in the c.n. of Ti (see Fig. 2). On going from $CaTiO_3$ ($t < 1$) to $BaTiO_3$ ($t < 1$) the ΔS_f value for the formation from the oxides changes sign and becomes negative. The tendency for the entropy of formation from the oxides to fall is found also in the zirconate group from $CaZrO_3$ to $BaZrO_3$. The stiffness of the M–O bond in the icosahedra increases as we approach the $t > 1$ region. This leads to greater ordering and to limited freedom of motion of large cation in the icosahedron, i.e. to a smaller entropy of formation from the oxides. In Ca, Sr, and Ba zirconates the freedom of the large cation increases from Ba to Ca, and the ΔS_f value increases in the same order. Although the entropy of the metahafnates of these elements has not been determined experimentally we can expect a similar behaviour. We should stress that the value of the tolerance factor t is strongly dependent on the choice of the system of ionic radii. We have chosen the system of Shannon and Prewitt[275], which is the most detailed and takes into account the spin state of the ion as well as the state of oxidation and the co-ordination number.

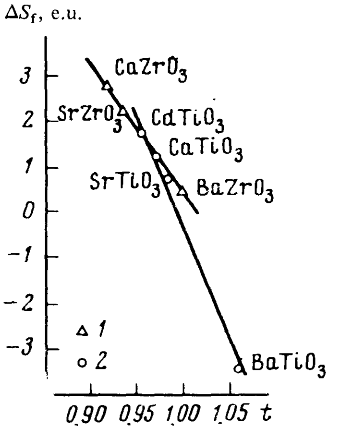

Figure 2. Entropy of formation of perovskites from the oxides (ΔS_f) against tolerance factor for (*1*) titanates and (*2*) zirconates.

Molecular-kinetic Aspects of the Chemical Physics of the Condensed State

A.I.Burshtein

Modern ideas on the elementary chemical step in condensed media are described in relation to reactions involving the transfer of energy, charge, a proton, and valence. It is emphasised that the rates of the above processes in solids and liquids are as a rule limited by the deficiency of free space and not of energy. Local fluctuations in entropy (the packing of the species), enabling the reactants to come into contact with one another in the correct coordination, assume particular importance because of this. The process is controlled either by the equilibrium density of such fluctuations or by the frequency of their generation, which is limited by molecular mobility.

The bibliography includes 81 references.

I. INTRODUCTION

The theory of the elementary chemical transformation in liquid and solid media is in an incomparably less satisfactory state than the theory of the elementary step in the gas phase. This is associated primarily with the fact that the mutual approach of the reacting species in the gas phase is described by the laws of mechanics, while in a dense medium their encounters take place in the course of random migrations in the solvent, i.e. are stochastic. However, the difference is not restricted to a difference in the kinematics of the encounters. Contact with the medium during the elementary step eliminates the energetic limitations which exist in the gas phase, but gives rise to steric hindrance in the reaction pathway associated with a deficiency of the free space required for the organisation of the reaction. Reaction rates in the condensed phase are frequently limited precisely by the amount of space liberated as a result of packing (entropy) fluctuations in the buffer environment surrounding the reacting species, and not in any way by the necessity to overcome energy barriers; the latter are known *a priori* to be not unduly high at a low temperature. Furthermore, when the ideas of gas-phase kinetics are formally applied to the condensed phase, the experimental activation energies are as a rule associated with definite energy barriers, even when they reach 3–4 eV, despite its being quite evident that barriers with this height are quite impossible to overcome. The causes of the very marked temperature dependence of the reaction rate constant should be sought not in the energetics of the elementary step, but in the type of molecular motion in the low-temperature condensed phase (diffusion, rotational mobility, viscous flow).

We shall consider initially the kinematic aspect of the problem and then the entropy-energetic aspect.

II. THEORY OF ENCOUNTERS

The rate constant for a bimolecular reaction occurring when the reacting species moving in a dense viscous medium encounter one another is defined by the expression

$$k = 4\pi R_e D, \tag{1}$$

where $R_e = R_e(D)$ is the effective radius of the encounter and D the diffusion coefficient. The gas-phase analogue of Eqn. (1) is the formula $k = \sigma v$, where $\sigma = \sigma(v)$ is the effective reaction cross-section and v the relative velocity of the colliding species. In a dense medium the diffusion coefficient is a measure of the rate of mutual approach and separation of the reacting species before the reaction (i.e. is an analogue of v). Accordingly, the $R_e(D)$ relation is the fundamental characteristic of the process mechanism. However, in contrast to $\sigma(v)$, this relation has been scarcely investigated owing to lack of an experimental method for the measurement of the diffusion coefficient.

Furthermore, the expected $R_e(D)$ relation is the same throughout according to the generally accepted point of view and is given by the formula[1]

$$R_e = R\frac{k_p}{k_p + 4\pi RD} = R\frac{k_p}{k_p + k_D}. \tag{2}$$

Both phenomenological parameters, namely the rate of reaction k_p during contact between the species and the distance R for which contact is established, are assumed to be constant and independent of the diffusion coefficient. The two-parameter Eqn. (2) constitutes the basis of the classification of reactions into kinetically and diffusion controlled. It is derived rigorously within the framework of the phenomenological "grey sphere" model, contact with which results in partial occurrence of the reaction[2]. The constancy of k_p and R is a consequence of the fact that the model rules out interaction at a distance and ignores its anisotropy and the role of motion at the instant of contact.

Furthermore, it became clear in the 1950s that this model is inapplicable to the description of reactions occurring over a considerable distance between the reactants. This happens, in particular, in the resonance transfer of electronic excitation in the long-range (dipole-dipole) interaction between the energy donor and acceptor. The interaction takes place over a distance amounting to several tens of Angstroms with the probability

$$W = a/r^6,$$

even if the distance r between the species remains unchanged during the reaction. However, the diffusion of species towards one another, which promotes their mutual approach, intensifies the energy transfer process, which is faster the smaller the value of r. In order to take into account this factor, Tunitskii and Bagdasar'yan[4] and a number of other workers[5,6] developed the theory of transfer at a distance accelerated by diffusion, and established that the flux of excited donors, directed towards the acceptor, is usually dissipated long before they come into direct contact (Fig. 1*a*). In this case Eqn. (1) includes the radius of the sphere within which all the donor excitations are quenched before the donors move away from their sites owing to diffusion and where all the excitations arising from outside are therefore destroyed. The more mobile the species, the closer they are able to approach one another before the energy transfer mechanism operates. For this reason, the effective radius of the quenching sphere

$$R_e = \frac{2\pi}{\Gamma^2(^1/_4)\sin(\pi/4)}\left(\frac{a}{D}\right)^{1/4} \tag{3}$$

decreases with increase of the rate of diffusion, although the reaction rate constant increases [see Eqn. (1)].

The picture of the process described above remains qualitatively valid also for any other interaction between the reactants, even in a short-range process such as the "exchange" interaction

$$W = W_0 e^{-2\varkappa(r-R_0)},$$

where κ^{-1} is the extent of the region of overlapping of the wave functions. In particular, such interaction is involved in the triplet–triplet energy transfer, which is forbidden by dipole factors[7]. However, it ensures electron transfer in glasses and frozen media over distances amounting to several molecular diameters[8-10]. In the absence of diffusion, these reactions are non-exponential, like the dipole–dipole energy transfer[11,12]. Only species present within the quenching zone, i.e. when $r \leqslant R_e$, react at this (static) stage. At a low concentration of the reactants, the fraction of such species is low, but the remaining reactive species are nevertheless destroyed owing to diffusion at a rate described by Eqn. (1), in which

$$R_e = R_0 + \frac{1}{2\varkappa}\left[\ln\frac{W_0}{4\varkappa^2 D} + 1.15\right], \tag{4}$$

as established by Fabrikant and Kotomin[13] and Doktorov and Burshtein[14].

The rates of both transport reactions described are limited by diffusion. However, Eqns. (3) and (4) contrast sharply with the constancy of $R_e = R = \text{const.}$, which follows from Eqn. (2) and corresponds to the usual hypothesis of diffusional control. A special investigation[15] showed that the "grey sphere" model is valid only when an extended interaction between the reactants can be replaced by a step with the equivalent thickness $R - R_0$ (Fig. 1*b*) and the latter must be small compared with the radius of closest approach R_0. Such a thin quenching layer is possible only in exchange quenching[15,16], but in this case too the step approximation $W(r)$ is possible only for a sufficiently high rate of diffusion: when $R_e(D)$ decreases to $R = R_0 + \frac{1}{2}\kappa$, Eqn. (4) is replaced by Eqn. (2), obtained for the "grey sphere" model[14]. On the other hand, if the reaction zone is insufficiently thin, agreement between the results of the distance and contact theories is achieved only at the kinetic stage (for a still higher rate of diffusion), and the phenomenological parameter

$$k_p = 4\pi\int_{R_0}^{\infty} W(r)\,r^2\,dr \tag{5}$$

acquires the significance of the total rate of reaction in the vicinity of the reaction centre.

Thus the distance theory not only includes the phenomenological contact model, but also imparts to it a microscopic significance. Furthermore, it describes the process also outside the limits of applicability of the contact model, when the rate of diffusion is very low. Despite these undoubted advantages, it is still very much inferior when compared with the theory of transfer reactions in the gas phase. The very fact that one begins with the locally defined probability $W(r)$ and not with the interaction Hamiltonian $\hat{H}(r)$ and a specific process mechanism demonstrates its inadequate microscopic significance. On the other hand, the very idea of transfer probability at any

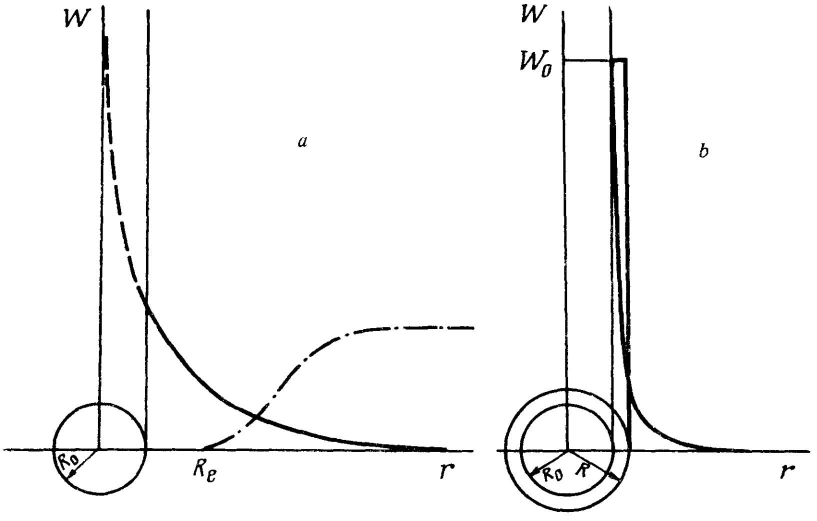

Figure 1. Dependence of the probability of quenching at a distance in dipole–dipole (*a*) and exchange (*b*) interactions on the distance between the reactants. The dash-dot line demonstrates how the stream of excited particles towards the sphere is dissipated in the presence of a strong long-range interaction.

point in space is specific to a condensed medium alone. In the gas phase one can only consider the results of the collision as a whole, but it is impossible to divide it into stages in an additive manner. The use of probabilities which are intrinsically additive becomes possible in condensed media, because any energy level E_i acquires a certain width Γ_i owing to the interaction with the solvent (Fig. 2). This restricts the free dynamic development of the transfer process to very short periods of the order of $(\Gamma_1 + \Gamma_2)^{-1} = \Gamma^{-1}$, after which the process begins to resemble to some extent α-decomposition occurring with the probability

$$W = \frac{2}{\hbar^2}\frac{b^2}{\Gamma_1+\Gamma_2},\ b = \langle 1|\hat{H}|2\rangle = b_0\,e^{-\varkappa(r-R_0)},$$

where $< 1|$ is the donor state, $|2 >$ is the acceptor state, and $E_1 \simeq E_2$. It is clear from this that the description of the transfer process throughout its extent in terms of probability is legitimate only when the encounters between the species during which the process takes place have a duration much longer than Γ^{-1}. Otherwise it is absolutely essential to generalise the theory in such a way that it permits a free dynamic development of the transfer process during the encounter.

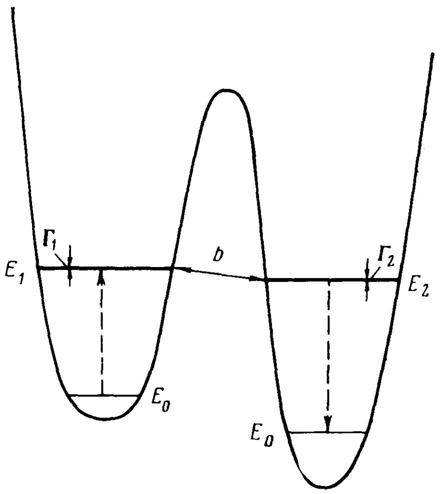

Figure 2. An energy scheme for the resonance transfer reaction. The dashed arrows indicate the excitation and deactivation of quasi-resonance levels.

Evidently the "encounter theory", which must satisfy this requirement, is not only kinematically more complex than the collision theory, but involves a greater number of parameters taking into account the interaction with the medium. The difficulties in devising this theory were overcome quite recently[14,16,17]. Formally, the apparatus of the theory describes resonance reactions in the liquid just as logically as in the gas. All the results of the distance theory were reproduced, and the limits of its applicability were established[14]. It was found that deviations from the "contact" formula (2) occur not only for slow diffusion, when it is overtaken by transfer at a distance, but also for extremely fast diffusion, which is able to switch the interaction on and off at a rate faster than the rate of relaxation[14]. In the latter case the interacting species can be regarded as just as free from interaction with the medium during the encounter as during the collision in the gas phase. The only difference is that the initiation and arrest of the interaction during the collision are predetermined in the course of free migration, while during the encounters between reactants in the liquid phase the occurrence of interaction is just as random as diffusion itself.

A general consequence of quantum mechanics is quadratic propagation in time of the resonance transfer process. At the dynamic stage, for very rapid diffusion, the probability of the reaction therefore depends quadratically on its duration τ_e, namely as $4b_0^2\tau_e^2/\hbar^2$, where $\tau_e = R_0/2\kappa D$. After multiplying by the frequency of encounters $(4\pi R_0 D)$, we obtain

$$k = \frac{4\pi R_0^3 b_0^2}{\hbar^2\varkappa^2 D}. \qquad (6)$$

This expression is the liquid-phase analogue of the Born approximation in the scattering theory. It follows from this that R_e diminishes quadratically as diffusion is accelerated:

$$R_e = \frac{R_0^3 b_0^2}{\hbar^2\varkappa^2 D^2}. \qquad (7)$$

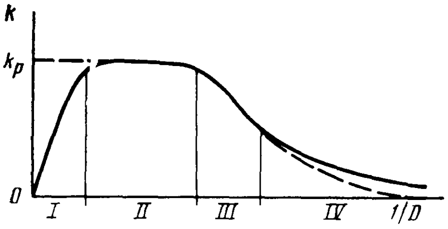

Figure 3. Dependence of the rate constant for a bimolecular reaction on the mutual diffusion coefficient: I) dynamic stage; II) kinetic stage; III) diffusion-controlled stage; IV) transfer over a long distance. The dashed curve illustrates the analogous relation obtained within the framework of the "grey sphere" model.

The qualitative deviations of the $R_e(D)$ or $k(D)$ relations (Fig. 3) from the generally accepted relations might become the subject of a special investigation if, together with the reaction rates, it was possible to measure molecular mobility. It is clear from the above formulae that this would make it possible to infer not only the type of interaction, but also its parameters, mechanism, and the "narrow" reaction stage. Unfortunately, the general kinetic standard procedure involves the measurement of the rate constant and at best its temperature dependence but never its dependence on D. This places liquid-phase kinetics in the same situation as that of its gas-phase analogue before the appearance of the molecular beam technique. No definite conclusions can be drawn about the intimate mechanism of the chemical reaction solely from the rate constant, while the choice of interaction parameters remains appreciably arbitrary.

Because of this, the theory continues to be extremely general. No other factors, apart from the charged state of the species[13,18,19], which hinders or promotes their mutual approach, are taken into account. Nevertheless, the interaction is almost always anisotropic. As a rule, the reaction centres occupy only a small section of the sphere associated with the molecule and rotational motion is an important factor, promoting contact between the reactants[20,21]. For example, this is the situation in spin exchange[22,23] and certain slow radical substitution reactions[24]. Furthermore, the reaction centre may be shielded by the solvation or hydration shell, the penetration of which (or residence in the latter) should limit the rate of the process in many instances. Finally, the presence of ligands in the reaction complex can both promote and hinder contact depending on the conformation, which should result in a direct dependence of the kinetically controlled reaction on the frequency of conformational transitions. It may be that, apart from the deviations from the contact model described above, caused by the unduly slow or unduly fast diffusion, there should be others associated with the fact that the molecule is not a sphere with a radius R and that contact with it is not simply of any type but must involve "adhesion" at the required site and in a convenient configuration. Although these claims are qualitatively evident, they have not been formulated in a strictly quantitative form, mainly because there is no possibility of comparing such a detailed theory with adequate experimental data.

III. REACTIONS CONTROLLED BY MOLECULAR MOBILITY

The transfer of an electron, proton, and valence in non-polar matrices does not as a rule require the overcoming of high potential barriers, and yet frequently shows an anomalously marked temperature dependence. We believe that this is evidence that the rate of diffusion of charge and valence is not limited by the height and extent of energy barriers but by the mobility of the matrix. Because of this, the observed rates of physicochemical processes are simply none other than the frequencies of molecular motions—vibrations, librations, and rotations, which have been the subject of acoustic and dielectric studies. Many specific examples discussed below support this claim.

Electron Transfer

In 1960 Tal'roze and Blyumenfel'd[25] observed a dark electrical conductivity $\sigma(T)$ in a large class of polymers with conjugated bonds. The anomaly was that activation energy for conduction in these substances varied from 0.2 to 4 eV, but the associated change in the pre-exponential factor (over the range of 60 orders of magnitude) fully compensated the changes in energy. In other words,

$$\sigma = \sigma_0 \exp(-E/k_B T),$$

but

$$\ln \sigma_0 = \alpha + \beta E, \tag{8}$$

where α and β are invariant in the given series of compounds (Fig. 4).

This phenomenon, called the compensation effect (CE), has been known in the physics of semiconductors since 1937 as the Meyer–Neidel effect[26,27], but it had been observed even earlier in chemical studies: in 1926 Constable[28] established that CE is characteristic of catalytic oxidation reactions and Roginskii and Rozenkevich found it in homogeneous unimolecular reactions[29]. After some controversy, Hinshelwood[30] recognised CE in 1947 as "one of the fundamental although incomprehensible relations of chemical kinetics", and subsequently Kobeko, who observed the effect in the most direct manner in styrene polymerisation reactions[31], concluded that "CE is a general law of chemical kinetics". In the 1960s CE was observed in the decomposition reactions of aliphatic azo-compounds and many hydroperoxides[32]. Furthermore, it was established that, in the reactions associated with alkaline hydrolysis[33], the compensation effect is to a large extent limited to an analogous compensation expressed by the temperature dependence of the solvent viscosity[34].

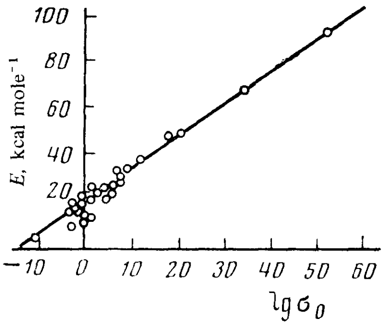

Figure 4. The compensation effect in the conductivities of a number of polymers according to Tal'roze and Blyumenfel'd[25].

The last observation might serve as the starting point for the interpretation of the effect in all its manifestations. However, there always remains the possibility that CE is associated with the very formulation of the experiment, the scope of which is frequently limited by the narrowness of the available temperature range. By a tendentious selection of specimens[35] or by postulating competition between two simultaneous reactions[36], it is easy to account for the compensation of the energy factor by the entropy factor if both are within reasonable limits. However, the CE observed in the electrical conductivity of organic structures[25] cannot for this reason be accounted for in a trivial manner, which gives rise to the problem of the origin of the exceptionally high activation energies appearing in the compensation series. Their occurrence in conduction in high-molecular-weight compounds was later confirmed for a large class of highly unsaturated polymers[37-39]. It is striking that the activation energy varies from specimen to specimen in a random manner, reaching 5 eV in certain cases. This phenomenon has been included as an experimental fact in monographs on organic semiconductors[40] and biopolymers[41], but a likely explanation for it has not so far been found.

The existence of activation energies exceeding all reasonable limits has been observed not only in electrical conduction, and not necessarily in the solid state. The activation energies for many catalytic processes[42] and a large class of liquid-phase enzymatic reactions, where CE is a universal phenomenon[43,44], are just as large. However, even if one admits that the phenomenon is non-trivial in a compensation series where the energies vary from several kcal mole^{-1} to 120 kcal mole^{-1} and more, one must treat with much caution many "simple" explanations of CE in series where the energy varies within reasonable limits. The widespread nature of the phenomenon makes it necessary to assume that its cause is extremely general and only its manifestations are not always anomalous (involving unduly large activation energies).

The appearance of activation energies of 4–5 eV is most paradoxical in electrical conduction, where the elementary step is particularly simple. The conductivity of the substance $\sigma = e\mu n$, where n is the concentration of current carriers and μ their mobility, is known to be linked to the diffusion coefficient by the Einstein relation:

$$\mu = \frac{eD}{k_BT}, \tag{9}$$

where e is the charge and T the temperature. In inorganic semiconductors the temperature relation $\sigma(T)$ is determined by the excitation of charges in the conductivity band, i.e. by the equilibrium current carrier density $n(T)$. However, a simple estimate shows that, when E = 2 eV, the forbidden gap is so wide ($2E$), that at room temperature there is not even one free carrier per specimen. In other words, in organic semiconductors with large values of E precisely the opposite situation should obtain: $n \simeq$ const., as in metals, and the temperature relation $\sigma(T)$ should originate mainly from the temperature dependence of the mobility of current carriers. The constancy of n can be explained by the fact that high-molecular-weight semiconductors contain a multiplicity of impurities, which need not necessarily be extraneous inclusions, consisting of low-molecular-weight oligomers with enhanced electron-donating or electron-accepting capacity, which ionise the main molecules. The current carriers thus generated move freely via the system of conjugated bonds within the molecule, experiencing difficulties only in the transfer from one molecule to another. If such transitions take place W times per second, their sum amounts to diffusion with the coefficient

$$D = \frac{a^2}{6}W, \tag{10}$$

where a is the scale of the spatial displacement of the current carrier in each elementary step of the intermolecular transfer (an analogue of the lattice period).

Taking into account Eqns. (9) and (10), it is reasonable to expect that the anomalous temperature relation $\sigma(T)$ is caused by the fact that the transition probability $W(T)$ is based on an activated process. However, until recently, it has been assumed that the electron independently traverses very large intermolecular distances, but not always "successfully" ($q \ll 1$[†]), repeating its attempts ν times per second from each end of the molecule. If this were so, it would be difficult to postulate any marked temperature dependence of the transition probability

$$W = \nu q. \tag{11}$$

In fact ν, the frequency of the intramolecular vibrations of the electron is constant, while the intermolecular transition is activated only when it takes place over a barrier. However, it is impossible to relate the observed activation energy to the height of this barrier. Even, for an attack frequency $\nu \simeq 10^{15}$ Hz, the transition through a 2 eV barrier would take place at a frequency of 10^{-7} Hz, i.e. only a few times per year.

The solution, pointed out by Gutmann as late as 1969,[45] is to abandon the usual treatment of charge migration as if the latter occurred in a frozen medium with a fixed geometry and positions of the molecules. In this approach, which is generally accepted in the theory of the solid state, the current carrier indeed has no choice but to overcome the barriers encountered in its path. In fact, there is always an alternative: either to pass through the barrier despite its considerable extent or to wait until it is lowered as a result of the mutual migration of molecules to such an extent that it becomes virtually "transparent". On the other hand, if the intermolecular distances are such that the barriers are on average insurmountable, only the latter possibility remains.

This is apparently the situation in organic semiconductors. The frequency of attempts ν in Eqn. (11) has the significance of the frequency of intermolecular contacts arising during thermal motion and not of the frequency of attacks (which is known to be high).

Table 1. Comparison of the activation energies for combustion and dielectric losses (measured in electron-volts).

Substance	$E_{\text{cond.}}$, eV	E_{loss}, eV
Chlorpromazine	1.5	1.4
Promethazine	1.5	1.37
Trifluoropyrazine	1.4	1.4
Poly(ethylene terephthalate)	1.65	0.66—0.87
Albumin	1.1	0.8
Polyacrylonitrile	0.85	0.61
Gelatin	1.5	1.14—1.3
Collagen	1.36	1.1

The probability of tunnelling at these instants $q \leq \frac{1}{2}$ can be very close to its limit ($\frac{1}{2}$) and the temperature dependence of conductivity, mobility, and the diffusion coefficient is then determined mainly by the temperature dependence of the frequency $\nu(T)$, which limits the rate of the process. Using these considerations, Gutmann decided to compare the measured activation energies for conduction and the dielectric losses, which constitute a direct means of measuring $\nu(T)$. The author notes that the "data compared proved to be very scanty because the objects investigated as dielectrics were as a rule not studied from the standpoint of their conductivity, and conversely".[45] Nevertheless he was able to make such a comparison (Table 1), partly on the basis of his own observations and partly on the basis of literature data, demonstrating the striking agreement of the results. The author explains the observed slightly higher activation energy for conduction (by 0.2 eV) by the necessary preliminary separation of the paired spins, which ensures the resonance mechanism of electron transfer. However, the main part of the activation energy and sometimes the entire activation energy is required solely for the creation of a "sterically convenient orientation of two molecules relative to one another, in which the energy barrier separating them is temporarily lowered".[45] In order to achieve this

---

[†] Here q is the fraction of successful attempts.

favourable configuration, the molecules must bend, twist, or execute librations within narrow confines, and this stage actually limits the rate of the process. Electron transfer is merely an example of the reactions which may be controlled by molecular mobility, ensuring that the reactants come into contact in the required coordination.

Unfortunately, we have no data permitting a comparison of the activation energies for conduction and dielectric relaxation in the series of polymers where CE is observed. However, there is no doubt that such comparison would reveal their identity. The enormous activation energies and their consequent compensation by anomalously large pre-exponential factors in the expression for the rate of relaxation of dielectric losses in polymeric media are encountered extremely frequently[46].

Naturally, by reducing CE in electrical conduction to CE in molecular mobility, we do not as yet explain this phenomenon. However, the demonstration of the very fact that the reaction is controlled by molecular motion is important for chemical kinetics. Whether or not CE constitutes an unambiguous indication of such control can be elucidated only by a wide-scale comparison of the results of acoustic, dielectric, and molecular-kinetic investigations of condensed media with the rates of the elementary chemical reactions which occur in the latter. To what extent such a comparison can succeed is seen most clearly in relation to a simpler system, which we shall now analyse.

Proton Transfer

The anomalously high intrinsic conductivity of ammonium salt crystals, which is higher by 5–6 orders of magnitude than that of the corresponding alkali metal salts, constitutes an important reason for giving preference to the proton mechanism of charge transfer rather than to the usual vacancy mechanism associated with the motion of heavy masses. However, this hypothesis became concrete only recently as a result of a multistage experimental study of the formation and migration of a free proton in a crystal lattice[47,48]. In order to identify the mechanism, the proton-donating NH_4HSO_4 admixture was introduced by cocrystallisation from aqueous solution into $(NH_4)_2SO_4$ (AS), and $NH_4H_2PO_4$ (ADP) crystals; the concentration of the admixture was followed by titrating the solution after dissolving the given single crystal in water. As expected, the conductivity increased linearly with increasing concentration of the electron-donating molecules.

By following the concentrations in specimens with admixtures (n_0), it is possible to determine in the simplest way the proton mobility $\mu(T) = \sigma(T)/en_0$ and to compare its temperature variation

$$\mu(T) = \mu_0 \exp(-E_m/k_BT) \tag{12}$$

with the temperature variation of the intrinsic conductivity

$$\sigma(T) = e\mu(T)\cdot n(T) = \sigma_0 \exp(-E/k_BT),$$

where

$$n(T) = \sqrt{\frac{k_d}{k_r}[NH_4^+]} \propto \exp\left(-\frac{E_0}{2k_BT}\right) \tag{13}$$

is the equilibrium density of the protons generated as a result of thermal dissociation

$$NH_4^+ + SO_4^{2-} \underset{k_r}{\overset{k_d}{\rightleftarrows}} NH_3 + HSO_4^-$$

(k_d and k_r are the dissociation and recombination rate constants respectively). This comparison makes it possible to separate the contributions to the activation energy E by the dissociation energy E_0 and by the activation energy for motion E_m: $E = E_0/2 + E_m$. The values of E_0 and E_m proved to be virtually identical for protons in AS crystals: E_m = 0.49 eV and E_0 = 0.5 eV (E = 0.76 eV). However, although the origin of E_0 is evident, the nature of E_m still needs to be analysed.

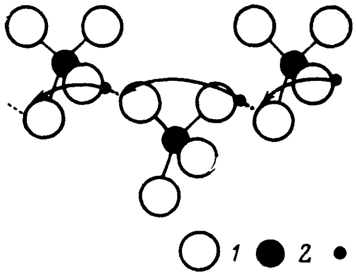

Figure 5. Schematic illustration of the multistage migration of a proton within and between the cells of the anionic sublattice: 1) oxygen atom; 2) sulphur atom; 3) proton. The arrows indicate the intraionic migrations of the proton and the circles illustrate the interionic migrations.

The migration of an intrinsic or impurity proton in the crystal lattice consists of elementary steps each of which is none other than a resonance transfer reaction of the type

$$HSO_4^- + SO_4^{2-} \underset{W}{\overset{W}{\rightleftarrows}} SO_4^{2-} + HSO_4^-. \tag{14}$$

The experimental mobility $\mu = (ea^2\gamma/k_BT)W$, where γ is the geometrical factor (instead of 1/6) taking into account the possibility of proton transfer to any of the anions forming part of the first coordination sphere, can be expressed in terms of the probability of this process W in accordance with Eqns. (9) and (10). Having measured μ, it is easy to calculate

$$W = \frac{\mu k_BT}{ea^2\gamma} = \nu q. \tag{15}$$

Evidently we encounter in Eqn. (15) the same alternative as in Eqn. (11). Although the probability W can be found readily, it is in no way clear to what the temperature dependence should be attributed: the probability of overcoming the barrier $q(T)$ separating the two anions or to the frequency of the approaches to the barrier $\nu(T)$. The latter is determined either by the rotation of the HSO_4^- ion or by proton transfer within the latter from one side to the other (Fig. 5). Rotation (a change in coordination) is a necessary condition for the translational motion of the charge carrier and it can be no less difficult than proton transfer along the line of the hydrogen bond between neighbouring lattice sites. In fact the distance between the sites in the tetragonal structure of the ADP crystal is 4.2 Å, while the distance traversed by the proton on moving from an oxygen atom of its "own" anion to a "foreign" anion does not exceed 0.35 Å. In this situation it is natural to suppose that the intramolecular transition may be the rate-limiting stage for the process as a whole.

Experimental proof of this was obtained by studying the temperature and frequency dependence of the complex dielectric constants of AS and ADP crystals. Direct measurements demonstrated the identity not only of the activation energies for conduction and dielectric relaxation, but also of the absolute values of the relaxation time τ_d and the rotation time $\tau_c = \nu^{-1}$ (Table 2) subject to the condition that $q = \frac{1}{2}$. The latter implies that whenever a favourable coordination is established the proton has sufficient time, while the coordination persists, to be equally distributed between neighbouring anions. The only difficulty is the creation of such a favourable situation and not the transfer step itself, which, judging from certain data[49], takes place at a frequency $\nu = 10^{13}$ s^{-1}, while the reorientation takes place, according to Table 2, at a frequency not greater than 10^6 times a second.

Table 2. Comparison of the activation energies and relaxation times for conduction and dielectric losses.

Ammonium salt	E_m, eV	E_d, eV	$10^5\tau_c$, s	$10^5\tau_d$, s
$(NH_4)_2SO_4$	0.49±0.03	0.51±0.04	3.3	5.5
$NH_4H_2PO_4$	0.54±0.03	0.50±0.04	8.3	4.6

Thus the seemingly elementary reaction (14) can be arbitrarily subdivided into two stages: the reorientation of the carrier anion

$$HSO_4^- \underset{\nu}{\overset{\nu}{\rightleftarrows}} SO_4H^-$$

and the intrinsic transfer (tunnelling) of a proton from one carrier to another:

$$SO_4H^- + SO_4^{2-} \underset{q}{\overset{q}{\rightleftarrows}} SO_4^{2-} + HSO_4^-,$$

the former being rate-limiting. This constitutes an example of a reaction controlled by molecular mobility in a pure form.

The ideas described apparently make it possible to consider the problem of the specific regulation of the rates of certain solid-phase protolytic reactions in a different way. Thus, on thermal decomposition, ammonium perchlorate (AP) initially dissociates:

$$NH_4ClO_4 \rightarrow NH_3 + HClO_4,$$

while the proton, having moved in the manner described above in the anionic AP sublattice, enters an unstable anion (ClO_4^- in the defective section of the lattice or as an impurity ClO_3^- anion) and destabilises it further, which leads to the initiation of the autocatalytic decomposition process. Consequently, by introducing additional protons into the AP lattice (from proton-donating additives) or by reducing the concentration of the conductivity protons present in the lattice (by introducing proton acceptors such as ammonia, HPO_4^{2-}, CO_3^{2-}, etc.), it is possible to decrease or increase correspondingly the thermal stability of this widely used solid-phase oxidant, which was recently demonstrated by direct experiments[50].

Recombination of Radicals

The thermal annealing of the radicals arising in a solid matrix under the influence of penetrating radiation has been the subject of chemical research in the course of two decades. After the discovery of the electron spin resonance method, these studies became particularly vigorous. However, despite the possibility of identifying radicals and of following their transformations, unambiguous and generally accepted explanations of the known anomalies in the kinetics of their recombination (pronounced departure from steady-state conditions, "shelves", etc.) have not so far been proposed. Virtually nothing is known about the mechanism of the spatial migration of radicals via molecular crystals, let alone glasses and polymers, and even diffusion coefficients have been measured only in exceptional instances. Nevertheless the mutual approach of radicals (or valences) in space constitutes a necessary preliminary stage before their recombination, which itself requires almost no activation energy. It is therefore natural to suppose that the rate of the process as a whole is as a rule limited by diffusion and that its temperature dependence and the CE frequently encountered in the process simply exhibit features characteristic of the temperature variation of the diffusion coefficient $D(T)$.

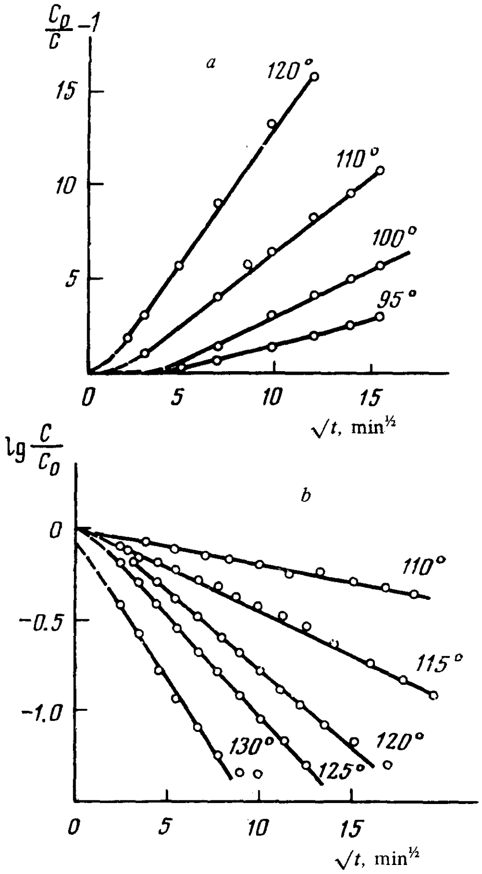

Figure 6. "Square root" plots designed to express in a linear form the kinetic curves for the unimolecular and bimolecular recombination of radicals in crystals of succinic (*a*) and 3,3-pentamethyleneglutaric (*b*) acids.

The present author and Tsvetkov[51] recently found direct evidence for this by observing that the kinetic curve for the unimolecular and bimolecular recombination reactions can be expressed in a linear form by plotting $\ln C$ and C^{-1} respectively against $\sqrt{t}$, whereas usually the variable plotted along the abscissa axis is t and not $\sqrt{t}$ (C is the concentration of radicals). The recombination in irradiated crystals of succinic and 3,3-pentamethyleneglutaric acids proceeds in this way at temperatures close to the melting point or the polymorphic transition temperature[51] (Fig. 6). Analogous "square root" kinetics had also been observed previously in vitreous matrices[52-55] and had been interpreted in the same spirit.

The decrease of concentration with increasing $\sqrt{t}$ always precedes the steady-state stage of the reaction, where it is controlled by diffusion ($k_p \gg k_D$) [see Eqn. (2)]. If after irradiation radicals are scattered throughout the bulk of the specimen randomly and uniformly and their motion in any direction takes place identically, then, according to the generally accepted theory[2], the rate constant for the diffusion-controlled reaction is

$$k_D(t) = 4\pi RD\left[1 + \frac{R}{\sqrt{\pi Dt}}\right]. \tag{16}$$

As in Eqn. (2), here R is the radius of the sphere which in this instance is "black". At the beginning of the annealing process the second term on the right-hand side of Eqn. (16) always predominates over the first and at this stage the recombination kinetics are therefore defined by the following equations:

$$(a)\ \frac{C_0}{C} - 1 = \tilde{k}\sqrt{t} \quad \text{or} \quad (b)\ \ln\frac{C}{C_0} = -\tilde{k}\sqrt{t}, \tag{17}$$

Indeed the $C(t)$ relation can be expressed in a linear form by means of the above "square root" plots and the effective reaction rate constant $\tilde{k}$ is

$$(a)\ \tilde{k} = 8R^2C_0\sqrt{\pi D} \quad \text{or} \quad (b)\ \tilde{k} = 8R^2M\sqrt{\pi D}, \tag{18}$$

where M is the concentration of the reactants involved in the first-order reaction. However, the non-steady stage, associated with the "square root" destruction of the species in direct proximity to the "black sphere", lasts only for an instant $t \ll R^2/\pi D$, i.e. for a very short time if R has molecular dimensions. During this period, only those few radicals which were generated along side one another or at a distance of one–two "steps" from one another can be destroyed. In fact a considerable proportion if not all the radical centres detected by ESR are destroyed in the non-steady stage of the reaction. Because of this, interpretation of the experimental data in terms of the above formulae yields for R a value many times greater than the size of the molecule or of the monomeric unit of the polymer: 40–80 Å. Such enormous capture radii can be accounted for solely by heterophase fluctuations in the prefusion region[56]: the appearance of unstable microscopic nuclei of the liquid phase within which the mobility of the species is very high. Two radicals which have entered such a "cauldron" have a greater chance of meeting and recombining, while a single radical simply moves in space, but over a considerable distance, of the order of magnitude of the fluctuation radius[51].

Unfortunately the situation remains paradoxical even if a hypothesis of this kind is adopted. When the radius of the black sphere, whose penetration leads to the inevitable destruction of radicals, is compared with the average distance between them at the beginning of annealing, the binary approximation within the framework of which Eqn. (16) was obtained ceases to be legitimate. Furthermore, certain kinetic curves indicate directly the internal inconsistency of their description in terms of this formula. This is clearly seen if the experimental results are expressed by a plot of $(C^{-1} - C_0^{-1})/t$ against $1/\sqrt{t}$; in this case Eqn. (16), describing the kinetics of bimolecular recombination, leads to a straight line[55], because

$$(C^{-1} - C_0^{-1})/t = 4\pi RD + 8R^2\sqrt{\frac{\pi D}{t}}. \tag{19}$$

The intercept which the line makes on the ordinate axis is none other than the steady-state rate of reaction (1). However, among the results quoted by Butyagin[55], there are also instances where the intercept is zero (Fig. 7, right-hand column); this involves the destruction of radicals in thermovulcanised rubber, where one can either assume that $R = \infty$ and $D = 0$, or that there is no steady-state stage in the reaction at all.

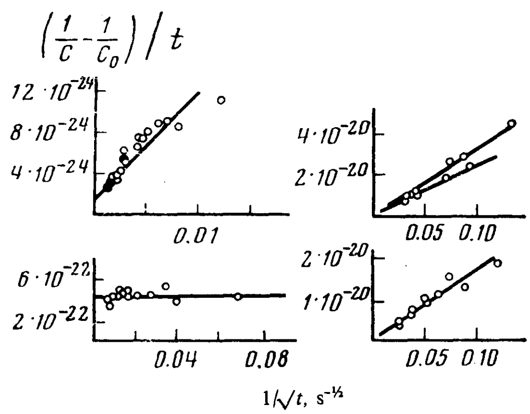

Figure 7. Kinetics of the destruction of radicals in the presence of a steady-state stage in the reaction (*a*) and in its absence (*b*) according to Butyagin[55].

The possibility of a non-steady-state course of the reaction from beginning to end merits special investigation. Such a possibility exists if diffusion takes place as a one-dimensional or two-dimensional process, but "square root" kinetics are obtained only in the one-dimensional case. The latter naturally arises if one of the radicals is always stabilised on the surface and the other in the bulk phase, or if both are formed at an edge dislocation consisting of a narrow (with a thickness of the order of magnitude of several atomic dimensions) tunnel in the crystal lattice. In order to ensure a markedly non-steady-state process, it is necessary to assume in addition that the initial distribution of radicals is very non-uniform. They must be generated close to one another compared with the distance by which they can be separated during diffusion. When the initial distribution is Gaussian with a width l, the destruction takes place in accordance with the law[57]

$$p = \frac{C}{C_0} = \frac{2}{\pi}\arctan\left(\frac{2}{l}\sqrt{\frac{Dt}{\pi}}\right), \tag{20}$$

if the radicals are assumed to be "black" and to recombine already in the first encounter.

The fundamental difference between Eqns. (20) and (19) is due to rejection of both fundamental assumptions of Waite's theory leading to Eqn. (16): the homogeneity of three-dimensional diffusion and the uniformity of the initial distribution of species. The process described by Eqn. (20) also consists of two stages; approximately half of the initial number of radicals are destroyed at each stage. However, the last stage is non-steady-state to the end and the recombination kinetics are close to the "square root" type whatever variables are used (Fig. 8). For any initial distribution $\varphi(x)$ (provided that it is narrow!), they can be represented in the following form:

$$\frac{C}{C_0}=\frac{l}{\sqrt{\pi D t}},\quad t\gg\frac{l^2}{D},\quad C\ll C_0, \tag{21}$$

where $l=\int\limits_0^\infty x\varphi(x)dx$ is the first moment of the distribution. Comparison of this destruction law with Eqn. (17a) readily shows that

$$\tilde{k}=\frac{\sqrt{\pi D}}{l}, \tag{22}$$

and $\tilde{k}$ therefore depends on the diffusion coefficient in exactly the same way as in Eqn. (18), although the values and significance of the spatial characteristics in the two formulae are different.

The above explanation of the profoundly non-steady-state nature of the process shows that at least the functional relation between the effective rate constants defined by Eqn. (18) and the diffusion coefficient can be accepted with confidence[‡]. This makes their comparison legitimate and their temperature dependence can be regarded as corresponding exclusively to the $D(T)$ relation. Although the constants for the two reactions investigated fit on the Arrhenius temperature relation $\tilde{k}=k_0\exp(-E/k_BT)$ and have similar values of $\tilde{k}$, the activation energies and the pre-exponential factors ($k_0=3\times10^{18}$ s$^{-1/2}$ and $E=36.4$ kcal mole^{-1} for 3,3-pentamethyleneglutaric acid, and $k_0=3\times10^{9}$ s$^{-1/2}$ and $E=18.4$ kcal mole^{-1} for succinic acid) differ from one another very markedly. Furthermore, a typical compensation effect due to diffusion is present. According to Eqn. (18), the activation energy for diffusion E_{q} is twice as large as the activation energy corresponding to the effective rate constant and reaches 3 eV for 3,3-pentamethyleneglutaric acid.

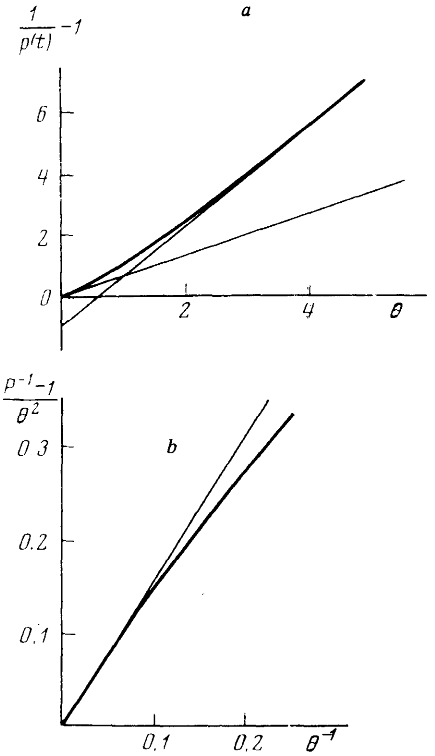

Figure 8. Kinetics of the non-steady-state recombination under the conditions of one-dimensional diffusion represented by plots in terms of the coordinates of Burshtein and Tsvetkov[51] (*a*) and Butyagin[55] (*b*); $p(t)=C/C_0$, $\theta=(2/l)\sqrt{Dt/\pi}$.

The compensation effect in the recombination of radicals had also been observed previously. It was interpreted phenomenologically as a result of the S-shaped pronounced $E(T)$ dependence, close to linearity[58]:

$$E(T)=E_0(1-\beta k_BT).$$

The steep decrease of the activation energy, which can explain the compensation effect in a narrow temperature range, was attributed to the unfreezing of the rotational mobility of the polymeric chain, i.e. not in any way "to the structure and properties of the radicals but to the structure of the polymer as a whole"[58]. Direct measurements performed on pure amorphous glycerol showed that the activation energies for the rotation (dielectric losses) and recombination of radicals are identical[59]. On the other hand, the non-Arrhenius S-shape of the relation between $\ln k$ and $1/T$ was later confirmed by a special study of recombination in irradiated frozen benzene[60] and was regarded by the authors as evidence in support of the hypothesis that the activation barrier to self diffusion (or the migration of valence) decreases with increase of temperature. Finally, direct experimental confirmation has

---

[‡] Experimental evidence has become available quite recently, showing that the non-steady-state ("square root") kinetics are also characteristic of disproportionation reactions in the cage which do not require diffusion[80,81]. In particular[80], the reaction of the methyl radical with the matrix, $CH_3^{\cdot}+RH=CH_4+R^{\cdot}$, is markedly non-steady-state and proceeds in accordance with the law $C=C_0\exp(-\sqrt{kt})$. The difference between the rates of transformation of different radicals, which is the reason why the reaction is non-steady-state, may be attributed in this instance solely to the local inhomogeneity of the matrix, energetic or structural. The phenomenon has been interpreted[80] on the assumption that the transfer of H· has a tunnel and quasi-resonance mechanism and that the distribution of the resonance deficiency is Gaussian. The feasibility of this explanation of the "square root" decomposition shows that diffusion may not be the only cause of such behaviour and special proof is therefore required that it controls the process.

been obtained quite recently that the activation energies for recombination and diffusion in crystals are very close[61,62], i.e. that the nature of both phenomena is indeed the same.

IV. THE VACANCY MECHANISM OF MOBILITY

In view of the foregoing, it is natural to seek an explanation of the compensation effect outside the limits of chemical kinetics: in the mechanisms of the organisation of diffusion. However, the existence of a compensation effect is known reliably only for the diffusion of a number of metals into fused copper and for the self-diffusion of iron in its melts[63] (Fig. 9). Unfortunately the activation energies and pre-exponential factors in such cases vary outside the normal limits. On the other hand, in those instances where anomalies were encountered and were interpreted very successfully, the compensation effect had not been the subject of the investigation. We are dealing with extremely high (compared with potential barriers) activation energies and the correspondingly unduly high (by several orders of magnitude) pre-exponential factors in the expressions for the self-diffusion coefficients for atomic[64] and ionic crystals[65,66]. Despite the small scale of the effect, its explanation, which has withstood an experimental test, is the only reliable basis for considering the causes of the anomalously high activation energies and their compensation.

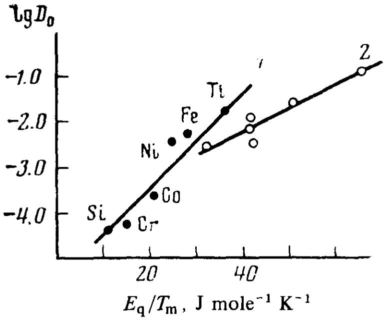

Figure 9. The compensation effect in the diffusion of metals in liquid copper (line *1*) and the self-diffusion of iron in Fe–C according to Shurygin and Shantarin[63] (curve *2*).

The migration of an atom (or ion) from its lattice site to a neighbouring site takes place most readily when the latter is vacant. Such a situation arises each time when the vacancy (Schottky defect) migrating in the crystal appears in the first coordination sphere. By treating such events as "encounters" between the vacancy and the ion, it is possible to determine their frequency by Eqn. (1), putting $R = a$ (a is the lattice constant), i.e. $W = 4\pi a D_V n_V$, where n_V is the equilibrium density of the vacancies and D_V is their diffusion coefficient. By migrating into a vacancy, the given species migrates over a distance $\sim a$, and the sequence of such migrations constitutes diffusion with the coefficient described by Eqn. (10), which in the given instance assumes the following form:

$$D = \gamma a^2 W = D_v P_v, \tag{23}$$

where $P_V \simeq a^3 n_V$ is the fraction of vacant sites in the crystal lattice. In this very familiar expression[65] D_V is a kinetic parameter and P_V a strictly equilibrium parameter. In principle, both depend on temperature, since the compensation effect in diffusion can originate both from kinetic and equilibrium causes.

Initially it was believed that the observed anomaly in the $D(T)$ relation is associated exclusively with the temperature relation $E_V(T)$ due to the barrier which the ion must overcome on being displaced into the nearest vacant site. The barrier between the sites is generated by the repulsion potential between neighbouring molecules and the ion must cross this barrier in order to enter the vacant site. The height of the barrier naturally depends on the distances between the sites. When the neighbouring molecules move apart as the crystal expands, liberating a pathway, the height of the barrier should decrease with temperature and the decrease should be linear:

$$E_v = E_0 + \frac{\mathrm{d}E_v}{\mathrm{d}v}\left(\frac{\partial v}{\partial T}\right)_p T = E_0[1 - \lambda r T], \tag{24}$$

where E_0 is the height of the barrier at $T = p = 0$, $\lambda = (1/v)(\partial v/\partial T)_p$ the isobaric coefficient of thermal expansion, $r = -\mathrm{d}\ln E_V/\mathrm{d}\ln v$ a numerical parameter, which can be readily estimated provided that the repulsion potential is known (the specific volume $v \simeq a^3$). For example, we have $r = 4$ for $E_V \simeq 1/a^{12} \simeq 1/v^4$. The linear decrease of $E(T)$, pointed out for the first time by Frenkel'[64], constitutes an excellent imitation of the Arrhenius relation and, by causing an unduly high activation energy, necessitates the compensation of such increase by the pre-exponential factor:

$$D_v = D_a e^{-E_v/k_B T} = D_a e^{\lambda r E_0/k_B} \cdot e^{-E_0/k_B T} = D_0 e^{-E_0/k_B T}. \tag{25}$$

However, when the compensation effect originates in this way, the activation energies can only be a little higher than the usual values $[(E - E_0)/E_0 \simeq \lambda r T \simeq 1]$ and the pre-exponential factor should not differ unduly from the true value. Even for ionic crystals, where the pre-exponential factor is too high by only four orders of magnitude, the kinetic compensation effect can account for only two orders of magnitude, i.e. for half of the observed effect. In this connection, Mott and Gurney[65] pointed out that the remaining half of the effect is evidently associated with the analogous effect as a function of $P_V(T)$. The increase of the density of vacancies with temperature is determined by the thermodynamics of the crystals and can be very marked near the melting point or the polymorphic transition temperature. A completely analogous situation occurs in pure metals and solid substitutional solutions where atoms diffuse via the vacancy mechanism[64]. The latter is regarded as involving local fusion due to a random aggregation of vacancies[67,68].

The kinetic and equilibrium compensation effects make equal contributions to the observed undue increase of the pre-exponential factor for ionic crystals, but whereas the former is interpreted at a microscopic level, the latter is introduced exclusively to make the theory consistent with experiment. The formula for the effect found empirically by Bugakov[69]

$$D = D_m e^{E/k_B T_m} e^{-E/k_B T}$$

is identical with Eqn. (8) and identifies $(\beta k_B)^{-1}$ with the melting point T_m. As the melting point is approached, the density of vacancies increases sharply and the probability of their binary, ternary, and higher-order collisions, leading to aggregation and microfusion, increases still more steeply, providing the driving force for diffusion and the reactions which it controls.

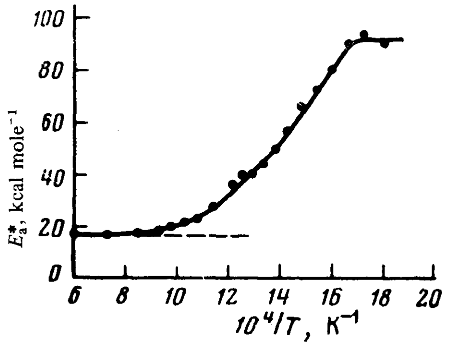

Figure 10. Dependence of the effective activation energy E_a^* for the viscous flow of the B_2O_3 glass over a wide temperature range.

In comparing the kinetic and equilibrium compensation effects as the possible causes of the appearance of anomalies of still greater magnitude, characteristic of molecular crystals and glasses, it is natural to give preference to the equilibrium effect. The fact that the temperature dependence of viscous flow and self-diffusion in such media has been attributed for a long time to the probability of the appearance of vacancies of molecular size v^* can be regarded as independent evidence in support of this choice. According to the free-volume theory[70,71], this probability is

$$P_v = \exp\left(-\frac{v^*}{v - v_0}\right), \qquad (26)$$

where v is the specific volume and v_0 is assumed equal to the intrinsic molecular volume (or the specific volume when $T = p = 0$). In the free volume theory the appearance of vacancies is attributed exclusively to entropy fluctuations; solely owing to the ordering of the structure and without an energy expenditure, such fluctuations lead to the accumulation of the free volume due to many molecules in one place, in the form of a cavity of specified size. Naturally, the greater the volume of this cavity v^*, the smaller the probability of its formation. On the other hand, the greater the average free volume per molecule $v - v_0$, the greater the frequency of cavities whose size is sufficient for spatial migration of the diffusing species in the latter. Consequently the isobaric temperature relation $P_V(T)$ is associated exclusively with thermal expansion. In vitreous matrices over a range of approximately 50°C near the glass point T_g the change in free volume is such that it converts Eqn. (26) into the so-called WLF formula[71,72] or Falcher's law:

$$P_v = \exp\left[-\frac{\text{const}}{T - T_0}\right], \quad T_0 < T_g. \qquad (27)$$

Despite its approximate nature, this law shows that the effective activation energy $(\partial \ln p_V/\partial T^{-1})_p$ increases rapidly with decrease of temperature and may be much greater than any potential barriers, as happens in the presence of the compensation effect.

Direct and precise measurements of the activation energy for low-temperature viscous flow and rotational relaxation in a reference glass such B_2O_3 showed[73] that the activation energy reaches 96 kcal mole^{-1} at low temperatures (Fig. 10). In the light of this finding, the appearance of an anomalous compensation effect in diffusion-controlled reactions such as recombination is quite natural.

Furthermore, since high activation energies and their compensation are characteristic of the rotational mobility of glasses, there is reason to expect that the compensation effect may be characteristic also of certain kinetically controlled reactions in glasses and liquids, which require contact between the reactants in the correct coordination. The stereospecificity of the reaction is expressed by the fact that its rate on contact between the reactants depends on the position of the point of contact on the reaction sphere of radius R:

$$k_p = k_p(\theta, \varphi),$$

where θ and φ are the angular coordinates of the point. In terms of the terminology of the model, this implies that the sphere is non-uniformly grey and, although there is a possibility of contact at any point with equal probabilities, owing to its different effectiveness, there is a multiplicity of different values of k_p, occurring with the probability

$$dW = f(k_p')\,dk_p'. \qquad (28)$$

Generally speaking, this distribution is diffuse compared with the model of a uniformly grey sphere, to which corresponds the distribution $f(k_p') = \delta(k_p' - k_p)$ or the model of a white sphere with grey spots, for which $f = (1 - q)(k_p') + q\delta(k_p' - k_p)$, where q is the steric factor equal to the relative area of the reactive surface. The relative rotation of the reactant simulates the rate of reaction during contact, and by virtue of this is capable of accelerating the process to some extent as a function of the form of $f(k_p')$. This implies that at the kinetic stage the process is controlled by rotational migration, the frequency ν of which may exhibit the same temperature dependence as the coefficient of translational diffusion. Griva and Denisov justly noted[28] that the proportionality $k = k_p \propto \nu$ (Fig. 11) "is a new phenomenon and is not predicted either by the theory of collisions in a liquid or by the activated complex theory". The authors explained this correlation on the hypothesis that, when it rotates, the molecule must overcome potential barriers generated by the environment. Orientation favourable for the reaction obtains in the vicinity of the maximum of one of the barriers. It is therefore reached only by molecules with sufficient rotational energy, the number of which is greater the faster the rotation. This view constitutes a modification of the activated complex theory in which an angular variable is the reaction coordinate[79].

However, the position favourable for reaction is not necessarily energetically unfavourable. If all the orientations are energetically equivalent, the rate of reaction is determined solely by its stereospecificity and by the mechanism of the reorientations and not in any way by the activation energy. This situation has been the subject of a special study for different models of chemical asymmetry under the conditions of jump reorientations by large and small angles in the cage. The rate of reaction over long periods, where it follows an exponential law, may depend on the frequency of the reorientations both linearly and in terms of the "square root" law ($\propto \sqrt{\nu}$).[74]

The dependence of the rate constant for the rotational or translational mobility of the reactant is a general feature of reactions controlled by molecular mobility, including those with kinetic limitations.

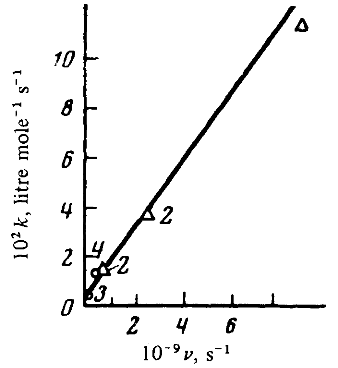

Figure 11. Direct proportionality between the rate constant for a liquid-phase reaction and the frequency of rotation of the reactant (a nitroxy-radical) at 22°C according to Griva and Denisov[24]: 1)–4) various solvents.

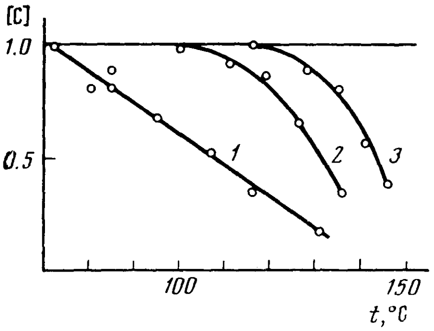

Figure 12. Curves for the annealing of radicals in crystalline adipic acid at different pressures: 1) 1 bar; 2) 2.8 kbar; 3) 4.15 kbar.

There exists a simple possibility of testing whether the process is activated and suffers from insufficient energy for its occurrence or from a deficiency of free space necessary for the organisation of the elementary migration step. The point is that $v = \text{const.}$ during isochoric heating and the probability defined by Eqn. (26) does not change as the temperature rises. This fact, namely the independence of the isochoric viscosity of simple liquids of temperature, has been used by Bachinskii as the basis of the free volume theory of viscosity[75]. Like Jost, having carried out isochoric measurements of diffusion coefficients in ionic crystals, he demonstrated very elegantly that the marked isobaric temperature relation $D(T)$, which is a consequence of thermal expansion, is abolished when the volume is fixed[66]. Assuming that the main factor in the recombination of radicals is the appearance of vacancies, which loosen the structure and facilitate the diffusion of species toward one another, the present author carried out an experiment involving the annealing of radicals in a high-pressure bomb, which makes it possible to prevent or hinder the expansion of the crystalline specimen during heating[76]. As expected, the recombination at the usual annealing temperatures did not occur at all, and the greater was the applied pressure, the higher was the rise in the heat treatment temperature necessary to achieve an appreciable transformation for a specified duration of heat treatment (Fig. 12).

Thus the only definite claim that can be made is that the compensation effect is associated with the steric difficulties in the organisation of the elementary step in a continuous medium. The liberation of space as a result of the aggregation of vacancies is more important than the accumulation of energy, which in any case cannot be used to achieve migration through a dense screen of molecules. Having been uniformly distributed in the first coordination sphere, the nearest neighbours create an impenetrable potential barrier and only fluctuations in their packing can create a breach in this wall. It is therefore not surprising that all investigators, whatever their concern (diffusion into metals[63], recombination of radicals[58-60], or solvation phenomena[77]), inevitably concluded that the compensation effect has a cooperative mechanism. The difficulties associated with the differentiation of the assembly of molecules involved in the elementary step, out of the total number present, constitute a problem which has not been solved theoretically and which is relatively unsusceptible to experimental investigation. However, progress in this field is necessary, since it is potentially capable not only of explaining the elementary step but also of leading to the discovery of means of controlling it.

---o0o---

Even a simple change of emphasis, involving a change of attention from the energy to the entropy (packing) factor, is methodologically important for the chemical physics of the condensed state. The present author recently re-examined from this point of view the entire set of facts associated with the destruction of radicals generated by penetrating radiation in solid matrices[78]. It was found that the heterophase fluctuations associated with the transient local softening of the structure should lead in the first place (long before the unfreezing of diffusion) to the destruction of radical pairs and, increasing in scale with increasing temperature, should successfully "anneal" radicals increasingly remote from one other, which has been indicated by experimental data. When the fluctuations reach an extent sufficient not only for the establishment of contact but also for the spatial migration of the molecules, the static annealing of radical pairs gives way to diffusion-controlled destruction of randomly scattered radicals. Concepts of this kind might change from qualitative or semiquantitative ideas to rigorous constructions if the nature of molecular mobility did not have to be guessed at from indirect chemical data and could be inferred fairly definitely from direct physical measurements.

Unfortunately the chemical physics of condensed media has greatly outstripped molecular physics, and the lagging behind of the latter makes it virtually pointless to accumulate further uninterpreted data on the rate constants for elementary reactions in solid and liquid molecular media.

Nevertheless information about the structure of catalytically active centres, the complex, solvation, and hydration shells, the defective structures of crystals, and the short-range order in liquids, and especially the extension of the extremely scanty available information about molecular mobility in all such systems might sharply reduce the arbitrary features in the interpretation of chemical processes and permit a critical choice between the physical models of the elementary step.

The Mechanism of the β-Elimination Reaction

M.A.Aleskerov, S.S.Yufit, and V.F.Kucherov

The latest studies on the mechanisms of the β-elimination reaction are considered and described systematically. The use of stereochemical and isotope effect data for the recognition of different types of reaction mechanisms is discussed.
The bibliography includes 232 references.

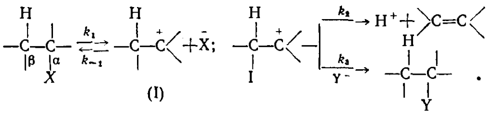
I. INTRODUCTION

Systematic research on the β-elimination mechanism began in 1927 when Ingold[1] attempted to investigate reactions of this type. Subsequently numerous studies devoted to the elucidation of the details of the mechanism were carried out[2-12]. All the mechanisms of the elimination reactions were divided into three classes[1-6]: *E*1, *E*2, and *E*1c*B*, in which the C−H bond is dissociated after, simultaneously with, or before the dissociation of the C−X bond respectively. There are also certain other less thoroughly investigated types of mechanisms.

II. THE *E*1 MECHANISM

1. General Characteristics of the β-Elimination Reaction via the *E*1 Mechanism

In 1935 Hughes[13] investigated a mechanism in which the slow stage is the ionisation of the initial reactant (substrate) preceding the rapid decomposition of the resulting carbonium ion. This unimolecular mechanism was called the *E*1 mechanism:



(1)

The carbonium ions (I) formed in the slow stage are subsequently consumed both in the elimination reaction and in nucleophilic substitution as a result of the interaction with the solvent molecules Y (or YH) or with other nucleophiles Y^- in the medium.

The occurrence of the reaction via the *E*1 mechanism is favoured by a molecular structure and media such that heterolysis of the C−X bond is faciliated[14]. In particular, the structural characteristics of the molecule, promoting the stabilisation of carbonium ions, play an important role[10,15]. For this reason, reactions via the *E*1 mechanism are more characteristic, for example, of tertiary, secondary, and α-aryl-substituted halides than of primary halides. Since the ability to carry a full positive charge is not characteristic of carbon atoms, stable carbonium ions have as a rule structures permitting extreme delocalisation of the positive charge[10,15]. The most important external factor, promoting a decrease of the positive ionic charge on carbon atoms, is solvation, because the vacant orbitals of the carbon atoms interact with the non-bonding electrons of the solvent molecules. Indeed, polar solvents promote the formation of carbonium ions and facilitate a reaction via the *E*1 mechanism, which competes in fairly strongly solvating but weakly nucleophilic media not only with the bimolecular *E*2 mechanism but also with the S_N1 mechanism. The elimination of toluene-*p*-sulphonic acid from *exo*-norbornyl toluene-*p*-sulphonate under the influence of a strong base in hydrocarbon solvents proceeds "purely" via the *E*2 mechanism. The same reaction in a tertiary alcohol involves predominantly the *E*1 mechanism[16]. The rates of the *E*1 reaction for menthyl and neomenthyl toluene-*p*-sulphonates in aprotic polar solvents vary in parallel with the dielectric constant of the solvent[17].

If the eliminated group X is an anion, its solvation by solvent molecules facilitates to a considerable degree the heterolysis of the C−X bond. In this case a smaller ion (for example Cl^-) will be solvated more effectively than a more diffuse ion (for example Br^-). When X is varied in the reactions of t-BuX in ethanol at 75°C, the ratio of the yield of the olefin to that of the substitution products increases in the sequence $\overset{+}{S}Me_2$ (0.18) < I (0.32) < Br (0.36) < Cl (0.44). When ethanol is replaced by acetic acid, the ratio changes in the same sequence, but to a more marked extent: from 0.12 for $\overset{+}{S}Me_2$ to 0.73 for Cl.[18] Since the solvation of anions is very important, weakly acid solvents (which interact with anions via hydrogen bonding) have a more ionising effect than basic solvents.

Since the carbonium ions formed as a result of the reversible heterolysis of the C−X bond can interact with the solvent, it is necessary that the β-hydrogen atoms should be split off rapidly. In the general case this last reaction stage has a low activation energy (~4 kcal mole^{-1}) and is highly exothermic; it is also favoured by the presence of substituents which are capable of being conjugated with the double bond formed.

If the rate of the carbonium ion formed in the slow stage of the reaction is decided in the subsequent rapid stages involving the elimination of a proton or interaction with the solvent, then the yield of the elimination product (as well as the ratio of the isomers if the latter are formed) should not depend on the nature of X for the given alkyl. Indeed this is approximately true for t-butyl, t-pentyl, s-octyl, and menthyl halides and the corresponding 'onium compounds in aqueous solvents[19]. In a series of t-butyl compounds whose ionisation potential varies by a factor of 900 the same relative yield of the olefin are obtained throughout the series with a variation of ±15%. Under these conditions, the carbonium ion decomposes immediately, although the counterion (leaving ion) is still very close; it is actually possible that the two ions form an unseparated ion pair. In media with high dielectric constants, such as nitromethane and acetonitrile, the ions acquire considerable freedom and even the above slight difference (15%) in the yields of the olefin vanishes.

Thus the *E*1 mechanism is preferred, provided that all or some of the following conditions are fulfilled: the presence at the α-carbon atom of substituents which may delocalise the positive charge on this atom and can become involved in conjugation with the double bond formed between the α- and β-carbon atoms; an enhanced capacity of the leaving group for ionisation; the presence of a highly solvating medium; the absence of a strong base which alters the mechanism to *E*2. All these conditions promote the heterolysis of the α-C–X bond without the simultaneous cleavage of the β-C–H bond.

2. Stereochemistry of Elimination Via the *E*1 Mechanism

As early as 1940, Hückel[20] showed that the stereochemistry of β-elimination depends on the reaction mechanism. Subsequently Hughes and Ingold[21] developed on the basis of stereochemical rules a theory of *E*1 and *E*2 reactions on which all subsequent studies of the stereochemistry of the elimination reaction are based.

The *E*1 reaction proceeds via a carbonium ion, the formation of which requires only the solvation of one carbon atom attached to the substituent, which is split off and the solvation of the substituent itself. The neighbouring carbon atom is not affected in this process. The second stage of the reaction, involving the elimination of a proton from a neighbouring carbon atom, does not impose special steric requirements, since the carbonium ion has a planar structure. For this reason, both *cis*- and *trans*- hydrogen atoms can participate in the *E*1 reaction. The relative amounts of olefins formed then frequently correspond to the thermodynamic stabilities, i.e. Zaitsev's [Saytzett's] rule holds. However, this rule cannot always be applied to elimination via the *E*1 mechanism, since in reality the situation is much more complex. The main aim of the examples quoted beflow is to give a general idea of the trend in research in this field.

The solvolysis of cyclopentyl derivatives proceeds at an unusually high rate (compared with acyclic and cyclohexyl analogues)[22,23], but in the majority of the published studies the yield of elimination products is not quoted. The studies by Hückel and coworkers[24], devoted to the alcoholysis of cyclopentyl toluene-*p*-sulphonate, permit the following conclusions: the reaction involves mainly the formation of ethers with a slight admixture of cyclopentenes; *cis*- and *trans*-2-alkylcyclopentyl toluene-*p*-sulphonates give rise to a large amount of cyclopentenes in which the Δ^1-isomer predominates; the *cis*-isomers react faster than the *trans*-isomers and gives a greater amount of the olefin. The stage determining the structure of the final product in these reactions is apparently the formation of an ion pair.

Analysis of the relative rates of solvolysis of isomeric monosubstituted cyclohexyl arenesulphonates is outside the scope of the present review, but it is discussed in detail in other reviews[22,23]. It is sufficient to say that the ratio of the rates of acetolysis, formolysis, and alcoholysis of axial 3- and 4-alkylcyclohexyl toluene-*p*-sulphonates to the rates of reaction of their equatorial analogues is of the order of 3.2–3.9.[25] The ratio of the rates involving the 3-substituted compounds does not differ greatly from the ratio of the rates for the conformationally similar 4-substituted analogues. The fact that the solvolysis of the axial toluene-*p*-sulphonate is faster may be attributed to the removal of steric hindrance on ionisation. This explanation presupposes that the two transition states for the ionisation of the axial and equatorial leaving groups can have different free energies, but the difference should be smaller than the difference between the free energies of the ground states. This approach appears to be quite reasonable[26].

The second factor responsible for the preferential ionisation of the axial leaving group compared with the equatorial group is that the positive charge formed is stabilised by the electronic interaction with the neighbouring β-C–H axial bond. This stabilisation can be regarded as a consequence of hyperconjugation or as a result of the involvement of the hydrogen atom in the stabilisation[27]. Whatever the nature of this stabilisation, it cannot be the decisive factor in the rate-limiting transition state in the formation of the cation as a result of the elimination of the equatorially oriented leaving group in the case of the chair conformation of the substrate, because the maximum effect requires the *trans*-orientation of the β-hydrogen and of the leaving group[26].

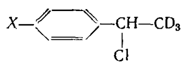
Examination of literature data[19,27–29] permits the conclusion that the *E*/*S*N ratio in the *E*1 reaction involving *cis*-2-alkylcyclohexyl derivatives is greater than for the *trans*-isomers, while *anti*-elimination yields exclusively the Δ^1-cyclohexene. The last effect is a consequence of the particular geometry of the six-membered ring (compared with the acyclic compound) and the greater stabilisation of the carbonium ion owing to the formation of a hydrogen bridge or hyperconjugation with the axial hydrogen atom in the β-position. As regards the *trans*-isomers, it appears that both *trans*-cyclohexyl and *trans*-4-t-butylcyclohexyl arenesulphonates are solvolysed, passing through the "twist" conformation in the transition state. The study of secondary isotope effects in the acetolysis of β-deuterated *trans*-4-t-butylcyclohexyl brosylates[27] and cyclohexyl toluene-*p*-sulphonates[30,31] as well as certain other data[32–34] lead to the same conclusion.

3. Isotope Effects in *E*1 Elimination

In principle, all three mechanisms of the β-elimination reaction can be distinguished by studying isotope effects[35]. More detailed differences within the limits of these broad classes can be effectively investigated by measuring the relative isotope effects for related compounds. Theoretical predictions and experimental findings obtained in the study of the isotope effects for the main types of mechanisms are given below. These predictions are qualitative and are based on the assumption that isotope substitution at the atom at which the type of bond is altered as a result of activation leads to an isotope effect (see, for example, Melander[36]). For more exact predictions, detailed calculations must be resorted to[37–40].

In the case of the *E*1 mechanism the primary isotope effect should be observed for a labelled group X and α-carbon [see scheme (1)], but not for labelled β-carbon and α- and β-hydrogens. Secondary isotope effects should be observed for α-hydrogens and for β-hydrogens not involved in the reaction. The carbonium ion (I) is a reactive intermediate species and appreciable β-carbon and α- or β-hydrogen isotope effects should not be observed in its decomposition[41]. If the reaction of (I) with Y has a high activation energy, then an isotope effect (slight or possibly even negative, since a bond is formed) should be observed when a labelled Y is used. The few available literature data on the isotope effect for a labelled group X are in the main consistent with the above predictions[42-49]. Numerous examples of α-hydrogen isotope effects in solvolytic and other substitution reactions have been published[50,51]. It has been shown that $E1-S_N1$ reactions have higher α-hydrogen isotope effects ($k^H/k^D = 1.15$ at 25°C) compared with the expected value, which corresponds to an appreciable weakening of the α-C–H bond in the activation process. One may assume that the elimination (or substitution) reactions in which α-hydrogen isotope effects differing markedly from the limiting values of the k^H/k^D ratio (at 25°C ~1.22 for X = F, ~1.55 for X = Cl, ~1.125 for X = Br, ~1.09 for X = I, and ~1.22 for X = OTs)[53] are manifested involve at least partially a mechanism different from $E1$ or S_N1.

The occurrence of a β-hydrogen isotope effect in $E1$ reactions has been demonstrated[51-57]. This can be accounted for by hyperconjugation—the delocalisation of sp^3-s electrons of the β-C–H bond over the α-p orbitals being formed. One might expect that the stabilisation by hyperconjugation of the positive charge generated on the α-carbon atom plays a smaller role when the positive charge is conjugated with a benzene ring, particularly one containing an electron-donating group, which thus leads to a decrease of the β-hydrogen isotope effect. The results of studies confirming this conclusion in relation to the solvolysis of 1-aryl-1-chloroethanes are listed below[51]:



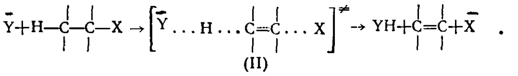
X	k^H/k^D
CH_3O	1.113
CH_3	1.200
H	1.224
NO_2	1.15
F	1.211

The standard value of the β-hydrogen isotope effect for the CH_3 group (data for t-butyl chloride[56]) is $k^H/k^D = 1.33$. All the values quoted above are significantly lower. The value for p-nitro-compounds is reduced compared with expectation owing to nucleophilic attack by the solvent on the α-carbon atom.

III. THE $E2$ MECHANISM

1. General Characteristics of β-Elimination Via the $E2$ Mechanism

The $E2$ mechanism is the commonest of all the elimination mechanisms and can be represented by the following scheme:



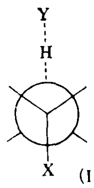
$$\bar{Y}+H-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-X \rightarrow \left[\bar{Y}\ldots H\ldots \overset{|}{\underset{|}{C}}=\overset{|}{\underset{|}{C}}\ldots X\right]^{\neq} \rightarrow YH+\overset{|}{\underset{|}{C}}=\overset{|}{\underset{|}{C}}+\bar{X} \quad (2)$$

(II)

According to this scheme, the reactant Y, called the base, removes a proton from the β-carbon atom of the substrate and the electron-accepting leaving group X is synchronously separated from the α-carbon atom. This mechanism does not involve any intermediate stages and thus has only one transition state between the reactants and the products. The reaction is of second order overall—of first order with respect to each reactant.

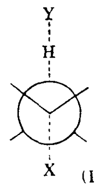
In his early studies Ingold[1] already pointed out that it is not obligatory that the dissociation and formation of bonds in an $E2$ reaction should occur absolutely synchronously; in 1956 Cram et al.[58] established that the structure of the transition state in $E2$ reactions may be different for different substrates under identical reaction conditions and may vary for the same substrate when the reaction conditions are altered. It has now been demonstrated that in reality there is a whole set of $E2$ mechanisms with different transition states[2,3,59,60] whose structure may vary smoothly with that of the substrate and the reaction conditions; these variations are limited on either side by extreme cases—$E1$-like and $E1cB$-like transition states—and do not extend beyond the region where true carbonium ions and carbanions exist. The mechanism is believed to be synchronous ($E2$) when a base is involved in the transition state, but there is no exchange of hydrogen atoms.

It is very important to emphasise that the type of the transition state is not a constant property of the substrate, but depends also on the nature of the solvent and the base. In such cases the predictions and interpretation of the experiments frequently become arbitrary and it is usually more correct to refer the reaction to a particular special case and to a specific type. Four main types of the transition states in $E2$ reactions are given below:



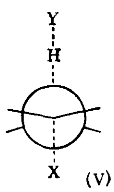
(III)

$E1cB$-like



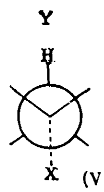
(IV)

Synchronous reactant-like



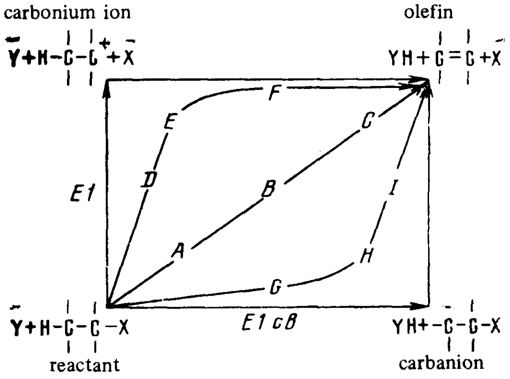
(V)

Synchronous olefin-like



(VI)

$E1$-like



Schematic illustration of the changes in the transition state in the elimination reaction (various types of the $E2$ mechanism).

A new method for the representation of a variety of transition states for $E2$ mechanisms, which proved to be the clearest and most convenient, was proposed recently[61]. The Figure represents schematically various $E2$ mechanisms on the basis of the potential energy surface diagram. Each section, denoted by a letter within the limits of the diagram, corresponds to a definite type of activated complex with its own potential energy surface; the positions of these sections relative to the species designated in the corners of the diagram indicate the structural characteristics of the various activated complexes and their positions on the reaction coordinate.

For example, the activated complex *A* is reactant-like (with a slight weakening of the β-C–H and α-C–X bonds and a slight double-bond character of the α-C–β-C linkage). According to Hammond's postulate[62], this activated complex may be formed in reactions giving rise to a very stable olefin.

The activated complex *F* is "carbonium ion- and olefin-like" with a significant weakening of the α-C–X bond, an appreciable double-bond character of the α-C–β-C linkage, and considerable transfer of a hydrogen atom from β-C to the base. Section *B* describes the "central" synchronous transition state. Thus the transition state in an *E*2 reaction can occupy any point within the given diagram, without going outside its limits.

The relations between the factors influencing the structure of the transition state are very complex, but the predictions described below appear to be well-founded and agree with the experimental data which will be examined subsequently.

Type (III) (the *H* region in the Figure) is favourable for compounds in which the β-hydrogen atom is labile owing to the inductive *–I* effect of α- or β-substituents; the rate of reactions proceeding via such an activated complex will be appreciably influenced by factors determining the acidity of the β-hydrogen. Such reactions are particularly facilitated in the presence of substituents delocalising the negative charge owing to conjugation or of substituents with *cis*-steric effects (see above). The use of strong bases as well as solvents which do not favour the ionisation of groups eliminated from the α-position also favours the occurrence of reactions with an *E*1*cB*-like mechanism.

The "*E*1-like" type (VI) (the *E* region in the Figure) is favoured by factors such as the presence of electron-donating substituents, which increase the electron density at the α-carbon atom, steric effects, and solvents favouring the extension of the C–X bond. The strength of the bases and the polar and steric effects of β-substituents have little importance in this instance, but the α-substituent, which delocalises the positive charge owing to conjugation, should influence the reaction rate.

Evidently types (IV) and (V) (*E*2 synchronous types; *A* and *C* regions in the Figure) have the characteristics of types (III) and (VI), but exhibit a specific sensitivity to α- and β-substituents and a high β-hydrogen isotope effect. In such cases bulky α- and β-substituents give rise to a pronounced *cis*-effect, since the double bond in the activated complex is fairly well formed, but small substituents may favour this type of transition state as a result of conjugation.

The influence of various factors on the structure of the transition state and the rate of *E*2 reactions has been examined in a number of reviews[3–12], from which it follows that in general low concentrations of the base favour unimolecular reactions (*E*1, S_N1). On the other hand, at a high concentration of the base, bimolecular reactions predominate (*E*2, S_N2), the relative contributions of which depend both on the structure of the substrate and on the ratio of the basicity of the base employed (attack on H) to its nucleophilic strength (attack on C).

Another approach is based on the hypothesis that the rate of *E*2 reactions depends in this instance on the H_- function at a high concentration of the base if there is a vigorous transfer of the proton to the base in the transition state[63]. The ratios of the rates of the base-catalysed elimination for para-substituted β-chloroethyl phenyl sulphones in anhydrous acetonitrile when Et_3N, $Et_2NCH_2.CH_2OH$, $EtN(CH_2CH_2OH)_2$, and $N(CH_2CH_2OH)_3$ are used as bases are 550 : 52 : 6.6 : 1 respectively[64]. This shows that the rate of reaction is correlated with the basicity of the bases. The Hammett reaction constants ρ for these reactions are respectively 1.81, 1.75, 1.72, and 1.64. Such variation of the reaction constant shows that the carbanionic character of the transition state becomes more pronounced with increasing base strength, moving into the *H* region (see Figure). Other investigators[65–67] arrived at the same result in studies of the influence of the base strength on the ratio of the yields of the products of *E*1, S_N1, *E*2, and S_N2 reactions and on the yield of isomeric olefins from various substrates. However, this type of correlation is not always observed[68–70]. The study of nine reactions in a concentrated NaOMe solution showed[71] that there is no direct correlation between the rates of reaction and the H_- acidity functions or the stoichiometric concentrations of the base.

The breakdown of the linearity in the relation between the rates of *E*2 elimination and base strength can be due to the smooth variation of the structure of the transition state[58] as the base strength is altered, which may lead to a change in mechanism. For this reason, in a study of the influence of the basicity of the medium both on the rate and the mechanism of the reaction, it is desirable not to confine the investigation to the measurement of the reaction rates alone and to determine also other characteristic reaction parameters (such as the reaction constant and the isotope effect) in order to be able to arrive at more clear-cut conclusions on comparing these parameters.

Such a combined study of the elimination of HBr from 2-arylethyl bromides in the t-BuOK–t-BuOH system has been carried out by Saunders and coworkers[72]. They investigated the influence of the addition of dimethyl sulphoxide (DMSO) on the rate, the isotope effect, the reaction constant, and the activation parameters of the above reaction. We observed that the addition of DMSO causes an unusually marked acceleration of the reaction (by a factor of 12 at 30°C for a 0.965 M DMSO solution and by a factor of 120 for the 2.23 M solution). Despite the fact that DMSO has a much higher dielectric constant than t-butyl alcohol, the value of *E* (and *Z*) for these solvents are almost identical[73]. Consequently there can be no great difference between their solvating capacities in relation to a neutral alkyl bromide and a transition state with a delocalised charge. Thus the acceleration could have been caused only by a change in the basicity of the t-butoxide. However, with increase of the DMSO concentration from 0.965 to 2.23 M, the rate of elimination for 2-phenylethyl bromide increases by a factor of 10, while the basicity changes only slightly (only by a factor of 1.5). The authors[74] believe that the usual basicities, determined experimentally, are unsuitable for the consideration of the influence of "basicity" on the structure of the transition state in the reaction. It was shown[74] that the base strength and the type of solvent are more important factors than the size of the base and the direction of its approach to the reagent. The association of the catalyst[75] as well as ion–dipole and ion–ion interactions between the base and the leaving group[76] play a particularly important role.

The idea that the hydrogen bonding and hence the "levelling effect" of protic solvents may influence the basicity of oxygen-containing anions was tested experimentally 35 years ago[77]. Furthermore, the polarity of the transition state in an $E2$ reaction is usually lower than that of the initial state, since the ionic charge of the base is distributed over a larger area. For this reason, polar solvents should reduce the reaction rate. Since the charge in the transition state of the elimination reaction is more delocalised, the decrease of the rate is in this case manifested to a greater extent than in the corresponding substitution reaction (S_N2), which frequently accompanies bimolecular elimination reactions[78,79].

There is no need to consider in detail each individual investigation in the present instance, but one must note that studies in recent years have been largely devoted to an experimental test of the above considerations. They showed that both variation in base strength and solvent polarity[80-82] and changes in the structure of the substrate[83-86] influences the rate of elimination[87,88] and lead to a change in the structure of the transition state, as a result of which it may occupy an infinity of positions on the potential energy surface between the limiting "$E1cB$-like" and "$E1$-like" types[89].

2. Stereochemistry of the Elimination Reaction Via the $E2$ Mechanism

Until recently[90] the stereochemical characteristics of $E2$ reactions were thought to be determined by Ingold's four-centre rule, which states that bimolecular elimination proceeds smoothly only when the four centres involved in the reaction lie in the same plane, i.e. when the substituents being eliminated are in the transoid conformation (in the *anti*-position relative to one another) or in an eclipsed cisoid conformation. For rigid cyclic systems, an analogous rule was formulated by Barton, while the steric limitations in elimination reactions involving bridged rings are determined by Bredt's rule.

However, the current views on the stereochemistry of the $E2$ reaction have altered radically; it has been established that, for *cis*-coplanar leaving groups, the $E2$ reaction proceeds just as fast as in the case where the groups are *anti*-periplanar and that *cis*-$E2$ elimination cannot be ruled out either in acyclic or cyclic systems.

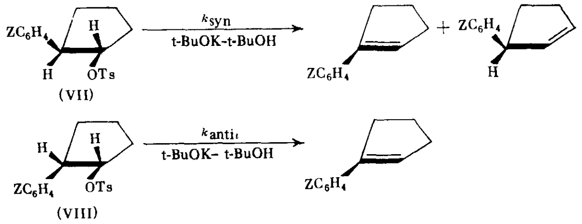
Furthermore, β-elimination reactions have been achieved with bridge compounds despite being "forbidden" by Bredt's rule. These problems are discussed in special reviews[25,91-96]. It is important to note that both the bulk of the base and of the leaving group and the degree of branching of the substrate molecule play a role in the alteration of the relative contributions of *cis*- and *trans*-elimination reactions[94,97-99]. Analysis of the proportions of the products of elimination from PhCHDCHDX (X = p-$MeC_6H_4SO_3$ or Cl) using t-BuOK in t-BuOH, DMSO, or benzene showed[100] that *syn*-elimination takes place only in benzene and that *syn*- and *anti*-elimination reactions lead to different primary hydrogen isotope effects. The above study gives an idea of the important role in *syn*-elimination of the ion pair formed by the base.

The latest studies on the general aspects of the stereochemistry of this reaction[101] as well as *syn*-elimination[102-104] again confirmed the influence of the formation of the ion pair on the stereochemistry of the process[105] and also the important role of the base and the solvent[106]. After it was discovered that macrocyclic ethers (crown ethers)[107] are able to be coordinated to alkali metal cations and to separate the complex ion pair formed by the base[108,109], investigators of the elimination mechanism acquired a valuable instrument for the elucidation of the role of ion pairs in *syn*- or *anti*-elimination. Such information can be obtained by comparing the steric results of the reaction of a given compound with a base in the presence and absence of the crown ether.

Data have been published[110] for the reaction involving elimination from *trans*-2-phenylcyclopentyl toluene-p-sulphonate in the t-BuOK–t-BuOH system at 50°C. In the absence of the crown ether, the ratio of 1-phenylcyclopentene (the *syn*-elimination product) and 3-phenylcyclopentene (the *anti*-elimination product) was 9.8–11.8 (depending on the reaction time). After the addition of the macrocyclic ether (dicyclohexyl-18-crown-6) in an amount equal to that of the base, the ratio became 0.43, i.e. the steric course of the reaction was altered sharply. An analogous result was achieved[111] also in the reactions of other alicyclic toluene-p-sulphonates with t-BuOK. The addition of the crown ether in this instance also drove the reaction along the *anti*-elimination pathway.

An interesting result was likewise obtained[112] in a study of the linear 5-decyl toluene-p-sulphonate with t-BuOK in t-butyl alcohol, benzene, and dimethylformamide (DMF). It was found that the base in the form of an ion pair and the ions separated by the crown ether are involved only in *anti*-elimination but in quite different ways: in the former case the product is mainly a *cis*-olefin and in the latter a *trans*-olefin. The influence of the crown ether is then manifested only in t-butyl alcohol and in benzene, while in DMF the ratio of the reaction products does not change when the crown ether is added. This finding evidently shows that in DMF the base exists in a fully dissociated state also in the absence of the crown ether. Thus the use of crown ethers established that weakly polar and protic solvents promote the reaction via the *syn*-elimination pathway, while in polar aprotic solvents *anti*-elimination predominates. Furthermore, it follows from these experiments that in the bimolecular reaction *syn*-elimination is caused by the base in the form of a close ion pair, while *anti*-elimination proceeds under the influence of the separated ions. The use of crown ethers for the investigation of the $E1cB$ mechanism is described by Hunter et al.[113]

Numerous studies in recent years were devoted to the stereochemistry of $E2$ reactions in alicyclic systems. The discovery that the *syn*-elimination accelerated by bases in the series of *trans*-2-arylcyclopentyl toluene-p-sulphonates (VII) is faster than the *anti*-elimination for the *cis*-isomers (VIII) leads not only to the conclusion that *syn*-elimination is a concerted reaction[93] but also indicates the dependence of the relative rates of synchronous elimination on the dihedral angle[100].



$$k_{syn}/k_{anti} = 9.1\ (Z = H);\quad \rho_{syn} = 2.8;\ \rho_{anti} = 1.5;\quad k^H/k^D = 5.6\ (50^\circ C)\ . \qquad (3)$$

The large *syn/anti* ratio, the more positive value of ρ for the *syn*-process, and an isotope effect which is close to a maximum, together with the undoubted second-order kinetics constitute rigorous proof of a *syn*-coplanar $E2$ mechanism with an appreciable carbanionic character (*H* transition state, see Figure). Owing to conformational limitations, *anti*-elimination from the *cis*-toluene-*p*-sulphonates (VIII) proceeds via an "$E1$-like" mechanism.

Preferential *syn*-elimination has also been demonstrated in a series of cyclo-octyl[25] and cyclodecyl[94,114–116] derivatives. Mainly *exo*-*cis*-bimolecular elimination predominates in the series of norbornyl derivatives[117–123]. In addition, it has been shown that the rate of reaction is strongly influenced by the steric strain in the ring. Thus the relative rates of β-elimination in the series of cyclopentyl, cyclohexyl, cycloheptyl, and cyclo-octyl toluene-*p*-sulphonates are 16.25, 1.0, 12.62, and 152.0 respectively[124].

The report of the synthesis of bridged olefins[125–129] initiated a new stage in the chemistry of bridged compounds. These olefins were obtained by the Hofmann cleavage of quaternary ammonium compounds and dehydrochlorination in the presence of collidine[129]. Bicyclo-[3,3,1]non-1-ene is also synthesised from a salt of *endo*-2-methanesulphonoxybicyclo[3,3,1]nonane-2-carboxylic acid[126]. The synthesis of these compounds constitute an evident infringement of Bredt's rule.

3. Isotope Effects in $E2$ Elimination

The primary isotope effects in the $E2$ mechanism should be observed when a labelled base, labelled α-carbon and β-carbon atoms, labelled group X to be eliminated, and labelled α-hydrogen are used. Secondary isotope effects can occur for α-hydrogen atoms and the non-eliminated β-hydrogen atoms. The isotope effect may then serve as a criterion for the elucidation of the structure of the transition state[130,131]. The isotope effect of the solvent (the replacement of water by D_2O) is studied for this purpose[132]. Saunders and Edison[133] found that the isotope effects k^H/k^D for compounds (IX, $Z = R^1 = R^2 = H$) with different leaving groups (X = Br, OTs, $\overset{+}{S}Me_2$, and $\overset{+}{N}Me_3$) are respectively 7.11, 5.66, 5.07, and 2.08. This series agrees with the increase of the carbanionic character of the activated complex and may be identified with the gradual transition from the *B* region to the *H* region (see Figure). Such changes should be accompanied by an increased shift of the β-hydrogen from the carbon atom to Y and thus by a decrease of the isotope effect, which is in fact observed. A similar result was obtained in another study[126].

$$\bar{Y} + Z{-}C_6H_4{-}\underset{}{CH(R^1)}{-}CH(R^2){-}X \rightarrow YH + Z{-}C_6H_4{-}C(R^1){=}CH(R^2) + \bar{X} \quad . \qquad (4)$$

(IX)

The influence of the reaction medium on the isotope effect has been observed in reactions of dimethyl-(β-phenylethyl)sulphonium salts (IX, $Z = R^1 = R^2 = H$, $X = \overset{+}{S}Me_2$).[134,135] The rate of the reaction of the HO^- ion with sulphonium bromide in a water–DMSO mixture increases sharply with increased DMSO content and the isotope effect of the medium k^{32}/k^{34} diminishes from 1.0074 in pure water to 1.0011 in ~20% DMSO. The β-hydrogen isotope effect in this range of solvent compositions does not vary appreciably, but, when the DMSO content increases still further, the ratio k^H/k^D passes through a maximum and then decreases again. The influence of the added DMSO was interpreted by the authors as a result of the increase of the effective base strength owing to a change in the degree of solvation, which displaces the activated complex in the direction of the carbanion-like transition state (from the *B* region to the *H* or *G* region). This should lead to a decrease of the polarisation of the α-C–S bond in the transition state, which entails a decrease of the sulphur isotope effect. On further increase of the DMSO content, the stability of the carbanion increases and the activated complex now becomes more reactant-like (i.e. shifts from the *C* region in the direction of the *A* region) in conformity with Hammond's postulate[62]. If it is supposed that in 20% DMSO the β-hydrogen in the transition state is transferred to the base Y to an extent greater than 50%, the addition of DMSO should initially lead to a transition state with a symmetrically linked β-hydrogen atom (to which corresponds the maximum value of k^H/k^D) and then to a state in which the β-hydrogen atom is displaced towards Y to an extent less than 50% (decrease of k^H/k^D) and this was in fact observed in the study quoted above[135]. Thus, when the DMSO content is increased, the position of the saddle point on the potential energy surface illustrated in the Figure will be displaced from the *B* region in the direction between the *G* and *H* regions and then back again towards the *A* region.

Willi[85] determined the primary isotope effects for the reactions of 2-deutero-2,2-diphenylethyl-*p*-Z-benzenesulphonates with sodium methoxide in methylcellosolve for Z = OMe, H, and NO_2 and obtained 5.27, 5.42, and 6.70 respectively. It appears that, when Z = OMe, the activated complex is in the *H* region and has a more pronounced carbanionic character. On passing to *Z* = H and NO_2, the degree of transfer of the β-hydrogen to the base diminishes, which brings it closer to the symmetrical position. β-Hydrogen isotope effects in $E2$ reactions have also been investigated in other studies[64,136–143].

In recent years data concerning the presence or absence of the β-hydrogen isotope effect have been widely used to solve the problem whether the $E2$ reaction proceeds via the *syn*- or *anti*-elimination mechanism in various systems[94,97,114,144–150]. It was shown[119,151,152] that *syn*-elimination predominates in norbornyl and bicyclo[2,2,2]-octyl derivatives. In these compounds $(k^H/k^D)_{anti} > (k^H/k^D)_{syn}$.

Finley and Saunders[153] carried out an extensive study of the primary β- and secondary α- and β-hydrogen isotope effects in the $E2$ reactions of cyclohexyl toluene-*p*-sulphonates in the presence of EtONa–EtOH and t-BuOK–t-BuOH. Both secondary isotope effects (α- and β-) are large (k^H/k^D = 1.14–1.15 and 1.36–1.51), while the primary β-effect is higher in t-butyl alcohol (k^H/k^D = 7.53) than in ethanol (k^H/k^D = 4.47). The structure of the activated complex in this reaction apparently corresponds to the "central" complex (*B* region, see Figure). The large secondary isotope effects are due to the appreciable sp^2 character of the α- and β-carbon atoms in the transition state. If this is so, then the primary β-hydrogen isotope effect in ethanol will correspond to the transition state in which the hydrogen atom is transferred from the β-carbon atom to the base Y to an extent less than 50%. The activated complex in t-butyl alcohol should then move in the direction of the symmetrical state acquiring at the same time carbanionic character and leading to an increase of the isotope effect, which has in fact been observed[153].

IV. THE *E*1*cB* MECHANISM

1. General Characteristics of β-Elimination Via the *E*1*cB* Mechanism

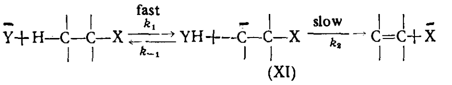
The *E*1*cB* mechanism is the third β-elimination mechanism proposed by Ingold[154]. It differs from the usual *E*2 mechanism by the fact that it corresponds to a two-stage process involving the formation of an intermediate discrete carbanion, while *E*2 elimination is a synchronous process proceeding via a single transition state from the substrate to the product[2,154]. Two main types of this mechanism are distinguished:

(1) Type *A*, in which the first rate-limiting stage is the bimolecular formation of a carbanion and the second stage is the relatively rapid removal of the leaving group from the α-carbon atom:

$$Y + H{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}X \xrightarrow{\text{slow}} YH + {-}\overset{-}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}X \xrightarrow{\text{fast}} \overset{|}{\underset{|}{C}}{=}\overset{|}{\underset{|}{C}} + \bar{X} \quad . \qquad (5)$$

(X)

(2) Type *B*, in which the first stage is the rapid reversible formation of a carbanion, while the second, rate-limiting stage involves the unimolecular decomposition of the carbanion; if the base is not in this case the lyate ion derived from the solvent, whose conjugate acid YH may be present in excess, second-order kinetics are observed:



$$\bar{Y} + H{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}X \underset{k_{-1}}{\overset{\text{fast}\ k_1}{\rightleftharpoons}} YH + {-}\overset{-}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}X \xrightarrow[k_2]{\text{slow}} \overset{|}{\underset{|}{C}}{=}\overset{|}{\underset{|}{C}} + \bar{X} \quad . \qquad (6)$$

(XI)

Second-order kinetics are usually observed for both types of the *E*1*cB* mechanism, as for the bimolecular *E*2 mechanism, since there is no kinetic criterion for distinguishing these mechanisms. If the pre-equilibrium carbanionic elimination (type *B*) takes place in protic solvents, then the β-hydrogen atoms of the substrate can exchange for the solvent protons at a rate exceeding the rate of elimination. Such exchange may be observed either by using a labelled substrate in an unlabelled solvent or conversely by using an unlabelled substrate in a labelled solvent. The occurrence of deuterium exchange is evidence for a pre-equilibrium *E*1*cB* mechanism; on the other hand, the absence of exchange indicates an irreversible *E*1*cB* mechanism (type *A*) or an *E*2 mechanism.

Breslow[155] suggested that, depending on the relative energetics, rapid hydrogen exchange may be an unrelated side reaction in *E*2 elimination. However, this hypothesis has been criticised[6,156,157]. In particular, Hine et al.[156], who investigated the elimination of HF from 2,2-dihalogeno-1,1,1-trifluoroethanes, established that in a methanol solution of methoxide the compounds exchange hydrogen at a significantly higher rate than that of their elimination reaction. The activating influence of the α-fluorine atoms and β-halogen atoms together with the well known difficulty of eliminating fluorine in the form of an anion from a saturated carbon atom (even more so from a carbon atom linked to other halogen atoms[158,159]) make it very likely that a carbanion is formed in this elimination reaction. Hine et al.[160] believe that, if the carbanion is formed, then in all probability it is an intermediate in the elimination reaction, since the transfer of its free electron pair should accelerate the formation of the olefin more effectively than the partial transfer of the same electron pair in the *E*2 transition states. In his study of the k_{OTs}/k_{Br} ratio as a criterion of the degree of dissociation of the C–X bond Hoffmann[161] also concluded that all the experimental examples known hitherto confirm this hypothesis. Thus the conditions and structures which ensure the formation and stabilisation of the carbanion favour the *E*1*cB* mechanism. The formation of a carbanion requires the abstraction of a proton from the CH acid. In elimination reactions bases are always used for this purpose. However, the presence of activating substituents, similar to the nitro- and carbonyl-groups, as well as other substituents with strong *–I* and *–M* effects may increase the acidity of the β-hydrogen to such an extent that the compound may give rise to a carbanion without the addition of an external base—the alkalinity of glass, for example, may be sufficient for this purpose. All the factors responsible for both the formation and stabilisation of carbanions are widely discussed in Cram's book[162]. These problems have been considered in a number of reviews[11,12,163-167] in relation to the elimination reaction. The influence of solvents on the reactions of carbanions is discussed in Ritchie's review[168].

Crosby and Sterling[169-171] investigated the influence of 17 activating groups on the rate and mechanism of the reaction

$$\bar{Y} + Z{-}CH_2CH_2{-}X \rightarrow Z{-}CH{=}CH_2 + \bar{X} + YH \quad , \qquad (7)$$

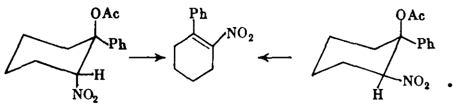
where X is the leaving phenoxy-group and Z represents activating substituents, which are listed below in order of decreasing activating influence:

$$NO_2,\ \overset{+}{P}Ph_3,\ \overset{+}{S}Me_2,\ COMe,\ CHO,\ SO_2OEt,\ SO_2Ph,\ SO_2Me,$$
$$CN,\ COOEt,\ SO_2N(CH_2Ph)_2,\ SOPh,\ CONH_2,\ SOMe,$$
$$CONEt_2,\ \overset{+}{N}Me_3,\ COO^-.$$

On passing from NO_2 to SOMe in this series, the reaction rate constant diminishes by a factor of 10^6. The rate constants are correlated with σ_R^-, but not with σ and σ*. This shows that the resonance stabilisation of the carbanion is an important factor in the activation of such systems. Furthermore, a satisfactory correlation is observed between the reaction rate constant and pK_a and the ionisation rate constant of the $Z-CH_3$ acid (a CH acid) as well as the rate constants for the nucleophilic addition of alkoxides to a series of vinyl compounds of the type $Z-CH=CH_2$.[172] Bearing in mind together with these findings the low values of the isotope effect and the reaction constant ρ as well as its insensitivity to changes in the substituents attached to the leaving phenoxy-group, the authors[169-171] concluded that elimination from these phenoxyethyl compounds proceeds via a pre-equilibrium *E*1*cB* mechanism at least for sulphoxides (Z = SOMe) and for compounds more reactive than the latter.

Rappoport and coworkers[173] compared the results obtained by Crosby and Stirling with data for the addition of various nucleophiles[172,174-180] and for nucleophilic vinyl substitution (which proceeds via addition and elimination)[181] with the approximate ionisation rate constants k_i and the dissociation constants K_a of the CH acids $Z-CH_3$[182] (for all the Z investigated by Crosby and Stirling). He concluded that all the data rigorously confirm the hypothesis of the *E*1*cB* mechanism of reaction (7).

The methoxide-catalysed *anti*- and *syn*-elimination of HOAc from the nitroacetates (XII) and (XIII) and the elimination of HOMe from the corresponding methoxy-compounds have been compared[183].



(XII) (XIII) (8)

It was established that the elimination of HOMe involves the reversible formation of a carbanion on treatment with MeOH–MeONa (*E*1c*B* mechanism, type *B*). Having considered the relative reaction rates, the effect of substituents, the deuterium isotope effects, and the activation parameters for the reactions of the acetoxy- and methoxy-compounds, the authors[183] concluded that elimination from both (XII) and (XIII) proceeds via an intermediate carbanion and that elimination with participation of mobile protons activated by the NO_2, MeCO, and CN substituents in general usually proceeds via the carbanionic mechanism.

This conclusion[183] is in full agreement with the conclusions reached by Crosby and Stirling, because the above substituents include the series of activating groups for which the *E*1c*B* mechanism has been demonstrated. It has been established[184] that the reactions of these compounds as well as their 4,4-dimethyl analogues in the presence of pyridine in $CHCl_3$–EtOH also proceed via the *E*1c*B* mechanism. For this reaction, the activation energy $E_a = 6.9$ kcal mole^{-1}, the activation entropy $\Delta S^{\neq} = -50$ e.u., the isotope effect $k^H/k^D = 4.5$, and the reaction constant $\rho = 1.45$, which is in full agreement with the proposed mechanism. A study[185] of the elimination of methyl alcohol from the isomeric *cis*- and *trans*-1-methoxy-2-nitro-1-phenylcyclopentanes also demonstrated the operation of a carbanionic mechanism for both isomers. Carbanionic mechanisms have been shown to occur in the elimination of substituted benzoic acids from 4-aroyloxy-2-butanones with formation of vinyl ketones[186], in the elimination of water from 2-cyano-1-hydroxy-2-(*p*-nitrophenyl)ethane[187], and in the elimination of AcOH from 9-acetoxy-10-methyl-*cis*-2-decalone[188]. Evidently, in all the examples β-hydrogen is activated by one of the groups which Crosby and Stirling investigated. Particular mention should be made of studies[189-191] which established convincingly by detailed kinetic investigations and the investigation of isotope effects that the β-elimination of water from 9-fluorenylmethanol in aqueous alkaline media and in alcohol proceeds via an *E*1c*B* mechanism with a slight contribution by the *E*2 mechanism.

The scope of this review does not allow a detailed consideration of the studies devoted to β-elimination from carbamates, various sulphones, etc.[192-196], for which the *E*1c*B* mechanism has been demonstrated.

There can now be no doubt about the possibility of β-elimination in activated systems by a carbanionic mechanism. Extensive studies have been carried out in this field on the influence of activating groups on the mobility of β-hydrogen and on the stabilisation of the carbanion formed. Furthermore, intensive research into the influence of the medium and bases on the kinetics and mechanism of this reaction is being prosecuted.

2. Stereochemistry of β-Elimination via the *E*1c*B* Mechanism

The hypothesis of complete *trans*(*anti*)-stereospecificity of *E*2 reactions was adopted at an earlier stage. It was confirmed for almost all the examples investigated and the manifestation of *trans*-specificity in the reaction was therefore regarded as sufficient evidence to assume the *E*2 mechanism. Any breakdown of this stereospecificity was therefore regarded as evidence for the operation of another mechanism. In particular *syn*-stereospecificity was frequently accounted for by the *E*1c*B* mechanism. However, now that it is known that an *E*2 reaction can be both *anti*- and *syn*-stereospecific, the occurrence of *syn*-elimination should not apparently be regarded as evidence for elimination via the *E*1c*B* mechanism. Nevertheless, Ingold[197] emphasised that the *E*1c*B* mechanism should be either *syn*-stereospecific or non-stereospecific. We shall now consider to what extent this postulate actually holds in relation to the available experimental facts.

Jones et al.[198] synthesised diastereoisomeric 5-butyl-2-hydroxycyclohexyl-*p*-tolyl sulphones and measured the rates of piperidine-catalysed bimolecular elimination DMSO for the corresponding *trans*,*trans*-, *cis*,*trans*-, and *trans*,*cis*-isomeric sulphonate esters. Since a conjugated sulphone is the only product of these reactions, the implication is that two of these sulphonates undergo *syn*-elimination, while the *cis*,*trans*-isomer undergoes *anti*-elimination (formally diequatorial elimination). The relative rates change at most by a factor of 1.4 and are insensitive to the nature of the leaving group (either OTs or OMe). The *trans*,*cis*-compound (axial OSO_2R), axial SO_2Ar) reacted faster. The addition of piperidine hydrochloride causes a slight but nevertheless appreciable decrease of the rate. However, when the reaction is carried out in a deuterated solvent, the takeup of deuterium is insignificant. These data were explained by a mechanism with irreversible formation of a carbanion (*E*1c*B*, type *A*). Preliminary investigation of analogous isomeric 4-t-butyl-2-chlorocyclohexyl phenyl sulphones yielded additional facts confirming the above conclusions (see also Refs. 199 and 200).

The base-catalysed elimination of acetic acid from 2-nitro-1-phenylcyclohexyl acetates (XII) and (XIII) proceeds via a carbanionic mechanism, since the *syn*-elimination from (XII) is faster than the *anti*-elimination from (XIII). An appreciable deuterium isotope effect was observed; both processes show similar sensitivities to changes in temperature, medium, and substituents[184, 201]. The inclusion of *gem*-dimethyl groups in the 4-position increases the rate of elimination from (XII) and decreases the rate of elimination from (XIII). Furthermore, the corresponding nitronate ion was detected spectrophotometrically during the reaction in a study[184,185] of methoxy-analogues of (XII) and (XIII). Comparison of kinetic data, isotope effects, and the influence of substituents for the acetoxy- and methoxy-derivatives established the occurrence in these reactions of carbanionic processes of three types[183]: with an irreversible second-order carbanionic mechanism for (XII) and (XIII), with a reversible second-order carbanionic mechanism for the methoxycyclohexyl compounds, and with an irreversible first-order carbanionic mechanism (see below) for the methoxycyclopentyl compounds $\{k_1$ is the rate constant for the rate-limiting stage and $k_2 \gg k_{-1}[BH]\}$. The study of Bordwell et al.[183] yielded convincing evidence for a carbanionic mechanism of the *syn*- and *anti*-elimination from these compounds. Ring deformation apparently plays an important role in these processes. Special mention was made of the fact that the synchronous *anti*-*E*2 mechanisms for compound (XII) and its methoxy-analogues did not compete with the carbanionic process. Thus both *syn*- and *anti*-elimination proceed in this instance via an intermediate carbanion.

In the base-catalysed dehydrochlorination of the diastereoisomeric 1-chloro-1,2-diphenyl-2-toluene-*p*-sulphonylethanes[202], the *erythro*- and *threo*-isomers underwent full *trans*- and *cis*-elimination respectively. Thus both diastereoeisomers yielded 2-toluene-*p*-sulphonyl-*cis*-stilbene. The authors suggest a synchronous mechanism for the *erythro*-isomer and a carbanionic mechanism for the *threo*-isomer. The same system was studied in another investigation[203].

The amine-accelerated elimination of HF from fluoroethanes activated by the sulphonyl group is *syn*-stereospecific[204]. The study of the isotope effect in this reaction indicates an *E*1*cB* mechanism involving the formation of an ion pair (see also Hunter and Shearing[205]).

There have been very few studies on the stereochemistry of the *E*1*cB* mechanism. However, the available examples have shown that the mechanism is more likely to be *syn*-stereospecific than *anti*-stereospecific: this is in its turn consistent with Ingold's hypothesis[197].

3. Isotope Effects in the *E*1*cB* Elimination

We considered above two generally accepted types of the *E*1*cB* mechanism. If the formation of the carbanion is the rate-limiting stage (type *A*), then the primary kinetic isotope effects should occur for the labelled base Y the β-carbon atom, and the eliminated β-hydrogen atom. Whether or not secondary isotope effects are observed under these conditions for the α-hydrogen atoms or the non-eliminated β-hydrogen atoms should probably depend on the change in the hybridisation of the β-carbon orbitals on formation of the carbanion. Since the carbanion decomposes solely into the reaction products, the observed rate should not be sensitive to isotope substitution at the α-carbon atom or in the leaving group X. On the other hand, if the formation of the carbanion (XI) is a fast and reversible stage and its conversion into the reaction products is rate-limiting (type *B*), primary kinetic isotope effects should be observed for the labelled group X, α-carbon, and β-carbon, while in the case of a labelled group Y and labelled β-hydrogen atoms, equilibrium isotope effects may be observed. Secondary isotope effects may occur also for α'-hydrogen atoms.

There are few literature data for isotope effects in *E*1*cB* reactions involving labelled Y, α-carbon, or X. Almost all the isotopic studies have been carried out with labelled β-hydrogen. The β-hydrogen isotope effects are characteristic of both *E*2 reactions and *E*1*cB* (type *A*) reactions. The latter can therefore be distinguished only by comparing the magnitudes of these effects[130,131].

The situation is much more complex for the *E*1*cB* (type *B*) mechanism. *E*2 and *E*1*cB* (type *A*) reactions can proceed with a normal isotope effect, characterising these mechanisms, while the *E*1*cB* (type *B*) mechanism will exhibit only a small equilibrium isotope effect reflecting the different equilibrium concentrations of carbanions in reactions (6) and (9):[35]

$$\bar{Y}+D-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-X \xrightleftharpoons{\text{fast}} YD+-\overset{-}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-X \xrightarrow{\text{slow}} \overset{|}{\underset{|}{C}}=\overset{|}{\underset{|}{C}}+\bar{X} \quad . \qquad (9)$$

In this case definite conclusions can be reached only by comparing the rates of elimination of the unlabelled substrate in the unlabelled solvent with the rate of elimination of the labelled substrate in the labelled solvent. A normal isotope effect will be observed if the reaction proceeds via the *E*2 or *E*1*cB* (type *A*) mechanism, while the equilibrium isotope effect (the isotope effect of the solvent) will obtain for the *E*1*cB* (type *B*) mechanism. If, as frequently happens, YH and YD are solvents, the effective concentrations are constant and equal and the ratio of the observed rates is then equal to the ratio of the isotopic equilibrium constants[35]. Depending on the bond energy in RH relative to YH, the above ratio can vary from a value less than unity (the usual case) to one slightly greater than unity.

In the elimination of methanol from 4-methoxy-2-butanone and 4-methoxy-2-pentanone with formation of 3-but-2-enone and 3-pent-2-enone via the *E*1*cB* mechanism the exchange of β-hydrogen atoms (in the α-position relative to the carbonyl group) with D_2O-OD^- is rapid and the overall isotope effect $k^H_{obs}/k^D_{obs} = 0.87$ and 0.77 respectively[206]. In full conformity with the *E*1*cB* (type *B*) mechanism, Crosby and Stirling[171] also observed a rapid exchange in the elimination of phenol from dimethyl-(2-phenoxyethyl)sulphonium iodide and methyl-2-phenoxyethyl sulphone ($k^H_{obs}/k^D_{obs} = 0.66$ and 0.78 respectively).

When acetic acid was eliminated from 2-acetoxy-1-nitro-2-phenylcyclohexanes and the corresponding cyclopentanes and in the elimination of methanol from *trans*-2-methoxy-1-nitro-phenylcyclopentane[183,184], large β-hydrogen isotope effects ($k^H_{obs}/k^D_{obs} = 4.9-8.1$) were observed in all the reactions, as expected for the *E*1*cB* (type *A*) mechanism with a more or less symmetrical transfer of β-hydrogen from β-carbon to Y.

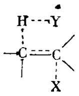
Yet another version of the *E*1*cB* mechanism was investigated by Rappoport[207-213] and Bordwell et al.[185] (see also Refs. 190, 195, 197, 198). If the entire substrate is converted into a carbanion under the influence of the base in the rapid stage of the reaction, further addition of the base no longer has any effect on the concentration of the carbanion and the elimination proceeds subsequently as a pseudo-first-order reaction. There is no isotope effect in such reactions, since the molecule no longer contains the isotopic atom in the rate-limiting stage. When HCN was eliminated from 2,6-dimethyl-4-(1,1,2,2-tetracyanoethyl)aniline in the presence of triethyl- or tri-n-butylamine, $k^H/k^D = 0.93$ was found[214]. Bordwell et al.[185] obtained $k^H/k^D = 1.7$ for the elimination of methanol from *trans*-2-methoxy-1-nitro-2-phenylcyclopentane using NaOMe–MeOH; k^H/k^D for the first stage (the formation of a carbanion) was normal and equal to 7.5. The same value was obtained for the formation of a carbanion from 2-nitro-1-phenylpropane using sodium t-butoxide in t-butyl alcohol[183].

When water is eliminated from 9-fluoroenylmethanol, different β-hydrogen isotope effects are observed in water and methanol, the exchange being faster than elimination in both water and methanol[191,215]. In agreement with the results of the majority of the above studies, the isotope effects in the exchange processes are large ($k^H/k^D \simeq 7$). For water, the overall isotope effect (the isotope effect of the solvent) is $k^H/k^D = 0.92$ (the rate of reaction of the unlabelled substrate in unlabelled water was compared with the rate of reaction of the labelled substrate in labelled water[215]). The corresponding value for methanol is 0.36. Such an isotope effect of the solvent should in fact be expected for the reversible substrate–carbanion stage when the *E*1*cB* (type *B*) mechanism operates. It is unlikely that a combination of the primary isotope effect and the isotope effect of the solvent would give rise to such a low overall value of k^H/k^D for the *E*2 mechanism. However, More O'Ferrall and Slae[215] concluded on the basis of a detailed analysis of the initial rates of reaction of a labelled substrate in a labelled solvent and of an unlabelled substrate in an unlabelled solvent that the competing *E*2 mechanism nevertheless makes a slight contribution to the reaction.

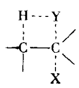
Thus it is seen from the data described above that the study of the isotope effects using substrates labelled in various positions makes it possible to distinguish both different mechanisms and different types of the same mechanism. The *E*2 and *E*1*cB* (type *A*) mechanisms can be distinguished by studying the isotope effects for substrates with labelled α-carbon or X.

V. THE *E*2*H*–*E*2*C* MECHANISMS

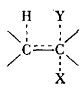
As early as 1956, de la Mare and Vernon[216] demonstrated the greater effectiveness of a weak base (the thiophenoxide ion) compared with a strong base (the ethoxide ion) in the elimination reaction which they catalysed (see the review of Saunders and Cockerill[163]). After this, it was frequently shown that very easy elimination is induced also by other weak bases, particularly halide ions in dipolar aprotic solvents[3,6,217–222]. Some workers[3,6,221–222] claimed that these reactions are more or less normal *E*2 reactions, but Winstein and coworkers[223] suggested that they be put in a separate *E*2*H*–*E*2*C* group, which was also supported by other workers[224,225]. It is suggested that, in the *E*2*H*–*E*2*C* range of mechanisms, the removal of β-hydrogen in the elimination reaction is accompanied to a greater or lesser extent and activated by attack by the Y base on the α-carbon atom ("from the rear" in relation to the C–X bond), as shown in models of activated complexes:



(XIV)
*E*2*H*



(XV)



(XVI)
*E*2*C*

It is seen from the models that (XIV) does not differ in any way from the central synchronous *E*2 mechanism; (XV) and (XVI) differ primarily by the fact that the base Y attacks α-carbon and not β-hydrogen as in the *E*2 mechanism. This in fact makes them similar to the transition state in the S_N2 substitution reaction, and for this reason all *E*2*H*–*E*2*C* mechanisms are combined under the general name "concurrent mechanisms". A characteristic feature of these reactions is that they are more effectively accelerated by weak bases provided that the latter are strong nucleophiles; the ratio of the products and certain characteristics of the reaction are altered somewhat under these conditions.

For example, treatment of secondary butyl and pentyl bromides as well as the corresponding toluene-*p*-sulphonates with strong nucleophiles and very weak bases in dipolar solvents (NBu_4Br in DMSO containing 2,6-lutidine) yields mainly the *trans*-olefin, in agreement with Zaitsev, while the reaction with a strong base and a weak nucleophile (t-BuOK–t-BuOH) yields mainly the *cis*-olefin, in agreement with Hoffmann[224]. Another communication[225] reported the influence of the alkyl, aryl, benzyl, bromo-, and methoxycarbonyl substituents on the rate of bimolecular elimination; according to the authors, the spectra of transition states ranging from *E*2*H* to *E*2*C* are obtained and the sensitivities of various transition states to changes in substituents are very different. The *E*2*C* transition state, which is olefin-like, gives a high yield of the most stable isomer (the *trans*-olefin according to Zaitsev), provided that the requirement that the hydrogen atom and the leaving group are in the *anti*-positions is not too rigorous. Similar results are quoted in other papers by Parker and coworkers[223,226–229].

McLennan and Wong[230] determined $\rho = 2.11$ for the dehydrochlorination of $(p\text{-}RC_6H_4)_2CHCCl_3$ (R = OMe, Me, H, F, Cl, Br, or NO_2) in ethanol at 65°C, which is accelerated by sodium thiophenoxide. For the S_N2 reaction involving the substitution of chlorine by thiophenoxide in $(p\text{-}RC_6H_4)_2CHCHCl_2$ (R = OMe, Me, H, Cl, Br), which leads to $(p\text{-}RC_6H_4)_2C{=}CHSPh$, $\rho = 0.41$. Comparison of these values with that obtained for an *E*2 reaction in the presence of $Et\bar{O}{-}EtOH$ ($\rho = 2.34$) led the author to the conclusion that in the latter case dehydrochlorination proceeds via an *E*2*H* transition state. The transition state in dehydrochlorination by a thiolate ion is *E*2*C*-like according to the author.

However, there have been very few studies on this problem; conclusions are frequently reached on the basis of secondary factors and those arrived at by one investigator are frequently disproved by others. Thus Parker, Winstein, and coworkers[223,224,231] proposed an *E*2*C* mechanism for the reactions of secondary and tertiary butyl halides in acetone under the influence of weak bases (halide ions), while the results of Eck and Bunnett[232] conflict with this finding. It has been shown that, in the β-elimination of HBr from 2-bromo-2,3,3-trimethylbutane and from t-butyl bromide in acetone or dioxan, induced by chloride ions, the more "hindered" substrate reacts faster than the less "hindered" one[232]. This finding shows that the ion of the base does not approach the α-carbon atom in the transition state as required by the *E*2*C* mechanism. Bunnett pointed out in his argument against the validity of the *E*2*C* mechanism (and the necessity for it)[6,223] that elimination in such systems proceeds via the normal *E*2 mechanism (*E*2*H* in terms of the new terminology of Winstein and Parker), but the relative nucleophilic reactivity of RS^-, RO^-, and tentatively Cl^- in relation to β-H depends on the degree of binding of the given base to the hydrogen in the transition state. When the base is strongly bound to the hydrogen, the alkoxide ion is more reactive, but, when the base interacts with β-hydrogen only slightly, the thiolate ion is a more effective base for the acceleration of an *E*2 reaction.

At any rate, as long as our understanding of the way in which the change in the solvating capacity of the solvent influences carbonium ions and carbanions in *E*2 reactions for different substrates with different bases is inadequate, one must be very cautious in adopting a particular view on this problem.

---o0o---

Examination of the data in this review and the studies which have not been described here owing to lack of space permits certain generalisations concerning the β-elimination mechanism. If the substrate does not contain activating groups at the β-carbon atom but does have a leaving group with an enhanced tendency towards ionisation and an electron-donating substituent at the α-carbon atom, then in a strongly solvating weakly acid medium (in the absence of a base) unimolecular elimination via an *E*1 mechanism takes place for this type of substrate.

On the other hand, if the substrate contains an electron-donating substituent, which increases the electron density at the α-carbon atom, and an electron-accepting substituent, which induces a positive charge on the β-carbon atom, then, when the medium consists of a strong base in an aprotic polar solvent, bimolecular elimination via an $E2$ mechanism takes place. Accordingly, any group which may neutralise the induced positive charge on the β-carbon atom by giving up electrons inhibits the reaction via an $E2$ mechanism.

If the electron-accepting group at the β-carbon atom and the base employed are moderately strong, then elimination proceeds via an "$E1$-like" $E2$ mechanism at a moderate rate. As the electron-accepting capacity of the substituent at the β-carbon atom becomes more pronounced and the strength of the base increases, there is also an increase in the rate of elimination. The elimination mechanism over a certain range of changes of this kind is then gradually altered from the "$E1$-like" type to the central synchronous type and further to the "$E1cB$-like" type, while remaining within the framework of the $E2$ mechanism. On further increase of the electronegativity of the group at the β-carbon atom and of the strength of the base employed, the bond between the β-hydrogen and carbon is weakened to such an extent that the substrate gives up this hydrogen in the form of a proton and forms a carbanion, the $E2$ mechanism being thus converted into an $E1cB$ (type A) mechanism. On the other hand, if the substrate contains a fairly strong electron-accepting group capable of stabilising the conjugate base of the substrate (such as C=O, C=N, NO_2 etc.), then the bond linking the β-hydrogen atom becomes so labile that there is no necessity for a very strong base and even in the presence of weak bases the substrate splits off this hydrogen in the form of a proton during the rapid reversible stage, forming the conjugate base—a carbanion, which loses the leaving group in the subsequent slow stage by a unimolecular process, being converted into an olefin, i.e. an $E1cB$ (type B) mechanism operates.

Thus one may conclude that each of the above specific types of the β-elimination mechanism is, strictly speaking, possible only for a specific compound under fixed conditions and that any changes in the structure of the substrate and in the reaction conditions lead to a shift of the mechanism towards the type which is preferred under the new conditions. Since the transition from one mechanism to another takes place gradually, the simultaneous occurrence of the reaction via two adjacent mechanisms is possible under borderline conditions.

The Role of One-electron Transfer in Substitution Reactions

Z.V.Todres

The principal examples of substitution reactions which involve an intermediate one-electron transfer stage are examined. Attention is concentrated on the causes which make this stage important and its relations with other stages in the mechanism are analysed. It is noted that the application of the ideas of one-electron transfer to the mechanisms of all substitution reactions without exception is invalid. Cases of the activation of substitution reactions under conditions favouring electron transfer are discussed. The urgent need for studies in this field is demonstrated and certain tasks for the immediate future are formulated.

The bibliography includes 68 references.

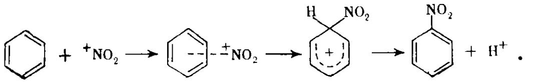
I. INTRODUCTION

The aim of the present review is to discuss the evidence supporting the presence of a one-electron transfer stage in the mechanisms of certain substitution reactions. Numerous studies in which the existence of such a stage explains the observed facts but is justified mainly by logical considerations have been left outside the scope of this review. Attention has been concentrated on reactions for which the existence of an electron transfer stage has been proved. The review includes fundamental examples. The causes which make the electron transfer stage real and the interrelations between this stage and others in the mechanism are discussed. Together with reactions which clearly proceed via a one-electron transfer stage, cases are considered where radical-ions are formed in a secondary reaction pathway and not the main pathway. It is shown that in certain reactions it is possible to increase the yield and rate of formation of the final products by creating conditions favouring the electron transfer stage.

II. THE CONCEPT OF THE ONE-ELECTRON TRANSFER STAGE IN A SUBSTITUTION REACTION

The concept of one-electron transfer as an intermediate stage in inorganic reactions has proved extremely fruitful and is supported by extensive experimental data obtained in the 1940s–1950s. The development of these ideas occurred simultaneously with the development of the foundations of nuclear chemistry and technology[1]. The problem of the role of one-electron transfer in organic reactions was considered during the last 15 years[2-8]. During this period, the development of new methods for the investigation of unstable or relatively unstable species, such as electron transfer products, led to the possibility of their wide-scale investigation. One may say that such species were extremely unfamiliar in organic chemistry during earlier periods.

After the first studies, which drew the attention of organic chemists to the important role of one-electron transfer in reactions, many investigators began to consider the mechanisms of virtually all reactions from the standpoint of oxidation-reduction processes. However, as experimental data accumulated, it was shown that the idea of the one-electron stage should be used in moderation (cf. Okhlobystin[9] and Beletskaya[10]). The hypothesis of one-electron transfer as an intermediate reaction stage presupposes that the reagent and the substrate are involved in an oxidation-reduction interaction. Subsequent stages involve the combination of the products arising as a result of the oxidation-reduction reaction. We shall consider as an example the nitration of benzene[11-13]. The substitution proceeds via the stages in the scheme below[14]:

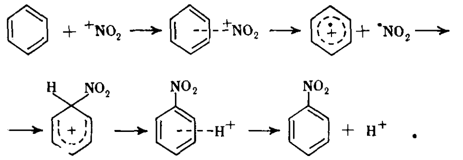


(1)

The process begins with the formation of a π-complex, which corresponds to partial charge transfer. Next the π-complex rearranges to a σ-complex with subsequent elimination of a low molecular weight species—a proton. Within the framework of perturbation theory[14], this is formulated as the formation of a transition state "from the perturbation of the π-system to the perturbation of a definite carbon atom". However, an isolated electron transfer stage is not considered in the perturbation theory[14]. At the same time, it follows from a theoretical study[15] that the approach of the reagent to the substrate bond subjected to attack alters the energy levels of the lowest unoccupied molecular orbital (LUMO) and the highest occupied molecular orbital (HOMO). The intermolecular distance over which the one-electron stage can take place depends on the degree of perturbation. When the distance is large, the products formed in this stage can emerge into the bulk of the reaction solution and when it is small they can recombine in the solvent "cage"[15].

Quantum-chemical calculations[12] have shown that the LUMO of the nitronium cation has an energy of −11.0 eV, while the HOMO of benzene has an energy of −9.24 eV. This makes theoretically probable yet another nitration stage, namely the transfer of an electron (a single charge) from the benzene HOMO to the nitronium cation LUMO;

this stage is represented in the general scheme (2). The species constituting the biradical pair may combine to form a σ-complex:



(2)

Thus one-electron transfer consists in the transfer of a single charge and not of a partial charge as in a π-complex. Partial transfer leads to charge-transfer complexes (CTC), while complete transfer results in the formation of radical-ions, radicals, or ions. The final products may be formed as a result of the combination of radicals derived from the reagent and the substrate, as in scheme (2). Another pathway is also possible, namely the decomposition of the substrate radical-ion with formation of a new radical capable of reacting with a second reagent molecule. This pathway is indicated in relation to the nucleophilic substitution reaction (3).[8] Such reactions are observed among both aromatic and aliphatic compounds and are classified as $S_{RN}1$ reactions:

$$RX \xrightarrow[-Y^{\cdot}]{+Y^-} (RX)^{\overline{\cdot}} \xrightarrow[-X^-]{} R^{\cdot} \xrightarrow{+Y^-} (RY)^{\overline{\cdot}} \xrightarrow[-(RX)^{\overline{\cdot}}]{+RX} RY \quad . \qquad (3)$$

In reactions of the $S_{RN}1$ type the one-electron transfer stage also plays an important role, initiating the transformation and imparting to it a chain mechanism.

We shall consider in greater detail the theoretical postulates and then shall analyse the experimental data characterising the role of one-electron transfer in the mechanism of substitution reactions.

III. THEORETICAL PROBLEMS

1. Thermodynamic Conditions for One-Electron Transfer

Electron transfer can occur only when the difference between the ionisation potential of the donor (I_D) and the electron affinity of the acceptor (E_A) is greater than zero ($I_D - E_A > 0$). In order to determine the sign of this difference, it is possible to compare the HOMO and LUMO energy levels of the substrate and the reagent. For electrophilic and nucleophilic substitution reactions of aromatic compounds, such comparisons can be made using Fig. 1. Evidently the LUMO levels of electrophilic reagents are lower than the HOMO levels of aromatic substrates. In principle, this creates the possibility of electron transfer from the HOMO level of the substrate to the LUMO level of the reagent. For the benzene nitration reaction, this stage was in fact taken into account in scheme (2). Furthermore, Fig. 1 shows that the HOMO level of the hydroxide anion lies above the LUMO levels of substrate molecules, while the HOMO level of the chloride ion lies above the LUMO level of nitrobenzene. Hence it follows that, when an aromatic substrate reacts with a nucleophile, an electron transfer stage is probable.

The calculation whose results are illustrated in Fig. 1 was performed approximately 20 years ago. Naturally, it was necessary to have a later confirmation of these results. Recent calculations by Epiotis[16] showed that relations of the type illustrated in Fig. 1 are confirmed and that they are valid for a wider range of substrates and reagents. Epiotis' study was undertaken to discover the correspondences between the reactivities at individual positions of the substrate molecule and the spin valences of the radical-ion in the same positions. Epiotis based his calculations on the perturbation theory, which, as stated above, does not treat electron transfer as an isolated stage. At the same time the fundamental scheme of orbital interactions obtained by Epiotis for the transition states of electrophilic, nucleophilic, and radical substitutions in aromatic compounds is of great interest for further exposition of the subject (Fig. 2).

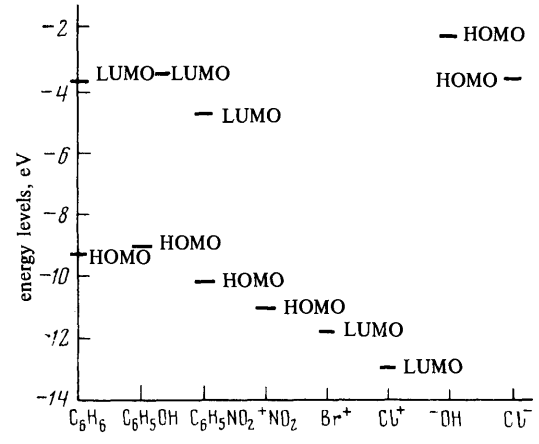


Figure 1. Energy level diagrams for some substrates and reagents in aromatic substitution[12].

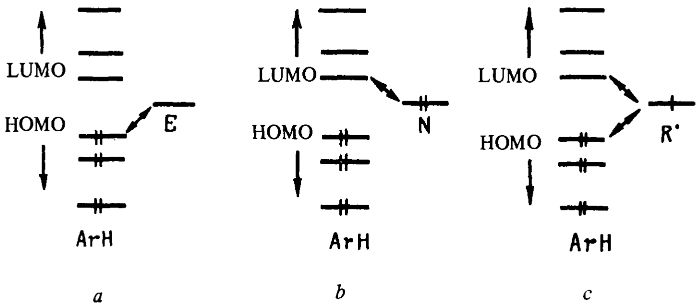

Figure 2. Schematic diagram of the orbital interactions of an aromatic molecule (ArH) with an electrophile (E), a nucleophile (N), and a radical (R·).[16]

Fig. 2 illustrates the types of orbital interactions which are analogous for nucleophilic and electrophilic substitution reactions to those discussed in connection with Fig. 1. For radical substitution, the type of interaction is determined by the nature of the radical R·. If the attacking radical is a nucleophile and has a low ionisation potential, the decisive factor for it is a donor type interaction (with LUMO). For an electrophilic radical with a high ionisation potential the decisive factor should be an acceptor type interaction (with HOMO).

However, one should note that both the calculations of Nagakura and Tanaka[12] and those of Epiotis[16] were performed without taking into account the influence of external substitution factors: solvation and coordination of the species in solution, the formation of hydrogen bonds, steric hindrance, etc. Under certain conditions, these factors may become decisive and may drive the reaction via a different pathway. The nature of the reacting species is also important. Calculations have been made recently[17] in order to determine the tendency of particular reagents to interact with the substrate via ionic or radical-ion pathways. The difference between these pathways is evident from a comparison of schemes (1) and (2). For example, it was found that, when benzene interacts with a proton, the one-electron mechanism is favourable until the substrate and reagents approach one another to a distance of 1.5–2 Å. The reaction of benzene with the nitronium cation can proceed via scheme (2) only over a range of distances from 1.5 to 2.5 Å, while benzene and the extremely reactive methyl cation can interact only via the ionic mechanism whatever the distance.

Electron transfer is preceded by the formation of a charge-transfer complex: $D + A \rightarrow [D^{\delta+}, A^{\delta-}] \rightarrow [D^{+\cdot}, A^{-\cdot}]$. When the CTC is subjected to additional polarisation under the influence of a third molecule (donor, acceptor, or solvent), electron transfer is facilitated[5].

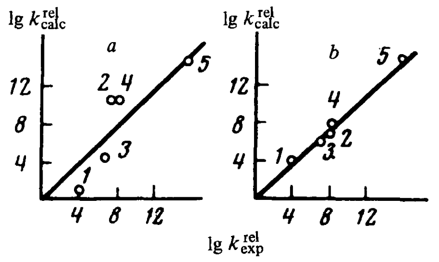

Figure 3. Relation between the experimental and calculated relative rate constants for the exchange of deuterium for protium in heteroaromatic compounds: 1) [3-D]thiophen; 2) [2-D]thiophen; 3) [3-D]furan; 4) [2-D]furan; 5) [2-D]pyrrole[19]; *a*) the values of k^{rel}_{calc} obtained taking into account only the localisation energy, which is proportional to the activation energy for electrophilic substitution; *b*) the values of k^{rel}_{calc} obtained taking into account not only the localisation energy but also the ionisation potential of the molecule involved in the deuterium–protium exchange.

Electron transfer in the reagent–substrate system can occur under the conditions of slight overlapping of the corresponding orbitals or when bridge groups (extraneous ions, solvent molecules) are involved. Electron transfer takes place over an extremely short period, amounting to 10^{-15} s. This is less than the time required for the alteration of the positions of the nuclei of the reacting molecules. Nuclei move over a period of 10^{-13} s or longer[5]. Consequently, the changes in the positions of nuclei take place approximately 100 times more slowly than the change in the electronic state. In conformity with the Franck–Condon principle[5], it is assumed that the positions of the nuclei remain unaltered during electron transfer. This implies that the electron transfer reaction can occur during the extremely short time intervals corresponding to a favourable disposition of the reagent, substrate, and the species present in solution.

2. The Donor–Acceptor Properties of the Reacting Species and the Kinetics of Substitution Reactions

It has been established[18] that the interaction of many heteroaromatic molecules with electrophiles is faster the lower the ionisation potential of the substrate. The calculated rate constants for these reactions agree with experimental values only when models taking into account the electron-donating properties of the heteroaromatic molecule are used[19] (Fig. 3).

The rate constants for the nitration of aromatic hydrocarbons by acetyl nitrate in acetic anhydride, calculated relative to benzene (k^{rel}), vary linearly (Fig. 4) with the ionisation potentials I of the hydrocarbons[20]. There is a similar relation between the ionisation potentials and the relative rate constants for the isotope exchange of hydrogen in an acid medium involving aromatic compounds (Fig. 5).[20]

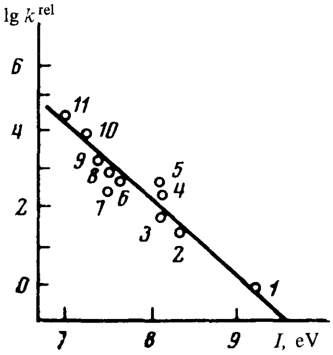

Figure 4. Relation between I and k^{rel} for the nitration of aromatic compounds: 1) benzene; 2) biphenyl; 3) naphthalene; 4) phenanthrene; 5) triphenylene; 6) chrysene; 7) fluorene; 8) fluoranthene; 9) coronene; 10) pyrene; 11) perylene[20].

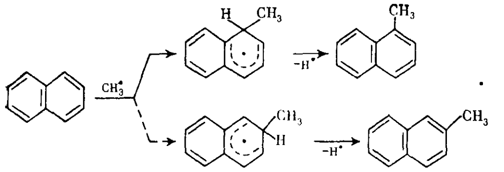
For radical substitution, the kinetics and direction of the reaction must be determined by the degree of localisation of electron density in individual positions in the molecule and not by its ionisation potential or electron affinity. However, it has been found that the rate of radical substitution in the series of alkylbenzenes varies linearly with ionisation potential, as for other reactions involving states with charge separation[21]. This also confirms the dependence of the site of substitution in the methylation of naphthalene on the polarity of the solvent[22] (acetyl peroxide was used as a source of methyl radicals).

The π-electron density in the naphthalene molecule is distributed non-uniformly: it is greater in the α-position than in the β-position, which ensures the preferential binding of the methyl radical to the α-carbon atom of naphthalene. If the methylation of naphthalene proceeds in accordance with the homolytic substitution mechanism (4), then it is unrelated to the appearance of charged intermediate states. This implies that the site of substitution should not depend on the polarity of the medium.



(4)

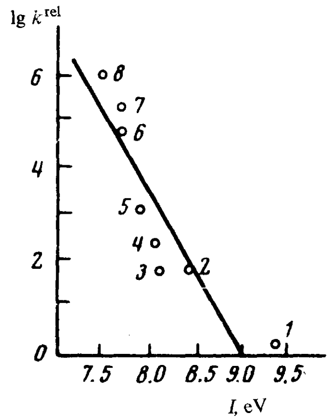


Figure 5. Relation between I and k^{rel} for hydrogen isotope exchange in an acid medium involving aromatic compounds: 1) benzene; 2) biphenyl; 3) terphenyl; 4) naphthalene; 5) chrysene; 6) pyrene; 7) 1,2-benzanthracene; 8) anthracene; 9) perylene[20].

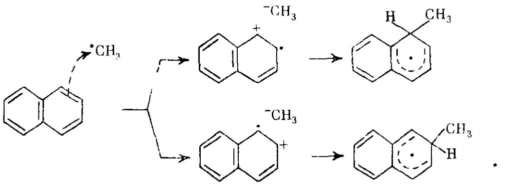
Table 1. The influence of solvent polarity on the selectivity of the homolytic methylation of naphthalene[22].

Solvent	ε*	Ratio of yields of α- and β-methylnaphthalenes	Solvent	ε*	Ratio of yields of α- and β-methylnaphthalenes
Benzene	2.3	7.0	*o*-Dichlorobenzene	9.9	5.8
Chlorobenzene	5.6	6.2	Pyridine	12.3	4.0

*The static dielectric constant ε was adopted as a characteristic of the polarity, which is valid when solvents belonging to a single series of aromatic compounds are compared[23].

In considering reactions (4), one must emphasise that neither the methyl radical nor the naphthalene molecule can themselves be in any way polarised in a polar solvent and give rise to states with separated charges. A dipolar structure is not characteristic of the methyl radical and naphthalene has an ionisation potential too high for this[22]. However, it follows clearly from Table 1 that the selectivity of the homolytic methylation of naphthalene decreases with increasing solvent polarity. The greater the solvent polarity, the more effective the stabilisation of the polar transition state which implies, according to Hammond[24], a greater decrease of the activation energy for the formation of charged species.

In the homolytic methylation of naphthalene the polarity of the solvent has such a significant effect on the reaction selectivity that the authors[22] explained this effect by the formation of species with a unit charge and not merely a fractional charge. Scheme (5) shows how naphthalene radical-cations arise in the interaction between the reagent and the substrate. Here it is important that the degree of stabilisation of the naphthalene radical-cation is independent of whether the positive charge is located at the α- or the β-carbon atom.



(5)

Owing to the stabilisation of the α- and β-"cations" by the polar solvent, the reactivities of the α- and β-position in naphthalene do not differ quite so much and the selectivity of the methylation reaction is accordingly reduced. Whereas in benzene (ε = 2.3) α-methylnaphthalene is formed seven times faster than β-methylnaphthalene, in pyridine (ε = 12.3) the rate of its formation is only four times greater[22].

3. The Site of Substitution and the Distribution of Spin Density in the Radical-Ion of the Reacting Molecule

If the interaction between the substrate and the reagent begins with one electron transfer, a biradical pair should be formed. The nature of the subsequent transformation should depend on the properties of the species involved in the biradical pair. In particular, the substrate radical-ion may be converted into a σ-electron radical with ejection of an ionogenic group. Such interaction of a σ-radical with the reagent leads to a radical-ion of the final product and these species should combine at the site of the radical free valence. If the substrate radical-ion does not show a tendency to eject the ionogenic group, its combination with the radical derived from the reagent is possible. The formation of a new bond is then most probable in the position where the spin density is a maximum. In other words, there should be a correspondence between the nature of the distribution of spin density in the radical-ion and the position which the substituent enters in the corresponding uncharged molecule.

The quantitative characteristics of the distribution of spin density can be obtained from the ESR spectrum of the radical-ion. The ESR spectrum makes it possible to determine the hyperfine interaction constant for the *i*th hydrogen atom a_i^H. This constant is directly proportional to the spin density of the *i*th carbon atom to which the *i*th hydrogen is linked[25].

Under these conditions, different degrees of delocalisation of the unpaired electron in radical-ions with charges of different signs is then possible for the same molecule[26]. Consequently, when electrophilic substitution is considered the site of substitution data must be referred to the properties of the radical-cation, while in nucleophilic substitution correlation with the properties of the radical-anion is required. We may note that the formation of radical-cations or radical-anions has been demonstrated experimentally in the substitution reactions of aromatic compounds[25].

Table 2 shows that the site of electrophilic substitution of aromatic compounds is clearly related to the values of a_i^H for the corresponding radical-cations.

Table 2. Comparison of the properties of a series of aromatic compounds and the corresponding radical-cations.

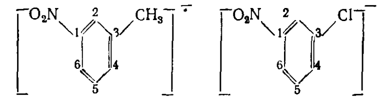
Compound	Reaction	Reactivity in different positions	Order of variation of a_i^H for different positions
NN-Dimethylaniline	Bromination	4 > 2 > 3 (Ref.27)	4 > 2 > 3 (Ref.28)
Naphthalene	Nitration	1 > 2 (Ref.29)	1 > 2 (Ref.30)
Naphthalene	T-H exchange	1 > 2 (Ref.31)	1 > 2 (Ref.30)
Anthracene	Acylation	9 > 1 > 2 (Ref.25)	9 > 1 > 2 (Ref.30
Biphenylene	Nitration	2 > 1 (Ref.32)	2 > 1 (Ref.33)
Azulene	Nitration	1 > others (Ref.34)	1 > others (Ref.35)

When azulene is nitrated, the 1-position is the most reactive[34] and the electron density is a maximum in the same position in the radical-cation[35]. However, in the azulene radical-anion the maximum density is concentrated in the 6-position[36, 37].

Table 3. Comparison of the values of a_i^H and E_{act} for the substitution of chlorine by an ethoxy-group on treatment of chloronitrobenzenes and chlorodinitrobenzenes with an ethanol–piperidine mixture.

Compound	a_i^H in ESR spectrum of radical-anion G, (Refs.38 and 39)	E_{act}, kcal mole^{-1} (Ref.40)
Nitrobenzene	$a_2^H = a_6^H = 3.30$; $a_4^H = 3.82$	—
2-Chloronitrobenzene	$a_6^H = 3.30$; $a_4^H = 3.92$	18.1
4-Chloronitrobenzene	$a_2^H = a_6^H = 3.42$	17.1
1,3-Dinitrobenzene	$a_2^H = 2{,}77$; $a_4^H = a_6^H = 4{,}49$	—
2-Chloro-1,3-dinitrobenzene		12.2
4-Chloro-1,3-dinitrobenzene		10.7

Interesting correspondences have also been formed for nucleophilic reactions. The relative rates of substitution of chlorine in chloronitrobenzene under the influence of various nucleophiles agree satisfactorily with the constants a_i^H for the radical-anions. However, the treatment must be based on the values of a_i^H for the radical-anions of nitro-derivatives without chlorine. (The hyperfine interaction constants of the radical-anions of chloronitrobenzene and nitrobenzene are virtually the same.) Table 3 shows that the constant a_2^H (a_6^H)† of the radical-anion of 4-chloronitrobenzene is close to a_2^H (a_6^H) of the nitrobenzene radical-anion; exactly the same correspondence between the constants a_6^H and a_4^H is observed for the 2-chloronitrobenzene–nitrobenzene pair. Here $a_4^H > a_2^H$ in the nitrobenzene radical-anion. The substitution of the chlorine in 4-chloronitrobenzene by an ethoxy-group is easier and requires a smaller activation energy than the corresponding substitution in 2-chloronitrobenzene. The spin density in the 4-position of the 1,3-dinitrobenzene radical-anion is higher than in the 2-position $(a_4^H > a_2^H)$. The reactivity of 4-chloro-1,3-dinitrobenzene in nucleophilic substitution is correspondingly greater than that of 2-chloro-1,3-dinitrobenzene. The displacement of chlorine by the methoxide ion[16] in 4-chloro-3-methylnitrobenzene is faster than in 6-chloro-3-methylnitrobenzene (Table 4, Nos. 1 and 2) which agrees with the finding that the spin density in the 4-position of the 3-methylnitrobenzene radical-anion is greater than the 2-position[41] [cf. scheme (6)]. The same correspondence may be noted between the values of a_i^H for the 3-chloronitrobenzene radical-anion[39] [see scheme (6)] and the relative rate constants for the substitution by the methoxide ion[16] of the chlorine atoms at the *i*th carbon atoms (Table 4, Nos. 3 and 4).



$a_6^H = 3.30$ G $a_4^H = 4.07$ G

$a_4^H = 3.88$ G $a_6^H = 3.20$ G

(6)

Table 4. The relative rate constants for the substitution of chlorine by a methoxide ion in certain chloronitrobenzenes in methanol at 25 °C.[16]

No.	Initial compound	Reaction product	k^{rel}
1			1
2			3.6
3			1
4			2.6

Thus the theoretical postulates described above support the possibility of the formation of substrate radical-ions and reagent radicals at the initial stage of the substitution reaction. There is evidence in support of a further combination of the radical-ion with the reagent radical or ion. The decomposition of the substrate radical-ion with formation of a secondary radical capable of interacting with another reagent molecule is also likely. Naturally, the agreement between the results of calculations and particular experimental data cannot by itself serve as proof that the one-electron transfer stage really occurs. For this, it is necessary to analyse the results of studies on the mechanisms of many specific reactions. Our discussion of theoretical problems was based on data for aromatic

---

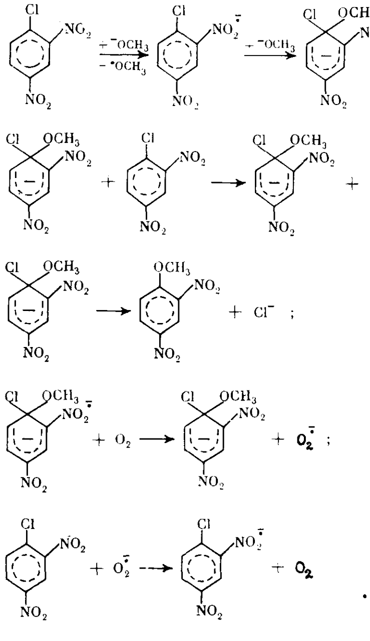
† The numbering of the positions in substituted nitrobenzenes begins with the atom linked to the nitro-group.

compounds: since the stability of aromatic radical-ions is high, they have been detected more frequently and more fully characterised. Thus, in considering specific reactions, we shall deal primarily with substitution in aromatic compounds.

IV. THE ROLE OF ONE-ELECTRON TRANSFER IN AROMATIC SUBSTITUTION REACTIONS

1. Nucleophilic Substitution

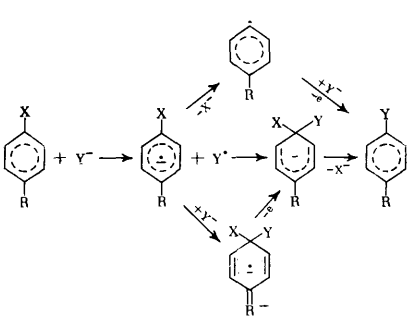
When 1-chloro-2,4-dinitrobenzene is treated with sodium methoxide, 2,4-dinitroanisole is formed. It has been established[42] that the reaction mixture contains the radical-anions of the starting material and the final product. Mechanism (7), which includes chain transfer steps involving electron exchange with participation of organic molecules and oxygen, has been put forward on the basis of ESR data for the accumulation and consumption of radical-anions[42]:



(7)

The catalytic effect of oxygen indicated by mechanism (7) agrees with the finding that nucleophilic reactions of aromatic nitro-compounds are an order of magnitude slower in nitrogen than in air. Benzoquinone or tetracyanoethylene inhibits such reaction; they are accelerated under the influence of light and are faster in glass apparatus than in cast iron apparatus[42]. All these findings support a radical mechanism of the reaction. An important feature of the mechanism of aromatic substitution reactions [mechanism (7)] is that it constitutes a harmonious combination of newly formulated concepts with earlier ideas, leading ultimately to a σ-complex as the usual precursor of the substitution product.

The radical-anion may not be converted into the substitution product solely via a radical-dianion as in scheme (7). The radical-anion may be converted into a free radical and then into the final product, bypassing the σ-complex. These possibilities are described in the scheme[42]



(8)

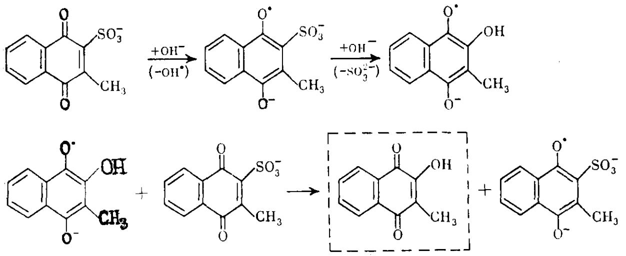
All the pathways taken into account in scheme (8) are based on the hypothesis of one-electron transfer with formation of a radical-ion. Apart from the data quoted above, the formation of the radical-anion is indicated by numerous kinetic studies[42]. The σ-complex obtained in the reaction exhibits the effect of chemically induced nuclear polarisation[43] (the CINP effect).

At the same time scheme (8) emphasises that the reactions of aromatic compounds with nucleophiles can proceed via different mechanisms with participation of various intermediate species. The contribution of each mechanism depends on the reaction conditions, including the effect of the structure and the medium. The same initial compounds may give rise to final products with identical structures via different mechanisms. This leads to the problem of estimating the contribution of a particular mechanism and the criterion should be the type of the rate-determining intermediate species rather than the reaction order. According to Shein[42], the classification of the mechanisms of the nucleophilic substitution reactions of aromatic compounds based on the reaction order, generally accepted at the present time, is inadequate. He suggested[42] that the mechanisms be classified in terms of the type of intermediate species: radical-ion, free-radical, carbanionic, etc. mechanisms. Reactions involving several species are also possible, for example, the process with a mechanism of the radical-ion–radical-dianion–σ-complex type indicated in scheme (7). The fundamental characteristics of scheme (7) have been attributed[42] to many other nucleophilic substitution reactions of aromatic compounds, including the substitution of chlorine by a methoxy-group in 4-chloronitrobenzene. In the latter case the formation of the main product is accompanied by that of a side product—4-nitrophenol (yield up to 15%). The ambiguity in the treatment of the pathways leading to the side product is striking. According to Shein's data[42], the main product (4-nitroanisole) is oxidised. Solodovnikov[44] justified a fundamentally different pathway—the oxidation of the radical-anions of the initial compound. The ambiguity of the treatment becomes of fundamental importance, because, according to Solodovnikov[44], virtually all 4-chloronitrobenzene radical-anions are converted into 4-nitrophenol. It was concluded on this basis that the "formation of 4-chloronitrobenzene radical-anions is a reaction taking place simultaneously with the substitution reaction"[44]. If this conclusion is accepted, one must assume that the substitution reaction itself proceeds either via a non-radical mechanism or via cryptoradical mechanism, where radical species are formed and combined in a solvent "cage" without emerging into the solution. It is so far difficult to make a choice between Shein's[42] and Solodovnikov's[44] treatments.

There is a greater unanimity in the treatment of the mechanism of another nucleophilic reaction—the substitution of a nitro-group in 1,2-dinitrobenzene (DNB) by a hydroxy-group. Various investigators have established the following facts: (1) that the reaction of DNB with OH^- ion in aqueous dimethyl sulphoxide results in the formation of 2-nitrophenoxide and nitrite only[45]; (2) that a long-lived DNB radical-anion is formed on mixing the reactants[45,46]; (3) that in the system considered the electron donor is indeed the OH^- ion, which is converted into the short-lived $OH^{\cdot}$ radical[46]; (4) that a σ-complex containing an OH group at the tetrahedral carbon atom is formed in the pathway to 2-nitrophenoxide[45]; (5) that the initial DNB and the σ-complex are not involved in electron exchange with one another[45]; (6) that the reaction of DNB with $O_2^{\overline{\cdot}}$ also leads to the substitution of the nitro-group by a hydroxyl and that DNB forms a radical-anion[47]; (7) that in the interaction of DNB with OH^- the one-electron transfer leading to the formation of the radical-anion takes place in the first stage with participation of uncharged DNB; [45] (8) that the kinetic curve for the accumulation and consumption of the DNB radical-anion is S-shaped and that the curve for the accumulation of 2-nitrophenoxide is parabolic (the start of the descending branch of the curve for the radical-anion corresponds to an inflection in the curve for the final product)[45]; (9) that kinetic calculations agree with experimental data only when the DNB radical-anion is regarded as the starting material in the substitution of a nitro-group by an OH^- ion[45].

A radical-ion mechanism has also been adopted[48] for the substitution of chlorine in 2-chloro-9,10-anthraquinone by a methoxy-group under the influence of sodium methoxide. The reaction represents a typical instance of substitution; during its course, 2-chloroanthraquinone radical-anions are formed, their number initially increasing to a maximum and then falling sharply. The addition of an inhibitor (benzo-1,4-quinone) lowers the rate of formation of radical-anions, which entails also a decrease of the rate of formation of 2-methoxyanthraquinone. If the radical-anions were obtained via a secondary pathway, the rate of formation of the final product should not have increased following the introduction of an inhibitor. It should have actually increased, since the oxidation of the radical-anions involves the regeneration of uncharged substrate molecules, which implies that the radical-ion mechanism is decisive in the given instance. Other nucleophilic reactions of anthraquinones are also associated with the formation of radical-anions: hydroxylation of 9,10-anthraquinone-2-sulphonic acid[48]; hydroxylation, alkoxylation or cyanation of the homoaromatic ring of 9,10-anthraquinone condensed in the 1,2-positions with the 2,1,5-oxadiazole ring[49]. However, the authors[48,49] adduce arguments according to which the one-electron reduction of the quinone takes place simultaneously with the main nucleophilic reaction. For example, it has been found that the concentration of anthraquinone-2-sulphonate radical-anions ceases to depend on the duration of the reaction with the alkali after a certain time interval and the overall yield of the radical-anion does not exceed 10%.[48] The introduction of inhibitors [oxygen, potassium hexacyanoferrate(III)] prevents the formation of radical-anions and the yield of 2-hydroxyanthraquinone actually increases somewhat[48]. In this case the radical-ion pathway in the process is not the main one.

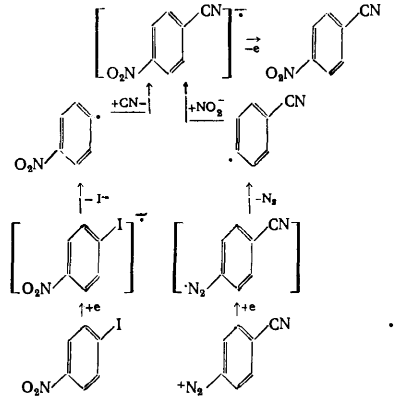
This example shows that the inclusion of the electron transfer stage in the reaction mechanism must be justified in each individual case. It is of interest that another representative of the class of quinone sulphonates—sodium 3-methyl-1,4-naphthoquinone-2-sulphonate—also gives rise to a radical-anion on reaction with alkali. The final product is 2-hydroxy-3-methyl-1,4-naphthoquinone. As the reaction proceeds, the number of radical-anions reaches a maximum and then falls immediately and at this instant the concentration of the final product begins to increase[48]. When inhibitors [oxygen, potassium hexacyanoferrate(III)] are introduced, neither the accumulation of radical-anions nor the formation of the final product is observed[48], which shows that the hydroxylation of 3-methyl-1,4-naphthoquinone-2-sulphonic acid proceeds via a radical-ion salt in accordance with the chain mechanism



(9)

etc.

The results concerning the "reconstruction" stages in the nucleophilic substitution of 4-iodonitrobenzene by a cyanide ion, quoted by Russell et al.[8], are of interest. One-electron reduction at an electrode in the presence of cyanide leads to the 4-iodonitrobenzene radical-anion. Like other halogeno-derivatives, 4-iodonitrobenzene readily splits off a halide ion in the radical-anionic state and is converted into a 4-nitrophenyl radical (a radical of the σ-electron type). The latter reacts with a cyanide ion and gives rise to a 4-cyanonitrobenzene radical-anion. The same radical-anion may be arrived at by reducing a 4-cyanobenzenediazonium salt with dithionite in the presence of nitrite. One-electron oxidation by the initial substrate converts the radical-anion into neutral 4-cyanonitrobenzene:



(10)

Singh and Kumar[50] obtained data showing that the substitution of a diazo-group linked to an aromatic compound by iodine also proceeds via an electron transfer stage. When arenediazonium fluoroborates are treated with potassium iodide in methanol (under nitrogen), iodobenzenes are formed:

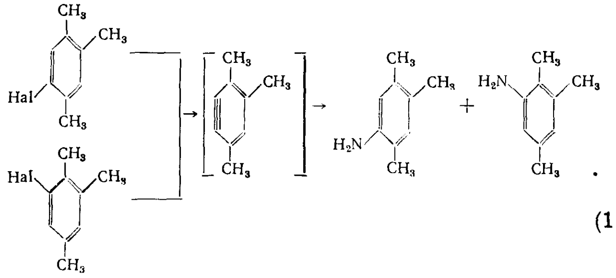
$$ArN_2^+ + I^- \longrightarrow ArN_2^{\cdot} + I^{\cdot};\quad I^{\cdot} \longrightarrow {}^1\!/_2 I_2;$$

$$ArN_2^{\cdot} \xrightarrow{-N_2} Ar^{\cdot};\quad Ar^{\cdot} + I^- \longrightarrow Ar{-}I^{\overline{\cdot}}; \tag{11}$$

$$ArI^{\overline{\cdot}} + ArN_2^+ \longrightarrow \boxed{ArI} + ArN_2^{\cdot} \text{ etc.}$$

Mechanism (11) is consistent with the known ability of the iodide ion to transfer one electron and also with the fact that the reaction is accelerated on irradiation with light and is inhibited in the presence of oxygen. In the presence of electron-accepting substituents in the benzene ring, the reaction rate increases, falling if electron-donating substituents are present. In the reaction involving 4-nitrobenzenediazonium, nitrobenzene, elemental iodine, and formaldehyde were found together with 4-iodonitrobenzene[50]. Formaldehyde is formed when 4-nitrophenyl radicals abstract hydrogen atoms from the solvent—methanol ($CH_3OH \rightarrow CH_2O$). Despite a careful search, neither 3-iodonitrobenzene nor 4-nitroanisole could be found among the products. This disproves another possible mechanism—cine-substitution involving the formation of dehydrobenzene.

The relation between cine-substitution and radical-ion mechanisms has been examined[51]. The reactions of 5- and 6-halogenopseudocumenes with potassium amide in liquid ammonia lead to 5- and 6-pseudocumidines, both isomeric amines being obtained regardless of whether the 5- or 6-position in the initial molecule contains a halogen atom. The nature of the halogen atom does not affect the ratio of the amino-derivatives obtained in the reaction of chloro- and bromo-derivatives; the ratio is constant and close to 1.5. The isomer ratio is not constant only for iodo-derivatives, being 0.63 and 5.86 when 5-iodopseudocumene and 6-iodopseudocumene are used respectively as starting materials. According to the authors[48], the cine-substitution mechanism is the only one in the reactions of chloro- and bromo-derivatives,



(12)

The reaction of iodopseudocumenes ArI proceeds not only via mechanism (12) but also via one-electron transfer:

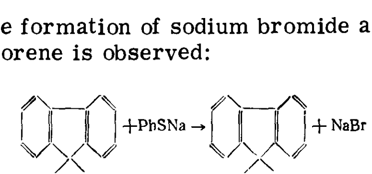
$$\mathrm{ArI} \longrightarrow (\mathrm{ArI})^{\overline{\cdot}} \longrightarrow \mathrm{Ar}^{\cdot} + \mathrm{I}^{-};$$

$$\mathrm{Ar}^{\cdot} + \mathrm{NH}_2^{-} \longrightarrow (\mathrm{ArNH}_2)^{\overline{\cdot}}; \qquad (13)$$

$$(\mathrm{ArNH}_2)^{\overline{\cdot}} + \mathrm{ArI} \longrightarrow \boxed{\mathrm{ArNH}_2} + (\mathrm{ArI})^{\overline{\cdot}} \text{ etc.}$$

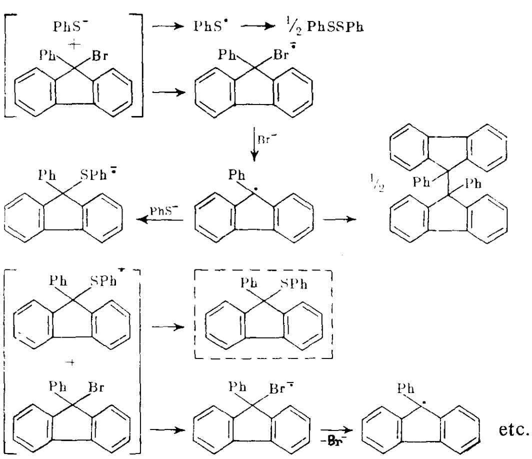
The hypothesis that mechanisms (12) and (13) operate simultaneously has been confirmed by experiments in the presence of radical-trapping agents: the introduction of 2-methyl-2-nitrosopropane or tetraphenylhydrazine alters the ratio of the pseudocumidines and makes it equal to 1.5 (for both 5- and 6-iodopseudocumenes). A characteristic feature of the iodopseudocumene radical-anions is that they split off a halide anion more readily than other halogeno-derivatives. As a result pathway (13), involving an electron transfer stage, becomes important.

The necessity to take into account the radical stage in nucleophilic substitution is also indicated by the results of a study of the mechanism of the introduction of an arylthio-group into 9-bromo-9-phenylfluorene[52]. When this bromo-derivative is treated with sodium thiophenoxide in dimethylformamide (DMF) in an atmosphere of nitrogen (30°C, 4 h), the formation of sodium bromide and 9-phenyl-9-phenylthiofluorene is observed:



(14)

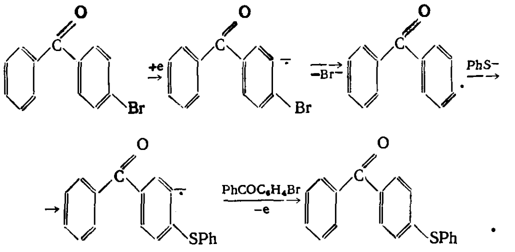
Sodium bromide is obtained quantitatively and the yield of the nucleophilic substitution product is only 42% of the theoretical value. The substrate and the nucleophile are also involved in other reactions which lead to 9,9-diphenylbifluorenyl (in 38% yield) and diphenyl disulphide (in 30% yield). The formation of these substances, which are indicated in scheme (15), conflicts with the usual ideas concerning nucleophilic substitution. Attention should be drawn to the fact that, in the presence of radical traps (oxygen and tetrabromo-*o*-benzoquinone), the formation of both the side products enumerated above and of the products resulting from the introduction of the arylthio-group is retarded[52]. Consequently the stage involving electron transfer from the nucleophile to the substrate occurs in the main reaction pathway, as in scheme (15). A phenylthiyl radical and a substrate radical-anion are formed in this stage. Both radical products are involved in further reactions: the phenylthiyl radical gives rise to diphenyl disulphide, while the substrate radical-anion is converted into a 9-fluorenyl radical. The latter reacts in two ways. It dimerises to bifluorenyl and, on reacting with a nucleophile, gives rise to a radical-anion of the "nucleophilic substitution product". Chain propagation is ensured by electron transfer from the above radical-anion to an unreacted substrate molecule, which loses a bromine atom and then reacts with the nucleophile, etc.



(15)

Mechanism (15) differs from mechanisms of the S_N1 or S_N2 type precisely by the inclusion of the one-electron oxidation-reduction stage. The driving force in this stage may be the ease of elimination of a bromide anion and the formation of a fluorenyl radical unsaturated in the 9-position, next to the stabilising benzene rings.

It has been shown[53] that the introduction of arylthio-groups into bromo-derivatives may be "stimulated" by creating conditions which promote the primary formation of radical-anions. Nucleophilic substitution of bromine by the thiophenoxide ion in 4-bromobenzophenone requires extremely severe conditions. When potentials are applied, the reaction proceeds readily and with a high yield (80%). It is sufficient to employ potentials which ensure solely the formation of substrate radical-anions (the potential and the amount of current passed through the system are strictly controlled). Next comes the chemical reaction in the bulk of the solution with formation of 4-phenylthiobenzophenone[53]:

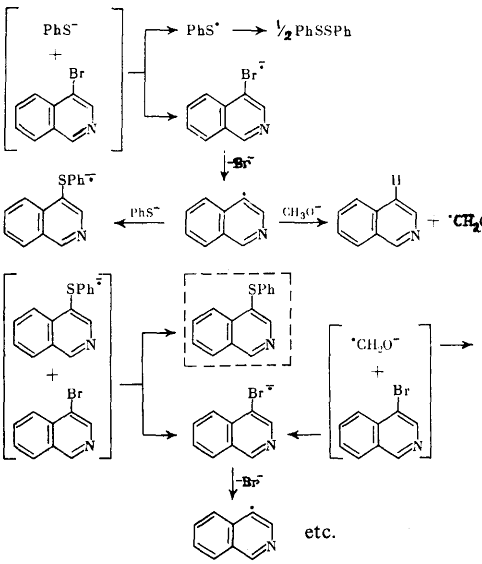


(16)

Nucleophilic substitution may be accelerated also without applying potentials, by introducing into the reaction mass substances which can behave as powerful electron donors. Thus sodium methoxide catalyses the introduction of an arylthio-group into 4-bromoisoquinoline by sodium thiophenoxide [scheme (17)].[54]

The introduction of sodium methoxide constitutes together with the introduction of thiophenoxide, yet another electron source for the generation of substrate radical-anions. However, if the thiophenoxide is converted into a phenylthiyl radical, as a result of electron transfer to the substrate, and then into the disulphide and is thus removed from the reaction sphere, substrate radical-ions are generated in the presence of methoxide ions with retention of a major proportion of the thiophenoxide. The overall rate of introduction of the arylthio-group in the presence of sodium methoxide increases and the yield of 4-phenylthioisoquinoline rises. However, the yield of side product—an unsubstituted isoquinoline—also increases with formation of only traces of the product of a competing substitution reaction—4-methoxyisoquinoline.

The introduction of azobenzene suppresses the effect of sodium methoxide, which confirms the radical-chain mechanism of the reactions via the scheme[54]:



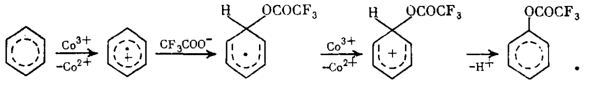
(17)

The formation of the phenylthiyl radical in reactions (15) and (16) was inferred from the isolation of diphenyl disulphide[52,64]. Bank and Noyd showed directly[55] that the phenylthioxide ion is involved in nucleophilic substitution and gives rise to a phenylthiyl radical. If styrene is added to a reaction mass containing 2-butyl nosylate (2-butyl 4-nitrobenzenesulphonate) as the substrate and sodium thiophenoxide as the reagent‡, the styrene polymerises with incorporation of phenylthiyl radicals. The corresponding sulphur-containing oligomer was isolated and characterised. When the thiophenoxide is mixed with styrene in the absence of the nosylate, the oligomer is not formed. When a radical trap (t-butyl phenyl nitrone) was introduced into the reaction mass, the reaction of 2-butyl nosylate with lithium thiophenoxide was retarded and the product of the addition of the phenylthiyl radical to the nitrone was detected by ESR. This indicates the formation of phenylthiyl radicals in the main pathway of the nucleophilic reaction.

2. Electrophilic Substitution

The study of the mechanisms of electrophilic substitution is extremely difficult, because aromatic radical-cations are much less stable than the radical-anions. Much less information has therefore been obtained about the role of one electron oxidation in the mechanisms of these reactions than for nucleophilic substitution in aromatic compounds.

Kochi et al. recently found a method of synthesising and stabilising radical-cations in trifluoroacetic acid, which consists in rapid mixing and freezing of solutions of the aromatic compound and thallium(III) or cobalt(III) trifluoroacetate[56]. When frozen solutions are heated, it is possible to observe well resolved ESR spectra of aromatic radical-cations. The latter are converted into aryl trifluoroacetates. It has been shown[56] that two oxidant molecules are consumed per molecule of the aromatic compound; the rate-limiting stage is one-electron oxidation with formation of a radical-cation. The reactions involving benzene can be represented as follows[56]:

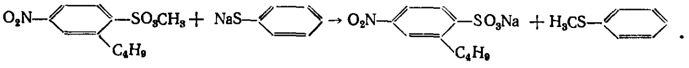


(18)

The anodic acetoxylation of aromatic compounds in acetic acid solutions containing alkali metal or tetraalkylammonium acetates proceeds quite analogously to oxidative substitution [reaction (19)]. Investigations have shown[57] that the process begins with one-electron oxidation at the anode and is followed by the stages indicated in scheme (18). The reaction proceeds very readily also at potentials very remote from the oxidation potential of the acetate ion (+2.00 V relative to sat. c. e.)§. For example, the lowest anodic potential at which ring acetoxylation of anisole can be observed is 1.20 V.[57] The acetate ion in the final product originates from the acetate salt and not from acetic acid: when the acetate is replaced by tosylate or perchlorate with the same cation, the acetoxylation of anisole does not occur even when acetic acid is used as the solvent[57].

---

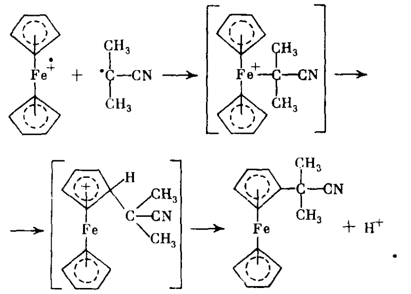
‡ The final result of this reaction can be represented schematically as follows:



$$O_2N{-}C_6H_4{-}SO_3CH_3(C_4H_9) + NaS{-}C_6H_5 \rightarrow O_2N{-}C_6H_4{-}SO_3Na + H_3CS{-}C_6H_5 \;(C_4H_9)$$

§ sat. c. e. = aqueous saturated calomel electrode.

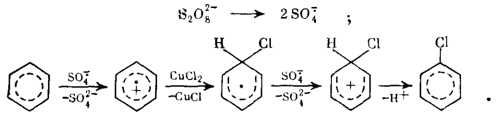
The radical-cation pathway in the substitution reaction is also illustrated in scheme (19).[58] In contrast to reaction (18), the radical-cation of the substrate interacts with a radical and not with an anion and the second one-electron oxidation stage is therefore not required in reaction (19):



(19)

The substitution product (α-cyanoisopropylferrocene) is formed in a yield up to 50% from ferrocene, copper fluoroborate, and azobisisobutyronitrile in acetonitrile at 80°C. In the absence of copper fluoroborate, which oxidises ferrocene to ferrocenium, the reaction does not occur, which implies that cyanopropyl radicals interact solely with ferrocenium and not with ferrocene. The product does not contain an unpaired electron and is therefore inert in relation to further substitution. This is an advantage of reaction (19) over Friedel-Crafts alkylation, in which products with an alkyl substituent undergo further substitution more readily than the initial ferrocene[58].

Copper(II) salts combine the properties of a one-electron oxidant[58] and a radical source[58, 59]. An interesting version of a radical-cation process is illustrated in the following scheme[59]:

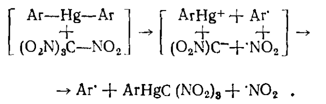


(20)

The reactions examined hitherto constitute instances of somewhat unusual substitution. They all proceed via a radical-ion pathway, because the substrate is introduced into the reaction after deliberate preliminary oxidation to the corresponding radical-cation. Studies on the mechanisms of the reactions which proceed as "typical" substitution processes without oxidation by an extraneous reagent are of interest. An example of "typical" substitution is the dark chlorination of benzene derivatives. In his study of the chlorination of toluene in acetic acid, Kochi[60] concluded that a toluene radical-cation is formed at an intermediate stage and that it reacts further with chlorine to give a chloro-derivative. The author bases this conclusion on the appearance of a well resolved ESR signal due to the radical-cation when acetic acid solutions of the substrate and chlorine are mixed directly in the spectrometer cell. Unfortunately, no data are quoted in his communication[60] concerning the kinetics of the accumulation and consumption of the radical-cation during the chlorination process and it is therefore impossible to decide whether the radical is formed in the main or a secondary reaction pathway.

However, one must emphasise that electrophilic substitution via electron transfer is promoted by two important factors[60]: aromatic molecules are oxidised at fairly low potentials; the electrophile (for example, a halogen) readily undergoes one-electron reduction. Similarly the nitronium ion, which is directly or indirectly involved in aromatic nitration, can be readily reduced to nitrogen dioxide[60].

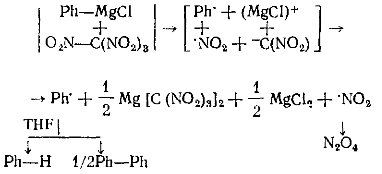
In our discussion of the nitration of benzene within the framework of scheme (2), we noted that, apart from the stage involving the formation of π- and σ-complexes, the interaction of benzene with the nitronium cation can also include an electron transfer stage. The σ-complex should then be obtained as a result of the combination of the benzene radical-cation and the $^{\cdot}NO_2$ radical. The decomposition of the σ-complex leads to nitrobenzene. If the decomposition is rapid, occurring over a period up to 10 s, the resulting nitrobenzene should give rise to a CINP effect. However, the effect could not be observed[61], although according to ^1H NMR data the reaction was not arrested appreciably in the σ-complex formation stage. Thus the electron transfer stage in reaction (2) was not confirmed experimentally. However, one should note that this stage may be unfavourable precisely for the nitration reaction owing to the low reactivity of the $^{\cdot}NO_2$ radical in the liquid phase. This idea is suggested by the results of a study of the interaction of aryl derivatives of tin, magnesium, and mercury with tetranitromethane in sulpholane[62]. For example, in the reaction of diarylmercury with tetranitromethane[62], the aryl and $^{\cdot}NO_2$ radicals are formed in an intermediate stage [see scheme (21)]. Despite the high reactivity of the aryl radical, it is scarcely attacked by the $^{\cdot}NO_2$ radical and gives rise mainly to an aromatic hydro-carbon as a result of reaction with the solvent. The trinitromethyl anion combines with the arylmercury cation, while the $^{\cdot}NO_2$ radical is probably stabilised in the form of nitrogen tetroxide and is subsequently consumed in secondary oxidation reactions:



$$\left[\begin{array}{c} Ar{-}Hg{-}Ar \\ + \\ (O_2N)_3C{-}NO_2 \end{array}\right] \rightarrow \left[\begin{array}{c} ArHg^+ + Ar^{\cdot} \\ + \qquad + \\ (O_2N)C^- + {}^{\cdot}NO_2 \end{array}\right] \rightarrow$$

$$\rightarrow Ar^{\cdot} + ArHgC(NO_2)_3 + {}^{\cdot}NO_2 \quad . \qquad (21)$$

The amount of ionic character of the carbon–metal bond affects the ease of the electron transfer reaction. Whereas tetranitromethane reacts with aryl derivatives of mercury and tin only after heating for many hours at 80°C, the reaction with phenylmagnesium chloride occurs after mixing the reactants and requires a reduced temperature (−50°C). However, the overall result of the reaction is independent of the nature of the carbon–metal bond: in each of the instances considered, tetranitromethane does not play its characteristic role of a nitrating agent. Only traces of nitrobenzene are formed and the main organic product is benzene. In the reaction with phenylmagnesium chloride, biphenyl (in 20% yield) is formed together with benzene (in 55% yield); tetranitromethane gives rise to the magnesium salt of trinitromethane under these conditions (in 80% yield):



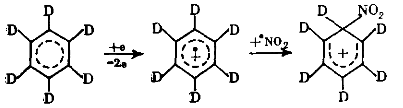
$$\left|\begin{array}{c} Ph{-}MgCl \\ + \\ O_2N{-}C(NO_2)_3 \end{array}\right| \rightarrow \left[\begin{array}{c} Ph^{\cdot} + (MgCl)^+ \\ + \qquad + \\ {}^{\cdot}NO_2 + {}^-C(NO_2) \end{array}\right] \rightarrow$$

$$\rightarrow \underset{\underset{Ph{-}H \quad 1/2Ph{-}Ph}{\downarrow\ THF}}{Ph^{\cdot}} + \frac{1}{2}Mg[C(NO_2)_3]_2 + \frac{1}{2}MgCl_2 + \underset{\underset{N_2O_4}{\downarrow}}{{}^{\cdot}NO_2} \quad . \qquad (22)$$

Nitrogen tetroxide is known to react with phenyl magnesium chloride[62]. However, reaction (22) is so rapid that the nitrogen tetroxide evolved has insufficient time to react with the initial phenylmagnesium chloride and impair the agreement, noted above, between the yields of the electron donor and acceptor conversion products. The authors[62] attribute the formation of biphenyl in reaction (22) to the oxidation of the dimeric form of phenylmagnesium chloride. The possibility of the recombination of phenyl radicals after their emergence from the cage is rejected[62] on the grounds that biphenyl is not formed in the reactions with Ph_2Hg and Ph_4Sn. The main result of the reaction of tetranitromethane with aryl derivatives of mercury, tin, and magnesium is the generation of $Ar^\cdot$ and $^\cdot NO_2$ radicals, which hardly interact with one another in the liquid phase.

In the gas phase the $^\cdot NO_2$ radical may acquire the needed reactivity. This is indicated by the ion–cyclotron resonance data analysed below[63]. Perdeuterobenzene and nitrogen tetroxide were admitted into the mass spectrometer chamber, whereupon the $(C_6D_6NO_2)^+$ ion, corresponding to the product of the addition of the nitro-group to perdeuterobenzene without the displacement of deuterium, i.e. a σ-complex, was detected. The authors[63] used double resonance in order to determine the species on the energy of which depends the rate of formation of the σ-complex. It was found that the rate depends unambiguously on the energy of the $C_6D_6^{\dotplus}$ radical-cations and is independent of the energy of the $^+NO_2$ cations[63]. This implies that the $C_6D_6^{\dotplus}$ and $^\cdot NO_2$ species, and not C_6D_6 and $^+NO_2$, are the precursors of the σ-complex:

$$N_2O_4 \longrightarrow 2\,^\cdot NO_2\ ;$$



(23) .

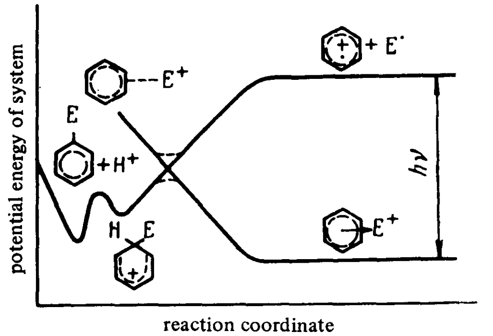


Figure 6. Variation of the potential energy in the substitution of benzene by an electrophile (E^+).

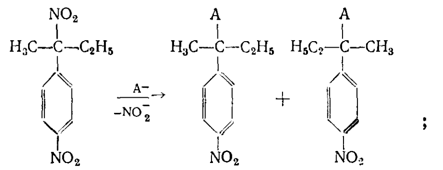
It has been noted[64] that one-electron transfer is a possible but not necessarily a discrete stage of the reaction involving substitution in aromatic compounds. We shall now consider how the potential energy of the system varies during the substitution. Fig. 6 illustrates such variation for electrophilic substitution in an aromatic compound[20]. Before the start of the reaction, the potential energy of the system is a maximum; a decrease of this energy is observed when a π-complex is formed. The separation (transfer) of the single charge in the π-complex leads to a readical-cation of the aromatic compound and an electrophile radical. The energy increases by *hν*, and the system acquires a different energy profile. The quantity *hν* determines the probability of the electron transfer stage. The radical-ion–radical pair ($C_6H_6^{\dotplus} + E^\cdot$) can rearrange into a σ-complex, which corresponds to a well in the new energy profile. The further decrease of energy is attributed to the formation of an electrophilic substitution product and the elimination of a proton. The energy curves cannot intersect. A gap, bounded by dashed semicircles, arises. It is small, which ensures the possibility of a transition from one curve to the other. In other words, the reaction may proceed via the pathway involving reverse electron transfer from $E^\cdot$ to $C_6H_6^{\dotplus}$ with return to the initial state. The initial compounds (benzene and the electrophile) then give rise to π- and σ-complexes along the pathway to the final product without forming radical species in the intervening stages.

The radical stage becomes more probable when the energy gap *hν* becomes sufficiently narrow to be overcome as a result of collision energy or under the conditions of a more favourable organisation of the solvation shell. The gap *hν* is more easily overcome in interactions which lead to relatively stable electron transfer products or when these products decompose into rapidly and irreversibly reacting species. The gap can be easily overcome when there is a considerable difference between the oxidation-reduction potentials of the substrate and the reagent (in other words, between their LUMO and HOMO levels). In certain cases the distance *hν* can be crossed with the aid of external influences: by the application of potentials, by the introduction of a stronger donor or acceptor, by irradiation, and by initiation with participation of a third molecule (a donor, or an acceptor, or a solvent).

Naturally, the above factors should promote the electron transfer stage not only in substitution reactions of aromatic compounds but also in substitution reactions involving a series of aliphatic compounds.

V. ONE-ELECTRON TRANSFER IN ALIPHATIC SUBSTITUTION REACTIONS

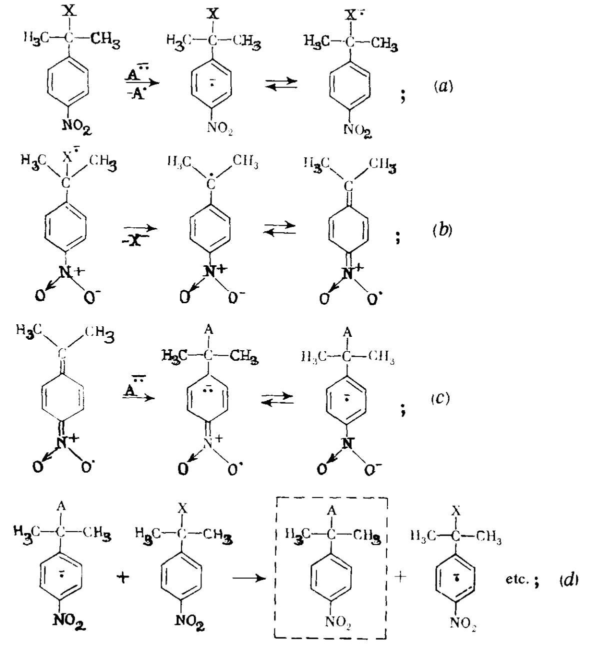
Among the first studies dealing with the radical stages in the mechanism of substitution reactions of aliphatic compounds, those of Kornblum's school[7] occupy an important place. In his studies of substitution at a saturated tertiary carbon atom Kornblum compared the behaviour of α-cumenyl chloride, α-nitrocumene, and their 4-nitro-derivatives in relation to anions. It was found that only the cumenyl compounds containing the nitro-group in the 4-position undergo substitution in the α-position. The reaction proceeds equally well with small and bulky anions. Such insensitivity to steric hindrance makes it possible to obtain highly branched products. When 4-nitrocumenyl chloride is treated with sodium thiophenoxide in argon or in nitrogen, two products are formed: 4-nitro-α-phenylthiocumene and 4,4′-dinitrobicumenyl. It is remarkable that, on reacting with sodium thiophenoxide, the optically active substrate gives rise to a racemic substitution product. Racemisation is observed also on treatment with sodium nitrite [scheme (24)]. In the presence of nitroxy-radicals or aromatic nitro-compounds, the substitution reaction is suppressed. Oxygen sharply retards the formation of substitution products, but promotes the formation of 4-nitrocumenyl hydroperoxide. Illumination has a marked initiating influence:



(24)

$A = C_6H_5S$, or NO_2.

The above findings fit logically within scheme (25), where a dual role is attributed to the anion A^-: that of an electron donor [stage (*a*)] and of the species undergoing addition [stage (*c*)]:



(25)

$A = C_6H_5S$ or NO_2; $X = Cl, N_3, C_6H_5SO_2, NO_2$, or OAr.

Scheme (25) explains two characteristics of the reaction: its applicability to 4-nitro-substituted substrates alone and its insensitivity to steric factors. The presence of the nitro-group in the 4-position ensures the delocalisation of the excess electron and thus promotes the formation of the radical-anion [stage (*a*)]. Stage (*a*) involves the unhindered aromatic nitro-fragment of the 4-nitrocumenyl system. Stage (*b*) consists of intramolecular elimination and is likewise not controlled by steric factors. Stage (*c*) includes the addition of the anion A^- to the planar system of the free radical. The free radical exhibits a high reactivity and is susceptible to attack by the anion. Consequently stage (*c*) may be rapid; this is important, because stage (*c*) propagates the chain of reactions (25). Chain branching takes place in stage (*d*), where the radical-anion of the substitution product transfers one electron to an uncharged substrate molecule. The one-electron transfer at this stage proceeds as in other cases, rapidly and independently of steric factors[7]. As a result, substitution at the strongly hindered carbon atom involves a sequence of stages which is as a whole distinguished by a low sensitivity to steric effects. The ease of reaction (25) depends on the ease with which the anion A^- gives up an electron to the 4-nitrocumenyl system and thereby initiates the chain of stages (*a*)–(*d*).

If the above sequence of transformations takes place and stage (*c*) is indeed rapid and irreversible, such behaviour can be used to extend the limits of applicability of the reaction. The possibility arises of obtaining substitution products also with anions which do not enter into the reaction or react extremely slowly. The point is that the nitrocumenyl radical can be captured not only by the anions some of which have been used to generate this radical but also by other anions. A catalytic amount of a reactive nucleophile may induce the reaction of a less reactive (or completely inert) nucleophile with 4-nitrocumenyl chloride and α,4-dinitrocumene. This prediction, made by Kornblum, proved to be fully justified[7]. In the absence of elimination, sodium azide and α,4-dinitrocumene do not react (control time—48 h). In contrast to sodium azide, the lithium salt of 2-nitropropane reacts with α,4-dinitrocumene in the dark and after three hours gives the α-substitution product in 87% yield. If α,4-dinitrocumene (1 mole) is treated with sodium azide (2 moles) in the presence of the lithium salt of 2-nitropropane (0.1 mole), the entire initial α,4-dinitrocumene is converted in the absence of illumination over a period of 3 h into pure 4-nitrocumenyl azide in 97% yield. Such "stimulation" of the reaction has been observed also for the nitrocumenylchloride–sodium nitrite pair. Typical one-electron donors such as sodionaphthalene have been used successfully as "stimulating" agents[7].

According to Russell et al.[8] the substitution reactions in the series of α-x-α-nitroalkanes also involve a stage in which nitro-radical-anions are formed. The lithium salt of 2-nitropropane has also been used in this reaction as an electron donor. The formation of 2,3-dimethyl-2,3-dinitrobutane is accelerated under the influence of light; oxygen, dinitrobenzene, and free radicals have an inhibiting effect. The reactions have been described by the following scheme[8]:

$$(CH_3)_2C(NO_2)^- Li^+ + (CH_3)_2C(NO_2)X \longrightarrow (CH_3)_2\dot{C}(NO_2) + (CH_3)_2C(NO_2)X^{\dot{-}}\,Li^+;$$

$$(CH_3)_2C(NO_2)X^{\dot{-}}Li^+ \longrightarrow (CH_3)_2\dot{C}(NO_2) + LiX;$$

$$(CH_3)_2\dot{C}(NO_2) + (CH_3)_2C(NO_2)^-Li^+ \longrightarrow (CH_3)_2C(NO_2)C(CH_3)_2(NO_2)^{\dot{-}}Li^+; \qquad (26)$$

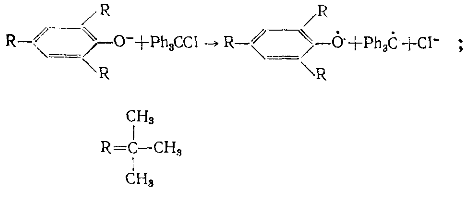
$$(CH_3)_2C(NO_2)C(CH_3)_2(NO_2)^{\dot{-}}Li^+ + (CH_3)_2C(NO_2)X \longrightarrow$$

$$\longrightarrow \boxed{(CH_3)_2C(NO_2)C(CH_3)_2NO_2} + (CH_3)_2C(NO_2)X^{\dot{-}}Li^+ \text{ etc.}$$

$X = Cl, CN$, or NO_2.

Mechanism (26) has been extended to a large series of practically important reactions of 2,2-dinitropropane and 2-bromo-2-nitropropane with other carbanions[8].

The kinetics of the electron transfer stage in nucleophilic substitution at a saturated carbon atom have been investigated[65,66] and model systems in which stable free radicals are formed in the reactions have been examined. This enabled the author to investigate the kinetics of electron transfer on the basis of the accumulation of the radicals. The interaction of triphenylmethyl chloride with a sterically hindered phenoxide in accordance with the scheme



(27)

was chosen as a model of nucleophilic substitution. The model was justified in the following way.

"Since nucleophilic substitution involves the replacement of one anion by another and the electron may be regarded as the simplest nucleophile, the very formation of radicals in reaction (27) constitutes in essence the simplest type of nucleophilic substitution of a halogen by an electron"[66]. The initial rate of accumulation of phenoxy-radicals is related to the phenoxide and triphenylmethyl chloride concentrations by the equation

$$w_0 = \left.\frac{d\,[\mathrm{Ar\dot{O}}]}{dt}\right|_{t\to 0} = k_1\,[\mathrm{Ph_3CCl}] + k_2\,[\mathrm{Ph_3CCl}]\,[\mathrm{ArOK}]^2 \qquad (28)$$

where the constant k_1 describes the rate of dissociation of Ph_3CCl into ions, the first term of the equation being independent of the concentration [ArOK]. The authors[9, 65, 66] believe that this term corresponds to the reaction of the ionised triphenylmethyl chloride or the free triphenylmethyl cation with the phenoxide:

$$\begin{aligned} &\mathrm{Ph_3CCl} \rightleftarrows \mathrm{Ph_3C^+} + \mathrm{Cl^-} \quad ; \\ &\mathrm{Ph_3C^+} + {}^{-}\mathrm{OAr} \rightarrow \mathrm{Ph_3\dot{C}} + {}^{\cdot}\mathrm{OAr} \quad . \end{aligned} \qquad (29)$$

The second term of Eqn. (28), which is quadratic in the phenoxide concentration, corresponds to electron transfer on collision of three molecules when the reaction involves undissociated triphenylmethyl chloride:

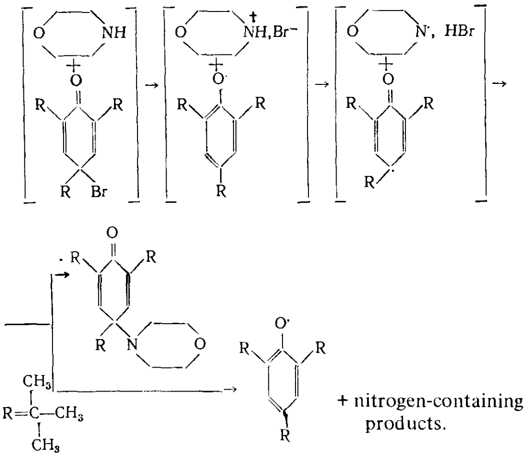
$$\mathrm{ArO^-} \ldots\ldots \mathrm{Ph_3CCl} \ldots\ldots \mathrm{MOAr} \rightarrow \mathrm{ArO^{\cdot}} + \mathrm{Ph_3C^{\cdot}} + \mathrm{Cl^-} \ldots\ldots \mathrm{MOAr} \ . \qquad (30)$$

The contribution of reactions (29) and (30) is determined by the solvating capacity of the solvent. When tetrahydrofuran (THF) is replaced by dimethoxyethane (DME), the contribution of reaction (29) increases almost by a factor of 2. In DMF only reaction (29) takes place, while in heptane reaction (30) occurs exclusively. The kinetic characteristics of the above model reaction have also been observed in the "typical" nucleophilic substitution of the halogen in alkyl halides by an alkoxy-group. In solvents of low polarity such reactions are frequently of third order overall (of first order with respect to the alkyl halide and of second order with respect to the alkoxide), but in highly polar solvents the reaction may be of first order with respect to the alkyl halide and of zero order with respect to the alkoxide. In solvents of moderate polarity there is a possibility of the simultaneous occurrence of the first- and third-order reactions[9, 65, 66]. On the basis of the kinetic study of electron transfer from the phenoxide to triphenylmethyl chloride, the authors[9, 66] suggest that the alcoholysis of alkyl halides be regarded as an oxidation-reduction reaction in accordance with the schemes below:

$$\begin{aligned} &\mathrm{RX} \rightleftarrows \mathrm{R^+} + \mathrm{X^-};\ \mathrm{R'O^-} + \mathrm{R^+} \rightarrow [\mathrm{R'O^{\cdot}} + \mathrm{R^{\cdot}}] \rightarrow \mathrm{R'OR}\ ; \\ &\mathrm{R'O^-} \ldots\ldots \mathrm{R{-}X} \ldots\ldots \mathrm{MOR} \rightarrow [\mathrm{R'O^{\cdot}} + \mathrm{R^{\cdot}}] + \mathrm{X^-} \ldots\ldots \mathrm{MOR}; \end{aligned} \qquad (31)$$

$$[\mathrm{R'O^{\cdot}} + \mathrm{R^{\cdot}}] \rightarrow \mathrm{R'OR} \quad . \qquad (32)$$

These schemes represent a generalisation based on the results of studies of the model reaction which stops at the stage involving the formation of radical species incapable of combining with one another[¶]. The study of the amination of quinobromides undertaken by Bubnov[66], in which the liberation of radicals from the cage is accompanied by their combination with formation of the final S_N2 substitution products, is therefore of fundamental importance. When morpholine is used as the amine, the degree of liberation of the radicals from the cage is ~10% (according to ESR data). This implies that 90% remains as the contribution of the substitution process. Indeed the yield of quinamines in the syntheses proved to be 85%. The entirely satisfactory agreement between the yield of the reaction product estimated from kinetic ESR data and from independent chemical data may be regarded as part of the evidence in support of the following scheme:

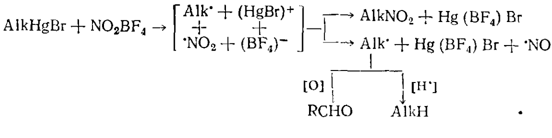


(33)

The electrophilic substitution reaction[67]

$$\mathrm{AlkHgBr} + \mathrm{NO_2BF_4} \rightarrow \mathrm{AlkNO_2} + \mathrm{Hg\,(BF_4)\,Br} \qquad (34)$$

also proceeds as an oxidation-reduction process. The yield of the nitro-derivative in this process is low; in addition, an aliphatic hydrocarbon and an aldehyde are obtained. The authors explain these features of the process by mechanism (35), which involves the intermediate formation of a radical-cation from alkylmercury bromide. The latter gives rise to a highly reactive alkyl radical. The nitronium cation captures an electron and is converted into the ·NO radical. The latter is relatively inactive [cf. schemes (22) and (23)]. For this reason, the reaction of alkyl radicals with nitrogen dioxide proceeds to only a slight extent, a considerable proportion of the radical emerging from the cage into the bulk of the solution. Nitrogen dioxide radicals are probably consumed in secondary oxidation reactions and alkyl radicals either split off hydrogen from the solvent and form a hydrocarbon or are oxidised and give rise to an aldehyde[67]:



$$\mathrm{AlkHgBr} + \mathrm{NO_2BF_4} \rightarrow \begin{bmatrix} \mathrm{Alk^{\cdot}} + (\mathrm{HgBr})^+ \\ + \qquad + \\ {}^{\cdot}\mathrm{NO_2} + (\mathrm{BF_4})^- \end{bmatrix} \rightarrow \begin{cases} \mathrm{AlkNO_2} + \mathrm{Hg\,(BF_4)\,Br} \\ \mathrm{Alk^{\cdot}} + \mathrm{Hg\,(BF_4)\,Br} + {}^{\cdot}\mathrm{NO_2} \\ \quad \xrightarrow{[\mathrm{O}]} \mathrm{RCHO} \qquad \xrightarrow{[\mathrm{H^{\cdot}}]} \mathrm{AlkH} \end{cases} \qquad (35)$$

---o0o---

The above data show that the one-electron transfer stage is both possible and frequently observed in the mechanisms of substitution reactions. At the same time it is evident that there is no justification for applying the hypothesis of one-electron transfer to all cases without exception. In each specific reaction the one-electron

---

[¶] The question of the validity of this generalisation gave rise to a controversy. It was emphasised that the formation of radicals only as the final products makes the reaction too different from other nucleophilic substitution reactions and actually necessitates "its classification as not an S_N reaction, but as an oxidation-reduction process"[10].

transfer stage requires experimental proof. The development of such studies is urgently required because it leads to the synthesis of the required final products or to an increase of their yield and of the rate of their formation. The main problem is to determine the subsequent fate of the species arising after the one-electron transfer. These species may undergo transformations of the $S_{RN}1$ or S_N2 type along the pathway to the final product. Transformations which take place via complexes containing a tetrahedral carbon atom belong to reactions of the S_N2 type. The complexes may be obtained both as a result of recombination in the biradical pair and after emergence from the solvent "cage" with subsequent attack by a further molecule of the reagent. Reactions of the $S_{RN}1$ type involve the elimination of the ionogenic group from the primary radical-ion and the subsequent addition of the reagent at the site of the free valence.

The possibility of recombination in the biradical pair is difficult to test and data characterising reactions of this type are still ambiguous. This has given rise to a sceptical[10] and sometimes extremely negative[68] assessment of the one-electron transfer hypothesis. Reactions involving the liberation of a radical-ion from the solvent "cage" or the formation of secondary radicals are more readily susceptible to investigation. This field is now attracting much attention and has already yielded results which are of both theoretical and practical importance.

Further development of such research requires, however, the solution of many more fundamental problems. It is necessary to know the difference between the oxidation-reduction potentials of the reagent and the substrate established under reaction conditions. It is necessary to discover the features which determine the state of equilibrium in electron transfer reactions. An important factor is the stability of the species formed on electron transfer. It is therefore essential to discover what factors promote the stabilisation and destabilisation of such species and what general changes in reactivity accompany the transition of the substance to the radical-ion state. All these problems are new to organic chemistry. The principal obscurities are associated with the insufficiency of information about the nature of the chemical behaviour of radical-ions. At the present stage the development of studies devoted to the role of the oxidation-reduction stages in the reaction mechanism depends on the level of our knowledge concerning the transformation of a given substance as a result of electron transfer.

The Problem of Tetrahedrane

N.S.Zefirov, A.S.Koz'min, and A.V.Abramenkov

The theoretical and experimental studies on tetrahedrane—a highly strained compound—are surveyed. The bibliography includes 87 references.

III. Experimental approaches to the synthesis of tetrahedrane 166

I. INTRODUCTION

After Baeyer proposed his "strain" theory based on simple geometrical considerations, organic chemists devoted much experimental labour, perseverance, and intellectual effort to the synthesis of highly strained structures. Purely geometrical approaches frequently serve as a starting point in the synthesis of skeletal and polycyclic compounds. It is sufficient to point out as an example the synthetic research in the field of tri- and penta-prismanes and related structures[1-5], propellanes[6], cubane[7-9], homotetrahedrane[10,11], dodecahedrane[12-14], etc., let alone the thoroughly developed field of the chemistry of adamantane[15], its heterologues[16], and higher derivatives ("adamantalogues")[17,18]. The fact that polyhedranes with a high symmetry are aesthetically attractive is itself a sufficient stimulus for "molecular design"[19]. However, the continued attention devoted by chemists to skeletal and polyhedral structures is naturally not due solely to abstract interest; these compounds frequently possess surprising properties, which makes their synthesis of interest from both theoretical and practical points of view. In particular, the chemistry of adamantane provides numerous examples of this. We may note here the problem of "molecular strain"[20], the dependence of the bond properties on the distortion of valence angles (for example, $J_{^{13}C-H}$ and the change in hybridisation), the stereochemistry of the inductive effect[22-24], etc., which have been examined using skeletal and polyhedral structures as models.

Organic molecules belonging to the T_d symmetry point group, the simplest of which is tetrahedrane (I), are of special interest in this respect.

(I)

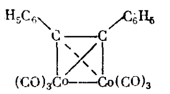
(III) X = X' = BCl
(IV) X' = CH₃C, X = B(C₂H₅)₃
(V) X' = RC, X = Co(CO)₃



(VI)

From the topological point of view, this molecule is interesting because its hydrocarbon skeleton constitutes the simplest connected cubic graph[25]. The very marked distortion of all the valence angles in the molecule should lead to enormous strain, which apparently reaches its limiting value for an organic molecule. We may also formulate several problems which make the task of synthesising tetrahedrane structures exceptionally urgent. The enormous strain in the tetrahedrane molecule should lead to a unique reactivity of the σ-bonds. Examples of a sharp change in the electronic structure of a formally single bond owing to strain, as, for example, in certain propellanes[6] and dehydroadamantane[26], are known in the literature. This property should be particularly striking in the tetrahedrane molecule. Another problem is associated with the study of the optical activity of structures having tetrahedral symmetry but no chiral centre. This problem has also been considered in relation to adamantane derivatives[27-29]. Finally heterotetrahedranes, in which new specific problems arise, such as that of the basicity of the heteroatom (nitrogen, phosphorus), complex formation, etc., might also be of considerable interest.

We may note that non-carbon tetrahedral structures, which may be assigned at least formally to heterotetrahedranes, have now been described. The simplest heterotetrahedrane is the P_4 molecule (II).[30] Tetrahedral structures are known for boron derivatives, for example (III)[31] and (IV)[32]. The cobalt clusters (V)[33] or (VI)[34] have the molecular topological form of tetrahedrane†.

However, the synthesis of the tetrahedrane carbon skeleton is of greatest interest. There is as yet no clear-cut description of the synthesis of tetrahedrane and only indirect evidence is available for the existence of molecules of this type. Nevertheless the literature devoted to this problem is fairly extensive and, bearing in mind the enormous fundamental importance of the problem, we thought it is useful to survey it, noting both theoretical and experimental advances.

II. THEORETICAL STUDY OF TETRAHEDRANE

As stated above, tetrahedrane is the most strained system among all possible saturated compounds containing

---

†This concept was introduced by one of the present authors (N.S.Zefirov) and by V.N.Drozd, V.I.Sokolov, and I.V.Stankevich. By the term molecular topological form, we understand the figure in the usual sense of the word plus certain singular points (atoms within the figure, the centre of inversion). For example, the molecular topological form for tetrasubstituted methane is a tetrahedron with a single singular point, while for hexasubstituted ethane it is an octahedron with two singular points. This concept serves as a basis for the definition of the most important stereochemical concept—that of configuration (configuration is the stereochemical equivalent of the topological form of the molecule). For the tetrahedron molecules considered in this study, the molecular topological form is a tetrahedron without internal points.

three-membered rings. The angular geometrical parameters of this molecule are fully determined by its symmetry and only the C–C and C–H distances can vary independently. Comparison of the geometry of tetrahedrane with that of bicyclo[1,1,0]butane shows that the dihedral angle between the three-membered rings in the latter is close to 126°, whilst in the tetrahedrane the corresponding angle should be 70°32'.[35] In this connection the problem arises of the thermodynamic stability of tetrahedrane in relation to the family of the isomeric C_4H_4 structure. Among these, we may note structures with closed shells such as those of methylenecyclopropene (VII), vinylacetylene (VIII), and cyclobutadiene (IX)‡. However, the main factor which determines the possibility of the existence of an isolated tetrahedrane molecule is the form of the potential energy hypersurface for the C_4H_4 system (in particular the presence of a minimum at the point corresponding to the tetrahedral configuration and the size of the potential barriers separating tetrahedrane from its possible conversion products).

(VII)

$CH_2{=}CH{-}C{\equiv}CH$

(VIII)

(IX)

(X)

Apart from the structures enumerated above, the system comprising two acetylene molecules and the biradical (X), obtained from tetrahedrane following the dissociation of a single C–C bond, may be assigned to systems of this kind. Regardless of thermodynamic stability, in the presence of large potential barriers the tetrahedrane molecule might exist as a long-lived metastable species. The most important theoretical study of the present problem is therefore that of the potential energy of the C_4H_4 system as a function of the geometrical configuration of the nuclear skeleton.

1. Investigation of the Potential Energy Surface for the C_4H_4 System

Since the geometry of the C_4H_4 system is determined by eighteen independent variables (geometrical parameters), the potential energy can be represented by a hypersurface in a 19-dimensional space. A quantum-mechanical calculation even for a small section of such a hypersurface is impossible in the present state of computing technique. By virtue of these factors, theoretical estimates of the energies of individual isomers with specified geometries are easiest at the present time. Calculations of the total energies of various isomers having the formula C_4H_4 and their estimation from thermodynamic characteristics have been made within the framework of semiempirical molecular orbital methods[36,38–40]; non-empirical quantum-mechanical calculations have become possible recently[37,41–43].

The relative distribution of the C_4H_4 isomers in terms of energies, based on the results of a non-empirical calculation by the Hartree–Fock method[43], is illustrated in Fig.1. One should bear in mind that in this approximation the energies obtained for certain systems are much too high. This applies particularly to cyclobutadiene (IX) and one must therefore expect that the difference between the energies of tetrahedrane and cyclobutadiene is much greater than 30–50 kcal mole^{-1}. An adequate description of the above system becomes possible when configurations with open shells are introduced into the wave function. In the calculations taking into account the configuration interaction the energy of the ground state of tetrahedrane is found to be higher by 70.3 kcal mole^{-1} than that of cyclobutadiene[41]. Similar values (73–84 kcal mole^{-1}) are given by the semi-empirical PPP, PNDO, and MINDO methods[36,38,39]. Comparison of the energies of cyclobutadiene and two acetylene molecules leads to highly conflicting results, depending on the method of calculation. Thus, according to semi-empirical calculations, the energy of the cyclobutadiene molecule is lower than that of the pair of acetylene molecules by an amount ranging from 2 to 50 kcal mole^{-1}.[36,44] However, the results of a non-empirical calculation by the method of configuration interaction, according to which the pair of acetylene molecules has a lower energy than that of the cyclobutadiene molecule, are more reliable, the difference being estimated as 0–30 kcal mole^{-1}.[37,41] If one takes into account the lower limit of the semi-empirical estimate, then, presumably, cyclobutadiene and a pair of acetylene molecules constitute virtually isoenergetic systems.

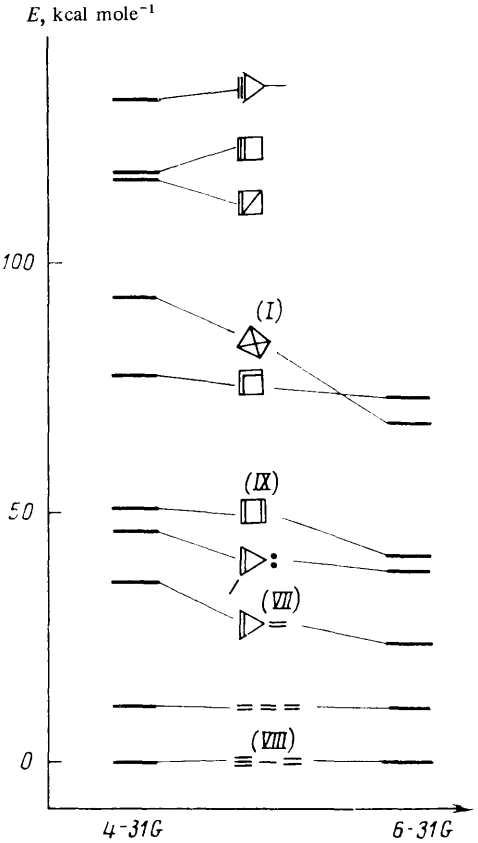


Figure 1. The relative energies of a number of C_4H_4 isomers (relative to but-3-en-1-yne) calculated in terms of the one-determinant approximation of the MO SCF method using 4-31 G and 6-31 G extended Gaussian basis sets[43].

---

‡ The simple Hückel molecular orbital method leads to a triplet configuration for the ground state of cyclobutadiene. For further details, see Dewar and Gleicher[36] and Buenker and Peyerimhoff[37].

When the possible pathways towards the isomerisation of tetrahedrane are considered, direct conversion into cyclobutadiene or decomposition into two acetylene molecules are thought to be unlikely, since these processes are forbidden by the principle of the conservation of orbital symmetry[42]. The most probable initial stage in the isomerisation is the dissociation of one of the C–C bonds with formation of the bicyclobutyl biradical (X). According to the results of a non-empirical calculation, the planar biradical should have an energy higher by 30–50 kcal mole^{-1} than that of tetrahedrane and higher by 100–120 kcal mole^{-1} than that of cyclobutadiene[41]. Estimation of the energy of the non-planar biradical with the geometry of bicyclobutane itself by semi-empirical methods leads to higher values than the energy of tetrahedrane by an amount ranging from 2 to 11 kcal mole^{-1}.[39] The equilibrium geometry of the biradical was not determined, since the above estimates are only approximate. Nevertheless they permit the assumption that tetrahedrane and the bicyclobutyl biradical have similar energies, that of the biradical being lower. The most probable schematic distribution of energy levels corresponding to tetrahedrane, cyclobutadiene, the biradical (X), and a pair of acetylene molecules, constructed on the basis of the above calculations, is presented in Fig. 2.

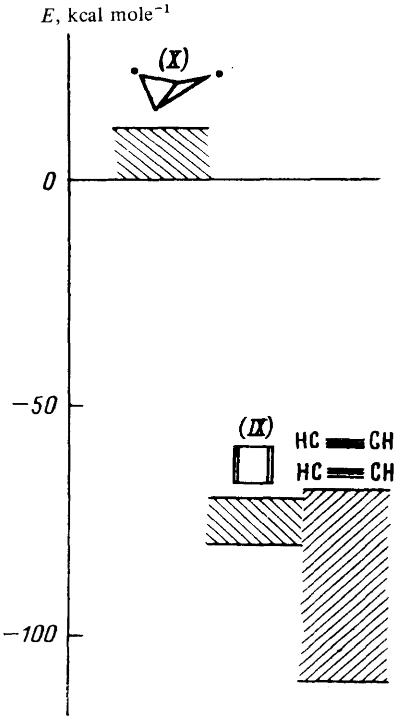

Figure 2. The probable energy ranges of the possible tetrahedrane conversion products (the tetrahedrane energy was adopted as the zero level).

The enthalpies of formation of tetrahedrane at 0 K, estimated from the total energies calculated by different methods, agree to within 15 kcal mole^{-1}; the following values have been obtained: 146.1 kcal mole^{-1} (PNDO method[38]), 135.2 kcal mole^{-1} (MINDO method[39,40]), and 129–137 kcal mole^{-1} (non-empirical calculation by the MO SCF method in terms of an extended Gaussian basis set[42]). The strain energy in tetrahedrane is estimated as 142.8 kcal mole^{-1} with a deviation from additivity (i.e. from the sum of the strain energies of the four three-membered rings) of 18.0 kcal mole^{-1}.[40] The first ionisation potential of tetrahedrane (the removal of an electron from the 1*e* orbital), calculated in terms of the PNDO approximation, is 9.58 eV,[38] in good agreement with the non-empirical calculation, which gives 10.35 eV.[41] For comparison, we may indicate the ionisation potentials of certain hydrocarbons[45]: 12.71 eV for methane, 11.50 eV for ethane, 11.07 eV for propane, 10.63 eV for n-butane, 10.6 eV for cyclobutane, 10.06 eV for cyclopropane, 9.45 eV for spiropentane, and 8.74 eV for cubane.

As already mentioned, the construction of the complete potential energy hypersurface for the C_4H_4 system is too difficult. However, in the region of the equilibrium geometry of tetrahedrane the calculation of the potential energy surface becomes possible in view of the high symmetry of the molecule. The number of types of normal vibrations is 8, and the potential energy matrix contains only 13 independent elements (without taking into account the symmetry, the number of the independent matrix elements would have been 171). Calculation performed by the non-empirical MO SCF method yields positive force constants for all the normal vibrations[42], which means that a local minimum on the C_4H_4 potential energy surface corresponds to tetrahedrane. The equilibrium geometrical parameters are $R_{\text{C-H}} = 1.054$ Å and $R_{\text{C-C}} = 1.482$ Å, the accuracy of the determination of which is estimated as to within 0.01 Å. The force constants for the extension of the C–H and C–C bonds proved to be 6.5 and 4.6 mdyn Å^{-1} respectively. Comparison with other hydrocarbons permits the conclusion that the C–H bond in tetrahedrane is similar to the analogous bond in acetylene, while the C–C bond is close to the ordinary single bond.

Sections through the potential energy surfaces of the excited electronic states of tetrahedrane, corresponding to the extension of the C–C bonds with a fixed C–H distance and retention of tetrahedral symmetry, have also been obtained[41]. It was found that none of the excited states is bound in relation to such deformation, at least for C–C distances ranging from 1.38 to 1.69 Å.

The possibility of the prolonged existence of an isolated tetrahedrane molecule can be inferred from the estimate of the barrier to the transformation into the bicyclobutyl biradical (X).[42] It has been suggested that motion along the reaction coordinate along the initial section corresponds to an increase in the length of one of the C–C bonds with a simultaneous change of the C–C–H angles. With increase of the distance between the nuclei of the C–C bond ruptured in this transformation to 1.812 Å (which corresponds to an increase in the dihedral angle between the three-membered rings of approximately 20°) and following the optimisation of the C–C–H angles, the energy increases by 18 kcal mole^{-1} compared with that of the equilibrium tetrahedral configuration. This value is adopted as the lower limit of the potential barrier. Calculation for the first excited triplet state of the deformed tetrahedrane molecule yields 45 kcal mole^{-1} as the vertical excitation energy, whence it follows that the excited state does not influence the initial stage of the isomerisation process.

2. The Electronic Structure of the Tetrahedrane Molecule

In order to elucidate the nature of the chemical bonds in the tetrahedrane molecule, it is of interest to calculate the distribution of electron density and to analyse the wave functions. The distribution of the valence electron density has been calculated[46] by the extended Hückel method. In each of the three-membered tetrahedrane rings, the electron density is distributed in the same way as in the cyclopropane molecule. In particular, there are two electron density maxima on the outer side of each of the edges of the tetrahedron formed by the straight lines joining the C nuclei. At the centre of the tetrahedron and in the centre of each face, the electron density has a minimum. Overall, the pattern obtained shows that the nature of the C–C bond in tetrahedrane is close to that of a single bond in saturated hydrocarbons and differs significantly from the acetylenic bond.

Much attention has been devoted to the study of the hybridisation in tetrahedrane[42,47–49]. According to the results of various calculations, the localised hybrid molecular orbitals corresponding to the C–C bonds have 79–83% of *p* character and deviate from the direction of the bond by 30–39°. The hybrid molecular orbitals of the C–H bonds have 45–62% of *p* character. For comparison, we may note that the fractions of *p* character in the molecular orbitals of the C–C and C–H bonds of cubane are 80 and 61% respectively and that the distortion of the hybrid molecular orbital in the direction of the C–C bond is by approximately 11°. In cyclopropane the molecular orbitals of the C–C bonds have 81% of *p* character. Thus the amount of *p* character in the hybrid molecular orbitals of the C–C bonds in tetrahedrane is greater than in other saturated systems with small rings, which confirms the intuititive idea that the tetrahedrane structure involves maximum strain.

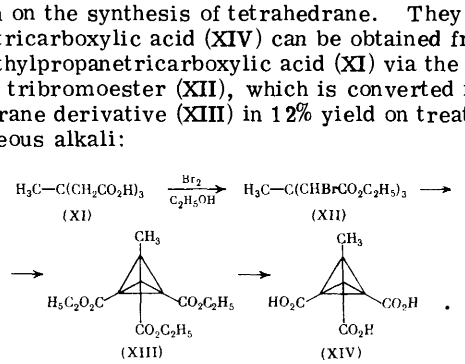
The correlation between the hybridisation parameters and the NMR constants has been used[42] to estimate the constants for the spin–spin interaction of the nuclei. The value $J_{^{13}\mathrm{C-H}}$ = 240 Hz obtained for tetrahedrane is intermediate between the values of $J_{^{13}\mathrm{C-H}}$ for cyclopropene (220 Hz) and acetylene (251 Hz). The value $J_{^{13}\mathrm{C-}^{13}\mathrm{C}}$ = 7.1 Hz for tetrahedrane is smaller than for cyclopropane (10 Hz) and bicyclobutane (21 Hz).

In conclusion, we may mention the theoretical prediction of the reactivity of tetrahedrane. The results of a study of the interaction of the valence electrons with an external charge within the framework of the electrostatic model based on the Hellmann–Feynman theorem have been used to examine the protonation reaction[50]. The equilibrium constant obtained shows that the tetrahedrane molecule should be protonated at pH $\leqslant$ 16.2. Despite its extremely approximate nature, this estimate indicates a high reactivity of tetrahedrane.

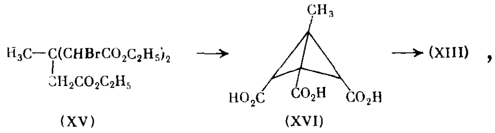
Summarising the theoretical studies, we may conclude that tetrahedrane corresponds to a metastable state of the C_4H_4 system and that the lifetime of an isolated molecule in the ground state may be fairly long. Electronic excitation should lead to the decomposition of the tetrahedrane molecule. Its high tendency towards protonation apparently necessitates the complete exclusion of all compounds containing mobile hydrogen atoms in attempts at synthesis.

III. EXPERIMENTAL APPROACHES TO THE SYNTHESIS OF TETRAHEDRANE

Beesly and Thorpe[51] were the first to propose a method for the synthesis of a compound having the tetrahedrane structure and must be regarded as the pioneers in the research on the synthesis of tetrahedrane. They found that the tricarboxylic acid (**XIV**) can be obtained from ββ-dimethylpropanetricarboxylic acid (**XI**) via the corresponding tribromoester (**XII**), which is converted into the tetrahedrane derivative (**XIII**) in 12% yield on treatment with aqueous alkali:

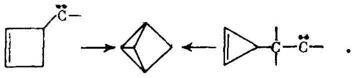


They also quote the experimental conditions for the synthesis of compound (**XIII**) from the tricarboxylic acid (**XIV**) formed on cyclisation of the dibromotriester (**XV**). The synthetic scheme and the absence of olefinic bonds according to the results obtained for the reaction of the product with bromine and potassium permanganate,



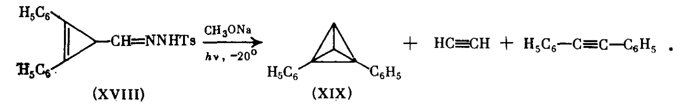
are believed to constitute proof of the proposed structure (**XIII**). In a separate article in the same volume of the Journal of the Chemical Society[52] Ingold carried out a simple calculation of the Baeyer strain and concluded that the existence of structures of this kind is possible.

For a long time chemists found the results of the above studies[51] surprising but reliable[53]. Furthermore, the ester formed by the acid (**XIV**) and cellulose was recommended for industrial manufacture[54] because of certain "useful" properties. However, almost forty years later Larson and Woodward[55] failed in their attempt to reproduce the synthesis of the acid (**XVI**) from compound (**XV**). When the latter was treated with an aqueous solution of alkali, the main reaction products were acetic acid and the initial acid (**XI**); no cyclic compounds could be isolated from the reaction mixture. The study by Larson and Woodward stimulated the development of research on the synthesis of highly strained compounds. The structure of tricyclo[1,1,1,$0^{2,5}$]pentane (**XVII**) was closest to that of tetrahedrane. It was obtained by two different methods in accordance with the following schemes[10,11,56]:

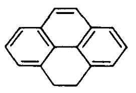


(XVII)

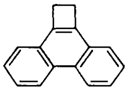
It is not fortuitous that compounds capable of generating in different ways a carbene centre linked to a cyclopropene ring have been proposed as precursors for the specific synthesis of tetrahedrane. Masamune and Kato[57] reported in 1965 the photochemical decomposition of the sodium salt of the tosylhydrazone of Δ^2-2,3-diphenylcyclopropenealdehyde (**XVIII**) into diphenyltetrahedrane with a yield of 0.1%. The structure of the product, having the overall formula $C_{16}H_{12}$ and a melting point of 133.5°C, was confirmed by infrared, ultraviolet, and ^{1}H NMR spectroscopic data. However a year later, the authors[58] proposed structures (**XX**) or (**XXI**) for the product of the above reaction, i.e. the structures of isomeric hydrocarbons which should have the same physicochemical characteristics as those proposed previously for the tetrahedrane derivative (XIX).



(XVIII) (XIX)

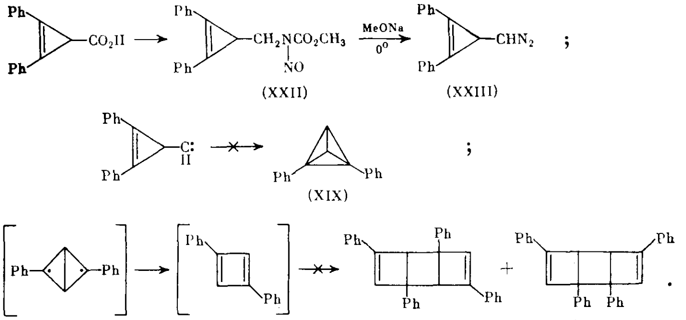


(XX)



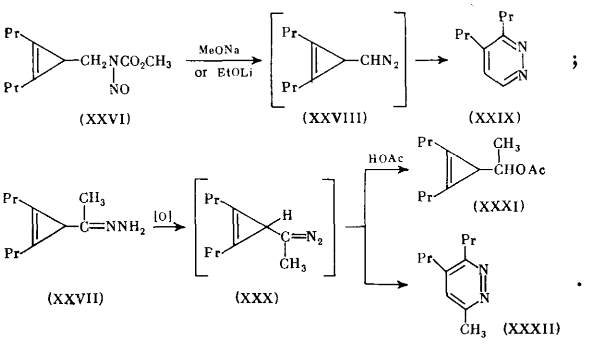
(XXI)

The prospect of using a substituted cyclopropenylcarbene attracted many investigators. For this reason, other reactions were used to generate this intermediate species and in all cases much attention was devoted to proving the formation of the carbene precursor—the corresponding diazo-compound. For example, Δ^2-2,3-diphenylcyclopropenyldiazomethane (XXIII), obtained[59] by treating with sodium methoxide the corresponding *N*-nitrosourethane (XXII), synthesised in six stages from 1,2-diphenylcyclopropenecarboxylic acid, was identified by its infrared spectrum. The diazoalkane (XXIII) proved to be extremely unstable in relation to the action of water and protic compounds. Its photolysis and thermolysis yielded neither tetrahedrane derivatives nor dimeric products based on cyclobutadiene.



(XXII) (XXIII) (XIX) (XXIV) (XXV)

The only product that could be identified was diphenylacetylene. The conditions for the synthesis and the reactivities of diazo-compounds of the cyclopropene series were carefully investigated somewhat later[60]. Two methods were used to synthesise them: the decomposition of the *N*-nitrosourethane (XXVI) and oxidation of the hydrazone (XXVII). The decomposition of the *N*-nitrosourethane by various bases and in different solvents led in all cases to a mixture of substances, among which only 3,4-dipropylpyridazine (XXIX) could be regarded as a product formed as a result of the 1,4-sigmatropic rearrangement of dipropylcyclopropenyldiazomethane (XXVIII).

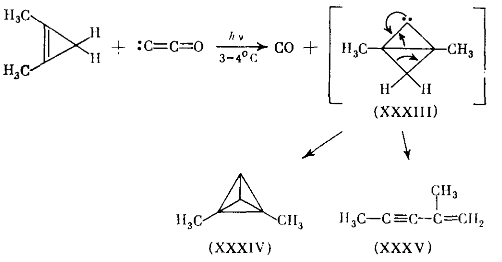


(XXVI) (XXVIII) (XXIX) (XXXI) (XXVII) (XXX) (XXXII)

Analysis of the reaction mixture obtained in the oxidation of the hydrazone (XXVII) by lead tetra-acetate or mercury(II) oxide also led to the conclusion that the corresponding diazo-compound is formed as an intermediate. Since the subsequent transformations of the diazo-alkane (XXX) into the corresponding pyridazine are slow, oxidation with lead tetra-acetate initially involves a faster decomposition of this unstable compound into the acetate (XXXI), while oxidation with mercury(II) acetate leads to the formation of the pyridazine (XXXII). The authors[60] do not quote data concerning the behaviour of the diazo-compounds on heating or irradiation but note that but-1-yne was not detected in any of the reactions.

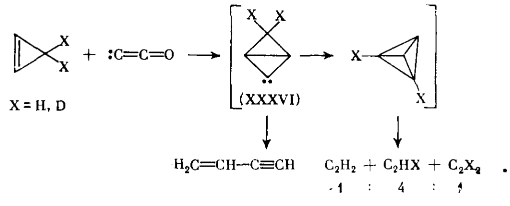
Another pathway, in which cyclopropene was also used as the initial compound, presupposed the intermolecular addition of the carbene generated from carbon suboxide. This method consisted in the photolysis of the latter in solution in 1,2-dimethylcyclopropene[61]. It was postulated that the carbene generated from C_3O_2 following the elimination of carbon monoxide may add to the olefinic bond of cyclopropene with formation of the intermediate bicyclic carbene (XXXIII), which may be stabilised by conversion into the tetrahedrane (XXXIV) as a result of intramolecular insertion into one of the C–H bonds.

$$C_3O_2 \xrightarrow{h\nu} CO + :C{=}C{=}O \ ;$$



(XXXIII) (XXXIV) (XXXV)

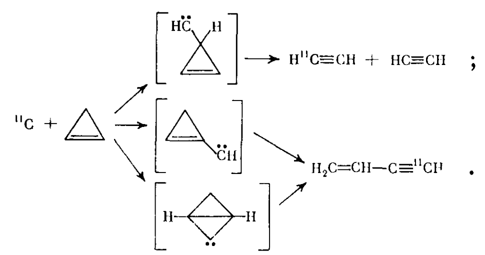
However, after irradiating the reaction mixture, it was possible to isolate only 2-methylpent-1-en-3-yne (XXXV) as the main photolysis product and pent-2-yne, which was formed as a result of the rearrangement of the initial 1,2-dimethylcyclopropene. The strain in the carbene (XXXIII) is apparently fairly high, so that its rearrangement to the acyclic hydrocarbon (XXXV) is faster than the intramolecular insertion with formation of the strained tetrahedrane ring. In a subsequent report Shelvin and Wolf[62] showed that, when a mixture of carbon suboxide and cyclopropene is irradiated, acetylene, which may be a product of the decomposition of the intermediate tetrahedrane, is formed in addition to vinylacetylene. The fact that acetylene is formed from tetrahedrane was confirmed using cyclopropene labelled with deuterium in the 3-position. Mass-spectrometric analysis of the acetylene fraction established that the compounds C_2H_2, C_2HD, and C_2D_2 are present in the reaction mixture in proportions of 1 : 4 : 1, which indicates the distribution of deuterium atoms at different carbon atoms of the tetrahedrane molecule, formed as a result of intramolecular insertion in the bicyclic carbene (XXXVI):



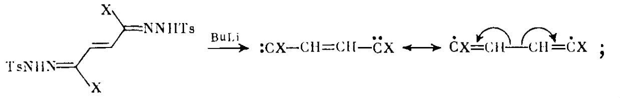
(XXXVI)

Additional data confirming the intermediate formation of tetrahedrane were obtained using carbon suboxide in which the central atom was labelled with ^{14}C. The authors[62] note that cyclobutadiene cannot be an intermediate in this reaction, because insertion of the ketocarbene in the C–D or the vinyl C–H bond should predominate in this case. However, it has been shown earlier that $:C_2O$ usually adds more readily to the multiple bond. Furthermore, the decomposition of cyclobutadiene into two acetylene molecules is also uncharacteristic[63].

Atomic carbon generated in a nuclear reactor and triplet carbonylcarbene generated by the photolysis of carbon suboxide have also been used as the carbene capable of adding to cyclopropene. Quantitative analysis of the composition of the reaction products led to the hypothesis of the intermediate formation of tetrahedrane in this case too:

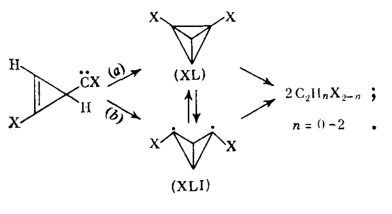


One of the possible approaches to the synthesis of tetrahedrane, which also included carbenes as intermediates, was proposed in 1973 by Rodewald and Lee[65]. They chose the bistosylhydrazone of *trans*-butenedial (XXXVII) as the source of the dicarbene. The decomposition products of the lithium salt of compound (XXXVII) at 140°C in tetrahydrofuran were collected at −80° and −190°C and investigated by preparative gas–liquid chromatography (GLC). Vinylacetylene, benzene, cyclo-octatetraene, and *syn*-$\Delta^{3,7}$-tricyclo[4,2,0,$0^{2,5}$]octadiene, which might have been formed from cyclobutadiene, were absent from the condensates. The only decomposition product was acetylene (unidentified polymers were also present). Having used the deuterium-labelled bistosylhydrazone (XXXVIII) as the starting material and having determined the distribution of the label by analysing the resulting acetylenes for deuterium, the authors proposed[65] the following mechanism for the formation of acetylenes with participation of tetrahedrane as one of the intermediates:



(XXXVII), X = H; (XXXVIII), X = D (1)

(2)

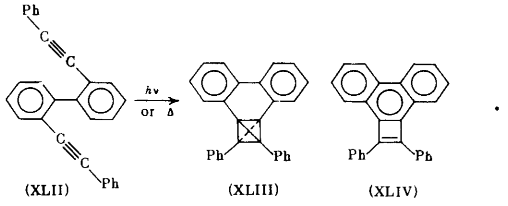


(3)

Only C_2HD may be formed in reactions (1) and (2). The proportions of C_2H_2, C_2HD, and C_2D_2 should be 1 : 4 : 1 for pathway (*a*) and 1 : 6 : 1 for pathway (*b*) (if the process is irreversible) or 1 : 4 : 1 [if the equilibrium between (XXXIX) and (XLI) is established 4–5 times faster than the rate of formation of acetylene]. The experimental distribution is 4.4% C_2D_2, 77.1% C_2HD, and 18.5% C_2H_2, showing that reaction (3) does occur and, although reactions (1) and (2) predominate, the tetrahedrane (XL) and the bicyclobutyl radical (XLI) serve as precursors of the acetylenes. Thus the determination of the quantitative composition of the acetylenes suggests that the intermediate (or the transition state) may be the symmetrical tetrahedrane or the biradical from which the tetrahedrane can also be formed.

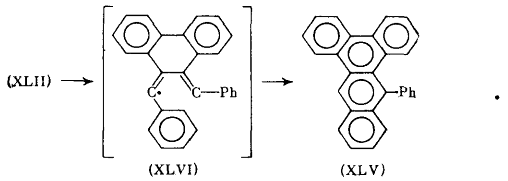
The dimerisation of acetylenes has been considered as another approach to the synthesis of tetrahedrane. In one of the first studies on these lines[66] it was shown that, when a mixture of acetylene and dideuteroacetylene is heated at 1200–1800 K, neither dimeric products nor HD are formed. The absence of deuterium exchange showed that tetrahedrane is not formed under these conditions.

However, Kandill and Dessy[67] reported in 1966 the possibility of the cyclisation of two acetylene groups into the tetrahedrane fragment. When 2,2′-di(phenylethynyl)-biphenyl (XLII) was photolysed or heated, an isomeric compound was obtained to which the structure of the tetrahedrane (XLIII) or the cyclobutadiene (XLIV) was attributed on the basis of the ultraviolet spectra:



(XLII) (XLIII) (XLIV)

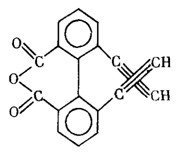
This structural assignment aroused a considerable controversy in the literature. White and Sieber[68] showed initially that the isomer obtained by Kandill and Dessy[67] is 9-phenyldibenzo[*a*,*c*]phenanthrene (XLV), which may be formed from the intermediate biradical (XLVI). Photolysis of compound (XLII) under different conditions and its subsequent thermolysis at 100°C did not lead to the formation of any compound other than (XLV):



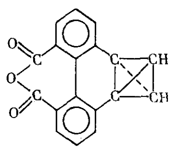
(XLVI) (XLV)

When compound (XLII) was heated at 150°C, compound (XLV) was again obtained together with unidentified compounds having high melting points and resembling phenanthrene according to their ultraviolet spectra. On the other hand, substances indicating at least the intermediate formation of tetrahedrane were not obtained in either thermal or photochemical processes.

Another diacetylene—6,6′-diethynyldiphenic anhydride (XLVII)—proved to be very stable under the conditions of pyrolysis (180°C) and photolysis[69]. No products, including those which might indicate the formation of the corresponding tetrahedrane (XLVIII), were found.

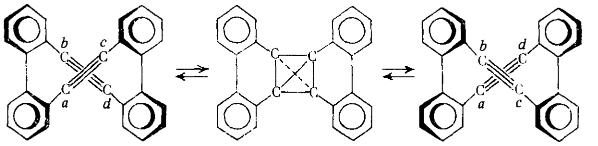


(XLVII)



(XLVIII)

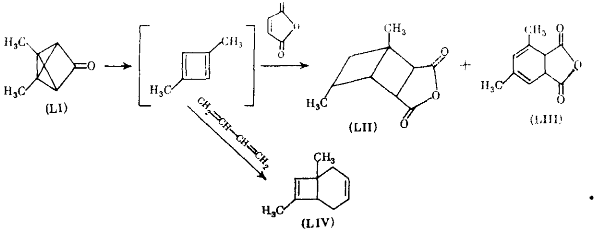
Nevertheless the idea of the possibility of synthesising tetrahedrane from acetylenes was not abandoned by investigators. For example, Staab and coworkers[70,71] undertook the synthesis of 9,10,19,20-tetradehydro[*a*,*c*,*g*,*i*]cyclododecene (XLIX)—a macrocyclic compound with crossed triple bonds in which structural factors favour the transannular interaction of the triple bonds. The possibility of such interaction was demonstrated by a number of chemical transformations, which justified the hypothesis that the acetylenic linkages are fairly close to one another. In order to confirm the possible formation of the tetrahedrane (L) from the diacetylene (XLIX), the authors[70,71] attempted to resolve the latter into enantiomers A and B and to detect the corresponding structural isomer which might have been formed by the irradiation of compound (XLIX) as a result of the transitions (XLIXA) ⇌ tetrahedrane ⇌ (XLIXB):



(XLIXA) (L) (XLIXB)

It was not possible to demonstrate the occurrence of photoracemisation, because the attempt to resolve compound (XLIX) into enantiomers chromatographically was unsuccessful. The authors[70,71] believe that the intermediate cyclobutadiene structure is preferable, but the problem whether it is formed from compound (XLIX) or via the tetrahedrane (L) remains open.

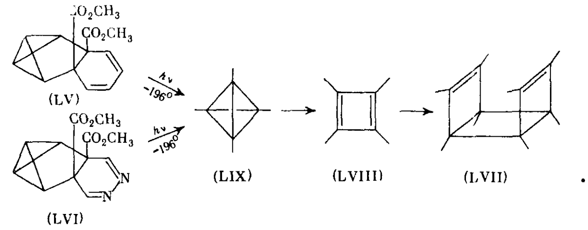
Yet another of the possible pathways to the synthesis of tetrahedrane was discovered by Masamune and coworkers[72], who investigated the thermolysis and photolysis of tricyclo[2,1,0,$0^{2,5}$]pentan-3-one. Thermolysis of the dimethyl derivative (LI) at 105.7° C gave very low yields of a mixture of compounds $C_{12}H_{16}$ (*m/e* 160), whose structures were not determined. Heating of compound (LI) in the presence of two equivalents of maleic anhydride was accompanied by the decomposition of the initial substance at a constant rate and led to the formation of compounds (LII) and (LIII). At a lower temperature (90°) only compound (LII) was detected; on heating, it rearranges to compound (LIII). When compound (LI) was treated with butadiene, a 30–40% yield of only 1,7-dimethylbicyclo[4,2,0]octa-3,7-diene (LIV) was obtained. On the basis of the composition of the products and the finding that the rate of decomposition of compound (LI) remains constant regardless of the presence of a "trapping agent", the authors[72] proposed a mechanism involving 1,3-dimethylcyclobutadiene as an intermediate and not the corresponding tetrahedrane:



(LI) (LII) (LIII) (LIV)

At the same time an attempt was made to investigate the composition of the photolysis products of compound (LI). It was irradiated with a high-pressure mercury lamp at 25° for 4 h until the attainment of 94% conversion of the initial compound. Acetylene (2%), propyne (6%), and butyne (2%) were found in the condensate collected at −190° C. By analogy with other studies, which were already discussed above, the authors[72] believe that the intermediate formation of tetrahedrane is probable in view of the presence of acetylene.

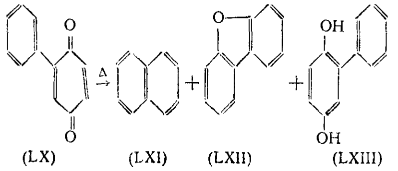
Polycyclic compounds (LV) and (LVI) have also been suggested as other tetrahedrane precursors containing the bicyclobutane fragment[73]. Photolysis of the diester (LV) in a matrix led to the formation of the cyclobutadiene dimer (LVII), but the authors[73] believe that the methyltetrahedrane (LIX) was formed as an intermediate and not tetramethylcyclobutadiene (LVIII), which could not be detected by infrared spectroscopy. It was suggested that the tetrahedrane isomerises to cyclobutadiene, which rapidly dimerises, the formation of the dimer (LVII) being faster than the valence [2 + 2] isomerisation (LIX) → (LVIII). As regards the transformation of the heterocyclic compound (LVI) owing to photolysis at 25° C, an analogous series of transformations [(LVI) → (LIX) → (LVIII) → (LVII)] was proposed on the basis of the composition of the products[73]:



(LV) (LVI) (LIX) (LVIII) (LVII)

However, according to the literature[63], thermal isomerisation of tetrahedrane to cyclobutadiene is forbidden on symmetry grounds; the proposed mechanism is then incorrect.

Ions with the tetrahedrane structure have been detected in the mass spectra of certain compounds. For example, vacuum flash thermolysis (800° C) of phenyl-1,4-benzoquinone led to the isolation[74] of three substances: naphthalene (54%), 2-hydroxydibenzofuran (8%), and phenyl-1,4-hydroquinone (8%).



(LX) (LXI) (LXII) (LXIII)

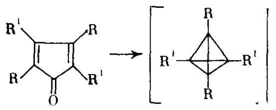
According to the authors[74], naphthalene is formed via a stage involving the loss of two CO molecules from phenyl-1,4-benzoquinone and subsequent intramolecular stabilisation of the butadiene biradical (LXIV), cyclobutadiene (LXV), or the tetrahedrane (LXVI). This hypothesis is based on the fact that the mass spectra of 1,4-benzoquinones[75] contain the peak of the $C_4R_4^+$ ion, which is more likely to represent a tetrahedrane than a substituted cyclobutadiene:

(LXIV)

(LXV)

(LXVI)

The formation of the tetrahedrane structure (LXVII) has been observed[76] in the mass spectra also on fragmentation of substituted cyclopentadienols and cyclopentadienones:

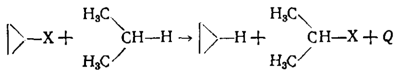


(LXVII)

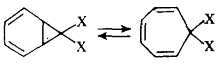
However, the determination of the exact structure of the ions in the gas phase by mass spectrometry is exceptionally difficult. A classical example is the controversy concerning the structure of the $C_7H_7^+$ ion to which the structure of the symmetrical propylium ion was attributed[77,78] on the basis of experiments with an isotope label, which was not confirmed by subsequent investigations[79,80]. Evidently the conclusion about the structure of ions of the type $C_4R_4^+$ and a reliable assignment of the tetrahedrane structure to the latter will become possible after a detailed investigation using the ion-cyclotron resonance technique[81].

---o0o---

Thus, despite the considerable efforts by both theoreticians and experimenters, the problem of tetrahedrane has not been solved. Furthermore, the main question whether or not tetrahedrane can exist as a stable (metastable) species remains obscure. Strictly speaking, the unsuccessful attempts at synthesis cannot be regarded as proof of the instability of the compound, and the history of organic chemistry confirms this[82]. Here one may note two approaches to the experimental solution of the problem. The first involves the fixation of tetrahedrane in a matrix and the demonstration (for example by spectroscopy) of its structure or its generation in the gas phase and direct (for example by electron diffraction) demonstration of its structure. In the second approach, tetrahedrane derivatives containing substituents capable of specific stabilisation of the tetrahedrane molecule are to be synthesised. The substituents can be selected on the basis of the following considerations, in the discussion of which valuable comments have been made by Prof. P. v. R. Schleyer. On the one hand, the stabilising effect of the substituents on the three-membered ring may be estimated by considering the heat of the following "isodesmic"[83,84] process:



Unfortunately the available literature, thermochemical data do not allow a broad comparison. On the other hand, data for certain "isodesmic" equilibria may serve as the starting point. As an example, one may quote the electrocyclic equilibrium of the norcarane (LXVIII) and cycloheptatriene (LXIX) structures. If the substituent X stabilises the three-membered ring specifically, then the equilibrium should be displaced to the left relative to X = H; if the substituent causes destabilisation, the shift should be to the right. Examination of the experimental data shows that the parent hydrocarbon (X = H) exists almost wholly in form (LXIX)[85,86], while the dicyano-derivative (X = CN) exists exclusively in form (LXVIII):



(LXVIII) (LXIX)

Thus the presence of cyano-groups should presumably stabilise the tetrahedrane skeleton (particularly bearing in mind the potential possibility of the ready protonation of tetrahedrane; see above). Furthermore tetracyanotetrahedrane would be of interest as a member of a class of nitrogen-carbon compounds (tetracyanomethane, tetracyanoethylene, and percyanoadamantane; for a systematic account of percyano-compounds, see Makhon'kov[87]), but consideration of this and related problems is outside the scope of the present review.

Organic Peroxides of Alkali Metals (Alkali Salts of Hydroperoxides)

N.A.Sokolov and Yu.A.Aleksandrov

Methods of making non-solvated lithium, sodium, and potassium salts of hydroperoxides in hydrocarbon media are considered. Results on the kinetics and mechanism of thermal decomposition of alkali organic peroxides and the reactions of these compounds with alcohols, aldehydes, ketones, esters, and nitriles are discussed. The role of complex formation by the alkali salts of hydroperoxides with donors of protons and Lewis bases is considered. Methods of making organic and organoelemental peroxides based on salts of the hydroperoxides are discussed. 167 references.

I. INTRODUCTION

Organic peroxides of Group I metals (salts of organic hydroperoxides) are peroxide compounds of the general formula ROOM, where R is an alkyl, aryl, or acyl radical, and M is a metal of Periodic Group I.[1] Organic peroxides (OP) of lithium, sodium, and potassium are now known. Analogous compounds of rubidium and caesium or of the metals of the copper subgroup have not been described.

Alkali metal OP's are of interest to investigators as starting materials for making the OP of elements of other groups[1-5], as intermediates in the autoxidation of organic derivatives of alkali metals, for the oxidation of hydrocarbons in the presence of alkalis, etc.

Ten years has elapsed since progress in the field of the chemistry of organic peroxides of the alkali metals was discussed[1]. This period has been marked by considerable range of investigations of metal-containing OP. Some of the results obtained for the OP are important in principle. All this has stimulated the preparation of the present review. It discusses, as far as possible, all the works on methods of synthesis and the investigation of the properties of the anhydrous OP, and also the kinetics and mechanism of conversion of salts of the hydroperoxides in aqueous or non-aqueous solutions. Works on the kinetics and mechanism of deformation decomposition of alkali salts of peroxo-acids and H_2O_2 are not included since this could be the subject of a special review.

II. METHODS OF PREPARATION

The simplest and most widely used method of making the alkali metal OP is based on the reaction of hydroperoxides with the metal hydroxide or alkoxide in aqueous or alcoholic solution respectively. This method is used widely for the separation and purification of hydroperoxides and in the preparation of dialkyl peroxides and esters of peroxo-acids. However, when hydroperoxides react with a hydroxide or alkoxide, usually crystalline solvates of hydroperoxide salts with water[6-9] or alcohol[10-12] are obtained. The water or alcohol cannot be removed completely from such solvates without decomposition of the initial peroxide.

Kharasch and coworkers[13] were the first to obtain sodium cumyl peroxide in hydrocarbon solution by reaction of the hydroperoxide with sodium or its amalgam. However, during this process 20–45% of the hydroperoxide, depending upon the nature of the solvent, was reduced to the alcohol and the alcohol and alkoxide formed are very difficult to separate from the sodium salt of the hydroperoxide. It seemed impossible to obtain the pure salt by this method[13,14]. A product containing 70–75% sodium cumyl peroxide was obtained by the reaction of cumyl hydroperoxide with metallic sodium in ether. The impurities were 1-methyl-1-phenylethanol (15–20%) and its alkoxide (10%).[14]

The alkali OP are formed as intermediates in the autoxidation of the corresponding organometallic compounds (OMC). However, the pure salt of the hydroperoxide usually also cannot be obtained by this method owing to its rapid reaction with the OMC [1]:

$$RM + O_2 \rightarrow ROOM \quad ,$$
$$RM + ROOM \rightarrow 2ROM \quad .$$

Peroxides were obtained in significant yield only in the oxidation of alkyl-lithium[15,16]. Thus the hydroperoxide was obtained in 28–67% yield in the autoxidation of butyllithium in ether or hydrocarbon solution at –75°C after hydrolysis of the lithium butyl peroxide formed[15,16]. 75–85% of the active oxygen was obtained in the autoxidation of indenyl-3-lithium in ether at –75°C.[16]

Non-solvated alkali metal OP were obtained by reaction of hydroperoxides with alkali metal amide, hydride, or t-butoxide at 0–20°C in an aprotic solution. Only slight reduction of the hydroperoxide took place. The gaseous products formed (ammonia, hydrogen) are easily removed; the solvent and t-butyl alcohol in the reaction with lithium t-butoxide) are also distilled off at reduced pressure[17].

The non-solvated salts were obtained from hydroperoxides by the action of lithium or sodium hydride in tetrahydrofuran or ether[18]:

$$ROOH + MH \rightarrow ROOM + H_2 \quad .$$

It was shown, by the examples of the reactions of tetralin hydroperoxide [1,2,3,4-tetrahydro-1-naphthyl hydroperoxide] with NaH in ether, and also of peracetic acid with LiH and NaH in tetrahydrofuran, that here (unlike the reaction of a hydroperoxide with a metal) it is not reduced[18]. However, it was recently noted[19] that when triphenylmethyl hydroperoxide reacts with NaH in ether the yield and purity of the sodium salt of the hydroperoxide are not very satisfactory.

Unlike peroxo-acids, the alkyl and arylalkyl hydroperoxides react very slowly with LiH at 20°C. Thus lithium hydride reacts rapidly, with evolution of heat, with perdecanoic acid[17], but for cumyl hydroperoxide the conversion is negligible even after 48 h.

The method most widely used for obtaining sodium and potassium OP is based on the reaction of a hydroperoxide with sodium[20-23] or potassium[24,25] amides in a hydrocarbon:

$$\mathrm{ROOH + MNH_2 \rightarrow ROOM + NH_3} \quad .$$

Pure sodium cumyl and triphenylmethyl peroxides were obtained for the first time by this reaction as were their solutions in a hydrocarbon free from significant amounts of impurities (alkoxide, alcohol, or hydroperoxide).[22,23] Hydroperoxides react rapidly with ground sodium or potassium amide at 0–20°C. Removal of ammonia from the reaction mixture by reducing the pressure facilitates an increase in the reaction rate[23-25]. It is noteworthy that an alkali metal amide should not contain as impurities ions of variable-valency metals, which decompose hydroperoxides readily. Therefore amides obtained by the reaction of a metal with liquid ammonia in the presence of an iron salt should not be used. Sufficiently pure sodium and potassium amides are easily obtained by passing ammonia through molten alkali metal at 350°C.[23,26]

When cumyl hydroperoxide reacts with sodium amide in toluene the sodium salt which is formed passes into the solution. After the almost complete removal of the toluene at reduced pressure and the addition of ether large crystals of sodium cumyl peroxide containing 99.5–99.8% of the main substance is obtained[22]. This compound readily absorbs moisture in the air but in a sealed vessel at 0°C remains without appreciable decomposition for several months[22].

Belyaev and Nemtsov[14] obtained a complex of sodium cumyl peroxide with cumyl hydroperoxide ROONa.ROOH. Cryoscopy showed that at a concentration of 0.08 M the complex is a dimer [ROONa.ROOH]$_2$ but dissociates to the monomer during dilution. In the infrared spectrum of the complex (in CCl_4), in addition to the narrow band of the vibrations of the OH group in the 3500 cm^{-1} range there is a broad band 350 cm^{-1} away in the lower frequency range. The displacement of the band of the OH vibrations is due to the formation of a hydrogen bond. The monomer of the complex is formed due to the hydrogen bond and the dimer is due to dipole–dipole interaction[14].

The thermodynamics of dissociation of the complex ROONa.ROOH (where R is cumyl) into the initial components was investigated by NMR.[27] The temperature dependence of the chemical shift of the proton of the OOH group was used to calculate the heat of dissociation of the complex, 12.7 ± 1.0 kcal mole^{-1}. The energy of the hydrogen bond in the complex is three times that in the hydroperoxide associate.

Potassium cumyl and t-butyl peroxides, sodium t-butyl peroxide, and also their complexes with hydroperoxide[24,25,28] have been obtained. Potassium t-butyl peroxide and its complex with the hydroperoxide were precipitated as they were formed in toluene or heptane. Under analogous conditions potassium cumyl peroxide appears in the solution. After removing the excess of potassium amide and distilling off the solvent at 20°C a viscous mass remains; when this is heated at 50°C and 0.1–0.5 mmHg a colourless solid containing 96–97% potassium cumyl peroxide is obtained. This compound deliquesces rapidly in air. In the absence of moisture at 0°C the active oxygen content had not decreased after 50 days. The salt thus obtained dissolved well in aromatic and aliphatic hydrocarbons and in ethers[25]. However crystalline potassium cumyl peroxide obtained by spontaneous crystallisation from toluene solution at 20°C does not dissolve in aprotic solvents[29].

When solutions of cumyl hydroperoxide and its potassium salt in heptane are mixed the complex

$$\mathrm{C_6H_5C(CH_3)_2OOK \cdot HOOC(CH_3)_2 \cdot C_6H_5}$$

is precipitated[25]. It seems that the hydrogen bond in the complex with the potassium salt should be stronger than those in the analogous sodium and lithium compounds, owing to the greater basicity of the K salt. The complexes of the hydroperoxide and its alkali salt are considerably less stable thermally than the non-solvated salts[14,22,25]. The decomposition temperature of potassium cumyl peroxide, determined thermographically, is 140–150°C, that is, 70–80 K higher than for its complex with cumyl hydroperoxide[25]. This is evidently due to weakening of the O–O bond in the complex under the influence of the hydrogen bond[30].

A method recently proposed for making salts of hydroperoxides was by the reaction of hydroperoxides with sodium bistrimethylsilylamide in ether[19]:

$$\begin{gathered}\mathrm{ROOH + NaN[Si(CH_3)_3]_2 \rightarrow ROONa + HN[Si(CH_3)_3]_2} \quad , \\ \mathrm{R = n\text{-}C_4H_9, \quad t\text{-}C_4H_9, \ (C_6H_5)_3C} \quad .\end{gathered}$$

This is a fast reaction. The sodium salt of the hydroperoxide was precipitated in high yield.

An attempt to obtain sodium triphenylsilyl peroxide $(C_6H_5)_3SiOONa$ by this method was unsuccessful. This compound decomposes in the presence of the strong base $NaN[Si(CH_3)_3]_2$, NaH, $NaNH_2$, or $n\text{-}C_4H_9Li$ even between −80° and −20°C with the formation of phenoxide and $[(C_6H_5)_2SiO]_x$.[19]

Lithium alkyl peroxides are obtained by the reaction of hydroperoxides with lithium t-butoxide in an aprotic solvent[17]:

$$\mathrm{ROOH + (CH_3)_3COLi \rightarrow ROOLi + (CH_3)_3COH.}$$

The reaction takes place readily at 0–20°C. Lithium t-butoxide has several advantages over alkoxides of primary and secondary alcohols and also over the analogous sodium and potassium compounds[17]. It is soluble in hydrocarbons therefore its solutions are readily obtained by heating the metal with a hydrocarbon solution of the alcohol[17,31,32]. t-Butyl alcohol and its alkoxides are stable in the presence of oxygen[32] or peroxides[33], whereas alcohols containing an α-hydrogen are oxidised readily by peroxides[33-36]. Alkoxides of primary and secondary alcohols are oxidised very readily by oxygen[32,37-39] and apparently by peroxides. Owing to steric hindrance and the acidic properties, t-butyl alcohol has less tendency to form complexes, especially with lithium salts, which have a lower basicity than the analogous sodium and potassium compounds. The lithium salts of the tertiary hydroperoxides are isolated after the solvent and t-butyl alcohol have been distilled off in a vacuum at 20°C. Thus lithium cumyl and lithium t-butyl hydroperoxides of 99.0–99.8% purity were first obtained in heptane[17]. Lithium cumyl peroxide is a white hygroscopic powder soluble in aromatic hydrocarbons. This peroxide ignites spontaneously when heated to 100–115°C. Lithium t-butyl peroxide is readily soluble in various organic solvents; when heated without a solvent it ignites spontaneously at 130–135°C.[17]

The lithium, sodium, and potassium salts of the primary hydroperoxides are insoluble in aprotic solvents and are immediately precipitated during the preparation[40,41]. The alkali salts of the secondary aliphatic hydroperoxides apparently also cannot be obtained in hydrocarbon or ethereal solution[41]. The poor solubility of the alkali salts of the primary and secondary hydroperoxides in aprotic solvents seems to be explained by the high degree of association of these salts. Even salts of tertiary hydroperoxides (namely, lithium and potassium cumyl peroxides) are associated into tetramers in benzene and cyclohexane[29].

Lithium salts of secondary arylalkyl hydroperoxides can be obtained in solutions. For example, solutions of lithium 1-phenylethyl peroxide in ether, heptane, and ethylbenzene have been obtained. However, after the solid salt had been isolated it did not redissolve in aprotic solvents. When 1-phenylethyl hydroperoxide reacts with lithium t-butoxide in ether, which is then removed at 0–20°C, a salt of the hydroperoxide (97% pure) is obtained, it ignites spontaneously at 91–92°C.[41]

It is difficult to obtain the corresponding non-solvated salts by the reaction of hydroperoxides with potassium or sodium t-butoxide, since they rather firmly bond alcohol in a complex, unlike the analogous lithium compounds. The alcohol is difficult to remove from the complex ROOK.HOC$(CH_3)_3$ (where R is cumyl) even by heating in a vacuum[25]. True, potassium t-butyl hydroperoxide with a little t-butyl alcohol as impurity is obtained by heating the complex at 50°C in a high vacuum[42]. Apparently it is no less complicated to obtain a non-solvated salt by the reaction of a hydroperoxide with sodium methoxide[43]. Here in addition to the formation of a stable solvate with methanol, the alcohol and its alkoxide can be oxidised.

The sodium salts of acyl hydroperoxides (peroxo-acids) are made by reaction with sodium hydroxide. Anhydrous salts can be obtained with the aid of this reaction[44]. Sodium perbenzoate is usually made by the reaction of sodium methoxide with benzoyl peroxide in a mixture of alcohol and chloroform:

$$C_6H_5\overset{O}{\overset{\|}{C}}-O-O-\overset{O}{\overset{\|}{C}}-C_6H_5+CH_3ONa\rightarrow C_6H_5\overset{O}{\overset{\|}{C}}-O-O-Na+CH_3-O-\overset{O}{\overset{\|}{C}}-C_6H_5\ .$$

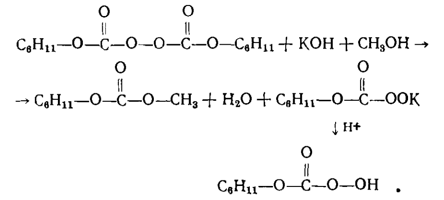
The same products are formed if instead of the alkoxide the alkali hydroxide in ethanol[45] or methanol[46] is taken:

$$R-\overset{O}{\overset{\|}{C}}-O-O-\overset{O}{\overset{\|}{C}}-R+NaOH+CH_3OH\rightarrow R-\overset{O}{\overset{\|}{C}}-O-O-Na+CH_3-O-\overset{O}{\overset{\|}{C}}-R+H_2O\ .$$

The explanation[46] is that when the water concentration is low the equilibrium of the reaction

$$CH_3OH+{}^-OH\rightleftharpoons CH_3O^-+H_2O$$

is shifted almost completely to the right[47]. The methoxide ion formed is more nucleophilic than the hydroxide ion[48]. *O*-cyclohexylmonoperoxocarbonic acid was obtained and isolated in the pure state by the reaction of dicyclohexylperoxodicarbonate with potassium hydroxide in methanol followed by the action of acid. It is evidently the first representative of an *O*-alkylmonopercarbonic acid[46].



$$C_6H_{11}-O-\overset{O}{\overset{\|}{C}}-O-O-\overset{O}{\overset{\|}{C}}-O-C_6H_{11}+KOH+CH_3OH\rightarrow$$
$$\rightarrow C_6H_{11}-O-\overset{O}{\overset{\|}{C}}-O-CH_3+H_2O+C_6H_{11}-O-\overset{O}{\overset{\|}{C}}-OOK$$
$$\downarrow H^+$$
$$C_6H_{11}-O-\overset{O}{\overset{\|}{C}}-O-OH\ .$$

Individual alkali metal OP and methods for making them are listed in Table 1.

Table 1. Methods of making organic peroxides of the alkali metals.

Peroxide	Method of preparation	Ref.
$(CH_3)_3COOLi$	ROOH + $(CH_3)_3COLi$ (heptane, 20°)	17
$C_6H_5C(CH_3)_2OOLi$	ROOH + $(CH_3)_3COLi$ (heptane, 20°)	17
$C_6H_5CH(CH_3)OOLi$	ROOH + $(CH_3)_3COLi$ (ethyl ether, 20°)	41
$CH_3C(O)OOLi$	ROOH + LiH (tetrahydrofuran)	18
$C_6H_5C(CH_3)_2OONa$	ROOH + $NaNH_2$ (toluene, 20°)	22
$(C_6H_5)_3COONa$	ROOH + $NaNH_2$ (toluene, 20°)	23
$(CH_3)_3COONa$	ROOH + $NaN[Si(CH_3)_3]_2$ (ether)	19
$CH_3CH_2CH_2CH_2OONa$	ROOH + $NaN[Si(CH_3)_3]_2$ (ether)	19
—OONa	ROOH + NaH (ether)	18
$CH_3C(O)OONa$	ROOH + NaH (ether)	18
$CH_3CH_2CH_2C(O)OONa$	ROOH + NaOH (water, alcohol, 0°)	44
$HC(O)OONa$	ROOH + NaOH (water, alcohol, 0°)	49
$C_6H_5C(CH_3)_2OONa.HOOC(CH_3)_2C_6H_5$	ROONa + ROOH (cumene, pentane)	14
$C_6H_5C(CH_3)_2OONa.HOOC(CH_3)_2C_6H_5$	ROONa + ROOH (toluene, heptane)	22
$(CH_3)_3COONa.HOOC(CH_3)_3$	2ROOH + C_2H_5ONa (toluene + ethanol, 20°)	28
$(CH_3)_3.COONa.(CH_3)_3COH$	ROOH + $(CH_3)_3CONa$ (t-butyl alcohol)	10
$C_6H_5(CH_3)_2COOK$	ROOH + KNH_2 (toluene, 20°)	25
$(CH_3)_3COOK$	ROOH + KNH_2 (toluene, 20°)	25
$(CH_3)_3COOK$	heating $(CH_3)_3COOK.(CH_3)_3COH$ in a high vacuum, 50°	42
$(C_6H_5C(CH_3)_2OOK.HOOC(CH_3)_2C_6H_5$	ROOH + KNH_2 (toluene, 20°)	25
$(CH_3)_3COOK.HOOC(CH_3)_3$	ROOH + KNH_2 (toluene, 20°)	25
$(CH_3)_3COOK.2HOOC(CH_3)_3$	ROOH + KNH_2 (toluene, 20°)	25
$(CH_3)_3COOK.(CH_3)_3COH$	ROOH + $(CH_3)_3CONa$ (t-butyl alcohol)	10
$(CH_3)_3COOK.C_2H_5OH$	ROOH + KOH (ethanol, 0–2°)	12

III. THERMAL DECOMPOSITION

Studies of the decomposition of the alkali metal OP can be divided into three groups, depending upon the subject and conditions of the investigation. The first group comprises investigations [13,22,29] in which the thermal decomposition of the non-solvated compounds in hydrocarbons was studied. The second group covers the investigation of the thermal decomposition of complexes of the alkali OP with water and hydroperoxide in hydrocarbon solutions. Most of the papers relate to the third group; they describe an investigation of the decomposition of hydroperoxides in aqueous-alkaline solutions. An alkali salt of the hydroperoxide is an intermediate product of this reaction.

The thermal decomposition of the alkali OP in hydrocarbons at 80–130°C has been investigated[29]. The decomposition of potassium cumyl peroxide is described by a first-order kinetic equation. The hydrocarbon used as solvent has little effect on the rate of decomposition of the peroxide (Table 2). The decomposition products are given in Table 3.

Table 2. Kinetic parameters of the thermal decomposition of the alkali organic peroxides (c_0 = 0.1 M).[29]

Peroxide	Solvent	10^5k, s^{-1} (at 110°C)	E, kcal $mole^{-1}$	lg A
$C_6H_5C(CH_3)_2OOK$	n-nonane	13.3	28.6	12.3
$C_6H_5C(CH_3)_2OOK$	cumene	7.0	29.0	12.4
$C_6H_5C(CH_3)_2OOK$	*m*-xylene	7.1	29.3	12.6
$C_6H_5C(CH_3)_2OOK$	t-butylbenzene	7.2	29.2	12.6
$(C_6H_5)_2CCH_3OOK$	t-butylbenzene	30.7	24.2	10.3
$(C_6H_5)_3COOK$	t-butylbenzene	18.4	21.4	8.5
$C_6H_5C(CH_3)_2OONa$	t-butylbenzene	19.7*	25.2	11.6

*10^4 k, litre $mole^{-1}$ s^{-1}.

A decomposition mechanism has been proposed[29]:

$$\begin{gathered}
\mathrm{ROO\,(L)}_n \rightarrow \mathrm{RO^{\bullet}} + {}^{\bullet}\mathrm{OK} + n\,\mathrm{L} \quad , \\
{}^{\bullet}\mathrm{OK} + \mathrm{SH} \rightarrow \mathrm{KOH} + \mathrm{S^{\bullet}} \quad , \\
\mathrm{RO^{\bullet}} + \mathrm{SH} \rightarrow \mathrm{ROH} + \mathrm{S^{\bullet}} \quad , \\
\mathrm{RO^{\bullet}} \rightarrow \mathrm{C_6H_5C\,(O)\,CH_3} + {}^{\bullet}\mathrm{CH_3} \quad , \\
\mathrm{C_6H_5C\,(O)\,CH_3} + 3\mathrm{ROOK} \rightarrow \mathrm{C_6H_5C\,(O)\,OK} + \mathrm{HC\,(O)\,OK} + 2\mathrm{ROH} + \mathrm{ROK} \quad , \\
\mathrm{S^{\bullet}} + \mathrm{S^{\bullet}} \rightarrow \mathrm{S{-}S} \quad .
\end{gathered}$$

During the decomposition of the associates there is a breaking of one peroxide bond after the act. The other peroxide molecules in the associate can be ligands (L) in relation to the decomposing molecule. A decrease in the strength of the peroxide bond being changed can be expected, as was noted for solvates with hydroperoxide and water[50]. The acetophenone formed in the partial decomposition of the cumyloxy-radicals readily undergoes a molecular reaction with potassium cumyl peroxide[51]. The yield of benzoic acid (a product of the oxidation of acetophenone) can be used to determine that the decomposition of the potassium salt of the hydroperoxide takes place by 60–80% by a free-radical reaction and 40–20% by a molecular reaction with the ketone. The ratio of the rates of these reactions depends on the nature of the solvent. The greater the rate of reaction of the free radical with the solvent, the less the part played by the molecular reaction.

Ethane is formed in the decomposition of potassium cumyl peroxide in n-nonane, but there are no gaseous products when the reaction is carried out in aromatic hydrocarbons. The explanation could be that the methyl radicals are added to the aromatic ring of the solvent[52] but are dimerised in nonane with formation of ethane[29]. The ${}^{\bullet}$OK radical evidently removes hydrogen from the solvent[53] with the formation of an alkali hydroxide. The absence of gaseous oxygen and of oxidation products of the solvent is characteristic[29]. The absence of oxygen in the decomposition of sodium cumyl peroxide in a hydrocarbon was noted earlier[13].

Table 3. Decomposition products of alkali organic peroxides (c_0 = 0.2 M).[29]

Peroxide	Reaction temp., °C	Solvent	Reaction time, h	Yield, moles per mole peroxide decomposed				
				$C_6H_5C(CH_3)_2OH$	$C_6H_5C(CH_3)_2OM$	$C_6H_5C(O)OM$	$HC(O)OM$	MOH
$C_6H_5C(CH_3)_2OOK$	110	n-nonane*	6	0.90	0.05	0.05	0.05	0.74
$C_6H_5C(CH_3)_2OOK$	110	cumene**	6	0.89	0.07	0.08	0.08	0.65
$C_6H_5C(CH_3)_2OOK$	110	t-butylbenzene	6	0.82	0.08	0.09	0.10	0.78
$C_6H_5C(CH_3)_2OONa$	120	t-butylbenzene	6	0.80	0.09	0.10	0.08	0.75
$C_6H_5C(CH_3)_2OOLi$	80	benzene	12	0.60	0.20	0.22	0.21	0.30
$C_6H_5C(CH_3)_2OOLi$	90	t-butylbenzene	6	0.83	0.09	0.11	0.11	0.74

*The decomposition products contain 0.03 mole ethane per mole peroxide decomposed.
**The bicumyl in the products was determined qualitatively.

Sodium and lithium cumyl peroxides decompose analogously. However, the kinetics of the processes differ significantly: the decomposition of the sodium salt is described by a kinetic equation for a second-order reaction, but the lithium salt decomposes with a clear induction period. Table 2 gives the kinetic parameters for the decomposition of sodium cumyl peroxide. The activation energy for the decomposition of lithium cumyl peroxide, calculated from the temperature dependence of the induction period, is 23.0 kcal $mole^{-1}$.[29]

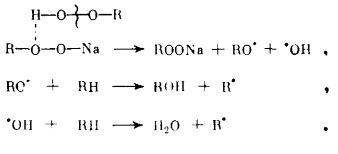
The difference in the formal kinetics of the decomposition of the peroxides is explained by the influence of the reaction products, above all the alkoxides. It seems that the formation of a complex of the peroxide with the alkoxide can change the strength of the O–O bond[29].

The decomposition of the salts in a hydrocarbon is greatly accelerated by additions of hydroperoxides, which is explained by the formation of the complexes ROOM.HOOR, which are less stable thermally[14,22,28,50]. The kinetics and mechanism of the decomposition of the complex

$$C_6H_5C(CH_3)_2OONa \cdot C_6H_5C(CH_3)_2OOH$$

in cumene have been studied[54,55]. The kinetic order with respect to the complex is 1.35, which the investigators explained by the occurrence of parallel reactions for the decomposition of the monomer and dimer of the complex (the latter is less stable thermally). The activation energy for the decomposition of the complex is 18.0 kcal $mole^{-1}$.[27,55] The decomposition of the complex initiates the polymerisation of styrene in bulk at 20–60°C more effectively than the decomposition of cumyl hydroperoxide. Belyaev and Nemtsov[55] think that the O-O bond of the hydroperoxide in the complex is broken, being weakened by the hydrogen bond. In the molecule of the salt, which is an acceptor of a proton, they think that the O-C and O-O bonds become stronger. However, other results[50] which will be considered below do not support these conclusions.

A mechanism for the decomposition of the complex is proposed:



$$\begin{array}{l} \text{H—O}\}\text{O—R} \\ \;\vdots \\ \text{R—O—O—Na} \longrightarrow \text{ROONa} + \text{RO}^{\bullet} + {}^{\bullet}\text{OH} , \end{array}$$

$$\text{RO}^{\bullet} + \text{RH} \longrightarrow \text{ROH} + \text{R}^{\bullet} ,$$

$$^{\bullet}\text{OH} + \text{RH} \longrightarrow \text{H}_2\text{O} + \text{R}^{\bullet} .$$

Acetophenone is formed as a result of the decompositon of the RO$^{\bullet}$ radical. Belyaev and Nemtsov[55] explain the yield of acetophenone being lower than in the thermal decomposition of the hydroperoxide by the increased strength of the C-CH_3 bond in the complexes. We think the small yield of acetophenone in the decomposition of these complexes is explained by ketones containing α-hydrogen being readily oxidised by salts of hydroperoxides and their complexes[51].

This scheme does not explain the formation of oxygen and 1-methyl-1-phenylethanol (1.5 moles per mole hydroperoxide decomposed). It is suggested therefore[55] that molecular decomposition of the dimer of the complex is more probable:

$$(\text{NaOOR})_2 \begin{bmatrix} \text{R—O—O—H} \\ \text{H—O—O—R} \end{bmatrix} \rightarrow 2\text{ROONa} + 2\text{ROH} + \text{O}_2 \quad .$$

The oxygen which has been formed by a chain free-radical mechanism oxidises cumene to its hydroperoxide, the decomposition of which also gives an additional amount of 1-methyl-1-phenylethanol.[55]

The decomposition of the complexes ROOK.ROOH and ROOK.$2H_2O$ (where R = cumyl) in benzene and toluene has been investigated[50]. The thermal decomposition of these complexes in solution is rather rapid even at 70-80°C. The main products of the reaction are 1-methyl-1-phenylethanol, potassium benzoate, and oxygen (Table 4). Potassium formate is also formed during decomposition in benzene[56].

Table 4. Decomposition products of the complexes with water and a hydroperoxide[50] (concentration 0.2 M).

Complex	Reaction temp., °C	Solvent	Yield, moles per mole complex decomposed		
			1-methyl-1-phenyl ethanol	potassium benzoate	oxygen
$C_6H_5C(CH_3)_2OOK \cdot 2H_2O$	80	toluene	1.0	0.29	none
$C_6H_5C(CH_3)_2OOK \cdot 2H_2O$	70	benzene	0.8	0.18	0.11
$C_6H_5C(CH_3)_2OOK \cdot C_6H_5C(CH_3)_2OOH$	70	toluene	2.0	0.38	0.24

The decomposition of the complex with water in benzene or toluene is described well by a first-order kinetic equation, as is the decomposition of the complex with the hydroperoxide in toluene. However the decomposition of this complex in benzene slows down sharply after the concentration of the peroxide compound has fallen to approximately half the initial value[50]. Table 5 gives the effective rate constants and activation energies for the decomposition of the complexes in benzene or toluene. The thermal decomposition of the complexes with loss of peroxide oxygen proceeds more readily than the decomposition of the potassium salt or the hydroperoxide separately.

Table 5. Rate constant and effective activation energies for the decomposition of the complexes of potassium cumyl peroxide with water and with a hydroperoxide (concentration 0.1 M).[50]

Complex	Solvent	$10^5 k$, s^{-1} at 70°C	E, kcal $mole^{-1}$
$C_6H_5C(CH_3)_2OOK \cdot 2H_2O$	benzene	19.4	25.3
$C_6H_5C(CH_3)_2OOK \cdot 2H_2O$	toluene	11.9	22.6
$C_6H_5C(CH_3)_2OOK \cdot C_6H_5C(CH_3)_2OOH$	toluene	40.8	19.3
$C_6H_5C(CH_3)_2OOK \cdot C_6H_5C(CH_3)_2OOH$	benzene	3.67*	23.9*

---

*$10^5 w_0$, mole $litre^{-1}$ s^{-1}.

**Calculated from the temperature coefficient of the initial rate.

Additions of an inhibitor (1-naphthylamine) do not affect the decomposition of the complex of potassium cumyl peroxide with water in toluene. This shows that a molecular reaction of the inhibitor with the peroxide compound does not occur, just like the chain reaction for decomposition.

The rate of loss of peroxide oxygen in the decomposition of the complex in cumene increases with the concentration of 1-naphthylamine. The explanation is that 1-naphthylamine inhibits the radical-chain oxidation of cumene to its hydroperoxide by the oxidation formed in the decomposition of the complexes. The rate of decomposition of 1-naphthylamine in benzene showed that 10-20% of the complex decomposes with formation of free radicals:

$$\text{ROOK} \cdot 2\text{H}_2\text{O} \rightarrow \text{RO}^{\cdot} + {}^{\cdot}\text{OK} + 2\text{H}_2\text{O} \quad ,$$

$$\text{ROOK} \cdot \text{ROOH} \rightarrow \text{RO}_2^{\cdot} + \text{RO}^{\cdot} + \text{KOH} \quad .$$

The complexes decompose predominantly by molecular reactions:

$$2\,[\text{ROOK} \cdot 2\text{H}_2\text{O}] \rightarrow 2\text{ROH} + 2\text{KOH} + 2\text{H}_2\text{O} + \text{O}_2 \quad ,$$

$$\text{ROOK} \cdot \text{HOOR} \rightarrow \text{ROK} + \text{ROH} + \text{O}_2 \quad ,$$

$$\text{ROK} + \text{ROOK} \cdot \text{HOOR} \rightarrow \text{ROH} + 2\text{ROOK} \quad .$$

The occurrence of the last exchange reaction is explained by the fact that decomposition of the complex of potassium cumyl peroxide with the hydroperoxide in benzene is greatly retarded after the concentration of peroxide oxygen has been reduced to approximately half.

The cumyloxy-radical detaches hydrogen from cumene and toluene to form 1-methyl-1-phenylethanol and a radical of the solvent, which is oxidised by the oxygen formed. In benzene, the cumyloxy-radical decomposes into the methyl radical and acetophenone, which is readily oxidised by potassium cumyl peroxide by a molecular mechanism[51]. In the decomposition of the complexes in toluene at 70° and 80°C, benzoic acid is formed due to oxidation of the solvent.

The lower thermal stability of the complex with water apparently shows the considerable drop in the dissociation energy of the O–O bond in the formation of a hydrogen bond. The influence of water cannot be explained by the formation of hydroperoxide due to the hydrolysis of its salt, since the degree of hydrolysis under the conditions of the reaction is low owing to the acidity of the hydroperoxide being much greater than that for water[50].

The decomposition of complexes of sodium t-butylperoxide with the hydroperoxide and water was investigated[28]. Sodium cumyl peroxide hexahydrate decomposes slowly at 60–70°C.[9] It loses active oxygen completely after 2 h at 115°C. Decomposition proceeds mainly according to the scheme:

$$C_6H_5C(CH_3)_2OONa \cdot 6H_2O \rightarrow C_6H_5C(CH_3)_2OH + \frac{1}{2}O_2 + NaOH + 5H_2O\ .$$

This main process is accompanied by the formation of acetophenone and methanol, which react with the initial compound:

$$\begin{gathered} C_6H_5COCH_3 + 4C_6H_5C(CH_3)_2OOH + 3NaOH \rightarrow \\ \rightarrow C_6H_5C(O)ONa + Na_2CO_3 + 3H_2O + 4C_6H_5C(CH_3)_2OH; \\ CH_3OH + 2C_6H_5C(CH_3)_2OOH + NaOH \rightarrow HCOONa + 2H_2O + 2C_6H_5C(CH_3)_2OH\ . \end{gathered}$$

The formation of a little bicumyl shows that free-radical decomposition of the hexahydrate takes place[9]:

$$C_6H_5C(CH_3)_2OONa \cdot 6H_2O \rightarrow C_6H_5C(CH_3)_2O^{\cdot} + {}^{\cdot}ONa + 6H_2O\ .$$

The radical which is formed removes hydrogen from the solvent. The solvent radicals are oxidised by the oxygen released in the molecular decomposition of the peroxide or are dimerised. Additions of the hydroperoxide accelerate the decomposition of sodium cumyl peroxide hexahydrate in cumene at 80°C.[8] The highest reaction rate was observed at a molar ratio of 2 : 1 between the hydroperoxide and its salt. Decomposition of the salt without addition of hydroperoxide was slower by a factor of almost 2. Kharasch and coworkers[13] obtained analogous results.

When mixtures of sodium cumyl peroxide hexahydrate with the hydroperoxide or 1-methyl-1-phenylethanol in cumene was heated briefly to 80°C and then cooled rapidly a crystalline trihydrate was precipitated. The formation of this compound is explained by the existence of the equilibrium[8]:

$$ROONa \cdot 6H_2O + n\,A \rightleftarrows ROONa \cdot 3H_2O + n\,A \cdot 3H_2O\ ,$$

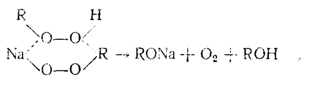
where A is an acceptor of water.

Kharasch and coworkers[13] proposed an ion-molecular mechanism for the decomposition of hydroperoxide:

$$RO_2^- + ROOH \rightarrow RO^- + ROH + O_2\ .$$

They think[13] that free radicals are not formed and postulate the direct transfer of the oxygen atom from the peroxide anion to a reductant, which could be the non-dissociated hydroperoxide molecule or an alcohol with an α-hydrogen atom.

A mechanism of alkaline decomposition of hydroperoxide into a six-membered cyclic active complex was proposed[3,57]:



Apparently, molecular decomposition of the complexes of alkali OP with hydroperoxide and water takes place in the six-membered cyclic active complex. However, as an analysis of the products shows[29] that such a mechanism does not take place in the decomposition of the non-solvated alkali OP on hydrocarbons. It seems that an important part in the molecular decomposition of salts of hydroperoxides with release of oxygen is played by their solvation with the formation of a hydrogen bond.

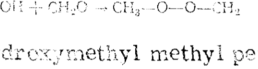
The decomposition of a hydroperoxide and its salt in water by a free-radical mechanism could be due to traces of metals of variable valency. This is shown by the decrease in the rate of formation of oxygen by additions of small quantities of EDTA.[58]

The kinetics of decomposition of cumyl hydroperoxide in the presence of NaOH in various solvents was studied recently[59]. The alkaline decomposition of *m*- and *p*-di-isopropylbenzene dihydroperoxides in aqueous solution and also the decomposition of the crystalline hydrates of their disodium salts were investigated[60,61]. The primary product of the alkaline decomposition of the dihydroperoxides are hydroxyhydroperoxides, and the final products are carbinols, acetylbenzenes, carbonic acids. Belen'kii and coworkers[61] suggest the formation of atomic oxygen, which oxidises the primary decomposition products. We think the formation of the acids is explained by the reaction of the dihydroperoxide salt with the ketone formed as intermediate product.

A method of alkaline decomposition of hydroperoxides on an ion-exchange resin containing an active group of a quaternary ammonium base has been proposed[62].

Primary and secondary hydroperoxides decompose in an alkaline medium much more rapidly than the tertiary compounds. However, the sodium salts of hydroperoxides which contain α-hydrogen can also be obtained and in certain instances isolated[63]. The main products from the alkaline decomposition of primary and secondary hydroperoxides are the corresponding aldehydes or ketones; alcohols and acids can also be formed. Hydrogen is produced in the alkaline decomposition of the lower primary alkyl hydroperoxides. A brief review of the reactions in the alkaline decomposition of primary alkyl hydroperoxides has been published[64].

Methyl hydroperoxide decomposes in alkaline solution to form hydrogen, methanol, and formic acid[65]. Ethyl hydroperoxide decomposes with release of a very small amount of gas but when formaldehyde is added hydrogen is released. It is formed as a result of the alkaline decomposition of an alkyl hydroxymethyl peroxide, which is an intermediate product:

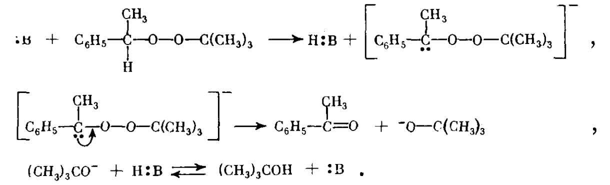


$$\begin{gathered} CH_3OOH \rightarrow CH_2O + H_2O \\ CH_3OOH + CH_2O \rightarrow CH_3{-}O{-}O{-}CH_2OH\ . \end{gathered}$$

Rieche[66] obtained hydroxymethyl methyl peroxide and ethyl hydroxymethyl peroxide. It was confirmed that these peroxides decompose in an alkaline medium with the formation of hydrogen, formic acid, and an alcohol, and in the second instance acetaldehyde also.

It was shown later[64] that n-butyl 1-hydroxyethyl and n-butyl 1-hydroxybutyl peroxides, unlike n-butyl hydroxymethyl peroxide, decompose in the presence of a base with the formation of a very small amount of gas. It was therefore concluded that hydrogen is formed from the hydroxymethylperoxo-group $O{-}O{-}CH_2OH$.

Not only hydroperoxides but also peroxides containing a hydrogen atom in the α-position decompose readily in an alkaline medium[67]. Peroxide compounds with either arylalkyl or alkyl radicals decompose readily. For example, 1,2,3,4-tetrahydro-1-naphthyl hydroperoxide is converted into α-tetralone [3,4-dihydro-1(2H)naphthalenone]. Isopropyl hydroperoxide rapidly forms acetone[68]. Kornblum and De La Mare[67] proposed a mechanism for the decomposition of peroxide compounds containing α-hydrogen, in the presence of a base (B):



$$:B + C_6H_5-C(CH_3)(H)-O-O-C(CH_3)_3 \longrightarrow H:B + [C_6H_5-\ddot{C}(CH_3)-O-O-C(CH_3)_3]^- ,$$

$$[C_6H_5-C(CH_3)-O-O-C(CH_3)_3]^- \longrightarrow C_6H_5-C(CH_3)=O + {}^-O-C(CH_3)_3 ,$$

$$(CH_3)_3CO^- + H:B \rightleftarrows (CH_3)_3COH + :B .$$

This mechanism is widely encountered (for example, cf. Hawkins[69]), but the formation of a carbanion in the decomposition of peroxide compounds, especially alkyl ones, in water or low-polar solvents, seems improbable.

Acrylonitrile does not retard the alkaline decomposition of tetralin hydroperoxide [1,2,3,4-tetrahydro-1-naphthyl hydroperoxide (Ed. of Translation)] in alcohol–water solution. The formation of a polymer during this reaction also is not observed, unlike the similar reaction in neutral solution. The explanation could be that free radicals are not formed in the alkaline decomposition of the hydroperoxide[70].

Syrkin and Moiseev[71] suggested that the alkaline decomposition of dialkyl peroxides containing an α-hydrogen proceeds in a cyclic transition state.

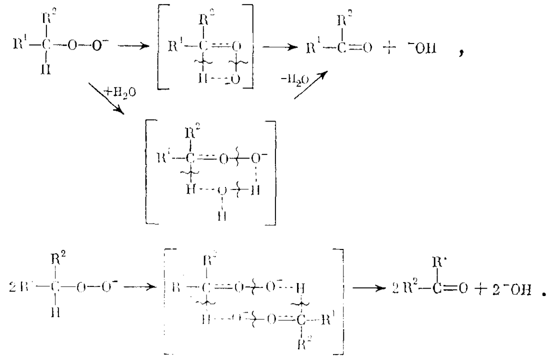
The kinetics of the alkaline decomposition of hydroperoxides with an α-hydrogen have been studied recently[40,41,72]. Hofmann and coworkers[72] investigated the kinetics of the decomposition of 4-n-heptyl, cyclohexyl, 1,2,3,4-tetrahydro-1-naphthyl, 1-phenylethyl, and cumyl hydroperoxides in methanol in the presence of sodium or potassium hydroxide. In addition to ketones, the decomposition products contained the corresponding alcohols. In investigating the kinetics of the process they obtained reproducible results only for 1,2,3,4-tetrahydro-1-naphthyl and 1-phenylethyl hydroperoxides. Additions of a little Complexone III did not alter the rate of decomposition of 1,2,3,4-tetrahydro-1-naphthyl hydroperoxide, but somewhat retarded the decomposition of 1-phenylethyl hydroperoxide and depressed the decomposition of the other hydroperoxides investigated (at 40°C). The inhibiting influence of the complexone is explained by these hydroperoxides decomposing according to a radical mechanism under the action of traces of heavy metal ions. The formation of alcohols is explained by the occurrence of free-radical reactions. The proportion of alcohols in the decomposition of the 1,2,3,4-tetrahydro-1-naphthyl and 1-phenylethyl hydroperoxides is insignificant. It is concluded that alkaline decomposition of these hydroperoxides proceeds according to the Kornblum–De La Mare mechanism.

The kinetics of decomposition of alkali salts of s-butyl and 1-phenylethyl hydroperoxides[41] and also of a substituted benzyl hydroperoxide[40] in aqueous solutions have been investigated. The rate constant of the first-order decomposition of a peroxide increases linearly with its initial concentration. The explanation could be that the decomposition proceeds by first- and second-order reactions in parallel:

$$w_{\text{eff}} = k_1c + k_2c^2;\ k_{\text{eff}} = k_1 + k_2c .$$

The straight lines obtained in coordinates of k_{eff} against c_0 were used to calculate the rate constants of the first- and second-order reactions at various temperatures. The rate of decomposition of the hydroperoxide salt in water is independent of the nature of the alkali cation (lithium, sodium, potassium)[40,41]. For the decomposition of the salt of s-butylhydroperoxide, $k_1 = 4.1 \times 10^8 \times \exp(-21\,000/RT)\ s^{-1}$, $k_2 = 3.2 \times 10^{11} \times \exp(-24\,700/RT)$ litre mole^{-1} s^{-1}; for the decomposition of the salts of 1-phenylethyl hydroperoxide $k_1 = 5.0 \times 10^6 \times \exp(-16\,500/RT)\ s^{-1}$, $k_2 = 6.7 \times 10^{11} \times \exp(-23\,000/RT)$ litre mole^{-1} s^{-1}.[41] The replacement of the ethyl group of the secondary hydroperoxide by a phenyl group considerably accelerates the decomposition of its alkali salt. The rate of decomposition of the sodium salts of the isomeric butyl hydroperoxides at 90°C fall in the order: primary > secondary > tertiary[41].

The simple composition of the products (during the decomposition of a salt of 1-phenylethyl hydroperoxide, acetophenone and the alkali hydroperoxide are formed quantitatively) and the low activation energy shows that decomposition of the peroxide anion with α-hydrogen takes place in a cyclic transition state. A six-membered transition state is the most favourable energetically, therefore the formation of such a state involving water is probable. Formation of an eight-membered cyclic transition state is suggested for a second-order reaction:



IV. REACTIONS WITH ORGANIC COMPOUNDS

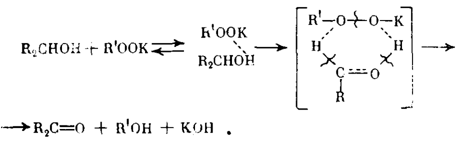
The alkali OP readily undergo nucleophilic substitution, addition, and elimination. The peroxide anion is a nucleophile with increased reactivity owing to the so-called α-effect.

The reactions of these peroxides with alkyl halides and acyl halides are nucleophilic substitutions and proceed with retention of the O–O bond and formation of dialkyl peroxides and peroxoacid esters respectively. Analogous reactions with organoelemental halogeno-derivatives are the main method for obtaining the OP of various elements. The primary stages of the reaction of hydroperoxide salts with carbonyl compounds and their heteroanalogues are nucleophilic additions. The decomposition of the salts of primary and secondary hydroperoxides with the formation of aldehydes and ketones are nucleophilic eliminations, as was discussed above[41,67,72].

The reactivity of the non-solvated alkali peroxides has been studied only recently[51,73-77]. Previously[78-86] the reaction of aqueous alkali salts of hydroperoxides with hydrocarbons[79,80], alcohols[13], aldehydes[81], ketones[81-84], and nitriles[13,58,78,86] were investigated. The reaction of the complex ROONa.ROOH with acetophenone and benzoquinone is also reported to take place comparatively readily[54,55]. It was found that even the addition of small quantities of water to a non-solvated peroxide greatly reduces its reaction rate with organic compounds[51] and can also change the composition of the products formed[75].

As already stated, the thermal decomposition of the non-solvated alkali OP in hydrocarbon solutions takes place at a significant rate only at 80–130°C.[29] However, in hydrocarbons in the presence of aldehydes, ketones, alcohols (with α-hydrogen), and esters these peroxides decompose rapidly even at 10–50°C.[51,73,76,77]. The rate of decomposition of the peroxide in the presence of these compounds increases in the order RQOLi < ROONa < ROOK. These reactions take place through intermediate complexes (with an alcohol) or peroxide compounds. Therefore when there is an excess of an organic compound the decomposition of the peroxide is described by a first-order kinetic equation and has zero or even negative order with respect to the other component[51,73,76].

As the initial concentration of diphenylmethanol is increased there is first an increase in the rate constant of the decomposition of potassium cumyl peroxide, which passes through a maximum at the equimolar ratio of the reagents, then decreases. This type of relation shows the formation of a 1 : 1 complex of the peroxide with the alcohol, a complex which decomposes readily with loss of the peroxide oxygen. The complex can be formed because of a hydrogen bond. The decomposition mechanism proposed for such complexes is through a six-membered cyclic transition state[73]:



The calculated kinetic parameters for the decomposition of the complexes of potassium cumyl peroxide with diphenylmethanol and 1-phenylethanol in benzene. For the complex with diphenylmethanol $k = 2.0 \times 10^9 \times \exp(-18\,300/RT)\ s^{-1}$, and for the complex with 1-phenylethanol $k = 2.5 \times 10^9 \times \exp(-18\,500\ RT)\ s^{-1}$.

Table 6. Kinetic parameters for the decomposition of lithium cumyl peroxide (0.1 M) in the presence of XC_6H_4CHO (0.4 M) in benzene.[76]

Substituent X	10^5k, s^{-1} (at 30°C)	E, kcal mole^{-1}	lg A
H	17.0	22.8	12.7
p-Cl	13.8	22.0	12.0
p-Br	15.8	22.8	12.7
p-CH_3O	29.2	18.3	9.7

The kinetics and mechanism of the reaction of lithium cumyl peroxide with benzaldehyde and substituted benzaldehydes at 20–40°C have been investigated in detail[76]. As the initial concentration of aldehyde is raised the rate constant for the decomposition of the peroxide first increases linearly, and then the increase slackens and stops. The analogous relation was obtained for the reaction of potassium cumyl peroxide with acetophenone, acetone, and ethyl methyl ketone.[51] This type of dependence of the rate of decomposition of the peroxide upon the concentration of the carbonyl compound is explained by the formation of an intermediate peroxide owing to the reversible nucleophilic addition of the peroxo-group to the carbonyl carbon. The decomposition of the intermediate peroxides proceeds through a cyclic transition state[76]:

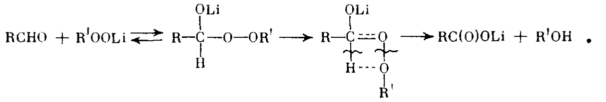


Table 6 gives the kinetic parameters of the decomposition of lithium cumyl peroxide in benzene in the presence of benzaldehyde or substituted benzaldehydes. The measurements were made in an excess of the aldehyde, when the equilibrium is shifted almost completely to the side of formation of an intermediate peroxide compound.

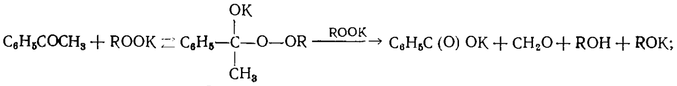
The reaction of potassium cumyl peroxide with acetophenone can be represented as[51]:



$$C_6H_5COCH_3 + ROOK \rightleftarrows C_6H_5-\underset{\displaystyle CH_3}{\overset{\displaystyle OK}{C}}-O-OR \xrightarrow{ROOK} C_6H_5C(O)OK + CH_2O + ROH + ROK;$$

$$CH_2O + ROOK \rightarrow HC(O)OK + ROH\ .$$

Table 7. Kinetic parameters for the decomposition of potassium cumyl peroxide (0.1 M) in the presence of ketones (0.4 M) in benzene.

Ketone	10^4k, s^{-1} (at 20°C)	E, kcal mole^{-1}	lg A
Acetophenone	5.5	16.4	9.0
Ethyl methyl ketone	2.8	14.7	7 4
Acetone	4.7	15.5	8.2

Table 7 gives the kinetic parameters for the decomposition of potassium cumyl peroxide in the presence of ketones. The results were obtained in an excess of the ketone, when a further increase in its concentration has little effect on the rate of decomposition of the peroxide. The kinetic parameters for Tables 6 and 7 relate to the slowest stage—the decomposition of the intermediate peroxide.

The alkali OP react with esters according to the scheme[77]

$$CH_3C(O)OC_2H_5 + 2ROOK \rightarrow 2CH_3C(O)OK + 2ROH \ (\text{at } 20°),$$

$$C_6H_5C(O)OC_2H_5 + 2ROOK \rightarrow C_6H_5C(O)OK + CH_3C(O)OK + 2ROH \ (\text{at } 70°).$$

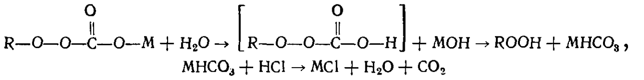
The first stage of the reaction is evidently also nucleophilic addition of a peroxo-group to the carbonyl carbon. In this instance this stage is the slowest. Therefore the reaction is first order with respect to each reagent and second order overall.

Carbon dioxide readily releases a hydroperoxide from its alkali salt in aqueous solution. This reaction is used widely for the separation and purification of the hydroperoxides. In the absence of water salts of the hydroperoxides in benzene are added to carbon dioxide with the formation of the alkali salts of arylalkyl monopercarbonic acids[74,75]:

$$R-O-O-M + CO_2 \rightarrow R-O-O-\overset{\displaystyle O}{\overset{\|}{C}}-O-M\ .$$

$R{=}C_6H_5C(CH_3)_2$, M=Li, Na, K

These compounds are hydrolysed by water with the formation of a hydroperoxide and when acidified carbon dioxide is also released. It seems that initially an unstable arylalkylmonopercarbonic acid is formed, which is decomposed into a hydroperoxide and carbon dioxide[74,75]:



$$\mathrm{R{-}O{-}O{-}\overset{\overset{\displaystyle O}{\|}}{C}{-}O{-}}M + \mathrm{H_2O} \rightarrow \left[\mathrm{R{-}O{-}O{-}\overset{\overset{\displaystyle O}{\|}}{C}{-}O{-}H}\right] + M\mathrm{OH} \rightarrow \mathrm{ROOH} + M\mathrm{HCO_3},$$
$$\mathrm{MHCO_3 + HCl \rightarrow MCl + H_2O + CO_2}$$

The reactions of hydrocarbons, aldehydes, and ketones with t-butyl and cumyl hydroperoxides in the presence of potassium hydroxide have been investigated[79-84]. An intermediate product is undoubtedly a hydrated salt of the hydroperoxide which is formed rapidly. Hydrocarbons (benzene, cumene, *p*-xylene, ethylbenzene, t-butyltoluene, tetralin, and *p*-isopropyltoluene) reduce hydroperoxides to alcohols at 70–80°C; oxygen is released only on heating in benzene. The alkyl groups of aromatic hydrocarbons are oxidised to alcohols, aldehydes, ketones, or carboxyl groups[79,80]. Thus *p*-xylene is mainly converted into *p*-methylbenzaldehyde and the corresponding acid, *p*-t-*p*-t-butyltoluene is oxidised to *p*-t-butylbenzyl alcohol, *p*-t-butylbenzaldehyde, and *p*-t-butylbenzoic acid, and ethylbenzene to acetophenone and benzoic acid. Goto and coworkers[79] suggested that the potassium salt of the hydroperoxide gives a complex with the hydrocarbon which is rearranged with the formation of oxidation products. However, it was shown later[50] that the decomposition of potassium cumyl peroxide hydrate in a hydrocarbon partly takes place with the formation of free radicals, which initiate the radical-chain oxidation of the hydrocarbons by the oxygen released.

Formaldehyde, acetaldehyde, and propionaldehyde are oxidised by hydroperoxide in aqueous alkaline solution at 25–35°C to the corresponding acids[81]. The reaction takes place through an intermediate peroxide which is formed in the reversible addition of the peroxide anion to the carbonyl carbon and decomposes by an ionic mechanism[81].

The reaction of t-butyl hydroperoxide with ketones in the presence of potassium hydroxide in chlorobenzene at 80°C has been investigated[82-84]. Diaryl ketones (benzophenone, *p*-nitrobenzophenone, and fluorenone)[82] do not change under these conditions. The main oxidation products of the arylalkyl ketones are the corresponding benzoic acid and an alcohol, obtained from the alkyl group of the ketone[83]:

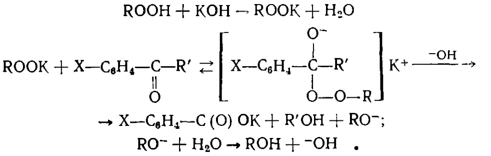
$$\mathrm{Ar{-}C\,(O){-}R \xrightarrow[KOH]{(CH_3)_3\,COOH} ArC\,(O)\,OH + ROH} \quad .$$

Thus in the oxidation of acetophenone and *p*-methylacetophenone the main products are methanol and the corresponding benzoic or *p*-toluic acid.

Aliphatic ketones react in two ways:

$$\mathrm{RC\,(O)\,R'} \xrightarrow[\mathrm{KOH}]{\mathrm{(CH_3)_3\,COOH}} \begin{cases} \rightarrow \mathrm{RC\,(O)\,OH + R'OH} \\ \rightarrow \mathrm{R'C\,(O)\,OH + ROH} \end{cases} \quad .$$

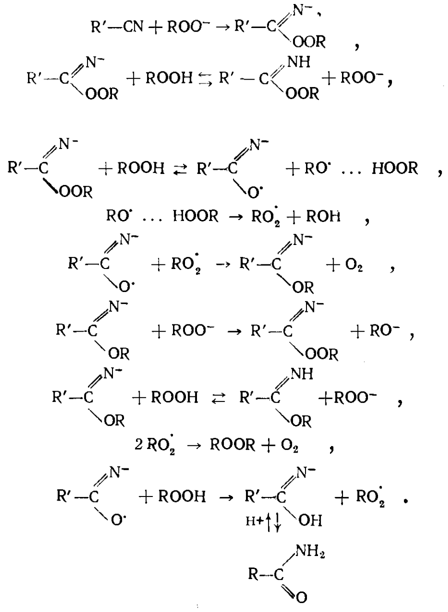
Maruyama[83,84] proposed the reaction mechanism:



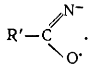
$$\mathrm{ROOH + KOH \rightarrow ROOK + H_2O}$$
$$\mathrm{ROOK + X{-}C_6H_4{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}R'} \rightleftarrows \left[\mathrm{X{-}C_6H_4{-}\overset{\overset{\displaystyle O^-}{|}}{\underset{\underset{\displaystyle O{-}O{-}R}{|}}{C}}{-}R'}\right]\mathrm{K^+} \xrightarrow{^-\mathrm{OH}}$$
$$\mathrm{\rightarrow X{-}C_6H_4{-}C\,(O)\,OK + R'OH + RO^-;}$$
$$\mathrm{RO^- + H_2O \rightarrow ROH + {}^-OH} \quad .$$

The results of these investigations differ considerably from those obtained earlier[51]. In the oxidation of acetophenone by the aqueous potassium salt of a hydroperoxide in benzene at 70°C, benzoic and formic acids were observed[51]. Not one mole, but about three moles of the peroxide are decomposed per mole ketone oxidised.

Karasch and coworkers[13] found that the decomposition of cumyl hydroperoxide in the presence of 3 mole % of its sodium salt is strongly accelerated by an addition of 3–4% dinitriles, for example, succinonitrile. During this the hydroperoxide decomposes rapidly even at room temperature with the formation of 1-methyl-1-phenylethanol and oxygen. In this system secondary alcohols are oxidised rapidly to ketones. These investigators[13] suggested that nitriles form complexes with the hydroperoxide, which are readily decomposed without the formation of free radicals. A radical-chain mechanism was found later for the reaction[58,85,86]. Berger[86] proposed a scheme for the decomposition of t-alkyl hydroperoxides in the presence of a substituted benzonitrile and a base:



The first stage of the reaction is the addition of a peroxide anion to the nitrile group with the formation of an intermediate peroxide. This peroxide decomposes at the O–O bond with formation of an alkoxy-radical and a stable anion-radical



The radicals react with the hydroperoxide to give a peroxy-radical. The reactions of the latter lead to the formation of oxygen. According to the scheme one molecule of the nitrile decomposes several molecules of the hydroperoxide; the nitrile is gradually converted into an amide.

The peroxide anion, which contains in its composition a nitrile group, is unstable. Thus the hydroperoxide

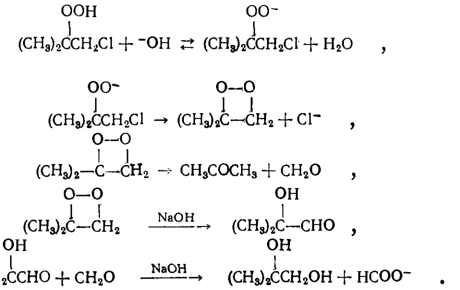
$$\mathrm{(CH_3)_2C(CN)OOH,}$$

unlike other tertiary hydroperoxides, decomposes readily in the presence of alkali. The decomposition products are acetone and cyanate ion[87].

To investigate the factors which determine the size of the α-effect in nucleophiles, the reactivity of the peroxide anions in substitutions at the saturated and aromatic carbon atom and also in reactions with carbonyl and nitrile carbon atoms in aqueous solution was studied[78].

The kinetics of the reactions between organic halogen derivatives (*o*-chlorobenzyl chloride, allyl bromide, propyl bromide) and potassium t-butyl peroxide at 30° and 50°C in methanol have been investigated[88]. The activation energy is 21–23 kcal $mole^{-1}$. The activation energies for the reactions of organic halogeno-derivatives with alkoxides are similar.

The intramolecular reaction of the peroxide anion with the halogen derivatives takes place during decomposition of chloro-t-butyl hydroperoxide with an aqueous methanol solution of NaOH at 16–40°C.[89]



The decomposition of the intermediate 1,2-epidioxyethane is the limiting stage. At initially equimolar concentrations of hydroperoxide and alkali, 1,2-epidioxyethane decomposes with the formation of acetone and formaldehyde. When there is an excess of NaOH the rate of conversion of 1,2-epidioxyethane into the hydroxyaldehyde becomes considerable.

Petukhov and coworkers[90] studied the interaction of lithium t-butyl peroxide with polyhalogenomethanes. As in the reaction of polyhalogenomethanes with lithium alkyls the intermediate product is a halogenomethyl derivative of lithium, which decomposes with the formation of a halogenocarbene:

$$\begin{array}{l}(CH_3)_3COOLi + CHCl_3 \rightleftarrows (CH_3)_3COOH + \underset{\displaystyle LiCl + :CCl_2}{\underset{\downarrow}{LiCCl_3}}\end{array} \quad .$$

The formation of halogenocarbenes is proved by the production of a halogenonorcarane in the presence of cyclohexene.

V. USE

Preparation of Organic and Organometallic Peroxides

The method used most frequently is based on the reaction of nucleophilic replacement of a halogen atom in the corresponding organic or organometallic compound (cf. reviews on peroxides[1-5,91-97]):

$$RX + R'OOM \rightarrow ROOR' + MX \quad ,$$

R and R′ are organic or organoelemental radicals, X = Cl or Br, and M = Li, Na, or K.

In the preparation of peroxides stable against hydrolysis a hydrated salt obtained in the reaction of a hydroperoxide with a hydrated alkali hydroperoxide can be used[7,11,98]. The reaction takes place at 20°C or under gentle heating in an organic solvent in which the alkali halide is insoluble (hydrocarbon, alcohol, mixture of alcohol and ketone).[99] However, it must be taken into account that primary and secondary alcohols, and also ketones, are oxidised comparatively readily by salts of hydroperoxides[51,73].

Esters of peroxo-acids are obtained by the reaction of salts of hydroperoxides with acid chlorides[100-102].

The purest organometallic peroxides are obtained in the best yield from anhydrous salts formed in reaction between hydroperoxides and sodium[20-23] or potassium[25] amide, sodium hydride[18], and lithium t-butoxide[17]. The best solvents for making organometallic peroxides are hydrocarbons, which are the most inert to the initial compounds and to the peroxides obtained. Alcohol[103-105] can be used as the solvent when the initial organometallic compound and the peroxide product do not undergo alcoholysis. However, the salt obtained by the reaction of a hydroperoxide with sodium or potassium methoxide can contain a certain amount of alkoxide owing to the equilibrium[21].

When the organometallic compound is hydrolysed slightly the hydrated salt obtained by the reaction between a hydroperoxide and KOH in hydrocarbon medium is used. However, it was noted recently that the method based on the reaction of a hydroperoxide with a base (KOH, pyridine)[106,107] cannot be employed for obtaining large quantities of dialkyl t-butyl peroxophosphates owing to side-reactions[108]. The method using an anhydrous hydroperoxide salt is better.

Razuvaev and Fedotova[109] were the first to obtain an organomercury peroxide by the reaction:

$$C_6H_5HgCl + NaOOC(CH_3)_2C_6H_5 \rightarrow C_6H_5HgOOC(CH_3)_2C_6H_5 + NaCl \quad .$$

Other organomercury peroxides were obtained similarly[110-112]. When mercury(II) chloride reacts with ROONa in a mixture of benzene and ether, mercury bis(cumyl peroxide) is obtained[113], but with a peroxo-acid and NaOH in water the mercury salt of the peroxo-acid is obtained[114].

Razuvaev, Graevskii, and their coworkers[115-117] were also the first to obtain aluminium OP by the reaction:

$$(C_2H_5O)_2AlCl + NaOOC(CH_3)_2C_6H_5 \rightarrow (C_2H_5O)_2AlOOC(CH_3)_2C_6H_5 + NaCl \quad .$$

Boron OP[118,119] and an organothallium peroxide[120] have also been obtained similarly.

The preparation of the organometallic peroxides of Periodic Group IV elements was also described in detail in a review[121]. Salts of hydroperoxides have been used to obtain organometallic peroxides of silicon[19], germanium[21,122], tin[20,21,103-105,123], and lead[20,21] of the general formula R_3MOOR'. Thus the organosilicon peroxides R_3SiOOR' are obtained in especially good yield in the reaction of trialkyl- and triphenyl-chlorosilanes with an anhydrous salt R′OONa in an aprotic solvent[19]. The sodium salt of trimethylsilicon hydroperoxide, which can be obtained from a symmetrical peroxide undergoes analogous reactions[124,125]:

$$(CH_3)_3SiOOSi(CH_3)_3 + C_2H_5ONa \rightarrow (CH_3)_3SiOC_2H_5 + NaOOSi(CH_3)_3 \quad .$$

When silicon-containing acyl chlorides react with an anhydrous salt ROOLi in ether, esters of organosilicon peroxocarboxylic acids are obtained, in which the peroxide oxygen is separated from the heteroatom by a hydrocarbon moiety[126-131]:

$$R_3Si(CH_2)_nC(O)Cl + LiOOR' \rightarrow R_3Si(CH_2)_nC(O)OOR' + LiCl \quad ,$$
$$R{=}CH_3,\ C_2H_5,\ n{=}1,2,3; \quad R'{=}(CH_3)_3C,\ C_6H_5(CH_3)_2C \quad .$$

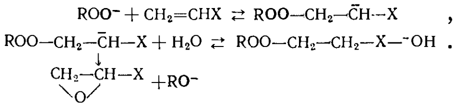
A large number of phosphorus[108,132-140], arsenic[141-143], and antimony[141-144] OP have been made by using alkali salts of hydroperoxides.

The interaction of ROOK with tetra-alkylammonium[145] and quanidinium[146,147] halides in methanol has been used to obtain salts of hydroperoxides and corresponding nitrogenous bases:

$$R_4NCl + KOOR' \rightarrow R_4NOOR' + KCl \quad ,$$
$$R = CH_3,\ C_2H_5,\ n\text{-}C_4H_9,\ R' = (CH_3)_3C,\ C_6H_5C(CH_3)_2 \quad ,$$
$$(RNH)_2C{=}NR \cdot HCl + KOOR' \rightarrow (RNH)_2C{=}NR \cdot HOOR' + KCl \quad .$$

Sym-triazine peroxides have been obtained by the reaction of salts of hydroperoxides with 2,4,6-trichloro-1,3,5-triazine.[148,149] The lithium salt of t-butyl hydroperoxide replaces only two chlorine atoms in the 2,4,6-trichloro-1,3,5-triazine molecule but under the action of the more reactive potassium salt of the hydroperoxide all three chlorine atoms are replaced by peroxide groups[149].

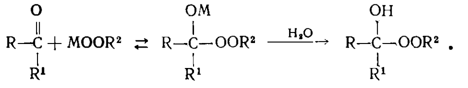
Organic peroxides can also be obtained by the addition of a peroxide anion to alkenes containing an electron-withdrawing substituent X.[150-152] A certain amount of epoxide is also formed:



$$ROO^- + CH_2{=}CHX \rightleftarrows ROO{-}CH_2{-}\bar{C}H{-}X \quad ,$$
$$ROO{-}CH_2{-}\bar{C}H{-}X + H_2O \rightleftarrows ROO{-}CH_2{-}CH_2{-}X{-}{}^-OH \quad .$$

Peroxoalkyl phosphonates are obtained by the reaction of salts of hydroperoxides with alkenyl phosphonates[153].

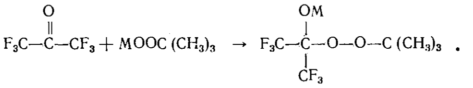
The reaction of salts of hydroperoxides with carbonyl compounds leads to α-hydroxyperoxides[51,76,154]:



$$R{-}C({=}O){-}R^1 + MOOR^2 \rightleftarrows R{-}C(OM)(R^1){-}OOR^2 \xrightarrow{H_2O} R{-}C(OH)(R^1){-}OOR^2 \quad .$$

$R = H$, alkyl; $M = Li, Na, K$

Fluorinated peroxides containing an alkali metal, which serve as initiators of the polymerisation of alkenes (especially fluoroalkenes), have been obtained in this way[155]:



$$F_3C{-}C({=}O){-}CF_3 + MOOC(CH_3)_3 \rightarrow F_3C{-}C(OM)(CF_3){-}O{-}O{-}C(CH_3)_3 \quad .$$

$M = Li, Na, K$

As already stated, when anhydrous alkali salts of hydroperoxides react with carbon dioxide percarbonates are obtained $R{-}O{-}O{-}C(O){-}OM$ where M = Li, Na, or K and R = cumyl[74,75].

Preparation of Hydroperoxides, Alcohols, and Other Oxygen-Containing Compounds

Salts of hydroperoxides are obtained when organolithium and organomagnesium compounds are oxidised by oxygen at −75°C,[15,16], when the salts are acidified the hydroperoxide is released. The yield can reach 75 to 85%.[16]

Decomposition of salts of hydroperoxides with the formation of free radicals is used for initiating the oxidation of hydrocarbons, for example, cumene to a hydroperoxide[156-159]. Phenol and acetone are obtained in the acid decomposition of cumyl hydroperoxide but the product from alkali splitting is 1-methyl-1-phenylethanol, which is dehydrated to α-methylstyrene[160].

The preparation of hydroperoxide salts is widely used in the separation of hydroperoxides from the reaction mixtures obtained by the oxidation of hydrocarbons and also for purifying hydroperoxides[160,161].

Alkali Organic Peroxides—Intermediate Products in the Production of Inorganic Peroxide Compounds of Alkali Metals

Alkali alkoxides of secondary alcohols are oxidised readily at 0–20°C with the formation of alkali metal inorganic peroxide compounds[37-39,162]. Depending upon the conditions (nature of the alkali metal, solvent, additive) an alkali metal hydroperoxide, peroxide, or superoxide is formed. The intermediate oxidation products are the unstable alkali salts of hydroperoxides of secondary alcohols $R_2C(OH)OONa$ and $R_2C(ONa)OONa$, which decompose into the ketone and inorganic peroxide compound. The greatest interest is in the production of sodium superoxide NaO_2 in the catalytic oxidation of sodium under mild condition in aprotic polar organic solvents[163,164]. The catalysts are aromatic ketones, hydrocarbons, or nitrogen-containing compounds, which easily form organic (ketyl or complex) compounds with an alkali metal. During its oxidation the superoxide is formed and the catalyst is regenerated. This preparation of NaO_2 can be carried out at 0–20°C and atmospheric pressure. In industry NaO_2 is obtained by the oxidation of Na_2O_2 at high pressures and temperature,[162].

Other Regions of Use

Salts of hydroperoxides are used as initiators of the polymerisation of alkenes[165]. The polymerisation of ethylene is carried out at 145–175°C and a pressure of 200–1000 at. in a medium of alcohol, hydrocarbon, or water. Copolymers of ethylene with styrene, α-methylstyrene, methyl vinyl ketone, vinylpyridine, acrylic and methacrylic acids, methyl and ethyl acrylate, or methacrylate can be obtained and also these individual vinyl compounds can be polymerised[165]. Salts of hydroperoxides were recently proposed for use as components of detergents[166].

Unlike the lithium, sodium, and potassium OP, there have been very few studies of the corresponding magnesium and alkaline earth compounds. This seems to be due to their insolubility in organic solvents. We know of only a few papers which describe the preparation of the OP of these metals by the reaction of hydroperoxides (or peroxo-acids) with the corresponding bases (oxide[10], hydride[18], organomagnesium compound[167]). Thus when hydroperoxides react with strontium or barium oxides the salts $M[OOC(CH_3)_3]_2$ are obtained[10], where M = Sr or Ba. Peracetates have been obtained in the reaction between calcium and barium hydrides with the peroxoacid in tetrahydrofuran[18].

The reaction of the organomagnesium compounds $ROMgC_5H_{11}$, $ROMgR^1$ and R^1_2Mg with cumyl hydroperoxide or with hydrogen peroxide in ether at 0°C the magnesium OP $ROMgOOR^2$, $ROMgOOMgOR$, and $R^1MgOOMgR^1$, where $R = (CH_3)_3C$, $R^1 = C_6H_5$, and $R^2 = C_6H_5C(CH_3)_2$, are obtained[167].

State of the Theory of Iso-free Volume and Glass Formation in Amorphous Polymers

Yu.S.Lipatov

Methods of determining the free volume fraction of polymers at the glass formation temperature and the concept according to which all polymers have a universal free volume fraction at the glass point are considered critically. The concept of iso-free volume in glass formation can be regarded only as a rough approximation and the free volume fraction is a function of several variables including the flexibility of the polymeric chain and the nature of the molecular packing. The development of the theory of glass formation by amorphous polymers on the basis of the free volume concept is considered and it is shown that a free volume distribution function has to be introduced for the correct description of the process. Conclusions are drawn concerning the inapplicability of the iso-free volume concept for describing glass formation processes in amorphous polymers. The possibilities of a more adequate description of glass formation are discussed. 69 references.

I. THE FREE VOLUME CONCEPT AND ITS CONNECTION WITH GLASS FORMATION BY AMORPHOUS POLYMERS

Many of the properties of high- and low-molecular-weight substances (viscosity, thermal, mechanical, relaxation, etc.) and processes in them (diffusion, permeability, sorbtion) are connected with the molecular mobility and structure of these compounds, determined by the degree of ordering of the molecules. The structure and properties of such substances can be described from the thermodynamic viewpoint through configuration free energy[1] and enthalpy[2]. However, phenomenologically one of the most convenient ideas is excess or free volume. According to Covacs[3], free volume is a characteristic of the disorder of the structure and determines the rate of molecular rearrangements. This characteristic is closely connected with the configuration mobility of a liquid and its thermodynamic parameters and could be classified among the fundamental characteristics of the liquid state if the existing theory could give a precise definition of the concept of free volume and methods for its determination.

Actually, the most important properties of liquids, and above all viscosity and capability of glass formation, show they contain a free volume, which can be represented as holes or vacancies of approximately molecular dimensions, rated to the irregular packing of the molecules. Although, according to Ferry[4], the free volume per 1 g substance, v_f, is very difficult to determine, it is a useful semiquantitative concept. In particular, the greater part of the thermal expansion coefficient of liquids is due to an increase in the free volume, whereas its lesser part is linked with the anharmonicity of the relation between potential energy and the interatomic or molecular distances.

The concept of free volume is based on the Doolittle empirical equation[5], which connects viscosity with specific free volume:

$$\ln \eta = a + b/f, \tag{1}$$

where a and b are constants,

$$f = (v - v_0)/v, \tag{2}$$

v and v_0 are the actual and occupied volumes of the liquid at temperature T:

$$v - v_0 = v_f.$$

By occupied volume is meant the proper total volume of the molecules.

The concept of free volume proved very useful and was employed for the theoretical description of many processes in liquids, including processes in polymers. A theory of the diffusion of low-molecular substances in polymers[6,7], a theory of thermal conductivity[8], a theory of solutions and solubility of polymers[9], etc. were developed on the basis of the free volume concept. However, the free volume concept was used most extensively in the theory of viscoelastic properties of polymers, developed by Williams, Landell, and Ferry, and stated in detail in Ferry's monograph[4]. According to this theory, the change in the viscosity of a liquid with temperature in the range from T_g to T can be described with the aid of a normalisation coefficient

$$a_T = \eta_T/\eta_{T_g}.$$

By using Doolittle's equation (1) connecting the viscosity and the free volume, we can obtain:

$$\lg a_T = \frac{-(B/2{,}303 f_g)(T - T_g)}{f_g/\alpha_f + T - T_g}, \tag{3}$$

where f_g is the free volume fraction at T_g, B a constant, and α_f is regarded as a coefficient for the increase in free volume (see below). The values of f_g found experimentally according to this equation are the same (0.025 ± 0.003) for most polymers.

Bueche[10] further developed the theory of viscoelastic properties based on the free volume concept, by starting from the assumption that some element of the structure can be displaced when the fraction of local relative free volume f exceeds some critical value f_c. The frequency ν of the corresponding molecular process can be expressed by the equation

$$\nu = \nu_g \exp[-Nf_c(1/f - 1/f_g)],$$

where ν_g is the frequency at T_g. When (as will be considered below)

$$f = f_g + \alpha_f(T - T_g), \tag{4}$$

then

$$\ln(\nu/\nu_g) = \frac{Nf_c/f_g\,(T - T_g)}{T - T_g + f_g/f}\,.$$

This equation is identical in form with Eqn. (3).

Simha and Boyer[11] were the first to use the free volume concept in considering processes of glass formation in amorphous polymers. By analogy with Eqn. (2) they assumed that the free volume fraction at the glass formation temperature is

$$f_g = (v_g - v_{0g})/v_g = 1 - v_{0g}/v_g, \tag{5}$$

where v_g and v_{0g} are the actual volume and the volume occupied by the molecules, at T_g. On assuming that the specific free volume is a linear function of temperature then clearly condition (4) will be observed, at which

$$\alpha_f = (\partial f/\partial T)_p \simeq 1/v\,[(\partial v/\partial T) - (\partial v_0/\partial T)]_p. \tag{6}$$

Eqn. (5) can also be written in the form

$$f_g = [v_g - v_{0l}(1 + \alpha_g T_g)]/v_g \simeq [v_g - v_{0l}(1 + \alpha_g T_g)]/v_{0l},$$

where v_{0l} is the occupied volume in the initial state, $T = 0$, α_g the coefficient of expansion of the vitrified liquid below T_g. In this definition, f_g is found from the difference between the actual volume and the volume which the liquid would have at the glass formation temperature were the volume of the liquid v_{0l} to increase with the expansion coefficient α_g characteristic of the vitreous state. Then the actual volume at the glass point is

$$v_g = v_{0l}(1 + \alpha_g T_g),$$

and the free volume fraction equals

$$f_g = [v_{0l}(1 + \alpha_l T_g) - v_{0l}(1 + \alpha_g T_g)]/v_{0l}.$$

From this relation we have[11]

$$(\alpha_l - \alpha_g)T_g = f_g = K_1. \tag{7}$$

In 1950 Fox and Flory[12] introduced the concept according to which the glass formation temperature corresponds to the state of iso-free volume. This concept has been developed[13,14], is used widely, and with slight modification provides a basis for various theories of glass formation[11,15,16]. The constant value found by Simha and Boyer[11] for K_1 for various polymers served as confirmation of the definition of iso-free volume as the volume corresponding to the glass formation temperature.

If it is also assumed that at T_g the partial free volume is constant for all polymers, then having determined this volume as

$$K_2 = (v - v_{0l})/v,$$

it can be shown that

$$K_2 = \alpha_l T_g.$$

Actually, K_2 can be written as:

$$K_2 = \frac{v_{0l}(1 + \alpha_l T) - v_{0l}}{v_{0l}(1 + \alpha_l T)} = \frac{\alpha_l T}{1 + \alpha_l T} \simeq \alpha_l T.$$

Eqn. (6) also suggests that the ratio of the linearly extrapolated volumes v_{0g} and v_{0l} at $T = 0$, K is almost independent of the nature of the polymer. Then

$$v_{0g}/v_g = (1 + \alpha_l T_g)/(1 + \alpha_g T_g) = 1 + (\alpha_l - \alpha_g)T_g - \alpha_g(\alpha_l - \alpha_g)T^2 \simeq 1 + K_1.$$

It was found that $K_1 = 0.113$ and $K_2 = 0.164$ for most of the polymers. Hence the expressions for K_1 and K_2 characterise corresponding states in the free volume terms.

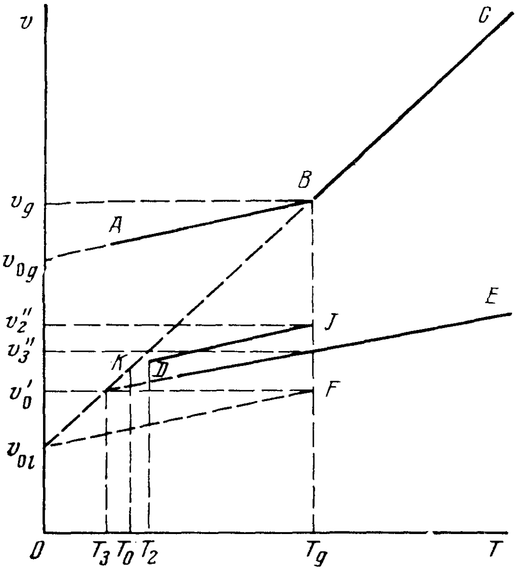

Figure 1. Scheme for the calculation of free volume characteristics in various theories.

II. METHODS OF CALCULATING THE FREE VOLUME FRACTION AT THE GLASS FORMATION TEMPERATURE

In the definitions considered above the free volume fraction depends on which volume was taken as the initial value for the state, that is, on the method of calculation. Even in this very fact some vagueness is introduced into the physical significance of free volume. In this connection, we will consider various computational methods of determining the initial volume, since on this depends the calculated fraction of the free volume at T_g.

Fig. 1 shows schematically the variation of specific volume with temperature. Here the line *ABC* represents the curve of the change in actual volume of an amorphous polymer during passage through T_g. The segment *AB* (with slope α_g) corresponds to the vitreous stage, segment *BC* (with slope α_l) to the highly elastic state. The straight line *DE* parallel to *AB* corresponds to a change in volume in the crystalline state if it is assumed (as is usual[11,17]) that the coefficients of thermal expansion in the vitreous (α_g) and crystalline (α_c) states are equal. On extrapolating the segment *BC* to 0 K, the value of v_{0l} is obtained, and extrapolating *AB* gives the value of v_{0g}. Hence the free volume fraction according to Simha and Boyer is determined (the segment $BF = \Delta\alpha \cdot T_g$, is the occupied volume v_0').

According to Williams–Landell–Ferry, the occupied volume is taken to be the quantity v_2'' obtainable by extrapolation of the volume of the liquid corresponding to some temperature T_2, determinable from the viscometric results[15,18] parallel to AB up to T_g (the segment BJ). According to Tobolsky's determination[19], the occupied volume v_3'', corresponds to the volume of the specimen in the crystalline state at T_g. According to Miller[20], the free volume is determined from the relation to the temperature T_0 entering into the Fogel equation for the temperature dependence of viscosity. Point K represents a hypothetical volume larger than for the crystalline state, but less than for the glass at the same temperature. Consequently, the free volume here is somewhat greater than that determined according to Williams–Landell–Ferry.

According to Miller,

$$v_f = v - v_0 = 0 \quad \text{at} \quad T = T_0.$$

Then at any other temperature

$$v_f = \Delta\alpha\,(T - T_0), \tag{8}$$

where

$$\Delta\alpha = \alpha_l - \alpha_g.$$

Correspondingly at T_g

$$v_f = \Delta\alpha\,(T_g - T_0). \tag{9}$$

According to the Simha–Boyer theory,

$$\Delta\alpha \cdot T_g = K_1$$

By equating the $\Delta\alpha$ in expressions (8) and (9) we can obtain the following relation:

$$K_1/(v_f)_{T_g} = T_g/(T_g - T_0).$$

Covacs[3] gives yet another definition of the free volume fraction. Since the extrapolatable volume of the supercooled liquid reaches the volume of the crystalline state v_c at some temperature $T_c > 0$ K this critical temperature can be compared with $T_{g,\infty}$ the limiting temperature of glass formation at infinitely slow cooling, assuming that in the crystalline state the free volume is zero. Then the quantity f_g defined according to Doolittle can be compared with the $f_{g,c}$ characterising the excess free volume of a glass compared with the crystal:

$$f_{g,c} = (v_g - v_c)/v_g.$$

The comparison of f_g and f_c for amorphous polymers is naturally difficult since the volume v_c can be found experimentally only when the polymer is capable of crystallising. In this approach it is assumed that $\alpha_c \simeq \alpha_g$; thus for polystyrene usually $f_{g,c} = 2f_g$. It is usually assumed that the free volume fraction varies with the temperature in accordance with relation (4), where the coefficient of expansion is determined by Eqn. (6). According to Ferry[4], when the macroscopic coefficient of expansion α_l at temperatures higher than T_g reflects the appearance of free volume, then $\alpha_f = \alpha_l - \alpha_g = \Delta\alpha$ should apply. Actually, the $\Delta\alpha$ found experimentally correspond well with the values of α_j calculated from the Williams–Landell–Ferry theory. In addition, we wish to emphasise that the actual value of $\Delta\alpha = \alpha_f = \alpha_l - \alpha_g$ is not the coefficient of expansion of the free volume as such, but the temperature coefficient of the free volume fraction. Elementary calculation shows that the actual increase in volume above T_g cannot be equal to $v_g\alpha_f(T - T_g)$, if v_g is determined by starting from the actual specific volume at T_c and the known f_g.

As is evident from what has been stated, irrespective of the method of estimating the occupied volume adopted in the various theories the free volume fraction is always determined by Eqn. (5) and consequently the values of f_g calculated by the various methods do not agree with one another. This emphasises that this is not an absolute quantity and shows the need to regard it only as a convenient parameter for describing the properties of a liquid. Even in 1963, Boyer[17] noted that the free volume at T_g is constant only under certain conditions and varies with the molecular mass, the degree of cross-linking, and other characteristics of the polymer.

III. THERMODYNAMIC AND MOLECULAR EXAMINATION OF THE FREE VOLUME CONCEPT

Hirai and Eyring[21] found that the quantity $\Delta\alpha . T_g$ depends on ϵ_h, the energy of hole formation:

$$\Delta\alpha \cdot T_g = (\varepsilon_h/RT_g)\exp[-(\varepsilon_h/RT)].$$

By taking $f_g = 0.02$, they theoretically calculated the value $\Delta\alpha . T_g = 0.08$. According to their views:

$$\varepsilon_h/RT_g \simeq -\ln f_g.$$

Since ϵ_h is proportional to the cohesion energy density E, it can be shown that

$$T_g = [\Delta H' + ME]/(-R\ln f_g),$$

where

$$\Delta H' = \Delta H_f - \Delta H_h,$$

ΔH_f is the heat of fusion, ΔH_h is that part of the heat of fusion associated with the "fusion" of the holes, and M is a constant.

The free volume concept as applied to processes of glass formation was developed further in Miller's work[20,22]. The basis of Miller's ideas was that if any excess function

$$\Delta X\,(\text{liquid}) - X\,(\text{crystal})$$

is extrapolated to zero at some temperature exceeding 0 K;[22] these temperatures correspond to the excess volume equalling zero. Miller showed that the excess entropy and excess volume are reduced to zero at the same temperature, corresponding to the temperature T_0 in the Fogel equation. According to Miller, the coefficient A in the Fogel equation:

$$\lg\eta = \lg A + B(T - T_0)$$

is connected with the weighed mean number of the bonds in the macromolecule z_w by the ratio:

$$\lg A = \lg K + 3.4\lg z_w.$$

From these two equations, at T_g:

$$\lg\eta_g = \lg K + 3.4\lg z_w + B(T_g - T_0).$$

The parameters for the vinyl polymers give the relation $B/(T_g - T_0) \simeq 15$. From the standpoint of ideas about free volume:

$$\lg\eta \propto b/(v_f)_{T_g}.$$

From this it can be shown that:

$$(v_f)_{T_g}/b = (T_g - T_0)/2, \quad 3b \simeq 0.029.$$

This corresponds to the value given by the Williams–Landell–Ferry theory. Hence in principle the idea of iso-free volume follows directly from the viscosimetric measurements. The difference in the definition of the free volume according to Miller from the Simha–Boyer definition is that

$$(v_f)_{T_g} = \Delta\alpha\,(T_g - T_0) \approx 0.11 - \Delta\alpha T_0,$$

and the last term is not constant for different vinyl monomers. Hence

$$0.11/(v_f)_{T_g} = T_g/(T_g - T_0).$$

Miller[23] suggested that the right-hand side of this equation equals the number of monomeric units at T_g in the "cooperative unit", z_g^*. Then

$$z_g^*(v_f)_{T_g} = 0.11.$$

This condition is another criterion of the glass–liquid change. According to this determination the greater the free volume fraction left for segmental motion movement, the less the "cooperative unit" which is required for this movement to maintain the state of isomobility at T_g. An analogous concept was proposed by Bueche[24], who considered the variation in the free volume and greatest free volume f_c, necessary for the movement of a group of n units.

From what has been stated above, Miller assumes[25] that there is a relation

$$z_g^* S_c = A,$$

where S_c is the configuration entropy. Miller was the first to present the problem of whether the concept of free volume reflects the configuration entropy changes which are taken into account by the parameter z_g^*, the cooperative unit for segmental motion.

It is generally accepted that the viscous flow of polymeric liquids is connected with the rotation of the segments of chains, that is, with conformation entropy. From this point of view Miller assumes that the Simha–Boyer equation is incorrect, since according to it the relative free volume is zero at 0 K, and not at $T = T_0$; under this condition K_1 should be constant. Hence we here again encounter the fact that the constancy or non-constancy of the free volume fraction at T_g depends on how this fraction is expressed. Subsequently, from a consideration of the viscosity of melts at various temperatures and pressures Miller[26] concluded that the mobility of polymeric liquids depends to a much greater extent on the thermal factor than on the volume and that any versions of the free volume theory connecting the viscosity with the relative free volume fraction are inapplicable in real examples.

In all the examples considered above the concept of free volume is based on the position that free volume plays the main part in the properties of a liquid. Meanwhile Miller[27] notes correctly that the whole theory of liquids presumes that the intermolecular potential energy $U(r)$ is an important factor, which determines molecular friction. At the same time the free volume fraction f is connected solely with the intermolecular distance; all the equations which include f are incomplete owing to the absence of an energy term from them. According to Miller[27], for a hypothetical liquid at 0 K the kinetic energy is zero and the volume v_0 is determined exclusively by the potential energy of interaction U_0. The value of U_0 should be closely connected with the vaporisation energy ϵ_0 at 0 K. Hence the parameters ϵ_0, v_0, and the "zero" cohesion energy density, $(\epsilon_0/v_0)_0$, provide a basis for determining the free volume, $v_f = v - v_0$.

There has been shown to be an empirical relation connecting the compressibility coefficient of the liquid β with the free volume fraction:

$$-\beta \simeq kf^2(1-f).$$

Here $\beta = 1/v(\mathrm{d}v/\mathrm{d}p)_\mathrm{T}$ at $p = 1$ atm. It was suggested that

$$-f^2(1-f) \approx 5\beta\,(\varepsilon/v)_0,$$

or

$$-f^2 \approx 5\beta\varepsilon_0/v.$$

In this consideration, energetic and volume factors are introduced into the equations which describe the compressibility of the liquid, and from the standpoint of molecular theory these factors essentially determine the properties of liquids.

On the other hand, in a series of papers after that of Hirai and Eyring[21] ideas have been developed concerning the energies of formation of unit free volume or of 1 mole of holes. The latest of these views was developed by Kanig[28], who simultaneously introduced a refinement into the concept and definition of the free volume. By starting from the position of Frenkel', [29] Kanig divides the free volume into two parts, one of which is determined solely by the thermal vibrations of the atoms in the lattice of a real crystal or liquid, and the other consists of the vacancies or holes proper in the liquid, which make possible an exchange of particles with the sites, that is, ensure the very existence of the liquid state. For this example, new definitions of the free volume fractions are introduced:

$$\varphi_{f_1} = \frac{N_1 v_{f_1}}{N_1 v_{f_1} + N_2 v_{f_2}},$$

$$\varphi_{f_2} = \frac{N_2 v_{f_2}}{N_1 v_{f_1} + N_2 v_{f_2}},$$

where N_1 and N_2 are the numbers of holes and molecules in the system, v_{f_2} is the volume determined by the thermal vibrations, and v_{f_1} the volume determined by the holes. These expressions involve the ratio of the proper volume of the vacancies and the "volume of the vibrations" to the total free volume, as distinct from the usual definition, which includes the ratio of the free volume to the total volume:

$$f_g = \varphi_1^* = \frac{v_1^*}{v_1^* + v_2^*},$$

where v_1^* is the partial volume of the holes, and v_2^* the partial volume of the molecules at T_g, including the volume due to the thermal vibrations. In the first instance, by starting from the total dilatometric curve it can be shown that (Fig. 2) the segment BE represents the quantity

$$N_2 v_{f_2} = T_g \mathrm{d}v_g/\mathrm{d}T,$$

and the segment EL the volume of the vacancies

$$N_1 v_{f_1} = T_g \mathrm{d}v_l/\mathrm{d}T - T_g \mathrm{d}v_g/dT.$$

Hence the free volume is defined as the segment BL:

$$N_1 v_{f_1} + N_2 v_{f_2} = T_g\,\mathrm{d}\,v_l/\mathrm{d}\,T.$$

From many experimental results Kanig deduced that the free volume fraction at T_g usually determined is not constant and that for characteristics of the state of iso-free volume it is more desirable to use the quantities φ_{f_1} and φ_{f_2}, referred to the glass formation temperature, $\varphi_{f_1}^*$ and $\varphi_{f_2}^*$. Then from Fig. 2,

$$\varphi_{f_1}^* = \frac{v_{0g} - v_{0l}}{v_g - v_l},$$

$$\varphi_{f_2}^* = \frac{v_g - v_{0g}}{v_g - v_{0l}}.$$

Actually, it appeared that the quantities $\varphi_{f_1}^* \simeq 0.64$ and $\varphi_{f_2}^* \simeq 0.36$ are less different for different polymers than is the quantity usually determined. The fractions $\varphi_{f_1}^*$ and $\varphi_{f_2}^*$ are, according to Kanig, constants independent of the nature of the substance and which characterise the corresponding states at the glass formation temperature. The relations given show that at the glass formation temperature there should be a constant ratio between the volume of the vacancies and the volume determined by the thermal vibrations, at which translational motion of the molecules becomes possible. In particular, these quantities enter into the equation describing T_g as a function of the degree of polymerisation.

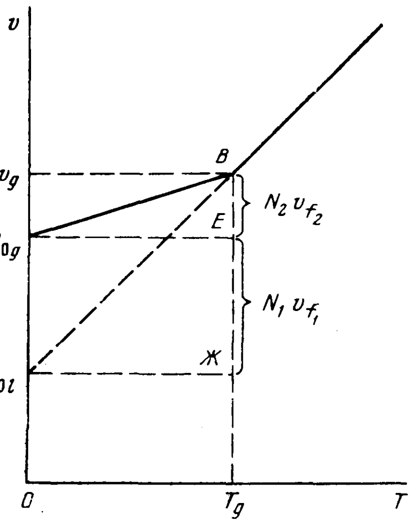

Figure 2. Scheme for the calculation of free volume characteristics after Kanig.

Kanig[30] has introduced allowance for the temperature dependence of the quantity $\varphi_{f_1}^*$, determined from the results for the free volume fraction defined by him above, Below T_g, as the temperature is reduced $\varphi_{f_1}^*$ increases owing to the decrease in the volume due to the vibrations when there is "freezing" of the volume of the vacancies. Above T_g, there is an increase in $\varphi_{f_1}^*$, due to the increase in the volume of the vacancies being faster than the increase in the volume due to the vibrations. At $T = T_g$ the quantity $\varphi_{f_1}^*$ is a minimum. From the condition for an extremum $d\varphi/dT = 0$ it can be found that $\varphi_{f_1}^* = (\alpha_l - \alpha_g)/\alpha_l$. This actually gives the same value for $\varphi_{f_1}^*$, also without allowance for the temperature coefficient. However, Kanig introduces a refinement, according to which for the corresponding states at T_g there are extremal values $\varphi_{f_1}^*$ and $\varphi_{f_2}^*$, which are constants irrespective of the nature of the substance.

Experimental verification of the relations obtained by Kanig and given by him[31] showed that the traditional definition of the free volume fraction according to Fox and Flory or according to Williams, Landell, and Ferry can lead to the best agreement with experiment when allowance is made for the geometric parameter α. Kanig[31] began from the fact that the partial free volume $\varphi_1^* = f_g$ at the temperature of glass formation, as stated above, can be regarded only to a rough approximation as a constant, the mean value of which corresponds to the universal value obtained by the Williams-Lindell-Ferry theory. The real picture is that polymers with more flexible chains exhibit lower values of φ_1^* than polymers with rigid chains. Consequently, Kanig considers it necessary to introduce a parameter a for a characteristic of the corresponding states. The basis for such introduction is the thermodynamic consideration of a polymer melt as a mixture of chain molecules *2* with holes *1* assuming that the melt is saturated with holes at any temperature. By the introduction into the consideration of the energies of interaction in pairs W_{11} (hole–hole), W_{21} (polymer–hole), and W_{22} (polymer–polymer) the partial thermodynamic characteristics of the dilution of the melt with holes can be calculated. The following parameters enter into these expressions: O_1 the contact surfaces of a mole of holes, and O_2 the contact surfaces of a mole of repeating units of the polymer. For the displacement of n_2 moles (links) of the polymeric chains and n_1 moles of holes it can be shown that

$$1/\varphi_{f_1} \simeq \frac{n_2 O_2}{n_1 O_2} \simeq \frac{O_2/v_2}{O_2/v_1} \frac{n_2 v_2}{n_1 v_1} \simeq \frac{1}{a} \cdot \frac{1}{\varphi_1},$$

if it is assumed that

$$n_1 v_1 \ll n_2 v_2$$

and

$$\varphi_1 = \frac{n_1 v_1}{n_1 v_1 + n_2 v_2}, \quad \varphi_2 = 1 - \varphi_1,$$

where v_1 and v_2 are the molar volumes of the holes and links, and $a = (O_1/v_1)/(O_2/v_2)$. Here a has the physical significance of a parameter determining the size and form of the macromolecules. Kanig assumes that this parameter is more real for the description of the molecule than the coordination number usually employed. From this he deduces an expression for the glass formation temperature:

$$T_g = -\frac{(1 - a\varphi_1^*) H_{0i}^*}{R(\ln \varphi_1^* + \varphi_2^*)} = -\frac{\Delta H_1^*}{R(\ln \varphi_1^* + \varphi_2^*)},$$

or

$$T_g = K(\varphi_1^*) \Delta H_1^*,$$

where

$$H_{0i} = O_1 \cdot \Delta W_{12}, \quad \Delta W_{12} = -{}^1/_2 (W_{22} + W_{11});$$

the asterisk shows that all the values relate to T_g. Hence the glass formation temperature is related to the free volume and the energy of formation of the holes, and consequently depends on the intermolecular energy ΔW_{12} and the geometric factor a. Starting from the method of consideration used, Kanig found[31], that

$$T_g \Delta\alpha^* = K(\varphi_1^*, a) = \frac{\varphi_1^*}{2a_1\varphi_1^* + (\varphi_2^*)^2/(\ln \varphi_1^* + \varphi_2^*)},$$

where $\Delta\alpha^*$ is the difference between the expansion coefficients above and below T_g. Clearly, this equation would correspond to the Simha–Boyer empirical equation were the quantity K to be constant, that is, in accordance with the iso-free volume theory, were constant and the value of the parameter a would be the same for all polymers.

Kanig's approach has the advantage in comparison with the others that there is a relation between φ_1^* and a with those parameters determined experimentally, such as $\Delta\alpha$ and ΔC_p (change in heat capacity on going from glass to liquid) and also with ϵ_g the molar energy of cohesion at T_g. This allows φ_1^* and a to be calculated from the experimental results. The mean values thus determined with allowance for the concept of iso-free volume are:

$$\bar{\varphi}_1^* = 0.0235 \pm 0.0050$$

(mean error ± 21%) and

$$\bar{a} = 3.15 \pm 0.35$$

(mean error ±11%). On the one hand, the correspondence found for the universal value in the Williams–Landell–Ferry theory indicates that the free volume is that volume determined by the holes; on the other hand, from what has been stated it seems that the Simha–Boyer constant is a complex function of φ_1^* and a. The obtaining of an experimental relation between

$$\frac{\varphi_1^*}{2a\varphi_1^* + \varphi_2^{*2}/(\ln \varphi_1^* + \varphi_2^*)} \cdot \frac{1}{T_g}$$

shows a significant departure from linearity. φ_1^* not being constant shows that the iso-free volume concept is not strictly true.

IV. STATE OF THE ISO-FREE VOLUME DURING GLASS FORMATION

The idea that the free volume fraction, determined experimentally using various equations, at the glass formation temperature depends on the type of molecular movements was first expressed in 1967 [32,33] in connection with results on the relaxation of volume for various polymeric systems. Calculations made on the basis of curves for finding equilibrium volume[32,33] allowed the relaxation time to be determined for different temperatures and then the free volume fraction at T_g was determined by the equation of the Williams–Landell–Ferry theory from the calculated quantities a_T and the $\Delta\alpha$ found.

On accepting the validity of the main position of the theory concerning the universal dependence of the coefficient of reduction a_T on the difference $T - T_g$, f_g can be determined from the results for $\Delta\alpha$ and the theoretical values of a_T calculated from the universal values of the coefficients C_1^g and C_2^g of the Williams–Landell–Ferry theory. The value found in this calculation corresponds to the universal one. However, when experimental values of a_T, and not theoretical ones, are used, the calculated free volume fraction, by remaining constant, will be significantly higher than the universal value and be $f_g = 0.08$–0.09. In considering this fact it is necessary to take into account that the value of f_g in the Williams–Landell–Ferry theory comes from results on dynamic mechanical properties, when relaxation processes are connected with the appearance of segmental mobility. In this instance the value of f_g for many polymers is close to universal, since it corresponds to the size of the holes necessary for the migrations of small structural units which determine the relaxation properties under these experimental conditions. However, it was found[33,34] that in polymers there are isophase transformations connected with the mobility of the structural units larger than statistical segments up to the processes which determine the mobility of the supermolecular formations. It is quite evident that the motion of the large structural elements requires a large hole dimension or a large free volume. It must therefore be assumed that in investigating various relaxation mechanisms the free volume fraction needed for the migrations of structural units of various dimensions can be determined. This also follows from other results[32,33] corresponding to the relaxation process with long periods, that is, with kinetic units of large dimensions. It is also quite evident that at the same density of molecular packing (volume of intermolecular vacancies) the actual free volume necessary for effecting one motion or another will be determined by the nature of these movements.

Actually, depending upon the type of molecular motion and the size of the corresponding movement of the kinetic unit the mobility can appear only at a definite value of the free volume, which therefore will depend on the type of the molecular motions. When the free volume is sufficient for the motion of relatively small structural units, for example, of segments, but insufficient for the motion of larger segments of the chains or of the chains as independent kinetic units, then the well-known non-correspondence between the values of T_g determined by different methods occurs. The same conclusion was reached by Sanchez[35], who found theoretically that the mean size of the holes increases with T_g. He assumes that this is connected with the higher T_g for polymers having more rigid chains. The packing of the rigid chains cannot be so compact as that of flexible chains, as a result of which the mean size of the holes increases. For example, for low-molecular-weight compounds the free volume fraction at T_g is less than for polymers, which is regarded as the result of the greater mobility of small molecules, for the realisation of which a smaller free volume is required. According to Mandelkern and coworkers[36], the Simha–Boyer rule should not be observed at all, since the $\Delta\alpha$ for various systems in which T_g can differ significantly lie within narrow limits, $(2.5$–$4.0) \times 10^{-1}$ K^{-1}. However, Simha and Boyer[37] consider such a conclusion erroneous owing to the incorrect treatment of the experimental results.

The limitations of the picture predicted within the framework of the Simha–Boyer theory lead to a search for new ways of improving it. It was carried out by Simha and Weil[38] who allowed for the temperature dependence of the coefficients α_l and α_g, which led to the need for extrapolating the volumes for the liquids to temperature below T_g with the aid of non-linear functions connecting volume and temperature. Such a consideration is based mainly on the fact that in a series of polymers with increasing side-chain length there is a systematic decrease in $\Delta\alpha \cdot T_g$, which suggests that there should be a considerable decrease in f_g in such systems.

According to Simha and Weil[38] there is a need to reconsider the postulate of free volume at T_g. On taking into account the temperature dependence of α_l and α_g, Simha and Weil[38] gave the following alternative expression for the free volume fraction:

$$(v_f)_{T_g} = 1 - \exp\left[-\int_0^{T_g} (\alpha_l - \alpha_g)\,\mathrm{d}T\right] \equiv (v_{0g} - v_{0l})/v_{0g}, \tag{10}$$

where v_{0l} and v_{0g} are the experimental and absolute zero volumes of the liquid and glass corresponding to the non-linear functions of the temperature dependence of both the expansion coefficients. Hence v_f is independent of temperature in the range $0 \leqslant T \leqslant T_g$, since the second identity is observed in this range of temperatures. Hence v_f can be regarded as a characteristic of the packing density of the glass at absolute zero. The first equality can be formally extended to the range $T > T_g$ by extending the upper limit of integration, which requires extrapolation of the vitreous state into the liquid region.

On the other hand, the occupied volume is simply v_{0l}, and hence

$$(v_f)_{T_g} = 1 - \exp\left[-\int_0^{T_g} \alpha_l \mathrm{d}T\right] \equiv (v - v_{0l})/v. \qquad (11)$$

Eqns. (10) and (11) give the most general expression for the Simha–Boyer rule. Simha and Weil[38] showed that since $\alpha \leqslant 8 \times 10^{-4}$ K^{-1} and $T_g < 5 \times 10^2$ K, for most of the polymers the exponents can be replaced by a series yielding

$$(v_f)_{T_g} \approx \int_0^{T_g} (\alpha_l - \alpha_g)\,\mathrm{d}T\left[1 - {}^1/_2\int_0^{T_g} (\alpha_l - \alpha_g)\,\mathrm{d}T\right]$$

and

$$(v_f)_{T_g} \approx \int_0^{T_g} \alpha_l \mathrm{d}T\left[1 - {}^1/_2\int_0^{T_g} \alpha_l \mathrm{d}T\right].$$

From the first equation, by neglecting the quadratic terms, we find that

$$(\alpha_l - \alpha_g)\,T_g \approx (v_f)_{T_g} + [\alpha_l n/(n+1) - \alpha_g m/(m+1)]\,T_g,$$

where α_l and α_g should be taken at T_g; n and m are constants. Hence the constancy of the left-hand part of the last equation does not signify that the free volume is constant, but quite the contrary. Since Eqns. (10) and (11) involve integration of the function $\alpha_l(T)$ over the range $0 \leqslant T \leqslant T_g$, not realisable experimentally, Simha and Weil give a method for the necessary extrapolation using reduced functions of temperature and pressure. Application of Eqn. (11) to the experimental results showed that there is a systematic decrease in the product $(\alpha_l - \alpha_g)T_g$ as the length of the linear side-chains of the polymers in the methacrylate series is increased. The experimental results also showed that the value of $(v_{0g} - v_{0l})/v_{0g}$ is not constant at T_g, whereas the ratio $(v - v_{0l})/v$ at T_g is comparatively stable. It was found that the main part of the discrepancies between the f_g for the individual systems at T_g is connected with the contribution of the vitreous rate to the free volume.

The change in the value of f_g for the various polymers can be significantly less when allowance is made for the non-linear temperature dependence of the specific volume of the polymer in the liquid and vitreous states. The decrease in f_g as the temperature is reduced also follows from Moacanin and Simha[39], who considered the entropy of mixing of holes and segments with allowance for the temperature dependence of the hole concentration needed for the minimisation of the free energy. The temperature T_2 at which the system is in equilibrium and the product $\Delta\alpha \cdot T_2$ in the Gibbs–DiMarzio theory[40] are functions only of the free volume v_g. The constancy of the product $\Delta\alpha \cdot T_2$ at $T = T_2$ corresponds to the constancy of $\Delta\alpha \cdot T_g$, if the temperature T_2 is proportional to T_g.

The results described above suggest that the concept of iso-free volume at T_g cannot be considered as proved and it is disproved by new experimental results. Consequently several papers[27,30] suggest that at T_g the liquid and polymer are not in a state of iso-free volume but in a state of iso-viscosity (the iso-viscous state).

In connection with this a modification of the Simha–Boyer rule was proposed, which can be expressed in the form[41]:

$$\frac{{}^1/_2\,[(\mathrm{d}v/\mathrm{d}T)_l + (\mathrm{d}v/\mathrm{d}T)_g]\,T_g}{v_g} = K_3.$$

The constant K_3 depends upon the type of bond in the main chain of the polymer and is constant for each class of polymer. Ellerstein[41] assumes that the physical interpretation of this equation can be combined with the concept of iso-free volume. However, in practice the introduction of this correction implies, as we assume, a departure from the concept of iso-free volume. There are other arguments against the ideas of iso-free volume. Thus, Kastner[42] observed that the dielectric losses decrease during isothermal decrease in volume, which shows that relaxation time depends on the free volume. However, the reduction factor calculated assuming that the relaxation time is determined solely by the free volume differs significantly from that found experimentally.

Serious objections against the concept of iso-free volume have been expressed[43] on the basis of published results[44]. It was shown that β-relaxation in poly(methyl methacrylate) and poly(hydroxypropylene glycol) under constant pressure and constant volume conditions proceed analogously. This is difficult to reconcile with the concept assuming that the changes in viscosity and mean relaxation time are due mainly to a change in free volume. To keep this concept in force it is necessary to postulate the existence of a large negative expansion coefficient for the occupied volume.

A departure from the Simha–Boyer equation for linear polymers with increase in the length of the side-radical was observed by Simha[45]. Mandelkern and coworkers[36] used many published results and their own experiments to try to find the limits of applicability of the Simha–Boyer equation. $\Delta\alpha \cdot T_g$ and $\Delta\beta \cdot T_g$ were plotted against T_g, where

$$1/v\,[(\partial v/\partial T)_l - (\partial v/\partial T)_g] \equiv \Delta\alpha$$

and

$$[(\partial v/\partial T)_l - (\partial v/\partial T)_g] \equiv \Delta\beta.$$

It was found that $\Delta\alpha \cdot T_g$ and $\Delta\beta \cdot T_g$ are not constant and consequently the Simha–Boyer equation is of restricted application. The results obtained show that $\Delta\alpha \cdot T_g$ increases with T_g therefore it is incorrect to use concepts including the product $\Delta\alpha \cdot T_g$ as a universal constant in theoretical investigations of glass formation. Mandelkern and coworkers[36] emphasise that this conclusion does not touch the free volume theory itself or its role in glass formation phenomena.

Practical arguments in support of the concept of iso-free volume and attempts at the direct determination of f_g from experimental results have not been given. Thus whereas Curro[46] found $f_g = 0.0261$ for poly(methyl methacrylate) on the basis of a determination of free volume from results on the difference in the specific volume of a polymer and its partial volume in solution, Buniyat-Zade and Ismailov's studies[47] of the temperature dependence of specific volume gave $f_g = 0.025$ for linear polyethylene, whereas for branch-chain or with graft acrylonitrile chains the f_g considerably exceeds the universal value, reaching 0.127. In considering the state equation of the polymers and the characteristics of the vitreous state, Curro[46] found that the agreement between the experimental results and the product $\Delta\alpha \cdot T_g$ is only semiquantitative. It was also shown[48] that the relation between T_g and pressure, which is predicted by the iso-free volume concept, is not observed by many polymers which also casts doubt upon it. Letunovskii and Zelenev[49] calculated the free volume fraction by starting from the relation they proposed:

$$T_\infty = T_g - f_g/(\alpha_l - \alpha_g),$$

where T_∞ is the temperature at which the viscosity tends to infinity. Assuming that there is a better basis for this equation, since it does not contain the arbitrary quantity B of the Williams–Landell–Ferry equation, Letunovskii and Zelenev[49] found $f_g = 0.0048$ for poly(methyl methacrylate) which is significantly lower than the universal value. The lower free volume fraction at T_g for n-alkanes and polyethylene than for vinyl polymers has been found[1,50].

A very interesting approach to the theoretical prediction of the limiting value of $\Delta\alpha \cdot T_g$ has been published[35]. Free volume theory has been used to consider the thermodynamics of the mixing of molecules with holes. As a result Sanchez[35] concluded that

$$T\alpha_h = \frac{E_h/RT}{\exp(1 - 1/r + E_h/RT) - 1}, \tag{12}$$

where α_h is the fraction of thermal expansion associated with the change in the concentration of the holes (expansion of the free volume), E_h the hole formation energy,

$$r = M/\rho v_h N_A,$$

N_A is Avogadro's number, M the molecular mass, ρ the density of a hole-free liquid at absolute zero, and v_h the hole volume. The $1/r$ term is very small for polymer systems and then $T\alpha_h$ is a function only of E_h/RT. The quantity α_h is identified with the experimentally determinable change in the coefficient of thermal expansion at T_g, that is:

$$T_g\alpha_h = T_g \cdot \Delta\alpha.$$

The graph constructed from Eqn. (12) shows that the predicted value of $\Delta\alpha \cdot T_g$ passes through a maximum at a value of 0.159, which corresponds to $E_h/RT = 0.841$. Almost all the values of $\Delta\alpha \cdot T_g$ given in the literature lie below this theoretical limit. The hypothetical value of $\Delta\alpha \cdot T_g$ varies relatively little with hole formation energy. For E_h/RT between 0.5 and 2.0 we have $0.105 < \Delta\alpha \cdot T_g < 0.159$.

It has been shown[35] that changes in the difference between the expansion coefficients at T_g can be predicted from the constant of the Williams–Landell–Ferry equation ($T_\infty = T_g - C_2$). Then

$$\Delta\alpha = 2(T_\infty/T_g)[\exp(1 + 2T_\infty/T_g) - 1]^{-1}.$$

Here it is assumed that $T_\infty = T_2$, where T_2 is the temperature of a second-order transformation, according to the Gibbs–DiMarzio theory[40]. The free volume is then determined as:

$$v_f = (v - v_\infty)/v_0,$$

where v_∞ is the macroscopic volume of the liquid at the temperature T_∞ and v_0 is the volume of the molecules.

Theory predicts that at the T_0 appearing in the Fogel equation the iso-free volume state should occur. However, consideration of the calculated values of f_g shows that this does not take place. Other examples of departures from the behaviour predictable within the framework of the iso-free volume concept have been described[51,52]. We have already noted Kanig's conclusion about the variation of f_g with the flexibility of the polymeric chain[31] and our conclusion about dependence upon the packing density[32,33]. In this connection it is desirable to consider the problem of whether there really exists a definite relation between the free volume fraction at the glass formation temperature and the molecular parameters of the polymeric chain.

V. VARIATION OF THE FREE VOLUME FRACTION AT THE GLASS FORMATION TEMPERATURE WITH THE MOLECULAR PARAMETERS OF LINEAR POLYMERS

As noted above, the constancy of f_g for various polymers differing in their chemical structure is only a rough approximation. From several qualitative arguments and results on glass formation in a series of polyurethanes it was suggested[53] that the experimentally observable change in free volume for different polymers can be connected with their molecular parameters, above all with the flexibility of the chain. It is now desirable to prove this in detail by finding the relation between the free volume and the nature of the molecular packing.

For this purpose it is convenient to use the definition of the free volume fraction given by Litt and Tobolsky[19], that is, to state, in accordance with Fig. 1, that the occupied volume is v_3''. From an analysis of results on the molecular parameters of a series of polymers there is a definite tendency towards an increase in the ratio v_3''/v_g as the size of the side-groups of the polymeric chain is increased. The ratio of the volumes of the polymer in crystalline v_c and amorphous v_a states is connected with the characteristic parameter of the chain a/σ, where a is the thickness of the chain determined by the dimensions of the elementary cell and σ a steric factor or the flexibility parameter of the isolated polymeric chain, which usually can be estimated from measurements of the characteristic viscosity in the ideal solvent[54]. A relation was found between v_c/v_a and a/σ.[55,56] It was found that there is a definite tendency for v_3''/v_g to increase with a/σ.

It can be proved that the ratio v_3''/v_g equals the ratio of the packing factors of the polymer in the amorphous and crystalline states K_a/K_c at T_g, since by definition

$$K_a = N_A v_i/v_a \quad \text{and} \quad K_c = N_A v_i/v_c;$$

here v_i is the van der Waals' volume of the repeating unit of the chain, and N_A Avogadro's number. We note that the calculated values of $(K_c)_g$ correlate with the characteristic parameter of the chain a/σ, and the ratio between them can be expressed as follows:

$$(K_c)_g = 0.9(1 - 0.058\, a/\sigma). \tag{13}$$

Hence we can state that the free volume fraction at the glass transformation temperature, as determined according to Eqn. (2) will be less when the packing of the chains in the bulk of the polymer becomes looser. This conclusion agrees with the analogous quantitative conclusion reached earlier[35,34].

Presumably this conclusion is general for all polymers in the amorphous state. However, Eqn. (13) cannot be applied directly to polymers which do not crystallise, since then v_3'' or a is unknown. In trying to extend to these polymers the ideas expressed above we can propose another definition of f_g, analogous to the Simha–Boyer expression:

$$f_g=(\alpha_l-\alpha_g)(T_g-T''),$$

where T'' is a comparison temperature connected with the occupied volumes v_0'', v_3'', and v_2'', as is shown in Fig. 1. For example, $T''=0$ K corresponds to the Simha–Boyer theory, $T''=T_3$ to the Little–Tobol'skii theory, and $T''=T_2$ corresponds to the Williams–Landell–Ferry definition. We obtained[53] the following empirical equation, connecting T_g with the chain rigidity parameter σ:

$$T_g=A(\sigma-b), \tag{13a}$$

in which A and b are constants. This equation can be compared with the Simha–Boyer equation (7). If now it is assumed that A is proportional to K_1, Eqn. (7), and $\Delta\alpha$ is proportional to $(\sigma-b)^{-1}$ and then Eqns. (7) and (13a) are solved for T_g, we obtain:

$$\Delta\alpha, \mathrm{K}^{-1}=4.2\cdot10^{-4}(\sigma-1)^{-1}. \tag{14}$$

As was shown above, our results[53] are a basis for this assumption. Consequently, if the assumed proportionality between the parameters of the equations is real, the constant K_1 in Eqn. (13) does not have to be the same for all the polymers.

Clearly $\Delta\alpha$ is actually not constant but increases with the flexibility of the chain (that is, with decrease in σ). Hence if the Simha–Boyer equation and our Eqn. (13) are valid, the relation between $\Delta\alpha$ and $\Delta\alpha\sigma$ should be straight lines with slope unity. And actually $\Delta\alpha$ has a tendency to increase as σ is reduced, although this behaviour also cannot be described quantitatively by Eqn. (14). The departure of the experimental points from the theoretical line becomes especially significant when $\Delta\alpha$ is reduced.

It is noted that the best agreement between the experimental values of $\Delta\alpha$ and the theoretical relation is observed for those polymers which obey the Simha–Boyer rule. This again emphasises that f_g is not constant. A more complete representation of the relation between $\Delta\alpha$ and σ is given by the relation between $\lg\Delta\alpha$ and $\Delta\alpha\sigma$, for which considerably better agreement is observed between the experimental points and the theoretical straight line even for those polymers which do not obey the Simha–Boyer rule.

It seems possible to give a qualitative explanation of the observed relation between $\Delta\alpha$ and the rigidity parameter σ. By definition, α_g depends on the anharmonicity of the thermal vibrations of the individual molecules or of the groups they contain and hence the physical nature of α_g is approximately the same for polymers and low-molecular weight liquids. On the other hand, the nature of α_l is not the same. The value of α_l for liquids is reduced as the forces of intermolecular interaction are increased, whereas T_g increases[16], and therefore it is natural to expect an approximately constant product $\Delta\alpha\cdot T_g$, that is, the Simha–Boyer rule is satisfied.

For polymers the quantity α_l does not depend solely on the intermolecular interaction, which affects the mean distance between the centres of gravity of the molecular groups of the chain, but also on the ability of the macromolecules to undergo conformational transformations, which are closely connected with the flexibility of the chain. Then for polymers we can write approximately

$$\Delta\alpha=(\alpha_l)_p-\alpha_g=(\alpha_l-\alpha_c)_m+\Delta\alpha_{\mathrm{conf}},$$

where the indices m and p refer to the polymer and monomer, $\Delta\alpha_{\mathrm{conf}}$ is the additional contribution to $(\alpha_l)_p$ due to the change in the number of conformations of the chains in the melt[56]. Hence it seems that the numerical value of the coefficient $\Delta\alpha$ for the polymers will depend significantly on the size of the "polymer" contribution $\Delta\alpha_{\mathrm{conf}}$, which apparently will be different for polymers with chains of different flexibility.

The conclusion that the free volume fraction at T_g is not a universal constant for linear polymers of different molecular structure can be confirmed qualitatively by the following arguments[57]. We assume that at temperature much lower than T_g the polymeric chains are in a state with minimal energy of the intermolecular interactions, that is, the fraction of the bonds with high energy equals zero[40]. On the other hand, the equilibrium of the fraction of bent chains at $T>T_g$ obey Boltzmann statistics. Then the fraction of bent chains at T_g can be determined from the well-known relation:

$$\varphi_g=[\exp(-\varepsilon/kT_g)]/[1+\exp(-\varepsilon/kT_g)]. \tag{15}$$

From Eqn. (15), the fraction φ_g decreases with increase in ϵ/kT. On taking into account the fact that an increment of volume for a single bent bond will be greater than for a straight bond, this indicates that the fraction of the free volume f_g at T_g which can be identified with the quantity φ_g of Eqn. (15) will actually decrease as the packing density of the polymers in the crystalline state is reduced. Treatment of the experimental results on the variation of the glass formation temperature with the flexibility of the polymeric chain[57] showed that by starting from general equation (13) an expression can be obtained for linear polymers relating T_g with the free volume in the following manner:

$$T_g=T_g(\mathrm{LPE})+[\sigma-\sigma(\mathrm{LPE})]\cdot Y(f_g),$$

where σ(LPE) refers to linear polyethylene, and $Y(f_g)$ is a function which can be determined from the experimental results.

Hence the results considered show the need for reconsidering the concept of glass formation temperatures as corresponding to the state of iso-free volume. It is remarkable that f_g decreases as a/σ is increased. These changes are brought about mainly by variations in the packing coefficients in the crystalline state, whereas the packing coefficients in the amorphous state $(K_a)_g$ remain almost constant. It seems reasonable to assume that this quantity $(K_a)_g$ should be chosen as a measure of the free volume at glass formation temperature. In other words, the determination of the occupied volume as a characteristic volume or van der Waals' volume of a repeating unit of a chain with a low (approximating to zero) thermal expansion coefficient is the most suitable. Such an approach does not conflict with the possible definition of free volume discussed by Bondi[58].

VI. THE CONCEPT OF FREE VOLUME DISTRIBUTION

From the standpoint of the ideas introduced that the free volume fraction at T_g is not constant even for the same type of molecular movements in different polymers and for different types should be different, a consideration of the distribution of the free volume in a system is of interest.

The concept of free volume distribution was developed by Turnbull and Cohen[16]. It is based on the assumption that molecular movements, like transport phenomena, take place only when the vacancies or holes in a body have dimensions greater than some critical value v^*. This critical volume arises as a result of the redistribution of free volume in the system. It is assumed that such a redistribution of free volume takes place without consumption of energy. The concept of excess volume is therefore introduced:

$$\bar{v} - v_0 = \overline{\Delta v}$$

(where $\bar{v}$ is the specific volume and v_0 the volume of the molecules) and the free volume is v_f, such that

$$\overline{\Delta v} = v_f + \Delta v_c,$$

where Δv_c is the volume determined by the thermal vibrations.

It was suggested[16] that only part of the excess volume v_f can be redistributed without consumption of energy. This takes place above the critical temperature T_2. In this instance the thermal expansion of the amorphous phase at low temperatures is due solely to the anharmonicity of the thermal vibrations of the molecules. Hence $v_f \simeq 0$ at the $T < T_2$ and $\Delta\bar{v} \simeq \Delta v_c$. It is also suggested that in this instance an increase in entropy due to the change in volume is also very small. As the temperature is raised and a certain value of Δv is reached the main contribution starts to be the expansion of the "free" for redistribution volume,

$$v_f = \alpha\bar{v}_m(T - T_2),$$

where α is the mean expansion coefficient, and $\bar{v}_m$ the mean volume of the molecules in the temperature range from T_2 to T_g.

The free energy of the amorphous phase should be a minimum when the free volume is distributed in a random manner. Since a random distribution of the volume occurs only in the amorphous, and not the crystalline, phase, under the condition $\Delta\bar{v} > \Delta\bar{v}_g$ the amorphous phase should be more stable than the crystalline, owing to the positive configuration entropy, determined by the definite distribution of the free volume. Therefore, according to Turnbull and Cohen[16], the glass formation temperature of the amorphous phase is defined as the temperature at which the excess volume reaches the value $\Delta\bar{v}_g$, above which a free volume exists.

The probability that the free volume at a given temperature exceeds some value v^* is, according to Fujita[6], given by the relation

$$P(v^*) = \exp[-Bv^* | \langle v \rangle],$$

where $\langle v \rangle$ is the mean free volume of one molecule, that is, the total free volume divided by the number of molecules; B is a numerical factor close to unity. Another definition can also be introduced—the mean free volume per unit volume, that is, the mean free volume fraction f. On putting $Bv^* = C$, then

$$P(C) = \exp(-C/f).$$

These ideas were used to describe diffusion in polymers of low-molecular-weight substances[59]. The mobility of the molecules m_d in the medium will depend on the probability that the molecule will appear in a neighbouring hole is large enough to ensure its displacement. We will use C_d to denote the value of C corresponding to the least hole size necessary for such a displacement. Then

$$m_d = A_d \exp(-C_d/f),$$

where A_d is a factor depending upon the size and form of the solvent molecules.

Litt[60] developed ideas about the least possible diameter b^* of a hole associated with a macromolecule for effecting molecular or segmental motion. According to him, only a hole with a diameter not less than b^* can affect the viscosity. Hence a modified Doolittle equation can be obtained:

$$\ln(\eta/\eta_0) = \pi^{1/2}/[A(T^*/T)^{3/2}(1 + T^*/T)^{-1}\exp(T^*/T)],$$

where

$$A = {}^4/_3\,\pi b^* n,$$

n is the number of molecules per 1 cm^3, $T^* = 4\pi b^{*2}\epsilon/k$, ϵ is the surface tension, k the Boltzmann constant, and T^* the characteristic temperature. The A varies from 0.75 for flexible to 1.4 for rigid polymers. The constant $T_g/T^* = 0.360 \pm 0.1$ was observed for many systems. It is suggested that such a modification of the free volume theory improves its physical reliability. Thus, whereas according to the Williams–Landell–Ferry equation $f \simeq 0$ at $T_g = 50°C$, and then $\ln\eta \rightarrow \infty$, in the example under consideration f/f decreases monotonically at $T < T_g$ reaching zero only at 0 K.

The need to divide free volume into its constituent components was also stated by Razumovskaya and Bartenev[61]. It was noted that the free volume fraction according to Williams–Landell–Ferry is less than its estimate from other results, for example, from compressibility. According to Razumovskaya and Bartenev's results[61], for several polymers the free volume fraction at the glass formation temperature reaches 10–15%, whether it is calculated from compressibility results or from assumptions concerning the additivity of volume for different atomic groups. Mason[62] explains this difference by certain "holes" having lost their characteristic mobility, termed "frozen". Reference is made here not to a quantitative retardation of the hole migration process, but to the complete exclusion of some of the holes from the process. Hence a distinction must be made between the geometric free volume (~10–15% of the entire volume), which corresponds to the Simha–Boyer definition, and the physical free volume, determined by the relaxation time (3%).

The physical free volume v_f is defined as $v_f = v_d n^*$, where v_d is the volume of excited holes, n^* the number of excited holes. The fraction of excited holes at the glass formation temperature will then be $n^*/n = f^*/f_{eff} \simeq 0.1$, where n is the total number of holes in the system, f^* the fraction of physical free volume, and f_{eff} the fraction of geometric free volume. Glass formation is regarded from this standpoint as "freezing" of the characteristic frequencies, which is accompanied by a decrease in the free volume and mobility of the holes. In this it is suggested that molecular rearrangements are brought about by the movement of holes corresponding to definite kinetic units with a characteristic frequency of the thermal vibrations. Such a position corresponds to the ideas we have developed that the motion of parts of different size or different groups of atoms requires a different free volume.

Actually, results on the isothermal contraction for several polymers[3] treated on the basis of the free volume theory show that the quantitative kinetics are not described by a simplified model of the polymer with a single mean relaxation time. Many investigations showed that instead of one relaxation process, relaxation spectra and a distribution of relaxation times must be considered. Kastner[59] attempted to connect this distribution with the free volume distribution. In this connection, Covacs concluded[3] that in considering only the mean parameters of macroscopic specimens (complex modulus, volume, heat content, etc.) the free volume concept should be linked with the change in the molecular mobility and with different types of molecular movements. These processes include a wide distribution of delay times, which can be associated with the local distribution of holes.

Mason[62] developed ideas about the distribution of free volume to explain the diffuseness of the change from the vitreous state to the liquid by assuming the localisation of part of the free volume, which distinguishes the polymeric substance from the true liquid state, where the free volume is not localised. In connection with rubber vulcanisers Mason assumes that in the non-cross-linked state there can still be an arbitrary distribution of the free volume v_f connected with the free volume v_f' of each monomeric unit. Taking the universal value of 0.025 for f_g in this, he assumes that the mean volume per monomeric unit is expressed as

$$\bar{v}' = M_v/nN_A,$$

where M is the molecular mass of the rubber, n the number of monomeric units in the molecule, and v the specific volume. The monomeric specific free volume f' will be defined as

$$f' = v_f'/\bar{v}' = (nN_A/M_v)v_f'.$$

The geometry of the packing can be characterised by distribution functions $P(f')$ which represent the density of the monomeric units with the specific free volume[62].

The effective T_g for a monomeric unit is determined by the condition $f' = f_g$. Hence the number of monomeric units in 1 g rubber at temperature T_g equals

$$n_g = \int\limits_0^{f_g} P\mathrm{d}f'$$

in the vitreous state and

$$n_l = \int\limits_{f_g}^{\infty} P\mathrm{d}f'$$

in the liquid state; under normalisation conditions

$$\int\limits_0^{\infty} P\mathrm{d}f' = N_A n/M.$$

Hence the distribution coefficient is

$$\alpha = \left(\int\limits_0^{f_g} P\mathrm{d}f'\cdot\alpha_g + \int\limits_{f_g}^{\infty} P\mathrm{d}f'\cdot\alpha_l\right)\Big/\int\limits_0^{\infty} P\mathrm{d}f'$$

and

$$\alpha - \alpha_g = \frac{M(\alpha_l - \alpha_g)}{N_A n}\int\limits_{f_g}^{\infty} P\mathrm{d}f'.$$

In the last equation it is assumed that at an arbitrary temperature T there are units present in both the vitreous and in the liquid state, as determined by the distribution coefficient. The coefficient α is regarded here as the sum of the expansion coefficients of each region with allowance for the numerical fraction of the units.

The value of the integral, representing the number of monomeric units found in the liquid state decreases from $N_A n/M$ at a temperature above T_g (where $\alpha = \alpha_l$) to zero below T_g (where $\alpha = \alpha_g$). When all the monomeric units have the same specific free volume f', then the change into the liquid state will take place at a single temperature. The "blurring" of the change for some interval of T is connected with the distribution of f' and the temperature interval in which α decreases from α_l to α_g gives a measure of the width of this distribution. Hence assuming a normal distribution of f' at a temperature above T_g the mean value of f' will equal the macroscopic f, and the distribution will be:

$$P = P(f) = \frac{1}{\sigma\sqrt{2}}\exp\{-[(f' - f)^2/2\sigma^2]\},$$

where σ is the dispersion. Hence with allowance for the normalisation conditions, we have:

$$\alpha - \alpha_g = \frac{M(\alpha_l - \alpha_g)}{N_A n}\,\frac{1}{\sigma\sqrt{2}}\int\limits_{f_g}^{\infty}\exp[-(f' - f)^2/2\sigma^2]\,\mathrm{d}f'.$$

Close to T_g the value of σ can be taken as constant, and then the temperature enters into the function being integrated only through f. Bearing in mind the equations obtained, Mason[62] succeeded in calculating the distribution of the free volumes for monomeric units $P(v_f')$ with vulcanisers which are characterised by a different cross-linking density.

Ideas about the free volume distribution provide a significant contribution to understanding the mechanism of the glass formation processes in polymers and in the development of free volume theory. The need for taking into account the free volume distribution in the system was also shown in passing by Kanig[31] and Sanchez[35]. However, ten years elapsed before a new treatment of the problem of free volume distribution based on the ideas of the distribution of holes according to size appeared. Kilian[63] analysed glass formation from the viewpoint of thermodynamics as the displacement of the polymeric chains with holes of homogeneous dimension, the mixture being regarded as a saturated solution of linear chains, containing y_p repeating units. However, since the vacancies or holes exhibit a distribution in sizes, a quasistatistical glass formation temperature is considered at which glass formation takes place according to a cooperative mechanism. From this we calculated the partial molar enthalpy of mixing with allowance for the zero interaction of the holes with one another and of the holes with the polymer. It is assumed that the formation of holes in the medium always requires the same excess enthalpy. On this basis Manabe and Takayanagi[64] obtained the following equation for T_g:

$$\frac{1}{T_g} = \frac{R}{A_p^h\varphi_p}\cdot\frac{1}{y_p} + \frac{A_p^s}{A_p^h} + \frac{R}{A_p^h y_{Li}\varphi_p^2}\left\{\frac{y - \varphi_p}{\bar{y}_i}\,y_{Li} - \ln\varphi_{Li} - 1\right\},$$

$(i = 1, \ldots, N)$,
where A_p^h is the specific entropy of formation of any holes, A_p^s the excess entropy of formation of the holes, $\varphi_p = y_m n_m/\Sigma y_i n_i$, y_{Li} is the hole size, $\bar{y}_i$ the mean particle size in the mixture, φ_{Li} the fraction of holes of size i. From this equation, it follows that for a polymeric system in which there is a distribution of holes according to sizes,

the volume fraction of holes φ_{Li} should be different and depend on y_{Li}. From the thermodynamic point of view, for each fraction of holes there is a quantity y_{Li}, which should satisfy the condition of thermodynamic equilibrium.

Comparison of the last equation with published results relating T_g with the chain length y_p showed[63] that if the normalisation condition is taken to be

$$\Sigma \varphi_{Li} = 1 - \varphi_p,$$

then

$$\varphi_{Li} = \left[\frac{(1-\varphi_p)\, e}{(1-\varphi_p)\, e + 1} \right]^{y_{Li}} \cdot \frac{1}{e}$$

is a distribution function for the holes according to size. When the iso-free volume condition $\varphi_L(T_{g\infty}) = \text{const}$ is obeyed, the distribution function φ_{Li} is also invariant with respect to the system.

Calculations of the entropy of formation of the holes showed that it is negative, that is, there cannot be a statistically disordered homogeneous distribution of holes. However, Kilian[63] considers as problematical the distribution of holes according to the condition $1 \leqslant y_{Li} = \infty$ without a connection with the molecular structure. The distribution function is monotonic for a saturated mixture and the volume fraction of holes of large dimension rapidly decreases as y_{Li} is increased. It is assumed that the ideas about distribution correspond best to the statistical nature of the molecular configurations in the liquid phase. According to Frenkel', the free volume in a liquid in principle is not connected with the sizes of the molecules but is comparable with the atomic dimensions[29]. It must be taken into account that the holes should be distributed irregularly, at least in a polymer to ensure that a variety of types of molecular movement is possible.

The concept of free volume distribution was developed further by Manabe and Takayanagi[64-66], who applied it to the glass formation temperatures of mixtures of two polymers. Comparison of the theoretical ideas with experiment showed that a different distribution of the free volume is possible in mixtures. They found experimental proof that the glass formation temperature corresponds to the iso-free volume state. The same T_g can also correspond to different distribution functions owing to a difference in the structure of mixtures. Hence although the free volume is an important characteristic of the glass formation process, different distribution functions of T_g correspond to different distribution functions of free volume.

The inapplicability of the concept of iso-free volume to mixtures of polymers was also shown in studies[68, 69] based on theoretical ideas about the distribution and localisation of the free volume in heterogeneous polymeric systems.

---o0o---

The results of the many investigations reviewed in the present paper suggest that the concept of glass formation as a state of iso-free volume cannot be regarded as justified, either theoretically or experimentally. This became especially clear after it was observed that even for the same polymer the free volume fraction could change depending upon the conditions of formation of its structure[68]. All this shows that although the concept of free volume is physically reasonable, its use to describe the properties of polymers involves considerable difficulties in some instances. This restriction is evident particularly clearly in considering glass formation as a process corresponding to the iso-free volume condition.

Therefore one of the main tasks in the field of free volume theory and the theory of glass formation is the development of new concepts and the production of new parameters of corresponding states. Thus, Miller[23] introduces the concept that glass formation corresponds to an iso-relaxation state, and at molecular masses below critical it corresponds already to the condition of an "iso-viscous" state. We assume that since the free volume concept itself characterises the state of ordering of the system (especially when we consider the free volume distribution function), then the thermodynamic description of the processes which take place during glass formation through configuration entropy and the breakdown of the kinetic description of this process is more hypothetical. According to Adam and Gibbs[1], glass formation takes place when the system reaches some minimum configuration entropy. Its value can be calculated from the relation:

$$\Delta S_c = \Delta C_p \ln (T_g/T_0),$$

where ΔC_p is the jump in heat capacity during glass formation. Such an approach shows, in particular, that the quantity ΔS_c can also reflect the effects connected with the existence and distribution of free volume. Hence ideas about glass formation as an isentropic transformation, in accordance with the Gibbs–DiMarzio theory, can be extremely promising.

Industrial Applications of Amino-acids

M.S.Sadovnikova and V.M.Belikov

Aspects of the use of amino-acids in various branches of industry—as food additives and surface-active agents, in the production of polymeric materials, in electrochemical manufacture, etc.—are surveyed on the basis of works of reference and the patent literature up to 1975. A list of 273 references is included.

V. Other fields of applications 204

I. INTRODUCTION

During recent years the manufacture of amino-acids has been actively developed throughout the world (Table). Their chief consumers, ensuring a steady demand, have been the food industry, in which sodium glutamate is used as a flavour intensifier, and lysine as an additive to increase the nutritional value of bread, animal husbandry, and poultry farming, where lysine, tryptophan, threonine, and methionine are used to increase the food value of protein feeds.

World production of amino-acids (1974).

Product	Annual production, tonnes	Method*
Sodium *L*-glutamate monohydrate	200 000	M, X
L-Methionine	50 000	X
L-Lysine monohydrochloride	20 000	M
L-Tryptophan	20	X
L-Threonine	20	X
Glycine	2 000	X

---

*M = microbiological; X = chemical.

The present review does not cover such well known fields of application as animal husbandry, parenteral feeding, etc., on which a vast review literature exists. Special attention is paid to less well known trends—the possible use of amino-acids in pharmacology and cosmetics, as food additives and surface-active agents, in the synthesis of polymeric materials, as pesticides, in the electrochemical industry, etc. Several fields of application have not been developed because of the very high cost of amino-acids, due mainly to the low volume of production. The recognition of new consumers will help to increase production and thereby ensure the comprehensive application of amino-acids.

II. THE FOOD INDUSTRY

The chief consumer of amino-acids at the present time is the food industry. Problems of the enrichment of food products with indispensable amino-acids and of balancing the diet (i.e. adding the missing amino-acids to low-quality proteins) have been widely discussed in the Soviet[1-3] and foreign[4-8] literature, so that we will not dwell on them. Food products can be enriched with lysine, threonine (rice, wheat, sorghum, etc.), tryptophan (maize, wheat). and methionine (soya-bean and peanut flour). However, the balancing of cereal products with pure amino-acids (other than lysine) has not yet found widespread application in the food industry[3], although it improves the nutritional properties of vegetable protein. *L*-Threonine and *L*-tryptophan have not yet found practical application for product enrichment, yet vigorous research has been undertaken on the possible use of these important saturated amino-acids, which is prevented by their high price. Among possible fields of application of these and other amino-acids are babyfoods[1], enrichment of low-calorie food[1,6,9-11], dietetic feeding[12-15], and special diets for cosmonauts[16].

While possessing extremely interesting and diverse properties, amino-acids have come to find application in the food industry, as microbiological and chemical methods for obtaining them have developed, mainly as seasonings, to confer taste and aroma on food products, and as antioxidants.

The main requirement to be met by various kinds of food additives is that they should not be toxic. In the opinion of many experts amino-acids, being together with proteins natural constituents of food products, fully satisfy this requirement. Many publications have appeared, including Refs. 17–19, on the determination of the degree of toxicity of amino-acids.

Glutamic acid has become the most widely used in the food industry: salt sodium glutamate is commonly employed as an effective taste intensifier. It is widely used to improve the taste of meat and vegetable dishes[20], as a mixture with table salt, and for modifying the taste of synthetic sweetening agents[21]; in many countries it is added to all products during canning, freezing, or prolonged storage[3,20]. The patent literature suggests that the boundaries of its application continue to be extended[22-28]; in Japan its production has formed the starting point for industrial methods of obtaining amino-acids, and has stimulated vigorous research on the application of other amino-acids in this way.

In fact many amino-acids possess their own unique flavour and are important elements in the taste of food products. These properties of individual amino-acids have been studied by many investigators and in especial detail by groups under the leadership of Yoshida[29] and of Solms[30,31]. The usual pure amino-acids were found to be respectively tasteless or with a barely perceptible taste (*D*-alanine, *D*- and *L*-arginine, *D*- and *L*-aspartic acid, *D*-glutamic acid, *L*-histidine, *D*- and *L*-isoleucine, *D*- and *L*-lysine, *D*- and *L*-proline, *D*- and *L*-serine, *D*- and *L*-threonine, and *D*- and *L*-valine), sweet (in order of diminishing sweetness—*D*-tryptophan, *D*-histidine, *D*-phenylalanine, *D*-tyrosine, *D*-leucine, *L*-alanine, and glycine), bitter (in order of diminishing bitterness—*L*-tryptophan, *L*-phenylalanine, *L*-tyrosine, and *L*-leucine), and "sulphurous" (*D*- and *L*-cysteine and *D*- and *L*-methionine); *D*-isomers of bitter amino-acids are usually sweet. *L*-Aspartic and *L*-glutamic acids exhibit a sour taste, but when neutralised their solutions have a pleasant flavour; their *D*-isomers are tasteless. These results confirm the relation between the taste and the configuration of amino-acids. The taste is assumed to be due to "three-point" stereospecific adsorption on taste receptors in the surface of the tongue[7].

The majority of methyl, ethyl, benzyl, and t-butyl esters of α-amino-acids have a bitter taste or are tasteless. However, the hydrochloride of the t-butyl ester of *L*-alanine possesses an intensely sweet taste: a given weight is equivalent in sweetness to ~75 times that weight of sucrose[32].

The taste of a product is determined not only by the amino-acids but also by its content of mononucleotides (such as inosinic and guanylic acids), organic acids, sucrose, and inorganic acids. Peptides and metabolites of amino-acids (such as betaine and creatine) promote complexity, the "bouquet" of flavour sensations. A great contribution to the taste of plant products is made by glutamic acid, and also by other amino-acids, organic acids, and sucrose. Free amino-acids present in certain foodstuffs may completely determine the taste; in other products amino-acids or their mixtures either strengthen the taste or supply body to it[7,33,34]. The buffering properties of amino-acids also influence flavour[34]. A required taste sensation can be matached by combining various chemical substances, including amino-acids. At the present time amino-acids can be used to strengthen and improve the flavour characteristics of many food products. However, only monosodium glutamate and glycine have found practical application for these purposes.

Glycine is a typical example of sweet amino-acids, exhibiting a "refreshing" sweetness equivalent in intensity to that of sucrose. At the present time it is widely used in the Japanese food industry for the manufacture of seasonings, non-alcoholic drinks, soups, marinades, various fish products, and delicatessen (0.1–1% in amount depending on the type of product)[7,35–38]. It not only serves as sweetening agent but also creates the foundation of a taste or improves the flavour, by mitigating bitterness and saltiness. It is used also for the modification of artificial products to remove an unpleasant aftertaste.

Amino-acids and mononucleotides act synergistically with respect to taste: the effect of the flavouring agent sodium inosinate is strengthened by the addition of sodium monoglutamate. The synergistic effect of mononucleotides is evident also in combination with sodium *L*-aspartate, *L*-asparagine, and glycine, which is used in recipes for seasonings to improve the taste of foodstuffs and drinks[36,39–41].

Patent information has appeared on such taste-improving agents as *L*-lysine palmitate[42] and glutamylglycylserine[43]. A wide search is being made for new sweetening agents, especially those of peptide character. The taste of peptides is independent of the type of component amino-acids, being determined by the overall structure of the peptide. Dipeptides formed by sweet amino-acids are generally tasteless, whereas peptides containing residues of bitter amino-acids all, without exception, have a bitter taste. In 1969 the discovery was reported[44] of the methyl ester of *L*-aspartyl-*L*-phenylalanine, possessing a sweet taste (sweeter than sucrose by a factor of 150). Investigations on the dependence of taste on structure have shown that a dipeptide must contain aspartic acid to be sweet. Many sweetening agents have since been patented, representing various modifications of this dipeptide[14,45,46]; they can be used for dietary products (e.g. for diabetics). The methyl esters of *L*-aspartyl-*O*-t-butyl-*L*-serine and *L*-aspartyl-*O*-t-pentyl-*L*-serine are sweeter than sucrose by factors of 130–200, and similar to the latter in the character of the sweet taste, have no odour or unpleasant aftertaste, and can be used to improve the flavour of chocolate, confectionery, tea, farinaceous products, fruit juices, etc.[47,48] Much information has been published on the possible application as sweetening agents of both peptide and non-peptide derivatives of aspartic acid[12,14,44–53]. Either *D*- or *DL*-tryptophan can be used as synergist, intensifying the sweetness of saccharin and eliminating its inherent unpleasant aftertaste[45,53,54].

One of the chief reactions producing aroma in almost all food products is Maillard's, consisting in the interaction of the amino-groups of peptides, amino-acids, and proteins with the glycosidic hydroxyl of sugars. This reaction is especially important when the aroma results from heating the food, e.g. bread or meat[55]. According to Tressl[56] several hundred aromatic compounds, many formed by reactions between amino-acids and reducing sugars, have been identified in the aroma of products that have been subjected to heat. Thus, although most individual amino-acids are odourless, when heated with other compounds they yield odours that are specific to the given type of amino-acid. Herz and Shallenberger[57] studied the aroma produced when certain amino-acids were heated with glucose at 100 and 180°C for 1 h, and found that glycine, proline, methionine, valine, and arginine yielded the odours respectively of caramel, bread, potatoes, chocolate, and burnt sugar.

As early as the 1960s it was noted that the Maillard reaction offered great prospects of "synthesising" food odours[20], and attention has now been paid to its utilisation. Since the decisive role of the reaction is indicated by the appearance of the aroma of bread from valine, leucine, proline, and lysine in model experiments, it is recommended that a mixture of these amino-acids or the products obtained by heating the mixture with saccharides should be added to improve the flavour and aroma of farinaceous confectionery, and proline mixed with dihydroxyacetone in bread manufacture[58,59]. Valine and phenylalanine have already been used in Japan to improve the aroma of rice pastry. *L*-Lysine is added to coffee (10–70 mg/100 ml) for the same purpose[60]. It has been proposed[61] to introduce amino-acids (arginine, leucine, valine, lysine, etc.) together with dihydroxyacetone into tobacco, on the view that during curing they react with the latter to form aldehydes, which confer agreeable properties on the smoke.

Lysine, ornithine, histidine, arginine, aspartic acid, alanine, valine, leucine, isoleucine, and proline can serve as active ingredients of various deodorants for food products[62-64]. The specific odour of rice that has been stored for a long time can be removed by adding *L*-cysteine, *L*-lysine, and *L*-histidine[65]. Thus the definite influence of amino-acids on taste and aroma has led various investigators to make repeated attempts to improve the organoleptic indices of food products.

For several years Miyake et al. studied the influence of basic amino-acids on the taste properties of meat products. They showed that the organoleptic characteristics (tenderness, taste, odour) were improved by treating raw meat with basic amino-acids, especially arginine[66]. Patents have appeared on the use of histidine, lysine, cystine, and arginine to improve the quality of meat and fish products[67,68]. In the manufacture of sausages from the meat of warm-blooded animals or fish the fat distribution and the gelatinisation of the products are improved by the addition of 0.1−1% of a *D*-amino-acid (alanine, arginine, cysteine, etc.)[69].

Individual amino-acids and their mixtures can be introduced into compositions simulating the taste and odour of natural foodstuffs. Cysteine and cystine are important constituents in the creation of “meaty” odours, and are introduced into compositions possessing the taste of meat[7,20,27,70]. Monosodium *L*-glutamate must also be present to produce a fully “meaty” odour and flavour[26,27,70,71]. For example, a mixture of a hexose and a pentose is heated with cysteine or cystine in the presence of water to give compounds having the taste of meat. They are mixed in definite proportions with the hydrolysate of a vegetable protein, monosodium glutamate, sucrose, alanine, glycine, and a mixture of inosine and guanyl monophosphates. Heating the mixture alone and together with fats produces the flavours of soup and of gravy respectively[70]. Pentoses such as ribose and xylose are more active than are hexoses. Methionine is used to make a flavouring with the smell and taste of potatoes[72]. Such synthetic compositions will become especially timely in the future in connection with the production of artificial foods[26,27,70-74].

The development of the food industry has entailed an increasing demand for large quantities of antioxidants. The antioxidising properties of methionine have been known for a long time; it is widely used in edible oils and fats, in which a strong effect is apparent, with a favourable influence on the organoleptic indices of the product[75,76]. Progress has now been made in the use of other amino-acids for these purposes.

Soboleva and her coworkers[77] studied the antioxidant properties of several amino-acids in soft and hard margaine, vegetable oil, and butter. All the amino-acids used tended to inhibit oxidising processes in fats, but the efficiency of a particular amino-acid depended considerably on the type of fat. *DL*-Lysine, *DL*-tryptophan, and *DL*-methionine are effective antioxidants for the fatty base of soft and hard margarine; *L*-arginine hydrochloride, *DL*-tryptophan, *L*-cysteine, and *DL*-methionine for vegetable cooking fat; and *L*-arginine hydrochloride, *L*-asparagine, *DL*-norleucine, and especially methionine for butter. The introduction of synergists improves the antioxidant properties of amino-acids: mixtures with chemical antioxidants—butoxytoluene and butoxyanisole—are more effective than are the individual components.

Glycine is a good antioxidant for such emulsifiers as mono- and di-glycerides. Several amino-acids were studied in model experiments using methyl linoleate[78]. The best results were obtained with histidine and tryptophan, which can be added to powdered milk to preserve it from the most frequent defect of milk products—the “oxidised” aftertaste resulting from the autoxidation of milk fat[78,79]. Individual amino-acids, their derivatives, and various compositions with other compounds have been patented for use as antioxidants[38,80-83]. Lipids in food can be freed from rancidity by adding a salt of a basic amino-acid (such as lysine) and phytic acid[82]. Alkyl esters of aspartylphenylalanine $HOOC.CH_2.CH(NH_2).CO.NH.CH(CH_2C_6H_5).COOR$ (where $R = CH_3$, C_2H_5) are readily soluble in oils and fats, cause neither an unpleasant odour nor discoloration when heated, and can be used as antioxidants and emulsifiers for foodstuffs[83]. *N*-Acetylmethionine has a stronger antioxidant effect than methionine in cooking oil[84].

Many investigators have studied the antioxidant action of the coloured products formed by the Maillard reaction, first reported for melanoidins[85]. The coloured products formed from amino-acids and reducing sugars play an important part in stabilising fats against oxidation[86]. As a threose, dihydroxyacetone is more reactive towards amino-acids than are pentoses and hexoses, and therefore Ito et al.[87] have compared (in a model system) the antioxidant activity of the coloured products obtained with dihydroxyacetone, glucose, and xylose respectively. This shows strong variation with the sugar and with the amino-acid. The most active sugar (the threose dihydroxyacetone) gives products exerting the greatest antioxidant effect. Among amino-acids the best results are shown by methionine, leucine, isoleucine, and valine. Products obtained from certain amino-acids and dihydroxyacetone are far more effective than butoxyanisole. These results enabled compositions prepared from dihydroxyacetone and amino-acids such as alanine, leucine, histidine, methionine, phenylalanine, threonine, and tryptophan to be recommended as food antioxidants for oils and fats[88].

Glycine, alanine, lysine, ornithine, arginine, and glutamic and aspartic acids react with sugars (glucose, fructose, etc.) under certain conditions (pH 11−13 at 100−120°C) to give food colorants having an antioxidant effect, adsorbing oxygen, and inhibiting lipoxidase[89].

Cysteine is able to occupy a special position in the food industry because of its mercapto-group and hence specific physicochemical properties. Laboratory and industrial research on *L*-cysteine and *L*-cystine has shown that their introduction into many foodstuffs (meat and meat products, milk products, bread, farinaceous confectionery, etc.) has a considerable favourable effect. These amino-acids show great promise for stabilising the quality of foodstuffs—for slowing down enzymic browning reactions, stabilising ascorbic acid, retarding the autoxidation of fats, strengthening the effect of food preservatives, and also aromatising foodstuffs[90-97]. In Japan it is permissible to add cysteine as antioxidant to natural fruit juices. Cysteine is effective against the browning of foodstuffs, since it suppresses the formation of coloured compounds (melanoidins) by reducing intermediate products; or else free radicals formed from cysteine inactivate the intermediates. Since free cysteine is readily oxidised, it is normally used in the form of the relatively stable hydrochloride. During storage of a natural fruit juice ascorbic acid, being a reductant and hence opposing browning reactions, is gradually oxidised, with browning and decrease in the nutritional value of the product. This can be prevented by adding cysteine hydrochloride. A stable food antioxidant containing equimolecular proportions of ascorbic acid and cysteine has been patented[93].

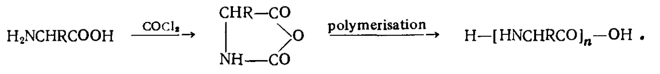
According to various authors cysteine as a reductant can also be used to improve the baking process (improve the rheological properties of the dough) and the quality of the bread[90,94–97]. Use together with ascorbic acid alone or mixed with potassium bromate gives a bread of improved structure, flavour, and aroma in a shorter time (this has already been introduced into practice in the USA, England, and Japan). Cysteine is considered to make the dough softer, by rapid reaction with gluten accompanied by cleavage of S–S bonds, while the oxidant slowly restores the elasticity, forming new S–S cross-links. Sulphur-containing amino-acids—methionine, *L*-cysteine, *L*-cysteinyl-*L*-cysteine—have been recommended for enriching phosphorylated starch, which serves as a gelling agent in foodstuffs and drinks[98].

The storage of perishable foodstuffs is one of the most important problems facing the food and canning industry. Glycine can be used to lengthen the storage life to fish products: addition of 1–2% (to improve taste and aroma) revealed that the growth of slime-forming bacteria was suppressed for some time. It is assumed that glycine inhibits biosynthesis of the cell walls of such bacteria, e.g. *Bacillus subtilis*[99]. A proposed deodorant for the oral cavity contains a reaction product of copper gluconate and glycine[100]. Derivatives obtained by the reaction of *L*-, *DL*- and *D*-glutamic acid with alkylamines and alcohols have been patented[101] for the protection of products from damage by micro-organisms. Increased storage life in the preservation of various foodstuffs—meat, fish, etc.—has been claimed[102] for the addition of a lauroyl-amino-acid (-leucine, -glycine). A method has been developed[103] for preserving foodstuffs by forming a coating from a prolamine and an amino-acid (alanine).

The list of amino-acids permitted as food additives in Japan comprises[104] *DL*-alanine, *L*-arginine-*L*-glutamate, sodium *L*-aspartate monohydrate, *L*-glutamic acid, sodium *L*-glutamate monohydrate, glycine, *L*-histidine hydrochloride monohydrate, *L*-isoleucine, *L*-lysine hydrochloride, *L*-lysine *L*-aspartate, *L*-lysine *L*-glutamate dihydrate, *DL*- and *L*-methionine, *L*-phenylalanine, *DL*- and *L*-threonine, *DL*- and *L*-tryptophan, and *L*-valine. Those permitted in the USA are[105] *DL*- and *L*-alanine, *L*-arginine, *L*-arginine hydrochloride, *DL*-aspartic acid, *L*-cystine, *L*-glutamic acid, ammonium *L*-glutamate, sodium *L*-glutamate monohydrate, potassium *L*-glutamate, *L*-glutamic acid hydrochloride, glycine, *DL*- and *L*-isoleucine, and *DL*- and *L*-leucine, *L*-lysine hydrochloride, *DL*- and *L*-methionine, *DL*- and *L*-phenylalanine, *L*-proline, *DL*- and *L*-serine, *L*-threonine, *DL*- and *L*-tryptophan, *L*-tyrosine, and *L*-valine.

III. USE OF AMINO-ACIDS IN THE SYNTHESIS OF POLYMERS

Polyamino-acids are usually obtained by the polymerisation of *N*-carboxyanhydrides prepared by the action of carbonyl chloride on the amino-acids:



Their skeletal structure resembles that of proteins, but their properties differ greatly from those of natural proteins, since they contain only one kind of amino-acid. Although various copolymers have already been synthesised, as yet they are of no practical value. Nevertheless, the structures of polyamino-acids are similar to those of such natural proteins as silk and leather, and therefore are regarded as suitable materials for the production of synthetic fibres and leather. Their use as raw material for synthetic fibres, films, and coatings of vinyl leathers was suggested by Woodward 20 years ago[7]; but these materials were then uneconomic as silk substitutes. Later glutamic acid became widely used in the Japanese food industry, and the development of methods for producing it more cheaply led to the use of polyglutamates as coatings for artificial leathers.

Poly(methyl *L*- and *D*-glutamate) are obtained by polymerisation of the *N*-carboxyanhydrides of γ-methyl *L*- and *D*-glutamates, prepared by treating the glutamates with carbonyl chloride in the presence of an appropriate polymerisation initiator in a suitable solvent[106–109]. The resulting polymer is soluble in halogenated hydrocarbons and has a highly regular linear structure, forming right-handed and left-handed α-helices from the initial *L*- and *D*-anhydrides respectively.

Two types of polymers based on γ-methyl glutamate (PGS—in the form of a solution in both cases, since PGS becomes insoluble after removal of the solvent, and moulding requires the direct use of a solution of the polymer)—unmodified PGS (commercial designation PLG) and modified PGS (PLG-N)[106–109]—which can be used e.g. for manufacture of artificial leather, synthetic fibres, and films for edible packings, are manufactured in Japan. Wet spinning gives a fibre closer than other synthetic fibres to natural silk in appearance and "feel", similar in strength and elongation, and surpassing it in resistance to weathering[107,110]. The practical value of PGS is evident in the usual application of an approximately 10% solution to coat the surface of vinyl leathers, which then become very closely similar to natural leather, highly resistant to heat, water, chemicals, and dirt, with good dyeability and several other valuable properties[109,111]. All this has resulted in the widespread use of such leathers in the manufacture of handbags, suitcases, furniture, clothing, and footwear.

Research on the preparation and properties of polyamino-acids is being vigorously pursued: polymerisation conditions[108,112,113] and effective moulding methods[110,114] are being worked out, and polymers based on other amino-acids—e.g. aspartic acid[111,115–117], glycine[115], alanine[118,119], and lysine[115,119,120]—have been synthesised. Many papers have appeared on the preparation of copolymers of amino-acids, which opens up great opportunities for modifying the properties of the resulting materials. The copolymer of γ-methyl *L*-glutamate with 1% of *L*-methionine, obtained from the corresponding *N*-carboxyanhydrides, will give a fibre of enhanced strength in comparison with the fibre without added methionine[121]. Several copolymers of *L*-leucine with *L*-cystine varying in composition and molecular weight have been synthesised[122], from which fibres have been obtained by wet spinning. X-Ray diffraction and infrared spectroscopy indicate that the fibres comprise α-helices with cystine bridges. The mechanical properties show strength and elasticity not inferior to those of wool. In contrast to wool fibres, however, whose modulus of elasticity increases appreciably at deformations > 20%, these synthetic fibres develop plasticity in this range of deformations.

Modification of poly-*D*-glutamic acid and poly-*L*-aspartic acid with styrene gives resins suitable for the production of a silklike fibre with enhanced alkali resistance[123]. Copolymers of *DL*-methionine and *L*-leucine form flexible films able to transmit water vapour slowly. Oxidation of the methylthioethyl groups by hydrogen peroxide to methylsulphonium groups strengthens the hydrophilic properties of these films, the rate of passage of vapour through a film increasing rapidly with the number of groups oxidised. The permeability of such films to carbon dioxide and oxygen is strongly dependent on the ratio of methionine to leucine. The above properties are of interest in connection with possible use of the films in various prostheses, in particular in artificial kidneys[124].

The main trend in improving the quality of synthetic polymeric materials is chemical modification of their structure. A great variety of materials having special properties, not present in the usual natural and synthetic fibres, can be obtained in virtue of the physical and chemical structural peculiarities of various modifications of polyamino-acids. Such properties include enhanced stability to chemical reagents and various physical factors, the ability to be resorbed in functioning tissues of the organism, etc. The modified polymers may find application in many branches of science and technology, such as medicine, foodstuffs, the pharmaceutical industry, etc. Films or fibres from polymers containing acid groups (poly-*L*-glutamic acid) modified with di-isocyanates become semipermeable and water-resistant, which is very important for their use in dialysis or surfery[125]. Threads for surgical sutures are obtained from readily hydrolysable fibre- and film-forming polymers based on amino-acids and hydroxy-acids[126] $[NH.CH(CH_3).COO.C(CH_3)_2.CO]_n$, $[NH.CH(CH_2C_6H_5).COO.[CH_2]_2.CO]_m$, etc.

A very important property of polyamino-acids is their non-toxicity and inertness towards the tissues of the macro-organism. On the other hand, the production of polymers possessing biological activity—antimicrobial, anti-inflammatory, anaesthetic—is of great interest. Polyamino-acids impregnated with bactericides, antiseptics, and antibiotics in various dressings and emergency remedies are very convenient for the prophylaxis and treatment of open wounds and skin diseases[127,128].

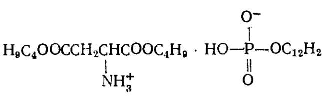
Medicinal preparations have recently become widely used in which coatings protect the contents of a tablet from the environment (moisture, air, light), prevent irritation of the stomach by mucosa by the medicinals, localise the action of the latter, etc. A protective coating for medicinal preparations has been developed from a copolymer of glutamic acid and an alkyl glutamate: it is odourless, sufficiently stable to the action of the gastric juices, and readily soluble in weakly acidic or neutral media[129].

Amino-acids and their derivatives can also fulfil various functions as additives to synthetic polymers and resins: they act as stabilisers, plasticisers, hardening accelerators, etc.[130-142] The copolymerisation of acrylonitrile (or methacrylonitrile) with $\alpha\beta$-unsaturated acids (e.g. itaconic) in the presence of glutamic acid and asparagine yields a water-soluble resin suitable as a binder or a modifier for paints and adhesives[130]. Because of their amphoteric character, amino-acids (glycine, lysine, aspartic acid) can be used to accelerate the hardening of phenol–formaldehyde resins[131]. To improve the resistance to sticking of goods from optically active γ-esters of glutamic acid, its *N*-substituted ethers may be added as plasticisers, possessing good compatibility with the base[132].

Glycine is used to increase the adhesion of silicone rubber to metal surfaces[136]. A γ-ethyl *L*-glutamate–*DL*-alanine copolymer coating has been proposed to eliminate tackiness, due to migration of the plasticiser, in moulded goods made of plasticised poly(vinyl chloride)[137]

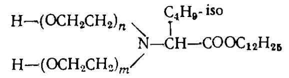
During recent years considerable attention has been paid in synthetic-fibre plants not only to the usual finishing methods (washing, removal of impurities, drying) but also to treatment of the fibres with surface-active agents, which confers optimum frictional properties. Amino-acid derivatives can be used for this purpose[138].

One of the most serious defects of synthetic and acetate fibres is their great tendency to become electrified, which increases the adsorption of dust and creates difficulties in use. Surface-active salts of diesters (e.g. butyl) of aspartic and glutamic acids with monophosphates containing a single higher alkyl group



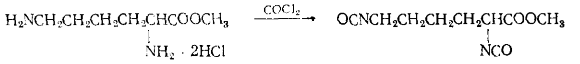
$$H_9C_4OOCCH_2\underset{\displaystyle NH_3^+}{\underset{|}{C}}HCOOC_4H_9 \cdot HO{-}\overset{\displaystyle O^-}{\overset{|}{\underset{\displaystyle O}{\underset{\|}{P}}}}{-}OC_{12}H_{25}$$

have been investigated for the purpose of lowering and removing the static charge on synthetic fibres. The electrifiability of nylon and polyester fibre was considerably diminished after treatment with a 0.4% methanolic solution of the quaternary ammonium salt formed by dibutyl aspartate with dodecyl hydrogen phosphate[139]. Amino-acid derivatives that dissolve readily in polyalkenes were prepared and studied with the aim of improving the antistatic properties of the latter. Thus the product of the condensation of dodecyl-leucine with oxiran



proved an excellent antistatic agent for polyethylene[140]. Derivatives of amino-acids may serve as antistatic agents for the most diverse synthetic polymers—polyamide, polyester, polyacrylonitrile, poly(vinyl chloride), polyalkene, etc.[141,142]

Finally, a very important possibility is the use of diamino-acids such as lysine and ornithine as raw material for polyamides or for the di-isocyanates employed in the manufacture of polyurethanes. The latter are obtained on the large scale by polymerising polyisocyanates (di- or poly-functional) and polyols containing at least two hydroxy-groups (e.g. glycols, polyethers, polyesters, etc.). They are widely used for the production of adhesives, foam plastics, protective coatings, and artificial leather. The action of carbonyl chloride on the dihydrochloride of the methyl ester of *L*-lysine in *o*-dichlorobenzene at 150°C followed by distillation yields methyl 2,6-di-isocyanatohexanoate, a liquid having a high boiling point[143]:



$$H_2NCH_2CH_2CH_2CH_2\underset{\displaystyle NH_2\cdot 2HCl}{\underset{|}{C}}HCOOCH_3 \xrightarrow{COCl_2} OCNCH_2CH_2CH_2CH_2\underset{\displaystyle NCO}{\underset{|}{C}}HCOOCH_3$$

The decisive factor in assessing the toxicity of different di-isocyanates is their volatility. Being less volatile, the above di-isocyanate is less toxic than tolylene di-isocyanate, a fact of importance for the manufacture of polyurethanes.

IV. SURFACE-ACTIVE DERIVATIVES OF AMINO-ACIDS

Introduction of a hydrophobic moiety into one or other of the two hydrophilic functional groups in an amino-acid—amino and carboxy—will yield two types of surface-active compounds—anion-active and cation-active.

N-Acylamino-acids obtained by the action of chlorides of higher aliphatic acids belong to the first class. The initial amino-acids are most often aspartic (*N*-alkylaspartic) and especially glutamic (*N*-alkylglutamic)[144-147].

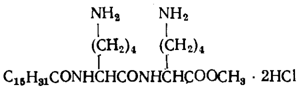
The surface tension, the film-forming and emulsifying power, and the pH of such surface-active compounds can be modified by varying the length of the carbon chain of the acyl group (usually C_{8-22}) and the number of alkaline components used to neutralise the carboxyls. The aliphatic acids most frequently employed are lauric, stearic, oleic, and palmitic. The best surface-active properties are possessed by *N*-acylglutamates[147,148]

$$\mathrm{HOOCCH_2CH_2}\underset{\substack{|\\ \mathrm{NHCOR}}}{\mathrm{CH}}\mathrm{COOH}$$

aui acyl residue (C_8—C_{22}).

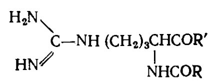
N-Lauroyl-*L*-glutamate salts exhibit better wetting, emulsifying, and dispersing properties than does the widely used sodium dodecanesulphonate[147]. The monosodium salt gives better results than does the disodium salt of the *N*-acylglutamate in model experiments with carbon blacks and powdered iron(III) and titanium(IV) oxides.

Esters of amino-acids obtained by the action of higher alcohols are cation-active surfactants, examples being the tetradecyl esters of glycine, serine, and aspartic acid, as well as dioctyl and dioctadecyl aspartates[149,150]. Cationic detergents, predominantly amines and quaternary ammonium salts, disturb membrane permeability and are highly active towards both Gram-positive and Gram-negative bacteria, which makes them useful in certain special applications, as disinfectants and antiseptics[151]. Several cationic surface-active derivatives of basic amino-acids, e.g. the hydrochloride of the methyl ester of palmitoyl-*L*-lysyl-*L*-lysine



$$\mathrm{C_{15}H_{31}CON H}\underset{}{\overset{\substack{\mathrm{NH_2}\\ |\\ (\mathrm{CH_2})_4\\ |}}{\mathrm{CH}}}\mathrm{CONH}\overset{\substack{\mathrm{NH_2}\\ |\\ (\mathrm{CH_2})_4\\ |}}{\mathrm{CH}}\mathrm{COOCH_3}\cdot 2\mathrm{HCl}$$

are also strongly bactericidal[152]. Arginine derivatives (their salts and esters) having the formula



$$\begin{matrix}\mathrm{H_2N}\diagdown & & \\ & \mathrm{C{-}NH(CH_2)_3}\underset{\substack{|\\ \mathrm{NHCOR}}}{\mathrm{CH}}\mathrm{COR'} \\ \mathrm{HN}\diagup\!\!\!\diagup & & \end{matrix}$$

RCO— acyl residue (C_8—C_{18});
$R'=OCH_3$, OC_2H_5, NH_2,

exert an antimicrobial and antifungal action, and can be used as disinfectant and antiseptic agents in dental powders, toothpastes, toilet lotions, etc.[153,154] The sodium salt of lauroylsarcosine, possessing a strong bactericidal effect together with good foaming power, is widely used in Japan for such purposes[7].

Amphoteric surface-active compounds have been prepared from alanine and from aspartic and glutamic acids[155]. A considerable number of publications have appeared on the possible use of surface-active derivatives of amino-acids in various wetting agents, emulsifiers, dispersants, bactericides, etc.[156-163] These derivatives merit special attention in connection with the growing contamination of the environment by industrial and domestic refuse, since they are biologically "soft", readily decomposed by bacteria under natural conditions. Wetting agents based on amino-acid derivatives, while possessing essentially the same wetting power as soap, do not have the two main defects of the latter: they are not harmed by acids or by hard water. Examples of possible applications of surface-active derivatives of amino-acids are given below. Thus wetting compositions in solid form have been proposed, containing as active component a salt of an *N*-acylated amino-acid[157]. Sodium, potassium, and ammonium salts of water-soluble amines are used, or salts of basic amino-acids, e.g. lysine or ornithine. *N*-Acylaspartic and *N*-acylglutamic acids can be employed both in optically active and in racemic forms. Several papers have appeared on the application of *N*-acylglutamates[158,159] and derivatives of aspartic acid[160,161] in cosmet products. *N*-Acyl-*N*-alkyl-β-alanine salts $RCONR'CH_2CH_2COOX$ (in which RCO represents a C_{8-22} acyl residue, R′ a straight-chain or branched C_{1-8} (cyclo)alkyl, and X hydrogen, an alkali metal, ammonium, or an aminoethanol or a bis- or tris-hydroxyethylamine radical) are present in wetting agents[162] and liquid shampoos[163] possessing good surface-active properties and foam-forming and wetting power.

Reaction of an aliphatic glycerol monester with glutamic (better with *L*-glutamic) and pyroglutamic acids under reduced pressure at 200°C yields odourless and tasteless surface-active compounds[164].

N-2′-Hydroxyethylglycines $HOCH_2CH_2NRCH_2COOH$ (where $R = CH_2CH_2OH$, CH_3, C_4H_9) have been recommended[165] as a base for detergents. From glycine have been obtained[138] new *N*-carboxymethylamides of perfluorocyclohexanecarboxylic acid $C_nH_{2n+1}ACONHCH_2COOH$, where A represents the perfluorocyclohexane ring and $n = 0-4$, whose sodium, potassium, or ammonium salts are used as surface-active agents in the polymerisation of fluorinated alkenes and of acrylates. They are present to the extent of 0.001–0.002% in polishing mixtures. The potassium salt of *N*-ethyl-*N*-perfluoro-octanesulphonylglycine has been introduced as a levelling agent into a liquid composition for cleaning floors[166], to ensure the formation of a semilustrous, polished, and dust-resistant film on the surface.

Detergent compositions on derivatives of aspartic acid (e.g. the sodium salts of *NN*-biscarboxymethylaspartic acid) are claimed[167] to possess the same cleansing power as those containing sodium tripolyphosphate. A proposed method for obtaining *N*-decanoylamino-acids and peptides (employed as surface-active and bactericidal agents) involves esterification of decanoic acid with 3-hydroxypyridine or 8-hydroxyquinoline followed by treatment of the esters with aqueous solutions of sodium or potassium salts of amino-acids or peptides[168]. A mixture of salts of *N*-alkanoylamino-acids (e.g. an *N*-alkanoyl-*L*-valine salt), an *N*-hydroxyalkylamide, and a salt of phenol [sic: "carboxylic acid salt" in Ref. 169—Ed. of Translation] gives a detergent composition of low toxicity and better wetting power than standard compositions[169].

V. OTHER FIELDS OF APPLICATION

1. Electrochemistry

Amino-acids have not yet found practical application in electrochemistry, apparently because of their high cost, but quite a number of patents have been granted on their possible use. They serve as complexing agents, and also have a good buffering effect on the electrolyte, thereby ensuring its stability and the production of high-quality deposits. The patent literature suggests that the use of amino-acids for the electrochemical production of various coatings and alloys has many advantages. Special attention has been paid to glycine[170-191], which increases the rate of electrodeposition by factors of 5–6 when present in the electrolytes. In the formation of a chromium–cobalt alloy glycine keeps the pH within the range 0.5–1;[170] its use in solution for the application of lead selenide coatings to dielectric materials makes it possible to obtain uniform, firmly adherent layers without activation of the substrate[171].

Good-quality palladium–nickel alloy deposits can be obtained only over a narrow range of current densities from an electrolyte containing palladium and nickel chlorides together with ammonia. This disadvantage is removed by adding glycine to the electrolyte[173]. The composition of the alloy and the deposition conditions in the presence of this amino-acid have been studied in detail[174]. Palladium-plating electrolytes can be based[175] on glycine and ethylenediaminetetra-acetic and diethylenetriaminepenta-acetic acids, which form palladium complexes differing in stability. The electrolytes are non-toxic and stable, enabling high-grade metal deposits to be obtained. The throwing power of the electrolytes has been studied, the physicochemical characteristics of the deposits are presented, the rules for obtaining high-quality deposits are elucidated, and electrolytes are proposed for palladium-plating (glycine content 44 g $litre^{-1}$). Good palladium deposits are obtained at a certain pH.[175]

Glycine is used together with Trilon B as a complexing agent in the deposition of nickel–tin[176] and nickel–tin–molybdenum[177] alloys. It serves as complexing agent in chemical nickel plating[178,179]. In the application of cobalt[180] and ruthenium[181] its use tends to stabilise the solution and diminish the porosity of the coating. In combination with cadmium oxide and ammonium chloride glycine increases the stability and the throwing power of the electrolyte used to obtain finely crystalline cadmium–tin alloy deposits[184]. Bright, dense chromium–cobalt alloy deposits, adhering well to the substrate and possessing high abrasion and corrosion resistance, can be obtained[185] from an electrolyte containing glycine and sodium dodecyl sulphate (respectively 50–250 and 0.05 g $litre^{-1}$). The electrolyte is stable in operation, and its composition can be adjusted by adding a previously prepared complex of the chromium compound and the amino-acid.

In a process for obtaining an iron–nickel–chromium alloy similar in composition to the chromium–nickel stainless steel Kh18N9 glycine is introduced into an electrolyte containing potassium chrome alum together with nickel and iron sulphates, in order to increase the buffer capacity of the electrolyte, raise the pH of hydration of chromium, and increase the thickness of the coating[186].

Glutamic acid hydrochloride is recommended for use with ammonium chloride at elevated temperatures below the melting point for the cleaning of gold alloys containing small quantities of tin, indium, germanium, antimony, and silicon[192]. A patent has appeared on the application of glutamic acid as a hydrotropic agent for increasing the throwing power of the electrolyte in the electrodeposition of zinc and other metals[193].

A chromium–nickel alloy can be obtained from an electrolyte containing the sulphates together with an amino-acid, e.g. cysteine[194]. This has great disadvantages over other processes, since chromium contents of 10–90% can be obtained depending on the electrolyte concentration and the electrolysis schedule. Furthermore, the proposed electrolyte enables this alloy to be obtained at room temperature, which improves the working conditions considerably. During recent years research has been undertaken in the USSR on copper-plating electrolytes containing various complexing and surface-active additives, including amino-acids, with the aim of replacing the poisonous and unstable cyanide electrolytes[195].

2. Photography

Reports have appeared on the possibility of using amino-acids in photography; mainly cysteine and cystine are recommended. To accelerate the one-stage photoprocess the amino-acids are introduced (together with 5-mercapto-1-phenyltetrazole as antifogging agent and ascorbic acid as accelerator) into the processing formulation containing metol, quinol, and sodium sulphite, carboxymethylcellulose, thiosulphate, and hydroxide. In the presence of 5-mercapto-1-phenyltetrazole cystine or cysteine improves the quality of the positive image, by increasing the maximum density and ensuring neutrality of tone[196].

Cysteic acid or a derivative can be added also for stabilisation purposes and to eliminate bronzing in the receiving layer of the positive material for the one-stage photographic process, which includes a latex—a copolymer of butadiene and methyl methacrylate—silicic acid, and an activator[197].

The use of cysteine hydrochloride has been patented as an agent for controlling the colour of images in developers not containing metol, amidol, *N*-benzyl-*p*-aminophenol, or *p*-aminophenol. Good results are obtained by the use of developers containing *NN*-diethyl-*p*-phenylenediamine, kojic acid, and cysteine hydrochloride in certain proportions[198].

Double salts of compounds $HS[CH_2]_nCH(NHR)COR'$ (where $n = 1-4$; $R = H$, or a lower or substituted acyl; and $R' = OH$, a lower acyloxy-group or a substituted amino-group) have been proposed to improve development and sensitometric characteristics in diffusion developers for half-tone print negatives[199]. The introduction of cysteine, its hydrochloride, cysteinylglycine, or *N*-methylcysteine hydrochloride into a devloper containing quinol as main component enhances appreciably the maximum density while preserving the same minimum density (fog) on development under the usual conditions[199]. Cysteine can also serve as chemical sensitiser of the negative or positive emulsion layer in the planographic printing plates employed in lithography[200].

Arginine and its salts have been suggested for rapid development of the latent image in a silver-halide emulsion film containing at least one developer[201]. Several surface-active derivatives of aspartic acid have been prepared and studied[202,203]. A series of *N*-alkyl-*N*-sulphosuccinyl derivatives of aspartic acid, possessing a branched structure and containing several hydrophobic and hydrophilic groups, show high wetting and emulsifying power. Disodium diethyl *N*-decyloxypropyl-γ-sulphosuccinylaspartate meets most closely the requirement for the washing of photographic emulsions[203].

3. Pesticides

Losses in agriculture due to pests, weeds, and plant and animal diseases are extremely high, approximately one-third of all agricultural production. Chemical plant-protection agents are widely used to diminish them, and intensive research is being undertaken to find new preparations, whose application is not only an important condition for eliminating the huge losses but also one of the most economic ways of intensifying agriculture[204]. Derivatives of such an important class of biologically active natural compounds as amino-acids have been the subject of numerous investigations on these lines. The demands on pesticidal preparations have increased sharply during recent years: they should not leave harmful residues in the environment, and their toxicity towards warm-blooded animals and man should be low. Amino-acids are of definite interest in this connection, since they are readily biodegradable, and their decomposition products are non-toxic.

The most diverse derivatives of many amino-acids have been investigated as weed-killers. Among all the known physiologically active compounds aryloxyalkanoic acids are the most highly active towards plants. Individual members of this group have found wide practical application as agents in the struggle against weeds (in high concentrations) and as growth stimulants (in low concentrations). Many derivatives of amino-acids have been described, one of the commonest herbicides in this series being 2,4-dichlorophenoxyacetic acid (2,4-D). These derivatives were obtained by reaction between the acetyl chloride and the amino-acid in the presence of sodium hydroxide or pyridine. When the herbicidal effect was tested, 2,4-dichlorophenoxyacetyl-*D*-amino-acids were found to be almost inactive, although the corresponding *DL*- and *L*-derivatives approached 2,4-D in activity[205,206].

Glycine derivatives that are nitrogen analogues of aryloxyacetic acids—*N*-2,4- and *N*-2,5-dichlorophenylglycines, *N*-2,4-dinitrophenylglycine, *N*-*o*- and *N*-*p*-chlorophenylglycines and *N*-phenyl-, *N*-*p*-hydroxyphenyl-, *N*-*p*-carboxyphenyl-, and *N*-1′-naphthyl-glycines—exhibit herbicidal activity. However, replacing the ethereal oxygen in phenoxyacetic acid by an imino-group lowers the activity by factors of 3–5.[205] Glycine often serves as initial compound for the production of herbicides, e.g. aminophosphonate[207] or *N*-phosphonomethylglycines[208].

Derivatives of *N*-benzoylalanine may serve as selective herbicides[209,210]. Novel amino-acid derivatives—*NN*-disubstituted alanines $R_nC_6H_{5-n}N(R'Y(COR''$, where R = Hal, Alk, AlkO, $n = 0-5$, R′ = Alkylene, R″ = Alk, AlkO, Ar, ArOAlkylene, and Y = COOH, *N*-mono- or *NN*-disubstituted NH_2CO—can be used[211] in any way known for herbicides, as solutions, dusts, and wettable powders, alone or mixed with other active components, with or without the use of surface-active dispersants or emulsifiers. A formulation containing a synergistic mixture of the ethyl ester of *N*-benzoyl-*N*-3,4-dichlorophenylalanine and 2,4-dichlorophenyl *p*-nitrophenyl ether has been claimed[212].

Substances used to remove leaves from various cultivated plants—termed defoliants—are closely related to herbicides. Not only compounds involved in the biosynthesis of *L*-lysine—pyridine-2,4-, -2,5-, and -2,6-dicarboxylic acids—but also *L*-lysine itself can form the basis of products that accelerate the fall of leaves from trees[213].

The action of amino-acid derivatives on the germination and growth of a plant depends on whether the latter is di- or mono-cotyledonous[214]. Thus *N*-benzoyl-*L*-aspartic acid and *N*-benzoyl-*L*-valine inhibit the germination of rice, and *N*-α-phthaloylacetyl-*L*-methionine retards that of horseradish. Phenacetyl-α-leucine slows down the early stage in the germination of dicotyledons, but does not affect monocotyledons. The mechanism of such inhibition is regarded as consisting in suppression of the action of lipase: the energy necessary for germination ceases to be supplied from the fats[215].

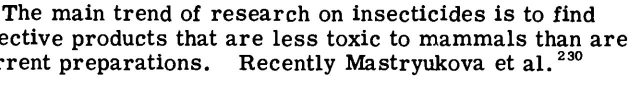
Several attempts have been made to use amino-acids as plant-growth regulators. Tryptophan, being a precursor of indolylacetic acid (a heteroauxin)—a true phytohormone—effectively accelerates the growth of plants[216]. *L*- and *DL*-Methionine, its metal (e.g. calcium and barium) salts, and its aliphatic (e.g. ethyl) esters have proved efficient growth stimulants for cucumbers, tomatoes, kidney beans, apple and orange trees, etc.[217] Watering cucumber seedlings with a solution containing proline together with uracil (each 1%) stimulates their growth and then increases the yield. A more concentrated solution of the same amino-acids (up to 30%) is a fertiliser for rice shoots[218].

Products containing *N*-purin-6′yl-*L*-phenylalanine, -cysteine, or -threonine as active component have been patented as new plant-growth regulators. Preparations based on these compounds prevent the decomposition of chlorophyll, increase leaf size, and accelerate plant growth[219]. Cysteine hydrochloride is a component of a preparation which stimulates the growth of maize, tomato seedlings, and fruit-tree saplings[220].

Many derivatives of amino-acids have been suggested as fungicides. Preparations based on glutamine derivatives $RNHCOCH_2CH_2CH(NHR)COOH$, where R = H or a lower alkyl, have been successfully used against diseases of citrus plants[221]. These products are non-toxic and are ineffective *in vitro*. Threonine and its *N*-formyl and *N*-benzoyl derivatives have the same effect[222]. The dodecyl ester of valine and other higher alkyl (tetradecyl, octadecyl, etc.) esters of various amino-acids have been patented as fungicides and bactericides for field-crop cultivation and horticulture[223,224].

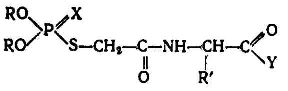
Investigation of the fungicidal action of higher aliphatic *N*-acyl derivatives of amino-acids (their sodium salts and methyl and ethyl esters) and of esters of amino-acids with higher alcohols has shown many of them to be effective *in vivo* against the most common disease of rice *Piricularia oryzae*, although they exhibit no activity *in vitro*; prophylactic use gives the greatest effect[224,225]. Since these amino-acid derivatives have low toxicity and are readily biodegradable, they fully deserve attention as agricultural chemicals that do not pollute the environment. It has been reported[226] that salts of alkylamines with such amino-acids as glycine, alanine, and pyroglutamic acid have proved effective against the diseases of rice. Several *N*-phenylacetyl- and *N*-naphth-1′-ylacetyl-amino-acids (derivatives of glycine, *L*-alanine, *L*-serine, *DL*-methionine, etc.) have been claimed[227] as bases for fungicidal preparations. Copper and nickel salts of amino-acids (valine, methionine, threonine, etc.) have been suggested[228] for use against diseases of citrus plants and rice. These salts are stable in water and have low toxicity towards warm-blooded animals; they are readily obtained by the action of copper sulphate and nickel dichloride respectively on the amino-acid in the presence of ammonia, an alkali-metal carbonate, or a strong base. In another patent[229] copper salts of *D*- and *L*-glutamic and *L*-aspartic acids or mixed copper salts of these acids and di- or tri-basic acids, such as phthalic or benzene-1,3,5-tricarboxylic acid, added to increase the stability of the preparations, are recommended for the struggle against duckweed and pathogenic fungi[229].

Glycine is used in the preparation of the thiadiazinethione fungicide tetrahydro-5′-methyl-2′-thionothiadiazin-3′-ylacetic acid, which satisfactorily suppresses nematodes, fungi, and weeds[204]:



The main trend of research on insecticides is to find effective products that are less toxic to mammals than are current preparations. Recently Mastryukova et al.[230]

have made detailed studies on a novel type of selective insecticides and acaricides comprising derivatives of phosphoro-thiolic and -thiolothionic acids containing residues of amino-acids, their esters, and their methylamides



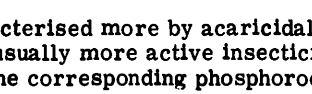
$X{=}O, S$; $Y{=}OH, OC_2H_5, NHCH_3$;

$R{=}CH_3, C_2H_5, NHCH_3$; $R'{=}H, CH_3$, iso-C_3H_7,

iso-C_4H_9, $CH_2C_6H_5$, n-C_3H_7, $CH_2C_6H_4OH$, $CH_2CH_2SCH_3$ etc.

The thio-organophosphorus compounds obtained, containing residues of acylated amino-acid derivatives, are either anticholinesterases (when $X = O$) or are converted into cholinesterase inhibitors by enzymic oxidation ($X = S$). The authors started from the view that the selectivity of such preparations may be based on differences in the sensitivity of arthropods and warm-blooded animals to the action of cholinesterase inhibitors and also on differences in the metabolic processes to which insecticides are subjected in the two types of organisms. In the first case it would probably be very significant whether or not the preparation is complementary to the active centre of the choline esterases or choline receptor. Examination of the physiological activity of these compounds showed that both their toxicity and their selectivity is strongly dependent on the nature of the amino-acids forming part of the molecule. Thus the β-alanine derivative ($R = C_2H_5$, $Y = S$) is a relatively strong insecticide comparable with Thiophos and a quite weak acaricide; the α-alanine derivative ($R = C_2H_5$, $R' = CH_3$, $Y = S$) is a strong acaricide (like Thiophos) and only a moderate insecticide. The corresponding valine derivative ($R = C_2H_5$, R' = iso-C_3H_7, $Y = S$) has still more marked acaricidal properties (twice as strong as Thiophos), but is almost devoid of insecticidal effect[230]. Derivatives of amino-acid methylamides ($Y = NHCH_3$) are more toxic to warm-blooded animals than are the corresponding esters. The selectivity of the action on arthropods is less marked in this series, although all the compounds are somewhat stronger acaricides. Great prospects are opened up for seeking selective preparations in this series[230].

Thio-organophosphorus compounds containing amino-acid fragments do not leave harmful residues in the environment, since the products of their decomposition and metabolism (acids of phosphorus, glycollic and thioglycollic acids, and biogenic amino-acids) are non-toxic. Methods have been developed for synthesising this series of compounds from salts of the corresponding thio-acids of phosphorus and chloroacylated derivatives of various amino-acids[231-233]. The same workers[234] investigated the analogous series of methylphosphonothiolothionates

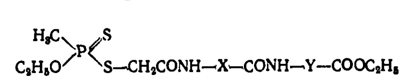


$R{=}H, CH_3$, iso-C_3H_7, iso-C_4H_9, $CH_2CH_2SCH_3$; $X{=}OH, OC_2H_5$

which are characterised more by acaricidal activity. However, they are usually more active insecticides and acaricides than are the corresponding phosphorodithioates and, of course, more toxic to warm-blooded animals. Thus changing from the dithiophosphate derivative of the ethyl ester of glycine to the corresponding dithiophosphonate involves increases in animal toxicity and in acaricidal and aphicidal effects by factors of 5.3, 40, and 30 respectively. The compounds obtained include active insecticides and acaricides having moderate toxicity towards animals[234].

Compounds obtained by adding dialkyl hydrogen thiophosphates to esters of *N*-acylated cysteine also possess insecticidal properties[235-237].

The next step on these lines was to study a series of derivatives of *O*-ethyl hydrogen methylphosphonodithioate containing in the detachable moiety of the insecticide a peptide fragment comprising residues of two amino-acids[238]



X and $Y{=}CH_2$, $CH_2{-}CH_2$, $CH(CH_3)$, $CH(C_3H_7$-iso$)$

on the assumption that formation of a dipeptide group in the side-chain may affect the specificity of sorption of these compounds by increasing the complementarity of the peptide fragment to the active centre of the enzyme[238]. Preparations of this series proved to be inferior to dithiophosphonates containing a single amino-acid residue, both in general insecticidal action and in selectivity, despite the slightly lower animal toxicity. It was concluded that further modification of the products with the accumulation of amino-acid residues was pointless[238].

In view of the rapidly increasing demands on pesticides, and also substantial difficulties involved in introducing them, the Reviewers feel that special interest attaches to the possible use of amino-acids as additives improving the properties of products already in use in agriculture. Thus it has been recommended to add aspartic acid and its salts to organophosphorus, organochlorine, and carbamate insecticides to stimulate the growth of the treated plants and remove the phytotoxic effect of the preparations[239]. Tryptophan stabilises the unstable cyclic *o*-hydroxybenzyl phosphate insecticides[240]. Arginine and its salts increase the solubility of the plant-growth stimulant gibberellin A_3 in aqueous solutions, which considerably expands the boundaries of its possible application[241]. Gibberellins may find practical application for the cultivation of ornamental plants and of grapes[204].

Derivatives of glutamic and aspartic acids may serve as stabilisers for dichlorovinyl dimethyl phosphate (DDVP, Dichlorophos), which during recent years has found widespread application in the fight against various harmful insects and mites in agriculture and public health[242]. Aspartic acid and methionine have been patented as stabilisers in fungicidal compositions[243].

The efficiency of insecticides is often enhanced by combination with attractants, which enable certain types of pests and the loci of infection to be detected in good time, so that measures can be taken to prevent their further dissemination. Use of such mixtures enables the resistance of insects to be overcome, eliminates the need to treat vast areas, diminishes the consumption of insecticides, and lowers the infectiousness of water, soil, and food products, while leaving certain useful species unaffected. The most common food baits are protein hydrolysates, whose mixtures with insecticides are employed against Eastern, Mediterranean, Natal, and Mexican fruit-flies, etc.[244] Addition of the protein hydrolysates increased the efficiency of the insecticides by factors of 3–12. The greatest effect was achieved by adding brewer's yeast or casein and yeast hydrolysates to the insecticides[244]. Many orders of insects, especially Diptera, respond to individual amino-acids, which apparently serve as nourishment. Glutamic acid is an effective attractant for the Mediterranean fruit-fly[244]. Lysine, while being an attractant for mosquitoes, attracts also Mexican, Eastern, Mediterranean, and melon flies. In the campaign against fruit-flies in the Hawaiian Islands it was observed that certain amino-acids are necessary for abundant egg-laying, which is promoted by acid and enzymic hydrolysates[244].

4. Motor-fuel Additives

To prevent the formation of deposits in the carburettors of interna-combustion engines it is proposed[245] to add to petrol 0.0005–0.1% of asparagine derivatives $R'NHCOCH_2.CH(NHR)COOH$, where R and R′ represent secondary and tertiary hydrocarbon radicals up to C_{22}. These compounds possess anticorrosive and dispersive properties, preventing carbonisation and icing[246–248]. Substituted amides of aspartic acid combined with succinates of diethylenetriamine, triethylenetetramine, and tetraethylenepentamine act as ashfree dispersing agents in the form of additives to hydraulic fluids[249].

5. Cosmetics

The buffering action of amino-acids, helping to maintain the normal functioning of the skin (by controlling the pH), the protective effect against bacteria, and the surface-active properties of amino-acid derivatives, as well as the favourable physiological action, have enabled amino-acids to be introduced into cosmetics.

In hair colorants it is recommended that ammonia could be replaced by arginine carbonate[250] or by glycine, *L*-alanine, or valine mixed with ammonium carbonate[251]. The use of 0.1–20% of arginine carbonate in hair-bleaching formulations diminishes the injury to the hairs while achieving the same bleaching effect as with formulations containing 9% of ammonium hydroxide[252].

Amino-acids are used in creams and hair conditioners as nutrients, improving the sheen and conferring softness. An especially favourable effect on hair is exerted by cysteine, on whose derivatives many papers have appeared in this connection. Like thioglycollic acid, cysteine and its derivatives can be used as reductants in cold[253,254] and permanent[255] waving. Derivatives or cysteine $RSCH_2CH.(NHR)COOH$ and methionine $RS[CH_2]_2CH(NHR)COOH$, where $R = HOCH_2CH_2$ or $NH_2CH_2CH_2$, have been proposed in various formulations ensuring a better, grease-free appearance of the hair[256]. Derivatives of cysteine and cysteamine may form the basis for shampoos against dandruff[257]. For the treatment of seborrhoea and other diseases characterised by enhanced secretion of sebum, formulations have been patented containing as active component the compound $RSCH_2CH(NH_2)COOH$ [where $R = (C_6H_5)_3C$, $(C_6H_5)_2CH$, $C_6H_5CH_2$, $HOOC[CH_2]_{2-4}$,[258] $HOOC[CH_2]_{1-2}$, and their salts with inorganic and organic acids)[259] or cystine derivatives[260]. Other patents have appeared on cysteine derivatives that can be used in cosmetics[261–263].

A proposed hair lacquer is based on salts (alkali-metal or amine) of poly-α-amino-acids (polyaspartic and polyglutamic)[122].

Great attention is paid in cosmetology to the so called natural moisturising factor (NMF).[7] It was shown not long ago that skin dryness is due not to loss of liquids from the horny layer, as had been thought previously, but to loss of NMF, which plays an important part in the retention of water. Since the main components of NMF are free glycine, threonine, alanine, aspartic and glutamic acids, serine, and pyrrolidonecarboxylic acid, the use in cosmetics of various amino-acids, their derivatives, and protein hydrolysates is based on control of the normal functioning of the skin. Patents have appeared on the application of enzymic hydrolysates of lactalbumin[264] and plankton[265], and on the use of condensates of amino-acids and sugars as nutrients and moisturising agents[266]. Amino-acids are present as moisturising and antiseptic agents in skin creams and toothpastes[153,154,267].

Aspartic acid and its derivatives have diverse applications in cosmetics[161,268–271]. Thus a salt of the acid can be used in photosensitive pigments for the treatment of keratodermatitis[269]. Addition to cosmetic preparations of aspartic acid or its derivatives together with vitamin B_6 is effective in preventing drying of the skin and for counteracting ageing[270].

A disadvantage of amino-acids with respect to their use in cosmetics is their hydrophilic character, which hinders their imbibition by skin. Their absorption can be improved by combining their use with alkaloids[272].

Surface-active derivatives of amino-acids can be applied fn the most diverse cosmetic products[149,150,154,158,163,268]. Derivatives of glutamic acid

$$M^+[OOCCH_2CH_2{-}CH(NHCOR)COO^-]H$$

where M = Na, Li, $(C_2H_5)_4N$ and RCO is a C_{12-18} aliphatic acyl, possess several cosmetically valuable properties[158]. Apart from the excellent wetting and foaming power, *N*-acylglutamates do not irritate the skin, since their pH of 5.5–6.5 is similar, whereas a solution of ordinary soap is slightly alkaline. They are more effective than the latter for hard water, have an antimicrobial effect, and readily undergo biological degradation without polluting the environment. Sodium acylglutamates are used as foundations or components in shampoos, detergents, etc. They can be usefully added to various domestic synthetic detergents obtained from petroleum or alcohols to mitigate their irritant action on the skin (e.g. in kitchen products). Detergent compositions containing salts of *N*-acylglutamic acids and betaines have a favourable action on skin and possess good cleansing power[159]. Butyl *N*-acylglutamates *L*-$RNHCH(COOC_4H_9)CH_2CH_2.COOC_4H_9$ (where R represents lauroyl, miristoyl, or stearoyl) are recommended for use in lip salve[273].

The Formation of High-temperature Materials by Direct High-frequency Fusion in a Cold Container

V.I.Aleksandrov, V.V.Osikov, A.M.Prokhorov, and V.M.Tatarintsev

A new technology of the formation of high-temperature non-metallic crystals, glasses, and fused ceramic materials is described. It is based on the method of direct induction fusion in a cold container. An account is given of the physical foundations of the technology and the technological apparatus is described. The possibilities and advantages of the new technology in the synthesis of pure high-temperature compounds in melts, in the growing of single crystals of oxide compounds, and in the preparation of high-temperature glasses and polycrystalline fused ceramics are demonstrated. The properties of the new materials are described. The bibliography includes 83 references.

I. INTRODUCTION

Single crystals, glasses, and fused ceramic materials based on non-metallic high-temperature compounds are widely used in modern engineering and industry. The components of optical apparatus, the working elements of lasers and masers, the refractory components of metallurgical apparatus and glass furnaces, the elements of electrothermal devices, electrodes, and insulating elements of magnetohydrodynamic current generators represent a by no means complete list of the applications of high-temperature non-metallic materials. In this review the term "high-temperature materials" is understood to include not only materials capable of operating at high temperatures (1500° C and above) but also materials obtained at a high temperature regardless of the temperature at which they are subsequently employed. Materials of this type include single crystals, glasses, and polycrystalline ceramics based on oxides, fluorides, nitrides, borides, and certain other compounds.

The technology of high-temperature materials is an independent branch of engineering with its own methods, apparatus, and unsolved problems. The latter include (1 the formation of new single crystals, glasses, and fused ceramics requiring for this purpose temperatures in excess of 2000° C, necessitating the development of fundamentally new technological processes; (2) the formation of single crystals with an ideally homogeneous crystal structure; this condition requires that the technological processes be performed with parameters effectively stabilised over a long period; (3) the formation of single crystals, glasses, and fused ceramics with high chemical purity; thus the majority of laser crystals and glasses must not contain admixtures of iron, copper, certain lanthanides, and certain other impurities in amounts exceeding $10^{-4}\%$, while glasses for optical fibre connectors must not contain certain optically active impurities in amounts greater than $10^{-6}\%$; this condition necessitates the development of special "pure" technological processes in which the initial specially pure reagents are not contaminated; (4) the formation of materials under specific oxidation-reduction condition; (5) the formation of such materials in large amounts with the minimum expenditure of natural resources—energy, water, etc., and also with the minimum amount of waste.

A particular difficulty faced by technologists does not arise from each of the individual problems described but from their combination. For example, a high temperature can be readily achieved in industrial arc fusion processes, but in this method of fusion it is difficult to maintain the chemical purity of the material, to establish the necessary oxidation-reduction conditions, and to ensure the stability of the crystallisation process. On the other hand, fusion with the aid of radiation beams fully ensures a high purity of the material and the required oxidation-reduction conditions, but it is impossible to obtain large amounts of the material. Other existing technological processes which serve as the basis of the synthesis of high-temperature materials can also be shown to have weak features. We shall examine, for example, the existing process for the growing of high-temperature single crystals. Single crystals are most frequently grown from the melt by the Czochralski method[1] involving drawing on a seed. An amount of the crystallisable substance is placed in a metallic crucible heated in a resistance furnace or by high-frequency currents. The crucible plays the role not only of the container but also of a heating body from which heat is transferred to the melt. This method yields many crystals used in modern engineering—the yttrium–aluminium garnet, ruby, leucosapphire, lithium niobate and tantalate, the gadolinium–gallium garnet, lanthanum fluoride, and many others. A weak feature of this technology is the crucible, the choice of materials for the manufacture of which is very limited. These are platinum-group metals: platinum (m.p.1769° C), iridium (m.p.2450° C), and platinum–rhodium alloys (m.p. 1769–1950° C). In a few instances it is possible to employ molybdenum (m.p.2700° C), tungsten (m.p.3400° C), or graphite. The material of the crucible must be more refractory than the material contained in it and it must not interact chemically with the melt and the atmosphere surrounding it. Unfortunately, none of the materials enumerated above possesses the entire set of the necessary properties and this creates serious obstacles to the development of the technology of high-temperature crystals. An analogous problem arises also in the technology of glasses and fused ceramic materials.

We believe that the technology discussed in this review may claim to provide a general solution to the problem of the formation of high-temperature materials from the melt. It is based on the method of direct high-frequency fusion in a cold container. The process includes three principal elements: (1) induction fusion of the substance by high-frequency currents; (2) the retention of the melt in a cold shell having the same composition as the melt; (3) initiation of the process by a special procedure—start fusion.

These elements have been proposed independently at different times by different investigators. Thus it was suggested in 1905 that metals be fused in a solid shell of the same metal[2]. The idea proved so fruitful that it initiated the wide-scale incorporation of garnissage fusion in pyrometallurgy. An electric arc, an electron beam, or a plasma flame were suggested as the energy sources for the fusion of the metal[3]. Induction fusion of the metal in a cold container was proposed later[4,5], but, for reasons which will be described below, this procedure was not introduced on a large scale. Attempts were also made to employ high-frequency fusion in a garnissage in order to obtain semiconductors[6,7]. The idea of employing induction heating in a shell of the solid phase also for high-temperature electrically non-conducting or weakly conducting (in the solid state) materials arose a comparatively long time ago. In 1961 Monforte[8] achieved the fusion of ferrites: Clark and Chapman[9] described the preparation of crystalline uranium dioxide blocks; the relevant patents have been published[10,11]. In the USSR an attempt of this kind was made[12] to obtain crystals of iron-containing garnets.

In the middle 1960's studies designed to create the technology of high-temperature materials based on direct high-frequency fusion, the development of the necessary apparatus, and the synthesis of individual materials were begun at the Lebedev Physical Institute of the USSR Academy of Sciences[13-15]. The first apparatus for the fusion of high-temperature non-conducting (in the solid state) substances become available at the Physical Institute at that time and the fundamental characteristics of the process were understood. At the same time the search was begun for conditions corresponding to the fusion and crystallisation of compounds of different classes fluorides, halides, oxides, and complex oxide compounds. The conditions for the preparation of single crystals, glasses, fused ceramic materials, including multiphase compositions, were investigated. Ruby and leucosapphire single crystals, grown by drawing on a seed became available; single crystals of stabilised cubic zirconium and hafnium dioxides (fianits) were obtained for the first time as well as small single crystals of scandium, yttrium, gadolinium, and erbium oxides. Many fused high-temperature compounds were obtained and their properties proved to be more effective than those of the analogous materials prepared previously by solid-phase synthesis. Among these mention must be made of compounds such as mullite, β-sodium-alumina, yttrium, lanthanum, and other lanthanide chromites, the titanates, zirconates, and hafnates of Group II and III elements, high-temperature glasses, and other materials. The first attempts already showed that the new technology has many advantages.

1. The process temperature has no apparent limitations and may reach 3000° C and above.

2. The absence of contact between the melt and chemically different substances guarantees a high "purity" of the process. The materials obtained have a chemical purity which is at least not inferior to that of the initial components. In many instances the purity actually proves to be higher, because volatile impurities such as the oxides of alkali metals, chlorides, nitrates, sulphates and certain others are burnt off at a high temperature.

3. The processes may be carried out in various gaseous atmospheres: in air, in oxygen, in hydrogen, in neutral gases, and also *in vacuo*, which makes it possible to establish various oxidation-reduction conditions and to carry out oxidative, reductive, or neutral fusion of the materials.

4. The process is very convenient for carrying out chemical reactions in the melt at high temperatures, for example, in the synthesis of complex oxide compounds. Virtually any type of chemical reactions with participation of a melt in both single-phase and heterophase systems can be achieved.

5. The fusion and crystallisation process can be carried out not only periodically but also continuously.

The sum of the above advantages shows that there are good reasons for devising a universal industrial process for the synthesis of high-temperature single crystals, glasses, and fused ceramic materials.

The reports published in recent years have shown that the new technique for the fusion of high-temperature materials is widely used both in the USSR[16] and abroad. For example, it appears that advances have been made in researches of this kind in the USA, where the fusion and crystallisation of zirconium dioxide[17] and certain other high-temperature materials have been achieved at the CERES Company under Wenckus' supervision and at the Bell Laboratories.

II. THE TECHNIQUE OF DIRECT HIGH-FREQUENCY FUSION IN A COLD CONTAINER. PHYSICAL PRINCIPLES, APPARATUS, AND ELEMENTS OF THE TECHNOLOGY

The theory of the heating of materials in an alternating electromagnetic field has been developed in detail[18-20]. Here we shall merely quote the conclusions of the theory, which will assist us in subsequent understanding of the characteristic features of the high-frequency heating of non-metallic high-temperature materials.

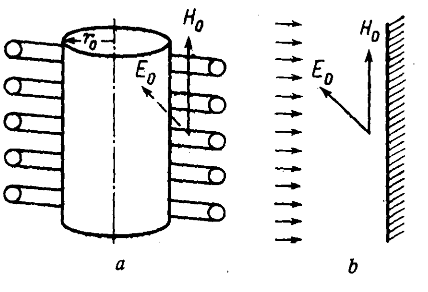

Figure 1. Schematic explanation of the heating of electrically conducting materials by high-frequency currents: *a*) semi-infinite cylinder in a cylindrical electromagnetic field; *b*) interaction of planar electromagnetic waves with a planar semi-infinite object.

Fig. 1 presents a typical scheme which explains the heating of electrically conducting bodies by a high-frequency current. A cylindrical body of the conducting material is in an alternating electromagnetic field with a cylindrical configuration established by a multiturn inductor. The efficiency of the heating of the cylinder depends on the nature of the energy of the high-frequency field absorbed and is determined both by the electrical and magnetic properties of the material, on the one hand, and the frequency of the alternating electromagnetic field, on the other.

In order to derive formulae relating the electric and magnetic field strengths in the material and the energy flux, on the one hand, to the electrical conductivity and the magnetic permeability of the substance, on the other, use is made of Maxwell's equations. The displacement current is neglected assuming that it is small compared with the conduction current. This approximation is undoubtedly valid for metals and is not unduly rough for the class of materials considered here. If the simpler case of the interaction of a planar electromagnetic wave with a planar half-bounded body (Fig. 1*b*) is considered, then, after transformation of Maxwell's equations and the conversion of the vector form into the coordinate form, it is possible to obtain the law governing the decrease of the amplitudes of the magnetic and electromagnetic field strengths:

$$H_{\mathrm{ampl}} = H_0 e^{-\frac{z}{\Delta}} \text{ and } E_{\mathrm{ampl}} = H_0 \frac{\sqrt{2}\, e^{-\frac{z}{\Delta}}}{\gamma\Delta},$$

where H_0 is the amplitude of the magnetic field strength on the surface of the body, z the distance from the surface (depth), γ the specific conductance of the body, and Δ a quantity characterising the attenuation of the amplitudes of E and H; the last quantity is equal to the thickness of the layer in which H_{ampl} and E_{ampl} diminish by the factor e and is called the depth of penetration. It has been shown that

$$\Delta = 5{,}03 \cdot 10^3 \sqrt{\frac{\rho}{\mu_r f}} \ (\mathrm{cm}), \qquad (1)$$

where ρ is the resistivity of the material, μ_r its magnetic permeability, and f the frequency of the electromagnetic field. The flux of the active energy in the body at a depth z also depends on Δ:

$$S_a = H_0^2 \frac{e^{-\frac{z}{\Delta}}}{2\gamma\Delta}. \qquad (2)$$

After substituting $z = 0$ and $z = \Delta$ in this formula, we find that the energy $S_{0a} - S_{\Delta a} = 0.864\, H_0^2/2\gamma\Delta = 0.864\, S_{0a}$ is evolved in a layer of material with a thickness Δ. This justifies the assumption in technical calculations that virtually the entire energy of the high-frequency field is absorbed in a surface layer with a thickness Δ.

We now return to the scheme in Fig. 1*a*. The law governing the attenuation of H, E, and S with increasing depth is derived in the same way as for the planar case (Fig. 1*b*) with the sole difference that the vector form of the equations is transformed into the coordinate form using a cylindrical coordinate system. In the "cylindrical" case the distribution of H, E, and S with respect to the radius of the cylinder at a specified field frequency f is no longer determined by the quantity Δ but by the ratio $r_0\sqrt{2}/\Delta$, where r_0 is the radius of the cylinder and Δ has the same significance as for the planar case. This makes it possible to tabulate data for the depth of penetration of fields into different materials. One should note that the depth of penetration of the electromagnetic wave into the cylinder is determined by the radius of the latter, apart from the properties of the material and the field frequency. One must therefore recall that Δ for a cylinder is not the true depth of penetration. It has been shown that, for $r_0\sqrt{2}/\Delta > 10$, the functions $H(r)$, $E(r)$, and $S(r)$ are of the same type as for the planar case. When $r_0\sqrt{2}/\Delta < 10$, special methods, which have been described in detail[18], must be used to derive the laws governing the distribution of H, E, and S in the cylinder. We shall not examine specific instances of the interaction of the high-frequency field with bodies having different configurations, since we should then inevitably enter the field of technical calculations, which is of only specialised interest (particularly since gross assumptions are made in these calculations, the main one being failure to take into account the finite length of the cylindrical body, i.e. failure to take into account end effects).

Table 1. Specific conductances of certain solid and fused non-metallic materials.

Compound	State	Temp., °C	Specific conductance, Ω cm	Ingot
LiF	melt	900	$1.2\cdot10^{-1}$	21
NaF	melt	1020	$1.9\cdot10^{-1}$	21
KF	melt	900	$2.6\cdot10^{-1}$	21
NaCl	melt	800	$3.3\cdot10^{-1}$	21
MgO	solid	2000	$5\cdot10^{2}$	22
SiO_2	solid	1700	$9\cdot10^{3}$	22
ZrO_2	solid	2000	1	22
Y_2O_3	melt	2430	$5\cdot10^{-2}$	23
Y_2O_3	solid	1500	$3\cdot10^{1}$	79
Al_2O_3	solid	1875	$2.2\cdot10^{4}$	22
Al_2O_3	melt	2200	$1\cdot10^{-1}$	24

In order to assess the possibility of the high-frequency fusion of non-metallic high-temperature materials (oxides, fluorides, halides, etc.), it is necessary to know the electrical properties of these materials in the solid state and in the melt. Since the vast majority of materials of this kind are non-magnetic, $\mu_r = 1$. Unfortunately the available literature data are extremely scanty. Table 1 presents the electrical conductivities of certain solids and fused non-metallic materials[21-24]. Evidently materials of the type in which we are interested have resistivities in the range 0.01–100 Ω cm at temperatures close to the melting point; on fusion, the conductivities of the materials increase, the increase being pronounced in many instances. It is also seen that at low temperatures their resistivities are 10^4–10^{14} Ω cm, i.e. they are effective dielectrics. Fig. 2a illustrates the temperature variation of the resistivity of alumina in the solid (corundum) and fused states, obtained in air[24]. Evidently the resistivity decreased on fusion by more than two orders of magnitude and amounted to 0.1 Ω cm in the melt. Fig. 3 presents a family of $\Delta = (\rho)$ curves for various electromagnetic field frequencies, calculated by Eqn. (1). Using Fig. 3, it is possible to determine the frequencies required to heat the chosen material. For example, a high-frequency generator with a frequency ranging from 500 kHz to 10 MHz should be used for an alumina melt; the depth of penetration then has reasonable values in the range 2.2–0.5 cm. Fig. 3 leads to the conclusion that the range of substances which can be fused by the induction method is restricted to those with resistivities in the melt of approximately 10 Ω cm. Otherwise the required frequencies are outside technically reasonable limits.

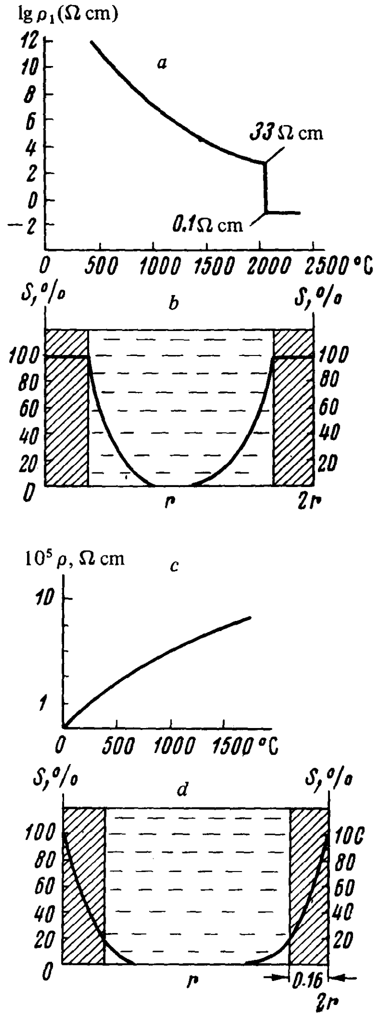

Figure 2. Temperature variation of the resistivity (ρ) and radial distribution of the energy of the high-frequency field (S) absorbed by a two-layer cylinder consisting of solid (outer shaded layer) and liquid (inner region) phases having identical chemical compositions: *a*) alumina; *b*) steel; *c*) Al_2O_3 cylinder, electromagnetic field frequency 5 MHz; *d*) steel cylinder, electromagnetic field frequency 2500 Hz.

The above discussion shows that (1) the melts of the majority of non-metallic high-temperature compounds can be effectively heated by high-frequency currents with the aid of accessible technical means; (2) the heating of these substances from room temperature to the melting point directly by the high-frequency field cannot be achieved.

We shall now consider certain characteristics of the direct high-frequency heating of non-metallic materials in a cold container which follow from the electrical properties of materials of this type. Fig. 2 compares typical temperature variations of the resistivities of a non-metallic material which is a dielectric in the solid state (Fig. 2*a*) and of a metal (Fig. 2*b*). The fundamental difference between these two types of materials is clear from the figures: in the first case the resistivity of the melt is lower by several orders of magnitude than that of the solid phase, while in the second case the resistivity of the melt is higher than that of the solid metal. Figs. 2*c* and 2*d* illustrate schematically for the two instances the nature of the absorption of the energy of the high-frequency field by a double-layer cylinder, the outer shell of which consists of the solid phase and the inner part is occupied by a melt having the same composition as the shell. This model reflects exactly the situation in which we are interested. Since the resistivity of the solid shell is lower than that of the melt in the case of the metal, it follows that, in conformity with Eqns. (1) and (2), it absorbs the major part of the energy of the high frequency field and shields the melt (Fig. 2*d*). The situation is different for a material with a "descending" temperature variation of the resistivity. Here the solid phase is in essence "transparent" to the electromagnetic field and does not prevent its penetration into the melt, while it is not itself heated by the field (Fig. 2*c*). Thus direct induction heating in a cold container is, as it were, specially designed for materials with a descending electrical resistivity–temperature curve and is relatively unsuitable for metals. In direct high-frequency fusion the metal melts in its entirety and a solid shell between the melt and the cold container does not remain, which naturally deprives this technique of its attractive feature—chemical purity; high-frequency fusion of non-metallic materials is free from this disadvantage. The "favourable" distribution of the power generated always leaves, between the melt heated to a high temperature and the cooled container, a layer of the solid phase unheated by the field where the entire temperature difference is "quenched". As will be shown below, this finding makes direct high-frequency fusion of non-metallic materials in a cold container energetically convenient.

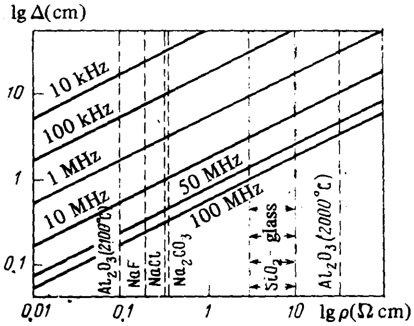

Figure 3. Family of $\Delta = \varphi(\rho)$ curves for various frequencies of the electromagnetic field.

Thus the high-frequency fusion of refractory dielectrics can be divided into two components: the heating of the material from room temperature to the melting point (which cannot be achieved directly by the induction method) and the maintenance of the substance in a fused state by supplying the energy of the high-frequency field. We shall examine the first component, the so called start fusion process (Fig. 4*a*). In the first place we shall determine the amount of the initial solid material which must be fused to enable the resulting melt to be heated by the field and grow in volume. A condition for its "viability" is the inequality

$$V \cdot P > K(T_m - T_0)\pi D^2, \tag{3}$$

where V is the volume of the starting melt, P the power absorbed by unit volume of the melt, K the coefficient of heat transfer from the melt to the heat exchanger (the cooling water), T_m the temperature of the melt, T_0 the temperature of the heat exchanger, and D the drop diameter. The heat of the phase transition is excluded from consideration, because the fusion process can be carried out in principle as slowly as desired. For a drop diameter D much smaller than the internal diameter of the container, the assumption that the specific absorbed power P remains constant is not unduly approximate. We obtain from formula (3) the expression

$$D > \frac{6K}{P}(T_m - T_0). \tag{4}$$

The above inequality shows that, for the specified electromagnetic field strength and electrical conductivity of the melt (they determine the value of P), the critical dimension of the drop of the melt depends mainly on the thermally insulating properties of the solid phase. Thus, having satisfied condition (4), we obtain a "viable" drop of the melt, which absorbs the energy of the high-frequency field and increases in size as a result of the fusion of the surrounding solid phase.

In order to answer the question whether the fusion process proceeds until the complete fusion of the entire solid phase or ceases at some stage, we shall examine the condition for phase equilibrium, i.e. for the spatial stability of the interface between the melt and the solid phase (Fig. 4*b*). Phase equilibrium implies that the temperature at any point on the interface is equal to the melting point (T_{fu}) and does not vary with time. The amount of heat given up by the melt to the solid wall (on the assumption of complete mixing of the melt) is $Q_1 = \alpha_1(T_m - T_b)F\tau$, where α_1 is the heat transfer coefficient, T_b the temperature at the boundary between the solid and liquid phases, F the heat transfer surface area, and τ the time. The amount of heat transferred through the layer of the solid phase with a thickness σ_s and a thermal conductivity λ to the heat exchanger is $Q_2 = (\lambda/\sigma_s)(T_b - T_0)F\tau$. In the steady state $T_b = T_m$ and $Q_1 = Q_2$. We then obtain $\alpha(T_m - T_{fu})(\lambda/\sigma)(T_m - T_0)$ or

$$\frac{\lambda}{\sigma_s \alpha} = \frac{T_m - T_{fu}}{T_{fu} - T_0}, \tag{5}$$

where $T_m - T_{fu} = \Delta T$—a quantity characterising the superheating of the melt. When $\Delta T \to 0$, we have $\sigma_s \to \infty$, which implies that the melt must be superheated in order to maintain the phase equilibrium. We shall assume that λ, α, and T_0 are independent of σ_s, whereupon

$$\sigma_s \Delta T = \text{const}. \tag{6}$$

It is seen from Eqns. (5) and (6) that the system responds by a decrease or increase of the thickness of the layer of solid phase to an increase or decrease of T_m. On the other hand, the complete fusion of the solid phase requires infinite superheating. Furthermore, any processes in the solid shell leading to a change in its thermal conductivity (for example sintering) disturb the phase equilibrium and require a change either in the temperature of the melt or in the thickness of the solid layer. The state of phase equilibrium is also influenced by the nature of the mixing of the melt, which determines the coefficient of heat transfer. The requirement for superheating, which determines the very existence of the melt in the scheme under consideration, constitutes a marked difference between the cold container and the heated crucibles usually employed: in the latter case the temperature of the melt may be made as close as desired to that of the melting point and in certain cases the melt is actually supercooled. The inevitable superheating of the melt in the cold container has certain important consequences in its crystallisation, particularly in the growing of single crystals (see below).

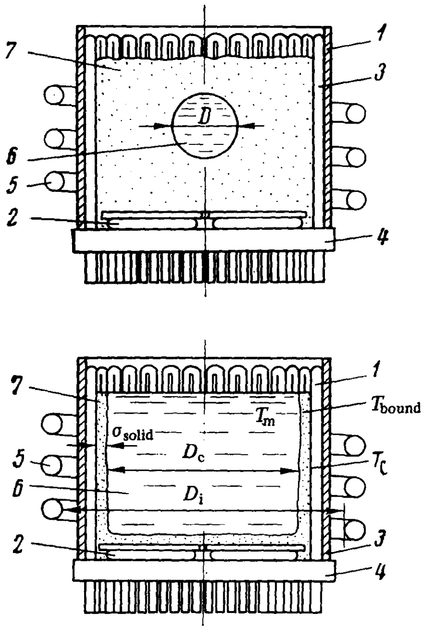

Figure 4. Schematic illustration of fusion (*a*) and of the state of equilibrium in the melt–solid system (*b*) in a cold container: 1) tubular water-cooled element; 2) water-cooled bottom; 3) insulating quartz cylinder; 4) retaining ring made of an insulating material; 5) inductor of the high-frequency generator; 6) melt; 7) charge.

We shall discuss further yet another important characteristic of the cold container–solid shell–melt system. We shall examine how the system responds to a decrease in the power ΔP absorbed by the melt (caused, for example, by the uncontrolled decrease of the power of the high-frequency generator). The decrease of the power immediately causes a decrease of T_m, which disturbs the phase equilibrium: the thickness of the solid shell begins to increase—the ratio of the diameter of the charge (D_c) to that of the inductor (D_i) diminishes. Under these conditions, either (1) a new state of equilibrium is established with a larger value of σ_S or (2) uncontrolled complete setting of the melt takes place. The point is that, with increase of σ_S, there is a simultaneous diminution of the diameter of the region of the melt which constitutes the charge in the inductor of the high-frequency generator; the coupling with the inductor diminishes at the same time. On the other hand, with increase of the thickness of the solid shell, the thermal insulation also increases and the heat flux from the melt in the cold container diminishes. The laws governing the decrease of the power absorbed by the melt and of the heat losses under these conditions are different. Figs. 5*a* and 5*b* represent schematically two possible versions of the response of the system to the decrease of the power of the generator. The result is to a large extent determined by the thermal conductivity of the solid phase: the higher the thermal conductivity the less stable the system. The occurrence of the spatial instability of the phase boundary during high frequency fusion of high-temperature non-metallic materials is a new factor which specialists working in the field of the high-frequency heating of metals did not encounter. This effect has a major influence on the apparatus and technological conditions in the fusion and crystallisation of specific high-temperature materials.

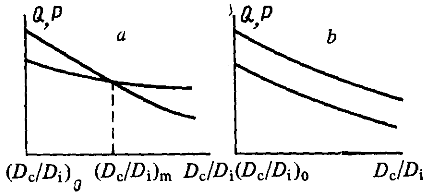

Figure 5. Response of the melt–solid phase system in a cold container to the decrease of the power of the generator: *a*) stable system; *b*) unstable system (D_m = melt diameter; D_i = inductor diameter).

Several types of apparatus have been developed at the Lebedev Physical Institute of the USSR Academy of Sciences for the direct high-frequency fusion and crystallisation of non-metallic high-temperature materials[13-15]. Each type of apparatus consists of a high-frequency generator with an oscillatory power ranging from 10 to 80 kW and a frequency from 1 to 13 MHz, a working chamber with water-cooled walls, a container, and a system for the stabilisation of the power of the generator and of the flow of cooling water. The high-frequency generator can be used in conjunction with both single-circuit and two-circuit schemes. Its characteristic feature is that it must be capable of stable operation at the maximum potential under the conditions of sharp changes in the charge: virtually in the range from its complete absence (at the start fusion stage) to the maximum charge. The working chamber serves to establish the required atmosphere (inert gas, reducing, or oxidising atmosphere). In order to maintain a constant average temperature of the melt and the phase equilibrium in the melt–solid shell system, devices stabilising the anodic potential (or the heater of the generator electronic valve) and the stream of cooling water are used.

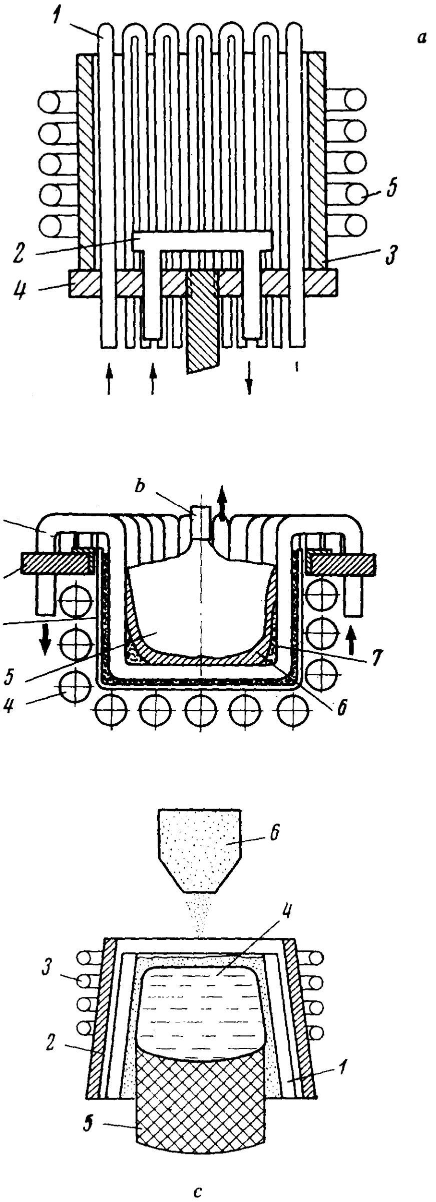

Figure 6. Design of cold containers: *a*) multielement cold container for the periodic fusion and crystallisation of refractory non-metallic materials [1) tubular water-cooled element; 2) water-cooled bottom; 3) insulating quartz cylinder; 4) insulating Micalex ring; 5) inductor of high-frequency generator]; *b*) multielement cold container for the periodic fusion and crystallisation of refractory non-metallic materials with a thermal conductivity in the solid state exceeding 6 W m^{-1} K^{-1} [1) tubular water-cooled element; 2) insulating Micalex insulating ring; 3) insulating quartz beaker; 4) inductor of high-frequency generator; 5) melt; 6) layer of crystallised melt; 7) charge; 8) growing crystal]; *c*) multielement cold container for the continuous fusion and crystallisation of refractory non-metallic materials [1) double-walled water-cooled conical container; 2) insulating quartz shield; 3) inductor of high-frequency generator; 4) melt; 5) block of crystallised material; 6) hopper with charge].

The design of the cooled container must meet a number of special requirements. In the first place, since the energy source is outside the container, the latter must be "transparent" to the energy. This means that it must be either made of a dielectric material or, when the container is made of a metal, must have slits which prevent the closure of circuits generating circular currents. Furthermore, the container must be made of a material with a high thermal conductivity and must be vigorously cooled with water (or another heat

exchanger). Several types of containers made of dielectric materials (quartz glass) and various metals (copper, aluminium) were developed at the Physical Institute.

The containers illustrated in Fig. 6 proved to be the most suitable for the fusion and crystallisation of refractory non-metallic materials. One of them (Fig. 6*a*) makes it possible to fuse and crystallise a large number of different materials (Tables 2 and 3). In order to obtain crystals of materials whose thermal conductivity in the solid state is higher than 6 W m^{-1} K^{-1}, it is more useful to use a container of a different type (Fig. 6*b*), which makes it possible to supply energy not only from the lateral surface of the melt but also from below. The container illustrated in Fig. 6*c* is designed for the continuous fusion and crystallisation of materials.

Direct experimental determination of the efficiencies of the above types of apparatus showed that 50–60% of the electrical power supplied to the apparatus is evolved in the container with the melt.

The technological fusion process includes three stages. It begins with the formation of the "seed" melt, which, as stated above, can be achieved only by means of an additional source of heat. The following procedures have been used for this purpose: (1) fusion by supplying radiant energy; (2) fusion with the aid of flames; (3) heating and fusion by means of an electric arc; (4) fusion by introducing into the test substance an extraneous conducting material—the heating body. The most convenient method for the fusion of oxide and certain other types of materials is start fusion based on the use of small amounts (usually several grammes) of a metal whose atoms enter into the composition of the material to be fused: aluminium in the case of alumina, yttrium in the case of yttrium oxide, etc.[14] When the high frequency generator is switched on, the lumps of metal introduced into the charge are heated by the energy of the high frequency field and melt the surrounding charge. As fusion proceeds, the metal is oxidised by atmospheric oxygen and the resulting oxide mixes with the melt without contaminating it. After the critical volume of the starting melt has been exceeded under the influence of the high-frequency field, the entire charge gradually melts with the exception of the layer in contact with the cooled walls of the container. Fresh portions of the charge are added to the melt until the attainment of the required volume. This is the second, transitional stage of the process. As the charge melts, equilibrium is established, which may be maintained indefinitely. This is the third stage of the fusion process. When the high frequency generator is switched off, rapid mass crystallisation or vitrification of the melt takes place and polycrystalline ingots or glasses are obtained. On slow directed crystallisation of the melt by the gradual decrease of the power of the generator or slow lowering of the container with the melt relative to the inductor, it is possible to obtain large single-crystal blocks. Single crystals can also be obtained by drawing on seeds. The crystallisation and glass formation processes will be described in greater detail below in the sections devoted to specific materials.

III. THE COLD CONTAINER—AN EFFECTIVE CHEMICAL REACTOR

The most important element of the technology of high-temperature materials is the chemical synthesis of the compounds, since the majority of the materials are complex compounds: complex oxides, oxygen-containing salt-like substances, complex fluorides, and mixed or simple compounds into which admixtures have been introduced. In order to obtain single crystals, a glass, or a ceramic material, it is necessary to synthesise initially the required compounds from simple starting materials. As a rule, the synthesis is carried out by the method of solid-phase reactions. For this purpose, the starting materials in the form of finely dispersed powders are carefully mixed and then heated at a temperature below the melting point of the reaction product. The temperature is usually 0.5–0.7 of T_{fu}. The mechanism of chemical reactions in the solid phase is complicated[25]. However, regardless of the details, the diffusion of atoms of one of the components (or those of both components) through a layer of the solid reaction products is an inevitable stage. Diffusion coefficients in solids are usually small (10^{-6}–10^{-12} $cm^2 s^{-1}$), so that diffusion is a bottleneck in the solid-phase reaction, restricting its velocity.

Owing to the low rate of solid-phase reactions, the synthesis is long and it is difficult to bring the process to completion, so that the reaction product contains as a rule an admixture of the unreacted components, i.e. it is not homogeneous. In reactions in melts, diffusion is no longer a "bottleneck", because, firstly, its rate in liquids is much higher than in solids and, secondly, liquids can be vigorously stirred either forcibly or by convection, as a result of which the rate of reaction increases still further. Furthermore, liquid reaction products can be subsequently crystallised and their chemical purity and structural perfection can be thereby improved. Despite its obvious advantages, the synthesis of high-temperature compounds in the melt, particularly when compounds with $T_{\text{fu}} \approx$ 2000°C are concerned, is used to a very limited extent. One can mention only a few studies where synthesis in a melt was carried out using a solar furnace[26,27], a rotating plasma furnace[28], or arc furnaces[29].

As already pointed out in the introduction, a cold container in which the melt of the initial substances or reaction products is heated by high-frequency currents can serve as an extremely universal and at the same time "clean" high-temperature chemical reactor. Using this technique, we were able to synthesise many complex oxides. Together with the reaction equations, these compounds are listed in Table 3. Most of the reactions enumerated are coupling reactions and take place in a homogeneous system. However, some of these are of the combined type: together with the interaction of the liquid components, there is a heterogeneous reaction involving the components of the gaseous atmosphere. A relevant example is provided by the solid solution of zirconium and hafnium dioxides which were synthesised[15] and then stabilised by lanthanide or variable-valence transition metal oxides. The rate of the reaction and the form of its products vary as a function of the composition of the gaseous atmosphere. Another example of a combined reaction is the synthesis of solid solutions of yttrium, lanthanum, and other lanthanide chromites with an admixture of magnesium, calcium, strontium, and barium chromites. Depending on the atmosphere, the electrical conductivity of these substances varies sharply.

The study of the kinetics of coupling reactions in melts showed that the chemical interaction of the initial components proceeds at a rate equal to the rate of solution of the particles of the solid components (lumps) in the melt of the reaction products, i.e. actually at the rate of fusion. The rate of fusion in typical instances is 0.1–1.0 kg min^{-1}, depending on the superheating of the melt, its viscosity, and the heat of the phase transition on fusion of the components. Thus the homogeneous chemical equilibrium in the systems which we investigated is established over a period ranging from several seconds to several minutes. The study of the reaction products by X-ray diffraction, microscope, electron microscope, and spectroscopic methods has invariably shown that, for a strictly stoichiometric composition of the initial mixture of components, the content of the latter in the final product does not exceed 0.01–0.1 vol.%. The kinetic curve for the synthesis in the melt (curve *2*) is compared in Fig. 7 with the corresponding curve for the solid-phase synthesis (curve *1*); the comparison evidently favours the synthesis in the melt.

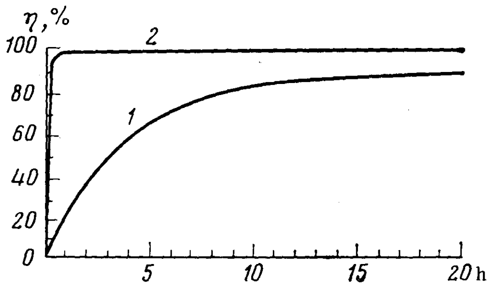

Figure 7. Kinetic curves (yield of reaction product η plotted against time): 1) for reactions in a mixture of three solid phases: $CaCO_3 + Fe_2O_3 \rightarrow CaFe_2O_4$; 2) for the reaction in the melt[25] $CaO + ZrO_2 \rightarrow CaZrO_3$ (the authors' data).

The situation is somewhat more complex in heterophase reactions, where the fused substance reacts with the gaseous atmosphere. Here it is necessary to examine two limiting cases.

(1) The active component of the gaseous atmosphere is insoluble in the melt. In this case the contact surface is restricted to the open surface of the melt. The rate of reaction is limited by the diffusion of gas molecules through the interface and the diffusion of reaction products in the bulk of the melt if the melt is not stirred or if the rate of stirring may be neglected. The viscosity of the melt therefore plays an important role here. The dependence of the rate of equilibration on the viscosity of the melt is clearly revealed when the rates of combustion of the starting metal and the reduction products in melts comprising lanthanum oxide, mullite ($3Al_2O_3.2SiO_2$), and the glass $La_2O_3.Al_2O_3.6SiO_2$ are compared. The viscosity of the melt increases sharply on passing from La_2O_3 to $3Al_2O_3.2SiO_2$ and particularly to a glass. In full conformity with this finding, the rates of combustion of metallic aluminium and the reduction products dispersed in the bulk of the melt are very different. Aluminium is combusted in 5–10 min in the La_2O_3 melt and in 15–20 min in the mullite melt; in a glass melt aluminium is not combusted after 10 h at 2000° C.

(2) The active component of the gaseous atmosphere is soluble in the melt; the rate of the heterophase reaction is then no longer limited by the rate of diffusion of the reaction products. An example of heterophase reactions with vigorous dissolution of the gaseous component is provided by the oxidation of the reduction products and metallic aluminium in Al_2O_3, $YAlO_3$, $Y_3Al_5O_{12}$, $MgAl_2O_4$, and certain other melts. It has been established experimentally that the melts of these substances dissolve large amounts of gaseous oxygen[30]. Thus a melt of alumina in contact with air dissolves more than 40 vol.% of oxygen. In this case the heterophase equilibrium is established after 5 min for a volume of the melt of 0.5 litre. When melts crystallise rapidly, the dissolved oxygen is evolved vigorously, the melt "boils", and the solidified block is threaded by a large number of large pores.

IV. THE FORMATION OF SINGLE CRYSTALS. THE GROWING OF LEUCOSAPPHIRE AND RUBY CRYSTALS

The growing of crystals from a melt in a cold container has many characteristic features compared with the usual method where they are grown in heated crucibles (the Czochralski, Stockbarger, Kiropoulos, or zone crystallisation methods). We shall consider these characteristics in connection with the method of crystallisation of the melt.

The Growing of Crystals by Drawing on a Seed

When crystals are grown by drawing on seeds (in the usual version this involves the Czochralski method) the following conditions must be observed: (1) a strictly defined distribution of temperature in the melt and in the crystallisation front must be established, namely the temperatures in the crystallisation front, i.e. in the middle part of the surface of the melt, must be lower than at any other point in the melt and (2) the temperature in the crystallisation front must be effectively stabilised. Convective streams in the melt play a major role in the distribution of temperature. Figs. 8*a* and 8*b* present photographs of the convection patterns on the surfaces of Al_2O_3 and $3Al_2O_3.2SiO_2$ melts in a cold container. The nature of the pattern depends on the generator frequency, the electrical conductivity of the material, the superheating and viscosity of the melt, and its diameter. The first pattern is typical of the majority of melts which we have investigated. The appearance of an irregular pattern, varying with time, is caused by the bulk-phase nature of the heating owing to the comparatively large depth of penetration by the high frequency field.

The required radial temperature gradient and stabilisation of the convection pattern were achieved by increasing the frequency and the diameter of the melt. Fig. 9 presents a plot of the distribution of temperature on the surface of an Al_2O_3 melt 80 mm in diameter at a field frequency of 5.28 MHz. Evidently in this case the radial temperature gradient satisfies the condition for the growing of crystals by drawing on a seed. However, here too the fluctuations in convective streams over a period of time remain significant. The majority of melts which we obtained had a low viscosity and only some of them, whose compositions incorporated glass-forming components such as SiO_2, were viscous. The absence of a convection pattern on the surface of the $3Al_2O_3.2SiO_2$ melt (Fig. 8*b*) is encountered rarely and is due to the high viscosity of the melt.

The possibility of growing crystals by drawing on a seed depends on the temperature of the melt and the thermal conductivity of the crystal. For normal crystal growth from the melt, it is necessary that the temperature of the latter at the crystallisation front, i.e. under the crystal, should be lower than at other points on the surface of the melt (Fig. 10). This requires that the heat loss from the surface of the melt under the crystal (Q_1) should exceed the heat loss from the open melt surface (Q_2). At high temperatures Q_2 is determined mainly by the radiation from the surface. Q_1 for "grey" bodies, such as the majority of refractory crystals at a temperature close to the melting point, is determined by the thermal conductivity of the crystal. Normal crystal growth is possible only for $Q_1 > Q_2$; otherwise uncontrolled crystal growth in the tengential direction begins. This effect is encountered in the growing of high-temperature crystals by the Czochralski method. In the case under consideration the situation is aggravated by the fact that, firstly, the melting points of the materials are in many cases 2000° C and above and, secondly, by the fact that, owing to the very essence of the method, superheating of the melt is needed. All these factors lead to considerable radiation losses from the surface of the melt, the attainment of the condition $Q_1 > Q_2$ is hindered, and uncontrolled tangential crystal growth results.

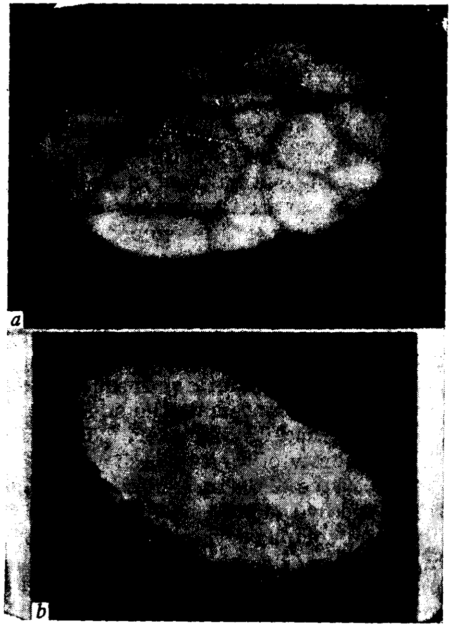

Figure 8. Convection patterns on the surface of the melt: *a*) Al_2O_3; *b*) $3Al_2O_3.2SiO_2$ (mullite).

The Growing of Crystals by Lowering the Crucible

In this case the growing of crystals in a cold container also differs significantly from that in the usual "hot" crucible by the Stockbarger–Bridgman method. The point is that, over the entire interface, the melt is in contact with a polycrystalline phase having the same composition. When the temperature of the melt is reduced, its crystallisation begins immediately at numerous nuclei already present. In this case it is almost impossible to grow a single crystal, since directed crystallisation of a large number of blocks takes place. However, as the growth of crystals proceeds in a large volume of the melt, the number of crystal blocks diminishes owing to selection by virtue of the different rates of growth and, after the complete crystallisation of the melt, the ingot is found to consist of a not unduly large number of single crystals. Thus it is possible to obtain small but quite perfect Sc_2O_3, Y_2O_3, Al_2O_3, and $Y_3Al_5O_{12}$ crystals as well as those of certain other compounds. Best results were achieved when single crystals of stabilised cubic zirconium and hafnium dioxides were grown by this procedure (see below).

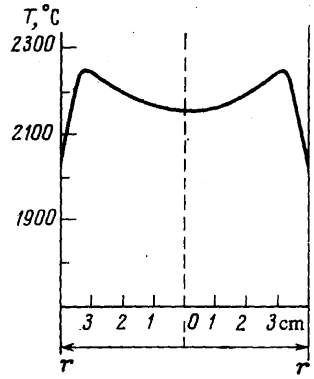

Figure 9. Radial temperature gradient on the surface of an alumina melt.

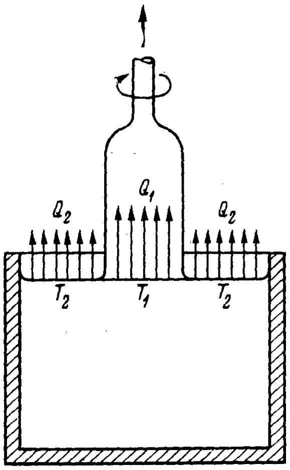

Figure 10. Schematic explanation of the nature of the thermal field in the zone of crystal growth by the Czochralski method.

Growth from Solution in the Melt

When crystals are grown from solutions in melts, the melt is highly superheated in the initial stage. This makes it impossible to employ the cold container technique in its pure form, since the solid shell fuses because of the identity of its composition with that of the melt. The difficulty may be overcome by employing the method used for the first time to grow semiconductor crystals[31], where the solid shell consists of a cylinder, pressed beforehand, of material having the same composition as the crystallising material (Fig. 11). In this case the saturated and superheated melt is in equilibrium with the solid shell. On the other hand, if the temperature at the solution–solid shell interface is non-uniform at different points, there is a possibility of the transfer of material from hotter to colder regions via the gradual dissolution of the shell and crystallisation of the dissolved material on the nuclei in the colder part of the volume (Fig. 11). Thus crystals may be grown from solutions in melts heated to temperatures much higher than are permitted by the platinum crucibles employed in processes of this kind (~ 1400–1500° C). The chemical corrosiveness of the melt does not play a role in this case. In a broader sense this technique can be used not only for crystallisation but also for the synthesis of substances in heated melts via coupling, substitution, exchange, etc. reactions.

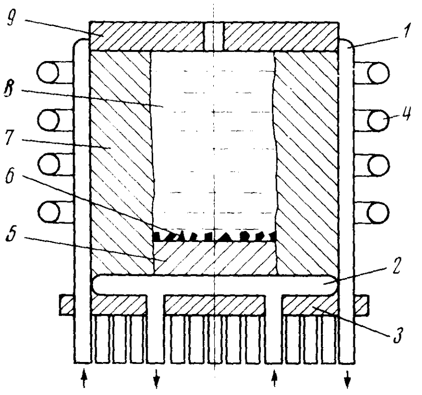

Figure 11. Schematic illustration of crystallisation from solution in a melt in a cold container: 1) tubular water-cooled element; 2) water-cooled bottom; 3) retaining ring of insulating material; 4) inductor of high-frequency generator; 5), 7), and 9) polycrystalline ceramic material having the same composition as the charge; 6) crystals; 8) melt.

The Growing of Sapphire and Ruby Crystals[32-35]

The growing of leucosapphire and ruby crystals in a cold container is to a large degree determined by the following factors: (1) the relatively low electrical conductivity of the Al_2O_3 melt; (2) its low viscosity; (3) the high solubility of gaseous oxygen in the melt; (4) the high thermal conductivity of solid corundum. The first two features lead to the formation of a fluctuating convection pattern generated by the variations in temperature at the crystallisation front. The third feature results in the evolution of oxygen at the boundary with the solid phase during the crystallisation of the oxygen-saturated melt. As a result, under the conditions of small temperature oscillations, small oxygen bubbles are incorporated in the growing crystal and give rise to light scattering regions.

On the one hand, the high thermal conductivity of corundum stabilises the crystal growth, ensuring a rapid removal of heat and preventing tangential growth, and, on the other hand, there is rapid removal of heat from the melts through the solid shell to the cold container, which leads (together with the low value of the specific power absorbed by the Al_2O_3 melt) to spatial instability of the interface between melt and the solid shell and to the necessity for high degrees of superheating of the melt. In order to attain prolonged stable growth of sapphire and ruby crystals, we therefore used the containers and inductors illustrated in Fig. 6*b*. This configuration of the container ensures uniform heating of the melts not only from the sides but also from below[14]. Fig. 12 presents a photograph of a growing sapphire crystal. The crystal diameter was regulated by altering the positions of the mobile shields located over the melt. The rate of drawing was 10–30 mm h^{-1} and the rate of rotation varied from 20 to 140 rev min^{-1}. In those cases where the convection pattern fluctuated markedly planetary rotation of the crystals was achieved by means of a special mechanism. During such rotation, the crystal intersects a large number of regions at different temperatures and the temperature of the front is averaged out; optical inhomogeneities associated with the entrainment of oxygen bubbles accordingly disappear. The crystallisation front in such crystals is virtually planar.

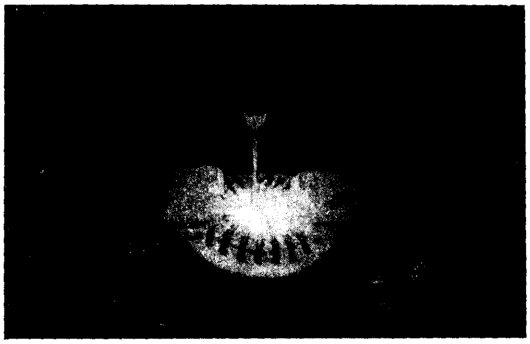

Figure 12. Photograph of a growing sapphire crystal.

Single crystals of sapphire and ruby with different orientations, up to 160 mm long and up to 35 mm in diameter, were obtained in this way. The crystals have characteristics which follow from the specific features of their preparation. The density of the dislocations in the basal plane was 10^2–10^3 cm^{-2}. A planar crystallisation front leads to a uniform radial distribution of chromium atoms in the ruby crystal. The distribution of chromium along the length of the ruby crystals was inhomogeneous: during the drawing process, the concentration of chromium fell, which is associated with the decomposition of chromium oxide in the melt during its superheating. In order to equalise the concentration of chromium over the length of the crystal, the melt was provided with a programmed "supplementary supply" of powdered chromium oxide from a special bunker was used.

V. THE PREPARATION AND PROPERTIES OF CRYSTALS OF STABILISED CUBIC ZIRCONIUM AND HAFNIUM DIOXIDES (FIANITS)

The monoclinic zirconium and hafnium dioxide crystals, obtained from solutions in the melt, have already been described[36]. The preparation of these crystals by the hydrothermal method is described in another communication[37]. In both cases small crystals several millimetres in size were obtained. The high melting points (Table 2), polymorphic transformations, and the high chemical corrosiveness of the melts precluded the growing of the crystals of these oxides from the melt. We developed a method for obtaining crystals of stabilised cubic zirconium and hafnium dioxides (fianits) from the melt[13,15,38]. The initial components (ZrO_2 and HfO_2) were of "specially pure" grade. The stabilising components were magnesium, calcium, strontium, barium, scandium, yttrium, lanthanum and other lanthanide oxides at concentrations up to 40 mole %.

The charge was placed in a water-cooled copper container (Fig. 6*a*), metallic zirconium, hafnium, or yttrium being used for the start fusion. The crystals were grown at 3000° C by the slow lowering of the container with the melt relative to the inductor. The growth time was 8 h. 1.5–6 kg of single-crystal blocks, up to 8 cm long and with a cross-sectional area up to 10 cm^2, was obtained simultaneously on our apparatus (Fig. 13). The crystals grown in this way were then annealed in vacuum or gas furnaces.

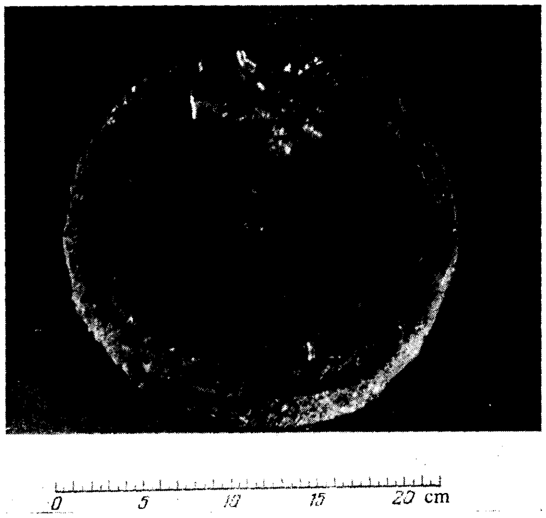

Figure 13. A block of zirconium dioxide crystal.

The Structure of the Crystals

The X-ray diffraction analysis[39] was performed on a DRON-0.5 apparatus using CuK_α radiation. The lattice constant of the crystals of stabilised zirconium dioxide was determined to within 0.001 Å from the (531) peak. The degree of order in the structure was characterised by the ratio of the intensities of the (600) and (200) lines and the normalised widths of the (531) peaks at the level of half their height. According to the results of the X-ray diffraction analysis, the crystals stabilised by X_2O_3 consisted in the main of the stabilised high-temperature crystal form with a cubic lattice of the fluorite structural type. The space group was $^5O_h - Fm3m$. Fig. 14 presents the experimental and calculated lattice constants and the number of vacancies in ZrO_2 as a function of the concentration of the stabilising oxide. The calculation was based on the hypothesis of close-packed spheres of different radii and the following formula was used:

$$d = 2.31\left(R_{Zr} + R_O + \frac{2m\Delta R}{100+m}\right), \qquad (7)$$

where d is the lattice constant, R_{Zr} and R_O are the radii of zirconium and oxygen ions (0.81 and 1.40 Å) respectively, m is the concentration of Y_2O_3 (mole %), and ΔR the difference between the radii of yttrium (0.90 Å) and zirconium ions. Eqn. (7) and the plots in Fig. 14 show that the concentration dependence of the lattice constant is not linear. The diffractometer traces for the specimens with 6 mole % Y_2O_3 contain split lines which, together with the deviation of the lattice constant towards higher values, shows that these specimens include both cubic and distorted tetragonal phases. Naturally, under these conditions the Y_2O_3 concentration must be referred solely to the cubic phase, which results in an increase of its lattice constant to 5.136 Å. The content of the tetragonal phase in the specimens can be estimated from these data: it amounts to approximately 25 vol. %, which agrees with the peak intensities on the diffractometer traces.

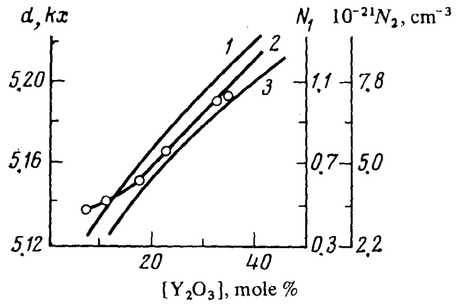

Figure 14. Variation of the lattice constant and of the number of vacancies in a ZrO_2–Y_2O_3 crystal as a function of the Y_2O_3 content: 1) lattice constant d calculated from Eqn. (2); 2) experimental values of d; 3) number of vacancies in the anionic sublattice (N_1—in the unit cell; N_2—in 1 cm^3).

The number of anionic vacancies V per unit cell was determined from the formula $V = 4m/(100+m)$. The plot in Fig. 14*a* shows that each unit cell of the crystal with 33 mole % Y_2O_3 contains one O vacancy, which corresponds to 7.1×10^{21} in 1 cm^3. Fig. 15 presents curves characterising the degree of order in the structure. Evidently the degree of order is a maximum in the presence of 15 mole % Y_2O_3. With decrease of the Y_2O_3 concentration, the degree of order falls sharply owing to the incomplete stabilisation of the cubic structure. With increase of m above 20%, the order in the structure also breaks down owing to the gradual rearrangement of the fluorite type lattice into the lattice of the solid solution of ZrO_2 in Y_2O_3.

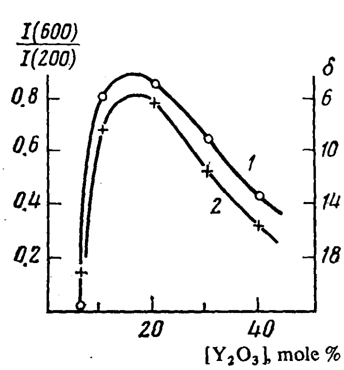

Figure 15. Variation of the degree of order as a function of the Y_2O_3 content: 1) width of (531) line at the level of half its height; 2) ratio of the intensities of the (600) and (200) lines.

Table 4. The densities of zirconium dioxide single crystals as a function of the concentration of the stabilising Y_2O_3 admixture (ρ_1 calculated from X-ray diffraction data and ρ_2 determined by hydrostatic weighing).

$[Y_2O_3]$, mole %	ρ_1, g cm^{-3}	ρ_2, g cm^{-3}	$[Y_2O_3]$, mole %	ρ_1, g cm^{-3}	ρ_2, g cm^{-3}
10.3	5.920	5.910	19.8	5.661	5.655
13.8	5.868	5.863	31.2	5.596	5.603
16.3	5.766	5.800	35.9	5.538	5.543

We calculated the densities of the single crystals from the X-ray diffraction data[39]. These results (ρ_1) together with the experimental values obtained by hydrostatic weighing (ρ_2)[40] are presented in Table 4. The appreciable decrease of the density of the crystals is caused both by the increase of the volume of the unit cell and by the increase of the concentration of the oxygen vacancies. Electron microscope studies, carried out using a "Stereoscan" raster microscope, confirmed that the specimens with 6 mole % Y_2O_3 consist of two phases. The photograph clearly shows inclusions having different structures and orientations. The structure of the crystals with 10–20 mole % Y_2O_3 is homogeneous. The X-ray diffraction data showed that the specimens with 30 mole % Y_2O_3 have a disordered single-phase structure. Nevertheless the electron micrographs showed patterns characteristic of two-phase systems. Presumably a phase having a Y_2O_3 concentration different from the average value, in which the given type of lattice is preserved with somewhat altered parameters, is segregated in these specimens.

Structural Substitutions and Point Defects

The results of the X-ray diffraction analysis and the density measurements showed that the stabilised ZrO_2 and HfO_2 crystals are substitutional solid solutions in which the cations of the stabilising oxide substitute Zr^{IV} ions (atoms). Since we are dealing here with heterovalent substitution, the formation of the solid solution is accompanied by the immediate appearance of several point defects. In terms of structural elements[41], the pattern has the following appearance.

(1) $Zr(Hf)O_2$–AO solid solutions, where A = Mg, Ca, Sr, or Ba. Here the structural elements are as follows: Zr_{Zr}—a zirconium ion in the cationic fluorite sublattice; A_{Zr}—a cation of the stabilising oxide at a site of the zirconium sublattice; V_O—a vacancy at an oxygen subsite of the fluorite sublattice; O_O—an oxygen ion at an anionic lattice site.

The concentrations of the structural elements are related as follows: when the mole fraction of AO in $Zr(Hf)O_2$ is n_1, the fraction of cationic sublattice sites occupied by the A ions is $[A_{Zr}] = n_1$ and the fraction of vacant anionic sublattice sites is $[V_O] = n_1$, which implies that each bivalent ion A introduces one oxygen vacancy.

(2) $Zr(Hf)O_2$–B_2O_3 solid solutions, where B = Sc, Y, La, or Ln. In this case the relative concentrations of the structural elements can be formulated thus: $[B_{Zr}] = 2n_2$; $[V_O] = n_2$; this implies that one oxygen vacancy is introduced by each two tervalent B ions.

Thus stabilisation by the addition of extraneous oxides introduces into the ZrO_2 and HfO_2 crystal lattices a large number of point defects, which greatly influence (as will be shown below) the physical properties of these crystals, particularly the electrical and spectroscopic properties.

Optical Inhomogeneity

The majority of the stabilised ZrO_2 and HfO_2 single crystals which we obtained exhibited a high degree of optical perfection. However, defects were encountered in certain specimens; we shall consider[42] the most typical of these. The optical inhomogeneity of a solid solution is known to be largely determined by the uniformity of the distribution of the solution components, which depends in its turn on the effective partition coefficient. We determined[42] the partition coefficient of Y_2O_3 in the ZrO_2–Y_2O_3 solid solution, and the effective partition coefficient was calculated by the method of Vigdorovich et al.[43] The Y_2O_3 concentration along the length of the crystal was determined by chemical analysis. In the presence of 10 mole% Y_2O_3, the partition coefficient is 1.088.[42]

The study of ZrO_2–Y_2O_3 and HfO_2–Y_2O_3 crystals under the microscope using crossed Nicol prisms revealed a weak inhomogeneity of the extinction caused by internal stresses. The angle between the optical axes was close to 90°. The difference between the refractive indices n_1 and n_2, obtained from the formula $\Delta\lambda = \alpha(n_1 - n_2)$ and a colour nomogram (for a plate thickness $d = 1.5$ mm), was 7.7×10^{-4}. Conoscopic studies showed that isotropic ZrO_2–Y_2O_3 and HfO_2–Y_2O_3 crystals become biaxial and optically positive under the influence of residual stresses, but the degree of deformation is small. The optical indicatrix of the crystals consists of a weakly deformed sphere, slightly extended in the direction of the [011] crystal growth axis. In order to eliminate internal stresses, the crystals were subjected to high-temperature annealing *in vacuo* or in nitrogen. The rate of evaporation of the crystals at different temperatures was determined beforehand and it was found that appreciable evaporation begins at 2100° C. The rates of evaporation at this temperature were $(7-9)\times10^{-6}$ g cm^{-2} s^{-1} for $ZrO_2-Y_2O_3$ and $(3-5)\times10^{-6}$ g cm^{-2} s^{-1} for $HfO_2-Y_2O_3$ (the Y_2O_3 concentration was 10 mole % in both cases). These results showed that it is desirable to carry out the annealing at temperatures not exceeding 2100° C.

The dislocation structure was investigated by the chemical etching method. The most suitable etch is the $2HNO_3 + 3HF$ mixture. The typical density of dislocations in the [111] plane was 5×10^6 cm^{-2}. The etching pits were triangular in shape and were distributed extremely non-uniformly; their density increased markedly at the edges of the single crystal blocks. After annealing, the dislocation density decreased by an order of magnitude.

It has been noted that the crystals become black after annealing *in vacuo* (10^{-3} mmHg) at 2000° C with subsequent rapid cooling (at a rate of 450 K h^{-1}).[42] For low cooling rates, there was no blackening. When the blackened crystals were heated in air at 1200° C, their initial colour and transparency were restored. The blackening is associated with a partial loss of oxygen and the formation of colour centres, the retention of which on rapid cooling is due to the quenching of the reduced state of zirconium. During slow cooling, there is apparently sufficient time for a rearrangement of the lattice and the "reduced" zirconium is reoxidised by atmospheric oxygen.

One of the most characteristic forms of inhomogeneity in the crystals investigated consists of knotlike defects distributed at right angles to the direction of growth. They can be readily seen on shadow-projection patterns recorded by the shining point method[42]. The nature and distribution of the light-scattering particles were investigated using a laser ultramicroscope[42]; the observations were made at an angle of 90° to the direction of the incident beam from the He–Ne laser ($\lambda = 0.63$ μm). In certain $ZrO_2-Y_2O_3$ crystals with an additional admixture of erbium, cerium, and neodymium oxides, microscopic and submicroscopic particles with dimensions ranging from 0.03 to 8 μm were readily seen under the microscope. In highly defective specimens the average density of these particles reached $(0.5-1)\times10^6$ mm^{-3}. Under the influence of prolonged high-temperature vacuum annealing, the scattering particles increase in size and their number diminishes almost by a factor of 2. In $ZrO_2-Y_2O_3$ crystals without an additional admixture light scattering was observed in the form of a Tyndal cone, its intensity depending significantly on the purity of the initial substances and the conditions of crystal growth. Microscope studies showed that in this case the scattering is due to particles with dimensions of the order of 0.1 λ. The Y_2O_3 concentration does not affect the size and number of particles; on the other hand, the addition of a second admixture frequently resulted in the appearance of scattering centres.

Optical Properties

The first measurements of the refractive indices of stabilised ZrO_2 and HfO_2 single crystals were made by Aleksandrov et al.[40] In a later study[42] the refractive indices were measured on a precision goniometer by the prism method; the results of the measurements for $ZrO_2-Y_2O_3$ and $HfO_2-Y_2O_3$ are presented in Table 5, which also illustrates the dependence of the refractive index on the wavelength. It was noted[42] that the refractive index varies along the crystal length, the variation reaching several thousandths, which is due to the non-uniformity of the yttrium oxide concentration.

Table 5. The refractive indices *n* of zirconium dioxide single crystals as a function of yttrium oxide concentration (mole %).

λ, μm	Refractive index *n*			
	$[Y_2O_3]=9$	$[Y_2O_3]=11$	$[Y_2O_3]=15$	$[Y_2O_3]=17$
0.4358	2.2224	2.2101	2.1783	2.1232
0.5461	2.1856	2.1737	2.1434	2.0949
0.5779	2.1790	2.1669	2.1372	2.0897
0.5893	2.1768	2.1653	2.1352	2.0881
0.6328	2.1718	2.1581	2.1287	2.0826

Spectroscopic properties

A characteristic feature of the stabilised ZrO_2 and HfO_2 crystals is a large number of a wide variety of impurities at high concentrations, sometimes reaching 10 mole %. The phase homogeneity of the crystals is unaffected. Lanthanide elements, iron-group elements, chromium, vanadium, titanium, and many others can be introduced into these crystals. Many impurities can exist in several valence states in solid solutions based on ZrO_2 and HfO_2. In essence these solid solutions represent a whole class of substances, which, while retaining their macrostructure and phase homogeneity, can exhibit a variation in their physical properties within wide limits. We shall quote several examples of the spectroscopic properties of solid solutions based on ZrO_2 and HfO_2 with different impurities, illustrating the characteristics of these systems in relation to other impurity-containing crystals used in optics and quantum electronics.

1. Spectra of ZrO_2 and HfO_2 with an admixture of tervalent lanthanides. These crystals are of interest in view of the possibility of their employment in quantum electronics[44–46]. Fig. 16*a* illustrates the combined absorption spectrum of $HfO_2-Y_2O_3-Nd_2O_3$ (0.7 wt.%) at 300 K; Figs. 16*b* and 16*c* illustrate the absorption spectrum of Nd^{3+} ($^4I_{9/2} \rightarrow {}^4F_{3/2}$ transition) and the luminescence spectrum ($^4F_{3/2} \rightarrow {}^4I_{11/2}$ transition) of the same crystal, both recorded at 300 K on a DSF-12 spectrometer. The width of the Stark components of the spectra depends only slightly on temperature and amounts to 100 cm^{-1}. Analogous Nd^{3+} spectra were observed for $ZrO_2-Y_2O_3-Nd_2O_3$ crystals. The measured lifetime of the $Nd^{3+}(^4F_{3/2})$ level was 450 ± 30 μs in both cases. The lasing effect of Nd^{3+} in $ZrO_2-Y_2O_3$ and $HfO_2-Y_2O_3$ was investigated in an elliptical illuminator with an IFP-800 xenon pulse lamp. The resonator consisted of external dielectric mirrors with reflectivities of 99.9 and 97% for $\lambda = 1.06$ μm. A lasing effect was observed for $ZrO_2-Y_2O_3-Nd_2O_3$ crystals at a wavelength of 1.0609 μm and for $HfO_2-Y_2O_3-Nd_2O_3$ crystals at a wavelength of 1.0604 μm. The thresholds of the lasing effects of crystals between 24 and 32 mm long and between 3 and 6 mm in diameter were in the range 7–20 J. The widths of the laser lines were 34 and 38 Å respectively[44]. Thus, in terms of their spectroscopic and laser properties, the crystals of solid solutions based on ZrO_2 and HfO_2 occupy a position intermediate between crystals and glasses, exactly like other crystalline solid solutions

with a disordered structure. It has been noted[47] that the inhomogeneous broadening of the lines in the spectra of lanthanide ions in solid solutions is associated with the number of intrinsic and impurity point defects and increases with increase of the concentration of the impurities introduced.

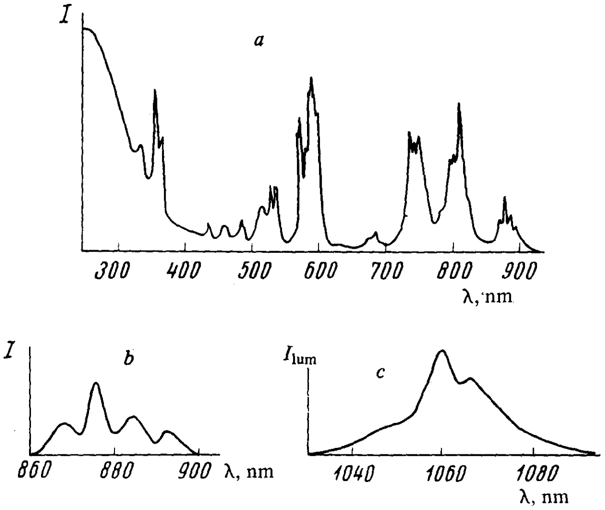

Figure 16. Optical spectra of HfO_2–Nd^{3+} crystals: *a*) absorption spectrum of HfO_2–Y_2O_3–Nd^{3+} (0.7 wt.%) crystals at 300 K: *b*) Nd^{3+} absorption band corresponding to the $^4I_{9/2} \rightarrow {}^4F_{3/2}$ transition; *c*) luminescence spectrum corresponding to the $^4F_{3/2} \rightarrow {}^4I_{11/2}$ transition at 300 K (*I* — line intensity).

The same characteristics of the spectra are typical also for ZrO_2–Er_2O_3–Ho_2O_3 and ZrO_2–Er_2O_3–TmO_3 crystals[46], which are of interest for lasers emitting in the region of wavelengths of approximately 2 μm. Here Er_2O_3 plays simultaneously the role of the stabiliser of the cubic structure and of the sensitiser of holmium and thulium. The lifetimes of the upper working $Ho^{3+}(^5I_7)$ and $Tm^{3+}(^3H_4)$ levels were 6.2 and 1.2 ms at 300 K and 6.6 and 2.5 ms at 77 K respectively. The lifetime of the $^4I_{13/2}$ level of the Er^{3+} ion without Ho^{3+} or Tm^{3+} admixtures was 8.5 ms. In the presence of Ho^{3+} and Tm^{3+} the luminescence of Er^{3+} originating from the $^4I_{13/2}$ level could not be recorded. The lasing effects of ZrO_2–ErO_3 (20 mole %)–Ho_2O_3 (1 mole %) and ZrO_2–Er_2O_3 (20 mole %)–Tm_2O_3 (1 mole %) crystals were observed in an elliptical illuminator with an IFP-2000 xenon pulse lamp. The laser crystals in the form of cylinders 33 mm long and 6.7 mm in diameter were placed in a quartz Dewar vessel with liquid nitrogen. Silver mirrors were deposited on the end-faces of the crystals; the reflection coefficients of the mirrors at the operational wavelengths were 100 and 95%. The lasing effect threshold amounted to 400 J for Ho^{3+} and 420 J for Tm^{3+}; the wavelengths of the lasing effects were 2.115 μm for Ho^{3+} and 1.896 μm for Tm^{3+}, which corresponds to the $^5I_7 \rightarrow {}^5I_8$ and $^3H_4 \rightarrow {}^3H_6$ transitions. For 800 J pumping, a lasing effect appeared in both crystals at $\lambda = 1.620$ μm. The results of the study of these crystals showed that they can find applications in redesigned lasers, since they have much narrower thresholds than glasses for a broad spontaneous emission spectrum.

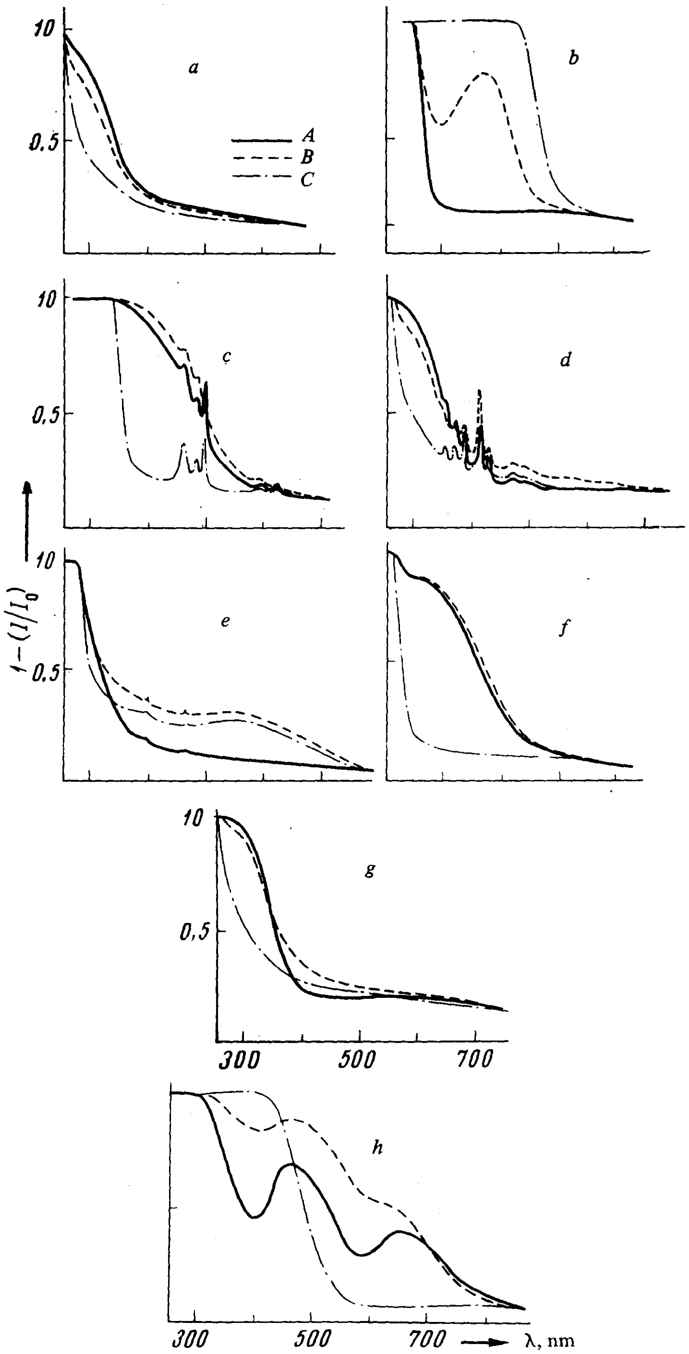

Figure 17. Absorption spectra of ZrO_2–Y_2O_3 crystals grown in air (*A*), after γ-irradiation (*B*), and after vacuum annealing (*C*): *a*) inactivated crystals with $d = 5.47$ mm; crystals activated by the addition of various lanthanides: *b*) Ce, $d = 2.23$ mm; *c*) Pr, $d = 1.90$ mm; *d*) Sm, $d = 0.5$ mm; *e*) Eu, $d = 1.48$ mm; *f*) Tb, $d = 1.61$ mm; *g*) Yb, $d = 4.54$ mm; *h*) Cr, $d = 0.96$ mm.

2. Spectroscopic properties of $Zr(Hf)O_2-Y_2O_3$ crystals with variable-valence impurity ions. In the study of crystals of solid solutions based on ZrO_2 and HfO_2 with impurities it was noted that their optical properties are sensitive to the oxidation-reduction heat treatment conditions and to the effect of ionising radiation. As a rule, these were crystals with admixtures of elements tending to undergo a change in their valence state. These results are of interest not only for spectroscopy but also from the standpoint of the structures of the crystals and the transformations of the structures of point defects. We shall quote data for $ZrO_2-Y_2O_3$ crystals activated by lanthanide and chromium ions[48]. The Ce, Pr, Sm, Eu, Tb, Yb, and Cr concentrations were 0.5 wt.%. The initial substances had the following purities: ZrO_2 was of "specially pure" grade, Y_2O_3 and lanthanide oxides were 99.999% pure, and chromium oxide was of "chemically pure" grade. The absorption spectra were recorded immediately after growing the crystals in air (spectra A) and then after each of the following types of treatment: (1) after exposure to ^{60}Co γ-rays at room temperature up to a dose of 10^7 rad (spectra B); (2) after vacuum annealing at 1800° C (spectra C). The spectra are presented in Fig.17. They evidently vary as a function of the type of treatment of the crystals, the nature of the changes being related to the activator introduced. Only slight changes in the ultraviolet spectrum are observed for the inactivated crystals and crystals with samarium and ytterbium; the changes for the crystals activated with cerium, praseodymium, terbium, europium, or chromium are much more appreciable and they are accompanied by the appearance of new bands or disappearance of old ones in the visible part of the spectrum. The spectrum of the $ZrO_2-Y_2O_3-Ce$ crystal, subjected to additional annealing in an oxidising atmosphere after vacuum annealing, agreed with that of the initial crystal (spectrum A). Heat treatment of γ-irradiated crystals results in the disappearance of bands induced by irradiation; γ-irradiation at 77 K made all the crystals opaque in the visible part of the spectrum. On subsequent heating to room temperature, they were gradually decolorised.

Spectra A

A striking feature of the absorption spectra of the crystals grown in air is the absence of Ce^{3+} bands from the spectrum of $ZrO_2-Y_2O_3-Ce$ and the presence of an absorption band in the region of 3500–6000 K of the spectra of the Pr^{3+} and Tb^{3+} containing crystals together with the absorption bands due to Pr^{3+} and Tb^{3+}. An analogous band in the range 3000–5000 Å appears in the spectra of the γ-irradiated $Y_3Al_5O_{12}-Pr$ and $Y_3Al_5O_{12}-Tb$ crystals, where it is associated with the presence of Pr^{4+} and Tb^{4+} ions[49]. The tervalent Ce^{3+}, Pr^{3+}, and Tb^{3+} ions in the crystals are known to pass readily to the tervalent state[50]. Bearing this feature in mind as well as the oxidising conditions during crystal growth and the favourable conditions for the tetravalent state of the impurity in the ZrO_2 lattice, one may conclude that the entire cerium and part of the praseodymium and terbium are incorporated in the tetravalent state into the crystals of cubic ZrO_2 during the growth process. Under these conditions, admixtures of samarium, europium, ytterbium, and chromium are present as tervalent ions.

Spectra B

γ-Irradiation of crystals containing admixtures of cerium and europium in air leads to the appearance of new bands, compared with spectra A; these are the bands of the Ce^{3+} and Eu^{2+} ions. After irradiation of the crystals containing praseodymium and terbium, the intensity of the band at 3500–6000 Å increases slightly owing to the additional conversion of part of Pr^{3+} and Tb^{3+} into Pr^{4+} and Tb^{4+}. Spectrum B of the crystal with an admixture of chromium does not permit an unambiguous determination of the factor with which the increase of the intensities of the bands present in spectra A is associated. One may assume tentatively that the crystal grown in air contains Cr^{4+} together with Cr^{3+}. The increase of the band intensity can then be attributed to the conversion of Cr^{4+} into Cr^{3+} on γ-irradiation.

Spectra C

It follows from Fig.17 that vacuum annealing has a strong influence on the absorption spectra of the crystals. The band in the range 2600–3700 Å disappears from the spectra of $ZrO_2-Y_2O_3$ crystals and crystals containing samarium and ytterbium; the 3500–6000 Å band disappears from the spectra of crystals with praseodymium and terbium, only the bands characteristic of the lanthanides remaining. By analogy with the $Y_3Al_5O_{12}-Pr$ and $Y_3Al_5O_{12}-Tb$ crystals the absorption band in the region from 3000 Å to the edge of the intrinsic absorption may be identified with the $4f \rightarrow 5d$ transitions in the Pr^{3+} and Tb^{3+} ions. As in spectra B, bands due to Ce^{3+} and Eu^{2+} appear in spectra C of $ZrO_2-Y_2O_3-Ce$ and $ZrO_2-Y_2O_3-Eu$. A new band arises in the region of 4000 Å in the spectrum of the crystal with chromium and the Cr^{3+} bands vanish. All these changes indicate the reduction of activators during vacuum annealing, which is most likely to be associated with the formation of atomic oxygen during this process and its removal from the lattice. Repeated annealing in an oxidising atmosphere restores the original state of the specimens, i.e. the changes occurring on heating the specimens *in vacuo* to 1800° C lead to reversible changes in the nature and concentration of point defects. With increase of the temperature of the vacuum annealing, the changes become irreversible: the crystals blackened *in vacuo* remain turbid after heat treatment in air[42]. The results suggest that the disappearance of the Cr^{3+} bands after vacuum annealing indicates the conversion of Cr^{3+} into Cr^{2+}, while the decrease of the intensity of the 2600–3700 Å band in spectra B and its complete disappearance from spectra C of $ZrO_2-Y_2O_3$, $ZrO_2-Y_2O_3-Sm$, and $ZrO_2-Y_2O_3-Yb$ crystals shows that the band is due to defects having an effective positive charge and containing a captured electron—most probably oxygen vacancies.

Thus the formation of colour centres in the activated crystals of cubic $ZrO_2-Y_2O_3$ solid solutions on γ-irradiation and heat treatment is associated mainly with the capture of charge carriers by activator centres and is determined by their nature. The relatively high radiation stability of $ZrO_2-Y_2O_3$ crystals at room temperature is due to the small depth of the majority of "intrinsic" capture levels in the forbidden gap.

Electrical Properties

It has been established[51] that the ionic type of conductivity predominates in the ZrO_2 ceramics stabilised by CaO, SrO, Y_2O_3, and La_2O_3. Data have been published[52] for the conductivities of polycrystalline zirconium and hafnium dioxide specimens in the temperature range 500–1300° C. Fig. 18 illustrates the temperature dependence of the resistivities of ZrO_2–Y_2O_3 (10 mole %) and HfO_2–Y_2O_3 (10 mole %) single crystals, obtained by the three-probe method[53]. At low temperatures the experimental points lie on curves described by the equation $\rho = 1.6 \times 10^{-4} \exp(1.20/kT)$ for HfO_2–Y_2O_3 (10 mole %) and $\rho = 3.1 \times 10^{-5} \exp(1.12/kT)$ for ZrO_2–Y_2O_3 (10 mole %), where kT is expressed in eV and ρ in Ωcm. The resistivities of various specimens of ZrO_2–Y_2O_3 single crystals having the same nominal compositions differed appreciably in the low temperature region, apparently owing to the different concentrations of defects in the crystals grown under different conditions. If an electric field is applied to a crystal heated to 300° C and above, then a coloured region arises at the negative electrode, which then begins to grow towards the anode. A broad band appears in the absorption spectrum near the intrinsic absorption edge (of the kind obtained after γ-irradiation of the crystals); it can be fairly justifiably assigned to oxygen vacancies which have captured electrons.

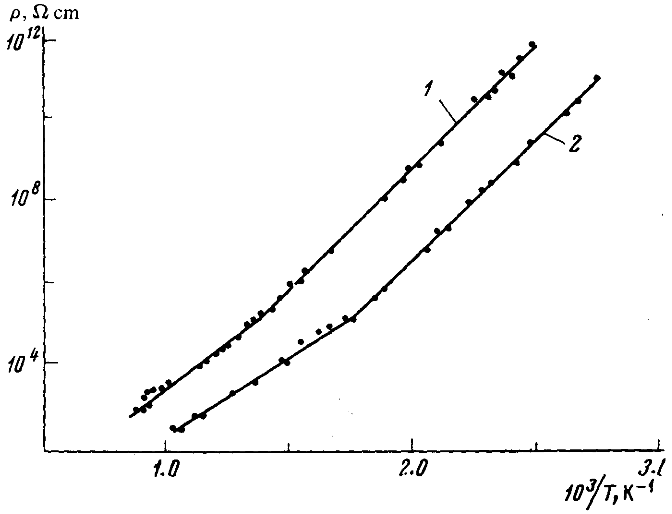

Figure 18. Temperature variation of the resistivity of single crystals: 1) HfO_2–Y_2O_3 (10 mole %); 2) ZrO_2–Y_2O_3 (10 mole %).

Fig. 19 presents the frequency dependence of ϵ tan δ for ZrO_2–Y_2O_3 (10 mole %) and HfO_2–Y_2O_3 (10 mole %), while Fig. 20 shows the temperature dependence of ϵ and tan δ.[53] The relatively small variance of ϵ shows that the polarisation of the crystals investigated has a relaxation mechanism and may be caused by the displacement of weakly bound oxygen vacancies or impurity ions. Fig. 20 shows that ϵ increases with temperature.

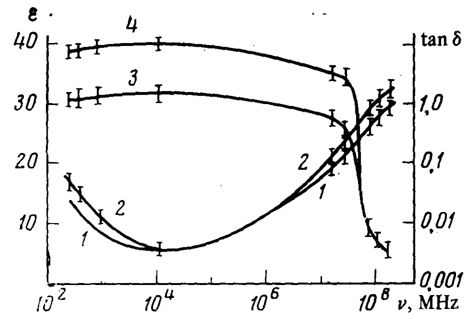

Figure 19. Frequency dependence of ϵ and tan δ for HfO_2–Y_2O_3 (10 mole %) single crystals [1) tan δ; 3) ϵ] and ZrO_2–Y_2O_3 (10 mole %) single crystals [2) tan δ; 4) ϵ].

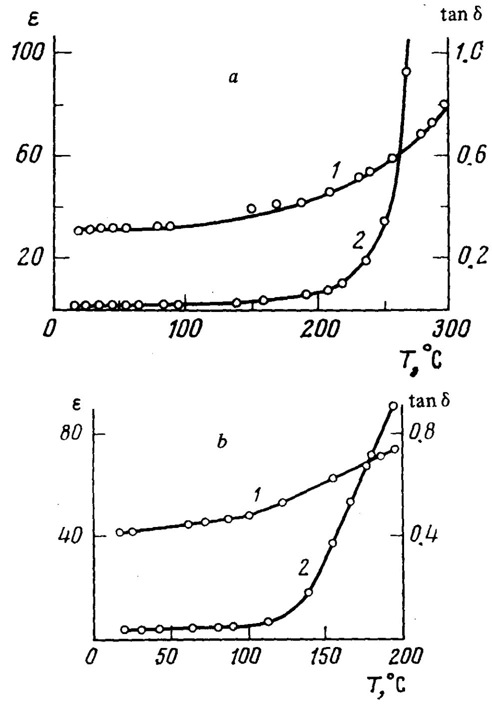

Figure 20. Temperature dependence of ϵ and tan δ for different single crystals: *a*) HfO_2–Y_2O_3 (10 mole %); *b*) ZrO_2–Y_2O_3 (10 mole %); 1) ϵ; 2) tan δ.

The electrical conductivities of zirconium dioxide single crystals have been investigated[54] at temperatures between 800° and 1900° C. The measurements were performed either in a tubular graphite furnace in a vacuum of 0.1 mmHg or in an inert atmosphere by the four-probe method using 50 Hz a.c. on the apparatus already described[55]. The electrical conductivity was measured both with a gradual increase of temperature from 800° to 1900° C and with subsequent stepwise cooling[54]. This made it possible to take into account the influence of the defects associated with the partial reduction of the crystals. Comparison of data for single crystals and ceramic specimens having the same composition showed that the single crystals have a specific conductance greater by a factor of 1.5. Fig. 21 presents data for ternary systems containing 10 mole % of the stabilising impurity and 1 wt.% of one of the lanthanide oxides. Evidently, after the addition of the second admixture, the electrical conductivity increases. It initially rises from cerium to praseodymium and then falls for neodymium and again rises from neodymium to terbium.

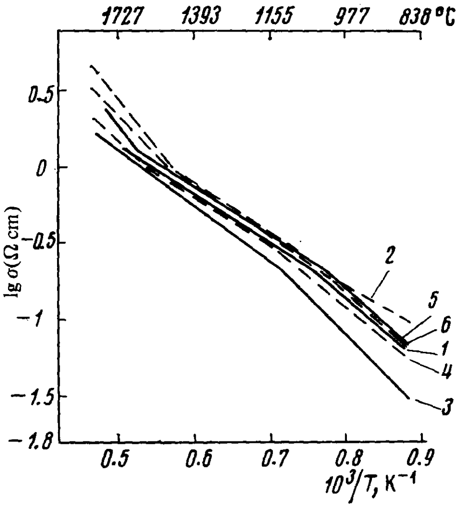

Figure 21. Temperature dependence of the resistivities of single crystals: 1) ZrO_2–Y_2O_3 (10 mole %) + 1 wt.% CeO_2; 2) ZrO_2–Y_2O_3 (10 mole %) + 1 wt.% Pr_6O_{11}; 3) ZrO_2–Y_2O_3 (10 mole %) + 1 wt.% Nd_2O_3; 4) ZrO_2–Y_2O_3 (10 mole %) + 1 wt.% Sm_2O_3; 5) ZrO_2–Y_2O_3 (10 mole %) + 1 wt.% Tb_2O_3; 6) ZrO_2–Y_2O_3 (10 mole %) + 1 wt.% Yb_2O_3.

Elastic, Photoelastic, and Acoustic Parameters

The elastic, photoelastic, and acoustic properties of ZrO_2–Y_2O_3 and HfO_2–Y_2O_3 single crystals have been measured[56–58] by the method of Mandelstam–Brillouin light scattering. The studies were performed on the experimental apparatus already described[59]. An Ar^+ laser served as the source of light at a wavelength of 5145 Å. The scattered light spectrum was investigated with the aid of a Fabry–Perot étalon, scanned as a function of pressure, and was recorded photoelectrically using a photon counting technique. The results of the data interpretation are presented in Tables 6–8. Analysis of the results led to the following findings:

1. In ZrO_2–Y_2O_3 and HfO_2–Y_2O_3 solid solutions there are directions of excited and scattered light for which longitudinal waves hardly contribute to light scattering. Analogous results had been obtained previously for non-cubic sapphire[61] and lithium niobate crystals[62].

2. The velocities of the longitudinal and transverse sound waves in ZrO_2–Y_2O_3 solid solutions depend significantly on the direction of their propagation, i.e. these cubic single crystals are strongly anisotropic with respect to the velocity of sound.

3. The constants C_{11} and C_{44} vary monotonically with the Y_2O_3 concentration, while C_{12} varies non-monotonically.

4. The elastic anisotropy of ZrO_2–Y_2O_3 crystals is very considerable and varies from 2 to 2.6 depending on the Y_2O_3 content. It follows from Table 7 that the photoelastic anisotropy of these crystals is just as great. It increases from 1.80 to 2.85 with increasing Y_2O_3 concentration.

By virtue of a unique combination of their physical and physicochemical properties, fianit single crystals may be used in optics, high-temperature engineering, quantum electronics, and in the manufacture of jewellery. Fig. 22 presents photographs of technical articles (lenses, prisms, windows, crucibles, laser elements, and electrodes) made of fianits.

VI. PREPARATION OF HIGH-TEMPERATURE GLASSES

The glasses are usually prepared in gas or electrical furnaces in platinum or ceramic crucibles[63]. The same problems then arise as in the growing of crystals from the melt: (1) the difficulty of obtaining a product uncontaminated by the material of the crucible and (2) the difficulty of obtaining glasses at temperatures above 1600–1700° C. The first experiments on the preparation of glasses in a cold container were described by Aleksandrov et al.[14] and a later report[64] dealt with the preparation of glasses in quartz beakers exposed to a stream of gas with direct heating of the glass mass by high-frequency currents.

Certain properties of new high-temperature R_2O_3–Al_2O_3–SiO_2 glasses, where R_2O_3 = scandium, yttrium, or lanthanum oxide or the oxide of another lanthanide, are described below[65]. The preparation of glasses in a cold container has characteristic features distinguishing it from the preparation of crystals. In the first place the glasses do not have a distinct melting point and there is therefore also no distinct interface between the melt and the solid phase. The transition from the solid substance adjoining the walls of the cold container to the melt is gradual via a vitreous substance with a gradually diminishing viscosity. Another characteristic feature is the high viscosity of the glass melt, which hinders convection, mixing of the components, the removal of the glasses, and ultimately the homogenisation of the melt and the formation of a glass of a high optical quality. Fig. 23 presents a scheme for the preparation of high-temperature optically homogeneous glasses. We used a cooled stirrer in order to agitate the viscous melt. A crust of solid glass grows on the part of the stirrer immersed in the melt, so that stirring does not result in the contamination of the material.

Table 8. Velocity of sound in HfO_2–Y_2O_3 (10 mole %) {direction of exciting light [110]}.

Direction of scattered light	Wave*	Velocity of sound, km s^{-1}
$[\bar{1}10]$	L	6.29±0.04
$[\bar{1}10]$	T_2	2.50±0.02
[001]	qL	5.46±0.02
[001]	T_2	3.20±0.01
[001]	qT_1	3.48±0.04

*Notation: L = longitudinal sound wave; T_2 = transverse sound wave with the direction of polarisation at right angles to the scattering plane; T_1 = ditto with the direction parallel to the scattering plane. The prefix q indicates that the sound wave is quasi-longitudinal or quasi-transverse.

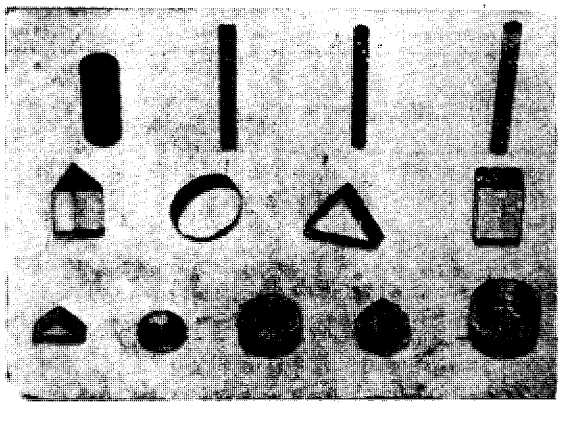

Figure 22. Photograph of technical articles made of fianits.

The glass was prepared over a period of several hours. The melt in the container was then cooled to 800° C and the resulting block was removed from the container and transferred to a Silit furnace for annealing (at 800° C), which was continued for 8 h. In order to obtain specimens of specified shape, the glass melt was poured into graphite boats. Glass blocks weighing up to 1.5 kg each were thus prepared. The glasses were optically homogeneous and did not contain bubbles or sections which had not been fused. Small bubbles were present only in a narrow region of the viscous melt adjoining the walls of the container.

Physicochemical Properties

The softening temperature of the metasilicate section through the Y_2O_3–Al_2O_3–SiO_2 system is in the range 1100–1300° C and increases with decrease of the Y_2O_3 concentration[65]. Analogous data were obtained also for scandium, lanthanum, and erbium glasses. The nature of the dilatometric curves for glasses with small amounts of added R_2O_3 is of interest (2–10 wt.%). Up to 1000° C normal thermal expansion of the glasses is observed, at 1000–1050° C the specimens undergo a sharp contraction, which terminates just as abruptly on further increase of temperature, and softening begins only above 1300° C (Fig. 24). An exothermic effect on the differential thermograms corresponds to the termination of the primary contraction (at 1000–1050° C) and an endothermic effect corresponds to the onset of softening. The exothermic peak is higher the smaller the content of the oxide R_2O_3. This effect is associated with the crystallisation of the glass. X-Ray and micro-X-ray spectroscopic studies on the specimens showed that, when glasses with small amounts of added R_2O_3 crystallise, the mullite phase ($3Al_2O_3.2SiO_2$) is produced. With increase of the R_2O_3 content, crystals of tervalent metal silicates or aluminosilicates begin to be formed. Glasses containing Sc_2O_3 and La_2O_3 exhibit the highest and lowest capacities for crystallisation respectively, which is due to the difference between the basic properties of the oxides.

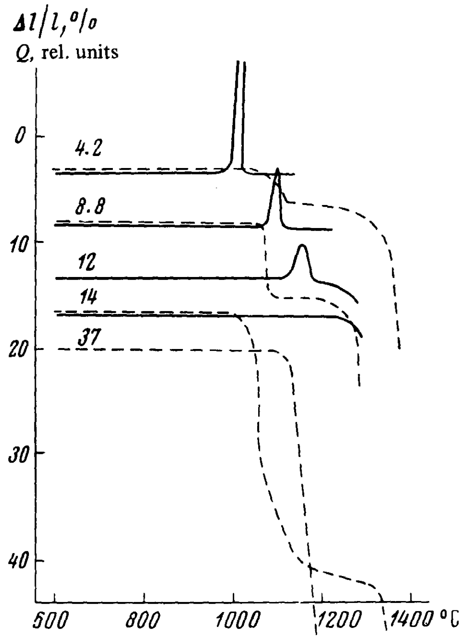

Figure 24. Dilatometric curves (shown dashed) and differential thermograms (shown continuous) for Er_2O_3–Al_2O_3–SiO_2 glasses (the numbers against the curves represent molar percentages of Er_2O_3). The origins of coordinates for the $\Delta l/l$ curve have been displaced along the ordinates axis relative to the upper curve.

Physicochemical and Electrical Properties

Table 9 presents the properties of certain high-temperature glasses obtained in a cold container[65]; the corresponding properties of quartz glass are included for comparison[66]. Evidently the mechanical properties of the glasses are similar to or somewhat superior to those of fused quartz, the softening temperatures of the glasses approaching that of quartz, while their refractive indices are higher than that of quartz. In contrast to the quartz glass, it is easy to introduce various admixtures, including lanthanides, into the glasses.

VII. THE PREPARATION AND PROPERTIES OF FUSED POLYCRYSTALLINE CERAMIC MATERIALS

The preparation of fused polycrystalline materials, used to make cast or pressed ceramic articles, differs little in principle from the process described above, which occurs in the course of high-temperature chemical reactions or when the crystals and glasses are synthesised. The melt having the required composition, prepared by the method described above, is kept for some time in the superheated state for homogenisation and then cooled rapidly. This results in the mass crystallisation of the melt and the latter sets in its entirety into a polycrystalline ingot consisting of fairly large crystalline grains. The fusion is usually carried out in containers having the design illustrated in Fig. 6*a*. Containers shown in Fig. 6*c* are used for the continuous fusion of the polycrystalline ingot.

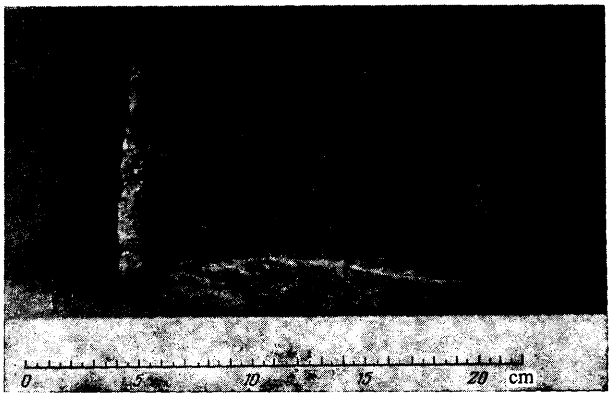

Figure 25. Photograph of a polycrystalline yttrium oxide ingot.

As an example, Fig. 25 presents a photograph of an yttrium oxide ingot. Its structure, indicating the form of the crystallisation isotherm, is clearly seen. We are in essence dealing here with directed crystallisation, since, even after the instantaneous switching off of the high-frequency generator, the large mass of the melt cools non-uniformly (faster at the water-cooled walls than in the centre), as a result of which a temperature gradient is established in the bulk of the melt. Furthermore, a very large number of crystal nuclei, on which crystallisation takes place, are present at the walls of the solid shell. There are no nuclei in the central part of the melt and the onset of nucleation and crystal growth requires some supercooling. Nevertheless, even under these temperature conditions, some materials crystallise in the bulk phase, simultaneously in all parts of the melt. Yttrium chromite and yttrium aluminium garnet melts crystallise in this way (in air). As a result, ingots of these materials do not consist of large elongated blocks but comprise small isometric crystals. The nature of the crystallisation of the melt (directed or bulk phase) determines the homogeneity of the chemical and phase compositions of the ingot. This applies particularly to incongruent crystallisation and especially to the crystallisation of melts having a complex composition.

Figure 26. Electron micrograph of an $LaCrO_3$ ingot to which 7 mole % of calcium chromite has been added.

The Preparation and Properties of Electrically Conducting Fused Oxide Ceramic Materials

Oxide ceramic materials exhibiting ionic or electronic conduction have recently become important in connection with the development of high-temperature technology. Among the technical problems requiring the use of such materials, mention may be made of the formation of heating elements for furnaces giving temperatures up to 2000° C in an oxidising medium, the formation of the electrode walls of magnetohydrodynamic generators, and the development of sensors of the composition of the atmosphere at high temperatures. The manufacture of ceramic partitions with ionic conduction for new chemical current sources also represents an important problem. A new type of conducting material—lanthanum and lanthanide chromites having the general formula $RCrO_3$ and containing an admixture of calcium chromite—was proposed in 1960.[67] Later these materials were investigated[68-71] and it was found that they exhibit electronic conduction, the conductivity being fairly high even at room temperature.

A method has been developed for the synthesis and crystallisation of scandium, yttrium, lanthanum, and lanthanide chromites from the melt in a cold container[13,15]. The chromites obtained from the melt have a well-formed crystal structure and a high chemical purity and phase homogeneity. Certain properties of the fused chromites and the ceramics based on them are given below. Fig. 26 presents electron micrographs of the cleavage plane of the $LaCrO_3$ ingot containing an admixture of 7% of calcium chromite. The photographs clearly show crystalline grains of the lanthanum–calcium chromite solid solution and drops of the eutectic composition enriched (as shown by the X-ray microspectroscopic analysis) in calcium oxide, displaced to the boundaries between the crystals. The chromite ingots were ground and ceramic articles were made from the resulting powder by various procedures of ceramic technology.

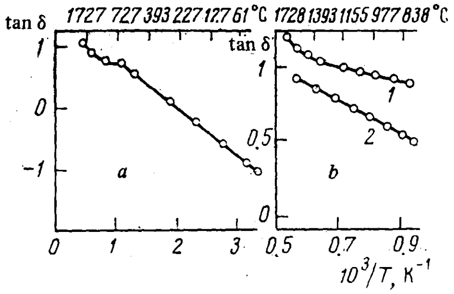

Figure 27. Temperature dependence of the electrical conductivity of a lanthanum chromite specimen to which 7 mole % of calcium chromite has been added: *a*) directly after preparation; *b*) heating in air (curve *1*) and cooling in argon (curve *2*).

Fig. 27 illustrates the temperature variation of the specific conductance of the ceramic made from fused lanthanum chromite with an admixture of calcium†. This material exhibits a high electrical conductivity even at room temperature. An interesting feature of the chromite ceramic is the marked dependence of its electrical conductivity on the oxidation-reduction properties of the atmosphere. A high conductivity in the temperature range between room temperature and 1000° C is ensured only after heat treatment of the specimens in an oxidising atmosphere. Heat treatment in a reducing or a neutral atmosphere or *in vacuo* sharply increases the resistivity of the ceramic in the low-temperature region (Fig. 27). Reheating in an oxidising atmosphere fully restores the initial conductivity. X-Ray diffraction studies on melted lanthanum chromite showed that the material subjected to reductive annealing contains only one phase ($LaCrO_3$). After heat treatment in an oxidising medium, the X-ray diffraction patterns show, together with the lines of the above phase, new lines indicating the appearance of an admixture of a new phase. Thus one may conclude that the electronic conductivity below 1000° C is associated with the formation in the material of admixtures in which the valence of chromium is higher than 3. The melted chromites obtained readily

---

†The conductivity data for the lanthanum and yttrium chromite ceramics were obtained by E.G.Spiridonov and V.G.Gordon at the High Temperature Institute (IVTAN).

combine with other metallic and non-metallic phases, initiating a new series of multiphase materials.

One of the most attractive ceramic materials for the manufacture of components with ionic low-temperature conduction for new current sources is Na-β-alumina having the composition $Na_2O.11Al_2O_3$.[72,73] By virtue of the characteristic features of the crystal structure of this compound, Na^+ ions are highly mobile even at 300° C, which makes it possible to employ the Na-β-alumina ceramic for partitions in sodium–sulphur accumulators. This compound is usually synthesised by sintering the initial components (Na_2CO_3 and Al_2O_3) below the melting point (m.p. 1930° C)[73,74]. It is then difficult to drive the reaction to completion and to ensure the absence of admixtures of non-conducting phases which increase the electrical resistivity of the product. Na-β-alumina has been synthesised and crystallised in the melt using the technique of direct high-frequency fusion in a cold container[74]. The starting materials were Al_2O_3 and Na_2CO_3 with a high degree of purity. The components were mixed and heat-treated for 2 h at 1000° C in order to remove the bulk of CO_2. After this the mixture, which had partly interacted, was transferred to a cold container and fused. The starting metal was aluminium. After the fusion of the material, the melt was maintained for 10–20 min at ~ 1980° C, whereupon the components reacted fully and the melt was homogenised. The power supplied to the melt was then gradually reduced and crystallisation was carried out. Single crystals grew on the surface of the melt in the form of square planar plates, the size of the sides of which reached up to 20 mm. The entire ingot was found to consist of fine crystalline blocks. The ingots were ground and ceramic articles were made from the powder. The densities of the specimens obtained were in the range 3.17–3.19 g cm^{-3} and the resistivities, measured using 150 kHz a.c. at 300° C, were 3–10 Ω cm.

If impurities are introduced to synthesise electrically conducting materials (we have in mind non-metals), then the electrically insulating materials must exhibit a high degree of chemical purity and structural perfection. In this respect the technique under consideration has many possibilities. A number of high-temperature insulating materials have been obtained: calcium and strontium zirconates and hafnates and yttrium, scandium, etc. oxides[15]. They all exhibit a high chemical purity, phase homogeneity, structural perfection and as a result have effective electrically insulating properties up to 2000° C. Owing to their high melting points, it is difficult to obtain these materials with a high purity, excluding the possibility of impurity conductivity, by other methods.

Another class of substances with interesting "electrical" properties, which are successfully obtained by crystallisation in a cold container, are dielectrics of the type of lanthanide titanates and zirconates (Table 3).[75]

The Preparation and Properties of Fused Materials for Refractory Ceramics

Refractory polycrystalline ceramics are widely used in metallurgy, chemistry, and high-temperature technology. The main requirements which must be met by such ceramics is high thermal stability and chemical stability at high temperatures. Both these properties are closely related to the chemical purity and structural perfection of the material of the ceramic. The use of the method of direct high-frequency fusion in a cold container[15] led to the preparation of fused polycrystalline ingots of many refractory materials: mullite, yttrium, scandium, and certain lanthanide oxides, spinels, zirconates, ternary aluminium, zirconium, and silicon oxide compounds (bakor) and certain silicates (Tables 2 and 3). Several examples are given below.

1. Mullite[76-78]. By virtue of its excellent thermal stability, this compound, which melts at 1910° C, is one of the most effective refractory materials. It is usually synthesised by the method of solid-phase reactions, which is time consuming and yields a product contaminated by the phases of the unreacted components. The mullite ingot obtained by crystallising the melt in a cold container consists of long prismatic needles oriented in the direction of crystallisation of the ingot. Analysis of the ingots showed that the crystalline phase in any part of the ingot has a composition differing from that of the individual compounds $3Al_2O_3.2SiO_2$ and $2Al_2O_3.SiO_2$ and corresponds to an intermediate composition in the region of a continuous series of solid solutions[76,77]. Table 10 presents certain properties of the ceramics obtained from fused mullite.

2. Y_2O_3, Gd_2O_3, Er_2O_3, and Sc_2O_3.[79-83] The dense polycrystalline yttrium oxide ceramic is highly refractory, has effective dielectric and mechanical properties, and is involatile. We used yttrium oxide of type Y–O with an overall impurity content of ~ 0.1% for fusion

and crystallisation[82]. The fusion process was initiated with metallic yttrium having the corresponding purity. In order to obtain an ingot consisting of large crystals, after heat treatment for 15–20 min the container with the melt was lowered at a rate of 100–200 mm h^{-1} relative to the inductor, which resulted in directed crystallisation of the melt. The ingot obtained was colourless on the outside, but after cleavage it was seen that its internal regions were intensely coloured greyish-blue. After annealing in air at 1200° C, the colour disappeared. These findings showed that, even on fusion in air, yttrium oxide is partly reduced, which leads to the formation of colour centres. As the outer parts of the material in contact with the oxidising atmosphere are cooled, the previously reduced yttrium is reoxidised to the tervalent state. Fig. 25 presents a photograph of an yttrium oxide ingot consisting of large crystals. A granular ceramic material was obtained from fused Y_2O_3 by pressing using a liquid binder; some of its properties are presented in Table 10.

Fused polycrystalline gadolinium, erbium, and scandium oxides are extremely promising as high-temperature constructional materials. The preparation of these substances does not differ in principle from the preparation of crystalline yttrium oxide. Some of the properties of the granular ceramics obtained from fused Sc_2O_3, Gd_2O_3, and Er_2O_3 [81-83] are presented in Table 10.

---o0o---

Examination of the possibilities of the new technology and the study of the properties of the materials obtained with its aid permit the following conclusions.

Direct high-frequency fusion in a cold container has major technological advantages. For example, it is possible to obtain with the aid of this technique multiphase eutectic compositions and structured compound materials of the metal–oxide and oxide–oxide types by direct fusion and crystallisation of the melt in a cold container as well as new glasses, single crystals, and single-phase ceramic materials, some of which were described above.

By virtue of its fundamental advantages and the ease of its practical application, the method described above constitutes a satisfactory basis for the creation of an effective industrial technology for the preparation of a large class of high-temperature non-metallic materials on which progress in many modern branches of engineering and industry depends significantly.

The method has also many possibilities for scientific research at high temperatures: in the study of chemical reactions in the melt, heterophase equilibria, the physical and physicochemical properties of melts, etc., and also for studies on the chemistry of high-temperature materials.

Not only the final products but also fused half-finished articles for use in the growing of sapphire, garnet, etc. single crystals and in glassmaking by traditional methods can be obtained by means of the technology involving fusion in a cold container.

Radiation Effects in the Chemistry of Group IVB Elements (Silicon, Germanium, Tin, and Lead)

N.V.Fomina, N.I.Sheverdina (deceased), and K.A.Kocheshkov (deceased)

Data concerning the effect of ionising radiation on the principal reactions in organometallic synthesis involving Group IVB elements are considered: radiolysis of organometallic compounds of Group IVB elements, addition to the C=C bond, redistribution of radicals, reactions leading to the substitution of functional groups or organic substituents at the metal atom, reactions involving the organic group, and direct synthesis of organometallic compounds from the metal and alkyl halides.
The bibliography includes 104 references.

CONTENTS

I. Introduction 238
II. Radiation stability of compounds containing silicon, germanium, tin, and lead atoms 238
III. Radiation-chemical hydrometallation 239
IV. Direct synthesis in the field of ionising radiation 241
V. The effect of radiation on the radical redistribution reaction 242
VI. Reactions under the influence of ionising radiation not involving the metal-carbon bond 242

I. INTRODUCTION

Physical methods for the stimulation of chemical processes have been acquiring increasing importance in synthetic chemistry. Together with methods whose application dates back to the XIXth century (electrochemistry and photochemistry), various types of radiation (laser, ultrahigh-frequency, and γ-radiation) have found fairly extensive applications during recent decades[1].

This review is devoted to the experience gained in the use of γ-radiation in reactions of Group IVB elements. There are many reviews in the literature demonstrating the wide scope of the application of ionising radiation in organic synthesis; however, the reactions of Group IVB elements have been described fragmentarily (for example, direct synthesis has been described for tin and hydrometallation for silicon)[2-13]. The influence of ionising radiation on reactions of Group IVB elements has not been considered systematically, although extensive data have accumulated in the literature on this problem.

II. RADIATION STABILITY OF COMPOUNDS CONTAINING SILICON, GERMANIUM, TIN, AND LEAD ATOMS

In the study of the influence of radiation on chemical reactions the main task was to discover whether radiation-chemical synthesis is possible. From the standpoint of the utilisation of substances in radiation-chemical synthesis, data on radiation stability and pathways leading to the decomposition of molecules under the influence of high-energy radiation are very important.

Brinskman et al.[14] investigated the mode of dissociation of chemical bonds in organometallic compounds of Group IVB elements and showed (by ESR) that for low energies the decomposition involves mainly the M-C bond, while for high energies the situation becomes more complicated.

It was found for trichloromethylgermane at −196° C that the primary radiolysis products are the $CH_3^{\cdot}$ and $GeCl_3^{\cdot}$ radicals, which enter into secondary reactions via two pathways:

$$CH_3GeCl_3 \xrightarrow{h\nu} CH_3^{\cdot} + GeCl_3^{\cdot},$$

$$\begin{array}{l} GeCl_3^{\cdot} + CH_3GeCl_3 \xrightarrow{1} HGeCl_3 + Cl_3GeCH_2^{\cdot} \\ \qquad\qquad\qquad\quad \xrightarrow{2} GeCl_4 + CH_3GeCl_2^{\cdot} \end{array} .$$

The secondary processes proceed mainly via pathway 2.

The decomposition of silicon compounds under the influence of temperature and an electron beam has been most widely investigated (in connection with the development of the method for the preparation of semiconducting silicon films)[15,16]. The decomposition is usually carried out in the gas phase at elevated temperatures (150-200° C) and electron energies in the range 250-800 eV. (We may note that the thermal decomposition of organosilicon compounds begins above 500° C.) A study of the decomposition of triethylvinylsilane under the influence of an electron beam showed that the rate and mode of decomposition of organosilicon compounds depend less on electron energy and more on the temperature of the support and the vapour pressure of the organosilicon compound. Below 100° C and at a high vapour pressure, polymers are formed, while at higher temperatures elemental silicon is produced[17]. The radiolysis of tetrasubstituted organosilicon compounds proceeds in different ways depending on the phase state of the substance. The gas-phase radiolysis of tetramethylsilane leads ultimately to a complex mixture of products[18,19]: H_2 ($G = 8.56$), C_2H_6 ($G = 4.23$), CH_4 ($G = 1.28$), $C_2H_5Si(CH_3)_3$ ($G = 4.52$), and $(CH_3)_6Si_2$ ($G = 1.4$), where G is the radiation-chemical yield (mol./100 eV). A more detailed study of the mechanism of the radiolysis using the O_2 and NO radical trapping agents established that the majority of the products are formed as a result of secondary processes. The primary stages in the radiolysis are reactions involving the elimination of a hydrogen atom from the organic group:

$$(CH_3)_4Si \rightsquigarrow (CH_3)_3SiCH_2^{\cdot} + H^{\cdot}$$

or the elimination of the methyl radical

$$(CH_3)_4Si \rightsquigarrow (CH_3)_3Si^+ + CH_3^{\cdot} + e^- \quad .$$

Hydrogen and methane are formed as a result of atomic reactions and molecular elimination reactions, while ethane is produced as a result of the recombination of methyl radicals.

The study of the radiolysis of tetramethylsilane by ESR[20] in the solid phase permitted certain comparisons between hydrocarbons and organosilicon compounds. It was shown that the yield of free radicals in alkyl- and aryl-substituted organosilicon compounds hardly differs from that observed in hydrocarbons ($G \simeq 5$), which is consistent with the comparable Si–C and C–C bond dissociation energies. The ESR spectra of irradiated (77 K) alkylchlorsilanes[2] indicate the dissociation of the C–H, Si–C, and Si–Cl bonds, while free radicals are formed from the corresponding carbon compounds mainly as a result of the dissociation of the C–Cl bond. The yield of radicals in the radiolysis of unsaturated organosilicon compounds has been determined[22].

In contrast to the gas phase[18], the radiolysis of tetramethylsilane in the liquid phase[23] is characterised by an increase of the contribution of reactions involving the abstraction of hydrogen by methyl radicals from tetramethylsilane molecules and an increased yield of methane (G_{CH_4} = 4.8 mol./100 eV, while in the gas phase G_{CH_4} = 1.28 mol./100 eV). The yield of bis(trimethylsilyl)ethane and bis(trimethylsilyl)methane also increases with a corresponding decrease of the yield of ethane and ethyltrimethylsilane. The yield of "intrinsic" radical trapping agents—C_2H_4, C_2H_2, and C_3H_6—decreases by a factor of 50–100.

The thermal decomposition of organogermanium compounds, like that of organosilicon compounds, has been thoroughly investigated in connection with the necessity to prepare films of semiconducting germanium[15]. We may note that the thermal decomposition of organogermanium compounds is observed only above 350° C.

The available information about the radiation-thermal decomposition of organogermanium compounds is very scanty. Brinskman et al.[14] and Duval[24] disagree as regards the determination of the principal pathway in the decomposition of organogermanium molecules under the influence of radiation. Duval suggests that, even in the photochemical decomposition, the reaction involves the C–H bond and not the Ge–C bond, as claimed previously by Brinskman et al.[14] Magat and coworkers[25,26] demonstrated the formation of the $GeCl_3^{\cdot}$ radical and possibly also $GeCl^{\cdot}$ and the Cl_2^- ion ($G \simeq 0.5$) in the radiolysis of inorganic germanium halides.

In the determination of the radiation stability of tetraalkyl compounds of germanium it was shown[27] that an appreciable yield of the final radiolysis products is not observed in the field of ^{60}Co γ-radiation at 200° C over a period of 24 h: a germanium mirror is formed on the walls of the vessel at 250° C. Germanium tetrahalides do not undergo significant changes under analogous conditions.

The thermal decomposition of organotin compounds and their decomposition under the influence of electrons has been described in detail in a review[15]. The authors[15] note that the thermal decomposition of the majority of the organotin compounds investigated begins at ~ 300° C. Metallic tin is produced at an appreciable rate from an organotin compound at 200° C in the field of γ-radiation[27].

Dunn and Oldfield[28] investigated the radiolysis products of organotin compounds in benzene, hexane, and pentafluorobenzene. They showed that the radiolysis leads to the formation of traces of stepwise decomposition products:

$$R_3SnCl \rightsquigarrow R_4Sn + R_2SnCl_2 \quad ,$$
$$R_2SnCl_2 \rightsquigarrow R_4Sn + R_3SnCl + SnCl_4 \quad ,$$
$$RSnCl_3 \rightsquigarrow \text{residue} \quad ,$$
$$R_3SnOSnR_3 \rightsquigarrow R_2SnO.$$

The action of radiation on ethyltrimethylstannane and tetramethylstannane results in the formation of mainly the trialkylstannyl radical. The radiolysis of tetrabutylstannane in pentafluorobenzene leads to the formation of dibutyldifluorostannane (0.1%) and tributylfluorostannane (7.8%). The preferential formation of the trialkylstannyl radical during radiolysis is consistent with mass-spectrometric data for the elimination of alkyl groups from alkyl compounds of tin[29]. Irradiation of tetramethylstannane at 77 K also leads to the dissociation of the C–H bond and the formation of the $CH_3Sn{-}CH_2^{\cdot}$ radical. Prolonged irradiation results in the formation of species with an average number of tin atoms less than unity (in contrast to photolysis). Metallic tin is not produced during radiolysis[30-32].

As regards organolead compounds, it is known only that, in contrast to tetramethylstannane, irradiation of tetramethylplumbane at low temperature is accompanied by the liberation of metallic lead[33] and that its radiolysis in the gas phase leads to a complex mixture of products[34,35].

The available data on the radiolysis of organometallic compounds of Group IVB elements show that the dissociation of the element–carbon bond is one of the main pathways to the decomposition of the molecule under the influence of high-energy radiation. This suggests that the use of radiation methods in organometallic synthesis is desirable.

III. RADIATION-CHEMICAL HYDROMETALLATION

Reactions involving addition to a carbon–carbon double bond proceed in high yields via a radical-chain mechanism. Many examples of the initiation of such reactions by ultraviolet light are known[36]. The overall mechanism of reactions involving addition to a double bond can be represented by a series of consecutive or parallel stages[6].

(1) The generation of a free radical as a result of the action of ionising radiation on the molecule of the substance undergoing addition (the addend):

$$M \rightsquigarrow R^{\cdot} \quad , \tag{1}$$

where $R^{\cdot}$ is the chain propagating radical. The efficiency of the action of radiation depends to a large extent on the ability of the addend to decompose in the field of radiation with formation of free radicals.

(2) Initiation of the chain reaction as a result of the addition of the carrier radical to the double bond:

$$R^{\cdot} + R_1CH{=}CHR_2 \rightarrow R_1CHR{-}CHR_2^{\cdot} \quad . \tag{2}$$

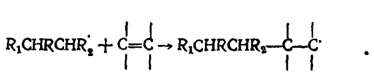
The rate of the second stage must be high, slow addition resulting in the formation of short chains and the possibility of dimerisation. The rate of reaction (2) is influenced by the structures of both the addend and the olefin. In the general case the rate of addition decreases on passing from ethylene to aromatic olefins in the sequence ethylene > substituted ethylenes > higher aliphatic alkenes > cycloalkenes > aromatic alkenes. Substitution by polar groups, for example halogens, lowers the reactivity of the double bond, but perhalogeno-compounds nevertheless react comparatively effectively. A terminal double bond is more reactive than an inner double bond. The $R^{\cdot}$ radical can in principle add to any carbon atom of a substituted ethylene, giving a mixture of isomeric products, but in each specific case the problem of the mode of addition requires special consideration[6].

(3) The complex radical $R_1CHR-CHR_2^{\cdot}$, formed in reaction (2), can in principle react in two ways: with the olefin or with an addend molecule. If the addend molecule is attacked by the carrier radical, we have the "normal" propagation of the chain reaction:

$$R_1CHR-CHR_2^{\cdot}+M\rightarrow R_1CHRCH_2R_2+R^{\cdot} \quad , \qquad (3)$$

etc.

(4) The radical formed in reaction (2) attacks an olefin molecule



$$R_1CHRCHR_2^{\cdot}+\overset{|}{\underset{|}{C}}=\overset{|}{\underset{|}{C}}\rightarrow R_1CHRCHR_2-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}^{\cdot} \quad . \qquad (4)$$

The reaction results in the formation of polymeric products.

(5) The radical formed via reaction (4) may attack an addend molecule with formation of a chain-propagating radical (a carrier radical) and a 1 : 2 adduct (a telomerisation reaction). Adducts with compositions corresponding to a ratio greater than 1 : 3 are rarely encountered.

A mechanism agreeing with the general scheme[37,38] has been demonstrated in many instances for compounds of Group IVB elements.

Chain initiation:

$$HSiCl_3 \rightsquigarrow H^{\cdot}+SiCl_3^{\cdot} \quad , \qquad (1')$$

$$SiCl_3^{\cdot}+CF_2=CF_2\rightarrow CF_2-CF_2SiCl_3^{\cdot} \quad . \qquad (2')$$

Chain transfer:

$$CF_2CF_2SiCl_3^{\cdot}+HSiCl_3\rightarrow CHF_2CF_2SiCl_3+SiCl_3^{\cdot} \quad . \qquad (3')$$

Chain termination:

$$CF_2CF_2SiCl_3^{\cdot}+H^{\cdot}\rightarrow CHF_2-CF_2SiCl_3 \qquad (4')$$

Telomerisation:

$$CF_2CF_2SiCl_3^{\cdot}+CF_2=CF_2\rightarrow CF_2CF_2CF_2CF_2SiCl_3^{\cdot} \quad .$$

The reaction mechanism for alk-1-enes can be represented similarly[38]:

$$HSiCl_3 \rightsquigarrow H^{\cdot}+SiCl_3^{\cdot} \quad ; \qquad (1'')$$

$$SiCl_3^{\cdot}+RCH=CH_2\rightarrow RCHCH_2SiCl_3^{\cdot} \quad ; \qquad (2'')$$

$$RCHCH_2SiCl_3^{\cdot}+HSiCl_3\rightarrow RCH_2CH_2SiCl_3+SiCl_3^{\cdot} \quad . \qquad (3'')$$

Stage (3) is rate-determining for the reactions of simple olefins. Stage (4′) plays a major role when more complex unsaturated compounds, such as allyl chloride, allyl acetate, and *cis*-1,2-dichloroethylene, are involved in the reaction. It leads to the formation of 1 : 2 adducts and high-boiling compounds[38].

Radical-chain mechanisms of the type quoted above describe satisfactorily the majority of reactions of silicon compounds with olefins, but Lampe et al.[39] believe that an ionic mechanism operates in the addition reactions of unsubstituted silanes:

$$SiH_4 \rightsquigarrow SiH_3^{+}+H^{\cdot}+e \quad ,$$

$$CH_2=CH_2+SiH_3^{+}\rightarrow CH_2-CH_2SiH_3^{+} \quad ,$$

$$CH_2-CH_2SiH_3^{+}+SiH_4\rightarrow CH_3CH_2SiH_3+SiH_3^{+} \quad ,$$

etc.

The literature data for the interaction of silicon compounds with olefins in the field of ionising radiation are fairly extensive. Studies by various workers have made it clear that the structure of the silane undergoing addition has a decisive influence on the result of the reaction. It is essential to distinguish the following main cases: unsubstituted silanes of the type SiH_4; silanes substituted only by organic groups (alkylsilanes of the type R_nSiH_{4-n}); silanes substituted by halogens as well as organic groups (alkylchlorosilanes); silanes substituted by halogens only; finally, silanes without a hydrogen atom, for example, tetrachlorosilane. The reactivity of many aliphatic silicon compounds increases with respect to the double bond in the sequence

$$R_3SiH < R_2SiHCl < RSiHCl_2 < HSiCl_3 \quad .$$

This can be accounted for by a decrease in the above sequence of the hydride character of the hydrogen atom, which facilitates the homolysis of the Si–H bond under the influence of radiation.

An increase of the rate of reaction of aromatic compounds has been observed[40] on passing from dichlorophenylsilane to chlorodiphenylsilane and triphenylsilane. Apart from the unusual addition mechanism postulated by Lampe et al.,[39] the possibility of stepwise addition with formation of products having the structure $CH_3CH_2SiH_2CH_2CH_3$ together with 1 : 1 and 1 : 2 adducts should be noted for unsubstituted silanes[41]. Methylsilane and dimethylsilane mixed with ethylene (in proportions of 1 : 3 or 1 : 5) react in the gas phase[39,42] at 50°C to give a 1 : 1 adduct with the radiation-chemical yield $G = 38$ mol./100 eV and a 1 : 2 adduct with a yield of 15 mol./100 eV. Triphenylsilane adds to cyclohexene and oct-1-ene[43] under the conditions of γ-irradiation to give low yields of cyclohexyltriphenylsilane and octyltriphenylsilane. A comparatively high yield of nonyltriphenylsilane (radiation-chemical yield $G = 200$ mol./100 eV and a chemical yield of 66%) was obtained in the reaction with non-1-ene[44].

Under analogous conditions, naphthenes give very low yields, while alk-2-enes hardly react at all. The addition of alkylsilanes to vinylsilanes is of interest[45]:

$$(C_6H_5)_3SiH+(C_6H_5)_3SiCH=CH_2 \rightsquigarrow (C_6H_5)_3SiCH_2CH_2Si\,(C_6H_5)_3 \quad .$$

Very small yields have been obtained, but an increase of the latter may be expected when sources with a higher power are used.

Silanes containing chlorine atoms together with organic substituents react more vigorously. A radiation-chemical yield of ~ 200 mol./100 eV is reached in many reactions, the chemical yield amounting to ~ 50% under these conditions (80% for high doses). A large number of organosilicon compounds have been obtained by the radiation-chemical addition of alkylchlorosilanes to olefins with different structures (ethylene, propene, hexafluoropropene, cyclopentene)[30,40,46,47]. The main studies in this field have been carried out by Zimin and coworkers[47]. The authors found that the yields of products in reactions with unsaturated hydrocarbons vary appreciably with temperature, while those of reactions with fluoro-olefins are independent of temperature.

Among silicon compounds, trichlorosilanes are the most reactive in relation to olefins. The yield reaches 10^3 mol./100 eV in the radiation-initiated addition to olefins. The addition of trichlorosilane to ethylene, isobutene, C_5-C_8 alk-1-enes, certain alk-2-enes, cyclopentene, cyclohexene, allyl chloride, allyl acetate, 1,2-dichloroethylene, and polyfluoroalkenes has been described[38,40,46,47].

On the basis of the mechanism of the addition reaction described, one may assume that silicon compounds without hydrogen atoms are incapable of adding to olefins. On the other hand, it is known that the halides of certain elements, for example phosphorus[48,49], do add to olefins under the influence of ionising radiation. The data available at the present time do not allow an unambiguous answer to the question concerning the possibility of the addition to olefins of organosilicon halides without a hydrogen atom.

In the radiolysis of a mixture of tetrachlorosilane with methyl methacrylate and styrene[50], addition products were not isolated and only polymerisation of the above monomers was initiated. Shostenko et al.[51] attempted to add tetrachlorosilane and tetrachlorogermane to alk-1-enes. The addition products were isolated but the radiation-chemical yield proved to be very low (~ 1 mol./100 eV) and the process was complicated by many side reactions.

The nature of the addend plays a decisive role in radiation-chemical hydrosilylation reactions, but the nature of the olefin in many cases also alters the course of the reaction significantly. Thus γ-irradiation of a mixture of trichlorosilane and vinyl acetate leads to the formation of ethyl 2-trichlorosilyl ether apart from the 1 :1 and 1 :2 adducts. By selecting the reactant ratio, it is possible to make the reduction of the carbonyl group to the methylene group the main process[52]. The reaction of allyl derivatives is complicated by the formation of telomers[41,46] of the type $CH_3CH(X)CH(X)CH_2Y$, where $X=CH_2Cl$ or CH_2OOCH_3 and $Y=SiCl_3$ or $SiCl_2CH_3$. It was noted in a study of the hydrosilylation of polychlorofluorocyclobutene, polyfluorocyclobutene, and cyclopentene initiated by γ-radiation that the presence of an organic substituent at the silicon atom greatly retards the reaction[53,54]. Apart from the expected addition products, reduction products were obtained as a result of the exchange of Cl atoms for hydrogen atoms. The reactivity decreases on passing from butenes to pentenes[53,54].

The addition of germanium compounds to olefins in the field of ionising radiation has been scarcely investigated; this problem is merely touched on in the study mentioned above[51].

Liquid-phase hydrostannylation takes place with a high radiation-chemical yield at room temperature[55,56]. Kocheshkov and coworkers[57] developed a method for the radiation-chemical hydrostannylation in order to synthesise many organotin compounds, including those which are difficult to obtain or which have been described for the first time. The authors showed that, in contrast to hydrosilylation, radiation-chemical hydrostannylation takes place at room temperature. Low reaction temperatures are responsible for the specific reaction pathway leading to the formation of products of the "normal" addition to the double bond. Side products or products of the polymerisation of the initial olefins have scarcely been detected. The reaction has been carried out for olefins having different structures: hex-1-ene, hept-1-ene, oct-1-ene, styrene, allyl alcohol, etc; the radiation yield is ~ 10^3 mol./100 eV in all cases.

A study of radiation-chemical hydrostannylation[58] using triethylstannane and hept-1-ene as a model showed that the rate of reaction is described by S-shaped kinetic curves, which are typical of branched-chain processes. The activation energy (1.5 kcal $mole^{-1}$) shows that the role of temperature as a factor increasing the rate of the process is in this case small. The relation between the rate of reaction and the dose rate is quadratic; the induction period observed at low dose rates (2 h for 5 rad s^{-1}) diminishes with increasing dose rate; when irradiation is interrupted, the reaction stops.

IV. DIRECT SYNTHESIS IN THE FIELD OF IONISING RADIATION

The interaction of metals with alkyl halides (direct synthesis) is an important method for the preparation of organometallic compounds:

$$M + RHal \rightarrow RMHal\ ,$$

where M is the metal, R the organic group, and Hal the halogen. Group IVB elements react with alkyl halides under severe temperature conditions, which differ strongly depending on the nature of the metal and the halogen atom and the reaction temperature is frequently above the limit corresponding to the pyrolytic decomposition of alkyl halides. For example Rochow's method, used nowadays for germanium, consists in passing the alkyl halide vapour over a germanium-copper mixture heated to 300–350° C; alkyl halides containing more than four carbon atoms decompose under these conditions. It is necessary to carry out special studies in order to intensify the direct synthesis and to find milder reaction conditions.

The usefulness of radiation in direct synthetic reactions is based on the following considerations. It follows from studies of the mechanism of the direct synthesis in recent years that electron transfer from the metal atom to the molecule of the organic halide is the most important stage of the reaction of the metal with the alkyl halide, responsible for the formation of the M–C bond[59-63]. Electron transfer results in the formation of active radical species. (The ideas about the mechanism of the direct synthesis of organosilicon and organogermanium compounds are developing mainly in relation to catalytic gas-phase processes involving copper[64,65].) It is appropriate to mention here that the formation of organic radicals (for example by irradiation) promotes a more vigorous direct synthesis. The formation of radicals in the radiolysis of alkyl halides has been frequently observed even in early investigations[66,67]; subsequently it was shown that, with increase of temperature, radiation-induced processes in liquid alkyl halides (isomerisation) may take place quantitatively[68].

The influence of γ-irradiation on the direct synthesis was investigated for the first time by Kocheshkov and coworkers[69,70] in the reaction between powdered tin and butyl bromide. They showed that, in the absence of irradiation, tin does not react with boiling butyl bromide, while on irradiation with ^{60}Co γ-rays the reaction proceeds at an appreciable rate even at room temperature. The radiation-chemical yield is 50–58 mol./100 eV. The lack of thermal experiments under comparable conditions precludes the consideration of the magnitude of the effect of irradiation, but in this instance any decrease of reaction temperature below the boiling point of the alkyl halide is of great practical importance: the necessity for employing an excess pressure during the reaction is obviated.

Subsequently research on the radiation-chemical synthesis of organotin compounds was developed in order to devise an experimental industrial plant[71-82]. The study of the process over a wide temperature range showed that the radiation-chemical yield may be increased to 10^3 mol./100 eV.

The interaction of metallic tin and alkyl halides is an extremely complex process, the rate and direction of which depend significantly on many factors: the nature of the initial reactants and their mass ratio, temperature, dose rate, rate of stirring of the reaction mixture, and the presence of impurities. It has been shown that the reaction is to a large extent specific, with formation of dibromodibutylstannane and a certain amount of bromotributylstannane[69,70]. An increase of temperature accelerates the reaction[71], the optimum temperature of the synthesis of dibromodibutylstannane being 95° C; a further increase of temperature leads to a decrease of the reactivity of tin, probably owing to its aggregation. Temperature also influences the proportions of the final products: when the temperature is reduced, the content of tribromobutylstannane increases. According to Vereshchinskii and coworkers[72], the effective activation energy is 12 kcal mole^{-1}, while according to Fentiman and coworkers[81,82] it is 35 kcal mole^{-1} at 95° C and shows a tendency to vary with temperature. By varying the irradiation dose rate from 0.7 to 220 rad s^{-1}, it has been shown that the rate of reaction is proportional, other conditions being equal, to the square root of the absorbed dose rate. In the synthesis of dibromodibutylstannane under optimum conditions the radiation-chemical yield is 1600–2100 mol./100 eV. The radiation-chemical yield varies with the length of the carbon chain in the alkyl halide, decreasing with increase in chain length.

Vereshchinskii and coworkers[78] and Fentiman and coworkers[81,82] noted an appreciable induction period in the reaction and discussed various methods for eliminating it[79,81]. The preparation of the tin surface, the particle size, and the method of obtaining tin affect both the rate of the process and the proportions of the reaction products[71,72,81].

It is noteworthy that the nature of the halogen in the alkyl halide is very important. Alkyl chlorides do not react[82]. The effect of irradiation in the reaction of alkyl halides with a mobile halogen atom, for example, allyl bromide, is manifested by a decrease of the induction period[83].

The effectiveness of the influence of γ-radiation on the direct synthesis of organotin compounds stimulated research on the role of γ-radiation in the direct synthesis of organogermanium compounds. The influence of radiation and the reaction between germanium and alkyl bromides has been studied by Kocheshkov and coworkers[84,85]. It has been shown that γ-radiation has different effects on the direct synthesis of organogermanium compounds in the liquid and gas phases. Under steady-state conditions, gaseous butyl bromide reacts with germanium powder at 240° C over a period of 13 h only to an extent of 10–12%, while on γ-irradiation (at a dose rate of 100 rad s^{-1}) the extent of the reaction is 20–25% even at 160° C, i.e. the temperature of the onset of the reaction under irradiation conditions is reduced by 100° C. At 220–230° C the germanium charge has been consumed to an extent of 80–85%, i.e. almost quantitatively. The radiation-chemical consumption of germanium (at 200° C) after 13 h amounts to 5×10^2 mol./100 eV, which indicates a chain mechanism of the process. In the liquid phase the influence of γ-radiation is much weaker: the temperature thresholds of the reactions of germanium with butyl bromide and hexyl bromide are reduced by only 20° C. The temperature dependence of the degree of reaction also shows that the thermal stage plays an important role in the liquid phase. The radiation-chemical consumption of germanium in the liquid phase is $\sim$ 50 mol./100 eV.

The quantitative compositions of the products obtained under the influence of γ-radiation in the gas and liquid phases are different. In the liquid-phase reaction the main product is tribromobutylgermane, as in the experiments without irradiation. A mixture of tribromobutylgermane and germanium tetrabromide in proportions of 1 : 3 is obtained in the gas phase. The radiation-chemical yields of tribromobutylgermane in the liquid and gas phases are approximately the same, amounting to 50 mol./100 eV under the following conditions: 200° C, reaction time 13 h. Thus γ-radiation makes it possible to reduce appreciably the temperature of the reaction of germanium with gaseous alkyl halides, but it leads to the formation of an undesirable product—germanium tetrabromide. The process occurring in the gas phase under the influence of γ-radiation can be driven towards the formation of organogermanium compounds by adding copper. In the presence of copper, the content of germanium tetrabromide in the reaction mixture decreases and the yield of tribromobutylgermane increases[84,85].

V. THE EFFECT OF RADIATION ON THE RADICAL REDISTRIBUTION REACTION

If it is assumed that the rate of the radical redistribution reaction

$$R_4M + MX_4 \rightleftarrows \Sigma R_nM_{4-n}$$

depends on the M–C bond strength, one may postulate a stimulating effect of γ-radiation since the molecules of the initial organometallic compounds decompose in the field of ionising radiation at the M–C bond[23-26,29].

Kocheshkov et al.[86] found that the reaction between tetra-alkylstannane and germanium tetrahalide in the field of γ-radiation can be carried out at room temperature. In the absence of radiation the analogous reaction takes place above 200° C.[87,88]

The reaction between tetra-alkylstannane and germanium tetrahalide takes place with transfer of only one organic group regardless of the initial reactant ratio, in contrast to the analogous reaction between tetra-alkylstannane and tin halides. Under the joint influence of radiation and an increased temperature, the abstraction of a second organic group from tetra-alkylstannane is observed, but only monosubstituted organogermanium compounds are formed[27]. The reaction proceeds in accordance with the equation

$$R_4Sn + 2GeHal_4 \rightarrow R_2SnHal_2 + 2RGeHal_3 \ .$$

The thermal radical redistribution reaction between tetra-alkylstannane and germanium tetrahalides takes place only in the presence of a catalyst. Under the influence of radiation, the reaction may be carried out at 200° C with transfer of a single organic group[89].

VI. REACTIONS UNDER THE INFLUENCE OF IONISING RADIATION NOT INVOLVING THE METAL–CARBON BOND

Chlorination, oxidation, and polymerisation reactions, which are fairly well known in the radiation-chemical synthesis of organic compounds, can be in principle initiated by irradiation of the organic group[2-4]. However, there are few experimental data concerning Group IVB elements. Dzhagatspanyan and coworkers[90-93] investigated the radiation-chemical chlorination of organochlorosilanes. The radiolysis of a mixture of chlorine and dichlorodimethylsilane leads to the formation of a 30% yield of a monochloro-substituted product with traces of a dichloro-product. The composition of the chlorination products is independent of temperature and the yield is only slightly temperature dependent. The yield is also independent of the dose rate, but decreases significantly in the presence of oxygen. In the reactions of dichloromethylphenylsilane and trichlorophenylsilane the result depends significantly on temperature. Vigorous incorporation of chlorine in the benzene ring, analogous to that in photochemical chlorination, is observed in the range 0–20° C, but above 100° C ring substitution begins; both processes take place simultaneously at intermediate temperatures. Oxygen does not inhibit the reaction at 100–150° C, which suggests an ionic reaction mechanism. Substitution in the methyl group was not observed under the conditions of radiation-chemical chlorination.

Table 1. Radiation-induced reactions of silicon, germanium, tin, and lead compounds.

Compound	Irradiation conditions	Radiolysis products	Radiation-chemical yield, mol./100 eV	References
R_4Si	electron-beam decomposition gas phase, 150°C	Si	—	15, 16

Irradiation of triethylvinyl-, trimethoxyvinyl-, triethoxyvinyl-, diethylvinyl-, dichloromethylvinyl-, and trichlorovinyl-silanes with ^{60}Co γ-rays leads to the formation of a viscous polymer with a radiation-chemical yield ranging from 20 to 320 mol./100 eV.[94,95] Both γ-initiated polymerisation and polymerisation under the influence of

β-rays have been investigated for allyl derivatives of silicon[96]. Triethylvinylstannane and triphenylvinylstannane polymerise[97] in the field of γ-radiation at 80°C with a radiation-chemical yield of 140–220 mol./100 eV. The polymerisation product consists mainly of dimers and trimers.

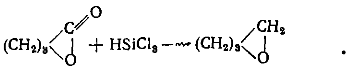
Certain reactions leading to a change in the mobile groups at the metal atom in the field of radiation have been described. The homolytic reduction of organic halides by silicon hydrides in the field of ^{60}Co radiation or in a stream of accelerated electrons, observed in early investigations[98], takes place under comparatively mild conditions:

$$RCl + HSiR'_3 \rightsquigarrow R'_3RSi + HCl \quad .$$

The reaction has been studied in a series of investigations by Zimin and coworkers[99–103]. The authors showed that, under the most severe conditions of synthesis, the temperature does not exceed 300° C, i.e. is less than the temperature of the radiation-chemical decomposition of organochlorosilanes. Fluorinated organic halides react at a lower temperature (100–120° C) than the non-fluorinated compounds (170–180° C), which has been shown for chlorobenzene and pentafluorobenzene. The activation energies for the reactions are respectively 2–4 and 12–13 kcal mole^{-1}. The average radiation-chemical yield is 600 mol./100 eV and a quadratic relation has been observed between the radiation-chemical yield and the dose rate.

The authors[99–103] concluded that the radiation-chemical reduction of organic halides by silicon hydrides is of interest as a convenient method for synthesising organosilicon compounds. The data obtained are sufficient to design an enlarged radiation-chemical plant for the synthesis of organochlorosilanes[102].

Inorganic silanes may be used for the radiation-chemical reduction of organic compounds: the quantitative synthesis of cyclic ethers from lactones has been described[104]:



In conclusion we may note that ionising radiation has a significant influence in many instances (Tables 1–4)† on the chemical reactions of the elements under consideration. This factor can be used successfully in practical synthesis.

The Photochemical and Radiation-chemical Stability of Molecules. Unimolecular Reactions Involving the Abstraction of a Hydrogen Atom

V.G.Plotnikov and A.A.Ovchinnikov

The ways in which electronically excited molecular systems are deactivated are examined, a theory of the non-adiabatic and predissociation mechanisms for the decomposition of molecular systems with elimination of a hydrogen atom is described, and the isotope effect in this reaction is discussed and compared with experimental data. The photochemical stability of molecules of different classes, radical-cations, and radicals is explained on the basis of the theoretical results. The evolution of atomic hydrogen (formation of radicals) in low-temperature radiation-chemical experiments is associated with the position of the lowest triplets state of the molecules, their ionisation potentials, the polarity of the medium, and the energies of the C-H bonds in the radical-cations.

The bibliography includes 93 references.

I. INTRODUCTION

One of the fundamental problems in photochemistry and radiation chemistry is that of the relation between the structure of molecules and their resistance to the action of radiation. The theoretical aspects of this problem are examined below for unimolecular reactions involving the abstraction of a hydrogen atom. Reactions of this type are some of the most common in the photochemistry and radiation chemistry of hydrogen-containing compounds[1-3].

Correct ideas about the relation between the structure of molecules and their stability were put forward for the first time by Voevodskii and Molin[4], who related the stability of the molecule to the energy of its lowest excited state. According to their hypothesis[4], molecules in which the energy of the first excited singlet state exceeds the bond dissociation energy are unstable; when the opposite situation obtains the molecular stability increases sharply. It has been shown[5,6] that the decomposition of electronically excited complex molecules with elimination of a hydrogen atom can proceed with an appreciable probability via a predissociative mechanism only in triplet states and molecular stability must therefore be related to the positions of the lowest triplet state. The approaches on which the studies of Voevodskii and Molin[4] and Plotnikov[5,6] were based are similar, the difference consisting only in the nature of the states involved in the molecular decomposition. However, this does not mean by any means that the conclusions reached by the two sets of workers lead to identical results, since there exist molecules (for example the benzene molecule) in which the energy of the lowest triplet state is lower than that of the bond undergoing the dissociation, while that of the lowest singlet state is higher.

The explanation of the radiation-chemical stability of molecules towards the elimination of hydrogen atoms solely with allowance for the decomposition of electronically-excited molecules[2,4,7,8] cannot be complete, because hydrogen atoms can also be formed in the decomposition of electronically-excited radical-cations. The mechanism of the non-adiabatic decomposition of molecular radical-cations, radicals, and molecules with elimination of a hydrogen atom has been discussed[9] and it has been shown that the probability of the reaction is determined mainly by the energy of the bond undergoing dissociation, which is large for molecules and cannot be small for radicals and radical-cations.

In all the studies quoted above, it was assumed that the decomposition with elimination of a hydrogen atom proceeds in electronically excited states. In principle, there is a possibility of another decomposition mechanism, reducing to the transformation of electronic energy into the vibrational energy of the system with its subsequent concentration, by fluctuations, in the bond undergoing dissociation. The rate of such a process ($\sim 10^6$ s^{-1} for molecules with only a few atoms) decreases exponentially with increase of the number of vibrational degrees of freedom of the system[10,11]. Hence it will be necessary to conclude that the stability of the molecules increases with increase of their complexity and that polymeric molecules are stable, which conflicts with experimental data[1-3]. The independence of pressure of the quantum yield of hydrogen atoms[12,13] also shows that the contribution of the fluctuation decomposition mechanism is small, because otherwise an increase of pressure, which leads to an increased rate of vibrational relaxation, should decrease the yield. In a condensed phase the quasi-equilibrium mechanism of the decomposition of polyatomic systems[10,11] is still less likely, since the lifetime of the vibrationally excited states is extremely short (10^{-11} to 10^{-12} s) in consequence of the vigorous vibrational relaxation processes, which suppress the decomposition process. In the case of systems with only a few atoms (CH_4, H_2O) the vibrational relaxation time is long—up to 10^{-2} s, and the fluctuation mechanism of their decomposition in the ground electronic state (!) cannot be fully ruled out[14-16].

The attempts to describe photochemical reactions with elimination of a hydrogen atom by a mechanism involving a redistribution of vibrational energy cannot be regarded as satisfactory, because they either did not account for the vibrational relaxation[17], or dealt with $\sigma\sigma^*$ and $n\sigma^*$ states of molecules with only a few atoms[18], for which the potential surface is not of the bonding type, and consideration of the redistribution of vibrational energy to a large extent lacked physical significance. It follows from the foregoing that the decomposition of polyatomic electronically excited systems takes place without passing through the stage of the redistribution of vibrational energy by fluctuations. Direct experimental and theoretical evidence for this conclusion will be presented later.

The ways in which electronically excited molecular systems are transformed and the mechanism of the elimination of a hydrogen atom will be considered below, and on this basis the photochemical and radiation-chemical stability of molecular systems will be explained. Since the experimental data for this process have been described systematically in a number of monographs[1-3,19-21] and reviews[22,23], we confined ourselves to giving references to these sources, using the data of original studies only when necessary.

II. ELECTRONIC ENERGY LEVELS OF MOLECULAR SYSTEMS

This section presents information about the nature of the electronically excited states of molecular systems required for further consideration. The Hamiltonian of a molecular system H can be formulated as the sum of the Hamiltonian in the adiabatic approximation H_0, the non-adiabatic operator V, and the spin–orbital interaction operator H_{so}. The eigenfunctions of the Hamiltonian H_0 consist of product of electronic, vibrational, and rotational functions. For a condensed phase, the rotational motion of polyatomic systems is impossible, and one need consider only the electronic and vibrational functions and the corresponding states.

The states of a system with a Hamiltonian H_0 are characterised by a definite electron spin and may be classified in terms of the multiplicity. The majority of molecules have a singlet ground state (S_0) and can have both singlet (S_1, S_2, ...) and triplet (T_0, T_1, ...) electronically excited states. The triplet state T_0 is the excited state of molecules with the minimum energy. The first excited S_1 state lies somewhat above (by 10^3–10^4 cm^{-1}) the triplet state T_0. Other triplet states are frequently distributed between the T_0 and S_1 states[24]. The ground and first electronically excited states of singly charged radical-ions and radicals derived from organic molecules are doublets. There is very little information about the distribution of quartet states in these systems and they are apparently usually located above the first excited state. (As an example, one may quote the allyl radical, for which calculations with complete allowance for the configuration interaction in terms of the π-electron approximation[25] have shown that the quartet level lies above the first excited doublet.)

Another important characteristic of the electronic states of molecular systems is their orbital nature, determined by the nature of the electronic transition which results in the given state. In molecules of organic compounds it is possible to distinguish three types of electrons: π, σ, and n. The wave function of π and σ electrons are delocalised over the molecule. (In molecules containing heteroatoms, there naturally exist π and σ orbitals, with the maximum values corresponding to the location of the heteroatom. This maximum is usually low and the wave function is delocalised over the entire molecule.) The n-electron wave function is non-zero only in a limited region of the molecular system. The π- and σ-electron orbitals can be both bonding and antibonding, and are designated in the latter case by π^*, and σ^*; n-orbitals are non-bonding.

In conformity with the foregoing, electronic states of the following types are possible in molecular systems: $\pi\pi^*$, $\sigma\sigma^*$, $n\sigma^*$, $\sigma\pi^*$, $\pi\sigma^*$, and $n\pi^*$; these arise as a result of electronic transitions between the above orbitals. All these states are characterised by a definite multiplicity. In molecular spectroscopy and photochemistry the following notation has been adopted for electronic states, indicating their multiplicity and electronic nature: $S_{\pi\pi^*}$, $T_{\pi\pi^*}$, $S_{n\pi^*}$, $T_{n\pi^*}$, etc. (We may note that the eigenvalues of the Hamiltonian H_0 corresponds to these states and are not mixed under the influence of the operators V and H_{so}. This classification is possible if the distance between the states is significantly greater than the matrix elements of the operators V and H_{so}, which never exceed ~100 cm^{-1}.) For further consideration, it is important to note that, in all the states except $n\pi^*$ and $n\sigma^*$, the electrons are delocalised over the molecular system. Electrons in the $n\pi^*$, and $n\sigma^*$ states are localised near the heteroatom containing the n electrons.

The radical-cations derived from long paraffinic molecules occupy a special place among molecular systems[26]. Despite the fact that the ground state is of the σ-type, it is localised in a fairly small region of the large molecule. The reason for this is that, on localisation of a hole in the middle part of the molecule, the energy decreases by approximately 0.5 eV owing to the change in the C–C bond length. The localisation region then corresponds to 4–5 bond lengths (6–7 Å).

The electronic excitation of the molecular system entails a change in bond lengths (and in the general case also in bond angles) and in vibration frequencies. The rate of non-adiabatic transitions, including transitions involving the fragmentation of the molecular system, depends on these parameters and also on the extent to which the corresponding vibrations are anharmonic. The changes in bond lengths and vibration frequencies on electronic excitation may be inferred from the vibronic absorption and luminescence spectra of molecular systems. Together with vibrational spectra, they make it possible to determine also the anharmonicity of the vibrations. For many compounds, particularly aromatic compounds and their derivatives, these spectra have been investigated[24,27-29] and it has been found that (1) the change in the vibration frequencies of polyatomic molecules on electronic excitation is small in most cases compared with the vibration frequencies†; (2) the changes in bond lengths are also

---

† An appreciable change in the vibration frequencies of the C–O group is observed on $n \rightarrow \pi^*$ transitions in carbonyl compounds[27], which is due to the local nature of the transition.

small and, what is particularly important for further discussion, there is no significant change in the C–H bond lengths regardless of the nature of the state; (3) the majority of molecular vibrations can be described in terms of the harmonic approximation but the stretching vibrations of the C–H bonds (and in general R–H bonds) exhibit appreciable anharmonicity. The last conclusion is valid for any system containing a hydrogen atom, because the anharmonicity of the vibrations increases with decrease in the reduced mass of the oscillator.

The absorption spectra of aliphatic compounds are as a rule structureless[1] and it is therefore difficult to determine from them the change in the geometrical parameters of the molecule on electronic excitation. However, one may make the general claim[5,30] that the changes in these parameters are small, in molecules containing a large number of identical bonds, after $\pi \rightarrow \pi^*$, $\sigma \rightarrow \sigma^*$, $\sigma \rightarrow \pi^*$, and $\pi \rightarrow \sigma^*$ electronic transitions if one considers states with a comparatively low energy, not exceeding 10 eV (see Section VII). Since the electronic transitions in the above energy range are due to the delocalised electrons of the C–C bonds and the bonds between carbon atoms and the heteroatom[31,32], electronic excitation should alter the lengths of these bonds alone; the C–H (and in general R–H) bonds change insignificantly. This applies also to $n\pi^*$ and $n\sigma^*$ states. Few data are available at present for the electronic spectra of radical-cations (see Pshezhetskii et al.[19] and Bogatyreva and Buchachenko[22] together with the literature which they quote). However, for reasons stated above, one may assume that in these systems too the changes in bond lengths on electronic excitation are small and, what is most important, frequently do not involve the C–H (R–H) bonds.

The above conclusions, which follow from experimental data and theoretical considerations, constitute the basis of the theoretical models for reactions involving the elimination of a hydrogen atom. Certain deviations from such models will be indicated below (see Section VIII).

III. DEACTIVATION PROCESSES INVOLVING EXCITED MOLECULAR STATES

Following optical excitation or excitation by electron impact, the molecular system passes from the ground electronic states to an excited state (in the general case a vibronic state), which corresponds to an eigenvalue of the Hamiltonian H_0. For a long time, this postulate was assumed without proof and conditions under which it is valid were established only comparatively recently[33,34]. These conditions reduce to the following: (1) in the region of the excitation energy there is one state of the system with the Hamiltonian H_0 to which transition from the ground state is allowed; (2) the excitation is due to a source whose spectral line width exceeds the width of the excited state[35]. In classical (non-laser) photochemistry and radiation-chemistry the above conditions are fulfilled.

This applies not only to a free molecule, but also to a molecule in a solvent. In this case, during the first instant after excitation, the system is also in a state which is an eigenstate of the Hamiltonian H_0. (For this, it is necessary that the interaction of the vibrations of solvent molecules with the electronic excitation in the given molecule should be weak.) If the initial state is vibrationally excited, it relaxes owing to the interaction of the vibrations of the molecule of the compound with those of the molecules of the solvent. In polyatomic systems the rate of vibrational relaxation is extremely high, amounting to $10^{11}-10^{13}$ s^{-1}.[24] In molecular systems consisting of a small number of atoms (H_2, N_2, CH_4, etc.) the rate of vibrational relaxation may be much smaller (down to 10^{-2} s^{-1}), as stated above, and may depend very markedly on the amount of vibrational energy[14]. This effect is due to the relatively small number of vibrational modes in such systems and the anharmonicity of the vibrations.

The states of the Hamiltonian H_0 are not eigenstates of the system Hamiltonian H and therefore undergo spontaneous radiationless decomposition under the influence of the operators V and H_{SO}. Irreversible radiationless decomposition can occur only when the system in the final state has a continuous (quasi-continuous) energy spectrum[33,34,36,37]. Polyatomic molecules have a quasi-continuous spectrum of vibrational levels when the vibrational excitation energies exceed 1 eV. In the case of molecules with only a few atoms the energy levels are insufficiently closely spaced, and in isolated molecules of this kind radiationless transitions to not occur. In impurity molecules radiationless transitions are always possible, because the overall spectrum of states of the system is quasi-continuous owing to the vibrational states of the solvent molecules. The rate of the radiationless transitions in the condensed phase may depend on the strength of the interaction of the vibrations of the impurity and solvent molecules, i.e. on the rate of vibrational relaxation[38-41]. Another cause of the existence of a continuous spectrum of states of the system is associated with the possible photochemical reactions. We shall consider these possibilities below and here we shall deal with radiationless transitions involving a large number of closely spaced discrete states. By definition, processes of this type do not lead (in the first stage) to chemical transformations in the system and are referred to as conversion processes.

The following instances of conversion are distinguished. If the transition is between electronically excited states with the same multiplicity, the corresponding process is called an internal conversion process. When the distance between the electronically excited states does not exceed ~1 eV, the rate of internal conversion is very high, amounting to $10^{11}-10^{12}$ s^{-1}.[24,27,42] In the vast majority of molecules, the distance between the neighbouring electronically excited states is ≤ 1 eV, and internal conversion processes in such systems are therefore very rapid. The azulene molecule[24], in which the distance between S_1 and S_2 states is ~1.7 eV, constitutes an exception. A process involving a change in the multiplicity of the states as a result of the transition is referred to as intercombination conversion (singlet–triplet or $S-T$ conversion). The rate of such conversion depends very strongly on the spin–orbital coupling of the states of the system and on its other characteristics[24,43,44]. The rate of $S-T$ conversion between $\pi\pi^*$ states of aromatic molecules is $10^{6}-10^{8}$ s^{-1}.[15] The rate of $S-T$ conversion between $\pi\pi^*$ and $n\pi^*$ states is very high (~$10^{10}-10^{11}$ s^{-1}) owing to the appreciable spin–orbital coupling between them[24,43]. The rate of $S-T$ conversion in aliphatic hydrocarbons should also be high[44]. If the system finds itself in the ground electronic state as a result of a radiationless transition, the process is called degradation of electronic energy. One should then distinguish two types: an internal degradation process (for example an S_1 S_0 transition in which the multiplicity of the states does not change) and an intercombination degradation process (involving a change in multiplicity, for example T_0 S_0).

In most molecules the S_1 state is located at a considerable distance from S_0 ($\geqslant$2.5 eV). Internal degradation in such systems is unlikely (its rate is $\sim 10^5$ s^{-1}) and cannot compete with the radiative decomposition of the S_1 state and the $S-T$ conversion[42,45]‡. As the energy of the first excited state of the system decreases, the role of the internal degradation process increases, and, in systems in which the energy of the first excited state is less than ~1.5 eV, it may become the main pathway to the deactivation of the excited state[42]. The rate of intercombination (T_0–S_0) degradation also depends very strongly on the energy of the excited state. The characteristic rate of this process in aromatic hydrocarbons at low temperatures is $\sim 10^{-1}$ s^{-1}. For molecules with the lowest $T_{n\pi^*}$ state, the probability of this process is much greater, and its rate is $\sim 10^2-10^4$ s^{-1}.[24,27] Electronically excited states may naturally decompose also via radiative channels. In allowed electronic transitions the rate of radiative decomposition is 10^8-10^9 s^{-1}. In symmetry-forbidden electronic transitions (the $\pi \to \pi^*$ electronic transition in benzene and the $n \to \pi^*$ transitions in carbonyl compounds) the rate of the radiative transition is somewhat lower and amounts to 10^5-10^6 s^{-1}. The probability of radiative transitions forbidden by multiplicity is much lower and their rate is $10^{-3}-10^3$ s^{-1}.[24,27]

IV. THE DISTRIBUTION OF VIBRATIONAL ENERGY IN THE INITIAL STATE

The rate and mode of decomposition of an electronically excited system depends significantly on the amount of vibrational energy and particularly on the nature of its distribution among the vibrational degrees of freedom. We are primarily interested in the possibility of the non-equilibrium excitation of the stretching R–H bond vibrations. The degree of excitation of these vibrations depends on the way in which the electronic state is "prepared".

Following optical excitation or excitation by electron impact, the probability of the excitation of vibrational states is determined by the corresponding Franck–Condon factor§. At low temperatures only those vibrations can be excited whose characteristics (frequency and/or equilibrium value of the normal coordinate) change in the electronic transition. In the majority of hydrocarbon molecules and their substituted derivatives the stretching C–H bond vibrations are not of this kind (see Section II), so that one cannot expect their significant excitation. The vibrational energy in such systems during the first instant after the electronic transition is concentrated in the stretching C–C bond vibrations or in the vibrations of a carbon–heteroatom bond.

The vibrational energy is distributed in a different manner if the electronic state $|f\rangle$ is formed as a result of internal conversion from a higher excited state $|i\rangle$. Because of the considerable anharmonicity of the R–H bond vibrations, their significant excitation in this process is to be expected. We shall demonstrate this in relation to a simple model. Suppose that the system has two vibrational degrees of freedoms, one of which is associated with the anharmonic R–H bond oscillator and the other with a vibration which can be described in terms of the harmonic approximation. (In aromatic hydrocarbons the C–C vibrations may be regarded as being of this kind with a high degree of accuracy.) The harmonic vibration is characterised by the difference Δ between the values of the equilibrium coordinate in the $|i\rangle$ and $|f\rangle$ states. For simplicity, we shall assume that the characteristics of the R–H bond vibrations in the $|i\rangle$ and $|f\rangle$ states are identical. The rate of internal conversion from the zero-point vibrational state corresponding to the electron energy level i, accompanied by the excitation of the nth vibration of the R–H bond and the mth harmonic vibration corresponding to the electron energy level f, is proportional to the square of the matrix element:

$$\frac{1}{\mu}\left\langle i\left|\frac{\partial}{\partial x}\right|f\right\rangle\left\langle 0\left|\frac{\partial}{\partial x}\right|n\right\rangle\langle 0|m\rangle. \tag{1}$$

Here μ and x are the reduced mass and the internal coordinate of the R–H vibration reckoned from the equilibrium value x_0; $|i\rangle$ and $|f\rangle$ are the electronic wave functions and $|0\rangle$, $|n\rangle$, and $|m\rangle$ are the vibrational wave functions. In order to calculate the value of the quantity defined by formula (1), one may employ the Morse functions for the R–H bond and the functions of the harmonic oscillator for the second vibration. The Morse potential is

$$U(x) = D(e^{-2\alpha x} - 2e^{-\alpha x}), \tag{2}$$

where D is the bond dissociation energy, $\alpha = \omega(\mu/2D)^{1/2}$, and ω is the zero-point vibration frequency of the oscillator. The wave functions of the discrete spectrum are of the following form[46]:

$$|n\rangle = \left[\frac{\alpha\Gamma(2s_0-n+1)}{n!\Gamma(2s_0-2n+1)\Gamma(2s_0-2n)}\right]^{1/2} y^{s_0-n}e^{-y/2}\cdot F(-n, 2s_0+1-2n, y), \tag{3}$$

where $s_0 = 2D/\omega - 1/2$, $0 \leqslant n < s_0$, $y = (2s_0+1)e^{\alpha x}$, $\Gamma(z)$ is the gamma-function, and $F(\alpha, \gamma, z)$ is a degenerate hypergeometric function. Using Eqn. (3), it is easy to obtain[47] an expression for the vibrational factor of the R–H bond in formula (1):

$$\left|\left\langle 0\left|\frac{\partial}{\partial x}\right|n\right\rangle\right|^2 = \frac{\alpha^2}{4}n!\,\frac{\Gamma(2s_0+1-n)(2s_0-2n)}{\Gamma(2s_0)}. \tag{4}$$

The calculation of the Franck–Condon factor $\langle 0|m\rangle$ with the functions of the harmonic oscillator presents no difficulty[48]:

$$|\langle 0|m\rangle|^2 = \frac{e^{-\eta}}{m!}\eta^m,\quad \eta = \frac{\Delta^2\mu'\omega'}{2}, \tag{5}$$

where ω' and μ' are the frequency and mass of the harmonic oscillator. The average values of the quantum number n are presented below as a function of the difference between the electronic energies ΔE_{if} of the i and f electron energy levels and the parameter s_0:

ΔE_{if}, eV	0.5 eV	1 eV	1.5 eV	2 eV
$s_0=15$	0.1	0.8	3.6	4.6
$s_0=30$	0.06	0.5	0.96	2.1

The following values of the parameters were selected: $\omega = 3000$ cm^{-1}, $\omega' = 1500$ cm^{-1}, and $\eta = 1$. Evidently the probability of the excitation of the R–H bond vibrations in a non-adiabatic transition increases with increasing anharmonicity of the vibrations (with decrease of the bond energy) and with increase of ΔE_{if}. For typical values $\Delta E_{if} \simeq 1-2$ eV, the R–H bond vibrations are significantly excited. This result may be obtained only when account

---

‡ This also show that decomposition of the majority of molecules cannot proceed via the mechanism involving the concentration of vibrational energy by fluctuations.

§ It is postulated that the corresponding electronic transition is symmetry-allowed.

is taken of the anharmonicity of the R–H vibrations, since in terms of the harmonic approximation the R–H vibrations with $n > 1$ are not excited at all in our model.

It is noteworthy that the above result is comparatively new, because it had been assumed earlier that in the internal conversion the energy is transmitted more or less uniformly to all the vibrational modes of the system. The average energy of the ν-mode is then determined (in terms of the harmonic approximation) by the parameter Δ_ν, the vibration frequencies ω_ν, and the amount of energy converted ΔE_{if}.[49] For higher and lower values of ΔE_{if}, the high-frequency and low-frequency vibrations are excited preferentially. The vibrational energy is always delocalised over the molecule in the harmonic approximation. As shown above, allowance for the anharmonicity of the vibrations leads to the possibility of the localisation of the vibrational energy in an individual bond.

An excited state may arise also as a result of intercombination conversion, which occurs under the influence of the spin–orbital interaction and (in terms of second-order perturbation theory) a non-adiabatic interaction. For intense spin-orbital interaction (~10 cm^{-1}), which depends little on the internuclear distances, the interconversion does not entail a significant excitation of the C–H bond vibrations. An example is provided by the transitions between the $n\pi^*$, and $\pi\pi^*$ states of different multiplicity. If the spin–orbital coupling is weak (~0.1 cm^{-1} for aromatic hydrocarbon molecules), terms describing the contribution of the non-adiabatic interaction may contribute significantly to the probability of the transition. In this case the excitation of the C–H vibrations is more likely in a radiationless transition.

V. NON-ADIABATIC DECOMPOSITION

A molecular system in the adiabatic vibronic state $|i\{n\}\rangle$ has a finite probability of a transition under the influence of the non-adiabatic operator to a continuum of $|f\{s\}\rangle$ states, provided that their multiplicities are identical. $\{n\}$ and $\{s\}$ are understood as sets of indices characterising the wave functions of the nuclei $|\{n\}\rangle$ and $|\{s\}\rangle$. The possibility of a continuous spectrum of $|f\{s\}\rangle$ states in any electronic state is determined by the finite value of the bond energy of the atoms in the system. In the region of energies exceeding the dissociation energy of any of the bonds the energy spectrum is continuous and the corresponding wave functions describe the motion of the decomposition products moving apart to infinity. The transitions of the system to such states will be considered here.

The $|i\{n\}\rangle$ state should be understood as an excited vibronic state of the R–H system. The $|f\{s\}\rangle$ states correspond to a continuous energy spectrum of the R$^\cdot$ + H system. The energy of the $|i\{n\}\rangle$ state should naturally exceed the dissociation energy of the R–H bond in the $|f\rangle$ state. The electronic wave functions $|i\rangle$ and $|f\rangle$ for molecules may be calculated by one of the methods of quantum chemistry; we shall make use of the wave functions found by the LCAO-MO method. The situation is somewhat more complex for wave functions describing the motion of nuclei.

The vibrational wave functions $|\{n\}\rangle$ are products of the functions of normal oscillators of the system. The $|\{s\}\rangle$ wave function can also be represented as the product of the function describing the relative motion of the R and H fragments and the vibrational wave functions of the R fragment. The forms of the normal coordinates in the $|i\rangle$ and $|f\rangle$ states are evidently not the same and the above representation of the $|\{n\}\rangle$ and $|\{s\}\rangle$ functions is unsuitable for the calculation of the rates of transition. It is seen that, when the dispersions of the vibration frequencies of the R–H bonds are neglected, the $|\{n\}\rangle$ and $|\{s\}\rangle$ functions are products of the vibrational functions of individual R–H bonds and the functions of the normal oscillators of the remainder of the molecule. The dispersion of the frequencies of the C–H(R–H) bond vibrations is small (~100 cm^{-1}) compared with the vibration frequency (~3000 cm^{-1}) and particularly the bond dissociation energy; for this reason, its neglect leads to very small changes in the decomposition probability. This is even more valid for anharmonic oscillators, because allowance for anharmonicity leads to an effective decrease of the intensity of their interaction[50].

We shall employ the Morse functions as the vibrational wave functions of R–H bonds. The $|\{n\}\rangle$ wave function is the product of the $|n_\nu\rangle$ wave functions, the discrete states of the Morse potential for individual R–H bonds, and the functions of the normal oscillators in the remainder of the molecule. The wave function of the final state is the product of the wave function $|s\rangle$ of the continuous spectrum of the Morse potential, which describes the motion of the eliminated hydrogen atom, and of the wave functions $|n'_\nu\rangle$ of the rest of the system, including the remaining R–H bonds. The vibrational quantum numbers n'_ν may differ from the initial numbers n_ν. The rate of the transition $|i\{n\}\rangle$ $|f\{s\}\rangle$ under the influence of the adiabatic operator is described by the following expression in terms of the first-order perturbation theory[9]¶:

$$k = 2\pi \left| \frac{1}{\mu} \left\langle i \left| \frac{\partial}{\partial x} \right| f \right\rangle_{x=0} \left\langle \{n\} \left| \frac{\partial}{\partial x} \right| \{s\} \right\rangle \right|^2, \ (\hbar = 1), \tag{6}$$

The vibrational factor defined by Eqn.(6) is

$$\left\langle \{n\} \left| \frac{\partial}{\partial x} \right| \{s\} \right\rangle = \left\langle n \left| \frac{\partial}{\partial x} \right| s \right\rangle \prod_\nu \langle n_\nu | n'_\nu \rangle, \tag{7}$$

where the product of the Franck–Condon factors $\langle n_\nu | n'_\nu \rangle$ is evaluated with respect to all the normal oscillators and bonds except the bond undergoing dissociation. In order to obtain the total probability of the abstraction of any hydrogen atom (per unit time), the expression for k must be summed with respect to finite vibrational states of the fragment R and with respect to all the R–H bonds. Furthermore, Eqn.(6) must be averaged with respect to the initial vibrational distribution.

The wave functions of the continuous spectrum of the Morse potential are of the form

$$|s\rangle = \frac{|\Gamma(-s_0 + is)|}{|\Gamma(2is)|\,(2\pi v)^{1/2}}\, y^{-1/2} W_{s_0+1/2,\, is}(y), \tag{8}$$

where $v = (2E/\mu)^{1/2} = \alpha s/\mu$, $s = (2\mu E)^{1/2}/\alpha$, and $W_{s_0+1/2,is}(y)$ is the Whittacker function. Function (8) is normalised with respect to the delta-function of energy E, which is reckoned from the dissociation energy L.

¶ It is noteworthy that terms containing derivatives with respect to other coordinates of the molecule may contribute to k. Since the difference between the bond lengths in the $|i\rangle$ and $|f\rangle$ states is small (see Section II) and the integral $\langle n|s\rangle$ for low values of n is therefore close to zero, these terms may be neglected. This applies also to the non-adiabatic interaction term containing second derivatives of the electronic functions with respect to internuclear coordinates. The expression for k is quoted in terms of atomic units.

The Franck–Condon factors reach their maximum value for $n_\nu \simeq n'_\nu$ under the conditions of a small change in the equilibrium value of the coordinate of the oscillator (Δ_ν). When $n = 0$ and for $n'_\nu \ll s_{0\nu}$, when the harmonic approximation is valid, we have[42,48]

$$|\langle 0 | n'_\nu \rangle|^2 = e^{-\eta_\nu} \eta_\nu^{n'_\nu} (n'_\nu!)^{-1}, \quad \eta_\nu = \Delta_\nu^2 \mu_\nu \omega_\nu / 2. \tag{9}$$

Calculation of the integral $\left\langle n \left| \frac{\partial}{\partial x} \right| s \right\rangle$ for an unchanged length ($\Delta = 0$) and vibration frequency of the R–H bond† in the $|i\rangle$ and $|f\rangle$ states gives[47]

$$\left|\left\langle n \left| \frac{\partial}{\partial x} \right| s \right\rangle\right| = S_{ns} = \frac{\mu (2s_0 - 2n)}{8\pi n! s} \frac{|\Gamma(-s_0 + is)|^2 \cdot |\Gamma(s_0 + 1 + is)|^4}{\Gamma(2s_0 + 1 - n) \cdot |\Gamma(2is)|^2}. \tag{10}$$

The integral $\left\langle n \left| \frac{\partial}{\partial x} \right| s \right\rangle$ may be also calculated analytically for $\Delta \neq 0$. When $n = 0$, we have

$$\left|\left\langle 0 \left| \frac{\partial}{\partial x} \right| s \right\rangle\right|^2 = S_{0s} \left[\xi^{s_0+1} F\left(s_0 + 1 + is, s_0 + 1 - is; 1; \frac{1-\xi}{2}\right) + \right.$$
$$\left. + s_0 (\xi - 1) \xi^{s_0} F\left(s_0 + 1 + is, s_0 + 1 - is; 2; \frac{1-\xi}{2}\right)\right]^2, \tag{11}$$

where $\xi = e^{\alpha\Delta}$ and $F(\alpha, \beta; \gamma; z)$ is a hypergeometric function. The expressions for the quantities $\left\langle n \left| \frac{\partial}{\partial x} \right| s \right\rangle$ when $n \neq 0$ can also be represented by the product of S_{ns} and a function $\Phi(s_0, s, n, \Delta)$, which is not quoted here because of its cumbersome form. The fundamental dependence of the factor $\left|\left\langle n \left| \frac{\partial}{\partial x} \right| s \right\rangle\right|^2$ on n is contained in the multiplier S_{ns}.

The expression for S_{ns} when $s_0 \gg 1$, $n \ll s_0$, and $s \geqslant 1$ can be greatly simplified if the asymptotic expression for the gamma-function is used[47]:

$$S_{ns} \simeq \frac{\pi^{1/2} \mu}{n! 2^{2s_0}} s_0^{3/2} (2s_0)^n (1 + s^2/s_0^2)^{s_0+1/2} \exp\left(-2s \arctan \frac{s}{s_0}\right). \tag{12}$$

If the decomposition takes place in the nth vibrational state of the bond undergoing dissociation and all the remaining numbers $n_\nu = 0$, one can write

$$k = \frac{2\pi^{3/2}}{\mu} |\beta|^2 F \prod_\nu \eta_\nu^{n'_\nu} e^{-\eta_\nu} (n'_\nu!)^{-1}, \tag{13}$$

where $\beta = \left\langle i \left| \frac{\partial}{\partial x} \right| f \right\rangle_{x=0}$ and the function

$$F = \pi^{-1/2} \mu^{-1} \left|\left\langle n \left| \frac{\partial}{\partial x} \right| s \right\rangle\right|^2.$$

For the majority of molecules, the parameter η_ν is non-zero only in the case of certain oscillators; under these conditions, its characteristic value is close to unity[48,51]. In this instance the multipliers with $n'_\nu \leqslant 1$ make the maximum contribution to Eqn. (13). Hence it follows that $\prod_\nu \eta_\nu^{n'_\nu} e^{-\eta_\nu} (n'_\nu!)^{-1} \sim 0.1$ and the fragment R can acquire a small amount of vibrational energy during the decomposition process, provided that this is allowed by energy factors. The fundamental dependence of k on the molecular parameters is contained in the multiplier F.

Fig. 1 illustrates the variation of F with s_0 for $n = \Delta = 0$; evidently F decreases sharply with increase of s_0. The dependence of F of the parameter s is illustrated in Fig. 2. When $s = 0$, we have $F = 0$, but, when $s \simeq 0.5$ ($E \simeq 10^2$ cm^{-1}), F already reaches a maximum and then slowly decreases. Fig. 3 illustrates the variation of F with the length of the bond undergoing dissociation in the excited state; evidently the decomposition probability increases as the bond length is diminished. With increase of bond length, F initially decreases somewhat and then assumes a value virtually equal to that corresponding to $\Delta = 0$.

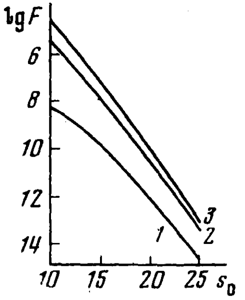

Figure 1. Dependence of the factor F on the parameter s_0 ($\Delta = 0$, $n = 0$); s: 1) 10; 2) 5; 3) 1.

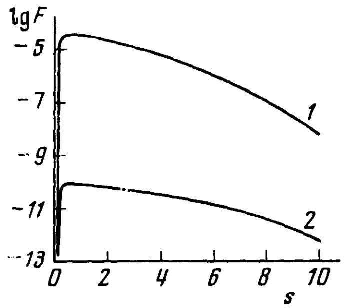

Figure 2. Dependence of the factor F on the parameter s ($\Delta = 0$, $n = 0$); s_0: 1) 10; 2) 20.

It follows from Eqn. (12) that the factor F increases very rapidly with increase of the vibration quantum number of the R–H oscillator in the initial state. Since $2s_0 \geqslant 10$, the excitation of the R–H bond vibrations leads to an increase in the probability of dissociation by more than an order of magnitude for each vibrational quantum.

In the Appendix to the present review it is shown that in many interesting cases $|\beta|^2 \simeq 2$ a.u. The constant for the elimination of a hydrogen atom is then given by

$$k \simeq 10^{14} \cdot F \ (\text{s}^{-1}). \tag{14}$$

---

† We may note that the value of $\left\langle n \left| \frac{\partial}{\partial x} \right| s \right\rangle$ for $n \ll s_0$ (this is the case which we are in fact considering) is independent of the bond dissociation energy in the excited state, because the functions $|n\rangle$ are converted into the function of the harmonic oscillator when $n \ll s_0$.

The results of the calculation by Eqn. (14) of the rate constants for the decomposition of molecular systems with elimination of a hydrogen atom for different R–H bond energies are presented below:

D, eV	1.5	2.0	2.5	3.0	3.5	4.0	4.5
s_0	7.6	10.3	13.0	15.7	18.4	21.1	23.8
lg k, (s^{-1})	10.7	9.3	7.8	6.3	4.8	3.3	1.7

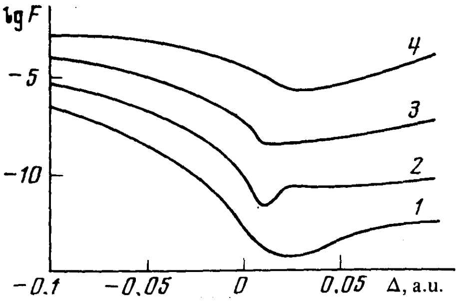

Figure 3. Dependence of the factor F on the parameter Δ ($s = 1$, $n = 0$); s_0: 1) 25; 2) 20; 3) 15; 4) 10.

In all cases it was assumed that $\omega = 3000$ cm^{-1}, $s = 1$, $\Delta = 0$, and $n = 0$. Several important conclusions follow from the above data: (1) the probability of the elimination of a hydrogen atom via a non-adiabatic mechanism from electronically excited molecular systems, for which $D \simeq 4-4.5$ eV (the majority of hydrocarbon molecules), is very low when $n \simeq 0$, and the quantum yield of the dissociation of the R–H bonds cannot exceed $\sim 10^{-3}$. (2) With decrease of the bond energy to 2.5–3.5 eV, the values of k become comparable to the rates of decomposition of the lowest singlet states of the majority of molecules, and the quantum yield of the decomposition in such systems may become appreciable. (3) If the bond energy becomes $\lesssim 2$ eV (paraffin radical-cations), the values of k exceed not only the rate constants for the radiative decomposition, but also the rate constants for internal conversion and vibrational relaxation. In this situation the quantum yield for the elimination of a hydrogen atom approaches unity.

$|\beta|^2 \simeq 2$ a.u. has been estimated for the case where the R–H bond is located in the part of the molecule where the excitation is localised (for example, a C–H bond of benzene). With increase of the distance R between the bond undergoing dissociation and the region where the wave function of the excited state is appreciably different from zero, the matrix element diminishes as R^{-2}. Therefore the constant k should be estimated, for example, in the case of the toluene molecule, from the formula $k \simeq$ $k \simeq 10^{12} F$. This must be taken into account when specific systems are considered.

It follows from the results presented that, other conditions being equal, the weakest R–H bond in the molecule will be preferentially dissociated. In most instances this has been observed experimentally, and henceforth we shall concentrate attention (without additional stipulations) on the description of the dissociation of the weakest R–H bond. One should bear in mind that the energy of the R–H bonds in excited electronic states is frequently smaller than in the ground state. Hence it follows that the probability of decomposition in the highest electronically excited states with formation of the fragment R in an electronically excited state may be much greater than the probability of the process involving the formation of the fragment R in the ground state. This decomposition pathway ($\overset{*}{M} \rightarrow \overset{*}{R} + H$) can be significant in the gas phase, but not in the condensed phase, since the lifetime of the highly excited states of molecular systems is very short in the condensed phase.

VI. PREDISSOCIATIVE DECOMPOSITION

We noted above (Section II) that, owing to the delocalisation of the electronic excitation over the molecular system, there are no significant changes in bond lengths if the number of bonds is large. However, the delocalisation may be infringed if the length of one or several equivalent bonds changes. In this situation a level may arise in the system with the localisation of the excitation energy at an individual bond [30,52], which leads to its dissociation. We shall examine the conditions for the appearance of such a level in a simple model of N equivalent two-electron bonds, weakly interacting with one another. Such are the C–H bonds of the majority of molecules.

The wave function of the ground state of the system can be described in the following form in terms of the zeroth approximation:

$$\Psi_0 = \hat{A} \prod_{n=1}^{N} \varphi_n^0 (R_n, \mathbf{r}_{1n}, \mathbf{r}_{2n}), \tag{15}$$

where $\hat{A}$ is the antisymmetrisation operator and $\varphi_n^0 (R_n, \mathbf{r}_{1n}, \mathbf{r}_{2n})$ is the wave function of the ground state of the nth bond, which depends on its length R_n and the electron coordinates $\mathbf{r}_{1n}$ and $\mathbf{r}_{2n}$. The dependence of the energy of each bond on R_n has the form of the $E^0(R_n)$ Morse curve and the energy of the entire system is

$$\sum_{n=1}^{N} E^0(R_n)$$

reaching a minimum for the equilibrium values of $R_n = R_n^0$.

The wave function of the excited state of the system can be expressed as the product of the wave functions $\varphi^1(R_n, \mathbf{r}_{1n}, \mathbf{r}_{2n})$ of the excited states of individual bonds (the strong bond approximation):

$$\Psi_j = \sum_{n=1}^{N} c_{jn} \hat{A} \varphi_n^1 (R_n, \mathbf{r}_{1n}, \mathbf{r}_{2n}) \prod_{\substack{n' \neq n \\ n'=1}}^{N} \varphi_{n'}^0 (R_{n'}, \mathbf{r}_{1n'}, \mathbf{r}_{2n'}). \tag{16}$$

The dependence of the energy $E^1(R_n)$ of an individual bond in the excited state on its length naturally differs from the function $E^0(R_n)$, which actually makes possible the localisation of the excitation energy at an individual bond. Using the variational principle for the energy, we obtain a system of equations defining E_j and c_{nj}:

$$\left[\sum_{\substack{n'=1 \\ n' \neq n}}^{N} E^0(R_{n'}) + E^1(R_n)\right] c_{nj} + \beta (c_{n+1,j} + c_{n-1,j}) = E_j c_{nj}, \tag{17}$$

where β is the resonance integral for the interaction of adjacent bonds.

We shall consider the dependence of wave functions (16) on the length of one of the bonds. If all the R_n are equal to their equilibrium values R_n^0, then E_j and c_{nj} are defined by the expression

$$E_j = (N-1)E^0(R_n^0) + E^1(R_n^0) + 2\beta\cos\frac{j\pi}{N+1},$$
$$c_{nj} = \sqrt{\frac{2}{N+1}}\sin\frac{jn\pi}{N+1}, \quad 1 \leqslant j \leqslant N. \tag{18}$$

In this case excitation delocalised over the entire system corresponds to each value of j. The change in bond order on excitation amounts to $\sim N^{-1}$, which is responsible for the small change in the $E_j(R_n)$ relation in the vicinity of R_n^0 when $N \gg 1$ compared with the $E^0(R_n)$ relation.

The change in the length of one of the bonds alters the matrix element in Eqn. (17) corresponding to this bond. The remaining matrix elements may then be regarded as invariant. The solution of this type of system of equations has been considered[53] and it has been shown that the $(N-1)$th solution again corresponds to the delocalisation of the excitation over the system and is described by an equation of type (18). However, one of the levels has a wave function (for $N \to \infty$) which decreases exponentially with increase of the distance from the selected bond n_0:

$$c_n = \exp[-|n_0 - n|\varkappa(R_{n_0})],$$
$$\sinh\varkappa(R_{n_0}) = [E^0(R_{n_0}) + E^1(R_{n_0}^0) - E^0(R_{n_0}^0) - E^1(R_{n_0})]/2\beta. \tag{19}$$

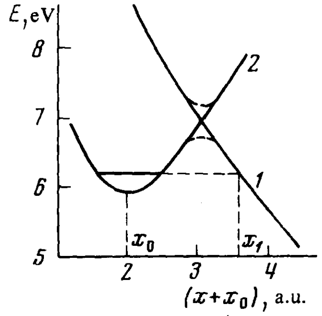

Figure 4. The energy levels of the localised (triplet) (curve 1) and delocalised (curve 2) states as a function of the C–H bond length.

It is seen from Eqn. (19) that the excitation may be localised if $\varkappa(R_{n_0}) \neq 0$. This situation is observed when the excitation energy decreases with increase in bond length, which implies that the excitation may be localised when the electron energy level of the excited state of an isolated bond is of the repulsive type. The energy of the system in state (19) is described by a curve with an activation barrier (Fig. 4) and the elimination of a hydrogen atom under the conditions of low excitation energies corresponds to a transition through the barrier.

In the region of excitation energies of hydrocarbons and their substituted derivatives not exceeding ~10 eV, the repulsive electron energy level of the C–H bond is of the triplet type[5]. The functions corresponding to this level describe the relative motion of the hydrogen atom and the radical in the ground electronic state moving apart to infinity.

The problem of the calculation of the rate of decomposition of molecular systems via a mechanism involving the localisation of the electronic excitation energy at the bond undergoing dissociation (which we shall call the predissociative mechanism) has already been examined[5,6]. It has been shown that the bond dissociation corresponds to a transition of a hydrogen atom from the energy level of a binding (delocalised) state to the repulsive energy level of the state where the electronic excitation is localised at an individual bond. Fig. 4 illustrates cross-sections of the potential surfaces for these two states as a function of the coordinate of the stretching vibrations of the R–H bond.

If the initial (delocalised) state is of the triplet type, then the localisation of the energy at an individual bond is due to an electron–electron (exchange) interaction. For a singlet initial state, the transition to a repulsive energy level can occur only under the influence of a relatively weak (see below) spin–orbital interaction. Hence follows immediately the important conclusion that the decomposition with elimination of a hydrogen atom can occur with a high probability only in triplet states.

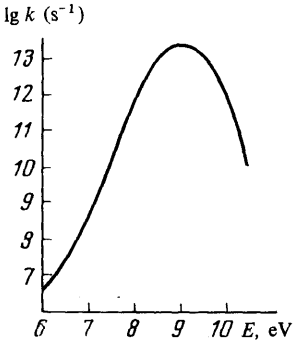

Figure 5. Dependence of the rate constant for the predissociative elimination of a hydrogen atom on the excitation energy.

Evidently the probability of the decomposition will depend on the relative positions of the energy levels of the initial and final states. As shown in Section II, the position of the energy level of the initial state for fairly complex molecules is determined solely by the electronic excitation energy. The position of the repulsive energy level depends on the bond dissociation energy and the energy of the exchange repulsion of the electron of hydrogen from the unpaired electron of the radical. (The remaining interactions are naturally also reflected in the position of the repulsive energy level, but their extent changes little from molecule to molecule.) The C–H bond dissociation energy is reduced in those cases where the unpaired p-electron is delocalised in the radical formed. The greater the degree of delocalisation of the unpaired electron, the smaller the energy of the exchange repulsion between hydrogen and the radical. Thus, as a result of the decreased bond energy, the repulsive energy level is lowered and the dissociation probability is a maximum for the weakest of the R–H bonds. This conclusion is therefore common to non-adiabatic and predissociative mechanisms.

The use of the formula of the first-order perturbation theory to calculate the rate constant for predissociation with rupture of the R–H bond yields the expression

$$k = 2\pi|\beta|^2|\langle n\}|\{s\}\rangle|^2, \tag{20}$$

where β is the matrix element of the electron–electron (spin–orbital) interaction between the initial and final states and $|\{n\}\rangle$ and $|\{s\}\rangle$ designate, as before, the wave functions of the nuclei in the initial and final states. Owing to the weak dependence (for slight displacements of the nuclei) of the operators of the electron–electron and spin–orbital interactions, Eqn.(20) includes the factor governing the overlapping of the nuclear functions of the initial and final states. It is noteworthy that Eqn.(20) is applicable in the region where the potential curves of the localised and delocalised states differ little from the true curve plotted taking into account their interaction. In the region of the intersection of the potential curves Eqn.(20) yields only an approximate estimate, somewhat smaller than the exact value. This region diminishes with increase in the number of bonds in the molecule.

The wave functions $|\{n\}\rangle$ are chosen in the same form as in the description of the non-adiabatic decomposition. Since the decomposition takes place, as a rule, in vibrational states with small quantum numbers ($n \lesssim 3$), the harmonic oscillator function may be adopted as the vibrational wave functions. This makes it possible to obtain, without loss of accuracy, an expression for k in a form suitable for calculation.

The wave functions $|\{s\}\rangle$ have a more complex form than those described in Section V. The point is that the potential surface of the final state is of the repulsive type not only in the direction of the stretching vibrations of the bond undergoing dissociation, but also in the direction of its deformation vibrations. Depending on the stretching vibration coordinate x, a function Ax, where A is the slope of the plot of the repulsive energy level, may be fitted to the potential surface. The parabolae By^2, where $B < 0$, may be fitted to the dependence of the repulsive electron energy level on the deformation displacements of the hydrogen atom[6]. Accordingly, the products of the Airy function[46] and two Whittacker functions[47] are used as the functions of the final state of the bond being dissociated. For the remaining bonds, the harmonic oscillator functions are used.

The calculations[6] yield an expression for k:

$$k = \frac{\sqrt{3}\pi|\beta|^2}{2}\prod_{\nu}\frac{\eta_\nu^{n'_\nu}e^{-\eta_\nu}}{n'_\nu!}\int_{-\infty}^{+\infty}\cosh^{-1}\left(\frac{z\pi}{2}\right)e^{\frac{\pi z}{6}}S^2\left(\delta-\frac{\omega_2}{A}+\frac{z\omega_2}{\sqrt{3}A}\right)dz, \tag{21}$$

where $\delta = x_1 - x_0 = (E_0 - E)/A$, where E_0 is the energy of the repulsive triplet level at the point of equilibrium (in the ground state) of the R–H bond, E is the energy of the initial state after the subtraction of the energy transformed into the energy of the vibrational excitation of the fragment R, and ω_2 is the deformation vibration frequency of the R–H bond. E_0 in most cases exceeds significantly (by 2–4 eV) the energy of the R–H bond. The remaining notation is the same as in Eqn.(9). The function $S(y)$ is defined by

$$S(y) = \left(\frac{2^{10}\mu}{A^2\pi^3\omega_1^3}\right)^{1/12}(2^n n!)^{-1/2}\left[\frac{\partial^n}{\partial t^n}S(t)\right]_{t=0},$$

$$S(t) = \exp\left(t^3-\frac{c^3}{\alpha^3}t+\frac{a}{2}y+\frac{b}{2}\right)\Phi\left(yc+d-\frac{2c}{\alpha}t\right), \tag{22}$$

where μ is the reduced mass, ω_1 the frequency of the stretching vibrations of the R–H bond, n the vibrational quantum number characterising the excitation of the stretching vibrations of the R–H bonds in the initial electronic state, $\alpha = \sqrt{\mu\omega_1}$, $c = (2\mu A)^{1/3}$, $a = c^3/\alpha^2$, $b = c^6/6\alpha^6$, $a = c^4/4\alpha^4$, and $\Phi(z)$ is the Airy function. In order to obtain the complete rate of elimination of hydrogen atoms, Eqn.(21) must be averaged with respect to the initial vibrational (electronic) states and summed with respect to the possible final states.

For rough estimates, the following formula may be used to calculate k:[5,54]

$$k = \frac{2\pi}{A}|\beta|^2\prod_{\nu}\frac{\eta_\nu^{n'_\nu}e^{-\eta_\nu}}{n'_\nu!}\Omega_n^2(\delta), \tag{23}$$

where $\Omega_n(\delta)$ is the function of the harmonic (anharmonic) oscillator of the stretching R–H bond vibration. The wave function $\Omega_0(\delta)$ is of the form

$$\Omega_0(\delta) = \left(\frac{\mu\omega_1}{\pi}\right)^{1/4}\exp(-\mu\omega_1\delta^2/2). \tag{24}$$

Hence it is seen that, when the parameter δ (i.e. the excitation energy) is altered, k passes through a maximum, where $E = E_0$ and $\delta = 0$. A similar variation of k is obtained when Eqn.(22) is used.

The parameter β has been estimated[5,55,56]. In the case of decomposition in triplet $\pi\pi^*$ states of aromatic (unsubstituted) hydrocarbons β is defined by the expression $\beta \simeq 10^{-2}N^{-1}$ a.u., where N is the number of carbon atoms in the molecule. Hence it is seen that the probability of the elimination of a hydrogen atom decreases as N^{-1}. For the lowest triplet states of aromatic hydrocarbons, β is defined by the expression $\beta \simeq 10^{-2}N^{-1/2}$ a.u., so that the probability of the decomposition of the molecule with elimination of a hydrogen atom is independent of molecular size for aliphatic hydrocarbons. A similar situation obtains also for the $n\sigma^*$ states of substituted aliphatic hydrocarbons.

Bearing in mind that, as in Section V, the quantity

$\prod_{\nu}\exp(-\eta_\nu)\eta_\nu^{n_\nu}(n_\nu'!)^{-1} \simeq 0.1$ and using $\beta = 10^{-2}$ a.u., we

obtain the following expression for k:

$$k(\mathrm{s}^{-1}) \simeq 10^{12}\int_{-\infty}^{\infty}\cosh^{-1}\left(\frac{\pi z}{2}\right)\exp\left(\frac{\pi z}{6}\right)S_n^2\left(\delta-\frac{\omega^2}{A}+\frac{\omega_2 z}{\sqrt{3}A}\right)dz. \tag{25}$$

The evaluation of the integral in Eqn.(25) does not present difficulties in most cases[6]. Since $n'_\nu \lesssim 1$, the vibrational energy of the fragment R cannot be large. Fig. 5 illustrates the variation of k with the parameter E calculated by Eqn.(25) for the following values of other parameters: $\omega_1 = 3000$ cm^{-1}, $\omega_2 = 1100$ cm^{-1}, $A = 0.1$ a.u., $E_0 = 9$ eV, and $n = 0$.

The $k(E)$ relation for decomposition in excited singlet states is of the same type. Since β for the dissociation of R–H bonds does not exceed several cm^{-1} in this instance[44], the values of k are reduced compared with decomposition in triplet states by 6–7 orders of magnitude. This means that the rate of decomposition in singlet states cannot be significant even for high excitation energies.

A few words may be said about the temperature dependence of the rate of decomposition. As already mentioned at the beginning of this Section, when the excitation energies do not exceed E_0, the elimination of a hydrogen atom is a process involving penetration through an activation barrier. k is independent of temperature at low values of the latter, in the present instance when $T < \omega k_B^{-1}$, where k_B is the Boltzmann constant, and ω is the C–H bond vibration frequency. Since $\omega \gtrsim 1000$ cm^{-1}, k acquires its low-temperature (quantum) value already at

300–400°C. At higher temperatures k increases with increase of T.

If the lowest triplet state of the molecule is located in the region of the maximum on the $k(E)$ curve, the molecule decomposes with a high probability in this state and the process involves elimination of a hydrogen atom. (We do not take into account other possible photochemical reactions.) With decrease of the energy of the lowest triplet state, the probability of decomposition diminishes. In this case, when the energy of the lowest triplet state is smaller than the bond dissociation energy, the elimination of a hydrogen atom is possible only in the highest excited triplet states. Internal conversion, which in most cases is very rapid and suppresses the predissociation process, competes with the above process. In certain molecules the rate of internal conversion may be reduced owing to the characteristics of their structure (see Section IX).

One should bear in mind that, for molecules with a small (smaller than E_0) ionisation potential, the maximum in the function $k(E)$ is in the region of the ionised states of the molecule. The excited (superexcited or autoionisation) states ionise rapidly in this situation ($10^{13}-10^{15}$ s^{-1}). This pathway to the decomposition of molecules, which does not itself lead to chemical changes in the molecule, constitutes an additional factor increasing the stability of molecules with respect to the elimination of a hydrogen atom. We may note that in the condensed phase the ionisation potential is lower than its value in the gas phase[57,58].

The stability of the molecules (in relation to the elimination of a hydrogen atom) is thus related to the positions of the triplet states, the ionisation potential, and the probability of deactivation processes‡. When specific systems are considered, one must of course bear in mind also the efficiency of the formation of triplet states. All the foregoing considerations are applicable (except for the names of the states) also to radicals and radical-cations. For this reason and also because the energy of the excited states of these systems is usually low[3,22,59,60] and the predissociative mechanism cannot therefore make a large contribution, the latter will not be discussed in detail.

VII. THE ISOTOPE EFFECT

The isotope effect in elimination reactions, which is defined as the ratio of the rate constants for the elimination of H and D atoms, can be used to test theoretical ideas about the process mechanism. Since the quantum yield is the main experimental characteristic of photochemical reactions, we shall consider briefly the conditions whose fulfilment is necessary for the observation of the influence of the isotope effect on the yield of the reaction[56].

We shall designate the rate constant for the dissociation of the C–H bond by k_H and that for the dissociation of the C–D bond by k_D. Suppose that the rate of deactivation of the excited states by all the pathways except decomposition is characterised by the constants k and k' respectively in the case of light and deuterated molecules. Then the quantum yield of the dissociation of the C–H and C–D bonds can be formulated thus:

$$Q_H = \frac{k_H}{k_H + k}, \quad Q_D = \frac{k_D}{k_D + k'}.$$

For low irradiation times, the rate of accumulation of products (the yield) is proportional to the quantum yield of the decomposition and we have for the ratio of the rates of accumulation of the light and deuterated molecules during photolysis

$$\frac{u_H}{u_D} = \frac{k_H}{k_D} \cdot \frac{k_D + k'}{k_H + k}. \tag{26}$$

If $k = k'$, $k' \gg k_D$, and $k \gg k_H$, then $u_H/u_D = k_H/k_D$, so that only in this case is the experimental ratio of the rates of accumulation of products equal to the ratio of the bond dissociation rate constants. Since the inequality $k_D + k' < k_H + k$ always holds, the ratio u_H/u_D gives the lower limit of the true value of the isotope effect.

It follows from the results presented in Sections V and VI that the isotope effect and its dependence on the excitation energy differ for the non-adiabatic and predissociative mechanisms. We shall consider initially the predissociative decomposition mechanism. The replacement of a hydrogen atom by a deuterium atom leads to an increase of μ by a factor of ~ 2 and to a decrease of ω_1 by a factor of $\sim\sqrt{2}$. It is readily seen that, for all the values of the parameter E, the change in the transition energies of the molecule on deuteriation may be neglected in the calculation of k_H/k_D without appreciable error. We then obtain from Eqn. (24)

$$\frac{k_H}{k_D} = 2^{-1/4} \exp\left[\mu\omega_1\delta^2 (\sqrt{2}-1)\right] = 2^{-1/4} \exp\left[\frac{\mu\omega_1}{A^2}(E - E_0)^2 (\sqrt{2}-1)\right]. \tag{27}$$

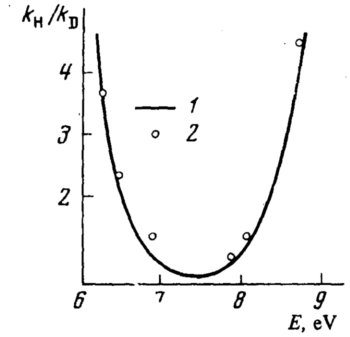

Figure 6. The isotope effect in the predissociative elimination of a hydrogen atom: 1) theory; 2) experiment[61].

Hence it is seen that the isotope effect exhibits a characteristic dependence on the excitation energy. For low excitation energies ($E < E_0$), the isotope effect is large. It decreases with increase of excitation energy, passes through a minimum when $E = E_0$, and then rises to high values again. Eqn. (27) refers to the decomposition in the zero-point vibrational state. A similar although more complex dependence has been observed also for the decomposition in vibrational excited states.

---

‡ Studies have been published recently[94,95] in which it has been shown that the decomposition of hydrocarbon molecules in T states takes place with elimination of a hydrogen atom via a predissociative mechanism.

The dependence of the isotope effect on the excitation energy has been studied experimentally[61] in relation to the two-quantum decomposition of triphenylmethane with dissociation of the central C–H bond. The triphenylmethane molecule satisfies the requirements specified at the beginning of this Section, and the measured ratio $u_H/u_D = k_H/k_D$.[56]

Fig. 6 presents the dependence of k_H/k_D on E, calculated by Eqn. (21), together with the experimental values[61]. The only parameter which was varied in order to obtain the best agreement with experiment was the energy of the vertical transition to the repulsive E_0 energy level. Thus $E_0 = 7.4$ eV was found. Evidently not only qualitative but also quantitative agreement between the theoretical and experimental variations of k_H/k_D with E is observed. This result constitutes a convincing demonstration of the predissociative mechanism for the decomposition of electronically excited polyatomic molecules with elimination of a hydrogen atom. We shall present below (Section VIII) yet another experimental result of this kind.

The isotope effect in a non-adiabatic elimination reaction depends very strongly on the bond energy. The replacement of a hydrogen atom by a deuterium atom leads to an increase of the parameter s_0 in Eqn. (10) by a factor of $\sim\sqrt{2}$. The data in Section V show that the rate of decomposition decreases almost by an order of magnitude for bond energies $\lesssim 2$ eV and by more than an order of magnitude for higher bond energies. Unfortunately no experimental data are at present available for the isotope effect in a non-adiabatic elimination reaction.

VIII. PHOTOCHEMICAL STABILITY OF MOLECULAR SYSTEMS

In this Section we shall show in relation to specific examples how the photochemical stability of molecules can be related to their structures using the above theoretical results. In conformity with the initial task, we shall consider only the photochemical R–H bond dissociation reactions. Before proceeding to the consideration of specific systems, we shall define yet again the region of applicability of the concepts described. The most important hypothesis among these is that the change in the potential surface of the molecule in the excited state is little different from that in the ground state. Molecules with a small number of atoms (of the type of H_2O), in which there is a significant change in the geometrical characteristics of the system on electronic excitation due to the small number of bonds, constitute an evident exception. Molecules containing either a weak R–H bond, the excited orbitals of which have the minimum energy, constitute a less evident exception. The lowest excited state of such a system corresponds to local excitation of this bond, with a significant change in the nature of the dependence of the potential curve on the bond length. A characteristic example of this is provided by molecules containing an S–H bond (mercaptans). This can be readily demonstrated by comparing the absorption spectra of mercaptans and aliphatic sulphides. The absorption spectra of mercaptans are located further towards long wavelengths than the spectra of the sulphides[62]. The opposite relation is observed in oxygen- and nitrogen-substituted aliphatic compounds when O–H (N–H) bonds are replaced by O–C (N–C) bonds[1]. Aliphatic compounds containing C–C, C–H, C–N, C–O, C–S, N–H, and O–H (but not S–H) bonds are therefore the objects of our consideration.

In modern photochemistry, there are two situations differing in the methods whereby excited states are generated. For low intensities of the exciting light, the system in an excited state has not had sufficient time to absorb a second quantum. The evolution of the electronic states of the system in this situation is described by a simple kinetic scheme, where there is a possibility of transitions to the lowest electronic states only (at low temperatures). For high light intensities, the system, which is in the triplet state, can absorb a second light quantum with a high probability, this being accompanied by a transition to highly excited triplet states§. The photochemistry of molecules is in this case referred to as two-quantum photochemistry[23] and differs from the classical one-quantum photochemistry. As can be seen from the foregoing factors, in a theoretical treatment these two cases must also be distinguished. We shall examine the one-quantum case first.

1. Aromatic Hydrocarbons

The energy of the C–H bond in the molecules of aromatic hydrocarbons is 4.5 eV.[63] The rate of elimination of atoms from such systems cannot therefore exceed $10^2\ s^{-1}$ if the decomposition takes place from the ground vibrational state. The lifetime of the lowest singlet state of the benzene molecule, the energy of which is sufficient for the dissociation of the C–H bond, amounts to 10^{-7} s.[24] It follows from this that the quantum yield of the elimination of hydrogen atoms on excitation by the light corresponding to the first absorption band cannot exceed 10^{-5}. This value agrees with numerous experimental data[1].

When the benzene molecule is excited to high singlet states ($\lambda < 1849$ Å), the quantum yield of the cleavage of the C–H bond in the gas phase increases[65], which can be explained by several causes: (1) singlet–triplet conversion may lead to highly excited triplet states, where decomposition via a predissociative mechanism takes place. (2) Internal conversion can result in the formation of a highly vibrationally excited benzene molecule in the first singlet state, where the probability of the dissociation of a C–H bond may become very appreciable, in conformity with Eqn. (12). (3) Non-adiabatic decomposition with formation of a C_6H_5 radical in an electronically excited state may also make a definite contribution. All these mechanisms are unlikely in the condensed phase, where the rates of internal conversion and vibrational relaxation are high.

The introduction of alkyl substituents into the benzene molecule diminishes somewhat the photochemical stability of the molecule under the same excitation conditions. This was to be expected in view of the results described in Section V, because these molecules contain a C–H bond in the alkyl substituent with a dissociation energy of approximately 3.6 eV. Despite the fact that the bond is remote from π-electron system of the molecule, where the excitation is localised, calculations (see Section VI) have shown that the rate of its dissociation exceeds by

---

§ For still higher excitation intensities, transitions from the lowest excited S_1 state to the upper singlet states also become significant[64], but transitions of this kind do not introduce any significantly new features into the photochemical behaviour of molecules, because this situation corresponds to low intensities of the high-frequency excitation field.

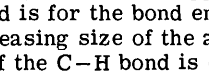
more than an order of magnitude the rate of dissociation of the bonds in the benzene ring. The quantum yield of the dissociation of the C–H bonds in the alkyl substituents of benzene (toluene, ethylbenzene, t-butylbenzene, mesitylene, and others[1]) exceeds 10^{-4}, which is greater by an order of magnitude than the corresponding value for benzene and agrees well with the estimated value of k quoted here.

Aromatic compounds (naphthalene, anthracene, etc.) having a more extensive chain of conjugated bonds than benzene and their substituted derivatives are still more stable. This is associated with the fact that the energy of the lowest singlet (and even more so triplet) states is insufficient for the dissociation of the C–H bonds.

2. Aliphatic Hydrocarbons

The dissociation energy of the C–H bonds in aliphatic hydrocarbons is approximately 4 eV.[63] Decomposition via a non-adiabatic mechanism cannot therefore contribute much to the formation of atomic hydrogen in the photolysis of paraffins, the quantum yield of which is approximately 0.1.[1,12,13] Decomposition via a predissociation mechanism in the singlet state arising on photoexcitation is forbidden, as shown in Section VI. The only real mechanism of the decomposition of paraffin molecules with elimination of a hydrogen atom therefore involves predissociative decomposition in the triplet states, whose energy (~6–7 eV) [44,46] is more than sufficient for this reaction. According to Plotnikov's estimates[44], the rate of the singlet–triplet conversion in paraffins should be high (~10^9–10^{10} s^{-1}). Quantities of the same order of magnitude may be obtained also for the rate of elimination of a hydrogen atom in triplet states. The molecular elimination of H_2 [67] and certain other processes compete with the singlet–triplet conversion. Only the fraction of the molecules which pass to the triplet states undergo decomposition with elimination of a hydrogen atom. This in fact explains the finding that, despite the high rate of elimination of a hydrogen atom, the quantum yield of this process is appreciably less than unity on photoexcitation of paraffin molecules. The atom produced should possess a considerable kinetic energy ($\geqslant$1 eV).

The set of experimental and theoretical results makes it possible to postulate a mechanism for the photochemical decomposition of paraffin in the lowest excited states with formation of hydrogen:



3. Aldehydes and Ketones

The lowest singlet state of aliphatic aldehydes and ketones is the $n\pi^*$ state, the energy of which is ~3.4–3.7 eV.[1,24] The experimental dissociation energies of the H–COR bond in aldehydes show an appreciable scatter, but the overall trend is for the bond energy to increase somewhat with increasing size of the alkyl group R. Thus the lowest energy of the C–H bond is estimated as 3.02 eV in formaldehyde and 3.69 eV in the CH_3CHO molecule[68]. If this is so, the dissociation of the C–H bond in formaldehyde via a non-adiabatic mechanism should be much faster than in the molecules of more complex aldehydes. Experimental data[1] confirm this conclusion: the elimination of atomic hydrogen is significant only in the photochemistry of formaldehyde and is not observed for more complex aldehydes.

The C–H bond dissociation energy in ketones is approximately 4 eV,[63] so that it exceeds the energy of the lowest excited singlet state. This explains the experimental finding that the elimination of a hydrogen atom on excitation of ketones with light corresponding to the first absorption band is not observed. Only for very high excitation energies (~6–7 eV), where predissociative decomposition via triplet states becomes possible, is there an appreciable contribution by reactions involving the elimination of a hydrogen atom (acetone in the gas phase)[1].

4. Substituted Aliphatic Compounds

The energy of the lowest singlet excited state of aliphatic alcohols, ethers, and amines is of the $n\sigma^*$ type and amounts to ~6 eV,[1,69] while the C–H bond dissociation energy in these compounds is ~4 eV.[63] It is seen from these data that, although the dissociation of C–H bonds via a non-adiabatic mechanism in $S_{n\sigma^*}$ states is possible, its contribution is small. The predissociative decomposition in triplet states, which are located in the vicinity of the lowest singlet, is much more effective. Since the elimination of an H_2 molecule competes with the intercombination conversion process which precedes the decomposition, as in aliphatic hydrocarbons, the elimination of a hydrogen atom is not the only (and perhaps not the decisive) reaction. The introduction into the molecule of O, N, S, etc. atoms with a nuclear charge greater than that of a carbon atoms leads to an increase of the rate of the singlet–triplet conversion[44], which should result in an increased role of the hydrogen atom elimination reaction of such molecules, compared with hydrocarbon molecules. Here one must of course take into account the change in the position of the lowest triplet state on substitution. It may turn out that substitution leads to a sharp decrease of the energy of the T state, which increases the stability of the molecule. (This in fact occurs when an S atom is introduced into the molecule of an aliphatic sulphide.) The experimental data available hitherto[1] confirm this tendency, since the yield of atomic hydrogen in the photolysis of alcohols, ethers, and amines is always higher than in the photolysis of paraffins. Unfortunately the mechanism of the photolysis of aliphatic compounds with substituents has been studied less thoroughly than that of aliphatic hydrocarbons. This factor precludes a quantitative comparison of the theoretical and experimental results.

Aromatic alcohols, ethers, and amines are much more stable than their aliphatic analogues, which can be accounted for by the low energy of the triplet states of aromatic compounds

5. Certain Radicals

The bond energy D of the hydrogen atom in many radicals is greatly reduced compared with its value in the initial molecules[63]:

R	H—CO	C_2H_5	C_2H_3	H—CHOH
D, eV	~0.8	~1.7	~1.7	~1.2

Comparison of the above data with the results in Section V shows that radicals are as a rule less stable than the parent molecules. Indeed, for a bond energy $\lesssim 2$ eV, the rate of elimination of the hydrogen atom exceeds 10^9 s^{-1}, i.e. is higher than the rate of radiative transitions. For bond energies less than ~1 eV, the decomposition takes place with a quantum yield of ~1, if the excitation energy exceeds the energy threshold of the reaction, regardless of the position of the lowest excited state. The available experimental data for photochemical reactions of radicals [22] confirm this conclusion.

6. Radical-cations Derived from Organic Molecules

The R–H bond energy in radical-cations derived from organic molecules depends very markedly on their structure. Its value (D^+) may be expressed in terms of the energy of the R–H bond in the initial molecule (D) and the difference between the ionisation potentials (ΔI) of the molecule and the radical: $D^+ = D - \Delta I$. In most cases $\Delta I > 0$ and $D^+ < D$. Hence it follows that radical-cations are as a rule less stable than the initial molecules. (There are also exceptions. Thus $\Delta I < 0$ for the aniline molecule.)

ΔI for aliphatic compounds is 2–3 eV,[63] but in the case of aromatic compounds it is appreciably less. Thus it amounts to ~1.4 eV for the toluene molecule[63]. These data show that the energy of the C–H(R–H) bond in radical-cations derived from aliphatic molecules is 1–2 eV, while the value for radical-cations obtained from aromatic molecules is much higher, being close to ~3 eV. We may note that the C–H bond energy in the CH_2 groups of the radical-cations derived from aliphatic hydrocarbons is smaller by 0.5 eV than the corresponding value for the CH_3 groups.

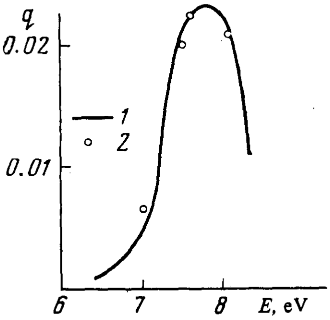


Figure 7. Dependence of the quantum yield of the elimination of a hydrogen atom from the triphenylmethane molecule on the triplet excitation energy: 1) theory; 2) experiment[61].

Comparison of the above data with the results of Section V shows that the radical-cations of aliphatic compounds are much less stable than those of aromatic compounds. This conclusion has been confirmed experimentally [70,71]. The fact that the energy of the first excited doublet state of the radical-cations is frequently small (~1–2 eV) [26,59,60] provides further justification for the above conclusion. Whereas the rate constant for the elimination of a hydrogen atom from aliphatic compounds is high and the elimination process may compete with internal conversion, in aromatic compounds it is almost completely suppressed. The hydrogen atom should be eliminated with a high probability from the central part of the radical-cations derived from paraffins.

We shall now consider briefly the two-quantum excitation of organic molecules. Such excitation gives rise to highly excited triplet states, where C–H bonds may be dissociated via a predissociative mechanism[72]. (This process is not of course the only one possible. Highly excited triplet states very frequently undergo ionisation or preionisation, and not predissociation, particularly when polar solvents are used[23,73].) The case of the two-quantum excitation of molecules is of particular interest, since it makes it possible to compare the theoretical result for the dependence of the probability of predissociation on the energy of the excited state (see Section VI) with experiment.

The $k(E)$ relation has been studied experimentally[61]. Fig. 7 illustrates the theoretical relation, calculated by Eqn.(25) using the parameters characteristic of the C–H bond, together with the experimental results. Evidently there is not only qualitative, but also quantitative agreement between the theoretical and experimental data.

The above examples show how the causes of the different photochemical stabilities of molecular systems having different structures may be understood using theoretical conclusions.

IX. RADIATION-CHEMICAL STABILITY OF MOLECULAR SYSTEMS

The yield of stabilised radicals is used as a quantitative criterion of the stability of molecules in the radiation chemistry of condensed media at low temperatures, because hydrogen atoms are not detected in most cases. The possibility of employing these data to compare the theoretical conclusions of Sections V and VI with experiment is not evident. Strictly speaking, the theory described is applicable to the yield of atomic hydrogen and its use to describe the yield of radicals may be to some extent qualitative. The point is that unimolecular reactions are not the only possible pathway to the formation of radicals. Radicals whose structure is identical with that of the radicals obtained from the parent molecules following the elimination of a hydrogen atom may arise as a result of the ion–molecule reaction

$$RH^+ + RH = R^{\cdot} + RH_2^+$$

and others. The relative contributions of unimolecular and other radical-generating processes are not at present known with sufficient accuracy[21], but the yield of radicals is usually appreciably (by a factor greater than 2) higher than that of stabilised electrons and therefore radical-cations[19]. Hence follows the conclusion that the unimolecular pathway to the formation of radicals is one of the most important. Apart from the causes already indicated, yet another factor prevents a quantitative comparison of theoretical conclusions with experiment: the amount of radicals detected may not agree with its initial value, because the initial radicals may disappear in numerous reactions (disproportionation, recombination, isomerisation, etc.). For this and other reasons (see below), in comparing the conclusions of Sections V and VI with experiment one must employ data obtained at temperatures as low as possible.

In describing unimolecular hydrogen elimination process in radiation chemistry, one must bear in mind the following two factors. The effect of ionising radiation on molecular media leads to the formation of not only neutral excited molecules, but also of electronically excited radical-cations. According to estimates[74], the yields of ionised and electronically excited species are approximately the same. The decomposition of radical-cations with elimination of a hydrogen atom and subsequent recombination of the radical-cation R^+ with an electron constitutes an additional pathway (unimolecular in the sense of the formation of hydrogen atoms) to the formation of radicals in radiolysis, compared with photolysis. The natures of the primary excited states of molecules formed on radiolysis and on excitation by light are different. Under the conditions of radiolysis, excitation takes place when electrons collide with the molecules. The optically forbidden singlet—triplet transitions become allowed under these conditions (particularly for the resonance energies of the electrons) and the possibility of the excitation of triplet states, bypassing singlet states, arises.

There is yet another possibility of the direct excitation of triplet states, associated with the recombination reactions of radical-cations and electrons. The ratio of the amount of triplet states formed under these conditions to the amount of singlet states is three, provided that the orientations of the spins of the unpaired electron of the radical-cation and the electron with which it recombines are independent[75]. Under real conditions, this ratio depends also on a number of factors [the spin relaxation time and the distribution of radical-cations and electrons (see, for example, the paper of Magee and Huang[76] and the literature quoted therein¶)].

The direct formation of excited triplet molecules on radiolysis should lead to an increase of the yield of atomic hydrogen compared with its yield on photolysis. Experimental data confirm this conclusion. Thus the ratio of the yield of atomic hydrogen to that of molecular hydrogen is close to unity in the radiolysis of aliphatic hydrocarbons[3]. In photolysis the ratio is approximately 0.1 (see Section VIII).

We shall now consider specific systems. In order to demonstrate the generality of the approach, we shall divide molecules into groups in terms of their radiation-chemical stabilities and not chemical classes. All organic compounds can be divided arbitrarily into three groups: compounds in which the yield of radicals per 100 eV of absorbed energy $G > 1$, compounds for which $G \simeq 1$, and compounds for which $G \ll 1$. The reasons for this subdivision will be made clear below.

1. The first group of compounds includes aliphatic hydrocarbons, alcohols, ethers, amines, and many polymers. Table 1 lists the experimental values of G for these compounds and includes the energies of the lowest triplet state (E_T) and the C–H bond dissociation energies in a neutral molecule (L).[63] The value of E_T for the majority of molecules was determined as the difference between the energy of the lowest singlet state[1,68] and the singlet–triplet splitting. The latter was assumed to be 1 eV for aliphatic hydrocarbons ($\sigma\sigma^*$ states) and 0.5 eV for the remaining compounds ($n\sigma^*$ states)[44]. The values of E_T thus obtained are apparently somewhat higher than the true values[66], but for our purposes an improvement in the accuracy of E_T is unimportant. We may also note that all these compounds, with the exception of amines, have a high ionisation potential ($\geqslant$9 eV). Depending on the molecular structure, its value for amines varies from 7.6 eV to 9 eV.[63] The data in Table 1 permit the conclusion that there is a high probability of the elimination of hydrogen atoms via a predissociative mechanism from molecules of compounds in the first group in the excited triplet state.

Table 1. The values of G, E_T, and D for compounds of the first group.

Compound	G	References	E_T, eV	D, eV
Cyclohexane	4	77	7	4,08
n-Hexane	4.7	20	7	4,1
n-Heptane	4.4	20	7	4,1
n-Decane	3.6	20	7	4.1
Methyl alcohol	5.2	78	6,4	3.96
Ethyl alcohol	6.4	78	6,4	3.9
Aliphatic amines	3—5	79	5.1	4.05
Ethers	2—4	79	6	3.9
Polyethylene	5.8	8	7	4
Polypropylene	4.8	8	7	3.9
Poly(vinyl alcohol)	2.8	8	6	3.9
Polyvinylformal	5	8	6,4	3.9
Polyamides	2,4—3.1	8	5.3	3.9
Poly(ethylene glucol)	4—4.8	8	6	3.9

Since the ionisation potentials of the compounds listed in Table 1 are high, one may expect the formation of a large number of highly excited triplet states on charge recombination. The hydrogen atom formed in this reaction has a high kinetic energy and in its first collision may abstract a hydrogen atom from a neighbouring molecule. This may explain the stereospecificity of the formation of radical pairs in solid paraffins[80]. The energy of the C–H(O–H, N–H) bonds in the radical-cations derived from the molecules of the first group is ~1 eV.[21,71] In conformity with the results in Section V, this leads to high rate constants for the elimination of a hydrogen atom from electronically excited radical-cations.

Thus both pathways to the formation of radicals discussed here occur with a high probability for compounds of the first group. It is so far difficult to estimate their relative contributions.

2. The second group includes compounds with $G \simeq 1$. Table 2 presents examples of some of them. The data listed in this table show that the energy E_T is in most cases (where it is known exactly) lower than the energy of the C–H bond. In conformity with the results in section VI, the probability of the elimination of a hydrogen atom from the excited molecules is determined by the ratio of the rate constants for the elimination and internal conversion processes. It is readily seen that the latter depends in this instance on the molecular structure. In

---

¶ Apart from the factors quoted by Magee and Huang[76], the ratio of the yields of triplets and singlets is also influenced by processes involving the polarisation of the medium, the electronic matrix element of the transition, and the Franck–Condon factor of the vibrations of the molecules and the medium. These problems have not as yet been investigated theoretically.

highly excited reactive $\sigma\sigma^*$ and $\pi\sigma^*$ ($\sigma\pi^*$) states the excitation is delocalised over the entire molecule. The lowest triplet state is localised in a comparatively small part of the molecule (at a benzene ring, a double bond, or an S–S bond). The spatial separation of the excited states causes a decrease of the rate of internal conversion between highly excited states and the $\pi\pi^*$ ($n\sigma^*$) state with increase of the number of CH_2 group (N) as N^{-1}. When $N \gg 1$, conversion processes cannot suppress the decomposition processes. All the foregoing considerations apply also to the excited states of the radical-cations derived from the molecules of the second group.

Table 2. The values of G, E_T, and D for compounds of the second group.

Compound	G	References	E_T, eV	D, eV
Ph—$C_{17}H_{35}$	0.8	81	3.5	3.7
Ph—C_9H_{19}	0.59	81	3.5	3.7
Ph—C_7H_{15}	0.46	81	3.5	3.7
Ph—C_5H_{11}	0.55	82	3.5	3.7

 ($n = 4$—12)	1	79	<4	~4

The second group thus includes compounds where one or both of the given pathways to the formation of radicals are incompletely suppressed. Some of the compounds of the second group should be included in the third group. We placed them in Table 2 in order to demonstrate the continuity of the transition from the second to the third group.

The term intramolecular energy transfer is used in radiation chemistry instead of the term internal conversion. In other respects the above ideas are the same as those developed in studies by Voevodskii and coworkers[2].

3. The third group includes compounds with the highest radiation-chemical stability (Table 3). The data in Table 3 show that the energy of the lowest triplet state[24,27] of these compounds is lower than the C–H bond dissociation energy. One should not expect for these compounds anomalously long internal conversion times in the highest triplet states, since the excited states of these compounds are not spatially separated. The elimination of a hydrogen atom from the molecules in the highest triplet states is suppressed by internal conversion. An increase of the number of π electrons leads to a decrease of the rate constant for the elimination of a hydrogen atom (see Section VI) and to an increase of the internal conversion rate constant owing to the increase of the density of electronic states. This explains the decrease of G with the increase of the number of conjugated bonds in the molecule.

The energy of the bonds involving the hydrogen atoms in the radical-cations derived from the majority of the compounds listed in Table 3 is high (~3 eV [63,71]), so that the non-adiabatic reaction involving the elimination of a hydrogen atom from a radical-cation cannot compete with the decomposition reactions in the excited states. The ionisation potentials of all the compounds in the third group do not exceed 9 eV [63] and decrease sharply on passing to the condensed phase[57,58]. This means that the probability of the formation of highly excited triplet states on charge recombination is low and that their lifetime is short owing to ionisation processes. With increase of the polarity of the medium, the probability of the formation and the lifetime of the highest triplet states diminish, which may explain the decrease of G with increasing polarity of the medium (cf. for example, benzene and benzoic acid).

Table 3. The values of G, E_T, and D for compounds of the third group.

Compound	G	Refs.	E_T, eV	D, eV
Toluene	0.3	2	3.55	3.7
Benzene	0.2	2	3.66	4.7
Phenylacetylene	0.08	83	3.1	4.7
Diphenylacetylene	0.04	83	3.1	4.7
Biphenyl	0.05	82	2.8	4.7
Diphenyl disulphide	0.06	79	3.5	4.7
Thiophen	0.18	79	<4	4.7
Benzoic acid	0.05	2	3.35	4.7
Polystyrene	0.2	8	3.5	3.7
Poly(ethylene terephthalate)	0.4	8	3.5	3.7

The above results demonstrate the usefulness of the attempt to explain the low-temperature radiation-chemical stability of molecules (in the narrow sense under consideration) taking into account only the unimolecular radical formation reactions. The absence of contradictions between the theoretical and experimental data permits certain hypotheses concerning the possible role of the remaining radical formation processes, in the first place the role of ion–molecule reactions: the role of these processes at low temperatures is either small or the probability of their occurrence is correlated with the probability of unimolecular reactions. The discussion of this problem is outside the scope of the initial aim of this review and we shall therefore confine ourselves to certain general remarks.

The widely held view in radiation chemistry that ion–molecule reactions in the condensed phase make an appreciable (decisive according to some workers[19]) contribution to the formation of radicals in low-temperature radiolysis is based on the high cross-sections of these reactions in the gase phase[71,84,85]. However, it is incorrect to assume that these results are also valid for the condensed phase.

It follows from the general theory of reactions involving a change in charge distribution in the condensed phase[86-88] that their rates depend on the energy of the reorganisation (repolarisation) of the medium, decreasing exponentially with its increase. This leads to a non-zero activation energy for ion–molecule reactions in the condensed phase. The presence of an activation energy has been noted for ion–molecule reactions even of weakly polarised compounds such as molecular hydrogen[89]. At low temperatures ($k_BT \ll E_a$, where E_a is the activation energy) ion–molecule reactions therefore make a small contribution to the formation of radicals (naturally provided that $E_a \neq 0$).

The values of E_a are at present unknown, so that it is difficult to specify the temperature below which ion–molecule reactions are unimportant for the given system. Experimental studies of the temperature dependence of the yield of radicals at $T < 77$ K may be of primary importance in this connection. Since the rates of unimolecular reactions involving the elimination of atomic hydrogen are independent of temperature, such data make it possible to estimate the contributions of different pathways to the formation of radicals at low temperatures. (We may note that the yield of CH_3 radicals in the radiolysis of methane at 4.2 K is the same as the yield of atomic hydrogen[90].)

Another important difference between the condensed and gas phases, which must be taken into account in considering ion–molecule reactions, is that the lifetime of the separated charges in non-polar media is extremely short ($\lesssim 10^{-10}$ s).[3,91] The recombination process will thus compete with ion–molecule reactions, increasing the contribution of the unimolecular radical formation process.

Unfortunately there is as yet no common point of view on the problem of the relation between ion–molecule reactions and the electronic structures of the species involved in them. One can only claim that aliphatic molecules and cations show a greater tendency to undergo such reactions than aromatic species, because the ionisation of aromatic molecules does not involve R–H (C–H) bonds. The probability of ion–molecule reactions is particularly high for aliphatic alcohols and amines, because the ionisation of their molecules involves the elimination of an n electron, together with an oxygen or nitrogen atom, and a significant decrease of the proton elimination energy.

Thus it is to be expected that the probability of ion–molecule radical-formation reactions is correlated with the probability of unimolecular reactions, and that the contribution of the latter at low temperatures is decisive, although exceptions are possible.

The contents of this section are part of the general theory of the radiation-chemical behaviour of molecules The creation of this theory is a task for the future.

X. CONCLUSION

The results quoted demonstrate the usefulness of the application of theoretical considerations in the interpretation of the photochemical and radiation-chemical properties of molecular systems. There is no doubt that interesting results are to be expected along these lines in the future. We believe that the theory will develop along two paths: the refinement of the models already examined and the development of models of processes which have not as yet been investigated. In refining the models, one should bear in mind primarily the possibility of reactions involving the elimination of a hydrogen atom and the formation of radicals in electronically excited states. This path is of considerable importance in the vacuum photolysis of gas-phase molecules. Among problems which have not been investigated as yet, the development of the theory of the non-adiabatic and predissociative elimination of molecular hydrogen, of the dissociative addition of electrons, and of the formation of excited states by recombination is important. The problem of the theoretical description of ion–molecule reactions in the condensed phase is of particular interest. The successful solution of such problems requires further experimental investigation of the spectra of radicals and radical-cations and of the temperature dependence of the yield of radicals in radiolysis.

XI. APPENDIX

Here we shall describe the estimation of the electronic component of the matrix element of the non-adiabatic operator. The expression for β can be transformed into

$$\beta = \left\langle i \left| \frac{\partial U}{\partial x} \right| f \right\rangle_{x=0} [\Delta E_{fi}(0)]^{-1}, \tag{A.1}$$

where U is the operator of the Coulombic interaction of the electrons and nuclei of the system and $\Delta E_{fi}(0)$ is the difference between the electronic energy levels f and i at the point corresponding to the equilibrium configuration. By choosing the system in such a way that the x axis coincides with the direction of the R–H bond, one can obtain for the derivative $\partial U/\partial x$

$$\frac{\partial U}{\partial x} = \sum_i \left[\frac{z_1 e^2 m_2 (X_1 - x_i)}{(m_1 + m_2)\,|\mathbf{R}_1 - \mathbf{r}_i|^3} - \frac{z_2 e^2 m_1 (X_2 - x_i)}{(m_1 + m_2)\,|\mathbf{R}_1 - \mathbf{r}_i|^3} \right], \tag{A.2}$$

where m_1 and m_2 are the masses, z_1 and z_2 the effective charges, $\mathbf{R}_1$ and $\mathbf{R}_2$ the radius-vectors, X_1 and X_2 their x components for the nuclei of the hydrogen atom and the atom to which it is linked, and $\mathbf{r}_i$ and x_i are the radius vector and its x component for the ith electron. The operator (A.2) is of the one-electron type and the general expression for its matrix elements between arbitrary configurations can be found in Kaplan's book[92]. If $|i\rangle$ is the excited state and $|f\rangle$ is the ground state, then

$$\left\langle i \left| \frac{\partial U}{\partial x} \right| f \right\rangle = \sqrt{2} \left\langle \varphi_i \left| \frac{\partial U}{\partial x} \right| \varphi_f \right\rangle, \tag{A.3}$$

where φ_i and φ_f are the molecular orbitals between which the electronic transition takes place. In other cases the expression for the numerator in Eqn. (A.1) differs from that in Eqn. (A.3) by an unimportant numerical multiplier. When φ_i and φ_f are described by a linear combination of atomic orbitals. The main contribution to β comes in most cases from two-centre integrals for the interaction of the electrons of the atom to which the hydrogen atom is linked with the nucleus of the hydrogen atom. Their calculation presents no difficulty, since they are expressed in terms of the derivatives of two-centre quantum-chemical integrals with respect to the internuclear distance R.[93] For example, in the case of $\pi-\pi^*$ transitions of aromatic molecules, this integral is

$$\gamma = \left[2p_z 2p_z \left| \frac{X_1 - x}{|\mathbf{R}' - \mathbf{r}|^3} \right.\right] = \frac{1}{R^2} - \frac{18}{\alpha^2 R^4} + \left(\frac{18}{\alpha^2 R^4} + \frac{18}{\alpha R^3} + \frac{8}{R^2} + \frac{2\alpha}{R} + \frac{\alpha^2}{4} \right) e^{-\alpha R}, \tag{A.4}$$

where α is the Slater charge of the carbon atom for the $2p_z$ functions. Assuming that $R = 2$ a.u., and $\alpha = 3$, we obtain $\gamma \simeq 0.15$ a.u. The integrals with other functions of the valence shell of the carbon atom and other atoms in the Second Period have similar values. The expression $\gamma = R^{-2}$ can be used for estimates, provided that $R > 3$ a.u.

Taking into account only two-centre integrals for the interaction of atoms with the nearest carbon atom, we obtain the following expression for β in the decomposition of aromatic hydrocarbons in the $\pi\pi^*$ states:

$$\beta = C_{ni} C_{nf} \gamma (\Delta E_{if}(0))^{-1},$$

where C_{ni} and C_{nf} are the coefficients of the expansion of φ_i and φ_f with respect to the atomic orbitals of the carbon atom from which the hydrogen atom is eliminated. If the molecule contains N carbon atoms, then $C_{ni} \simeq C_{nf} \simeq N^{1/2}$ and $\beta \simeq N^{-1}\gamma[\Delta E_{if}(0)]^{-1}$. After summation with respect to all the hydrogen atoms, we find that $k \simeq N^{-1}$. Thus the stability of molecules increases with increase in the number of conjugated bonds. The values $N \lesssim 6$ are of real interest. Bearing in mind that $\Delta E_{if} \simeq 0.1$ a.u., we obtain $|\beta|^2 \simeq 2$ a.u. For molecules containing a large number of bonds, $|\beta|^2$ is much smaller than this value.

In the decomposition of molecules in $\sigma\sigma^*$ states, which can be described in terms of the strong bond approximation, k is independent of N, and the same value (i.e. 2 a.u.) may be used for $|\beta|^2$. If the decomposition takes place in the $n\pi^*$ and $n\sigma^*$ states of molecules or $\sigma\sigma^*$ states of radical-cations, then k is independent of molecular size owing to the localisation of states, and it may be assumed that $|\beta|^2 \simeq 2$ a.u.

^{13}C NMR Spectroscopy of Substituted Cyclohexanes

N.M.Sergeev and O.A.Subbotin

New possibilities are demonstrated in the study of the conformations and dynamics of ring inversion in substituted cyclohexanes by ^{13}C NMR spectroscopy compared with other methods of chemical and physical analysis.
The bibliography includes 106 references

I. INTRODUCTION

^{13}C NMR spectroscopy employing the natural abundance of the ^{13}C isotope ($\sim$1.1%) has become extremely common in recent years. Progress in the technique of the recording of weak NMR signals, due to the introduction of pulsed Fourier transform NMR spectroscopy (FT),[1] permitted a wide-scale employment of this method in studies on complex objects, particularly natural products. The general principles of ^{13}C NMR and its applications are described in a number of reviews[2,3] and monographs[4-6]. Among the applications of the method, special mention should be made of stereochemical research associated with the determination of the steric structures of organic molecules. The term "stereochemical research" is used in its widest sense, including the study of the possible conformations (conformational analysis) and the kinetics of intramolecular rearrangements (dynamic stereochemistry).

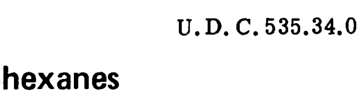
The aim of the present review is to analyse the results of the application of the ^{13}C NMR method to the study of substituted cyclohexanes. These compounds are of practical interest for organic chemistry and are traditional objects of classical conformational analysis[7].

II. CONFORMATIONAL ANALYSIS AND DYNAMIC STEREOCHEMISTRY OF SUBSTITUTED CYCLOHEXANES

Studies on the structures of cyclohexane derivatives have an extremely long history, the main landmarks of which are the classical studies by Sachse[8], Hassel[9], and Barton[10]. Starting from the 1950s, these compounds have been vigorously investigated with the aid of various chemical and physical methods; the numerous publications on this topic are analysed in a number of monographs[11,12] and reviews[13-15].

The present review deals only with the problems of experimental conformational analysis. Dashevskii's monograph[12] gives some idea about the tasks of theoretical conformational analysis, associated with calculations of the energies and geometrical structures of the conformers.

The aims of conformational analysis and the fundamental terminology employed in reports on the structures of substituted cyclohexanes can be illustrated in relation to monosubstituted derivatives $C_6H_{11}X$. One usually considers the equilibrium between only two forms (conformers), with the axial and equatorial orientations of the substituent X respectively:



(Ia) (Ie)

The conformational equilibrium is regarded as involving a rapid interconversion or inversion of the ring, $(Ia) \rightleftharpoons (Ie)$, which can be described by two rate constants:

$$k_{ae} = \varkappa \frac{kT}{h} \exp(-\Delta G^{\neq}_{ae}/RT),$$
$$k_{ea} = \varkappa \frac{kT}{h} \exp(-\Delta G^{\neq}_{ea}/RT), \quad (1)$$

where κ is the transmission coefficient and $\Delta G^{\neq}$ the free energy of activation;

$$\Delta G^{\neq} = \Delta H^{\neq} - T\Delta S^{\neq}, \quad (2)$$

where $\Delta H^{\neq}$ and $\Delta S^{\neq}$ are the enthalpy and entropy of activation. In the general case $k_{ae} \neq k_{ea}$ (a non-degenerate process). The equilibrium in the reaction $(Ia) \rightleftharpoons (Ie)$ may be characterised by the equilibrium constant K:

$$K = p_e/p_a = k_{ae}/k_{ea} = \exp(-\Delta G^0/RT), \quad (3)$$

where p_a and p_e are the equilibrium concentrations of the axial and equatorial conformers, it being assumed that

$$p_a + p_e = 1. \quad (4)$$

The quantity $-\Delta G°$ is called the conformational energy; the term "A-value" is frequently used:

$$A = -\Delta G^0 = G_a - G_e, \quad (5)$$

where G_a and G_e are the free energies of the axial and equatorial conformers.

In the general case, when several substituents are present, the conformational equilibrium also involves only two conformers (A_1 and A_2); the equilibrium constant and the conformational energy for the process $(A_1) \rightleftharpoons (A_2)$ are defined as follows: $K = p_2/p_1$ and $-\Delta G° = G_1 - G_2$. In the specific instance of monosubstituted cyclohexanes it is assumed that $A_1 = (Ia)$ and $A_2 = (Ie)$.

Conformational Analysis

The main task in conformational analysis is the experimental determination of the equilibrium concentrations of the conformers. Evidently this task includes as a necessary stage the proof that only two forms are involved in the equilibrium at appreciable concentrations. Together with the *a*- and *e*-conformers examined above, which are derived from the chair conformation, other conformers derived from the boat (II) or twist-boat (III) conformations are also sometimes considered:

(II)

(III)

Numerous theoretical estimates of the energies of a wide variety of non-chair forms of cyclohexane[16,17] have shown that the hypothesis that the chair form is most favourable is in fact justified, but the experimental proof of this was obtained only quite recently by Anet and coworkers[18]. These investigators detected the non-chair forms of cyclohexane by the method involving rapid freezing of the high-temperature equilibrium. For this purpose, gaseous cyclohexane, heated to approximately 800 K, was condensed, after vacuum evaporation, onto a CsI plate cooled to 20 K. It was thus possible to assume that the composition of the conformers in the condensate reflects the nature of the conformational equilibrium at high temperatures. It was shown by infrared spectroscopy that, together with the chair form, the condensate contains the twist-boat form. Estimates showed that the enthalpy of the twist-boat conformation exceeds by 5.5 kcal mole^{-1} that of the chair conformation. Assuming that the entropy contribution is close to zero, one may conclude that the content of the twist-form at room temperature does not exceed 0.01%. In the study of the conformational equilibria of substituted cyclohexanes, the negligible contribution of the non-chair forms is assumed without proof.

In order to determine the conformational equilibrium constant K, various methods have been used; Jensen and Bushweller[15] concluded on the basis of a comparison of numerous investigations that the method involving the measurement of the integrated intensities in high-temperature ^{1}H NMR spectra is the most accurate. On the basis of this method, the authors[15] proposed a system of "best" (i.e. most accurate) A-values for a number of substituents X. However, in view of the difficulty of the interpretation of the ^{1}H NMR spectra, the method cannot be regarded as a universal procedure for the measurement of the equilibrium constants K, which has been confirmed by the results of certain studies[13,15].

Investigators as a rule confine themselves to the determination of the conformational equilibrium constant at a single temperature, which permits the subsequent determination of the free energy ΔG_T at the same temperature. Naturally, on a wider scale conformational analysis involves the determination of the values of K over a fairly wide range of temperatures and the calculation from the $K(T)$ relation of the enthalpies and entropies of the reversible process (ΔH° and ΔS°).

An important feature of studies on conformational equilibria, consisting in the necessity to take into account the influence of intermolecular interactions (i.e. of the medium), should be noted. In many instances the influence of the medium is very significant[14,19]; this factor hinders the comparison of the results of different studies carried out in different media. As a rule equilibrium constants are measured by NMR in solutions where the test compound can be subjected to different chemical or physical influences. Thus there is a risk of the incorrect application of the parameters of the conformational equilibrium obtained in one solvent (for example in carbon disulphide, which is most suitable for NMR studies) to other conditions.

This factor, in particular, necessitates a certain amount of caution in comparing the results of studies on conformational equilibrium in almost neutral solutions and in solutions with added paramagnetic shift reagents[20], where additional complex-formation processes undoubtedly occur.

The Study of the Properties of Individual Conformers

This involves the investigation of the complete geometry of the conformers and also, in principle, the study of their other chemical and physical properties. This aspect is in fact of fundamental interest for theoretical organic chemistry in connection with the search for conformational features of molecules responsible for the selective courses of chemical reactions. Studies in this field constitute an important stage on the way to an effective employment of cyclohexane derivatives in fields such as pharmacology and the chemistry of insecticides and perfumes.

The Study of the Dynamics of the Conformational Transformation (Ring Inversion)

This involves the determination of the rate constants for ring inversion k_{ae} and k_{ea} and the calculation from these data of the free energies of activation $\Delta G^{\neq}_{ae}$ and $\Delta G^{\neq}_{ea}$. Within a wider framework, the study of the dynamics of ring inversion includes the determination of the rate constants over a wide temperature range and the calculation of the enthalpy ($\Delta H^{\neq}$) and entropy ($\Delta S^{\neq}$) of activation. The easiest method for the investigation of the dynamics of ring inversion in substituted cyclohexanes is NMR, which makes it possible to determine the rates of chemical processes from characteristic dynamic effects in the spectra[21-23].

The solution of the above problems requires the use of the entire set of the chemical and physical methods available at present. However, the specific limitations characteristic of particular methods sharply restrict the region of their applicability. Furthermore, there exist many limitations due to the specific features of the compound investigated, namely the chemical instability of the compound, its low solubility, and the narrow range of temperatures employed. Attention should also be drawn to certain limitations which are rarely mentioned in the literature but which are extremely fundamental. One of these is associated with the methodological difficulties in the isolation of the individual conformers, which requires the use of a special low-temperature technique. Only one report is at present available[24], concerning the isolation by low-temperature multistage recrystallisation of the equatorial conformer of chlorocylcohexane. Analysis of studies on polysubstituted cyclohexane has shown that even the much simpler problem of separating a mixture of isomers entails significant technical difficulties[45]. These difficulties apparently arise from the inadequate knowledge of the adsorption of substituted cyclohexanes. Another fundamental difficulty is caused by the lack of methods for the investigation of strongly displaced equilibria (in other words of high-energy conformations). The relative error of the methods of measurements used in conformational analysis as a rule increases sharply with increase of the equilibrium constant. A conformational energy ≥2 kcal mole^{-1} corresponds to equilibrium constants of 200 and above and the study of the conformational equilibrium becomes virtually impossible.

New possibilities arising from ^{13}C NMR spectroscopy in the solution of the problems formulated above are discussed below. Before describing them, we shall deal with the general characteristics of the method.

III. ^{13}C NMR SPECTROSCOPY. GENERAL CHARACTERISTICS, SCOPE, AND LIMITATIONS

The vast majority of measurements of ^{13}C NMR spectra are nowadays performed by pulsed Fourier NMR. As a rule the ^{13}C NMR spectra are recorded under the conditions of the complete suppression of spin–spin interaction with protons. In commercial NMR spectrometers the suppression of the interaction with protons (or proton decoupling) is achieved with the aid of the noise modulation of the high-frequency field, the carrier frequency of which is the same as the resonance frequency of protons. Proton decoupling is accompanied not only by the merging of the multiplets but also by an increase of the integrated signal intensities as a result of specific cross-relaxation phenomena arising on proton pumping (the so called Nuclear Overhauser Effect (NOE). Thus proton uncoupling leads to an evident simplification of the spectra; one line in the ^{13}C–{H} NMR spectrum corresponds to each chemically non-equivalent carbon atom in the molecule. The position of this line in the spectrum relative to the line of the reference substance, which is tetramethylsilane $(CH_3)_4Si$, or the chemical shift of the ^{13}C nucleus is the most important spectroscopic parameter. Numerous data quoted in monographs[4,5] have shown that ^{13}C nuclei are more effective "indicators" of chemical non-equivalence than, for example, protons. Comparison of the range of variation of the chemical shifts of ^{13}C and ^{1}H nuclei, $\Delta\delta(^{13}C)$ and $\Delta\delta(^{1}H)$, carried out in a number of studies[4,5,25] for the corresponding series of model compounds showed that

$$\Delta\delta\,(^{13}C) = k\Delta\delta\,(^{1}H), \qquad (6)$$

where the proportionality coefficient is 10–30 (depending on the series of compounds).

These two factors, namely the simple form of the ^{13}C–{H} NMR spectra and the high sensitivity of the chemical shift of ^{13}C nuclei to changes in the electronic environment were in fact responsible for the great interest by chemists in ^{13}C NMR.

In order to assess the nature and amount of information which can be obtained from ^{13}C NMR spectra, it is sufficient to examine the results of the study of the conformational state of chlorocyclohexane, a compound typical for the series under consideration[26]. The ^{13}C–{H} NMR spectra of chlorocylcohexane, measured in the temperature range from 193 to 273 K, are presented in Fig. 1. The changes observed in the spectra with increase of temperature indicate the occurrence of chemical exchange [in the present case of the conformational transformation (I*a*) ⇌ (I*e*)]. Two groups of signals (four signals in each group with the intensity ratios 1 : 2 : 2 : 1) can be distinguished in the spectrum measured at 193 K and referring to the conformers (I*e*) and (I*a*). The lower-intensity signals refer to the conformer (I*a*), since it had been shown previously for chlorocyclohexane[9] that $K = p_e/p_a > 1$. Further assignment of the signals to $C_\alpha(C_1)$, $C_\beta(C_2, C_6)$, $C_\gamma(C_3, C_5)$, and $C_\delta(C_4)$ carbon atoms of each conformer is possible. This assignment is based on the integrated intensities, the analysis of the dynamic broadening of individual spectral lines, the employment of other recording techniques, as well as literature data for chloro-substituted hydrocarbons[27]. Only four signals are observed in the spectrum obtained at 273 K, which indicates the rapid inversion of the ring in chlorocyclohexane. The assignment of the spectra lines measured at 273 K follows from the assignment of the signals in the low-temperature spectrum but it can also be based on independent data[28].

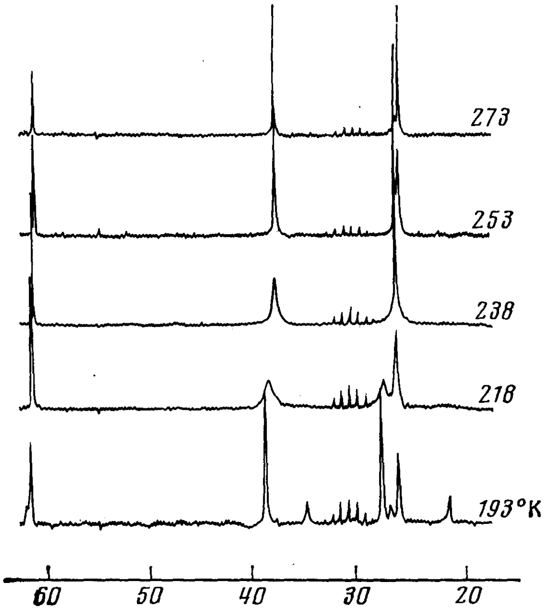


Figure 1. ^{13}C NMR spectra of chlorocyclohexane with complete proton coupling. The lower-intensity signals in the low-temperature spectrum refer to the axial conformer. The multiplet in the region of 30 p.p.m. is the signal of deuteroacetone used as the reference signal.

In conformity with the problems described above, it is possible to arrange systematically in the following manner the information which follows from the temperature-dependent ^{13}C NMR spectra.

1. Conformational Analysis

The number of conformers may be determined from spectra measured at 173–193 K. Using the integrated intensities *I* of the signals of the individual conformers A_1 and A_2, one can determine the equilibrium constant *K*:

$$a_i = I_2/I_1 = K, \qquad (7)$$

where subscript *i* corresponds to the *i*th pair of carbon atoms. The concentrations of individual conformers may be determined from the spectra measured at room temperature using the following equation for the spectral parameter averaged with respect to the conformers:

$$\langle\theta\rangle=\sum_i p_i\theta_i=p_1\theta_1+p_2\theta_2, \tag{8}$$

where the chemical shifts δ or the spin–spin coupling constants J may be used as θ.

2. Dynamics of Ring Inversion

Using the parameters of the line form in the NMR spectra in the regions corresponding to intermediate exchange and the well developed procedures for the treatment of such temperature-dependent spectra[21-23], it is possible to determine the rate constants k_{ae} and k_{ea}. If such measurements are carried out over a wide range of temperatures, the activation parameters for the process can be found: $\Delta G^{\neq}$, $\Delta H^{\neq}$, and $\Delta S^{\neq}$.

3. Chemical Shifts and the Spin–Spin Coupling Constants

The chemical shifts of the ^{13}C NMR signals of the individual conformers, δ_i^1 and δ_t^2, can be determined from spectra measured at 173–193 K. If the test compound contains other magnetic nuclei (^{19}F, ^{31}P, etc.) then information about the spin–spin ^{13}C–X coupling constant (where X is the ^{19}F, ^{31}P, etc. isotope) may be derived from ^{13}C NMR spectra under the conditions of complete decoupling from protons. Unfortunately it is so far impossible to obtain information about the $J(^{13}C-^{1}H)$ constants, which is due to the difficulties in the recording and analysis of monoresonance ^{13}C NMR spectra. Definite advances have been achieved in recent years in the analysis of monoresonance ^{13}C NMR spectra of certain types of organic compounds[29]. This suggests that eventually it will be possible to use information about the $J(^{13}C-^{1}H)$ constants also for substituted cyclohexanes, which is of significant stereochemical interest.

The ^{13}C NMR method suffers from certain limitations.

(a) Limitations due to the low value of the "signal/noise" ratio. Despite the advances towards an increase of sensitivity achieved in recent years as a result of the introduction of pulsed FT,[30] the problem of sensitivity in the measurement of ^{13}C NMR spectra remains extremely urgent. In particular, each spectrum illustrated in Fig. 1 required the accumulation of ~1000 pulses for a solution concentration of about 30 wt.%. With overall 10 s intervals between the pulses, the recording of each spectrum required ~3 h. Reduction of the solution concentration by a factor of 2 would entail an increase in the time required for the experiment by a factor of 4. This factor precludes studies on sparingly soluble substances.

(b) Limitations due to the distortions of signal form. When ^{13}C NMR spectra are recorded under the conditions of complete decoupling from protons using pulsed methods (FT), the NMR signal form (particularly the integrated intensity) may be distorted by a number of factors. The most important of these are (1) the non-identical increase of the intensities of the signals due to different ^{13}C nuclei owing to the different values of the NOE factors, (2) signal saturation arising as a consequence of unduly short periods of pulse repetition, (3) errors introduced by the limited power of the computer, and (4) other sources of apparatus error associated with the presence of lateral signals due to rotation, the contribution of dispersion to the recorded signal, the frequency dependence of the signal intensity, and the influence of the inhomogeneity of the exciting field $\dot{\gamma}H_1$ ($\dot{\gamma}=\gamma/2\pi$, γ being the gyromagnetic constant). A more detailed analysis of these factors may be found in the papers by Freeman and Hill[31] and by Jones and Sternlicht[32].

(c) Limitations associated with the necessity for the complete assignment of the spectrum. ^{13}C NMR spectra with complete decoupling from protons show only singlet lines due to non-equivalent carbon atoms. Although in many instances the assignment of the lines is fairly evident, in practice, for example in the analysis of complex mixtures, the problem of the assignment of the lines is not trivial. Various methods have been described for the assignment of spectral lines using modifications of $^{13}C-\{^{1}H\}$ double resonance[34], additive schemes for the calculation of ^{13}C chemical shifts[25,27], spin–lattice relaxation times for ^{13}C nuclei (T_1),[35,69] and induced shifts resulting from the addition of paramagnetic shift reagents have been described[20]. Although the use of these methods does increase the total amount of work which must be performed in the investigation, it results, in principle, in the solution of the assignment problem in almost all cases.

Analysis of the scope and limitations of the ^{13}C NMR method have shown that in principle the method can be used to solve all the problems formulated above. An important limitation concerns the study of the influence of the medium, because the measurement of ^{13}C NMR spectra in dilute solutions is difficult (certain data of this kind are described by Schneider and Freitag[33] and Pehk et al.[36]). Studies on substituted cyclohexanes have so far been made only in concentrated solutions. The problem of the investigation of the properties of individual conformers within the framework of ^{13}C NMR spectroscopy naturally reduces merely to the interpretation of the information which follows from the NMR spectra, i.e. the chemical shift of the ^{13}C nuclei and the spin–spin coupling constants involving such nuclei. Furthermore, useful information about the correlation times for molecular motion can be obtained by measuring the spin–lattice relaxation times and NOE factors.

IV. CONFORMATIONAL ANALYSIS USING ^{13}C NMR

1. TEMPERATURE RANGE

The experimental data available at the present time have shown that the accuracy of the measurement of the conformational equilibrium constant K is to a large extent determined by the temperature range employed. The following characteristic temperature ranges can be distinguished for NMR spectroscopy.

Temperatures Below 173 K

In this temperature range ring inversion becomes very slow (here and henceforth we are considering the NMR time (scale), so that the signals of the individual conformers should be observed. However, owing to experimental difficulties (the choice of solvent, the establishment of a high concentration in the solution, and the design characteristics of the transducers), studies in this temperature range have not so far been made with the aid of ^{13}C NMR.

Temperatures in the Range 173–193 K

Here ring inversion is slow and the signals of individual conformers are observed. They are adequately resolved, which permits correct integration and determination of the equilibrium constant.

Temperatures in the Range 193–243 K

An intermediate rate of inversion obtains. This leads to a significant broadening of the spectral lines and their overlapping (Fig. 1), which prevents the separate integration of the signals due to the conformers. The study of conformational equilibrium in this temperature range requires prolonged experiments with calculation of the total spectral line form. It is perhaps possible to quote only one example of a fairly thorough analysis of spectra in this temperature range carried out by Bovey et al.[37] for the inversion of fluorocyclohexane (joint analysis of ^{19}F and ^{1}H NMR spectra).

Temperatures above 243 K

Ring inversion is rapid and the ^{13}C NMR spectra show averaged signals. This temperature range is of particular interest, since it includes room temperature—the most important for practical purposes. The ratio of the concentrations of the conformers p_1 and p_2 may be estimated by Eqn. (8). It must be emphasised that there are many specific problems which significantly hinder the use of equations for the average parameters (see the reviews of Jensen and Bushweller[15] and Garbish[36]). Such estimates frequently lead to a decrease of the accuracy of the calculated equilibrium constants or in general to doubtful and contradictory results.

2. ASSIGNMENT OF THE SPECTRAL LINES

In conformational analysis the correct assignment of the spectral lines is of greatest importance. The assignment procedure presents no difficulties, provided that the chemical shifts of non-equivalent carbon atoms differ by more than 2–3 p.p.m. For the correct assignment of the lines in the spectra of monosubstituted compounds, it is sufficient to use symmetry considerations, integrated signal intensities, and data concerning the influence of the substituent on the chemical shift of the ^{13}C nuclei in model saturated hydrocarbons[39-42]. An extremely effective procedure for the assignment of the lines of polysubstituted compounds, involves the comparison of the experimental shifts with calculated additive data[43-45]. Among the special assignment methods useful for the analysis of the spectra of substituted cyclohexane, mention should be made of the procedure based on the study of the dynamic broadening of the spectral lines, which permits the identification of the signals due to pairs of nuclei undergoing exchange. One should also note that the employment of integrated intensities should be approached with a certain amount of caution, because incorrectly selected conditions for the recording of the spectrum in pulsed FT may lead to considerable distortions of the signal intensities up to the disappearance of certain signals from the spectrum.

3. EQUILIBRIUM BETWEEN THE CONFORMERS AT TEMPERATURES IN THE RANGE 173–193 K

The constant K for the equilibrium between two conformers A_1 and A_2 of a substituted cyclohexane is determined from the integrated signal intensities in low-temperature spectra. Since several ^{13}C signals are observed for each conformer (six in the general case), there is a possibility of averaging with respect to the corresponding pairs of signals:

$$K = \frac{1}{N}\sum_{i=1}^{N} \alpha_i. \tag{9}$$

The problem of the accuracy of the measurement of the conformational equilibrium constants is of significant interest for conformational analysis. Since the integrated intensities are influenced by many distortions, the problem of the errors of the measurements requires special examination. Subject to certain simplifying assumptions, the ratio of the integrated intensities of two signals in the spectrum (for pulsed FT) is related to the required quantity $K = p_2/p_1 = M^{\mathrm{i}}_{\mathrm{Z},2}/M^{\mathrm{i}}_{\mathrm{Z},1}$, where M_{Z} is the projection of the nuclear magnetisation vector onto the z axis) by the expression

$$\alpha_i = \frac{I_i^2}{I_i^1} = \frac{(\eta(C_i^2)+1)}{(\eta(C_i^1)+1)} \cdot \frac{[1-\exp(-t/T_1(C_i^2))]}{[1-\exp(-t/T_1(C_i^1))]} \cdot K, \tag{10}$$

where the first term takes into account the difference between the Nuclear Overhauser effects for the ith pair of signals C^1_{i} and C^2_{i}, while the second term defines the difference between the saturation factors for the same signals[31,32]; $\eta = \mathrm{NOE} - 1 = I_{\mathrm{p}}/I_0 - 1$, where I_{p} and I_0 are the integrated signal intensities with and without proton decoupling respectively. The correct employment of Eqn. (10) for quantitative analysis thus requires data for NOE factors and the spin-lattice relaxation times $T_1(^{13}C)$. The time t in Eqn. (10) corresponds to the total interval between the pulses, equal to the sum of the sampling time of the free induction signal and the arrest time[4]. Technical difficulties in the measurement of NOE and of the relaxation time T_1 constitute serious obstacles to the use of ^{13}C NMR data in quantitative analysis. More detailed analysis shows[39,46,50,80] that the relaxation times of protonated carbon atoms (i.e. atoms forming part of methylidyne and methylene groups) are almost fully determined by the dipole–dipole mechanism and the NOE factors for such nuclei are therefore close to the theoretical value of 2.99.[3,4] There are also data showing that the relaxation times of the ^{13}C nuclei of substituted cyclohexanes do not exceed 3 s at 1733–193 K.[69] Hence it follows, in particular, that the distortions due to the differences between the relaxation times may be significantly reduced by using intervals of 8–10 s between the pulses. The accuracy of the measurement of the equilibrium constant K also depends on the value of the latter, the errors being a minimum for almost degenerate equilibria and increasing almost linearly with increase of K. Despite the fact that in most cases the correct analysis of the errors has not been carried out, presumably in real systems it is very difficult to achieve an accuracy better than to within 10%.

The results of a study of the conformational equilibria for a series of monosubstituted cyclohexanes at 163 to 204 K are presented in Table 1. It follows from these results that the standard relative error $\Delta\Delta G^\circ/\Delta G^\circ$ of the conformational energies in the range −0.3–1.8 kcal mole^{-1} is about 10%. The ^{13}C NMR data can be compared with those of Jensen and Bushweller[15] ("best" A-values)

(Fig. 2). Evidently the results obtained by these two methods of measurement of conformational energies are correlated, but the conformational energies found from ^{13}C NMR spectra are systematically higher by 20% than the values derived from ^{1}H NMR spectra. These discrepancies may be caused, particularly, by the fact that ^{13}C NMR measurements are made as a rule in much more concentrated solutions than those used for the measurement of low-temperature ^{1}H NMR spectra. The discrepancies are largest for $X = F$ (37%) and $X = OCH_3$ (36%). The problem of the true causes of these discrepancies is still obscure and requires a more detailed analysis of the errors of both methods.

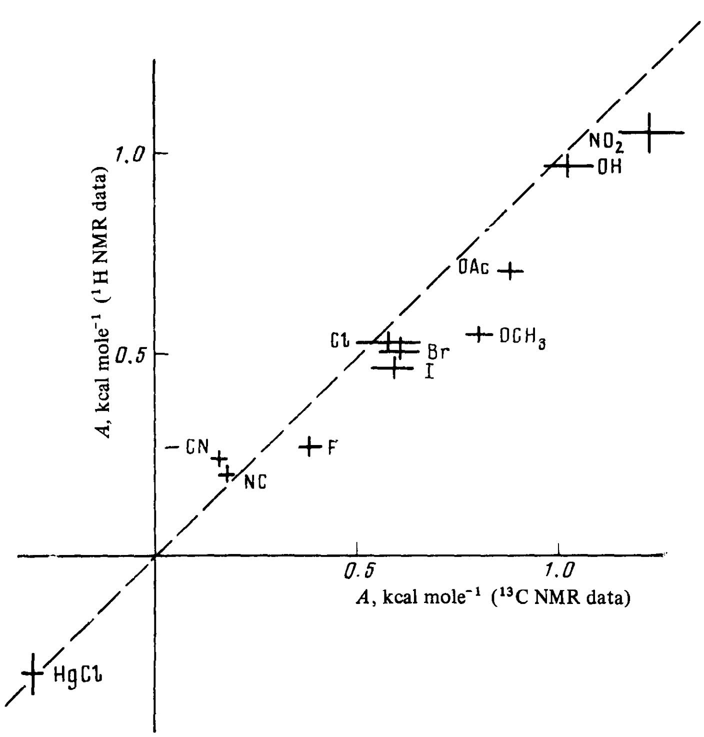

Figure 2. Comparison of the conformational energies obtained with the aid of ^{13}C and ^{1}H NMR for certain substituents in monosubstituted cyclohexanes.

Despite the fact that the problem of the relative accuracies of different methods of measurement of conformational energies has not been finally elucidated, ^{13}C NMR has already permitted progress in several important cases. In particular, it has been possible to obtain for the first time spectroscopic evidence for the existence of the axial conformer of methylcyclohexane—the classical object of conformational analysis—and to measure $-\Delta G_{173°} = 1.8 \pm 0.1$ kcal mole^{-1}.[42] Previous attempts to solve this problem[51] were based on indirect reasoning and yielded significantly divergent values (ranging from 1.5 to 2.0 kcal mole^{-1}).[7,52] This and other examples (nitrocyclohexane, cyclohexanol[42]) have shown that ^{13}C NMR is the most suitable method for the investigation of high-energy conformations. Another example of the successful application of ^{13}C NMR is provided by the study of mercury-substituted cyclohexanes[49]. Earlier conformational analysis of these compounds was complicated by the difficulty of interpreting the ^{1}H NMR spectra[53]. When ^{13}C NMR was used, it was possible to assign the signals on the basis of the $J(^{13}C-^{199}Hg)$ constants[54] and to show that the axial conformer predominates ($-\Delta G_{183°} = -0.30$ kcal mole^{-1}). The mercury-substituted compounds constitute the only example of systems with the preferential axial orientation of the substituent in a series of monosubstituted cyclohexane derivatives. This stabilisation is probably due to weak coordinate bonds formed between the hydrogen atoms in the γ-positions and the mercury atom, with participation of vacant 5*d* orbitals. Presumably such "anomeric" effects can be observed also for other organometallic derivatives of cyclohexane[84] (see also Table 1).

The still limited data available for polysubstituted cyclohexane derivatives do not allow a detailed elucidation of the characteristics of the conformational equilibrium over a fairly wide range of conditions (temperature, solvent) and types of substituents. The most interesting results were obtained with the aid of ^{1}H NMR[19,55-57] and ^{19}F NMR [58,59] but these methods cannot be regarded as universal either.

The attempts to employ ^{13}C NMR to investigate polysubstituted cyclohexanes using integrated spectral intensities are still not numerous[45,60-63], but they clearly show that the method makes it possible to overcome successfully the difficulties associated with the isomeric purities of the test systems.

In considering the conformational equilibria involving disubstituted cyclohexanes it is useful to divide the equilibria into two types: (1) the equilibrium between the *aa*- and *ee*-conformers, which obtains in 1,2-*trans*-, 1,3-*cis*, and 1,4-*trans*-isomers; (2) the equilibrium between the *ae*- and *ea*-conformers in 1,1-, 1,2-*cis*-, 1,3-*trans*-, and 1,4-*cis*-isomers. When the substituents are the same, the conformational transformation of type (2) is degenerate, so that $\Delta G = 0$. The experimental conformational energies $A_{\text{exp}}(X, Y)$ for compounds of types (1) and (2) are listed in Tables 2 and 3 respectively. In addition, the tables list the conformational energies obtained by the additive approach. The additive conformational energy A_{add} can be represented as the sum (or difference) of the conformational energies of both substituents, i.e.

$$A_{\text{add}}(X, Y) = A(X) + A(Y) \quad (\text{for } aa \rightleftharpoons ee), \tag{11}$$
$$A_{\text{add}}(X, Y) = A(X) - A(Y) \quad (\text{for } ae \rightleftharpoons ea).$$

The data quoted in Table 1 may be used as the A-values for specific substituents. The factors R, which are a measure of conformational non-additivity, may be determined from the experimental values of $A_{\text{exp}}(X, Y) = -\Delta G°(X, Y)$ and the calculated values of A_{add}:

$$R = A_{\text{add}}(X, Y) - A_{\text{exp}}(X, Y). \tag{12}$$

The following features may be deduced from the results (see also other studies[15,59] where other methods were used).

1. The *ee*-form is destabilised in the presence of bulky substituents (Br, Cl, CH$_3$), in *trans*-1,2-isomers (or the *aa*-form undergoes additional stabilisation), the destabilisation factor varying from 0.1 kcal mole^{-1} (for fluoroiodocyclohexane[59]) to 2 kcal mole^{-1} (for di-iodocyclohexane[64]); it probably increases with increase of the bulk of the substituent.

2. The diaxial form of *cis*-1,3-isomers is exceptionally unfavourable as a result of 1,3-*syn*-diaxial interactions of the bulky substituents. Theoretical estimates for such interactions have been carried out by Bailey et al.[57] in relation to the *syn*-diaxial interaction of the methyl group and fluorine, chlorine, bromine, or iodine atoms. The calculated energies of these interactions, amounting to 0.34, 7.34, 15.07, or 28.37 kcal mole^{-1} respectively (the calculations were performed with the aid of the Hill potential[65]), show that the repulsion energy for the substituent increases with increasing bulk of the latter, causing the destabilisation of the diaxial conformer.

*Method of integrated intensities[62] (for solutions in CS_2).

**The conformational energies based on ^{13}C NMR data (for solutions in CS_2) were used in the calculation of $A_{add}(X, Y)$.

4. The deviations from additivity for 1,4-*cis*-, 1,3-*trans*-, and 1,2-*cis*-isomers involved in transformations of the $ea \rightleftharpoons ae$ type are comparatively small (the values of R are $\sim\pm0.2$ kcal mole^{-1}) and on the whole the additive scheme can be used to predict the conformational composition of such isomers.

The conformational equilibria of polysubstituted (three and more substituents) cyclohexanes have not been investigated so far by ^{13}C NMR in the range 173–193 K. It is to be expected that the method will find applications in the immediate future in the study of these and related systems (decalins, tetralins, steroids, etc.)

4. CONFORMATIONAL EQUILIBRIUM AT TEMPERATURES NEAR 300 K

In the high-temperature region the equilibrium parameters are determined using the equation for average parameters [Eqn. (8)]. If it is assumed that only two conformers are involved in the equilibrium (the equatorial and axial conformers in the case of monosubstituted cyclohexanes), then it follows from Eqn. (8) that

$$p_2 = \frac{\langle\theta\rangle_i - \theta_i^2}{\theta_i^2 - \theta_i^1} \qquad (13)$$

and

$$K = \frac{\langle\theta\rangle_i - \theta_i^1}{\theta_i^2 - \langle\theta\rangle_i}. \qquad (14)$$

Thus, provided that the spectroscopic parameters θ_i^1 and θ_i^2 are known under stereochemically rigid conditions, it is possible to determine from the average value the fractions of the conformers and the equilibrium constants.

It is noteworthy that the problem of the interpretation of the averaged spectroscopic parameters measured at temperatures ensuring a rapid conformational transformation is of general interest for the conformational analysis of organic compounds. This is due to the fact that in many systems which are of interest as regards their conformations[12,13] (cyclopentanes, cycloheptanes, cyclohexanones, dioxans, piperidines, etc.) it is extremely difficult to create conditions sufficient to "freeze out" individual conformations. In systems of this kind this requires measurements at temperatures in the range 123–173 K, which is not always possible. This fact explains the great interest in the interpretation of averaged spectroscopic parameters in terms of conformational equilibria[66]. The available reviews on the application of the method of averaged parameters (substituted cyclohexanes[13,15], rotational isomers of ethane-like molecules[38,67]) show that this method of studying equilibria should be used with much caution. The fundamental difficulties make it necessary to take into account the temperature dependence of the spectroscopic parameters of rigid systems. This implies that in principle one cannot use in Eqns. (13) and (14) the parameters θ_i^a and θ_i^e obtained from low-temperature measurements.

In describing the results of the application of the method of averaged parameters to substituted cyclohexanes, it is useful to consider separately the chemical shift data and the spin–spin coupling constants. The former are of considerable practical interest, since they can be measured in all cases. On the other hand, the use of averaged spin–spin coupling constants (in those cases where the relevant data may be determined from the spectrum) apparently leads to more accurate results, because according to some data[66] the constants are less affected by temperature.

Eqns. (13) and (14) can be used in two ways[62]. One of them, which may be called experimental, involves the use as θ_i^e and θ_i^a of the experimental chemical shifts of the ^{13}C nuclei of individual conformers obtained from spectra measured at 173–193 K. In principle, the method can be modified by studying experimentally the temperature dependence of the chemical shifts in the accessible temperature range (123–200 K) and extrapolating the relation obtained to higher temperatures. However, ^{13}C NMR studies of this kind have not so far been made and the chemical shifts δ_i^e and δ_i^a were assumed to be independent of temperature, which probably introduced a systematic error. The second way of using Eqns. (13) and (14), which may be referred to as the computational procedure, consists in using the chemical shifts calculated in accordance with some scheme; different empirical and semiempirical methods may be used in the calculation. The evident requirement which must be met by the computational scheme is that the calculated chemical shifts should be sufficiently accurate. The required level of accuracy ($\Delta\delta$) follows directly from Eqns. (13) and (14): the error must be significantly less than the range of variation of the shift, i.e. $\Delta\delta < |\delta_i^e - \delta_i^a|$.

A satisfactory computational scheme for the calculation of chemical shifts has not so far been proposed for monosubstituted cyclohexanes and the experimental method was therefore used in the study of the conformational equilibria at 300 K.[39] The only attempt to employ the computational method, undertaken by Pehk and Lippmaa[28], involved the use of the chemical shifts for the corresponding t-butyl derivatives $(CH_3)_2XCH$.[4-6] When the chemical shifts of the conformers cannot be measured experimentally at low temperatures (for example, owing to the limited solubility of the corresponding monosubstituted compound), this procedure is the only one available for the estimation of the equilibrium constant. However, the analogy with the t-butyl derivatives is probably extremely approximate and the method can be recommended only for qualitative estimates.

Table 4. Parameters of the conformational equilibria for halogenocyclohexanes at 298 K according to ^{13}C NMR chemical shifts and their comparison with the results obtained by other methods.

*The chemical shifts are expressed in p.p.m. relative to C_6H_{12} (from the paper by Subbotin and Sergeyev[39]).

**Taken mainly from Squillacote et al.[18] (see also Refs. 53 and 37).

Both the averaged chemical shifts (see also Table 4) and the shifts of the individual conformers (see Table 11) of many monosubstituted cyclohexanes are known[39-42], which makes it possible to examine the problem of the applicability of the experimental method to the study of the conformational equilibrium at 298 K. The corresponding results are presented in Table 4 for halogenocyclohexanes.

In the calculation of the fraction of the equatorial conformer p_e by Eqn. (13) the experimental chemical shifts of the ith carbon atoms ($i = \alpha$, β, γ, or δ) taken from Subbotin and Sergeyev[39] were used for the a- and e-conformers. Table 4 presents for comparison the fractions of the equatorial conformer obtained from results found by other methods (^{1}H NMR and ^{19}F NMR) using an analogous procedure[15].

It follows from the data in Table 4 that the values of p_e corresponding to different atoms are significantly scattered. In certain cases absurd results ($p_e > 1$) are obtained. The above deficiencies are a consequence of the temperature dependence of the chemical shifts of the individual conformers. The available estimates of the influence of temperature on the chemical shifts of individual substances quoted in the literature have shown[68-70] that the "temperature coefficients" may reach 1 p.p.m. per 100°C. The experimental method for the investigation of high-temperature equilibria is therefore ineffective when the difference between the chemical shifts of the ith atoms of the conformers is small (1 p.p.m. and less). In particular, this is characteristic of the δ-carbon atoms in monosubstituted cyclohexanes.

The error in the calculation in accordance with this scheme may be reduced by several formal procedures. Firstly, it is possible to exclude from consideration the results to which correspond relatively small differences $|\delta_i^e - \delta_i^a|$. Secondly, in the calculation of the average value it is possible to introduce "statistical weights" for the results of individual measurements[62]:

$$\langle p_e\rangle = \sum_i f_i p_e^i \tag{15}$$

where

$$f_i = \frac{|\delta_i^e - \delta_i^a|}{\sum\limits_{i=1}^{N} |\delta_i^e - \delta_i^a|} \tag{16}$$

is the "statistical weight" of p_e^i.

In this procedure more reliable estimates of p_e^i, obtained for larger differences $|\delta_i^e - \delta_i^a|$, have a larger statistical weight and formally one can permit the inclusion of results leading to $p > 1$ or $p < 0$. Data obtained by this method are in reasonable agreement with literature estimates (see Table 4). For polysubstituted compounds, the computational as well as the experimental method may be used to measure the constant K and the additive values of the chemical shifts of the conformers may be used as the calculated values.

Both methods for the investigation of the high-temperature equilibria based on calculations in accordance with an additive scheme have been used to investigate the conformations of isomeric methylcyclohexanols[62]. It follows from the data in Table 5 that the two methods give similar results. The conformer with the equatorial orientation of the methyl group (the ea-conformer in terms of the notation of Subbotin et al.[62]) predominates in all cases. The fraction of this conformer is a minimum for the 1,2-*cis*-isomer and a maximum for the 1,3-*trans*-isomer. The above tendency has been confirmed by low-temperature measurements (Table 5).

As regards the use of spin–spin coupling constants in the study of high-temperature equilibria, we may note that the experimental data available hitherto are extremely limited and refer mainly to fluorinated cyclohexanes[39,71], i.e. consist of $J(^{13}C-^{19}F)$ constants. By analogy with averaged chemical shifts, here too it is possible to distinguish two procedures for the interpretation of the results, but, since a satisfactory scheme for the calculation of spin–spin coupling constants does not yet exist, only the experimental procedure has so far been tested. Constants for the spin–spin coupling of the ^{19}F nuclei with all the non-equivalent ^{13}C nuclei of fluorocyclohexane have been found for both conformers at 183 K as well as the average spin–spin coupling constants at 300 K. These data can be used in Eqn. (14) to estimate the fraction of the equatorial conformer at 300 K, as was done in the analysis of the chemical shift (i.e. the "statistical weights" of the individual measurements are introduced) (Table 6).

Table 5. The fraction of the dominant conformer $\langle p_e\rangle$ in isomeric methylcyclohexanols (according to the conformationally averaged ^{13}C NMR chemical shifts at 300 K [62]).

Compound	$\langle p_e\rangle_{exp}$	$\langle p_e\rangle_{calc}$	$p_e^{l.t.*}$
cis-1-Hydroxy-2-methylcyclohexane	0.74	0.84	0.81
trans-1-Hydroxy-3-methylcyclohexane	0.83	0.96	0,93
cis-1-Hydroxy-4-methylcyclohexane	0.81	0.85	0,88

*Obtained from low-temperature ^{13}C NMR spectra by measuring the integrated signal intensities for the individual conformers.

Table 6. The spin–spin coupling constants $J(^{13}C-^{19}F)$ for fluorocyclohexane at 300 K and the fractions of the equatorial conformer.

Parameter	Position of carbon atom			
	α	β	γ	δ
$J(^{13}C-^{19}F)$, HZ	170.6	19.0	7.6	1.5
p_e^*	0.69	0.66	0.64	0.50
f_i	0.26	0.20	0.51	0.05

*The value averaged with respect to the positions of the carbon atom is $\langle p\rangle = 0.66$.

The average fraction of the equatorial conformer thus obtained (0.66) agrees with the value found from the chemical shifts (0.65; Table 4). Since the spin–spin coupling constants are less influenced by factors such as temperature and the solvent, one may expect their successful application in conformational analysis.

5. ENTHALPIES AND ENTROPIES OF THE REVERSIBLE CONFORMATIONAL TRANSFORMATION ACCORDING TO ^{13}C NMR DATA

From the theoretical standpoint, the enthalpy $\Delta H°$ and entropy $\Delta S°$ of the conformational transformation are of greatest interest rather than its free energy ΔG_T° because these quantities are related to the structures of the conformers. However, their experimental determination is extremely difficult, because it requires the measurement of the equilibrium constants over a very wide temperature range. The experimental data on this problem are extremely fragmentary[15] and have not been subjected to a critical analysis. Since ^{13}C NMR permits measurements of the equilibrium constant K in two temperature ranges (173–193 K and in the vicinity of 300 K), attempts have been made to determine $\Delta H°$ and $\Delta S°$ from $\Delta G_{183°}$ and $\Delta G_{300°}$.[61,62] The results of these estimations for a series of substituted cyclohexanes are compiled in Table 7; however, one should note that, despite the relatively greater accuracy of the determination of $\Delta G°$ (on average to within 10–20% for $\Delta G°$—to within a quantity of the order of 0.5 kcal mole^{-1}), the enthalpies and entropies of the reversible conformational transformation determined from the difference of two ΔG°_{T} values at close temperatures are obtained with an accuracy to within ~0.3 kcal mole^{-1} and 1.5 e.u. respectively[72]. It follows from the analysis of the errors that the accuracy diminishes rapidly with increase of the equilibrium constant (for $K > 1$). It is therefore hardly useful to pose the question of the theoretical interpretation of the enthalpies and entropies of the reversible conformational transformation. At any rate, the available data (Table 7) show that the entropies of the transformation are as a rule in the range ±1 e.u. This implies that the qualitative interpretation of the temperature dependence of the conformational equilibrium may be based on the hypothesis that there is no entropy contribution.

Table 7. The conformational energies and the enthalpies and entropies of the reversible conformational transformations for a series of substituted cyclohexanes[61,62].

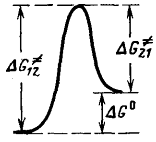
V. DYNAMICS OF RING INVERSION IN SUBSTITUTED CYCLOHEXANES

As already pointed out, the changes in the NMR spectrum occurring when the specimen temperature is altered (Fig. 1) may be used to analyse the dynamics of ring inversion (to solve this problem, it is necessary to find four activation parameters: the values of $\Delta H^{\neq}_{12}$ and $\Delta S^{\neq}_{12}$ characterising the transformation of the more stable conformer into a less stable one ($e \rightarrow a$ for monosubstituted cyclohexanes) and the values of $\Delta H^{\neq}_{21}$ and $\Delta S^{\neq}_{21}$ characterising the reverse process. Here we have

$$\Delta G^{\neq}_{12} = \Delta H^{\neq}_{12} - T\Delta S^{\neq}_{12}; \quad \Delta H^{\neq}_{12} = \Delta H^{\neq}_{21} - \Delta H^0;$$
$$\Delta G^{\neq}_{21} = \Delta H^{\neq}_{21} - T\Delta S^{\neq}_{21}; \quad \Delta S^{\neq}_{12} = \Delta S^{\neq}_{21} - \Delta S^0. \tag{17}$$

If the equilibrium parameters $\Delta H°$ and $\Delta S°$ are known, the problem reduces to determining two parameters (for example, $\Delta H^{\neq}_{12}$ and $\Delta S^{\neq}_{12}$; see the scheme below).



Before proceeding to the analysis of the results of the study of ring dynamics obtained with the aid of ^{13}C NMR, it is necessary to consider certain characteristics of the NMR method. In the first place we may note that the method is perhaps the only available procedure for the investigation of the dynamics of ring inversion in substituted cyclohexane. Data found by other methods are extremely limited (see, for example, Refs. 73 and 74) and have not been analysed critically. Among the different versions of the NMR method, ^1H NMR[55] and ^{19}F NMR[37,59] have become common. Studies by ^{19}F NMR are naturally restricted to fluorinated cyclohexanes (the so called method of the fluorine label proposed by Roberts[75]). When ^1H NMR is used, a fundamental difficulty arises because of the complex multiplet nature of the spectra due to the strong coupling between the spins in the spectra of substituted cyclohexanes. A correct interpretation of the dynamic effects requires in this case the use of the formalism of the density matrix[21,22]. The degrees of the systems of equations and the dimensions of the corresponding matrices obtained in this type of description increase rapidly with increase of the number of interacting spins. As a rule powerful computers must be used even for three spins, and, when there are five non-equivalent groups of interesting spins, the problem is virtually insoluble even when the best of modern computers are used. For certain special systems (for example, deuterated compounds), the degree of the systems of equations may be significantly reduced[76] but hitherto the formalism of the density matrix has not been used in studies on the dynamics of the inversion of cyclohexane derivatives.

It is also necessary to consider the general limitations in the study of the form of the potential surface for the ring inversion reaction by NMR. In examining these limitations one may begin with the phenomenological Bloch–McConnell equations for two-position exchange[23,77]. All inversions in substituted cyclohexanes belong to this type of exchange with two stable A_1 and A_2 states. Fig. 3 shows the region where NMR may be used to investigate two-position exchange (the shaded region). The limitations arise from the following considerations. Firstly, the modulus $|\Delta G^{\neq}_{12} - \Delta G^{\neq}_{21}|$ must not exceed 2 kcal mole^{-1}, which implies that the study of strongly displaced equilibria (or high-energy conformations) is difficult. Secondly, the values of $\Delta G^{\neq}_{12}$ and $\Delta G^{\neq}_{21}$ are limited from below by the low temperatures actually attained (6 kcal mole^{-1} for

120 K and 8 kcal mole^{-1} for 170 K). Thirdly, the limitations at the upper end are caused by the maximum attainable temperature in NMR transducers (473 K, which corresponds to ΔG = 24 kcal mole^{-1}). The region actually investigated proves to be even narrower, bearing in mind that the accuracy of the measurement of the dynamic broadening decreases rapidly with increase of the "degree of non-degeneracy" of the process. This fact reflects the real situation, which arises, in particular, in the study of substituted cyclohexanes. In fact the majority of the investigations of the dynamics of ring inversion by ^{1}H NMR [55,76,78] were devoted to degenerate systems. The inversion of non-degenerate systems has been studied using three models (fluorocyclohexane[37], 1,2-*trans*-fluoroiodocyclohexane[59], and 3-chloro-1,1-difluorocyclohexane[58]) by ^{19}F NMR. Some of the results obtained by ^{1}H and ^{19}F NMR are compiled in Tables 8 and 9.

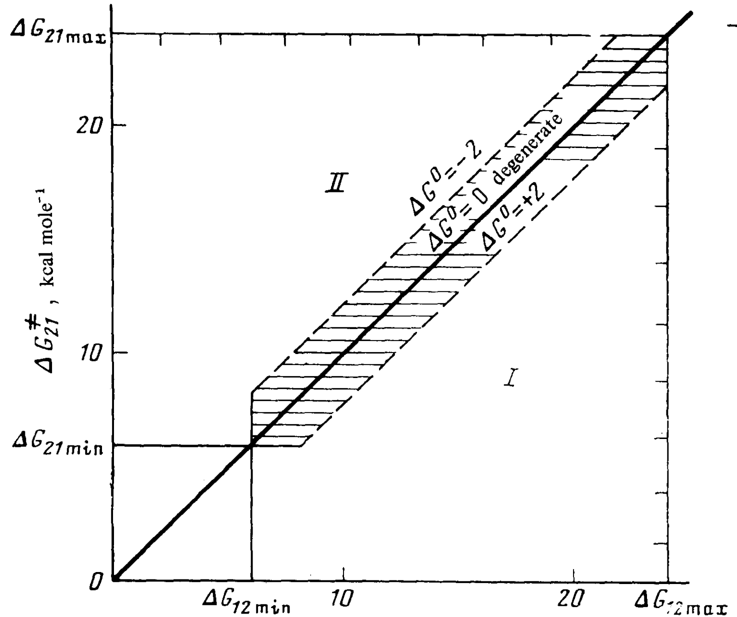


Figure 3. Energy diagram for the $(A_1) \rightleftharpoons (A_2)$ transformations. The values of $\Delta G_{\max}$ and $\Delta G_{\min}$ correspond to the maximum and minimum free energies of activation which can be measured by NMR; I—region where conformer A_1 predominates; II—region where conformer A_2 predominates.

^{13}C NMR also has many practical advantages over other versions of the NMR method in the study of intramolecular dynamic processes[27,81]. The most important advantage is that ^{13}C NMR spectra measured under the conditions of complete decoupling from protons do not contain spin multiplets and therefore permit the employment of a simpler formalism based on the Bloch–McConnell equation. The second advantage consists in a wider range of variation of the chemical shifts (exceeding by a factor of ~20 the range of the proton chemical shifts), which makes it possible, in principal, to carry out measurements on faster processes. However, one should note that studies on ring inversion processes in substituted cyclohexanes by ^{13}C NMR have so far been comparatively restricted and devoted mainly to degenerate processes (see Table 8). Non-degenerate inversion has been studied in only one instance, namely the inversion of chlorocyclohexane (see Table 9). In this last instance the prospects for the employment of ^{13}C NMR are so far extremely problematical. The data presented for degenerate processes undoubtedly show that the ^{13}C NMR method is more universal.

Table 8. The activation parameters for ring inversion in substituted cyclohexanes (the degenerate case).

*The methyl group is designated by a circle.

**T_r is the temperature of stereochemical rigidity at which the rate of exchange is 1 s^{-1}. The values of T_r were determined from the approximate formula $T_r \simeq \Delta H/(\Delta S + 58.2)$, which follows from Eqn. (1) for $k = 1$ s^{-1}.

Despite the achievements in the experimental studies on inversion processes, a consistent method for the interpretation of these data has not so far been put forward in the literature. This is due to the general state of the theoretical description of the process under consideration[12,16,17]. The available estimates[17], carried out by Westheimer's method (a version of the method of atom–atom potentials) are in only qualitative agreement with experimental data and in all cases the accuracy of the latter is significantly higher than that of the calculation.

Table 9. The activation parameters for ring inversion in substituted cyclohexanes (the non-degenerate case).

In view of the present lack of a quantitative theory of conformational transformations, many investigators are rightly interested in various approximate methods for the analysis of the inversion dynamics, which make it possible to establish the occurrence of ring inversion and to determine the approximate thermodynamic characteristics of this process. The free energies of activation, calculated directly from the rate constants defined by Eqn. (1) at a specified temperature, may be used as characteristics of this kind. Sometimes the specified temperature is the temperature of stereochemical rigidity T_r,[82] which is determined from the nature of the broadening of the lines in the slow exchange stage (T_r is the temperature at which the exchange rate constant is 1 s^{-1}). For degenerate inversions investigated by ^{13}C NMR, the values of T_r are listed in Table 8. One should note that T_r varies within wide limits (142–196 K). We may point out that quite recently it proved possible to establish with the aid of ^{13}C NMR that γ-hexamethyl-(*aeaeae*)-cyclohexane is rigid even at room temperature and undergoes inversion only on heating to 370 K; estimates of the free energy of activation gave 17.6 kcal mole^{-1}.[83] The ^{13}C NMR method is the most effective and universal procedure in the search for anomalous inversion barriers.

VI. CHEMICAL SHIFTS OF ^{13}C NMR NUCLEI IN INDIVIDUAL CONFORMERS OF SUBSTITUTED CYCLOHEXANES

In those cases where there are adequate grounds for the assumption that the conformational equilibrium is strongly displaced towards one conformer, it is possible to employ high-temperature spectroscopic data (for 300 K) as the individual spectroscopic characteristics of the dominant conformer. This approximation is valid for the majority of alkyl groups; the corresponding chemical shifts are listed in Table 10. However, in the general case where the nature of the conformational equilibrium is unknown, it is necessary to investigate low-temperature spectra. The relevant data for monosubstituted cyclohexanes are listed in Table 11. Data obtained by optimising the additive scheme for the determination of chemical shifts are quoted for the methyl group[44].

Table 10. ^{13}C NMR chemical shifts (δ, p.p.m.) in monosubstituted cyclohexanes $C_6H_{11}X$ (X is a substituent with a conformational energy ≥2 kcal mole^{-1}).

*Relative to cyclohexane (according to Pehk and Lippmaa[28])

In general, additive schemes for the compilation of ^{13}C chemical shifts have been widely used (see, for example, the selection of data in the review of Martin et al.[25]), particularly as one of the most effective methods for the assignment of spectral lines. Additive schemes are devised with the aid of a system of increments $\Delta_i(X)$, each of which characterises the influence of the substituent X on the shifts of the *i*th atom of the unsubstituted molecule. The index *i* describes the possible positions of a cyclohexane carbon atom relative to the substituent. Thus the ^{13}C NMR chemical shifts adjusted to the chemical shift of cyclohexane (27.50 p.p.m. relative to tetramethylsilane in terms of the δ-scale) can be regarded as the increments $\Delta_i(X)$.

Additive schemes for the calculation of ^{13}C NMR chemical shifts have been used successfully in the analysis of the spectra of dichlorocyclohexanes[46], methylcyclohexanols[62], a series of 1,2-disubstituted compounds[61], polymethylcyclohexanes[43], methyl derivatives of methylcyclohexanol[85], chloromethyl derivatives[86], etc. In most cases the deviations did not exceed 2 p.p.m. Appreciable upfield deviations (>2 p.p.m.) have been observed systematically in only one case—in the analysis of the shifts of the $C_{(1)}$ and $C_{(2)}$ atoms in 1,2-disubstituted compounds. The non-additivity of the shifts observed for 1,2-disubstituted cyclohexanes is probably general, because analogous deviations (sometimes referred to as the "*ortho*-effect") have been found also for other 1,2-disubstituted compounds: benzene[4], cyclopropane[87], ethylene[88], and cyclo-octane[99] derivatives. We may note that, for the diaxial orientation of the substituents, this effect is a maximum (Table 12). Thus the phenomenon is probably due to the overall influence of electronic and steric factors.

*Data obtained by optimising the additive scheme for the calculation of the chemical shifts for polysubstituted compounds.

In principle the inclusion of non-additive corrections may lead to an improvement of the agreement between the experimental and calculated chemical shifts. An improved scheme of increments has been proposed so far only for polymethylcyclohexanes[44] and it was possible to achieve agreement with experiment within the limits of several tens of p.p.m. As regards the increments $\Delta_i(X)$ themselves, the upfield shift of the signal of the γ-carbon atom in the axial conformer (on average by 5–6 p.p.m. relative to the equatorial conformer) is the most interesting feature. This shift (the so called γ-effect), first observed by Grant and Cheney[89] for methylcyclohexanes, is interpreted in the general case as reflecting the interaction "through space" of the hydrogen atoms attached to the γ-carbon atoms in the ring with the substituent.

Table 12. The non-additive corrections for the calculation of ^{13}C NMR chemical shifts for substituted carbon atoms in 1,2-derivatives of cyclohexane (in p.p.m.).

Conformation*	Substituents		
	CH_3, CH_3	Cl, Cl	Br, Br
	2.45[44]	4.7[42]	6.5[61]
	—	6.7[42]	9.2[61]
	3.43[44]	6.9[42]	—
	2.91[44]	6.9[42]	—

---

*The atom considered is designated by a filled circle.

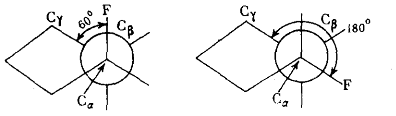
According to Grant and Cheney[90], the γ-effect depends on the distance r_{CH} and the angle θ which the C–H bond of the methyl group makes with the C...H line. The above dependence is described by the formula

$$\Delta\gamma = 1680 \cosh\,\theta \cdot \exp(-2.67 r_{CH}). \qquad (18)$$

The simplicity of this purely geometrical model explains why γ-effects have aroused interest in the literature on the conformational analysis of six-membered heterocycles[91,92]. It is noteworthy that in certain cases the γ-effect is weaker (for example, in the case of the F, OCH_3, and NO_2 substituents; see Table 11) and is altogether absent for mercury-substituted compounds[49]. The attempts at experimental determination of the dependence of $\Delta\gamma$ on r_{CH} (or r_{CX}) were unsuccessful (see, for example, the analysis of the γ-effects in fluorine-substituted steroids[93]).

By considering now the narrower class of halogenocyclohexanes, it is possible to trace the dependence of the chemical shifts on the electronegativity of the substituent (Fig. 4). With increase of Pauling's electronegativity E, the chemical shifts of the α-carbon atom increase, those of the β- and γ-atoms decrease, and for β-atoms the dependence is close to linearity. The corresponding differences $\Delta\delta = \delta_i^e - \delta_i^a$ are $\Delta\delta_\alpha = -7-5$, $\Delta\delta_\beta = 2.5-4.5$, $\Delta\delta_\gamma = 4-6$, and $\Delta\delta_\delta = 0--1$ (all the values are expressed in p.p.m.).

Comparatively little is known about the spin–spin coupling constants[44] involving ^{13}C nuclei (in substituted cyclohexanes); some results may be found in the papers of Subbotin and Sergeyev[39] and Weigert and Roberts[71]. A study of the low-temperature spectra of fluorocyclohexane showed all the $^{13}C-^{19}F$ spin–spin coupling constants for the interaction involving the carbon atoms in the individual conformers are different (these constants are listed in Tables 13). The $^3J(^{13}C-^{19}F)$ constant undergoes the most pronounced changes. The difference between the corresponding constants is probably due to the dependence of the constant $^3J(^{13}C-^{19}F)$ on the dihedral angle Φ between the $FC_\alpha C_\beta$ and $C_\alpha C_\beta C_\gamma$ planes. The dihedral angles are 60° and 180° for the axial and equatorial conformers respectively.



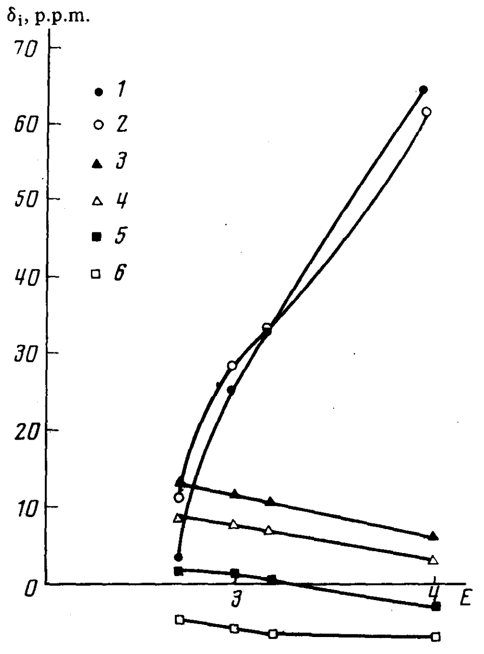


Figure 4. Dependence of the ^{13}C NMR chemical shift of the α-, β-, and γ-carbon atoms in the axial (a) and equatorial (e) conformers of halogenocyclohexanes on Pauling's electronegativity: 1) α_e; 2) α_a; 3) β_e; 4) β_a; 5) γ_e; 6) γ_a.

Assuming that the dependence of the constants $^3J(^{13}C-^{19}F)$ on the dihedral angle Φ is described by the "Karplus" curve corresponding to a function of the type $A + B\cos^2\Phi$, it is possible to estimate from the data in Table 13 the coefficients A and B, which yields $A = -2.5$ Hz and $B = 14$ Hz; thus the constant $^3J(^{13}C-^{19}F)$ probably changes sign in the vicinity of $\Phi = 0$. The absolute sign of the constant $^3J(^{13}C-^{19}F)$ is discussed by Hinton and Jaques[94].

There is at present no reliable information about the constants $J(^{13}C-H)$ for the compounds under consideration. The limited data obtained from ^{13}C NMR spectra of certain cyclic compounds[4,95] show that the constants $^1J(^{13}C-H)$ can be used in stereochemical studies, since a difference is observed between the constants for the axial and equatorial protons†.

Table 13. The spin–spin coupling constants $J(^{13}C-^{19}F)$ (Hz) for fluorocyclohexane conformers at 183 K.[39]

SSC constant	Position of carbon atom			
	α	β	γ	δ
J_a,	167.0	21.5	1.0	<1
J_e,	172.2	17.7	11.5	2.0
$\lvert J_e - J_a \rvert$	5.2	3.8	10.5	~1

The constants $J(^{13}C-^{13}C)$ for coupling between carbon atoms linked by a σ bond may become yet another useful source of information. In recent years there has been a significant growth of interest in studies on these spin–spin coupling constants[97,98] in connection with advances in the technique of the recording of ^{13}C NMR spectra and in the calculation of spin–spin coupling constants. In particular, Gunther and Herrig[98] proposed on the basis of a compilation of experimental data an equation describing the dependence of $^1J(^{13}C-^{13}C)$ on the C–C bond length. If both carbon atoms are sp^3-hybridised, the equation becomes

$$J(^{13}C-^{13}C) = (-167.2 \pm 9.4)\,r_{CC} + (294.4 \pm 13.5). \qquad (19)$$

The constants $J(^{13}C-^{13}C)$ for the class of compounds under consideration have been reported so far only in the case of methylcyclohexane[42] (equatorial conformer). The $^{13}C-^{13}C$ constants for the corresponding C–C bonds are indicated below:

The similarity of the constants for the given compound shows that the C–C bond lengths differ very insignificantly (not more than by 0.02 Å).

oOo

Thus ^{13}C NMR spectroscopy has permitted definite progress in the solution of the classical problem of conformational analysis involving the study of equilibria between the conformers of substituted cyclohexanes. This progress consists in a significant expansion of the range of objects investigated, the discovery of universal methods for the measurement of equilibrium constants, and experimental study of ring inversion dynamics. In certain cases

---

†The ^{13}C–H constants for cyclohexane itself have been obtained in a recent study[105] of the low-temperature ^{13}C NMR spectra of $[D_{11}]$cyclohexane: $^1J(^{13}C-H_a) = 122.44$; $^1J(^{13}C-H_e) = 126.44$; $^2J(^{13}C-H_a) = -3.94$; $^2J(^{13}C-H_e) = -3.69$; $^3J(^{13}C-H_a) = 2.12$; $^3J(^{13}C-H_e) = 8.12$; $^4J(^{13}C-H_a) = -0.31$; $^4J(^{13}C-H_e) = -0.50$ (all the values are expressed in Hz).

the accuracy of these methods, based on ^{13}C NMR spectra, is not inferior to that of other physical and chemical methods.

We may recall that ^{13}C NMR spectroscopy has been used recently to solve also other more complex problems of dynamic stereochemistry. In particular it has been possible to achieve with the aid of ^{13}C NMR a definite understanding of the conformational transformations in cyclo-octane[99], some of its derivatives[100,101], certain moderately large and large saturated rings[102], and cyclic ketones[103,104].

Study of Short-lived Chlorine- and Sulphur-containing Radicals by the Spin-trapping Method

R.Kh.Freidlina, I.I.Kandror, and R.G.Gasanov

The general aspects of the method for the identification and study of short-lived radicals in the liquid phase by EPR using spin-trapping agents are discussed and the available literature data for the application of the spin-trapping method to the study of short-lived chlorine- and sulphur-containing radicals and reactions involving them are surveyed. Certain methodological solutions, which make it possible to use the method in the study of complex radical reactions, are examined.

The bibliography includes 91 references.

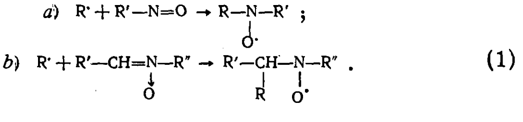
I. INTRODUCTION

Many free radicals are extremely unstable paramagnetic species and their identification by EPR is possible only when their steady-state concentration is sufficiently high. The existing methods for the direct investigation of short-lived radicals in the liquid phase by EPR therefore consist either in a constant maintenance of a fairly high concentration of the radicals in the spectrometer resonator (flow method[1,2]) or in an increase of the lifetime of the radicals by reducing the temperature[3,4]. These methods suffer from the following disadvantages. In the first case considerable amounts of starting materials are required, and in the second account must be taken of the fact that radical processes can take place in different ways depending on the temperature, so that the results obtained, for example, at −100°C, do not always agree with the reaction mechanism at room or higher temperatures[5,6]. Furthermore, the above methods are very complex experimentally.

Towards the end of the 1960s, a new method was developed for the investigation of the EPR of short-lived radicals in the liquid phase called the "nitroxide method"[7] or the "spin-trapping method"[8]. The essential feature of this method is that the short-lived radicals R˙ formed during the homolytic reaction add to a "spin-trapping agent" (a nitroso-compound, a nitrone, or another suitable radical acceptor) specially introduced into the reaction mixture, which leads to the formation of nitroxy-radicals ("spin-adducts"[8]), for example:



$$a)\quad R^{\cdot}+R'{-}N{=}O \rightarrow R{-}\underset{\substack{|\\ O^{\cdot}}}{N}{-}R'\ ;$$

$$b)\quad R^{\cdot}+R'{-}CH{=}\underset{\substack{\downarrow\\ O}}{N}{-}R'' \rightarrow R'{-}\underset{\substack{|\\ R}}{CH}{-}\underset{\substack{|\\ O^{\cdot}}}{N}{-}R''\ . \qquad (1)$$

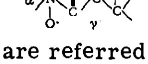
The nitroxy-radicals formed are in many cases sufficiently stable for investigation by EPR. The EPR spectrum of the spin-adduct makes it possible to arrive at a conclusion concerning the structure of the radical R˙ detected†.

This method naturally suffers from the usual disadvantages of an indirect procedure compared with direct procedures. Nevertheless it has many advantages which have ensured its extensive development and application‡. The largest of spin labels available makes it virtually universal for the detection of a wide variety of radicals. The method is extremely simple experimentally and does not require large amounts of starting materials.

Several reviews devoted to studies on a wide range of different radicals by this method were published in 1970–71.[7,8,14]. However, during this initial period of the development of the method, studies were performed mainly on model reactions, i.e. those where known radicals were generated, and the possibility of their detection by particular trapping agents and the relation between the EPR parameters and the structure of the "trapped" radical were investigated, new trapping agents were proposed, etc. The results served as the basis for the

---

†The following nomenclature is used to designate the positions in nitroxy-radicals[9]:



(the RR′NO˙ radicals are referred to in the literature as "nitroxide" and "nitroxy-radicals"[10]. Rozantsev[11,12] argues convincingly that the term "nitroxy-radical" is more justified and this is the term which we shall use in the present review).

‡The method became rapidly popular and, as early as 1971, a paper was published[13] warning investigators against being unduly attracted by this procedure and indicating the limits of its applicability.

employment of the spin-trapping method for the investigation of certain fairly complex radical processes.

Many new investigations devoted to both the development of the method and to its employment in the study of radicals and mechanisms of radical reactions, have now accumulated in the literature. In this review we shall deal mainly with the application of the spin-trapping method to the study of chlorine- and sulphur-containing radicals and the reactions involving them.

II. GENERAL PROBLEMS OF THE SPIN-TRAPPING METHOD

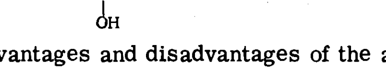
The nitroxy-radicals formed as a result of the addition of short-lived radicals to the trapping agent are characterised primarily by a triplet signal in the EPR spectrum due to the interaction of the unpaired electron with the ^{14}N nucleus. The *g*-factors for different nitroxy-radicals are very similar[7], but, depending on the substituents at the nitrogen atom, the hyperfine interaction constant a_N for different nitroxy-radicals varies within fairly broad limits—from 4–5 G for diacylnitroxy-radicals[15] to 25 to 28 G for alkoxyalkylnitroxy-radicals[16]. Even the values of a_N for different spin-adducts can therefore yield, to a first approximation, information about the nature of the short-lived radical detected by the trapping-agent. Furthermore, if nuclei with non-zero spins are present in the α- and β-positions relative to the nitroxy-group, then the EPR spectrum shows an additional splitting of the lines of the main triplet. Thus the hyperfine structure (HFS) of the spectrum and the hyperfine interaction (HFI) constants provide in this case additional and very important information for the identification of the "trapped" radical. Lines for hyperfine interaction with more remote nuclei are resolved only in exceptional individual instances; as a rule, hyperfine interactions are manifested only by a smaller or greater broadening of the lines of the main triplet.

It is noteworthy that the spin-trapping method is very convenient and effective for demonstrating the radical mechanism of a particular reaction and for the qualitative identification of the radicals formed. The method has been used recently also to investigate reactions proceeding via a one-electron transfer mechanism (see, for example, Refs. 17–19). As regards the determination of quantitative data, for example, the relative concentration of the radicals formed, then in the general case this cannot be done on the basis of a comparison of the integrated intensities of the spectra of their spin-adducts. This is because not all the radicals are trapped to an equal extent and not all the spin-adducts are equally stable. Quantitative estimates therefore require the knowledge of the relative rates of reaction with the given trapping agent of the radicals being compared and of the rates of the subsequent transformations of the nitroxy-radicals formed. It is therefore of interest to note the studies published recently on the quantitative determination by the spin-trapping method of the yields of radicals formed in the radiolysis of methanol under various conditions[20,21].

1. Spin-Trapping Agents

The range of compounds used as spin-trapping agents is now fairly wide. As already mentioned, nitroso-compounds and nitrones are mainly used for this purpose.

a) Nitroso-compounds. Tertiary or aromatic nitroso-compounds are as a rule used as trapping agents, so that the EPR spectrum of the spin-adduct formed is not complicated by the hyperfine interaction with the β-hydrogen atoms of the nitroso-compound. Among non-aromatic nitroso-compounds, 2-methyl-2-nitrosopropane (nitroso-t-butane, MNP) and its deuterated analogue[14], as well as 2-methyl-2-nitroso-3-butanone (MNB)[7] are most frequently used. 2-Nitroso-2-trifluoromethylhexafluoropropane[22] and trisethoxycarbonylnitrosomethane[23] have been proposed recently. A number of workers put forward a very interesting combination in a single compound of sources of the spin-trapping agent and of the radicals[24-29]. They showed that, when aryl-*N*-hydroxytriazenes are oxidised by lead dioxide, aryl radicals and a nitroso-compound, capable of behaving as a spin-trapping agent, are formed simultaneously:



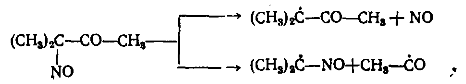
$$\underset{\displaystyle\ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ OH}{Ar{-}N{=}N{-}N{-}R} \xrightarrow{PbO_2} Ar^{\cdot} + N_2 + R{-}N{=}O \quad . \tag{2}$$

The advantages and disadvantages of the above trapping agents are widely discussed in the literature; MNP is the most universal agent. It will be clear from subsequent exposition (see Sections III–V) that the majority of radicals react with MNP to form fairly stable and readily identifiable spin-adducts. However, this compound suffers also from many disadvantages. Firstly, it is dimeric in the solid state, and is converted into the active monomeric form in solution to only a slight extent; complete transformation into the monomeric form is achieved under the influence of radiation[30]. Secondly, when acted upon by lead dioxide or ultraviolet light, or on heating[8], MNP may decompose·

$$\begin{gathered}(CH_3)_3C{-}N{=}O \rightarrow (CH_3)_3\dot{C} + NO,\\ (CH_3)_3\dot{C} + (CH_3)_3C{-}N{=}O \rightarrow [(CH_3)_3C]_2N{-}\dot{O},\end{gathered} \tag{3}$$

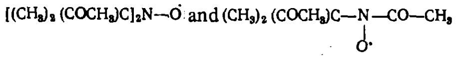
and the resulting t-butyl radicals may add to the initial molecule to form a nitroxy-radical, the spectrum of which consists of a triplet with $a_N = 15–17$ G (depending on the solvent used)[16]. This triplet is frequently so intense that it may overlap the lines corresponding to the other spin-adducts formed§. In addition, when MNP is used, the reaction mixture often has to be freed from oxygen to avoid the formation of certain secondary radicals[32].

MNB is also present as an inactive dimer, which partly dissociates in solution to the monomer[7]. Ultraviolet irradiation promotes such dissociation, causing at the same time the fragmentation of the nitroso-compound into radicals:



$$(CH_3)_2\underset{\displaystyle NO}{\underset{|}{C}}{-}CO{-}CH_3 \longrightarrow \begin{cases} (CH_3)_2\dot{C}{-}CO{-}CH_3 + NO \\ (CH_3)_2\dot{C}{-}NO + CH_3{-}\dot{C}O \end{cases} \tag{4}$$

These add to the initial molecule to form the spin-adducts



$$[(CH_3)_2(COCH_3)C]_2N{-}\dot{O} \text{ and } (CH_3)_2(COCH_3)C{-}\underset{\displaystyle O^{\cdot}}{\underset{|}{N}}{-}CO{-}CH_3$$

characterised in the ESR spectrum by triplets with $a_N = 14$ to 15 G[16] and 7–8 G[7] respectively.

A distinctive feature of this trapping agent is that radicals containing chlorine atoms at the radical centre cannot be detected with its aid[33]. This limits its applicability, on

---

§Since the main absorption band of MNP is in the region of 680 nm, its fragmentation may be avoided by using shorter-wavelength radiation[31].

the one hand, and constitutes a significant advantage in the selective detection of various radicals in complex homolytic reactions, on the other (see Section V).

2-Nitroso-2-trifluoromethylhexafluoropropane (nitrosoperfluoro-t-butane, NFB) is an extremely convenient trapping agent for chlorine-containing radicals. For example, its spin-adduct with $Cl_3C^{\cdot}$ has an EPR spectrum which can be more readily interpreted than that of the corresponding MNP adduct (see Section III). A disadvantage of NFB is, as for the other nitroso-compounds mentioned above, its decomposition under the influence of radiation. The nitroxy-radical formed as a result of a secondary reaction,

$$(CF_3)_3C{-}N{=}O \rightarrow [(CF_3)_3\dot{C} + NO\ ,$$

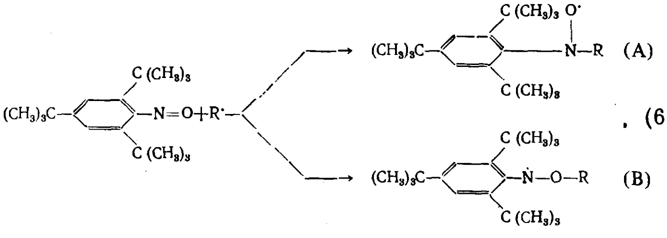
$$(CF_3)_3\dot{C} + (CF_3)_3C{-}NO \rightarrow [(CF_3)_3C]_2N{-}\dot{O}\ , \qquad (5)$$

gives rise to a triplet with a_N = 11.9 G in the spectrum, with very appreciably broadened (~6 G) lines owing to hyperfine interaction with γ-fluorine atoms[34].

The application of trisethoxycarbonylnitrosomethane is so far restricted to isolated examples only[23]. It is apparently convenient for the detection of alkyl radicals. There are as yet no literature data for investigations of chlorine- and sulphur-containing radicals with its aid.

Among aromatic nitroso-compounds, only nitrosobenzene was used in the early stages[8]. However, although this trapping is fairly universal, it suffers from a significant disadvantage: the EPR spectrum of the corresponding spin-adducts consists of many components owing to hyperfine interaction with the *o*- and *p*-hydrogen atoms in the benzene ring (the splitting by the *m*-hydrogen atoms is as a rule insignificant—less than 1 G). This hinders to a large extent the identification of the "trapped" radical.

Nitrosodurene[35] and 2,4,6-tri-(t-butyl)nitrosobenzene, proposed subsequently[36,37], are much more convenient in this respect. The latter trapping agent is of interest also because, depending on the nature of the radical combining with it, different spin-adducts are formed:



. (6)

Primary alkyl radicals as well as phenyl and phenylthio-radicals give rise to the nitroxy-radical A, while tertiary radicals form the anilino-radical B; secondary radicals form a mixture of the two products. The spin adducts A and B can be readily distinguished on the basis of their ESR spectra (the *g*-factors for A and B are respectively 2.006–2.007 and 2.0035–2.0040).[36]

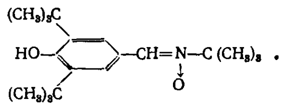
An advantage of this trapping agent is that it is monomeric also in the solid state and, furthermore, even if it does decompose under the influence of ultraviolet radiation[38], it never gives any additional EPR signals under these conditions. It is apparently unsuitable for the identification of radicals of the type $\dot{C}Cl_3$ and $\dot{C}HCl_2$.[36]

(b) Nitrones. Among nitrones, *N*-t-butyl α-phenyl nitrone (BPN) is most frequently used as a spin-trapping agent[8].

$$C_6H_5{-}CH{=}\underset{\downarrow \atop O}{N}{-}C(CH_3)_3\ .$$

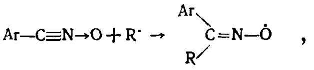
In addition, the use of *N*-t-butyl nitrone[39], α-*N*-diphenyl nitrone[40] and cyclic nitrones[8,41] has been described. The advantages and disadvantages of nitrones have been analysed in detail in a review[8]. We shall mention only that, in contrast to nitroso-compounds, nitrones make it possible to detect chlorine (see Section III) and hydrogen atoms[8,20]. However, they suffer from the important disadvantage that the spectrum of the spin-adducts formed as a result of the addition of short-lived radicals (see Scheme 1, b) has a hyperfine structure due solely to the splitting of the lines by the interaction with the nitrogen and β-hydrogen atom (a triplet of doublets). For the majority of spin-adducts, a_N and $a_{H-\beta}$ depend little on the structure of the trapped radical. An unambiguous identification of the radicals is therefore often possible only on the basis of the comparison of the resulting EPR spectrum with that of the corresponding spin-adduct, obtained by a standard procedure[8]¶.

A very interesting "bifunctional" trapping agent has been proposed[42]:



Alkyl and aryl radicals add to it with formation of nitroxy-radicals, while alkoxy-radicals abstract the hydroxyl-hydrogen, giving rise to a stable phenoxy-radical.

(c) Other trapping agents. Aromatic nitrile oxides, forming very stable spin-adducts (iminoxy-radicals) with short-lived radicals



$$Ar{-}C{\equiv}N{\rightarrow}O + R^{\cdot} \rightarrow \begin{matrix} Ar \\ R \end{matrix}\!\!>\!C{=}N{-}\dot{O}\ , \qquad (7)$$

are extremely convenient trapping agents for hydrocarbon radicals[43]. However, they are relatively unsuitable for chlorine-containing radicals, because of an unduly low value of a_{Cl} (for example, a_{Cl} = 0.5G for $Ar{-}\underset{CCl_3}{\underset{|}{C}}{=}N{-}\dot{O}$).

The above data permit the conclusion that complex radical reactions should evidently be investigated with the aid of various trapping agents, taking into account their advantages and disadvantages, selectivity, etc, and not just a single trapping agent.

2. Experimental Conditions

Most of the reactions described in the literature were investigated directly in the resonator of the EPR spectrometer. A small amount of the trapping compound is usually added to the experimental reaction mixture and the sealed tubes containing the solution are placed in the resonator where they are irradiated, heated, or cooled (depending on the conditions required for the reaction). As a rule, the reaction mixture is not freed from oxygen. However, it has been shown (see, for example, Zubarev et al.[20]), that the presence of oxygen reduces the intensity of the spectral

---

¶The use of N-t-butyl α-(2,4,6-trimethoxyphenyl) nitrone, the spin-adducts of which are characterised by a much greater sensitivity of $a_{H-\beta}$ to the nature of the trapped radical than for the spin-adducts of other nitrones, has been described recently[89].

signals and broadens individual lines. When necessary, oxygen is removed by evacuation or by passing a stream of an inert gas through the reaction mixture in the course of 10–15 min. Depending on the polarity of the reaction mixture, cylindrical or planar tubes are used[36].

The concentration of the trapping compound is as a rule 0.001–0.05 M for nitroso-compounds and 0.05–0.06 M for nirtones. Evidently the above concentrations are extremely approximate, since the choice of the concentration of the trapping agent for each given chemical reaction depends on a number of factors. Indeed, in the general case, apart from interaction with the molecules of the trapping agent, the test radicals are involved in other competing reactions with the molecules of the medium M:

$$\text{Initiator} \rightarrow \dot{R}_1 \quad , \tag{8}$$

$$\dot{R}_1 + M \xrightarrow{k_1} \dot{R}_2 \quad , \tag{9}$$

$$\dot{R}_1 + RNO \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} R_1RN{-}\dot{O} \quad , \tag{10}$$

$$\dot{R}_2 + RNO \underset{k_{-3}}{\overset{k_3}{\rightleftarrows}} R_2RN{-}\dot{O} \quad . \tag{11}$$

The formation of spin-adducts at an adequate concentration requires that the conditions $k_2 \gg k_{-2}$ and $k_2 \gg k_{-3}$ be fulfilled. It follows even from this simple scheme that the ratio of the concentrations of the nitroxy-radicals $R_1RN\dot{O}$ and $R_2RN\dot{O}$ in solution in the steady state depends on the concentration of the trapping agent, the substance M, and the rate constants k_1 and k_2. Thus, without knowing the constants (the constants k_2 are known only in a few instances[44–46]), it is impossible to determine beforehand the required concentration of the trapping compound.

(a) Solvents. The choice of solvent has been discussed in detail[7]. The most convenient solvent above 5°C is apparently benzene, since, in contrast to many other solvents employed, it does not form radicals under the experimental conditions†. Methylene chloride is frequently used at low temperatures[7], but one should note that, following ultraviolet irradiation in the presence of MNP, signals due to the nitroxy-radical $H{-}CO{-}\underset{\dot{O}}{\underset{|}{N}}{-}C(CH_3)_3$ formed via a side reaction, consisting of a triplet of doublets with $a_N = 7.0$ and $a_H = 1.41$ G are usually observed in this case[47].

(b) Temperature. The reactions are as a rule carried out at room temperature, but the stability of many nitroxy-radicals depends significantly on temperature. Furthermore, as already mentioned, the reaction may lead to different radicals, depending on temperature. Therefore, in the study of radical processes by the spin-trapping method, the temperature plays an extremely important role (see Section V). It is noteworthy that the parameters of the EPR spectra of nitroxy-radicals are almost independent of temperature.

(c) Methods of generating radicals. This problem has been discussed in fair detail in a number of studies[7,8,14,48]. Here it is of interest to note certain differences between the photochemical methods for the generation of radicals which are investigated directly and radicals identified in the form of their spin-adducts. Owing to the very short lifetime of the radicals, ultrahigh-pressure 1–2 kW mercury lamps are used to obtain them in sufficient concentrations when a flow method[2] is used and in low-temperature experiments[4]. In the study of radicals by the spin-trapping method it is sufficient to employ 100–150 W mercury lamps. It is desirable that the arrangement for ultraviolet irradiation should include appropriate filters, gratings, and diaphragms for regulating the wavelength and intensity of the incident light. Since certain nitroxy-radicals are fairly stable above room temperature, many of them can be obtained by thermal as well as photochemical methods[47].

Numerous chlorine-containing radicals have been obtained by abstracting hydrogen from the correspoding chloroalkanes by the phenyl radicals formed in the oxidation of hydroxytriazenes (Scheme 2).[28] Thiyl radicals are as a rule generated by ultraviolet and γ-irradiation of the corresponding disulphides and thiols. In addition, they can be generated by abstracting hydrogen from thiols by various radicals obtained thermally or photochemically. Sulphonyl radicals are obtained from the corresponding sulphonyl halide as a result of the abstraction of the halogen by triethylsilyl radicals or photochemically (see Section IV).

III. EPR SPECTRA OF NITROXY-RADICALS—SPIN-ADDUCTS OF CHLORINE-CONTAINING RADICALS

Chlorine-containing nitroxy-radicals with one, two, and three chlorine atoms in the β-position, i.e. $R_nCCl_{3-n}N(\dot{O}){-}R'$, are in many cases sufficiently stable to be investigated by EPR under steady-state conditions. This applies particularly to spin-adducts of chlorine-containing radicals with MNP and its perdeutero- and perfluoro-derivatives as well as nitrosodurene.

The hyperfine structure of the spectra of chlorine-containing nitroxy-radicals is extremely complex. This is caused, firstly, by the fact that the chlorine nucleus has a spin of 3/2, which leads to $2n \times 3/2 + 1$ (n is the number of equivalent β-chlorine atoms) lines in the spectrum and, secondly, it arises because the two chlorine isotopes present in natural chlorine in fairly large amounts (75.53% of ^{35}Cl and 24.47% of ^{37}Cl) have different magnetic moments, (0.821 and 0.683 μ_B respectively) which leads to an increase of the multiplicity of the spectral lines as a result of the interaction of the unpaired electron with these nuclei.

This Section describes studies carried out on model examples of known chlorine-containing radicals in order to develop further the spin trapping method as well as studies in which the method has been used to investigate complex chemical processes involving the intermediate formation of short-lived chlorine-containing radicals.

Chlorine-containing radicals can be arbitrarily divided into three groups: (1) chlorine atoms; (2) mono- and poly-chloromethyl radicals; (3) higher chlorine-containing radicals.

1. Chlorine

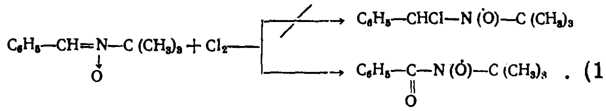
The spin-adducts of chlorine of the type $Cl{-}N(\dot{O}){-}R$ are unknown. The attempt to add chlorine to MNP[8] has been unsuccessful, which indicated, according to the

---

†Certain aryl radicals can add to benzene with formation of the corresponding substituted cyclohexadienyl radicals, which are then detected by the trapping agent[90,91].

author[8], the instability of the expected spin-adduct. The preparation of the nitroxy-radicals $R^1R^2CCl-N(\dot{O})R$, formed both by the interaction of chlorine donors with nitrones[8,49-52] and by the addition of the radical $R^1R^2\dot{C}Cl$ to nitroso-compounds, has been described. The first method of obtaining β-chloronitroxy-radicals is discussed below.

The interaction of chlorine with α-phenyl-t-butylnitrone (PBN) in benzene at room temperature leads to the benzoyl-t-butylnitroxy-radical and not to the spin-adduct—t-butyl-α-chlorobenzylnitroxy-radical[53]:



$$C_6H_5-CH{=}\underset{\downarrow\atop O}{N}-C(CH_3)_3 + Cl_2 \to \begin{cases} \not\to C_6H_5-CHCl-N(\dot{O})-C(CH_3)_3 \\ \to C_6H_5-\underset{\|\atop O}{C}-N(\dot{O})-C(CH_3)_3 \end{cases} \quad (12)$$

The same nitroxy-radical is formed in the reaction of PN with nitrosyl chloride[53], *N*-chlorosuccinimide[39], and poly-nitro-compounds[54].

*The values of a_{Cl} for ^{35}Cl and ^{37}Cl respectively.

Figure 1. The EPR spectrum of the t-butyl-α-chlorobenzylnitroxy-radical in benzene[49].

Subsequently it was possible to obtain t-butyl-α-chlorobenzylnitroxy-radicals by the interaction of PBN with t-butyl hypochlorite in the absence of oxygen[49] (Table 1, No. 1). The resulting EPR spectrum is illustrated in Fig.1. The doublet with a small splitting (a_H = 0.75 G) refers to the β-hydrogen atom. The overlapping quartets result from the hyperfine interaction with the ^{35}Cl and ^{37}Cl nuclei. It is clear from the spectrum that the larger splitting constant corresponds to $a_{^{35}Cl}$ = 6.05 G and the smaller constant corresponds to $a_{^{37}Cl}$ = 4.88 G.

The same spectrum has been obtained following the interaction of PBN with trichlorosilane and chlorotrimethylsilane[49]. The authors suggest that in this case the reaction proceeds with the intermediate formation of t-butyl hypochlorite. The mechanism of the formation of monochloronitroxy-radicals has not been investigated by this procedure[49]. t-Butyl-monochlorobenzylnitroxy-radicals have been obtained also in the photolysis of sulphuryl chloride in the presence of PBN[51,52] (Table 1, No. 2). The authors believe that in this case a chlorine atom adds to PBN.

On the basis of the EPR spectrum in CCl_4 of the product obtained by treating PBN with t-butyl hypochlorite in a gaseous phase[49] (Table 1, No. 3), the authors attributed the structure $C_6H_5CCl_2-N(\dot{O})C(CH_3)_3$ to the nitroxy-radical obtained.

The EPR spectra of the spin-adducts of various radicals with the cyclic nitrone 5,5-dimethyl-1-pyrrolin-1-oxyl (DMPO) have been obtained[50]. According to the results, chlorine as well as t-butyl hypochlorite react with DMPO to form a dichloro-derivative (Table 1, No. 4).

It is seen from the foregoing that at least some of the nitroxy-radicals investigated are products of more complex processes than the direct addition of chlorine to the trapping agent. This is particularly clear from the last two examples, since substitution of β-hydrogen by chlorine also occurs in these reactions.

2. Mono- and Poly-Chloromethyl Radicals

(a) The trichloromethyl radical. The trichloromethyl radical has been widely investigated because of its considerable role in synthetic organic chemistry[55-57] and because it is readily obtained when CCl_4, $CHCl_3$, and CCl_3Br are acted upon by radical-forming agents as well as in the photolysis of CCl_3Br.

The study of the spin-adducts of the radicals $CCl_3^{\bullet}$ with nitroso-compounds initially involved many difficulties. When $CCl_3^{\bullet}$ radicals are generated by the irradiation of $CHCl_3$ or CCl_4 with ultraviolet light in the presence of benzoyl peroxide and various nitroso-compounds, the more stable chlorocarbonyl nitroxy-radicals $Cl-CO-N(\dot{O})-R$ are formed together with the trichloromethylnitroxy-radicals $\dot{C}Cl_3-N(O)-R$, which led to confusion in the determination of the parameters of the spectra of trichloromethylnitroxy-radicals (for a more detailed discussion, see below). On the other hand, the first correctly identified nitroxy-radical of this type, namely $(CCl_3)_2N\dot{O}$, was detected[58] in the synthesis of trichloronitrosomethane and not in a mixture known to contain $\dot{C}Cl_3$ radicals[58]. The constants a_N = 11.8 G and a_{Cl} = 1.25 G were determined in this investigation[58] which constituted the first example of the determination of the hyperfine coupling constants for β-chlorine atoms in nitroxy-radicals (Table 2, No. 1). These data were subsequently confirmed[48].

The spectrum of the nitroxy-radical $CCl_3-N(\dot{O})-C(CH_3)_3$ was described for the first time by Leaver et al.[31] It was characterised by the following parameters: a_N = 12.73; a_{Cl} = 2.41 G; g = 2.0065 (Table 2, No. 5). This spectrum was obtained on irradiation (λ ≃ 300 nm) of a solution of indole or its methyl derivatives in solution in CCl_4 containing MNP. The same workers stated[59] that this spectrum can be obtained by abstracting hydrogen from $CHCl_3$ in the presence of MNP. When a spectrum with a resolved hyperfine structure, due to the interaction with the four

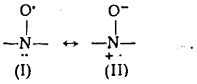
*****t-butyl peroxide.

******the values of a_{Cl} for ^{35}Cl and ^{37}Cl respectively.

possible combinations of the nuclei of chlorine isotopes in the CCl_3 group, is obtained, each line of the main triplet of the ^{14}N signal should be split into 72 lines, of which only 10 were observed. The authors calculated the spectrum by an iterative procedure using the method of least squares; they took into account only the two most important isotope combinations: $^{35}Cl_3$ and $^{35}Cl_2{}^{37}Cl$. The best agreement with the experimental spectrum was obtained for $a_{^{35}Cl}$ = 2.46 G and $a_{^{37}Cl}$ = 2.05 G. Subsequently, the formation of the spin-adducts of the trichloromethyl radical with MNP was noted repeatedly (Table 2, Nos. 2-6).

It has been noted[49] that a_{Cl} for the bistrichloromethylnitroxy-radical is appreciably less than for the t-butyltrichloromethylnitroxy-radical (1.25 and 2.3 G respectively). The authors point out that this may be associated with the lower spin density at the nitrogen atom in the bistrichloromethylnitroxy-radical. The more pronounced electron-accepting properties of the CCl_3 group compared with the $(CH_3)_3C$ group favour structure (I) rather than structure (II):



$$\overset{O^{\cdot}}{\underset{\cdot\cdot}{-N-}} \leftrightarrow \overset{O^{-}}{\underset{+\cdot}{-N-}}$$

(I) (II)

(see also Refs. 14 and 60). The constants a_N differ less than the constant a_{Cl}. The authors[49] also do not rule out the possibility that the small difference between the planarities of the nitroxy-group, caused by the differences between the steric interactions in the above radicals, may likewise give rise to differences between the hyperfine coupling constants a_N and a_{Cl}.

The splitting of the ^{14}N signal due to the commonest combinations of chlorine isotopes (present in the mixture) in the CCl_3 group, i.e. $^{35}Cl_3$ and $^{35}Cl_2{}^{37}Cl$, was achieved for the first time by Perkins et al.[61] The EPR spectrum obtained when $CHCl_3$ was acted upon by TBP in the presence of MNP (Table 2, No. 2) consisted of three ten-component groups of lines, which partly overlapped (Fig. 2). It is seen from the insert in the figure that the extreme line is split into two components, which can be accounted for by the presence of different chlorine isotope combinations.

It has been shown[28] that the oxidation of 3-t-butoxy-1-phenyltriazene by lead dioxide (Scheme 2) in chloroalkanes leads to the formation of chlorine-containing radicals, which interact with the MNP formed simultaneously. The EPR spectrum then shows signals due to the corresponding spin-adducts. In particular, when the reaction was carried out in $CHCl_3$ or CCl_4, the product was the nitroxy-radical $CCl_3-N(\dot{O})-C(CH_3)_3$, whose spectrum was identical with that described by Perkins et al.[61] (Table 2, No. 6).

When a solution of TBP in chloroform containing benzonitrile *N*-oxide or *p*-chlorobenzonitrile *N*-oxide as the spin-trapping agent was irradiated with ultraviolet light (see Scheme 7), a spectrum with a_N = 32.7 G, a_{Cl} = 0.5 G, and g = 2.0048, corresponding to an iminoxy-radical with the CCl_3 group in the *syn*-position relative to the N-O bond, i.e.  , was obtained (Table 2, No. 9).[43] The formation of an iminoxy-radical by the oxidation of chloroaldoxime has also been described[62].

The values of a_N for the spectrum obtained in the detection of the trichloromethyl radical with the aid of 2-nitroso-2-trifluoromethylhexafluoropropane are greater and those of a_{Cl} are smaller (Table 2, No. 8) than for the corresponding spin-adduct obtained when the $CCl_3^{\bullet}$ radical adds to MNP; the spectrum of the spin-adduct with the fluorinated trapping agent is therefore better resolved (Fig. 3)[22].

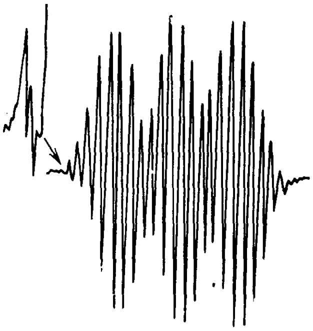


Figure 2. The EPR spectrum of the $CCl_3-N(\dot{O})-C(CH_3)_3$ radical. The insert on the left represents the splitting of the extreme line due to the presence of $^{35}Cl_3$ and $^{35}Cl_2{}^{37}Cl$.[61]

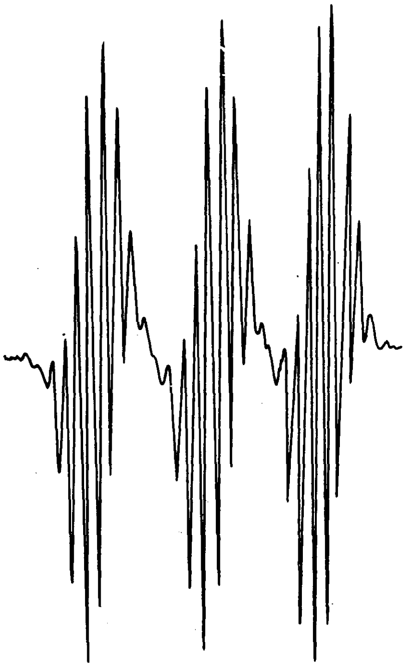

Figure 3. The EPR spectrum of $(CF_3)_3C-N(\dot{O})-CCl_3$.[66]

The trichloromethyl radical has also been detected with the aid of nitrosodurene when a solution of TBP in chloroform was irradiated and also when chlorine was abstracted from CCl_4 by triethylsilyl radicals[35] (Table 2, No. 10).

(b) The Hal−CO−N($\dot{O}$)−R nitroxy-radicals. Nitroxy-radicals of the type

$$Hal-\underset{\underset{O}{\|}}{C}-N(\dot{O})R$$

(III)

are some of the most important radicals of this kind, obtained by a side reaction during the formation of the spin-adducts of the trichloromethyl radical with nitroso-compounds. Ultraviolet irradiation of solutions of benzoyl peroxide (BP) in CCl_4 or $CHCl_3$ as well as the photolysis of CCl_3Br in benzene in the presence of nitroso-compounds lead to the formation, together with other nitroxy-radicals, of radicals whose EPR spectrum is a triplet with $a_N = 6.5$ G and $g = 2.0070$.[63] These spectra were initially assigned to the spin-adducts of the $CCl_3^{\bullet}$ radical with nitroso-compounds[63]. The assignment was found to be erroneous when spectra of the nitroxy-radicals

$$CCl_3-N(\dot{O})-R$$

(IV)

were obtained in a number of studies with quite different hyperfine structures and hyperfine coupling constants (Table 2).

In one of the early investigations Chalfont[64] observed the formation of two long-lived radicals in the photolysis of CCl_3Br in the presence of MNP. One of these radicals was identified as the nitroxy-radical (IV), where $R = C(CH_3)_3$. It was erroneously assumed that the other radical, having $a_N = 6.65$ G, may be the bromine-containing nitroxy-radical $Br-N(\dot{O})-C(CH_3)_3$. This hypothesis was disproved when irradiation of CBr_4 in benzene in the presence of MNP led to a nitroxy-radical whose EPR spectrum had a similar constant $a_N = 6.5$ G, but contained a well resolved quartet with $a_{Br} = 2.1$ G.[47] On the basis of the results of Mackor et al.[30], Torssell[48] was the first to point out that the nitroxy-radicals with such a low constant a_N (6.5–6.7 G) probably have the structure of acylalkylnitroxy-radicals.

Subsequently Hartgerink et al.[63] reinvestigated the photolysis of CCl_4 and concluded[65] that the spectra under consideration (with $a_N = 6.5$ G and $g = 2.0070$) are due to the chlorocarbonylnitroxy-radicals (III). A well resolved splitting of the signal due to the β-chlorine in species of type (III) could never be detected.

The photolysis of CBr_4 in the presence of MNP leads to the formation of the bromocarbonylnitroxy-radical $Br-CO-N(\dot{O})-C(CH_3)_3$ with $a_N = 6.7$ G, $a_{Br} = 2.0$ G, and $g = 2.0071$.[65] These data were subsequently confirmed in yet another study[47]. The results quoted[47] for the photolysis of CCl_3Br show that the corresponding nitroxy-radicals (III) are undoubtedly formed in the presence of MNP or its perdeutero-derivative. Although the authors[47] assign the EPR spectrum (with $a_N = 6.65$ G and $a_{Hal} = 0.5$ G), obtained in the photolysis of CCl_3Br in the presence of a deuterated trapping agent, to the chlorine-containing radical nitroxy-radical (III) with Hal = Cl and $R = C(CD_3)_3$, adequate data for this assignment are not available and one cannot rule out the possibility of forming the bromocarbonylnitroxy-radical (III), with Hal = Br, or a mixture of two halogenocarbonylnitroxy-radicals. In particular, the above assignment conflicts with the observation[47] that the lines of the main ^{14}N triplet in the EPR spectrum of the nitroxy-radical obtained by the photolysis of CCl_3Br in the presence of MNP (Fig. 4) show a quartet splitting, which, although poorly resolved, is nevertheless sufficient to calculate a_{Hal}. On the basis of the spectrum obtained following the irradiation of bromotrichloromethane in the presence of MNP, Gasanov et al.[66] also determined the constants a_N = 6.7 G and a_{Br} = 2.2 G.

Figure 4. The EPR spectrum of the nitroxy-radical obtained on ultraviolet irradiation of CCl_3Br in the presence of MNP.[47]

This difference between the parameters of the spectra obtained on irradiation of CCl_4 and CCl_3Br may be attributed to the fact that in the latter case the $Cl-CO-N(\dot{O})-C(CH_3)_3$ spectrum is overlapped by another spectrum with similar parameters, but with a better resolution of the splitting in the quartet. It apparently corresponds to the nitroxy-radical $Br-CO-N(\dot{O})-C(CH_3)_3$.

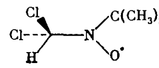
All the halogenocarbonylnitroxy-radicals obtained in the photolysis of bromotrichloromethane in the presence of trapping agents are therefore designated in Table 3 as $Hal-CO-N(\dot{O})-R$. The photolysis of CCl_4 or CCl_3Br in the presence of secondary nitroso-compounds (Table 3, Nos. 7–10) leads to the formation of the nitroxy-radicals $Cl-CO-N(\dot{O})-CHR_2$ whose spectrum shows splitting due to the β-hydrogen (a_H = 2.7–2.8 G).[63]

It has been suggested[47,65] that the nitroxy-radicals (III) are products of secondary reactions of the spin-adduct (IV) formed initially. The following evidence is quoted in support of this hypothesis: the gradual appearance of signals due to species (III) as the signals due to the adduct (IV) disappear, the high intensity of the signals in the spectra of (III), and the failure of the attempt to obtain (III) by the addition of the $Cl\dot{C}O$ radical (generated by the photolysis of phosgene or dibromocarbonyl in the presence of benzoyl peroxide) to MNP. Several possible versions of the mechanism of the above reaction are discussed in the studies indicated, but there has been no experimental confirmation of any of the suggested mechanisms.

(c) The $\dot{C}HCl_2$ and $\dot{C}H_2Cl$ radicals. The preparation of the spin-adducts of MNP with the $\dot{C}HCl_2$ and $\dot{C}H_2Cl$ radicals in the oxidation of 3-t-butyl-3-hydroxy-1-phenyltriazene by lead dioxide in CH_2Cl_2 and CH_2ClI respectively has been described[28] (Table 2, Nos. 11 and 14). In the first instance a multicomponent spectrum was obtained, whose analysis showed that the unpaired electron in the above spin-adduct interacts with the ^{14}N nucleus and the two equivalent chlorine nuclei. The spectrum contains lines which the authors assigned to the isotopic forms (V) and (VI):

$$\underset{(V)}{H^{35}Cl_2C-N(\dot{O})-C(CH_3)_3}; \quad \underset{(VI)}{H^{35}Cl^{37}ClC-N(\dot{O})-C(CH_3)_3}.$$

The relative content of form (V) is 56.8% and that of (VI) 37.2%. The ratio of the hyperfine coupling constants $a_{^{37}Cl}/a_{^{35}Cl}$ = 0.83 is equal to the ratio of the magnetic moments $\mu_{^{37}Cl}/\mu_{^{35}Cl}$ = 0.832; hyperfine coupling with β-hydrogen was not observed. Similar observations were also made in a study[47] of the EPR spectrum of the nitroxy-radical $HCCl_2-N(\dot{O})-C(CD_3)_3$ (Table 2, No. 12). The absence of splitting by β-hydrogen was explained[28] by the fact that the preferred conformation



in which the proton is located in the plane of the molecule, is apparently formed in the given instance.

*g = 2.0070.

**It has been erroneously described[63] as $CCl_3-N(\dot{O})-R$ (see Refs. 65 and 47).

***CCl_4 + RNO + $h\nu$.

****$CHCl_3$ + $(C_6H_5COO)_2$ + RNO + $h\nu$.

***** CCl_3Br + RNO + $h\nu$.

The EPR spectrum of the nitroxy-radical $H_2CCl{-}N(\dot{O}){-}C(CH_3)_3$ consists of a superposition of the spectra of the two isotopic forms containing ^{35}Cl and ^{37}Cl. The spectrum includes lines corresponding to the interaction of the unpaired electron with the ^{14}N nucleus, the ^{35}Cl and ^{37}Cl nuclei, and the two equivalent protons[28] (Table 2, No. 14).

The $\dot{C}HCl_2$ radical, generated by the ultraviolet irradiation of methylene chloride in the presence of TBP, was also identified as the spin-adduct with 2-nitroso-2-trifluoromethylhexafluoropropane[22] (Table 2, No. 13). As for the spin-adduct of the same trapping agent with $\dot{C}Cl_3$, the value of a_N for the above compound is greater and that of a_{Cl} smaller than for the spin-adduct of the $\dot{C}HCl_2$ radical with MNP.

When hydrogen is abstracted from CH_2Cl_2 by the radicals formed in the decomposition of di-t-butyl peroxydioxalate at 30°C in the presence of perdeutero-2-methyl-2-nitrosopropane, the spectrum of the formyl derivative $HCO{-}N(\dot{O}){-}C(CD_3)_3$, for which $a_N = 7.0$ G and $a_H = 1.41$ G, was obtained togehter with that of the spin-adduct of the $\dot{C}HCl_2$ radical (Table 2, No. 12).[47]

3. Higher Chlorine-Containing Radicals

The study of higher radicals, containing one or two chlorine atoms at the radical centre, by the spin-trapping method in most cases involved the solution of chemical problems (see Section V), so that the examples compiled here do not constitute a systematic series. In all the cases investigated, MNP or its deutero-analogues were used to bind the $R\dot{C}Cl_3$ radicals.

The spectra of the spin-adducts of the $CHCl_2\dot{C}Cl_2$ radical with the above two trapping agents show a hyperfine structure due to the interaction of the unpaired electron with the ^{14}N nucleus and the nuclei of the two non-equivalent chlorine atoms (Table 4, Nos. 1 and 2). It has been suggested[47] that the non-equivalence of the chlorine atoms is associated with the high energy barrier to the rotation of two such atoms about the C–C bond in the tetrachloroethyl group. Theoretical analysis showed that the ratio of the constants $a_{^{35}Cl}$ and $a_{^{37}Cl}$ is in this case such that only components corresponding to the predominance of the form with two ^{35}Cl atoms should be detected in the EPR spectrum; the presence of other isotopic forms is revealed only by the "blurring" of the hyperfine structure of the spectrum[28].

The oxidation of 3-t-butyl-3-hydroxy-1-phenyltriazene in tetrachloroethylene takes place in an interesting manner[28]. It apparently entails the formation of the telomeric radicals $C_6H_5(CCl_2CCl_2)_n^{\cdot}$, which bind the MNP formed simultaneously; in this case it was also possible to detect the splitting by the ^{35}Cl and ^{37}Cl nuclei (Table 4, No. 5).

It has been shown[33,66] that, in the system of radicals formed via a rearrangement according to the scheme

$$\underset{(VII)}{XCH_2\dot{C}HCCl_3} \xrightarrow{\varrho} \underset{(VIII)}{XCH_2CHCl\dot{C}Cl_2}\ ,$$

$$X = CCl_3 \text{ or } (CH_3)_3CO \qquad (13)$$

the radicals (VIII) combined selectively with MNP and did not give rise to a stable spin-adduct with MNB, while the radicals (VII) gave rise to an EPR spectrum in the presence of MNB but not in the presence of MNP. These two trapping agents behave similarly also in relation to the radicals (IX) and (X), which are present simultaneously in solution[51]:

$$\underset{(IX)}{XCH_2\dot{C}HCCl_2F} \xrightarrow{\varrho} \underset{(X)}{XCH_2CHCl\dot{C}ClF}\ ,$$

$$X = CCl_3 \text{ or } CHCl_2\ . \qquad (14)$$

***Formed as a result of rearrangement with 1,3-migration of hydrogen atoms.

****The values of a_{Cl} for ^{35}Cl and ^{37}Cl respectively.

According to the results of Camaggi et al.[47], the interaction of t-butoxy-radicals with 1,1-dichloroethane and αα-dichlorotoluene in the presence of MNP yielded EPR spectra characteristic of acetyl- and benzoyl-t-butylnitroxy-radicals respectively, and not of chlorine-containing nitroxy-radicals.

The nitroxy-radicals $CH_2ClCHCl-N(\dot{O})-C(CH_3)_3$ (Table 4, No. 9), in the EPR spectrum of which there is no splitting by β-hydrogen, was obtained by the oxidation of aryloxytriazene with lead dioxide in dichloroethane[28]. The authors suggest that the hydrogen atom in this nitroxy-radical is close to the nodal plane of the *p*-orbital of the nitrogen atom occupied by the unpaired electron. In this arrangement the extent of the interaction of the unpaired electron with β-hydrogen is a minimum.

IV. EPR SPECTRA OF NITROXY-RADICALS—SPIN-ADDUCTS OF SULPHUR-CONTAINING RADICALS

The study of the free radicals formed as intermediates in various reactions of organosulphur compounds under the influence of ultraviolet and γ-radiation or of thermal initiation is of great importance both for the elucidation of the mechanisms of such processes and for the solution of problems which are extremely important from a practical point of view[55,67].

However, direct detection of thiyl radicals by EPR in the liquid phase is evidently impossible owing to their π-orbital degeneracy[68,69]. Furthermore, recent studies have shown that RS$^{\cdot}$ radicals cannot be investigated by EPR in the solid phase: many of the earlier reports apparently refer to the dimeric species $RS^{\cdot}SR_2$ and not to RS$^{\cdot}$ radicals[68].

The spin-trapping method makes it possible to obviate these difficulties and its use for the identification of sulphur containing radicals is apparently of particular interest. Fairly numerous examples of the study of a wide variety of sulphur-containing radicals by this method are now known. The radicals investigated can be arbitrarily divided into three groups: (1) thiyl radicals RS$^{\cdot}$, (2) sulphonyl radicals $RSO_2^{\cdot}$, and (3) other radicals in which the unpaired electron is at a carbon or oxygen atom (C and O radicals), while the sulphur-containing group is attached to a β- or γ-carbon atom.

The data discussed below illustrate examples of the investigation of sulphur-containing radicals of each of these three types with the aid of spin-trapping agents. Comparison of these results shows that the EPR spectra of thiyl- and sulphonyl-nitroxy-radicals, $RS-N(\dot{O})-R'$ and $RSO_2-N(\dot{O})-R'$, are characterised in the general case only by a ^{14}N triplet, but the values of a_N and of the *g*-factor can frequently serve as adequate criteria for the identification of these nitroxy-radicals.

1. The Thiyl Radicals

The first attempt to identify by EPR free radicals with an unpaired electron at a sulphur atom in the form of spin-adducts with a trapping agent (MNP) was undertaken in 1968.[70] Solid polycrystalline specimens of various aminoacids were γ-irradiated and then dissolved in an aqueous solution of MNP and placed in the resonator of the EPR spectrometer. However, in contrast to all other examples, sulphur-containing aminoacids (cysteine, cystine, and methionine) altogether failed to give rise to any EPR signals under these conditions. This enabled the authors to conclude that the adducts of the RS$^{\cdot}$ radicals with MNP are evidently much less stable than the adducts of C radicals.

A study was therefore made of the possibility of identifying with the aid of MNP the thiyl radicals formed on photolysis of thiols and disulphides directly in the resonator of the spectrometer[31]. The RS$^{\cdot}$ radicals were generated by irradiating solutions of butane-1-thiol or di-n-butyl sulphide in oxygen-free heptane with light having λ = 245 and 300 nm respectively. It was possible to avoid in this way the secondary formation of the di-t-butylnitroxy-radical from MNP, which complicates the EPR spectrum (see Section II). When dibutyl disulphide was irradiated in the presence of MNP, a spectrum consisting of a triplet with a_N = 18.52 G and *g* = 2.0071 was obtained. The authors assigned it to the spin-adduct of the $C_4H_9S^{\cdot}$ radicals with the trapping agent. The adduct (Table 5, No. 10) indeed proved to be very unstable: the EPR signals disappeared almost immediately after irradiation ceased. Apart from the above triplet, the spectrum showed another less intense triplet with a_N = 14.93 G and *g* = 2.0058, the origin of which the authors could not establish. After the irradiation of butanethiol, the triplet corresponding to the spin-adduct of the $C_4H_9S^{\cdot}$ radical was also detected[31,59].

$^{*}a_{H(CH_3)}$ = 1.2 G.
$^{**}a_{H\text{-}o} = a_{H\text{-}p}$ = 2.52 G; $a_{H\text{-}m}$ = 0.86 G.
$^{***}a_{H\text{-}m}$ = 0.85 G.

The EPR spectra of the spin-adducts of other thiyl radicals (iso-$C_3H_7S^{\cdot}$, $C_6H_5S^{\cdot}$) with MNP were observed by the same workers[71] in the photochemical reduction of benzophenone by thiols and sulphides. The spectra consisted of triplets having similar g-factors and a_N constants in the range 16.5–18.5 G (Table 5, Nos. 5, 6, 11, and 12).

It is noteworthy that, when thiophenol is used for the photochemical reduction of benzophenone in the presence of MNP, the formation of not only the $C_6H_5S-N(\dot{O})-C(CH_3)_3$ nitroxy-radical, but also of the $H-N(\dot{O})-C(CH_3)_3$ t-butylnitroxy-radical (which may be formally regarded as the spin-adduct of a hydrogen atom and MNP), whose spectrum has $a_N = 13.6$ G, $a_{H(NH)} = 12.36$ G, and $g = 2.0062$, was observed[71]. It is of interest to compare with this result a study[72] where it was shown that thiophenol is reduced to a nitroso-compound on ultraviolet irradiation:

$$2RNO + 2C_6H_5SH \rightarrow 2R-N(\dot{O})-H + (C_6H_5S)_2 \quad . \qquad (15)$$

The EPR spectrum then shows (for $R = t\text{-}C_4H_9$) a triplet of doublets with $a_N = 13.1$ G, $a_H^{NH} = 11.2$ G, and $g = 2.0063$. The authors[72] do not mention the formation under these conditions of the t-butylphenylthionitroxy-radical, but it is seen from the spectrum quoted in their paper that it is formed: the spectrum shows a low-intensity triplet with $a_N = 16.6$ G.

The spectra of the spin-adducts of MNP with different aliphatic RS˙ radicals (Table 5, Nos. 1–4 and 7) have been recently described by Wargon and Williams, who investigated the γ-radiolysis of thiols, sulphides and disulphides at temperatures between −50° and −110°C.[73] The constants a_N and the g-factors which they obtained (16.7–18.9 G and 2.0062–2.0064) are close to those quoted above. It is noteworthy that the spectrum of the spin-adduct of the $CH_3S^{\cdot}$ radical shows clearly the splitting of the lines of the ^{14}N triplet into quartets due to the interaction with the hydrogen atoms of the methyl group ($a_H = 1.2$ G; Table 5, No. 1). For other RS˙ radicals, the splitting of the signals by hydrogen atoms is much less intense, and the hyperfine coupling is manifested solely by increased width of the lines of the main triplet.

The characteristic constant $a_N = 16.5$–18.5 G can serve as a criterion of the assignment of such a triplet in the EPR spectrum to the spin-adducts of MNP with thiyl radicals. Another characteristic feature of the spectra of these spin-adduct is the rapid disappearance of the signal after irradiation has been stopped, i.e. the low stability of the radical. For example, these data enabled the authors[74,75] to assign the triplet with $a_N = 16.5$ G, observed in the complex EPR spectrum during the photolysis of acetophenone diphenylmercaptal, to the spin-adduct of the $C_6H_5S^{\cdot}$ radical with MNP (Table 5, No. 13; see also Section V).

Because of the ease of the generation of thiyl radicals from disulphides and thiols, many systematic studies devoted to the investigation of new spin-trapping agents contain data about the adducts of RS˙ radicals with such agents. For example, the detection of thiyl radicals with the aid of nitrosodurene[35], nitrosobenzene[76], and 2,4,6-tri-t-butylnitrosobenzene[36] has been described (Table 5, Nos. 14–18). The nitroxy-radicals formed under these conditions have relatively high values of a_N.

It is seen from the data presented that thiylalkyl- and thiylaryl-nitroxy-radicals are in general characterised by higher values of a_N than dialkyl- and alkylaryl-nitroxy-radicals and by a g-factor which is appreciably displaced downfield compared with that of the free electron. This can be apparently accounted for by the fact that the spin-orbital coupling constant for heteroatomic substituents such as sulphur is fairly considerable (approximately 382 cm⁻¹).[31]

The data at present available also make possible the conclusion that neither temperature nor the solvent have a significant influence on the parameters of the spectra of thiylnitroxy-radicals.

*$g = 2.0061$; the parameters of the EPR spectra of a large number of $RSO_2-N(\dot{O})-R'$ nitroxy-radicals have also been published by Wajer et al.[78], but, since they were obtained by procedures other than the spin-trapping method, they are not considered here.

2. Sulphonyl Radicals

The EPR spectrum of the $RSO_2-N(\dot{O})-R'$ nitroxy-radical ($R = R' = CH_3$) was obtained for the first time by Lagercrantz[77]. The spectrum was recorded in a study of the reaction of dimethyl sulphoxide with nitrogen dioxide. The assignment was based on the hyperfine structure: the lines of the main ^{14}N triplet are split owing to hyperfine coupling with two non-equivalent H atoms of the methyl group ($a_H = 11.0$ G and $a_{H'} = 0.094$ G). The values of a_N and the g-factor for the spectra of radicals of this type (12.2 G and 2.0059 respectively) were obtained for the first time. The validity of this assignment was fully confirmed in a study[78] where the spectra of a number of sulphonylnitroxy-radicals of the above type (R = aryl and R′ = alkyl, phenyl, phenylsulphonyl, etc.) were investigated. These nitroxy-radicals were obtained either by the oxidation of N-alkyl- or N-aryl-benzenesulphonylhydroxylamines by lead dioxide:

 (16)

$$RNO + C_6H_5SO_2H \rightarrow R-\underset{\substack{|\\OH}}{N}-SO_2C_6H_5 \xrightarrow{PbO_2} R-\underset{\substack{|\\O^{\cdot}}}{N}-SO_2C_6H_5 \quad , \qquad (16)$$

or by the photolysis of N-methyl-N-nitrosotoluene-p-sulphonamides in solution in methylene chloride or toluene in the presence of MNP:

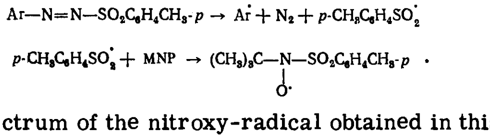
 (17)

$$p\text{-}CH_3C_6H_4SO_2-\underset{\substack{|\\NO}}{N}-CH_3 \xrightarrow[h\nu]{MNP} (CH_3)_3C-\underset{\substack{|\\O^{\cdot}}}{N}-SO_2C_6H_4CH_3\text{-}p \quad . \qquad (17)$$

The spectra of the resulting nitroxy-radicals are characterised by the constants $a_N = 11$–12 G (a_N is somewhat less than 10.1 G only for the bisbenzenesulphonylnitroxy-radical) and $g = 2.0061$ (Table 6, No. 1). Such a high value of a_N is unusual for nitroxy-radicals with powerful electron-accepting substituents of this kind (for example $a_N = 4-5$ G for diacylnitroxy-radicals)[15]. The authors[78] explain this by the fact that the nitrogen in sulphonylnitroxy-radicals has a pyramidal structure, and the unpaired electron occupies an orbital with enhanced s-character.

Unfortunately the authors of the above investigations say nothing about the stability of the sulphonylnitroxy-radicals investigated, which is an important characteristic of the spin-adducts in the spin-trapping method.

The detection of toluene-*p*-sulphonyl radicals with the aid of MNP was also noted in the photolysis and thermolysis of *p*-tolyl arylazo sulphones[40]:



$$\mathrm{Ar{-}N{=}N{-}SO_2C_6H_4CH_3\text{-}}p \rightarrow \mathrm{\dot{Ar}} + \mathrm{N_2} + p\text{-}\mathrm{CH_3C_6H_4SO_2^{\cdot}}$$

$$p\text{-}\mathrm{CH_3C_6H_4SO_2^{\cdot}} + \mathrm{MNP} \rightarrow \mathrm{(CH_3)_3C{-}\underset{\displaystyle \underset{|}{} \atop O^{\cdot}}{N}{-}SO_2C_6H_4CH_3\text{-}}p \quad . \qquad (18)$$

The spectrum of the nitroxy-radical obtained in this way had $a_N = 12.5$ G and $g = 2.0061$. To confirm this assignment, the same nitroxy-radical was obtained by an independent procedure: by the photolysis of toluene-*p*-sulphonyl iodide in the presence of MNP (Table 6, No.2). The authors note a very low stability of this nitroxy-radical—its half-life is only 44 s, so that its spectrum disappears rapidly after irradiation ceases. The formation of the same nitroxy-radical has been noted[79] in the detection with the aid of MNP of toluene-*p*-sulphonyl radicals generated via the mechanism.

$$\begin{aligned}
&[\mathrm{(CH_3)_3COOCO}]_2 \rightarrow 2\,\mathrm{(CH_3)_3C\dot{O}} + 2\mathrm{CO_2} \quad ,\\
&\mathrm{(CH_3)_3C\dot{O}} + \mathrm{(C_4H_9)_3SnH} \rightarrow \mathrm{(CH_3)_3C\dot{O}H} + \mathrm{(C_4H_9)_3Sn^{\cdot}} \quad ,\\
&\mathrm{(C_4H_9)_3Sn^{\cdot}} + p\text{-}\mathrm{CH_3C_6H_4SO_2Cl} \rightarrow \mathrm{(C_4H_9)_3SnCl} + p\text{-}\mathrm{CH_3C_6H_4SO_2^{\cdot}} \quad . \qquad (19)
\end{aligned}$$

The photochemical decomposition of benzenesulphonyl halides $C_6H_5SO_2Hal$ (Hal = F, Cl, or Br) was investigated by the spin-trapping method[51,52]. These compounds may decompose both at the C–S and at the S–Hal bonds[80]. This can lead to the formation of either $C_6H_5SO_2^{\cdot}$ or $HalSO_2^{\cdot}$ radicals, or both. The adducts of these radicals with MNP should give rise to triplets with similar values of a_N in the EPR spectra. Nevertheless, the employment of independent methods for the generation of these radicals (for example, $ClSO_2^{\cdot}$ from SO_2Cl_2, $FSO_2^{\cdot}$ from SO_2FCl, etc.) and allowance for the different stabilities of the corresponding spin-adducts enabled the authors[51,52] to make unambiguous assignments of the EPR spectra (Table 6, Nos. 3–12, see also Section V).

Thus one may conclude that $RSO_2^{\cdot}$ radicals may be identified with the aid of the spin-trapping method, and the differences between the stabilities of their spin-adducts can serve as additional information in the assignment of extremely similar signals in the EPR spectra of the latter.

There are no literature data for other trapping agents used in the detection of sulphonyl radicals. One can only note that, in the photolysis of SO_2Cl_2 in the presence of t-butyl phenyl nitrone, it is possible to detect only the adduct of a chlorine atom with the trapping agent[52]; the $ClSO_2^{\cdot}$ radical evidently does not give rise to stable spin-adducts with the nitrone.

In the study of radical reactions of various sulphones (initiated by the $\dot{O}H$ radicals formed in the photolysis of hydrogen peroxide), in the presence of MNP and MNB as trapping agents, it is impossible to detect the spin-adducts of the sulphonyl radicals[81]. Some of the sulphones investigated totally failed to give rise to radical signals visible in the EPR spectrum, while others formed radicals by abstraction of a hydrogen atom from the methylene group adjoining the sulphonyl group (these were in fact detected by the trapping agents)[81]. It is of interest to note that, under these conditions, the sulphoxides R_2SO give rise to alkyl radicals $R^{\cdot}$ (identified from the spectra of their spin-adducts)[81]. On this basis, the authors[82,83] developed a method for the radical alkylation of aromatic and heteroatomic compounds by sulphoxides.

3. Other Sulphur-Containing Radicals

In the study of the radical reactions of organosulphur compounds by the spin-trapping method the formation of the spin-adducts of not only $\dot{S}$ radicals, but also of sulphur-containing $\dot{C}$ radicals is frequently noted. For example, in a study, already mentioned above[71] the $(CH_3)_2\dot{C}{-}S{-}CH(CH_3)_2$ radicals were detected (as their spin-adducts with MNP) together with iso-$C_3H_7S^{\cdot}$ radicals in the photochemical reduction of benzophenone by isopropyl sulphide. The formation of $\dot{C}$ radicals ($\dot{C}H_2SH$, etc.), identified from the spectra of their spin-adducts, was also noted in the γ-radiolysis of thiols[73] below −70°C. Apart from the $C_6H_5S^{\cdot}$ radicals, other sulphur-containing $\dot{C}$ and $\dot{O}$ radicals were detected in the photochemical reactions of acetophenone diphenylmercaptal[74,75] (Table 7, Nos. 1–6). This reaction is discussed in greater detail in Section V.

The data presented in Table 7 show that the constants a_N for the MNP adducts with $\dot{C}$ radicals containing the thiyl group in the β-position vary in the range 12–15 G, which is in general characteristic of dialkylnitroxy-radicals[16,84]. The adducts of MNP with $\dot{C}$ radicals containing the SO_2Cl group in the β-position have a much lower value of a_N (approximately 7 G; see Table 7, No. 7), i.e. of the same order of magnitude as for acylalkylnitroxy-radicals[85].

With the exception of isolated examples, there have so far been no studies of the possibility of the selective detection of particular organosulphur radicals with the aid of various spin-trapping agents (virtually all the investigations have been carried out solely with MNP), but this approach may prove to be extremely promising in this field also.

V. THE APPLICATION OF THE SPIN-TRAPPING METHOD IN THE STUDY OF THE MECHANISMS OF CERTAIN REACTIONS OF ORGANOCHLORINE AND ORGANOSULPHUR COMPOUNDS

This Section deals with examples, which have already been partly considered, where spin-trapping agents were used to investigate complex radical reactions of organochlorine and organosulphur compounds. The experimental facts accumulated in systematic studies (i.e. in those where radicals of known structure were detected with the aid of spin-trapping agents and the parameters of the EPR spectra of the corresponding spin-adducts were described) made it possible to assign them subsequently on the basis of the parameters of the observed EPR spectra to the spin-adducts of particular radicals formed in the course of a chemical reaction. Radical reactions include, as a rule, the intermediate formation of various radicals (owing to chain propagation and transfer, rearrangements, etc.). If these reactions are carried out in the presence of spin-trapping agents, very complex EPR spectra, corresponding to a mixture of various nitroxy-radicals, are therefore observed. The individual lines are then frequently superimposed, which greatly

Table 7. Parameters of the EPR spectra of R–N(Ȯ)–C$(CH_3)_3$ nitroxy-radicals (spin-adducts of MNP with sulphur-containing radicals).

****$a_{H(CH)} = 1.5$ G.

hinders the interpretation of the spectrum. However, certain procedures which make it possible to simplify this task have been used recently.

1. The Selectivity of Spin-Trapping Agents

It was already noted above (see Section II) that certain spin-trapping agents are capable of detecting particular short-lived radicals to different extents. The selectivity of various spin-trapping agents in relation to radicals of different types has been used by the present authors[33]. As shown previously[86], a study of the rearrangement of polychloroalkyl radicals with 1,2-migration of the chlorine atom in accordance with Eqn.(13) yielded spectroscopic proof of the simultaneous presence in the reaction mixture of both radicals—the rearranged radical (VIII) and the non-rearranged radical (VII). Fig. 5 illustrates the EPR spectra obtained in the photochemically initiated reaction of TBP with 3,3,3-trichloropropene in the presence of MNP and MNB. Fig. 5 shows that MNP detects selectively only the rearranged radical (VIII); for X = $(CH_3)_3CO$, the spectrum with the characteristic splitting by the two β-chlorine atoms corresponds to the $(CH_3)_3COCH_2CHClCCl_2$–N(Ȯ)–C$(CH_3)_3$ nitroxy-radical (Table 4, No. 4), while MNB combines only with the non-rearranged radical (VII): the spectrum with doublet splitting by β-hydrogen corresponds to the $(CH_3)_3COCH_2CH(CCl_3)$–N(Ȯ)–C$(CH_3)_2COCH_3$ radical. Analogous results were obtained also in other instances of the rearrangement of radicals with 1,2-migration of chlorine[86,87].

The use of the selectivity of spin-trapping agents also permitted the study of the photochemical decomposition of various sulphonyl halides[51,52]. It was shown, for example, that SO_2Cl_2 decomposes on ultraviolet irradiation into $ClSO_2^{\bullet}$ radicals and $Cl^{\bullet}$ atoms, the former being selectively detected by MNP and the latter by BPN. The decomposition of benzenesulphonyl chloride involves the dissociation of the C–S bond together with that of the S–Cl bond[51,52]:

$$C_6H_5SO_2Cl \rightarrow C_6H_5^{\bullet} + ClSO_2^{\bullet} \quad . \qquad (20)$$

Phenyl radicals were detected with the aid of BPN and chlorosulphonyl radicals were detected with the aid of MNP.

The available data do not as yet show why certain trapping agents are incapable of detecting particular radicals. This can probably be accounted for by two causes: either the trapping agent does not react with the radical owing to unfavourable polar or steric effects or the spin-adduct formed is insufficiently stable for its identification by EPR. Nevertheless, the above purely empirical approach to the study of radical reactions, using the selectivity of various spin-trapping agents, appears to be extremely convenient and promising.

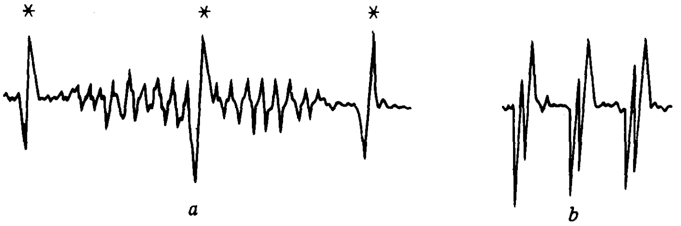

Figure 5. The ESP spectra of the nitroxy-radicals formed in the photochemical reaction of TBP with 3,3,3-trichloropropene[33]: *a*) in the presence of MNP (the triplet corresponding to the spin-adduct of MNP with t-butoxy-radicals is designated by asterisks); *b*) in the presence of 2-methyl-2-nitroso-3-butanone.

2. The Different Stabilities of Spin-Adducts

It was already noted previously that the adducts of spin-trapping agents, particularly of MNP, with various radicals have different stabilities. The time required for the disappearance of their signals from the EPR spectrum varies from several seconds to many hours. The possibility therefore arises of identifying certain radicals present in a mixture with other radicals by recording the

EPR spectrum immediately at the beginning of the reaction and after some time. The initial complex spectrum in some instances becomes greatly simplified owing to the destruction of less stable nitroxy-radicals.

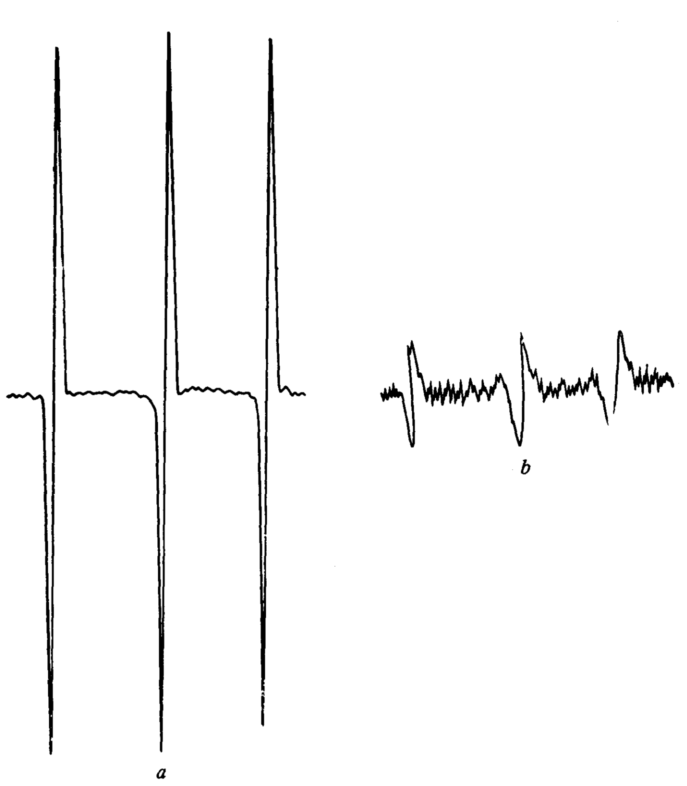

Figure 6. The EPR spectrum of a benzene solution of $C_6H_5SO_2Cl$ [52]: *a*) on ultraviolet irradiation; *b*) 2 min after the cessation of irradiation.

This procedure has been used successfully[51,52]. Ultraviolet irradiation of a benzene solution of benzenesulphonyl chloride in the presence of MNP gave an EPR spectrum consisting of a triplet with a_N = 12.0 G (Fig. 6*a*). When 2 min elapsed from the cessation of irradiation, the spectrum showed a much less intense triplet with a_N = 11.7 G (Fig. 6*b*); subsequently its intensity did not change for at least 30 min. This suggested that the triplet in Fig. 6*a* is a result of the superposition of signals due to two different nitroxy-radicals with similar values of a_N. Such nitroxy-radicals might be the spin-adducts of MNP with the $C_6H_5SO_2^{\cdot}$ and $ClS_2^{\cdot}$ radicals. By generating these radicals using independent methods [Schemes (21) and (22)] in the presence of MNP,

$$\begin{gathered} SO_2Cl_2 \xrightarrow{u,v,} \dot{S}O_2Cl + Cl^{\cdot} \quad , \\ \dot{S}O_2Cl + MNP \rightarrow \underset{(XI)}{ClSO_2 - N(\dot{O}) - C(CH_3)_3} \quad ; \end{gathered} \qquad (21)$$

$$\begin{gathered} C_6H_5SO_2Cl + [(CH_3)_3CO]_2 + (C_2H_5)_3SiH \xrightarrow{2537 Å} C_6H_5SO_2^{\cdot} + (CH_3)_3COH + (C_2H_5)_3SiCl \quad , \\ C_6H_5SO_2^{\cdot} + MNP \rightarrow \underset{(XII)}{C_6H_5SO_2 - N(\dot{O}) - C(CH_3)_3} \quad ; \end{gathered} \qquad (22)$$

it was shown that the nitroxy-radical (XI) is stable for a long time, while the signals due to the nitroxy-radical (XII) vanish almost immediately after irradiation ceases. The conclusion that the photochemical decomposition of benzenesulphonyl chloride involves the dissociation of both C–S and S–Cl bonds was thus confirmed[51,52].

The different stabilities of the spin-adducts of MNP also permitted the elucidation of the mechanism of another extremely complex reaction—the addition of bromochloroacetic acid to oct-1-ene with photochemical initiation. This process can be represented by the following scheme[88]‡:

$$\text{Initiator} \longrightarrow R^{\cdot} \quad ,$$

$$R^{\cdot} + HOOCCHClBr \longrightarrow RBr + \underset{(XIII)}{HOOC\dot{C}HCl} \quad ,$$

$$(XIII) + CH_2{=}CHC_6H_{13} \longrightarrow \underset{(XIV)}{HOOCCHClCH_2\dot{C}HC_6H_{13}} \quad ,$$

$$(XIV) \begin{cases} \xrightarrow{\circ\ 1,3\text{-}H} \underset{(XV)}{HOOC\dot{C}ClCH_2CH_2C_6H_{13}} \\ \xrightarrow{CH_2=CHC_6H_{13}} \underset{(XVI)}{HOOCCHClCH_2CH(C_6H_{13})CH_2\dot{C}HC_6H_{13}} \quad , \end{cases}$$

$$(XVI) \xrightarrow{\circ\ 1,5\text{-}H} \underset{(XVII)}{HOOC\dot{C}ClCH_2CH(C_6H_{13})CH_2CH_2C_6H_{13}} \quad .$$

The scheme shows that, when the reaction is carried out in the presence of MNP, the formation of five spin-adducts corresponding to radicals (XIII)–(XVII), may be expected. The spin-adducts of radicals (XIV) and (XVI) as well as (XV) and (XVII) should not have different EPR spectra. Thus the problem reduces to the identification of three nitroxy-radicals:

$$\underset{(XVIII)}{HOOCCHCl{-}N(\dot{O}){-}C(CH_3)_3}, \quad \underset{(XIX)}{RCH_2CH(C_6H_{13}){-}N(\dot{O}){-}C(CH_3)_3} \quad ,$$

$$\underset{(XX)}{RCH_2CCl(COOH){-}N(\dot{O}){-}C(CH_3)_3} \quad .$$

The spectrum of radical (XVIII) is extremely complex and hinders the identification of other signals, overlapping them. However, special experiments showed that the stability of radical (XVIII) is very low, and its spectrum disappears almost immediately when irradiation ceases. It was therefore possible to identify the nitroxy-radicals (XIX) and (XX) by recording the spectrum several minutes after stopping irradiation.

In certain cases the spin-adducts have a very low stability and their EPR spectra cannot be recorded at all at room temperature. The study, mentioned previously, of the homolytic rearrangement of acetophenone diphenylmercaptal, occurring under the influence of ultraviolet irradiation, is of interest in this connection[74,75]. By carrying out this reaction in the presence of the MNP spin-trapping agent, it was possible to identify all the intermediate radicals in conformity with the scheme

$$C_6H_5C(SC_6H_5)_2CH_3 \longrightarrow \underset{(XXI)}{C_6H_5\dot{C}(SC_6H_5)CH_3} + \underset{(XXII)}{\dot{S}C_6H_5} \quad ,$$

$$(XXI) \xrightarrow{O_2} C_6H_5\underset{\underset{\textstyle O^{\cdot}}{|}}{C}(SC_6H_5)CH_3 \quad (XXIII) \quad ,$$

$$(XXIII) + C_6H_5C(SC_6H_5)_2CH_3 \longrightarrow \underset{(XXIV)}{C_6H_5C(SC_6H_5)_2\dot{C}H_2} \quad ,$$

$$(XXIV) \xrightarrow{\circ} \underset{(XXV)}{C_6H_5\dot{C}(SC_6H_5)CH_2SC_6H_5} \quad ,$$

$$(XXV) + DH^{\S} \longrightarrow C_6H_5CH(SC_6H_5)CH_2SC_6H_5 \quad .$$

---

‡The symbols 1,3-H and 1,5-H denote rearrangements involving 1,3- and 1,5-migrations of a hydrogen atom respectively.

§DH is a hydrogen donor.

At room temperature the EPR spectrum shows signals corresponding to the spin-adducts of radicals (**XXI**), (**XXII**), (**XXIV**), and (**XXV**). Only at a low temperature (between −65° and −50°C) was it possible to detect the spectrum of the spin-adduct of radical (**XXI**) (Table 7, No. 7) and hence elucidate the stage involving the initiation of this reaction.

Thus the method of spin-trapping agents has been used successfully recently to investigate a wide range of radical reactions of organochlorine and organosulphur compounds. The value of this method is particularly evident in those cases where the reactions proceed via several pathways, leading to a complex mixture of products. The identification of the intermediate radicals in these systems yields important information about the reaction mechanism, the role of individual stages, etc.

The Mechanism of the Elimination of Ammonia in the Condensation of Primary Amino-compounds and Certain Syntheses of Nitrogen-containing Heterocycles

B.A.Geller

Studies on the mechanism of the elimination of ammonia in the interaction of two amino(imino)-compounds or two amino-groups in the same compound, carried out using ^{15}N, are considered. Taking into account the difference between the properties of the amino-groups, several mechanisms, which explain the experimental findings, are proposed. The ideas developed have been used to interpret the mechanisms of reactions which have not been investigated by the ^{15}N isotopic method. The bibliography includes 70 references.

I. INTRODUCTION

The reactions of amino-compounds with one another, accompanied by the elimination of ammonia, are very common in preparative and industrial practice and have therefore become important. These include the synthesis of secondary amines from primary amines, the synthesis of *N*-aryl- or *N*-alkyl-amides from unsubstituted amides and primary amines, the Fischer synthesis of indoles, the Bucherer or Borsche synthesis of carbazoles, and other reactions involving the formation of nitrogen-containing heterocycles. The determination of the pathways whereby nitrogen migrates in these processes constitutes a convenient and direct method for the elucidation of the relative reactivities of nitrogen atoms in the $-NH_2$, $=NH$, and NH_3^+ groups linked to various organic residues. The knowledge of the rules governing the variation of reactivity in series of amino-compounds is in its turn quite essential for the elucidation of the mechanisms of the corresponding processes and for the prediction of the pathways followed in new or hitherto uninvestigated reactions.

The study of the above reactions can also yield direct evidence for the relative reactivities of amino-groups. In other reactions of amines, such as, for example, solvolysis, interaction with aryl halides, acyl chlorides, etc., the mechanism of the process and its rate depend both on the nature of the amines and on the nature of the other reactant, so that the correlation between the rate constants and other parameters, on the one hand, and the properties of amines, on the other, frequently breaks down.

The pathways followed in the migration of nitrogen can naturally be elucidated only with the aid of the isotope technique. Isolated studies in this field began to be published from 1943 when concentrated ^{15}N preparations became available. Systematic research was carried out by the present author in 1954–1964 and by a group of German investigators in 1952–1967. The present author believes that the time has come to survey the results of all the studies carried out hitherto using heavy nitrogen and to describe the observed characteristics and mechanisms of the reactions. An attempt should also be made to use the results obtained with the aid of ^{15}N in order to elucidate the mechanisms of reactions which have not as yet been determined by the isotopic method.

II. CONDENSATION OF TWO AMINO-COMPOUNDS OR AMIDES

Reactions involving the condensation of two amines with elimination of ammonia have been known for more than 100 years. Nevertheless, the study of this process from the standpoint of the reactivity of the nitrogen atoms immediately poses a difficult problem: which nitrogen atom in the two amines is converted into ammonia? In certain cases a cautious prediction of the answer to this question can be made, as will be seen from the account below (for example, in the interaction of an amine with an amide). The general solution of this problem with the aid of the ^{15}N isotope can be achieved on the basis of the scheme

$$RNH_2 + R^1\overset{*}{N}H_2 \rightarrow RNHR^1 + \overset{*}{N}H_3 \quad .$$

One of the initial amines is prepared with an increased content of ^{15}N in the amino-group relative to the natural abundance (0.365% ^{15}N) and the site from which the amino-group is eliminated can be determined from the concentration of ^{15}N in ammonia and (or) the secondary amine. The results of isotopic analyses obtained in the first studies on the amine condensation reactions[1-4] are presented in Tables 1 and 2.

The uniform distribution of ^{15}N between the reaction products on condensation of labelled aniline hydrochloride with unlabelled aniline indicates rapid proton exchange between the anilinium ion and the aniline molecule via the mechanism

$$Ph\overset{*}{N}H_3^+ + PhNH_2 \rightleftharpoons Ph\overset{*}{N}H_2 + PhNH_3^+ \quad .$$

The ease of conversion of the arylammonium ion into an amine and conversely suggests that weakly basic amines can react under these conditions in the form of free bases. The catalytic role of the acid consists in facilitating proton transfer via the general mechanism of Brønsted acid–base catalysis[5].

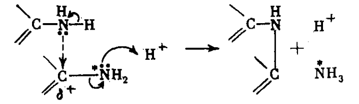
The results of the study of the condensation of [^{15}N]-benzamide with arylamines[1,2,6] are presented in Table 3. According to current ideas, ammonia is formed preferentially from the amide, which can be readily accounted for by the decrease of the basicity of the amide group NH_2 under the influence of the carbonyl group†.

Table 1. The condensation of primary amines in the presence of hydrochloric acid[1,2,6].

Starting substances				^{15}N content in reaction products, %	
labelled (% content of ^{15}N indicated in brackets)	$K_b \cdot 10^{10}$	unlabelled (0.37% ^{15}N)	$K_b \cdot 10^{10}$	secondary amine	NH_4Cl
Aniline (3.00)	3.82	Aniline	3.82	1.62	1.47
Aniline (2.15)	3.82	1-Naphthylamine	0.84	2.15	0.67
Aniline (9.3)	3.82	4-Aminophenol	66.0	9.0	0.46
1-Naphthylamine (9.3)	0.84	4-Aminophenol	66.0	3.25	5.35
1-Naphthylamine (8.4)	0.84	4-Chloroaniline	1.0	0.37	—
1-Naphthylamine (8.4)	0.84	3-Chloroaniline	0.3	0.40	—
Aniline (3.0)	3.82	n-Butylamine	$4 \cdot 10^6$	2.9	—

However, these studies firmly established that part of the amino-nitrogen is incorporated in *N*-arylbenzamide in reactions involving 1-naphthylamine and 9-aminophenanthrene; this unexpected result will be explained below.

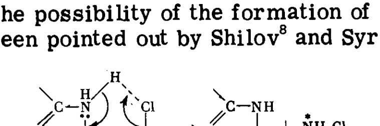
Since the essential feature of the condensation reaction involves the substitution of the amino-group by an aryl-amino-group, one can assume in principle that the reaction involves nucleophilic substitution:



(1)

The stronger base plays the role of the nucleophilic and adds to the positively charged carbon atom of the polarised C–N bond with the aid of the free electron pair of the nitrogen. On formation of the secondary amino-group, the previously more basic nitrogen atom loses a proton, which adds (evidently via the mediation of a catalyst) to the weakly basic amino-group, forming ammonia.

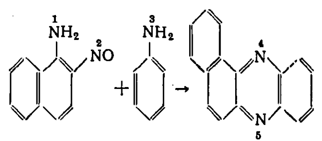
One cannot rule out the possibility that the reaction proceeds via an energetically favourable six-membered complex[7]; the possibility of the formation of such complexes has been pointed out by Shilov[8] and Syrkin[9]:

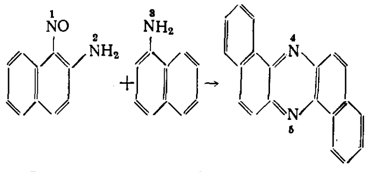


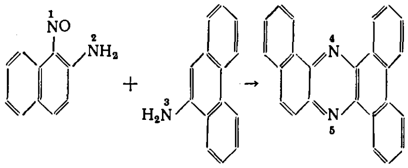
(2)

Comparison of the pathways leading to the elimination of amino-groups with the dissociation constants of the bases listed in Table 1 indicates the absence of a consistent relation between them. In the reaction of aniline with 1-naphthylamine the amino-group is split off from the weaker base, while in reactions of 3-chloroaniline with 1-naphthylamine or of aniline with n-butylamine it is split off from the stronger base; in the reaction of 4-chloroaniline with 1-naphthylamine, where the basicities of the two reactants are almost identical, the NH_2 group is split off wholly from only one component (1-naphthylamine), while in the condensation of nitrosonaphthylamine with 1-naphthylamine (Table 2) and of benzamide with polycyclic amines (Table 3), it is split off from both components. Nevertheless the mechanism described by Eqns. (1) and (2) provides for the elimination of the less basic amino-group. All the data obtained cannot therefore be accounted for by the S_N2 mechanism [described by Eqns. (1) and (2)] and, while remaining fundamentally correct, it needs to be revised. We may recall that the NH_2 groups attached to alkyl, aryl, or acyl residues differ sharply in their properties. Their basicity also varies within the limits of the same class of compounds as a function of the substituents, an increase of the number of benzene rings, steric hindrance, and other factors.

Table 2. Condensation of nitrosonaphthylamines with aromatic amines[3,4].

No. of expt.	^{15}N content, %				
	N (10)	N (2)	N (3)	N (4)*	N (5)*
					


1	0.37	0.37	8.6	8.4	0.37
2	0.37	8.7	0.37	0.37	8.6
					


3	0.37	0.37	8.6	0.37	5.5
					


4	0.37	8.7	0.37	0.37	8.6
5	10.1	0.37	0.37	9.9	0.37

*The ^{15}N content among the $N_{(4)}$ and $N_{(5)}$ atoms in the products was determined from the average ^{15}N concentration in both positions (by analysis) and the 0.37% content at one of them (known from the experimental conditions).

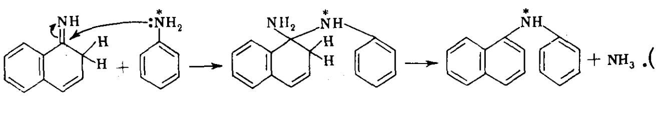
Taking into account these relations, one may suggest that there should be several mechanisms of the interaction of amino-compounds with one another. In the aromatic series, where the difference between the basicities of the amines are in most cases small, the possibility of the

---

† The elimination of the amide nitrogen of urea has been demonstrated using ^{15}N in well known studies on the synthesis of uric acid by the condensation of urea with uramil[20] or diaminouracil[20,21].

formation of quinonoid structures plays a significant role. In the instances investigated by the present author, where 1-naphthylamine always loses its amino-group on condensation with an amine of the benzene series (except 4-aminophenol which requires separate consideration), the monocyclic amine reacts with the quinonoid form of 1-naphthylamine. The basicity of the latter is suppressed and the reactive group

is subjected to nucleophilic attack by the NH_2 group:

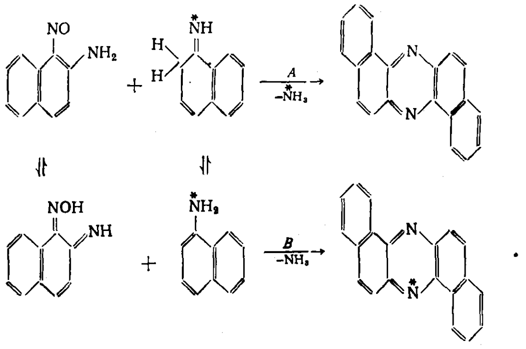


(3)

Table 3. Condensation of $[^{15}N]$-benzamide with amines[1,2,6].

Amines	^{15}N content, %			Amount of benzamide nitrogen in N-aryl-benzamide, %
	in initial benzamide	in N-aryl-benzamide	in NH_4Cl	
Aniline	2.15	0.51	2.07	~0
4-Aminophenol	9.30	0.44	—	~0
1-Naphthylamine	8.16	0.77	7.25	5
9-Aminopenanthrene	8.75	2.1	5.7	21

When 1-naphthylamine condenses with 1-nitroso-2-naphthylamine, the stabilities of the quinonoid structures are approximately the same, which leads to the loss of nitrogen by both components (the nitroso-group is not split off; see Table 2). The reaction mechanism may be represented by the scheme



The results of isotopic analysis[3,4] showed that the contributions of pathways *A* and *B* are 38% and 62% respectively. This can be explained by the fact that the formation of the quinonoid form from nitrosonaphthylamine may be facilitated by the conjugation of the amino-group with the N=O group. Among the amines investigated by the present author, 9-aminophenanthrene shows the greatest tendency towards the formation of quinonoid structures. In the interaction with 1-nitroso-2-naphthylamine (Table 2) it therefore always reacts as the quinone imine and its amino-group is lost completely.

The condensation of aniline with n-butylamine[2] (which is 10^6 times stronger as a base) is accompanied by the elimination of the more basic amino-group only, in complete conflict with the mechanism involving reactions (1) and (2). One must suppose that the following reaction occurs in this instance:

$$PhNH_2 + Bu\overset{*}{N}H_2 \xrightarrow{H^+} Ph\ddot{N}H_2 + H_3\overset{*}{\underset{+}{N}}-CH_2-(CH_2)_2CH_3 \longrightarrow$$

$$\longrightarrow Ph-NH-Bu + \overset{*}{N}H_4^+ \quad . \qquad (4)$$

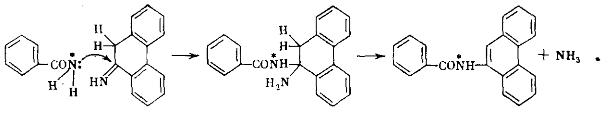
The very strong base therefore exists mainly as the alkylammonium ion, which is subjected to nucleophilic attack by the aromatic amine. Mechanism (4) must undoubtedly occupy an important place among amine condensation reactions, since these processes usually occur in the presence of acid catalysts. As will be shown below, the involvement of amines as ammonium ions can be postulated also in the interaction of amines with not quite so greatly different basicities and also in the cyclisation of the intermediate complexes containing two amino- or imino-groups.

The reactions with participation of 4-aminophenol may occur mainly (with aniline) or partly (with 1-naphthylamine) via mechanism (4), since 4-aminophenol is 17 times more basic than aniline. Furthermore, there exists a hydrolytic mechanism with preliminary formation of hydroquinone. This reaction pathway has been demonstrated experimentally[2].

The main pathway in the condensation of an amine with an amide is determined by the mechanism of the nucleophilic substitution at the carbonyl carbon atom, which is positively charged owing to the polarisation of the C=O group. An analogous mechanism has been adopted for the acylation or nitrosation of amines[10] and for the addition of nucleophiles to sulphonamides[11]. The same mechanism has also been proposed for the reaction of hydrazine with monoarylurea[12] and for the transamination of *N*-arylacetamides[13]. It may be that the condensation proceeds via a six-membered cyclic complex [see Scheme (2)]. A similar complex has been proposed by Syrkin and Moiseev[14] to account for the hydrolysis of benzamide in an acid medium. The role of the acid catalyst is to enhance the positive charge of the carbonyl carbon atom as a result of the protonation of the oxygen atom.

The second reaction pathway, leading to the elimination of amino-nitrogen, involves the participation of 9-aminophenanthrene or 1-naphthylamine in the quinonoid form and of benzamide as the nucleophile. The mechanism of this reaction can be represented by Scheme (5) below.

The results obtained in the condensation of amines with amides have shown that, in a system containing several benzene rings, the delocalisation of the electron density of the free electron pair of nitrogen and the concomitant formation of an imine may compete with the analogous phenomena in benzamide.



(5)

Further investigations[15-18] provided new evidence confirming the above mechanisms. Table 4 compiles the results obtained in these studies. They also show that, on condensation with both stronger and weaker amines of the benzene series, 1-naphthylamine usually loses its amino-group, but retains it on interaction with 9-aminoanthracene. Such behaviour of amines is fully consistent with the mechanism represented by Scheme (3), according to which the ability to split off NH_2 groups is determined by the stability of the quinoid structures and increases in the sequence: monocyclic amine < dicyclic amine < tricyclic amine.

Table 4. Condensation of two amino-compounds[15-19].

Labelled component	Amine of benzene series	pK_b	Amount of nitrogen from the amine of the benzene series in the secondary amine formed, %
1-Naphthylamine (pK_b = 10.04)	*o*-Toluidine	9.48	100

	p-Phenetidine	8.80	35*

* Calculated by the present author from experimental literature data[17] (an incorrect calculation is quoted in the relevant paper[17]).

In many reactions (see Table 4) labelled nitrogen was found to be distributed within the reaction products—the secondary amine and ammonia[15-17]. Having noted that in these instances an amine more basic by 1–2 orders of magnitude reacts with 1-naphthylamine, one may assume that the former is partly converted into an $ArNH_3^+$ salt and then interacts via mechanism (4). Thus mechanisms (3) and (4) compete in this instance. The second reaction pathway should naturally be associated with the proton-accepting properties of the stronger base. Indeed the authors found that the degree of elimination of the imino-group is satisfactorily correlated with the dissociation constant of the amine of the benzene series and the Hammett σ constant of the substituent in the benzene ring. Individual straight lines were obtained for condensation with 1-naphthylamine, 8-aminoquinoline, and 5-aminoquinoline.

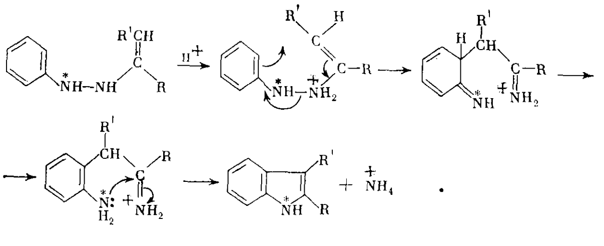
In the experiments on the condensation of urea with aniline and methylamine hydrochlorides an unexpected result was obtained—the elimination of the urea nitrogen[15]. The mechanism of the interesting reaction between urea and acetamide may be treated only qualitatively in the sense that ammonia is eliminated from both amides. The degrees of involvement of urea and acetamide nitrogen in the formation of acetylurea cannot be calculated from the analytical determination of ammonia (as was done by Krumbiegel and Hübner[15]), because the latter is obtained also from urea via a side reaction involving the formation of biuret.

Summarising the findings described above, one may say that mechanisms (1), (2), (3), (4), and (5),[1,2,6,7] as well as substitution at the carbonyl carbon atom of the amide[10], acting independently or competing with one another, can explain all the results obtained hitherto for the condensation of amines. The basicity of amines is correlated with the degree of elimination of the amino-group within narrow limits of pK_b values for reactions of similar amines with the same reactant (the second amino-compound)[19].

III. SYNTHESES OF HETEROCYCLIC COMPOUNDS

In certain syntheses of heterocycles from nitrogen-containing substances intermediates or short-lived complexes are formed in which there are at least two amino-groups. In most cases these reactions are complex, comprise many stages, and different aspects of their mechanisms may be discussed. Here they will be considered from only one standpoint—which amino-group is eliminated on cyclisation (in the form of ammonia) and the mechanism of such elimination.

The situation described is encountered in numerous Fischer syntheses of indole and carbazole derivatives from aldehyde or ketone arylhydrazones. It has been established with the aid of ^{15}N that, in the cyclisation of acetophenone[22] and acetone[23] phenylhydrazones, the amino-group attached to the aliphatic end of the intermediate diamine is eliminated, while the much less basic aromatic amino-group enters into the indole ring. This result can be readily explained by the mechanism developed on the basis of numerous studies[24,25], according to which the more basic $-NH_2$ (or $=NH$) group is protonated by the acid. This induces a positive charge on the carbon atom adjoining the nitrogen atom and the former is subjected to nucleophilic attack by the aromatic amino-group:

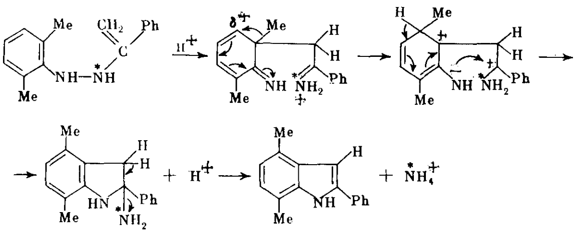


(6)

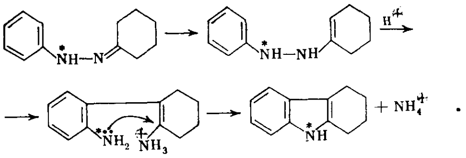
A special case of reaction (4), in which two amines with markedly different acid properties interact, may be seen in mechanism (6). The mechanism is in principle unaffected by the fact that two amino-groups in the intermediate complex (compound) interact rather than two different amines.

The migration of nitrogen in accordance with mechanism (6) has been confirmed by subsequent investigations. A study of the reductive contraction of the [2-^{15}N]-4-phenylcinnoline ring showed that the formation of the indole derivative is accompanied by the elimination of the aliphatic amino-group[26]. Suvorov et al.[27] cyclised acetaldehyde phenylhydrazone in order to obtain an indole labelled with ^{15}N, free from substituents in the pyrrole ring. Having labelled the nitrogen in the 1-position in the first experiment and that in the 2-position of phenylhydrazine in the second, they obtained results agreeing with elimination of the aliphatic amino-group from the intermediate diamine. A study of the reaction of acetophenone 2,6-dimethylphenylhydrazone also revealed the elimination of the amino-group from the aliphatic end of the intermediate complex[28]. In clear conflict with mechanism (6), the authors[28] present a mechanism where the less basic amino-group (aromatic amino-group and even the NH group of the secondary amine) is protonated twice.

The present author suggests that this mechanism is erroneous, particularly since a result consistent with experiment is obtained via mechanism (7), postulated here with correct allowance for the relative basicities. Results which can be explained by mechanism (4) have been obtained[29] in a study of the cyclisation of cyclohexanone phenylhydrazone. The 10.1% excess of ^{15}N among the nitrogen atoms in the 1-position of phenylhydrazine was fully incorporated in tetrahydrocarbazole [Scheme (8)].



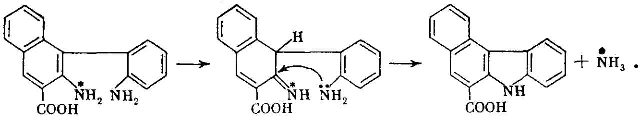
(7)



(8)

Analogous reactions involving aromatic compounds lead to carbazole derivatives. Clusius and Barsh[30] investigated one such reaction—the formation of benzocarbazole-carboxylic acid from 2,3-hydroxynaphthoic acid and phenylhydrazine labelled with ^{15}N. The main reaction pathway (the contribution of which amounts to 88.5%) involves the elimination of the amino-group from the naphthalene ring [Scheme (9)]‡. It is easily seen that mechanism (6) is unsuitable in this instance; it requires the elimination of the more basic amino-group from the benzene ring, which conflicts with experimental findings.

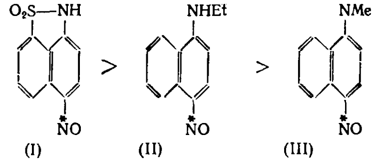
In order to account for these results, the present author suggests a mechanism of type (3), according to which the intermediate reacts as an iminoamine with a quinonoid structure of the naphthalene ring [Scheme (9)]. Cyclisation of this diamine leads to a carbazole derivative which does not contain ^{15}N, in agreement with experiment.



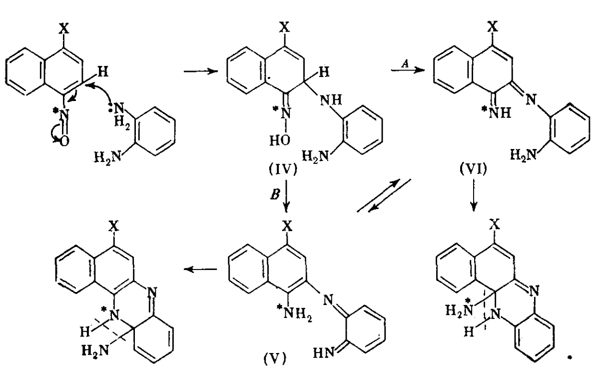
(9)

Holt and McNae[31] investigated the mechanisms of the interaction of [2-^{15}N]-phenylhydrazine with 2-naphthol. A small proportion of ^{15}N (~0.5%) was incorporated in the benzocarbazole formed under these conditions. It was shown that the labelled and unlabelled benzocarbazoles are formed by different reactions. The intermediate formation of the [2-^{15}N]-phenylhydrazone of 1,1-dihydro-2-oxonaphthalene followed by stages analogous to those in the Fischer synthesis of indole was postulated. The mechanism proposed for the main reaction pathway—the formation of unlabelled benzocarbazole with participation of the protonated "benzene" NH_2^- group—is unsuitable, because it would lead to the elimination of this group, which conflicts with the experimental results. The present author suggests that the main reaction proceeds via an intermediate diamine with participation of the quinonoid structure of 2-aminonaphthalene, by analogy with Scheme (9). The side reaction (its contribution is approximately 5%), leading to labelled benzocarbazole, evidently proceeds via the *ortho*-semidine rearrangement of the hydrazone. Other versions of the incorporation of ^{15}N into benzocarbazole proposed by the author[31] are erroneous, because they conflict with isotopic data for similar reactions.

The synthesis of phenazine derivatives from aromatic nitroso-compounds and *o*-phenylenediamine is accompanied by the evolution of ammonia. In the study of the pathway followed in the migration of nitrogen in such reactions it was found[32] that the nitroso-group labelled with ^{15}N is almost completely eliminated in the form of ammonia from the nitrosonaphthosultam (I), to the extent of 55% from *N*-ethyl-4-nitroso-1-naphthylamine (II), and to the extent of 23% from *NN*-dimethyl-4-nitroso-1-naphthylamine (III). The remainder of the ^{15}N is incorporated in the phenazine derivative.



Scheme (10) was proposed to account for these results. The intermediate complex (IV) formed initially may be subsequently converted into compounds (V) and (VI), which are in equilibrium. This leads to the elimination of different imino-groups, with and without ^{15}N, which results in the distribution of heavy nitrogen among the reaction products.

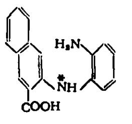


(10)

The position of the (V) ⇌ (VI) equilibrium is determined by the nature of the substituent X. The sultam group has electron-accepting properties and promotes the formation of complex (VI), from which ^{15}N is eliminated; the contribution of the reaction via pathway *B* is insignificant—not more than 3% (which may even be due to experimental

---

‡The side reaction involving the incorporation of ^{15}N in benzocarbazolecarboxylic acid proceeds to the extent of 11.5% (determined from its isotopic analysis) or to the extent of approximately 5% (found by the analytical determination of ammonia). The authors postulate the *ortho*-semidine rearrangement with formation of the intermediate



.

error). The introduction of an electron-donating substituent stabilises complex (V) and increases the basicity of the amino-group attached to the naphthelene ring; the reaction with the nitrosoamine (II) therefore proceeds to the extent of 50% via pathway *B*. The substituent with still more marked electron-donating properties in compound (III) promotes a further increase of the contribution of pathway *B*, which predominates in this instance.

IV. REACTION MECHANISMS

Examination of the literature data and the experimental studies described here lead to the conclusion that the dissociation constants of the bases do not always determine the mode of dissociation of the C–N bond in nucleophilic condensation reactions between two amines. The correspondence between the rate constants and the pK_b values for the amines breaks down also for other nucleophilic substitution reactions. For example, the rate of the reaction of 1-chloro-2,4-dinitrobenzene with chloroanilines and 1-naphthylamine decreases in a series which is not related to the variation of the basicity of the amines[32]:

	p-Chloroaniline	*m*-Chloroaniline	1-Naphthylamine
$k_{45°}$	$2{,}8 \cdot 10^{-3}$	$0{,}86 \cdot 10^{-3}$	$0{,}36 \cdot 10^{-3}$
pK_b	10,0	10,52	10,04

The first stage of the interaction between the two amines [Scheme (1)] involves attack by the nitrogen atom of the nucleophilic component on the positively charged carbon atom of the second amine. This stage should therefore be promoted by a higher electronic charge density at the nitrogen atom and a positive charge on the carbon atom. Sixma[33] used the energy of the localisation of the free electron pair at the nitrogen atom as the criterion of nucleophilic reactivity. It has been shown[34] that the electronic charge is greater the lower the localisation energy. In the reactions of a series of polycyclic amines with 1-chloro-2,4-dinitrobenzene, Sixma found that the logarithms of the rate constants for the reactions vary linearly with the charge on the nitrogen§, provided that steric factors do not interfere.

The dissociation constants of the bases may also be to some extent proportional to the electronic charge on the nitrogen atom. For example, an approximately linear relation has been found between pK_a and the electronic charge q_N for a series of methylbenzacridines[35]. However, the correspondence between pK_a and q_N breaks down to a large extent for many bases with different molecular skeletons (Table 5).

The first stage of reaction (1) is promoted by electron-accepting substituents as well as other factors intensifying the positive charge on the carbon atom of the electrophilic molecule and ultimately increasing the amount of double-bond character of the C–N linkage. The increase of the C–N bond order leads ultimately to the formation of a quinonoid structure. Compounds with quinonoid structures show a greater tendency towards nucleophilic substitution reactions. Bunnett and Zahler[36] believe that this problem is still obscure, but quote evidence in support of the latter assertion. Thus halogenonitrobenzenes have a higher C–N bond order and react very readily with nucleophiles. It is also known that quinoneimines are more readily hydrolysed than amines. Thus, amino-compounds which readily give rise to quinonoid forms should combine with a nucleophile more readily, eliminating their amino-group at the same time. Presumably in the reaction of two aromatic amines the electrophile is the compound whose quinonoid form is more stable and which has a higher conjugation energy. It has been found experimentally that the degree of elimination of the amino-group increases in the sequence aniline < 1-naphthylamine < 9-aminophenanthrene[1,2]. This series has been compared (Table 6) with the electronic charges on the nitrogen atom q_N (calculated by the Slater–Pauling method[37]), the charges on the exocyclic carbon atom of the hydrocarbon analogue of the amine q_C, and the C–N bond orders[33]. Table 6 also shows that the oxidising potential of the corresponding quinone decreases, i.e. the stability of the quinonoid form increases, in the direction in which the ability of the amine to split off the amino-group increases[38].

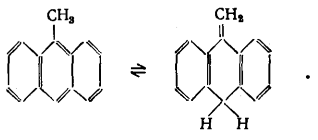
Table 5. Relation between the electronic charge on the nitrogen (q_N) and pK_a for the base[35].

Compound	q_N	pK_a
Pyridine	1,190	5,23
Isoquinoline	1,202	5,33
1-Aza-anthracene	1,205	5,05
Quinoline	1,221	4,91
Acridine	1,227	5,60

Table 6. Comparison of the reactivities of aromatic amines with the charges on the nitrogen (q_N), the charges on the exocyclic carbon atom (q_C), the bond orders P_{CN}, and the oxidation potentials of quinones (E).[7]

Parameter	Aniline	1-Naphthyl-amine	9-Amino-phenan-threne
q_N	1,841	1,817	—
q_C	0,571	0,450	0.446
P_{CN}	1,160	1,180	—
E, b	0.794	0,576	0.460

The increase of the ability to form quinonoid structures with increase of the number of benzene rings also follows from the benzenoid–quinonoid tautomerism of methyl derivatives or aromatic hydrocarbons. Thus, whereas 9-methylanthracene exists mainly in the benzenoid form [Scheme (11)], the quinonoid form predominates in methylpentacene. According to Syrkin and Dyatkina[39], this behaviour is caused by the increase of the π-electron energy of the quinonoid tautomer with increase of the number of rings:

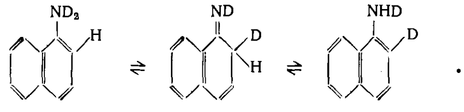


(11)

---

§ For simplicity, the charge on the exocyclic carbon atom in the hydrocarbon analogue of the amine  was calculated.

The formation of the quinonoid forms of polycyclic amines might serve as a convenient pathway for the migration of protons of the amino-groups to the ring and conversely. Such exchange has been investigated using deuterium introduced into the amino-group[40]. No exchange involving aniline was observed in a neutral medium, but it occurred at an appreciable rate at 180–200°C in the 2- and 4-positions of 1-naphthylamine. Since the rate of exchange was independent of the concentration of amine in the tetralin solution, the following intramolecular mechanism involving an intermediate quinonoid structure was proposed for the exchange:



(12)

This process could also proceed via a π-complex¶. An increase of electron density in the 2- and 4-positions promotes the addition of the amine proton in these positions with formations of a quinonoid tautomer†.

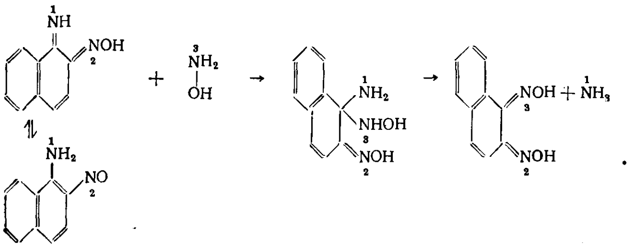
The foregoing discussion permits the conclusion that the benzenoid-quinonoid tautomerism in the reactions of polycyclic aromatic amines plays an important role. Here it was demonstrated in relation to the interaction of two amines, but there is no doubt that the conclusion is of more general validity.

The acid–base properties of amines also play a significant role in determining the mode of dissociation of the C–N bonds in the reactions under consideration. As we have seen quantitative relations have been observed in specific instances[19] between the reactivities of the amines, the pK_b values, and the Hammett σ constants. In elucidating the mechanism of the elimination of ammonia one must therefore take into account the relative basicities of the reacting amino-groups.

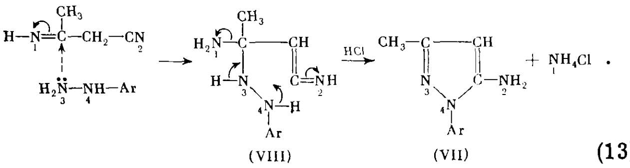
V. INTERPRETATION OF THE MECHANISMS OF PROCESSES WHICH HAVE NOT BEEN INVESTIGATED USING ^{15}N

In this section an attempt will be made to apply the ideas developed above for the mechanism of the condensation of amines to analogous reactions in which the nitrogen migration pathways have not been established by isotopic methods using ^{15}N.

2-Nitroso-1-naphthylamine reacts with hydroxylamine to form 1,2-naphthoquinone dioxime[43]. The mechanism of this reaction can be represented as follows:



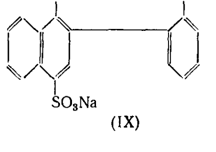
The reaction of diacetonitrile with arylhydrazines in the presence of hydrochloric acid[44] leads to 5-amino-1-aryl-3-methylpyrazoles (VII), which are used as the nitrogen-containing components in the synthesis of dyes. It appears that the arylhydrazine nitrogen atoms attack the carbon atoms of the nitrile and imino-groups to form $N_{(3)}$–C and $N_{(4)}$–C bonds. An intermediate complex (VIII) should be formed in the initial stage and ammonia containing the nitrogen atom of the imino-groups of the diacetonitrile is eliminated from it [Scheme (13)]. The polarisation of the $N_{(1)}$–C bond promotes the protonation of the $N_{(1)}$ atom by the acid present.



(13)

When phenylhydrazine reacts with aminonaphthalene or naphthols, the products are hydrazo-compounds, which are converted into carbazole derivatives in the presence of acid[45]. In particular, the reaction of phenylhydrazine with 4-, 5-, 6-,[46] and 7-sulphonic acid of 1-naphthylamine[47] in the presence of sodium bisulphite yielded the corresponding benzocarbazolesulphonic acids. The hydrazo-compound detected in these studies is obtained by the nucleophilic substitution of the "naphthalene" amino-group by the phenylhydrazyl residue. The reaction is favoured by the tendency of the substituted naphthylamine to form a quinonoid structure containing the HN=C< group. This mechanism explains why such reactions proceed with bicyclic and tricyclic amines but not with amines of the benzene series: the conjugation of the free electron pair of the nitrogen with the π electrons of the ring, which largely determines the capacity for the formation of the quinonoid form, is insufficient for this purpose in the benzene series.

According to isotopic data, the cyclisation of the intermediate diamine (IX), which has also been detected in the reaction medium[46], should proceed in reactions of this kind[2 3 16 31] with elimination of the amino-group from the naphthalene ring:



(IX)

The elimination of the "benzene" NH₂ group, which can be achieved, for example, by the *ortho*-semidine rearrangement of the hydrazo-derivative, is in this case still less likely than in the cyclisation of the [2-^{15}N]-phenylhydrazone of 1,1-dihydro-2-oxonaphthalene[31] owing to the presence of the sulpho-group. To demonstrate the occurrence of the side reaction (its contribution is probably less than 5%), an experimental test using ^{15}N is required.

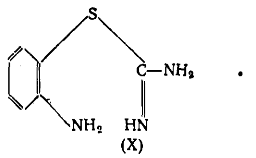
The mechanism of the Fischer synthesis of indole derivatives from the phenylhydrazones of aliphatic or alicyclic ketones and aldehydes has been fairly clearly established (as a result of numerous studies, mainly those of Robinson's school). In the last stage of this mechanism ammonia is eliminated solely from the aliphatic component of the intermediate diamine. It has been shown[24, 31] that the

---

¶ An intramolecular mechanism involving π-complexes has been proposed for proton exchange involving toluidine hydrochloride in the solid phase[41].

† The four versions of the bimolecular mechanism proposed[42] for the self-exchange in aromatic amines do not conflict with these conclusions, because they refer to proton exchange in the presence of the alkaline catalyst PhNDK.

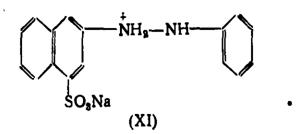
protonation of the aliphatic amino-group plays an important role in the elimination of ammonia. This mechanism is invoked in many investigations of the Fischer synthesis of indole derivatives[48,49]. In certain studies cyclisation mechanisms without protonation but with conversion of the aliphatic amino-group into an imino-group, for example, with formation of structure (X), [50-52] has been suggested:



(X)

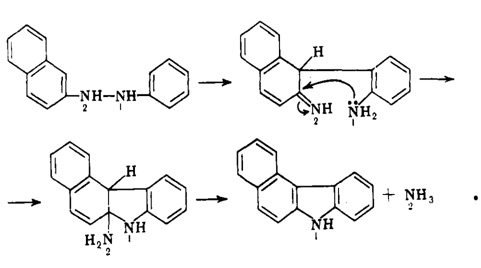
This mechanism should lead to the same ammonia elimination pathway, but it is in essence not unambiguous, because the aromatic amino-group can also be converted in certain cases into an imino-group and this would lead to its elimination in the form of ammonia, which conflicts with isotopic data.

Drawing an analogy between the Bucherer and Fischer syntheses, Seeboth[53] proposed a mechanism with the intermediate structure (XI):



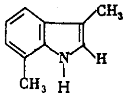
(XI)

The mechanism involving this structure, where the less basic nitrogen atom is protonated, appears to be doubtful. An analogous mechanism has been suggested in a paper[54] dealing specifically with the Bucherer reaction. Furthermore the Bucherer synthesis of benzocarbazole can be described by mechanism (14) with participation of the quinonoid form of naphthalene. The acid, which promotes the elimination of ammonia, catalyses the process via the general mechanism of acid catalysis:

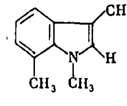


(14)

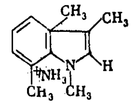
Mechanisms consistent with isotopic data are usually suggested in the literature for the interpretation of the Fischer syntheses of indoles and carbazoles, i.e. it is postulated that the amino-group attached to the aliphatic (or alicyclic) part of the molecule is always eliminated from the intermediate diamine (or dienoneimine). Only in two papers by the same workers[55,66] are mechanisms proposed in which the aromatic amino-group is eliminated to an equal extent. In these studies the interaction of *N*′-methyl-2,6-dimethylphenylhydrazine with propanal, 2-methylpropanal, and 2-methylcyclohexanone was investigated. Thus the reaction with propanal yielded a substance with structure (XIII) in addition to the normal indole (XII):



(XII)

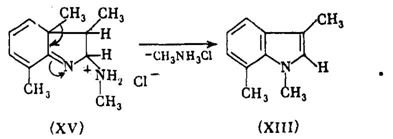


(XIII)



(XIV)

To explain this, the authors postulate a side reaction involving the formation of the intermediate (XIV) from which compound (XIII) is obtained by the elimination of the aromatic amino-group. Apart from the fact that this mechanism conflicts with all isotopic data for reactions of this kind, it is by no means necessary for the explanation of the experimental data presented. Product (XIII) can be obtained from the intermediate (XV), the formation of which via mechanism (15) in the course of the normal Fischer synthesis was confirmed by the above authors themselves with the aid of ^{1}H NMR. The methyl group migrates from the benzene ring to the nitrogen atom and the quinonoid structure is converted into the more stable benzenoid structure:



(15)

The interaction of amines with amides proceeds more readily than the reaction between two amines. Aniline reacts with urea at 160°C even in the absence of acids, forming diphenylurea[57]. Davis and Underwood[58] found a general method for the preparation of symmetrical diarylureas involving the heating of urea with primary aromatic amines. The mechanism of this reaction with aliphatic and aromatic amines of the benzene series gives rise to no doubts and evidently reduces to the elimination of the amide group. This can also be said of the reactions of mesidine with urea and of mesitylurea with hydrazine[12] as well as reactions of glycine and ethylglycine with urea[59] and of 2- and 3-aminopyridines with urea[60]. However, categorical predictions should not be made for the interaction of urea with 6-aminoquinoline[60], since, according to the present author's data[6], the dicyclic amine can lose part of its amino-nitrogen on reaction with an amide.

The reactions between an arylurea and an arenesulphonamide has been described[61]. One of the amides plays the role of the nucleophile:

$$RSO_2NH_2 + R'NHCONH_2 \rightarrow RSO_2NHCONHR' + NH_3 \quad .$$

The site from which the aminogroup is eliminated may be determined only by introducing ^{15}N into one of them. Admittedly one may assume that the withdrawal of electron density from the nitrogen atom in the sulphonamide is more pronounced than the corresponding effect in urea and the latter therefore retains its nitrogen atoms.

In transamination reactions amines displace one another from secondary amines, *N*-arylamides, and other complex compounds. Since transamination is associated with the competition between the reactivities of the interacting amines, it is of interest to examine these amines.

Stavrovskaya[62] investigated the transamination of benzyldiethylamine with various aromatic amines in hydrochloric acid:

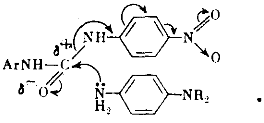
$$PhCH_2N(C_2H_5)_2 + ArNH_2 \xrightarrow{HCl} PhCH_2NHAr + NH(C_2H_5)_2 \quad .$$

Although the K_b values for the aromatic amines investigated varied in the range $(4-2000) \times 10^{-12}$, the yields of arylbenzylamines changed little (20–35%). The cause of this should be sought in the fact that all these weak amines displace diethylamine, which is a stronger base by 5–6 orders of magnitude. Evidently this possibility arises due to the presence of the acid, which converts the initial tertiary amines into the electrophilic ammonium ion. The low yields of the transamination product can be explained by the reversibility of the process and the more marked nucleophilic properties of diethylamine. A similar transamination involving n-aminobenzyldiethylamine was observed in another study[63].

Many instances of transamination have been observed in the series of urea derivatives. In the study already quoted[58] mention is made of the reaction of the symmetrical dimethylurea with aniline, which leads to the formation of diphenyl- and partly ethylphenyl-urea. Gerchuk et al.[64] carried out an extensive study of transamination in the series of substituted ureas. The results, which the present author compared with the basicities of the amines, permit the conclusion that the equilibrium in reaction (16) has shifted towards the displacement of the less basic amine. The authors propose a mechanism involving the preliminary decomposition of the arylurea to an aryl isocyanate, which reacts more readily with the stronger bases:

$$\text{ArNHCONHAr} + 2\text{Ar'NH}_2 \rightleftharpoons \text{Ar'NHCONHAr'} + 2\text{ArNH}_2 \quad . \qquad (16)$$

The same view is held by Kutepov and Potashnik[65], who investigated the interaction of bis(trichlorophenyl)ureas with aniline. However, this mechanism conflicts with the stability of arylureas, which has been pointed out by Heintz[59]. One may add that this type of exchange of amines has been found in the series of entirely stable *N*-arylacetamides. One must therefore assume that transamination takes place (see also Kogan and Kutepov[66]) via a nucleophilic substitution reaction, evidently involving an S_N2 mechanism. The redistribution of electron density in the intermediate complex (XVI) promotes the elimination of the weaker base.

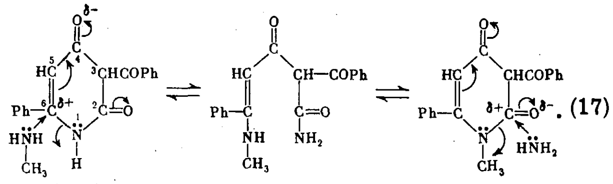


(XVI)

Transamination involving *N*-arylacetamides[13] takes place under very severe conditions (260°C, 100 atm, 2–5 days). The reaction of acetylpentylamine takes place more readily with aliphatic amines than with aniline. Primary amines also react more vigorously. The reactivity of amines in this process increases greatly as the phenyl groups become more remote, which can be seen from the following sequence:

aniline ≪ benzylamine < β-phenylethylamines.

The reactivity of the amino-groups is not correlated with their basicity. The authors therefore attribute much importance to steric hindrance. The mechanism of the transamination reaction is treated as a reversible nucleophilic substitution reaction; this conclusion has also been confirmed by other data[67]. Ridel' and Gerchuk[68] found that transamination takes place much more readily in the presence of hydrochloric acid, which can be accounted for by the induction of a positive charge on the carbonyl carbon atom on protonation. Like Porai-Koshits[69], they found that the strong base is displaced by the weak one. In certain cases this can be explained by the great excess (by a factor of 15–20) of the weaker base.



(XVII) (XVIII) (17)

The exchange of amines has been observed by Petrenko-Kritchenko and Shettle[70] when the "ammonia derivative of dehydrobenzoylacetic acid" (XVII) was acted upon by methylamine or aniline: there is a reversible exchange of the R–N< residues, where R = H, Me, or Ph. The present author suggests that this exchange begins with the addition of the amine to the $C_{(2)}$ or $C_{(6)}$ atom [Scheme (17)]. After ring opening, the intermediate aminoamide (XVIII) is formed‡ and this can again cyclise, regenerating the starting substances or giving rise to substitution products, which can be accounted for by the reversibility of this reaction.

Natural and Synthetic Acetylenic Antimycotics

O.G.Yashina and L.I.Vereshchagin

The available information about natural and synthetic acetylenic compounds exhibiting antifungal activity is surveyed and it is shown that the class of acetylenic compounds with functional groups is extremely promising as regards the search for new drugs, particularly in view of the increase of the number of strains which have acquired immunity to the preparations used at the present time.

The bibliography includes 227 references.

I. INTRODUCTION

Fungal diseases (mycoses) affect man, various animals, and plants. Agents responsible for mycoses are numerous and the clinical symptoms are various[1-6]. Fungal diseases of the skin, caused by parasitic fungi or dermatomycetes, are encountered in all regions of the world. Humanity has suffered from mycoses since ancient times. They are highly contagious and give rise to chronic conditions. Clinical observations have shown that dermatophytes, which have become adapted by evolution to the skin and its derivatives, can sometimes affect also internal organs, bone tissue, and the central nervous system[5-7]. Although skin mycoses affect mainly the surface layers of the skin, they constitute a serious problem for the health service since the incidence of certain skin mycoses is comparable to that of the common cold or dental caries and the treatment of patients with skin mycoses is enormously expensive[4-5]. The problem of the chemotherapy of patients with fungal inflections has attracted the attention of a wide range of specialists-dermatologists, pharmacologists, biochemists, and chemists[6-10].

Antifungal antibiotics (griseofulvin, nystatin, and others) have occupied a leading place among the drugs and in connection with methods for the modern treatment of mycoses. However, it would be incorrect to assume that the problem of the treatment of dermatomycoses has been fully solved. Numerous communications devoted to the description of complications and failures in the employment of recognised antimycotics have been published[6,7]. The spectrum of their activity frequently limited: fungal strains resistant to these antibiotics have appeared. Hitherto, preparations with adequate activities and lacking side effects have been missing from the arsenal of antifungal agents. The acute nature of the problem of the chemotherapy of fungal diseases requires the improvement of the existing medicinal preparations and has stimulated a persistent search for new antimycotics.

The search for active antifungal preparations is based on various classes of compounds[6,11]. Natural antibiotics of the acetylenic series, containing carbofunctional groups in their structure, are extremely promising[8,11-16].

II. NATURAL ACETYLENIC ANTIMYCOTICS

Acetylenic compounds are fairly common in nature as metabolites of many plants and as antibiotics generated by fungi and actinomycetes[8,11-17]. It has been established that acetylenic and polyacetylenic fragments can enter into the composition of the molecules of a wide variety of natural organic substances, but the functions of these highly unsaturated compounds in the metabolism of plants and microorganisms remain not altogether clear[12].

The majority of the acetylenic compounds have been isolated from plant essential oils and fats and from fungal culture liquids[11,13-15]. The classical studies[15-23] provide an idea about the systematic research on natural poly-ynes and the enormous effort by several schools of investigators—those of Sörensen in Norway, Bu'Lock and Jones in England, and Bohlmann in Germany. The experimental data on all natural polyacetylenes known at the beginning of 1971 have been successfully surveyed in a monograph describing many aspects of the problem[12].

Comprehensive studies on the poly-ynes encountered in nature have shown that, apart from their theoretical interest, associated with the elucidation of their role in the biosynthetic processes involving the living cell, they are of considerable practical interest in view of their high biological activity. Many natural polyacetylenes retard the growth of various bacterial and fungal species even at high dilutions. According to Shemyakin's data[8], antifungal activity has been noted among 353 antibiotics (this number has now increased). The pronounced antifungal activity of natural poly-ynes investigated in this respect has attracted particular attention. The best known of these are capillin (I), wyerone (IV), agrocybin (VI), biformene (VII), nemotin (IX), and others.

Capillin has attracted the steady attention of investigators by virtue of its high antifungal activity and comparatively simple structure. Capillin has in fact led to the publication of numerous studies devoted to the synthesis and investigation of the biological properties of analogous and related compounds[24-36]. This diacetylene was isolated in 1957 from the essential oil of *Artemisia capillaris* and the formula of 1-phenylhexa-2,4-diyn-1-one (I) proposed for it was confirmed by synthesis[28,31]:

$$\mathrm{CH_3{-}C{\equiv}C{-}C{\equiv}CH \xrightarrow[C_6H_5CHO]{NaNH_2} CH_3{-}C{\equiv}C{-}C{\equiv}C{-}CHOH{-}C_6H_5 \rightarrow}$$

$$\mathrm{\xrightarrow[AcOH]{CrO_3} \underset{(I)}{C_6H_5{-}CO{-}C{\equiv}C{-}C{\equiv}C{-}CH_3}} \quad .$$

The acetylenic compound (II), called capillene, had been isolated previously[32] from the essential oil of plants of the same genus. It transpired later that it is identical with agropyrene[33] and "dehydroagropyrene"[37].

$$\mathrm{\underset{(II)}{C_6H_5{-}CH_2{-}C{\equiv}C{-}C{\equiv}C{-}CH_3}}$$

The demonstration of the identity of agropyrene from *Agropyrum repens* and capillene from *Artemisia campestris* and determination of the structure were preceded by research prosecuted by several investigators over a period of almost three decades. Thus Harada[29,30] determined more accurately the formula of capillene and confirmed it by synthesis in accordance with the following scheme:

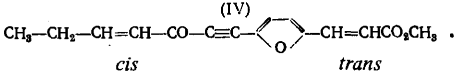
$$C_6H_5{-}CH_2{-}C{\equiv}CH \xrightarrow[CH_3C{\equiv}CI]{MgBrC_2H_5} \underset{(II)}{C_6H_5{-}CH_2{-}C{\equiv}C{-}C{\equiv}C{-}CH_3} .$$

It was shown later that capillene is oxidised to capillin on prolonged storage in air. Both capillene and capillin exhibit an exceptionally strong antimicrobial activity and also high activity against various phytopathogenic fungi. Capillin arrests the growth of dermatophytes in a nutrient medium at very low concentrations (0.25 μg ml^{-1}).[24,28] In tests of its antifungal activity in experiments on animals, capillin proved to be active against *Trychophyton asteroides*[25,38]. Several representatives of aromatic acetylenic compounds closely related to capillin have been isolated from plants of the *Compositae* family: capillon, capillarin, and desmethylcapillin[39-41]. It is noteworthy that an unsaturated hydrocarbon (III) with four conjugated triple bonds, whose antifungal activity surpasses that of capillin, has been detected in extracts from higher plants[42].

$$\underset{(III)}{CH_3{-}CH{=}CH{-}(C{\equiv}C)_4{-}CH{=}CH_2}$$

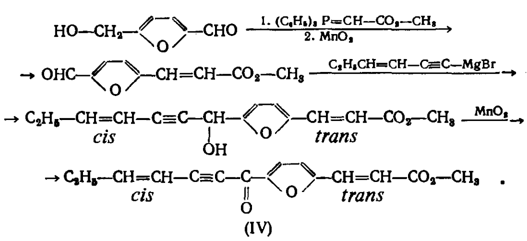
Natural thienyl- and furyl-poly-ynes with a wide variety of structures exhibit a high antibiotic activity[8,11,12,15,43-57]. Among poly-yne metabolites of higher plants, an extremely effective antimycotic has been detected[43,58,59]—a disubstituted furan derivative. The crystalline compound was isolated from a *Vicia faba* extract. Oxidation of the natural product with potassium permanganate yielded furan-2,5-dicarboxylic acid. According to ^{1}H NMR and mass-spectrometric data, it was possible to postulate two structures, (IV) and (V), for this compound[12,43,58,59]:

(IV)



(V)

The validity of formula (IV) was demonstrated by synthesis from 5-hydroxymethylfurfural[58,59]:



(IV)

The ketoester (IV), called wyerone, can suppress the growth of many pathogenic fungi—*Alternaria brassicicola*, *Aspergillus niger*, *Uromyces fabae*, and *Glomerella cingaluta*—at a concentration of approximately 10 μg ml^{-1}.

Polyunsaturated products from fungal microorganisms are highly polar substances with functional groups. Powerful acetylenic antimycotics—agrocybin (VI)[60,61] and biformene (VII)[62-64]—have been isolated from the culture liquids of basidiomycetes.

An unstable crystalline triyne (VI) has been isolated by extraction from the culture liquid of the fungus *Agrocybe dura.*[60,61] Analysis of spectroscopic data and specific synthesis showed that agrocybin has the structure of the amide of 8-hydroxyocta-2,4,8-triynoic acid (VI)[65,66]:

$$HO{-}CH_2{-}C{\equiv}C{-}C{\equiv}CH + HC{\equiv}C{-}COOMe \xrightarrow[CuCl]{O_2}$$
$$\rightarrow HOCH_2C{\equiv}C{-}C{\equiv}C{-}COOMe \xrightarrow{NH_3} \underset{(VI)}{HOCH_2{-}(C{\equiv}C)_3\,CONH_2} .$$

A high antifungal activity is characteristic of agrocybin, but its toxicity is also high: LD_{50} for mice is 60 mg kg^{-1}.[61]

Biformene is an interesting polyacetylenic antibiotic[62-64]. In the study of the antibiotic activity of this poly-yne it was noted that it is active *in vitro* against various representatives of gram-positive and gram-negative microbes and the mycobacteria responsible for tuberculosis. It exhibits a fairly high activity as an antimycotic (0.5–4 μg ml^{-1}), but it did not show a therapeutic effect in tests on animals. After a series of studies, structure (VII) was established for biformene. According to ultraviolet and infrared spectra, its molecule contains a triyne system and an unsubstituted ethynyl group. Since hydrogenation of the natural product led to nonane-1,2-diol, the structure of the triynediol (VII) was proposed for biformene[63,67,68]:

$$\underset{(VII)}{HC{\equiv}C{-}C{\equiv}C{-}C{\equiv}C{-}CH_2{-}CH\,(OH){-}CH_2OH} .$$

The synthetic nona-4,6,8-triyne-1,2-diol (VII), obtained by Bohlmann[69], did not correspond to natural biformene as regards its properties. The epoxide (VIII) proved to be identical with the natural poly-yne[70]:

(VIII)

A whole series of similar epoxides were later isolated from plants of the *Compositae* family[71,72].

A fairly large class of compounds, incorporating the allene-diacetylene group as a structural element, has been discovered among natural poly-ynes. Many compounds of this type exhibit a broad-spectrum antimicrobal activity[73-77].

A mixture of antibiotics (IX)–(XII), present in the culture liquids of *Poria tenium*, *Poria corticola*, and the basidiomycete B-841, has been described[73-75]. The pronounced antifungal effect of nemotin (IX) against many strains of various fungi (0.06–16 μg ml^{-1})[74] has been noted. Its activity does not decrease in the presence of blood serum. Nemotin is the lactone of nemotinic acid (X); the biological activity of compound (X) is close to that of (IX) in terms of its bactericidal spectrum, but its fungicidal activity is different.

(IX)

$$\underset{(X)}{HC{\equiv}C{-}C{\equiv}C{-}CH{=}C{=}CHCH\,(OH)\,(CH_2)_2{-}COOH}$$

The reliability of structures (IX) and (X) was confirmed by the study of their infrared spectra and isomerisation products. Comparison of the entire set of chemical and spectroscopic characteristics made it possible to identify in the mixture of metabolites of the B-841 fungus the antibiotics odyssin (XI) and odyssic acid (XII)—the methyl homologues of compounds (IX) and (X) [73-75]:

(XI)

$CH_3—(C≡C)_2—CH=C=CHCH(OH)(CH_2)_2—COOH$.

(XII)

The study of the biologically active products of the metabolism of microorganisms stimulated the development of a new field of organic synthesis—research on new compounds with antifungal properties.

III. SYNTHETIC ACETYLENIC ANTIMYCOTICS

The literature data show that acetylenic compounds have recently aroused interest ss drugs [11,35,43,76-87]. The spectrum of the biological activity of acetylenic compounds is unusually broad: they behave as convulsants, anticonvulsants, local anaesthetics, analgesics, hypotensive agents, ganglion-blocking agents, and antibacterial agents [76], and many acetylenic preparations are frequently more active, less toxic, and more readily assimilated by the organism than their olefinic or saturated analogues. The presence of the triple bond in the molecule apparently lowers the toxicity and improves the degree of absorption and metabolism of certain drugs.

Interest in the analogues of natural acetylenic antibiotics has been shown particularly in the last 10–15 years. During this period, mono-, di-, and vinylacetylenic ketones [11,26,27,35,43,77,83,85,88-93], acetylenic ketoacids [94,95], esters [35,76,77,85,87,96-100], and other acetylenic compounds [11,76-81] were synthesised in order to investigate their biological properties.

The successful synthesis of complex unsaturated compounds with functional groups has a sound methodological basis in the chemistry of acetylene [11,12,76,100-106]. Many poly-ynes have been obtained by oxidative dimerisation[101,102] and asymmetric condensation[102-104]. They are frequently synthesised in connection with the systematic investigation of acetylenic compounds with properties prediced beforehand[35,36,43,78-80,83-87,90,107-118]. Unfortunately a rigorous scientific theory, which would be able to eliminate empiricism from the synthesis and modification of the molecules of known antibiotics and would enable a purposeful search for new drugs with specific therapeutic activity, is still lacking[119].

The fungicidal activity of natural polyacetylenes depends to a large extent on their structure [12,34,77] and in most cases the activity is rigorously selective, which gives rise to the hope that new synthetic analogues with selective antifungal activity will be obtained [35,43,83-87,110-122].

1. Acetylenic Carbonyl Compounds

The antifungal activity of acetylenic carbonyl compounds is attributed to the presence in their molecules of the conjugated ketoethynyl group [25,26,35,77,123]. The hypothesis of the biological specificity of the ketoethynyl group –CO–C≡C– in the capillin molecule and the assumption that this fragment is responsible for the antifungal effect was formulated in two investigations [25,26]. It was confirmed and justified by extensive experimental data on the synthesis of acetylenes with carbofunctional groups and results amplifying the available information about the influence of various structural elements on fungicidal properties [35,43,83,85-87,90,124-135]. Joint investigations by chemists and microbiologists have shown that any structural changes in the ketoethynyl group (the breakdown of conjugation, the introduction of double bonds) cause an appreciable decrease of activity or a sharp change in the nature of the activity of the preparation [35,43,77,81,83,85-87,90,128,132]. It was found that the nature of the substituents at the CO group and the triple bond has little influence on the antibiotic activity, but determines the irritant action and the pharmocological properties of acetylenes with carbofunctional groups [35,36,81,86,135]. The replacement of the phenyl group in capillin itself by chlorophenyl, methoxy-, and thienyl groups leads to a decrease of the antifungal activity and an increase of the irritant action[27,37]. There are data [86,130,136] showing that the irritant action may be greatly reduced by introducing a hydroxy-group into the α-ethynylketone molecule or by the replacement of the alkyl group by the phenyl group. The increase of the length of the carbon chain of the alkyl substituent to C_4 increases the activity of capillin and capillene analogues, but a further increase in chain length lowers the activity[81].

Many investigators attempted to elucidate the relation between antifungal activity and the degree of unsaturation (the number of triple bonds in the antimycotic molecule)[26,35,83-87,121,133,135]. It was shown [83,86,129] that the second acetylenic fragment introduced into the conjugation chain of furylphenylacetylenic ketones (XIII) enhances the antifugal properties somewhat, but the triynones (XIII, $n = 3$) already show a sharp decrease of both fungistatic and bacteriostatic activities:

; $n = 1, 2, 3$.

(XIII)

The small biological effect of the triynone (XIII) has been explained [129] by its low solubility in water and its decomposition after the incubation of cultures in a thermostat for many hours. Cases are known where the introduction of a second acetylenic bond into the molecule lowers the antimycotic effect [84,133,134].

Since the use of the known natural antimycotics of the propynone series is precluded by their high toxicity, new methods have been proposed and applied in the search for analogues with low toxicity [35,43,83,137-139] and the known methods have been improved. Fairly extensive data have now been accumulated on the synthesis of α-acetylenic ketones. Surveys of the chemical properties and the methods of synthesis of α-ethynylketones have been published [35,140,141]. The generally accepted methods are not always suitable for the preparation of ketones with other functional groups, owing to the exceptional reactivity of the α-ethynylcarbonyl group. The triple bond in α-ethynylketones is highly activated by the adjacent carbonyl group and readily undergoes various nucleophilic addition reactions. The most rational method for the preparation of ethynylketones is the oxidation of secondary acetylenic alcohols. The use of active manganese dioxide [142] as well as chromium trioxide in sulphuric or acetic acid made it possible to obtain a wide range of acetylenic ketones (XIV)–(XXVI) with various structures by the oxidation of the corresponding alcohols and glycols [35,43,83,85,87,90,99,137,143]:

$R{-}CO{-}(C{\equiv}C)_n{-}R'$;
(XIV) $n = 1, 2, 3$

$R{-}C{\equiv}C{-}CO{-}C{\equiv}C{-}R'$;
(XV)

(XVI) $n = 1, 2$
(XVII) $n = 1, 2$

$R{-}CO{-}(C{\equiv}C)_nCO{-}R$;
(XVIII) $n = 1, 2$

$R{-}CO{-}C{\equiv}C{-}CH{=}CH_2$;
(XIX)

$RR'C(OH)(C{\equiv}C)_n{-}CO{-}R''$;
(XX) $n = 1, 2$

$R{-}C{\equiv}C{-}CO{-}CH{=}CH{-}R'$;
(XXI)

$RR'C(OH)C{\equiv}C{-}CH_2{-}CO{-}R''$;
(XXII)

$RR'C(OH)CH_2{-}C{\equiv}C{-}CO{-}R''$;
(XXIII)

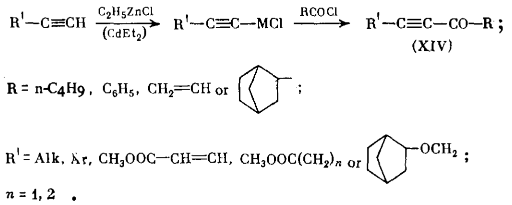
$R{-}O{-}C(R'R'')(C{\equiv}C)_n{-}CO{-}R'''$;
(XXIV) $n = 1, 2$

$R{-}CO{-}C{\equiv}C{-}CH_2Hal$;
(XXV)

$R{-}CO{-}CH_2C{\equiv}C{-}Hal$;
(XXVI)

R, R′, R″ = furyl, pyridyl, thienyl, or norbornyl.

High yields of monoacetylenic and vinylacetylenic ketones, acetylenic diketones, and ketoacid esters have been obtained by the reaction of ethynylzinc or ethynylcadmium reagents, resembling the Iotsich complex in terms of their reactivity, with the chlorides and anhydrides of aliphatic and aromatic acids [85,113-116]:



$$R'{-}C{\equiv}CH \xrightarrow[(CdEt_2)]{C_2H_5ZnCl} R'{-}C{\equiv}C{-}MCl \xrightarrow{RCOCl} \underset{(XIV)}{R'{-}C{\equiv}C{-}CO{-}R};$$

R = n-C_4H_9, C_6H_5, $CH_2{=}CH$ or ;

R′ = Alk, Ar, $CH_3OOC{-}CH{=}CH$, $CH_3OOC(CH_2)_n$ or ;

$n = 1, 2$.

Ethynylketones (XIV) are active against *Trichophyton gypseum* and a ketone with the norbornene substituent at the carbonyl group showed a distinct therapeutic effect on an experimental model of dermatomycosis [85,86].

The pentadiynone group, analogous to capillin, is retained in the diacetylenic ketones (XIV, $n = 2$), obtained by the oxidation of secondary diacetylenic alcohols with manganese dioxide [35,83,85,126,127]:

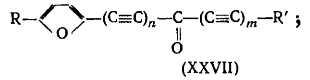
$$\left.\begin{array}{l} R{-}CHOH{-}C{\equiv}CH + BrC{\equiv}C{-}R' \xrightarrow{H_2Net} \\ R{-}CHO + HC{\equiv}C{-}C{\equiv}C{-}R' \xrightarrow{MgBrEt} \end{array}\right| \rightarrow R{-}CHOH{-}(C{\equiv}C)_2{-}R' \rightarrow$$

$$\xrightarrow{MnO_2} \underset{(XIV)}{R{-}CO{-}(C{\equiv}C)_2{-}R'} .$$

Triacetylenic and tetra-acetylenic ketones have been obtained in accordance with the same scheme [35].

In order to improve the stability of polyunsaturated capillin-like compounds, use was made of silylacetylenic derivates with a high fungicidal activity in relation to *Trichophyton gypseum* and *rubrum*. [117]

In contrast to benzoylacetylenes, furoylacetylenes (XXVII) exhibit a strong antifungal activity combined with a lower toxicity. This observation initiated systematic research into furylalkynes [35,43,83,86]. The monoacetylenic ketone 1-(2-furyl)-5-phenylpent-4-yn-3-one is known [92] to be active not only against *Trichophyton* but also against *Candida* and many other fungi.



(XXVII)

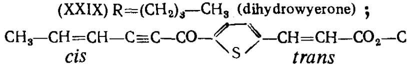
$n = 0, 1$; $m = 0, 1$; R=H, Br, Cl, I, NO_2, or COOH;

R′ = alkyl, aryl, 5-bromo-2-furyl, OH, OCH_3, or OC_2H_5.

A fairly high activity against pathogenic fungi, resembling that of the natural precursor wyerone (IV), is shown by its synthetic analogues (XXVIII)–(XXX) [44,58,59]:

(XXVIII)–(XXIX)

(XXVIII) R=*cis*-$CH{=}CH{-}CH_3$ (norwyerone) ;
(XXIX) R=$(CH_2)_3{-}CH_3$ (dihydrowyerone) ;



(XXX)

The high antifungal activity of the ketones (XIV) has been noted in a number of patents [89,92,144-148]: data obtained in recent years [35,36,83,85,86,118,144-156] are evidence showing that studies on the practical applications of these substances have been carried out, for example, in the fight against the fungal diseases of plants [150]. A pronounced antifungal activity is characteristic of all the ketones tested. Dermatophytes are particularly sensitive to acetylenic ketones. A common property of ethynylketones is their weak activity against strains of yeast-like fungi and actinomycetes [35,43,83,85,86]. Mention should be made of data [81,82,85,86,122,135] concerning the activity of ethynylketones against the tuberculosis mycobacterium. The high tuberculostatic activity of α-ethynylketones is shown not only *in vitro* but also *in vivo* [35,85,86,135].

Presumably the likely mechanism of the antibiotic activity [157-160] of α-acetylenic ketones is analogous or similar to the mechanism proposed for the activity of $\alpha\beta$-diunsaturated ketones. The antibiotic effect of $\alpha\beta$-diunsaturated ketones has been explained in well known studies [161,162] by their tendency to interact with the sulphhydryl groups of enzymes, which are important for the vital activity of microorganisms. Reactions of this kind with nucleophiles of the SH type are in fact characteristic of ethynylketones to an even greater extent than of vinylketones. The mechanisms of the action of various antifungal substances are not the same. There are data showing [160] that acetylenic derivatives exhibit a more restricted activity on the cytoplasmic membrane than polyenes. It may be that the selective antifungal activity of the acetylenic preparation is associated with the breakdown of the functions of the cell wall, although it need not be of the same type as in polyenes [160]. The tendency to explain the mechanism of the action of antibiotics at a molecular level has been dominant in recent years [9,158,163,164]. The quantum-mechanical treatment of pharmacological problems—the correlation of activity with parameters of the electronic structures of active compounds—appears to be extremely promising [165]. In future we may expect a sharp increase of attention devoted to this problem, without the solution of which the specific synthesis of therapeutically valuable derivatives of natural antibiotics appears to be impossible.

2. Acetylenecarboxylic Acids and Their Derivatives With Antifungal Activity

Amongst natural poly-yne acids and their derivatives, a number of powerful antimycotics have been discovered [8,12,65,73-75], which led to a vigorous search for new antifungal agents based on unsaturated carboxylic acids. Even the structurally simplest propiolic acid and its esters are active against many fungi, while methylpropiolic acid also possesses antibacterial properties. A further increase in the number of methylene groups reduces the bacteriostatic activity and enhances the fungistatic activity. Judging from patent data [166-168], ω-iodoalkynoic acids (XXXI) and their esters (XXXII) are also active against mycoses [169,170]:

$$\underset{(XXXI)}{IC{\equiv}C{-}(CH_2)_n{-}COOH};\ n = 1{-}7\quad \underset{(XXXII)}{IC{\equiv}C{-}(CH_2)_8{-}COOR} .$$

In experiments on the mycelia of *Trichophyton* and a yeast-like fungus a study was made of acetylenic acids derived from furan[171-173]. It was shown that the presence of the ketoethynyl group combined with the furan ring in the molecule promotes fungistatic activity, but the introduction of substituents (a bromo- or nitro-group) in the 5-position in the furan ring reduces the fungistatic activity and sharply enhances the bacteriostatic activity.

The esters (XXXIII) of acetylenecarboxylic acids and polyhydric alcohols suppress the growth of bacteria and fungi even at a very low concentration[174]:

$$HO{-}(CH_2)_n{-}OH + R{-}C{\equiv}C{-}CO_2H \xrightarrow[H^+]{C_6H_6} R{-}C{\equiv}C{-}COO(CH_2)_nOCO{-}C{\equiv}C{-}R\ .$$

(XXXIII)

The fungistatic activity of dicarboxylic acid esters is somewhat greater than that of the acids themselves, the second carboxy-group having little effect on the activity[77,175,176]. It has been suggested that different esters of acetylene-dicarboxylic acid as well as its salts be used to control the fungal diseases of rice[177].

In the series of dimethyl dicarboxylate esters of the type $(CH_3OC_2{-}(CH_2)_2{-}(C{\equiv}C)_n{-}(CH_2)_2{-}CO_2CH_3$ (XXXIV) the fungicidal activity increases sharply on passing from diacetylenic to tetra-acetylenic derivatives[121]. A similar behaviour has also been observed for monocarboxylic acids of type (XXXV)[121]:

$$C_4H_9{-}(C{\equiv}C)_n{-}R\ ;$$

(XXXV)

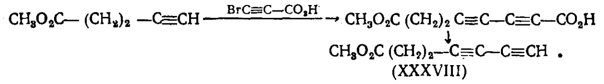
$R{=}(CH_2)_m{-}CO_2H$, CO_2H, or $CH{=}CHCO_2H$; $m = 0{-}2$.

Kucherov and coworkers[121,178] investigated systematically the pathways leading to the formation of many polyunsaturated mono- and di-carboxylic acids. In order to elucidate the dependence of biological activity on structure, the nature of the functional groups, and the number of triple bonds, acids of two types, (XXXVI) and (XXXVII), were examined[178]:

$$R{-}(C{\equiv}C)_m{-}(CH_2)_n{-}COOH \qquad R{-}(C{\equiv}C)_m{-}(CH{=}CH)_n{-}CH_2CH_2{-}COOH\ .$$

(XXXVI) (XXXVII)

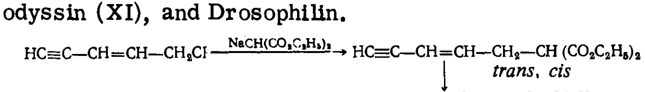
The Chodkiewicz condensation[102-104] served as a basis for the syntheses, which required the development of easy methods for the formation of fragments with a terminal acetylenic bond, as in compound (XXXVIII):



$$\begin{array}{l} CH_3O_2C{-}(CH_2)_2{-}C{\equiv}CH \xrightarrow{BrC\equiv C-CO_2H} CH_3O_2C(CH_2)_2C{\equiv}C{-}C{\equiv}C{-}CO_2H \\ \qquad\qquad\qquad\qquad\qquad\qquad \downarrow \\ \qquad\qquad\qquad\qquad\qquad CH_3O_2C(CH_2)_2{-}C{\equiv}C{-}C{\equiv}CH\ . \end{array}$$

(XXXVIII)

A series of polyunsaturated acids (XXXVII) have been obtained (in yields up to 50%) by the oxidative condensation of the vinylacetylenic acid (XXXIX) and its bromide with different acetylenic acids, alcohols, and hydrocarbons[178]. Carboxylic acids (XXXVII) containing the vinylacetylene group are related to the natural antimycotics—nemotin (IX), odyssin (XI), and Drosophilin.

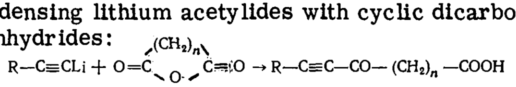


$$\begin{array}{l} HC{\equiv}C{-}CH{=}CH{-}CH_2Cl \xrightarrow{NaCH(CO_2C_2H_5)_2} HC{\equiv}C{-}CH{=}CH{-}CH_2{-}CH(CO_2C_2H_5)_2 \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad \downarrow \quad \textit{trans, cis} \\ \qquad\qquad\qquad\qquad\qquad HC{\equiv}C{-}CH{=}CH{-}CH_2CH_2CO_2H\ . \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad \textit{trans} \end{array}$$

(XXXIX)

Many vinylacetylenic acids exhibit a powerful selective activity in relation to certain types of pathogenic fungi at concentrations (*in vitro*) comparable to those of the strongest antimycotics (capillene, odyssin).

The method for the preparation of unsaturated keto-acids developed by Bergel'son et al.[95] was extended by Bergel'son and Grigoryan to the synthesis of ketoacids with terminal double and triple bonds[179]. Ketoacids of the type $R{-}C{\equiv}C{-}CO{-}(CH_2)_n{-}COOH$ (XL) have been obtained by condensing lithium acetylides with cyclic dicarboxylic acid anhydrides:



(XL)

Acetylenic ketoesters with low toxicity, which suppress *in vitro* the pathogenic dermatophytes *Microsporon lanosum* and *Achorion schönleini* at concentrations of 1–2 $\mu g\ ml^{-1}$ and *Trichophyton gypseum* at a concentration of 6 $\mu g\ ml^{-1}$, have been obtained by this method. It is noteworthy that the high antifungal activity of the unsaturated ketoester (XL, $R{=}C_4H_9$, $n = 3$) depends on the presence of its molecule of the conjugated ethynylketone group, since its ethylene analogue is less active and the corresponding saturated ketoester altogether fails to suppress the growth of the above fungi[95].

Fungicidal agents have been found recently not only among the esters[160,169,170,174,180-184], but also among the amides of acetylenic acids[185-189]. The propiolamides (XLI)-(XLIII) are particularly active[135,186]:

$$HC{\equiv}C{-}COCl + H_2N{-}(CH_2)_6{-}H_2N \rightarrow HC{\equiv}C{-}CONH{-}(CH_2)_6{-}HNCO{-}C{\equiv}CH\ ;$$

(XLI)

(XLII) m.p. 228° (XLIII) m.p. > 300°

In order to obtain compounds inhibiting the growth of microbes, studies have been made[190-193] of the synthesis and microbiological properties of acetylenic aminoacids. L-3-(2-propynylthio)alanine (XLIV) may be used as a fungicide active against certain parasitic fungi[191]:

$$HC{\equiv}CCH_2Br + HSCH_2CH(NH_2)COONa \xrightarrow{NH_3} HC{\equiv}C{-}CH_2S{-}CH_2{-}CH(NH_2){-}COOH\ .$$

(XLIV)

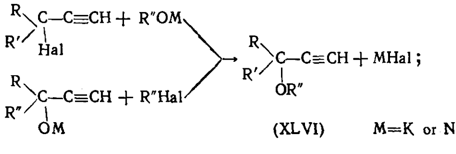
3. Propargyl Ethers

A series of studies have been made and a number of patents have been taken out concerning the synthesis and biological properties of aryl propargyl ethers (XLV), many of which are powerful fungicides[85,87,97-99,131,143,194-210]:

$$Ar{-}Y{-}CH_2{-}C{\equiv}C{-}R \quad Y{=}O \text{ or } S;\quad R{=}Hal \text{ or } H.$$

(XLV)

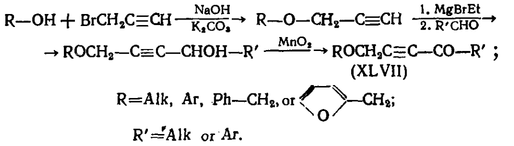
Direct and indirect methods are known for the preparation of ethers from acetylenic alcohols. Terminal propargyl ethers (XLVI) are usually obtained by the interaction of propargyl halides with alkoxides, derived from saturated alcohols, and phenoxides or by the interaction of alkoxides derived from acetylenic carbinols with alkyl halides. The ethers (XLVI) can serve as key substances in the synthesis of a wide variety of bifunctional acetylenes and aminopropargyl ethers exhibiting antifungal activity:



(XLVI) M=K or Na.

A convenient method[203,204] involves the hydroxypropargylation of norbornenes at the strained double bond in the presence of boron trifluoride etherate, which leads to *exo*-propargyloxynorbornanes in satisfactory yields (40 to 97%).

A specific synthesis of new antimycotics made it possible to develop an optimum version of the synthesis of propargyloxyketones (XLVII)[35,87,99]:



$$R{-}OH + BrCH_2C{\equiv}CH \xrightarrow[K_2CO_3]{NaOH} R{-}O{-}CH_2{-}C{\equiv}CH \xrightarrow[2.\ R'CHO]{1.\ MgBrEt} ROCH_2{-}C{\equiv}C{-}CHOH{-}R' \xrightarrow{MnO_2} \underset{(XLVII)}{ROCH_2C{\equiv}C{-}CO{-}R'}\ ;$$

R=Alk, Ar, Ph—CH₂, or

R′=Alk or Ar.

The introduction of the carbonyl group into ethers derived from acetylenic alcohols made it possible to increase their antifungal activity[82,87,99,130,131]. The study of the antibiotic properties of ketoethers in relation to a large series of strains *in vitro* showed that they exhibit a high antifungal activity, suppressing the growth of dermatophytes at concentrations of 1.2–1.56 μg ml^{-1}. The nature of the substituents at the ether and carbonyl groups plays a certain role, but it was not possible to establish a correlation between the structure of the compounds and their activity[87,99].

Fungistatic and germicidal agents have been discovered among benzthiazolyl propynyl sulphides[211,212]:

(XLVIII)

X = 5-Cl, 4-Me, 6-EtO, etc.

Unsubstituted alkyl ethynylvinyl sulphides HC≡C–CH=CHSAlk (XLIX) proved to be active against certain species of mould developing in PVC coatings in tropical climates[111].

4. Acetylenic Alcohols

The antimycotic activity of monoacetylenic alcohols is low compared with the corresponding carbonyl compounds[77,81,85,86,123], but the inhibiting activity of vinylacetylenic and diacetylenic alcohols is higher. Interesting reports have been published[213-216] about acetylenic carbinols as fungicides. Compounds having the general formula R–C≡CCXCH=CH–R′ (L), where R = phenyl or naphthyl and X = H or OH, are active against moulds on plants[213].

Fungistatic activity is also shown by alcohols with a short chain having a phenyl substituent adjacent to a triple bond[77,123]. The introduction of a double bond into short-chain primary alcohols in a position which results in conjugation with the triple bond enhances the fungistatic activity, particularly if the phenyl substituent and the triple bond are at the end of the molecule. The vinylacetylenic carbinol (LI) exhibits fungistatic activity; the same properties are also shown distinctly by the secondary alcohol (LII), in which the double bond is not conjugated with the triple bond, occupying the $\alpha\beta$-position relative to the carbinol carbon:

$$\underset{(LI)}{C_6H_5{-}C{\equiv}C{-}HC{=}CH{-}CH_2OH}\ ;$$

$$\underset{(LII)}{C_6H_5{-}C{\equiv}C{-}CH\,(OH){-}CH{=}CH{-}C_6H_5}\ .$$

Symmetrical acetylenic and diacetylenic glycols show a very insignificant fungistatic activity, while the asymmetric compounds are more active fungicides. The biological activity apparently depends on the effect of the functional groups on the polarisation of the triple bond[11,77,123]. By varying the structural fragments in the molecule (in order to find highly active water-soluble antimycotics), it was shown that the hydroxy-group in acetylenic ketones removes the irritant effect, increases somewhat the solubility of the compounds in aqueous media, and hardly alters the antifungal activity[35,80,86,131,136]. The antifungal activity of acetylenic ketoacid esters (XL)

$$n\text{-}C_4H_9C{\equiv}C{-}CO\,(CH_2)_3\,COOMe$$

disappears when hydroxy-groups are introduced into their molecules[95].

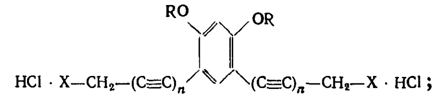
5. Nitrogen-containing Acetylenes

The presence of the amino-group as a rule increases the biological activity of acetylenic compounds[11,76,107,123,217,218]. The spectrum of the pharmacological activity of acetylenic amines is broad, but there have been no comprehensive and specific studies of the biological properties of acetylenic amines.

Data have been published recently on the antifungal activity of aminomethyl derivatives of aryl- and heteryl-acetylenes (LIII) with regularly varying structures[219-220]:

$$Ar\,(C{\equiv}C)_n\,H + HCHO + HNRR' \xrightarrow{CuCl} \underset{(LIII)}{Ar\,(C{\equiv}C)_n\,CH_2NRR'}\ .$$

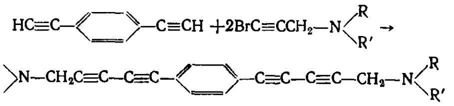
Kotlyarevskii and coworkers[219-223] investigated systematically the spectrum of the biological activity of amino-derivatives of arylpoly-ynes (LIV):



(LIV)

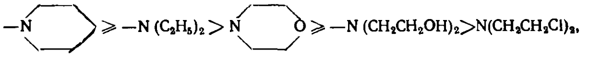
X = amine.

Conditions were found for the aminomethylation of diacetylenic compounds in which the main products are either monoamines or diamines. A monoamine may be used to obtain mixed diacetylenic diamines for oxidative dimerisation to tetra-acetylenic diamines or for the formation of triacetylenic diamines (LV)[223]:



(LV)

The majority of the compounds tested exhibit a pronounced bacteriostatic activity in relation to acid-resistant bacteria. The structures of the aromatic, acetylenic, and amine fragments influence appreciably the efficiency of their action. The introduction of an electron-donating substituent (CH_3O, CH_3) into the benzene ring and the increase of the degree of unsaturation of compounds (LIII, $n = 2$) result in an increase of biological activity. A further increase of the number of acetylenic groups ($n > 2$) results in a sharp decrease of activity. As the structure of the amine component of the molecule is varied, the antibacterial activity diminishes in the sequence

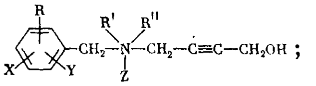


apparently in parallel with the decrease of the basicity of the amines[219]. It is of interest[84,134] that, among aryl-substituted aminoacetylenic compounds (LIV), amines with a single triple bond in each aliphatic chain are active against fungi. The introduction of the second triple bond into any aliphatic chain leads to the disappearance of activity.

The amino-group can form salts and, like the carboxy-group, may increase the solubility of the preparations in water[35,83-87,118]. In many cases this ionogenic fragment is introduced into the molecule by the Mannich reaction in accordance with the general mechanism

$$RC{\equiv}CH + CH_2O + HNR_2 \rightarrow RC{\equiv}C{-}CH_2NR_2 \quad .$$

In order to synthesise water-soluble antifungal preparations, certain derivatives of furan with functional groups[83], propargyl ethers derived from phenol and β-naphthol[118], a series of terminal acetylenic derivatives of bicycloheptane[85,203,204], and aryl- and heteryl-acetylenes[84,222] were aminomethylated. A series of quaternary ammonium compounds (LVI) exhibiting antifungal activity have been obtained by the quaternisation of tertiary amines[217]:



(LVI)

R', R'' = Alk; R = Alk (8-16 C atoms);

X, Y = CH_3, C_2H_5;

Z = salt-forming anion .

By employing a fungicidal solution (0.001%) of the hydrochloride of [1,4-bis-(2,4,6-trichlorophenoxy)-2-butynyl]dimethylamine and decahydroquinoline in the treatment of the *Verticillium* wilt of the cotton plant, an appreciable improvement of the crop was achieved[118].

Certain acetylenes whose structure incorporates a nitrogen-containing heterocycle are powerful antimycotics[208,209,224]. Thus 5-(3-iodopropargyloxy)-2-methylthiopyrimidine[209] is active (0.1–20 mg $litre^{-1}$) even against yeast-like fungi. It is noteworthy that the structures of these antimycotics frequently include the hydroxypropargyl fragment[208,209].

6. Acetylenic Hydrocarbons

Only a few poly-ynes with conjugated triple bonds have been investigated hitherto as antimicrobial preparations[77,123,225]. Apparently there is a relation between the number of conjugated triple bonds and antibiotic activity, but its nature is insufficiently clear[77].

Aliphatic hydrocarbons in which the triple bonds occupy the 1-ω-position exhibit a very weak antimicrobial activity[123]. In certain cases[226,227] halogeno-derivatives of hydrocarbons are highly active fungistatic agents. Halogenoalkynes are used to protect fruit from rotting. It may be that the biological effect of the most active iodoalkynes is to some extent due to the action of iodine[77,227].

In conclusion one should note that quantitative data on the antibiotic activities quoted by various authors do not always agree. This can probably be accounted for in the first place by the lack of standard strains (owing to the wide occurrence of cultures of microorganisms adapted to antibiotics) and in the second place by the lack of a sensitive method for the determination of the minimum inhibiting concentrations. Despite its approximate and fragmentary nature, the available information about biological activity make possible not only a qualitative but also a quantitative assessment of many compounds and assists in discovering specific relations. Although screening has not as yet become obligatory for all acetylenes with functional groups, interest in these compounds and the development of methods of synthesising them are to a large extent related to the prospect of investigating their biological properties[35,36,43,76-80,83,85,87]. However, biological tests are frequently episodic in character or are replaced by *a priori* guesswork.

Despite the considerable interest in the class of acetylenic antimycotics, the problem of their activity is largely considered at the level of *in vitro* tests. The decisive factor in the solution of the problem of the possible employment of this class of antimycotics as therapeutic agents is *in vivo* tests. Such studies are a problem for the future, although individual reports on this topic have already been published[25,35,85-87,99,135]. Since material costs are not the dominant factor in the study of drugs, the employment of acetylenes in this field is likely to be still greater in the future.

The Effect of Ionising Radiation on Dissolution Processes

V.V.Gromov

The influence of various effects associated with the preliminary exposure to ionising radiation (γ-quanta, accelerated electrons, heavy particles) of a solid during its dissolution in aqueous media is analysed, particular attention being devoted to the relation between the rate of dissolution and the radiation-induced charge on irradiated and radioactive substances.
The mechanism of the intensification of the dissolution process when the entire solvent-solid system is irradiated is analysed in relation to the dissolution of uranium oxides in sulphate and carbonate solutions. Procedures involving the employment of ionising radiation for the regulation of the rate of dissolution of solids are considered.
The bibliography includes 105 references.

I. INTRODUCTION

In many technological schemes dissolution is one of the principal operations which limits the economic parameters of the entire process. For this reason, the search for methods of improving the technology of the dissolution process is being prosecuted continuously. In this sense ionising radiation may be a very effective means of intensifying the dissolution of solids under certain conditions. However, despite the undoubted importance of the study of the influence of ionising radiation on the transfer of various substances to the liquid phase, until recently no systematic research in this field has been made.

The first report, by Simnad and Smoluchovski[1], concerning the considerable increase of the rate of dissolution of iron(III) oxide in hydrochloric acid after irradiation of the oxide with protons having an energy of 260 MeV was published in 1955. After this, the efforts of investigators were for a long time concentrated on the study of the radiation-stimulated corrosion and dissolution of various metals and alloys, which was dictated, and is still dictated, by the requirements of "atomic technology".[2]

Various crystalline inorganic salts remain virtually uninvestigated. These include alkali metal halides and numerous oxyacid salts, many of which are widely used in the processing of nuclear materials[3]. The present review is in fact devoted to the dissolution of inorganic salt crystals which have been irradiated with γ-quanta, electrons, and heavy particles. Analogous examples involving metals and organic substances are quoted only as an illustration in the description of the main results[3]. One should note that no reviews have been published hitherto on the effect of ionising radiation on the kinetics of the dissolution of crystalline inorganic compounds. In the present survey an attempt is therefore made to discuss certain aspects of this complex phenomenon, to give a systematic account, to analyse critically the results obtained, and to outline the likely future use of ionising radiation for the regulation of dissolution processes.

The intrinsic mechanism of the dissolution of various simple and complex substances is not considered. It is assumed that the reader is familiar with this problem, which is dealt with in specialist publications[4-6].

II. THE INFLUENCE OF DISSOLUTION CONDITIONS ON THE EFFICIENCY OF THE ACTION OF IONISING RADIATION

The first report about the influence of γ- and X-radiation and of a stream of neutrons on the dissolution of ionic crystals was published as late as 1961.[7] The authors were able to show that the rate of dissolution of sodium chloride after irradiation is a structure-sensitive factor and depends on the nature and concentration of radiation-induced defects. Subsequently this type of research was extended to the accumulation of quantitative data concerning the influence of radiation on the dissolution of crystalline substances in water and aqueous solutions. It was found that the radiation effect depends to a large extent on the dissolution conditions.

Two regions in the dissolution process are usually distinguished: the diffusion region, regulated by processes involving the transport of material in the liquid phase, and the kinetic region, in which the rate of dissolution depends in many aspects on the properties of the solid[4,5]. It is known that, for the majority of ionic compounds, the stage involving the interaction of the solvent with the ions located on the surface of the solid takes place almost instantaneously and the rate of dissolution is determined by diffusion processes in solution. In this case the influence of radiation-induced defects may be obscured, since mass transfer in the liquid phase is the slowest stage in the dissolution process. However, for a whole series of compounds (with low and sparing solubilities) the transition of salt ions into the solution is fairly slow and the process as a whole depends on the rate of interaction of the solvent with the solid, i.e. on its nature and structure, and evidently on the presence of radiation-induced defects (if these exist).

The distinctive features of the heterogeneous dissolution process controlled by diffusion are as follows:

(1) dependence of the rate of the process on the rate and direction of motion of the solvent;

(2) dependence of the rate of dissolution on the diffusion coefficient and the viscosity of the liquid in the boundary layer at the surface of the solid in which the dissolved substances or reaction products accumulate;

(3) comparatively low temperature coefficients of the rate of dissolution.

Non-diffusional dissolution (kinetic region) has the following characteristic features:

(1) as a rule relatively low absolute dissolution rate constants (K_v);

(2) invariance of the dissolution rate constant K_v for different rates of stirring;

(3) rapid increase of the coefficients for the rate of dissolution v with temperature.

The above features permit the conclusion that in the kinetic region the transfer of the molecules (ions) of the solid to the liquid phase is determined by the chemical interaction of the compound undergoing dissolution with the solvent. Under these conditions, the dissolution rate constant is in fact a structure-sensitive quantity, whose value is determined by the properties of the solid, such as the type of bond between the crystal lattice elements, the number and nature of the defects, the lattice energy, the type of crystal structure, etc. Naturally dissolution under these conditions is of greatest interest for the study of the influence of radiation-reduced defects on the transfer of ions or molecules or solids to the liquid phase.

The initial postulate of the modern theory of dissolution is the recognition of the existence of a boundary layer of solution at the surface of the solid with composition different from that corresponding to the state of saturation. Accordingly, the equation for the rate of dissolution of the majority of compounds in water can be expressed as follows[4]:

$$\mathrm{d}c/\mathrm{d}t=\frac{\gamma D}{D+\delta\gamma}\,S\,(c_0-c_t)^n\,, \tag{1}$$

where D is the diffusion coefficient, γ the rate coefficient of the interfacial process, δ the effective thickness of the boundary layer, S the surface area of the compound undergoing distribution, n the order of the dissolution reaction, c_0 the solubility of the given compound, and c_t the concentration of the given compound in solution at time t. It is readily seen from Eqn. (1) that the dissolution rate constant corresponding to a constant volume of the liquid phase is defined by the expression

$$K_v=\frac{\gamma D}{D+\delta\gamma}\,. \tag{2}$$

The order of the dissolution reaction in water is normally unity for the vast majority of compounds. Depending on the relation between the empirical coefficient γ and D/δ, a real dissolution process can have a diffusional or kinetic (interfacial) mechanism. In the latter case the entire process is determined by the kinetics (mechanism) of the interaction of the solvent with the surface of the solid. In conformity with these ideas, three main types of dissolution are possible:

(1) Purely diffusional: $\gamma \gg D/\delta$, i.e. $K_v \to D/\delta$ (diffusional region of the dissolution process);

(2) purely kinetic: $\gamma \ll D/\delta$, i.e. $K_v \to \gamma$ (kinetic region of the dissolution process);

(3) diffusion-kinetic region of the dissolution process, characterised by comparable rate coefficients for the interfacial and diffusion processes: $\gamma \simeq D/\delta$.

Usually the transition to the kinetic dissolution conditions is attained by increasing the rate of stirring of the liquid phase. The concentration difference between the surface layer and the bulk of the solution then becomes insignificant and diffusion processes may be neglected. One should also note that under industrial conditions it is more convenient to carry out the process in the kinetic region, since the removal of the substance undergoing dissolution into the bulk of the solution as a result of the motion of the liquid is then faster than in the diffusional region.

In the study of dissolution processes, experimental problems are of primary importance. Particular attention must be devoted to the reproducibility of the hydrodynamic experimental conditions. Failure to meet this requirement leads to considerable discrepancies between the results even in a series of seemingly identical experiments. Virtually any defects in crystal structures influence the rate of transfer of the ions from the solid to the liquid phase under kinetic dissolution conditions, where the rate limiting stage is the interaction of the species of the solvent and the solid. For example, it has been shown[7] that, when NaCl crystals irradiated with X-rays are dissolved, the effect of radiation is not manifested in any way under diffusional conditions, being appreciable only under kinetic conditions. In experiments with irradiated crystals it is therefore necessary to make sure in the first place that the process proceeds via a diffusional mechanism.

In the study of the role of radiation-induced defects in the dissolution of salts experiments are usually performed with a limited amount of solvent, i.e. under conditions where Eqn. (1) is valid. The rate of dissolution, i.e. the variation of the quantity dc/dt with time, dose, intensity of irradiation, and other parameters is selected as the structure-sensitive characteristic. The majority of conclusions concerning the influence of irradiation on dissolution have been reached precisely by studying the dependence of v on the magnitude of the effects of radiation. However, the rate of dissolution is not a fully reliable criterion of the given process, because it depends [see Eqn. (1)] on the surface area of the crystals and very frequently also on their shape and the micro-relief of the crystal faces.

Even in the kinetic region, v depends strongly on the concentration of the substance undergoing dissolution in the liquid phase (apart from the dependence on S). Furthermore, in the initial stage of the process the rate of dissolution is frequently affected by different random factors, which are difficult to control. With increase of the concentration of the dissolved substance in the liquid phase, the accuracy of the determination of c_t diminishes. As a result of all these factors, the conclusions reached on the basis of the variation of v ultimately become to a large extent qualitative.

A more objective parameter, which characterises the dissolution of the solid, is evidently the dissolution rate constant, which is independent of the variation of the surface area of the crystals during dissolution†.

If it is desirable to obtain a more rigorous relation between the nature and concentration of the radiation-induced defects and the dissolution of the irradiated specimen uncomplicated by the influence of "structure-surface" factors, it is necessary to determine the values of K_V.[8]

It should be noted that, when v_{irr} and $v_{non\text{-}irr}$ are compared, a case may be encountered where the rates of dissolution of the same specimen differ in magnitude but change to the same extent under the influence of irradiation. Naturally the ratio $v_{irr}/v_{non\text{-}irr}$ will then differ from unity and on this basis it would seem possible to conclude that the point defects generated by irradiation affect the entire process[7,9,10]. However, under these conditions K_V does not change, since it is determined from the slope of the curves relating v/S_t to $c_0 - c_t$.

When $v_{irr}/v_{non\text{-}irr}$ changes, all the observed effects may be associated with the breakdown of the surface structure, a change in the surface area, micro-cracking or sintering, etc. If K_V is determined, all the surface effects are usually excluded and the relation between (the number of) radiation-induced point defects and the rate of dissolution of the irradiated crystal is revealed in a pure form, since the dissolution rate constant characterises the number of species of the solid abstracted under the influence of the solvent per unit surface and per unit time.

Furthermore, attention must also be drawn to the influence of the concentration of the dissolved salt in the liquid phase c_t, which affects dc/dt according to Eqn. (1).

The choice of the method and the conditions for the dissolution of the given compound after its irradiation are determined by the fact that point (and linear) defects generated by the radiation are manifested most effectively at low rates of dissolution[14-18]. This is because, for high rates of the given process, the entire surface of the solid in contact with the solvent is "operative" (the influence of the defects is blurred) and, for low values of v, the dissolution takes place at the weakest site—at the defects whose linkages with the crystal matrix are deformed[12-18].

If in the study of dissolution kinetics it is necessary to detect fine effects associated with structural changes in the crystal, one must carry out experiments with low rates of dissolution. For readily soluble salts, this can be achieved using virtually saturated initial solutions[11-13]. Under these conditions, dc/dt varies very strongly even when the crystal structure is altered only slightly. For sparingly soluble compounds, there is no such limitation on the concentration of the solvent.

For example, experiments have been carried out[11-13] with NaCl, KCl, KBr, LiF, and KI in almost saturated solutions, where dc/dt was low and the dissolution did not occur from all the surface points behaving as single "active centres", but only at sites where defects accumulated. Using this method, it was possible to detect many side effects in the dissolution of irradiated crystals.

III. DISSOLUTION OF COMPOUNDS IRRADIATED WITH HEAVY PARTICLES

All the known defects in crystal structures (point, linear, two-dimensional, or three-dimensional defects) may be formed as a result of the irradiation of solids by a particular type of ionising particle.

The displacement of atoms in the crystal lattices of solids is one of the main effects of bombardment by heavy particles (neutrons, protons)[19]. Naturally this is accompanied by ionisation and excitation processes with formation of various "electronic" defects with all subsequent transformations of the kind occurring on γ-irradiation.

The relation between electronic defects and their complexes and dissolution processes has been shown experimentally to be very complex and it is extremely difficult to predict beforehand the nature of their influence on the rate of dissolution. The role of the displacement of atoms, which facilitates the transfer of the ions of the solid to the liquid phase as a result of the weakening of the bond between the displaced atom and the crystal lattice, is clearer. One should also bear in mind that the influence of the same type of defects on the properties of solids of different kinds may differ sharply. The main effects in

---

† However, K_V may depend also on the surface relief. It is therefore more correct to compare the values of K_V for specimens with identical surface topographies.

metals are linked with the displaced atoms. On the other hand, for ionic crystals, electronic defects are of decisive importance.

The macrodefects in the structure of the surface of the irradiated crystals have a considerable influence on the dissolution, such defects including evaporation pits, growth projections, radiation-induced cracking, and partial fusion of rugosities, which is observed both on irradiation with electrons[20-23] and on bombardment with heavy particles[24-27]. One should note that irradiation does not always create an excess concentration of defects. It sometimes happens that, following radiation annealing, the crystal actually becomes more perfect owing to the decrease of the number of "biographical" defects[19]. Furthermore, the concentration and nature of radiation-induced defects arising on storage of irradiated crystals usually change gradually as they interact with one another. There is a simultaneous alteration also in the properties of the given specimen. Consequently, dissolution may in some cases be accelerated after a given specimen is acted upon by radiation, while in others the dissolution of the same specimen may be retarded. This has in fact been observed experimentally.

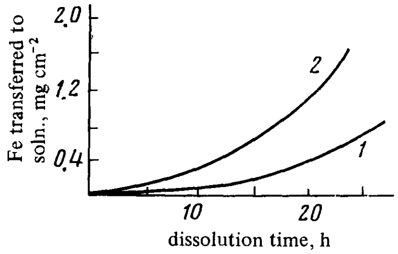

Figure 1. The rate of dissolution of Fe_2O_3 in 1 N HCl after irradiating the oxide with protons[1]: 1) non-irradiated specimen; 2) irradiated oxide; temperature 30°C.

Bombardment with neutrons or any accelerated heavy particles, which causes profound and persistent structural changes in the crystal lattice, has the greatest influence on the dissolution process. The first studies of radiation-kinetic effects on dissolution were instructive in this respect. Thus, Simnad and Smoluchovski[1] irradiated the oxide Fe_2O_3 with a stream of accelerated protons having an energy of 260 MeV, the density of the overall stream of protons reaching 10^{16} proton cm^{-2}. After irradiation, the oxide was dissolved in 1 N HCl solution and the liquid phase was analysed for iron by the periodic sampling method (Fig. 1). Fig. 1 shows that the irradiated oxide dissolves faster than the non-irradiated oxide. Such an increase in the rate of transfer of iron to the HCl solution can be explained by the appearance of a large number of bulk-phase defects (vacancies, displaced atoms, thermal peaks) as a result of the action of protons on the Fe_2O_3 crystal lattice. According to the authors[1], the characteristic change in the rate of dissolution as the latter proceeds is determined by two factors: the depletion of the surface in defects owing to their recombination, a greater ease of their diffusion in the surface region towards the interface (the loss of defects), and the gradual dissolution of the surface layer, which exposes the more damaged regions of Fe_2O_3. For this reason, an induction period is observed in the dissolution process.

The above publication was followed by a number of communications concerning the influence of irradiation with heavy particles on the rate of dissolution of purely ionic crystals in which not only the experimental results are described, but also an attempt is made to relate the observed effects to the formation of radiation-induced defects of a fully defined type.

A study has been made[10] of the dissolution of alkali metal halide crystals (NaCl, KCl, KBr) in their aqueous solutions after irradiation of the specimens with neutrons. Neutrons from an Ra–Be source were used. The most interesting result is the dependence of the quantity $v_{\mathrm{irr}}/v_{\mathrm{non\text{-}irr}}$ not only on irradiation but also on the duration of storage of the specimens after bombardment with neutrons before the start of dissolution (Fig. 2). The authors[10] suggest that, during the storage of the irradiated crystals (at 20°C), processes involving the thermal annealing of defects take place, which decreases the rate of dissolution. Furthermore, there is a possibility of the formation of new types of defects owing to the interaction of the primary defects, which leads to the stabilisation of the NaCl structure and a decrease of $v_{\mathrm{irr}}/v_{\mathrm{non\text{-}irr}}$. Unfortunately, the authors[10] did not put forward any hypothesis concerning the relations between v and a definite type of radiation-induced defect, and the irradiation conditions do not allow an exact determination of the integral neutron flux; no account is taken of the influence of γ-quanta accompanying the bombardment with neutrons either. However, in the above study a negative effect of neutron bombardment on the rate of dissolution was established for the first time and it was stated that the nature of the defects may have a decisive influence on the rate of transfer of the species from the solid to the solution. Further studies on these lines showed that the sensitivity of the rate of dissolution to irradiation with neutrons depends to a large extent on the type of crystal face. Anisotropy of the effect of radiation is characteristic of virtually all alkali metal halides. For example, the (100) face is most sensitive in KCl and NaCl crystals, while dissolution of the (110) and (111) faces proceeds at the same rate both before and after irradiation with neutrons (integral flux of 1 × 10^8 cm^{-2}).[10] One cannot rule out the possibility that this is associated with differences in the packing density of ions on the crystal faces, which leads, according to Naumov and Savintsev[12], to the following experimental relations between v on the crystal faces and the relative unsaturation of the solutions σ [σ is expressed as a fraction or as a percentage and is equal to $(c_0 - c_t)/c_0$)]:

$$v_{(110)} = R_1\sigma^{1.18}, \tag{3}$$

$$v_{(100)} = R_2\sigma^{1.65}, \tag{4}$$

where R_1 and R_2 are constants.

Interesting results for the influence of bulk-phase defects on the rate of dissolution were obtained by the above workers[12]. A layer 50 μm thick ("etching" with water) was removed before dissolution from KCl, NaCl, KBr, and KI crystals irradiated with the neutrons from an Ra–Be source and also with protons (E_{p} = 4.5 MeV, the intensity of the proton beam was 6 × 10^{10} proton $cm^{-2}s^{-1}$), which made it possible to disregard the macrodefects on the faces caused by bombardment with heavy particles. This was followed by the dissolution of the crystals. Neutron bombardment was accompanied by irradiation with γ-quanta having an energy of approximately 2 MeV, the crystals being exposed to a dose of 1.8×10^4 r. The energies of the protons and the neutrons were approximately the same and amounted to about 4 MeV. Experiments showed that, for large doses of heavy particles, the rate of dissolution, particularly under the conditions of low unsaturations, increases appreciably. The ratio $\nu_{irr}/\nu_{non\text{-}irr}$ decreases with increasing dilution of the solution (with increase of σ) and the influence of irradiation with heavy particles gradually becomes inappreciable. Irradiation with protons leads to a very marked increase in the rate of dissolution throughout the structure-sensitive region even for doses of the order of 10^{14} proton cm^{-2}.

Crystals such as those of LiF, the rate of dissolution of which is low, dissolve in pure distilled water ($\sigma \simeq \infty$) much more rapidly than the non-irradiated crystals, and a small change in the experimental temperature does not affect the nature of this relation. However, no hypothesis has been made concerning the relation between the change in ν_{irr} and the type of radiation-induced defects[12].

The increase in the rate of dissolution as a function of defects such as displaced atoms, dislocations, thermal peaks (wedges), etc. is more definite. For example, the density of dislocations in neutron-irradiated KCl crystals has been determined by an etching method[28] and it was found that immediately after irradiation the density of dislocations increases by a factor of 2.5 (to 7×10^5 cm^{-2}). Next, the number of dislocations decreases smoothly during storage at room temperature in accordance with the curve equivalent to the variation of $\nu_{irr}/\nu_{non\text{-}irr}$ for the same crystals (Fig. 2).

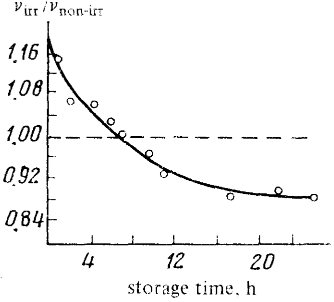

Figure 2. Dependence of the ratio of the rates of dissolution of irradiated and non-irradiated NaCl crystals on the duration of storage of the specimen at room temperature[10]. Solvent—25.85% solution of NaCl in water; integral neutron flux ~ 10^{11}–10^{12} neutron cm^{-2}.

An increase of ν_{irr} with increase of the integral flux of heavy particles was observed in all the systems investigated, and for equal fluxes the effect was greater for heavier particles. However, these conclusions are to a large extent qualitative, since neutron bombardment was always accompanied by intense γ-radiation, the influence of which was disregarded. Furthermore, even for equal integral fluxes and neutron and proton energies, the densities of the defects generated by these two types of radiation were different. Unfortunately, the concentration of even the total number of defects was not estimated. If this had been done, it would have been possible to compare the effects of neutrons and protons.

Naumov and coworkers[10–12] showed clearly for alkali metal halides that, under identical conditions, the greatest increase in the rate of dissolution is observed for crystals with the highest crystal lattice energy. This very important experimental fact can be used for the qualitative estimation of the influence of radiation on the dissolution process.

An increase in the rate of dissolution has been observed for the oxides Al_2O_3 and NiO and for mica[29] irradiated with accelerated krypton ions. The energy of the ions varied within a wide range (5–100 keV) and the integral fluxes were 5×10^{12} and 5×10^{13} cm^{-2}. The solvents were 3% HF for mica, NaOH solution for Al_2O_3, and concentrated HNO_3 for nickel oxide. The observed effect was attributed wholly to surface macrodefects on the irradiated specimens. This explanation appears to be quite likely, because krypton ions were absorbed by a thin layer of the test specimens, which made the surface amorphous, facilitating dissolution[29].

Table 1. Variation of the surface areas of solids as a result of exposure to neutrons and γ-quanta[30].

Substance	Type of radiation	Dose of No. of particles	Change in specific surface, % (the minus sign indicates a decrease and a plus sign indicates an increase)
TiO_2	γ	$1 \cdot 10^{22}$ eV g^{-1}	—15
C	neutrons	$7 \cdot 10^{19}$ neutron g^{-1}	0

It is not always possible to attribute the radiation-induced changes in the rate of dissolution solely to the effect of radiation on the structure and the surface area. For example, a study has been made[30] of the dissolution of oxides irradiated in a nuclear reactor in various media (H_2SO_4, HCl, NaOH). Measurements were made of the surface areas of the irradiated systems (Table 1) and it was found that, as a result of atomic displacements, thermal peaks, and sintering, the surface changes appreciably after irradiating the test specimens in the atomic reactor. Apart from all other factors, this process depends on the properties of the specimen: porosity, moisture content, degree of dispersion, and even the type of radiation-chemical reactions in the specimen. As a rule, the surface area decreased under the influence of irradiation with heavy particles. However, in these experiments[30] it was impossible to establish a clear relation between the changes in the rate of dissolution and the surface area.

Nevertheless in individual instances the role of the radiation-induced changes in the surface is shown quite clearly. Thus a study of the rate of transfer of uranium to the liquid phase when U_3O_8 irradiated with neutrons interacts with 0.1 *N* H_2SO_4 solution showed that the decisive factor in this process is the damage of the surface structure of the oxide[31], which causes complete surface amorphisation for integral fluxes in excess of 10^{17} neutron cm^{-3}.[32] Under these conditions, the rate of dissolution of the oxide increases. Fig. 3 shows that, for the doses investigated, there is an increase in the rate of transfer of uranium to the solution. There is a distinct difference in the behaviour of the irradiated and non-irradiated U_3O_8. One should note that the radiation-chemical decomposition of U_3O_8 under the influence of neutrons was scarcely observed, so that the solubility of this oxide in H_2SO_4 remained constant. This led to a gradual mutual approach of the dissolution curves for the irradiated and non-irradiated specimens, as the saturated solution was formed and the damaged surface layers dissolved. The time required for the equalisation of concentrations was approximately 10 days.

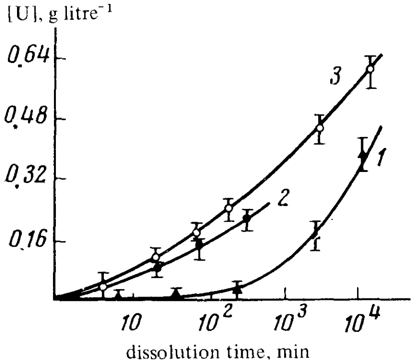

Figure 3. Kinetics of the transfer of uranium to the solution from neutron-irradiated U_3O_8: 1) non-irradiated U_3O_8; integral neutron flux (neutron cm^{-2}): 2) 1.2×10^{16}; 3) 1.2×10^{17}; temperature 30 ± 1°C.[31]

Table 2. The rate constants for the dissolution in water of various strontium sulphate specimens[33].

Specimen	$K_v = 10^7$ cm^{-2} s^{-1}
Non-irradiated	6.0
Irradiated with γ-quanta, dose 10^{20} eV g^{-1}	4.6
Irradiated by reactor radiation, 1×10^{18} neutron cm^{-2}	7.1
Radioactive crystals (50 mc of ^{35}S per gram of salt)	2.1

All the above examples involving crystalline compounds irradiated with neutrons are to some extent indefinite, since the contribution of the γ-quanta accompanying the neutron bombardment from any source was completely ignored in these experiments. In this respect the data of Gromov and Bespalova[33] throw some light on the problem, because they determined for the same object ($SrSO_4$ crystals) the influence of the mixed neutron and γ-radiation of the reactor, the separate effect of the γ-quanta from a cobalt source, and pure β-radiation (radioactive crystals) (Table 2). It was found that γ- and β-radiations retard the dissolution of strontium sulphate in water, while bombardment with neutrons accelerates it. Bearing in mind that neutrons and γ-quanta are active simultaneously in an atomic reactor, the acceleration of the dissolution process owing to the neutron flux alone is in fact much greater. One cannot rule out the possibility that neutrons, which cause very appreciable structural damage in the crystals, always promote dissolution. However, their influence may be masked and even completely suppressed by effects associated with the γ-radiation and the decrease of the surface area (see Jech and Kelly[29]), which was disregarded in the majority of investigations.

Summarising the discussion of the available experimental data, one may conclude that defects of the type of displaced atoms, dislocations, displacement zones, and interstitial atoms, which are very effectively generated on bombardment of the crystals with heavy particles, as a rule promote a more vigorous dissolution of the compounds.

IV. RELATION BETWEEN THE RADIATION-INDUCED DEFECTS AND THE DISSOLUTION OF COMPOUNDS IRRADIATED WITH γ-QUANTA AND ELECTRONS

In the first studies of the influence of X- and γ-rays and accelerated electrons on the kinetics of the dissolution of ionic crystals the extremely complex dependence of the rate of dissolution on the absorbed dose, on the degree of saturation of the liquid phase by the dissolved salt, and on the duration of storage of the irradiated compounds was already noted[7,9-12,28]. For example, it was found that a change in the concentration of the dissolved salt, even within narrow limits, has a significant influence on the ratio $v_{irr}/v_{non\text{-}irr}$ (Fig. 4). The data illustrated in Fig. 4 refer to the dissolution of NaCl crystals after exposure to X-rays[6]. According to the experimental conditions, the process occurred in the kinetic region of the dissolution reaction (Reynolds number $Re = 4000$). It is of interest to note that the ratio $v_{irr}/v_{non\text{-}irr}$ increases with increase of the NaCl concentration in solution, while the absolute difference between these rates diminishes, approaching zero as saturation is reached. The latter finding shows that the solubility of the irradiated crystals is equal to that of the non-irradiated crystals, i.e. radiation affects only the kinetic characteristics of the interphase interaction between the solid and the solvent.

In order to detect the change in solubility (c_0), which is a thermodynamic parameter, it is necessary to carry out experiments under adiabatic conditions; the energy evolved on dissolution (stored in the crystal during irradiation) then increases the temperature in the system, which affects c_0. Another procedure is evidently possible. The effect of radiation should then be strong enough to cause qualitative changes in the solid phase (the generation of chemical impurities, "fragments" of compounds, etc.), which might affect both the composition of the solution and c_0.

Berzina et al.[10] reached this conclusion in a study of the variation of the rate of dissolution of NaCl, KCl, and KBr crystals in aqueous solutions after irradiation on X-ray apparatus. In addition, they compared the changes in $v_{irr}/v_{non\text{-}irr}$ for the same specimens but different exposure doses (Fig. 5). Fig. 5 shows that, with increase of the radiation dose, the ratio of the linear rates of dissolution increases smoothly, other conditions being equal. Comparison of the data obtained for different salts also made it possible to establish the following empirical rule: if irradiation with X-rays leads to an increase of the rate of dissolution, the observed effect is greater the higher the energy of the crystal lattice of the given substance[10]. This rule holds in practice for a series of similar compounds (Table 3).

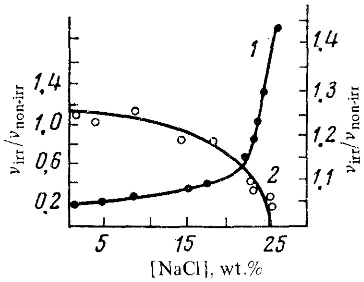

Figure 4. Dependence of the ratio (curve *1*) and the difference (curve *2*) of the linear rates of dissolution of irradiated and non-irradiated NaCl crystals on the salt concentration in solution; temperature 21°C; irradiation with X-rays[7].

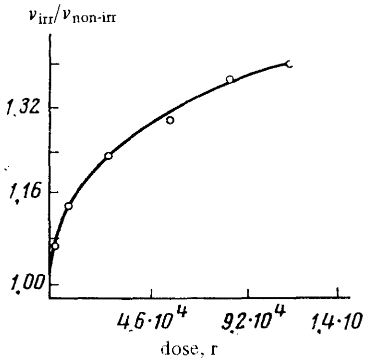

Figure 5. Dependence of the ratio of the rates of dissolution of X-irradiated and non-irradiated NaCl crystals on the dose[10]. NaCl concentration in solution used for the dissolution reaction 26 wt.%; temperature 21°C.

More detailed studies of the influence of X-rays (energy 8 keV) on the transfer of the ions of NaCl, KCl, etc., to the solution as a function of the degree of unsaturation σ have been made[11,12]. Anisotropy in the effect of radiation on different crystal faces was observed and it was established that irradiation not only accelerates, but also retards dissolution in certain ranges of σ. Thus, for a relative unsaturation of the solution less than 0.007, irradiation of an NaCl crystal leads to an increase in the rate of dissolution of the "100" face. When $\sigma > 0.007$, the rate of dissolution of this face is found to decrease, the maximum decrease corresponding to a dose close to 1×10^5 rad. With increase of the dose above 1.6×10^5 rad, the (100) face of the irradiated NaCl crystals then begins to dissolve once more at a higher rate than the non-irradiated face. For irradiated KCl crystals, the corresponding critical relative unsaturation resulting in a change in the sign of the effect of radiation on dissolution is $\sigma = 0.005$.

Table 3. Variation of the relative rates of dissolution on the (100) face of various X-irradiated alkali metal halide crystals (dose 1.2×10^5 rad).[12]

Crystal lattice energy, kcal mole^{-1}	Compound	Relative unsaturation σ					
		0.003	0.006	0.009	0.012	0.015	0.018
180	NaCl	1.65	1.10	0.90	0.90	0.90	0.93
164	KCl	1.15	0.97	0.83	0.78	0.76	0.82
158	KBr	1.06	0.99	1.00	1.00	1.00	1.00
149	KI	0.94	1.00	1.00	1.00	1.00	1.00

This complex relation between the rate of dissolution of the crystal face, the relative unsaturation of the solution, and the irradiation dose can be explained, according to the authors[11,12], by the fact that different structural defects in the crystal lattice affect the rate of dissolution of the irradiated compound to different extents (and sometimes in the opposite way). The above features are characteristic of the dissolution of the (100) face only, while along the other directions, (110) and (111), NaCl, KCl, and other alkali metal halide crystals are insensitive to the action of radiation[13].

The retardation of the transfer to the liquid phase of the ions of different substances irradiated with electrons, observed by many workers, is probably a fairly general phenomenon, which is frequently encountered. The same effect was noted for the dissolution of γ-irradiated uranium oxides U_3O_8 and UO_3 in sulphuric acid[31,34]. One cannot rule out the possibility that this type of action of γ-quanta can be accounted for by the radiation annealing of biographical defects owing to their recombination with the radiation-induced defects of opposite sign (for example, a vacancy and an atom in the interstices) generated under these conditions. The crystal then, as it were, becomes more perfect[35].

The first attempt to establish a relation between the change in the rate of dissolution of irradiated crystals and the concentration of defects of a particular type was apparently undertaken by Gromov and Bespalova[33], who investigated the influence of γ-quanta on the dissolution of strontium sulphate crystals in water. It was found that, with increase of the absorbed dose (regardless of the dose rate), the dissolution rate constant decreased smoothly to a constant value. For example, K_V for the non-irradiated salt was 6×10^{-7} cm^{-2} s^{-1}, while its minimum value (obtained for a dose of approximately 10^8 rad) was 3×10^{-7} cm^{-2} s^{-1}. Special experiments showed that electronic defects, i.e. holes and electrons localised at biographical defects, consisting mainly of the radical-ions SO_4^- and SO_3^- as well as e^-_{st} (the amount of SO_4^- exceeded that of SO_3^- almost by a factor of 10), are mainly formed in $SrSO_4$ under the influence of cobalt-60 γ-quanta[36-39]. The displacement of atoms and even more so of dislocations does not occur under these conditions. This facilitates the determination of the relation between the concentrations of definite radiation-induced defects and the rate of dissolution.

It was found that K_V decreases with increase in the concentration of SO_4^-, SO_3^-, and e_{st}^- (Fig. 6), i.e. there is a definite correlation between K_V and the number of electronic defects R. Without analysing the mechanism of the influence of the above defects on the transfer of Sr^{2+} and SO_4^{2-} ions to the liquid phase and solely on the basis of experimental data, the authors[33] represented the dissolution rate constant in the following form:

$$K_v = K_0 + K_{irr}, \tag{5}$$

where $K_{irr} = f(R)$, while K_0 is a constant. Bearing in mind that K_{irr} decreases exponentially with increase of the amount of R (Fig. 6), it is easy to obtain the final formula in the following form:

$$K_v = K_0 + K_1 \cdot \exp(-\alpha\,[R]), \tag{6}$$

where K_1 is a constant and α an empirical parameter with the dimensions particle^{-1}. When $[R] = 0$ (no irradiation), we have $K_V = K_0 + K_1$; when $[R] = [R]_\infty$ (maximum concentration of defects), we have $K_V \simeq K_0$. The values of K_1 and K_0 are determined from experimental data. The parameter α is found graphically from the slopes of the corresponding curves. Calculations have shown that the proposed formula describes satisfactorily the variation of K_V with the concentration of the radiation-induced defects of the electronic type.

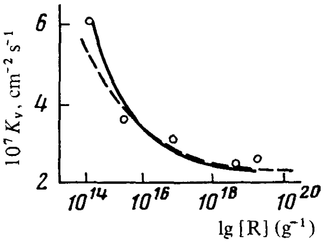

Figure 6. Dependence of the rate constant for the dissolution of $SrSO_4$ crystals on the concentration of defects (R) of the type SO_4^-, SO_3^-, and e_{st}^- in the crystal[33]. The dashed curve represents calculations by Eqn. (6).

Experiments with annealed $SrSO_4$ crystals provided satisfactory evidence for the relation between the decrease of K_V and the increase of the number of electronic defects. It was found that heat treatment at 400° C for 2 h restored the properties of the γ-irradiated specimens and that K_V for such specimens approached the value for the non-irradiated specimens[33]. In the course of this type of annealing, the SO_4^- and SO_3^- radical ions as well as e_{st}^- disappeared from the crystals, as shown by ESR.

The next step in refining the role of structural defects arising on irradiation was taken by Parkhaeva et al.[40] Crystals of natural (celestite) and synthetic strontium sulphate were subjected to the action of a stream of electrons with an energy of 3.5 MeV; the difference between these specimens was determined by impurities (thus the celestite contained approximately 1% of calcium, barium, magnesium, and potassium ions). Furthermore, the natural celestite crystals contained even before irradiation a fairly large number of SO_4^-, SO_3^-, and SO_2^- radical-ions, formed as a result of the β-decay of ^{87}Rb and the permanent level of background radiation. Thus the natural strontium sulphate had a fairly large number of biographical defects (an excess of dislocations cannot be ruled out either), which could serve as sites for the trapping of holes or electrons as well as sinks for the newly formed radiation-induced defects. As a result of irradiation with electrons having such large energies, displaced atoms should be formed in the $SrSO_4$ crystals in addition to the electronic defects and should be capable of stimulating the dissolution process. Indeed it was shown by ESR that in this instance the SO_3^-, SO_2^-, and SO_2^+ radical-ions as well as oxygen in the interstices are formed almost exclusively in the first stages of irradiation (up to 10^5 rad). SO_4^- radical-ions then gradually accumulate as well. Accordingly, the dissolution rate constant initially increases to a maximum and then gradually falls (Fig. 7).

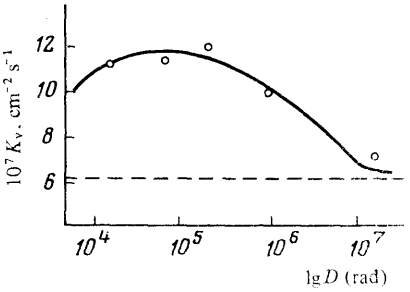

Figure 7. Variation of the rate constant for the dissolution of strontium sulphate as a function of the absorbed dose D after irradiation with fast electrons having an energy of 3.5 MeV. K_V for the non-irradiated crystals is represented by a dashed line[40].

Here there is competition between two types of defects—those which accelerate and those which retard dissolution. The gradual decrease of K_V is probably associated with the accumulation of point defects of the electronic type, in the present instance of SO_4^- and e_{st}^-, while the appearance of displaced atoms promotes dissolution. We may note that, with increase of electron energy to 5 MeV (the number of displaced atoms naturally increases under these conditions), the dissolution rate constant for a dose of ~ 10^5 rad increases approximately by a factor of 1.5 compared with K_V for specimens irradiated with electrons having energies of 3.5 MeV (also for a dose of 10^5 rad).

Extremely interesting results were obtained in a study[41] of the dissolution of γ-irradiated LiF crystals in distilled water containing iron ions. The authors showed that γ-radiation promotes the formation of two-dimensional defects in LiF crystals, which accelerated dissolution of the given salt on the (100) face. This was demonstrated by the appearance of double helices on the face undergoing dissolution, which did not occur in the absence of the radiation. The dissolution figures vanished almost completely and v correspondingly decreased after the annealing of the crystals in the course of 4 h at 550° C.

Summarising the data concerning the influence of γ-radiation and accelerated electrons on the dissolution of ionic crystals, certain conclusions may be drawn. Simple radiation-induced defects created by γ-quanta or accelerated electrons retard dissolution on irradiation under "milder" conditions (primary electronic or hole defects, for example, radical-ions, trapped electrons, etc.). The formation of displaced atoms, vacancies, and linear defects, which weaken the bonds in the crystal lattice and increase its free energy, promote the transfer of ions or molecules of the solid to the liquid phase. The formation of various associations of vacancies and displaced atoms as a result of postradiative processes can also retard dissolution. The sign of the effect of radiation on dissolution rate is therefore frequently reversed during the storage of such crystals.

V. THE INFLUENCE OF THE RADIATION-INDUCED CHARGING OF SOLIDS ON THE RATE OF THEIR DISSOLUTION

One cause of the retardation of the dissolution of irradiated crystals containing simple defects of the electronic type may be the radiation-induced charging of the dielectric crystals[40,42-47]. The appearance of an excess electric charge in irradiated solids was encountered for the first time after the discovery of radioactive elements and their accompanying radiations. Thus in 1900 Pierre and Marie Curie published the results of their experiments on the measurements of the charge of radium-containing barium salts[48]. This in fact has been used widely in the preparation of radioactive current sources (atomic batteries)[49-52].

In atomic batteries the source of radiation is usually surrounded by a weakly conducting medium—vacuum or a solid dielectric. In the latter case a space charge is gradually formed in the layer of the dielectric. The charging of dielectric materials is also observed, when they are irradiated with a stream of accelerated electrons and γ-quanta[51,53-65]. The concept of the charging of the bulk and surface of radioactive preparations has been used quite successfully recently to account for the characteristics of certain physicochemical processes involving the participation of radioactive solids[42,47,66-69].

The conditions for the formation of electric charges in irradiated materials have been fairly thoroughly investigated as a function of their dielectric properties[54,56,70-73]. A general theory of this phenomenon has been devised[51,52,59,61,73,74] and both empirical and theoretical formulae have been proposed, which make it possible to estimate both the magnitude of the radiation-stimulated charge[61,62] and the degree of polarisation of various specimens charged on irradiation[65,72]. A theory has been developed and measurements have been made of the accumulation of electric charges in radioactive crystals of inorganic salts[42,75-77].

Experiments have shown that, regardless of the mechanism of the formation of the radiation-induced charge and its distribution in the bulk of the solid, electric breakdown is observed under certain conditions, which is sometimes accompanied by the appearance of Lichtenberg figures[71,78-80]. This means that an electric field gradient, exceeding the breakdown potential, i.e. $E > 10^4-10^6$ V cm^{-1}, arises within the irradiated specimen. For example, when LiF crystals are irradiated with electrons having an energy of 1–2 MeV, tree-like channels—the tracks of electrical breakdown both during and after irradiation—develop within the crystal (for exposure doses of $1 \times 10^{15}-1 \times 10^{17}$ electron cm^{-2}). At the same time a large number of edge dislocations and particles of colloidal lithium appear along the channels and in the bulk of the crystal. All these features are superimposed on the radiation-induced defects[81]. The absence of electrical breakdown does not imply the absence of an excess of radiation-induced charge in dielectrics which have been irradiated with a stream of ionising particles; charging naturally leads to the appearance of bulk-phase polarisation, which persists for a long time after irradiation ceases.

Despite the fact that the charging of solids and the formation of a radiation-induced charge have been fairly thoroughly investigated, there has been virtually no systematic research concerning the influence of the electric field on the properties of solid specimens, the radiation-induced and radiation-chemical reactions in the latter, and also various heterogeneous processes. However, interesting information about the relation between the charge and properties of solids may be found in individual communications.

The formation of a radiation-induced charge has a marked influence on the kinetics of the formation and distribution of the radiation-induced defects in crystals[21,82], on the electron work function, and on the catalytic properties of solid oxide catalysts[66-68,83]. The influence of the electric field on the chemical and radiation-chemical processes in gases and liquids has been studied in detail (see Tal'roze's review[84]).

There are experimental data (admittedly only qualitative) concerning the appreciable influence of an external electric field and the charging of the solid phase on sorption phenomena in both liquid[47,85,86] and gaseous[68,69,87,88] phases. For example, anions[86] and negatively charged colloidal particles[85] are sorbed more effectively from solutions on positively charged crystals. Consequently the presence of an external electric field in a heterogeneous system, such as a solid–solvent system, or the appearance of excess charge at the interface on irradiation or polarisation alter appreciably the rates of processes involved in dissolution (sorption, crystallisation, orientation or disorientation of molecules at the interface, the rate of their migration in solution, etc.). All these factors make it possible to assume that the dissolution proper should also depend to a definite extent on the electric field in the system. The first experiments carried out on these lines confirmed the above hypothesis[45,46].

The theory of the dissolution of charged crystalline substances (dielectrics) has been most thoroughly developed at the present time. A possible relation between the charging of the crystals and the rate of their dissolution was postulated for the first time by Gromov and Bespalova[89] in a study of the dissolution of radioactive strontium sulphate crystals in water. Direct experiments then showed that NaCl, $SrSO_4$, etc. crystals, polarised by a permanent external electric field, dissolve more slowly than non-polarised compounds[45,90]. The polarisation of the solvent also has a definite influence; for this reason, the change in K_V depends in many respects on the ratio of the dielectric constants of the solid and liquid phases[90]. The intrinsic solubility of compounds is also very important (Fig. 8). Indeed, according to Fig. 8, with increase of the strength E of the field in which the crystals were polarised, K_V for celestite (the solubility of which is lowest among the substances investigated) decreases to the greatest extent. The relative decrease of K_V in series of salts of the same type (NaCl, LiF, NaF) is greater for lithium fluoride—a compound which is less soluble than NaF and which has a higher dielectric constant.

The observed changes in the rate of dissolution can be explained in terms of the general ideas of the dissolution theory and the hypothesis that K_V can be represented in the form of two multipliers, one of which does and one of which does not depend on the polarisation of the crystal[45]. Theoretical analysis of the influence of the charging of the crystals on the kinetics of their dissolution showed that the dissolution rate constant depends in a fairly complex manner on the dielectric properties of the crystal, the surrounding medium, the structure of the double layer at the crystal–solution interface, and the electric field strength within the crystal[45,91]. It has been established[45] that, with increase of the electric field strength in the crystal and for not unduly low bulk-phase concentrations in the liquid phase, K_V diminishes regardless of the sign of the charge localised in the crystal. The essential feature of this influence is that the polarised molecule (dipole) must perform additional work to overcome the electrostatic interaction forces on transfer from the charged specimen to the liquid phase.

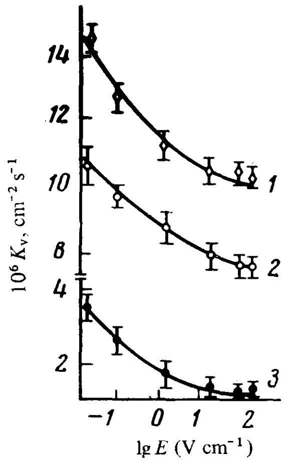

Figure 8. Variation of the rate constant for dissolution in water corresponding to different electric field strengths E (and hence different polarisations of the crystal)[90,91]: 1) NaF; 2) LiF; 3) $SrSO_4$.

Experiment showed that, in the dissolution of irradiated salts whose charge (and polarisation) is due to a non-uniform distribution in the bulk of the crystal of the carriers generated on irradiation, it is usually extremely difficult to isolate the influence of any one factor: charge, radiation-induced electronic defects, displaced atoms, or structural changes in the surface. This is because all the above consequences of the irradiation of the crystal are closely interrelated. However, we shall attempt to analyse the change in K_V for irradiated crystals which may be attributed to radiation-induced charging.

It has been established[36,38,39] that defects such as SO_4^-, SO_3^-, and e_{st}^- arise in $SrSO_4$ crystals irradiated with a stream of γ-quanta or accelerated electrons. At temperatures below −100° C for γ-irradiation or at room temperature for irradiation with electrons having an energy of approximately 1 MeV, only the SO_4^- radical-ions and thermalised electrons captured by traps are formed. Defects of the type of displaced atoms are not produced. Experiments with $SrSO_4$ crystals of this particular type were carried out by Parkhaeva et al.[40] The variation of the rate of dissolution of natural celestite ($SrSO_4$) irradiated with accelerated electrons having an energy of approximately 1 MeV is illustrated in Fig. 9.

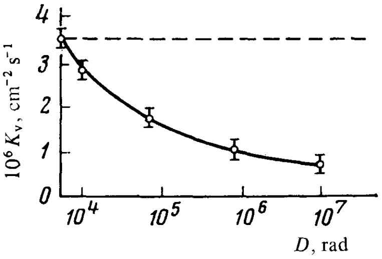

Figure 9. Dissolution of celestite single crystals in distilled water at 25° C after irradiation of the crystals with a stream of electrons having an energy of 3.5 MeV. The dashed line corresponds to non-irradiated crystals[40].

The experiments were performed as follows. The crystals were irradiated at 20–30° C (experiment showed that this entails the generation of the radiation-induced charge, SO_4^- radical-ions, and e_{st}^-) and were dissolved in distilled water at 25° C immediately after irradiation. Before dissolution, the outer layer of the crystal damaged by irradiation was removed by partial dissolution. Under these conditions, the changes in K_V could be attributed only to radiation-induced charging and the formation of electronic defects. Fig. 9 shows that celestite crystals freshly irradiated by electrons dissolve more slowly than the non-irradiated specimens. Evidently radiation-induced charging, the influence of which swamps that of radiation-induced effects, is of decisive importance in this instance. During the storage of crystals (for several months), the charge generated by irradiation partially leaked away (more precisely, the part of the charge not associated with the radiation-induced defects formed, whose concentration did not change during this period) and K_V increased somewhat, approaching the rate constant for the non-irradiated specimen. After thermal annealing, when all the defects disappeared, the properties of the irradiated and non-irradiated crystals were identical.

The results obtained for crystals of irradiated celestite can be explained satisfactorily by experiments with polarised specimens of the same mineral (Fig. 8, curve *3*)[90]: K_V decreases smoothly with increase of the strength of the electric field causing the polarisation of the crystal (cf. Figs. 8 and 9).

In another series of experiments, LiF crystals were irradiated with fast electrons[91]. The thickness of the LiF plates was chosen so that virtually all the electrons were absorbed in the specimen. In conformity with the theory of the radiation-induced charging and experimental determinations, the average excess space charge was negative. One of the irradiated crystals was placed in an electric field, the direction of which enhanced the radiation-induced polarisation. Others were placed in the field in such a way that its action promoted the depolarisation (the discharge) of the irradiated lithium fluoride. The results of these experiments are presented in Table 4, which shows that the smallest value of K_V is that of crystals in which the radiation-induced polarisation, caused by the non-uniformity of the distribution (and excess) of the charges, has been enhanced by the electric field. The decrease of polarisation as a result of the induced discharge of the irradiated LiF increases the rate of dissolution.

Table 4. Variation of the dissolution rate constant for electron-irradiated lithium fluoride crystals subjected to subsequent polarisation in an external 1500 V cm^{-1} electric field[91]*.

Experimental conditions	$10^6 K_V$, cm^{-2} s^{-1}
No field, crystal not irradiated	12.4
Field not applied to irradiated crystal	11.2
Electric field promotes discharge of irradiated crystal (depolarisation)	11.4
Electric field enhances polarisation of irradiated crystal	9.4

*The dose absorbed on irradiation amounted to 5 × 10^6 rad. Polarisation (depolarisation) time 48 h.

The experiments showed that on irradiation the influence of the radiation-induced charging can be observed in a pure form in certain cases. It is usually masked and partly swamped by the effect of radiation-induced defects. Evidently at least two opposed factors are manifested simultaneously in the irradiated compounds: the retardation of dissolution owing to the radiation-induced polarisation and the acceleration of the transfer of ions to the solution as a result of the formation of radiation-induced defects.

VI. RADIATION-CHEMICAL PROCESSES IN THE LIQUID PHASE AND DISSOLUTION

When the energy of ionising radiation is used to regulate dissolution processes, one can not only irradiate crystals before their interaction with the solvent, but an attempt can be made to act on the entire solvent–dissolved substance system. In this case the energy of the radiation is absorbed mainly by the liquid phase, because its amount is as a rule many times greater than that of the compound being dissolved. Furthermore, dissolution is usually rapid, and the radiation doses absorbed by the solid are much smaller than those which alter the rate of dissolution on preliminary irradiation of the crystals. Consequently the main radiation-induced processes occur in the liquid phase and the effect of radiation on dissolution is indirect—it is due to the interaction of the products of the radiolysis of the solvent with the solid phase.

Somewhat different conditions are possible in the dissolution of radioactive salts (the special case of dissolution directly during irradiation). It can be readily understood that here all the phenomena accompanying the dissolution of irradiated solids take place: radiation-induced charging, the accumulation of radiation-induced defects, breakdown of the structure of the surface, and radiolysis of the liquid phase. Bearing in mind that such salts are used in "atomic technology", the study of dissolution directly under irradiation is clearly of special interest.

The dissolution process has been studied directly in the field of γ-radiation, using the dissolution of the uranium oxides UO_2 and U_3O_8 in acid or alkaline media[92-94]; the rate of this process depends on the heterogeneous oxidation of uranium(IV) to uranium(VI)[95]. In the hydrometallurgical processing of uranium ores various oxidants (H_2O_2, O_2, MnO_2, etc.) are usually added to the liquid phase, which promotes the conversion of uranium(IV) into uranium(VI) and, in view of the higher rate of dissolution of uranium(VI) oxides compared with uranium(IV) oxides, this results in a more effective extraction of uranium from ores[96,97].

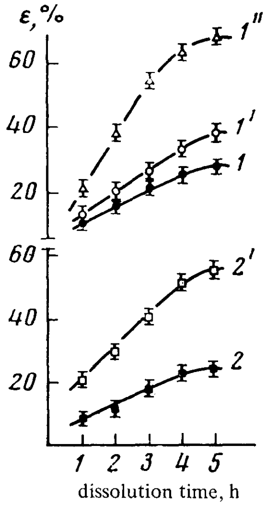

Figure 10. Variation of the degree of transfer of uranium ε to the liquid phase on dissolution of UO_2 and U_3O_8 in 0.1 N H_2SO_4: 1) U_3O_8, system not irradiated; 1′) and 2″) U_3O_8, system irradiated during dissolution using dose rates of 20 and 1.2 × 10^3 rad s^{-1} respectively; 2) UO_2, system not irradiated; 2′) UO_2, system γ-irradiated during dissolution using a dose rate of 1.2 × 10^3 rad s^{-1}.[92]

Experiments designed to investigate the dissolution process in the field of γ-radiation were performed with finely dispersed UO_2 and U_3O_8 powders, which were prepared by the usual methods[95]. Irradiation with ^{60}Co γ-rays was performed in air in open thermostatted vessels, with free access of air (aerated solutions). The dose rates used in the experiments were varied from 20 to 10^3

rad s^{-1}. The solvents consisted of 0.1 N H_2SO_4 and a carbonate solution (40 g $litre^{-1}$ of Na_2CO_3 and 30 g $litre^{-1}$ of $NaHCO_3$, pH ~ 10), which are used most frequently in the technology of the processing of uranium ores[96-98].

Fig. 10 presents the results of the determination of the degree of transfer of uranium (ϵ) to the solution for different dose rates. ϵ was determined from the expression

$$\varepsilon = ([U]_{soln.}/[U]_{solid}) \cdot 100, \qquad (7)$$

where $[U]_{soln}$ is the amount of uranium in the liquid phase at time t and $[U]_{solid}$ is the initial amount of uranium in the solid phase. Fig. 10 shows that, under the influence of γ-radiation, the degree of transfer of uranium to the liquid phase increases. At a dose rate of 1.2×10^3 rad s^{-1} ϵ increases approximately by a factor of 2.5 for U_3O_8 and 2.1 for UO_2. For higher radiation intensities, during prolonged dissolution (lasting more than 2 h), when the liquid phase was saturated with uranium and the consumption of H_2SO_4 began to have an effect, the increase in the rate of dissolution diminished. A similar relation between ϵ and the dose rate is characteristic of the dissolution of uranium oxides in the carbonate solution[93]. The influence of γ-radiation on the transfer of uranium to the solution was estimated in the above studies by comparing the rates of dissolution referred to unit surface area of the oxides.

The experiments showed that v is independent of the integral dose at least during the first hour, since the rate of dissolution of UO_2 remains constant in the course of γ-irradiation at a fixed dose rate. With increase of the dose rate, v steadily increases. The time interval corresponding to a constant value of v diminishes with increase of the dose rate, mainly owing to the gradual saturation of the liquid phase with uranium. The above features of the variation of v are characteristic of the dissolution of uranium oxides both in 0.1 N sulphuric acid and in the carbonate solution.

According to Gromov and coworkers[92,94], this shows that the decisive factor accelerating the transfer of uranium to the liquid phase (at least in the first stages of the dissolution process) is the interaction of the oxide undergoing dissolution with the radical products of the radiolysis of water, the concentration of which depends on the intensity of the radiation. This conclusion is confirmed also by experiments with radical acceptors, the addition of which to the solution sharply reduces the efficiency of γ-radiation. Thus the addition to the sulphuric acid solution of 1×10^{-4} M CH_3OH, which is an acceptor of OH radicals, decreased ϵ by a factor of 1.3 for a dose rate of approximately 400 rad s^{-1}.[94] Naturally, one cannot fully rule out the influence of the molecular products of the radiolysis of water, for example H_2O_2, etc., but their effect may be manifested only in later stages of the dissolution process when they have accumulated in sufficient amounts. At least during the first two hours, their influence may be disregarded.

Experiment showed that the increase of v with increasing dose rate (I) is not associated with the effect of radiation in the solid phase, since preliminary γ-irradiation of U_3O_8 or UO_2 *in vacuo* actually retards dissolution somewhat[31,34]. Consequently the acceleration of dissolution is caused by the oxidation of uranium(IV) to uranium(VI) by the products of the radiolysis of the liquid phase on the surface of the dissolving oxide. On this basis, the authors relate the rate of dissolution of uranium oxides to the intensity of γ-radiation. It was shown that, in the initial stages of the dissolution in both acid and carbonate media, the following relation holds[92]:

$$\lg v_I = \text{const} + {}^1\!/_2 \lg I, \qquad (8)$$

where v_I is the contribution to the overall rate of dissolution determined by the action of radiation. The main assumption in the derivation of the above formula is that the radical products of the radiolysis of water[99,100] namely OH and HO_2 in the sulphuric acid solution and O_2^- and CO_3^- in the carbonate solution, which are strong oxidants[101,102], play the main role in the dissolution process. These radical products oxidise uranium on the surfaces of the dissolving oxides to the hexavalent state, which accelerates the dissolution processes as a whole. In conformity with the adopted radiolysis mechanism, the steady-state concentration of the radical products of the liquid phase proved to be proportional to $I^{1/2}$, which in fact determines the final form of Eqn. (8).

The dependence of $\lg v_I$ on $\lg I$ in the dissolution of uranium oxides in sulphuric acid is illustrated in Fig. 11, which shows that the slope of the straight lines is 0.5 within the limits of experimental error, for both UO_2 and U_3O_8, in agreement with Eqn. (8). Deviations from the linear relation are observed for a dose rate of 1.2×10^3 rad s^{-1}, when the accumulated hydrogen peroxide (a molecular radiolysis product) probably accelerates the dissolution of the oxides. It was also noted that, after 2–3 h of dissolution, the experimental results ceased to agree with Eqn. (8). According to the authors[92] this is caused by the consumption of H_2SO_4 and the change in the surface area of dissolving oxides [in the derivation of Eqn. (8) the above parameters were assumed to be constant], which cannot be taken into account with adequate accuracy by the available methods. Eqn. (8) also holds fairly accurately in experiments involving the dissolution of UO_2 and U_3O_8 in the sodium carbonate solution[93,94]. The slope of the $\lg v_I$ – $\lg I$ straight lines for the carbonate medium is likewise 0.5, indicating the validity of the main assumptions made in the derivation of Eqn. (8).

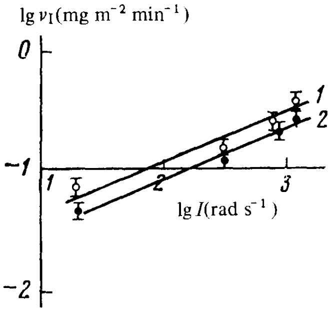

Figure 11. Dependence of $\lg v_I$ on the logarithm of the γ-radiation dose rate for UO_2 (line *1*) and U_3O_8 (line *2*) in the dissolution of the oxides in 0.1 N H_2SO_4. The values of v_I were calculated by Eqn. (8) for the range of dissolution times 0–60 min.[92,94]

Additional intensification of the dissolution of uranium dioxide can also be achieved as a result of the preliminary radiation-chemical solid-phase oxidation of uranium(IV) when the dry oxide is γ-irradiated in the presence of air. Thus X-ray diffraction showed that UO_2 acted upon by γ-quanta in air, for absorbed doses of approximately 10^8 rad, is converted into U_3O_8 to the extent of 20%. The radiation-induced oxidation of UO_2 in air probably proceeds via the following mechanism

$$UO_2 \xrightarrow{\gamma} (UO_2)^{*} + O_{2(air)} \text{ and } UO_2 \cdot mU_3O_8 \text{ or}$$
$$UO_2 + O_3 \xrightarrow{\gamma} n\,UO_2 \cdot m\,U_3O_8 \ . \tag{9}$$

The oxygen involved in the oxidation of UO_2 may be present in the dioxide itself (within pores and cracks) or can come from the surrounding medium.

The formation of uranium(VI) in uranium dioxide subjected to preliminary γ-irradiation affects also the rate of dissolution of UO_2, since the U(IV) → U(VI), transition limiting the rate of dissolution, takes place partly even in the solid phase under the influence of γ-irradiation[103-105].

Unfortunately the study of dissolution processes directly in the field of ionising radiation, which appears to be promising from the practical point of view, has so far been limited to the above system comprising uranium oxides and a sulphuric acid or carbonate solution[92-94,103-105].

Further studies on these lines will evidently yield much new and interesting practical and theoretical information.

VII. CONCLUSION

It follows from the data discussed that the rate of dissolution of irradiated solids is affected by many factors, which frequently act in opposition. Depending on the dissolution conditions, defects of only one type can be of decisive importance, while others play a passive role, although their concentration is in fact high.

The main effects of the radiation-kinetic phenomena in the dissolution process are associated with the formation of radiation-induced defects, a change in the structure of the surface, and the charging of the irradiated solid. However, their contribution is in many respects determined by the nature of the specific substance. For example, in the case of metals there is no point in taking into account the radiation-induced charging, since charges rapidly leak away and recombine with carriers of the opposite sign. This also applies to any non-metallic specimens whose intrinsic conductivity is more than 10^{-5} Ω^{-1} cm^{-1}.

The wide variety of the effects of radiation and their influence on the rate of dissolution creates certain difficulties in the study of the given phenomenon[43]. However, there are ways of reducing the influence of a particular change in structure on the dissolution process (Table 5). Table 5 shows that, in principle, it is possible to select conditions such that, after appropriate treatment of the irradiated compound, the effect of radiation on the dissolution process becomes insignificant.

A promising field for the utilisation of radiant energy in order to stimulate heterophase reactions (including dissolution reactions) involves the irradiation of the entire solid–solvent system. A necessary condition in this instance is the oxidation (or reduction) at the interface of the compound undergoing dissolution. If it limits the rate of dissolution, then ionising radiation may constitute an effective means of influencing the process as a whole.

Further development of studies on the practical utilisation of radiation-induced dissolution of solids depends on the solution of many theoretical and experimental problems.

Table 5. The influence of radiation-induced defects on the kinetics of the dissolution of solids[43].

Effect of radiation	Change in rate of dissolution	Method of reducing the influence of given effect
Displaced atoms and linear defects	acceleration	annealing
Trapped electrons or holes, radicals (electronic defects)	acceleration or retardation	annealing
Loosening of surface	acceleration	annealing, recrystallisation, dissolution of surface layers
Radiation-induced polishing of surface	retardation	annealing, prolonged storage of crystals before dissolution
Radiation-induced charging	retardation	
Dissolution of radiolysis products of solid	acceleration or retardation	annealing, change in liquid phase
Radiolysis products of liquid phase	acceleration (provided that dissolution process is accompanied by heterogeneous oxidation or reduction) have no influence on dissolution in the absence of oxidation (reduction) of solid phase	introduction of radical acceptors into liquid phase, experiments with non-oxidisable salts

1. The development of a theory of the influence of point defects of various types (primarily electronic) on the rate of dissolution.
2. The study of the effect of various impurities in the crystal lattice on the subsequent dissolution of the irradiated substances.
3. The study of the influence of a single definite type of defect on the values of K_V for various systems; the development of methods for suppressing (or forming) radiation-induced defects which are undesirable in the given specific instance. Evidently the use of the effect of light on the given system is extremely promising in this connection.
4. A wider employment of the effects of the irradiation of solid and liquid phases simultaneously; the selection of optimum conditions for the selective acceleration of the dissolution of complex systems under irradiation.

The development of these fields will not only extend and deepen our knowledge of the mechanisms of the dissolution of solids, but will undoubtedly make it possible to develop new practical methods for regulating heterophase processes.

The Interaction of Carbon Dioxide with Transition Metal Complexes

I.S.Kolomnikov and M.Kh.Grigoryan

The reactions of transition metal compounds involving the formation of CO_2 complexes, reactions with insertion of CO_2 in transition metal-hydrogen and transition metal-carbon bonds, and homogeneous catalytic processes in which carbon dioxide behaves as a reactant or a modifying ligand are considered. A special section is devoted to reversible reactions accompanied by elimination of carbon dioxide under the influence of transition metal compounds.
The bibliography includes 306 references.

VI. Insertion of carbon dioxide in the transition metal-carbon bond 344
VII. Catalytic processes with participation of carbon dioxide 347

I. INTRODUCTION

During the last five years there has been a considerable growth of interest in the reactions of carbon dioxide with transition metal compounds, primarily owing to the considerable advances made recently in the field of metal complex catalysis and in the first place in the activation of inert molecules (hydrogen, nitrogen, etc.) which leads to the expectation that catalytic processes involving carbon dioxide will also be carried out successfully. On the other hand, the CO_2 molecule may participate in catalytic processes also as a ligand capable of modifying the activity, selectivity, and specificity of catalysts. Evidently these two problems are most closely related to the synthesis and investigation of the transition metal complexes of carbon dioxide.

One may also note that the study of reactions involving systems based on transition metals is of considerable interest in view of the role that carbon dioxide plays in nature. Thus one may expect interesting results also when processes of this kind are simulated.

It has been believed for a long time that carbon dioxide reacts with transition metal compounds only in a "trivial" manner with formation of carbonates. However, recently many reactions have been discovered in which CO_2 behaves as a ligand or reacts to form new metal-C, C-H, or C-C bonds. This review is devoted to these new aspects of the carbon dioxide reactions.

II. PRINCIPAL PHYSICAL PROPERTIES AND STRUCTURE OF CARBON DIOXIDE

The carbon dioxide molecule is a linear triatomic molecule in which the carbon atom forms two equivalent bonds with oxygen atoms (of the σ and π types). According to spectroscopic data, the C=O bond length in the CO_2 molecule is 1.1615 Å,[1] which agrees with data obtained by electron diffraction[2].

There are fairly considerable discrepancies between calculated estimates of the heteropolarities of carbon dioxide: 75%[3,4], 10%[5,6], and virtually zero[7]. There are experimental literature data showing that the molecule has a permanent dipole moment (0.06×10^{-18} e.s.u.)[8], but, according to a later investigation[9], $\mu = 0$.

In the ground ${}^1\Sigma_g^+$ state ($D_{\infty h}$ symmetry group) sixteen electrons of the carbonyl molecule are distributed among the orbitals in the following manner: $(1\sigma_g)^2(1\sigma_u)^2(2\sigma_g)^2 . (2\sigma_u)^2(1\pi_u)^4(1\pi_g)^4$, where the least strongly bound π_g electrons are those of the lone electron pairs of the oxygen atom. Fig. 1 presents the energy level diagram for the CO_2 molecule; the energies of the atomic levels were taken from Siegbahn[10] and the experimental data (or, if these were lacking, calculated data) were taken from the review of Rabalais et al.[11] (Table 1). The data in Table 1 demonstrate a fairly good agreement between theory and experiment.

Table 1. Comparison of experimental and calculated lowest ionisation potentials (eV) of CO_2, CS_2, COS, allene, and keten.

Molecule	Experimental data (Refs.1,12-17)	MWH method (Ref.11)	Extended Hückel method (Ref.18)	CNDO method (Ref.19)	Hartree-Fock method (Ref.19)
O=C=O	13.78	14.05	17.20	14.55	14.81
	17.32	14.93	17.51	14.55	19.45
	18.08	17.68	18.14	16.83	2[illegible].23
	19.40	18.06	19.56	21.01	21.77
O=C=S	11.20	12.55	13.14	12.26	—
	15.08	13.67	14.67	13.81	—
	16.04	15.90	17.76	15.36	—
	17.96	16.50	18.40	19.32	—
S=C=S	10.09	11.33	12.24	11.33	—
	12.69	12.61	13.48	12.59	—
	14.47	14.44	14.18	13.28	—
	16.19	15.32	15.72	18.23	—
$H_2C=C=CH_2$	10.19	11.66	—	—	—
$H_2C=C=O$	9.60	11.49	—	—	—

Comparison of the energy level diagrams for the CO_2 molecule and the isoelectronic CS_2 and COS molecules (Fig. 2) shows that the highest occupied orbitals of the CO_2 molecule (π_g and π_u) lie appreciably below the corresponding CS_2 and COS orbitals[15].

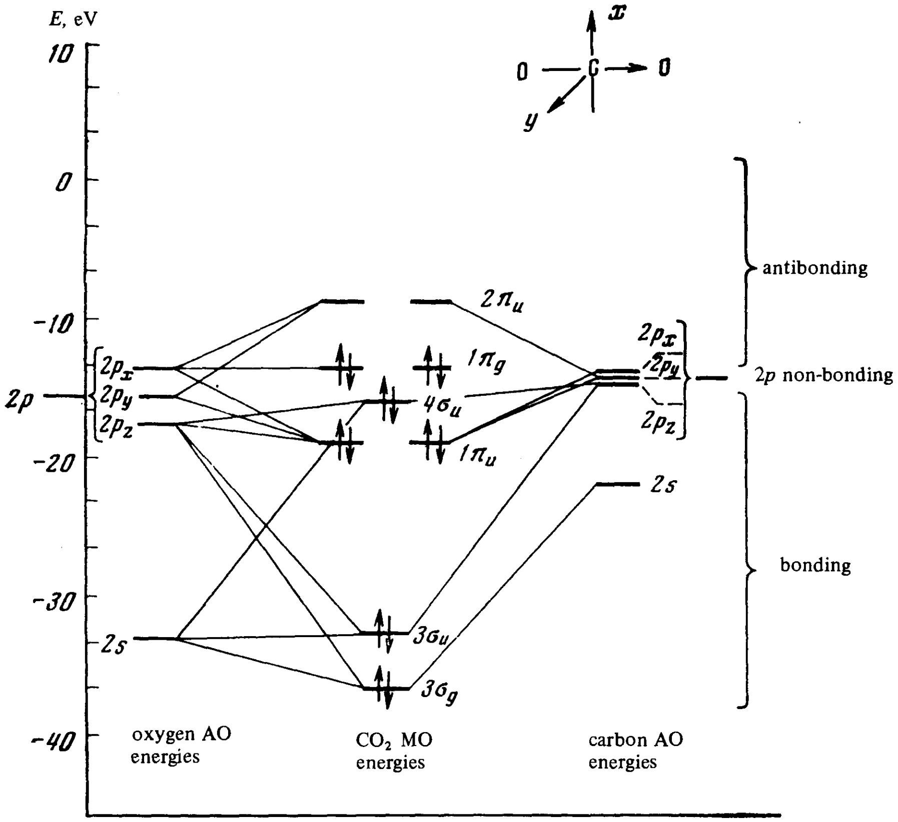

Figure 1. Molecular orbital diagram for the CO_2 molecule.

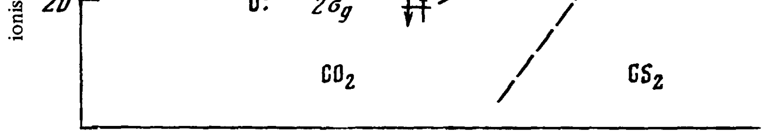

Figure 2. Electronic energy level diagram for CO_2 and CS_2 molecules according to photoelectron spectroscopic data.

Accordingly the ionisation potential of carbon dioxide (13.7 eV) is much higher than those of CS_2 (10.1 eV) and COS (11.2 eV). Thus the CO_2 molecule is a weaker electron donor than CS_2 or COS.

On the other hand, carbon dioxide has a low-lying $2\pi_u$ antibonding orbital, the position of which determines the electron affinity of the molecule [2.9 eV (Johnson and Albrecht[20]) or according to other (calculated) data ~ 3.8 eV (Buchel'nikova[21])]. These results appear to be rather too high. According to Berdnikov's calculated data[22], the electron affinity of CO_2 is ~ 0.5 eV, which agrees fairly well with experimental data[23,24].

The CO_2^+ species has been discussed[25-31] as a 15-electron species retaining its linearity in both the ground and excited states. The removal of one electron from the $1\pi_g$ orbital lengthens the C–O bond from 1.1615 Å ($^1\Sigma_g^+$) to

1.177Å ($^2\pi_g$) or 1.229 Å ($^2\pi_u$) [30] (Table 2). However, there are data showing that the anomalies in the infrared spectrum of CO_2^+ may be due to the bending of the excited molecule, the angle (168° ± 3°) corresponding to the distance r(CO) = 1.1830 ± 0.0004 Å.[32] The formation of the CO_2^{2+} ion has been observed by Newton and Sciamanna[33].

Table 2.

Molecule	Electronic state	Energy, eV	Bond length, Å	ν_1(symm.)	ν_2	ν_3(asymm.)
CO_2^+	$^2\Pi_u$	18.08	1.229	1131	560	1895
CO_2^+	$^2\Pi_g$	13.78	1.177	1280	632	2305
CO_2	$^1\Sigma_g^+$	0	1.163	1361	673	2379

The CO_2^- radical-ion, i.e. a species with a 17-electron configuration, has been obtained[34], in contrast to the extremely unstable CO_2^+ state, in a free form in a matrix on irradiation of sodium formate with high-energy γ-rays. Calculation of the valence angle by Coulson's method yielded 134°. According to the results of other workers[35, 36], the angle is 127 ± 8°. It is of interest that the O–C–O angle in sodium formate is 121.7° according to X-ray diffraction data[37].

It is noteworthy that Mulliken[4,38] and Walsh[39] predicted theoretically the possibility of the bending of the molecule on transition from the 16-electron linear configuration to the 17-electron configuration (i.e. from the $D_{\infty h}$ symmetry group to the C_{2v} symmetry group) (see also the review of Rabalais et al.[11]).

According to ESR data, the free electron in CO_2^- is localised at the carbon atom[20,36]. When the carbon atom is replaced by the ^{13}C isotope, the infrared band corresponding to the asymmetric vibrations of the carboxy-group shifts from 1671 cm^{-1} to 1626 cm^{-1} [36] (see also other data[20,40]).

The formation of the CO_2^- radical-ion has been postulated in a number of chemical and physicochemical studies: in the decomposition of oxalates in the presence of transition metals[41-43,44,45], in the electrochemical reduction of the CO_2 molecule[44,45], in electron transfer from a metallic surface on irradiation[46], in the reduction of carbon dioxide by amides[47] and alkali metal and alkaline earth metal amalgams[48-51], and in other reactions[52-56].

The most important physical properties of carbon dioxide are presented below:

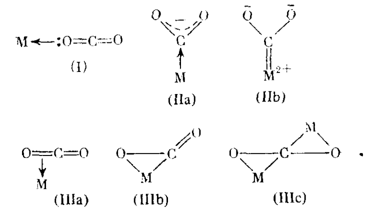
M.p. (5 atm)	-56.7°C
B.p. (sublimation at 1 atm)	-78.515°C
Density (at 0° and 1 atm)	1.9768 g litre^{-1}
Critical temperature	+31.3°C
Critical pressure	75.2 atm
Pressure corresponding to transition to liquid state (20°C)	58.46 atm
Heat of fusion (at 56.6°C)	2.24 kcal mole^{-1}
Standard free energy of formation	ΔF° = 94.260 kcal mole^{-1}
Standard entropy of formation	ΔS° = 51.011 cal mole^{-1} K^{-1}
Standard heat of formation	ΔH°_{298} = −94.08 kcal mole^{-1}
Temperature dependence of molar heat capacity (in the range 0–1400°C)	$C_p = 0.00326t + 0.00000079t^2 + 8.84$

III. TRANSITION METAL COMPLEXES OF CARBON DIOXIDE

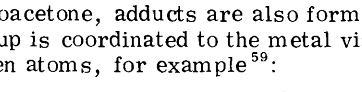
General consideration of the electron-donating and electron-accepting properties of carbon dioxide shows that there are several possibilities for the formation of complexes by CO_2 with transition metals. Complexes of the donor–acceptor type may be formed as a result of the transfer of the lone electron pair of the oxygen atom ($1\pi_g$ electrons) to the corresponding orbital of the metal atom (type I). In this case the transition metal plays the role of a Lewis acid. Interaction of this type is hindered by the comparatively high positive charge on the metal atom, the presence of low-lying vacant orbitals in the metal, and the presence of a free coordination site in the complex.

Another possibility may obtain as a result of the dative interaction involving the transfer of two electrons from the metal atom to the antibonding $2\pi_u$ orbital of carbon dioxide. In this case the CO_2 molecule is exhibiting electrophilic properties and a state of type IIa obtains. The transfer of two electrons from the metal atom to the antibonding orbitals of CO_2 may lead in the limiting case to the formation of a type IIb carbenoid complex. Clearly a low positive charge on the metal atom and the presence of electron-donating ligand in the complex will favour the formation of complexes of this type.

Finally the $1\pi_u$ orbital of the CO_2 molecule may interact with the corresponding vacant orbital of the metal with simultaneous transfer of the metal σ electrons to the vacant orbital of the CO_2 molecule which leads to the formation of a π-complex of type IIIa (or to the formation of a three-membered ring of type IIIb in the limiting case). Since the CO_2 molecule has two double bonds, an interesting possibility may arise when two metallic centres form a complex of type IIIb with a single carbon dioxide molecule:



It is remarkable that, when acetaldehyde acts on the ruthenium complex $(Ph_3P)_3RuCl_2$, a corresponding compound is formed in which the acyl group is coordinated to the metal atom by a π-type bond according to the authors[58]. When phosphine complexes of transition metals are acted upon by perfluoroacetone, adducts are also formed in which the carbonyl group is coordinated to the metal via both carbon and oxygen atoms, for example[59]:

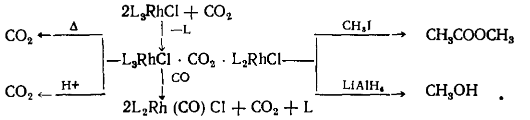


$$(Ph_3P)_4Pt + CF_3C(=O)CF_3 \rightarrow (Ph_3P)_2Pt\langle O{-}C(CF_3)_2 \rangle$$

The above structures naturally do not exhaust the entire wide variety of the possible types of complexes, particularly polynuclear complexes (complexes of this kind involve a combination of different types of complex formation reactions).

Since carbon dioxide is a less effective electron donor and a more effective electron acceptor than the isoelectronic CS_2 molecule, presumably complexes of type I are less typical for CO_2 and structures of type II and III are more typical (see the relevant reviews[60-64]. A fairly large number of CS_2 complexes are known[65,66], but the number of complexes with carbon dioxide which have been described is small.

The formation of complexes with carbon dioxide was observed for the first time for rhodium compounds[67]. Rhodium complexes of CO_2 are at present the most thoroughly investigated and we shall therefore begin our consideration of the available complexes by discussing the rhodium compounds. When carbon dioxide was allowed to interact with the complex L_3RhCl (where L = Ph_3P), a fairly stable adduct was obtained whose composition is $L_5Rh_2Cl_2.CO_2$ according to its chemical properties, the results of elemental analysis[67] and its infrared spectrum has an absorption band in the region of 1630 cm^{-1}. Chemical reactions also confirm the presence of coordinated carbon dioxide in the complex:



Carbon dioxide is evolved when the complex is acidified and pyrolysed. The formation of labelled carbon dioxide was demonstrated mass-spectrometrically in the thermal decomposition of the adduct formed in a $C^{18}O_2$ atmosphere[67]. Carbon dioxide is readily displaced from the complex by carbon monoxide.

It is interesting to note that the rhodium complex of carbon dioxide $L_5Rh_2(CO)_2(CO_2).C_6H_6$, obtained by an indirect procedure[68] (by oxidising the carbonyl group attached to the metal with oxygen), also has an asymmetric dinuclear structure according to molecular weight measurements. An interesting property of this complex is its ability to exchange the oxygen in a coordinated CO_2 molecule for dissolved molecular oxygen.

When the complex $[(Ph_3P)_2Rh(CO)]_2$ reacted with gaseous carbon dioxide at atmospheric pressure at room temperature in benzene, an asymmetric complex $(Ph_3P)_3Rh_2(CO)_2.(CO_2)_2.C_6H_6$ was again obtained[69,70]:

$$2\,[(Ph_3P)\,Rh\,(CO)_2] \xrightarrow{2Ph_3P} 2\,[(Ph_3P)_2Rh\,(CO)] \xrightarrow[-Ph_3P]{2CO_2} (Ph_3P)_3Rh_2\,(CO)_2\,(CO_2)_2\cdot C_6H_6\quad.$$

This complex is fairly stable and hardly loses carbon dioxide on exposure to air for several days. Carbon dioxide is evolved completely on pyrolysis and on treatment with acids or carbon monoxide. In the latter case the product is the complex $[(Ph_3P)Rh(CO)_2]_2$, i.e. the reaction is reversible also at atmospheric pressure:

$$2\,[(Ph_3P)Rh\,(CO)_2] \underset{2CO(-2CO_2;\;2Ph_3P)}{\overset{+2Ph_3P,\;2CO_2(-2CO)}{\rightleftarrows}} (Ph_3P)_3Rh_2\,(CO)_2\,(CO_2)_2\quad.$$

When the carbon dioxide is acted upon by oxygen, the familiar complex $(Ph_3P)_3Rh_2(CO)_2.CO_2$ is formed[68].

The infrared spectrum of the rhodium complex $(Ph_3P)_3.Rh_2(CO)_2(CO_2)_2$ contains, apart from the triphenylphosphine bands, two intense absorption bands in the region of 1600 cm^{-1} [ν(OCO)(asymm).] and 1355 cm^{-1} [ν(OCO)(symm.)] as well as a moderately intense band at 825 cm^{-1} [δ(OCO)]. When CO_2 in this complex is partly replaced by $^{13}CO_2$, the bands are split (Fig. 3). It is striking that the difference $\Delta = \nu(OCO)(assym.) - \nu(OCO)(symm.)$ amounts to 245 cm^{-1} for this complex, while $\Delta = 130$ cm^{-1} for the complex $L_3Rh_2(CO)_2.CO_2$ [ν(OCO)(asymm.) = 1498 cm^{-1}, ν(OCO)(symm.) = 1368, and δ(OCO) = 813 cm^{-1}]. This shows that in the rhodium complex with two CO_2 molecules there is an incomplete charge transfer from the metal atom to carbon dioxide, unlike the complex $L_3Rh_2(CO)_2.CO_2$ (cf. these data with those quoted by Peri[71]). The carbon dioxide in the $L_2Rh_2(CO)_2(CO_2)_2$ molecule is therefore retained less strongly, which is confirmed by chemical reactions. When olefins or oxygen are allowed to react with the complex $L_3Rh_2(CO)_2(CO_2)_2$, one carbon dioxide molecule is readily displaced with formation of the complex $L_3Rh_2(CO)_2.CO_2$.

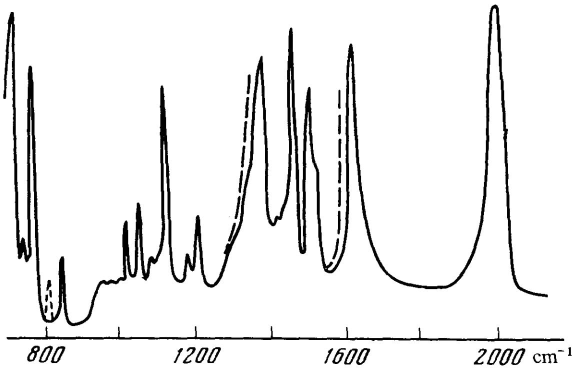


Figure 3. Infrared spectrum of the rhodium–carbon dioxide complex $(Ph_3P)_3Rh_2(CO)_2(CO_2)_2$ (the spectrum of the complex with $^{13}CO_2$ is indicated by dashed lines).

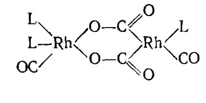
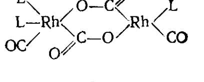
The complex $L_3Rh_2(CO)_2(CO_2)_2.C_6H_6$ is in all probability dinuclear, the two rhodium atoms being linked via two bent carbon dioxide molecules:





The appearance of three absorption bands in the spectrum of the coordinated carbon dioxide molecule instead of the two bands (2350 and 667 cm^{-1}) bands characteristic of the linear molecule (see Table 3) is associated with the bending of the CO_2 molecule on coordination.

Table 3. Vibration frequencies of the CO_2 molecule (cm^{-1}).

	solid (−190°C)	—	637	2280	73, 74
$^{14}CO_2$	gaseous	—	632	2226	75, 76

There are at present no X-ray diffraction data for carbon dioxide complexes of transition metals, but it is well known that the formation of complexes by carbon disulphide or allenes, which have linear molecules in the ground state, leads to the formation of compounds in which these molecules are bent. Thus it has been established by X-ray diffraction that the carbon disulphide molecule in the complexes $(Ph_3P)_2Pt.CS_2$ [77,78] and $(Ph_2P)_2Pd.CS_2$ [79] is bent (Fig. 4).

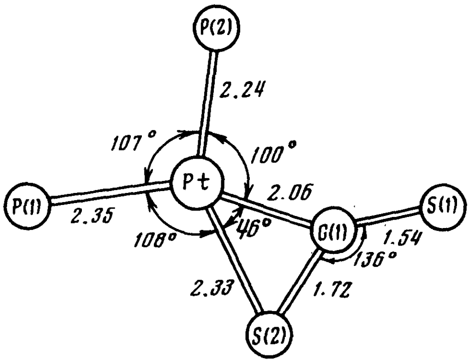

Figure 4. The structure of the platinum–carbon disulphide complex.

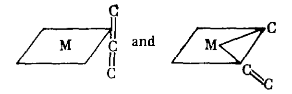
On the other hand, there are literature data showing that complexes of two types may be obtained with allene:



Thus in platinum, iron, and rhodium complexes[80-82] tetramethylallene is joined to the metal atom by a π-type linkage, while in the platinum complex $Pt(C_3H_4)(PPh_3)_2$ allene has a bent configuration[83].

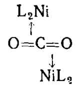
Apart from the absorption bands of physically adsorbed CO_2, the infrared spectra of chemisorbed carbon dioxide[71,84-99] contain other bands which the authors believe[71, 84-93] correspond to CO_2^- vibrations, the bands associated with the antisymmetric vibrations of the carboxy-group being located in the range 1570–1630 cm^{-1}, depending on the nature of the adsorbent, and those due to the symmetrical vibrations lying in the range 1320–1380 cm^{-1}.

The complexes $L_3Rh_2(CO)_2(CO_2).C_6H_6$ (2.83 μ_B) and $L_3Rh_2(CO)_2(CO_2)_2.C_6H_6$ (3.87 μ_B) proved to be paramagnetic[100] and their magnetic moments at room temperature (calculated per rhodium atom) are close to the spin-only value for two and three unpaired electrons respectively. It was shown in the same study that the anomalous paramagnetism of these complexes cannot be interpreted vigorously in terms of a model of the antiferromagnetic pair exchange in magnetically dilute dinuclear molecules.

The dimeric complex $(L_3RhH)_2.CO_2$, which Komiza and Yamomoto[101] obtained by passing carbon dioxide for a long time through a solution of the rhodium hydride $(Ph_3P)_4RhH$ in toluene, as well as the complex $L_5Rh_2Cl_2.CO_2$ [67] proved to be diamagnetic. The intense absorption band at 1460 cm^{-1} in the infrared spectrum of the resulting complex was attributed by the authors to the antisymmetric stretching vibrations of the OCO group, while the 1300 cm^{-1} band in the Raman spectrum was attributed to the symmetrical stretching vibrations of the same group. Carbon dioxide is evolved quantitatively from the complex on pyrolysis (at temperatures up to 200° C) and on acidification with sulphuric acid. On treatment with methyl iodide, carbon dioxide and methane are evolved.

The preparation of the complex $(Ph_3P)_3Co.CO_2$ in the form of a yellow compound inactive in air on treatment of $(Ph_3P)_3Co.N_2$ with carbon dioxide has been described[102]. When it is subjected to thermal decomposition or treated with sulphuric acid, the complex evolves CO_2. Its infrared spectrum has an absorption band in the region of 1890 cm^{-1}. The attempt[103] to obtain the analogous complex by treating the ethylene complex of cobalt $(Ph_2P)_3Co.(C_2H_4)$ with carbon dioxide at atmospheric or elevated pressure was unsuccessful.

The synthesis of the dinuclear nickel complex of carbon dioxide $\{[(C_6H_{11})_3P]_2Ni\}_2.CO_2$ by treating the corresponding nitrogenyl nickel complex with carbon dioxide has also been described[104]. The authors suggest that the metal atoms in this compound are coordinated via double bonds to the CO_2 molecule, which retains a linear structure:



$$\begin{array}{c} L_2Ni \\ \uparrow \\ O{=}C{=}O \\ \downarrow \\ NiL_2 \end{array}$$

An attempt has been made to obtain a platinum complex of carbon dioxide[105-107]. However, it was found that, when the complexes $(Ph_3P)_4Pt$ and $(Ph_3P)_3Pt$ react with CO_2 at an ordinary temperature and pressures up to 40 atm in the presence of traces of oxygen, carbonate complexes are formed (for further details, see below), while carefully purified carbon dioxide does not form stable products with platinum under these conditions, but the complex $(Ph_3P)_2Pt.CO_3$ is formed readily[108,109]. When the complex $(Ph_3P)_3Pt$ was treated with carefully purified carbon dioxide under pressure (40 atm) and a temperature in excess of 100° C, it was possible to obtain[61] a small yield of the compound $(Ph_3P)_2Pt.CO_2$, the infrared spectrum of which contains three intense absorption bands at 1640, 1370, and 1320 cm^{-1}. When the complex is pyrolysed, carbon dioxide is evolved.

Table 4. The energies of the $4f_{7/2}$ electrons of platinum ($L = Ph_3P$).

Compound	*E*, eV	Compound	*E*, eV
L_2PtCO_3	73.4	$L_2PtPhNCS$	73.1
L_2PtOCO_3	73.4	$L_2Pt(COPh)_2$	73.1
$L_2Pt(OOCH)_2$	73.4	L_2PtCS_2	73.0
$L_2Pt(OOCCH_3)_2$	73.7	$L_2Pt(COOMe)_2$	73.0
$L_2Pt(OOCEt)_2$	73.3	$L_2PtC_2H_4$	73.4
$L_2PtO_2\cdot(CH_3)_2CO$	73.3	$L_2Pt(PhC{\equiv}CPh)$	72.1
$L_2Pt\cdot O_2$	73.3	L_4Pt	71.7
L_2PtCO_2	73.2	Pt	71.3

A study of a series of platinum complexes with different types of ligand coordination (coordination to oxygen and carbon and coordination of the π-ligand type) by X-ray electron spectroscopy showed that the ability of the ligand to withdraw electrons from the metal atom decreases in the sequence (Table 4)[61]:

$$O_2 > CO_2 > CS_2 \sim PhNCS > COR > C_2H_4 > RC \equiv CR$$

The increase of the energy of the $4f_{7/2}$ electrons in the platinum complex of carbon dioxide relative to L_2PtCS_2 can be accounted for by the greater electronegativity of oxygen compared with sulphur.

Complexes of carbon dioxide and Group I metals (copper and silver) have also been obtained recently. When the complex $(Ph_3P)_2CuCH_3.CO_2$ is acted upon by carbon dioxide, the product is $(Ph_3P)_2CuOOCCH_3.CO_2$.[110] This complex is diamagnetic and evolves carbon dioxide on pyrolysis (above 200°C) and when treated with concentrated sulphuric acid. After the loss of carbon dioxide, the frequencies corresponding to the vibrations of the carboxylate group remain in the infrared spectrum, while the bands at 2620 (weak), 1600 (very strong), 1302 (very strong), 821 (moderately strong), and 648 (very weak) cm^{-1} disappear. On this basis, the authors[110] attribute the latter bands to the vibrations of coordinated carbon dioxide.

An interesting adduct was obtained when carbon dioxide was passed through a solution of copper complexes of ephedrine and its derivatives[111]. The authors investigated the ultraviolet spectra (λ = 250–260 nm) of these chelates in methanol solution and the visible spectra in benzene (Table 5). The study of the ultraviolet spectra showed that 1 : 1 adducts with carbon dioxide are formed in these solutions.

Table 5. Absorption spectra of copper(II) chelates in the visible region in benzene at 20°C.

Ligand in Cu^{II} chelate	λ^{*}_{max}, μm	ϵ^{*}, litre $mole^{-1}$ cm^{-1}	λ^{**}_{max}, μm	ϵ^{**}, litre $mole^{-1}$ cm^{-1}
(–)-Ephedrine	514	155	700	74
ψ-Ephedrine	500	121	700	82
N-Ethylnorephedrine	518	98	690	48
N-n-Butylnorephedrine	525	60***	660	41***

* $[Cu^{2+}]$ = 0.005 M.
** In the presence of CO_2.
*** Approximate value, because the chelate cannot be prepared in a crystalline form.

The thermodynamic functions for the complex-formation reaction between carbon dioxide and the complex Cu(ephedrine)$_2$ were determined[112] by gas–liquid chromatography (GLC): $\Delta G_{308} = -2.29 \pm 0.07$ kcal $mole^{-1}$, $\Delta H_{298-323} = 4.2 \pm 0.3$ kcal $mole^{-1}$; $\Delta S_{308} = -6.4 \pm 1.2$ kcal $mole^{-1}$ K^{-1}.

It is of interest that silver compounds also readily form stable complexes with carbon dioxide under mild conditions. Thus, when carbon dioxide is passed through a saturated solution of PhAg–$AgNO_3$ in ethanol at 0°C, a precipitate having the composition $C_7H_5O_2Ag_2$ is deposited[113]; its thermal decomposition results in the evolution of carbon dioxide. The infrared spectrum of this compound contains intense absorption bands in the region of 1496, 1326, and 828 cm^{-1} and moderately intense bands at 325, 290, and 280 cm^{-1}. The authors[113] concluded that a polymeric silver compound containing carbon dioxide is formed in this instance: $(C_6H_5AgCO_2Ag)_n$. An analogous complex was synthesised also from the corresponding *para*-substituted phenyl derivatives of silver.

Thus it is evident that a fairly large group of transition metals is capable of forming complexes with carbon dioxide. There is no doubt that the study of the complex formation reactions between carbon dioxide and transition metals constitutes an important branch of the chemistry of carbon dioxide and that the number of studies in this important field will increase in the immediate future and the problem of the structure of these compounds will be elucidated.

The problem of the isolation of fairly stable complexes with carbon dioxide was discussed above. However, in many cases the immediate formation of unstable CO_2 complexes in the course of various reactions has been postulated. There are literature data indicating the possibility of the formation of CO_2 complexes by the rupture of C–H bonds in transition metal formate complexes. On refluxing in benzene or on pyrolysis, the platinum formate complex $(Ph_3P)_2Pt(OOCH)_2$ decomposes into carbon monoxide and hydrogen[113]. On the other hand, when the solution contains the complex $(Ph_3P)_4Pt$, in which a C–H bond can be readily ruptured, the platinum formate complex decomposes with evolution of carbon dioxide[114], which has been attributed to the intermediate formation of a complex with CO_2, readily losing carbon dioxide via the mechanism

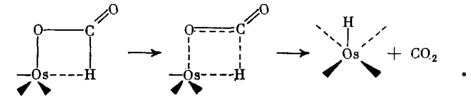
$$>\mathrm{PtOOCH} + \mathrm{Pt} \rightarrow \mathrm{PtOOCPt{-}H} \rightarrow CO_2 + \left\{>\mathrm{Pt{-}PtH}\right\} .$$

The intermediate formation of an unstable complex with carbon dioxide as a result of the intramolecular dissociation of the C–H bond in the formate group in all probability occurs in the reactions of ruthenium formate complexes[61,115]:

$$(Ph_3P)_3Ru\,(H)\,OOCH \rightleftarrows (Ph_3P)_3Ru\,(CO_2)\,H_2 \quad .$$

The formation of the ruthenium complex of carbon dioxide in one of the stages has been postulated for the reduction of unsaturated hydrocarbons with formic acid in the presence of the complex $(Ph_3P)_3Ru(H)Cl$ [116] and also for the decomposition of HCOOH in the presence of iridium complexes[117].

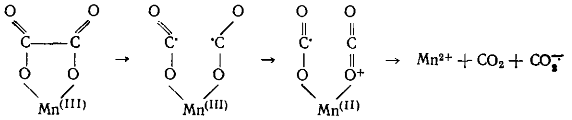
A complex with carbon dioxide is probably formed on thermal decomposition of osmium formate[118]:



When the cobalt formate complex $[Co^{III}(NH_3)_5OOCH]^{2+}$ is oxidised with manganese salts[119], the intermediate radical is fairly stable and reacts with another manganese species via the mechanism

$$\begin{aligned}[Co^{(III)}(NH_3)_5OOCH]^{2+} \xrightarrow{[MnO_4]^-;\ H+} \ & [Co\,(NH_3)_5OCO\,\cdot]^{2+} + HMnO_4 \\ & \downarrow \\ & [Co^{III}\,(NH_3)_5OH_2]^{3+} + CO_2 + [MnO_4]^- \quad .\end{aligned}$$

According to the results of other workers[120–123], the decomposition of oxalate in the presence of manganese salts also proceeds via the intermediate formation of a manganese complex of carbon dioxide:

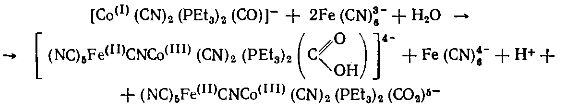


$$CO_2^{\cdot -} + Cl^{\cdot} \rightarrow CO_2 + Cl^- \quad .$$

(See also other investigations[124–127].)

In all probability analogous unstable complexes with carbon dioxide are formed in the decomposition of oxalic acid catalysed by copper[128,129], silver[130], mercury[131], and uranium[132] salts.

The intermediate formation of a cobalt complex of carbon dioxide was postulated[133] in a study of the mechanism of the oxidation of the $[Co^{I}(CN)_2(PEt_3)_2(CO)]^-$ complex with hexacyanoferrate(II) ions $Fe(CN)_6^{3-}$. Kinetic data confirm the occurrence of the equilibrium

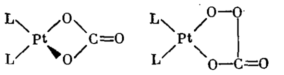


$$[Co^{(I)}(CN)_2(PEt_3)_2(CO)]^- + 2Fe(CN)_6^{3-} + H_2O \rightarrow$$
$$\rightarrow \left[(NC)_5Fe^{(II)}CNCo^{(III)}(CN)_2(PEt_3)_2\left(C\begin{smallmatrix}\diagup O\\ \diagdown OH\end{smallmatrix}\right)\right]^{4-} + Fe(CN)_6^{4-} + H^+ +$$
$$+ (NC)_5Fe^{(II)}CNCo^{(III)}(CN)_2(PEt_3)_2(CO_2)^{5-}$$

in solution. The authors[133] suggest that this mechanism operates also in the oxidation of carbon monoxide with oxygen catalysed by aquocobalamines[134-138].

IV. TRANSITION METAL CARBONATE COMPLEXES

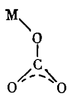
It is noteworthy that the widespread occurrence of the formation of transition metal carbonate complexes and their ability to evolve CO_2 on acidification of pyrolysis greatly hinder the identification of transition metal complexes of carbon dioxide or altogether prevent the formation of such complexes. As stated above, platinum and palladium complexes of the type $(Ph_3P)_4M$ (M = Pt or Pd) readily form carbonate complexes[105-109]. The possibility of the formation of a platinum carbonate complex on treatment of complexes of the type $(Ph_3P)_4Pt$ with carbon dioxide in the presence of traces of oxygen greatly depends on the nature of the coordinated ligand. Thus the carbonate complex is formed comparatively readily in the presence of the triphenylphosphine ligand, in the presence of the $(p\text{-tolyl})_3P$ ligand the yield of the corresponding complex is low, and in the presence of the $(p\text{-chlorophenyl})_3P$ ligand the complex is not formed at all. Carbonate complexes are formed when the complex $(Ph_3P)_2PtO_2$ reacts with carbon dioxide:



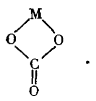
A platinum carbonate complex can be readily obtained when the complex *cis*-$(Ph_3P)_2PtCl_2$ is treated with Ag_2CO_3,[105] or when carbon monoxide is oxidised with oxygen coordinated to platinum[107]. Wilkinson and coworkers[107] made the following frequency assignments (cm^{-1}) in the infrared spectra of the compounds obtained:

Compound	$\nu(CO)$	$\nu(C-O)$(asymm.)	$\nu(C-O)$(symm.)	ν_{III}(symm.)	$\nu(O-O)$	$\nu(M-O)$	$\nu(M-P)$
L_2PtCO_3	1685 (s)	1185	980	815	—	363	409
L_2PtOCO_3	1678 (s)	1243	978	836	780	305	429

One may note that in general carbonates can behave as a monodentate [as in compounds (IV)] or bidentate [as in compounds (V)] ligand[139]:



(IV)



(V)

Nakamoto and coworkers[139] made a careful study of the infrared spectra of cobalt carbonate complexes and found that the C–O stretching vibrations in the monodentate carbonates give rise to absorption in the ranges 1360–1380 and 1450–1500 cm^{-1}, while the corresponding vibrations in the bidentate carbonates give rise to bands in the ranges 1260–1290 and 1590–1640 cm^{-1}, i.e. on the basis of infrared spectra it is virtually impossible to distinguish a transition metal complex of CO_2 from the carbonate complex. The structures of the carbonate and bicarbonate complexes have been discussed extensively[71,84-92] in connection with the study of the infrared spectra of chemisorbed carbon dioxide on metal oxides.

Like the ionic compound $CaCO_3$, where all the C–O bonds are equivalent, the platinum complex $(Ph_3P)_2PtCO_3$ has the structure[140] of a distorted square, also with equal C–O bond lengths.

The structure of the platinum peroxocarbonate complex[141] is probably analogous to that of the adduct $(Ph_3P)_2.PtO_2$.acetone. The oxygen in this complex is extremely reactive and readily oxidises triphenylphosphine with formation of a carbonate complex:

$$(Ph_3P)_2PtOCO_3 \xrightarrow{Ph_3P} (Ph_3P)_2PtCO_3 + Ph_3PO \quad .$$

There are also data demonstrating the ready formation of carbonate complexes when cobalt[103] and ruthenium[62] complexes react with carbon dioxide in the presence of traces of oxygen. In his attempt to obtain a molybdenum complex of carbon dioxide, Chatt synthesised a carbonate complex[142]. Carbonate complexes are readily formed also when an attempt is made to obtain a transition metal complex of carbon dioxide by an indirect method involving the oxidation of the carbon monoxide coordinated to the metal with molecular oxygen. An osmium carbonate complex has been obtained[143] by oxidising carbon monoxide with molecular oxygen:

$$(Ph_3P)_2OsCl(CO)NO \xrightarrow{O_2} (Ph_3P)_2OsCl(CO_3)NO \quad .$$

In discussing the mechanism of the formation of CO_2 when carbon monoxide and rhodium are oxidised with molecular oxygen, the authors[144] assume the formation of the unstable octahedral carbonate complex $[Rh^{III}(CO_3)(CO).Cl_3]^{2-}$, which readily gives off CO_2 in an acid medium.

The oxygen in a transition metal carbonate complex can be fairly reactive. Thus, when carbon monoxide was passed through a solution of the platinum carbonate complex $(Ph_3P)_2PtCO_3$, it was almost quantitatively oxidised[145] to CO_2, i.e. the reaction proceeded in accordance with the equation

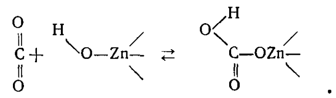
$$(Ph_3P)_2PtCO_3 + CO \rightarrow (Ph_3P)_2Pt + 2CO_2$$

Platinum carbonate complexes are used nowadays as catalysts for the synthesis of dimethylformamide from CO_2, H_2, and R_2NH and in the dimerisation of buta-1,3-diene to cyclo-octa-1,3,7-triene (see Sections V and VII respectively).

Ruthenium and rhodium bicarbonate complexes have been obtained recently[146,147] when the corresponding hydroxo-complexes were treated with carbon dioxide:

$$(Ph_3P)_2Rh(CO)OH + CO_2 \rightarrow (Ph_3P)_3Rh(CO)OCO_2H \quad ;$$
$$(Ph_3P)_4RuOH + CO_2 \rightarrow (Ph_3P)_4RuOCO_2H \quad .$$

These complexes are of some interest from the standpoint of the simulation of the action of a zinc-containing enzyme (carbonic anhydrase), which catalyses the reaction between carbon dioxide and water:



This type of analogy was drawn[148] in a study of the reaction of hydroxo-complexes of zinc with carbon dioxide. According to Riepe and Wang[149,150], in nature this process takes place in a hydrophobic cavity. There are data[151] showing that copper complexes also fulfill this function in nature.

V. INSERTION OF CARBON DIOXIDE IN A TRANSITION METAL–HYDROGEN BOND

Depending on the polarity of the transition metal–hydrogen bond, carbon dioxide can be inserted in the latter either with formation of formate complexes (normal insertion) or of metal-carboxylic acids (anomalous insertion):

$$O{=}C^{\delta+}{=}O^{\delta-} + M^{\delta+} - H^{\delta-} \rightarrow M{-}OOCH \ ;$$
$$O{=}C^{\delta+}{=}O^{\delta-} + M^{\delta-} - H^{\delta+} \rightarrow M{-}COOH \ .$$

The first reaction can serve as the basis of the catalytic reduction of CO_2 by molecular hydrogen with formation of formic acid derivatives, methanol, and other products. On the other hand, the reaction involving the formation of a metal-carboxylic acid can be of interest both for the synthesis of complexes of a new type and for the study of their properties, on the one hand, and for catalytic reactions involving the transfer of the carboxy-group to olefins and acetylenes, on the other.

It is noteworthy that, when CO_2 is inserted in a transition metal–hydrogen bond with formation of both a formate complex and a metal-carboxylic acid, the complex hydride may form a complex with a CO_2 molecule in the first stage, this being followed by insertion in the M–H bond. Thus, in a study of the kinetics of the analogous insertion of carbon disulphide in the transition metal–hydrogen bond in the complex $(Et_3P)_2Pt(H)Cl$, the authors [152] showed that the complex $(Et_3P)_2Pt(H)Cl.CS_2$ is formed in the first stage.

The insertion of carbon dioxide in a transition metal–hydrogen bond was observed for the first time [153] in relation to the cobalt complex $(Ph_3P)_3Co(N_2)H$. When CO_2 is passed through a solution of the complex, it is inserted in the Co–H bond with formation of the cobalt formate complex $(Ph_3P)_xCoOOCH$ as well as the complex $[(Ph_3P)_3.Co(CO)]_2$ resulting from the decarbonylation of the formate complex. The presence of the formate group was confirmed by the formation of methyl formate when the complex was treated with methyl iodide. The authors [153] noted the presence in the infrared spectrum of two broad absorption bands (at 1585 and 1370 cm^{-1}) corresponding to the asymmetrical and symmetrical vibrations of the COO^- groups.

A study of the reaction of carbon dioxide with the complexes $(Ph_3P)_3CoH_3$ and $(Ph_3P)_3Co(N_2)H$ established [154,155] the formation of a formate complex having infrared absorption bands at 1620 and 1300 cm^{-1}. In the presence of a deficiency of phosphine in solution, a mixture of a formate complex of unknown composition $(Ph_3P)_xCo(OOCH)$ and the decarbonylation product $(Ph_3P)_3Co(CO)H$ is formed. When the formate complex is acted upon by concentrated H_2SO_4, one mole of carbon monoxide and half a mole of H_2 are evolved per mole of the complex, while thermal decomposition results in the evolution mainly of carbon dioxide, hydrogen, and a small amount of carbon monoxide.

Special mention must be made of the reaction of sulphuric acid with transition metal formate complexes, which is a kind of test distinguishing metal formate complexes from carbon dioxide complexes (their infrared spectra are extremely similar) [155]. When formate complexes react with concentrated sulphuric acid, carbon monoxide is evolved, while carbon dioxide complexes evolve CO_2 under these conditions. When a cobalt formate complex is treated with dry HCl, formic acid is formed. The formation of a cobalt formate complex was confirmed in the above studies [154,155] also by synthesis on treating the corresponding hydride complex with formic acid.

When carbon dioxide was allowed to interact with the iron complexes $(Et_2PhP)_2FeH_4$ and $(Et_2PhP)_2Fe(N_2)H_2$, the iron formate complex $L_2Fe(OOCH)_2$ was obtained [156]. On treatment with ethyl bromide, the latter gives rise to the formate ester and on treatment with concentrated H_2SO_4 it decomposes, evolving CO:

$$L_2Fe\,(OOCH)_2 + 4C_2H_5Br \rightarrow FeBr_2 + 2HCOOC_2H_5 + 2LC_2H_5Br \ ;$$
$$L_2Fe\,(OOCH)_2 + H_2SO_4 \rightarrow FeSO_4 + 2H_2O + 2CO + 2L \ .$$

When carbon dioxide interacts with titanocene, a titanium formate complex is formed [157], in agreement with data [158] indicating the existence of the Ti–H bond in titanocene.

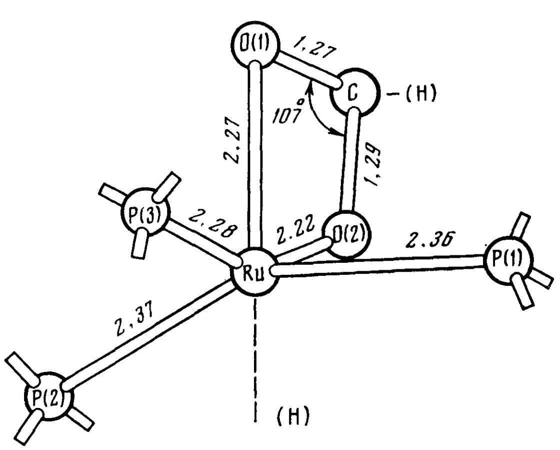


Figure 5. The structure of the ruthenium formate complex $(Ph_3P)_3Ru(H)OOCH$.

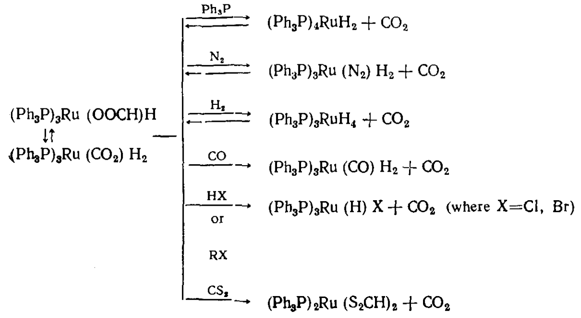
A ruthenium formate complex is formed [159,160] when carbon monoxide interacts with the complexes $(Ph_3P)_4.RuH_2$, $(Ph_3P)_3Ru(N_2)H_2$, and $(Ph_3P)_3RuH_4$. A compound having the composition $(Ph_3P)_3Ru(OOCH)H$ was obtained, its infrared spectrum containing, together with the absorption band due to the triphenylphosphine ligand and the band corresponding to the vibrations of the Ru–H bond (at 2010 cm^{-1}), also the following distinct bands: at 1565 (s.), 1420 (m.), 1370 (m.), 1355 (m.), 1340 (m.), 800 (s.), and 690 (v.s.) cm^{-1}. These bands are very close to those in the spectrum of the rhodium complex of CO_2 [67] and, on the other hand, virtually coincide with the frequencies of the ruthenium formate complex [161]. A detailed study of the infrared spectrum of the complex obtained by Kolomnikov and coworkers [159,160] showed that in the solid state it is a ruthenium formate complex. Thus, when carbon dioxide acts upon the deuterated complex $(Ph_3P)_3RuD_4$, the product is the complex $(Ph_3P)_3Ru(OOCD)D$, in the spectrum of which there are no 2910 (m.) and 2820 (m.) bands corresponding to the ν(C–H) vibrations and a band appears at 2150 cm^{-1} [the ν(C–D) band]. There is a corresponding disappearance of the $\nu(Ru{-}H) = 2010\ cm^{-1}$ band and its replacement by the $\nu(Ru{-}D) = 1450\ cm^{-1}$ band. The 1370 and 1355 cm^{-1} bands, which might be assigned to the deformation vibrations of the C–H bonds, are also missing from the infrared spectrum of the deuterated product. The residual bands are due to the vibrations of the OCO group.

X-Ray diffraction data[159,162] also confirm that in the crystalline state the compound obtained is a ruthenium formate complex in which hydride hydrogen is in the *trans*-position relative to the formate group (Fig. 5), i.e. the complex has a structure analogous to that of the known complex $(Ph_3P)_3Ru(H)OAc$.[163] However, when the formate complex was treated with methanol containing BF_3 and also with methyl iodide, the corresponding alkyl formates were not detected. It was found that the reactions of this complex[101,115,159,160], accompanied by the elimination of CO_2 under mild conditions, are unusual for the transition metal formate complexes described previously (see the mechanism below).

Carbon dioxide may be displaced from the ethylene complex or transferred to platinum when the complex interacts with $(Ph_3P)_2PtO_2$, forming the known carbonate $(Ph_3P)_2PtCO_3$.[61] It is specially noteworthy that the reactions of the ruthenium formate complex with triphenylphosphine, molecular nitrogen, and hydrogen are reversible (at atmospheric pressure and room temperature).



When the ruthenium formate complex reacts with carbon disulphide, the product is, as already mentioned, a dithioformate complex, which has the *cis*-structure according to X-ray diffraction data[164]. It has been shown[159] that on heating the formate complex $(Ph_3P)_3$.$Ru(OOCH)H$ is converted into the carbonylruthenium hydride complex $(Ph_3P)_3Ru(CO)H_2$, i.e. the formate fragment is decarbonylated. An analogous reaction involving the formation of a carbonyl derivative from a formate complex had been observed previously[155] for cobalt compounds. It has been shown quite recently[165] that under mild conditions CO_2 can serve as a source of CO for the synthesis of transition metal carbonyl complexes in the presence of reducing agents. Thus the complex $(Ph_3P)_3$.$RhCl$ interacts with CO_2 in the presence of the hydride $(EtO)_3SiH$ to form the complex $(Ph_3P)_2Rh(CO)Cl$ (in a quantitative yield)[165]. A carbonyl complex is formed in the presence of other silanes or aluminium hydrides. When the ruthenium complex $(Ph_3P)_3RuCl_2$ is introduced into the reaction, the product is the carbonyl complex $(Ph_3P)_3Ru(CO)Cl_2$. Presumably the silane aids to the transition metal complex in the first stage via an oxidative addition mechanism with formation of a transition metal–hydrogen bond and then CO_2 is inserted in this bond, forming a formate group, the decarbonylation of which leads to the formation of transition metal carbonyl complexes.

The formation of a formate fragment after the insertion of CO_2 in a cobalt–hydrogen bond in the complex was pointed out by Haynes et al.[166] On treatment with carbon dioxide, certain osmium, platinum, and iridium hydride complexes give rise to fairly unstable formate complexes which cannot be isolated in a pure state; however, their formation can be confirmed by treating the reaction product with methyl iodide and by isolating the formate ester[167].

The insertion of CO_2 in a transition metal–hydrogen bond can be used for the catalytic reduction of carbon dioxide. However, the process $CO_2 + H_2 \rightleftharpoons HCOOH$ is thermodynamically unfavourable under mild conditions. In order to displace the above equilibrium to the right, it is necessary to bind the formate fragment formed as a result of the reaction (for example, into a formamide or a formate ester) by adding the corresponding amine or alcohol to the reaction mixture.

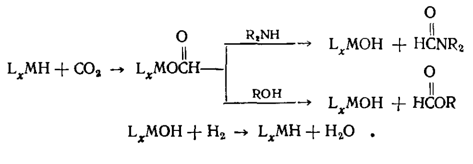
Thus it has been observed[166] that a whole series of transition metal complexes catalyse the formation of dimethylformamide in the reduction of carbon dioxide by molecular hydrogen in the presence of dimethylamine (Table 6). Other secondary amines, such as dipropylamine, pyrrolidine, and piperidine, also form rapidly the corresponding formamides. It proved impossible to extend the application of this reaction as far as the formation of *NN*-dimethylthioformamide by using carbon disulphide or carbon sulphide oxide in the presence of homogeneous hydrogenation catalysts.

Table 6. The reduction of CO_2 to dimethylformamide by molecular hydrogen in the presence of dimethylamine[166].

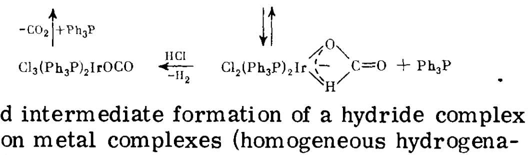
Catalyst	Catalyst concn., M	Me_2NH concn., M	Temp. *t*, °C	Yield, moles per mole of catalyst
$(diphos)_2CoH$	1.08	138	100	5
$(diphos)_2CoH$	0.05	131	125	1000
$(Ph_3P)_3RhCl$	0.3	122	100	43
$(Ph_3P)_3RhCl$	0.02	138	125	170
$(Ph_3P)_2Rh(CO)Cl$	0.38	144	100	1
$(Ph_3P)_2Ir(CO)Cl$	0.35	133	100	28
$(Ph_3P)_2Ir(CO)Cl$	0.2	138	125	1200
$(Ph_3P)_2PdCO_3$	0.79	159	100	120
$(Ph_3P)_2PtCO_3$	0.70	155	125	104
$(Ph_3P)_3Pt$	0.56	155	125	19
$(Ph_3P)_3RuCl_2$	0.39	132	125	8
$(Ph_3P)_3CuCl$	0.63	133	100	8

Formate esters have been obtained under similar conditions[167,168] using CH_3OH-BF_3 or $C_2H_5OH-BF_3$ mixtures as esterifying agents. Iridium and ruthenium complexes proved to be the most active catalysts. Although the formation of formaldehyde and methyl alcohol from carbon dioxide and hydrogen is thermodynamically favourable, these products were not detected in the reactions investigated[168]. Ruthenium complexes may catalyse the formation of formate esters also in the absence of BF_3. In a series of ruthenium complexes, the ruthenium(III) compound $(Ph_3P)_3RuCl_3$ proved to be the most active[65].

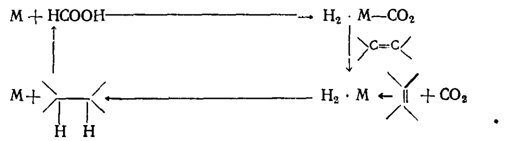
Formamides and formate esters are partly formed by the following mechanism in the reduction of carbon dioxide by molecular hydrogen in the presence of complex catalysts[167,168]:



The insertion of CO_2 in a transition metal–hydrogen bond and the reduction of carbon dioxide by molecular hydrogen in the presence of transition metal complexes are closely related to the reverse reaction—the decomposition of formic acid with evolution of carbon dioxide; this reaction is catalysed by various transition metal complexes[117,169–185]. It apparently proceeds via a stage involving the rupture of the C–H bond in the transition metal formate complex with transfer of hydrogen to the metal and the subsequent formation of a hydride complex with CO_2 as an intermediate. Thus it has been shown[117] that formic acid decomposes in the presence of an iridium catalyst via the following mechanism:



The suggested intermediate formation of a hydride complex when transition metal complexes (homogeneous hydrogenation catalysts) are acted upon by formic acid has been used for the catalytic transfer of hydrogen from formic acid to various organic substrates[184–193] (for further details, see Kolomnikov et al.[194]) via the mechanism



In the presence of catalytic amounts of $(Ph_3P)_3Ru(H)Cl$ in dimethylformamide formic acid reduces alk-1-enes rapidly and selectively to alkanes but does not reduce di- and tri-substituted alkenes (Table 7). It is noteworthy that under these conditions molecular hydrogen does not reduce olefins in the presence of the complex $(Ph_3P)_3$.$Ru(H)Cl$, i.e. the reduction of olefins by formic acid proceeds via intramolecular hydrogen transfer[192].

Table 7. The reduction of olefins by formic acid in the presence of $(Ph_3P)_3Ru(H)Cl$ in dimethylformamide (25°C, 3 h, HCOOH : olefin = 1 : 1).

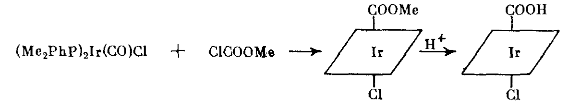
Compound	Reduction product	Yield, %
Oct-1-ene	n-Octane	100
Oct-4-ene	n-Octane	0
Hept-1-ene	n-Heptane	100
Hex-1-ene	n-Hexane	100
Methylcyclohexane	Methylcyclohexane	0
α-Methylstyrene	Cumene	0

Many other complexes of rhodium [L_3RhX, $L_2Rh(CO)X$, $L_3Rh(CO)H$, etc., where L = Ph_3P and X = Cl, Br, or I], iridium [$L_2Ir(CO)X$, $L_3Ir(CO)H$, L_3IrH_2Cl, etc.], ruthenium [L_3RuCl_2, L_4RuH_2, $L_3Ru(H)OAc$, and $L_3Ru(CO)(H)X$], platinum, and palladium, are also effective catalysts of the reduction of unsaturated compounds[186–191].

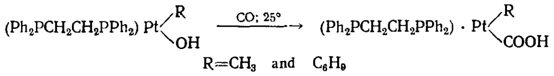
The hydrogenation[193] with formic acid of octatriene, formed in the course of the dimerisation of buta-1,3-diene by phosphine complexes of platinum and palladium of the type L_2MCl_2, has been observed:

Consequently the formation of formic acid from CO_2 and molecular hydrogen as well as the decomposition of formic acid catalysed by transition metal complexes proceed via the formation of formate complexes. Together with the synthesis of such compounds by subjecting transition metal hydride complexes to the action of CO_2 (see above), the formation of formates on reaction between formic acid and ruthenium and osmium[118,195–197], platinum[114], rhodium[198], and iridium[199] has been described. An unusual formate complex has been obtained for niobium[200,201]. According to X-ray diffraction data, the complex $\{[\pi\text{-}CpNbOOCH(OH)]_3O\}H$ contains oxohydroxo-groups apart from bridging bidentate formate groups. According to the authors[201], these groups are formed as a result of the decarbonylation of formic acid.

It may be supposed that transition metal complexes can interact with formic acid not only to form formate complexes but also with the initial rupture of the C–H bond and the formation of metal-carboxylic acids. Such cleavage of the C–H bond has been observed[202] in the reaction of formic acid with complexes of the type L_3IrCl_3 (where L = Me_2PhP, Et_2PhP, or Ph_3P), a complex with the Ir–COOH fragment being formed [ν(CO) = 1660, 1635, and 1610 cm^{-1} depending on the nature of the phosphine]. The properties of the complex proved similar to those of the iridium–carboxylic acid obtained previously by an indirect method[203] [ν(CO) = 1663 and ν(OH) = 3313 cm^{-1}].



A metal-carboxylic acid was obtained recently also from a platinum complex[204]:



$$(Ph_2PCH_2CH_2PPh_2)\,Pt\!\begin{smallmatrix}R\\OH\end{smallmatrix} \xrightarrow{CO;\ 25°} (Ph_2PCH_2CH_2PPh_2)\cdot Pt\!\begin{smallmatrix}R\\COOH\end{smallmatrix}$$

$$R{=}CH_3 \text{ and } C_6H_9$$

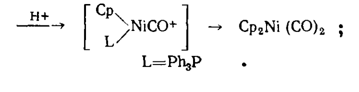
These compounds are stable in air in the solid state as well as in solution in methylene chloride or chloroform.

A metal-carboxylic acid is apparently formed also in the "anomalous" insertion of the CO_2 molecule in a Co–H bond when carbon dioxide interacts with the complex $[Ph_3P]_3Co(N_2)H$ in benzene solution. Methyl acetate is formed on treatment of the benzene solution with methyl iodide and then with a methanol solution of BF_3, as for iridium-carboxylic acids[103]:

$$[Co]H + CO_2 \rightarrow L_xCoCOOH \xrightarrow{MeI} MeCOOH \xrightarrow[-H_2O]{MeOH\cdot BF_3} MeCOOMe\ .$$

The formation of metal-carboxylic acids as intermediates has been suggested[205,206] in the oxidation of CO in the presence of mercury and silver salts.

The formation of cobalt-carboxylic acids[134–138], rhodium-carboxylic acids[207–210], and palladium-carboxylic acids[211,212] has been described. The formation of platinum-carboxylic acids has been suggested in the interaction of cationic carbonylphosphineplatinum complexes with water and in the hydrolysis of platinum-carboxylate esters[213,214]. The intermediate formation of a metal-carboxylic acid on treatment of an organonickel compound with carbon dioxide has been suggested in a recent study[215] undertaken to synthesise an organometallic analogue of a Grignard reagent:

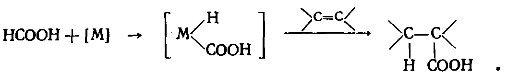


$$\begin{smallmatrix}Cp\\L\end{smallmatrix}\!NiBr + Mg \rightarrow \begin{smallmatrix}Cp\\L\end{smallmatrix}\!NiMgBr \rightarrow \left[\begin{smallmatrix}Cp\\L\end{smallmatrix}\!Ni{-}COOMgBr\right] \rightarrow \xrightarrow{H+} \left[\begin{smallmatrix}Cp\\L\end{smallmatrix}\!NiCO^+\right] \rightarrow Cp_2Ni\,(CO)_2\ ;$$

$$L{=}Ph_3P\ .$$

A study of the reaction of carbon dioxide with NaCo.(Salen)$_2$ (where Salen is *NN*′-bis-salicylethylenediamine) showed[216] that the formation of the sodium salt of cobalt-carboxylic acid is reversible. The absorption bands of the coordinated carbon dioxide in this compound are in the region of 1680, 1278, and 1213 cm^{-1}.

Presumably the formation of metal-carboxylic acids is an intermediate stage in the catalytic transfer of the COOH group from formic acid to unsaturated compounds via transition metal complexes:



$$\mathrm{HCOOH} + [M] \rightarrow \left[M\begin{smallmatrix} H \\ COOH \end{smallmatrix} \right] \xrightarrow{>C=C<} >\underset{H}{C}-\underset{COOH}{C}< \ .$$

This reaction, involving the addition of formic acid to unsaturated compounds, leads to the formation of higher carboxylic acids[61,217] (Table 8).

It is of interest that a platinum complex of the type (diphos)Pt  has been obtained recently[204]. Evidently this compound simulates to some extent the intermediate in the addition of the carboxylate group to an unsaturated compound.

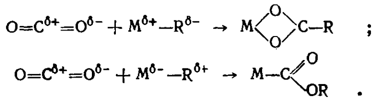
Table 8. The addition of formic acid to cyclohexene in the presence of metal complexes (100° C, 8 h, HCOOH : olefin = 1 : 1).

Catalyst	Solvent	Conversion, %	Yield of cyclohexanecarboxylic acid, moles per mole of catalyst
$(Ph_3P)_3RhCl$	—	7.0	39.0
$(Ph_2PH)_3RhCl$	—	7.3	42.0
$(Ph_3P)_2Ir(CO)Cl$	—	8.7	32.0
$RuCl_3$	DMF	2.1	3.0
H_2PtCl_6	Ethanol	7.0	18.0

VI. INSERTION OF CARBON DIOXIDE IN A TRANSITION METAL–CARBON BOND

The insertion of CO$_2$ in an M–C bond is well known and has been used successfully in the chemistry of non-transition metals[62]. However, reports of the insertion of gaseous CO$_2$ in a transition metal–carbon bond have appeared only very recently. Furthermore, such reactions are of great interest because they lead to the possibility of introducing CO$_2$ into catalytic and synthetic processes.

As in the reaction where CO$_2$ is inserted in a transition metal–hydrogen bond (see the previous Section), when it is inserted in a transition metal–carbon bond, two pathways may obtain—the "normal" pathway with formation of carboxylate complexes and the "anomalous" pathway with formation of metal-carboxylate esters:

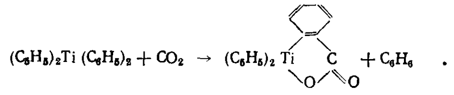


$$O{=}C^{\delta+}{=}O^{\delta-} + M^{\delta-}{-}R^{\delta+} \rightarrow M{-}C\begin{smallmatrix} {/\!\!/}O \\ \diagdown OR \end{smallmatrix} \ .$$

The normal insertion of CO$_2$ in transition metal–carbon σ bonds has been described for titanium, zirconium, zinc, cobalt, rhodium, and copper compounds. Thus it has been shown[218] that carbon dioxide is inserted in a titanium (zirconium)–carbon bond with formation of the corresponding acids after acidification. Organometallic compounds absorb up to two moles of CO$_2$ per mole of the complex and the reaction involving zirconium compounds proceeds at a rate higher by two orders of magnitude than for titanium compounds owing to the greater polarity of the zirconium–carbon bond. The authors[218] did not isolate the organometallic derivative from the reaction mixture but after hydrolysis yielded phenylacetic acid and triphenylcarbinol in equimolar amounts. The formation of phenylacetic acid is consistent with the mechanism of the "normal" insertion of CO$_2$ in a transition metal–carbon σ bond:

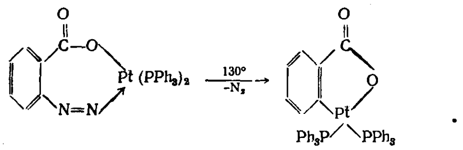
The insertion of CO$_2$ in a methyl–titanium σ bond has been observed[157] also in the reaction of dimethyltitanocene with CO$_2$ to form the —TiOOCCH$_3$ fragment. The infrared spectrum of the reaction products is identical with that of the known titanocene diacetate[219–221]. The presence of the acetate group has also been confirmed by the fact that, when the reaction product is esterified with methanol, methyl acetate is formed.

A fairly unexpected result was obtained in a study of the insertion of CO$_2$ in a titanium–carbon σ bond in diphenyltitanocene. At 80° C (this constitutes the condition for the thermal decomposition of diphenyltitanocene) and atmospheric pressure the reaction leads to the formation of a stable compound containing a five-membered ring incorporating a titanium atom, two *o*-carbon atoms of the benzene ring, and a CO$_2$ molecule[157,222,223]:



The compound obtained is diamagnetic. Its infrared spectrum contains a series of distinct bands together with the absorption bands of the phenyl and cyclopentadienyl groups: at 1660 (v.s.), 1620 (s.), 1280 (v.s.), 1130 (s.), and 880 (s.) cm^{-1}. A very intense band at 1660 cm^{-1} apparently corresponds to the ν(OCO) vibration. The frequency of this vibration is intermediate between the corresponding values for the ionised and unionised carboxy-groups. It is also of interest that in the region of the infrared spectrum characterising substitution of the benzene ring there are two bands: at 690 (m.) and 735 (s.) cm^{-1}; the region is as a rule uncharacteristic of 1,2-disubstitution.

It is noteworthy that an analogous infrared spectrum has been observed for a cyclic platinum complex obtained by the reaction of azocarboxylic acid followed by the elimination of nitrogen on heating [ν(OCO) = 1646 and 1620 cm^{-1}; ν(OCO) = 1305 and 1298 cm^{-1}][224,225]:



(VI)

On the other hand, the infrared spectrum of a cyclic organotitanium compound differs from that of Cp$_2$Ti(OOCPh)$_2$ (Cp = C$_5$H$_5$) [ν(OCO)(asymm.) = 1610 cm^{-1}; ν(OCO) (symm.) = 1410 cm^{-1}][226] or the paramagnetic complex $Cp_2Ti(OOCPh)$[227].

Behaviour unusual for *o*-substitution has been observed in the Raman spectrum of compound (VI). Whereas the Raman spectrum of dicyclopentadienyldiphenyltitanium, recorded for comparison, has the usual monosubstitution lines at 620, 994 (v.s.), and 1006 (w.) cm^{-1}, the spectrum of compound (VI) has no 620 cm^{-1} line, but there are two new lines: at 1011 (s.) and 1027 (w.) cm^{-1}. Similar spectroscopic behaviour has been observed for certain *o*-substituted benzenes, but the above intensity ratios are unusual for *o*-substitution.

X-Ray diffraction data[222,223] have shown that the Ti–C σ bond in this compound is appreciably shorter (2.20 Å) than in dicyclopentadienyldiphenyltitanium (2.27 Å) (Fig. 6). This finding is fully consistent both with the thermal stability of the bond (the substance does not decompose on heating to 190° C, in contrast to Cp_2TiPh_2) and with the chemical stability of the compound, in contrast to the titanium benzoate complexes with the usual coordination, which were mentioned above.

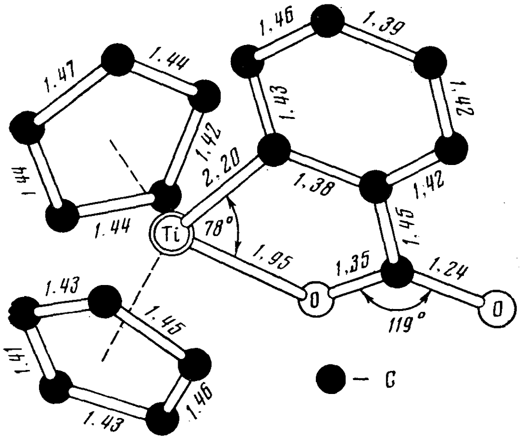


Figure 6. The structure of the complex $Cp_2TiOOCC_6H_4$.

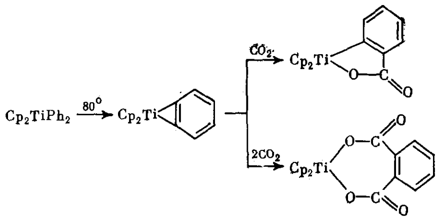
Other chemical reactions also agree with the proposed structure of the cyclic compound. Thus, on treatment with methanol containing BF_3 (at 100° C), methyl benzoate is formed, while treatment of the compound with methyliodide leads to the formation of a mixture of ethyl esters of benzoic and *o*-toluic acids. When the organotitanium complex is heated for a long time with hydrochloric acid, the products are benzoic acid and titanocene dichloride. It is noteworthy that the reaction of CO_2 with diphenyltitanocene takes place partly with insertion of a second carbon dioxide molecule in a titanium–carbon σ bond and the formation of a phthalate complex.

All the data obtained are consistent with the hypothesis[228] that the decomposition of diphenyltitanocene proceeds via the intermediate formation of a titanium–dehydrobenzene complex:



It is of interest that, when diphenyltitanocene interacts with tolane under the thermal decomposition conditions, a cyclic compound is also formed[229]:
