
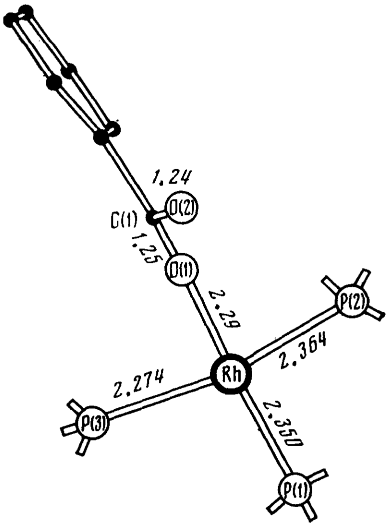

Figure 7. The structure of the rhodium benzoate complex $(Ph_3P)_3RhOOCC_6H_5$.

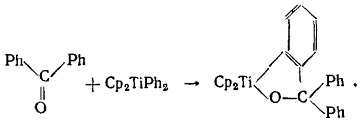
Ketones and isocyanates (analogues of CO_2) are similarly inserted in a carbon–titanium bond[230]. For example, when benzophenone reacts with diphenyltitanocene, a cyclic compound is formed:



Its hydrolysis leads to the formation of triphenylmethanol.

Carbon dioxide is readily inserted in a copper–carbon σ bond in the complex $(Ph_3P)_2CuCH_3$ with formation of the carboxylate complex $(Ph_3P)_2Cu(OOCCH_3)CO_2$ (see also Section IV) in tetrahydrofuran (THF) at –40° C and atmospheric pressure[110]. The NMR spectrum of the product (in pyridine) has a signal corresponding to the methyl of the acetate group (τ = 7.37 p.p.m.) but no signal due to the methyl group of the initial complex (τ = 10.3 p.p.m.). When the complex is treated with hydrochloric acid, acetic acid is produced:

$$CH_3COOCu\,(PPh_3)_2 \xrightarrow{3HCl} CH_3COOH + CuCl + PPh_3 \cdot HCl\ .$$

On the other hand, treatment with alkyl iodides results in the formation of the corresponding esters[110]:

$$CH_3COOCu\,(PPh_3)_2 \begin{cases} \xrightarrow{CH_3I} CH_3COOCH_3 \\ \xrightarrow{C_2H_5I} CH_3COOC_2H_5\ . \end{cases}$$

The same complex may be obtained when a methyl complex of mercury is treated with acetic acid:

$$(Ph_3P)_2CuCH_3 + CH_3COOH \rightarrow CH_3COOCu\,(PPh_3)_2 + CH_4\ .$$

The similarity of the infrared spectrum of the copper carboxylate complex with the spectrum of sodium acetate is evidence, according to the authors[110], for the ionic nature of the bond in the complex. The following assignment of the bands in the spectrum of the copper carboxylate complex $(Ph_3P)_2Cu(OOCCH_3)CO_2$ has been made (in terms of wavenumbers, cm^{-1}): ν(C–H) (asymm.) = 2980 (w.); ν(C–H)(symm.) = 2920 (w.); ν(OCO) (asymm.) = 1640 (s.); ν(OCO) (symm.) = 1393 (s.); $\nu(CH_3)$(rocking) = 1020 (w.); ν(C–C) = 925 (w.); ν(OCO) (symm.def.) = 622 (w.); bands corresponding to coordinated carbon dioxide: 2620 (w.); 1600 (v.s.); 1302 (v.s.); 821 (m.); 648 (w.).

When the unstable complex $[(PPh_3)_2Co(CO)C_2H_5]$, formed when acrolein interacts with the complex $(Ph_3P)_3Co(N_2)H$, was treated with CO_2, the product[103,231] was the carboxylate complex $(PPh_3)_2Co(OOCC_2H_5)_2$, which readily loses triphenylphosphine when an attempt is made to recrystallise it and is converted into cobalt propionate $Co(OOCC_2H_5)_2 . 3H_2O$.

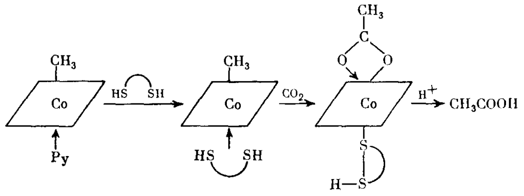
Carbon dioxide is readily inserted also in a rhodium–carbon σ bond in low-valence rhodium complexes of the type $(Ph_3P)_3RhR$, where R = CH_3 or C_6H_5, which results in the formation of carboxylate complexes of the type $(Ph_3P)_3RhOOCPh$.[232,233] When these complexes are treated with inorganic acids, the products are acids, whereas on treatment with BF_3-containing methanol the methyl esters of the corresponding acids are formed. Similar complexes may be obtained also when the complexes $(Ph_3P)_3 . RhOR$ or $(Ph_3P)_3RhOH$ are treated with stoichiometric amounts of acid in the presence of an excess of triphenylphosphine. The infrared spectrum of the benzoate complex contains bands characteristic of transition metal carboxylate complexes: ν(OCO) (asymm.) = 1608 (s.) and 1570 (s.) cm^{-1} as well as ν(OCO) (symm.) = 1360 (v.s.) cm^{-1}. According to X-ray diffraction data[231,233], the rhodium atom in the benzoate complex (Fig. 7) is coordinated to three Ph_3P ligands and the benzoate ligand via a monodentate linkage, which is very rarely encountered in transition metal carboxylate complexes. The coordination of rhodium is close to the square planar form slightly distorted owing to steric interactions between the bulky triphenylphosphine ligands.

On the other hand, many compounds containing stable transition metal–carbon σ bonds do not interact with CO_2. Thus benzylchromium $PhCH_2Cr$ is stable in a CO_2 atmosphere[234]: the attempts[62] to insert carbon dioxide in a cobalt–carbon σ bond in compounds of the type $RCo(CN)_5^{3-}$, where R = $PhCH_2$, Me, etc., were unsuccessful. However, the introduction of certain ligands into the reaction mixture favours such insertion in many instances. Thus it has been found[148] that organic nitrogen-containing bases catalyse the insertion of CO_2 in a zinc–carbon bond. The increase of the reactivity of diethylzinc in the complexes with *NNNN'*-tetramethylenediamine, bipyridyl, and *N*-methylimidazole has been explained[148] by the increased nucleophilicity of the ethyl–zinc bond:

$$Et{-}Zn{-}Et \cdot L + CO_2 \rightarrow EtCOOZnEt \cdot L\ ,$$

where L is an organic nitrogen-containing base.

It has been shown[235] that in the case of methylcobaloxime, in which the cobalt–carbon bond is exceptionally stable, the presence of thiols, which promote the polarisation of the transition metal–carbon bond, makes possible the insertion of CO_2 in a cobalt–carbon bond with formation of the carboxylate fragment:



Thus the interaction of CO_2 with complexes containing a transition metal–carbon σ bond is evidently one of the pathways to the formation of transition metal carboxylate complexes. The space available in the present review precludes a detailed consideration of the properties of these compounds and we shall therefore confine ourselves merely to literature references to the employment of carboxylates in catalysis[236–248] and the preparation of the carboxylate complexes of copper[249,250], vanadium[251–254], tungsten, molybdenum[255,256], rhenium[257], iron[256,258], cobalt[259], and uranium[260], as well as a wide variety of platinum group metal complexes[261–290].

As stated at the beginning of this section, CO_2 can be apparently inserted in a transition metal–carbon bond not only with formation of carboxylate complexes but also "anomalously" with formation of metal-carboxylic acid esters, i.e. compounds containing the M–COOR fragment. Presumably factors such as a low positive charge on the metal combined with the electron-donating nature of the ligands promote this type of anomalous insertion of carbon dioxide.

Indeed the interaction of cobalt complexes containing the ethyl–cobalt σ bond with CO_2 leads to the formation of the ethyl ester of the metal–carboxylic acid as well as the cobalt carboxylate complex (see above)[103,231]. The properties of the complex $(Ph_3P)Co(CO_3)_nCOOEt$ (n = 0.5–1.0) obtained under these conditions are analogous to the properties of the familiar transition metal complexes containing the M–COOR group.

On treatment with hydrochloric acid, carbon dioxide is evolved with formation of the complex L_2CoCl_2 and ethyl formate. When the complex is treated with methyl iodide, ethyl acetate is formed in high yield, while esterification of the compound with $MeOH–BF_3$, for example, gives rise to a mixture of methyl and ethyl formates and acetates[231]. Analogous results were obtained when the known platinum, cobalt, iridium, and rhodium complexes containing the M–COOR fragment are treated with an esterifying agent of the type $ROH-BF_3$ ($R = CH_3$ or C_2H_5). On the other hand, the interaction of carboxylate complexes of the type MOOCR with the $R'OH-BF_3$ mixture leads to the formation of RCOOR′ esters only, while complexes containing the M–COOR group yield a mixture of HCOOR and R′COOR.[65]

The cobalt complex containing the Co–COOEt group, obtained in solution when the complex $(Ph_3P)_3Co(N_2)H$ is treated with methyl chlorocarbonate, is readily decarbonylated with formation of a cobalt complex containing the CO and OEt ligands. This is the reverse of the reaction involving the formation of complexes containing the M–COOR fragment when metal carbonyls are treated with alcohols:

$$M{-}CO + OR^- \rightleftarrows M\langle{}^{OR}_{CO} \rightleftarrows MCOOR\ .$$

A fairly large number of transition metal complexes which are esters of metal–carboxylic acids are already known (see, for example, Angelici's review[291]).

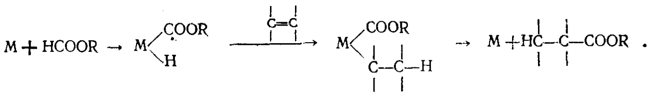
Reactions involving the rupture of a carbon–hydrogen bond in formic derivatives can be of interest for the addition of formamides or formate esters to unsaturated compounds:

$$HCOOR + {>}C{=}C{<} \xrightarrow{M} HC{-}C{-}COOR\ .$$

Table 9. The addition of ethyl formate in the presence of transition metal complexes (8 h, HCOOEt : olefin = 1 : 1).

Catalyst	Temp., °C	Initial olefin	Reaction product	Yield, moles per mole of catalyst
$(Ph_3P)_3RhCl$	140	Cyclohexene	Ethyl cyclohexanecarboxylate	5.3
$(Ph_2PH)_3RhCl$	180	ditto	Ditto	6.0
$(Ph_3P)_2Rh(CO)Cl$	180	»	»	0.8
$(Ph_3P)_2Ir(CO)Cl$	180	»	»	1.2
$(Ph_3P)Rh(CO)_2Cl$	180	»	»	3.3
$(Ph_3P)_3IrH_3$	180	»	»	0.2
$(Ph_3P)_3Os(CO)(H)Cl$	180	»	»	0.6
$(Ph_3P)_2Rh(CO)Cl$	180	$H_2C{=}CH_2$	CH_3CH_2COOEt	0
$(Ph_3P)_2Rh(CO)Cl$	180	$CH_3CH{=}CH_2$	$CH_3CH_2CH_2COOEt$	3.0
$(Ph_3P)_2Rh(CO)Cl$	180	$(CH_3)_2C{=}CH_2$	$(CH_3)_2CHCH_2COOEt$	0
$(Ph_3P)_2Rh(CO)Cl$	180	Hex-1-ene	Ethyl oenanthate	7.0

Such a reaction has been achieved[61] in the presence of various transition metal complexes (Table 9). The yield of the reaction product depends on the nature of the olefin, temperature, reaction time, and the olefin : formate ester ratio. In certain cases the dimerisation of olefins was observed as a side reaction. Rhodium compounds proved to be the most active, while platinum complexes were found to be inactive, probably mainly due to the high stability of the platinum–carbon bond. Presumably the addition of formate esters to olefins proceeds via a stage involving the rupture of a C–H bond in the esters and the formation of esters of metal–carboxylic acids as intermediates:



$$M + HCOOR \rightarrow M\langle{}^{COOR}_{H} \xrightarrow{C=C} M\langle{}^{COOR}_{C-C-H} \rightarrow M + HC{-}C{-}COOR\ .$$

It is noteworthy that the reaction of cyclohexene with the complex $(Ph_3P)Rh(CO)_2Cl_2COOEt$ led to the formation of ethyl cyclohexenecarboxylate.

In the synthesis of vinyl ethers from acetylene, alcohols, and carbon monoxide in the presence of palladium salts[292,293] the Pd–COOR fragment is formed in solution when the Pd–OR bond is acted upon by CO with subsequent transfer of the COOR group to acetylene.

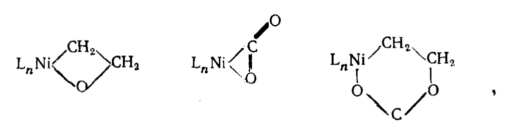
It is evident from the foregoing how large is the set of reactions associated with the problem of the insertion of carbon dioxide in a transition metal–carbon bond known at the present time. For example, the insertion of CS_2,[65, 66,294,295] or SO_2[296] in a metal–carbon bond, which is extremely common in the chemistry of organic derivatives of transition metals, may be included among reactions of this type.

VII. CATALYTIC PROCESSES WITH PARTICIPATION OF CARBON DIOXIDE

The catalytic reactions with participation of CO_2 can be divided into two main groups. The first group includes processes in which CO_2 is the starting material for the synthesis of various organic compounds, while the second group includes reactions in which CO_2 behaves as a ligand which modifies the catalyst. Processes involving the synthesis of formic acid derivatives (esters and amides) when CO_2 is reduced by molecular hydrogen to formate esters and formamides, which were discussed in Section IV, may be assigned to the first group of reactions.

Particular consideration should be given to reactions involving the reduction of CO_2 by molecular hydrogen in the presence of the graphite–$PdCl_2$–sodium heterogeneous catalyst[297]. Together with C_1–C_4 hydrocarbons, dimethyl ether is formed in high yield under mild conditions. The yield of the ether increases greatly in the presence of methanol or formamaldehyde and also when the catalyst is subjected to preliminary treatment with carbon monoxide. The formation of dimethyl ether has also been observed in the hydrogenolysis of methyl formate, which may be formed, according to the authors[297], as an intermediate in the reduction of CO_2.

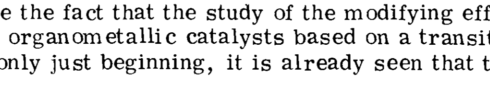
A number of workers[298-302] showed that certain organometallic compounds may catalyse the formation of polycarbonates from CO_2 and high-molecular-weight epoxides via the mechanism



$$n\left(\begin{array}{c} R \\ | \\ HC{-}CH \\ \diagdown O \diagup \end{array}\right) + n\,CO_2 \xrightarrow{Et_2Zn/water} \left(\begin{array}{c} R \\ | \\ CH_2{-}CH{-}O{-}\underset{\underset{O}{\parallel}}{C}{-}O \end{array}\right)_n - \ldots$$

Optically active polymers have been obtained by this procedure[349].

It has been shown recently[303] that the carboxylation of epoxides is catalysed by zerovalent nickel complexes. The author[303] points out the possible existence in the system of compounds of the following type:

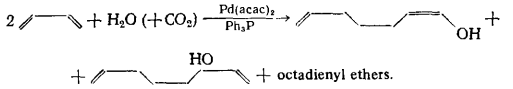


Despite the fact that the study of the modifying effect of CO_2 on organometallic catalysts based on a transition metal is only just beginning, it is already seen that this field is fairly promising from the standpoint of the synthesis of selective and specific catalysts. In this connection one should note that the use of CO_2 as the cocatalyst for the modification of the catalytic system is fairly common in the chemistry of organometallic compounds based on transition metals[62].

The influence of CO_2 on the catalytic properties of nickel, platinum, and palladium catalysts in the dimerisation of butadiene has been reported[304]. Whereas in the absence of a catalyst butadiene dimerises slowly to 4-vinyl-1-cyclohexene and CO_2 has no effect on this process, in the presence of the phosphine complex of platinum $(Ph_3P)_4Pt$ in an atmosphere of argon the yield of 4-vinyl-1-cyclohexene increases to 90–97%; a small amount of octa-1,3,7-triene is formed as a side product. When argon is replaced by CO_2, only *trans*-octa-1,3,7-triene is formed in the reaction. Similar results were obtained in the presence of the complexes $(Ph_3P)_4Pd$, $(Ph_3P)_4Ni$, and $[(PhO)_3P]_4Ni$. The authors[304] do not discuss the mechanism of the action of carbon dioxide but suggest that unstable CO_2 complexes are formed during the reaction. The attempts to isolate such complexes were unsuccessful.

It may also be that the catalysts are involved in this reaction as carbonate complexes (see Section IV). At any rate, according to the results of the same workers[305], octa-1,3,7-triene is formed from butadiene in the presence of a platinum carbonate complex.

It has been observed[306] that CO_2 has a significant influence on the formation of octadienols from butadiene and water in the presence of palladium catalysts. The interaction of butadiene and water in the presence of the $Pd(acac)_2$–triphenylphosphine system (acac = acetylacetonate) in argon leads to the formation of octatriene as the main reaction product. However, in the presence of carbon dioxide octadienols are the main reaction products and the yield of octatriene is insignificant. It is noteworthy that small amounts of carbon dioxide are sufficient for the formation of octadienols:



It is seen from the present review that the chemistry of carbon dioxide in systems involving transition metals is being as it were reborn. The data for the formation of complexes of carbon dioxide with transition metal compounds and the studies on the insertion of carbon dioxide in metal–hydrogen and metal–carbon bonds, considered in this review, demonstrate the extensive scope of the applications of these reactions in various chemical processes. Particular mention should be made of the reactions in which carbon dioxide is involved in catalytic processes, on the one hand, as the starting material for the synthesis of various organic compounds and, on the other, as a ligand modifying known catalysts.

Reactions of Transition Metals in the Atomic State

G.A.Domrachev and V.D.Zinov'ev

The formation of organometallic compounds and π complexes by the direct action of the atomic metal on organic and inorganic compounds is surveyed. The mechanism of these reactions is examined, and practicable recommendations are given for conducting them. A list of 100 references is included.

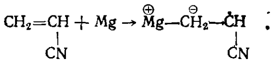
I. INTRODUCTION

During recent years research has been vigorously pursued on the reactions of various metals in the atomic state, as well as on individual valency-unsaturated species. The possibility of using atomic metals for preparative purposes has been studied[1-4]. Condensation of the vapours of magnesium and a monomer—styrene, α-methylstyrene, isoprene, acrylonitrile—together at $-196^{\circ}C$ yields yellow–orange frozen solutions. Thawing is accompanied by vigorous polymerisation, which is often explosive. Among polymerisation initiators—magnesium, zinc, cadmium, calcium, mercury—atomic magnesium has proved the most active[3,4]. Tin and lead do not exhibit activity, and in the ternary systems with a monomer and magnesium, inhibition of polymerisation has even been observed. Electron spin resonance has shown[2] that polymerisation is initiated by a radical formed by the reaction



$$CH_2{=}\underset{\displaystyle CN}{\underset{|}{CH}} + Mg \rightarrow \overset{\oplus}{Mg}{-}\overset{\ominus}{CH_2}{-}\underset{\displaystyle CN}{\underset{|}{\dot{C}H}} \quad . \qquad (1)$$

Such radicals, frozen in excess of the monomer on the cooled walls, initiate polymerisation at temperatures far below the melting point of the monomer. Extension of the fundamental reaction to the vapours of carbon[5] and transition metals[6] has now led to the establishment of a new field in the synthetic chemistry of organometallic compounds.

The Reviewers have now made a general survey of this problem, paying attention to theoretical aspects, assessing experimental methods and equipment, with the introduction of an actively and constantly extending range of compounds into reaction (1), and prospects for employing this reaction in synthetic organometallic and applied chemistry. Existing reviews[6-8] are devoted to particular problems or else give inadequate coverage of the most recent results.

Hitherto studied reactions of organic and inorganic compounds with transition metals in the atomic state can be divided into those involving addition and those involving oxidative incorporation of the metal at various bonds. The classification of organometallic compounds of transition metals according to types of ligands is at present regarded as more convenient. In reporting the factual material, however, we have slightly modified the classification by taking as basis the maximum possible number of electrons that the compound used in the synthesis is able to donate to the metal.

II. TYPES OF REACTIONS

1. Addition of Atomic Metals

(*a*) Reactions with eight-membered carbocyclic $h^8\pi$ donors (cyclo-octatetraene)

Hardly any reactions with cyclo-octatetraene have been reported, apart from a brief mention[9] of the synthesis of dicyclo-octatetraeneuranium. The cocondensation of gaseous iron with the hydrocarbon in the presence of trifluorophosphine forms $C_8H_8Fe(PF_3)_3$, the low yield of which is probably due to slight polymerisation of cyclo-octatetraene on reaction with atomic metals[10]. However, the synthesis of $(C_8H_8)_2M$ (where M = U, Th, Pu) from the dispersed metals and cyclo-octatetraene[11] indicates that these compounds can be obtained also by low-temperature cocondensation from the gaseous metals.

(*b*) Reactions with seven-membered carbocyclic $h^7\pi$ donors

Cycloheptatriene behaves differently towards different atomic metals. Thus the cocondensation of chromium vapour with cycloheptatriene gives a mixture of products, among which the complex $(C_7H_8)_2Cr$ and the component $C_{14}H_{17}Cr$ have been detected mass-spectrometrically[12-14]. The h^4-cyclohepta-1,4-diene-h^7-cycloheptatrienylchromium complex, corresponding to the compound $C_{14}H_{17}Cr$, had been described earlier[15]. The condensation of chromium vapour with cycloheptatriene and trifluorophosphine leads to the isolation of $C_7H_8Cr(PF_3)_3$,[12,14] but the cocondensation of cycloheptatriene with atomic molybdenum or tungsten gives the h^5-cycloheptadienyl-h^7-cycloheptatrienyl derivative, in which the former ligand is easily exchanged for cyclopentadienyl[16,17]. Iron vapour reacts smoothly with cycloheptatriene to give a good yield of $C_7H_9FeC_7H_7$,[13,18] in which the cycloheptadienyl and tropylium systems are coordinated to the iron atom and exhibit dynamic behaviour $C_7H_7 \rightleftharpoons C_7H_9$ in solution. The nuclear magnetic resonance and mass spectra of the product have been determined, and an X-ray structural analysis has been made[18]. Cobalt reacts with cycloheptatriene in the presence of trifluorophosphine to give an allyl derivative, h^3-cycloheptenyltetrakistrifluorophosphinecobalt, and tristrifluorophosphinecobalt hydride[19].

(*c*) Reactions with six-membered carbocyclic $h^6\pi$ donors (arenes)

The use of atomic metals has opened up wide prospects for synthesising diarene complexes of various metals, as well as complexes of functionally substituted benzene derivatives.

Diarene complexes of titanium $Aren_2Ti$ [where Aren = C_6H_6, $C_6H_5CH_3$, $C_6H_3(CH_3)_3$] have been obtained for the first time[20,21]. Dibenzenetitanium comprises reddish-orange crystals that are extremely sensitive to air; they sublime readily at 80°C (10^{-3} mmHg) and begin to decompose above this temperature. The structure of diarene complexes of titanium has been proved by the ^1H n.m.r., infrared, mass, and photoelectronic spectra[21]. In contrast to other methods, the yield of an organometallic compound obtained from the gaseous metal is a measure of the stability of the compound, since it is determined also by the reverse decomposition to the metal and the ligand. In some cases, however, the yield probably depends also on secondary processes. It is interesting to trace the variation in the yield (calculated on the metal vaporised) in a series of diarene complexes of vanadium[22-24]:

$$(C_6H_6)_2\,V\ (60\%),\ (C_6H_5CF_3)_2\,V\ (22\%),\ (C_6H_5F)_2\,V\ (13\%),$$
$$(C_6H_5Cl)_2\,V\ (7\%),\ (p\text{-}C_6H_4F_2)_2\,V\ (1\%).$$

Hexafluorobenzene forms with vanadium vapour an extremely reactive and explosive complex[22].

An immense number of diarene compounds of chromium have been obtained by the direct method. The first such derivative was dibenzenechromium[25,26], obtained in ~60% yield (calculated on the metal vaporised) by the interaction of chromium and benzene vapours. By removing the need for intermediate reagents, use of the metal in its most reactive form permits partial avoidance of the transalkylation and elimination processes that accompany Fischer reduction[27,28].

The compounds obtained include dibenzenechromium derivatives substituted by CH_3, C_2H_5, Cl, F,[12] $[CH_2]_nCOOR$ (n = 0–2),[29,30] t-C_4H_9,[19] iso-C_3H_7,[31] CF_3,[24] and C_6H_5[32] with various substituents[23,33-35]. Diarenechromium complexes have been obtained from polysubstituted arenes containing *o*-COOR,[36] *p*-F,[12] *m*-iso-C_3H_7,[31] *m*- and *p*-CF_3, and *o*-Cl.[24] Complexes have been prepared having different substituents in the ring (H, F, Cl, CH_3, CF_3) and different numbers of these substituents in the rings[33]. The ^{19}F n.m.r. spectra have been compared with those of the original organic molecules[33], and the ^{13}C n.m.r. spectra have been determined[34]. The synthesis of bisborazinechromium was reported[37], but no confirmation has subsequently appeared in the literature.

Mixed complexes can be obtained by the cocondensation of chromium vapour with a mixture of compounds:

$$Cr + Aren + n\,L \rightarrow (Aren)\,Cr\,(L)_n \qquad n = 1,\,3;\quad L = Aren',\quad PF_3\ . \tag{2}$$

Thus the complex $C_6H_6CrC_6HF_5$, stable in air, has been obtained from a mixture of benzene and pentafluorobenzene[38]. The acidic hydrogen atom in the second ligand is very readily replaced by a lithium atom on metallation with t-butyl-lithium in ethereal solution; various derivatives of the type $C_6H_5CrC_6H_5X$ could be obtained by replacing the lithium, with X = $Si(CH_3)_3$, Co_2Li, $C(CH_3)_2OH$, $CpFe(CO)_2$, $CpFeC_5H_4CHOH$.[36] Cocondensation of chromium vapour with a mixture of benzene and hexafluorobenzene gives $C_6H_6CrC_6F_6$.[32] Timms[19] obtained a series of mixed complexes $ArenCr(PF_3)_3$, where Aren = C_6H_6, C_6H_5F, 1,4-$C_6H_4F_2$, 1,3,5-$C_6H_3F_3$, 1,2,3,5-$C_5H_2F_4$, C_6HF_5, C_6F_6. The cocondensation of chromium vapour solely with hexafluorobenzene gives an extremely reactive, explosive complex[22,24].

Work on the preparation of diarene and mixed complexes of chromium, as well as vanadium complexes, reveals a tendency for the yield of the addition product to decrease with increase in the electron-accepting properties of the groups in the ring. However, certain complexes of chromium with halogenobenzenes are obtained in higher yield than are the complexes with benzene itself[12]. In a series of compounds of general formula $ArenCr(PF_3)_3$ maximum and minimum yields were obtained when the arene was respectively *p*-difluorobenzene and hexafluorobenzene[19]. An interesting distribution of yields is exhibited[24] by the compounds $[p\text{-}(CF_3)_2C_6H_4]_2Cr$ (38%), $(o\text{-}ClC_6H_4CF_3)_2Cr$ (33%), $[m\text{-}(CF_3)_2C_6H_4]_2Cr$ (17%), and $(C_6H_5CF_3)_2Cr$ (26%). The high yields of the diarene complexes of chromium containing two electron-accepting substituents in the benzene ring of the ligand are combined with unusual stability of these compounds in air. The decrease in the yields of complexes of polyhalogenated arenes is explained by an increasing tendency for dehalogenation to occur, but the high yield of $p\text{-}C_6H_4F_2Cr(PF_3)_3$ in comparison with $C_6H_6Cr(PF_3)_3$ by kinetic factors[19].

The cocondensation of chromium vapour with pyridine and trifluorophosphine produces a mixture of the two volatile compounds $\pi\text{-}C_5H_5NCr(PF_3)_3$ and $\sigma\text{-}C_5H_5NCr(PF_3)_3$[19,32]. The former is a true π complex of pyridine; it is stable in air for a short time. Its decomposition is promoted by moist air[19].

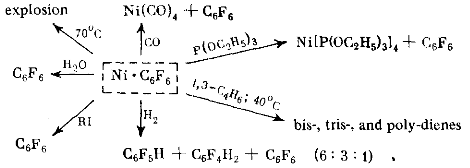
Elimination of electron-accepting groups (bromo, iodo, cyano) under the influence of the atomic metal is sometimes observed[33,37] in the preparation of diarene complexes by the cocondensation of chromium vapour with arenes. This is accompanied by resinification of the organic compound with formation of bound hydrocarbon products and chromium compounds in an oxidised state. Thus an almost theoretical yield of chromium tribromide is obtained by the cocondensation of chromium vapour with bromobenzene[33]. Analogous elimination of electron-accepting substituents from the benzene ring takes place in the Fischer preparation of diarenechromium derivatives[27,28]. The elimination is probably due to enhanced mobility of the substituent in the form of an anion in the actual diarene complex owing to transfer of electron density from the metal to the electron-accepting group.

Diarene compounds are not formed by the action of gaseous manganese on arenes[19]. The cocondensation of manganese vapour with a mixture of an arene and cyclopentadiene gives mixed complexes $ArenMnC_5H_4R$, where Aren = C_6H_6, $C_6H_5CH_3$, 1,3,5-$C_6H_3(CH_3)_3$, and R = H, CH_3.[19] Hydrogen begins to be evolved only at −120°C.[13,19] Since the reaction was conducted by feeding cyclopentadiene to the reaction vessel after the cocondensation of manganese and benzene, cyclopentadienyl derivatives are obviously not preliminary products. The yield of $C_6H_6MnC_5H_5$ calculated on the manganese vaporised is 2–3%,[13] whereas the yield of the same product from the reaction between manganese(II) chloride, phenylmagnesium bromide, and sodiocyclopentadiene is only 0.4%.[39] Direct synthesis is more convenient for the preparation of arenocene complexes of manganese, since this metal can be evaporated from a resistance vaporiser at a rate of 20–100 mg-atoms h^{-1}.[6]

The cocondensation of iron vapour with benzene obviously forms dibenzeneiron[25,31,40], but this explodes when the reaction mixture warms up to −50°C. If cyclopentadiene is added to this cocondensate at −196°C, a 40%

yield of ferrocene is formed on thawing out[25], but $C_6H_6FeC_5H_5$ is not formed. When the cocondensate of iron with benzene heats up to room temperature in an atmosphere of hydrogen, part of the benzene is hydrogenated to cyclohexane. Toluenebistrifluorophosphineiron has been isolated[40] from the cocondensation of iron vapour with toluene followed by addition of trifluorophosphine at −196°C. If buta-1,3-diene is used instead of trifluorophosphine, buta-1,3-dienetolueneiron is formed[40]. According to Timms[19] the stable eighteen-electron complex h^6-mesitylene-h^4-1,3,5-trimethylcyclohexa-1,3-dieneiron-(0) is formed by the cocondensation of iron vapour with mesitylene, but the formation of a diene ligand from this hydrocarbon is difficult to understand. With cyclohexa-1,3-diene iron vapour gives h^6-benzene-h^4-cyclohexa-1,3-dieneiron(0). When the cocondensate is heated to −20°C, the hydrocarbon undergoes catalytic disproportionation to cyclohexane and benzene.

Gaseous nickel does not react with benzene under conditions of direct synthesis. The nickel atom is not incorporated at a carbon–fluorine bond when atomic nickel acts on hexafluorobenzene[22], but an unstable, extremely reactive, and explosive complex of zerovalent nickel is formed. Proof of its formation is provided by its reactions



(3)

At low temperatures nickel probably gives unstable intermediate complexes with arenes. On heating or removal of the ligand atomic nickel undergoes aggregation to a highly active mass[24,41,42]. Like nickel, cobalt forms with hexafluorobenzene a complex that decomposes at −10°C.[22] Furthermore, mixed complexes of cobalt and nickel have been obtained, analogous to the iron compounds ArenFe.$(PF_3)_2$ and ArenFe-1,3-C_4H_6.[40]

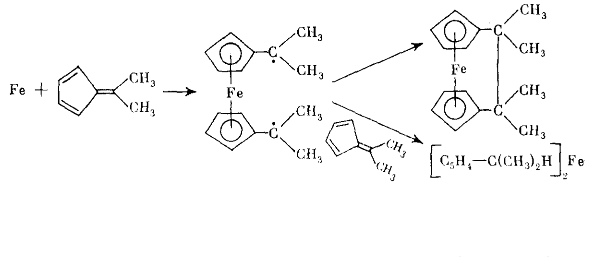
The reactions of atomic molybdenum and tungsten have been studied by two teams of investigators. Diarene complexes of molybdenum have been obtained with Aren = C_6H_6, $C_6H_5CH_3$, 1,3,5-$C_6H_3(CH_3)_3$,[20] $C_6H_5OCH_3$, $C_6H_5N(CH_3)_2$, C_6H_5F, C_6H_5Cl, and $C_6H_5COOCH_3$; and of tungsten with Aren = C_6H_6, $C_6H_5CH_3$, o-$C_6H_4(CH_3)_2$, $C_6H_5OCH_3$, C_6H_5F.[43]

Attempts to obtain arene derivatives of lanthanides (samarium, erbium) did not give definite results[9]. The volatile products obtained were not identified.

(*d*) Reactions with five-membered carbocyclic $h^5\pi$ donors (cyclopentadienyls, etc.)

These reactions are interesting if only because cyclopentadiene possesses a "spare" hydrogen atom for the formation of an h^5-C_5H_5–Metal bond. Cyclopentadiene therefore behaves differently depending on the nature of the metal.

The synthesis of ferrocene by the cocondensation of freshly distilled cyclopentadiene and iron vapour, in 60% yield based on the iron vaporised, was first reported by Timms[25]. Under these conditions nickel gave an 80% yield of h^5-cyclopentadienyl-h^3-cyclopentenylnickel. No subsequent communications have appeared on the synthesis of ferrocene, but in a review[6] Timms referred to Skell in connection with such a synthesis†. More recently the preparation of a mixture of 1,1′-di-isopropylferrocene and ferrocenophan has been reported[44] by the cocondensation of the vapours of iron and dimethylfulvene, for which the mechanism



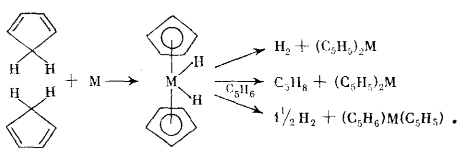
(4)

was suggested. Although the presence of bound ferrocene was not clearly demonstrated[44], the process is of great interest.

Hydrogen evolution is observed in the reaction of atomic chromium with monomeric cyclopentadiene[12], and a 50% yield of dicyclopentadienylchromium is obtained. The hydrogenation product cyclopentene is detected among the reaction products[12]. In the case of atomic cobalt the reaction with cyclopentadiene involves the formation of h^4-cyclopentadiene-h^5-cyclopentadienylcobalt in 50% yield calculated on the metal vaporised[6].

Manganese does not react with cyclopentadiene under conditions of direct synthesis (the mixed arene–cyclopentadienyl complexes have been discussed above). Especially interesting reactions occurred in the action of atomic molybdenum and tungsten on monomeric cyclopentadiene[45], when the di-h^5-cyclopentadienylmetal dihydrides were formed. The characteristics of the products agreed well with those of the compounds obtained in the traditional way[46]. The cocondensation of molybdenum or tungsten vapour with an equimolecular mixture of benzene (or an alkylbenzene) and cyclopentadiene gives a mixture of 20% of a diarene complex, 25% of a dihydride, and 55% of a monohydride[47]. The h^6-arene-h^5-cyclopentadienylmolybdenum monohydride obtained sublimes readily under 1 μmHg at 65°C. Preliminary results[47] on the action of atomic molybdenum and tungsten on indene indicate formation of a mixture of the di-indenylmetal, di-indenyl dihydride, and di-indenyl monohydride.

Thus results on the reactions of metal vapours—iron, chromium, cobalt, molybdenum, tungsten—with cyclopentadiene can be summarised on the hypothesis that all the reactions have the mechanism



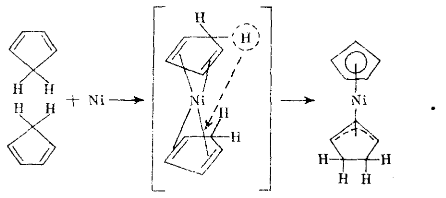
(5)

A possible alternative is intramolecular dehydrogenation–hydrogenation of the h^4-cyclopentadiene ligands with their

---

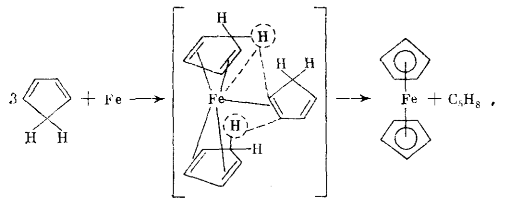
† The paper to which Timms[6] refers does not actually mention ferrocene[100].

aromatisation:



(6)

The coordinated double bond of a third cyclopentadiene molecule may also undergo intramolecular hydrogenation, facilitated by cooperation of the metal atom:



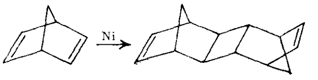
(7)

The mechanism of migration of the hydrogen atom is probably analogous to the hydride rearrangement. The stability of hydro-derivatives of transition metals (such as rhenium, niobium, tantalum, molybdenum, and tungsten) increases[48] with the atomic weight of the metal; hence, according to the above hypothesis, the same dependence should exist for the intermediate hydride complexes formed in the reaction of metal vapours with cyclopentadiene. It therefore seems to us possible that stable hydride complexes may be isolated when the vapours of other "heavy" transition metals undergo cocondensation with cyclopentadiene.

The cocondensation of nickel vapour with the *closo*-carborane $C_2B_9H_{11}$ gives the well known complex $(C_2B_9H_{11})_2Ni$.[19]

(*e*) Reactions with dialkene $h^4\pi$ donors

Reactions with cyclic dienes. The action of atomic nickel on cyclo-octa-1,5-diene gives the complex $(C_8H_{12})_2Ni^0$ [49] described earlier by Wilke[50], whereas with norbornadiene the *exo-trans-exo*-dimer is formed[49]



(8)

instead of an organometallic product. With atomic metals the former hydrocarbon gives several isostructural complexes $(C_8H_{12})_2M$, where M = Pt,[51] Fe.[10] The iron complex was synthesised at −120°C, iron being sputtered into a solution of the hydrocarbon in methylcyclohexane (other solvents have also been used). Formation of the complex is proved by its reaction with 2,2′-bipyridyl[10]:

$$(1{,}5\text{-}C_8H_{12})_2Fe + 2{,}2'\text{-Bipy} + HPF_6 \rightarrow (\text{Bipy})_2Fe(PF_6)_2 + 2\,(1{,}5\text{-}C_8H_{12})\,. \quad (9)$$

The action of trimethyl phosphite on the complex $(C_8H_{12})_2Fe$ entails[52] isomerisation of the ring with the formation of $1{,}3\text{-}C_8H_{12}Fe[P(OCH_3)_3]_3$; such isomerisation is not observed when carbon monoxide, phosphorus trifluoride, or t-butyl isocyanide is used instead of the phosphite. Bubbling nitrogen through an ethereal solution of the complex $(1{,}5\text{-}C_8H_{12})_2Fe$ and 1,2-bisdiphenylphosphinoethane gives[52] a nitrogen-containing complex $N_2FeP(C_6H_5)_2.CH_2CH_2P(C_6H_5)_2$. The complex $(1{,}5\text{-}C_8H_{12})_2Fe$ is a 16-electron compound; this governs its properties. It comprises pyrophoric crystals, which at −40°C decompose rapidly with the separation of iron. In solution in cyclo-octa-1,5-diene the complex is stable right up to 0°C. The ligands in the complex are easily replaced by cyclo-octatetraene, cycloheptatriene, and buta-1,3-diene[10].

Complexes isostructural with $(1{,}5\text{-}C_8H_{12})_2Fe$ have been obtained with cobalt, nickel, and platinum[53], among which the most stable is the cobalt complex, decomposing at −10°C. The action of atomic chromium has been studied on cyclo-octa-1,3- and -1,5-dienes[54,13]. Cocondensation of the former diene with atomic chromium in the presence of carbon monoxide involves isomerisation into the 1,5-diene, as in the reactions with molybdenum and tungsten hexacarbonyls[55]. Replacing carbon monoxide by trifluorophosphine yields[54] two compounds:

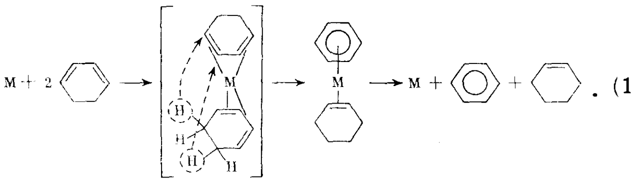
$$1{,}5\text{-}C_8H_{12} + PF_3 + Cr \rightarrow (1{,}5\text{-}C_8H_{12}Cr(PF_3)_4 + C_8H_{11}Cr(PF_3)_3H\,. \quad (10)$$

The expected cyclo-octa-1,5-dienetetrakistrifluorophosphinechromium (yield 1%) is accompanied by $C_8H_{11}Cr.(PF_3)_3H$ (yield 3%), a red solid formed also by the action of atomic chromium on cyclo-octa-1,3-diene in the presence of phosphorus trifluoride[54]. Furthermore, the complex $1{,}5\text{-}C_8H_{12}Cr(PF_3)_4$ undergoes the reaction

$$3(1{,}5\text{-}C_8H_{12})Cr(PF_3)_4 \xrightarrow{85°\,C} Cr(PF_3)_6 + 2C_8H_{11}Cr(PF_3)_3H + 1{,}5\text{-}C_8H_{12}) \quad (11)$$

when heated[54]. X-Ray examination shows[54] that $C_8H_{11}Cr.(PF_3)_3H$ is h^4-cyclo-octadienylhydrotristrifluorophosphinechromium, with the hydride hydrogen not localised on the chromium. The signal at τ = 22.4 ppm in the ^1H n.m.r. spectrum (in deuterotoluene at −50°C) is regarded as evidence of the presence of hydride hydrogen. A π-allyl hydride mechanism is postulated[54] for migration of the hydrogen atom to the ring.

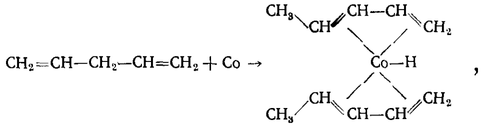
An interesting reaction is the catalytic disproportionation of cyclic dienes on cocondensation with chromium, iron, cobalt, and nickel in the vapour state. It is assumed that an intermediate complex is formed[16]:



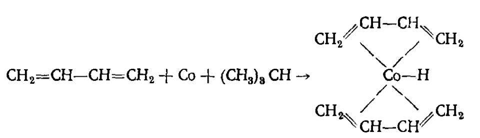
(12)

Reactions with acyclic dienes. Products of the action of atomic metals on acyclic dienes are not always clearly defined, but there is evidence that organometallic compounds are formed. Skell and his coworkers have undertaken a series of investigations[12,16,49,56] on the reactions between atomic metals and unsaturated hydrocarbons. Whereas with atomic aluminium the main reaction is addition at the double bond (σ bond),[56] atomic nickel forms π complexes having a pure π bond[49]. Deuterolysis of the reaction products from transition metals with dienes gives the original acyclic dienes. A certain quantity of deuterium detected in them is attributed to π-allyl hydride rearrangement. The cocondensation of atomic nickel with buta-1,3-diene leaves a grey residue, probably containing bridging butadiene ligands[49], from which a volatile yellow liquid was isolated (yield 2%) that proved to be bisbuta-1,3-dienenickel(0). Dissolution of this complex in liquid butadiene at −20°C gives a dark red organonickel compound $C_{12}H_{18}Ni$, identical with the dodeca-2,6,10-triene-*centro*-nickel(0) obtained by Wilke[50], hydrogenation of which forms n-dodecane.

Gaseous cobalt is a highly active catalyst for the isomerisation of alk-1-enes into non-terminal alkenes and of non-conjugated into conjugated compounds[16]. Such catalytic reactions, as well as certain polymerisation processes, are terminated by the formation of stable complexes of cobalt and certain other metals. Thus relatively stable complexes of cobalt are formed by the reactions[16]



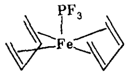
(13)



(14)

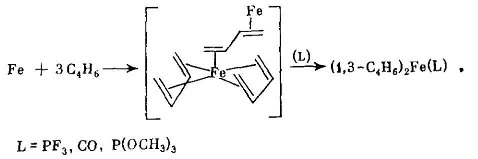
Formation of a hydride complex by the latter reaction takes place in the presence of compounds that readily liberate hydrogen.

The cocondensation of platinum vapour with buta-1,3-diene[51] gives a product that catalyses hydrogenation of excess of the butadiene at −78°C. Atomic iron on cocondensation with buta-1,3-diene yields a dark substance probably containing bridging butadiene ligands[40]. When the cocondensate was warmed up to −78°C and trifluorophosphine or carbon monoxide added, complexes $(1,3\text{-}C_4H_6)_2FeL$ were obtained, in which L = PF_3, CO, or $P(OCH_3)_3$. It is suggested[57] that the trifluorophosphine group is present in an axial position in the $(1,3\text{-}C_4H_6)_2.FePF_3$ molecule



.

The complex of chromium with buta-1,3-diene is obtained[57] by a reaction analogous to formation of the iron complex $(1,3\text{-}C_4H_6)_2Fe$. Crystals of the complex $1,3\text{-}C_4H_6Cr(CO)_4$ decompose above 0°C.[57] Such complexes are assumed to be formed by the reaction



(15)

L = PF_3, CO, $P(OCH_3)_3$

The use of trimethyl phosphite in reaction (15) gives not only the compound $1,3\text{-}C_4H_6FeP(OCH_3)_3$ but also another complex $1,3\text{-}C_4H_6Fe[P(OCH_3)_3]_3$. In an attempt to obtain $[2,3\text{-}(CH_3)_2C_4H_4]_3Fe$ it proved impossible to isolate only $2,3\text{-}(CH_3)_2C_4H_4Fe[P(OCH_3)_3]_3$.[58]

The cocondensation of molybdenum and tungsten vapours with buta-1,3-diene gave the previously unknown trisbuta-1,3-diene complexes[59], which sublimed readily and were stable in air. X-Ray examination showed[16] that the molybdenum or tungsten atom was equidistant from all the carbon atoms.

(*f*) Reactions with three-electron *n* and *π* donors

Reactions with inorganic compounds. When chromium vapour undergoes cocondensation with nitric oxide[6] the metal is oxidised to non-volatile compounds. Several compounds containing mixed ligands, including nitrosyl, have been obtained. Thus the yield of $PF_3Mn.(NO)_3$ is 25%, although this compound is not formed by the usual synthesis under pressure; in an atmosphere of carbon monoxide (1 atm at 20°C) it is converted quantitatively into $COMn(NO)_3$. Mixed ligands have been obtained[31] with cobalt and iron, e.g. $NOCo(PF_3)_2$. Thus an attempt to obtain the already known $Co(NO)_3$ by the cocondensation of cobalt vapour and nitric oxide gave a compound that was insoluble in inorganic solvents[31], whereas $Co(NO)_3$ is readily soluble. No final conclusion was reached on the structure of the product.

Reactions with organic compounds. Timms has shown[19] that, with tetra-allyltin used as source of allyl radicals, a 20−30% yield of di-*h*³-allylnickel can be obtained by cocondensation with the atomic metal. Tri-*h*³-allyliron could not be isolated under similar conditions. When the reaction was conducted in the presence of phosphorus trifluoride, however, a paramagnetic compound $h^3\text{-}C_3H_5Fe(PF_3)_3$ separated that contained a seventeen-electron shell and was stable in air[19]. Di-*h*³-allylbistrifluorophosphineiron, which contains an eighteen-electron shell, is obtained only in insignificant quantities.

Atomic cobalt acts on propene in the presence of phosphorus trifluoride to form a mixture[19] of $h^3\text{-}C_3H_5Co(PF_3)_3$ and $HCo(PF_3)_4$.

(*g*) Reactions with two-electron *n* and *π* donors

Reactions with inorganic compounds. Reactions with phosphorus trifluoride and with carbon monoxide have been most widely studied. It is difficult to obtain carbonyl derivatives by cocondensation with metal vapours because solid carbon monoxide has a high vapour pressure at −196°C. They are therefore obtained at lower temperatures (down to that of liquid helium) or by exchange reactions at relatively high temperatures, in which carbon monoxide interacts with intermediate compounds, acting as a stabilising ligand. The compounds $Ni(PF_3)_4$, $Pd(PF_3)_4$, $Cr(PF_3)_6$, and $[Co(PF_3)_4]_2$ have been obtained in yields respectively of 100%, 70%, 65%, and 50%.[6,8,25,29] The cocondensation of iron vapour with phosphorus trifluoride gives a mixture of 25% of $Fe(PF_3)_5$ and 25% of the dinuclear complex $(PF_3)_3Fe(PF_2)_2Fe(PF_3)_3$; the unstable compound $[Co(PF_3)_4]_2$ could not be definitely characterised. The previously known compound $(PF_3)_3.Co(PF_2)_2Co(PF_3)_3$[60] is not formed in this reaction. Like cobalt, iron forms a dinuclear complex[59] containing difluorophosphino-bridges.

The complexes $Ni(PF_2Cl)_4$ and $M[P(CH_3)_3]_4$ have been obtained with chlorodifluorophosphine and with trimethylphosphine, where M = Ni, Co, Pd.[59] The cocondensation of iron vapour with trimethylphosphine gave the previously unknown complex $Fe[P(CH_3)_3]_5$,[59] an extremely reactive solid. This compound is assumed to result from secondary reactions occurring on heating. The cocondensate of iron vapour and trimethylphosphine at −196°C is green, whereas the compound isolated is yellowish red. Nickel will form several complexes with phosphine[6,59]. The cocondensation of nickel vapour with phosphine at −196°C is accompanied by hydrogen evolution, which intensifies when the cocondensate heats up to room temperature. Tetraphosphinenickel could not be isolated because of the instability of the complex: only the mixed complex $Ni(PF_3)_2(PH_3)_2$ is obtained; it decomposes slowly above 0°C, but in the presence of phosphorus trifluoride is quantitatively converted into $Ni(PF_3)_4$.[59]

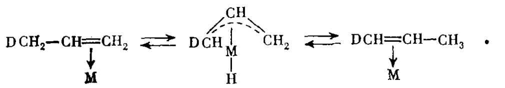
An interesting reaction, unique of its kind, occurs between nickel vapour and carbon dioxide:

$$Ni + CO_2 \rightarrow NiO + CO + Ni(CO)_4 \ . \qquad (16)$$

The tetracarbonyl is formed in 10% yield[8]. The formation of $Ni(CS)_4$ as an analogue of the tetracarbonyl is confirmed by infrared spectroscopy and mass spectrometry[61].

Many papers have appeared recently on the use of vibrational spectroscopy to study the action of atomic metals on various substances. Cocondensation of the metal with the substance has been conducted in an argon matrix at the temperature of liquid helium. This has proved the formation of carbonyls of various metals—nickel, chromium, manganese, iron, cobalt, europium, holmium, praseodymium, rhodium, neodymium, palladium, platinum, copper, silver, and iridium[13,62–71]—as well as carbonyls of intermediate composition. The formation of aluminium carbonyls $Al_x(CO)_2$ indicates[72] that carbonyl derivatives can be obtained with most metals. Complexes of nickel and palladium with molecular nitrogen $Ni(N_2)_n$ and $Pd(N_2)_m$, where $n = 1-4$ and $m = 1, 3$, are formed[73–75] at the temperature of liquid helium.

Reactions with alkenes. Skell and his coworkers[12,49,51,56] have shown how the character of the metal–alkene bond changes on passing from aluminium to chromium and then to nickel and cobalt. Deuterolysis of the organometallic products and analysis of the substances isolated has enabled the character of this bond to be deduced. True π complexes are assumed to be formed with nickel, and a certain proportion of σ bonding is postulated in the case of complexes of chromium with alkenes. It is often impossible to isolate individual compounds from the cocondensation of transition-metal vapours with alkenes, but the latter undergo various processes of catalytic conversion. Nickel and cobalt are the most active. The cocondensation of nickel and but-1-ene is accompanied by catalytic isomerisation into but-2-ene.[49] Similar isomerisation is observed[12] in the cocondensation of but-1-ene with chromium. The cocondensation of platinum with propene gives a grey substance, in which they are assumed[51] to be present in the proportions 1 : 1. π-Allyl hydride rearrangement as a mechanism of isomerisation of alkenes is confirmed by the selective cocondensation of nickel with 2- and 3-deuteropropenes[16]:



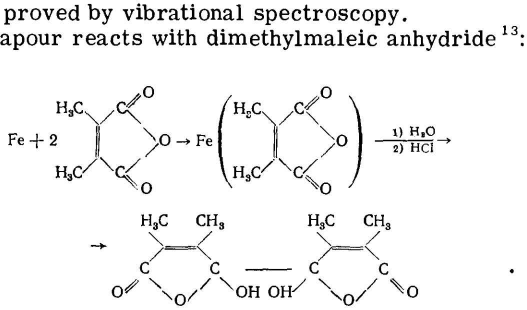
$$DCH_2{-}CH{=}CH_2(\downarrow M) \rightleftarrows DCH{\cdots}CH{\cdots}CH_2(M{-}H) \rightleftarrows DCH{=}CH{-}CH_3(\downarrow M) \ . \qquad (17)$$

This mechanism makes it clear why the quantity of 2-deuteropropene in the initial mixture remains unchanged, and why 1-deuteropropene appears after the reaction.

Attempts to prepare alkene–metal complexes isostructural with the known compound $(C_2H_4)_3Ni$ succeeded in yielding $(C_2H_4)_3Co$ and $(C_2H_4)_3Pd$ (decomposing at −60 and −30°C respectively)[53,76]. Alkene complexes of iron and chromium have not been detected. Bicyclo[2,2,1]heptane gave coloured complexes of palladium, chromium, and cobalt; the palladium complex $(C_7H_{10})_3Pd$ breaks down only at +5°C.[76]

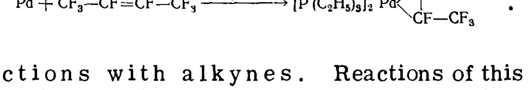
The formation of π complexes by the cocondensation of silver and copper vapours with ethylene or perdeuteroethylene has been confirmed by electron spin resonance[77]. Gold atoms did not form complexes with ethylene. The formation of copper complexees $(C_2H_4)_nCu$, with $n = 1-3$, has been proved by vibrational spectroscopy.

Iron vapour reacts with dimethylmaleic anhydride[13]:



(18)

The pyrophoric product (yield 10–15%) does not react with carbon monoxide. Hydrolysis of this compound of unknown structure leads to the linking of two anhydride molecules. The cocondensation of palladium vapour with perfluorobut-2-ene in the presence of triethylphosphine involves an interesting reaction[24]:



$$Pd + CF_3{-}CF{=}CF{-}CF_3 \xrightarrow{P(C_2H_5)_3} [P(C_2H_5)_3]_2Pd\Big\langle\begin{matrix} CF{-}CF_3 \\ | \\ CF{-}CF_3 \end{matrix} \ . \qquad (19)$$

Reactions with alkynes. Reactions of this type have been little studied. The cocondensation of nickel with alkynes gives mixtures of 1,2,4- and 1,3,5-trialkylbenzenes[49]. Trimerisation of alkynes is observed[12] also under the influence of atomic chromium. But-2-yne forms hexamethylbenzene, but terminal alkynes (but-1-yne, pent-1-yne) give mixtures of isomeric 1,2,4- and 1,3,5-trialkylbenzenes[12]. The low yield of these products does not indicate catalytic conversion, but analysis of the reaction products shows the presence of diarene complexes. Such complexes could have been postulated as intermediate compounds, promoting trimerisation of the alkynes. Obviously, only one arene ring is formed, which is attached for a certain time interval to the chromium.

Styrene undergoes polymerisation on cocondensation with iron vapour[58]. If the cocondensate heats up in an atmosphere of carbon monoxide to −20°C, a mixture of derivatives $C_6H_5CH : CH_2Fe(CO)_n$ is formed in which $n = 3-5$. Hardly any trimerisation of styrene takes place: the yield of triphenyl is ~1%.[58]

Molecular spectroscopy has been used[79] to investigate the action of nickel, palladium, and platinum on alkynes (hex-1-yne, 3-chloropropyne), but no concrete conclusions were reached on the formation of a definite type of complexes.

2. Incorporation of Atomic Metals

(*a*) Incorporation of atomic metals at carbon–halogen bonds

On cocondensation with an allyl halide atomic nickel gives the π-allylnickel halide[80]. The yield of the bromide is 80%, and that of the chloride 75%, but the product is contaminated with a mixture of C_{10-15} hydrocarbons. The cocondensation of platinum vapour with allyl chloride gives a yellow solid that decomposes at 160–170°C; reaction with triphenylphosphine forms $[C_3H_5PtCl.(C_6H_5)_3P]_x$, a compound known previously. The action of platinum on allyl chloride is assumed[51] to give a polymeric compound $(C_3H_5PtCl)_x$. The most widely reported reactions with nickel and palladium involve oxidative incorporation of the metal at the bond between an aryl, alkyl, or acyl carbon atom and the halogen:

$$M + RHal \rightarrow RMHal$$
$$M{=}Ni,\ Pd;\quad Hal{=}Cl,\ Br,\ I;\quad R{=}C_6F_5,\ C_6H_5,\ CF_3,\ CH_3,\ C_3F_7,\ C_3H_7. \tag{20}$$

The stability of the products is largely determined by the radical R.[81,82] Pentafluorophenylpalladium bromide (yield 13%) was a stable, greasy, orange-brown compound, which separated at room temperature and atmospheric pressure. It is stable in air for a short time. Its properties confirm its structure:

$$C_6F_5PdBr + Cl_2 \rightarrow C_6F_5Cl + PdClBr\ , \tag{21}$$

$$C_6F_5PdBr \xrightarrow[\text{(in benzene)}]{\Delta} C_6F_5{-}C_6F_5 + PdBr_2 + Pd\ . \tag{22}$$

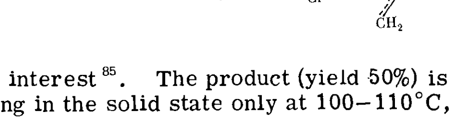
The freshly prepared bromide is able to react instantaneously with triphenylphosphine at room temperature, forming pentafluorophenylbistriphenylphosphinepalladium bromide as a white solid[81]. Pentafluorophenylpalladium bromide exists as a polymer in the solid state and as a dimer in solution. It reacts readily with various phosphine derivatives even at low temperatures. The PR_3 groups are assumed[83] to enter the *trans* position. Since compounds of type RMX are for the most part unstable, they have been isolated as complexes with phosphines[81-84]. Nickel and palladium exhibit great similarity of behaviour in reactions of incorporation, but the resulting nickel compounds are always less stable than the corresponding palladium compounds. Study of a large number of compounds has shown that incorporation of atomic palladium at a carbon–halogen bond becomes less easy according to the nature of the halogen in the sequence I > Br > Cl. The stability of the RPdHal compounds depends on the nature of R and diminishes in the sequence[24,84]

$$C_6F_5 > CF_3 \approx C_2F_5 \approx n\text{-}C_3F_7 > C_6H_5 > CH_3 \approx C_2H_5 \approx CF_2Br \approx iso\text{-}C_3F_7\ ^{24,\,84}.$$

All arylpalladium halides decompose thermally to the biaryl, palladium, and the palladium dihalide.

Metals can be incorporated at carbon–halogen bonds also in acyl halides[84]. The products RCOMHal decompose readily with decarbonylation[24,84]. The stability of the compounds RCOMHal diminishes according to the nature of R in the sequence $n\text{-}C_3F_7 > CF_3 > C_6F_5 > C_6H_5 > CH_3 > C_3H_7$.[84]

The incorporation of palladium into benzyl chloride



(23)

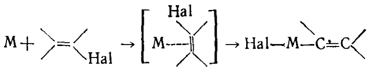
is of great interest[85]. The product (yield 50%) is stable, decomposing in the solid state only at 100–110°C, but in solution at 40°C. Such surprising stability, and also the spectral characteristics, indicate the presence of a π-allyl type of bond. There are data suggesting strong distortion of the benzene structure.

The cocondensation of palladium with trifluoroacetic anhydride followed by the addition of triethylphosphine involves the unusual reaction

$$Pd + \left(CF_3C\overset{O}{\diagup}\right)_2O \rightarrow \left[\left(CF_3C\overset{O}{\diagup}\right)_2O\cdot Pd\right] \xrightarrow{P(C_2H_5)_3} cis\text{-}[(PR_3)_2Pd(OCOCF_3)_2] \tag{24}$$

which is not finally understood[83]. The product is the salt-like bistriethylphosphinepalladium bistrifluoroacetate. A complex of a molecule of trifluoroacetic anhydride with a palladium atom is assumed to be formed as intermediate, but its structure is not yet clear.

The literature contains a brief mention[24] of reactions of platinum and titanium vapours yielding compounds of type RMX. Platinum gives the quite stable pentafluorophenylplatinum bromide, which reacts with triphenylphosphine. The *cis*- and *trans*-adducts are thus obtained, whereas the nickel and palladium analogues give only the *trans*-complexes. The compound "C_6F_5TiBr" is extremely unstable, and such a structure has only been postulated[24]. The cocondensate of titanium with bromopentafluorobenzene is able to cause the vigorous, almost explosive polymerisation of buta-1,3-diene at −78°C. The compound "C_6H_5TiBr" could not be stabilised by reaction with triphenylphosphine. An unsuccessful attempt was made[24] to incorporate palladium atoms at the C–CN bond in benzonitrile and benzilonitrile. Stereochemical aspects of incorporation in optically active compounds (1,1,1-trifluoro-, 2-chloro-, and 2-phenyl-ethanol) have been studied, and the results may be expected shortly[24]. The character of the bond (π or σ) in complexes of nickel, palladium, and platinum with halogenated alkenes



has been investigated[24].

No examples have been reported of the incorporation of transition-metal atoms at carbon–fluorine bonds. However, the formation of complexes of metals with hexafluorobenzene[22] involves vigorous decomposition of the cocondensate, probably owing to the exothermal character of the formation of metal–fluorine bonds. Incorporation of a metal at a carbon–fluorine bond occurs in the cocondensation of calcium with hexafluorobenzene[86].

(*b*) Dehalogenation with transition-metal atoms

One of the first reactions of this type was conducted by Timms[87,88], by the cocondensation of copper vapour with boron trichloride:

$$Cu + 2BCl_3 \rightarrow 2CuCl + B_2Cl_4\ .$$

With the proportions $Cu : BCl_3 = 1 : 6$ a 40% yield of B_2Cl_4 is obtained, which increases to 70% when the proportions are 1 : 20. In the cocondensation of copper vapour with methylboron dichloride in the proportions 1 : 6 the yield of $(CH_3)_2B_2Cl_2$ is 35% calculated on the copper vaporised.

Gold on cocondensation with ethyl bromide[19,32] gives products—butane, ethane, and ethylene—of the dimerisation and disproportionation of the ethyl radical, together with gold(I) bromide. Ethyl chloride does not react with gold. The cocondensation of nickel with ethyl bromide[19] forms a mixture of hydrocarbons—ethylene, ethane, and butane—in the molecular proportions 1 : 1 : 6; the residue contains much free nickel and a small quantity of its dibromide. The yield of hydrocarbons based on the nickel vaporised is only 10%: i.e. nickel is not such an effective dehalogenating metal as copper, gold, and silver. These three atomic metals are more selective reagents than are the alkali metals[19]: the product of the reaction of the optically active s-butyl chloride with copper and silver vapours retains 70% of the activity[19], whereas sodium gives the completely inactive 3,4-dimethylhexane.

It is of practical interest to obtain adducts of nickel with solvents[24,41,42]. On cocondensation with oxolan nickel gives a stable adduct, which is a good reagent for binding alkyl halides. Thus allyl bromide or benzyl chloride can be bound by means of the nickel–oxolan adduct at 40°C.

3. Reactions of Atomic Transition Metals with Compounds containing Active Hydrogen

(*a*) Synthesis of acetylacetonates

The preparation of chromium and iron acetylacetonates by cocondensation of the metal vapours with pentane-2,4-dione in the presence of oxygen was first reported by von Gustorf[89]. The yields of $CrAcac_3$ and $FeAcac_3$ were respectively 32% and 24%. In the absence of oxygen, compounds of the type $MAcac_2$ were obtained[13,63] with manganese, nickel, copper, iron, zinc, tin, and palladium in respective yields of 30%, 36%, 10%, 25%, 28%, 11%, and 10%. The aluminium complex $AlAcac_3$ has also been obtained, as well as acetylacetonates $MAcac_3$ of the rare-earth metals—erbium, dysprosium, and holmium[63].

(*b*) Reactions with alcohols

Chromium vapour reacts with methanol to form the methoxide $Cr(OCH_3)_3$ in 28% yield[13]. Reaction goes readily with isopropyl and t-butyl alcohols, but sparing solubility results in difficulties in purifying the products.

(*c*) Reactions with acids

Chromium reacts with hydrogen chloride at −196°C with the liberation of one mole of hydrogen per gram-atom of chromium vaporised[16]. Cocondensation with acetic acid yields a mixture of bi- and ter-valent salts, the relative composition of which depends on the experimental conditions[13].

(*d*) Reactions with water

Chromium reacts with water at −196°C to liberate half a mole of hydrogen, and the other half appearing on heating[16]. Atomic molybdenum and tungsten do not react with water at −196°C.

III. MECHANISM OF THE COCONDENSATION OF ATOMIC METALS WITH ORGANIC AND INORGANIC SUBSTANCES

No published assessment is available on the mechanism of the condensation of metal vapours with various substances (vapour-phase synthesis). The Reviewers feel it possible to consider this process by applying equilibrium thermodynamics to the direct synthesis of dibenzenechromium. An earlier thermodynamic calculation showed[90] that the equilibrium constant of the decomposition of dibenzenechromium

$$(C_6H_6)_2Cr\ (g) \rightleftarrows Cr\ (s) + 2C_6H_6\ (g) \tag{25}$$

increases with rise in temperature from 298 to 1000 K. Furthermore, calculation over the ranges 298–800 K and 10^{-5}–10^{7} atm showed that only at 10^{7} atm does the Gibbs free energy of process (25) change sign, i.e. that the equilibrium shifts towards formation of the complex.

To elucidate the mechanism of direct synthesis, which may be either a gas-phase or a gas–solid reaction, we can calculate the changes in Gibbs free energy ΔG (in kcal $mole^{-1}$) for the possible reactions under these conditions (chromium was regarded in the calculations as an ideal gas):

$$Cr\ (s) + 2C_6H_6\ (g) \xrightleftharpoons{298\ K} (C_6H_6)_2Cr\ (g) \quad (\Delta G = 27.2) \tag{26}$$

$$Cr\ (s) + 2C_6H_6\ (g) \xrightleftharpoons{298\ K} (C_6H_6)_2Cr\ (s) \quad (\Delta G = 18.9) \tag{27}$$

$$Cr\ (g) + 2C_6H_6\ (g) \xrightleftharpoons{298\ K} (C_6H_6)_2Cr\ (g) \quad (\Delta G = -57.4) \tag{28}$$

$$Cr\ (g) + 2C_6H_6\ (g) \xrightleftharpoons{298\ K} (C_6H_6)_2Cr\ (s) \quad (\Delta G = -65.5) \tag{29}$$

$$Cr\ (g) + 2C_6H_6\ (l) \xrightleftharpoons{298\ K} (C_6H_6)_2Cr\ (s) \quad (\Delta G = -62) \tag{30}$$

$$Cr\ (s) + 2C_6H_6\ (s) \xrightleftharpoons{77\ K} (C_6H_6)_2Cr\ (s) \quad (\Delta G = 16.4) \tag{31}$$

$$Cr\ (g) + 2C_6H_6\ (s) \xrightleftharpoons{77\ K} (C_6H_6)_2Cr\ (s) \quad (\Delta G = -70) \tag{32}$$

$$Cr\ (g) + 2C_6H_6\ (g) \xrightleftharpoons{1000\ K} (C_6H_6)_2Cr\ (g) \quad (\Delta G = -30.3)\ . \tag{33}$$

It thus becomes clear that reactions (28)–(30), (32), and (33) must be regarded as thermodynamically probable. Experimental observations indicate that equilibria (26), (27), and (31) are displaced to the left, since on the termination of synthesis the reaction vessel contains metallic chromium as a powder formed by the aggregation of atomic chromium and unable to react with benzene under normal conditions. Furthermore, the thermodynamically permitted reactions (28), (29), and (33) require a three-body collision, whose probability z_3 is almost zero: its ratio to the probability z_2 of a bimolecular gas-phase reaction is $0.01p$, where p (atm) is the pressure at 300 K;[91] since under conditions of direct synthesis $p = 10^{-4}-10^{-6}$ mmHg (i.e. $10^{-6}-10^{-8}$ atm), it becomes obvious that the probability of a three-body collision $z_3 = (10^{-8}-10^{-10})z_2$ is extremely small. As the free path of metal atoms at such pressures exceeds considerably the dimensions of all the reaction vessels used, direct synthesis must obviously be regarded as a gas–solid (metal–benzene) reaction (32). From this several conclusions may be reached concerning the mechanism of direct synthesis.

A metal atom incident on the surface of a condensed organic or inorganic substance will obviously lose its energy at the first collision with molecules of the latter (this can be deduced from the estimated kinetic energy of the atom). The local heating of the condensed phase facilitates diffusion of the metal atom and of molecules of the latter, which promotes the three-dimensional orientation favourable for interaction in the matrix. Intense vaporisation of the metal increases the probability of mutual encounter of the metal atoms and their aggregation. With inadequate dissipation of heat and the freezing of a thick layer on the walls of the reaction vessel, moreover, the substance may melt (reaction 30). The gas–liquid reaction is permitted thermodynamically, but the probability of mutual encounter and aggregation of metal atoms will be especially high under these conditions. In the condensed state the metal no longer reacts. This may explain the diminished yield of organometallic compound (relative to the theoretical yield based on the metal vaporised) and the formation of a metal powder, although the yield is governed, of course, also by the reverse decomposition of the organometallic compound to the metal and the organic compound.

The isolation of the metal atoms in the matrix can be assessed by means of the ratio of the number M of matrix atoms or molecules to the number R of metal atoms in the matrix. The spectroscopy of atoms isolated in a matrix[92] indicates that good isolation of atomic metals is achieved with $M/R \geqslant 300$. However, such data apply to a matrix which is inert with respect to the metal. Work on direct synthesis usually employs ratios of $M/R = 6-100$, since a large excess of the substance is obviously unnecessary, because of interaction with the atomic metal.

Further cooling of the walls of the reaction vessel (to the temperature of liquid helium) confers great "rigidity" on the matrix, and thereby impedes diffusion of the metal atoms and diminishes the probability of their aggregation. Furthermore, compounds that are unstable at the temperature of liquid nitrogen can be recorded spectroscopically at the lower temperature.

The above estimate provides a better understanding of the relation of direct synthesis to the thermal decomposition of organometallic compounds, e.g. a diarenechromium, which in turn enables us to assess the stability of an organometallic compound from its yield. The phase in which the metal separates plays an important part in displacing the equilibrium in thermal decomposition. Thus when chromium atoms are adsorbed on a solid (substrate) or when they aggregate to form a solid phase of metallic chromium, the synthesis–decomposition equilibrium should shift towards breakdown of the diarenechromium, because of the low mobility of chromium atoms in the solid phase. Calculation for the gas-phase reaction (33) at 1000 K shows, however, that the equilibrium is again displaced towards synthesis of dibenzenechromium if the chromium is in the gaseous state. In direct synthesis the chromium atom incident on the layer of condensed substance is more mobile than the chromium atom in contact with the substrate in the case of thermal decomposition, and the translational motion of the atom can be regarded as terminated only on formation of the organometallic compound or as a result of mutual aggregation of the atoms.

Analogous calculations can be made for the formation of ferrocene from atomic iron and cyclopentadiene:

$$\mathrm{Fe}\ (g) + 3\mathrm{C_5H_6}\ (g) \xrightleftharpoons{298\ \mathrm{K}} (\mathrm{C_5H_5})_2\mathrm{Fe}\ (g) + \mathrm{C_5H_8}\ (g)\ \ (\Delta G = -112) \tag{7}$$

$$\mathrm{Fe}\ (g) + 2\mathrm{C_5H_6}\ (g) \xrightleftharpoons{298\ \mathrm{K}} (\mathrm{C_5H_5})_2\mathrm{Fe}\ (g) + \mathrm{H_2}\ \ (\Delta G = -97) \tag{34}$$

$$\mathrm{Fe}\ (g) + 2\mathrm{C_5H_6}\ (g) \xrightleftharpoons{298\ \mathrm{K}} (\mathrm{C_5H_5})_2\mathrm{Fe}\ (g) + 2\mathrm{H}\ \ (\Delta G = +1)\,. \tag{35}$$

The free energies of these reactions at 77 K could not be calculated, unlike the case of the synthesis of dibenzenechromium, owing to the absence of thermodynamic characteristics for solid cyclopentadiene and of data on the temperature dependence of its heat capacity. However, these calculations suggest that reactions (7) and (34) will be thermodynamically feasible, involving as transition state a hydride or an eighteen-electron complex of iron (II, 1*d*). The existence of such an intermediate eighteen-electron iron complex [Eqn. (7) in II, 1*d*] can be regarded as proved by the presence in the reaction mixture of cyclopentene in equimolecular proportions to the ferrocene isolated[93].

IV. APPARATUS FOR DIRECT SYNTHESES

1. Vacuum System and Reaction Vessel

An ordinary high-vacuum system (Fig. 1), having fore vacuum and diffusion pumps, was used for the direct syntheses‡. The rate of evacuation can be increased by supplementing these with a booster pump, but normally this is not required, since the walls of the reaction vessel, cooled to −196°C, provide effective cryogenic evacuation of the substance supplied to the reaction vessel, by freezing it and thereby maintaining a high vacuum in the system.

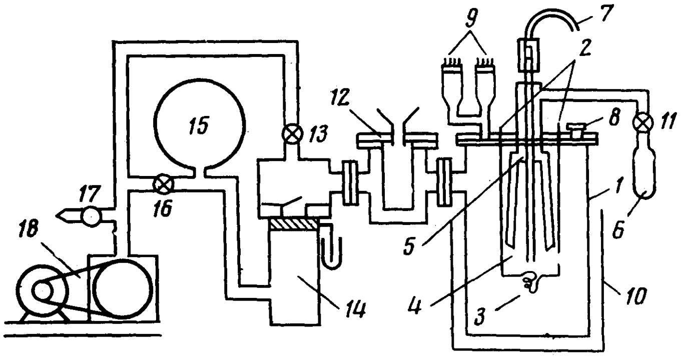


Figure 1. Diagram of apparatus for direct synthesis: 1) reaction vessel; 2) current leads; 3) vaporiser coil; 4) tube for supply of metal; 5) tube for supply of compound; 6) ampoule containing compound; 7) ampoule containing metal fragments; 8) viewing window; 9) manometric valves; 10) Dewar vessel; 11, 13, 16, 17) vacuum taps; 12) trap; 14) VA-01-1 vacuum unit; 15) ballast volume; 18) preliminary vacuum pump.

One or two traps filled with liquid nitrogen are placed between the high-vacuum system and the reaction vessel. They comprise detachable Dewar vessels. The reaction vessel with a flanged coupling and a copper or aluminium gasket is connected to the high-vacuum system through traps. Of the two forms of reaction vessel—with rigid coupling or rotating—the latter uses the same principle as in the rotary vaporiser, which is used in chemical laboratories for the vacuum evaporation of solvents. A complication in the present case is to make a stuffing box capable of rotation and operating in the pressure range $10^{-5}-10^{-6}$ mmHg (Fig. 2)§.

---

‡ In our laboratory the apparatus was based on a standard VA-01-1 vacuum unit. It is convenient to use as the ballast volume the inner vessel of an ASD-15 Dewar flask. Such a metal ballast volume is safe in operation and has a large capacity (15 litres).

§ The firm G.V. Planer Ltd. (Great Britain) manufactures equipment with a rotating glass reaction vessel (diameter 100 mm) and a resistance vaporiser; an electron-beam gun of type EBSI/H is also produced by the same firm.

The overall arrangement of the apparatus is straightforward, and solving the design problem of the rigidly fixed vessel presents no great difficulty. Cooling the walls of the reaction vessel gives rise to certain difficulties, since the use of glass Dewar vessels under these conditions is complicated by the relatively large diameter of the reaction vessel. The latter should therefore have a double or triple jacket (with the outer vessels connected to the vacuum system, while the inner vessel serves for pouring the liquid nitrogen) or else the reaction vessel should be immersed in a reservoir of liquid nitrogen, for which purpose a tank cast from foam plastic can be recommended. All the various forms of apparatus differ in the ways in which they solve the problem of vaporising the metal and feeding the organic or inorganic substance to the reaction vessel.

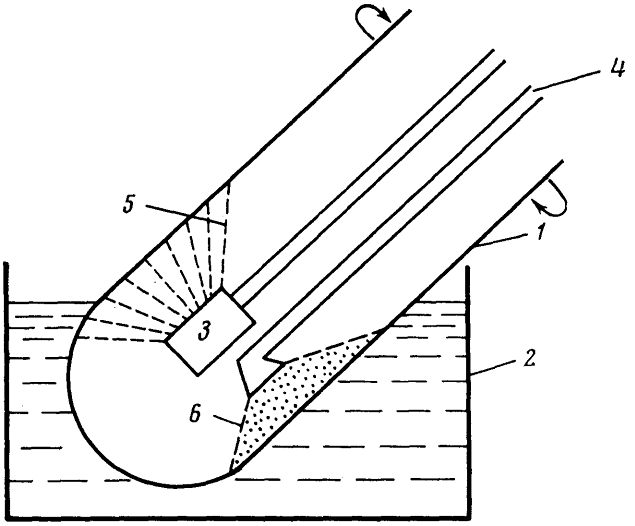

Figure 2. Diagram of rotating reaction vessel: 1) reaction vessel; 2) Dewar vessel; 3) electron gun; 4) delivery of compound; 5) metal vapour; 6) vapour of compound.

2. Vaporisation of the Metal in a Vacuum

The technology of the vacuum evaporation of metals is now well developed. Among the main methods for vaporising a metal—(*a*) from a resistance-heated vaporiser, (*b*) by induction heating of the metal in a container, (*c*) by electron bombardment of a specimen of the metal, and (*d*) by a laser beam—method (*a*) is the simplest and most practicable, but its application is restricted by the difficulty of vaprosing refractory metals. Processes (*b*) and (*c*) have the greatest prospects and are most convenient.

(*a*) Vaporisation from a resistance-heated vaporiser

In this process the metal vapour is obtained from a resistance-heated vaporiser basket made of tungsten or molybdenum wire (diameter 1–1.5 mm). The required shape is conferred on the vaporiser by means of a threaded conical mandrel (tungsten wire is wound on the cone while being heated in a flame). Such an evaporator is fixed in the clips of the current leads, which are situated in the flanged lid of the reaction vessel and are usually cooled with water.

The difficulty with a resistance evaporator is that the molten metal begins to flow along the coil and to "short" it, when vaporisation almost ceases and the coil burns out; at the same time the unmelted solid metal has a low vapour pressure and its rate of vaporisation is very small. Wetting of the coil with the molten metal can be avoided by using crucibles comprising the same vaporisers as before, but coated with aluminium or beryllium oxide[94]; such a coating is applied from an aqueous suspension of alumina¶. Use of a resistance evaporator permits the vaporisation of transition metals of the first series, copper, silver, gold, palladium, uranium, and also lanthanides. The employment of crucibles coated with aluminium oxide is restricted by the possibility of interaction with the molten metal. Such interaction takes place with chromium, and more electropositive metals cannot be vaporised from such a crucible.

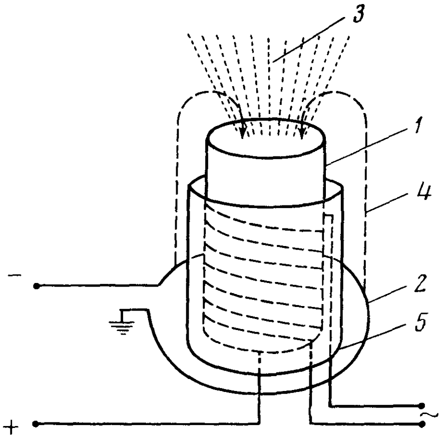

Figure 3. Diagram of electron gun: 1) crucible containing metal specimen (having a high positive potential) preheated by a coil; 2) preheated tungsten wire; 3) metal vapour; 4) flux of electrons; 5) cylindrical shield (having a slight negative potential).

Vaporisation can be effected by other modifications of this method. (i) The vaporiser may consist of a tungsten rod (diameter 3–4 mm) on which are wound in parallel a wire of the metal to be evaporated and a thin tungsten wire (diameter 0.3–0.5 mm). (ii) In the exploding wire method [57] a wire descending from a special container short-circuits the contacts and burns up, with production of a high density of metal vapour; here, however, polyatomic

---

¶ The crucible coating can be applied as a paste—aluminium in a silicate cement—the coated crucibles first being dried at 200°C and then annealed in a vacuum.

metal particles are formed. (iii) The vaporiser can be made from rolled molybdenum, tungsten, or niobium–tantalum alloy (combustion boat).

The source of supply for resistance vaporisers is an adjustable transformer capable of giving currents up to 100–150 A at voltages of 6–12 V.

(*b*) Induction heating

This method has advantages over the resistance heating of a metal specimen, but is hardly used at all in apparatus for the direct synthesis of organometallic compounds. It also has its problems in connection with the need to use a high-frequency oscillator[95].

(*c*) Electron bombardment

An electron gun is used in which the electrons emitted by a tungsten filament are focussed on a specimen of the metal to be vaporised. A compact design of electron gun has been proposed by the English firm G. V. Planer Ltd. (type EBSI/H) (Fig. 3).

Choice of power for the electron gun must be based on the enthalpy of vaporisation of the metal, the desired rate of evaporation, and also the inevitable accompanying energy losses. If the power is insufficient, the metal specimen may be preheated by a different method, e.g. resistance heating.

(*d*) Laser vaporisation

Use of a laser beam to vaporise metals in direct syntheses has been reported by von Gustorf[13,57]. A carbon dioxide laser of power 1.2 kW was focussed into a spot of diameter 1–2 mm. Vaporisation of metals of high melting point was effected from a heated crucible into which the laser beam was directed.

The dependence of the reflecting power of the metal on the wavelength must be taken into account for optimum utilisation of the laser energy. The most acute problem in the use of a laser is the "window" in the reaction vessel. Thus, whereas with other methods of heating metals a "window" is necessary only for periodic observations, being closed for the remaining time and not coated with a film of the condensed metal, in the present method the "window" should be open continuously for passage of the laser beam. A "sluice" is arranged to protect the "window" from sputtering in the evacuated reaction vessel: the pressure in the "sluice" is maintained at 0.1–0.01 mmHg by a jet of argon, which blows away metal atoms (of very small volume) travelling in the direction of the "window"[13].

3. Supply of Organic or Inorganic Substance

The supply of gases to the reaction vessel is structurally very simple, being effected through orifices in a tube placed at the centre of the vessel. The supply is controlled by means of a finely adjustable tap. Volatile liquids are supplied in the same way as gases, but organic compounds of high boiling point must be heated in an ampoule, and the whole tube along which they pass to the reaction must be warmed (to prevent their condensation inside the tube). A gaseous substance is uniformly distributed in the reaction vessel, and condenses on the walls. Delivery can be simplified by uniformly spraying the substance into the reaction vessel, since a gas–solid (metal–condensate) reaction takes place.

A sublimer is introduced into the reaction vessel for the delivery of solids. The substance may also be supplied dissolved in an inert solvent (C_{10-12} saturated hydrocarbons, etc.[10,19]).

4. Isolation of Organometallic Compounds Formed by Direct Synthesis

Methods of isolation depend on the nature of the compound obtained. Certain structural units should therefore be provided in the apparatus.

Volatile reaction products distil from the reaction vessel into a trap. For such purposes the easily detachable vessel is usually disconnected from the vacuum system and connected to another system, into whose trap the reaction product distils. Equipment fitted with a parallel evacuation line from the reaction vessel may also be used: this line is used for distilling off products while the main vacuum line is closed.

Use of such a system to isolate less volatile products is complicated by their condensation in the vacuum tubes and taps. An interchangeable flange with a receiver ("finger") cooled in liquid nitrogen can be employed for this purpose. When synthesis is complete, the main flange is replaced by the flange with the cooled receiver, on whose surface the reaction products sublime from the walls of the reaction vessel.

Various chemical reactions can be conducted at either room or low temperatures in order to isolate certain organometallic compounds. Diarenechromium complexes, for example, can be oxidised in the presence of water to the diarenechromium hydroxides, which can then be converted into the iodides or into neutral complexes[29,30]. Many examples have been reported of the isolation and proof of formation of unstable products of the cocondensation of atomic metals with organic compounds. The isolation of organometallic compounds RMHal (where M = Ni, Pd) as adducts with phosphines $RMHal.2PR_3$ is typical of such reactions.

To prove the formation of unstable compounds increasing use is being made of the spectroscopic recording (directly on the cooled caesium iodide window of the infrared spectrometer) of compounds formed by the low-temperature cocondensation of metal vapours with organic and inorganic substances[41,52,53].

V. POSSIBILITIES AND PROSPECTS

In the near future the technique of low-temperature cocondensation should take its place in chemical laboratories. It provides unusual opportunities for obtaining Grignard reagents by the cocondensation of magnesium vapour with halogenated organic compounds, and also for preparing an especially active magnesium mass by cocondensation with an inert solvent. Such a mass will give Grignard reagents with the most inert halogenated aromatic compounds. For example[24] the cocondensation of magnesium vapour with oxolan forms a complex that can be used for the synthesis of Grignard reagents:

$$\mathrm{Mg + Oxol} \xrightarrow{196^\circ\mathrm{C}} [\mathrm{Mg.Oxol}]- \left| \begin{array}{l} \xrightarrow{C_6H_5Cl;\ 35^\circ C} C_6H_5MgCl\ (80\%) \\ \xrightarrow{C_6F_5Br;\ 30^\circ C} C_6F_5MgBr\ (80\%) \\ \xrightarrow{CF_3Br;\ 30^\circ C} CF_3MgBr\ (1\%) \end{array} \right. \quad (36)$$

.

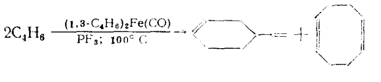
It is of practical interest to prepare a similar active mass of nickel. Thus the cocondensation of nickel vapour with oxolan produces a stable adduct, which is a very good reagent for binding alkyl halides[24,41,42]:

$$2C_3H_5Br + \text{Ni-Oxol} \xrightarrow{40° C} C_3H_5{-}C_3H_5 + NiBr_2 \tag{37}$$

$$2C_6H_5CH_2Cl + \text{Ni-Oxol} \xrightarrow{40° C} (C_6H_5CH_2)_2 + NiCl_2\ . \tag{38}$$

Such solvate complexes of metals are only now beginning to be investigated, but the results already obtained are extremely encouraging.

Complexes formed in cocondensation with atomic metals are often good catalysts for various processes. In the presence of phosphines at 100°C, for example, $(1,3\text{-}C_4H_6)_2.$ $.FeCO$[13] catalyses the dimerisation of dienes and other reactions:



(39)

. (40)

Extremely promising and interesting work has been done[96, 97] on the oligomerisation of butadiene catalysed by products of the cocondensation of vapours of transition metals—titanium, nickel, chromium, manganese, iron, cobalt, vanadium—with butadiene in benzene or toluene in the presence and in the absence of dimeric diethylaluminium chloride. With titanium and iron in the presence of $[(C_2H_5)_2AlCl]_2$ oligomerisation involved 100% conversion; nickel, chromium, vanadium, and manganese also showed great catalytic activity (respectively 90%, 60%, 43%, and 40%); but cobalt was relatively inactive (10%). On oligomerisation in the absence of aluminium complex the greatest catalytic activity was developed by iron, cobalt, nickel, and chromium (90%, 88%, 75%, and 62% respectively), whereas titanium was inactive (10%).

A simple and perhaps more economic process—cocondensation of metal vapours with organic compounds—may be used to prepare catalysts[97]. Titanium can be vaporised by an electron gun at a rate of 70 kg h^{-1}, which makes it possible to produce the catalysts on an industrial scale[98].

Direct synthesis enables especially pure organometallic compounds to be obtained. Thus whereas the usual Fischer preparation of bisethylbenzenechromium yields many homologues with different numbers of alkyl substituents, for example, the cocondensation of chromium vapour with ethylbenzene gives the individual compound bisethylbenzenechromium[99], which is very important in the use of organochromium compounds to obtain chromium films. The technical process requires substances of constant characteristics—boiling point, vapour pressure, viscosity, density, etc.—and use of this method enables standard substances to be obtained for the analysis of various mixtures of organometallic compounds, as well as for obtaining accurate spectral and other characteristics of particular compounds.

New Heterochain Polymers Based on Cyclic Imides of Carboxylic Acids

I.A.Arkhipova, B.A.Zhubanov, and S.R.Rafikov

Results are given for the use of cyclic imides of carboxylic acids and monomers for new thermostable polyimides and polyamides. Migration copolymerisation, polycondensation, and cycloaddition of imides of aliphatic, aromatic, and unsaturated structure are discussed. A list of 159 references is included.

I. INTRODUCTION

Anhydrides of di-, tri-, and tetra-carboxylic acids are used as starting materials for the synthesis of most thermostable polyheteroarylenes[1-3]. Use of these monomers in reactions with aromatic di- or tetra-amines yields processable polymers resistant to chemicals and radiation, which withstand prolonged heating to 300°C. However, the preparation and especially the purification of these anhydrides is associated with several difficulties[4]. Existing methods of obtaining polymers from them also have their defects[5], primarily the hydrolytic instability of the polymers formed in the first stage, as well as the complexity of achieving 100% cyclisation in the second stage. The search for other monomers structurally analogous to anhydrides and the development of new methods for synthesising thermostable heterochain polymers are extremely urgent tasks.

Cyclic imides of carboxylic acids are of definite interest in this connection[6]. Effective procedures for their synthesis by the vapour-phase oxidative ammonolysis of alkylbenzenes have been developed recently[3,7,8]. Good yields and ease of purification guarantee important advantages in comparison with anhydrides.

In the present Review we have attempted to summarise examples of the use of such monomers, describe new reactions in which they are used, and report the properties of the resulting polymers.

II. POLYCONDENSATION OF CYCLIC IMIDES WITH AMINES INVOLVING CLEAVAGE OF THE IMIDE RING

It has long been known that cyclic imides of carboxylic acids are able to react with several nucleophilic compounds. Until recently, however, these reactions were not studied in relation to polymer chemistry. Many investigations during the past 10–15 years have shown a promising future for the use of these reactions in synthesising macromolecular compounds. Amines are active nucleophilic components, undergoing aminolysis with imides to give diamides.

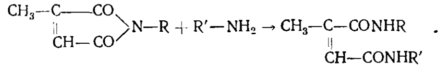
1. Aliphatic Imides

The first systematic investigation of the interaction of aliphatic imides with amines was undertaken by Sheremet'eva and her coworkers during the 1960s. Taking succinimides as examples, they showed[9] that amines in alcoholic solutions in the cold produce cleavage of the imide ring with formation of corresponding mono- or di-substituted diamides:

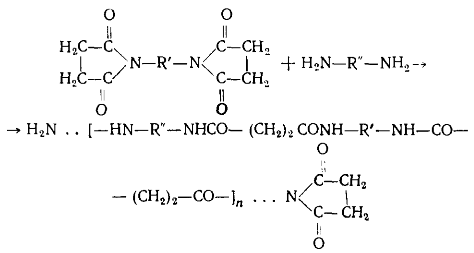
$R' = H, CH_3, C_6H_{11}$, [illegible] = Alk or cycloAlk .

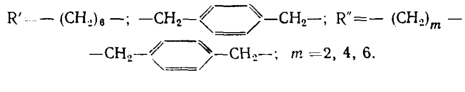
Imides of unsaturated dicarboxylic acids—maleic, citraconic, itaconic—may react differently with amines according to the conditions[9-11]. In anhydrous organic solvents only addition of ammonia and amines at the double bond takes place, with formation of corresponding derivatives of aspartic acid:

An aqueous solution of an amine causes aminolysis with formation of diamides and preservation of the double bond:



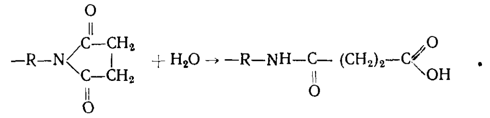
Polymers varying in chemical structure and properties can be obtained by applying these reactions to difunctional compounds. Sheremet'eva et al. were the first to show[12] that linear polyamides can be obtained by the aminolysis of disuccinimides:



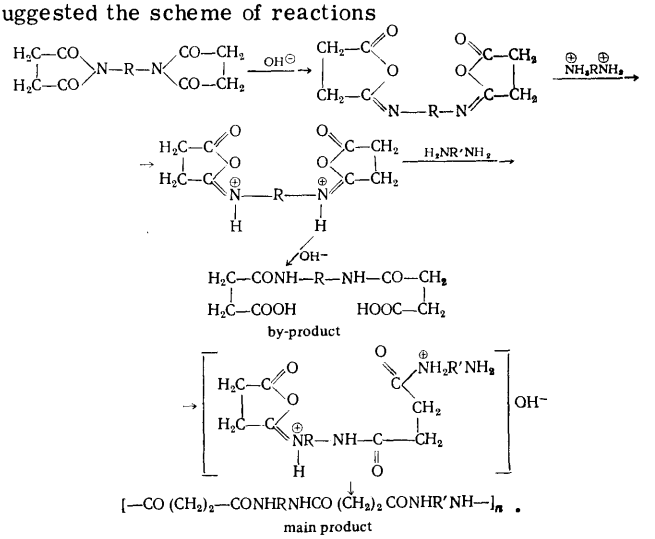


The reaction is conducted under mild conditions, in the cold with prolonged standing of solutions or suspensions of the imides with the amines in the presence of water in such solvents as dioxan, methanol, etc. Polyamides of molecular weight 16 000–20 000 are thus obtained. Reaction does not take place in dry organic solvents even after boiling for many hours[13].

Bisimides of glutaric, aspartic, and unsaturated acids have also been used as initial monomers in this reaction[14]. Mixed polyamides are obtained from bisimides and bisamines containing substituents R′ and R″ differing in structure. Conducting the reaction at room temperature eliminates transamidation and will yield mixed polyamides of strictly specified, regular structure, in which the hydrocarbon fragments R′ and R″ are arranged in a definite sequence in the macromolecule. Termination of the growing polymer chain may result from hydrolysis:

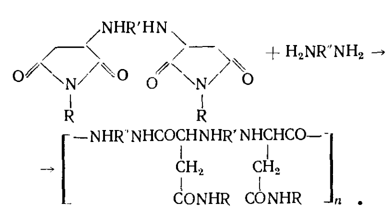


A comparative kinetic investigation of aminolysis and hydrolysis was made in the case of the action of amines on the hexamethylenebisimides of succinic and glutaric acids in order to determine the quantitative relation between these reactions[15]. For each of the bisimides the rate of aminolysis is several times greater than the rate of hydrolysis, and bisglutarimides are hydrolysed appreciably more rapidly than are bissuccinimides. Both processes—aminolysis and hydrolysis—are catalysed by hydroxide ions. The quantitative relation between hydrolysis and aminolysis depends on the pH. With succinimides both processes are second-order reactions with respect to the hydroxide ion, whereas with glutarimides they have the first order. The kinetic results obtained for succinimides suggested the scheme of reactions



Water is assumed[15] to activate both initial components. Amino-groups are converted into ammonium ions, while bisimides isomerise under the influence of hydroxide ions into bisisoimides. Azomethine groups are then protonated by the transfer of protons from ammonium ions. Under the influence of nucleophilic attack by the amine (in the main reaction) or by hydroxyl (in the secondary reaction of hydrolysis) the carbon–oxygen bond in the isoimide ring undergoes fission with formation of the main product and a by-product.

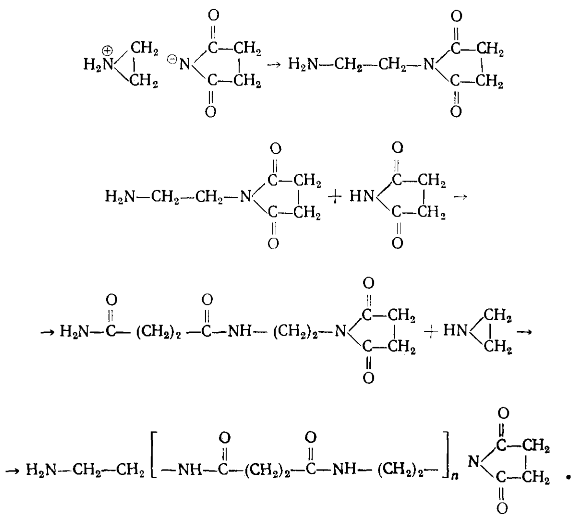
Bisimides of aspartic acid have also been used as initial monomers[16,17]:



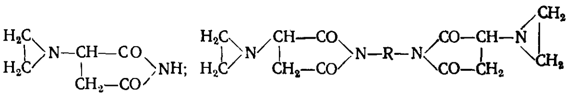
At room temperature they react with bisamides only on the addition of 20–30% of water to the solution. When the water content is increased to 50%, the viscosity of the resulting polymer is lower owing to chain termination by hydrolysis of the imide rings. Reaction does not take place in solutions of anhydrous organic solvents; but at higher temperatures (50–100 °C) the polymer is formed even without the addition of water. The resulting polyamidoimides contain secondary amino-groups in the chain, which strengthen the basic character of the polymer, with consequent improvements in its solubility and its dyeability by acid dyes, while the film- and fibre-forming properties are maintained.

The aminolysis of imides by amines has been used in several other cases. This reaction forms the basis of a process for obtaining crystalline polyamides distinguished by enhanced thermal stability resulting from the regular arrangement of amide groups[18]. The initial monomers are bissuccinimides and aliphatic or aliphatic–aromatic diamines, which are heated in a sealed ampoule at 150–200 °C for 1–5 h.

2,4- and 6,4-Nylons have been obtained by the action of ethylenediamine on ethylene-*NN′*-bissuccinimide and of hexamethylenediamine on hexamethylene-*NN′*-bissuccinimide respectively in a nitrogen atmosphere in a sealed ampoule at 200 °C.[19] Polyamides of high molecular weight have been obtained also[20] by the aminolysis of imides by secondary amines. Thus polyethylenesuccinamides of specific viscosity 0.28 dl g^{-1}, beginning to decompose at 290 °C, result from the interaction of succinimides with aziridine in the melt or in solution at 170 °C. The reaction was assumed[20] to involve formation of an ion-pair comprising an aziridine cation and a succinimide anion:



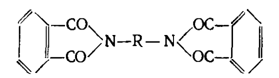
In order to combine imide and imine functional groups in the same molecule, 3-aziridin-1′-ylsuccinimide and 3,3′-diaziridinylbissuccinimides



have been prepared by the action of aziridine on maleimide and *NN*′-bismaleimides respectively. These monomers polymerise with cleavage of the imide and imine rings in the melt at 125°C to form cross-linked polymers that decompose at 300°C. Aminolysis of the imide ring has been used also to cross-link polymaleimides by treatment with aziridine or a diamine[21]. The imide ring is thus opened, and the resulting amide bonds promote formation of a three-dimensional structure in the polyamidoimide.

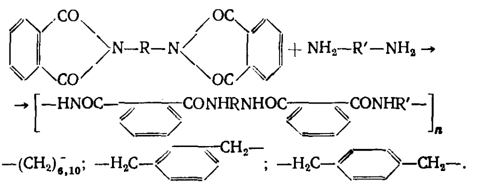
2. Aromatic Imides

Aromatic imides have also been used during recent years as initial monomers in the reactions of bisimides and bisamines involving cleavage of the imide ring. Investigations have been made[22–24] on the action of aliphatic and aliphatic–aromatic amines on *NN*′-disubstituted bisphthalimides



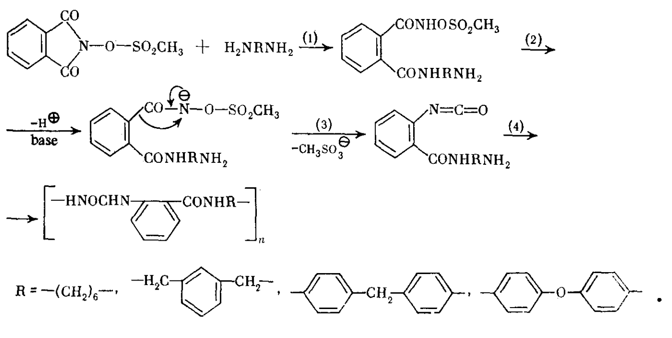
$R = -(CH_2)_n-;\ -m\text{-}C_6H_4-;\ -p\text{-}C_6H_4-;\ m\text{-},\ p\text{-}(CH_2)_2C_6H_4;\ n = 2,\ 4,\ 6.$

Reaction does not take place in water or in aqueous alcohol. In dry organic solvents at 20–95°C polyamides are formed:



The yield and the viscosity of the polymers depend on the nature of the hydrocarbon substituent attached to the nitrogen, the structure of the initial bisamine, and reaction conditions. Bisimides of aromatic or aliphatic–aromatic diamines proved relatively inactive: only oligomeric amides were obtained, and in some cases formation of an amide bond was not observed at all. Alkylenebisphthalimides are considerably more reactive: they react with aliphatic bisamines under homogeneous conditions—dissolved in a mixture of chloroform and alcohol at room temperature or in dimethylformamide (DMF), at 70°C (with 30% solutions in 70 h)—to form polymers of maximum viscosity 0.18 dl g^{-1} in ~40% yield. Under heterogeneous conditions—in suspension in toluene—polyamides of maximum viscosity 0.3 dl g^{-1} can be obtained in ~60% yield.

The presence of strongly electron-accepting substituents attached to the imide nitrogen tends to activate phthalimides towards aminolysis[25,26]. In particular, under mild conditions *N*-methanesulphonyloxyphthalimide[25] reacts both with aliphatic and with aromatic diamines with cleavage of the ring. The reaction is assumed to involve the four stages of (1) nucleophilic attack on the carbonyl by the amine, (2) removal by a base of a proton from the *O*-sulphonylhydroxamic acid, (3) removal of a methanesulphonate anion with subsequent rearrangement, and (4) addition of an amino-group to the isocyanate:



The reaction takes place in the presence of triethylamine or pyridine in *N*-methylpyrrolidone solution at room temperature to give polyphenyleneamidoureas in high yields (94–99%) but of comparatively low viscosity (0.12–0.34 dl g^{-1}), which may be due to chain termination as a result of secondary intramolecular cyclisation with formation of quinazolinedione. The unsymmetrical structure of the polymer chains is responsible for the high solubility of the polyamidoureas and their relatively low softening point (143–261°C).

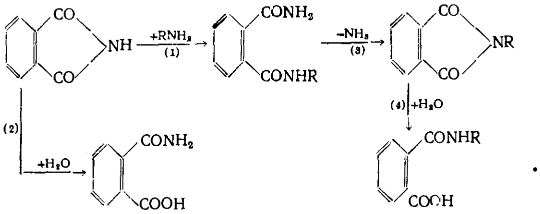
In contrast to *N*-substituted phthalimides, from which linear polyamides are obtained, aminolysis of the imides of aromatic tetracarboxylic acids permits the synthesis of cyclochain polymers, in particular polyimides.

Model monofunctional compounds (phthalimide, 4-cyanophthalimide, trimellitimide, etc.) have shown[27,28] that aminolysis does not occur under mild conditions in anhydrous organic solvents (dioxan, alcohol, DMF, acetone) at 5–20°C. Yet treatment of suspensions of imides with a solution of an aliphatic or an aliphatic–aromatic amine in water or a 1 : 1 mixture of water with an organic solvent leads to rapid interaction of the initial components. The yield of solid products of aminolysis is ~90% for all the imides investigated. From the aqueous filtrate 5–10% of amido-carboxylic acids can be isolated, whose formation indicates secondary hydrolysis of the initial imide ring. Unchanged initial imide is absent from the solid products of aminolysis, the conversion products being a mono-*N*-substituted *o*-bisamide and an *N*-substituted imide. For example, interaction of phthalimide with benzylamine yields *N*-benzylphthalimide and the monobenzylated bisamide of phthalic acid, forming respectively 30 and 70 wt.% of the mixture.

From this it may be assumed that the main reaction leads to subsequent partial cyclisation of *o*-bisamide groups with evolution of ammonia and formation of imides. Indeed, if an aqueous suspension of chemically pure monobenzylphthalamide is kept at 20°C for a few hours, *N*-benzylphthalimide is obtained. Brief (30–90 min) treatment of bisamides with hot water gives the same result. Yet boiling a bisamide in such organic solvents as dioxan, benzene, and pyridine did not result in cyclisation. Nor did heating the dry bisamide at 100°C for several hours produce any chemical change. Cyclisation is observed only above 150°C.

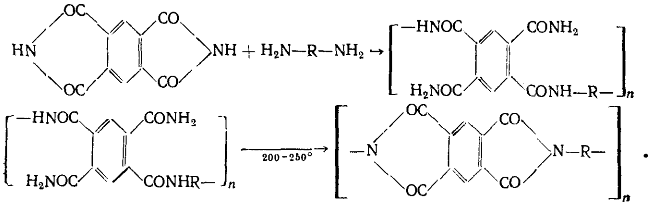
After being heated at 170–200°C for 1 h, bisamides are converted quantitatively into *N*-substituted imides. When *o*-bisamides are boiled in water for the same time, the yield of cylised products is only 50–70% (depending on the nature of the initial bisamide). Up to 50% of ammonium o-amido-carboxylates, products of the hydrolysis of N-substituted imides, then accumulate in the aqueous filtrate[27].

Thus the reaction between an aromatic imide and an aqueous solution of an aliphatic or an aliphatic-aromatic amine can be written



The main reaction of aminolysis (1) is accompanied by slight hydrolysis of the initial imide ring (2). The N-substituted o-bisamides formed in the main reaction are partly cyclised to N-substituted imides (3). The ammonia thus evolved promotes partial hydrolysis of N-substituted imide rings to amido-acids (4). Under the given conditions the main reaction—aminolysis (1)—occurs rapidly and constitutes 90–95%, while the yield of secondary hydrolysis products in reactions (2) and (4) is small, totalling <10%. This enabled the reaction to be extended to difunctional compounds.

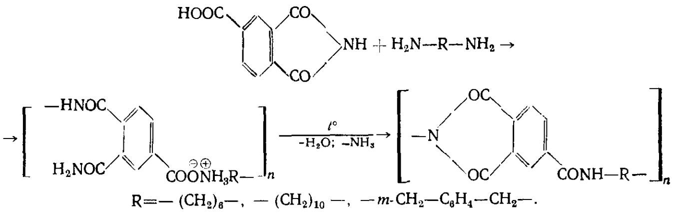
Linear polyimides are obtained[29-31] when the bisimides of pyromellitic and benzophenonetetracarboxylic acids are used as monomers with such bisamines as hexamethylenediamine, xylylenediamines, and bisaminomethylcyclohexane. The reaction takes place in two stages:



The prepolymers formed in the first stage are white powders soluble in strong mineral acids and containing polyamidoamides in the main structure. The infrared spectra of the polymers and investigations on model compounds show that the macromolecule contains also imide rings and salt groups. The first stage occurs at room temperature under heterogeneous conditions, in aqueous suspension. The reduced viscosity (measured for 0.5% solutions in concentrated sulphuric acid at 20°C) for the polyamidoamide from hexamethylenediamine and pyromellitimide was respectively 1.22, 1.08, and 0.91 dl g^{-1} on preparation in water, a 1 : 1 mixture of water and DMF, and a 1 : 1 mixture of water and ethanol, and did not exceed 0.04 dl g^{-1} in dry DMF, ethanol, or dioxan.

In the second stage imidisation occurs in the solid phase at 200–250°C. Cyclodeamination of polyamidoamides takes place more rapidly and at a lower temperature than cyclodehydration of the corresponding polyamido-acids. Polymers obtained from bisimides are therefore distinguished by greater completeness of cyclisation, and surpass in thermal stability polyimides based on analogous bisanhydrides[31]. The cyclised polyimides are insoluble and infusible heat-resistant dielectrics, which begin to decompose at 300–350°C.

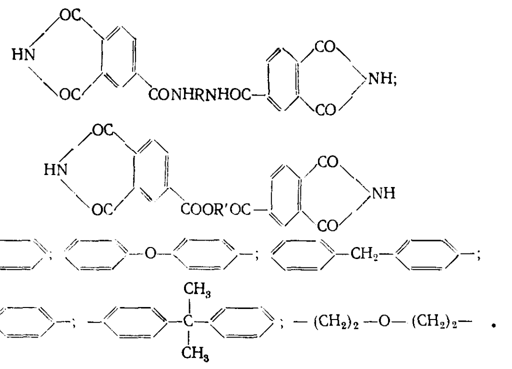
Soluble linear polyamidoimides can be obtained from trimellitimide as initial monomer treated with bisamines under analogous conditions[32]. In this case the first stage, conducted in aqueous solution at room temperature, gives oligomeric products containing amide, imide, and salt groups in the chain; in the second stage these products are heated in the melt at 200–250°C, when the salt and o-bisamide groups undergo polycondensation and cyclodeamination with the liberation of water an ammonia respectively to form polyamidoimides:



The resulting polymers, having $[\eta] = 0.40-0.75$ dl g^{-1}, are soluble in cresol and sulphuric acid, and soften at 210–245°C.

Polymers of analogous structure with $[\eta] = 0.08-0.15$ dl g^{-1} could be obtained in a single stage by the action both of aliphatic and of aromatic bisamines (hexamethylenediamine, ethylenediamine, bis-p-aminophenyl ether, diphenylmethane-pp'-diamine) on trimellitimide in DMF, dimethylacetamide (DMA), or cresol solution at the boiling point with azeotropic removal of the water liberated[33]. The melting points of the polymers vary from 170 to 340°C depending on the structure of the initial bisamine. Thermogravimetry in a stream of nitrogen indicates that decomposition begins at ~490°C.

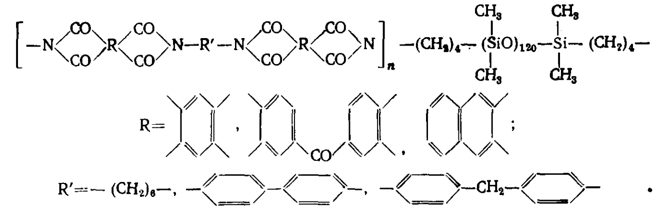
Polymers have been obtained under similar conditions from the bistrimellitimides[34]



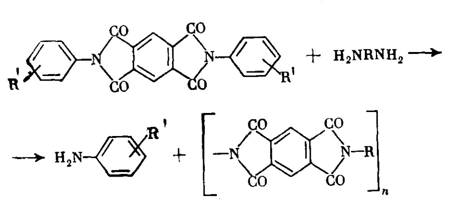
They have $[\eta] \leqslant 0.1$ dl g^{-1}, which indicates that the functional groups are relatively inactive under the given conditions. The polyetherimides, polyesterimides, and polyamidoimides formed are ordered polymers[34,35]. Regular arrangement of the structural units of macrochains ensures stronger intermolecular interaction between polar groups. This is why the ordered polymers have higher melting points and lower solubilities than similar polymers based on trimellitimide. However, ordered polymers differ little in thermal stability from unordered copolymers[35].

Block copolyimides of high molecular weight and viscosity ~1.0 dl g^{-1} have been obtained[36] by the stepwise reaction of aromatic bisimides first with aliphatic or aromatic bisamines and then with polyorganosiloxanediamines. The reaction takes place in solution in hexamethylphosphoramide (HMPA) or other strongly polar solvent (tetramethylurea, dimethyl sulphoxide (DMSO), N-methylpyrrolidone) with the monomers held for a long time (10–20 h) first at

20 and then at 70–80°C. This involves successive addition of the amine with cleavage of the imide ring and then cyclodeamination. The products are film-forming polyimides

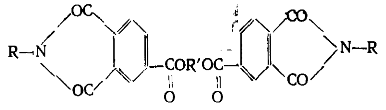


Imido-amine exchange between an *NN′*-diarylated pyromellitimide and an aromatic bisamine probably also occurs by a mechanism of successive opening and closing of the imide ring[37]. The reaction takes place in the melt at 250–300°C, with liberation of the corresponding aromatic amine and formation of an insoluble, infusible polyimide:



$R = Ar \quad R' = -OCH_3, -OC_2H_5, -OH, Hal$.

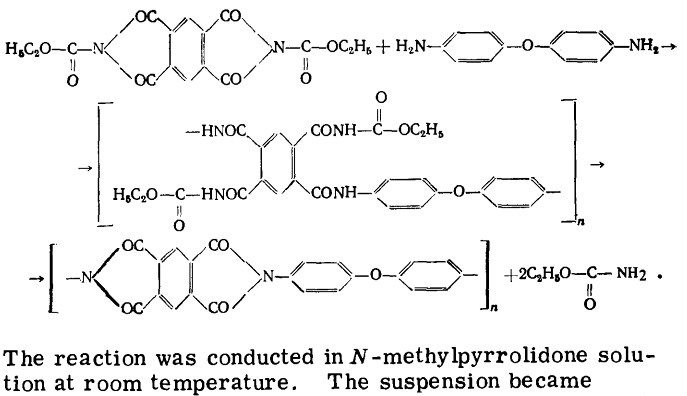
The same reaction has been applied under analogous conditions to diester-bistrimellitimides[38,39]



$R = Alk, Ar; \ R' = C_{6-30}\cdot Ar$.

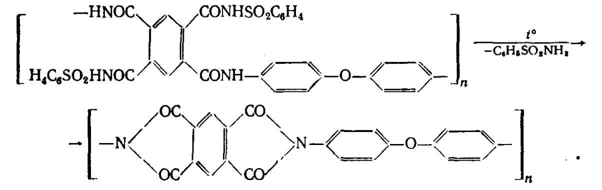
These monomers react in the melt with aliphatic, aromatic, or siloxane diamines to form soluble, fusible linear polyesterimides. The use of metals of Groups I and II–Vb or their oxides, hydroxides, imides, or salts as catalysts in this reaction enables polymers of higher molecular weight to be obtained.

The introduction of strongly electron-accepting substituents into the imide group enables the reaction to be conducted under milder conditions with formation of an easily processable and readily soluble polyamide as prepolymer. Such *N*-substituted bisimides include diethyl pyromellitimide-*NN′*-dicarboxylate[40–42], which has been subjected to two-stage polycondensation with diamines:

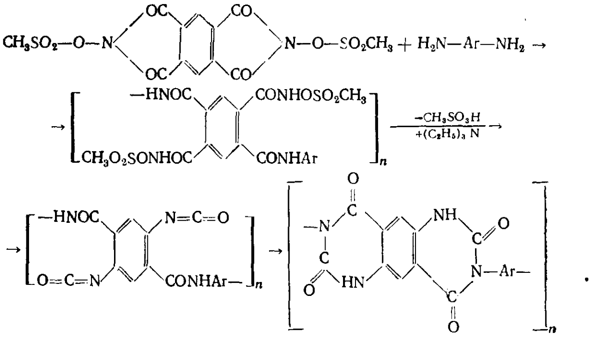


The reaction was conducted in *N*-methylpyrrolidone solution at room temperature. The suspension became homogeneous after being stirred for 1 h, but the viscosity continued to increase for 5 days, reaching 0.9 dl g^{-1}. A strong, flexible film was cast from the resulting polyamide solution, and was heated in a vacuum above 240°C for 5 h to form a polyimide.

A more vigorous reaction takes place between *NN′*-diphenylsulphonylpyromellitimide and bis-*p*-aminophenyl ether[43]. In solution at room temperature a polyamide of reduced viscosity up to 0.9 dl g^{-1} is formed within 30–60 min. A solution of a polymer (in contrast to solutions of polyamido-acids) has a stable viscosity, but even at 20°C such a polyamide gradually cyclises in solution, a process considerably accelerated by the presence of water. Complete conversion into the polyimide occurs when the polyamide films are heated at 160°C for 10 min. Cyclisation is accompanied by the separation of benzenesulphonamide as a by-product:



An analogous reaction between *NN′*-dimethanesulphonyloxypyromellitimide and aromatic bisamines yields new polymers, containing quinazolinedione rings in the chain[44]:



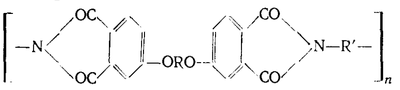
The reaction is conducted in *N*-methylpyrrolidone solution at room temperature in the presence of tertiary amines, which promote formation of the polyamidoisocyanate and subsequent isomerisation cyclisation. The polymers are obtained in theoretical yield with a specific viscosity of 0.25 dl g^{-1}. The comparatively low viscosity is due to separation of the polymer from the solution at an early stage. The resulting polypyrimidoquinazolinetetraones are soluble only in strong mineral acids, and are stable up to 400°C.

The above examples show that cyclic imides of aliphatic, unsaturated, and aromatic carboxylic acids are able to undergo ring cleavage on reaction with diamines. The activity of the monomers in this reaction is determined by their chemical structure and by the reaction conditions. With strongly basic aliphatic amines reaction takes place even at room temperature, when a necessary condition is often the presence of water, which probably activates both monomers. Linear polyamides are then formed from imides of aliphatic and unsaturated acids. Imides of aromatic tetracarboxylic acids yield polyamides containing *ortho* to the amide bond primary or secondary amide groups capable of cyclisation with the separation of a by-product of low molecular weight and the formation of linear polyimides. Under more severe conditions reaction takes place also with the less basic aromatic diamines, when a polyimide is obtained without separation of the prepolymer.

III. POLYCONDENSATION WITHOUT CLEAVAGE OF THE IMIDE RING

Recently cyclic imides of carboxylic acids have begun to be used also in polycondensations. Aromatic bisimides containing hydroxyl, carboxyl, and chlorocarbonyl as reactive functional groups are often employed as monomers in polyamidation and polyesterification with bisamines, bisisocyanates, and phenolic diols. Sometimes different types of functional groups are combined in the same molecule, and homopolycondensation is effected. These reactions enable us to obtain in a single stage polyimides containing also other hetero-bonds (amide, ester, etc.), in which unstable uncyclised *o*-amido-acid units are absent. The present Review omits many examples of such reactions reported for various imides of tri- and tetra-carboxylic acids, which have been discussed previously[3], and dwells only on comparatively unknown reactions.

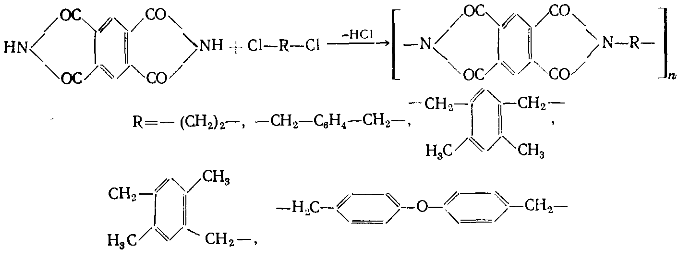
As already remarked, until not long ago imides of *o*-dicarboxylic acids were not used for the preparation of polymers. Several recent patents reveal the possibility of applying polycondensation to such monomers in order to synthesise the polyetherimides



R = Arylene; R′ = Arylene, Alkylene .

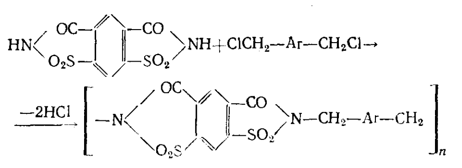
Bisnitrophthalimides are condensed with alkali-metal derivatives of dihydric phenols[45,46] or metal salts of aromatic dicarboxylic acids[47]. The reaction takes place in solution in DMF at 50°C. Bischlorophthalimides[48], bisfluorophthalimides[49], and bischloronaphthalimides[50] react similarly with alkali-metal bisphenoxides in polar solvents or their mixtures with aromatic hydrocarbons at high temperatures.

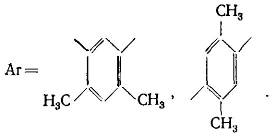
Polycondensation is applied also to unsubstituted imides of aromatic tetracarboxylic acids. Nishizaki and Fukami[51,52] were the first to suggest condensing the di-imide of pyromellitic acid with dihalides by Gabriel's reaction as a new method of synthesising polyimides:



Reaction occurs in the presence of basic catalysts in solution at 70°C to give a 50–80% yield of the polymer.

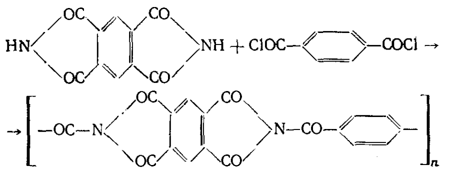
An analogous reaction has recently been reported between aromatic bischloromethyl derivatives and the bisimide of 4,6-disulphoisophthalic acid[53,54]:





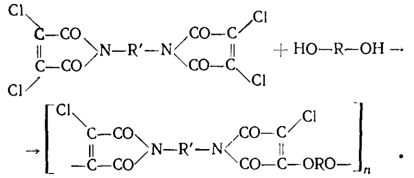
Polar amide solvents were used at the boiling point. Soluble polyimides having a specific viscosity of 0.2 dl g^{-1} were obtained after 5 h.

Imides of aromatic and alicyclic acids are capable also of polycondensation with chlorides of aliphatic and aromatic dicarboxylic acids[55]:

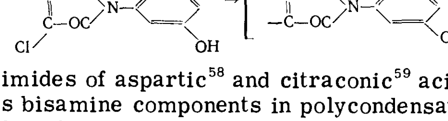


Reaction takes place in the presence of a catalyst—triethylamine, pyridine, aniline, copperII chloride, cobalt naphthenate, an organic compound of tin, or an alkali-metal salt of an organic or an inorganic acid—in solution at 80–200°C. The yield of polyimides exceeds 90%, and their specific viscosity 0.9 dl g^{-1} (for a 0.5% solution in concentrated sulphuric acid). The thermal stability of the polymers is above 350°C.

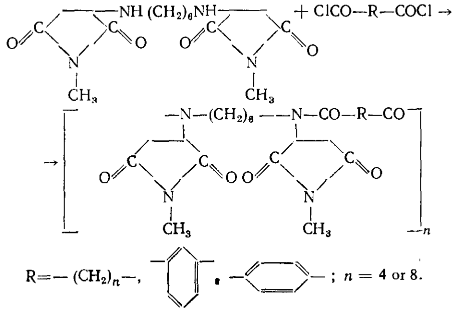
Imides of unsaturated and aliphatic acids undergo polycondensation by means of various functional substituents attached to carbon atoms. Thus the reaction of *N*-aryl-3,4-dichloromaleimides with phenols forms the basis of the synthesis of new polyethermaleimides[56,57]:



Use as initial monomers of 2,2-diphenylpropane-*pp*′-diol and a bisdichloromaleimide together with diphenylmethane-*pp*′-diamine gave a high yield of a polymer having specific viscosity 0.47 dl g^{-1}, capable of forming strong elastic films stable in nitrogen and in air at temperatures above 300°C. The 3,4-dichloro-*N*-*m*-hydroxyphenylmaleimide synthesised was capable of homopolycondensation:



Bisimides of aspartic[58] and citraconic[59] acids can be used as bisamine components in polycondensation with chlorides of dicarboxylic acids. Good yields are obtained of polyamides in which all hydrogen atoms in the amino-group are replaced by imide rings capable of various conversions[60]:



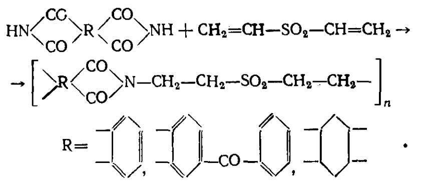
Complete aminolysis of imido-groups can be achieved by methylamine or they can be hydrolysed with alkali[60]. The main chain of the macromolecule does not break down, and new water-soluble polymers are formed.

IV. MIGRATION COPOLYMERISATION INVOLVING THE IMIDE RING

Since the nitrogen atom in an imide of a di- or tetracarboxylic acid is adjacent to two strongly electron-accepting carbonyl groups, the proton attached to the nitrogen atom is mobile. This enables unsubstituted amides to undergo proton-transfer reactions, so that migration copolymerisation can occur without cleavage of the imide ring.

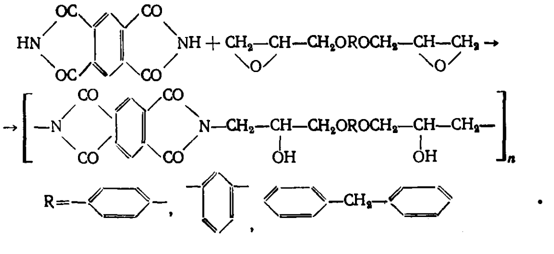
Among such reactions are the migration copolymerisation of unsubstituted bisimides of aromatic[61] and alicyclic[62] acids with dienes containing two active double bonds. Examples of such dienes that are used may contain α to a double bond a carbonyl group or an aromatic ring capable of activating it (e.g. divinylbenzene, diacrylates, vinyl esters of dicarboxylic acids, etc.). Reaction takes place in any suitable solvent at 80–120°C in the presence of a basic catalyst—an alkali or an alkaline-earth metal or its alkoxide, or a Grignard reagent—the quantity of which may vary from 0.0001 to 0.5 equiv. Polymers of high melting point, having specific viscosities of 0.35–0.65 dl g^{-1}, are formed in ~80% yield.

Russo and Mortillaro[63] suggested the use of divinyl sulphone as copolymerising diene:



The reaction is conducted in the presence of sodium t-butoxide in DMSO, DMF, or pyridine solution at 100°C. Infusible crystalline polymers of viscosity 0.09–0.23 dl g^{-1}, soluble only in concentrated sulphuric acid (in the case of aromatic imides) or in amide solvents (in the case of alicyclic imides), are formed in 50–80% yield. Their thermal stability is ~300°C independently of the structure of the monomer unit.

Linear polyimides containing hydroxyl groups have been obtained[64,65] from bisimides of aromatic tetracarboxylic acids and such diepoxides as the diglycidyl ethers of aromatic diols:



Reaction occurs in the presence of a tertiary amine or a quaternary ammonium salt as catalyst in solution at a high temperature. The yield of the resulting hydroxylated polyimides is 60–86%, with a specific viscosity of 0.1–0.34 dl g^{-1}. The polymers melt at 140–280°C, and vigorous decomposition begins at 300–400°C.

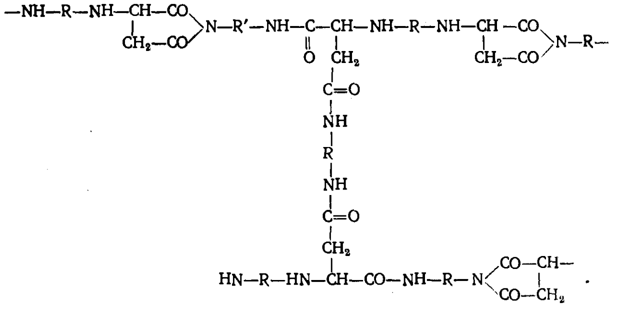
Bisimides of alicyclic tetracarboxylic acids react similarly with aliphatic and alicyclic diglycidyl ethers[66]. This gives oligomers having terminal epoxide groups, which are then hardened with anhydrides of dicarboxylic acids. In the presence of a highly effective catalyst—a chromium tricarboxylate—bisimides of aromatic or alicyclic acids may react also with epoxy-resins to form cross-linked polyimides[67].

V. REACTIONS AT THE DOUBLE BOND IN UNSATURATED IMIDES

As already mentioned, two reactive centres—an imide ring and a double bond—are present in mono- and bisimides of unsaturated dicarboxylic acids. The double bond enables such monomers to undergo several reactions characteristic of alkenes. Disregarding vinyl polymerisation with opening of the double bond by a radical mechanism (since the literature on this topic is vast and requires separate discussion), we shall consider only certain transformations of the double bond of unsaturated imides in migration copolymerisation with nucleophilic compounds and in the Diels–Alder reaction.

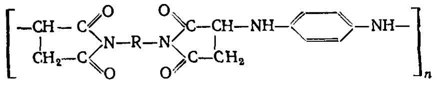
1. Migration Copolymerisation with Amines

In the migration copolymerisation of unsaturated imides with bisamines the chain grows by migration of hydrogen of the imide group to the double bond with the formation of secondary amine units. Polymers were first obtained in this way by Sheremet'eva[14]. When ethylene- and hexamethylene-bismaleimides are treated with such bisamines as phenylenediamine, hexamethylenediamine, ethylenediamine, and piperazine in aqueous alcohol, both reactive centres in the bisimide are involved, and a rubberlike cross-linked polymer is formed, containing imide rings and aspartamide segments in the chain

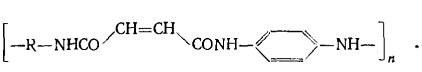


When carefully dried reagents are used in anhydrous organic solvents, the imide ring is preserved and only the double bond is involved. The linear polyaminoimides formed are soluble in several solvents, and have intrinsic viscosities of 0.05–0.18 dl g^{-1}. The molecular weight determined from the terminal amino-groups is 2000–9000.

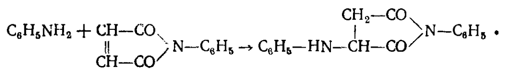
Reaction between dimaleimides and aromatic or aliphatic–aromatic diamines in the melt at 80–200°C yields[68] linear polyimides soluble in concentrated sulphuric acid and HMPA, resistant to abrupt changes in temperature, and beginning to decompose at 400°C. Such polymers comprise 85% of polyaminoimide units



and 15% of units of structure

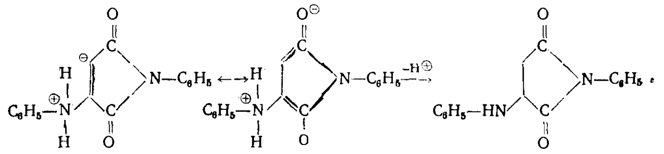


Study of the migration copolymerisation of bisimides of unsaturated acids with bisamines was then developed[69,70] by examining as model reaction the action of aniline on *N*-phenylmaleimide



$$C_6H_5NH_2 + \begin{matrix}CH-CO\\ \| \\ CH-CO\end{matrix}\!\!>N-C_6H_5 \rightarrow C_6H_5-HN-\begin{matrix}CH_2-CO\\ | \\ CH-CO\end{matrix}\!\!>N-C_6H_5\ .$$

Since the reaction velocity depends on the polarity of the medium, it was supposed[69,70] that the mechanism involved a charged intermediate product stabilised by the medium:



This mechanism suggests the possibility of acid and base catalysis. Indeed, weak protic acids (acetic, propionic, formic, maleic) exhibit a considerable catalytic effect.

Extension of this reaction to difunctional compounds—bismaleimides and aromatic diamines—yields the polyimides

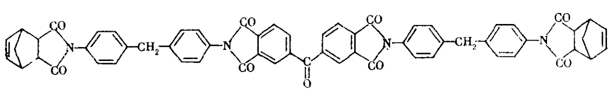
$$\left[-HN-\begin{matrix}CH_2-CO\\ | \\ CH-CO\end{matrix}\!\!>N-R-N<\!\!\begin{matrix}CO-CH_2\\ | \\ CO-CH-NH-Ar-\end{matrix}\right]_n$$

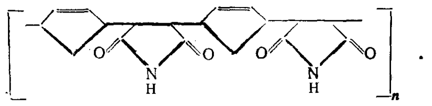
R = Alk, Ar.

Conducting the reaction in the presence of a catalyst—acetic acid—in cresol solution at 100–110°C for 3 days gives polyaspartimides as amorphous compounds softening at 210–300°C (depending on the chemical structure of the initial monomers) and having high melting points[70]. They are soluble in phenolic and amide solvents, their viscosity being $[\eta] = 0.25-0.6$ dl g^{-1}.

Migration polymerisation can be accomplished also in other phenolic solvents[71], benzonitrile, DMF, DMSO, nitrobenzene[72], and various phosphorus-containing compounds[73]. The use has been suggested also of such carboxylic acids as acetic, propionic, trifluoroacetic, formic, etc., which act as both solvent and catalyst[74]. Mineral acids and certain complex compounds may be used as catalysts[75].

Linear polyaminoimides obtained by the migration polymerisation of bisimides with bisamines can be hardened by heat, forming insoluble, infusible polymers of good heat and chemical resistance. The mechanism of thermosetting is not clear, but the presence of terminal amino-groups and double bonds, together with reactive secondary amino-groups and imide rings in the main chain, promotes various reactions—polymerisation, migration copolymerisation at the imide ring or the double bond, as well as other processes governed by the chemical nature of the macromolecular chain—leading initially to branching and then to cross-linking. For example, the oligomeric prepolymer[76] containining tetrahydro*endo*methylenephthalimide fragments as end-groups, is cross-linked on heat treatment at 260–300°C, without the evolution of volatile components. It is assumed that pyrolytic polymerisation takes place by a mechanism opposite to the Diels–Alder reaction, and the final polymer contains the units





Polyaminoimide prepolymers are most often set in the melt at 200–250°C, either in the presence or in the absence of radical or ionic catalysts. Any mono-or poly-functional compounds that react with the resin can be used in the hardening process. Thus 5–95 wt.% of the corresponding monoimides can be introduced[77,78] during setting into oligomeric prepolymers obtained from bisamines with bismaleimides, bistetrahydrophthalimides, or bistetrahydro*endo*methylenephthalimides, their addition lowering significantly the price of the required thermostable polymer. Alkene hydrocarbons or unsaturated ethers[79–81], condensation polyesters containing double bonds[82], epoxides[83], and epoxy-resins[84,85] have also been suggested as copolymerising and cross-linking additives.

The two-stage method, in which a soluble, fusible polyaminoimide obtained in the first stage is subsequently hardened, has proved extremely fruitful, and has led to the appearance of numerous patents claiming either modification of this method or new compositions that can be used as varnishes, glues, laminated materials, moulded articles, etc.[86–90] Thus products of the reaction of bismaleimides, biscitraconimides, bistetrahydrophthalimides, or bisitaconimides with di-, tri-, or tetra-amines (heated to 50–180°C in the absence of a solvent or in a polar solvent) have been proposed[91] for obtaining thixotropic aqueous suspensions of prepolymers. The resulting polymer is suspended in water and used as a paste for various purposes. After additional heat-treatment (at 250°C for 24 h) a glassfibre-reinforced plastic in which the binder is a similar composition based on diphenylmethane-*pp'*-bismaleimide and diphenylmethane-*pp'*-diamine withstands being heated at 250°C for 1000 h, with only a slight decrease in bending strength.

Prepolymers formed similarly by the migration copolymerisation of bismaleimides with bisamines in polar organic solvents can be modified, without isolation from the solutions, by the addition of anhydrides of polycarboxylic acids[92]. Some of the secondary amino-groups of the main polymer chain react, and carboxy-groups are introduced into the side-chain of the polymer. These ensure that the prepolymer becomes soluble in water on addition of a base. Such solutions have been proposed for electrodeposition on metal surfaces. The transparent protective coatings formed after further hardening at a high temperature are strong and chemically resistant.

Not only individual diamines but also oligomeric or polymeric bisamines[93,94], monoamines[95], and even ammonia[96] can be used in migration copolymerisation. The comonomers may be oligoimides[96–98] as well as bisimides. The migration copolymerisation of bisimides with bisamines and hardening are often combined into a single stage. Polymers are thus formed from mixtures of the initial monomers when heated in the melt[99–102]. To facilitate processing and lower the melting point phosphoric esters are sometimes added to the mixture[99,103]. The addition of polymerisation initiators such as dicumenyl peroxide, etc. accelerates cross-linking and lowers the setting temperature.

It must be noted in conclusion that the manufacture of polyaminoimides from bismaleimides and aromatic bisamines has now been established in several countries. On several criteria, including heat resistance, these polymers are little inferior to aromatic polyimides from tetracarboxylic bisanhydrides and bisamines. Yet the technology of their production and processing has several important advantages: as the prepolymers they are stable, and are easily processed by the same technology as for the usual thermosetting plastics; and the shape of articles on hardening is fixed without the evolution of volatile components[104,105].

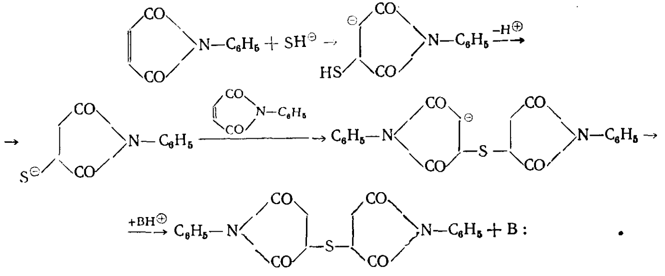
Such a resin is manufactured in France under the trade name Kerimid. Moulding materials such as Kinnel based on it, reinforced with glass fibres, are distinguished by their heat and flame resistance, with great stability towards the action of solvents. They are intended for use in aircraft construction, electronics, and the electronic industry[106-108]. Casting and moulding compositions of self-lubricating type are manufactured, filled with powdered tetrafluoroethylene, molybdenum sulphide, graphite, or carbon fibres. Such compositions possess not only great heat resistance but also low surface friction with insignificant abrasion. At high temperatures these materials surpass steel, light alloys, and titanium in their strength characteristics.

2. Migration Copolymerisation with Other Nucleophiles

Nitrogen-containing compounds other than amines are also used in migration copolymerisation with unsaturated imides, e.g. urea[109], hydrazines[110], dihydrazides[111], bisaldoximes[112-114], and bisimidic esters[115]. Various sulphur-containing compounds—hydrogen sulphide[116], dithiols[117,118], disulphinic acids[119]—are also employed.

Crivello[120] was the first to examine as model reaction the action of hydrogen sulphide on *N*-phenylmaleimide in various solvents, and found the reaction to be instantaneous in solvents of basic character (DMF, DMA, pyridine). If neutral or weakly acid solvents are sued, small quantities of a tertiary amine or other base (B:) must be present as catalyst. Hence it may be concluded that the primary attack on the double bond in the maleimide is initiated by the highly nucleophilic hydrogen sulphide anion, and the mechanism of the reaction can be written

$$H_2S + B: \rightleftarrows BH + SH^{\ominus}$$



The attempt to extend this reaction to difunctional compounds has been unsuccessful: the action of hydrogen sulphide and dithiols on bisdimaleimides in polar organic solvents at room temperature produces rapid gelation. The anionic polymerisation of bisimides initiated by thiolate ions is regarded as a competing reaction leading to cross-linking. However, this side reaction could be effectively suppressed by conducting polymerisation in weakly acid media or by adding to the reaction mixture small quantities (0.5–10%) of protonating agents such as inorganic acids (sulphuric, phosphoric), carboxylic acids (acetic, formic, benzoic), phenols, or various acid salts[116]. Catalytic quantities (0.01–0.001 wt.%) of such tertiary amines as tetramethylethylenediamine, tributylamine, etc. can be used to accelerate the reaction[118].

The reaction can be conducted in the usual organic solvents, in compounds of amide type, and also in aqueous emulsion. In the last case acid and neutral alkali-metal salts are used as catalysts. The most successful media were phenol and cresol, which acted both as solvents and as protonating agents. Thus the action of hydrogen sulphide under these conditions on bismaleimides[120] or oligomeric aminoimides containing two terminal double bonds[121] will give good yields of macromolecular polyimidosulphides, clear fibrous polymers having $[\eta] = 0.1–0.63$ dl g^{-1}, soluble only in highly polar liquids (DMSO, DMA, hexafluoroacetone hydrate) and resistant to the usual organic solvents. They melt at comparatively high temperatures (260–300°C) and are stable up to 325°C.

Replacement of hydrogen sulphide by a dithiol will yield polyimidosulphides having the structure

in which R and R′ are different bivalent organic radicals of aliphatic, aromatic, or heterocyclic type. The properties of the polymers depend on the structure of the main chain. Thus lengthening the segments between two sulphur atoms results in lower melting points and greater solubility of the polymers in the usual organic solvents.

Block copolymers containing polyimidosulphide and polysulphide units can be obtained by using oligomeric polysulphides of molecular weight 2000–8000 as second components in migration copolymerisation with bismaleimides[122,123]. The reaction is conducted in the presence of tetramethylethylenediamine in cresol or its mixture with dichloromethane at 40°C. Polymers containing ≥70% of polysulphides are thermoplastic elastomers; with lower contents of polysulphides they can be regarded as thermoplasts modified with rubbers. The strength properties of the block copolymers deteriorate with increase in the quantity of the polysulphide component, but are little affected by its molecular mass or the nature of the polyimidosulphide block. The thermal stability of the copolymers is determined by that of the polysulphide blocks.

Linear polyimidosulphides obtained by the migration copolymerisation of unsaturated bisimides with sulphur-containing monomers are hardened at 150–300°C either purely thermally or in the presence of organic peroxides.

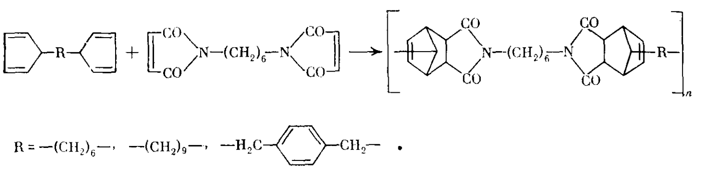
Polyimidosulphides, which are characterised by high mechanical strength and heat resistance, are recommended for the production of electrically insulating films and coatings, moulded goods, packing materials, and gas-separating membranes[117,119,124].

3. Cycloaddition

Reactions involving cycloaddition provide another promising and growing method for using unsaturated bisimides to obtain polyimides of various structures. The literature on this topic up to 1965 was presented in review papers[125,126] and in Korshak's monograph[127]. Therefore we shall discuss in some detail only results that have appeared during recent years.

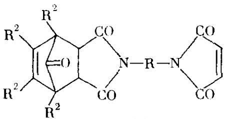
Bismaleimides are successfully used in photochemical homopolymerisation processes involving 2 + 2 cycloaddition, which yields polyimides containing alicyclic units in the chain[128,129], and also as dienophiles in copolymerisation with dienes involving thermal Diels–Alder 4 + 2 polyaddition. The latter type of reaction permits wider variation in the chemical composition and the properties of the polymers, since both cyclic and open-chain dienes can be used. Cyclopentadiene derivatives have been investigated in the greatest detail among diverse diene components. The copolymer of *m*-phenylene-*NN*′-bismaleimide with *p*-xylylenedi-5-cyclopentadiene was first mentioned by Upsom[130], who obtained an insoluble product from the reaction in the mass. Its composition and its insolubility suggest a cross-linked copolymer containing mainly units formed by vinyl polymerisation of the bismaleimide.

Further investigation showed[131] that Diels–Alder polyaddition uncomplicated by 1,2-polymerisation takes place in benzene and DMF solution with the formation of 1 : 1 copolymers:

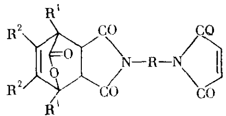


The resulting polyimides probably have relatively low molecular weights, since $[\eta] = 0.1–0.22$ dl g^{-1}, they soften at 110–240°C, and they dissolve in organic solvents. Raising the temperature of the reaction medium leads to the formation of polymers of lower viscosity, which indicates occurrence of the reverse Diels–Alder reaction.

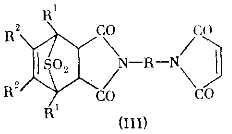
Polyimides of far higher molecular mass were obtained by Kraiman[132,133] and by Chow[134,135], using as monomers adducts of bismaleimides with cyclopentadienone (I), 2-pyrone (II), and thiophen dioxide (III)



(I)

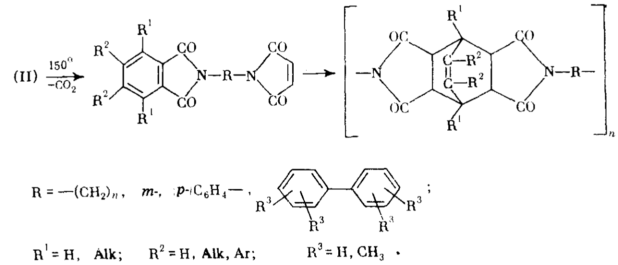


(II)



(III)

Such adducts contain both dienophile and diene reaction centres, but the latter is in an inactive, "protected" state. With rise in temperature either carbon dioxide or sulphur dioxide is evolved from the adducts (I)–(III), and the liberated diene bonds copolymerise rapidly with the dienophile end of the monomer to form a polyimide:



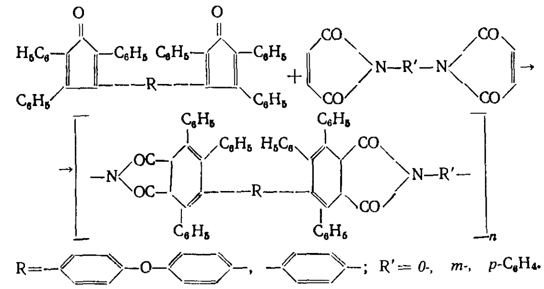
R = —(CH₂)ₙ, *m*-, *p*-C₆H₄—, ;

R¹ = H, Alk; R² = H, Alk, Ar; R³ = H, CH₃ .

The reaction is conducted in a solvent of high boiling point (bromobenzene, a halogenated aliphatic hydrocarbon, 1-chloronaphthalene)[132–135], when macromolecular polyimides having $[\eta] = 2.0$ dl g^{-1} can be obtained in times varying from 20 min to several days depending on the temperature. Under these conditions the Diels–Alder reaction is not complicated by the secondary vinyl-type polymerisation characteristic of free cyclopentadiene.

Polymers which either melt at low temperatures or soften at high temperatures are obtained depending on the nature of the substituent R in the di-imide. The nature of the substituents R¹ and R² in the diene monomer has little influence on the physical properties of the polyimides. The solubility, the high heat resistance, the strength, and the good film-forming and dielectric properties enable the resulting polymers to be used as high-temperature insulating films, fibres, and thermostable and chemically resistant plastics.

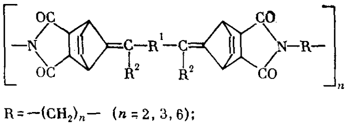
Interesting polyimides, capable of aromatisation, have been obtained from bismaleimides with phenylated derivatives of cyclopentadienone. Model monofunctional compounds[136,137] and monomers[138] have shown that the reaction conforms to the scheme



Polydihydrophthalimides are formed in theoretical yield: The reaction is conducted in boiling chloronaphthalene or trichlorobenzene solution to give maximum viscosities $[\eta] = 0.3–1.0$ dl g^{-1} for various polymers after 1–3 and 18–24 h respectively. The polymers are stable in air up to 300°C. They are dehydrogenated to the corresponding aromatic polyimides by the action of bromine or by heating in nitrobenzene solution. Under these conditions, however, the degree of conversion is probably not very high, since the temperature at which decomposition of the polymer begins has changed little after modification.

Quantitative aromatisation could be accomplished[136,137] by heating a carefully ground specimen of the polymer *in vacuo* at 350°C, when some decrease in viscosity was observed. The resulting polyimides do not lose weight in air up to 530°C: i.e. they are comparable in thermal stability with polyimides based on pyromellitic bisanhydride and aromatic bisamines. In contrast to the latter, however, they dissolve in several organic solvents.

Cyclicdienes other than cyclopentadiene derivatives are also used as monomers copolymerising with bisimides by the Diels–Alder reaction. Thus polyimides of high molecular weight

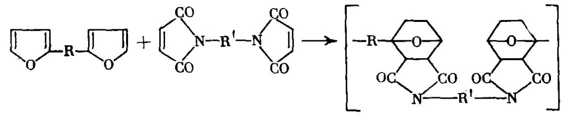


R = —(CH₂)ₙ— (*n* = 2, 3, 6);

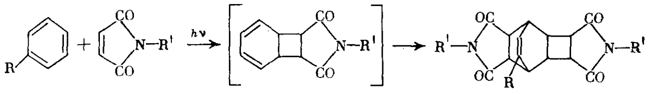
p- or *m*- C₆H₄, *p*-C₆H₄·C₆H₄, *m*-CH₂—C₆H₄—CH₂;

R¹ = Ar; R² = Alk, cycloAlk, Ar

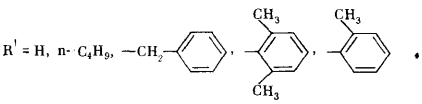
have been obtained[139] by copolymerisation with difulvenes in chloroform, DMF, or *N*-methylpyrrolidone solution at 60–70°C. Berlin et al.[140,141] showed the possibility of using ωω′-difuran derivatives as dienes:



For a long time aromatic compounds were not used as diene components, since it was considered that they were incapable of Diels–Alder condensation. However, later investigations have shown that maleimide and certain of its *N*-substituted derivatives, on exposure to ultraviolet radiation in the presence of a sensitiser, add to benzene and its homologues to form 2 : 1 adducts[142–145]. It is supposed that an intermediate equimolecular adduct formed by photoinitiated 1 + 2 cycloaddition is then involved in Diels–Alder 1 + 4 cycloaddition:

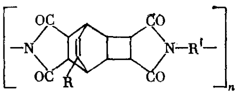


$R = H, C_nH_{2n+1}$ $(n = 1, 2, 10-13)$;



This reaction has recently been extended to bismaleimides to give corresponding macromolecular polyimides. Such polymerisation was first achieved by Stevens and Musa[146,147]. When solutions of various bismaleimides in a mixture of benzene and acetone are exposed in the presence of acetophenone to ultraviolet radiation for 18 h, the polyimides listed in Table 1 are obtained. The yield of polymer obviously depends significantly on the nature of the substituent R in the bisimide: thus the yield is 70–95% in the case of alkylenebismaleimides. The highest yield is observed with R = $[CH_2]_2$. Increasing the number of methylene units in the maleimide bridge lowers the yield, which may be due to intramolecular polymerisation of the double bonds and formation of cyclic bisimides of low molecular weight. If R = C_6H_4, which may be *meta-* or *para*-substituted, the yield of polymer falls to 15–30%. In such molecules the phenyl rings are probably coplanar with the maleimide rings, and this favours the appearance of low excited states which quench the photoexcitation of maleimide. Introduction of an *ortho*-substituent prevents coplanarity, and the yield of polymer then increases to 65–80%. All the polymers obtained begin to decompose at 360°C. Since change in the chemical structure has hardly any effect on the temperature at which decomposition begins, it is assumed[147] that degradation of the polymer chains begins with thermal decyclisation by a reverse Diels–Alder reaction.

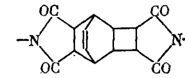
The reaction can be applied also to various homologues of benzene. Thus the use of various alkylbenzenes as comonomers[148] yields polymers of probable structure



$R = CH_3—, C_2H_5—, (CH_3)_2CH—, (CH_3)_3C—$;
$R' =$ Alkylene, Arylene .

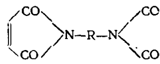
This view is based on analogy with the condensation of maleic anhydride with monosubstituted benzenes, in which cycloaddition takes place at the bond most remote from the substituent[149,150]. However, some results[151] indicate that the site of cycloaddition depends on the reaction temperature, and mixtures of isomers—or heterounit coplymers—may be obtained.

Table 1. Polyimides of general formula obtained by the polyaddition of bismaleimides to benzene[147].



R	Yield, %	R	Yield, %
$—(CH_2)_2—$	95		80
$—(CH_2)_3—$	80		15
$—(CH_2)_6—$	70		30
	65		85

Table 2. Polyimides obtained by the photoaddition of alkylbenzenes to bismaleimides[146].



Alkylbenzene	R					
	$—(CH_2)_6—$					
	yield, %	t_{soft}*, °C	yield, %	t_{soft}*, °C	yield, %	t_{soft}*, °C
Benzene	70	410	65	485	85	450
Toluene	40	380	45	390	89	400
Ethylbenzene	23	390	0	—	50	350
Cumene	28	390	0	—	60	420
t-Butylbenzene	34	425	44	370	85	400

---

*t_{soft} = temperature at which softening begins.

Table 2 gives the yield and the thermal stability of polymers obtained after the optimum time of exposure, which varied from 5 to 40 h for different imides[148]. The yield decreases significantly on passing from benzene to alkylbenzenes. On the basis of the inductive effect the reactivity should increase in the sequence—methyl < ethyl < isopropyl < *t*-butyl—but the steric effect would diminish the reactivity in the same sequence. The net effect determines the polymer yield for different hydrocarbons. The terminal members of the sequence show the same net effect of the opposing factors, so that the yields are similar. The absence of a polymer in the reaction of ethylbenzene and cumene with 3,3′-dimethylbiphenylbismaleimide may be due to greater steric hindrance caused by the *o*-methyl groups. The higher yield with the bismaleimide containing a sulphonyl group is probably due to the fortunate combination of the electron-donating power of the alkyl groups with the strong electron-accepting influence of the sulphonyl group. All the polymers obtained are either only partly soluble or completely insoluble in organic solvents and trifluoroacetic acid.

Soluble polyimides or analogous structure can be obtained in high yields from the reaction of bismaleimides with several benzene derivatives in the presence of acetophenone in solution in excess of the aromatic hydrocarbon or in a mixture of the latter with chloroform or alcohol during ultraviolet irradiation for 18–20 h.[152-154] The yield and the viscosity of the resulting polymers depend significantly on the nature and the concentration of the monomers, the temperature, the duration of exposure, and other factors[154-156]. Table 3 shows that hexamethylene-*NN'*-bismaleimide is the most active among the bisdienophiles investigated. The reactivity of the bismaleimide decreases sharply when the aliphatic is replaced by an aromatic bridge. A possible reason is diminished conjugation of the carbonyl group with the double bond. The comparatively low viscosity of the polyimides is probably due to precipitation of the polymers because of poor solubility in the reaction medium and to cessation of chain growth at low degrees of polymerisation.

Table 3. Polyimides from aromatic derivatives and bismaleimides[152-154].

Aromatic diene	R							
	$-(CH_2)_2-$		$-(CH_2)_6-$		$-(CH_2)_{10}$

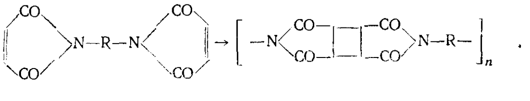
Chlorobenzene	19	0.02	20	0.04	—	—	7	0.03
Diphenyl ether	35	0.02	40	0.03	—	—	—	—

Raising the temperature and lengthening the time of irradiation increase the yield of polymers, which reaches its maximum value more rapidly the higher the temperature. With certain pairs of monomers, however, prolonged exposure at high temperatures (40–80°C) leads to diminished yields, probably because of breakdown of the thermally unstable reaction complex formed initially. Higher yields of polymer are obtained with increase in the concentration of the bismaleimide in the reaction mixture. The yield increases on addition of an inert solvent (acetone, chloroform, alcohol), because of improved solubility of the bisimide and hence the possibility of reaction occurring in more concentrated solutions.

In mixtures of solvents, however, the main reaction is accompanied by secondary homopolymerisation of the bisimide:



This leads to the formation of mixed polymers with cyclobutane rings in the chain, as is confirmed by fractionation and by infrared and nuclear magnetic resonance spectroscopy of the polymers[156].

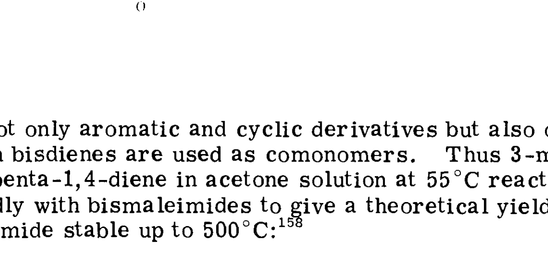
Mixed Diels–Alder polyimides have been obtained also by the copolymerisation of two aromatic dienes with bismaleimides[156,157]. The yield is 20–80%, and the intrinsic viscosity 0.01–0.15 dl g^{-1}. They are inferior to homopolyimides in thermal stability, and begin to decompose at 330–370°C. Increasing the content of substituted benzene segments in the chain in mixed polyimides based on benzene and alkylbenzenes produces a monotonic fall in viscosity.

An investigation of the influence of the composition of the initial mixture of aromatic hydrocarbons on the yield and the properties of the mixed polyimides has shown[157] that, according to their reactivity towards bismaleimides, they can be arranged in the sequence

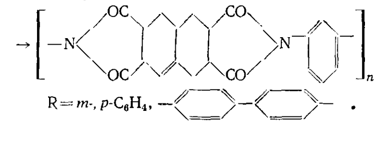
cumene ⩾ toluene > benzene ⩾ diphenyl ether > chlorobenzene.

It follows from this sequence, which coincides with that deduced from a study of homopolymerisation, that the rate of polymerisation increases when the aromatic hydrocarbon contains electron-donor substituents of small bulk, and decreases in the presence of electron-accepting substituents.

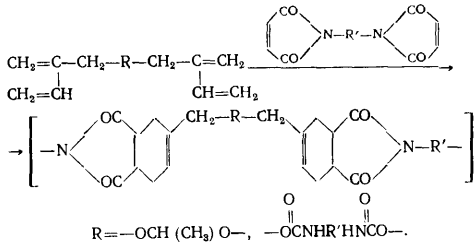
The above results show that under certain conditions many benzene derivatives are able to undergo Diels–Alder reactions with bismaleimides just as actively as cyclic dienes. Among other aromatic compounds only 9-anthraldehydebisazine and 1,5-di(anthr-9-yl)penta-1,4-dien-3-one have been mentioned[127] as developing the diene character of anthracene on reaction with bismaleimides:



Not only aromatic and cyclic derivatives but also open-chain bisdienes are used as comonomers. Thus 3-methylenepenta-1,4-diene in acetone solution at 55°C reacts rapidly with bismaleimides to give a theoretical yield of a polyimide stable up to 500°C:[158]

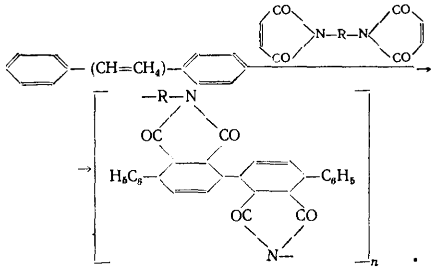


The same study used acetals and biscarbamates of 2-methylenebut-3-enol as bisbutadienes. Their polymerisation with phenylene-*m*- or *p*- or with biphenylylene-4,4′-bismaleimides in DMF solution at 100°C gave polyimides:

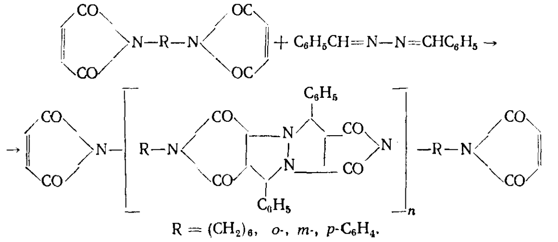


The yield for polymers varying in structure was 50–76%, with $[\eta] = 0.05–0.20$ dl g^{-1} and softening temperatures from 74 to 194°C.

Another example of an acyclic diene is 1,8-diphenyloctatetraene[125,126]. Polymers were obtained from it in theoretical yield, but the reduced viscosity was insignificant:



Benzylideneazine may act as a kind of acyclic diene in Diels–Alder reactions[159], adding at the 1,3-position to bismaleimides to form polyimides:



Polymerisation takes place in the melt at 180–190°C. The specific viscosity of the polymers is 0.13–0.30 dl g^{-1}, and their softening temperature 238–300°C.

Thus the Diels–Alder reaction ensures growth of the polymer chain to give linear polyimides when bisimides of unsaturated acids (mainly maleic) are treated with various dienes. The reaction takes place in solution or in the melt. The temperature and the duration of the synthesis are determined by the nature of the diene, the dienophile, and the solvent. In several cases active dienes react with bisimides under mild conditions, under which polymers of high molecular weight can be obtained. A peculiarity of this reaction is its reversibility, leading at high temperatures to formation of the initial components. Furthermore, the process is sometimes complicated by secondary 1 + 2 cycloaddition, causing cross-linking of the polymer chains.

Among the advantages of this reaction is that polyimides can be obtained with 100% imidisation. In most cases volatile reaction products are absent. These factors enable dense and non-porous polymers of high thermal stability to be obtained, which are promising for practical utilisation.

The above Review of published information shows that cyclic imides of di- and tetra-carboxylic acids are highly active monomers, and can be used in polycondensation, migration polymerisation, and cycloaddition reactions. The resulting open-chain or cyclic polymers possess several interesting properties.

Quantitative "Chemical Structure-Biological Activity" Relations

S.V.Nizhnii and N.A.Epshtein

The principal methods used to obtain quantitative relations between chemical structure and biological activity are reviewed and the postulates, possibilities, and prospects of these methods are examined.
The bibliography includes 299 references.

I. INTRODUCTION

The determination of the relations between the chemical structures of substances and their pharmacological activities is the most important task in the synthesis of highly effective and selective medicinal drugs. Biochemical pharmacology is as yet incapable of formulating rigorously the problems of specific synthesis. Nevertheless, an enormous scientific effort and capital investment are being devoted to the development of new drugs[1]. In this situation one is justified in attempting to compile empirical and semiempirical rules linking individual characteristics of the structures of substances and their effect on biological systems.

Extensive experimental data have now accumulated showing that there are definite relations between the physicochemical properties of a substance and its biological activity. The elucidation of the origin of the empirical relations between the properties of compounds *in vitro* and their biological action on the organism should make it possible to arrive at ideas concerning the mechanisms of biologically important chemical reactions and to establish on this basis well-founded recommendations for chemists working in the field of synthesis and, on the other hand, to predict the possible specificity and effectiveness of the biological action of newly synthesised substances, shortening thereby the laborious and expensive stages involving biological tests.

The possibility of determining structure-activity relations arose approximately one hundred years ago when it was observed[2] that the intensity of the narcotic action of certain substances decreases with increase of their solubility in water. A little later a relation was noted between narcotic activity and the distribution of substances in a water-lipid system[3,4]. A whole series of physicochemical parameters of substances, whose relation with narcotic activity and toxicity has been elegantly described by Lazarev[5,6], was established subsequently.

Despite the limited and qualitative nature of the majority of structure-activity relations observed in the first half of the XXth century, the justification of the hypothesis that the biological activity of a substance can be accounted for in individual instances by *in vitro* studies and described on the basis of the laws of physical chemistry and in terms of its concepts must be regarded as the general outcome of such relations.

Modern approaches to the structure-activity problem (based largely on the principles of physical and theoretical chemistry) are examined below. With their aid one may now hope to restrict the number of total syntheses and the biological screening of all substances which seem to be promising as medicinal drugs on the basis of general considerations.

The assertion that the structure of a substance and the biological response caused by it are involved in an unambiguous cause and effect relation, which is usually readily accepted on trust, must in fact be regarded as only one of the postulates underlying the approach to the structure-activity problem[7,8]. The most general postulates of this type may be reduced to the following.

1. The structure S of a chemical compound Y, designated by S_y, can be expressed in terms of a set of structural parameters $S_y = \{S_y^i\}$, where $i = 1, 2, \ldots, n$.

2. There is a relation between the structure of a substance and its biological activity, i.e. there is a function $F_y(S_y, A_y)$ relating the activity A of the substance Y to its individual characteristics—$F_y(S_y^i, A_y)$.

3. If the form of the function $F(S, A)$ has been established, the function may be extrapolated to compounds of the series Y_1, Y_2, Y_3,... with similar structures, differing to the substituents X_1, X_2,..., or by their positions in the molecule.

4. The sequence of the activities of a series of compounds, for example, $A_{X_1} > A_{X_2} > A_{X_3}$ may be deduced by analysing the set of functions $F_{Y_1}(F_{Y_1}, A_{Y_1})$, $F_{Y_2}(S_{Y_2}, A_{Y_2})$,... .

The prediction of biological activity is restricted to a series of compounds related by common structural features, it being implied that a "leading" structure has already been established and that the application of a particular approach should reduce the number of experimental tests on the biological activities of the members of the series.

In order to obtain a working model [i.e. $F(S, A)$], the reliability of which is to be subsequently estimated, it is suggested that the molecules of a biologically active substance undergo a series of physicochemical and chemical transformations in the organism: dissolution, sorption, partition, binding, chemical reactions, segregation, etc. Evidently, any of these stages or their combination may determine in each specific instance the specificity of the pharmacological action of the substance or may constitute the rate-limiting stage in the overall effect, determined as biological activity.

If the first condition holds, i.e. the physicochemical characteristics of the substance reflect its structure by a set of some of its parameters, then, in order to determine the form of $F_Y(S_Y, A_Y)$, it is necessary to obtain A in a quantitative form, namely $[A]$†. The quantity $[A]$, usually determined by means of biological tests, is, firstly, a statistical mean quantity and, secondly, it can reflect only the final results of the effect of the substance on the organism or the system simulating it. In fact the final result may be a consequence of one or several stages of the action of the substance. Hence it is clear that the most complex task in the determination of $F_Y(S_Y, A_Y)$ is the parametrisation of $[A]$.

If the observed biological response BR to the organism or the system simulating it to a certain substance is a consequence of a sequence of physicochemical processes involving the substance, then the time t elapsed between the onset of the action of the substance and its final result may be related to a stage controlling the rate of the process. If the substance at an initial concentration C_0, giving rise to a standard biological response, is introduced into the biological system, there is a probability N that an amount of the substance C_0N will reach sites with which it reacts and this leads to [BR]† after a period Δt. In this case the rate of the process can be represented in the following form (for a detailed treatment, see Section IV)[8,11,12]:

$$\frac{d[BR]}{dt} = KC_0N\bar{k}_i, \qquad (1)$$

where K is a proportionality coefficient relating the rate of the biological response[11,12] to the rate of the controlling stage, while $\bar{k}_i$ is the rate constant or equilibrium constant for this stage.

The above considerations and Eqn. (1) have not been rigorously proved. The point is that the standard biological response (ED_{50}, LD_{50}, etc.) does not contain in an explicit form information about the rate d[BR]/dt. Furthermore, in a real case the rate constant for the process $\bar{k}_i$ may be determined by any individual stage, a multiple repetition of such stages, or their combination. Function (1) should therefore be regarded merely as formally reflecting the relation between [BR] and a hypothetical rate-determining steady-state physical or chemical process. However, by introducing the additional postulate

$$\frac{d[BR]}{dt} = \text{const}, \text{ i.e. } KC_0N\bar{k}_i = \text{const}, \qquad (2)$$

it is possible to obtain a set of functions $F_Y(S_Y^i, A_Y)$ analogous to the experimentally observed set[9-11] (for further details, see Section IV), taking into account the fact that $1/C_0$ is usually employed as $[A]$.

The choice of $1/C_0$ as a measure of the effectiveness of the biological action of the substance $[A]$ cannot at present be rigorously justified. Nevertheless, the legitimacy of employing $1/C_0$ as a measure of A follows to some extent from experimental data[13-16] and a model of the equilibrium distribution[17]. Indeed if the chemical potentials of the substance at the site of its administration and at the site of its action are the same[17], its initial concentration (C_0) must determine its concentration in a specific region of the biophase (C_B), binding to which (i.e. reaction with this region) gives rise to the biological effect, since in this case the law of the partition of the substance between the phases C_B/C_0 = const. holds, whence the validity of $1/C_0$ as a criterion of the effectiveness of the biological action is evident. On the other hand, if the biological action of the substance is determined by the inhibition of a specific enzyme of the biophase, its inhibition rate constant may be used to estimate $[A]$ (O'Brien[13]); experimental evidence for the relation between $1/C_0$ and the inhibition rate constant has been obtained[15,16,18].

The theoretical case where the time of attainment of a definite state of inhibition of the enzyme is inversely proportional to C_0 is obtained for second-order reactions. Indeed, in this case $[A] = K_{0.5}^i = k_1(1/C_0)$ to within the constant k_1. In fact postulate (2) or its logarithmic form

$$\lg[A] = \lg(1/C_0) = \text{const} + \lg N + \lg K + \lg \bar{k}_i \qquad (3)$$

imply merely that, for the same rate of the rate-limiting stage, all the substances in the series, i.e. related compounds, should give rise to an identical biological response over a fixed time interval regardless of their structure and composition. Because of this, the quantity $-dC_{cr}/dt$, in the form $-dC_{cr}/dt = \bar{k}_iNC_0$, should be introduced directly into Eqn. (1) and not the formal quantity d[BR]/dt. In this form the problem is stated correctly and reduces to the determination of the dependence of $\lg(1/C_0)$ on various physicochemical parameters.

In order to facilitate the mathematical interpretation of Eqn. (3), it is assumed that the reaction limiting the rate of the process at a given stage is of first (or pseudofirst) order. This is possible if (1) only a small proportion of the reacting active centres in the organism interact with the test substance and (2) the substance is present in the organism in a considerable excess relative to the number of reactive sites. The second instance is frequently obtained under *in vitro* conditions, i.e. in a model physicochemical system, while the first probably obtains under the real conditions occurring when an organism is acted upon by the given substances.

The origin of the structure–activity relations is deduced by comparing the results of independent physicochemical and biological studies on the relevant substances. Table 1 presents the forms of biological action for which a correlation between the type of biological action of the substance and its physicochemical characteristics has been established empirically.

If it is assumed that Eqn. (3) is correct, then, for a quantitative expression of the influence of substituents on $\lg\bar{k}_i$ and hence on $\lg[A]$, it is necessary to take into account, to a first approximation, the hydrophobic, electronic, and steric components of the interaction, which may be represented in the form of their linear combination:

$$\lg\bar{k}_i = f_h(S_h) + f_e(S_e) + f_s(S_s). \qquad (4)$$

---

†Here and henceforth $[A]$ and [BR] are a quantitative measure of the activity, expressed in terms of the concentration, and a quantitative measure of the biological effect, expressed in terms of arbitrary units, respectively.

On combining Eqns. (3) and (4), we obtain

$$\lg [A] = \lg (1/C_0) = f_h(S_h) + f_e(S_e) + f_s(S_s) + \lg N + \text{const.} \qquad (5)$$

The specific form and significance of each term of Eqn.(5) can be found in different ways as a function of the model adopted or the available experimental observations (see below).

Table 1. The forms of biological action for which a quantitative correlation has been established with the physicochemical parameters of substances and the parameters of their model interactions.

Physicochemical characteristics of substance	Type of biological action	References	Sources of tabulated values of physicochemical parameters
Logarithm of partition coefficient $\lg P$	Bacteriostatic activity	77,84,87, 147-149	
	Narcotic activity	12,135,150, 151	41,176-178

We shall adopt the convention that all the approaches to the structure–activity problem, including the examination [in terms of Eqn. (3)] of specific physicochemical characteristics of the given substance, are semiempirical.

The contribution of the second group of methods (empirical methods) consists in a systematic analysis of studies of biological activity in order to discover the structural elements and their combinations characteristic of a particular type of activity. We have included in the same group methods for the estimation of the mathematical contribution of definite structural elements to the biological activity of the compound.

II. THE METHOD OF SUBSTRUCTURAL ANALYSIS. THE PATTERN RECOGNITION METHOD

Both these methods are based on the hypothesis that the biological activity of a substance is due to the presence in its molecule of definite structural elements (substructures).

The frequency of the activity of the substructure L characterises the contribution which the substructure makes to the probability that the compound is biologically active[19]. It is expressed numerically as the ratio of the number of biologically active substances containing a definite structural unit (B) to the total number of compounds analysed where this substructure is also encountered (T), i.e. $L = B/T$.

Using a descriptive system of fragment coding[20,21], capable of distinguishing 1200 structural fragments—functional groups, chains, rings, etc.—and 110 types of their combinations, a formalism[22] and a computer program were developed; the latter was capable of determining L for compounds differing appreciably in their chemical structure and exhibiting a known type of biological activity, which were compared with the same values for compounds analysed for potential biological activity.

The attempt[19] to estimate the antiarthritic-immunoregulatory activity of 850 preparations of different structures and with different mechanisms of their pharmacological activity in terms of the criterion L, regardless of tests based on physiological methods[23], led to the following findings:

(1) simple identification of the structural fragments characteristic of the most active substances of this group does not permit the choice, as was to be expected, of the optimum compounds and hence the determination of the sequence based on their increasing or decreasing activities;

(2) the experimental frequency tables for the activities of substructures, including the values of L for 492 structural fragments encountered in the most active compounds with a given type of activity, made it possible to establish a series of compounds based on decreasing activities and consistent with the experimental series‡.

Next the same program was used to search for substances with antiarthritic-immunoregulatory activity among 703 substances which had not yet been tested. It was shown[19] that the criterion L is suitable not only for the determination of the potential activities of a wide variety of types of compounds but also for the recommendation of the required combination of substructures in the synthesis of compounds previously unknown as antiarthritic-immunoregulatory agents.

Naturally in the form in which it has been proposed the criterion L cannot be referred directly to structure-active relations. When the pattern recognition method is applied[24,25], apart from the substructural principle of characterising substances their physicochemical parameters are introduced as well. In this case, a series of preselected chemical compounds with a definite specificity of their biological action (learning series including more than 100 substances) is represented by a surface in n-dimensional space, where the coordinates are formal equivalents of the structural fragment and the physicochemical parameters of the substance; the points on the surface correspond to individual compounds. The test substance or group of substances is treated formally in terms of the same features as the learning series after which one finds how close they are located in the given n-dimensional space to the points corresponding to the active compounds in the learning series. A special method[25] makes it possible to formulate individual groups of features in terms of space vectors, which makes it possible to reduce the number of variables and to discover fragments characteristic of active compounds. According to Chu et al.[24], the combined use of fragment and physicochemical criteria to characterise substances permitted the prediction with 80–90% probability of antitumour activity in a series of 17 previously uninvestigated compounds.

III. THE MATHEMATICAL ADDITIVE MODEL

The mathematical additive model (MAD)[26] is based on the hypothesis of the independent additive contribution of substituents to $[A]$ for a number of compounds Y_1, Y_2, Y_3,..., differing by the substituents X_1, X_2, X_3,..., the mathematical contribution of the molecular skeleton being assumed to be constant. Accordingly one can write

$$[A] = \sum_i a_i x_j + \lambda, \tag{6}$$

where a_i is the mathematical expression for the contribution of the ith substituent to $[A]$, $x_j = 0$ or 1 depending on the absence or presence of the ith substituent, and λ is the constant mathematical contribution of the skeleton to $[A]$.

The MAD imposes an additional limitation on the overall contribution of substituents to biological activity for the same position in the entire series of compounds. For example, if three substituents A, B, and C may exist in the same structural element, then

$$\sum_i^k a_i(\mathrm{A}) + \sum_i^l a_i(\mathrm{B}) + \sum_i^q a_i(\mathrm{C}) = k a_i(\mathrm{A}) + l a_i(\mathrm{B}) + q a_i(\mathrm{C}) = 0, \tag{7}$$

where k, l, and q are the numbers of compounds containing the substituents A, B, and C respectively in the given position. The contribution of any substituent can therefore be expressed in terms of a linear combination of the contributions of the remaining substituents. Evidently, if the series of compounds tested contains h structural elements, in which there may be m substituents, then the solution of the system of equations thus formulated requires n equations with $m - h$ independent variables. The individual contributions of the substituents can be used to calculate $[A]$ for compounds of the series which have not yet been investigated.

The scope of the MAD has been frequently analysed[27-32] and attempts have been made to improve the model[33,34]. Using the same hypothesis of additivity, Eqn. (6) can be written in the form

$$\lg \frac{[A_1]}{[A_0]} = \sum_i G_i x_j, \tag{8}$$

where the subscripts 0 and 1 refer to $[A]$ for the unsubstituted and substituted compounds, G_i is the logarithm of the change in $[A]$ when the ith substituent is introduced instead of $X_1 = H$, and x_j has the same significance as in Eqn. (6). For a homologous series, $\lg[A_0] = \text{const.}$ and Eqn. (8) becomes

$$\lg [A_1] = \sum_i G_i x_j + \text{const.} \tag{9}$$

This stage already simplifies the MAD greatly: firstly, the constant term proves to be the activity of the initial unsubstituted compound and not a derivative of the molecular skeleton; secondly, since $[A]$ in the modified model is considered in relation to the activity of a hydrogen-containing compound, one may disregard the restrictive relation (7), which reduces the number of equations.

Despite the artificiality of the hypotheses underlying the MAD (the additivity and independence of the contributions of the substituents), the agreement between the experimental and calculated values of $[A]$ may be satisfactory, provided that (a) successive structural changes in series of compounds are investigated and (b) the results of biological tests used for the determination of the relative contributions of substituents are sufficiently accurate[27].

---

‡In order to avoid "discoveries" compounds constituting the basis of the compilation of the Tables, these compounds were excluded from the total number of substances tested.

The fundamental effectiveness of the MAD may be demonstrated. We shall assume that it is necessary to test a series of compounds where the substituents may be located in four positions ($h = 4$) and the number of substituents in the compound is varied: $m = 2, 3, 4$, or 5. The theoretically possible number of variants of molecules is then 120. The number of structural elements which must be introduced into the MAD is $\Pi = \sum^{h} m_i + 1 = 15$, where unity represents the contribution of the molecular skeleton. Consequently, in order to determine theoretically the values of $[A]$ for 120 compounds, it is sufficient to carry out only 11 tests of their biological activity (i.e. $\Pi - h$ tests). In view of the low accuracy of biological experiments, in order to obtain a reliable result in practice, it is desirable to have the largest possible number of experimental data[28].

Allowance for the mutual influences of the substituents in the MAD constitutes a more realistic approach[31,32]. For this purpose, the terms G_i^*, taking into account the change in $[A]$ owing to the interactions of the substituents, are introduced into Eqn. (9):

$$\lg [A] = \sum_i G_i x_j + \sum_i G_i^{\bullet} x_i x_j \ldots + \text{const.} \tag{10}$$

For example, if the compound contains the substituents X_1, X_2, and X_3, then, when account is taken of their mutual influence, we have $\lg [A] = G_1 x_1 + G_2 x_2 + G_3 x_3 + G_1^* x_1 x_2 x_3 + G_2^* x_1 x_2 + G_3^* x_1 x_3 + G_4^* x_2 x_3 + \text{const.}$ It has been shown[34,35] that the use of this procedure makes it possible to take into account the influence of the relative positions of the substituents on biological activity. Naturally, in this case there is a sharp increase of the number of terms in the equation and hence of the number of necessary biological tests, which reduces the practical scope of the application of the mathematical model.

Attempts have been described to relate the mathematical additive model to the mechanism of the action of substances[34,36-40].

The results accumulated hitherto concerning the application of empirical methods for the estimation of $[A]$ show that fairly similar values of $[A]$ may be obtained by independent computational and experimental methods. The practical use of the above methods requires a generalisation, systematic arrangement and representation in a form suitable for computer calculations of the extensive experimental data from studies on the biological activity of chemical compounds, and the development of a single system for the mathematical representation of the structures of substances.

IV. THE MULTIPARAMETER REGRESSION METHOD

The qualitative relations established between the biological activity and physicochemical properties of substances[2-4] stimulated studies designed to discover the essential features of these relations. The first attempt of this kind involves the equilibrium distribution model (EDM).[17] It is based on the hypothesis that, after the introduction of the substance into a biological system, chemical equilibrium, determined by the equality of the chemical potentials (μ) of the substance in different phases, is established between its concentration at the site of administration and the concentration in the vicinity of the site of response. The constancy of the isonarcotic concentrations in the lipid phase C_{lip} followed from the results of tests on the narcotic activity of a wide variety of compounds[17]. At low concentrations $\mu = \mu_0 + RT \ln C$; hence, setting the values of μ for the lipid and aqueous phases equal and assuming that C_{lip} is constant, it is possible to obtain a relation between $\lg (1/C_0)$ and the partition coefficient of the substance in the biological system (P_{b}). The latter is as a rule unknown, but it has been established[17,41,42] that P for a model system (for example olive oil-water and octanol-water systems) may be used instead:

$$\lg (1/C) = a \lg P + b. \tag{11}$$

In Eqn. (11) $\lg P$ may be replaced by other physicochemical parameters of the substance, such as, for example, the parachlor (Pr), the molar volume (V_{M}), and the solubility ($\lg C_{\text{S}}$). The most complete information about structure-activity correlations based on the EDM has been published by McGowan[42]. On the basis of the theory of solubility, it is shown[42] that $\lg P$ can be represented by $\lg P = k_1 Pr + E_{\text{A}}$. On the other hand, the parachor may be related to $\lg C_{\text{S}}$ and V_{M} with the aid of the approximate relations $\lg C_{\text{S}} \simeq \lg C_l + k_2 Pr$ and $Pr \simeq k_3 V_{\text{M}}$, where E_{A} is a term taking into account the association of substances or their capacity for the formation of a hydrogen bond, C_l is the molar concentration of the substance recalculated for the pure liquid phase, and k are the corresponding proportionality coefficients. The relation between $\lg P$, on the one hand, and Pr, V_{M}, and $\lg C_{\text{S}}$, on the other hand, in the given model can be accounted for in terms of thermodynamic considerations, since the main contribution to $\lg P$ comes from the change in the entropy of the system owing to the rearrangement of the solvation shells of the molecules on passing from the aqueous to the organic phase. The degree of dehydration depends on a number of factors, in the first place on the size and polarity of the molecules of the substance and their packing density. $\lg C_{\text{S}}$, Pr, and V_{M} may be used as characteristics of these factors.

The possibility of using the additivity rules to predict the biological activity of substances on the basis of the additivity of the values of Pr and V_{M} was demonstrated for the first time with the aid of the equilibrium distribution model[42-44]. The limitations of the EDM are evident, since it takes no account of either the kinetics of the attainment of equilibrium in the system or of the mechanism of the chemical reactions occurring in it.

At the beginning of the 1960s Hansch and coworkers proposed an approach fundamentally different from the EDM. They suggested that the overall physicochemical process causing the biological response be regarded as a steady-state and not an equilibrium process[9]. They began with the assumption that the time interval corresponding to the biological test is insufficient for the attainment of chemical equilibrium. Hansch and Fujita[9] used the familiar scheme[45] for the biological activity of the substance:

$$\begin{array}{l} \text{Compound in extra cellular phase} \xrightarrow[\text{stage I}]{} \text{Site of action in cellular phase} \xrightarrow[\substack{\text{stage II} \\ \text{(rate-determining)}}]{\bar{k}_{\text{II}}} \\ \cdots \xrightarrow[\text{stage III}]{} \cdots \xrightarrow[\text{stage } n]{} \text{Biological response}. \end{array} \tag{12}$$

It was found that the principal stages at I and II—the migration of molecules from the very dilute solution outside the cell to a definite site within the cell and the chemical or physical process determining the overall rate of the biological response respectively. It was postulated that other stages (III...n) do not affect the observed biological response.

In order to derive a formula relating $\lg(1/C_0)$ to physicochemical parameters, Hansch and Fujita[9] used a phenomenological approach (see Section I). It follows from Eqn. (2), which can be rewritten in the form

$$\lg(1/C_0) = \lg N + \lg \bar{k}_{\text{II}} + \text{const} \qquad (13)$$

for scheme (12), that the problem reduces to expressing $\lg(1/C_0)$ in terms of the physicochemical parameters determining the values of $\lg N$ and $\lg \bar{k}_{\text{II}}$. On the basis of the relation observed by Collander[46,47] between $\lg P$ and the rate of migration of organic compounds through tissues and the nearly parabolic relation between $\lg(1/C_0)$ and $\lg P$ observed in a number of instances[9,12,48], it was assumed that N obeys the normal distribution law with respect to $\lg P$:

$$N = N_0 \cdot \exp\left[-\frac{(\lg P - \lg P_{\text{op}})^2}{b}\right], \qquad (14)$$

where P_{op} is the optimum value of P corresponding to the maximum value of $N = N_0$ and b is a constant. Hammett's equation

$$\lg \bar{k}_x = \rho\sigma + \lg \bar{k}_0, \qquad (15)$$

in which $\bar{k}_X$ and $\bar{k}_0$ represent the rate or equilibrium constants for *meta*- or *para*-substituted and unsubstituted benzene derivatives respectively (for the same reaction and under identical conditions), ρ is a constant for the given reaction, and σ the Hammett constant for the substituent, was used for the first time for the term $\lg \bar{k}_X$. After substituting Eqns. (14) and (15) in Eqn. (13), we obtain

$$\lg(1/C_0) = a_1(\lg P)^2 + a_2 \lg P + a_3\sigma + a_4, \qquad (16)$$

where a_1–a_4 are constants.

Eqn. (15) is a consequence of the application of the principle of linear free energy relations (PLE).[49–51] It can be used to express the rate or equilibrium constants ($\lg \bar{k}_X$) for a series of related compounds involved in similar reactions. One then obtains for different types of interactions equations which are analogous in form to Eqn. (15). Expressing $\lg \bar{k}_X$ in Eqn. (13) with their aid, it is possible to obtain a wide variety of equations taking into account the resonance, conformational, steric, and other factors influencing $\bar{k}_X$; in particular, the following expression has been obtained[11]:

$$\lg(1/C_0) = -a_1(\lg P)^2 + a_2 \lg P + a_3\sigma + a_4E_s + a_5, \qquad (17)$$

where E_S is the steric Taft parameter.

In order to take into account the influence of individual substituents on biological activity, i.e. in order to examine a series of compounds and also to calculate the values of $\lg P$ for substances which have not as yet been investigated, the substituent constant $\pi_X = \lg(P_X/P_0)$ was introduced by analogy with σ.[52] Here P_0 is the partition coefficient of the unsubstituted initial compound in a model system and P_X is the partition coefficient of the compound with the substituent X. It can be shown that π can also be obtained as a result of the application of the PLE to hydrophobic interactions. For a series of substances involved in a reaction j, variation of the substituent X yields

$$\lg(\bar{k}_x/\bar{k}_0) = \varkappa_j \lg(K_{xi}/K_{0i}), \qquad (18)$$

where K_i are the equilibrium constants for the standard reference reaction i, $\bar{k}_j$ are the rate constants for reaction j (K_{Xi} and $\bar{k}_{Xj}$ when the molecule contains the substituent X and K_{0i} and $\bar{k}_{0j}$ in its absence), and κ_j is the constant of reaction j. The type of interaction between the substituent and the reaction centre for reactions i and j is assumed to be the same. If the interaction is assumed to be hydrophobic, then evidently the equilibrium constant in a partition system of the oil–water type is none other than the partition coefficient of the substance P. The partition of the substance (i.e. its interaction with the solvent of the "solvation ⇌ desolvation" type with respect to one of the solvents) in the model system, for example octanol–water, may be used as the standard reference reaction. Then substitution of P_X and P_0 for the equilibrium constants K_{Xi} and K_{0i} in Eqn. (18) yields an equation similar to Hammett's equation in which the constant $\pi = \lg(P_X/P_0)$ is analogous to the Hammett constant σ:

$$\lg \bar{k}_x = \varkappa\pi + \lg \bar{k}_0. \qquad (19)$$

Like other reaction constants of the substituents, the constant π depends on the system in which it is determined[41,52], owing to the interaction of the substituents with other parts of the molecule. In practice this is taken into account by selecting for the calculation of π the corresponding model systems (molecules) similar to the molecules analysed.

By definition there is a linear relation between $\lg P_X$ and π_X, which made it possible to employ the corresponding values of π instead of $\lg P$ in equations of type (17):

$$\lg(1/C_0) = a_1\pi^2 + a_2\pi + a_3\sigma + a_4E_s + a_5 \quad . \qquad (20)$$

These can be calculated[41,52].

In contrast to the kinetic approach constituting the basis of Hansch's method, Franke and Oehme[8] described an attempt to obtain similar structure–activity relations on the basis of an equilibrium model. It is assumed in this case that the entire chain of chemical reactions leading to the final biological effect operates only in the establishment of the equilibrium at each stage. Thus the entire system may be characterised by the overall equilibrium constant

$$K_c = \prod_i K_i, \qquad (21)$$

which describes the equilibrium between the initial state (active substance D + receptor R) and the final state, identified with a "biological stimulus" St, corresponding to the Law of Mass Action. The concentration of the reaction product C_X, which is the main one for the observed biological action, was introduced[8] as a measure of St:

$$St = C_x = K_cC_DC_R. \qquad (22)$$

Subsequently a general equation of type (3) was obtained[8] by expressing the biological activity $[A]$ in the form

$$[A] = f(St) = f(K_cC_DC_R), \qquad (23)$$

taking into account the linear sections on the dose–activity curves, where

$$[A] = kSt, \qquad (24)$$

and introducing the transfer functions W (analogous to the function N in Hansch's method) in order to find the concentration of the active substance near the receptors. Eqns. (16), (17), and (20) are special cases of the type (3) equation. It is readily seen that in this case the use of Eqns. (21)–(24) constitutes a formal procedure which makes it possible to bring the physicochemical parameters determining K_C and W into correspondence with $\lg[A]$ or $\lg(1/C_0)$.

It is clear from the foregoing that there is at present no unique physicochemical theory corresponding to both the kinetic and equilibrium approaches. However, an attempt may be made to group the physicochemical features of compounds in accordance with their physical significance in order to take into account to the maximum possible extent the structural characteristics responsible for the biological activity shown by the compound. In many instances this facilitates the interpretation of structure–activity correlations and gives them a concrete physicochemical content.

We shall consider certain possibilities of a group of parameters (based on their physical significance) for the derivation of correlations. According to Eqn. (5), when N is expressed in terms of hydrophobic properties of the substance, then

$$\lg [A] = \lg (1/C_0) = f'_h(S_h) + f_e(S_e) + f_s(S_s) + \text{const}, \tag{25}$$

where f'_h is a function combining the partition phenomena and the hydrophobic interaction with the receptor.

Not only physicochemical parameters of the entire molecule but also certain substituent constants may be chosen as the S_i in Eqn. (25). The following parameters can be used under these conditions.

(1) as S_h: (a) $\lg P$ [11,12,41,48,53] or quantities associated with it—the Hansch constant π (the lipophilicity parameter)[11,12,41,52]; $R_M = (1/R_f - 1)$ or ΔR_M (analogue of π) from thin-layer partition chromatography[54-56]; the protein binding constants (determined for a model system)[12,41,57,58]; $\lg C_s$§, where C_s is the solubility in water[42,58,59]; (b) quantities related to molecular size and packing: the molar volume (V_M), the parachor (Pr), molar refraction (MR), the solubility parameter (δ), the diamagnetic susceptibility (χ_m), the molecular connectivity (χ),[42,60-67], and the molecular weight M [60]; (c) the molar attraction constant (F_a) [60,63,64]; (d) the hydrophilic–lipophilic balance (HLB) [68];

(2) as S_e: (a) different electronic substituent constants σ characterising the electron density at the reaction centre[8,11,12] if they can be expressed[69] as a linear combination of the constants $\mathscr{F}$ and $\mathscr{R}$, where $\mathscr{F}$ is the inductive constant, which takes into account only the inductive effect of the substituent on the functional group and $\mathscr{R}$ is the resonance constant, taking into account all the resonance interactions (the use of $\mathscr{F}$ and $\mathscr{R}$ [70-72] makes it possible to avoid the consideration of different types of σ in the correlation equations)¶. (b) The charge-transfer constant (C_T), which is a measure of the stability of the complex formed via charge transfer[78-80]; (c) various parameters characterising the electron density, bond orders, and bond lengths; parameters of the first kind include the changes in the ionisation constant ΔpK,[10,12,81,82] the ionisation potential I,[83] and the polarographic half-wave potential $\varphi_{1/2}$ [84]; parameters of the second kind include the molar electronic polarisation (P_E) [85-87] or simply the polarisability (α),[60,83] the dipole moment (μ),[12,88,89] and spectroscopic data (infrared, ultraviolet, NMR, etc.)[90-98]; (d) various quantum-mechanical parameters (see below).

(3) As S_s: (a) steric Taft constants (E_s),[11,12,99] determined analogously to σ, and the corrected steric interaction parameters $E_s^S = E_s + 0.306(n_H - 3)$ [12,100]; (b) the van der Waals radii (r_V).[37,101-103].

The literature data for structure–activity correlations have shown that the degree of the functions f'_h, f_e, and f_s in Eqn. (25) is as a rule not greater than the second, i.e. in the general case they correspond to a parabolic relation and are therefore characterised by certain extremum values corresponding to S_i^0. The extremum is determined from the condition

$$\left(\frac{\partial \lg (1/C)}{\partial S_{i=k}}\right)_{i \neq k} = 0$$

and corresponds to the optimum value of the corresponding physicochemical parameter for biological activity[10-12,104]. The possibility of an optimum value of S_h^0 can be explained in different ways[104]. It appears that the following most important factors for the occurrence of S_h^0, S_e^0, and S_s^0 may be distinguished: (a) metabolism or competing metabolic reactions in the biological system; (b) the obligatory complementarity of the molecule (or its active component) and the reacting region of the receptor; (c) a low concentration of the active molecules in the vicinity of receptors. Furthermore, in the study of enzymes *in vitro* the occurrence of S_i^0 can be due to micelle formation with entrainment of active molecules.

The number of parameters quoted above may be reduced if they are expressed by a quantum-mechanical procedure. It has been shown[105] that π as well as $\lg P$ can be expressed as a linear function of quantum-chemical parameters:

$$\pi = k_1 \sum_r |Q_r^T| + k_2 \sum_r S_r^E + k_3, \tag{26}$$

where $|Q_r^T|$ is the absolute value of the overall charge, S_r^E is the electrophilicity caused by the superdelocalisation of the electrons at the atom r, and k_1–k_3 are constants.

However, since the use of experimental values of π and $\lg P$ to determine structure–activity correlations yields satisfactory results in individual instances, it appears much more useful to employ quantum-chemical methods in order to express the term $f_e(S_e)$,[12,106-116], using various computational methods[116].

The following quantum-chemical quantities are used as parameters characterising reactivity†: the overall π-electronic charge $q_r(\epsilon)$‡ on the atom r; the overall ($\sigma + \pi$) charge on the atom r; the highest occupied (E_{HOMO}) and lowest unoccupied (E_{LUMO}) molecular orbitals; the electrophilic (S_r^E) and nucleophilic (S_r^N) characteristics of the influence of superdelocalisation[118,119]; the free valence index F_r (mainly for homolytic reactions)[114]; the atomic-orbital coefficient C_r.[120]

In the general case it is not clear which quantum-chemical parameters should be preferred for use in the structure–activity correlations. This depends on the proposed mechanism of the biological action of the compound and is usually related to the charge on the heteroatom (for example q_N on the nitrogen atom), to the energies E_{HOMO} and

---

§It has been shown[59] that, in the study of the biological activities of substances introduced into a biological system in a solid form, the rate of dissolution of this form must be taken into account in structure–activity correlations. This is because the correlation between the rate and C_s is poor.

¶In radical reactions it is still necessary to employ $\sigma^{\bullet}$ and E_R, because they are poorly correlated with $\mathscr{F}$ and $\mathscr{R}$.[73-77]

†They are calculated using parameters obtained from spectroscopic measurements, the ionisation potentials, etc. The corresponding values for the extensive Hückel method have been tabulated[117].

‡Here and henceforth the subscript r means that the corresponding quantity refers to the atom r in the molecule.

E_{LUMO} or to the difference $E_{\text{HOMO}} - E_{\text{LUMO}}$, and to S_N.[8,10,12,114,116] Hypotheses of this kind are not often found to be true in practice. This is probably because only the potential reactivity of the compound is considered by this procedure without taking into account the possible steric, conformational, and other parameters influencing the biological activity. Attempts have therefore been made to use various linear combinations of quantum-chemical parameters[114]. However, this procedure has not as yet been adequately investigated and its scope is not entirely clear.

V. ANALYSIS OF THE STRUCTURE-ACTIVITY RELATION BY HANSCH'S METHOD

As stated above, Hansch's method is used to express the biological activities of members of series of related compounds in the form of functions of physicochemical parameters characterising the structure of these compounds. As a rule, the relative importance of taking into account these parameters in the description of biological activity is not known beforehand, which makes it necessary to test a series of model equations containing various combinations of parameters. These equations are obtained by regression analysis, after which the best one is selected on the basis of the significance of the correlation coefficients. It is recommended[8,103] that certain rules be observed.

1. It is desirable to consider the greatest possible number of independent parameters.

2. The parameters S_i considered above are as a rule integral quantities characterising molecular properties in a complex manner; for this reason, there is a definite relation between them. The literature data show that the correlation between the S_i referring to the same interactions (for example to hydrophobic interactions) is much better than between parameters characterising different types of interactions (for example between $\lg F$ and σ).[70,121] This observation can be used as one of the empirical rules for the selection of various combinations of independent parameters S_i§.

3. After the preliminary examination of the possible versions of the set of parameters and comparison with the aid of regression analysis of a series of model equations, it is necessary to determine by means of Student's t distribution the levels of significance of individual coefficients. Parameters with a low level of significance are disregarded.

4. The multiple regression coefficient[122,123] R, the standard deviation, and the F test are used for the statistical assessment of the equations obtained. The square of the correlation coefficient (R^2) indicates the proportion of variations in data obtained from the corresponding equations. The closer it is to unity, the closer the functional relation obtained to the one sought. For similar values of R, it is necessary to take into account the standard deviations and to use equations with the smallest standard deviations. The F test is used to estimate the probability that the suitability of a particular type of equation is not fortuitous.

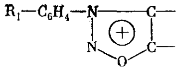
5. In order to exclude random correlations, it is recommended that at least five-six results of biological measurements are obtained for each physicochemical parameter tested[124].

6. Other conditions being equal, preference should be given to simpler equations.

7. In order to reduce the amount of calculations, to simplify them, and to avoid fundamental errors, it is necessary to take into account the reality of the mechanism of the phenomenon under consideration (see Section VIII), since it is possible to obtain on the basis of formal characteristics equations with satisfactory values of R^2 and a high significance according to the F test but having little in common with reality[125].

If possible, one should divide the substances compared into a series of definite substructures with common features, for example, substances with *cis*- and *trans*-positions of a certain group, series obtained by changing one substituent while those in other positions are kept constant, etc.[8] Such subdivision naturally simplifies the problem (a similar empirical approach was discussed in Section III). In order to derive equations for such a series of compounds, it is necessary to introduce an auxiliary parameter D, taking into account the difference between the substructures. For example, it has been used to take into account the steric difference between the *meta*- and *para*-derivatives of diethyl phenyl phosphate in the inhibition of cholinesterase[126]—it was set equal to unity for the former and to zero for the latter. The value of n_H, the number of hydrogen atoms linked to a definite atom in the molecule, for example, the nitrogen atom of an amino-group, may be chosen as D.[127] The auxiliary parameter may be used to combine equations taking into account the differences between the subgroups in order to determine the biological activity of particular stereoisomers only. In those cases where there are several subgroups, it is possible to introduce two or more auxiliary parameters[128].

Examination of polysubstituted compounds presents the greatest difficulties. In such cases it is not always possible to obtain an equation describing the correlation between the biological activity and the sum of identical substituent constants i.e. ($\sigma_i + \sigma_j$, $\pi_i + \pi_j$, etc.), because the influence of different types of substitution may have different effects on the biological activity. This problem is solved by substituting in the equation parameters characteristic of the particular type of substitution. For example, in describing the inhibition of oxidative dealkylation by compounds having the general formula



an equation with a high correlation coefficient is obtained only when the constants π and σ are taken into account separately for R_1 and R_2.[129]

The most complex case obtains when the biological activity of substances is influenced appreciably by their metabolism.

VI. THE QUANTUM-STATISTICAL APPROACH

Attempts to relate the biological activity of a substance to microscopic characteristics of the interactions in the substance-receptor system by a combination of quantum-statistical and statistical thermodynamic methods have been undertaken[94,130,131]. In order to obtain a working

---

§ In order to characterise the absence of a relation between physicochemical parameters, the so called individual correlation coefficients r, determined as dimensionless quantities, varying in the range $-1 \leq r \leq 1$, are used. The closer the value of r to 0, the more independent are the corresponding physicochemical parameters.

model, the following assumptions were made: (1) in a multistage process occurring from the instant of the introduction of the substance into a biological system until its interaction with the receptor resulting in biological activity, the probability of each stage is independent of that of other stages; (2) substances reach the sites of reception by virtue of Brownian-like motion; (3) the reaction sites consist of localised atoms; (4) the binding of the biologically active substance at a single receptor or group of receptor sites is independent of its binding at other sites in the system.

According to these hypotheses, the initial equation can be expressed in the form

$$\frac{d[BR]}{dt}=KC_0p_1p_2, \tag{27}$$

where K is a proportionality coefficient, C_0 the initial concentration of the substance, p_1 the probability of the completion of the stage involving the penetration of the substance to the receptor, and p_2 the probability of the binding of the substance to the receptor. Next is is postulated that p_1 varies in parallel with the parameter π, i.e. with the lipophilic properties, which are responsible for the passage of the substance through biological membranes,, and that p_2 varies in parallel with the adsorption of the substance at the receptor site or group of sites. If it is assumed that the binding of the substance to the receptor occurs at energetically indistinguishable sites, then p_2 should be wholly determined by the electronic structure of the heteroatoms of the substance adsorbed. For the specific examples which have been examined[94,131], it was postulated that the binding takes place via a carbonyl group, the energetic characteristics of the probability of the binding of which to receptors were determined from spectroscopic data.

The mathematical expression[131] relating the activity of the substance to the permeability of membranes to it and the probability of its interaction with the receptor includes the following parameters: the lipophilicity, the spectroscopically estimated distribution of the potential reactive centres (groups), and the chemical potential of the test substance in solution. It follows from the analysis of this expression that the most active compound may be found or synthesised when the substituent or its position in the molecule is chosen in such a way that it influences simultaneously the lipophilic properties of the compound and the energy state of the reactive group.

Insufficient reliable data are as yet available for the assessment of the predictive power of the method[130]. At the present time one can estimate only its fundamental advantage: the necessary parameters—the lipophilicity and the wavenumbers of the suggested reactive groups—may be determined experimentally fairly readily.

VII. THE USE OF FACTORIAL ANALYSIS IN THE DERIVATION OF STRUCTURE-ACTIVITY RELATIONS

Evidently the limitation of the above methods to any one type of biological activity is artificial. In order to solve rigorously the problem of the relation between structure and activity, it is necessary to take into account all possible physiological processes and to relate them to the entire set of physicochemical parameters characterising or determining each stage in the action of the given substance. The difficulties in this procedure are the unusual complexity of biological systems, the wide variety of reactions occurring in them, and the imperfection of our knowledge of their mechanisms and interrelations. Virtually the first attempt to take into account several possible versions of the interaction is a study[132] where the method of factorial analysis was used.

Mathematical factorial analysis may be formally applied to any complex multidimensional problem, provided that it can be represented by a sum of interrelated functions of certain variables, i.e. in the form

$$P(i,k)=\sum_{j=1}^{m}U(i,j)V(j,k), \tag{28}$$

where $P(i,k)$ is the measured property of the system in the ith case when k is varied, $U(i,j)$ is the jth factor for the ith case, and $V(j,k)$ is the jth variable factor for the given variable k; the summation is carried out with respect to all the factors j which are important[132]. In the relevant specific instance of the structure-activity relation, we have

$$[A](i,k)=\sum_{j}D(i,j)H(j,k), \tag{29}$$

where $[A](i,k)$ is the kth measured biological activity of substance i, $D(i,j)$ the jth property (physical or chemical) of the ith compound, and $H(j,k)$ the jth parameter (physiological) of the kth biological activity; the summation is carried out with respect to all j independent parameters which are necessary to take into account the results of tests.

The form of factorial analysis applied to the case described differs from the standard form by the fact that it includes the method of regression analysis as one of the factors[132,133] in the form of the identity factor. Thus, provided that the accuracy of the experimental data is known, it is possible to determine the number of independent abstract factors ("eigenvectors" according to Weiner and Weiner[132]) necessary for the complete characterisation of the factorial space, i.e. one can determine the number of variables influencing the system tested. Leaving on one side the discussion of the mathematical formalism used by Weiner and Weiner, we shall mention only that in this first stage the number of eigenvectors is equivalent to the dimension of the factorial space. The next step is the identification of each factor in the form of the specific level of its significance for each physiological response. For this purpose, the entire set of variables is compared with all possible physicochemical properties or parameters of the model interactions which are presumed to be important. Although Weiner and Weiner[132] used the characteristics of substances usually employed for semi-empirical models, this does not imply that one must necessarily employ the polarisability, the partition coefficients, etc. (Table 1).

Since the term $[A](i,k)$ in Eqn. (29) may be expressed and measured experimentally as the biological activity manifested in a kth case and the term $H(j,k)$ relates any physiological parameter to any property of the substance and the quantity $[A]$, the method of factorial analysis may be used to predict the uniqueness of the compound tested or to specify the set of properties giving rise to the maximum useful activity for a minimum number of side effects. The method of factorial analysis was tested by comparing the calculated data with the experimental results obtained by measuring the activities of 16 substances in a series of substituted compounds having the general formula $R_1-\overset{|}{N}-R_3$ in 11 types of biological and physiological action (including action on a specific type of activity, the antagonistic behavioural reflexes of the animal, and objective parameters of the state of the organism). It was established[132] that, in order that the model should reproduce the results of studies to within ±0.1 on a logarithmic scale, it is necessary to employ eight parameters describing, according to Weiner and Weiner[132], the main structural characteristics of substances. Unfortunately, a list of the properties employed is not given[132]; nevertheless the potential possibilities of this approach should stimulate the expansion and intensification of this field of research.

VIII. THE USE OF SEMIEMPIRICAL METHODS IN THE STUDY OF THE MECHANISMS OF REACTIONS OF BIOLOGICALLY ACTIVE SUBSTANCES

Apart from the selection of the optimum compounds, it is desirable to obtain, as a result of the analysis of the structure–activity relation, an idea about the mechanism of their biological activity. We shall consider one of the possible procedures for this purpose.

1. The conclusion as to which properties of the substances are the most important for their biological activity may be reached on the basis of the statistical significance of the physicochemical parameters in correlation equations.

2. Next one must determine the ways in which these properties influence the biological activity, beginning with the form of the function $f_i(S_i)$ [Eqn. (25)]. Here account must be taken of the fact that a parabolic form of the relation with $\lg P$ (or with other S_h) may be a consequence not only of the partition of the substance between the phases[12,134] but also of its hydrophobic binding to the receptor[58]. Because of this, only in the case of a linear relation with $\lg P$ can one conclude that hydrophobic binding is in fact the determining process[8].

In certain cases where a cross-product of terms of the type S_iS_j is introduced in Eqn. (25), the correlation is improved[10,135]. If S_i and S_j are substituent constants referring to a single type of interaction, such cross-product takes into account the mutual influence of the substituents[50]; otherwise, it takes into account the mutual perturbations of different types of interaction[8].

3. When the influence of hydrophobic binding is decisive, one can estimate approximately the dimensions of the binding region on the receptor from the values of the parameters S_h for which a discontinuity is observed in the functional dependence of $[A]$ on S_h.[58]

4. Certain conclusions about the mechanism of the motion of a given substance may be reached by analysing auxiliary parameters, which must be included in the equation to improve the correlation.

5. If possible one should calculate $\lg P_{op}$ (or the values of other S_h^0) and compare them with the corresponding values for other series of compounds giving rise to a similar biological response. For example, similar values of $\lg P_{op}$ obtain for a non-specific action of the substance. In particular, in the case of narcotic action identical values $\lg P_{op} \simeq 2$ were obtained for a series of substances with fundamentally different structures and compositions: barbiturates, thiamorpholidines, acetylenic alcohols, acetylenecarbamates, etc. This permits the conclusion that narcosis is due to a non-specific action by the substances and that substances with $\lg P_{op} \simeq 2$ are in general the most effective narcotics[12].

An approximate model of the biological activity of the substance may be obtained from the information derived by the above procedure but must be subsequently tested and refined by additional experiments.

Interesting prospects for the understanding of the mechanism of the most complex stage in the interaction of the substance in the organism—the formation of a complex with the receptor—arise from a theoretical treatment of Hansch's method[36,120]. Since the experimental determination of the type of substance–receptor bond is difficult, it has been suggested that the total energy change ΔE occurring on formation of the substance–receptor complex be used as a bond characteristic. If one considers a series of substances with the same type of biological activity, which is due to binding to particular receptors, then the difference between the activities of these substances may be expressed to a first approximation by the change in the free energy of formation of the substance–receptor complex:

$$\Delta[A] = -\left(\frac{1}{RT}\right)\Delta G + \text{const}, \qquad (30)$$

where $\Delta G = \Delta E + \text{const}$.

ΔE represents, according to the authors[36,120], the sum of the independent contributions of the electronic (ΔE^e), solvation (ΔE^d), steric (ΔE^s), and conformational (ΔE^p) components of the energy change. This hypothesis corresponds to a linear relation between the free energies[36]. The next problem is to express the different contributions ΔE^i in terms of experimental or calculated quantities. In order to calculate ΔE^e, for example, using the perturbation theory[136,137], we obtain

$$\Delta E^e = \sum_r \sum_s E_{rs} = \sum_r \sum_s \Bigg(\underset{\text{(I)}}{-\frac{Q_r Q_s e^2}{D_{rs} R_{rs}}} + \underset{\text{(II)}}{\sum_m \sum_n \frac{2C_{mr}^2 C_{ns}^2 \bar{\beta}^2}{E_m^* - E_n^*}} \Bigg), \qquad (31)$$

where E_{rs} is the electronic energy of the interaction between atoms r and s, Q_r and Q_s are the overall charges, e is the electronic charge, R_{rs} is the distance between atoms r and s, D_{rs} is the dielectric constant of the medium, $E_m^* - E_n^*$ is the energy difference between the highest occupied molecular orbital of the receptor and the lowest unoccupied molecular orbital of the compound, β is the exchange integral taking into account the interaction between the molecular orbitals, and C_{mr} and C_{ns} are the atomic orbital coefficients. Each pair of interacting atoms, in a molecule of the compound (s) and the receptor (r) is assumed to make an independent contribution to ΔE^e.

Since Eqn. (3) includes properties characterising the receptor, it cannot be used directly. For this reason, limiting cases are considered[36,120], corresponding to different relations between E_m^* and E_n^* in Eqn. (31).

1. The Case "Controlled by the Boundary"

If $E_m^* \simeq E_n^*$, the interaction between the corresponding orbitals is decisive for E_{rs}. Then term (I) can be neglected in Eqn. (31) compared with term (II). This case corresponds to the formation of a covalent bond between the molecules of the substance and the receptor. In order to determine the necessary properties corresponding to the receptor, it was suggested that, for a series of related compounds combining with the same receptor site, the coefficients C_{mr} are constant for each compound. Because of this we have

$$\Delta E^e = \sum_s a_s C_{ns},$$

where α_s includes C_{mr}. The following final expression is obtained for ΔE taking into account the solvation energy $\Delta E = \Delta E^e + \Delta E^d$:

$$\Delta E = \sum_s (\alpha_s C_{ns} - \lambda_{ns} Q_s \pm \lambda'_{ns} Q_s^2), \tag{32}$$

where, as mentioned above, the α_s are approximately constant for a series of substances interacting with the same receptor, while λ_{ns} and λ'_{ns} are constants obtained by examining ΔE^d.

An example of the correlation between $\lg(1/C_0)$ and the parameters included in Eqn. (32) is provided by the equation

$$\lg(1/C_0) = 8.8 C_{nN} + 237 Q_N - 1670 Q_N^2 + 6.6, \tag{33}$$

obtained for the bacteriostatic activity of sulphonamides against *E. Coli* [120]. The subscript N in Eqn. (33) refers to the nitrogen atom.

2. The Case "Controlled by the Charge"

This obtains if the difference between E^*_m and E^*_n is large. Then term (I) in Eqn. (31) is of decisive importance, compared with terms (II), and the interaction between atoms r and s is determined mainly by the total charges Q_r and Q_s. In this type of interaction the bond between the compound and the receptor is ionic. When account is taken of this factor, Eqn. (31) can be written as follows:

$$\Delta E = \sum_r \sum_s \left[-\frac{Q_r Q_s e^2}{D_{rs} R_{rs}} + 2\left(\sum_m C^2_{mr}\right)\left(\sum_n C^2_{ns}\right)\gamma \right], \tag{34}$$

where γ is the average value of the ratio $\beta^2/(E^*_m - E^*_n)$. Having assumed the constancy of C_{mr} and Q_r in relation to C_{ns} and Q_s respectively for a series of related compounds interacting with the same receptor and taking into account the fact that ΔE^d in the case controlled by the charge is zero, it is possible to obtain the following equation [36]:

$$\Delta E = \Delta E^e = \sum_s (\nu_{ns} Q_s + \xi_{ns} S_s^E), \tag{35}$$

where ν_{ns} and ξ_{ns} are constants and S^E_s is the parameter of the capacity for ultradelocalisation (see Section IV). The case commonest in practice is probably intermediate between the boundary cases examined above. It has been suggested that the following expression for ΔE be used for it [36]¶:

$$\Delta E = \Delta E^e + \Delta E^d = \sum_s (\nu_{ns} Q_s + \xi_{ns} S_s^E) + h \lg P. \tag{36}$$

The parameter π may be expressed similarly in terms of quantum-chemical characteristics [105] (see Section IV). Without considering the scope of Cammarata's method in the determination of biological activity, which is clearly limited by the complexity of the calculations, one must emphasise yet again that the principles underlying it may be productive in the treatment of the mechanism of the formation of the substance–receptor complex.

IX. THE SCOPE OF PRACTICAL APPLICATIONS, ADVANCES, DIFFICULTIES AND PROSPECTS

As can be seen from the foregoing discussion, there exist at present a number of approaches to the solution of the problem of the correlation between structure and activity, of different complexity and developed to different extents. They are compared in Table 2—the principles underlying the methods, their applications, and certain disadvantages are indicated. The practical value of correlations usually depends on three factors [138]: accuracy, simplicity, and the type of information necessary for use in an empirical equation. Evidently, as regards the "accuracy and simplicity" criteria, preference cannot be given to any one of the approaches described and only the future will show whether the apparently most progressive method of factorial analysis will justify itself. If the existing approaches are considered from the standpoint of the information employed in them, then in an implicit (additive model, substructure analysis) or explicit (factorial analysis) form such information can be expressed in terms of one of the specific types of the multiparameter regression model. Indeed it has been shown [139] that there is a relation between the contribution of substituents to biological activity and their physicochemical characteristics (the substituent constants π, σ, etc.), i.e. all the models enumerated contain common information, which is most clearly expressed in Hansch's model. This makes it possible to consider different approaches from the same standpoint and to justify to a large extent the attention which has been devoted in the literature to the multiparameter regression model.

More than 2000 equations of types (16), (17), and (20) for more than 20 000 chemical compounds have now been described [140]. Many of these have all the formal features (high correlation coefficients and statistical levels of significance) which at first sight permit the conclusion that a change of the substituents in the structure alters its hydrophobic, electronic, steric, and other properties, and hence the biological response elicited by the compound. According to Hansch's method, the last factor may be taken into account and expressed mathematically by the summation of the physicochemical properties of the substituted compounds. Approximately 50 relations, which have been used to predict the efficiency of the biological action of substances, are quoted in the literature [98,141–143]; the structure–activity correlatons are used much more widely to discover the mechanisms of the action of biologically active substances (see, for example, Refs. 8, 10–12, 18, 36, 95, 144, 145). The following causes responsible for a certain gap between theory and practice may be suggested.

1. The resultant biological activity of substances depends on their influence on many physiological processes occurring in the organism. The experimental limitation of the above method to any one type of biological activity, expressed in terms of the concentration of the substances giving rise to the given effect, is therefore too rough an approximation to reality to be used as a parameter. It appears that, only for a reliably established mechanism, for example, when the latter is determined by a particular enzyme, can the concentration of substances giving rise to a standard change in the concentration of the enzyme be used correctly to calculate $[A]$ in terms of the corresponding properties and characteristics of model interactions.

¶In Eqn. (36) $\lg P$ may be replaced by π.

Table 2. Principal methods for the determination of structure–activity correlations.

Method	Principle (hypothesis) underlying the method	Field of application	Disadvantages	Remarks
Mathematical additive model	The effectiveness of the biological activity of the chemical compound is determined by its structure and may be calculated as the sum of the contributions of the substituents in its molecule, the contribution of each substituent being independent of the presence of others (hypothesis of the additivity and independence of the contributions of substituents)	Prediction of the effectiveness of the biological activity in series of related compounds and hence reduction of the number of biological tests	Is inconsistent with the ideas concerning the influence of substituents on one another and hence on the physicochemical properties of the molecules of the given substance. The method is applicable only to series of compounds with the same type of biological activity	In order to improve it, the model may be (a) modified to take into account the mutual influence of substituents and (b) may be related to the multiparameter regression model. In both cases the model becomes considerably more complex
Substructural analysis	Arbitrary structural elements (fragments) are characterised by the frequency of their repetition in known biologically active compounds. The compound tested is analysed from the standpoint of the presence of such fragments. (Hypothesis—the biological activity of the substance is determined by the presence of particular structural elements.)	Non-experimental screening—prediction of the direction and effectiveness of the biological activity of substances. Determination of original structures	Has no physicochemical basis. The quantitative predictions of the effectiveness of biological activity are unreliable	In order to improve quantitative estimates, physicochemical characteristics of substances are introduced—this version of the procedure is referred to as the pattern recognition method
Multiparameter regression method	The set of parameters characterising model physicochemical processes occurring with participation of the given substance is correlated with its biological activity. (Hypothesis—the biological activity is determined by the structure and reactivity of the molecules of the given compound)	Prediction of the effectiveness of biological activity in series of related compounds without biological tests. The study of the mechanisms of biologically important chemical reactions	Is applicable to series of compounds. Does not allow the prediction of the direction of biological action. Conclusions concerning the effectiveness of substances are frequently erroneous	In order to reduce the number of parameters, one can use calculated or experimental quantum-chemical parameters—the quantum-statistical approach, the Cammarata method.
Factorial analysis	Relates the characteristics of the structure of the compound to the set of possible physiological results of its action. By sorting the possible variants, it established the ways in which the biological activity of substances arises and determines its effectiveness	Non-experimental screening—prediction of the direction and effectiveness of biological activity. Prediction of the uniqueness of the structure and form of activity and of side effects	Complexity. The scope of the method has not been adequately tested	Includes the multiparameter regression model as one of the factors

2. Apart from its evident advantages, the extensive application of mathematical statistical methods, which is characteristic of semiempirical approaches, to the structure-activity problem made the true pathways followed in the biological action of substances and reliable results statistically insignificant against the background of the enormous number of the results of biological tests obtained by different investigators. The low accuracy and reproducibility of biological experiments naturally have an effect under these conditions.

3. The use of regression methods to obtain correlation equations requires much greater caution than is frequently exercised in the literature. It is known that a number of independent variables can be correlated successfully using random terms if the latter are also independent. In reality, this situation means that our information about the mechanisms and the ways in which a particular type of biological activity is manifested is still insufficient to take into account the maximum number of parameters important for the manifestation of biological activity.

The above difficulties are fundamental and an attempt has been made only recently to eliminate some of them by means of factorial analysis[132]. Nevertheless there is at present no alternative to Hansch's method and its different versions in the formulation of quantitative structure–activity relations. This is mainly because the foundations of Hansch's method rest on the most general physicochemical principles, which probably serve as the basis of the mechanism of the action of biologically active compounds.

X. CONCLUSION

Summarising the foregoing review, it appears useful to put forward certain considerations applicable to the problem as a whole. The above methods for the determination of the types of functions relating quantitatively the characteristics of the structure of a substance and its biological activity are a natural consequence of the theoretical foundations of these methods and the types of interactions (in the set of all possible interactions) in the substance–biological object system which are taken into account.

It has been established reliably that the best correlation between biological activity in a series of substances and the partition coefficient ($\lg P$), the lipophilic constants of the substituent (π), and other characteristics associated with them is shown by substances exhibiting a non-specific type of biological action[†]. This implies that the chemical reaction which determines the outcome of the action of the substance occurs on the surface or within the cell membrane and that the site of the effective action of the compound is not localised. In practice such simple behaviour is probably rarely encountered.

[†] For example, it has been suggested[60] that a satisfactory correlation between $\lg P$ and π be used as a criterion for the estimation of the non-specificity of the biological action of the substance.

It is quite evident that the value of any structure–activity relation, not including the specificity characteristics as a factor of the manifestation of biological activity, is low. However, in the case of the specific binding of substances it is at present impossible to specify the number and types of parameters whose combination would be sufficient for an exhaustive and general solution of the problem of the determination of the structure–activity relation. This factor probably in fact explains the number of different parameters and their combinations (Table 1) which have been used to establish correlations and which are in essence difficult to extend further. It would appear that a satisfactory description of a theoretical relation in terms of experimental data should indicate that the model adopted reflects correctly the essential features of real processes and that the leading role among them is played precisely by those interactions which are taken into account in the corresponding correlation. Nevertheless, "astonishing freaks" in Hansch's words[146] (i.e. equations which are unrealistic in terms of their physical significance or ineffective in their predictive power but have high correlation coefficients), are discovered all too often when the results of empirical and semiempirical approaches are tested, which indicates most clearly certain significant miscalculations underlying the derivation of the corresponding equations. Whether this situation is a consequence of the impossibility of allowing completely for the entire set of different types of interactions between the substance and the organism and the lack of clear-cut principles whereby each specific situation can be reduced to a single equation of all the necessary parameters, or whether it is due to other less evident causes, is difficult to establish. Apart from the objective complexity of the problem, we believe that this is aggravated by the excessive employment of different versions of the approaches described above, frequently without adequate critical analysis of the results of biological tests used and the selected physicochemical parameters.

Future progress in the application of the procedures, outlined above, for the determination of quantitative structure–activity relations will probably be achieved by setting up a few fundamental experiments in combination with their profound theoretical elaboration and not by the excessive accumulation of new results. Furthermore, the main task—the parametrisation of biological activity, which cannot be regarded as finally completed in the form which exists at the present time—remains of primary importance.

In this connection it appears that real advances in the semiempirical approaches may be expected as a result of the narrowing of their fields of application, for example by restricting them to those cases where a definite type of biological activity may be characterised by the behaviour of molecular-biological, biochemical, and other models, and not by their limited extension to all types of biological activity *in vivo*.

o0o

The above review covers the literature up to 1975 inclusive. Among the papers published recently, mention should be made of the reviews on the mathematical additive model[286-287], the relations between this model and the multiparameter regression method (MRM),[287] the possibility of using the parachor in correlations between the chemical structures and biological activities of substances[288], a new "bilinear" model for a non-linear relation between the biological activities and hydrophobic properties of molecules[290], model equations for MRM for substances capable of ionising[291], a classification of therapeutic agents in conformity with pharmacophors for the pattern recognition method[292], the elucidation of the relative importance of steric parameters in relation to steroid hormones[293], and a compilation of tables of lipophilic parameters[294].

It has been suggested that new parameters be used in MRM: partition coefficients taking into account both the neutral and ionic forms of the given substance[295]; surface activity and the work of adsorption from the aqueous phase at the oil–water interface[296]; "hydrogen bonding" parameters[297]. Increasing attention is being attracted by different modifications of the capacity for molecular binding, which is readily susceptible to calculation whatever the complexity of the given compounds[298,299].

Bifunctional Catalysis

L.M.Litvinenko and N.M.Oleinik

The present state of the problem of bifunctional catalysis is considered and the influence of all possible factors (the structures of the reactants and catalysts, temperature, the properties of the medium, etc.) on the efficiency of bifunctional catalysts is discussed. The general characteristics of both the simplest bifunctional catalysts and enzymes are specified.
The bibliography includes 119 references.

I. INTRODUCTION

The concept of "polyfunctional catalysts" is nowadays fairly broad: substances of this kind may include both the simplest bifunctional compounds, such as acetic acid or 2-hydroxypyridine, and highly organised natural products such as enzymes. It is natural to suppose that all catalysts of this type have certain general properties, the determination of which for the simplest systems will make it possible to understand the characteristics of more complex systems. In other words, a low-molecular-weight bifunctional catalyst can be to a certain extent regarded as the simplest model of an enzyme, as has been frequently noted in the literature (see, for example, Refs. 1–4). There is no doubt that an increase in the complexity of the structure of a polyfunctional catalyst (for example, an increase of the number of groups involved in catalysis or an increase of the number of structural fragments in the skeleton to which the groups are attached) should lead to more or less significant changes in the mechanism of catalysis.

The problem of bifunctional catalysis by comparatively simple molecules is nowadays increasingly closely related to problems of polyfunctional catalysis by complex substances (polymeric catalysis, micellar catalysis, enzymatic catalysis). The ideas about bifunctional (and polyfunctional) catalysis are based on views developed by Lowry and Faulkner[5] as early as 1925 concerning the so called concerted catalysis, according to which two catalysts, acidic or basic, or in the general case electrophilic and nucleophilic, can act simultaneously on different parts of the reactants:

$$\mathrm{HY} + \mathrm{C{-}X} \xrightarrow{\mathrm{Nu+E}} \mathrm{Nu} \ldots \mathrm{HY} \ldots \mathrm{C{-}X} \ldots \mathrm{E} \rightarrow \mathrm{C{-}Y} + \mathrm{HX} + \mathrm{Nu} + \mathrm{E}, \quad (1)$$

where Nu and E are respectively the nucleophilic and electrophilic catalysts accelerating the displacement by the

HY molecule (a nucleophile) of the species X (a nucleophile) being eliminated from the electrophilic molecule C–X.

In 1938 Shilov[6] put forward the following idea about bifunctional catalysis. If two catalytic groups (Nu and E) form part of the same molecule and are located in a rigorously defined manner, then such a catalyst should be more effective than in the case where the two groups form part of different molecules. As we shall see below, this idea proved to be extremely fruitful. It was tested experimentally[7] in the catalysis of the mutarotation of tetramethylglucose (TMG) in benzene by 2-hydroxypyridine. It was found that the activity of 2-hydroxypyridine is much higher than that of a mixture of phenol and pyridine at the same concentration despite the fact that 2-hydroxypyridine is inferior to the monofunctional compounds as regards both acidic and basic strength. The high efficiency of such catalysis can be accounted for solely by its bifunctional nature and the formation of cyclic transition states† of type (I) (general scheme):

 (2)

$$\mathrm{H{-}Y} + \mathrm{C{-}X} \xrightarrow{\mathrm{Nu{-}Q{-}E}} \left[\begin{array}{l} \mathrm{H}\!\nmid\!\mathrm{Y}\cdots\mathrm{C}\!\nmid\!\mathrm{X} \\ \vdots \qquad\qquad \vdots \\ \mathrm{Nu{-}{-}Q{-}{-}E} \end{array}\right]^{\#}_{(\mathrm{I})} \longrightarrow \mathrm{C{-}Y} + \mathrm{H{-}X} + \mathrm{Nu{-}Q{-}E}, \qquad (2)$$

where Nu–Q–E is the bifunctional catalyst;

$$k_E + k_{Nu} \ll k_{Nu\text{-}Q\text{-}E}, \qquad (3)$$

where k are the corresponding rate constants, the subscript to which indicate the nature of a particular reaction. The involvement of cyclic transition states of this kind in the catalytic step should lower the energy barrier to the reaction (see Syrkin[8] and Section IV below) because electron transfer via the ring prevents a significant charge separation. The latter favours the reaction in a non-polar medium, which, as will be shown below, has also been confirmed experimentally.

Towards the end of the 1950s and particularly in the early 1960s, studies on bifunctional catalysis were expanded. The following examples of reactions for which the action of bifunctional catalysts has been investigated more or less systematically may be quoted: the mutarotation of monosaccharides[7,9–16], enolisation reactions and processes in which enolisation is the stage activating the reactants (condensation, halogenation, etc. reactions)[17–31], reactions involving nucleophilic substitution at aromatic[32–36] and carbonyl carbon atoms (see, for example, Litvinenko[37] and other references to work by the authors of the present review) and peptide synthesis[38–41].

We believe that, on the basis of the analysis of the studies carried out to date all bifunctional catalysts can be divided into three conventional classes differing in the nature of the action of the catalyst and the type of bond formed between the catalysts and the reactants in the course of the catalytic process.

II. TYPES OF BIFUNCTIONAL CATALYSTS

1. Tautomeric Bifunctional Catalysts

This term was introduced for the first time by Rony in 1969[11]. Catalysts of this type include all compounds which contain functional groups with opposed properties (nucleophilic and electrophilic) and which are involved in a tautomeric transformation of the catalyst:

 (4)

where Z is usually a carbon atom (but it can also be S, P, etc.), or a group of carbon atoms in a chain of conjugated bonds and forming part of the catalyst molecule, and A and B are usually O, S, or N. Such substances include carboxylic acids, their thio-analogues, sulphonic, sulphinic, phosphinic and other organophosphorus acids, derivatives of arsenic acid, 2-hydroxypyridine and analogous compounds, pyrazoles, etc. They are effective as catalysts when a proton has to be transferred during the reaction from one section of the reactant–substrate reaction complex to another, which promotes, overall, electron redistribution in the system and hence the reaction. The above catalysts have yet another characteristic feature—they are capable of forming hydrogen-bonded dimers (see, for example, data on the dimerisation of carboxylic acids[43], benzenesulphonic acid[43], 2-hydroxypyridine[44], and pyrazole[45]). The experimental facts show that substances incapable of such dimerisation usually do not exhibit bifunctional catalytic activity.

Catalytic activity is characteristic solely of the monomeric form of the catalyst. The formation of dimers blocks the functional centres of the catalyst and thus prevents the catalytic process, reducing the concentration of the active form of the catalyst[12,15,46,47]. The mechanism of the action of catalysts of this kind can be demonstrated in relation to the mutarotation of a monosaccharide or nucleophilic substitution at a carbonyl carbon atom:

 (5)

 (6)

Here R = aryl (Ar), alkyl (Alk), or R′CONHR″CH$_2$, X = halogen (Hal), RO, RS, RCO–O, etc., and Y–H = H$_2$O, ROH, RNH$_2$, ROCOCHR″NH$_2$, etc. In all cases bifunctional catalysts form associated species with the reactants via hydrogen bonding, which precede the cyclic transition states (II) or (III) and have structures similar to theirs. For example, the catalytic mutarotation of TMG can be represented as follows:

 (7)

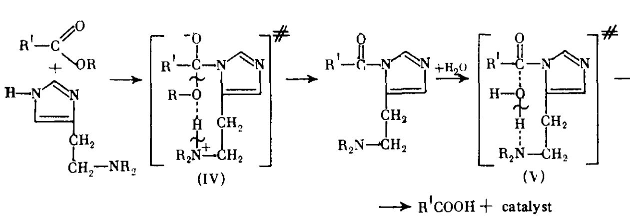
2. Covalent Bifunctional Catalysts

A characteristic feature of catalysts of this type is that, on interaction with the substrate, they form covalent bonds. Here we shall quote several examples of the hydrolysis of esters R′COOR and chloroalcohols as well as the elimination of 3-phosphoglyceraldehyde.

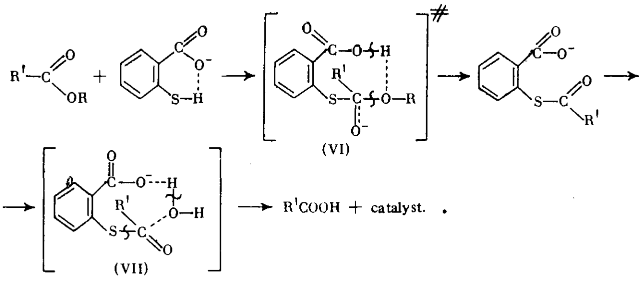
---

† For clarity, as in previous communications, the bond arising in transition states will be designated by dashed lines and the bond undergoing dissociation, by a crossed line.

The bifunctional mechanism of the catalysis of the hydrolysis of esters by *NN*-dialkylhistamine[48] [scheme (8)], incompletely ionised mercaptobenzoic acid[49] [scheme (9)] or catechol[50], etc. (see, for example Schatzle et al.,[51] Yakovlev and Rozengart[52], and Bender[1], pp.104–115) has been fully demonstrated:



(8)

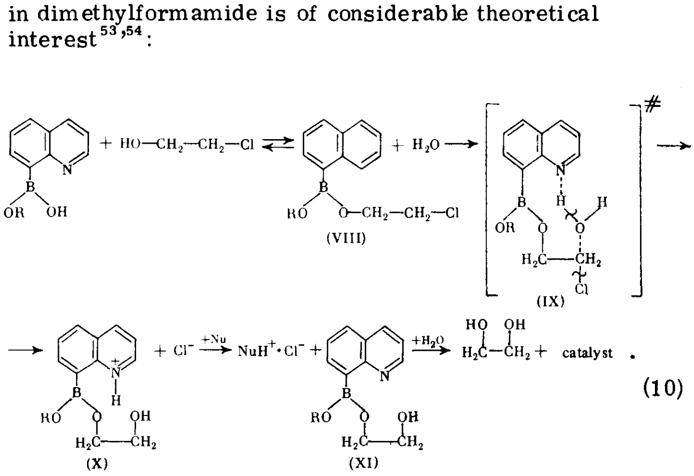


(9)

According to scheme (8) polyfunctional imidazole derivatives such as *NN*-dialkylhistamines, which are more active than imidazole itself by 1–1.5 orders of magnitude, initially add to the ester via their heteroaromatic ring, in such a way that the subsequent elimination of the outgoing group with the aid of the dialkylammonium centre in the side chain [transition state (IV)] is promoted; this results in the formation of an intermediate acylimidazole derivative. Since this amide does not differ greatly in its reactivity from that of the initial esters, it is natural to postulate catalysis by the dialkylamino-side group also in the subsequent hydrolytic stage [transition state (V)]. The anions of *o*-mercaptobenzoic acid [scheme (9)] and catechol behave similarly.

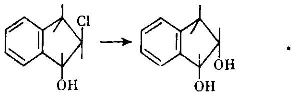
As regards the nature of their activity, the bifunctional catalysts considered resemble hydrolytic enzymes, which usually form covalently linked enzyme–substrate complexes with ester molecules.

The hydrolysis of chloroalcohols $Cl-(CH_2)_n-OH$ (where $n = 2$ or 3) in the presence of catalytic amounts of quinoline-8-boronic acid or its partial esters and collidine (Nu) in dimethylformamide is of considerable theoretical interest[53,54]:



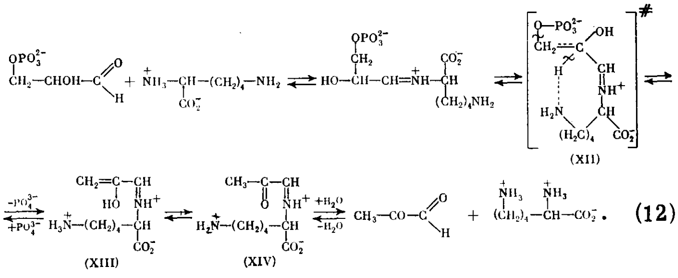
(10)

In this case quinoline-8-boronic acid accelerates the reaction approximately by an order of magnitude compared with the control experiment. It is of interest that quinoline-8-boronic acid exhibits a high stereospecificity in its activity, which may be demonstrated by the fact that, of the two possible stereoisomers of 2-chloro-1-indanol, only the *trans*-isomer undergoes catalytic hydrolysis. Under these conditions, the reaction proceeds with inversion of configuration, because only *cis*-1,2-indandiol is formed:



(11)

Certain elimination, enolisation, and isotope exchange reactions involving carbonyl compounds, catalysed by aminoacids and diamines, proceed with participation of covalently linked intermediates comprising the substrate and the catalyst. Thus lysine catalyses the conversion of 3-phosphoglyceraldehyde into pyruvic aldehyde[55] via the following mechanism:



(12)

According to scheme (12), a lysine molecule forms an immonium cation with the substrate via the 2-amino-group, which then decomposes with participation of the second amino-group via the cyclic transition complex (XII) and gives rise to the intermediate (XIII) and the latter hydrolyses and is converted into pyruvic aldehyde with regeneration of the catalyst.

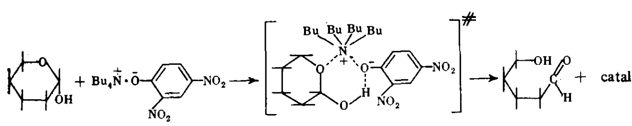
A similar mechanism of catalysis apparently obtains also in the exchange of deuterium in acetone-d_6 for hydrogen in an aqueous solution in the presence of diamines of the type $(CH_3)_2N-(CH_2)_n-NH_2$ (where n = 2, 3, 4, or 5) and polyethylene-imines[56], which are more effective approximately by an order of magnitude than the monoamines having similar pK_a values. As regards the nature of their action, the above diamine catalysts resemble the so called pyridoxal enzymes, in the presence of which pyridoxal phosphate forms with the substrate a Schiff base, which then undergoes various rearrangements (see, for example, Poltrak and Chukhrai[57] and Jencks[2], p.112).

Whereas tautomeric catalysts must contain two functional groups with opposite properties (nucleophilic and electrophilic), which undergo interconversions, this requirement is not obligatory for covalent catalysts. They therefore include substances containing functional groups of different types (nucleophilic and electrophilic—quinoline-8-boronic acid, monoanions of mercaptobenzoic acid and catechol, etc.) as well as groups of the same type (both nucleophilic—diamines and amino-acid anions).

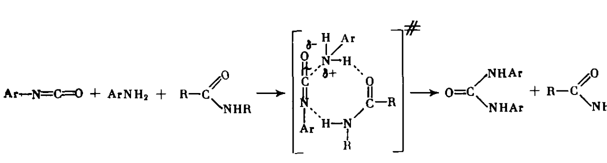
Yet another characteristic feature of covalent catalysts emerges from the foregoing considerations. Reactions with their participation must always involve intermediate stages with intramolecular catalytic action leading to the formation of cyclic transition states.

3. Bifunctional Solvation Catalysts

In a general form the mechanism of the action of solvation catalysts can be represented by scheme (2), but, in contrast to tautomeric catalysts, they are not directly involved in bond redistribution. Nor do these catalysts form covalent bonds with the reactants. Solvation catalysts activate via cyclic transitions states of type (I) certain sections of the reactants, either as a result of the formation of hydrogen bonds or as a result of electrostatic, dispersion, and other forces. Consequently, the nature of the forces in the interaction of a bifunctional solvation catalyst with reactants is the same as in specific and nonspecific solvation. As an example of catalytic reactions of this type, one may quote the catalysis by ion pairs formed from 2,4-dinitrophenoxide and tetra-alkylammonium of the mutarotation of TMG in benzene[16] [scheme (13)], the catalysis by amides of the reactions of phenyl isocyanate with amines[58] [scheme (14)], and the analogous reactions of ketens with alcohols[59]:



(13)



(14)

It follows from experimental data[58,59] that the above catalysts are less effective in reactions (13) and (14) by approximately 1–2 orders of magnitude than tautomeric catalysts such as carboxylic acids.

The acceleration of the solvolysis of t-butyl bromide[60] and the decarboxylation of malonic acid[61] by dihydric phenols and alcohols, which are appreciably more effective than the corresponding monofunctional analogues, may be apparently also regarded as solvation catalysis.

III. QUANTITATIVE FEATURES OF REACTION KINETICS

Analysis of all the available results shows that, among the three classes of catalysts discussed above, bifunctional tautomeric catalysts exhibit the greatest efficiency, because they promote bond redistribution as a result of the simultaneous transfer of two protons via the cyclic system without any appreciable charge separation. Since catalysts of this class have been most thoroughly investigated, we shall consider further the main characteristics of the action of tautomeric catalysts. The data quoted below will probably prove useful also in understanding the properties of other classes of polyfunctional catalysts.

1. The Influence of the Structure of Bifunctional Tautomeric Catalysts on Their Activity

The influence of the structure of bifunctional catalysts on their activity has been most thoroughly studied in relation to the acylation of arylamines by carboxylic acid halides and anhydrides[62–68], the aminolysis of esters[11,69], peptide formation[39,40,70], and the mutarotation of tetramethylglucose[7,9,10–13,15] in non-polar aprotic media. In the above studies the catalytic rate constants k_m were determined quantitatively on the basis of the following general relation between the observed rate constant k_{obs} and the analytical catalyst concentration m:

$$k_{\text{нб}} = k_0 + k_m m\alpha, \tag{15}$$

where k_0 is the non-catalytic rate constant, α the degree of dissociation of the catalyst dimers into monomers, and $m\alpha$ the concentration of the monomeric form of the catalyst. Eqn. (15) reflects quantitatively the fact, noted above, that only the monomeric form of the catalyst exhibits catalytic activity‡.

Table 1. The efficiencies of certain monofunctional and bifunctional catalysts in acylation and peptide formation* reactions (in benzene at 25°C).

No.	Catalyst	k_m, (1), litre^2 mole^{-2} s^{-1}	k_m/k_0, (1), litre mole^{-1}	k_m, (2), litre^2 mole^{-2} s^{-1}	k_m/k_0, (2), litre mole^{-1}

*** Reaction in chlorobenzene.

The bifunctional nature of the catalysis in the above instances has been demonstrated in relation to a large number of examples. Swain's evidence[7] in support of the bifunctional activity of 2-hydroxypyridine in mutarotation has already been mentioned. Table 1 presents data indicating the occurrence of bifunctional catalysis by carboxylic acids, 2-hydroxypyridine, and its derivatives in the peptide formation reaction and in the acylation of amines by an acid halide in benzene§. Thus 2-hydroxypyridine and its 5-bromo-derivative (Table 1, Nos. 2 and 3) are powerful catalysts both in the peptide formation reaction and in the

---

‡ In certain cases (mutarotation of TMG[10,12], acylation of strong amines[63], and peptide formation[39,40]) a correction must be introduced into Eqn. (15) for the formation of inactive associated species comprising the catalyst and the reactants (see also below).

§ Here and henceforth the catalytic activity of a particular catalyst is estimated as the ratio k_m/k_0. This quantity is extremely convenient for comparing the efficiencies of organic catalysts, exhibiting their activity in a wide variety of reactions under a wide variety of conditions.

acylation of arylamines by benzoyl fluoride, while 3-hydroxypyridine (Table 1, No. 8) and other monofunctional substances, containing only one acid or basic group, exhibit no activity (Table 1, Nos. 4–7). Acetic acid (Table 1, No. 1) exhibits a very high activity, while 3,4-dinitrophenol, which has a comparable acid strength (Table 1, No. 7, a monofunctional acid), as well as a base such as pyridine (Table 1, No. 6) show no catalytic activity whatever in the instance under consideration.

The data in Table 2 indicate the bifunctional nature of the catalysis by pyrazole in peptide formation. Indeed both phenol and *N*-methylpyrazole hardly catalyse the above reaction, while pyrazole itself is fairly effective. It is of interest that a pair of compounds such as imidazole and its *N*-methyl derivative exhibit low and approximately the same catalytic activities. Taking this factor into account as well as the fact that the disposition of the functional centres in imidazole is unfavourable for bifunctional catalysis and the considerable basicity of the latter pair of compounds (Table 2), we suggest that the usual base catalysis operates in this instance.

Table 2. The efficiencies of pyrazole, imidazole, and certain monofunctional compounds in the reaction of Z-gly-ONP (ONP = –O–  –NO_2) with t-BEG (in benzene at 25° C; $k_0 = 5.7 \times 10^{-4}$ litre $mole^{-1}$ s^{-1} [74]).

Catalyst	k_m, $litre^2$ $mole^{-2}$ s^{-1}	k_m/k_0, litre $mole^{-1}$	pK_a[77] (Ref.77)
Pyrazole (Ref.75)	1.74	3000	2.47
N-Methylpyrazole (Ref.75)	0.01	17	2.04
Phenol (Ref.85)	0	0	
Imidazole (Ref.76)	<0.49	<850	6.95
N-Methylimidazole (Ref.76)	0.49	850	7.33

The bifunctional mechanism of the catalysis by carboxylic acid and 2-hydroxypyridine derivatives is described by the general scheme (6). The mechanism of the catalysis by pyrazole can be represented by an analogous scheme[75].

Table 3 as well as other data (see, for example, Rony[11,12]) show that, among all the bifunctional catalysts investigated in a wide variety of different types of reaction, the highest catalytic activity is shown by carboxylic acids, phosphinic acids, and 2-hydroxypyridine.

An attempt was made[12] to investigate the catalytic activity of strong bifunctional acids such as benzenearsenic, benzenesulphonic, benzenesulphinic, etc. acids, in the mutarotation of TMG in non-polar media. Owing to experimental difficulties, it was not possible to calculate the values of k_m for the above substances. However, qualitative comparisons with other bifunctional catalysts showed that the strong acids have efficiencies comparable to those of phosphinic acids of the type R_2POOH, where R may be alkyl, aryl, and aryloxy-groups.

Depending on the nature of the reaction investigated, the relative activities of phosphinic acids, carboxylic acids, and 2-hydroxypyridine may vary. Thus carboxylic acids are most active in peptide formation, being followed in this respect by 2-hydroxypyridine and phosphinic acids (Table 3). In the mutarotation of TMG and in the acylation of arylamines by acetic anhydride phosphinic acids are the most effective and are followed in this respect by carboxylic acids and then 2-hydroxypyridine (Table 3, Nos. 1–8). The change in the order of the catalytic activities of bifunctional catalysts as a function of the nature of the model reaction may have a number of causes. We shall consider one of these.

Table 3. The efficiencies of bifunctional tautomeric catalysts (k_m/k_0, litre $mole^{-1}$) in various reactions in benzene and chlorobenzene at 25° C.

*Reactions: (1) mutarotation of TMG[12], $k_0 = 0.65 \times 10^{-5}$; (2) $C_6H_5COCl + m\text{-}ClC_6H_4NH_2$, $k_0 = 3.3 \times 10^{-3}$; (3) $(CH_3CO)_2O + m\text{-}ClC_6H_4NH_2$, $k_0 = 7.6 \times 10^{-4}$; (4) Z-gly–ONP + t-BEG, $k_0 = 5.7 \times 10^{-4}$; (5) Z-gly–OPAP + t-BEG, $k_0 = 2.0 \times 10^{-4}$ litre $mole^{-1}$ s^{-1}; reactions (1)–(4) were carried out in benzene and reaction (5) in chlorobenzene.
**Values taken from Kergomard and Renard[15], where, in contrast to Rony and Neff[12], no account was taken of the association of the catalyst with TMG, which decreases k_{obs}.

When arylamines are acylated by acid anhydrides and chlorides, bifunctional catalysts more acidic than acetic and benzoic acids (for example trichloroacetic acid) exhibit, together with the catalytic effect observed at low catalyst concentrations, also an inhibitory activity[63] as the catalyst concentration rises (see Fig. 1). This can be accounted for by the interaction of the catalyst with the amine, leading to the formation of an unreactive salt:

$$R{-}COOH + R{-}NH_2 \rightleftarrows RCOO^- \cdot \overset{+}{N}H_3R\ (XVII). \qquad (16)$$

Salt formation interferes with catalysis even more in the aminolysis of esters by aliphatic amines[81] and in peptide formation reactions[39,40]. In these reactions even acetic acid, which in this instance exhibits the highest activity, is catalytically active only at low concentrations (up to 0.01 M). At higher concentrations inhibition takes place. It is extremely likely that this is the reason as already mentioned, why the stronger phosphinic acids exhibit a much smaller catalytic effect in the peptide formation reaction than carboxylic acids and 2-hydroxypyridine.

The high catalytic activity of tautomeric catalysts has also been confirmed by the quantum-chemical calculations carried out by Gold[13] using the Hückel method: in the calculations account was taken of the fact that during the catalytic step, a π-electron distribution, analogous to that demonstrated in scheme (5), takes place in the catalyst. The interaction indices ξ calculated for these conditions constitute a linear combination of general perturbations in the functional groups of the catalyst during the formation of the cyclic transition state (II) and characterise the energy gain as a result of such electron distribution. The values of ξ for a number of catalysts are presented in Table 4. The indices reflect the capacity of the bifunctional catalyst for a tautomeric transformation in the course of the catalytic reaction. It follows from the data in Table 4 that there is a linear correlation between the values of $\lg k_{\text{obs}}$ (calculated for constant TMG and catalyst concentrations) and the interaction index ξ.[13] This suggests that the following linear relation should exist in its turn, other conditions being equal, between the catalytic activity of a bifunctional catalyst and the rate of conversion of its tautomeric form involved in the catalytic step into another form (the relation follows from the principle of the linear relation between the free energy changes):

$$\lg k_m = a + b \lg k_{\text{taut}}, \tag{17}$$

where k_{taut} is the rate constant for the tautomeric transformation. In this theoretical treatment the simplest case is one where both tautomeric forms are identical (carboxylic, phosphinic, sulphonic, etc. acids, pyrazole). Under these conditions, the catalyst is immediately regenerated in the course of the catalytic step. The constant k_{taut} is in this instant in essence the rate constant for proton exchange involving the catalyst dimers. The rate of the process can then increase only up to a limiting value determined by the rate of diffusion of the species in solution. Under these conditions, the catalytic activity of the bifunctional catalyst evidently also reaches the maximum possible value for a simple functional structure. Catalysis by diphenyl phosphate (Table 3, No. 8), which accelerates the mutarotation of TMG in benzene by approximately nine orders of magnitude, apparently approaches this limiting case. Such activity is comparable to that of enzymes (the lower limit of the acceleration of the reaction by the latter is by 9–11 orders of magnitude; see Jencks[2], p. 23).

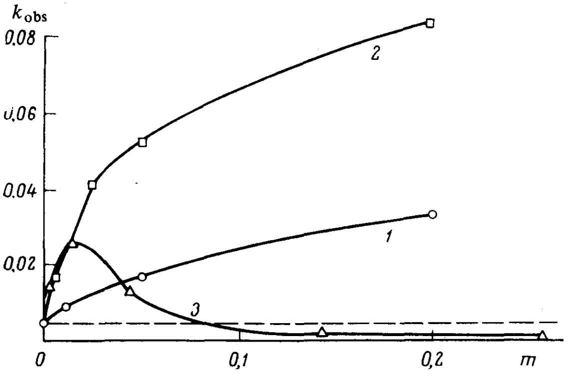

Figure 1. Dependence of the observed rate constant for the benzoylation of *m*-chloroaniline by benzoyl chloride on the analytical concentration (*m*) of carboxylic acids in benzene[63] at 25°C: 1) acetic acid; 2) monochloroacetic acid; 3) trichloroacetic acid.

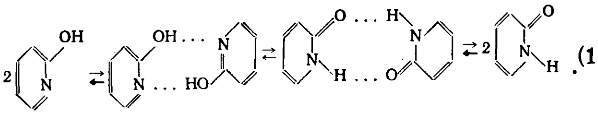
The situation is more complex for bifunctional catalysts whose tautomeric forms are structurally non-equivalent. An example is provided by 2-hydroxypyridine, the two tautomeric forms of which are different and the equilibrium between them is determined by the solvent[82]:



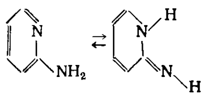
(18)

In conformity with the above considerations, the form which is more readily converted into the other tautomer, i.e. the less stable form present at a lower equilibrium concentration, should exhibit a higher catalytic activity. Or, what amounts to the same thing, the more stable form should exhibit a low catalytic activity. This conclusion is entirely logical and is indirectly confirmed by the examples quoted below.

Table 4. Comparison of experimental data for the catalytic activities of bifunctional catalysts in the mutarotation of TMG in benzene with the interaction indices ξ.[13]

Catalyst	k_{obs}, s^{-1}	ξ
Benzoic acid	0,0636	0.206
2-Hydroxypyridine	0.0163	0.0806
2-Hydroxy-4-methylquinoline	0.00638	0,0789
2-Aminopyridine	0.002	0,0230
Picric acid	0.00076	0

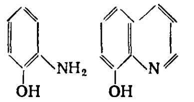
Substances for which tautomeric transformations are relatively unlikely show a lower catalytic activity or are altogether inactive. Thus 2-aminopyridine (Tables 3 and 4), which exists in the stable amino-form[83] (XVIII) whose conversion into the imino-form (XIX) via reaction (19) hardly occurs, behaves as a relatively ineffective catalyst in the mutarotation of TMG:



(XVIII) (XIX)

(19)

As already mentioned, 2-hydroxypyridine is an active catalyst of the peptide formation reaction and 2-aminophenol (XX)[11] and 8-hydroxyquinoline (XXI) (Table 3), which are incapable of undergoing a tautomeric transformation, are catalytically altogether ineffective:



(XX) (XXI)

Evidently carboxylic acid amides, for which form (XXIII) is thermodynamically unfavourable[84] and is not detected in a free state, do not exhibit bifunctional catalytic activity for the same reasons:

(XXII) (XXIII)

$$\mathrm{R{-}C}\genfrac{}{}{0pt}{}{\nearrow \mathrm{O}}{\searrow \mathrm{NH_2}} \;\rightleftarrows\; \mathrm{R{-}C}\genfrac{}{}{0pt}{}{\nearrow \mathrm{OH}}{\searrow \mathrm{NH}} \tag{20}$$

The absence of bifunctional activity in amides containing a hydrogen atom attached to the nitrogen atom has been frequently demonstrated[37,85] in relation to the acylation of arylamines by carboxylic acid halides and certain other related reactions.

Thus the bifunctional catalysis by the same amides in reactions involving phenyl isocyanates[58] and ketens[59] (see also the above discussion of solvation catalysts) must be assumed to have a solvation and not a tautomeric mechanism.

2. The Dependence of the Activities of Bifunctional Catalysts on Their Ability to Form Hydrogen Bonds

Yet another necessary condition for the manifestation of bifunctional catalytic activity is a distinct ability of the catalyst to form hydrogen bonds. This can be demonstrated in relation to catalysis by acetic acid and its thio-analogues of the acylation of arylamines by acetic anhydride and benzoyl chloride in benzene, and also in the mutarotation of TMG (Table 5). In the above experiments the structure of the reactant remained unchanged and only the nature of the catalyst was varied in such a way that it acquired different capacities for the formation of hydrogen bonds. Indeed, the catalytic activity of the acid fell sharply as the oxygen atoms were replaced by sulphur, although its strength increased significantly at the same time.

Table 5. The values of k_m (litre^2 mole^{-2} s^{-1}) and k_m/k_0 (litre mole^{-1}) for the reactions of benzoyl chloride and acetic anhydride with *m*-chloroaniline catalysed by acetic acid and its thio-analogues[80] and for the mutarotation of TMG[15] (in benzene at 25°C).

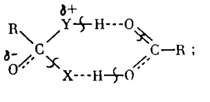
Catalyst	$C_6H_5COCl+ArNH_2$		$(CH_3CO)_2O+ArNH_2$		Mutarotation of TMG	
	k_m	k_m/k_0	k_m	k_m/k_0	k_m	k_m/k_0
CH_3—CO—OH	1.01	300	6.98	6200	0.26	40 000
CH_3—CO—SH	0.03	9	—	—	0.007	1 100
C_6H_5—CO—SH	0.03	9	0.47	400	—	—
CH_3—CS—SH	0	0	0	0	—	—

The main cause (although evidently not the only one) of the decrease of the efficiency of catalysis in the above series of catalysts is the reduced ability of the SH group to form hydrogen bonds[86,87], which hinders the combination of the participants in the catalytic step into cyclic transition states of type (II) or (III). Indeed, on passing from carboxylic acids to their thio-analogues, the capacity for association diminishes sharply. For example, thioacetic and thiobenzoic acids, which are relatively ineffective in catalysis, are not associated even in the liquid state[88]. However, dithioacetic acid, which exhibits no activity, is in fact capable of association (being significantly inferior in this respect to carboxylic acids), since it exists partly in the dimeric form in the liquid state; infrared spectra also indicate the presence of comparatively strong hydrogen bonds in this acid[88]. Thus the above catalysts can be arranged in the following sequences in terms of their catalytic activities and abilities to form hydrogen bonds:

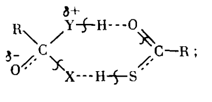
R—COOH ≫ R—COSH > R—CSSH (catalytic activity);

R—COOH ≫ R—CSSH > R—COSH (ability to form hydrogen bonds).

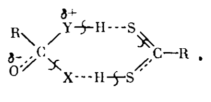
The lack of a parallel variation of these two properties can apparently be explained by the fact that the formation of a hydrogen bond is a necessary but not sufficient condition for the manifestation of catalytic activity, because, as stated in the previous section, the ability of the catalyst to undergo a tautomeric transformation or, what amounts to the same thing, to transfer a proton via hydrogen bonds in the cyclic transition state, is more important. The rate of proton transfer is known to decrease in the following sequence: OH ... O > OH ... N > SH ... O > SH ... N > SH ... S.[89-91]. In catalysis by acetic acid rapid proton transfer may be ensured by both hydrogen bonds [see, for example, compound (XXIV)]; in the analogous reaction involving thioacetic acid [transition state (XXV)], only one of the two bonds effects proton transfer (the overall transfer is retarded), while in the presence of dithioacetic acid [transition state (XXVI)] there is no hydrogen bond of this kind, although, as already mentioned, each separately can in principle be somewhat stronger than the bond involving the SH group of thioacetic acid.



(XXIV)



(XXV)



(XXVI)

The important role of the hydrogen bond in bifunctional tautomeric catalysis has also been confirmed by theoretical calculations[14] (within the framework of the LCAO-MO SCF method in terms of the CNDO/2 valence approximation), carried out for the mutarotation of glucose catalysed by 2-hydroxypyridine. The calculations showed that the two hydrogen bonds in the cyclic glucose–2-hydroxypyridine complex are stronger than the two isolated bonds and initiate the rearrangement of the electron cloud of the substrate and catalyst during the catalytic step.

Thus the hydrogen bond is the factor which ensures the optimum mutual approach and relative arrangement of the bifunctional catalyst and the reactant, i.e. one may assume that in tautomeric bifunctional catalysis the catalytic reaction must be always preceded by the preliminary formation of cyclic associated species via hydrogen bonding between the reactants and the catalyst. The existence of such species is very difficult to demonstrate experimentally because, by their very nature, they must be naturally extremely unstable. However, their existence is indicated by the formation during the reactions of stable associated species stimulated by the bifunctional catalyst: the cyclic dimers of bifunctional catalysts[10,15,46,47] and associated species formed from the catalyst and one of the reactants. The presence of the latter has been noted, for example, in the catalytic acylation of amines[63], peptide formation[39,40], or the mutarotation of TMG[10]. Such associated species decrease the concentration of the active form of the catalyst and of the reactants, which is manifested by kinetic factors (see, for example, Refs. 10, 15, 39, 40, 46, 47, and 63).

3. The Influence of Substituents in Bifunctional Tautomeric Catalysts on Their Activity

In many instances the influence of substituents in bifunctional catalysts (carboxylic and phosphinic acids and substituted derivatives of 2-hydroxypyridine, see Table 6) has been estimated by correlation analysis. The Taft or Hammett equation was used:

$$\lg k_m = \lg k_{m(\text{ст})} + \rho^*\sigma^* \text{ (or } \rho\sigma). \tag{21}$$

It follows from the data in Table 6 that the introduction of electron-accepting substituents, which tend to increase the acid strength of the electrophilic part of the catalyst molecule and at the same time diminish the basic properties of the nucleophilic component, leads to increased activity of the catalyst in the vast majority of reactions investigated (with the exception of catalysis by carboxylic acids in dioxan and by phosphinic acids in benzene for reaction No. 9 in Table 6). The positive sign of $\rho^*(\rho)$ shows that the acid function of the catalyst plays the main role in the catalytic action.

Table 6. The values of $\rho^*(\rho)$ characterising the influence of substituents in a bifunctional catalyst on its catalytic activity* (values calculated from literature data are indicated in brackets; the solvents are indicated by capital letters, also in brackets, next to the numerals: B = benzene; N = nitrobenzene; C = chlorobenzene; D = dioxan).

*The values of ρ are approximate, because it is not known which value should be adopted for substituents in the 5-position: σ_m or σ_p.

**R = H.

***R = $C_6H_5CH_2$–.

The low absolute values of ρ^* (ρ), sometimes approaching zero, usually constitute an additional confirmation of the bifunctional nature of the catalysis, because the increase of the strength of the acid function in the catalyst molecule should stabilise the cyclic structure of the transition state and the weakening of the nucleophilic function should play a destabilising role to approximately the same extent.

The compensation effect is manifested particularly clearly in catalysis by carboxylic and phosphinic acid in the aminolysis of esters and in peptide formation (see reactions Nos. 7 and 9, Table 6). The low value of ρ^* in the above instances can be accounted for by the fact that acylating agents with outgoing groups which are difficult to eliminate take part in these reactions (ArO is split off with greater difficulty than Cl, RCO–O, etc.[92]); in the elimination of these groups the abstraction of a proton from the attacking amine assumes great importance[93] and the role of the basic function of the bifunctional catalyst increases. The latter leads to more complete compensation of the effect of the acid and basic functions. The suggested enhancement of the role of proton abstraction from the attacking amine in the rate-determining stage with decrease in the tendency of the outgoing group to be eliminated is supported by the increased efficiency of base catalysis on passing from reactions involving acid anhydrides and halides, where there is no base catalysis[94], to the aminolysis of esters where the catalytic process involving a base-catalytic mechanism predominates over the non-catalytic process[93]. The role of the basic catalyst in the latter reactions reduces to the elimination of a proton from the attacking amine.

The negative values of ρ^* in the catalysis of the peptide formation reaction by carboxylic acids in dioxan and by phosphinic acids in benzene (Table 6, No. 9) may indicate that in this instance the basic function of the bifunctional catalyst predominates over the acid function in the catalytic step.

4. The Influence of the Nature of the Reactants on the Activity of Bifunctional Catalysts

It follows from the data in Table 3 that a change in the structure of the reactants has a very significant influence on the catalytic activity of bifunctional catalysts. We shall consider a few more examples. Suppose that the outgoing group X in the acylating agent consists of various halogen atoms (ranging from F to I), the nature of which determines to a significant extent the strength of the hydrogen bonds involving them. It follows from the data in Table 7 that in the case of the fluoro-derivative, which exhibits a particularly striking ability to form a hydrogen bond, acetic acid has an exceptionally high catalytic activity (see the values of k_m/k_0), which falls sharply on passing to reactions involving the remaining acid halides. It has been shown[96] that under these conditions there is a linear correlation between the activity of the catalyst and the capacity of the outgoing group (the halogen) for the formation of a hydrogen bond. The increase of the ability of the halogen to form a hydrogen bond facilitates, as already mentioned, the formation of cyclic transition states of type III and hence promotes the catalytic processes.

The high activity of acetic acid in the reaction involving anhydrides (Table 7) can also be explained by the fact that the anhydride oxygen atom is able to form strong hydrogen bonds.

Table 8 shows that the catalytic activity of acetic acid increases on passing from the reaction of *p*-nitrophenyl thioacetate with benzylamine to the corresponding reaction of *p*-nitrophenyl acetate, which is also consistent with all the foregoing considerations. In this connection one should also mention that in the series of thioesters the catalytic activity of acetic acid increases with enhancement of the electrondonating properties of the outgoing thiophenoxide group ArS. In the latter case the cyclic transition complex is formed via ring closure involving a hydrogen bond of the type $>$S...H–O–. This type of hydrogen bond can be fairly stable[97], while the opposite type $>$O...H–S is always very weak. This is why carboxylic acids catalyse the aminolysis of thioesters, while thiocarboxylic acids are almost ineffective in the reactions of acid anhydrides and halides.

Thus the experimental study of the influence of the structure of the reactants on the catalytic activity of the same bifunctional catalyst has confirmed the great importance of the formation of strong hydrogen bonds in cyclic transition states.

Table 7. Catalytic activity of acetic acid in the aminolysis of carboxylic acid halides[95] and anhydrides[78] (in benzene at 25° C).

Reaction	k_0, litre mole^{-1} s^{-1}	k_m, litre^2 mole^{-2} s^{-1}	k_m/k_0, litre mole^{-1}

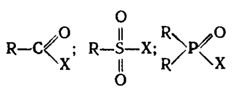
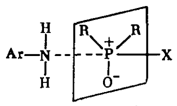
H	0.15	6.5	4 000 000
	$CH_3—CO—O—C_6H_4R$		
2.4-$(NO_2)_2$	59 000	0	0
p-NO_2	29	25	800 000

From the standpoint of the influence of the structure of the reactant on the catalytic activity, the problem of the efficiency of the same bifunctional catalyst (for example, a carboxylic acid) in the aminolysis of acylating agents differing in the nature of the electrophilic centre is of interest. Comparison of data for catalytic nucleophilic substitution reactions at unsaturated carbon, sulphur, and phosphorus atoms in the compounds



showed that bifunctional catalysis by the acids RCOOH is clearly manifested only in the first instance[98]. This finding can be accounted for by the fact that the reaction involving substitution at a carbonyl carbon atom proceeds via the formation of transition states or intermediates [see scheme (6)] in which the constituent fragment of the bifunctional catalyst is complementary to the fragment formed from the reactants. Thus in the stereochemical sense a catalytic reaction involving substitution at the carbonyl carbon atom is entirely feasible. On the other hand reactions in which substitution is carried out at sulphur and phosphorus atoms proceed via transition states (intermediates) with the bipyramidal structure (XXVII):



(XXVII)

where the nucleophilic and electrophilic centres, which might be attacked by the bifunctional catalyst, are in the axial positions, i.e. are separated to the maximum possible extent. Cyclic transition complexes in the above two instances cannot therefore be achieved for stereochemical reasons.

The above examples show yet again how important is not only the nature of the functional centres in bifunctional catalysts and reactants but also their favourable disposition, necessary for the formation of a cyclic transition complex.

Table 9. The influence of substituents in the acylating agent and the primary arylamine on the catalytic activity of acetic acid characterised by k_m/k_0 (litre mole^{-1}) (in benzene at 25° C).

R	Reaction			
	C_6H_5COCl+ $+R—C_6H_4NH_2$[99]	$(CH_3CO)_2O+$ $+R—C_6H_4NH_2$[78]	$(CH_3CO)_2S+$ $+R—C_6H_4NH_2$[100]	*m*-$Cl—C_6H_4—$ $—NH_2+R—$ $—C_6—H_4COCl$[101]
m-CH_3O	—	—	—	215
H	193	23 000	16 000	306
p-Cl	273	—	—	—
m-Cl	300	12 000	13 000	—
m-NO_2	—	6 700	15 000	487
p-NO_2	285	—	—	476

The influence of substituents in both reactants (Table 9) on the catalytic activity of acetic acid in aminolysis has been investigated in a number of studies. It has been found that substituents in the *m*- and *p*-positions, both in the acylated amine and in the acylating agent, have only a slight influence on the catalytic activity of the bifunctional catalyst. However, if the substituent is directly at the reaction centre, as, for example, in *N*-alkyl-*m*-nitroaniline, then its effect is manifested to a much greater extent. Data concerning the influence of *N*-alkyl substituents in *m*-$NO_2-C_6H_4-NHR$ on the catalytic activity of acetic acid in the reaction involving acetic anhydride in benzene at 25° C[102] are presented below:

R	10^3k_m, litre^2 mole^{-2} s^{-1}	k_m/k_0, litre mole^{-1}
H	850	6500
CH_3	28	540
C_2H_5	11	240
iso-C_3H_7	0.058	87

The data presented show that a gradual increase in the bulk of the substituent leads to a significant decrease of catalytic activity owing to the steric effect, while the role of the inductive effect is hardly significant under these conditions (cf. also in the data in Table 9). Consequently, N-alkyl groups in an aliphaticaromatic amine create steric hindrance to the formation of cyclic transition states, which reduces the activity of the bifunctional tautomeric catalyst.

5. The Influence of the Medium on the Activity of Bifunctional Catalysts

The problem of the influence of the medium on the activity of bifunctional catalysts has been investigated in many instances in relation to the reactions considered in this review. Analysis of the available results shows that, with increase of the polarity of a non-specific solvent, the reaction rate constants decrease in bifunctional catalysis. The quantitative dependence of the rates of catalytic reactions on the polar properties of the solvent is illustrated in Fig. 2, where the values of $\lg k_m$ are compared with the Kirkwood function. Line I refers to reactions involving the formation of a simple amide linkage in catalysis by acetic acid[78] and line II characterises the formation of a peptide bond catalysed by 2-hydroxypyridine[70]. The observed negative influence of the polarity of the medium agrees with the bifunctional mechanism of the catalysis. Indeed, as already mentioned, the small separation of the charges in the cyclic transition state of type III makes the polarity of the latter lower than that of the initial reactants. For this reason, polar solvents stabilise the initial state and hinder the formation of cyclic transition complexes, which reduces the rate.

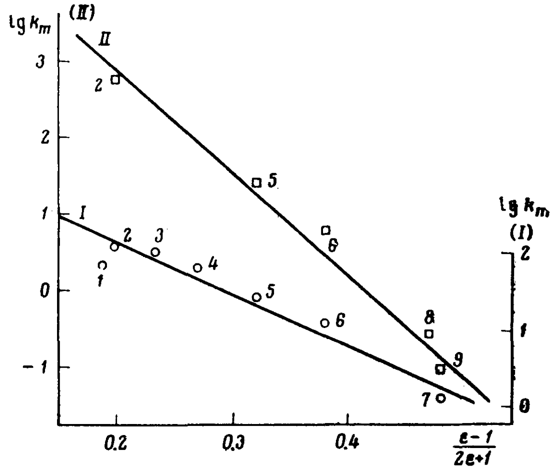


Figure 2. Dependence of $\lg k_m$ on $(\epsilon - 1)/(2\epsilon + 1)$ for the reaction of acetic anhydride with *m*-chloroaniline catalysed by acetic acid[78] (I) and for the reaction of the *p*-phenylazophenyl ester of *N*-benzyloxycarbonylglycine with *t*-butyl glycinate catalysed by 2-hydroxypyridine[70] (II) at 25° C; solvent: 1) hexane; 2) cyclohexane; 3)–5) cyclohexane–chlorobenzene mixtures with mole fractions of the latter of 0.106, 0.260, and 0.515 respectively; 6) chlorobenzene; 7) nitrobenzene; 8) benzonitrile; 9) acetonitrile. The values of $\lg k_m$ are plotted on the left-hand and right-hand ordinate axes for II and I respectively.

The results of a study of the catalytic activity of carboxylic acids in the reaction of 2,4-dinitrophenyl acetate with aniline in benzene and dioxan[69] at 25° C are presented below:

Catalyst	k_m/k_0, litre mole^{-1}	
	benzene	dioxan
$(CH_3)_3C—COOH$	11 000	5
$CH_3—COOH$	11 000	6
$ClCH_2—COOH$	19 000	10

The data presented (see also Rony[12]) show that the replacement of a non-specific solvent by a specific one (such as dioxan or alcohol¶), capable of forming strong hydrogen bonds with the reactants and the catalyst, also leads to a sharp decrease of catalytic activity because solvation by a specific solvent of the participants in the catalytic process and primarily of the catalyst itself, hinders the formation of cyclic transition states. Consequently the enhancement of the solvating capacity of the solvent (both specific and non-specific) leads to a decreased efficiency of bifunctional catalysis. Hence follows a conclusion which is important in practice: bifunctional catalysts are most effective in non-polar and weakly solvating media.

On the basis of the foregoing considerations, it is natural to expect that in water, which is a highly polar and specific solvent, bifunctional catalysis would be very difficult. For this reason, 2-hydroxypyridine behaves in aqueous solutions as an ordinary general basic catalyst, whose catalytic constant for the mutarotation of TMG falls on the usual Brønsted plot for basic substances with a slope $\beta = 0.37$.[12] Consequently the advantage of 2-hydroxypyridine as a bifunctional catalyst fully disappears in an aqueous medium. However, many reactions occurring in water are known in which bifunctional catalysis is nevertheless postulated. The carbonyl group is involved in one way or another in the above reactions; carboxylic acids, hydrogen phosphate anions, and dihydrogen phosphate anions may be used as bifunctional catalysts (in the hydrolysis of iminolactones[103], the addition of hydrogen peroxide to aldehydes[104], the hydration of aldehydes[105] and carbon dioxide[106], the hydrolysis of 1,3-diphenyl-2-imidazolium chloride[107], amides[108], acetimidate esters[109], etc.). One should note that the efficiency of bifunctional catalysts in water may be considerable[109].

Table 6 shows that, on passing from a non-polar solvent to a polar or specific solvent, the quantity ρ^*, characterising the sensitivity of the catalytic activity of the catalyst to the inductive influence of substituents in the latter (cf. reactions Nos. 2 and 3 and also 4, 5, and 6 in Table 6) decreases. The constant ρ^* sometimes changes sign under these conditions (reaction No. 9). In the latter case a specific solvent (dioxan) forms hydrogen bonds with the catalyst, reducing its acid function in the catalytic step[69], so that the basic function becomes dominant in catalysis (see also subsection 4 in this Section). Evidently, a similar function is fulfilled, albeit to a lesser extent, by non-specific solvents when their polarity is altered, which accounts for the decrease of ρ^* on passing from benzene to nitrobenzene.

IV. ENERGETIC PARAMETERS IN BIFUNCTIONAL CATALYSIS

The formation of cyclic transition states of type I is accompanied by a decrease of the energy barrier relative to processes proceeding via linear transition states

---

¶Phosphinic acids in alcohol do not catalyse the peptide formation reaction in contrast to their solutions in benzene[79].

(Tables 10 and 11; see also Section I). One of the main causes of such decrease of the activation energy on formation of cyclic transition states is electron transfer via the ring, i.e. via a closed bond redistribution chain (BRC) (see Poltorak and Chukhrai[57], p. 264), which prevents any significant charge separation and hence decreases the associated energy barrier. In addition, Shilov[110] examined yet another cause of the decrease of the activation energy, consisting in the steric characteristics of the formation of the cyclic transition state, as a result of which preference must be given to cyclic rather than linear transition states (even in the absence of a closed BRC system in the former). In other words, the cyclic system fixes the reacting species in the positions most favourable for the chemical process (the Franck–Condon principle). Both these factors are apparently manifested in catalysis by bifunctional tautomeric catalysts, while in the case of bifunctional covalent and solvation catalysts, where there is no electron transfer via a ring (there is no BRC), only the second factor operates, as a result of which the last two classes of catalysts are appreciably inferior, as already mentioned, to the first as regards their efficiency.

In discussing the energetic parameters of bifunctional catalysis, account must be taken of the complexity of catalytic reactions, i.e. of the fact that they consist of many stages. Since the catalyst forms preliminary associated species with the reactants (see Section I), the catalytic rate constant may be represented as the product of at least two constants:

$$k_m = K^* k'_m, \qquad (22)$$

where K^* is the equilibrium constant for the formation of the preliminary associated species and k'_m the rate constant for the reaction with participation of this associated species. According to Eqn. (22), the observed activation energy E_a is defined by the equilibrium[111]

$$E_a = E'_{a(m)} - \bar{Q}_V\ , \qquad (23)$$

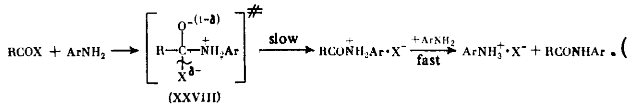
where $E'_{a(m)}$ is the activation energy for the stage characterised by the constant k'_m and $\bar{Q}_V$ the heat of formation of the preliminary associated species. Since $\bar{Q}_V > 0$, it follows that E_a is always less than the true value $E'_{a(m)}$. For this reason, the observed activation energies for catalytic reactions are negative in certain cases (see below), when $\bar{Q}_V > E'_{a(m)}$.

The energetic parameters were determined for the mutarotation of TMG (Table 10) and the acylation of arylamines by carboxylic acid chlorides, anhydrides, and esters (Table 11) stimulated by bifunctional catalysts. It follows from Table 10 that bifunctional catalysts of different types—2-hydroxypyridine and benzoic acid for the mutarotation of TMG—have virtually identical values of E_a and $\Delta S^{\#}$. On passing to basic monofunctional catalysts (pyridine and diethylamine), the values of E_a increase and those of $\Delta S^{\#}$ decrease. If the activation energies for catalysis by diethylamine and pyridine are extrapolated to the basicity of 2-hydroxypyridine, we obtain a value in excess of 20 kcal mole^{-1}. Consequently the activation energy for catalysis by 2-hydroxypyridine is lower by ~ 10 kcal mole^{-1} than the value predicted for general base catalysis. This corresponds to an increase of the rate of reaction by a factor of ~ 10^7. The increase of activation entropy on passing from basic to bifunctional catalysts is difficult to account for. For example, it has been suggested that this is associated with the change in the solvation shell of the transition complex (the freezing of the solvent in this shell)[12].

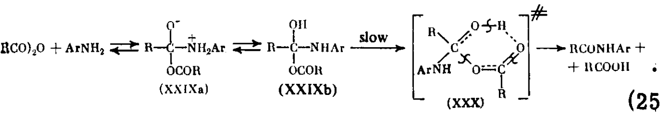
Whereas in the mutarotation of TMG the change from a monofunctional to a bifunctional catalyst leads to acceleration, mainly owing to the sharp decrease of the activation barrier, in the acylation reaction there is no such clear-cut behaviour. We may note that in acylation one may compare only the energetic parameters of the non-catalytic reaction (monofunctional catalysts are virtually ineffective) and the reaction stimulated by the bifunctional catalyst. Here it is possible to distinguish two groups of catalytic reaction.

1. Reactions to which correspond non-catalytic processes proceeding via non-cyclic transition states of type (XXVIII) [scheme (24)][100]. Reactions Nos. 1 and 3[100] and No. 5[112] belong to this class (Table 11).

2. Reactions to which correspond non-catalytic processes proceeding via cyclic transition states of type (XXX) or analogous states [scheme (25)][78,113]. These are reactions Nos. 2 and 4[100] and possibly Nos. 6[112] (Table 11):



(24)



(25)

Table 10. Energetic parameters for general base and bifunctional catalysis in the mutarotation of TMG in benzene[10,11].

Catalyst	E_a, kcal mole^{-1}	$-\Delta S^{\neq}$, e.u.	pK_a^{base} in H_2O
Benzoic acid	11.4	21.5	—
2-Hydroxypyridine	11.4	23.1	0.75
Diethylamine	14.3	26.3	10.98
Pyridine	>16.6	26.3	5.17

Table 11. Energetic parameters for non-catalytic (I) and carboxylic acid-catalysed (II) acylation of $C_6H_5NH_2$ in benzene (the catalyst was C_6H_5COOH in reaction Nos. 1 and 4 and CH_3COOH in all others).

No. of reaction	Acylating agent	E_a, kcal mole^{-1}	$-\Delta S^{\neq}$, e.u.	E_a, kcal mole^{-1}	$-\Delta S^{\neq}$, e.u.
		I		II	
1	C_6H_5COCl[100]	7.7	40.2	1.4	49.8
2	$(CH_3CO)_2O$[78]	0	71.7	0,9	48,2
3	$(CH_3CO)_2S$[100]	8.7	38.3	−1.8	54,2
4	$(C_6H_5CO)_2O$[100]	5.7	56.5	1.9	51.2
5	$CH_3CO{-}SC_6H_3(NO_2)_2$[112]	13.1	38.4	2.4	54.7
6	$CH_3CO{-}SC_6H_5$[112]	5.7	72.2	5.6	50.7

On passing from a non-catalytic to a catalytic process, both the activation energy and activation entropy for the first group of reactions decrease. This change of each energetic parameter has the opposite effect, as regards sign, on the rate of the process, but the positive influence of the change in activation energy greatly predominates, so that catalysis ensues. This is understandable because cyclic transition states are involved in the catalytic process, unlike the non-catalytic process, which favours a decrease of activation energy. The decrease of activation energy mentioned above can be explained by the high degree of order[114] in the structure of the transition state in catalytic reactions, which is also consistent with its cyclic structure.

In another group of reactions, the change from a non-catalytic to a catalytic process entails virtually no change in activation energy, because both processes proceed via cyclic transition states. On the other hand, the rate increases mainly as a result of the increase of activation entropy. The latter apparently shows that in this instance the structure of the transition state in the non-catalytic reaction is more ordered than that in the catalytic reaction.

The activation energies for all reactions catalysed by carboxylic acids are very high (Table 11), while the activation entropies are almost constant. On this basis one may assume that the mechanism of the catalysis by carboxylic acids is the same for all the acylating agents investigated, i.e. is described by the general scheme (6).

V. THE KINETIC ISOTOPE EFFECT OF DEUTERIUM

The cyclic structure of the transition state and the synchronous transfer of hydrogen atoms in the catalytic reaction with participation of bifunctional tautomeric catalysts is also confirmed by data obtained by isotopic labelling. Thus, when deuterated amines (in NH_2) and acetic acid (in OH) are used, a primary isotope effect is clearly observed in the case of acid halides (Table 12), becoming more intense on passing from the acid chloride to the fluoride, which forms stronger hydrogen bonds. This is consistent with the fact that, under the influence of a bifunctional tautomeric catalyst, two hydrogen atoms must be transferred in the rate-determining stage of the reaction. The increase in the ability of the reactant to form hydrogen bonds is in this case associated with the increase of the isotope effect (cf. C_6H_5COCl and C_6H_5COF). The comparatively small isotope effect is consistent with the possibility of hydrogen transfer via a cyclic transition state[116].

Table 12. The kinetic isotope effect of deuterium in the reactions of benzoyl chloride and acetic anhydride catalysed by acetic acid (CH_3COOH or CH_3COOD) (in toluene at 25°C).

Reaction	k_m^H/k_m^D
$C_6H_5COCl+p\text{-}Cl—C_6H_5NH_2$[96]	1.91±0.19
$C_6H_5COF+p\text{-}Cl—C_6H_4NH_2$[96]	3.34±0.50
$(CH_3CO)_2O+p\text{-}Cl—C_6H_4NH_2$[115]	1.00±0.10
$(CH_3CO)_2O+m\text{-}NO_2—C_6H_4—NH—CH_3$[115]	0.86±0.26

On the other hand, in reactions of acetic anhydride catalysed by a carboxylic acid the isotope effect is altogether absent, in contrast to the reactions of acid halides (Table 12). The latter can be accounted for by the fact that in reactions of acetic anhydride a symmetrical transition state (IIIb) may be postulated in the catalytic process, where B, A, and X are oxygen atoms. Swain's "solvation rule"[117] is therefore applicable in this instance; according to this rule, there is no isotope effect under the following conditions: firstly, if hydrogen is transferred between atoms of the same type; secondly, if the hydrogen in the transition state is not involved in reacting bonds[117], i.e. bonds which are ruptured and formed directly at the reaction centre.

In catalytic reactions involving anhydrides it is found that both parts of Swain's rule are satisfied. Furthermore, both hydrogen atoms in (IIIb) are transferred under completely identical conditions and synchronously, which leads to the cancelling of all the influences resulting from the replacement of hydrogen atoms by deuterium atoms.

In the analogous reactions of acid halides, where a transition state (IIIa) may be formed in conformity with the mechanism of the non-catalytic process, the first part of the rule never holds. The transfer of both protons should therefore not take place entirely symmetrically and, as already mentioned, a small but appreciable isotope effect is observed.

VI. CONCLUSION

As already mentioned at the beginning of the review bifunctional catalysts with a simple structure can be justifiably regarded as the simplest models of enzymes, because there is a definite similarity between these classes of substances. The similarity is manifested primarily by the fact that in both instances a major role is played by the preliminary association of the catalyst and the reactants, which results in the mutual approach and suitable relative orientation of the functional centres of the catalyst and the reactants, facilitating the reaction. Calculations[118] have shown that such mutual approach in enzymatic reactions reduces the length of the hydrogen bond to such an extent that a tunnel proton transfer at a rate exceeding that of diffusion-controlled processes becomes possible.

The next common feature of bifunctional catalysts and enzymes is the formation at the instant of the catalytic step of bond redistribution chains, which combine the reactant and catalyst molecules in the transition state into a single electronic system. The difference is that in enzymatic catalysis many-centre contacts are generated between the reactants and the catalysts, while in bifunctional catalysts only two-centre contacts, giving cyclic transition states, are produced. It is possible to distinguish two types of cyclic transition states.

1. States in which there is electron transfer via the ring formed when BRC undergo ring closure (bifunctional tautomeric catalysis). The occurrence of reactions via such states is particularly favourable, so that tautomeric catalysis is more effective than other types of bifunctional catalysis.
2. States in which BRC are either absent (solvation catalysis) or do not occur throughout the ring but only in the region where the catalyst is in contact with the reactants (bifunctional covalent catalysis).

Transition states of the first type are formed with participation of the catalyst, which contains two groups with opposite properties—electron-donating and electron-accepting—as a result of which these catalysts may be referred to as electrophilic-nucleophilic. Transition states of the second type may be formed, apart from the electrophilic-nucleophilic catalysts, by catalysts containing in their molecules active functional groups with identical properties. One can then speak, for example, of nucleophilic-nucleophilic [see, for example scheme (8)] or electrophilic-electrophilic catalysts. Although the possibility of the existence of catalysts of this kind is easy to imagine, they are nevertheless still unknown.

In order to explain certain aspects of enzymatic catalysis, a hypothesis has been used recently[119], according to which the hydrophobic sections of the enzyme form around the catalytic groups in its active centre a non-polar aprotic medium which ensures the most favourable conditions for the catalytic activity of these groups. The optimum conditions for bifunctional tautomeric catalysis occur, as shown above, precisely in non-polar aprotic media, which, firstly, confirms the above hypothesis, and, secondly, indicates yet another feature common to the two types of catalysis compared.

The problem associated with the selectivity of the action of organic catalysts is more complex. The fundamental difference between organic catalysts and enzymes is in fact associated with this factor and not solely with activity. Organic catalysts are naturally very selective but they are nevertheless greatly inferior in this respect to enzymes. A further search for ways of increasing the selectivity of the action of organic catalysts will apparently involve the synthesis of more complex molecules with a definite distribution of functional groups, some of which, for example, may play the role of substrate binding and orientation centres, while others are the catalytic groups proper.

In the search for more complex bifunctional and polyfunctional catalysts distinguished by a high activity and selectivity account must be taken of the conclusions reached in this review. (1) Bifunctional tautomeric catalysts exhibit the highest activity. (2) Their catalytic activity is manifested most strikingly in a solvent with a low solvating capacity. (3) Bifunctional catalytic activity is particularly high when conditions for the formation of strong hydrogen bonds are created in cyclic transition complexes. This depends on the nature of the catalyst itself and on the properties of the reactants and the medium. (4) Both the presence of the relevant functional groups in the bifunctional catalyst molecule and their steric disposition, ensuring the formation of a cyclic transition state, are very important for the manifestation of a high activity by such a catalyst. This is determined not only by the structure of the bifunctional catalyst but to an equal extent by the properties of the initial reactants.

Electrochemical Determination of Surface Area of Metals

E.I.Khrushcheva and M.R.Tarasevich

The fundamental principles of the electrochemical determination of the surface area of metals are discussed. Conditions of determination and methods of calculation are analysed for smooth and powdered metals of the platinum group, nickel, the copper subgroup, and carbonaceous materials. A list of 108 references is included.

I. INTRODUCTION

Study of the kinetics of heterogeneous processes requires a knowledge of the true surface area of the solid involved in the reaction. Several methods of determination based on the measurement of adsorption by volume or by weight have now been adequately developed and have been surveyed in detail in monographs and reviews[1-4].

Intensive work during the past decade has led to the widespread use of a new electrochemical method for determining the surface area of several metals in compact and powdered forms[5,6]. The possibility of determining true surface area from electrochemical measurements was first pointed out by Bowden and Rideal[7], and later by Shlygin and Frumkin[8]. Among the merits of this method, discussed quite fully by Brunauer[1], is its great sensitivity, which permits measurements on specimens of surface area down to 0.01 cm^2. The surface area of a catalyst can be measured electrochemically directly during the process when reaction takes place in an electrolyte solution[9,10]. These advantages, together with the rapidity of the measurements and the possibility of using readily available series-produced equipment, has attracted the attention of increasing numbers of research workers. However, no reviews hvve appeared on the electrochemical determination of surface area, which makes it difficult to choose the optimum procedure according to the nature of the metal and the conditions of measurement.

II. FUNDAMENTAL PRINCIPLES OF THE ELECTROCHEMICAL MEASUREMENT OF TRUE SURFACE AREA

The electrochemical method for determining the true surface area of a catalyst is based on measurement of the quantity of electricity consumed in changing the charge on the electrode in a given potential range. The theoretical basis of the method is Frumkin and Petrii's thermodynamic theory[11-13] of the surface state of electrodes that adsorb hydrogen and oxygen. It was shown[11-13] that in general the total (or thermodynamic) charge communicated to an electrode is consumed in charging the electrical double layer at the electrode-solution interface and in the adsorption of hydrogen, oxygen, or components of the electrolyte. The applicability of the thermodynamic theory to the surface state of a metal in an electrolyte solution was confirmed experimentally. In the case of a completely reversible system (e.g. a platinum electrode in the range of potentials for the adsorption of hydrogen) an unambiguous correspondence was established between the charge communicated to the electrode and its potential given by the charging curve. Either the charge consumed in adsorption (mostly of hydrogen) or the free charge (the differential capacitance of the electrical double layer) is determined experimentally. The surface coverage with adsorbed species or the capacitance of the double layer is found from investigations on electrodes of a given metal having a known true surface area (measured e.g. by the Brunauer-Emmett-Teller method). These values are then used as coefficients in determining the surface areas of other specimens of the same metal.

We shall now consider in greater detail the above two groups of methods, estimate their sensitivity, and assess the prospects of using them for various materials and experimental conditions.

1. Method of Charging Curves

Several modifications of the method of measuring charging curves can be used at the present time. They differ in the procedure for establishing conditions under which the whole of the electricity supplied to the electrode is consumed in changing its charge.

Frumkin and Shlygin[8,14,15] developed a technique of slow determination of charging curves on electrodes having a large true surface area. The curves were obtained from a solution saturated with an inert gas, to eliminate involvement in the electrochemical process of hydrogen or oxygen dissolved in the electrolyte. Powdered materials were placed in an electrically conducting gauze[16] to serve as current lead. Charge transfer can be effected by contact between the powder and an inert lead[17]. The quantity of electrochemically active impurities can be diminished[18] by decreasing the volume of the solution. Slow equilibrium charging curves can then be obtained at low current densities even on smooth electrodes.

A method was suggested[7,19] for obtaining rapid galvanostatic charging curves at high current densities. This would eliminate the effect of foreign solutes, which might have diffused to the electrode surface if the curves were determined slowly.

The above methods now find widespread use in electrochemical research.

Fig. 1 shows a typical charging curve for a platinum electrode in 1 N sulphuric acid, obtained at low current densities (the rapid galvanostatic curve is similar in shape)[20] (here and subsequently electrode potentials are given relative to the potential of a reversible hydrogen reference electrode in the same solution). The curve exhibits two arrests (region *I* and *III*) with a high pseudocapacitance. Ionisation of adsorbed hydrogen takes place in the region of the first arrest:

$$MH_{ads} \rightarrow H^+ + \bar{e} + M.$$

The second arrest corresponds to the discharge of water molecules with the formation of adsorbed oxygen or surface oxides:

$$M + H_2O \rightarrow MO_{ads} + 2H^+ + 2\bar{e}.$$

The two arrests are separated by a region *II* having a low capacitance, where a large proportion of the electricity is consumed in changing the charge on the double layer.

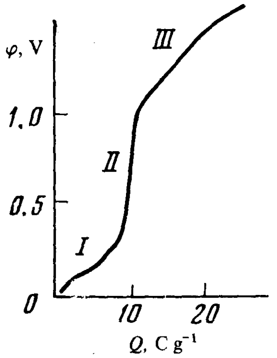

Figure 1. Charging curve for platinum in 1 *N* sulphuric acid at 20°C.[20]

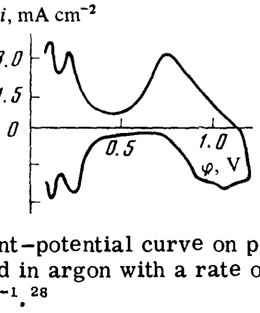

Figure 2. Current–potential curve on platinum in 1 *N* sulphuric acid in argon with a rate of application of potential of 1 V s^{-1}.[28]

Charging curves are now commonly obtained by a potentiodynamic method, first used for this purpose by Will and Knorr[21] and by Kolotyrkin and Chemodanov[22]. Electronic apparatus has been designed for this method[23-25] and investigations have been made on the surface state of various metals[16,24,26,27]. With linear scanning of the potential at a rate $v = \partial\varphi/\partial\tau$ the i–φ curves (Fig. 2)[28] determined by means of triangular voltage pulses represent essentially the differential form of the galvanostatic Q–φ curves: $I = v\partial Q/\partial\varphi$. Maxima on the potentiodynamic i–φ curve therefore correspond to maxima on the galvanostatic curve. The potentiodynamic method can be applied both to smooth[16,29,30] and to finely divided[16,31] electrodes. It yields highly reproducible results, largely because of the reproducible surface state of the electrodes obtained by periodic electrochemical oxidation and reduction[32,33] or by programmed pretreatment of the surface[24]. However, limitations on the rate of application of the potential, due to the disperse character of specimens, must be borne in mind when using this method.

The true surface area can be calculated from each of the above regions of the charging curve. However, the hydrogen region is generally used, because the deposition and removal of hydrogen are more reproducible than the corresponding processes with oxygen. In calculating the quantity of electricity corresponding to the hydrogen adsorbed, we must introduce a correction for the charging of the double layer and the evolution of molecular hydrogen. Finding the charge consumed in the evolution of hydrogen is a more difficult problem. In order to prevent the evolution of molecular hydrogen, therefore, the determination of slow charging curves does not extend beyond potentials 30–50 mV more positive than the reversible hydrogen potential.

The quantity of hydrogen adsorbed is determined from the area below the potentiodynamic i–φ curve bounding the hydrogen region (Fig. 2). This is equivalent to integrating the Q–φ curve:

$$Q = \frac{1}{v}\int_{\varphi_1}^{\varphi_2} i \cdot d\varphi$$

The end-point for measuring the quantity of electricity consumed in the adsorption of hydrogen on platinum was taken[34] to be the potential of the minimum preceding the evolution of hydrogen. This corresponds to the assumption that the quantity of electricity required for the adsorption of hydrogen at $\varphi < \varphi_{min}$ is balanced by the charge involved in the evolution of hydrogen at $\varphi > \varphi_{min}$. A similar postulate was made for other metals[35]. It has been suggested[36] that i–φ curves should be obtained at a low temperature (down to −72°C) to diminish the influence of hydrogen evolution on the quantity of hydrogen adsorbed.

The oxygen region of the charging or potentiodynamic curve can also be used to calculate the true surface area[30,37-42]. However, this gives rise to additional complications owing to the non-equilibrium character of the adsorption of oxygen and the time variation of the strength of its bonding to the surface[16,27,43,44]. As a result, the quantity of oxygen adsorbed depends on the current density used to obtain the charging curve or on the rate of application of the potential.

In order to calculate surface coverage of an electrode by hydrogen and oxygen it is necessary to know the quantity of electricity consumed in forming a hydrogen or oxygen monolayer. It is supposed that one hydrogen or oxygen atom is adsorbed on one metal atom. Polycrystalline electrodes are generally used in electrochemical investigations, so that most workers[16,37-40,45-47] start from the interatomic distance in determining the number of surface atoms. In the case of platinum this corresponds to 1.31×10^{15} atoms cm^{-2} true surface. Monolayers of hydrogen or oxygen on platinum then require consumptions respectively of 210 and 420 μC cm^{-2}. These values are used directly to calculate coverage by oxygen θ_H and θ_O. By no means in all cases is it possible to measure separately the quantities of electricity consumed in the adsorption of hydrogen and oxygen and in charging the double layer. If the regions in which these processes occur overlap (e.g. on nickel, silver, and carbonaceous materials), some numerical coefficient, determined by the charge necessary to change the electrode potential in the given range, must be used in calculating the true surface area.

In the electrochemical determination of surface area it must be borne in mind that the character of the charging curve is influenced significantly by the composition of the electrolyte[11]. This is due to the simultaneous adsorption of hydrogen and oxygen and of components of the electrolyte on the electrode surface. During recent years these phenomena have been investigated in detail on smooth and finely divided platinum[48-51] and palladium[52,53] electrodes. Thus for a palladium electrode in the presence of various anions and cations coverage with hydrogen decreases in the sequences

$$H_2SO_4 > H_3PO_4 > HCl > HBr \qquad KOH > NaOH > CsOH > Ba(OH)_2 > Ca(OH)_2.$$

In determining the surface area of a catalytic electrode, therefore, it is desirable to obtain galvanostatic or potentiodynamic charging curves in a standard electrolyte, whose components do not undergo strong specific adsorption. Organic impurities in the solution influence substantially the character of adsorption and the quantity of hydrogen adsorbed[54]. Special methods of purifying solutions have been described[33,52,55-57], ensuring that experiments can be conducted under sufficiently uncontaminated conditions. This is especially important in the investigation of smooth electrodes.

2. Measurement of Differential Capacitance

Another method for determining true surface area involves measuring the differential capacitance of the double layer. The relaxation time of the double layer is considerably shorter than typical times of adsorption and exchange accompanied by complete or partial transfer of charge across the interface. We can measure the capacitance of the double layer by high-frequency a.c.[58,59] or pulse[59] methods with short resolving times ($\sim 10^{-6}$ s), and use the result to estimate true surface area. It is usually assumed in this method[60-65] that the capacitance of the double layer is the same on different metals, equal to the capacitance of the mercury electrode (16–20 μF cm^{-2}). However, recent accurate measurements indicate[66] that different metal electrodes may differ in capacitance by 50–100%. Relaxation methods for measuring the differential capacitance of the double layer are applicable only to smooth electrodes, which is an important restriction on their use for determining true surface area.

Isolated attempts were made[8] to determine the capacitance of the double layer by means of slow charging curves. However, these methods cannot be regarded as successful, since in most cases processes involving adsorption of electrochemically active species also occur in the "double layer" region. It was shown[67] by Frumkin's thermodynamic method[11] that oxygen already begins to be adsorbed on platinum at potentials more positive than 0.3 V.

Comparison of the two groups of electrochemical methods for determining true surface area—by obtaining charging curves and by measuring differential capacitance—indicates that the former are simpler, more generally applicable, and reliable. It therefore forms the basis of most electrochemical techniques for measuring true surface area. Recently the possibility has been discussed of determining this property from the rate of an electrode reaction with a known specific exchange current[68].

III. DETERMINATION OF TRUE SURFACE AREA OF VARIOUS MATERIALS

Specific methods for measuring true surface area of various metals are governed by the nature of the latter, the ability to adsorb hydrogen and oxygen. Specific surfaces of most metals that have been investigated electrochemically are determined from the adsorption of hydrogen. They include metals of the platinum group—platinum, palladium, rhodium, iridium, ruthenium, and osmium—together with nickel. With platinum and rhodium the potential range for the adsorption and desorption of hydrogen is quite clearly defined. With ruthenium and nickel the potential ranges for the adsorption of hydrogen and oxygen overlap. The adsorption of hydrogen on palladium (and to some extent also on nickel) is complicated by the dissolution of hydrogen in the bulk of the electrode. Hydrogen is hardly adsorbed at all on gold, copper, and silver, on which surface area is determined from the adsorption of oxygen or the polarisation capacitance in a certain potential range. The last method is used also to determine surface areas of carbonaceous materials.

1. Platinum Metals and Nickel

Platinum and rhodium

Galvanostatic charging curves have been used to investigate the surface coverage of finely divided platinum and rhodium powders by adsorbed hydrogen and oxygen[10,16]. The potentials at which adsorbed hydrogen is completely removed from the surfaces of these metals are respectively 0.40 and 0.27 V (in 1 *N* sulphuric acid). The quantity of hydrogen adsorbed was determined by the method of tangents. No correction was made for the capacitance of the double layer, so that values of θ_H were rather too high.

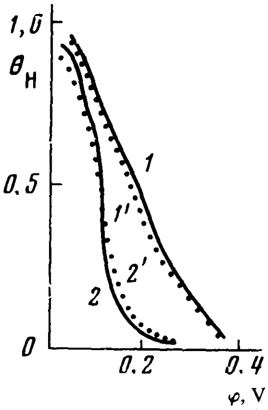

Figure 3. Potential dependence of surface coverage with hydrogen of: 1) platinum powder ($s = 20$ m^2 g^{-1}); 1′) smooth platinum electrode; 2) rhodium powder (20 m^2 g^{-1}); 2′) smooth rhodium electrode[16].

However, the contribution of this capacitance does not[51] exceed 5–7%, which is smaller than the error in the BET method. Knowing the true surface area of powders measured by the BET method, we can calculate values of θ_H on platinum and rhodium at various potentials.

Monolayers of hydrogen on platinum and rhodium surfaces correspond in electrical units to 210 and 220 μC cm^{-2} respectively. Fig. 3 shows that surface coverage of both platinum and rhodium powders with hydrogen reaches a monolayer ($\theta_H \approx 1$) near the reversible hydrogen potential. Similar results have been obtained on a single crystal of platinum[70]. The surface area of platinum and rhodium is independent of the method of obtaining the powders or their degree of dispersion, so that the hydrogen region of the charging curve can be used to determine the true surface area of these powdered metals[16]. Galvanostatic charging curves on the powders were compared with $i-\varphi$ curves obtained by means of triangular voltage pulses on smooth electrodes. Good agreement was obtained for $\theta_H-\varphi$ curves on smooth and dispersed electrodes (Fig. 3). The technique can be used also to determine the true surface area of platinum–rhodium alloys[71].

The possibility has been considered[37-41] of measuring the true surface area of platinum from the adsorption of oxygen. Surface coverage was then determined as the ratio of the quantity of electricity consumed in the adsorption of oxygen to double the quantity corresponding to a monolayer of hydrogen: $\theta_O = Q_O/2Q_H$. However, diverse values have been published—1.76,[37] 1.83,[38] 1.05,[41] and 1.24 [40] V—for the potential at which $\theta_O \approx 1$. Such divergence is due to the non-equilibrium character of the adsorption of oxygen and to accumulation of the gas on the electrode surface with time.

Ruthenium

Comparison of the electrochemical determination of the true surface area of ruthenium black[72] with the BET method showed that the quantities of electricity consumed in adsorption of hydrogen near the reversible hydrogen potential are 280 and 218 μC cm^{-2} in aqueous sulphuric and hydrochloric acids respectively. The former value corresponds to a monolayer. Determination of true surface area from the charge consumed in the double-layer region gave markedly overestimated values, owing to the presence of adsorbed oxygen on the ruthenium surface in this range.

Palladium

The possibility of determining the true surface area of palladium powders from the adsorption of hydrogen has been subjected to detailed investigation[16,52,53,73]. The complexity of such determination is due to the dissolution of hydrogen in the bulk of the metal. A typical charging curve obtained on powdered palladium in 1 *N* sulphuric acid is reproduced in Fig. 4. Over the range of potentials 0–0.08 V hydrogen dissolves with the formation of α and β phases. It is adsorbed at $0.08\ \text{V} < \varphi < 0.28$ V; some adsorption of hydrogen is observed also at $\varphi < 0.08$ V.[52] A technique was proposed[52,53] for separating the quantity of hydrogen adsorbed and desorbed in the potential range of chemisorption, and determining the surface coverage with chemisorbed hydrogen at each potential on the assumption that θ_H is independent of the degree of dispersion of the specimens. This assumption was confirmed for palladium powders of true surface area 0.3–100 m^2 g^{-1}. Fig. 5 illustrates the dependence of surface coverage of palladium with hydrogen over the potential range 0–0.28 V in 1 *N* sulphuric acid (curve *1*). It follows from these results that the quantity of hydrogen chemisorbed at 0.075 V corresponds to $\theta_H = 0.82$, but at potentials close to zero $\theta \approx 1$. The calculations were based on the hypothesis that the quantity of electricity consumed in coverage with a monolayer of hydrogen was 210 μC cm^{-2}.

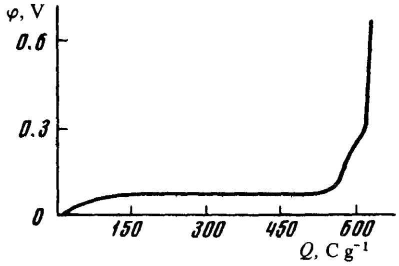

Figure 4. Charging curve on palladium powder (30 m^2 g^{-1}) over the range 0–0.7 V in [1 N] sulphuric acid at 25°C.[73]

Investigation of the influence of anions (PO_4^{3-}, Cl^-, Br^-, and SO_4^{2-}) [52] and of cations (K^+, Na^+, Cs^+, Ca^{2+}, and Ba^{2+})[53] on the adsorption of hydrogen on palladium showed that the course of the charging curves in the region of the $\alpha-\beta$ phase transition is almost independent of solution composition, whereas the chemisorption of hydrogen is affected significantly by the nature of anion and cation. The surface coverage θ_H diminishes with increase in the adsorbability of the anions (Fig. 5). A similar pattern is observed with cations[53].

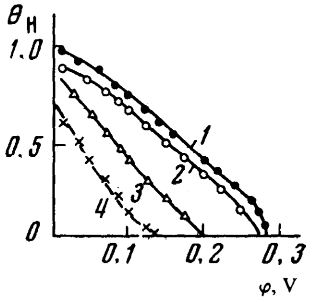

Figure 5. Potential dependence of surface coverage of palladium powder with hydrogen in 1 *N* acids: 1) sulphuric; 2) orthophosphoric; 3) hydrochloric; 4) hydrobromic.[52]

Thus the true surface area of palladium powders can be determined from the adsorption of hydrogen. The divergence between the results and values obtained by the BET method does not exceed 10%.[16]

The $\theta-\varphi$ curves calculated for smooth palladium electrodes from potentiodynamic $i-\varphi$ curves obtained with the potential applied at 20 mV s^{-1} were found[16] to coincide with $\theta-\varphi$ curves for finely divided powders. This indicates the possibility of using potentiodynamic curves to determine true surface areas of smooth palladium electrodes.

The total quantity of electricity representing the adsorption of hydrogen dissolved in and adsorbed on palladium in the range 0–0.3 V cannot be used to measure the surface area of palladium, as had been suggested[74], since the quantity of hydrogen dissolved is independent of the surface area. Thus this quantity is approximately the same for powders having surface areas of 39 and 3 m^2, whereas the quantity of hydrogen adsorbed differs more than tenfold[16].

The true surface area of smooth palladium has been determined[42] from the adsorption of oxygen under conditions such that in 1 N sulphuric acid a monolayer is formed at $\varphi \simeq 1.0$ V, in agreement with results obtained by other workers[52,53,73].

Nickel

The electrochemical behaviour of nickel near the potential of the reversible hydrogen electrode has been less well studied than that of the platinum metals. There is no generally accepted view on the mechanism of the adsorption and dissolution of hydrogen and the formation of oxide layers in this potential region[75–85]. The widespread use of nickel in electrocatalysis (liquid-phase hydrogenation, chemical current sources, etc.) has given rise to repeated attempts to develop electrochemical methods for determining its true surface area. These methods usually involved determining the capacitance of the double layer (using alternating current[86–88], from the fall in potential after polarisation had been switched off[89], and from charging curves[90]). The calculation was based on various values for the differential capacitance of the double layer (from 10[91] to 100 μF cm^{-2}).[90] Therefore these procedures can hardly be recommended for determining the true surface area of nickel without adequate experimental support. A method based[92] on measurement of the adsorption of thallium and sodium ions is merely comparative.

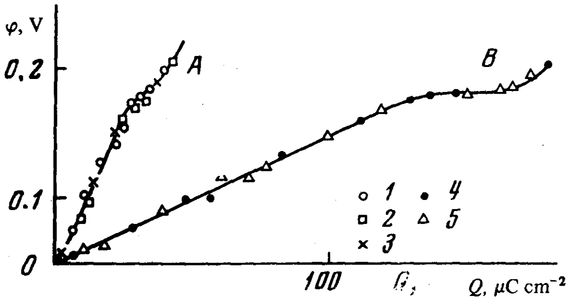

Figure 6. Charging curve per unit surface area (measured by the BET method) of nickel: A) Raney; B) carbonyl; 1) sintered electrode of A; 2) sintered electrode of a mixture of 50% A + 50% B; 3) powder in a grid of A; 4) powder in a grid of B; 5) sintered electrode of B.[81]

The most soundly based method for determining the true surface area of smooth and finely divided nickel was developed by workers who showed[81–85] that hydrogen does not undergo bulk dissolution in nickel at $\varphi \geqslant 0.03$ V. A similar conclusion was reached by another worker[79]. Surface areas (measured by the chemisorption of oxygen from the gas phase) of various nickel powders were compared[81–83] with the slopes of the linear portion of the equilibrium galvanostatic charging curve (Fig. 6) over the range 0.03–0.17 V. The pseudocapacitance calculated per unit true surface area was 1120 μF cm^{-2}. Such a value was explained by the occurrence of electrochemical processes involving adsorbed layers of neutral species.

$$H_{ads} + OH^- \rightarrow H_2O + \bar{e},$$

$$Ni + x\,OH^- \rightarrow Ni\,(OH)_x + x\,\bar{e}.$$

Determination by a vacuum–electrochemical method of the surface coverage of nickel with hydrogen and with oxygen showed that $\theta_H > 0.95$ and that $\theta_{OH} < 0.5$ and 0.2 at $\varphi \simeq 0$ and 0.17 V respectively. These results make it possible to determine the true surface area of finely divided nickel in this potential range.

If it is assumed that the nature of the adsorbed species is the same on smooth and powdered specimens, the results can be used to investigate smooth electrodes[83,85]. Potentiodynamic i–φ curves are then obtained in alkaline solution over the range 0.03–0.18 V, and the quantities of electricity at different rates V of application of the potential are extrapolated to $V = 0$. The result is compared with the value 1120 μF cm^{-2}. The electrode must be subjected to a special (stepwise) treatment at 0.2, 0.1, and 0 V in order to obtain reproducible results[83]: otherwise a different value may be obtained for the pseudocapacitance per unit surface area of the nickel powder[80].

The electrochemical method for determining the true surface areas of platinum metals and nickel has found practical application in investigating electrocatalytic processes on porous gas-diffusion and liquid electrodes. It has been used to determine the surface area of the catalyst in porous electrodes[93] during preparation and operation[41,94,95], in measuring the distribution of liquid and gas porosity[94], for determining the surface area of platinum metals on a carrier[96], and also in calculating the kinetic parameters of electrochemical reactions[93].

2. Metals of the Copper Subgroup

Hydrogen is not readily adsorbed on copper, silver, and gold, in contrast to metals of the platinum group, so that surface coverage with hydrogen cannot be used to determine the true surface areas. Therefore either the potential range corresponding to the adsorption of oxygen is used (copper and gold), or else some segment of the charging or potentiodynamic i–φ curves on which the polarisation capacitance has been determined in preliminary experiments (silver).

Gold

An electrochemical method has been developed[16,29] for determining the true surface area of finely divided and smooth gold from the adsorption of oxygen. The surface coverage in acid solutions was calculated from charging curves or from potentiodynamic curves over the range 1.3–1.7 V. On the assumption that one oxygen atom is adsorbed on one metal atom the coverage of finely divided gold reaches a monolayer at 1.7 V. The adsorption of oxygen obeys similar laws on smooth and finely divided gold: the specific adsorption is the same on such electrodes. Good agreement is found between surface areas obtained from charging curves and by the BET method.

Copper

The quantity of surface oxide Cu_2O forming a monolayer in a given potential range is determined[97]. Conditions required[97] indicate that surface area is most conveniently measured in alkaline solutions. The quantity of electricity corresponding to a monolayer of copper(I) oxide is 180 μC cm^{-2}.[98] The quantity of oxide is calculated from the arrest on the charging curve in the range 0.87–0.47 V. It can be found also by obtaining potentiodynamic curves with the potential applied at 2–10 mV s^{-1}. This method has been used to determine the true surface area of copper coatings having a roughness factor of 2–10. It has found application in studies of the corrosion of copper[99].

Silver

Determination of true surface area from the adsorption of oxygen on silver, in contrast to gold and copper, is difficult because of the formation of multilayer deposits. The adsorption of oxygen on silver powders in the range 0.25–0.8 V gives in several cases[100] good agreement with BET results. The roughness factor of smooth silver electrodes has been estimated[101,102] from the quantity of electricity determined from i–φ curves obtained by the application of triangular voltage pulses over the potential range 0–0.2 V, in which it was assumed[101,102] that the quantity of electricity was consumed only in charging the double layer of the silver electrode.

A more rapid method proposed[31] for determining the surface area of silver powders involves applying the triangular pulse to the electrode after cathodic reduction of the latter at negative potentials, with i–φ curves obtained in the range 0.2–0 V applied at the rate 3–40 mV s^{-1}. As before[101,102] this potential range is regarded[31] as corresponding to charging of the double layer. It was assumed for the calculation that the true capacitance of silver in this potential range is 50 μF cm^{-2}. The results agree well with those obtained by the BET method.

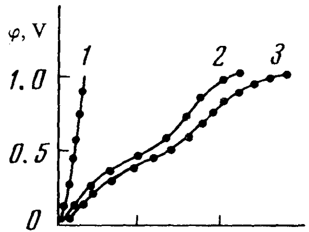

Figure 7. Charging curves on silver powders differing in specific surface (m^2 g^{-1}): 1) 2.5; 2) 3.0; 3) 10.[100]

The true surface areas of silver powders prepared in various ways were measured[100] by the BET method and compared with electrochemical measurements by means of slow charging curves in 0.1 N aqueous potassium hydroxide. Charging curves on silver powders are plotted for various specific surfaces in Fig. 7. Comparison of BET surface areas with the quantity of electricity consumed in the range 0–0.25 V showed that for almost all the silver powders $Q/s_{\mathrm{BET}} = 0.02 \pm 0.003$ mC cm^{-2}. Hence the true surface area of silver can be determined from the polarisation capacitance in the potential range 0–0.25 V.

3. Carbonaceous Materials

Measurement of the specific surface of carbonaceous materials is one of the most important and difficult tasks. Development of an electrochemical method is impeded by the existence of such materials in various modifications (coal, carbon black, graphite, pyrographite, vitreous carbon), whose electrochemical properties depend in considerable degree on their structure and the method of measurement. Appreciable difficulties may result also from the presence of micropores, of dimensions comparable with the radii of hydrated ions, in several carbonaceous materials (e.g. in activated carbon). This would lead to a change in the capacitance of the double layer.

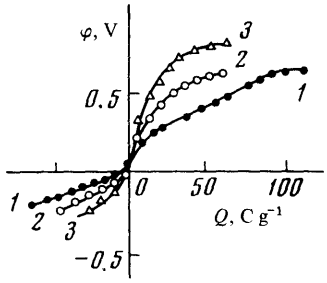

Figure 8. Charging curves obtained in 0.01 N sulphuric acid on: 1) activated carbon (surface area 710 m^2 g^{-1}); 2) carbon black (760); 3) graphite (670).[107]

The adsorption of oxygen and hydrogen on various carbonaceous materials has been investigated in electrolyte solutions[103-108]. Fig. 8 shows typical charging curves on activated sugar charcoal, PM-100 carbon black, and graphite in 0.01 N sulphuric acid[107]. The capacitance is minimal in the potential range 0.05–0.25 V. This segment of the charging curve corresponds to the capacitance of the double layer. Values of the capacitance for coal, carbon black, and graphite are 7.0, 4.5, and 2.5 μF cm^{-2} true surface area. Hydrogen is adsorbed at potentials more negative than those corresponding to the double-layer region, and oxygen at more positive potentials. Results obtained for coal and carbon blacks having different surfaces in 0.1 N sulphuric acid indicate that the "oxygen" portion of the charging curve can be used to determine the true surface areas of these adsorbents. With coal the mean polarisation capacitance is 28 ± 2 μF cm^{-2} for surface areas of 450 and 710 m^2 g^{-1}, which corresponds to an accuracy of 10%; but with carbon black the mean value is 13 ± 2 μF cm^{-2} over the range 160–760 m^2 g^{-1}, corresponding to an accuracy of 15%. For KhS-72 carbon black and AG-3 carbon the polarisation capacitance in the same potential range was respectively 15 and 19 μF cm^{-2}.[108] Deviations from the results of

Ref. 107 may be due to technical differences in the production of the carbonaceous materials.

An attempt was made[106] to use a.c. polarisation to measure the surface area of porous carbonaceous materials (coal and graphite of various brands), which reduces to determining the capacitance of the double layer. As noted above, however, the specific capacitance of the double layer depends on the nature of the carbonaceous material[107]. Hence the capacitance values used to calculate specific surface area from electrochemical data require special experimental justification.

oOo

The electrochemical method for determining true surface area is now sufficiently developed for platinum metals, the copper subgroup, nickel, and certain types of carbonaceous materials. It has been successfully used to study several electrolytic processes at electrodes of these materials. The number of research topics to which the electrochemical determination of surface area is applicable will increase as investigation of the structure of the double layer and of adsorption from electrolyte solutions on other metals and alloys is extended. Another important line of development of the electrochemical method is to measure the surface area of metallic or semiconducting catalysts on carriers, of platinum on carbon, oxides on carbon, and nickel and silver powders stabilised by oxides.

The Reactivity of Carbanions

A.A.Solov'yanov and I.P.Beletskaya

Ionic species involved in the reactions of alkali and alkaline-earth metal salts of CH-acids with various electrophiles are discussed, as well as the factors influencing the relative concentrations of these species. The reactivities of carbanions and their ion-pairs in nucleophilic substitution and addition and in electron and proton transfers are examined in terms of quantitative experimental results. A list of 140 references is included.

III. Kinetic approach 428
IV. Reactions of carbanions 429

I. INTRODUCTION

Many reactions of organic compounds involve carbanions, negatively charged species in which the charge—more often part of the charge—is concentrated on the carbon atom. It is now well known that the mechanism, the stereochemical direction, and the kinetics of these reactions are determined by the reactivities of the diverse forms in which carbanionic species exist in solution, as well as by their relative concentrations. However, although considerable progress has been made in studying the physical properties of ionic species, the state of information on their reactivity is still unsatisfactory.

The main purpose of the present Review is to analyse kinetic data obtained for the reactions of CH-acid salts of alkali and alkaline-earth metals, since they are almost the only sources of carbanions that have been studied in this respect. These salts have ionic structures (organolithium compounds form an exception, for the carbon-lithium bond in them is not always ionic in character[2]): i.e. they are ionophores[1], the ionic species of which exist in steady concentrations in solution, which considerably facilitates kinetic analysis.

We shall disregard the reactions of ambident anions, which develop a dual reactivity, for they have been discussed quite thoroughly[3-6]. The section on proton-transfer reactions leaves out of consideration investigations on kinetic acidity in isotope-exchange reactions in CH-acids, processes which have been discussed in sufficient detail[7-10]. Furthermore, the reactivities of carbanions are assessed from their rates of formation, which is not altogether correct, owing to the occurrence of a recovery stage that cannot be strictly allowed for, quite apart from the possible participation of both free ions and ion-pairs in these reactions, whose contributions have not been separated.

The fundamental studies by Cram showed that the character of the carbanionic species involved in isotope exchange has a decisive influence on the stereochemical result of the reaction. However, the absence of accurate kinetic parameters for each ionic species compels us to exclude the stereochemistry of the reactions of carbanions from consideration.

II. TYPES OF REACTIVE SPECIES

The complicated character of the problem of determining the reactivity of carbanions lies in the existence of their source compounds in solution not only as free ions C^- and M^+ but also as contact or solvent-separated ion-pairs C^-M^+ or $C^-\|M^+$, aggregates of ion-pairs $(C^-M^+)_n$ or $(C^-\|M^+)_n$, and more complex ionic structures, e.g. $(C^-)_{n-1}(M^+)_n$ and $(C^-)_n(M^+)_{n-1}$. In general these species differ in reactivity, which suggests that the environment has a great influence on the rates of reactions involving a carbanion. All the ionic species are interrelated by the rapidly established equilibria

$$\begin{tikzcd} C^-M^+ \arrow[rr, shift left, "K_1"] \arrow[dr, shift left] & & C^-\|M^+ \arrow[ll, shift left] \arrow[dl, shift left] \\ & C^- + M^+ \arrow[ul, shift left, "K_2"] \arrow[ur, shift left, "K_3"'] & \end{tikzcd} \qquad (1)$$

$$\begin{tikzcd} n\,(C^-M^+) \arrow[r, shift left] & (C^-M^+)_n \arrow[l, shift left] \arrow[r, shift left] \arrow[dr, shift left] & C^- + (C^-)_{n-1}\,(M^+)_n \arrow[l, shift left] \\ & & M^+ + (C^-)_n\,(M^+)_{n-1} \arrow[ul, shift left] \end{tikzcd} \qquad (2)$$

$$\begin{tikzcd} n\,(C^-\|M^+) \arrow[r, shift left] & (C^-\|M^+)_n \arrow[l, shift left] \arrow[r, shift left] \arrow[dr, shift left] & C^- + (C^-)_{n-1}\|(M^+)_n \arrow[l, shift left] \\ & & M^+ + (C^-)_n\|(M^+)_{n-1} \arrow[ul, shift left] \end{tikzcd} \qquad (3)$$

which are easily displaced in a particular direction by varying the reactant concentrations, changing the nature of the medium or its temperature, introducing unreactive ions or solvating additives, applying an external electric field, etc. These equilibria must be considered because the contributions of the above ionic species to the observed rate constant can be determined, and the factors influencing the reactivity of the carbanion revealed, only if the species actually present in solution and their concentrations are known.

1. Ion-pairs and Free Ions

The equilibrium between contact and solvent-separated ion-pairs was first investigated by Smid et al.,[11-24] who chose as model the fluorene salts of alkali and alkaline-earth metals, using mainly a simple spectral and conductometric technique. Subsequent investigations of this equilibrium in solutions of other salts of carbanions[12,25-32] and salts of radical-anions[33,34] established almost the same laws, governing the influence of the medium, the nature of the ions, and the temperature, as those discovered by Smid et al. We shall not discuss details, since numerous excellent reviews and monographs have appeared on this topic[22,33-85], but will report briefly the principal laws.

The constant K_1 depends on the structure of the carbanion, the size and charge of the cation, the nature of the solvent, and the temperature. The influence of the structure of the carbanion on the equilibrium between contact and solvent-separated ion-pairs is determined by both electronic and steric factors. In general increase in the degree of charge delocalisation in the anion should favour the formation of solvent-separated ion-pairs. Thus in oxolan the value of K_1 for the sodium salts of 1,2- and 3,4-benzofluorenes exceeds several times that for fluorenylsodium[11]. The reason for the higher proportion of contact ion-pairs of the sodium salt of 1,3-diphenylbut-1-ene than of the sodium salt of 1,3-diphenylprop-1-ene in the same solvent is the increased effective charge on the carbanion due to the inductive effect of the methyl group[28].

The negative charge of a mesomeric anion containing a heteroatom may be concentrated mainly on this atom, with a consequent strengthening of electrostatic interaction between the oppositely charged parts of the ion-pair, which complicates their separation by the solvent. This provides an explanation of the presence solely of contact ion-pairs in solutions of alkali-metal salts of 9-cyanofluorene[36] and methyl fluorene-9-carboxylate[37] in dimethoxyethane.

Among structural factors that may influence the position of the equilibrium between the different types of ion-pairs we must include the presence at the anionic centre of substituents capable of impeding direct contact between the ions. Thus under the same conditions the proportion of solvent-separated ion-pairs is always smaller in solutions of alkali-metal salts of fluorene than in those of the corresponding salts of 9-2′-methylpentylfluorene[12].

Solvent-separated ion-pairs can be formed only in solvents that are capable of surrounding at least one of the ions with a dense solvate sheath. In the usual media (dipolar aprotic solvents, solvents of ether type) it is the metal cation in the usual ion-pairs of carbanions that interacts with the solvent. Therefore the position of the equilibrium between intimate and loose ion-pairs depends primarily on how well specifically solvated is the gegenion. In solvents of ether type (oxolan, dimethoxyethane, diethyl ether, oxan) the proportion of solvent-separated ion-pairs always increases with decrease in the radius of the alkali-metal cation in the sequence

$$Cs^+ < Rb^+ < K^+ < Na^+ < Li^+.$$

This is the situation in solutions of alkali-metal salts of fluorene[11], triphenylmethane[30], 1,3-diphenylbut-1-ene[26,28] and 1,3-diphenylprop-1-ene[27,28], indene[30], 4,5-methylenephenanthrene[32], and 1- and 2-methylnaphthalenes[31].

On passing from salts of alkali metals to those of alkaline-earth metals (difluorenyl-barium, -strontium) the proportion of solvent-separated ion-pairs diminishes considerably[13,14], as a consequence both of increase in the electrostatic interaction in salts of doubly charged cations and of the great hindrance to their solvation. Here, too, the equilibrium shifts towards solvent-separated ion-pairs with decrease in the radius of the cation[14]. Formation of solvent-separated ion-pairs is considerably favoured by increasing the polarity of the solvent and its solvating power for the cation, the latter factor often being dominant. The proportion of loose ion-pairs in alkali-metal salts of fluorene increases (i) as the solvent becomes more basic[15,16] in the sequences

dioxolan < oxan < 2,5-dihydrofuran < oxolan < oxetan,
dioxan < 3,4-dihydropyran < oxetan,
oxolan ≪ hexamethylphosphoramide, dimethyl sulphoxide

(ii) on passing from uni- to bi- and multi-dentate solvents[15,16] in the sequences

oxolan ≪ 2-methoxymethyloxolan,
m-dimethoxybenzene < oxolan < *o*-dimethoxybenzene

and (iii) with increase in the number *n* of oxyethylene units in glymes (dimethyl ethers of polyethylene glycols) $CH_3O[CH_2CH_2O]_nCH_3$ added in small quantities to ethereal solvents[17,18]

$$1 < 3 < 4 < 5 < 6 < 7 < 9 < 22.$$

Analogous regularities are observed on examining equilibria between ion-pairs of alkali-metal salts of 9-2′-methylpentylfluorene[12], triphenylmethane[30,38], 1,3-diphenylalkenes[25-28], and other systems[30-32].

However, the greatest effect on the equilibrium between ion-pairs is exerted by crown polyethers[39] and cryptates[40]: small additions to solutions of carbanion salts of alkali metals[19,20] or alkaline-earth metals[10] increase K_1 by several powers of ten.

Lowering the temperature causes the equilibrium between ion-pairs in solutions of carbanion salts to shift towards solvent-separated pairs in all the systems studied, since at low temperatures solvation is less disturbed by the thermal motion of the molecules. Incorporation of solvent into the ion-pair is accompanied by decreases in enthalpy and entropy. Table 1 gives some idea of the thermodynamic parameters of the transition of intimate into loose ion-pairs, as well as the magnitude of the equilibrium constants.

Table 1. Thermodynamic parameters of the equilibrium (1) between contact and solvent-separated ion-pairs at 25° C.

The dissociation equilibria—between ion-pairs and free ions (equilibrium constants K_2 and K_3)—are influenced by the same factors—structure of carbanion, size and charge of gegenion, nature and temperature of medium—as is the equilibrium between ion-pairs. These factors have considerably less influence on the dissociation of solvent-separated ion-pairs, in which interionic interaction is appreciably weaker. It must also be borne in mind that the work of diluting oppositely charged ions to an infinite distance (i.e. dissociation) is done mainly at the stage of introducing the first solvent molecule between them. It is by no means always possible to isolate the parameters relating to dissociation of ion-pairs of a certain type, since the measured dissociation constant [calculated from the Fuoss conductance equation] is a composite quantity: $K_D^{-1} = K_2^{-1} + K_3^{-1}$. Hence the enthalpy and entropy of dissociation are also composite[16]:

$$\Delta H_D = \Delta H_3 + \Delta H_1(1+K_1)^{-1}; \quad \Delta S_D = \Delta S_3 + \Delta S_1 \cdot (1+K_1)^{-1}.$$

It is not surprising, therefore, that not only K_D but also the observed values of ΔH_D and ΔS_D vary with temperature, owing to the shift in the equilibrium between the ion-pairs.

The data in Table 2 show that in the large majority of cases the enthalpy and the entropy of dissociation are negative; moreover, they usually decrease in absolute magnitude with fall in temperature. This was to be expected, since at low temperatures the terms $\Delta H_1(1+K_1)^{-1}$ and $\Delta S_1(1+K_1)^{-1}$ make smaller contributions to the observed functions. The magnitudes of ΔH_D and ΔS_D depend both on K_1 and on the thermodynamic parameters of the transition of contact into solvent-separated ion-pairs (Table 1). If ΔH_D (and of course ΔS_D also) reach limiting values unaffected by further fall in temperature[14,21], this would suggest that ion-pairs of only one type (solvent-separated) exist in solution under these conditions. If variation of the temperature does not affect the enthalpy of dissociation, this also indicates that free ions are formed from ion-pairs of a single type, but they may be either contact[14,21,36] or solvent-separated[14,16,21]. The type can be decided from the magnitudes of ΔH_D, which are higher for close ion-pairs (by factors of 2–3[14,16,21,28,41]), and also from spectral data[22].

The thermodynamic approach to the problem of the dissociation of ion-pairs[47,48], in which the solvent is regarded as an unstructured isotropic dielectric, leads to the Denison–Ramsey equations

$$\Delta H_D = \frac{Ne^2}{a\varepsilon}\left(1+\frac{\partial \ln \varepsilon}{\partial \ln T}\right), \tag{4}$$

$$\Delta S_D = \frac{Ne^2}{a\varepsilon}\left(\frac{\partial \ln \varepsilon}{\partial T}\right)+\Delta S_T, \tag{5}$$

in which a is the distance between the ionic centres of the pair, while ΔS_T represents the increase in entropy due to the appearance of two species instead of one. Since the temperature coefficient $\partial \ln \epsilon/\partial \ln T$ is always negative, and for liquids exceeds unity in absolute magnitude[49], the values of ΔH_D and ΔS_D predicted by Eqns. (4) and (5) are also negative, in excellent agreement with experimental results. However, coincidence of calculated and experimental magnitudes of ΔH_D (and ΔS_D) is observed only when transition of the ions from the ion-pairs to the free state is not accompanied by changes in their solvent sheaths, i.e. usually on the dissociation of solvent-separated pairs[14,16,21,38], which provides a further test for the structure of the dissociating species.

Since the formation of solvent-separated from contact ion-pairs and that of free ions from both types are similar in character, ions being separated by one or more solvent molecules in both cases, they are governed by the same laws. For purely carbanionic systems the dissociation constant increases with decrease in the size of the cation[14,16,21,38,50] and with increase in its charge[14] (Table 2). However, the presence of a heteroatom in the organic anion reverses the dependence of the dissociation constant on the cationic radius[36,44] (Table 2). Transfer to a solvent possessing greater solvating power for the cation and a larger dielectric constant produces a sharp increase in the dissociation constant[38,42,44-46] (Table 2); it is probable that all three equilibrium constants—K_1, K_2, and K_3—increase. Solvating additives in the solution also increase the dissociation constant, of course[14,44]. In some cases[51] a linear correlation can be observed between the logarithm of the dissociation constant and the reciprocal of the dielectric constant of the medium.

Values of the dissociation constant may serve as a measure of the relative stabilities of the anions formed by dissociation[46,52]. The electron-donor character of methyl groups is responsible for the increase in K_D in the sequences of lithium derivatives (Table 2)[46]

poly-2,3-dimethylbutadienyl < polyisoprenyl < polybutadienyl,

poly-α-methylstyryl < polystyryl

Here the increase in stability of the anions is consistent with the fall in their reactivity[46,52]. However, such a rule would probably apply only to the dissociation of contact ion-pairs. The stability factor is less significant in the dissociation of solvent-separated ion-pairs (it affects, of course, the value of K_1). In any case, the dissociation constants of solvent-separated ion-pairs of lithium salts of substituted fluorenes are closely similar, although values of pK_a in the corresponding series of CH-acids vary by 4 units[37] (Table 2).

The dissociation constant of cyclopentadienyl-lithium is only around 5% of that of indenyl-lithium[46], although the pK_a of indene is 3.5 units higher[53]. Solutions of these salts, however, contain both contact and solvent-separated ion-pairs[30].

2. Aggregates of Ion-Pairs

The aggregation of ion-pairs (Eqns. 2 and 3) has been considerably less well studied than the equilibria between ions and ion-pairs or between contact and solvent-separated pairs, from both kinetic and thermodynamic points of view. Therefore the number of theoretical models created to describe these processes is also small: Fuoss and Kraus[54] examined the possibility of the formation of ion-triplets, and Pettit and Bruckenstein[55] that of symmetrical ion quadrupoles and sexapoles. The reason for the association of ion-pairs of carbanions is obviously dipole–dipole interaction, so that these aggregates are usually met in media of low polarity, such as aliphatic hydrocarbons and benzene[56,57]. Association in polar media such as oxolan is usually due to special causes, e.g. difunctionality of the polymer chain[50] or a doubly charged cation[68,69]. The stability of aggregates of ion-pairs and their degree of association depend significantly on the size of the alkali-metal cation and the structure of the anion. Polystyryl-lithium in benzene, cyclohexane, toluene, and heptane[58-60] and poly-α-methylstyryl-lithium in aliphatic hydrocarbons[63] are dimerised; polyisoprenyl-lithium in heptane, toluene, and certain other hydrocarbons forms tetramers[60-62]; and polybutadienyl-lithium[60,54] forms hexamers. On passing from this last compound to polybutadienylpotassium the degree of association of the ion-pairs falls[64] from 6 to 2. In benzene polystyrylsodium is dimerised down to concentrations of $\sim 10^{-5}$ M, dimers of potassium ion-pairs break down at $\sim 10^{-3}$ M, and caesium ion-pairs do not associate at all in this solvent[65]. In cyclohexane polystyrylpotassium is slightly associated, but the rubidium and caesium salts are monomeric[67]. Additions of solvating solvents such as oxolan tend to break down association complexes of ion-pairs in hydrocarbon media[65,66].

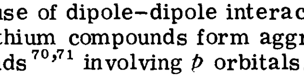
Quantitative information on the association of ion-pairs of carbanions is almost completely lacking. The equilibrium constant of the dimerisation of polystyrylpotassium is 3mM in cyclohexane at 40° C,[67] and 0.6mM in benzene at 20° C[65] ($\Delta H = 7.6$ kcal mole^{-1}).

Whereas organolithium compounds containing resonance-stabilised groups, e.g. benzyl, allyl, diphenylmethyl[56-67], associate because of dipole–dipole interaction of ion-pairs, simple alkyl-lithium compounds form aggregates with multicentre bonds[70,71] involving p orbitals. In hydrocarbons, ether, or benzene these aggregates usually comprise four[72,73] or six[74-76] monomer units. X-Ray examination indicates that tetrameric alkyl-lithium compounds have a tetrahedral structure, with lithium atoms at the corners of the tetrahedron, and alkyl groups located above the centres of the faces[72].

The association of ion-pairs of carbanions in hydrocarbons involves only the contact type. In ethers, however, solvent-separated ion-pairs also are able to associate[23]: in oxolan fluorenylsodium ion-pairs separated by a crown polyether form dimers. Increase in the dipole moment and the possibility of denser packing of ions in the dimer are probably significant here[23].

Linear carbon-chain polymers having an active centre at each end of the chain exhibit unusual behaviour. The anion formed on the dissociation of one ion-pair of difunctional polystyrylcaesium in oxolan cyclises with the ion-pair at the other end to form an intramolecular triple ion[50].

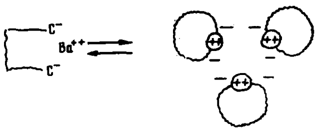
Bolaform electrolytes—caesium and sodium salts of $\alpha\omega$-difluoren-9-ylpolymethylenes



(I)
$n = 2, 3, 4$ and 6

in oxolan—form analogous triple ions[24]. The cyclisation constant increases with the number of methylene units and on passing from sodium to caesium. Formation of cyclic triple ions of sodium salts has a very low probability because the sodium cation is well solvated by oxolan.

In oxolan polystyrylbarium associates into a trimer, forming a "rosette" (**II**)[68]:



II

III. KINETIC APPROACH

The observed reaction rate constant for a compound capable of existing in more than one form is a composite quantity which, provided that the rate of establishment of equilibrium between these forms greatly exceeds the reaction velocity, can be written

$$k_{\text{obs}} = \sum_i k_i \alpha_i, \tag{6}$$

where α_i is the proportion of a given ionic species and k_i is the rate constant. Obviously, calculation of the thermodynamic activation functions from the temperature dependence of the observed rate constant may in general give incorrect results. Nor does the observed constant give a true idea of the reactivity of the ions. On the other hand, it is also clearly impossible in any case to isolate the individual rate constants k_i by means of Eqn. (6). Even in cases in which only two ionic species are in equilibrium in solution, three independent variables—the rate constants of the two species and the proportion α of one of them (the proportion of the other is $1 - \alpha$)—occur in this equation. The constants can then be determined in only one way—by varying the value of α and solving the set of linear equations

$$k_{\text{obs}} = k_1\alpha + k_2(1-\alpha) = k_2 + \alpha(k_2 - k_1). \tag{7}$$

The rate constants can also be determined graphically, by plotting k_{obs} against α, when the slope gives the difference $k_2 - k_1$, while the intercept on the ordinate axis is k_2. When these reactive species contain different numbers of ions (e.g. an ion and an ion-pair, or an ion-pair and an aggregate of ion-pairs), the quantity α can be varied by varying the concentration. When, however, the reactive species contain the same number of ions (contact and solvent-separated ion-pairs), variation of α requires the introduction of solvating additives, which displace the equilibrium towards the species having the greater interionic distance. However, this case is fraught with unpleasant consequences: firstly, free ions may be formed, i.e. yet another reactant species; and secondly, a solvent-separated ion-pair whose cation is solvated by the additive may differ in reactivity (though slightly) from an ion-pair whose cation is solvated simply by the solvent.

Obviously, it is impossible to vary the temperature or the dielectric constant of the medium, since this would entail a change in the values of the constants themselves.

Reactive systems comprising two species are among the most thoroughly studied. Many kinetic data have been assembled especially on the reactions of ionophores present in solution as an equilibrium mixture of ion-pairs and free ions. The observed rate constant for such systems can be represented by an equation suggested by Acree[77]:

$$k_{\text{obs}} = \alpha k_{\text{ion}} + (1-\alpha) k_{\text{ip}}, \tag{8}$$

where k_{ion} and k_{ip} are the reaction rate constants of ions and ion-pairs respectively, while α is the degree of dissociation calculated from conductivity data for solutions of the ionophores. In cases in which the degree of dissociation does not exceed a few percent, it can be expressed by the equation

$$K_D = \frac{C\alpha^2}{1-\alpha} \approx C\alpha^2 \ (\alpha \ll 1) \tag{9}$$

in the form $\alpha = (K_D/C)^{1/2}$, where C is the concentration of the ionophore. Formula (8) is then transformed into the very frequently used equation[36,38,42,44,50,52,78-102]

$$k_{obs} = k_{ip} + (k_{ip} - k_{ip}) \frac{K_D^{1/2}}{C^{1/2}}. \tag{10}$$

In order to evaluate k_{ip}† and k_{ion} from (10) it is sufficient to know the dissociation constant K_D. If for some reason this cannot be measured, only k_{ip} can be calculated from Eqn. (10).

The degree of dissociation α can be varied also by means of the common-ion effect, by introducing into the solution a compound that dissociates considerably better than test reagent to give one of the components (unreactive, of course) of the ion-pair. Examples of such compounds are alkali-metal tetraphenylborates[36,38,50,52], triphenylcyanoborates[42], and perchlorates[81,82]. The observed rate constant will then be given by[50,85]

$$k_{obs} = k_{ip} + (k_{ion} - k_{ip}) \frac{K_D}{[M^+]}, \tag{11}$$

where $[M^+]$ is the concentration of the common ion (in the present case the cation) calculated from the dissociation constant of the additive (since only a minute proportion of the free M^+ ions in the solution results from dissociation of the reactive ionophore). Simultaneous solution of (10) and (11) enables k_{ion}, k_{ip}, and K_D to be found without the need for conductometric measurements[38,50,82]. It is possible, of course, to use[81,82,103] Eqn. (11) independently of (10).

Table 3. Estimated contributions by free ions and ion-pairs to observed rate constant.

*Approximate values.

Concluding our examination of the kinetic aspect of the joint involvement of free ions and ion-pairs in a reaction, we give some estimates‡ of the contributions by these species to the observed rate constant as functions of k_{ion}/k_{ip} and α, and for clarity values of α for certain dissociation constants and concentrations of the salt most frequently met in practice (Table 3). These data lead to further conclusions: firstly, if ions and ion-pairs differ greatly (10^3–10^4) in reactivity, ions are in effect the sole reactants, even if their proportion does not exceed 1%, a situation characteristic of the reactions of many salts whose dissociation constants exceed 10^{-8} M (e.g. Table 2); secondly, the contribution by ion-pairs becomes considerable only with a relatively small difference in reactivity between the two ionic species ($k_{ion}/k_{ip} \approx 10$) and at very low degrees of dissociation, as is typical of preparative experiments, in which large reactant concentrations are used.

Aggregates of ion-pairs make hardly any contribution to the observed rate constant, so that their role is usually merely to lower considerably the concentration of reactive ion-pairs[65,67]. If the equilibrium between the ion-pairs and their association complexes is displaced towards the latter, the observed rate constant can then be expressed[104]

$$k_{obs} = K_A^{-1/n} k_{ip} n^{-1/n} C^{1/n}, \tag{12}$$

where n is the association factor, K_A the association constant, k_{ip} the true reaction rate constant of the ion-pairs, and c the concentration of the reactant. The slope of the double logarithmic plot of observed rate constant against reactant concentration enables us to determine the association factor n and hence calculate the effective rate constant $k_{eff} = K_A^{-1/n} k_{ip}$[65,67,104]. If by varying the concentration we can bring the system into a region in which the equilibrium is completely displaced towards monomeric ion-pairs, the rate constant k_{ip} determined in this region (in which $k_{eff} = k_{obs} = k_{ip}$) enables us to calculate the equilibrium association constant K_A from k_{eff}[65,67,104].

The calculation is considerably more complicated in systems in which several reactive species are present[36,42,83,94], but this does not prevent determination of their reactivity, though less accurately.

IV. REACTIONS OF CARBANIONS

Reactions in which reactivities of carbanions have been studied, and various factors influencing them have been investigated, include nucleophilic substitution at a saturated carbon atom (alkylation of carbanions), nucleophilic addition (mainly polymerisation of vinyl monomers), and processes involving proton and electron transfer. These four types of reactions will be discussed below.

1. Nucleophilic Substitution

The reactivity of carbanions in nucleophilic substitutions has been studied only on the fluorenyl system (9-RFl^-M^+)[36,37,45,78-82,105]. However, such restriction to a single hydrocarbon has not prevented (and may have helped) establishment of the effects on reactivity of the most diverse

---

† The value of k_{ip} obtained from the intercept relates to all types of ion-pairs present together in the solution: i.e. it can be written in the form (6), where k_i will represent the reactivity of the ith kind of ion-pairs.

‡ These estimates are valid for any pair of ionic species in equilibrium, e.g. for contact and solvent-separated ion-pairs. The only difference is that the calculation of α requires that Eqn. (9) should be replaced by a different formula, representing the given type of equilibrium.

factors—substituents at the anionic centre, the size of the alkali-metal cation, the nature of alkylating and leaving groups, the character of the solvent. The general scheme of the reactions appeared to be

In all cases association of the carbanion with the cation deactivates the nucleophile: with one exception (the reaction of 9-cyanofluoren-9-ylsodium with benzyl fluoride[81,82]—Table 5) the rate constant of the free ion exceeds that of the ion-pair: i.e. $k_{ion}/k_{ip} > 1$. This was to be expected, since the activated complex formed in the reaction of the ion-pair (III) differs from that for reaction of the free carbanion (IV) (coordination of the cation M^+ with the leaving group X^- in the transition state is a special case):

$$M^+C^- \rightarrow M^+C^{\delta-} \ldots C^{\delta+} \ldots X^{\delta-} \quad C^- \rightarrow C^{\delta-} \ldots C^{\delta+} \ldots X^{\delta-}$$

(III) (IV)

The presence of the cation in (III) tends to localise the charge on the carbanion, which prevents formation of a new ethylenic bond or else increases the effective distance between the charged centres of the anion, thereby weakening the Coulombic interaction of the reactants.

Hence the ratio k_{ion}/k_{ip} for a fixed anion structure should increase with the interaction between the ionic moieties of the pair. For contact ion-pairs the ratio may be expected to increase in the sequence $Cs^+ < K^+ < Na^+ <$

Li^+. On the other hand, on passing from contact to solvent-separated ion-pairs, in which the oppositely charged components are a long distance apart, the relative reactivity of the carbanion should decrease considerably. This is indeed the case: in the reactions of the lithium salts of fluorene and of its 9-methyl and 9-phenyl derivatives in dimethoxyethane solution, where their ion-pairs are separated by the solvent, the ratio is only $k_{ion}/k_{ip} = 2$–3[37] (Table 7).

The dependence of the ratio on the size of the cation is different in dimethoxyethane from that in t-butyl alcohol: in the ether the reactivity of the ion-pairs increases in the sequence $Li^+ < Na^+ < Cs^+$[36] (Table 4), but in the alcohol in the sequence $K^+ < Na^+ < Li^+$[81] (Table 5). However, although it can be accepted[36] that contact ion-pairs are present in dimethoxyethane, the situation in t-butyl alcohol is not altogether clear. In any case, this question has not been specially investigated[81], and the possibility of the solvation of ambident anions (as is the anion of methyl fluorene-9-carboxylate) by hydrogen bonding[107] does not exclude the presence of solvate-separated ion-pairs in solutions of the alkali-metal derivatives of this ester.

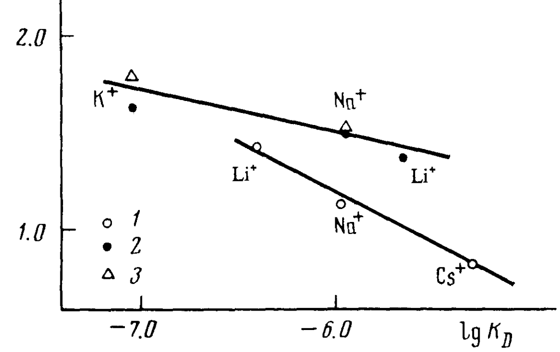

Figure 1. Correlation of relative reactivity of carbanion with dissociation constants of its ion-pairs (Tables 4 and 5): 1) C_2H_5I; 2) $C_6H_5CH_2Cl$; 3) $C_6H_5CH_2Br$.

Nevertheless, the variation of the ratio in one or other system can be predicted from the dissociation constant of the ion-pairs, the parameter which ultimately characterises their stability. Fig. 1 shows double logarithmic graphs of the dependence of k_{ion}/k_{ip} on K_D based on data obtained for the benzylation of alkali-metal salts of methyl fluorene-9-carboxylate with benzyl chloride and bromide in t-butyl alcohol and for the alkylation[36] of alkali-metal salts of 9-cyanofluorene with ethyl iodide in dimethoxyethane. In the latter case the mean value for the three salts investigated $k_{ion} = 0.078\ M^{-1}\ s^{-1}$ was used for the correlation, with a correction for the involvement of the sodium salt of solvent-separated ion-pairs[80]. The linearity of the graphs indicates the existence for these systems of a free-energy relation of the type

$$\lg \frac{k_{ion}}{k_{ip}} = A + B \lg K_D , \qquad (14)$$

while the negative slopes suggest that the reactivity of an ion-pair decreases with increase in the interaction between its components, as had been postulated for the transition state (III). Results for the action of benzyl chloride and bromide on alkali-metal salts of methyl fluorene-9-carboxylate lie on the same graph, which indicates a parallel variation in the reactivity of ions and ion-pairs in both processes. A relation of type (14) is satisfied for certain other nucleophilic substitutions[94].

A formal kinetic interpretation of the reactivity of the anion, with the aim of explaining why it may exceed considerably that of ion-pairs in the benzylation of alkali-metal salts of 9-substituted fluorenes, but also may have the same activity ($k_{ion}/k_{ip} \approx 1$), has been based[81,82] on the scheme

$$\begin{tikzcd}
M^+C^- + RX \arrow[r, shift left, "k^1_{ip}"] \arrow[d, shift right, "K_D"'] & (\text{Complex})_1 \arrow[l, shift left, "k^{-1}_{ip}"] \arrow[r, "k^2_{ip}"] & CR + MX , \\
M^+ + C^- + RX \arrow[u, shift right] \arrow[r, shift left, "k^1_{ion}"] & (\text{Complex})_2 \arrow[l, shift left, "k^{-1}_{ion}"] \arrow[r, "k^2_{ion}"] & CR + MX .
\end{tikzcd} \qquad (15)$$

With reversible formation of intermediate complexes, which can be termed specific solvation of one reactant by the other or e.g. coordination of the cation by the leaving group, k_{ip} and k_{ion} will actually become respectively $k^1_{ip}k^2_{ip}/(k^{-1}_{ip} + k^2_{ip})$ and $k^1_{ion}k^2_{ion}/(k^{-1}_{ion} + k^2_{ion})$. It is clear that, with operation of the mechanism (15), the ratio k_{ion}/k_{ip} will be determined by the relations between the rate constants of the individual stages; it can vary within wide limits, and be either greater or less than unity.

The influence of the medium on the reactivity of the 9-cyanofluoren-9-ide anion can be traced in its reactions with ethyl iodide[45,80,105] (Table 4) and with benzyl halides[81,82,105] (Table 5). A distinguishing feature of the first reaction is the absence of a clear effect of the dielectric constant, which is typical of nucleophilic substitution[109]. Thus the rate constant has the same value in dimethoxyethane and in hexamethylphosphoramide ($\epsilon = 7.2$ and 30 respectively[110]); on the other hand, it decreases on passing from dimethylacetamide, dimethylformamide, and acetonitrile to ethanol (37.8, 36.7, 37.5, and 24.5[110]). This type of effect of the medium is usually interpreted in terms of the degree of solvation of the reactants and the activated complex[109].

Since the rate constant for the reaction of the 9-cyanofluoren-9-ide anion with ethyl iodide falls in parallel with the shift of the absorption band maxima of the anion to shorter wavelengths[45], it can reasonably be assumed that the factor determining the reactivity of a nucleophile is its degree of solvation. The observed sequence of variation in the solvating power of solvents

DME ≈ HMPA < DMAA < DMFA < DMSO < ethanol

characterises the solvation of the most diverse anions[109], both typically "hard" (Cl^-, N_3^-, CN^-, Br^-) and typically "soft" (SCN^-, I^-). Increase in the solvating power of dipolar aprotic solvents for these species is accompanied by decrease in the logarithm of the activity coefficients of the anions $\lg\gamma_{Y^-}$, the variation in the logarithm for each anion being almost the same in character despite the difference in absolute magnitude[109]. This enables us to compare the reactivity of the 9-cyanofluoren-9-ide anion with the logarithm for other anions (Fig. 2). In the present case we have used values of $\lg\gamma_{Y^-}$ for the thiocyanate ion, which probably resembles the 9-cyanofluoren-9-ide anion in softness, although analogous correlations exist with the logarithm for other anions. The linear dependence of

$2 + \lg k_{\mathrm{ion}}$ on $\lg \gamma_{\mathrm{SCN^-}}$ for four solvents (Fig. 2) is a further confirmation of the dominant role of solvation particularly of the anion. The misplacement of the point for acetonitrile is probably due to some specific effects of solvation of the activated complex.

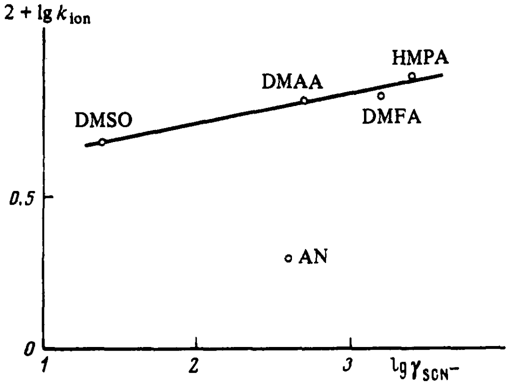

Figure 2. Correlation of reactivity of 9-cyanofluoren-9-ide anion with activity coefficients $\lg \gamma_{\mathrm{SCN^-}}$ in a series of dipolar aprotic solvents.

The rate constant k_{ion} for the reaction with ethyl iodide decreases by a factor of 6 on passing from dimethoxyethane to ethanol (Table 4). The effect of the solvent is considerably stronger in the reactions with benzyl halides: the ratio of the rate constant in t-butyl alcohol to that in ethanol is respectively 32 and ~ 50 for benzyl chloride and bromide (Table 5). Operative factors here are probably the lower solvating power of the higher alcohol and its lower dielectric constant (11.2 and 24.5[110]). It is also possible that the activated complex is differently solvated by alcohols in the reactions of the anion with benzyl halides and with primary alkyl halides[109].

The reactivity of a carbanion (indeed of any other species) depends mainly on its stability, which may be measured by the pK_a of the original CH-acid. Apart from this, we can compare the actual rate constants of the carbanion with dissociation constants of its ion-pairs[46,52] and also with its anodic oxidation potential[111]. In reactions of anions of 9-substituted fluorenes with butyl bromide in dimethoxyethane the rate constant k_{ion} increases as the hydrocarbon becomes less acidic (Table 7), while the graph of the dependence of $\lg k_{\mathrm{ion}}$ on pK_a is a straight line of slope 0.35.[37] The rate constant increases also with decrease in the dissociation constant of contact ion-pairs (lithium salts of 9-cyanofluorene and methyl fluorene-9-carboxylate—Table 7). In reactions with benzyl halides (Table 7), however, change in the character of the substituent at the anionic centre has hardly any effect on the reactivity of the nucleophile[81,82]. This was explained[81] in terms of the transition state, in which rupture of the carbon–halogen bond occurred to a considerably greater extent than formation of a new carbon–carbon bond. However, these deductions are in no way supported by kinetic data.

On the other hand, the increase in the rate constant for reaction of the 9-cyanofluoren-9-ide anion with benzyl chloride and bromide, on the introduction of electron-donor and electron-acceptor substituents in *meta*- and *para*-positions[105] (Table 6), presupposes synchronous rupture of the old bond and formation of the new. In this case the transition state is stabilised both by acceptors (which increase the degree of rupture of the carbon–halogen bond in comparison with the degree of formation of the carbon–carbon bond) and by donors (which increase the degree of formation of the new bond in comparison with the degree of rupture of the old bond)[105]. This transition state corresponds to a mechanism of nucleophilic substitution intermediate between S_N1 and S_N2. This would be supported by the absence of a first-order reaction with respect to the electrophilic reagent, but measurements were made[105] at only one concentration of the benzyl halide.

Reaction velocities both of free anions and of their ion-pairs are strongly dependent on the character of the leaving group and on the alkyl group. The general rules are the same for alcohols and for dimethoxyethane: $F < Cl < Br$[81,82]; $Cl < Br < I$[36,105]; $C_6H_5CH_2 \gg CH_3 > C_2H_5 > \text{iso-}C_3H_7 > \text{t-}C_4H_9$;[105] and $CH_3 > C_2H_5 > C_3H_7 > C_4H_9$.[36] Thus the rate increases as the carbon–halogen bond becomes weaker and decreases with diminution in the effective positive charge on the α carbon atom and with intensification of the steric hindrance to attack by the nucleophile due to introduction of α-alkyl groups. Variations in $k_{\mathrm{ion}}/k_{\mathrm{ip}}$ in the reactions of carbanions and their ion-pairs are usually successfully interpreted[36,105] in terms of Pearson's principle[112] of hard and soft acids and bases.

2. Proton Transfer

Very great interest has been taken in proton-transfer reactions, so that many researches have been undertaken on them. We shall consider firstly studies in which the nature of the reactant species has been accurately established, and quantitative information obtained on their reactivity. We note at once that available data are largely contradictory, and the general picture is by no means clear.

Table 8. Rate constants for the reactions of polystyrylsodium and -potassium with triphenylmethane[38] at 25° C.

Cation	Solvent	k_{ion}, $M^{-1}\,s^{-1}$	k_{ip}, $M^{-1}\,s^{-1}$	$\frac{k_{\mathrm{ion}}}{k_{\mathrm{ip}}}$
Na^+	oxolan	178	0.15	1190
Na^+	DME	138	11	12.5
K^+	oxolan	142	<0.2	>710

Smid has investigated several proton-transfer reactions in which CH-acids act as donors, and alkali-metal salts of such acids as acceptors[17,38,113]. In the reactions of triphenylmethane with polystyrylsodium in oxolan and dimethoxyethane and with polystyrylpotassium in oxolan[38] the free anions possess the greatest reactivity, with closely similar rate constants in the two solvents (Table 8).

Since k_{ip} cannot be determined accurately, it is difficult to know how the cation influences the reactivity of the ion-pairs. On the other hand, the considerable increase in k_{ip} on passing from oxolan to dimethoxyethane suggests that solvent-separated are more active than contact ion-pairs, since the proportion of the latter is considerably higher in dimethoxyethane[43,83]. Thus the reactivity of the ionic species of "living" polystyrene towards triphenylmethane increases in the sequence from the contact to the solvent-separated ion-pair and then to the free carbanion.

Investigations on the reactions of the lithium, sodium, caesium, and tetrabutylammonium salts of fluorene with 1,2- and 3,4-benzofluorenes in oxolan, dimethoxyethane, and dioxan were more qualitative in character[17]. In almost all cases the observed rate constant increases with the concentration of the fluorenide, which would appear to prove that the free fluorenide anion is the most reactive. However, this increase is considerably larger than is to be expected for a mechanism of simultaneous involvement of ions and ion-pairs in the reaction. Thus for the reaction of fluorenyl-lithium with 3,4-benzofluorene in oxolan the constant increases by a factor of 60 when the concentration of the lithium salt is diminished by a factor of 260,[17] although at most a 16-fold increase would have been expected. In the reaction of 1,2-benzofluorene with the sodium salt of fluorene in dioxan the constant increases by a factor of 23 when the concentration of the salt decreases by a factor of 35.

The results were explained[17] on the hypothesis that ion-pairs of fluorenyl-lithium and fluorenylsodium associate, with possible formation in dioxan of aggregates of five ion-pairs, although this postulate is inconsistent with these workers' own conductivity measurements on the salts[11,15,16]. In the reaction of the caesium salt of fluorene with 1,2-benzofluorene in oxolan and dioxan the rate constant increases very moderately with dilution, which is consistent with the simultaneous participation of ions and ion-pairs in detaching the proton[17]. In this case the caesium contact ion-pair is less reactive than the fluorenide anion. A solvent-separated ion-pair may be either more or less reactive than a contact ion-pair depending on the solvent (dimethoxyethane or oxolan)[17].

There are many obscurities also in an investigation[114] on the protonation of the lithium and sodium salts of 1,3-diphenylpropene by fluorene in oxolan, 2,5-dimethyloxolan, and 2,3-dihydropyran. In oxolan the sodium salt has almost thousandfold the activity of the lithium salt. In this solvent 1,3-diphenylallyl-lithium comprises solely solvent-separated ion-pairs, whereas 1,3-diphenylallylsodium is a mixture of loose and intimate ion-pairs. From this it was concluded that contact ion-pairs are considerably more reactive[114]. On the other hand, in 2,5-dimethyloxolan, in which both salts are present only as contact ion-pairs, the difference in reactivity reaches a factor of almost 10^5: the rate constants at 23°C are respectively ~ 0.002 and 195 M^{-1} s^{-1} for lithium and sodium. No allowance was made for the role of free ions (although measurements were made at concentrations of 10^{-4}–10^{-3}M) or association complexes of ion-pairs of 1,3-diphenylallyl-lithium, whose formation is very likely in this system. The exotic structure suggested[114] for the intermediate complex is frankly speculative.

In spite of some uncertainty in the reactivities of the ionic species, the results obtained by Smid[17,38,113] indicate that the rate constant for proton transfer from a CH-acid to a carbanion is independent of the difference in pK_a between the donor and the conjugate CH-acid of the carbanion. In the reaction of the polystyryl anion with triphenylmethane in oxolan we have[38] $k_{ion} \approx 150\,M^{-1}\,s^{-1}$ with $\Delta pK_a \approx 3.5$. On the abstraction of a proton by the fluorenide anion from 9-methylfluorene under the same conditions[38] $k_{ion} \approx 100\,M^{-1}\,s^{-1}$ with $\Delta pK_a \approx 0$. Less obviously the observed rate constants[38] for protonation of the dianion of 1,1-diphenylethylene by 9-propylfluorene ($\Delta pK_a \approx 10$) and of fluorenylsodium by 1,2-benzofluorene (~ 2) are approximately 20 and 10^3 M^{-1} s^{-1} (in oxolan at 25°C).

A similar conclusion was reached by Ritchie[115], who investigated proton transfer between CH-acids and carbanions in dimethyl sulphoxide[115-118]. In this solvent alkali-metal salts of CH-acids are probably completely dissociated at low concentrations, so that the observed rate constants can be regarded as those of the free carbanions. At high concentrations of the salts, however, ionic association begins to influence the rate of proton transfer. Thus for fluorene and fluorenyl-lithium in dimethyl sulphoxide at 25°C at a salt concentration of ~ 0.5M the proton-exchange rate constant is ~ 0.5 M^{-1} s^{-1}.[119] Yet the rate constants for proton transfer between substituted fluorenes and their carbanions at concentrations of $\sim 10^{-4}$M vary over the range 10^3–10^4 M^{-1} s^{-1}.[116-118] It is quite possible that not only ion-pairs but also their aggregates are present at high concentrations of fluorenyl salts even in such a polar solvent as dimethyl sulphoxide.

Association plays an especially important part in the reactions of alkyl-lithium compounds. In the metallation of triphenylmethane in oxolan the reactivity of the lithium alkyls is determined not by their basicity or the acidity of the original CH-acids but by the stability of the aggregates[120,121]. With the concentration of the alkyl-lithium compound 0.1M the relative metallation rate constant increases in the sequence from methyl (1.0), vinyl (4.2), phenyl (6.3), n-butyl (23), allyl (90), to benzyl (450); the corresponding sequence at 0.01M concentration increases from methyl (1.0), phenyl (2.8), vinyl (4.3), allyl (14), n-butyl (20), to benzyl (150).

Table 9. Kinetic parameters[122,123] of the protonation of the benzyl anion and its ion-pairs in oxolan at 24°C.

Donor	Cation	$10^{-8}k_{ion}$, M^{-1} s^{-1}	$10^{-8}k_{ip}$, M^{-1} s^{-1}	$\frac{k_{ip}}{k_{ion}}$
H_2O	Na^+	0.53	55	104
MeOH	Li^+	2.3	3.4	1.5
MeOH	Na^+	2.3	58	25
MeOH	Bu_4N^+	2.3	6.0	2.6
EtOH	Na^+	1.4	37	26
EtOD	Na^+	1.2	21	17.5
t-BuOH	Li^+	0.16	9.7	61
t-BuOH	Na^+	0.16	13	81
t-BuOH	Bu_4N^+	0.16	4.6	29

The technique of pulsed radiolysis[122,123] has enabled rate constants to be determined for the very fast reactions involving protonation of the benzyl anion and its anion-pairs by various proton-donor compounds in oxolan. Benzyl anions were formed on the irradiation of solutions containing dibenzylmercury; in the presence of sodium tetraphenylborate[122] or of lithium or tetrabutylammonium perchlorate[123] their cations combine rapidly (in the case of the sodium ion the rate constant is 1.5×10^{11} M^{-1} s^{-1}) with benzyl anions to form the corresponding ion-pairs. Whether or not these salts are present the solutions contain only one ionic species, which facilitates considerably analysis of the kinetic data.

The results are quite remarkable (Table 9). Firstly, the reactivity of the ionic species increases with the acidity of the alcohol (definite rules of this type are not found in protonations involving CH-acids as donors[38,115-118]). Secondly, the rate constants for protonation of the carbanion are far smaller than the values typical of diffusion-limited processes (e.g. for detachment of a proton by the conjugate bases of NH- and OH-acids[124]). Finally, the most interesting result is that ion-pairs are considerably more active than the free carbanions. The explanation advanced[122] for this last fact was that a transition from the delocalised (benzyl) anion to an anion having a very high degree of localisation of negative charge (an oxo-anion, RO^-) takes place during the reaction. The activated complex, which will be characterised by greater charge localisation than in the original carbanion because of the involvement of an oxygen atom donating a proton, should be more stable in the presence of a cation because of the Coulombic interaction energy. From this point of view stabilisation of the activated complex by the cation would not be expected during protonation of carbanions by CH-acids, which is consistent with Smid's observations[38].

When the stability of the benzyl type of anion is enhanced, e.g. by the introduction of electron-accepting substituents into the ring, the rate constants for protonation by water and alcohols decrease[125]. Thus k_{ion} for the reaction of $C_6F_5CH_2^-$ with water and methanol in oxolan is respectively 3.3×10^6 and 1.2×10^6 M^{-1} s^{-1}. In this case, however, not only does the absolute reactivity of the carbanion decrease but the relative reactivities of the ionic species are reversed. The sodium ion-pair of the perfluorinated benzyl anion reacts at little more than one-tenth of the speed of the carbanion $k_{ip} = 4.3 \times 10^5$ M^{-1} s^{-1}. The results obtained are not yet sufficient to explain the divergence from the results for protonation of the unsubstituted benzyl anion[122,123].

The stereochemistry of protonation may provide information on the nature of the reactant species. Thus in the protonation[126] of the lithium and sodium salts of 9,10-dialkyl-9,10-dihydroanthracene in ether, oxolan, and hexamethylphosphoramide contact ion-pairs give a *cis*-product, whereas loose ion-pairs and free carbanions yield a *trans*-product.

3. Electron Transfer

Although the oxidation of carbanions is quite widely used for preparative purposes[127,128], hardly any kinetic study has been made of these processes. Quantitative information on the reactivity of ions and ion-pairs has been obtained only for oxidation of the sodium salts of 9-substituted fluorenes (with cyano, methoxycarbonyl, benzoyl, methylsulphonyl, phenylsulphonyl as substituent) by molecular oxygen in t-butyl alcohol and its mixtures with dimethyl sulphoxide[82,103,129], in which fluorenone is formed in at least 85% yield independently of the nature of the substituent. Even in this case, however, the kinetic parameters (Table 10) cannot be regarded as absolutely reliable, since corrections could not be made for salt effects due to sodium perchlorate and tetraphenylborate added§ to the reaction medium. The absence of a dependence of k_{ion} and k_{ip} on the stability of the carbanions (which may be measured by the pK_a of the original [substituted] hydrocarbon—CN 11.4,[108] $COOCH_3$ 12.9,[108] $SO_2C_6H_5$ 15.0[81]), as well as the variation of the ratio k_{ion}/k_{ip} from values exceeding unity ($R = SO_2C_6H_5$) to values less than unity (R = CN), suggests a mechanism of type (15).[82] As a consequence of the formation of an unstable intermediate product (though of unknown structure) in the oxidation of sodium methoxycarbonylfluoren-9-ide, the rate of appearance of fluorenone is only 2% of the rate of consumption of the salt[82]. The greater reactivity of the ion-pair than of the carbanion may be due[82] to involvement of the cation in stabilising the transition state (R = CN), although this may be hindered by bulky substituents at the reaction centre ($R = SO_2C_6H_5$).

Table 10. Kinetic parameters[82,103] of the oxidation by molecular oxygen of the sodium salts of 9-substituted fluorenes (9-RFl^-Na^+) at 30°C.

Solvent	R	10^4k_{ip}, s^{-1}	10^4k_{ion}, s^{-1}	$\frac{k_{ion}}{k_{ip}}$
$t\text{-}C_4H_9OH$	CN	83	60	0.72
$t\text{-}C_4H_9OH$	COOMe	160	—	~1
$t\text{-}C_4H_9OH$	SO_2Ph	0.75	13	17.3
$t\text{-}C_4H_9OH$ + 1 M DMSO	CN	3.73	0.69	0.185
$t\text{-}C_4H_9OH$ + 1 M DMSO	SO_2Ph	0.195	1.34	6.9

The rate of oxidation of the 2-phenyldibiphenyleneallyl carbanion by molecular oxygen is greatly influenced[130] by the form in which the ion exists in solution (free or paired with an alkali-metal cation). The increase in the relative rate of oxidation in the sequence from dimethyl sulphoxide and dimethylformamide (1), pyridine (50), dimethoxyethane (~ 570), oxolan (2100), 2-methyloxolan (50 000), to diethyl and di-n-butyl ethers (> 10^5), i.e. with decrease in dielectric constant and solvating power, suggests that the most reactive species is the contact ion-pair.

In the oxidation by molecular oxygen of the triphenylmethyl anion[131,132], formed in small quantities in the presence of alkali-metal hydroxides or alkoxides, however, ion-pairs probably possess insignificant activity. In any case this provides an interpretation of the increase in the relative reaction velocity in the sequence[131] from t-butyl alcohol (< 1) through 80% pyridine–t-butyl alcohol (2), 80% dimethylformamide–t-butyl alcohol (39), 80% dimethyl sulphoxide–t-butyl alcohol (110), and 80% hexamethylphosphoramide–t-butyl alcohol (128) to hexamethylphosphoramide (> 230) or the acceleration of the process by additions of dicyclohexyl-18-crown-6.[132] Similarly, the rate of oxidation of 9-phenylfluorene, 9-methylfluorene, and 1,1-diphenylethane in the presence of potassium t-butoxide increases on passing from t-butyl alcohol to hexamethylphosphoramide[131]. It is interesting, however, that, when nitrobenzene is used as oxidant[132], the ion-pairs of the triphenylmethyl anion become more reactive than the free carbanion.

The oxidation by aromatic nitro-compounds (nitrobenzene, *m*-dinitrobenzene, *p*-nitrobenzonitrile, and 1,3,5-dichloronitrobenzene) of anions of 9-substituted fluorenes[133,134] (with methoxyl, methyl, isopropyl, amino, and

---

§ For the determination[82,103] of reaction rate constants of ions and ion-pairs the degree of dissociation of the sodium salts was varied by adding the perchlorate and the tetraphenylborate: i.e. the calculations were based on an equation of type (11).

hydroxyl as substituent), formed in the presence of alkali-metal and tetra-alkylammonium methoxides in methanol, is represented by the scheme

$$\begin{gathered} RH + B^- \rightleftarrows R^- + BH, \\ R^- + PhNO_2 \rightrightarrows R^\cdot + PhNO_2^{\dot{-}}, \\ R^\cdot \rightarrow {}^1/_2\,R{-}R, \\ PhNO_2^{\dot{-}} \rightarrow {}^2/_3\,PhNO_2 + {}^1/_2\,PhNO^{\dot{-}}, \\ PhNO^{\dot{-}} + R^\cdot \rightarrow \text{Nitrone}. \end{gathered} \qquad (16)$$

The complicated mechanism prevents determination of rate constants for individual stages. The rate of consumption of 9-methoxyfluorene in the presence of nitrobenzene decreases[134] in the sequence of methoxides

potassium > tetramethylammonium ≈ lithium.

4. Nucleophilic Addition

Quantitative information on the reactivity of the carbanions and their ion-pairs has been obtained for addition to a double bond[42,43,50,65,67,68,82-102,135,136] and for the cleavage of cyclic oxides of alkenes[33,137,138]. Current views on the influence of various factors on the kinetics and the mechanism of reactions involving carbanionic species are based primarily on results obtained by Szwarc and his coworkers[85-88] in an investigation of the anionic polymerisation of vinyl monomers, i.e. addition to a double bond. We shall consider only the main rules characterising these processes.

Table 11. Reaction rate constants of free ions and ion-pairs in the anionic polymerisation of alkenes at 25° C.

Anion*	Solvent	k_{ip}, $M^{-1}\,s^{-1}$					k_{ion}, $M^{-1}\,s^{-1}$	Ref.
		Li^+	Na^+	K^+	Rb^+	Cs^+		
Polystyryl	cyclohexane	—	—	7.7	22.5	19	—	67
Polystyryl	benzene	—	—	47	24	18	—	65
Polystyryl	dioxan	0.9	3.4	20	21.5	24.6	—	139
Polystyryl	oxan**	19.5	17.5	30	40	—	130 000	140
Polystyryl	oxolan	160	80	~50	~50	~22	65 000	50

Polyisoprenyl	oxan**	0.20	—	—	—	—	2 800	92

*The polystyryl, poly-*p*-methoxystyryl, poly-*o*-methylstyryl, poly-α-methylstyryl, and polyisoprenyl anions react respectively with styrene, *p*-methoxystyrene, *o*-methylstyrene, α-methylstyrene, and isoprene.

**Measurements made at 30° C.

Addition of an alkene molecule to an active chain-growth centre leads every time to reproduction of the centre, so that we can regard anionic polymerisation of an alkene (neglecting effects of the polymer chain, which have little significance in the formation of a carbon-chain polymer[85]) simply as a reaction of the type

$$\geqslant C^-M^+ + \rangle C{=}C\langle \;\rightarrow\; \geqslant C^-M^+, \qquad (17)$$

where $\geqslant C^-M^+$ denotes an alkali-metal salt of a CH-acid capable of reacting either as a free ion, an ion-pair, or any other more complicated ionic species (Eqns. 1–3). Table 11 gives the most characteristic rate constants k_{ion} and k_{ip} obtained for the polymerisation of vinyl monomers (more complete information can be obtained from the above references).

The anionic polymerisation of alkenes is characterised by large differences in reactivity between free carbanions and contact ion-pairs: in solvents in which few if any solvate-separated ion-pairs are present (dioxan, oxolan, oxan, 2-methyloxolan) k_{ion} exceeds k_{ip} by factors of 10^3–10^4 (Table 11). On passing to solvents possessing a high solvating power for alkali-metal cations (dimethoxyethane, glymes), however, values of k_{ip} increase sharply[89,93], because of the higher proportion of solvent-separated ion-pairs, whose reactivity is as much as 30–50% of that of the free carbanions[42,43,83].

The presence of both loose and close ion-pairs in solution sometimes leads to an anomalous temperature variation of k_{ip}. Thus lowering the temperature from 50 to 0° C leads to an increase in k_{ip} for the reaction of polystyrylsodium with styrene in dimethoxyethane[83], and only at lower temperatures does the activation energy acquire the normal positive value. This is because the activation energy E_a determined from the Arrhenius dependence includes not only the true activation energy for the reaction of solvent-separated ion-pairs E_s but also a negative quantity ΔH_1 representing the equilibrium between ion-pairs: $E_a = E_s + \Delta H_1(1 - K_1)^{-1}$. The contribution by contact ion-pairs is insignificant, since their reactivity is only 0.1–0.01% of that of solvent-separated ion-pairs, and can be neglected[83]. The activation energy E_a can be either positive or negative depending on the absolute values of E_s and ΔH_1, as well as the value of K_1 at the given temperature.

If the solvent is unable to separate the ion-pairs, the Arrhenius graph will be linear[83,43,95]. The measured k_{ip} constants then represent the reactivity only of contact ion-pairs. For the polymerisation of styrene in dioxan k_{ip} increases[139] in the sequence

$$Li^+ < Na^+ < K^+ < Rb^+ < Cs^+,$$

since increase in the size of the alkali-metal cation facilitates separation of the ionic fragments in the transition state; in this case $\lg k_{ip}$ is a linear function of $(r_{M^+} + 2)^{-1}$, where r_{M^+} is the radius of the cation. On polymerisation of the same monomer in cyclohexane and benzene, in which ion-pairs are definitely of the contact type[65,67], or of α-methylstyrene in dioxan[91], no definite tendency for k_{ip} to vary with the cationic radius is observed, which suggests that other factors are operating, besides the energy of electrostatic interaction between carbanion and gegenion.

It is noteworthy that the characteristics of the solvent—its dielectric constant and solvating power—do not in fact affect the reactivity of contact ion-pairs (Table 11). Rubidium and caesium ion-pairs react at almost the same rate in the polymerisation of styrene in cyclohexane, benzene, dioxan, oxan, and oxolan. Only with the sodium and lithium salts does k_{ip} increase in the sequence dioxan < oxan < oxolan, but this is now due to the participation of solvent-separated ion-pairs in the reaction. It may therefore be assumed that chain growth, like many other bimolecular reactions, involves formation of an intermediate complex, whose conversion into the product is the limiting stage. A similar complex is probably formed also in the reaction between the alkene and the free carbanion. In any case, k_{ion} also does not depend explicitly on the nature of the solvent[96]: in hexamethylphosphoramide, dimethoxyethane, oxolan, oxan, 2-methyloxolan, mixtures of oxolan with dioxan and with benzene, and oxepan it has the respective values 92 000,[42] 40 000,[83] 65 000,[50] 130 000,[140] 30 000,[97] 60 000,[98] 40 000–70 000,[99] and 100 000 [100] $\mathrm{M^{-1}\,s^{-1}}$. We can compare, for example, hexamethylphosphoramide and oxepan: in these solvents the polystyryl anion has almost the same reactivity (k_{ion} = 92 000 [42] and 100 000 [100] $\mathrm{M^{-1}\,s^{-1}}$), although the dielectric constants—30 [110] and 5.06 [100]—differ sixfold. Solvation of the carbanion would obviously play an insignificant part, although it has been adduced[89,90] to explain the effect of an electric field on the rate of the anionic polymerisation of substituted styrenes.

Studies have appeared recently[68,69,136] on the anionic polymerisation of vinyl monomers in the presence of cations of bivalent metals, but analysis of the kinetic data is made difficult by the formation of association complexes and the two-stage mechanism of the dissociation of alkaline-earth metal salts.

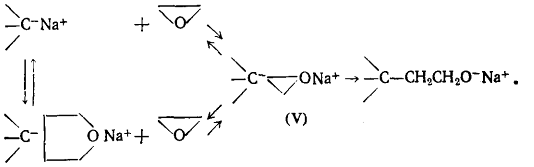
The polymerisation of 2-vinylquinoline[101] and of 2-, 3-, and 4-vinylpyridines[102,135] yields polymers capable of solvating the alkali-metal cation of an ion-pair to a greater extent than the monomers. Furthermore, the nitrogen atom of the pyridyl group is involved in delocalisation of the negative charge[135]: i.e. the growing anion is ambident. The combination of these effects leads to rules characterising the reactivity and the electrical conductivity of alkali-metal salts of these "living" polymers that differ from those observed for such salts of the polystyryl anion.

Table 12. Kinetic parameters[82] of the reactions of sodium salts of 9-substituted fluorenes (9-$\mathrm{RFl^-Na^+}$) with acrylic esters in t-butyl alcohol at 30° C.

Methyl ester	R	10^3k_{ip}, $\mathrm{M^{-1}\,s^{-1}}$	10^3k_{ion}, $\mathrm{M^{-1}\,s^{-1}}$	$\frac{k_{\mathrm{ion}}}{k_{\mathrm{ip}}}$
Acrylate	CN	760	760	1
Acrylate	COOMe	1700	1700	1
Acrylate	$\mathrm{SO_2Ph}$	1600	1600	1
Methacrylate	CN	8.6	8.6	1
Methacrylate	COOMe	10	400	40
Methacrylate	$\mathrm{SO_2Ph}$	34	2200	65
Crotonate	CN	5.2	5.2	1
Crotonate	COOMe	7.6	70	9
Crotonate	$\mathrm{SO_2Ph}$	6.7	690	103

Whereas free carbanions are far more active than contact ion-pairs in the polymerisation of vinyl monomers, these species have in most cases the same reactivity in the reactions of the sodium salts of 9-substituted fluorenes (9-$\mathrm{RFl^-Na^+}$) with methyl acrylate, methacrylate, and protonate in t-butyl alcohol[82] (Table 12). Formation of the Michael product is assumed to have a mechanism of type (15). The variation of the reactivity of the acrylic esters is due both to polar factors and to steric factors (e.g. resulting from introduction of a methyl group).

The formation of intermediate complexes of carbanions and their ion-pairs with electrophiles, leading to a mechanism of type (15), is assumed in nucleophilic substitutions[82], in nucleophilic additions[52,137,138], and in electron-transfer processes[82]. However, it is by no means always possible to detect them: usually only kinetic evidence is available. Such a complex can be detected spectroscopically in the reaction of sodium 9-methylfluoren-9-ide with oxiran[137] in oxan and oxolan at −30° C. The intermediate complex (V) is actually formed by separation of a contact ion-pair by a reactant molecule or by displacement of a solvent molecule from a solvent-separated ion-pair:



(18)

The presence in the epoxide molecule of two centres—electrophilic (a carbon atom) and nucleophilic (the oxygen atom)—makes a push–pull mechanism possible in this reaction[52,137,138], which may be so efficient that the reactivity of the contact type of ion-pair will exceed considerably that of the free carbanion[52,138]. Such is the situation e.g. in the cleavage of the epoxide ring of fluoradenylsodium in oxiran solution[138]. The observed rate constant increases with the concentration of the salt and with the introduction of excess of sodium tetraphenylborate. On the other hand, on the addition of solvating additives—crown polyethers and cryptate (diazahexaoxobicyclic polyether $[\mathrm{N(CH_2CH_2[OCH_2CH_2]_2)_3N}]$)—the rate constant drops sharply. Reaction of the lithium salt of fluoradene is characterised by similar rules. However, the caesium salt is extremely unreactive, perhaps because the large caesium cation is only slightly electrophilic.

Table 13. Kinetic parameters[52] of the reactions of alkali-metal salts of carbanions with oxiran in oxolan at 25° C.

Anion	Cation	k_{ip}, $\mathrm{M^{-1}\,s^{-1}}$	k_{ion}, $\mathrm{M^{-1}\,s^{-1}}$	$\frac{k_{\mathrm{ion}}}{k_{\mathrm{ip}}}$
Polytolanyl	$\mathrm{Na^+}$	0.065	1.1	17
Polystyryl	$\mathrm{Li^+}$	$7.2\cdot10^3$	~200	0,03
Polystyryl	$\mathrm{Na^+}$	13,8		13
Polystyryl	$\mathrm{K^+}$	6.0		33
Polystyryl	$\mathrm{Rb^+}$	3.4		57
Polystyryl	$\mathrm{Cs^+}$	1.7		122
Poly-α-methylstyryl	$\mathrm{Na^+}$	120	2900	24

The importance of the size of the alkali-metal cation for a push–pull mechanism of ring cleavage in oxiran follows also from the data[52] in Table 13. Although the increase in k_{ip} with decrease in cationic size from caesium to sodium in the salts of the polystyryl anion might indicate formally an increase in the contribution by solvent-separated ion-pairs, the sharp drop in k_{ip} on passing to the lithium salt ($k_{\mathrm{ion}}/k_{\mathrm{ip}} \approx 0.3$) can result only from electrophilic collaboration of the lithium cation. The difference in relative reactivities of the carbanions on reaction with the epoxide and with the alkene also suggests that the cation plays an important part in the transition state: in the former case $k_{\mathrm{ion}}/k_{\mathrm{ip}}$ varies between 10 and 100 (Table 13), but in the latter between 1000 and 10 000 (Table 11).

The reactivities of the polystyryl, polytolanyl, and poly-α-methylstyryl anions towards oxiran may be measured by the dissociation constants of their sodium salts[52]: k_{ion} is greater the smaller is K_{D}, and the dependence of lgk_{ion} on lgK_D' is linear. Thus the dissociation constant reflects the stability of these species, as in the case of the anions of 9-substituted fluorenes.

The Structural Factors and Reactivity of Biphenyl

A.P.Zaraiskii

Data on the structure, conformations, and reactivity of biphenyl in solutions have been examined critically and the importance of the conformational factor for the reactivity of biphenyl is repudiated.
The bibliography includes 103 references.

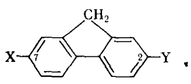
I. INTRODUCTION

The electrophilic substitution and displacement reactions involving a substituent in the 4-position in biphenyl have been widely investigated. A careful study by Stock and Brown[1] has shown that in reactions of this kind biphenyl does not obey the Selectivity Relations for the SE reactions of a series of monosubstituted benzenes. The behaviour of biphenylylene systems (I) in transmitting the electronic influences of substituents to the reaction centre in the 4-position is also unusual. Their capacity for transmitting such effects is greatly reduced compared with the corresponding phenylene and certain bridged structures, where the aromatic rings are separated by an atom with a lone electron pair[2,3]:

(I)



(II)

The cause of most of these specific phenomena has been recognised[1,2] as the non-coplanarity of the aromatic rings of biphenyl in solution, which may appreciably disrupt the conjugation between them. The possibility of the system becoming coplanar in the transition state has been regarded as significant[1,2]. In particular, a confirmation of this hypothesis has been seen in the greater reactivity of the 2-position of the planar fluorene molecule (II, X = Y = H) when account is taken of the possible influence of the methylene units and also, seemingly, in the fact that fluorene obeys satisfactorily the Selectivity Relations for a series of monosubstituted benzenes[1]. On the other hand, the possibility of different degrees of conjugation between the non-attacked ring and the reaction centre as a function of a measure of the electrophilic properties of the reactant has been postulated for biphenyl[4-6]. The conformational factor was not regarded as of decisive importance[5,6], but the evidence for this was probably insufficient[1,6].

II. CONFORMATIONAL ANALYSIS OF BIPHENYL

Numerous studies have been devoted to the problem of the steric structure of biphenyl. In the crystalline state the benzene rings are located in the same plane[7-15]. The rings in the biphenyl molecule in the vapour state are not in the same plane and the dihedral angle between their planes is 42–45°.[16-19] The non-planar conformation of the isolated molecule has been explained theoretically as a consequence of the repulsion of atoms not linked by valence forces[20-31].

Direct X-ray and electron diffraction methods, which are effective in the determination of the conformations in the crystalline and vapour states of biphenyl, are unsuitable for its solutions. The results obtained by other methods are contradictory, but the reasons for this have not been discussed. The appreciably lower degree of displacement from coplanarity or even the absence of coplanarity for the molecule in solution compared with the vapour state can be readily accounted for. The low energy barrier to the rotation of the biphenyl rings from the equilibrium to the planar disposition, which amounts to 0.4–4.0 kcal $mole^{-1}$ according to various estimates[21-23,26,27,29,31-34], is evidently overcome when the molecules are packed to form crystals. Since the effective volume of the molecule with the coplanar disposition of the rings is smaller than for the non-coplanar disposition, the internal pressure factor of the solvent should promote the former[35]. The dependence of the conformation of biphenyl, determined from vibrational spectra, on the nature of the solvent has been stressed[36]. The planar conformation of the solute molecule predominates in a structured solvent forming hydrogen bonds, probably owing to the ordering of the species in the environment or owing to unexplained specific effects. Thus the nature of the medium may be responsible for the ambiguity of the results of conformational analysis.

In the number of studies dealing with the vibrational spectra of biphenyl in solutions and in the melt, a qualitative conclusion was reached that the molecules are to some extent non-coplanar[37-42]. The angle of twist of the molecule has been estimated as 22–45° from the shift or changes in the intensities of the vibrational bands when crystalline biphenyl melts or is dissolved[43-48]. On the other hand, the vibrational spectra of biphenyl or its deutero-analogues in solution or in the melt have been interpreted[32,49-52] on the assumption that the conformation is planar.

According to ultraviolet spectroscopic data, biphenyl has an intense (ϵ = 17 000–19 000) conjugation band near 250 nm, corresponding to the first $\pi-\pi^*$ electronic transition, which has been attributed both to the planar conformation[53-55] and to the fact that the angle between the fragments is appreciably less than 45° ($\leqslant$ 20°).[56-63] Measurements of the anisotropy of the electrical polarisability[64] and diagmagnetic susceptibility[65] have led to the conclusion that the rings of the biphenyl molecule are located in the same plane in solutions.

The conformation of biphenyl in solution has been investigated in relation to biphenyl itself and its derivatives also using dipole moment[66] and light scattering[67–69] methods, electron paramagnetic resonance of the radical-anions[70,71], and NMR in the nematic phase[72]. Semi-empirical quantum-chemical calculations have been made of the conformation of biphenyl from its reactivity in nitration[73]. In some of these studies the dihedral angle between the planes of the rings was estimated as less than or equal to 30°,[66,68,69,71,72] while in others the closeness of the rings to the coplanar disposition was pointed out[67,70,73].

Thus theoretical and experimental studies (about 50 in all) on the conformations of biphenyl in solutions do not provide an unambiguous solution to the problem. However, as mentioned above, it has usually come to be assumed that biphenylylene systems and biphenyl itself are non-coplanar in solutions, like biphenyl in the gas phase, and the nature of their reactivities has been determined on this basis[1,2]. As will be shown below, this approach is unjustified, at least in relation to biphenyl.

III. STRUCTURAL FACTORS AND CONJUGATION IN BIPHENYL

Despite the fact that the ambiguity of the results of the determination of the conformation of biphenyl in solutions may be to some extent attributed to the very nature of the phenomenon (see, for example, Wilk[36]) a definite trend concerning the methods of investigation may be observed in the complete set of the available literature data. A planar or nearly planar conformation of biphenyl is indicated by methods involving the measurement of physical parameters about the direct dependence of which on conjugation (in this instance between the phenyl fragments) there is no doubt: the position and intensity of the long-wavelength absorption band in the ultraviolet spectrum[59a, 56], the anisotropy of the electrical polarisability of the molecules (the Kerr electro-optical effect[64]), and their diamagnetic susceptibility (the Cotton–Mouton effect[65]).

In biphenyl, which constitutes a weakly conjugated system comprising two aromatic rings[41,74], the conjugation depends on the angle between the planes of the rings and on the length of the central bond. As regards the relation between these two factors, until recently in theoretical studies the length of the bond between the rings was assumed to be constant for different angles of rotation or it was assumed that, as the angle between the planes of the rings increases, the degree of conjugation falls and there is a corresponding increase in the length of the bond[25,62,73,75]. However, experimental data indicate the opposite: as the biphenyl molecule ceases to be planar, i.e. when biphenyl passes from the crystalline to the vapour state, the length of the bond between the rings diminishes[12,13,17–19] approximately by 0.008–0.018 Å owing to the rapid decrease of the repulsive force between non-bonded atoms. This fact began to be taken into account very recently in quantum-chemical calculations on the biphenyl molecule[27,29,30], which is quite justified because the usual accuracy in the determination of the length of bonds between carbon atoms is to within 0.002 Å.[76]

So yet another cause of the contradictory results of the determination of the angle of twist of the central bond of biphenyl in solution become understandable. Methods where the degree of conjugation between the fragments is determined do not indicate or scarcely indicate the differences between the planar molecule (crystalline state) and the molecule in solution; there might be no difference, if, firstly, the conjugation were virtually independent of the type of conformation or, secondly, if under these and other conditions the molecule were planar. The second possibility must be rejected in the general case according to the results of studies by other methods. Thus careful analysis of the symmetry of the molecule on the basis of infrared and Raman spectra of biphenyl in the melt and in solutions, i.e. by methods which are not related to the conjugation between the rings, reveal a D_2 symmetry group or a non-polar conformation[39]; the same conclusion was reached by the authors of a number of other studies mentioned above. However, the first possibility remains.

Calculations have shown that the conjugation of the rings in biphenyl can indeed be independent of the angles between their planes when the latter are small (this is probable and is characteristic of biphenyl in solution). The ring conjugation energy found by different workers is 5–7 kcal mole^{-1}.[74] It is usually believed that this quantity is equal to the increase of the energy of the central bond owing to its π-component compared with the energy of a single bond between trigonal carbon atoms. When the rings rotate by an angle φ = 30–45°, the conjugation energy decreases in proportion to $\cos^2\varphi$,[77] i.e. by 1.5–3.0 kcal mole^{-1}. However, this would be true for a constant length of the central bond, whereas in reality the latter diminishes. The energy increment owing to the contraction of the bond may be estimated, for example, by employing the proportionality between the order and length of the bond, on the one hand, and between its order and its energy, on the other[78a,79]. More correct values should be obtained using Dewar and Schmeising's tractrix equation[80] for the relation between the length and energy of a bond of this kind. Similar ranges of values correspond to both methods of calculation: 1.8–3.9 and 1.5–3.4 kcal mole^{-1} respectively. In order to determine the increase in the energy of the π-component, it is necessary to introduce a correction for the change in the σ-component, which is positive or negative depending on what value is adopted for the equilibrium length of a "single" C_{sp^2}–C_{sp^2} bond—greater or smaller than in biphenyl. However, there is at present no definite answer to the question of the length of this bond: investigators have expressed divergent views and the range of probable values is 1.48 to 1.53 Å.[27,28,59c,78b,81b] Nevertheless, if the correction to the change in the σ-component for different probable lengths of the σ-bond is calculated using the harmonic approximation to the Morse curve[82a], values not exceeding 0.3–0.6 kcal mole^{-1} are obtained; in our discussion they can be disregarded. A stabilisation energy of the π-component of the bond between the rings similar to the values obtained above, which is up to 3.0 kcal mole^{-1} and depends on the contraction of the bond, can be derived from the dependence of the "spectroscopic" resonance integral on the distance between the carbon atoms[59c].

We thus see that the decrease of the conjugation energy owing to the rotation of the biphenyl rings may be compensated by the simultaneous contraction of the bond between the rings, particularly if account is taken of the fact that the angle of rotation may be much less than 30 to 45° and a significant contraction of the bonds between the biphenyl ring should occur even when their angles of rotation are small, owing to the rapid weakening of the nonbonding interactions in systems of this kind[27,59d].

The changes in the energy of the π-component of the bond can be set equal to the changes in the π-electron energy of the molecule[82b] and, if the latter are small or absent, then, for methods where the degree of conjugation is measured, the difference between the planar and slightly staggered molecular systems vanishes. One must therefore agree with the claim that the "estimation of the twist angles from ultraviolet spectra in such systems is extremely doubtful and risky, since... spectra calculated from the results of conformational analysis are almost independent of the twist angle"[83]. The phenomenon under discussion can thus be regarded as experimentally and theoretically well-founded.

This claim may not prove to be entirely correct, since in a number of studies[56-63] based on ultraviolet spectroscopic data small but significantly non-zero twist angles have been obtained for the central bond of biphenyl in solution, namely 18–23°. However, when the position of the first ultraviolet band of biphenyl in the spectra of solutions is compared with that in the spectra of the crystalline material, a correction must be applied for the "red shift" in the spectrum of the crystals. Its actual value for biphenyl is unknown and the arbitrary nature of the selection of such corrections[59e] virtually permits the assumption that the difference between the band positions is zero. If a small difference (1.5–3 nm or of 0.7–1.4 kcal mole^{-1}) between the energies of the $\pi-\pi^*$ transitions in both states remains even after the introduction of the correction, it may be caused by the distortion of the molecular skeleton of biphenyl in the crystal field[12-15], which should lead to a bathochromic shift of the conjugation band[59,84,85].

The extinction coefficient of the $\pi-\pi^*$ transition band in the biphenyl crystal cannot be determined owing to technical difficulties[57]. On the other hand, in the estimation of the angle of twist of the bond between the rings by comparing the extinction coefficients of this band in solutions of biphenyl and planar fluorene, the entire difference between them was attributed[56] solely to the non-coplanarity of the rings of the former. However, in the fluorene molecule the central bond is shorter than in biphenyl. This follows both from experimental data[86] and from a comparison of the results of semiempirical quantum-chemical calculations using the σ^+_{Ar} constants for the above compounds[87]. The greater intensity of the fluorene band may be caused in addition by the specific influence of the bridge group[88]. It is therefore of interest to note that biphenyl in solution exhibits a somewhat more intense conjugation band than 9,10-dihydrophenanthrene (φ = 20° according to the model)[89].

Quantitative allowance for the above correction factors is extremely difficult or impossible. However, without it the instances of the application of ultraviolet spectroscopic methods to the conformational analysis of biphenyl can be used merely for the purpose of illustration.

The problem of the role of the conjugation between the rings in the study of the vibrational spectra of biphenyl is probably less well defined in view of the complexity of the interactions between the electronic and vibrational levels. The role of such conjugation varies as a function of the choice of particular bands and presumably the validity of the band assignment does not always guarantee the reliability of the final conclusions, because it is also not clear to what extent the crystalline state of the molecule may serve as an adequate model for the planar conformation. It is therefore difficult to give preference to the results of one study rather than another. Qualitative conclusions about the type of conformation based on the analysis of the symmetry of the molecule in solution are for this reason most significant.

IV. THE STRUCTURE AND REACTIVITY OF BIPHENYL IN SOLUTIONS

The foregoing considerations throw serious doubt on the validity of many postulates which have come to be widely held, namely:

(1) the low transmission coefficient of the *p*-biphenylylene system $\pi' = \rho_{\text{p-C}_6\text{H}_4\text{C}_6\text{H}_4}/\rho_{\text{p-C}_6\text{H}_4} \simeq 0.3$ can be accounted for by its non-coplanarity[2];

(2) the failure of biphenyl to obey the Selectivity Relations for the series of monosubstituted benzenes can be accounted for by the non-coplanary of its molecule[1];

(3) the behaviour of fluorene as regards Selectivity Relations is different to that of biphenyl (a claim which aroused controversy at one time)[1,6,90];

(4) when account is taken of the activating influence of the bridge unit, the reactivity of fluorene in electrophilic substitution in the 2-position exceeds that of biphenyl in the 4-position owing to the non-coplanarity of the molecule of the latter[1].

Bearing in mind the considerations set out in the previous section, we shall examine these postulates in greater detail.

1. The low transmission coefficient π' of the biphenylylene molecular system (I) cannot be explained by its non-coplanarity, because the values of π' for the analogous fluorenylene system (II) are significantly the same[3,91]. We were unable to find any literature data on which a different claim could be based and were forced to conclude that the opposite views[2] are in all probability due to a misunderstanding.

2. The reactivity of biphenyl is higher than that of benzene owing to ring conjugation[92], which facilitates electron transfer to the reaction centre [ions (III) and (IV), *E* being an electrophile].

(III)

(IV)

The conjugation effects are most important in highly selective reactions with large values of the constant ρ^+; according to modern views, the transition states in such reactions are structures closest to those of carbonium ion σ-complexes. For the most selective of the known reactions—molecular bromination ($\rho^+ = -12.1$)—the 4-position in biphenyl is more reactive than a single position in the benzene ring by a factor of 2920.[1] This is equivalent to a difference between the free energies of activation amounting to $\Delta\Delta F^{\neq} = (RT \lg 2920)/\lg e \simeq 5$ kcal mole^{-1}, which corresponds to the energy of conjugation via the central bond. The agreement in this instance is probably not fortuitous and this approach reveals an interesting aspect of the comparison of kinetic and thermodynamic (structural) factors in reactivity. The characteristic feature of the molecular structure of biphenyl (I′)

(I′)

namely that the bond between the rings (as well as the atoms involved in it) contributes a definite additional $\pi(p)$-electron density, is manifested by the corresponding stabilisation of the transition state, which is evident from a comparison of ions (III) and (IV). In this approach there is no justification for postulating the inclusion of rotation and mutual approach of the rings in the reaction coordinate[1]. Evidently the conformational factor is immediately excluded from consideration if the initial state in solution involves a predominately planar conformation. The opposite case must in fact be considered.

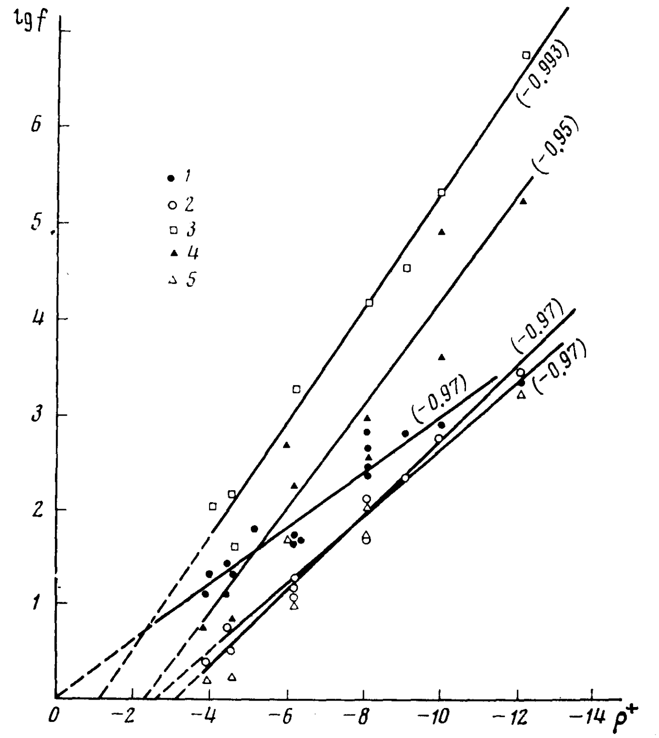


Figure 1. Dependence of the logarithms of the partial rate factors on ρ^+ in reactions with moderate and high selectivities[1] (the correlation coefficients are indicated in brackets): 1) *p*-tolyl; 2) 4-biphenylyl; 3) 2-fluorenyl; 4) 1-naphthyl; 5) 2-naphthyl.

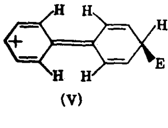
Biphenyl does not obey Selectivity Relations for monosubstituted benzenes, which is evident from a comparison with toluene in Fig. 1. In reactions with moderate and high selectivities involving biphenyl the linear plot of $\lg f_{4\text{-Ph}}$ against ρ^+ (f is a partial rate factor) does not pass through the coordinate origin and has a higher slope than the analogous plot for toluene. In the most selective reaction (molecular bromination), the *para*-position in biphenyl is actually more reactive than in toluene. The explanation of these phenomena, involving the hypothetical carbonium ion (V)



(V)

as the model of the transition state, appears to be unlikely, as well as the claim that the degree of stabilisation of such an ion increases as a result of the contraction of the bond between the rings[1]. Indeed comparison of ion (V) not only with ion (III) but also with ion (IV) reveals that the formation of its structure requires an additional energy expenditure in order to disrupt the second aromatic π-electron sextet, to overcome the barrier to rotation, and to overcome increased non-bonded repulsions—in all about 60 kcal mole^{-1} (36 + 4 + 20 kcal mole^{-1} respectively; the non-bonding repulsion was estimated from known potential functions[28]). It is difficult to specify an energy source whereby such expenditure could be compensated. On the other hand, it is evident that a definite energy gain corresponds to structure (III).

The lower reactivity of biphenyl compared with toluene in the majority of reactions (Fig. 1) likewise need not be explained by the presence of an energy barrier to the rotation of the rings[1]. Using modern ideas about the transition state in electrophilic aromatic substitution as the product of the overall contribution of the σ- and π-complex structures[93,94], it is easy to find an acceptable explanation. For ionic or highly polar reactants (low values of ρ^+), the structure of the transition state is closer to that of π-complexes and the negative inductive effect of the phenyl substituent as well as the positive inductive effect of the methyl group begin to play an important role.

Thus, consideration of the reactivity of biphenyl does not require its molecular system to be coplanar in the transition state. Here it is important to know a significant fact—the equality of the entropies of activation for biphenyl, fluorene, and 9,10-dihydrophenanthrene in one of the most selective reactions—molecular chlorination[95]. Since biphenyl should possess some freedom of rotation of the rings about the central bond in solution (initial state), this finding does not support model (V) for the transition state.

The nature of the reactivity of biphenyl suggests that it can be only formally included among monosubstituted benzenes and that in essence it gravitates towards the group of polycyclic hydrocarbons (Figs. 1 and 2). Their distinctive features are a large size and conjugation of the π-electron systems. In general this creates better conditions for the delocalisation of the positive charge in the substitution step than in the usual benzene derivatives. The observed rates of highly selective reactions for compounds of this kind are much higher than would follow from the Selectivity Relations for monosubstituted benzenes. The foregoing is illustrated in Fig. 2 for the molecular chlorination and bromination reactions. A similar phenomenon has also been observed for the sulphonation of nitrobenzene with sulphuric acid ($\rho^+ = -10$).[99] Evidently the behaviour of biphenyl shows a greater similarity to that of fluorene, naphthalene, and other polycyclic hydrocarbons than to monosubstituted benzenes. It is striking that the reactivities of the 1- and 2-positions in naphthalene in relation to moderately selective reagents are several times lower than that of the *para*-position of toluene, whereas in the highly selective chlorination and bromination reactions naphthalene is more reactive than toluene by several orders of magnitude[1]. This finding can be explained, so far only qualitatively, on the basis of the same hypotheses as in the case of biphenyl.

3. One of the main pieces of evidence quoted by Stock and Brown[1] against Neuman's objection[6] to their conclusion that biphenyl and fluorene behave differently in electrophilic substitution is the, at first sight, greater variation of the $\sigma^+_{4\text{-Ph}}$ constants in various reactions compared

with the $\sigma^+_{2\text{-Fl}}$ constants. However, the present author believes that in this case one can only speak of the variation of free energies, i.e. of the absolute and not relative variations of the constants. Fig. 3 clearly shows that the variation of the free energy of activation in the reactions of fluorene on average exceeds the corresponding variation for biphenyl. The problem of the causes of such variation is not the subject of the present review[99,100]. We shall also set aside the problem of the existence of a single scale of the Hammett–Brown constants for polycyclic hydrocarbons, applicable to all electrophilic substitution reactions. In view of the specific nature of polycyclic hydrocarbon systems, they cannot be accommodated within the same framework with monosubstituted benzenes. This fact is very likely to underlie the phenomenon under consideration.

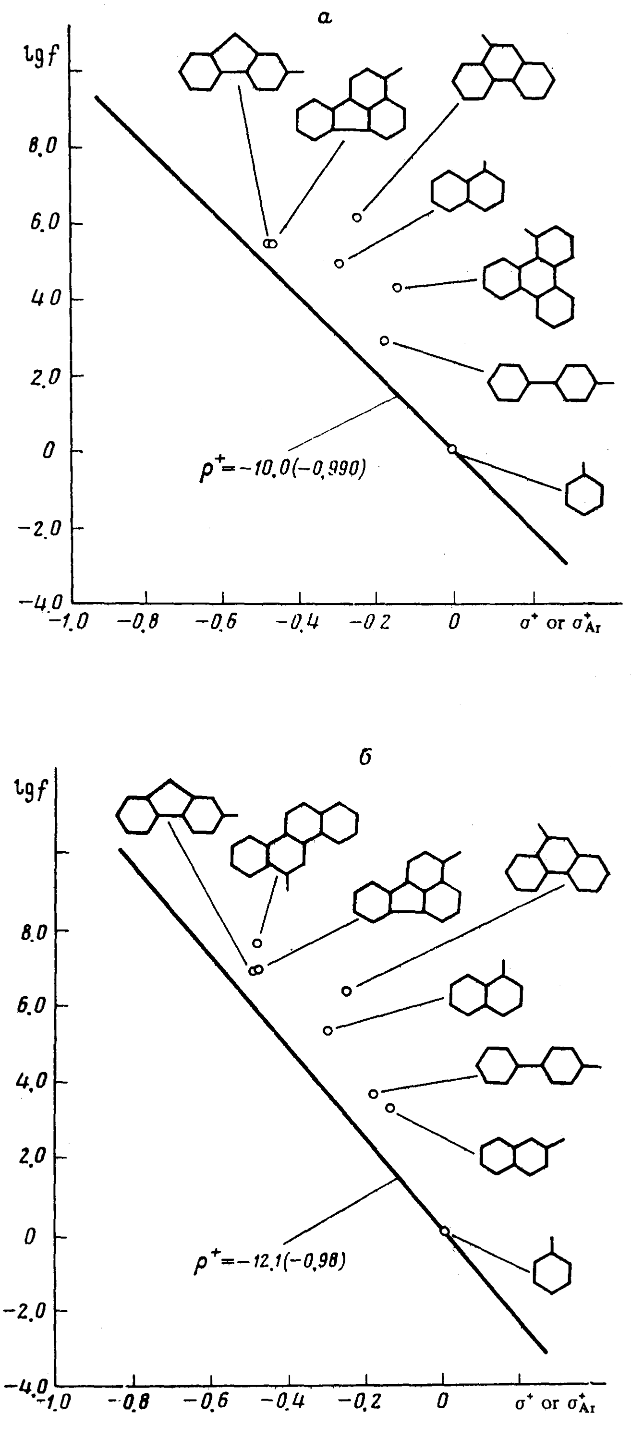


Figure 2. The Selectivity Relation for monosubstituted benzenes (straight lines) and for polycyclic hydrocarbons (circles): *a*) molecular chlorination in acetic acid[1,81b]; *b*) molecular bromination in acetic acid[1,96]. The values of σ^+_{Ar} were taken from Refs. 97–99 or calculated by Kachurin's method[99] from data quoted by Streitwieser[81c]; the correlation coefficients for monosubstituted benzenes are indicated in brackets.

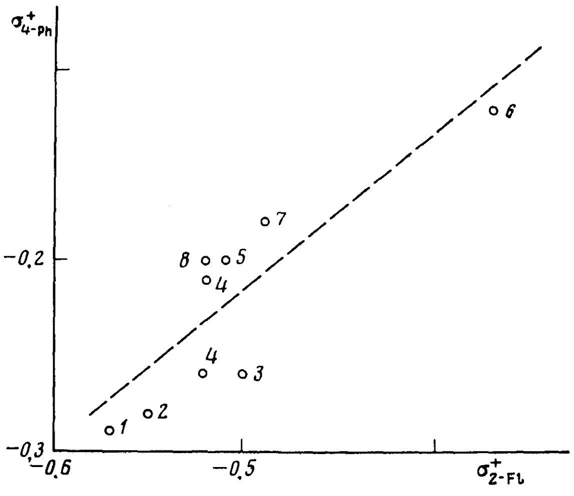

Figure 3. Variation of the constants $\sigma^+_{4\text{-Ph}}$ and $\sigma^+_{2\text{-Fl}}$ in various reactions[1] (the constants ρ^+ are indicated in brackets): 1) bromination (–12.1); 2) chlorination (–10.0); 3) acetylation (–9.1); 4) protodetritiation (–8.1); 5) nitration (–6.2); 6) protodesilylation (–4.6); 7) solvolysis of t-cumenyl chlorides (–4.5); 8) mercuration (–4.0); the slope of the dashed straight line is 0.83.

4. There is no need to resort to the conformational factor also in the treatment of the differences between the reactivities of fluorene and biphenyl. Compared with biphenyl, the bond between the rings in fluorene is shorter by 0.011–0.021 Å.[12,13,86] Using the average value 0.016 Å we find (see Section III) that it corresponds to an additional conjugation energy of 2.5 kcal mole^{-1} or to an acceleration of the highly selective reaction by a factor of ~ 70. If account is taken of the influence of the methylene bridge group[1], good agreement with experiment is achieved. This result is particularly interesting in view of the fact that quantum-chemical methods did not yield an interpretation of the reactivity of fluorene consistent with experiment and it was necessary to resort to the strained ring hypothesis[101-103].

Thus the characteristic behaviour of biphenyl in electrophilic substitution reactions can hardly be legitimately explained by the non-coplanarity of its molecule in solution.

Biphenyl is a special case of a substrate whose structure is intermediate between that of monosubstituted benzenes and polycyclic hydrocarbons. In contrast to the latter, the bond between the aromatic fragments of its molecule is appreciably weakened. The central bond is sometimes actually regarded as in essence a single bond[78c]. This fact is important for the understanding of the set of data known as the positive bridge effect, the conditions for the manifestation of which have been examined in a recent review[3].

γ-Piperidinones in Organic Synthesis

N.S.Prostakov and L.A.Gaivoronskaya

Methods for the synthesis of γ-piperidinones and their derivatives, including physiologically active compounds, are considered and the results of studies designed to establish the structures of certain tertiary γ-piperidinols are discussed. Research on the applications of γ-piperidinones in the syntheses of various heterocyclic compounds is surveyed.
The bibliography includes 415 references.

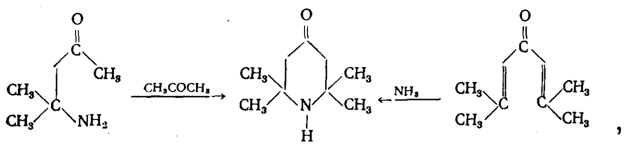
I. INTRODUCTION

Among piperidine derivatives, γ-piperidinones are of primary importance from synthetic, theoretical, and applied standpoints. The development of the synthetic chemistry of piperidine and of the conformational analysis of substituted piperidine bases as well as the synthesis of effective medicinal drugs and of new nitrogen-containing heterocyclic systems are all branches of the chemistry of heterocyclic compounds associated with γ-piperidinones.

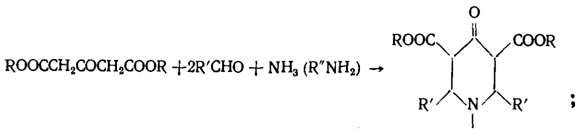
This paper deals with studies carried out mainly in the last twelve years, which characterise the development of certain branches of the chemistry of piperidine and of heterocyclic compounds related synthetically to γ-piperidinones. Studies designed to determine the steric structures of tertiary γ-piperidinols—the starting materials for the synthesis of effective analgesics—are also considered. In the solution of the problems of the configuration and conformation of compounds of this type contradictory conclusions have sometimes been reached. Numerous experimental data have now been obtained, which makes possible an objective and correct conclusion about the steric structures of γ-piperidinols.

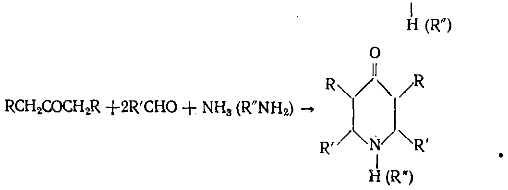
The methods of synthesis of γ-piperidinones are comparatively limited, and can be assigned to two groups as regards the type of reactions involved.

1. The condensation of carbonyl compounds with ammonia or primary amines: of acetone with ammonia (the synthesis of triacetoneamine), of diacetoneamine with ketones, of acetonedicarboxylate esters with aldehydes and ammonia or primary amines, of ketones of β-ketoacid esters with aldehydes and ammonia or primary amines, and of divinyl ketones with ammonia or primary amines. The methods of synthesis of γ-piperidinones from 2-cinnamoyloxirans and primary amines[1,2], from alkenyl β-diethylaminoethyl ketones and methyl amine[3,4], and from diacetone alcohol, ketones, and ammonia[5] are similar to the last method described above. The first γ-piperidinone—2,2,6,6-tetramethyl-4-piperidinone—has been synthesised by the above procedures:

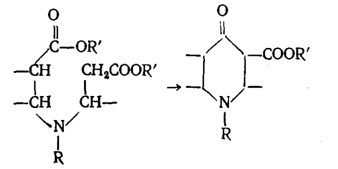


as well as many γ-piperidinones with different ring substituents:





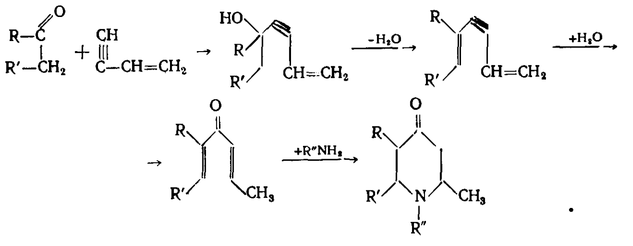
2. Cyclisation of aminodicarboxylate esters by the Dieckmann method:



The bibliography of many studies concerning the development of methods of synthesis of γ-piperidinones has been published by Bel'skii et al.[6]

The alkylation and acylation of γ-piperidinones unsubstituted at the nitrogen atom as well as their cyanoethylation have been described. The synthesis of *N*-halogeno-γ-piperidinones has been reported. Treatment of triacetoneamine with perchloryl fluoride led to the isolation of 1-fluoro-2,2,6,6-tetramethyl-4-piperidinone[7]. When 2,5-dimethyl-4-piperidinone hydrochloride is treated with sodium hypochlorite, 1-chloro-2,5-dimethyl-4-piperidinone is formed and is then converted under alkaline conditions into 2,5-dimethyl-1,2-dehydro-4-piperidinone. The latter was isomerised to 2,5-dimethyl-5,6-dihydro-4-pyridone[8]. 1-Amino-2,6-diphenyl-4-piperidinone has been isolated on reducing the corresponding *N*-nitrosopiperidinone with lithium tetrahydroaluminate[9]. Bis-(2,2,6,6-tetramethyl-4-oxo-1-piperidyl) disulphide, which is formed on treating triacetoneamine with sulphur dichloride, dissociates at temperatures in the range 90–200°C with formation of stable radicals[10]. It has been established by spectroscopic methods that the tautomeric equilibrium involving 3,5-diethoxycarbonyl-4-piperidinones is to a large extent displaced towards the enolic form, which is stabilised as the chelate[11]. The ketonic and enolic forms of 3,5-diethoxycarbonyl-1-ethyl-2,6-diphenyl-4-piperidinone have been isolated[12]. The ratio of the *cis*- and *trans*-isomers of 1-alkyl-2,5-dimethyl-4-piperidinones has been determined chromatographically as a function of different substituents at the nitrogen atom. Under alkaline conditions, the equilibrium is displaced towards the *cis*-form on passing from the methyl to the t-butyl group[13].

Nazarov and his coworkers have made a significant contribution to the development of the chemistry of γ-piperidinones. The consecutive reactions which they devised, namely the condensation of vinylacetylene with ketones and dehydration of the resulting vinylacetylenic alcohols to divinylacetylenic hydrocarbons followed by the hydration of the latter to divinyl ketones, constitute a simple and easy method of synthesis of these previously difficult to obtain compounds.



Before Nazarov's work, the only divinyl ketone derivatives used in the syntheses of γ-piperidinones were phorone and dibenzylideneacetone. Nazarov's method made it feasible to synthesise γ-piperidinones with a wide variety of substituents in the piperidine ring, the mode of substitution depending on the structure of the ketones used in the condensation with vinylacetylene. 1,2,5-Trimethyl-4-piperidinone is synthesised by this method under industrial conditions[14].

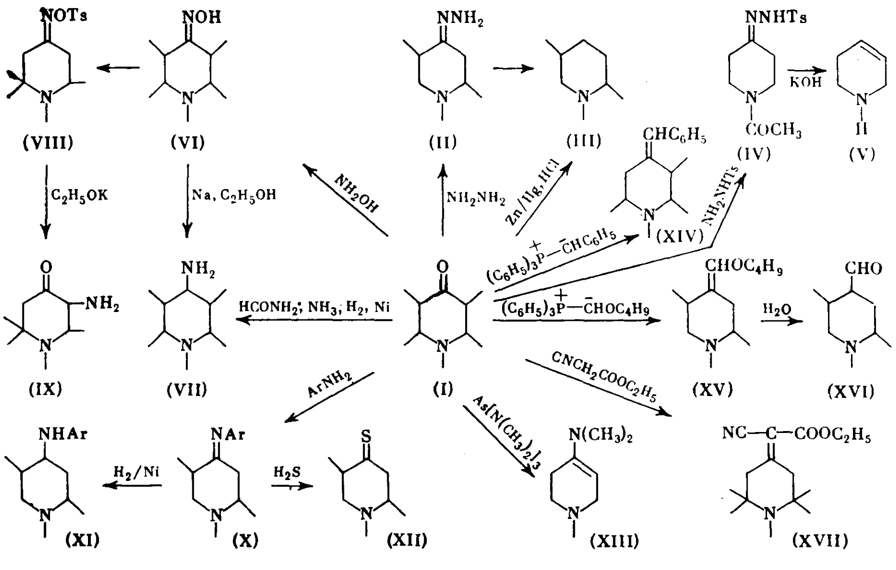
Tetrahydro-γ-pyrones, which are obtained, like γ-piperidinones, from divinyl ketones, are converted into γ-piperidinones by reaction with primary amines[15–17]. The conversion of 2,6-dimethyl-4-pyrone into 1,2,6-trimethyl-4-piperidinone via 1,2,6-trimethyl-4-pyridone and 1,2,6-trimethyl-4-piperidinol has been described[18].

A wide variety of reactions of γ-piperidinones involving the carbonyl group have been examined in a number of studies (Schemes 1 and 2). The reduction of γ-piperidinones (I) to piperidines (III) has been achieved via their hydrazones (II) [9,19–25] and also by the Clemmensen method [25]. Thermal decomposition of 1-acetyl-4-piperidinone toluene-*p*-sulphonylhydrazone in the presence of potassium hydroxide gave a quantitative yield of 1,2,5,6-tetrahydropyridine (V).[26] 1-Acetyl-3-ethoxycarbonyl-4-piperidinone was converted similarly into 1,2,5,6-tetrahydronicotinic acid[27]. The hydrazones of triacetoneamine substituted in the amino-group[28] as well as the hydrazones of this piperidinone with different substituents at the ring nitrogen atom (hydroxy-, nitroso-, etc.)[29] are used as polymer stabilisers. After the oxidation of 3,5-dimethyl-2,6-diphenyl-4-piperidinone semicarbazone with $[2NH_4NO_3\cdot Ce(NO_3)_4]$, a similarly substituted piperidinone was isolated. Its configuration has been determined[30].

The replacement of carbonyl oxygen by an amino-group in γ-piperidinones has been achieved by reducing their oximes (VI),[21,31–33] by the reaction of the piperidinones with formamide[34], and by reductive amination[35,36]. A number of acyl derivatives of γ-aminopiperidinones (VII) obtained in this way have been described[37]. β-Amino-γ-piperidinones (IX) have been synthesised by treating the sulphonate esters of γ-piperidinone oximes (VIII) with potassium ethoxide[38]. A number of Schiff bases (X), obtained from γ-piperidinones and primary amines, have been described; some of them have been reduced to aryl-(4-piperidyl)amines (XI).[39–43] Treatment of *N*-(1,2,5-trimethyl-4-piperidylidene)aniline with hydrogen sulphide yielded 1,2,5-trimethyl-4-thiopiperidinone (XII).[44] The hydrochloride of 1-methyl-4-thiopiperidinone was isolated in the form of a polymer after treating 1-methyl-4-piperidinone with hydrogen sulphide in an alcoholic solution of hydrogen chloride[45].

The interaction of 1-methyl-4-piperidinone with tris-(dimethylamino)arsine led to the formation of an enamine derived from piperidine, namely 1-methyl-4-dimethylamino-1,2,5,6-tetrahydropyridine (XIII).[46] Its analogue, 1-benzyl-5-methyl-4-(1-pyrrolidinyl)-1,2,5,6-tetrahydropyridine, has been described[47]. 4-Benzylidene-2,6-dimethyl- and 4-benzylidene-3-methyl-2,6-diphenylpiperidines (XIV) have been synthesised by the interaction

Scheme 1



of the corresponding piperidinones with triphenylbenzylidenephosphine[48]. (1-Methyl-$\Delta^{4,\alpha}$-4-piperidyl)acetonitrile and ethyl (1-methyl-$\Delta^{4,\alpha}$-4-piperidyl)acetate have been synthesised by the Wittig reaction from 1-methyl-4-piperidinone[49]. An analogue of the ethyl ester with a benzoyl group attached to the nitrogen atom has been described[50]. Ethyl (1-benzoyl-3-ethyl-$\Delta^{4,\alpha}$-4-piperidyl)acetate has been obtained by the same procedure[51]. Hydrolysis of 4-butoxymethylene-1,2,5-trimethylpiperidine (XV), which is obtained from 1,2,5-trimethyl-4-piperidinone and butoxymethylenetriphenylphosphine, results in the formation of 4-formyl-1,2,5-trimethylpiperidine (XVI)[52]. This aldehyde has also been obtained from the same piperidinone and chloromethyl ether[53].

(2,2,6,6-Tetramethyl-4-piperidylidene)cyanoacetate ester (XVII), formed on condensation of the cyanoacetate ester with triacetoneamine, is used as an intermediate in the synthesis of the medicinal drug "Temekhin"[42,54]. An analogous compound has been described[55]. The condensation of 1,2,6-trimethyl-4-piperidinone with malonodinitrile gave 4-dicyanomethylene-1,2,6-trimethylpiperidine[56].

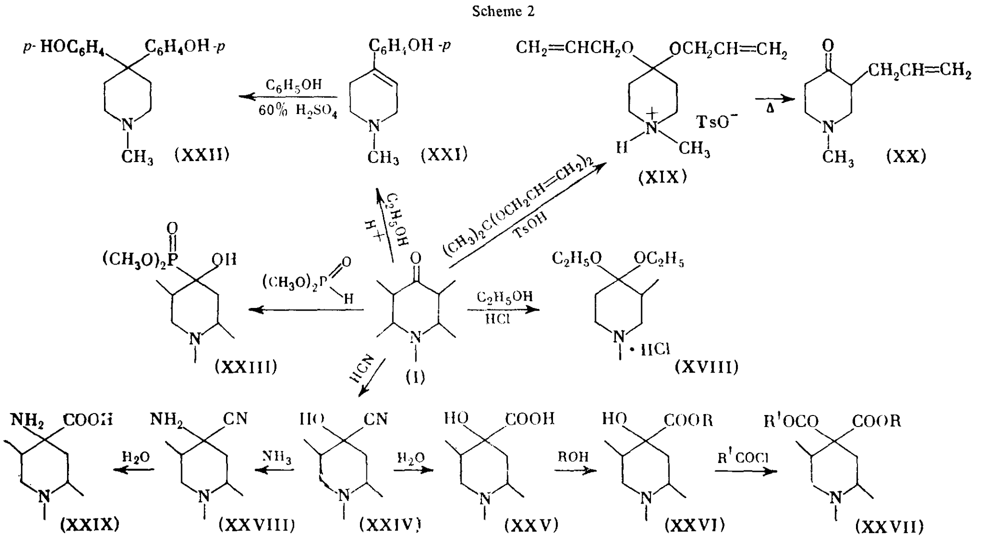
Scheme 2 presents reactions involving addition to the carbonyl group of γ-piperidinones. Triacetonamine ketals have been obtained by treating triacetoneamine with a mixture of the alcohol and benzene in the presence of toluene-*p*-sulphonic acid[57]. On crystallising γ-piperidinone hydrochlorides from an ethanol–ether mixture, their diethyl ketals (XVIII) are readily formed[58,59]. The quaternary salt (XIX) of toluene-*p*-sulphonic acid and 4,4-diallyloxy-1-methylpiperidine, obtained from piperidinone and acetone diallyl ketal in the presence of toluene-*p*-sulphonic acid, was converted into 3-allyl-1-methyl-4-piperidinone (XX) by heat treatment[60]. The condensation of 1-methyl-4-piperidinone with phenols under acid conditions has been investigated. Condensation with phenol led to the isolation of 4-(*p*-hydroxyphenyl)-1-methyl-1,2,5,6-tetrahydropyridine (XXI), which is converted into 4,4-di-(*p*-hydroxyphenyl)-1-methylpiperidine (XXII) on further interaction with phenol[61].

The condensation of 2,5-dimethyl- and 1,2,5-trimethyl-4-piperidinones with dimethyl phosphite has been achieved which led to the formation of 2,5-dimethyl and 1,2,5-trimethyl-4-(OO-dimethylphosphono)-4-piperidinols (XXIII)[62,63]. Diallyl phosphite and dipropargyl phosphite were used in analogous syntheses[64]. The usual procedures have been used to synthesise from γ-piperidinones the cyanohydrins (XXIV) and from the latter the hydroxy-acids (XXV) and their esters involving the carboxy-group [compounds (XXVI)] and the hydroxy-group [compounds (XXVII)].[65–71] Pinacones of the piperidine series—4-aryl(diaryl)-4-hydroxypiperidylmethanols[72]—have been obtained from γ-alkoxycarbonyl-γ-hydroxypiperidines and their pinacoline rearrangement to γ-acyl-γ-arylpiperidines has been carried out[73]. The conversion of γ-piperidinone cyanohydrins into γ-dialkylamino-γ-cyanopiperidines has been described and the latter have been converted into γ-dialkylaminopiperidines and γ-alkyl (aryl)piperidines[74,75]. γ-Amino-γ-carboxypiperidines (XXIX) have been obtained both from γ-amino-γ-cyanopiperidines (XXVIII)[76] and from γ-carboxy-γ-hydroxypiperidines (XXV).[77]

The second group of reactions of γ-piperidinones consists of their condensation reactions (Scheme 3). When γ-piperidinones (I) are condensed with benzaldehyde, both 3-benzylidene-[compounds (XXX)] and 3,5-dibenzylidene-derivatives [compounds (XXXI)] are formed[78–82]. Similar condensations with various aromatic aldehydes, including heterocyclic aldehydes, have been described[83–85]. 1-Acetyl-3-methoxycarbonyl-2,5-dimethyl-4-piperidinone (XXXII) has been obtained by the condensation of the corresponding piperidinone with dimethyl carbonate in the presence of sodium ethoxide[86]. The condensation of 1,2,5-trimethyl-4-piperidinone with formaldehyde, resulting in the 3-hydroxymethyl derivative (XXXIII) of this piperidinone, has been achieved[87]. 3-Dialkylaminomethyl-4-piperidinones (XXXIV) have been obtained by the Mannich condensation of γ-piperidinones[88–90]. Ethyl β-(3-ethoxycarbonyl-1-methyl-4-oxo-3-piperidyl)propionate (XXXV) has been obtained from 3-ethoxycarbonyl-1-methyl-4-piperidinone and ethyl acrylate in the presence of sodium hydride[58,91].

The cyanoethylation of γ-piperidinones with alkyl substituents in the β-position, which leads to the formation of β-alkyl-β-cyanoethyl-γ-piperidinones (XXXVI), has been described[92–95]. Further cyanoethylation of such piperidinones yielded $\beta\beta'$-di-(2-cyanoethyl)- and $\beta\beta\beta'$-tri-(2-cyanoethyl)-γ-piperidinones[96]. The condensation of 1,2,5-trimethyl-4-piperidinone (as well as its *N*-unsubstituted analogue) with bis-(β-methylvinyl) ketone leads to

Scheme 2



the formation of 1,2,5-trimethyl-5-(5-methyl-3-oxohex-4-en-1-yl)-4-piperidinone (XXXVII).[97] When 2,5-dimethyl-4-piperidinone was condensed with α-vinylpyridine in the presence of sodium, 2,5-dimethyl-5-[β-(2-pyridyl)-ethyl]-4-piperidinone (XXXVIII) was obtained[98].

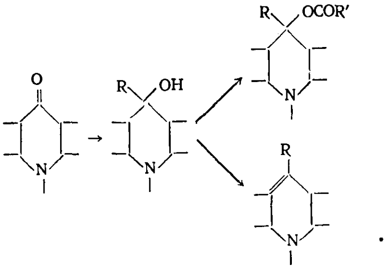
Treatment of 1-alkoxy-3-methoxycarbonyl-4-piperidinones with methyl iodide in the presence of sodium ethoxide yields 1-alkoxy-3-methoxycarbonyl-3-methyl-4-piperidinones[99]. The synthesis of 3-allyl-1-benzyl-4-piperidinone by alkylating 1-benzyl-4-piperidinone with allyl bromide after its preliminary treatment with sodium t-butoxide has been described[100]. Similar alkylation of γ-piperidinones has been described in another communication[55]. Treatment of 3-ethoxycarbonyl-1-methyl-4-piperidinone with benzyldimethylphenylammonium chloride and with allyldimethylphenylammonium bromide followed by hydrolysis and decarboxylation of the alkylation products yielded 3-benzyl(allyl)-1-methyl-4-piperidinones[101]. 1-Benzoyl-3-ethoxycarbonyl-3-propargyl-4-piperidinone (XXXIX) has been obtained from 1-benzoyl-3-ethoxycarbonyl-4-piperidinone and propargyl bromide[47].

Iminoxy-radicals (free radicals), which are chemically based on triacetoneamine and its derivatives substituted in the γ-position, occupy an independent place in the chemistry of γ-piperidinones[102-104].

II. SYNTHESES OF PHYSIOLOGICALLY ACTIVE PIPERIDINE DERIVATIVES FROM γ-PIPERIDINONES

The first physiologically active piperidine derivatives described, including medicinal drugs, consisted of esters of secondary γ-piperidinols. More than 80 reports have been published in which the reduction of γ-piperidinones to γ-piperidinols by various methods and their esterification are described. Some of the esters exhibit physiological activity, but have not found applications for different reasons. α-Eucaine (4-benzoyloxy-4-methoxycarbonyl-1,2,2,6,6-pentamethylpiperidine) and β-eucaine (4-benzoyloxy-2,2,6-trimethylpiperidine), which are powerful anaesthetics but exhibit an undesirable secondary activity, as well as a mydriatic preparation eucatropine (euphthalmine) (the ester of 1,2,2,6-tetramethyl-4-piperidinol and mandelic acid) are nowadays only of historical interest.

The esters of tertiary γ-piperidinols proved to be piperidine derivatives, obtainable from γ-piperidinones, which are important from the practical point of view. Various methods have been used to synthesis γ-hydroxy-derivatives with a tertiary hydroxy-group from γ-piperidinones; one of these involves the preparation of γ-piperidinols with the aid of organomagnesium and organolithium compounds[12,18,19,23,58,60,99-101,105-176]. Certain tertiary γ-piperidinols have been obtained from γ-piperidinones by the Reformatskii reaction[177,178]. The condensation of γ-piperidinones with ketones in the presence of ion-exchange resins, which results in the formation of tertiary γ-piperidinols containing β-hydroxyalkyl groups in the 4-position, has been described[179]:

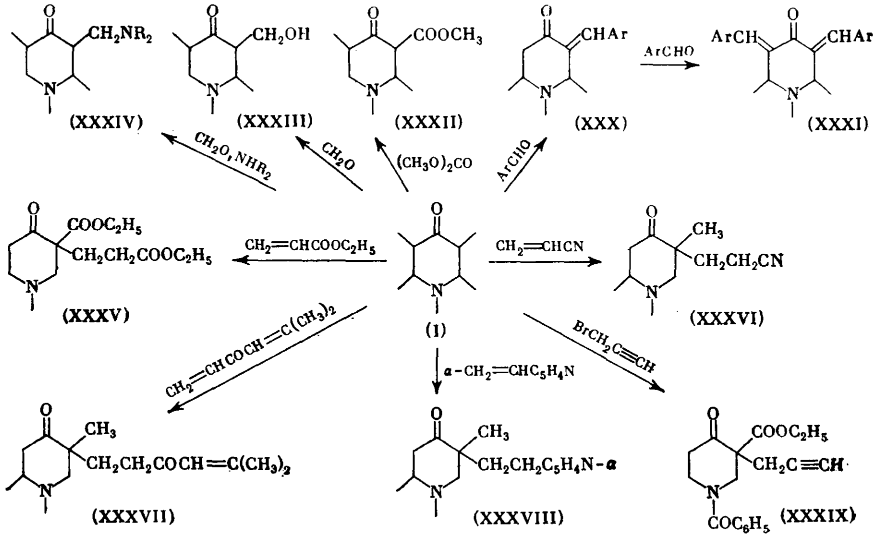


Many of the γ-piperidinols synthesised have been isolated in the form of individual isomers. Apart from the esterification of tertiary γ-piperidinols in order to obtain pharmacologically active compounds[18,19,99-101,105-109,112,114,116,117,120-122,124-126,128,129,131-133,135-137,139,142,146,148,150,155,158,167,170-175,180-197], their dehydration has also been studied, mainly in connection with the determination of the configurations of γ-piperidinols and the synthesis of piperidines which were used in the syntheses of pyridine bases[107,110,113,115,117,127,144-147,151,156,157,162,168,176,178,198-205].

The syntheses of tertiary γ-piperidinols and their esters have been carried out on a large scale. Effective analgesics have been found amongst them.

The ethers of tertiary γ-piperidinols have been inadequately investigated, partly due to certain difficulties in their synthesis. A method has been developed for the conversion of the esters of such alcohols into ethers by heating them with an excess of hydrogen chloride in an

Scheme 3



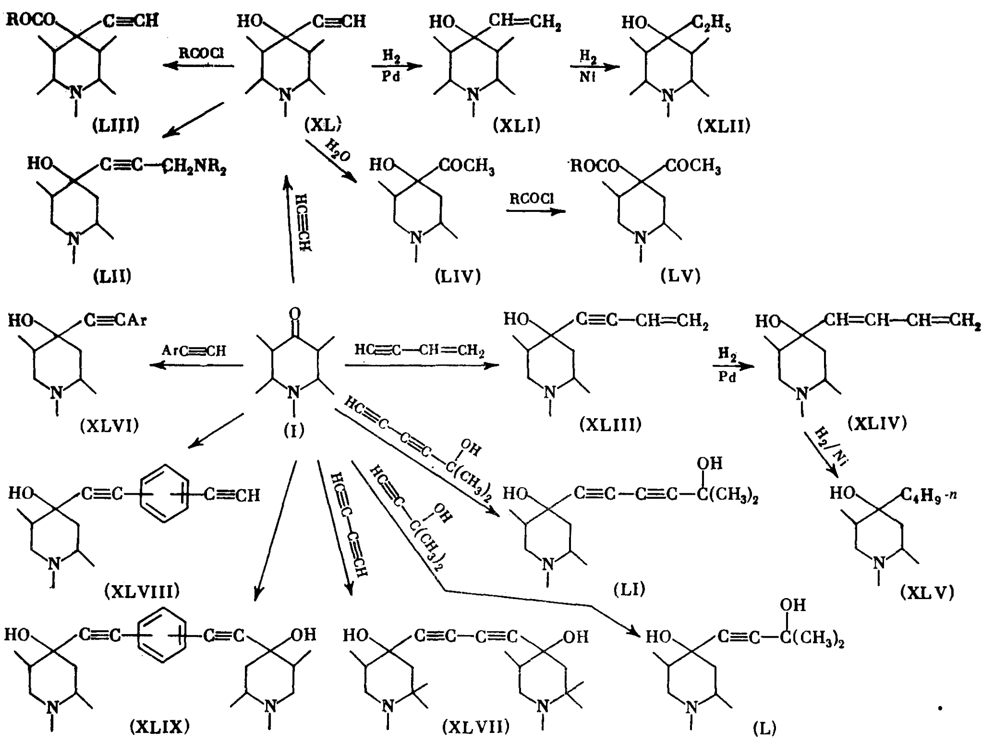
alcoholic solution. Thus 1-benzyl-4-ethoxy-4-α-furyl-3-methylpiperidine, which exhibits a considerable analgesic activity, has been obtained from 1-benzyl-4-α-furyl-3-methyl-4-propionyloxypiperidine[141,206,207]. The cyanoethylation of tertiary γ-piperidinols in the presence of potassium hydroxide leads to the formation of γ-(2-cyanoethoxy)piperidines[208]. The condensation of γ-piperidinones with acetylenic compounds has been carried out by familiar methods (Scheme 4). Many 4-ethynyl-4-piperidinols (XL) have obtained from γ-piperidinones (I), with various substituents in the ring and at the nitrogen atom, by condensation with acetylene; in many instances isomeric piperidinols were isolated and their steric structures established. Partial [to γ-vinylpiperidinols (XLI)] and complete to [γ-ethylpiperidinols (XLII)] hydrogenation of the ethynyl group has been achieved[69,112,180,184,209-233]. 4-Vinylethynylpiperidinols (XLIII) have been synthesised by condensing γ-piperidinones with vinylacetylene or vinylethynylmagnesium bromide. Partial [to piperidinols (XLIV)] and complete [to piperidinols (XLV)] hydrogenation of the vinylethynyl group has been achieved[112,114,234]. Analogous condensations of γ-piperidinones have been carried out with phenylacetylene[117,146,225,235,236] and naphthylacetylenes[237] [the synthesis of the piperidinols (XLVI)]. 4-Butadiynyl-4-piperidinols have been synthesised by the Chodkiewicz–Cadiot method from 4-ethynyl-4-piperidinols and bromo-derivatives of monosubstituted acetylenes[238]. The condensation of 2,2,5-trimethyl-4-piperidinone with diacetylene yielded a diacetylenic glycol—di-(4-hydroxy-2,2,5-trimethyl-4-piperidyl)-diacetylene (XLVII). An analogous glycol was obtained by the oxidative dimerisation of individual isomers from 4-ethynyl-1,2,5-trimethyl-4-piperidinol and was then hydrogenated[232,239,240]. Similar glycols have also been described[218].

Diethynylbenzenes with the ethynyl groups and other substituents in different positions in the benzene ring have been condensed with 1,2,5-trimethyl-4-piperidinone and condensation products involving both one [compounds (XLVIII)][238,241] and two [compounds (XLIX)][241,242] ethynyl groups have been obtained. The condensation of 1,2,5-trimethyl-4-piperidinone with ethynyldimethylmethanol [the synthesis of the glycol (L)][243] and of 2,5-dimethyl-4-piperidinone with diethynyldimethylmethanol [the synthesis of the glycol (LI)][219] have been achieved.

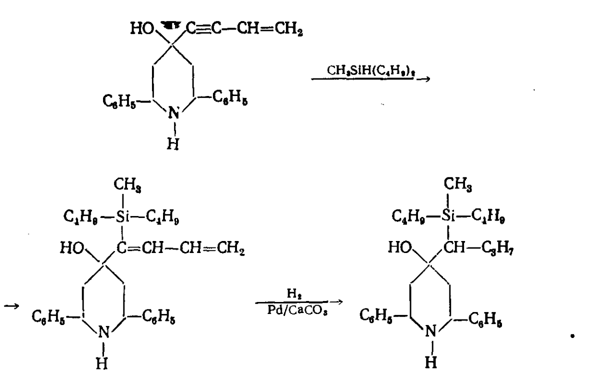
A large number of dialkylaminomethylethynyl derivatives (LII) of acetylenic piperidinols (XL) with terminal acetylenic hydrogen have been synthesised from the latter by the Mannich method[193,217,224,231,244-249]. The condensation of acetylenic piperidinols with ketones[250] and the cyanoethylation of the resulting glycols have been investigated[251]. The esters (LIII) of the acetylenic alcohols (XL) have been obtained and the triple bond has been hydrated [the synthesis of 4-acetyl-4-piperidinols (LIV) and their esters (LV)] and a number of other reactions involving the ethynyl group have been carried out[69,71,146,213,216,221,223,231,238,252-263]. The aminomethylation[264] and cyanoethylation[265-267] of acetylenic γ-piperidinols at the hydroxy-group as well as the preparation of their carbamates have been described. 4-Vinyl-4-piperidinols, obtained by the partial hydrogenation of 4-ethynyl-4-piperidinols by oxidation with hydrogen peroxide, have been converted into 4-epoxy-4-hydroxy-derivatives of piperidine.

Only limited studies have been made of the synthesis of silicon-containing piperidine derivatives, including tertiary γ-piperidinols. When 2,6-diphenyl-4-vinylethynyl-4-piperidinol was treated with dibutylmethylsilane in the presence of a Spier catalyst, 4-(1-dibutylmethylsilylbuta-1,3-dienyl)-2,6-diphenyl-4-piperidinol was

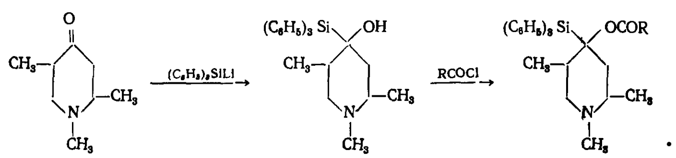
Scheme 4



isolated and then converted by hydrogenation into 4-(1-dibutylmethylsilyl-1-butyl)-2,6-diphenyl-4-piperidinol. An analogous reaction has been carried out with 1,2,5-trimethyl-4-vinylethynyl-4-piperidinol[268]:



Another example is provided by the synthesis of the isomeric 1,2,5-trimethyl-4-triphenylsilyl-4-piperidinols and their esters from 1,2,5-trimethyl-4-piperidinone and triphenylsilyl-lithium[269]:

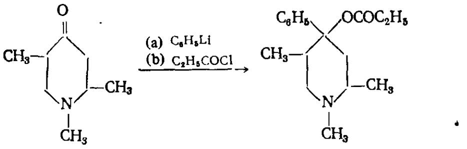


Pharmacological study of secondary and tertiary γ-piperidinols has shown that they are as a rule physiologically inactive. The analgesic activity of the isomeric 1,2,5-trimethyl-4-phenyl-4-piperidinols has been erroneously reported[270]. However, tertiary γ-piperidinols include the neuroplegic preparation 4-*p*-chlorophenyl-1-(3-benzoyl-1-fluoropropionyl)-4-piperidinol. According to preliminary data[269], 1,2,5-trimethyl-4-triphenylsilyl-4-piperidinol exhibits a bactericidal activity.

The most active analgesics proved to be the esters of propionic acid and tertiary γ-piperidinols with a phenyl substituent in the 4-position. Two of these preparations have been introduced into medical practice, namely prodine (α-prodine, Nisentil, anedol) and promedol, and have found extensive applications and have significantly limited the use of morphine as an analgesic.

Prodine (the hydrochloride of 1,3-dimethyl-4-phenyl-4-propionyloxypiperidine) was obtained as follows. The cyclisation of (β-methoxycarbonylethyl)-(β-methoxycarbonylpropyl)methylamine results in the formation of 5-methoxycarbonyl-1,3-dimethyl-4-piperidinone, from which 1,3-dimethyl-4-piperidinone is formed after hydrolysis and decarboxylation[271]. The reaction of this piperidinone with phenyl-lithium yielded a mixture of isomeric 1,3-dimethyl-4-phenyl-4-piperidinols and then the propionate esters of both isomers (α-prodine and β-prodine)[109]. The high analgesic activity of prodine has been reported[105]. The synthesis of compounds analogous to prodine has been described in reports of independent investigations[108,110].

1,2,5-Trimethyl-4-piperidinone is used in the synthesis of promedol (the hydrochloride of 1,2,5-trimethyl-4-phenyl-4-propionyloxypiperidine)[116,272]. In the technique employed promedol is obtained without isolating 1,2,5-trimethyl-4-phenyl-4-piperidinol by treating with propionyl chloride the lithium alkoxide derived from this alcohol:



The following method is more rational: synthesis of 1,2,5-trimethyl-4-phenyl-4-piperidinol, isolation (crystallisation and chromatographic separation) of the γ-isomer from the mixture of isomers, and esterification of the γ-isomer (yield more than 90%) with propionic anhydride in the presence of pyridine.

III. THE STERIC STRUCTURES OF CERTAIN TERTIARY γ-PIPERIDINOLS

Numerous studies have been devoted to the stereochemistry of secondary and tertiary γ-piperidinols. Studies of this kind are being vigorously continued also at the present time. In this review our aim is to examine research in this field associated with the chemistry of γ-piperidinols. This was done to some extent in a previous review[273], but the latter has already become obsolete.

We shall consider only studies associated with the investigation of the configurations and conformations of isomeric 1,3-dimethyl-4-phenyl-4-piperidinols and 1,2,5-trimethyl-4-phenyl-4-piperidinols. The choice of these compounds is dictated by several factors. In the first place, the γ-piperidinols are used as the starting materials in the syntheses of effective analgesic medicinal preparations—the isomeric prodines and the isomeric promedols. Among the numerous derivatives of γ-piperidinones, only these compounds have found extensive applications in medicinal practice. The conformational analysis of piperidine derivatives was initiated in studies undertaken to investigate the stereochemistry of the above piperidinols using in the first place chemical and then spectroscopic methods. Many workers who studied the structures of the isomeric prodines and promedols frequently reached contradictory conclusions. Whereas in the case of the isomeric 1,3-dimethyl-4-phenyl-4-piperidinols these contradictions were fairly rapidly eliminated, in the case of the 1,2,5-trimethyl analogues they accumulated in the course of time, which not only interfered with the solution of this specific problem but to some extent inhibited the development of the conformational analysis of piperidine systems. Unfortunately the authors who categorically adhered to an erroneous treatment of the mixture of isomeric 1,2,5-trimethyl-4-phenyl-4-piperidinols[270,274] later changed their views without reporting any reasons for the earlier incorrect conclusions[261,275].

The preparation of a mixture of isomeric 1,3-dimethyl-4-phenyl-4-piperidinols and the hydrochlorides of their propionates—the α-isomer (m.p. 212–214°C; 220–221°C according to other data[125]) and the β-isomer (m.p. 190 to 192°C; 195–196°C according to other data[125])—was first reported by Ziering and Lee[109], who also presented the experimental results for the isolation of the enantiomers of β-prodine with the aid of D-tartaric and L-malic acids. The diastereoisomers of 1,3-dimethyl-4-phenyl-4-piperidinol were designated as α-form (m.p. 100–101°C) and the β-form (m.p. 116–118°C) (the hydrochlorides of the corresponding propionates were indicated above). The following configuration, later shown to be erroneous, was initially attributed to them (on the basis of infrared spectroscopic data alone[276]): *cis*-disposition of the methyl group at $C_{(3)}$ and of the phenyl group at $C_{(4)}$ for the α-form and *trans*-disposition of the same substituents for the β-form[109,124]. Erroneous configurations were also assigned to structural analogues of the above α- and β-forms of piperidinols containing substituents other than the methyl group at $C_{(3)}$. The fact that these conclusions concerning structure, for example, for the α- and β-isomers of 3-allyl-1-methyl-4-phenyl-4-piperidinols[124], were unsound was demonstrated by Bell and Portoghese[60].

The problem of the configurations and conformations of the α- and β-isomers of 1,3-dimethyl-4-phenyl-4-piperidinols was solved initially by chemical and then by spectroscopic methods. The steric structures of the α- and β-isomers of 1,3-dimethyl-4-phenyl-4-piperidinols and their analogues (the α- and β-series), with other substituents at the nitrogen and $C_{(3)}$ atoms, were studied in a number of investigations. It was established that the proportion of piperidinols of the α-series is much greater than that of the compounds of the β-series owing to more favourable steric conditions for the formation of the former with the *trans*-disposition of the substituent at $C_{(4)}$ relative to that at $C_{(3)}$. The esters of the β-isomers of piperidinols hydrolyse at a higher rate than those of the α-isomers[277] and the β-isomers are more readily esterified than the α-isomers (axial hydroxy-group). The interaction of β-isomers of piperidinols with thionyl chloride involves the exchange of the hydroxy-group for chlorine, while the reaction of the α-isomers involves mainly dehydrochlorination. On the basis of these data, it was concluded initially that the α-isomer of the piperidinol corresponding to prodine has the structure of 1,3*e*-dimethyl-4*e*-phenyl-4-piperidinol[136,278,279]. It was established that the α- and β-isomers of piperidinols have infrared spectra with characteristic features[125].

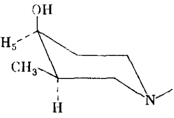
X-Ray diffraction analysis of α-prodine (the hydrochloride of the propionate of the α-isomer of 1,3-dimethyl-4-phenyl-4-piperidinol) showed that its molecule has the "chair" conformation with the phenyl group in the equatorial position, while the methyl group at $C_{(3)}$ is in the *trans*-position relative to the phenyl group at $C_{(4)}$.[280,281] X-Ray diffraction study of the hydrobromide and hydrochloride of β-prodine led to the conclusion that its molecule also has "chair" conformation, and that the methyl group at $C_{(3)}$ and the equatorial phenyl group are in the *cis*-positions[282-284]. An analogous conclusion about the configurations and conformations of the α-isomer of 1,3-dimethyl-4-phenyl-4-piperidinol (the CH_3 and equatorial C_6H_5 groups in the *trans*-position) and the β-isomer (the CH_3 and equatorial C_6H_5 groups in the *cis*-position) was reached on the basis of a study of their ^{1}H NMR spectra[150,285-288] as well as the spectra of their esters[289].

The results obtained in a study of the products of the dehydration of the isomeric α- and β-1,3-dimethyl-4-phenyl-4-piperidinols under the conditions of acid catalysis (*trans*-elimination, E2 mechanism) were also used to demonstrate the configurations of these piperidinols. Dehydration of the β-isomer under comparable conditions leads to the formation of 1,5-dimethyl-4-phenyl-1,2,5,6-tetrahydropyridine, while dehydration of the α-isomer results in the formation of approximately equal amounts of 1,3-dimethyl-4-phenyl, and 1,5-dimethyl-4-phenyl-1,2,5,6-tetrahydropyridines[151]. The same results were obtained in a study of the dehydration of the 4-*o*-tolyl analogues of the α- and β-isomers of this piperidinol[162].

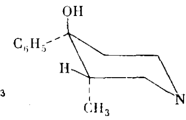
The synthesis of the enantiomers of the α-isomer of 1,3-dimethyl-4-phenyl-4-piperidinol from the enantiomers of 3-allyl-1-methyl-4-phenyl-4-piperidinol has been achieved. Treatment of the optical isomers of this piperidinol with osmium tetroxide and then with sodium periodate yielded the enantiomers of the 3-formylmethyl derivative, which was isolated in the form of hemiacetals. Decarbonylation of the latter yielded the enantiomers of the α-isomer of 1,3-dimethyl-4-phenyl-4-piperidinol $\{[\alpha]_D = +5.6$ and $[\alpha]_D = -5.8\}$.[290] The synthesis of α- and β-prodines (hydrochlorides) labelled with tritium in the phenyl group and the isolation of their optical isomers have been described. The following characteristics of the optical isomers were obtained:

(+)-[^{3}H] C_6H_5-α — m.p. 190—191°, $[\alpha]_D = +35.3°$;
(—)-[^{3}H] C_6H_5-α — m.p. 194—195°, $[\alpha]_D = -37.5°$;
(+)-[^{3}H] C_6H_5-β — m.p. 185—186°, $[\alpha]_D = +66.8°$;
(—)-[^{3}H] C_6H_5-β — m.p. 190—191°, $[\alpha]_D = -71°$.

The separation of the isomeric piperidinols into their enantiomers, which were subsequently propionylated, was achieved with the aid of tartaric and dibenzoyltartaric acids. It was established that the (+)-enantiomers are more active analgesics than the (−)-enantiomers[172,291]. Thus (+)-α-prodine is 25 times more active than (−)-α-prodine; the analogous β-prodines have activities differing by a factor of 13.[292] Thus one may assume that the problem of the configurations and conformations of the α- and β-isomers of 1,3-dimethyl-4-phenyl-4-piperidinols has been solved[293].



α-isomer



β-isomer

The problem of elucidating the steric structures of the three isomeric 1,2,5-trimethyl-4-phenyl-4-piperidinols, which are formed when 1,2,5-trimethyl-4-piperidinone reacts with phenyl-lithium, is more complex: the α-isomer (m.p. 106−107°C) from which α-promedol is derived (its analgesic activity is higher than that of morphine approximately by a factor of 4−6), the β-isomer (m.p. 102−103°C) from which isopromedol is derived (more active than promedol by a factor of 2−3), and the γ-isomer (m.p. 107−108°C) from which promedol is derived (more active than morphine by a factor of 2−3).[116] The racemic promedol was resolved into enantiomers; it was established that the (+)-enantiomer is approximately 9 times more active than the (−)-enantiomer[175]. The formation of only these three isomeric piperidinols has now been established by careful and repeated studies of the products of the reaction of 1,2,5-trimethyl-4-piperidinone with phenyl-lithium.

The existence of two isomers (*trans*- and *cis*- with respect to the methyl groups at $C_{(2)}$ and $C_{(5)}$ in 1,2,5-trimethyl-4-piperidinone) gave rise to no doubts, because interaction of this piperidinone with phenyl-lithium leads to the formation of three isomeric 1,2,5-trimethyl-4-phenyl-4-piperidinols. Experimental study of the isomerism of this piperidinone, which confirmed its existence in the *trans*- and *cis*-forms with the former, containing equatorial methyl groups, greatly predominating, was carried out with the aid of its ^{1}H NMR spectrum and the exchange of α-protons for deuterium[294]. The isolation of the *trans*-isomer of 1,2,5-trimethyl-4-piperidinone has been described[130].

In one of the first studies[127] associated with the solution of the problem of the configurations and conformations of the α- and γ-isomers of 1,2,5-trimethyl-4-phenyl-4-piperidinone chemical methods were used. The α- and γ-isomers of 2,5-dimethyl-, 1,2,5-trimethyl-, and 1-acetyl-2,5-dimethyl-4-phenyl-4-piperidinols were synthesised and related to one another by the usual transformations. The γ-isomers greatly predominated in the synthesis of the first two piperidinols. Since the N $\rightleftharpoons$ O acyl migration takes place in the γ-isomer of 1-acetyl-2,5-dimethyl-4-phenyl-4-piperidinol, it was concluded that the hydroxy-group in this isomer is in the axial position. In the α-isomer the N → O acyl migration takes place under more severe conditions with inversion of the configuration at $C_{(4)}$, since the same acetoxy-derivative is formed as from the γ-isomer. These transformations indicate the identical *trans*-equatorial dispositions of the methyl groups at $C_{(2)}$ and $C_{(5)}$ (the most favourable conformation for both the initial piperidinone and the piperidinols) in the α- and γ-isomers and of the equatorial disposition of the hydroxy-group in the α-isomer.

The same conclusion was reached in a study of the chromatographic mobilities of the γ- and α-isomers of 1,2,5-trimethyl-4-phenyl-4-piperidinol[295]. An analogous relation has been established for the γ- and α-isomers of 1,2,5-trimethyl-4-*m*-tolyl-4-piperidinol[157]. A quantitative study has been made[296] of the esterification of the α- and γ-isomers of 1,2,5-trimethyl-4-phenyl-4-piperidinol and it has been shown that the α-isomer, with the equatorial hydroxy-group, is esterified much faster than the γ-isomer. The same behaviour has been established in a study of the hydrolysis of the esters of both these isomeric piperidinols.

The infrared spectra of the γ- and β-isomers of 1,2,5-trimethyl-4-phenyl-4-piperidinol have the same characteristics as the spectra of the analogous 3-alkyl-4-aryl-4-piperidinols with the *trans*-disposition of the alkyl and aryl groups[200].

The configuration of the α-isomer of 1,2,5-trimethyl-4-phenyl-4-piperidinol has been indirectly confirmed[273,289,297]. Since β-prodine and α-promedol have almost the same analgesic activities in the series of the isomeric prodines and promedols, it has been suggested that they have the same *cis*-configurations of the CH_3 group in the β-position and the C_6H_5 group in the γ-position, which proved to be true.

Erroneous conclusions about the configurations and conformations of the isomeric α-, β-, and γ-1,2,5-trimethyl-4-phenyl-4-piperidinols were reached[270]. Unfortunately, in order to determine the steric structures of these isomers, the authors confined themselves to the results of qualitative esterification and dehydration experiments, which could not serve as a basis for the solution of conformational problems. The structure of 1,2*e*,5*e*-trimethyl-4*e*-phenyl-4-piperidinol was attributed to the α-isomer (m.p.106–107°C), which is actually 1,2*e*,5*e*-trimethyl-4*a*-phenyl-4-piperidinol, the structure of 1,2*a*,5*e*-trimethyl-4**a**-phenyl-4-piperidinol was attributed to the β-isomer (m.p. 102–103°C), which is actually 1,2*a*,5*e*-trimethyl-4*e*-phenyl-4-piperidinol, and the structure of 1,2*e*,5*e*-trimethyl-4*a*-phenyl-4-piperidinol was attributed to the γ-isomer (m.p. 107–108°C), which is actually 1,2*e*,5*e*-trimethyl-4*e*-phenyl-4-piperidinol. Shvetsov and Kucherov[270] also failed to take into account the published experimental data[127] concerning the determination of the structures of the isomeric 1,2,5-trimethyl-4-phenyl-4-piperidinols. In estimating the rates of esterification of γ-piperidinols isomeric at $C_{(4)}$ conclusions inconsistent with the fundamental principles of conformational analysis were reached[196,298]. Solely on the basis of "qualitative" observations, it was concluded erroneously that "the axially oriented hydroxy-group is more readily esterified ... than the equatorial hydroxyl"[196]. This conclusion conflicts with the above quantitative data for the esterification of the α- and γ-isomers of 1,2,5-trimethyl-4-phenyl-4-piperidinol[296].

Erroneous conclusions about the structures of the promedol and α-promedol piperidinols were reached in a study[274] related to a series of previous investigations[72,212,253]. Since the compounds to which the authors[274] related the steric structures of the α- and γ-isomers of 1,2,5-trimethyl-4-phenyl-4-piperidinol are the isomeric 4-ethynyl-1,2,5-trimethyl-4-piperidinols and 4-cyano-4-hydroxy-1,2,5-trimethylpiperidines, we need point out the erroneous conclusions concerning these compounds only, leaving aside other compounds described (the authors'[274] ideas about the steric structures of these compounds have now changed). The structure with the *cis*-disposition of the methyl group at $C_{(3)}$ and of the ethynyl group at $C_{(4)}$ was attributed arbitrarily[274] to the γ-isomer (m.p. 177 to 178°C) of 4-ethynyl-1,2,5-trimethyl-4-piperidinol. On the basis of chromatographic data alone, this conclusion was amended[299] and the structure with the *trans*-disposition of the same substituents was attributed to the above compound. Thus the conclusions concerning the steric structures of many derivatives of γ-piperidinols, including the isomeric 1,2,5-trimethyl-4-phenyl-4-piperidinols[72,212,253,274], were erroneous.

Shvetsov et al.[274] converted the γ-isomer of 4-cyano-1,2,5-trimethyl-4-piperidinol (m.p. 141–143°C) into the γ-isomer of 1,2,5-trimethyl-4-phenyl-4-piperidinol. However, since the erroneous configuration with the *cis*-disposition of the methyl group at $C_{(3)}$ and of the cyano-group at $C_{(4)}$ was attributed to the above cyanohydrin (later amended[275]), an erroneous conclusion was also reached about the structures of the isomeric 1,2,5-trimethyl-4-phenyl-4-piperidinols.

Subsequent studies confirmed the conclusions about the steric structures of the promedol alcohols arrived at by Prostakov and coworkers[127,273]. X-Ray diffraction of the α- and γ-isomers of 1,2,5-trimethyl-4-phenyl-4-piperidinol confirmed the *trans*-equatorial disposition of their methyl groups at $C_{(2)}$ and $C_{(5)}$ as well as the axial disposition of the phenyl group in the α-isomer and its equatorial disposition in the γ-isomer[300].

These conclusions[127,273] about the configurations and conformations of the α- and γ-isomers and also about the configuration of the β-isomer of 1,2,5-trimethyl-4-phenyl-4-piperidinol were fully confirmed in a study[301] based on infrared and ^{1}H NMR spectroscopic data. The inverted form, proposed previously by Prostakov and Mikheeva[273], was established for the conformation of the β-isomer. The occurrence of the chair–boat equilibrium, with the chair conformation predominating, was also demonstrated in solutions of the α- and β-isomers.

The ratio of the conformers of the isomeric promedols in solution was estimated from the difference between the free energies of the conformations with axial and equatorial phenyl groups. It follows from this estimate that conformers with the axial phenyl group constitute 97% of the α-isomer (alphapromedol, $\Delta F = -2.1$ kcal mole^{-1}), 62% of the β-isomer (isopromedol, $\Delta F = -0.3$ kcal mole^{-1}), while the corresponding conformer of the γ-isomer (promedol, $\Delta F = +7$ kcal mole^{-1}) does not exist[302].

By analysing ^{13}C NMR spectra, taking into account earlier studies, the following conclusions have been reached[303] about the structures of the isomeric 1,2,5-trimethyl-4-phenyl-4-piperidinols and their esters. The tentative conformations in deuterochloro-form are: α-isomer—1,2*e*,5*e*-trimethyl-4*a*-phenyl-4-piperidinol (the substance has the same conformation in the solid state); β-isomer—1,2*a*,5*e*-trimethyl-4*e*-phenyl-4-piperidinol; γ-isomer—1,2*e*,5*e*-trimethyl-4*e*-phenyl-4-piperidinol:(the substance has the same conformation in the solid state). The Table presents data for the true conformations of the isomers of 1,2,5-trimethyl-4-phenyl-4-piperidinol.

The configurations and conformations of the isomers of 1,2,5-trimethyl-4-phenyl-4-piperidinols.

Isomer	M.p., °C (Ref.116)	Structure of isomers	Studies in which their structure has been proved	Studies in which erroneous conclusions about the structures were reached
α	106—107		127,273,295,296, 297*,300*,301, 303*,304	270, 274

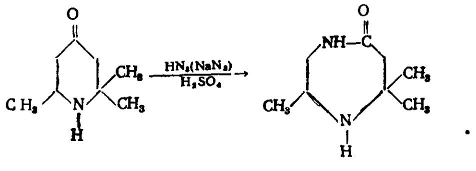
**Designated by the authors as the α-isomer[205,303].
***Configuration.

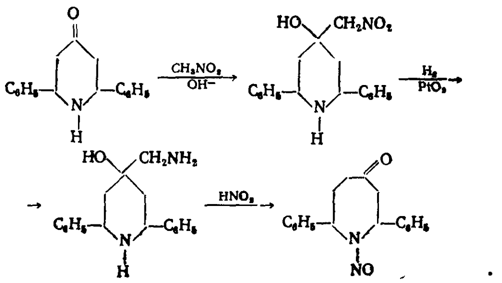
Thus, one may assume that the problems concerning the structures of γ-piperidinols, constituting the basis of effective analgesics, which has been discussed for many years, sometimes from opposed standpoints, have now been solved and that the conformational analysis of piperidine systems is now a fairly established part of the chemistry of nitrogen-containing heterocycles.

IV. γ-PIPERIDINONES IN SYNTHESES OF HETEROCYCLIC COMPOUNDS

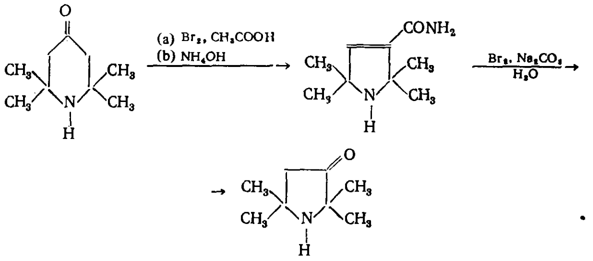
γ-Piperidinones are widely used in the syntheses of various heterocyclic compounds. Several examples of reactions of γ-piperidinones involving ring expansion have been described. 2,2,6-Trimethyl-4-piperidinone has been converted by the Schmidt reaction into 2,7,7-trimethyl-5-homopiperazinone:



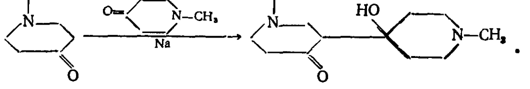
Analogous transformations have been achieved also for other γ-piperidinones[307–309]. The condensation of 2,6-diphenyl-4-piperidinone with nitromethane yielded 4-nitromethyl-2,6-diphenyl-4-piperidinol, which was reduced to 4-aminomethyl-2,6-diphenyl-4-piperidinol. Treatment of the latter with nitrous acid leads to the formation of 1-nitroso-2,7-diphenyl-1-aza-4-cycloheptanone[9]:



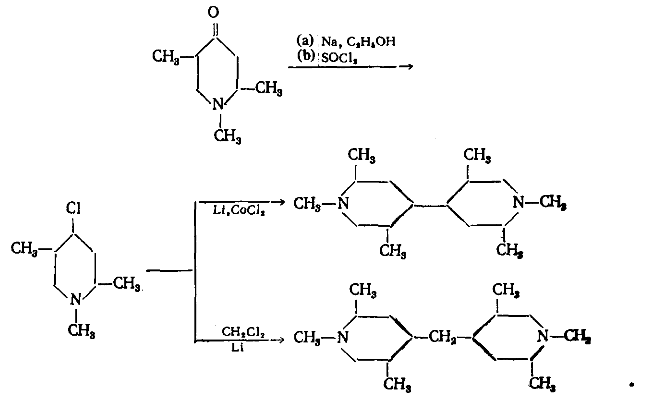
1-Benzyl-1-aza-3-cycloheptanone has been obtained from 1-benzyl-4-piperidinone by treating the latter with *N*-nitrosomethylurethane in the presence of barium oxide[310]. The synthesis of 2,2,5,5-tetramethyl-3-pyrrolidinone from triacetoneamine is an example of transformations of γ-piperidinones involving ring contraction. The amide of 2,2,5,5-tetramethyl-Δ^3-pyrrolinecarboxylic acid was obtained by treating with ammonia 3,3-dibromo-2,2,6,6-tetramethyl-4-piperidinone (formed on bromination of triacetoneamine) and was converted into a substituted 3-pyrrolidinone[311]:



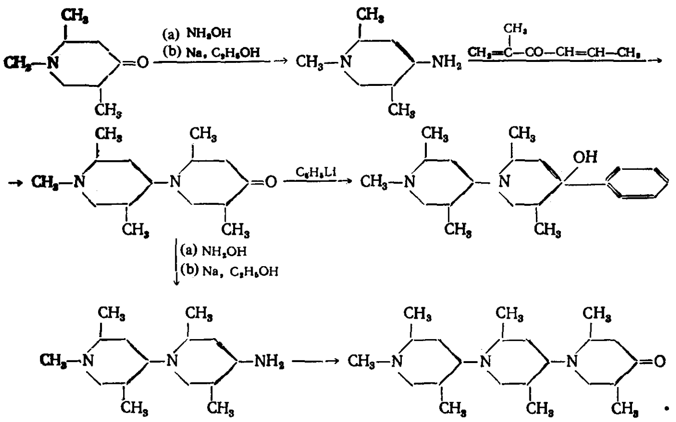
Several methods of synthesising di- and tri-piperidines from γ-piperidinones have been described. Intermolecular condensation of 1-methyl-4-piperidinone yielded a ketol—1-methyl-4-(1-methyl-4-oxo-3-piperidyl)-4-piperidinol[312]:



Bis(1,2,5-trimethyl-4-piperidyl) was obtained by treating 4-chloro-1,2,5-trimethylpiperidine with lithium or sodium in the presence of $CoCl_2$. Bis-(1,2,5-trimethyl-4-piperidyl)methane is formed from the same halogeno-derivative and methylene chloride in the presence of lithium[313]:

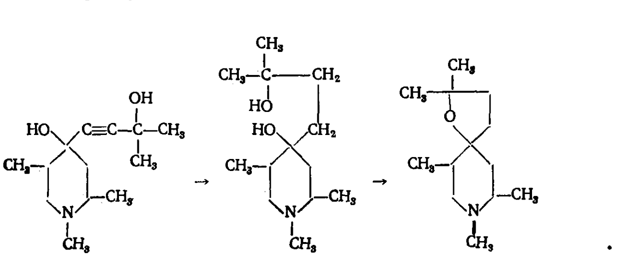


Condensation of 4-amino-1,2,5-trimethylpiperidine (obtained from the oxime of 1,2,5-trimethyl-4-piperidinone) with isopropenyl propenyl ketone yielded 2,5-dimethyl-1-(1,2,5-trimethyl-4-piperidyl)-4-piperidinone. Analogous transformations of this bicyclic system—the conversion of the oxo-group into an oxime group and then an amino-group and condensation of the resulting amine with isopropenyl propenyl ketone—led to the synthesis of terpiperidyl—2,5-dimethyl-4-(2,5-dimethyl-4-oxo-1-piperidyl)-1-(1,2,5-trimethyl-4-piperidyl)piperidine[153]:



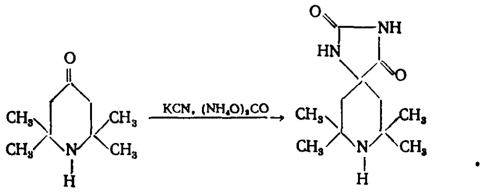
Synthesis of Spiro-compounds

The hydrogenation of 4-(3-hydroxy-3-methylbut-1-ynyl)-1,2,5-trimethyl-4-piperidinol (obtained by condensing 2,5-dimethyl-4-piperidinone with ethynyldimethylmethanol and subsequent N-methylation) results in the formation of a γ-glycol, the treatment of which with 10% sulphuric acid leads to its conversion into 2,2,7,8,10-pentamethyl-1-oxa-8-azaspiro[4,5]decane[243]:

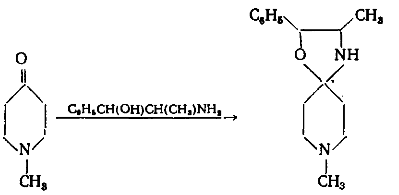


An analogous spiro-compound—2,2,7,10-tetramethyl-3-oxo-1-oxa-8-azaspiro[4,5]decane—is formed under the conditions of the hydration of the triple bond of 4-(3-hydroxy-3-methylbut-1-ynyl)-2,5-dimethyl-4-piperidinol[314]. Similar spiro-compounds have been described in other communications[315,316].

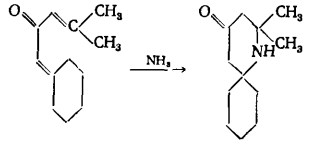
7,7,9,9-Tetramethyl-1,3,8-triazaspiro[4,5]decane-2,4-dione has been obtained from triacetoneamine, potassium cyanide, and ammonium carbonate. Analogous spiro-compounds have been synthesised from triacetoneamine substituted at the nitrogen atom[317] and also from 1,2,5-trimethyl-4-piperidinone cyanohydrin[318]. The syntheses of spirohydantoins, obtained from 1-alkyl-4-piperidinones, have been described[319,320]:



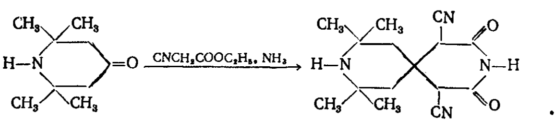
The condensation of 1-methyl-4-piperidinone with norephedrine leads to the formation of 3,8-dimethyl-2-phenyl-1-oxa-4,8-diazaspiro[4,5]decane[321]



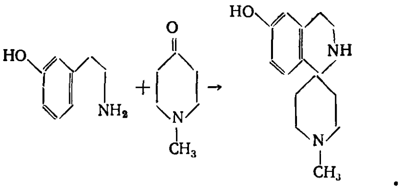
Analogous compounds substituted in the oxazolidine ring nitrogen have been described[322]. The reaction of the product of the condensation of mesityl oxide and cyclohexanone with ammonia (the method of synthesis of γ-piperidinones from divinyl ketones) yielded 2,2-dimethyl-4-oxo-1-azaspiro[5,5]undecane[323]:



The condensation of triacetoneamine with cyanoacetic ester and ammonia, resulting in the formation of 1,5-dicyano-8,8,10,10-tetramethyl-3,9-diazaspiro[5,5]-undecane-2,4-dione, has been achieved[324]:

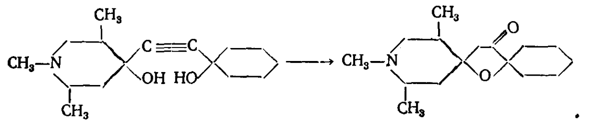


1′-Methyl-6-hydroxyspiro[1,2,3,4-tetrahydroisoquinoline-1,4′-piperidine] is formed when 3-(β-aminoethyl)-phenol is condensed with 1-methyl-4-piperidinone[325]:

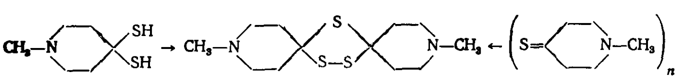


An analogous compound has been obtained from 2-amino-1-(3-hydroxyphenyl)ethanol[322].

The hydration of the triple bond of 4-[1-hydroxy-(1-cyclohexyl)ethynyl]-1,2,5-trimethyl-4-piperidinol involves the cyclodehydration of the resulting ketoglycol and leads to the formation of 1,3,4-trimethyl-14-oxo-7-oxa-3-azaspiro[5,1,5,2]pentadecane[252]:

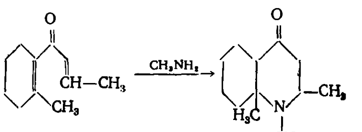


The crystallisation of the hydrochloride of 4,4-dimercapto-1-methylpiperidine and of the polymer of the hydrochloride of 1-methylthio-4-piperidinone (both substances have been obtained from 1-methyl-4-piperidinone) led to the isolation of the hydrochloride of dispiro-1,2,4-tritolane[45]:

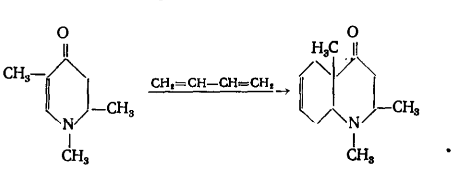


The Synthesis of Condensed Heterocyclic Compounds

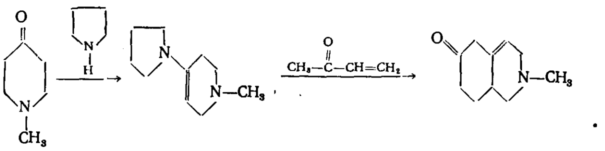
The method of synthesis of γ-piperidinones from divinyl ketones has been used to synthesise 1,2,8*a*-trimethyldecahydro-4-quinolinone, formed in the condensation of 2-methyl-Δ^1-cyclohexenyl propenyl ketone with methylamine[326]:



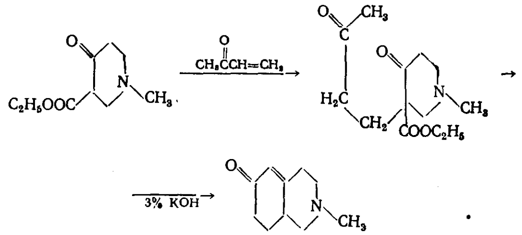
1,2,4*a*-trimethyl-1,2,3,4,4*a*,5,8,8*a*-octahydro-4-quinolinone is formed by the Diels–Alder reaction from 1,2,5-trimethyl-4-oxo-1,2,3,4-tetrahydropyridine (obtained from 1,2,5-trimethyl-4-piperidinone) and butadiene[327]:



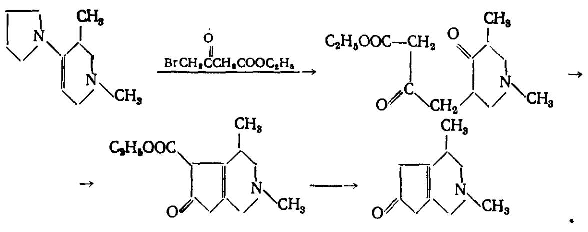
The condensation of 1-methyl-4-piperidinone with pyrrolidine results in the formation of 1-methyl-4-(1-pyrrolidinyl)-1,2,3,6-tetrahydropyridine, the reaction of which with methyl vinyl ketone gives 2-methyl-1,2,3,5,6,7,8,8*a*-octahydro-6-isoquinolinone[328]:



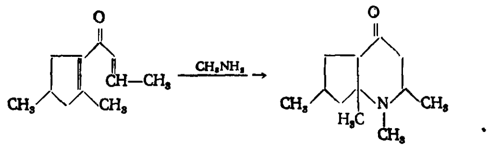
The condensation of 3-ethoxycarbonyl-1-methyl-4-piperidinone with methyl vinyl ketone has been used to synthesise 2-methyl-1,2,3,4,6,7,8,8*a*-octahydro-6-isoquinolinone[329]:



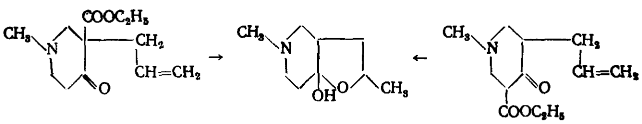
5-(γ-Ethoxycarbonyl-β-oxopropyl)-1,3-dimethyl-4-piperidinone, obtained from 1,5-dimethyl-4-(1-pyrrolidinyl)-1,2,3,6-tetrahydropyridine by cyclisation under the influence of potassium t-butoxide and subsequent decarboxylation of the condensation product, was converted into 2,4-dimethyl-2,3,4,5,6,7-hexahydro-1*H*-2-(6-pyrindinone)[47]:



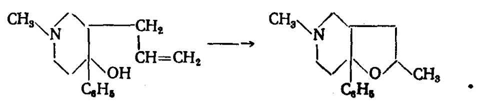
2,4-Dimethyl-Δ^1-cyclopentyl propenyl ketone (a divinyl ketone) reacts with methylamine and is converted into 1,2,6,7*a*-tetramethylperhydro-(4-pyrindinone)[326]:



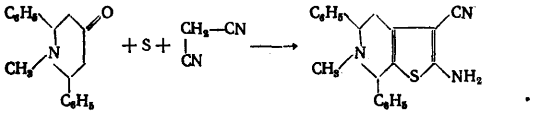
7*a*-Hydroxy-2,5-dimethylperhydrofuro[3,2-*c*]pyridine is formed on heating 3-allyl-3-ethoxycarbonyl-1-methyl-4-piperidinone as well as 3-allyl-5-ethoxycarbonyl-1-methyl-4-piperidinone with 20% hydrochloric acid. It is suggested that the removal of the ethoxycarbonyl group is accompanied by the simultaneous hydration of the double bond in the allyl group, which is followed by the formation of a hemiacetal[100,101]:



2,5-Dimethyl-6*a*-phenylperhydrofuro[3,2-*c*]pyridine was obtained under analogous conditions from 3-allyl-1-methyl-4-phenyl-4-piperidinol[100]:



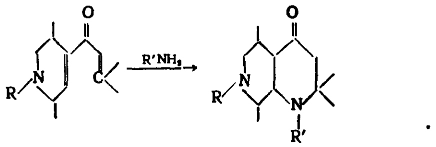
The condensation of 1-methyl-2,6-diphenyl-4-piperidinone with malonodinitrile in the presence of sulphur has been achieved and 2-amino-3-cyano-6-methyl-5,7-diphenyl-4,5,6,7-tetrahydrothieno[2,3-*c*]pyridine was obtained and was used in the synthesis of the condensed system of pyridothienopyrimidine[330]:



The analogous condensation of 1-(β-hydroxyethyl)-4-piperidinone with ethyl cyanoacetate and sulphur yielded 2-amino-3-ethoxycarbonyl-6-(β-hydroxyethyl)-4,5,6,7-tetrahydrothieno[2,3-*c*]pyridine[331].

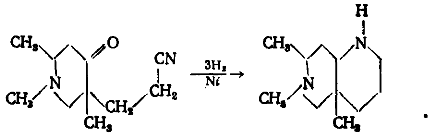
Synthesis of Fully or Partly Hydrogenated Naphthyridines

1,2,3,6-Tetrahydro-4-pyridyl vinyl ketones, substituted in the nitrogen-containing ring and in the β-position of the vinyl group, which are obtained from γ-piperidinones via 4-ethynyl-4-piperidinols[332] or 4-vinylethynyl-4-piperidinols[333], are converted into substituted perhydro-1,7-naphthyridines on reacting with primary amines:

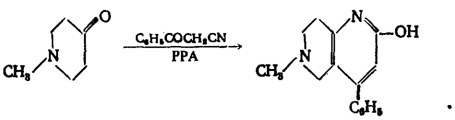


The same divinyl ketones have been used in the syntheses of piperidine–thiopyran (reaction with hydrogen sulphide) and piperidine–pyran (reaction with water) condensed systems[334,335].

Catalytic hydrogenation of 5-(β-cyanoethyl)-1,2,5-trimethyl-4-piperidinone led to the isolation of 4*a*,6,7-trimethyldecahydro[1,6]naphthyridine[92]:

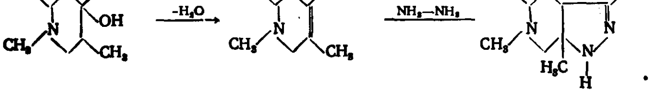


The condensation of 1-methyl-4-piperidinone with benzoylacetonitrile in the presence of polyphosphoric acid (PPA) led to the formation of 2-hydroxy-6-methyl-4-phenyl-5,6,7,8-tetrahydro[1,6]naphthyridine[336]:

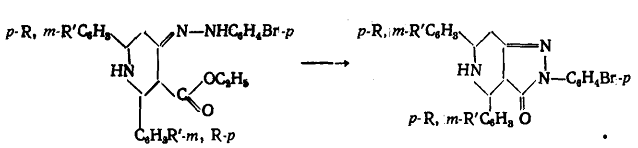


The Synthesis of the Condensed System Comprising Piperidine and Pyrazole

When the product of the dehydration of 4-ethynyl-1,2,5-trimethyl-4-piperidinol reacts with hydrazine hydrate, 2*a*,4,5,7-tetramethyl-2*a*,3,4,5,6,6*a*-hexahydropyrazolino[5,4-*c*]pyridine is formed[337]:

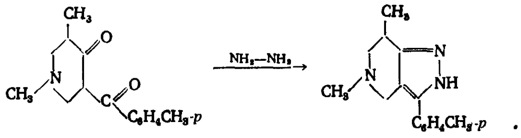


The intramolecular condensation of the *p*-bromophenylhydrazone of 3-ethoxycarbonyl-2,6-di-(*m*-methoxy-*p*-hydroxyphenyl)-4-piperidinone results in the formation of the corresponding 2,4,6-triaryl-3-oxo-3,3*a*,4,5,6,7-hexahydropyrazolo[4,3-*c*]pyridine[338]:

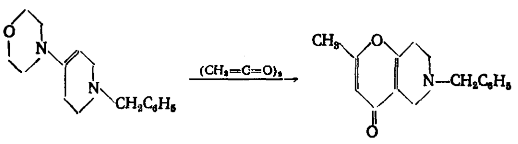


The syntheses of analogous condensed systems have also been described[339,340].

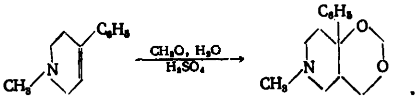
5,7-Dimethyl-3-*p*-tolyl-4,5,6,7-tetrahydropyrazolo[4,3-*c*]pyridine has been obtained by the reaction of 1,3-dimethyl-5-*p*-methylbenzoyl-4-piperidinone with hydrazine[341]:



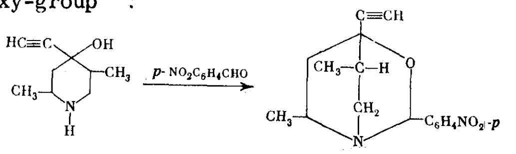
The analogous tetrahydropyrazolopyridine has been synthesised by condensing 1-acetyl-3-ethoxycarbonyl-4-piperidinone with phenylhydrazine[307]. 1-Benzoyl-4-morpholino-1,2,3,6-tetrahydropyridine (an enamine obtained from 1-benzyl-4-piperidinone) condensed with diketen to form 6-benzyl-2-methyl-5,6,7,8-tetrahydro-6-azochromone[342]:



6-Methyl-8*a*-phenyl-4*a*,5,6,7,8,8*a*-hexahydropyrido[4,5*α*]-1,3-dioxan has been synthesised by the Prins reaction from the product of the dehydration of 1-methyl-4-phenyl-4-piperidinol (obtained from 1-methyl-4-piperidinone)[343]:

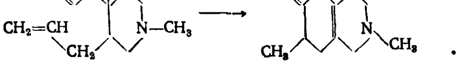


6-Ethynyl-4,7-dimethyl-2-*p*-nitrophenyl-1-oxa-3-azabicyclo[2,2,2]octane has been obtained from the γ-isomer of 4-ethynyl-2,5-dimethyl-4-piperidinol (with an axial hydroxy-group)[344]:

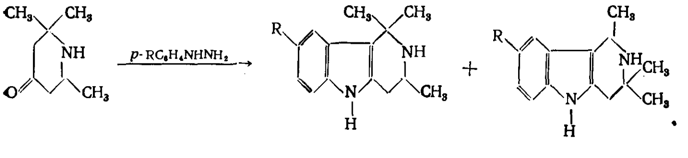


Synthesis of Tricyclic Heterocycles

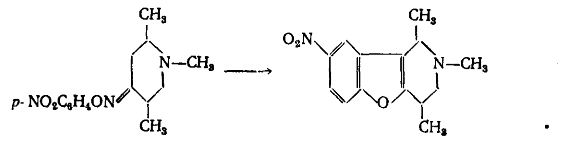
3-Allyl-1-methyl-4-phenyl-4-piperidinol, obtained from the corresponding γ-piperidinone, is converted on heating with 20% hydrochloric acid into 2,9-dimethyl-1,2,3,4,9,10-hexahydro-2-azaphenanthrene[100]:



The Fischer cyclisation of the arylhydrazones of certain γ-piperidinones has been investigated. In particular, the formation of 2,4,4-trimethyl-1,2,3,4-tetrahydro-γ-carboline and its isomer as regards the positions of the substituents in the nitrogen-containing six-membered ring has been demonstrated using the arylhydrazone of 2,2,6-trimethyl-4-piperidinone as an example. Analogous syntheses have also been described[345]:

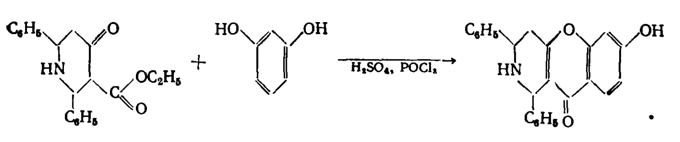


The cyclisation of the *p*-nitrophenylether of the oxime of 1,2,5-trimethyl-4-piperidinone to give 1,2,4-trimethyl-8-nitro-1,2,3,4-tetrahydrobenzofuro[3,2-*c*] pyridine has been achieved[346]:



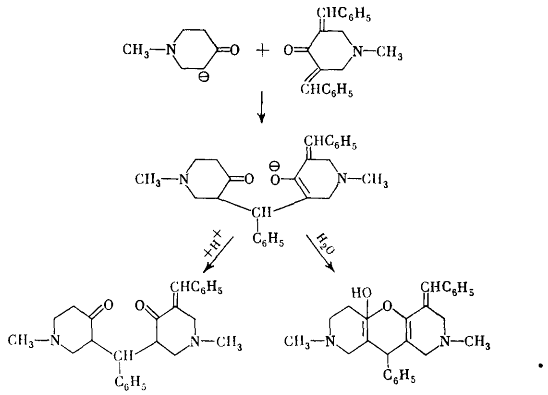
The condensation of *o*(*p*)-nitrophenyl ethers of the oximes of 1,3-dialkyl-4-piperidinones in ethanol in the presence of hydrogen chloride yielded 2,4-dialkyl-4*a*-ethoxy-1,2,3,4,4*a*,9*b*-hexahydro-6(8)-nitrobenzofuro[3,2-*c*]pyridine[347].

The condensed system comprising a partly hydrogenated pyridine and benzopyran has been obtained by the reaction of 3-ethoxycarbonyl-2,6-diphenyl-4-piperidinone with resorcinol[348]:

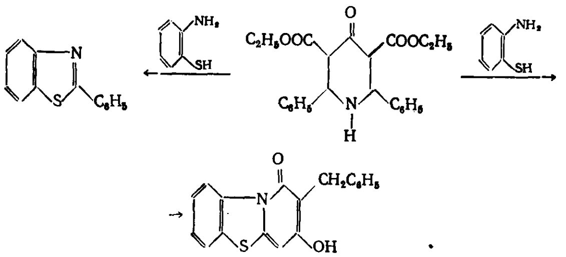


5-Oxo-1,2,3,4-tetrahydro-5*H*-[1]benzopyrano[3,4-*c*]-pyridines, substituted similarly in the dehydropiperidine and benzene rings, have been described in patents[349,350].

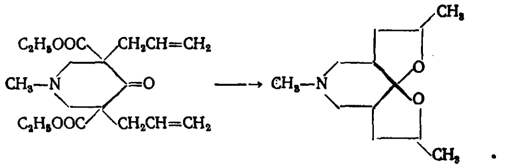
A complex mixture of substances is formed when γ-piperidinones interact with aromatic aldehydes in the presence of bases. When 1-methyl-4-piperidinone condenses with benzaldehyde, 3-benzylidene-5-[α-(1-methyl-4-oxo-3-piperidyl)benzyl]-1-methyl-4-piperidinone and 4-benzylidene-10*a*-hydroxy-2,7-dimethyl-9-phenyl-10-oxa-2,7-diaza-9*H*-1,2,3,4,5,6,7,8,8*a*,10*a*-decahydroanthracene are formed in addition to 3,5-dibenzylidene-1-methyl-4-piperidinone[80]. It has been suggested that there is initial Michael addition of the piperidinone anion to 3,5-dibenzylidene-1-methyl-4-piperidinone, whereupon the resulting enolate anion is converted in two steps into the above heterocyclic compounds[351,352]:



The reaction of *o*-aminothiophenol with 3,5-diethoxycarbonyl-2,6-diphenyl-4-piperidinone in boiling xylene led to the isolation of 2-phenylbenzothiazole and 2-benzyl-3-hydroxy-1-oxo-1*H*-benzo[*d*]pyrido[2,1-*b*]thiazole[353]. Their formation involves the cleavage of the piperidine ring, the mechanism of which has not so far been elucidated:

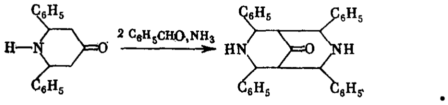


Hydrolysis of the diethyl ester of 3,5-diallyl-1-methyl-4-oxopiperidine-3,5-dicarboxylic acid followed by its decarboxylation is accompanied by the hydration of the allyl groups and the formation of the acetal derivative of 1,5′,5″-trimethylbis(tetrahydrofurano)-3′,2′ : 3,4 ; 2″,3″ : 4,5-piperidine[354]:

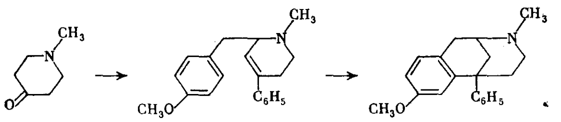


Synthesis of Bispidines

9-Oxo-2,4,6,8-tetraphenylbispidine is formed from 2,6-diphenyl-4-piperidinone, benzaldehyde, and ammonia[355]. Bispidines have also been synthesised by the condensation of γ-piperidinones with formaldehyde and methylamine[356,357]:



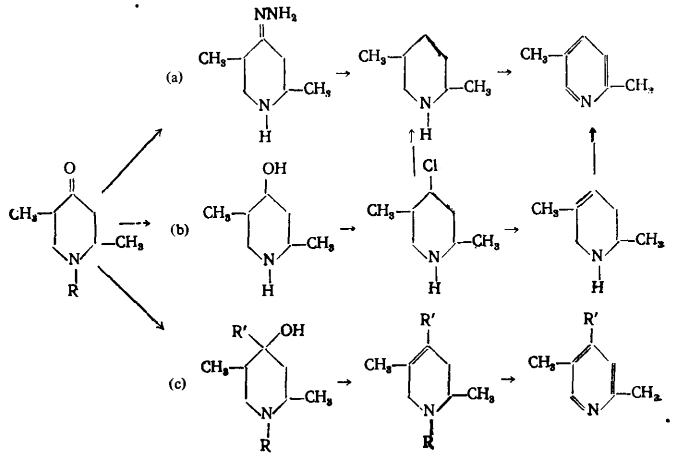
2-*p*-Methoxybenzyl-1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine was obtained by a series of successive transformations (phenyl-lithium synthesis, dehydration, formation of a salt with *p*-methoxybenzyl chloride, and its intramolecular Stevens rearrangement) from 1-methyl-4-piperidinone and was then converted by the Graebe method into a substituted benzomorphan[358]:



An analogous synthesis has been achieved starting from 1,3-dimethyl-4-piperidinone[359]. After treating 2-benzyl-1-methyl-4-piperidinone with 48% hydrobromic acid, 5-hydroxy-2-methyl-6,7-benzomorphan was isolated[360].

The ease of formation of γ-piperidinones substituted in a wide variety of ways makes it possible to employ them for the synthesis of pyridine bases. It has been shown for 2,6-diphenyl-4-piperidinol that, when it is treated with sulphur *in vacuo* up to 200°C, 2,6-diphenylpyridine is formed in approximately 90% yield[19]. It has been reported that tertiary γ-piperidinols are converted into pyridine bases on heating to 220–240°C with 20 wt.% of a palladium catalyst[134]. Pyriding has been obtained in a yield exceeding 90% on dehydrogenating piperidine (5% Pd, 300–400°C)[361]. A method has been developed for the dehydrogenation of piperidine bases to pyridine bases with the aid of a pyridine N-oxide[362].

In order to obtain pyridine bases from γ-piperidones, the following procedures are used: (a) reduction of γ-piperidinones by the Wolff–Kishner method to substituted piperidines with subsequent dehydrogenation in the presence of industrial K-12 and K-16 type catalysts[363]; (b) reduction of γ-piperidinones to γ-piperidinols, the replacement of the hydroxy-group in the latter by a halogen and then of the halogen by hydrogen, and dehydrogenation (or dehydrochlorination), dehydrogenation being the last stage; the yield in the dehydrogenation stage is more than 90%;[23,24,363]: (c) the conversion of γ-piperidinones into secondary and also tertiary piperidinols and their dehydration followed by the dehydrogenation and *N*-dealkylation of the resulting tetrahydropyridines[144–146, 202,203,364–368]:

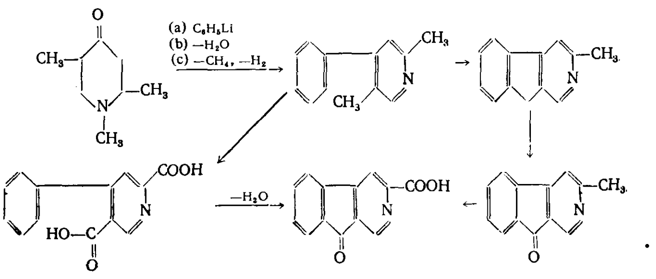


More than 150 individual pyridine bases with different structures have been obtained by means of these synthetic procedures from 1,2,5-trimethyl-4-piperidinone alone[34, 144–146,156–158,202,237,269,363–366,369–389].

γ-Piperidinones have become important starting materials in the syntheses of individual and substituted pyridine bases having specified structures. The study of the hydrogenation of 4-aryl- and 4-alkylaryl-pyridines obtained in this way established that, in the presence of catalysts such as rhenium heptasulphide, platinum sulphide, and palladium sulphide, only the pyridine ring undergoes selective hydrogenation, 4-aryl- and 4-alkylaryl-piperidines being formed in yields up to 99, 93, and 40% respectively. If the hydrogenation is carried out in alcohol, *N*-alkylation takes place simultaneously[390–393].

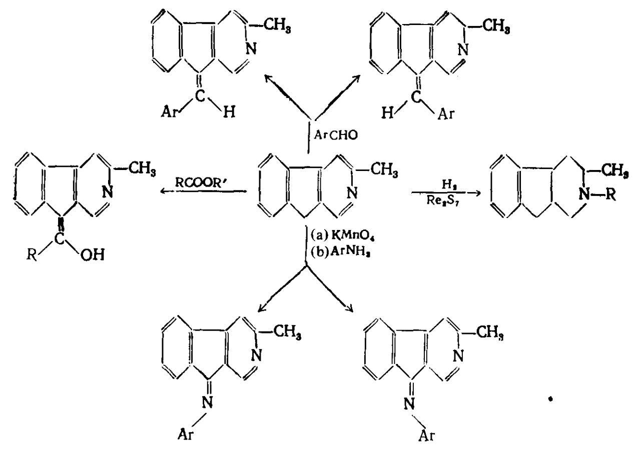
A characteristic feature of the structure of many pyridine bases obtained from 1,2,5-trimethyl-4-piperidinone is that the β-position contains a methyl group and the γ-position an aryl or alkylaryl group. These features have been used to synthesise condensed polycyclic nitrogen-containing heterocyclic compounds from such pyridine bases by dehydrocyclisation at 500–560°C in the presence of K-12 and K-16 catalysts.

2-Azafluorenes are formed from 4-aryl-3-methylpyridines, while 2,4-diaryl-3-methylpyridine gives rise to 2-aza and 4-aza-fluorenes[394]. An example of such syntheses is proved by the preparation of 3-methyl-2-azafluorenone and 9-oxo-2-azafluorene-3-carboxylic acid[373,395]. 9-Oxo-2-azafluorene-4-carboxylic acid was obtained similarly[203]:

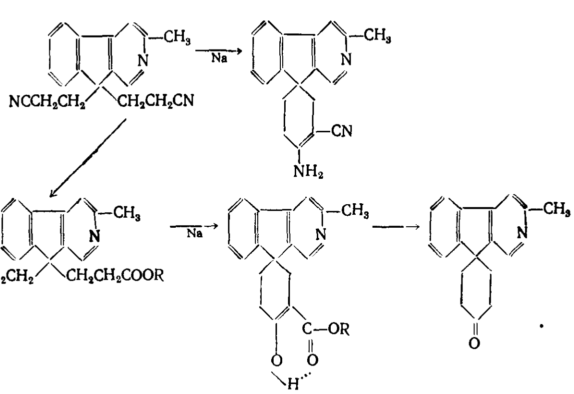


4-Aryl-2,5-dimethylpyridines with different alkyl substituents in the benzene ring have also been used to synthesise 2-azafluorenes[168,374]. The dehydrocyclisation of 3-methyl-2,4,6-triphenylpyridine (obtained from 1,3-dimethyl-2,6-diphenyl-4-piperidinone) leads to the formation of 1,3-diphenyl-2-azafluorene and 1,3-diphenyl-4-azafluorene. The former has also been obtained in the dehydrocyclisation of 2,6-diphenyl-4-*o*-tolylpyridine[176]. 3-Methyl-2-azafluorenone has been used in the syntheses of many 9-aryl(alkylaryl)-3-methyl-2-azafluorenols and their esters[396]. The geometrical isomers of 9-arylidene derivatives of 2-azafluorene and 3-methyl-2-azafluorene have been obtained in a study of their condensation with aromatic aldehydes, and it has been established that they are readily interconverted[397]. *N*-(3-Methyl-2-aza-9-fluorenylidene)arylamines, formed on condensation of 3-methyl-2-azafluorenone with aromatic amines, exist in the form of an equilibrium mixture of the *cis*- and *trans*-isomers (^{1}H NMR data)[398]. The enolic form is the stable structure of 9-acyl(aroyl) derivatives of 2-azafluorenes, its stabilisation being due to the interaction of the acid enolic hydrogen with the nitrogen of the pyridine ring[399,400]. When 3-methyl-2-azafluorene was reduced with sodium in alcohol, two isomers of 2-methyl-5*H*-indano[2,1-*c*]-piperidine were isolated[401] and their structures were subsequently examined[402,403]. It has been shown in a number of instances that the hydrogenation of substituted 2-azafluorenes in the presence of rhenium heptasulphide is selective, only the pyridine ring being hydrogenated with simultaneous reduction of the oxo- and hydroxy-groups in the 9-position and alkylation at the nitrogen atom when the hydrogenation is carried out in alcohol.

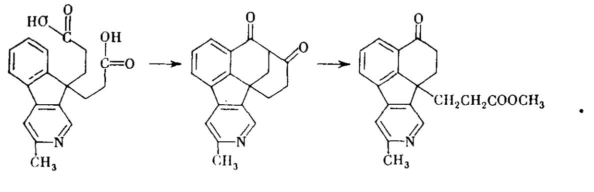
Two isomers of the indanopiperidine were also obtained in this instance[404,405].



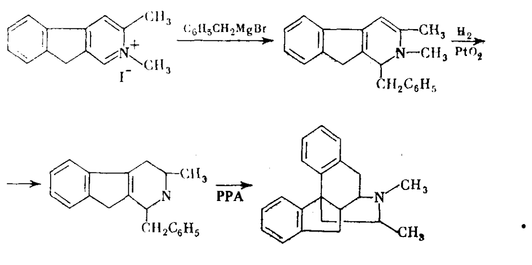
A new heterocyclic system—4'-amino-3'-cyano-3-methylspiro[2-azafluorene-9,1'-cyclohex-3'-ene]—has been obtained by the Dieckmann condensation from 9,9-di-(β-cyanoethyl)-3-methyl-2-azafluorene (synthesised by the Michael reaction from 3-methyl-2-azafluorene), while the condensation of 9,9-di-(β-ethoxycarbonylethyl)-3-methyl-2-azafluorene gave 3'-alkoxycarbonyl-4'-hydroxy-3-methylspiro[2-azafluorene-9,1'-cyclohex-3'-ene], which was subsequently converted into a spiroketone[406]. Analogous spirostructures have been obtained by the reaction of 3-methyl-2-azafluorene with αβ-unsaturated acid esters in the presence of sodium:



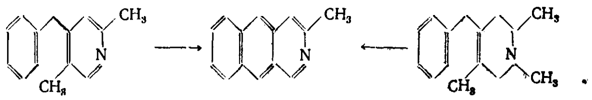
A new heterocyclic system—9-methyl-4,13-dioxo-8-aza-4,5,6,6*a*-tetrahydro-5,6*a*-propanofluoranthene—has been obtained by the cyclodehydration of 9,9-di-(β-carboxyethyl)-3-methyl-2-azafluorene under the influence of polyphosphoric acid. 6*a*-(2-Methoxycarbonylethyl)-9-methyl-4-oxo-8-aza-4,5,6,6*a*-tetrahydrofluoranthene is formed from this compound on treatment with methanol and sulphuric acid[407]:



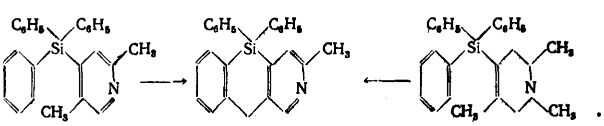
An analogue of morphinan—2,3-dimethyl-6,7-benzo-5,9-(1',2'-indano)-2-azabicyclo[3,3,1]non-6-ene—has been obtained from the methiodide of 3-methyl-2-azafluorene by a series of consecutive transformations[408]:



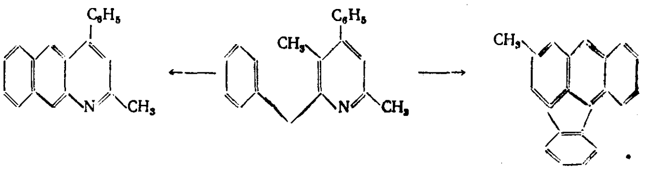
4-(2,5-Dimethyl)pyridines have been used to synthesise many benzo[*g*]isoquinolines, which have been little investigated. The same method (catalytic dehydrocyclisation) was used[383,385,396,409]:



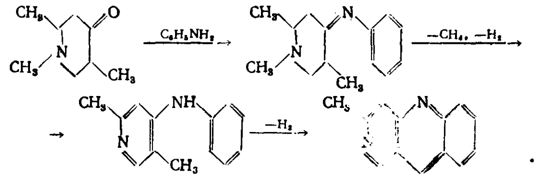
2,5-Dimethyl-4-triphenylsilylpyridine (it was synthesised from 1,3,6-trimethyl-4-triphenylsilyl-1,2,3,6-tetrahydropyridine) also undergoes dehydrocyclisation with formation of 2-methyl-9,9-diphenyl-9,10-dihydro-9-sila-3-aza-anthracene[410]:



The benzo[*g*]quinoline structure is formed on dehydrocyclisation of 2,5-dimethyl-4-phenyl-6-benzylpyridine, the products being 2-methyl-3-azabenzo[*f*]fluoranthene together with 2-methyl-4-phenylbenzo[*g*]quinoline[387]:

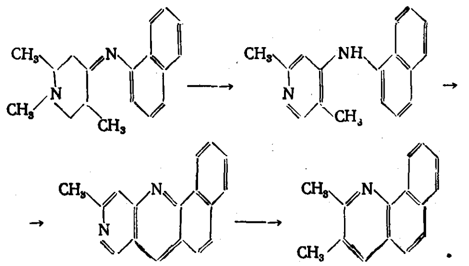


Yet another application of γ-piperidinones in the syntheses of heterocyclic compounds has been developed—the preparation from the latter of Schiff bases[41] and their catalytic transformations. It has been established[369] that *N*-(1,2,5-trimethyl-4-piperidylidene)aniline (obtained from 1,2,5-trimethyl-4-piperidinone and aniline) is converted in the presence of the K-12 catalyst at 470°C into (2,5-dimethyl-4-pyridyl)phenylamine, from which 7-methyl-2,3-benzo-1,6-naphthyridine is formed in the presence of the same catalyst[395]. The Schiff base obtained from 4-amino-1,2,5-trimethylpiperidine and benzaldehyde is converted into αβ'-lutidine at 400°C:[377]



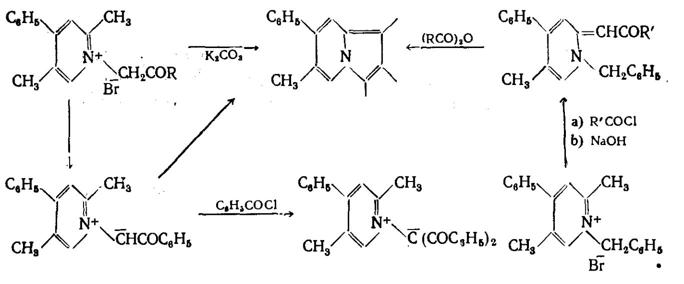
The reactions under analogous conditions of the Schiff bases obtained from 1,2,5-trimethyl-4-piperidinone and naphthylamines take place in a more complex manner.

N-(2,5-Dimethyl-4-pyridyl)-α-naphthylamine, 9-methylnaphtho[1,2-*b*][1,6]naphthyridine, and 2,3-dimethyl-4-azaphenanthrene have been obtained from *N*-(1,2,5-trimethyl-4-piperidylidene)-α-naphthylamine. The last Schiff base is apparently formed as a result of the degradation of naphthonaphthyridine[411]:

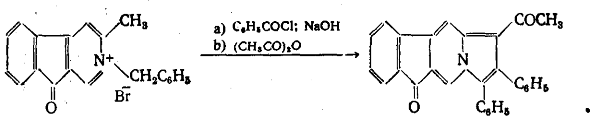


The following compounds were isolated after the analogous reactions of *N*-(1,2,5-trimethyl-4-piperidylidene)-β-naphthylamine: *N*-(2,5-dimethyl-4-pyridyl)-β-naphthylamine, 9-methylnaphtho[2,1-*b*][1,6]naphthyridine, and 2,3-dimethyl-1-azaphenanthrene[412].

The availability of substituted pyridine bases obtained from γ-piperidinones made it possible to expand the research into indolizine systems. Indolizines have been obtained directly from the quaternary *N*-β-oxoalkylpyridinium salts, from 1-benzyl-5-methyl-4-phenyl-3-phenacylidene-1,2-dihydropyridine, and from pyridine ylides. The stable dibenzoylmethylides were isolated in the study of the last group of compounds[368,413–415]:



A condensed system comprising indene and indolizine, namely 1-acetyl-5-oxo-2,3-diphenyl-5*H*-indeno[2,1-*f*]-indolizine, and other analogues have been synthesised[413,414]:



It follows from the present review that γ-piperidinones play an appreciable rôle in the development of the chemistry of piperidine and certain other heterocyclic compounds. The synthetic possibilities of γ-piperidinones in this respect have apparently been by no means exhausted.

The Methods of Synthesis and Properties of Conjugated Enallenic Hydrocarbons

I.Z.Egenburg

The methods of synthesis of conjugated enallenic hydrocarbons are surveyed and their physical and chemical properties are discussed.

The bibliography includes 90 references.

I. INTRODUCTION

Enallenic hydrocarbons containing the allene group conjugated with a double bond were obtained for the first time (with a rigorous demonstration of their structure) in 1958. The information available at the present time concerning the methods of synthesis and the chemical behaviour of these compounds is limited. However, the available data show that conjugated enallenes are interesting objects of study. The unusual stereochemistry of the allene group, which is particularly clearly manifested in enallenes, determines the ability of only one double bond of this group to participate in conjugation with the α-ethylenic bond, which is the reason for the unusual physical and chemical properties of these hydrocarbons. The likely usefulness of conjugated enallenic hydrocarbons in experimental organic chemistry has been demonstrated by their synthesis from aromatic and methylenecyclohexene compounds, which are relatively difficult to obtain, conjugated cyclopentenones, methylenecyclobutene derivatives, allenic alcohols, epoxides, etc. It has been established that the enallenic conjugated system of bonds occurs in certain natural antibiotics, attractants, and the pigments of algae, sea urchins, and the flowers and leaves of many plants. Allenic compounds with an α-ethylenic bond are also produced by many species of fungi. Since some of these compounds exhibit distinct antimicrobial and fungicidal activities, the study of the structure and biogenesis of natural enallenic derivatives is an important practical task.

The development of the chemistry of enallenic hydrocarbons is mainly due to the development of two fundamental preparative methods for their synthesis: the method of Petrov and Kormer and Bertrand's method. It is to be expected that further research in the chemistry of conjugated enallenic hydrocarbons will lead to the development of new methods of their synthesis and to extensive practical applications of these hydrocarbons.

II. METHODS OF SYNTHESIS

1. THE ANIONOTROPIC REARRANGEMENT OF ENYNE AND PROPARGYL SYSTEMS

(a) The Reduction of Halogenoenynes by Metals

Penta-1,2,4-triene (I), the parent compound of the class of conjugated enallenic hydrocarbons, was obtained for the first time by analogy with Ginzburg's method[1], on treating a mixture of the chloropentenynes (II) and (III)—derivatives of pent-1-en-4-yn-3-ol[2]—with the zinc–copper couple in butanol; the enallene (I) with 94% purity was isolated in 75% yield[3].

$$CH_2{=}CH{-}\underset{Cl}{CH}{-}C{\equiv}CH + HC{\equiv}C{-}CH{=}CH{-}CH_2{-}Cl \xrightarrow[BuOH]{Zn-Cu} CH_2{=}C{=}CH{-}CH{=}CH_2 .$$

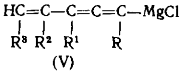
(II) (III) (I)

The use of the *trans*-isomer of the chloropentenyne (III) under these conditions made it possible to obtain compound (I) with 97% purity and in 70% yield.

During the reduction of chloroenynes with the zinc–copper couple, accompanied by the anionotropic rearrangement, an organozinc compound is apparently formed as an intermediate[4]. This is confirmed by the experimental observation of the formation of organomagnesium compounds in the reactions of analogues of the chloropentenyne (III) with magnesium. It has been shown[5,6] that the substituted chloropentenynes (IV) react with magnesium in ether at a low temperature to form the derivatives (V), which have the enallenic structure:

$$RC{\equiv}C{-}\underset{R^1}{C}{=}\underset{R^2}{C}{-}\underset{R^3}{C}HCl$$

(IV)



$$\underset{R^3}{HC}{=}\underset{R^2}{C}{-}\underset{R^1}{C}{=}C{=}\underset{R}{C}{-}MgCl$$

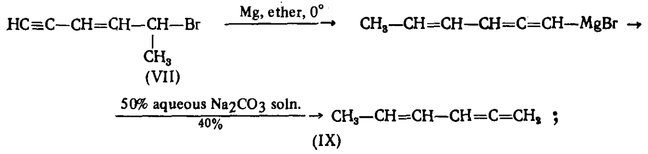
(V)

$$\underset{R^3}{HC}{=}\underset{R^2}{C}{-}\underset{R^1}{C}{=}C{=}\underset{R}{CH}$$

(VI)

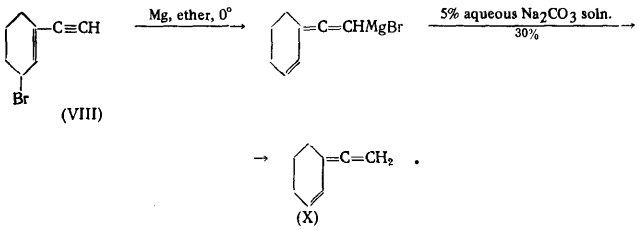
(a) $R{=}R^1{=}R^2{=}R^3{=}H$; (b) $R{=}R^2{=}R^3{=}H$, $R^1{=}CH_3$; (c) $R{=}R^3{=}H$, $R^1{=}R^2{=}CH_3$; (d) $R{=}R^1{=}R^2{=}H$, $R^3{=}CH_3$; (e) $R{=}CH_3$, $R^1{=}R^2{=}R^3{=}H$; (f) $R{=}H$, $R^1{=}R^2{=}R^3{=}CH_3$; (g) $R{=}H$, $R^1+R^2{=}$tetramethylene, $R^3{=}CH_3$; (h) $R{=}H$, $R^1{=}CH_3$, $R^2+R^3{=}$tetramethylene.

This discovery made it possible to use the above reaction to synthesise conjugated enallenic hydrocarbons. Thus the primary chloro-derivatives (IV, a–c, e) are converted, on treatment with magnesium and subsequent hydrolysis of the resulting organomagnesium compounds (V), into the corresponding enallenes (VI, a–c, e) in a satisfactory yield (31–55%).[5,6] The secondary chloroenynes (IV, d, f–h) do not react with magnesium either in boiling ether or in tetrahydrofuran (THF). However, the corresponding bromo-derivatives readily form organomagnesium compounds in the cold in ether, which has been demonstrated by the synthesis of the enallenic hydrocarbons (IX) and (X) from the bromo-derivatives (VII) and (VIII):



$$HC{\equiv}C{-}CH{=}CH{-}\underset{\underset{CH_3}{|}}{CH}{-}Br \xrightarrow{\text{Mg, ether, }0^\circ} CH_3{-}CH{=}CH{-}CH{=}C{=}CH{-}MgBr \rightarrow \xrightarrow[40\%]{50\%\text{ aqueous }Na_2CO_3\text{ soln.}} CH_3{-}CH{=}CH{-}CH{=}C{=}CH_2\ ;$$

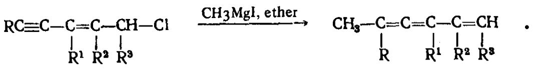
(VII) (IX)



(VIII) (X)

(b) The Interaction of Propargyl Halides, Halogenoenynes, and Ethers with Grignard Reagents

The chloropentenynes (IV, a–h) are converted into conjugated enallenes (XI) in 20–80% yield on treatment with methylmagnesium iodide in boiling† ether over a period of 2–3 h:[6,7]



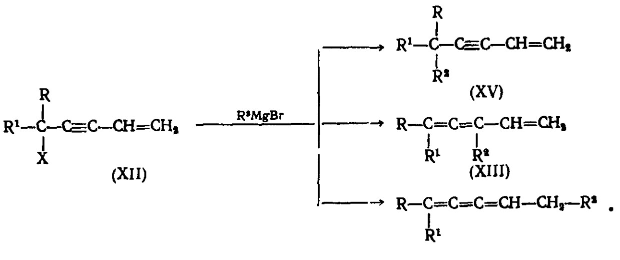
$$R C{\equiv}C{-}\underset{\underset{R^1}{|}}{C}{=}\underset{\underset{R^2}{|}}{C}{-}\underset{\underset{R^3}{|}}{CH}{-}Cl \xrightarrow{CH_3MgI,\text{ ether}} CH_3{-}\underset{\underset{R}{|}}{C}{=}C{=}\underset{\underset{R^1}{|}}{C}{-}\underset{\underset{R^2}{|}}{C}{=}\underset{\underset{R^3}{|}}{CH}\ .$$

(IV, a–h) (XI)

The enallenes (XI) were isolated from the reaction mixture by chromatographic methods. The above treatment of the chloroenyne (IV, f) gave a direct substitution product as the main reaction product. It has been established[6] that conjugated enallenes cannot be obtained from the chloroenynes (IV, a–h) using other Grignard reagents.

Comparison of the above two methods of synthesis of enallenes using chloropentenynes of type (IV) leads to the conclusion that the second method is preferable on the preparative scale, since it makes it possible to obtain the desired products with a higher purity and in higher yields. Furthermore, it permits the use of both primary and secondary chloroenynes.

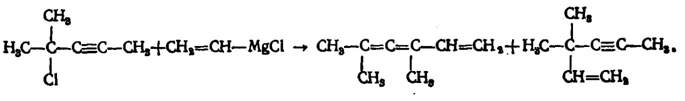
It has been shown[8] that the tertiary chlorides (XII, X = Cl) react with the Grignard reagent to form a mixture of enallenic and cumulenic hydrocarbons [compounds (XIII) and (XIV)], which are obtained from the initial compound as a result of a substitution reaction and the acetylene–allene–cumulene rearrangement. The reaction product contains a certain amount of the enyne hydrocarbon (XV) as a result of the "normal" substitution of chlorine in compound (XII)



$$R^1{-}\overset{\overset{R}{|}}{\underset{\underset{X}{|}}{C}}{-}C{\equiv}C{-}CH{=}CH_2 \xrightarrow{R^2MgBr} \begin{cases} R^1{-}\overset{\overset{R}{|}}{\underset{\underset{R^2}{|}}{C}}{-}C{\equiv}C{-}CH{=}CH_2 & \text{(XV)} \\ R{-}\underset{\underset{R^1}{|}}{C}{=}C{=}\underset{\underset{R^2}{|}}{C}{-}CH{=}CH_2 & \text{(XIII)} \\ R{-}\underset{\underset{R^1}{|}}{C}{=}C{=}C{=}CH{-}CH_2{-}R^2\ . & \text{(XIV)} \end{cases}$$

(XII)

The enyne (XV) is absent from the reaction mixture obtained by the analogous treatment of the ethers (XII, X = OAlk) and containing only compounds (XIII) and (XIV).[9] The overall yield and composition of the hydrocarbon mixture formed in the above reaction for different X, R, R^1, and R^2 are presented in Table 1. The reaction of vinylmagnesium chloride and 4-chloro-4-methylpent-2-yne (XVI) yields a mixture of the conjugated enallene (XVII) and the enyne (XVIII):[10]



$$H_3C{-}\overset{\overset{CH_3}{|}}{\underset{\underset{Cl}{|}}{C}}{-}C{\equiv}C{-}CH_3 + CH_2{=}CH{-}MgCl \rightarrow CH_3{-}\underset{\underset{CH_3}{|}}{C}{=}C{=}\underset{\underset{CH_3}{|}}{C}{-}CH{=}CH_2 + H_3C{-}\overset{\overset{CH_3}{|}}{\underset{\underset{CH{=}CH_2}{|}}{C}}{-}C{\equiv}C{-}CH_3 .$$

(XVI) (XVII) (XVIII)

Vinylmagnesium bromide and propargyl bromide react to form a 2·3 mixture of pent-1-en-4-yne (XIX) and penta-1,2,4-triene (I):[11]

$$HC{\equiv}C{-}CH_2{-}Br + CH_2{=}CH{-}MgBr \rightarrow \underset{\text{(XIX)}}{HC{\equiv}C{-}CH_2{-}CH{=}CH_2} + \underset{\text{(I)}}{CH_2{=}C{=}CH{-}CH{=}CH_2}\ .$$

Subsequent Bertrand isomerisation[12] of the mixture of hydrocarbons (XIX) and (I) on treatment with NaOH in methanol give the pure enallene (I). The latter can also be isolated by removing the enyne (XIX) from the reaction mixture on treatment with an alcoholic solution of silver nitrate.

Table 1. The overall yields and compositions of the hydrocarbon mixtures obtained in the reactions of the enynes (XII) with Grignard reagents[9].

Enyne derivative (XII)			R^2MgBr	Content in reaction mixture, %			Overall yield of (XIII) + (XIV) + (XV), %

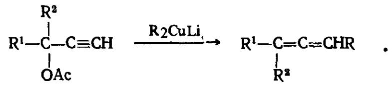
† Certain chlorides react at room temperature.

(c) Reduction of Enynyl Acetates with Dialkyl-lithium Cuprates

On treatment with dialkyl-lithium cuprates, propargyl acetates give high yields of alkylallenes[13]:



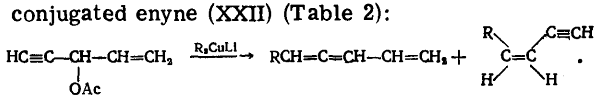
$$R^1{-}\overset{\displaystyle R^2}{\underset{\displaystyle OAc}{C}}{-}C{\equiv}CH \xrightarrow{R_2CuLi} R^1{-}\underset{\displaystyle R^2}{C}{=}C{=}CHR \;.$$

It has been shown[14] that this reaction can also be extended to the synthesis of conjugated enallenes when acetates having the enyne structures are used as the starting compounds.

Table 2. The compositions of the hydrocarbon mixtures obtained on treating the enynyl acetate (XX) with dialkyl-lithium cuprates R_2CuLi.[14]

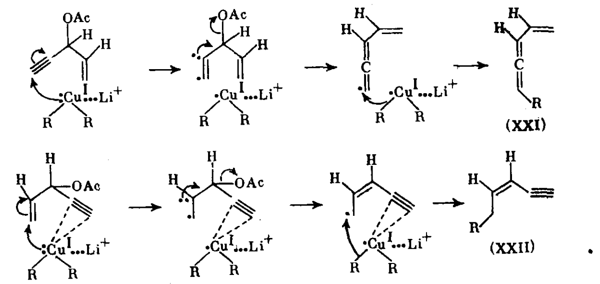
R	Content in reaction mixture, %		Overall yield of (XXI) + (XXII), %
	(XXI)	(XXII)	
CH_3	94	6	42
C_4H_9	80	20	60
C_8H_{17}	90	10	52

Thus the reaction of 3-acetylpent-1-en-4-yne (XX) with R_2CuLi in ether (between −20° and −30°C) results in the formation of the conjugated enallene (XXI) together with the conjugated enyne (XXII) (Table 2):



(XX) (XXI) (XXII)

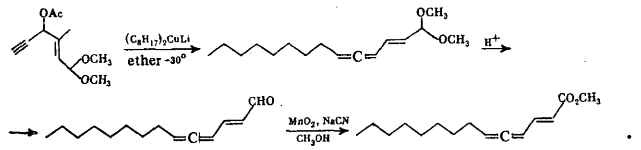
It follows from the data in Table 2 that the main reaction product is the enallenic hydrocarbon (XXI), the formation of which is believed[14] to be the result of the addition of dialkyl-lithium cuprate to the triple bond of the initial acetate (XX), while the enyne (XXII) results from the addition of the cuprate to the double bond:



(XXI)

(XXII)

The ester (XXIII), which is an insect attractant and is therefore of considerable interest, has been synthesised by this method[14]:



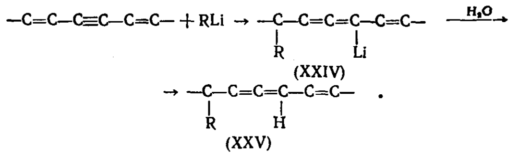
(XXIII)

2. REACTIONS INVOLVING 1,4-ADDITION TO ENYNE AND DIENYNE SYSTEMS

(a) The Addition of Organolithium, Organocalcium, and Organobarium Compounds to Conjugated Dienyne Hydrocarbons

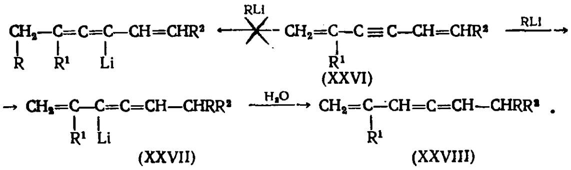
Petrov and Kormer developed a widely used preparative method of synthesising enallenes by treating conjugated dienyne hydrocarbons with alkyl-lithium in ether at a low temperature[15-19]. The following facts were established.

(1) The RLi reagent adds in the 1,4-positions of the enyne fragment of the conjugated dienyne system with formation of the lithium-containing adduct (XXIV) whose hydrolysis yields the enallene (XXV):



$$-C{=}C{-}C{\equiv}C{-}C{=}C- + RLi \rightarrow -\underset{\displaystyle R}{C}{-}C{=}C{=}\underset{\displaystyle Li}{C}{-}C{=}C- \;\xrightarrow{H_2O}$$
$$\text{(XXIV)}$$
$$\rightarrow -\underset{\displaystyle R}{C}{-}C{=}C{=}\underset{\displaystyle H}{C}{-}C{=}C- \;.$$
$$\text{(XXV)}$$

(2) The alkyl-lithium undergoes 1,4-addition, leading to the formation of an allenic system, only to the enyne fragments containing an unsubstituted vinyl group. Thus the dienyne (XXVI, $R^1 = CH_3$, $R^2 = H$) reacts with alkyl-lithium to form exclusively the lithio-derivative (XXVII)—the product of the addition of alkyllithium to the "vinylacetylene" fragment and not the "isopropenylacetylene" fragment of the dienyne system, as a result of which the enallenic hydrocarbon (XXVIII) is the sole product of the above reaction[16]:

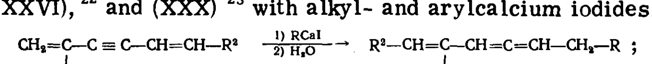


$$\underset{\displaystyle R}{CH_2}{-}\underset{\displaystyle R^1}{C}{=}C{=}\underset{\displaystyle Li}{C}{-}CH{=}CHR^2 \;\overset{RLi}{\nleftarrow}\; CH_2{=}\underset{\displaystyle R^1}{C}{-}C{\equiv}C{-}CH{=}CHR^2 \xrightarrow{RLi}$$
$$\text{(XXVI)}$$
$$\rightarrow CH_2{=}\underset{\displaystyle R^1}{C}{-}\underset{\displaystyle Li}{C}{=}C{=}CH{-}CHRR^2 \xrightarrow{H_2O} CH_2{=}\underset{\displaystyle R^1}{C}{-}CH{=}C{=}CH{-}CHRR^2 \;.$$
$$\text{(XXVII)} \qquad \text{(XXVIII)}$$

(3) The alkyl group of the reagent always adds to the terminal atom of the unsubstituted vinyl group.

The above characteristics of the addition of organolithium reagents to conjugated dienyne hydrocarbons can be accounted for by a coordination reaction mechanism[19]. The same characteristics hold also[20] in the reaction of aryl- and naphthyl-lithium with the dienyne hydrocarbon (XXVI, $R^1 = CH_3$, $R^2 = H$). Because of this, the enallenic hydrocarbon (XXVIII, $R = C_6H_5$, $2\text{-}CH_3C_6H_4$, $3\text{-}CH_3C_6H_4$, or α-naphthyl) is the only product of the above reaction.

Conjugated enallenic hydrocarbons can also be obtained by the reactions of the dienyne hydrocarbons (XXIX),[21] (XXVI),[22] and (XXX)[23] with alkyl- and arylcalcium iodides:



$$CH_2{=}\underset{\displaystyle R^1}{C}{-}C{\equiv}C{-}CH{=}CH{-}R^2 \xrightarrow[2)\,H_2O]{1)\,RCaI} R^2{-}CH{=}\underset{\displaystyle R^1}{C}{-}CH{=}C{=}CH{-}CH_2{-}R \;;$$

(XXIX): $R^1{=}H$, $R^2{=}H$; $R{=}C_2H_5$, $n\text{-}C_3H_7$, $n\text{-}C_4H_9$, $iso\text{-}C_4H_9$, $n\text{-}C_5H_{11}$;

(XXVI): $R^1{=}CH_3$, $R^2{=}H$; $R{=}C_2H_5$, $n\text{-}C_3H_7$, $n\text{-}C_4H_9$, $iso\text{-}C_4H_9$, $n\text{-}C_5H_{11}$, C_6H_5, $CH_3C_6H_4$;

(XXX): $R^1 = H$, $R^2 = CH_3$; $R = C_2H_5$, $n\text{-}C_3H_7$, $n\text{-}C_4H_9$.

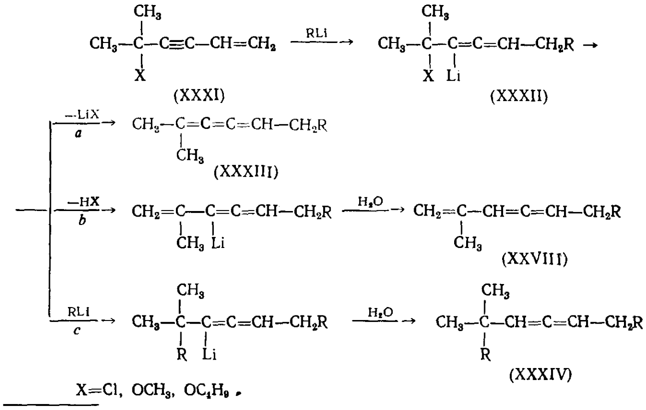
The above process, which takes place at room temperature over a period of several minutes, is, however, complicated by a competing reaction of the Wurtz type. The yield of enallenes does not exceed 30% in this instance.

Diethylcalcium[24] and diethylbarium[25] add similarly to the above dienynes. Demetallation of the adducts formed gives conjugated enallenes in 25–30% yield. On the other hand, the use of organolithium reagents in the reaction with dienynes (the method of Petrov and Kormer[15-19]) makes it possible to obtain conjugated enallenes in 70–80% yield.

However, there are certain limitations imposed by the very nature of the method, which makes it possible to synthesise only disubstituted enallenic hydrocarbons in which the number of carbon atoms in the chain is not less than eight‡.

(b) The Interaction of Organolithium Compounds with Tertiary Enynyl Halides and Ethers

On treatment with alkyl-lithium, tertiary ethers and chlorides having the general formula (XXXI) give rise to conjugated enallenic hydrocarbons (XXVIII) together with cumulenes and allenes[19,26]:

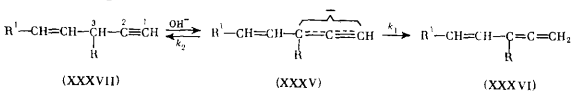


The first stage of the process consists of the 1,4-addition of the alkyl-lithium to the conjugated enyne system of compound (XXXI) with formation of the lithioallene (XXXII). The subsequent reaction of the latter leads to the formation of hydrocarbons (XXXIII) (pathway *a*), (XXVIII) (pathway *b*), or (XXXIV) (pathway *c*). The dependence of the yield of the conjugated enallene (XXVIII) on various factors has been demonstrated in relation to the interaction of the enyne ether (XXXI, X = OCH_3) with organolithium reagents. The most important of these are as follows: solvent polarity, the nature of the alkyl group in the alkyl-lithium, and reaction temperature. It has been shown that a high polarity of the medium leads to the preferential formation of the enallene (XXVIII), because it promotes a greater ease of the dissociation of the C–O bond in the ether. Thus the above ether interacts with n-butyl-lithium in THF at −60°C to form the enallenic hydrocarbon (XXVIII) with a small admixture of the cumulene (XXXIII), while in isopentane the cumulene is the exclusive product. The formation of the cumulene (XXXIII) is fully suppressed on raising the temperature to 0–30°C. In this case the reaction products are the enallene (XXVIII) (in 60% yield) and the hydrocarbon (XXXIV). Higher yields of compound (XXVIII) when the reaction is carried out in ether at −60°C are achieved by using an alkyl-lithium containing secondary or tertiary and not primary alkyl groups.

The influence of the C–O bond strength on the yield of the enallene (XXVIII) in the reactions of tertiary enynyl ethers with alkyl-lithium was discovered on comparing the products of the interaction of n-butyl-lithium with methoxy- and butoxy-derivatives of the hexenyne (XXXI, X = OCH_3 or OC_4H_9). As a result of the greater strength of the C–O bond in the latter ether, the reaction involving the elimination of lithium butoxide in the intramolecular conversion of the adduct (XXXII) predominates over the elimination of butyl alcohol. This is accompanied by the preferential formation of the cumulene (XXXIII). The reaction of the chloride (XXXI, X = Cl) with ethyl-lithium and n-butyl-lithium (in ether, between −30° and −40°C) leads to a mixture of the enallene (XXVIII) in 10–15% yield and the cumulene (XXXIII) in 20–30% yield.

3. THE PROTOTROPIC REARRANGEMENT OF NON-CONJUGATED ENYNE HYDROCARBON (ALK-1-EN-4-YNES)

Bertrand and coworkers developed a preparative method for the synthesis of conjugated enallenic hydrocarbons by the prototropic rearrangement of alk-1-en-4-ynes[12,27,28]. The rearrangement is catalysed by a base, which attacks the active methylene group of the enyne with formation of the ambident carbanion (XXXV). The stabilisation of the latter by the addition of a proton to the $C_{(1)}$ or $C_{(3)}$ atom leads to the enallene (XXXVI) or to the initial enyne (XXXVII) respectively:



(a) R=R¹=H; (b) R=H, R¹=CH_3; (c) R=H, R¹= iso-C_3H_7;
(d) R=CH_3, R¹=H; (e) R=CH_3, R¹=CH_3; (f) R=H, R¹=C_2H_5;
(g) R=n-C_3H_7, R¹ = H.

The proposed mechanism of the rearrangement[28] has been fully confirmed[29-31] in a study of the kinetics and in the determination of the thermodynamic parameters of the process involving enyne hydrocarbons (XXXVII, a–e) substituted in different ways. It has been established that the rate of conversion of the carbanion (XXXV) into the enallene (XXXVI) is many times higher than the rate of its conversion into the initial enyne (XXXVII), i.e. $k_1 \gg k_2$. The application of ultraviolet spectroscopy in combination with gas–liquid chromatography (GLC) made it possible to follow the content in the reaction mixture of both the initial enyne and the enallene formed and to establish that the rate of this reaction may be described by the second-order equation

$$v = k\,[OH^-][\text{alk-1-en-4-yne}].$$

In conformity with the proposed mechanism, the activation energy $E^{\neq}$ and activation enthalpy $\Delta H^{\neq}$ of the isomerisation of the enynes (XXXVIId) and (XXXVIIe), containing the alkyl substituent at the $C_{(3)}$ atom, are much higher than for compound (XXXVII, a–c).

In all the cases investigated the activation entropy $\Delta S^{\neq}$ is negative owing to the restriction in the transition state of free rotation about the $C_{(2)}$–$C_{(3)}$ bond due to the change in the hybridisation of the $C_{(3)}$ atom. The latter promotes a certain degree of separation of the substituents at $C_{(3)}$ owing to the increase of the valence angle resulting in higher values of $\Delta S^{\neq}$ for the isomerisation of the enynes (XXXVIId) and (XXXVIIe) compared with the hydrocarbon unsubstituted at $C_{(3)}$ [$\Delta S^{\neq}$ = −5.1 e.u. for the reaction (XXXVIId) → (XXXVId) and −45.6 e.u. for (XXXVIIa) → (XXXVIa)]. The transition of the $C_{(3)}$ atom from the sp^3

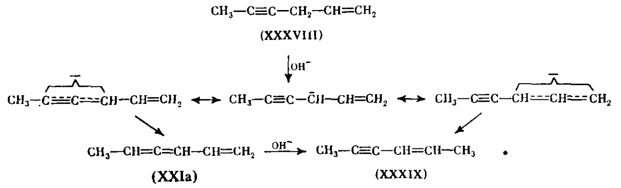
---

‡ Methyl-lithium does not add to conjugated dienynes[19].

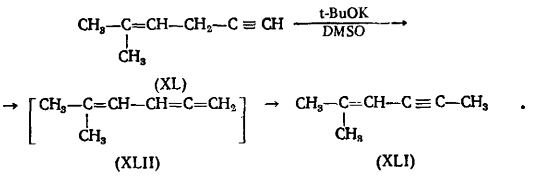
to the sp^2 state on formation of the carbanion (XXXV) greatly reduces the steric interaction of the methyl and ethynyl groups of the *cis*-isomer of the enyne (XXXVIIb), as a result of which the rate of isomerisation of the latter to the enallenic hydrocarbon exceeds by a factor of 3 the rate of isomerisation of the *trans*-isomer ($\Delta S^{\neq}_{cis} > \Delta S^{\neq}_{trans}$).

The intermediate formation of the carbonion (XXXV) explains the stereospecificity of the prototropic rearrangement of alk-1-en-4-ynes in the course of which the configuration of the double bond is maintained. It has been established for a large number of compounds that the above rearrangement takes place smoothly when alk-1-en-4-ynes are refluxed for 3–4 h with a 5% methanolic solution of NaOH, which results in the formation of enallenes with a high degree of purity[27,30].

In contrast to this, the prototropic rearrangement of hex-1-en-4-yne (XXXVIII), carried out under the same conditions, leads to the formation of a mixture of the enallene (XXIa) and the conjugated enyne (XXXIX), the latter being the main reaction product[32]. At 112°C the hydrocarbon (XXXVIII) is converted quantitatively into the enyne (XXXIX). The study of the time course of this process showed that in this case too the reaction takes place with participation of the enallene (XXIa), which isomerises rapidly at the given temperature to the enyne (XXXIX). It has been shown that the enallene is not a necessary precursor of the latter and that direct isomerisation of the initial hexenyne into the enyne (XXXIX) also occurs. Thus the reaction takes place as a parallel-consecutive process in conformity with the mechanism



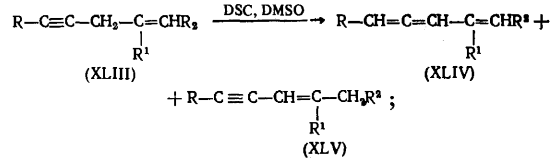
When 2-methylhex-2-en-5-yne (XL) was treated with t-BuOK in dimethyl sulphoxide (DMSO), the conjugated enyne (XLI) was the only product[33]. It has been suggested[33] that the intermediate enallene (XLII) is converted under the experimental conditions into the enyne (XLI) via the classical mechanism of the Favorskii allene–acetylene rearrangement:



$$\underset{(XL)}{CH_3{-}\underset{CH_3}{\underset{|}{C}}{=}CH{-}CH_2{-}C{\equiv}CH} \xrightarrow[DMSO]{t\text{-}BuOK} \underset{(XLII)}{\left[CH_3{-}\underset{CH_3}{\underset{|}{C}}{=}CH{-}CH{=}C{=}CH_2\right]} \rightarrow \underset{(XLI)}{CH_3{-}\underset{CH_3}{\underset{|}{C}}{=}CH{-}C{\equiv}C{-}CH_3}\ .$$

The unstable enallene (XLII) can be obtained[33] by carrying out the reaction under the conditions proposed by Bertrand.

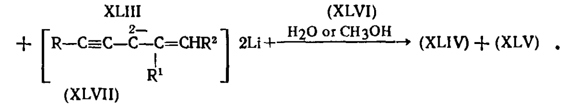
The instantaneous isomerisation of alk-1-en-4-ynes (XLIII) in DMSO, catalysed by the dimethylsulphenyl carbanion (DSC), has been investigated[34] and it has been established that the conjugated enallenes (XLIV) can be obtained only when alk-1-en-4-ynes containing a symmetrically substituted double bond, as in compounds (XLIII, c, d), are used. The conjugated enynes (XLV) are obtained by the isomerisation of the enynes (XLIII, a, b, e, f, g) with a terminal C=C bond under the same conditions, as a result of the subsequent prototropic transformation of the enallenes formed:



$$\underset{(XLIII)}{R{-}C{\equiv}C{-}CH_2{-}\underset{R^1}{\underset{|}{C}}{=}CHR_2} \xrightarrow{DSC,\ DMSO} \underset{(XLIV)}{R{-}CH{=}C{=}CH{-}\underset{R^1}{\underset{|}{C}}{=}CHR^2} + \underset{(XLV)}{R{-}C{\equiv}C{-}CH{=}\underset{R^1}{\underset{|}{C}}{-}CH_2R^2}\ ;$$

(a) $R=C_6H_5$, $R^1=R^2=H$; (b) $R=C_6H_5$, $R^1=CH_3$, $R^2=H$; (c) $R=C_6H_5$, $R^1=H$, $R^2=CH_3$; (d) $R=R^2=C_6H_5$, $R^1=H$; (e) $R=t\text{-}C_4H_9$, $R^1=R^2=H$; (f) $R\text{-}t\text{-}C_4H_9$, $R^1=CH_3$, $R^2=H$; (g) $R=n\text{-}C_6H_{13}$, $R^1=CH_3$, $R^2=H$.

Klein and Brenner described[34–36] the metallation of alk-1-en-4-ynes (XLIII) with butyl-lithium in ether at −90°C, leading to the intermediate formation of the mono- and di-lithio-derivatives (XLVI) and (XLVII). Protonation of the latter leads to a mixture of conjugated enallenes (XLIV), enynes (XLV), and initial compounds[34,35]:



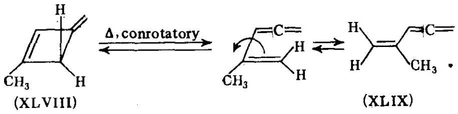
$$\underset{XLIII}{R{-}C{\equiv}C{-}CH_2{-}\underset{R^1}{\underset{|}{C}}{=}CHR^2} \xrightarrow[ether\ \ 90^\circ]{BuLi} \underset{(XLVI)}{\left[R{-}C{\equiv}C{-}\bar{C}H{-}\underset{R^1}{\underset{|}{C}}{=}CHR^2\right]} Li^+ + \underset{(XLVII)}{\left[R{-}C{\equiv}C{-}\overset{2-}{C}{-}\underset{R^1}{\underset{|}{C}}{=}CHR^2\right]} 2Li^+ \xrightarrow{H_2O\ or\ CH_3OH} (XLIV) + (XLV)\ .$$

The composition of the reaction mixture depends on the reaction conditions and also on which lithio-derivative, (XLVI) or (XLVII), is protonated[35].

4. PERICYCLIC REACTIONS

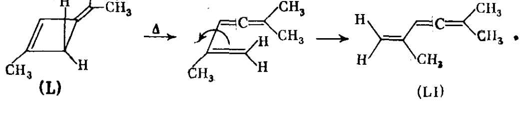
(a) Electrocyclic Transformation of Methylenecyclobutenes

The thermal conversion of methylenecyclobutenes into enallenes is analogous to the electrocyclic conversion of cyclobutenes into butadienes[37]. The opening of the ring of methylenecyclobutenes, which has a 4π-electron system, under thermally controlled conditions is conrotatory[38] and leads to the formation of enallenic hydrocarbons. For example, the pyrolysis (at 350–400°C) of 1-methyl-3-methylenecyclobutene (XLVIII) yielded 2-methylpenta-1,3,4-triene (XLIX):[39]



The process is reversible; the equilibrium reaction mixture contains ~51% of the enallene (XLIX) and ~49% of the methylenecyclobutene (XLVIII). It has been noted that[39] the latter is thermally more stable than alkylcyclobutenes as a result of the stabilising influence of the exocyclic C=C bond.

3-Isopropylidene-1-methylcyclobutene (L) is similarly converted into 2,5-dimethylhexa-1,3,4-triene (LI):[40]

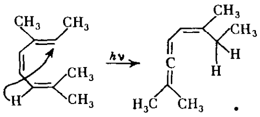


Data indicating the reversibility of this process are lacking; it was carried out by injecting compound (L) into the evaporator of the chromatograph (at 340°C) and trapping the reaction product (yield 45–55%) in a cooled trap.

Since methylenecyclobutenes are not readily available, this method of synthesis of conjugated enallenic hydrocarbons cannot be regarded as preparative.

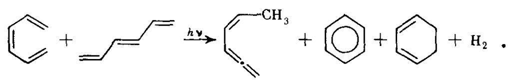
(b) The Sigmatropic Rearrangement of Conjugated Trienes

Conjugated enallenes are formed as a result of the photochemical sigmatropic rearrangement of conjugated trienes. This reaction includes a [1,5]-shift of hydrogen, which is symmetry-allowed as an antarafacial displacement^{41}. According to Crowly's data^{42,43}, the photolysis of allo-ocimene (LII) gives a 37% yield of the unstable enallene (LIII):



(LII) (LIII)

The enallene (IX), cyclohexa-1,3-diene (LV), benzene, and hydrogen have been obtained as the main reaction products by the vapour-phase photolysis of a mixture of the geometrical isomers of hexa-1,3,5-triene (LIV):^{44}



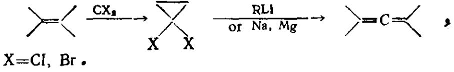
(LIV) (IX) (LV)

Similar products are obtained in the photolysis of cyclohexa-1,3-diene (LV).^{45,46} The enallene (IX) was obtained in this instance as a result of the electrocyclic conversion of the cyclohexadiene (LV) into the conjugated triene (LIV) ^{47} and the [1,5]-sigmatropic rearrangement of the latter.

The isomerisation of conjugated trienes to conjugated enallenes is of considerable interest, since it may be responsible for the biogenic synthesis of natural enallenes^{42}.

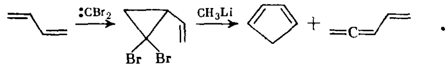
5. DEHALOGENATION OF *GEM*-DIHALOGENOCYCLOPROPANES

The dehalogenation by organolithium reagents$^{48-52}$ or active metals^{53,54} of *gem*-dihalogenocyclopropanes, obtained by the addition of dihalogenocarbenes to olefins, is one of the best methods of synthesising allenes:

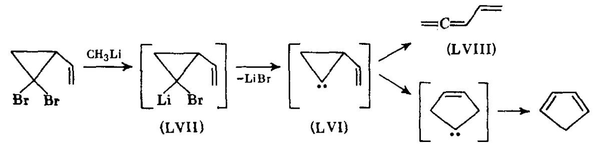


X=Cl, Br.

It might have been expected that conjugated enallenic hydrocarbons can also be synthesised from conjugated dienes by the above procedure. However, Skatteboel showed^{55,56} that, when *gem*-dibromovinylcyclopropanes are treated with methyllithium, cyclopentadienes are formed in 70–90% yield together with only small amounts of enallenic compounds:



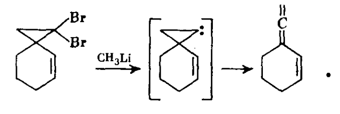
This anomalous course of the reaction can be tentatively^{55} regarded as a result of reactions of cyclopropylidene [the carbene§ (LVI)], generated when lithium bromide is eliminated from the intermediate (LVII). Two products of the above reaction—the enallene (LVIII) and the cyclopentadiene (LIX)—correspond to two different pathways in the transformation of the above carbene. On the one hand, it has been firmly established^{48,51,59} that cyclopropylidene can be converted directly into allene as a result of ring opening. On the other hand, there is a possibility of an intramolecular interaction of the carbene with the double bond, leading to a new carbene (LX). The latter is stabilised by forming the cyclopentadiene (LIX):



(LVII) (LVI) (LX) (LIX)

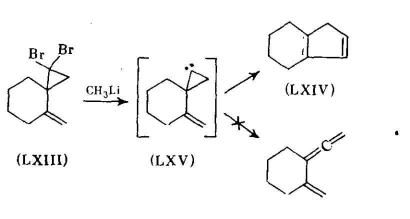
It has been shown^{60} that the preferential formation of an enallene or cyclopentadiene in the above reaction depends on the strain energy in the system formed and the stereochemistry of the intermediate cyclopropylidene. The *s-cis*-conformation of the latter promotes its intramolecular interaction with the double bond and hence the formation of the cyclopentadiene. The *s-trans*-conformation of cyclopropylidene (LVI) favours the direct opening of the three-membered ring with formation of the enallene.

The foregoing findings have been confirmed by the synthesis of the enallene (X), without an admixture of a cyclopentadiene derivative, from the dibromo-compound (LXI), which is an isomer with a rigidly fixed *s-trans*-structure and which gives rise to the intermediate cyclopropylidene (LXII) having the same conformation:



(LXI) (LXII) (X)

It has also been established that the dibromo-compound (LXIII) gives rise exclusively to the cyclopentadiene (LXIV) under the above conditions, which is promoted by the *s-cis*-conformation of the intermediate cyclopropylidene (LXV):



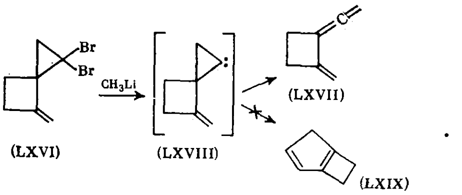
(LXIII) (LXV)

From this point of view, the formation of a mixture of enallenes and cyclopentadienes has been explained logically^{55} by the fact that the initial *gem*-dibromovinylcyclopropanes were mixtures of the *s-cis*- and *s-trans*-conformers.

The adduct of the carbene CBr_2 and 1,2-dimethylenecyclobutane (LXVI) reacts with CH_3Li to form exclusively the enallene (LXVII), despite the fact that this compound

§ It has been suggested^{57,58} that the cyclopropylidene obtained under these conditions is not a free carbene, but forms part of a carbene–lithium halide complex.

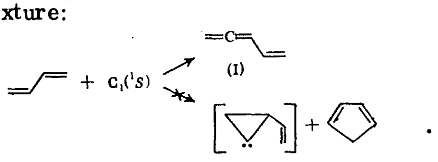
and the cyclopropylidene (LXVIII) are *s-cis*-conformers[60]:



(LXVI) (LXVIII) (LXVII) (LXIX)

The formation of the cyclopentadiene derivative (LXIX) is prevented in this case by the high strain energy of the system.

The data of Skell and Engel[61] are of theoretical interest in connection with the problem of the intermediate formation of cyclopropylidene as the precursor of enallene. It has been established that the reaction of buta-1,3-diene with a carbon atom in the metastable ^1S energy state in a neopentane matrix gives rise to penta-1,2,4-triene (I) only. The cyclopentadiene (LXX) is absent from the reaction mixture:



(I) (LXXV) (LXX)

It follows from calculations[62] by the MINDO/2 method that the activation energy for the opening of the cyclopropylidene (LXXI) ring to give the allene (LXXII) is much higher than the activation energy for the formation of strained systems such as spiropentane (LXXIII) and cyclopropene (LXXIV):

(LXXI)

$=C=$ (LXXII)

(LXXIII)

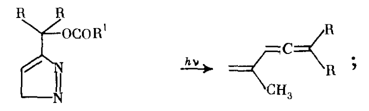
(LXXIV) .

The ring strain energy in cyclopentadiene (LXX) is less than the strain energies in the above system, as a result of which its formation from the postulated intermediate cyclopropylidene (LXXV) apparently requires a smaller activation energy than the formation of enallene (I).

The fact that cyclopentadiene (LXX) is not formed in the reaction under consideration rules out, in our view, the possibility of the formation of enallene (I) from the cyclopropylidene (LXXV)[¶].

6. SPECIFIC METHODS OF SYNTHESIS

Penta-1,2,4-triene is formed on dehydrobromination of 1,4-dibromopent-2-ene[63]. The latter is a readily available product of the bromination of piperylene. The mixture formed on dehydrobromination of the hydrocarbon contains 12.3% of enallene. 2,5-Dimethylhexa-1,3,4-triene has been obtained by a prototropic rearrangement from 2,5-dimethylhexa-2,3,4-triene under the influence of sodium methoxide or hydride[64]. It has been established[65] that the reaction mixture formed on solvolysis of 1-chloromethylene-2,2-dimethylcyclopropane contains 9% of 2-methylpenta-1,3,4-triene. 2,5-Dimethylhexa-1,3,4-triene (LXXVI) and 5-ethyl-2-methylhepta-1,3,4-triene (LXXVII) are obtained in 5% yield on photolysis of the pyrazolenine derivatives (LXXVIII, a, b) and (LXXIX) respectively[66]:

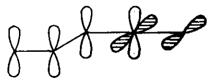


(LXXVIII): (a) $R = R^1 = CH_3$, (b) $R = CH_3, R^1 = C_2H_5$; (LXXIX): $R = C_2H_5$, $R^1 = CH_3$.

(LXXVI): $R = CH_3$; (LXXVII): $R = C_2H_5$

III. PHYSICAL PROPERTIES

The characteristics of the physical properties of the conjugated enallenic hydrocarbons are due to two factors: the cumulation of bonds and conjugation. According to the molecular orbital theory, the planes of two cumulated bonds are mutually perpendicular and the central carbon atom of the allene group, which is in the *sp*-hybridised state, is located on the same straight line with the extreme sp^2-hybridised carbon atoms in this group. Owing to the non-coplanarity of the cumulated bonds, only one of them can be involved in π–π conjugation with the α-ethylenic bond of enallene:



.

The conjugation[†] of the double bonds in enallenic hydrocarbons is manifested most clearly by the considerable increase of molecular refraction, by the increased magneto-optical molecular rotation, and by the intense absorption in the ultraviolet spectrum, characteristic of conjugated dienes.

1. MOLECULAR REFRACTION

Among all the allenic compounds without an additional double bond in the molecule, only disubstituted allenes with strongly branched groups exhibit a significant exaltation of molecular refraction (ΔMR).[68] It has been suggested[67] that the latter is due to the $\sigma - \pi$ conjugation of the substituents with the coplanar double bond of the allene group and does not exceed unity as a rule. The occurrence of $\pi - \pi$ conjugation in enallene molecules is responsible for the higher values of ΔMR of these compounds, which reach 2.5 in individual instances (Table 5).

2. MAGNETO-OPTICAL MOLECULAR ROTATION

According to Labarre's data[69,70], the experimental magneto-optical molecular rotations (MOMR) of conjugated enallenic compounds greatly exceed the calculated values. Unfortunately penta-1,2,4-triene is the only enallene whose properties have been investigated. Other data quoted in the above reports refer to conjugated enallenic alcohols. However, since the OH group does not influence the magneto-optical properties of these compounds significantly,

---

[¶] We have in mind "free" cyclopropylidene generated in the absence of Lewis bases.

[†] The specific influence of the cumulation of bonds on the physical properties of allenes has been described in an extensive review[67].

one may assume that the MOMR exaltation is due to the conjugated enallene group and amounts to ~110 μrad, as can be seen from the data in Table 3.

Table 3. The magneto-optical properties of enallene structures.

Compound	A^*, μrad	B^*, μrad	$E^*=A-B$, μrad
$CH_2=CH-CH=C=CH_2$	664	559	+105

 $CH_3-\underset{\displaystyle CH_3}{\underset{\vert}{C}}(OH)-CH=C=CH-CH=CH_2$	935	816	+119

---

* A is the experimental MOMR, B the calculated MOMR, and E the exaltation of MOMR.

Table 4. The magneto-optical properties of certain conjugated systems.

Conjugated system	E_{av}, μrad	Designation	Conjugated system	E_{av}, μrad	Designation
	+110	E_1		+63	E_3
	+119	E_2		+211	E_4

Labarre[70] also quotes the MOMR exaltations for certain other conjugated systems, which makes it possible to compare them with the values of E found for conjugated enallenes (Table 4). It also follows from the data in Table 4 that E_1 is close to E_2, but differs sharply from E_4. This finding constitutes additional confirmation of the fact that only one C=C bond in the cumulated system of enallene is involved in conjugation. The MOMR exaltation can also serve as a criterion whereby one can distinguish the conjugated enallene system from the conjugated triene and enyne system.

3. ULTRAVIOLET, INFRARED, AND ^{1}H NMR SPECTRA

Ultraviolet Spectra

The ultraviolet absorption spectra are widely used to investigate conjugated enallenic hydrocarbons. As expected, the conjugated enallene group behaves as a chromophore similarly to the conjugated diene system, exhibiting an intense absorption in the range 215–230 nm ($\epsilon \simeq 20\,000$) depending on the nature and number of substituents (Table 5). The absorption is due to a $\pi-\pi^*$ electronic transition.

Infrared Spectra

Because of the presence of characteristic intense absorption bands in the infrared, conjugated enallenic hydrocarbons can be reliably identified or detected in a mixture of unsaturated hydrocarbons by infrared spectroscopy. The infrared spectra of these compounds contain absorption bands characteristic of the allene group[71-73] and a conjugated double bond. The bands associated with the allene group include one in the range 1930–1950 cm^{-1} due to the assymetric stretching vibrations of the –C=C=C– system, a band in the region of 850 cm^{-1} due to the out-of-plane deformation vibrations of the C–H bonds of the terminal

$C=C=C\langle{}^{H}_{H}$

group (overtone at ~1700 cm^{-1}), and absorption at 875 cm^{-1} due to the analogous vibrations of the C–H bonds of the symmetrically disubstituted allene group. The last band is frequently not resolved or appears as a shoulder on the much more intense band close to it and due to the deformation vibrations of the C–H bond of the terminal α-ethylene group. On the other hand, the absorption band at 850 cm^{-1} is of great analytical value and its presence in the spectrum confirms reliably the presence of a terminal allene group in the enallene molecule.

The stretching and deformation vibration frequencies of the α-ethylenic bond in conjugated enallenes are the same as the corresponding vibration frequencies of the conjugated C=C bond in diene hydrocarbons. As an example, one may quote the characteristic positions in the spectrum in the range 1600–1640 cm^{-1} of the band due to the stretching vibrations of the α-ethylenic bond in enallenes[16,19].

Proton Magnetic Resonance Spectra

The ^{1}H NMR spectra of conjugated enallenes are complex and their interpretation is frequently difficult. It has been established[74] that the protons of the allene group located in the positive part of the anisotropy cone are subjected to a positive shielding effect and because of this their signals appear in a stronger field compared with the signals of olefinic protons. Among all the protons of the allene group, the H_A protons, attached to the atoms involved in the double bond of this group, which is non-coplanar with the α-ethylenic bond of the enallene (δ_{H_A} = 4.8 p.p.m.), absorb in the strongest field. The signal in the weakest field (δ_{H_B} = 5.9–6.3 p.p.m.) corresponds to the H_B proton[27]:

.

A characteristic feature of enallenic hydrocarbons and of all allenes is the occurrence of a strong proton–proton interaction via the allene system, which can be accounted for by the interaction of the σ electrons of the C–H bond and the π electrons of the double bond, which are in the same plane[67].

The physical properties of conjugated enallenic hydrocarbons are compiled in Table 5.

*The following enallenes have been characterised solely by spectroscopic methods: 1-methylene-2-vinylidenecyclobutane[60]; 3,4-dimethylpenta-1,2,4-triene[5,6,55]; 3-methylhexa-1,3,4-triene[6,7]; 5-methylhexa-1,3,4-triene[6]; 2,3-dimethylhexa-1,3,4-triene[6,7]; 6,6-dimethylhepta-1,3,4-triene[34]; 4,5-dimethylhepta-2,3,5-triene[6,7]; 2,6,6-trimethylhepta-1,3,4-triene[34]; 1-phenylpenta-1,2,4-triene[34]; 1-ethylidene-2-propenylidenecyclohexane[6,7]; 2-cyclohexenylpenta-2,3-diene[6,7]; 4-methyl-1-phenylpenta-1,2,4-triene[34]; 1-phenylhexa-1,2,4-triene[34]; 3-ethyl-5-methylnona-1,3,4-triene[8]; 5-methyl-3-phenylhexa-1,3,4-triene[8]; trideca-1,3,4-triene[14]; 3,5-diethylnona-1,3,4-triene[8]; 1,5-diphenylpenta-1,2,4-triene[34].

**The designations of the methods of synthesis correspond to those in Section II.

***The references to studies (and to the methods of synthesis employed in them) in which the physical constants of the given enallene are not quoted are enclosed in brackets.

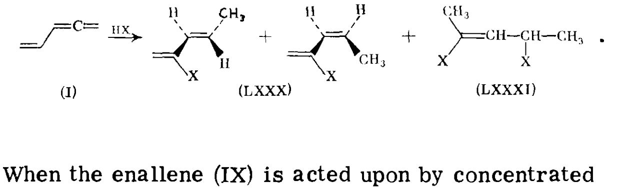
IV. CHEMICAL PROPERTIES

1. ELECTROPHILIC ADDITION

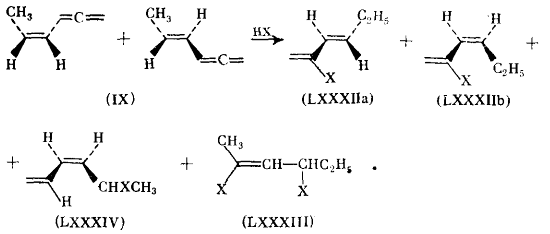
(a) The Addition of Hydrogen Halides[30,75]

When enallene (I) was treated with concentrated HCl, a 3 : 2 mixture of a monoadduct and a diadduct was obtained in 60% yield. The monoadduct is a mixture of the *cis*- and *trans*-isomers of 2-chloropenta-1,3-diene (LXXX, X = Cl) with a threefold excess of the latter isomer. Both geometrical isomers have been isolated by preparative GLC and characterised by infrared, ultraviolet, and ^1H NMR spectroscopy. The diadduct (LXXXI, X = Cl) has been identified as 2,4-dichloropent-2-ene.

The result of the addition of HBr to this enallene is quite analogous as regards the nature of the products and their proportions in the reaction mixture:

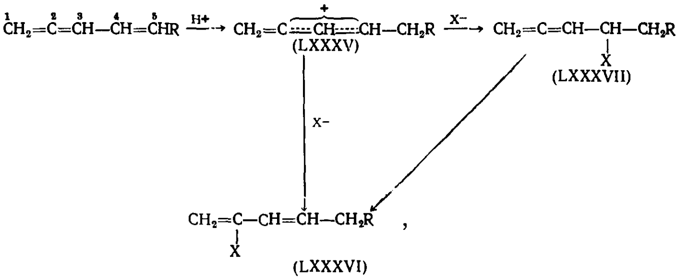


When the enallene (IX) is acted upon by concentrated HCl, a mixture of a monoadduct and a diadduct is again formed. The former, which makes up 65% of the product, is the virtually pure *trans*-isomer of 2-chlorohexa-1,3-diene (LXXXII, a; X = Cl). The *cis*-isomer of this compound has not been isolated, because of its low content in the reaction mixture. The diadduct has the structure of 2,4-dichlorohex-2-ene (LXXXIII, X = Cl):



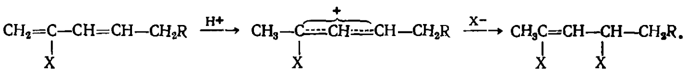
A more complex mixture of adducts was obtained (in 50% yield) when the enallene (IX) was acted upon by hydrobromic acid. According to GLC data, the mixture consists of five monobromides and two dibromides. Three monobromides were isolated by preparative GLC and one of the dibromides was isolated by fractional distillation; 70% of the mixture of monobromides consists of *trans*- and *cis*-2-bromohexa-1,3-dienes in the proportions (LXXXIIa) : (LXXXIIb) = 17 : 3; here X = Br. The third monobromide, which is 5-bromohexa-1,3-diene (LXXXIV, X = Br), was isolated in only a small amount. The structure of 2,4-dibromohex-2-ene (LXXXIII, X = Br) was assigned to the diadduct.

Thus hydrogen halides add to the enallenes (I) and (XIX) in the 1,4-positions in the conjugated ethylene–allene system, and there is also secondary 1,4-addition with formation of diadducts. The reaction mechanism[30,75] consists in the protonation of the $C_{(5)}$ atom of the enallene with formation of the carbonium ion (LXXXV). The latter is attacked by the reagent in the 2- or 4-position, which leads to the halogeno-derivatives (LXXXVI) and (LXXXVII) respectively:



where R = H or CH_3 and X = Cl or Br.

The halogenoallene (LXXXVII) was not detected in the reaction mixture probably owing to the rapid anionotropic rearrangement to the thermodynamically more stable halide (LXXXVI).[75] When a second HX molecule is added, the attack by the proton is directed by the halogen:

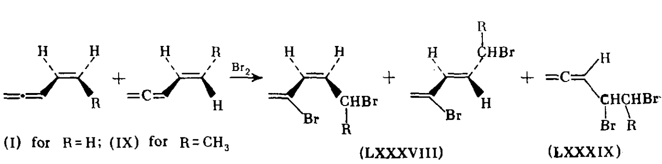


$$CH_2{=}\underset{X}{C}{-}CH{=}CH{-}CH_2R \xrightarrow{H^+} CH_3{-}\overset{+}{\underset{X}{C}}{\cdots}CH{\cdots}CH{-}CH_2R \xrightarrow{X^-} CH_3\underset{X}{C}{=}CH{-}\underset{X}{CH}{-}CH_2R.$$

The interaction of 3-methylpenta-1,2,4-triene and 3-methylhexa-1,2,4-triene with hydrogen halides has also been investigated[30]. However, owing to the rapid polymerisation of these hydrocarbons and the halogeno-derivatives formed, the nature of the processes occurring has not been established.

(b) The Addition of Bromine[30]

The study of the interaction of bromine with conjugated enallenic hydrocarbons is complicated by the difficulty of separating the products. Thus, when penta-1,2,4-triene (I) was brominated, a mixture of three dibromo-derivatives, which could not be separated by distillation, was obtained in 40% yield. According to spectroscopic data, it contained the *cis*- and *trans*-isomers of 1,4-dibromopenta-2,4-diene (LXXXVIII, R = H) and 1,2-dibromopenta-3,4-diene (LXXXIX, R = H):

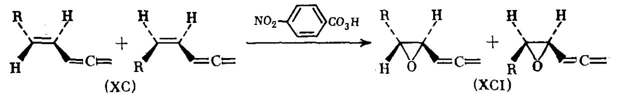


(I) for R=H; (IX) for R=CH_3 (LXXXVIII) (LXXXIX)

The bromination of hexa-1,2,4-triene (IX) also led to a mixture of two dibromo-derivatives (in 30% yield), which could not be separated by distillation. In conformity with spectroscopic data, the structures of the *cis*- and *trans*-isomers of 2,5-dibromohexa-1,3-diene (LXXXVIII, R = CH_3) was attributed to them, the latter being the main product; the 1,2-adduct is not formed in this case.

(c) Epoxidation By Peracids

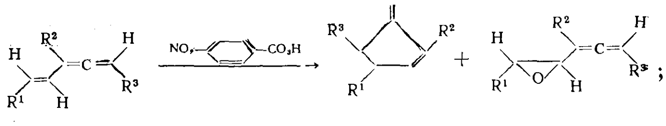
This reaction of conjugated enallenic hydrocarbons was investigated for the first time in relation to the epoxidation of the enallene (XC) by *p*-nitroperbenzoic acid[76]. In all cases the only reaction products are the epoxy-derivatives of α-allenes (XCI), which were not described previously:



(XC) (XCI)

R = H, CH_3, C_2H_5, or n-C_3H_7 .

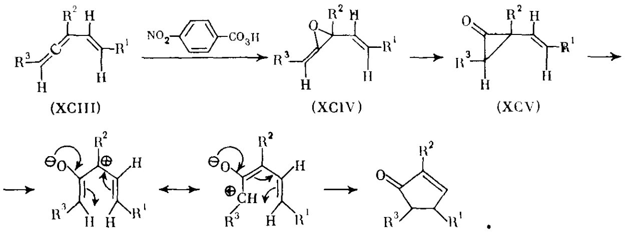
Their geometrical isomers were separated by preparative GLC. It was shown that the ratio of these isomers is determined solely by the ratio of the *cis*- and *trans*-isomers of the initial enallenes, which confirms the stereospecificity of this reaction. It was subsequently established[30,77,78] that the alkylation of the allene group alters the course of the reaction and leads to the formation of the conjugated cyclopentenone (XCII) as the sole or main product:



(XCIII) (XCII) (XCVII)

R^2 or R^3=Alk .

This reaction pathway was explained by the authors as the results of a series of consecutive processes: (1) the epoxidation of the alkylated and therefore fairly nucleophilic allene group of the enallene (XCIII) with formation of the epoxide (XCIV); (2) the tautomeric transformation of the epoxide (XCIV) into the cyclopropanone (XCV); (3) the electrocyclic transformation of the latter into the 1,3-dipole (XCVI) and the subsequent intramolecular 1,3-dipole cycloaddition leading to the formation of the conjugated cyclopentenone (XCII):



(XCIII) (XCIV) (XCV)

(XCVI) (XCII)

Table 6 presents the results of the study of the above reaction.

Table 6. The epoxidation of the conjugated enallenes (XCIII) by *p*-nitroperbenzoic acid[30].

Enallene (XCIII)	Content in reaction mixture, %		Overall yield of (XCII) + (XCVIII), %
	(XCVII)	(XCII)	
(a) $R^1{=}R^3{=}H$, $R^2{=}CH_3$	0	100	60
(b) $R^1{=}R^3{=}H$, R^2 = n-C_3H_7	0	100	60
(c) $R^1{=}R^2{=}CH_3$, R^3 = H(*trans*)	35	65	60
(d) $R^1{=}R^2{=}H$, R^3 = n-C_3H_7	5	95	55

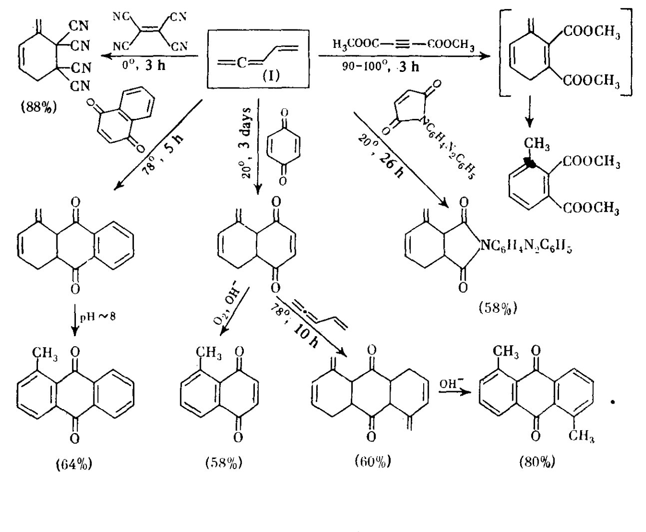
It is noteworthy that, when both the allene group and the α-ethylenic bond are alkylated in the enallene, they are both acted upon, in competition, by the electrophile, which leads to the formation of a mixture of the cyclopentenone (XCII) and the allene epoxide (XCVII). The epoxidation reaction of the enallene (XCIIIc) may serve as an example. It has been shown[30,79] that allene epoxides are valuable starting materials for the synthesis of many hitherto unknown or difficult to obtain compounds such as α- and β-allenic alcohols, vicinal allenic diols, enynyl alcohols, etc. Furthermore, the epoxidation of enallenes by peracids can serve as a method of synthesis of compounds with the hydrindan structure.

2. PERICYCLIC REACTIONS

(a) Thermal Cycloaddition

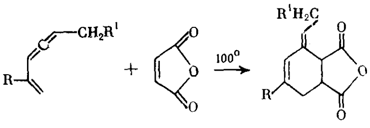
Conjugated enallenes are formally capable of participating in thermal cycloaddition reactions of two types: $[_\pi 2 + {}_\pi 2]$ and $[_\pi 4 + {}_\pi 2]$. A characteristic feature of compounds with a cumulated system of double bonds is known to be the first of the above transformations, which results in the formation of cyclobutane derivatives[80], while dienes with a conjugated system of bonds are involved preferentially in the $[_\pi 4 + {}_\pi 2]$ cycloaddition reaction, which leads to the formation of cyclohexene derivatives. The simultaneous presence in the molecule of the conjugated enallene of cumulated and conjugated diene systems constitutes an interesting problem as regards their competition in the cycloaddition reaction.

The possibility of the involvement of conjugated enallenes in the Diels–Alder reaction, which is a type of $[_\pi 2 + {}_\pi 2]$ cycloaddition, was demonstrated for the first time[3] in relation to the reaction of penta-1,2,4-triene (I) with different dienophiles. This hydrocarbon reacts under mild conditions with tetracyanoethylene and derivatives of maleic and acetylenedicarboxylic acids and quinone. The reactions which have been carried out and the products obtained are indicated schematically below:



Many of the adducts indicated in the above scheme are methylenecyclohexene derivatives, which are difficult to obtain in other ways. The ready aromatisation of certain compounds makes enallene (I) a valuable starting material for the synthesis of aromatic compounds which are difficult to obtain.

Fedorova and Petrov[18] investigated the reactions of the enallenes (XCVIII) and maleic anhydride at 100°C. Homologues of the anhydride of 3-alkylidene-4-cyclohexene-1,2-dicarboxylic acid (XCIX) were obtained in all cases:



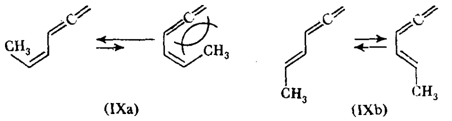
(XCVIII) (XCIX)

(a) $R = CH_3$, $R^1 = C_2H_5$; (b) $R = CH_3$, $R^1 =$ n-C_4H_9;
(c) $R =$ t-C_4H_9, $R^1 = C_2H_5$;
(d) $R =$ t-C_4H_9, $R^1 =$ n-C_4H_9 .

Further condensation does not take place despite the presence in the adduct (XCIX) of a conjugated diene group, which is believed[18] to be due to steric factors.

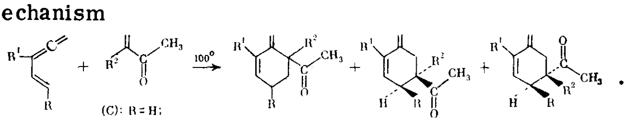
The mechanism of the thermal $[_\pi 4 + {}_\pi 2]$ cycloaddition of conjugated enallenes has been determined in a study of their reactions with but-1-en-3-one (C) and 2-methylbut-1-en-3-one (CI).[30,81,82] It has been shown that the reaction proceeds via a concerted cyclic mechanism, which is symmetry-allowed as a $[_\pi 4_s + {}_\pi 2_s]$ process, in which all the π orbitals are involved suprafacially. A direct consequence of this mechanism is the requirement of a definite, namely cisoid, conformation of the reacting enallene, so that the addition of the dienophile must be preceded by the conversion of the energetically more favourable transoid conformation of the hydrocarbon into the cisoid conformation.

Such transformation of the *cis*-isomer of hexa-1,2,4-triene (IXa) is difficult for steric reasons and it does not therefore react with the above ketones. Under these conditions, the *trans*-isomer of the enallene (IXb) actively interacts with the ketones:



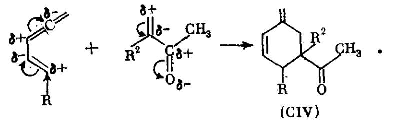
(IXa) (IXb)

The conjugated enallenes (CII) react with $\alpha\beta$-unsaturated ketones as the diene components in accordance with the mechanism



(CII) (C): R = H; (CI): R = CH3 (CIII) (CIV,a) (IVb)

The experimental data obtained are compiled in Table 7. The structures of the products have been reliably demonstrated by spectroscopic methods (infrared, ^{1}H NMR, and ultraviolet), by mass spectrometry, and by their conversion into the corresponding aromatic compounds in order to determine the position of the acetyl group in the adduct which indicates the relative orientations of the dienophile and enallene in the transition state. This orientation is unambiguous and leads to the exclusive formation of the adduct (CIV) subject to the condition that the terminal $C_{(5)}$ atom of the α-ethylenic bond of the enallene (CII) has an alkyl substituent (i.e. $R \neq H$):



(CIV)

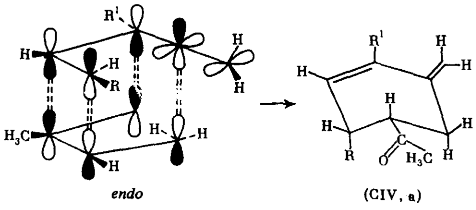
Otherwise a mixture of the adducts (CIII) and (CIV) is formed with the latter greatly predominating. The ratio of the adducts depends little on whether there is an alkyl substituent at the $C_{(3)}$ atom of the hydrocarbon and on whether the C=C bond of the ketone is alkylated, which rules out a zwitter-ionic mechanism of the cycloaddition.

Table 7. The compositions of the reaction mixtures obtained in the interaction of the enallenes (CII) with αβ-unsaturated ketones[82].

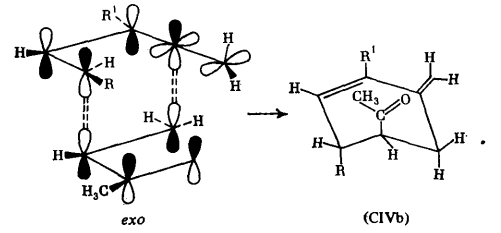
Groups in (CII)-(CIV)			Overall yield of (CIII) + (CIV), %	Fraction of adduct (CIII), %	Fraction of adduct (CIV), %	Fraction of adduct (CIVa) in (CIV), %	Fraction of adduct (CIVb) in (CIV), %
R	R^1	R^2					
H	H	H	60	28	72	—	—
H	CH_3	H	75	20	80	—	—
H	n-C_3H_7	H	70	15	85	—	—
H	H	CH_3	40	21	79	—	—
CH_3	H	H	50	0	100	75	25
iso-C_3H_7	H	H	65	0	100	82	18
CH_3	CH_3	H	75	0	100	80	20
CH_3	H	CH_3	35	0	100	100	0

In the reaction of the enallenes (CII, R ≠ H) with the ketone (C) the adduct (CIV) was obtained as a mixture of the *cis*- and *trans*-isomers, (CIVa), and (CIVb), respectively. It was established that the former is the kinetically controlled product and the latter the thermodynamically controlled product of the reaction. The fact that the kinetically controlled *cis*-adduct greatly predominates (Table 7) supports the concerted mechanism. If a two-stage mechanism operated, the ratio of the geometrical isomers (CIVa) and (CIVb) would have been determined by the thermodynamic equilibrium.

The kinetic control of the ratio of the stereoisomeric adducts in the reaction under consideration can be accounted for on the basis of the Woodward–Hoffmann rules[38], which take into account the interaction between the frontal orbitals of the reacting molecules. The interaction between the lowest unoccupied orbital (LUMO) of the conjugated diene system of the enallene and the highest occupied orbital (HOMO) of the ethylenic system of the αβ-unsaturated ketone in the transition state, with *endo*- and *exo*-dispositions of the reacting molecules, is illustrated schematically below:



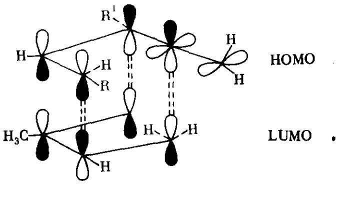
endo (CIV, a)



exo (CIVb)

The more effective overlapping of the π orbitals of the two systems in the case of the *cis*- adduct (*endo*-addition)[‡] leads to a decrease of the activation energy for its formation relative to that for the *trans*-adduct (*exo*-addition). Because of this, the *cis*-adduct (CIVa) is the kinetically controlled main product of the reaction.

An alternative treatment of the interaction of the LUMO of the ethylenic bond of the dienophile and the HOMO of the diene system of the enallene leads to the conclusion that such interaction is energetically less favourable owing to a smaller secondary orbital effect even for the most favourable *endo*-disposition of the reacting molecules:

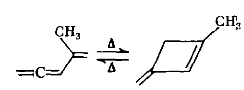


The absence of compounds with the cyclobutane structure among the products shows that, under the experimental conditions, there is no competition between the allene and conjugated groups of the conjugated enallenes, i.e. the reaction proceeds solely via the $[\pi 4_s + \pi 2_s]$ cycloaddition mechanism.

It is noteworthy that this reaction is of great interest for synthesis. The thermal cycloaddition of enallenes to unsaturated ketones can be widely used in the synthesis of monocyclic terpenoids, particularly derivatives of β-phellandrene[30,81]. Furthermore it has been shown[30] that the base-catalysed prototropic rearrangement of certain adducts with structure (CIII) easily leads to cyclic conjugated trienones.

(b) Electrocyclic Reactions

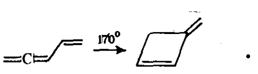
Much interest has been aroused recently by uncatalysed thermal reactions of triene hydrocarbons containing the allene group[84]. The electrocyclic transformation of the latter has become a preparative method for the synthesis of certain exotic cyclic hydrocarbons. However, there are few data concerning the thermal behaviour of conjugated enallenes. It has been established[39] that pyrolysis of 2-methylpenta-1,3,4-triene (XLIX) in pentane at 350–450°C leads to the formation of 1-methyl-3-methylene cyclobutene (XLVIII). With increase of the duration of pyrolysis, the fraction of the hydrocarbon (XLVIII) in the reaction mixture remained constant, which indicated the attainment of equilibrium. The reversibility of the process was also demonstrated by the pyrolysis of methylenecyclobutene (XLVIII) and the discovery that the ratio of the hydrocarbons (XLIX) and (XLVIII) in the reaction mixture remains constant:



(XLIX) (XLVIII)

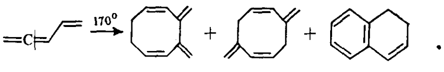
[‡] αβ-Unsaturated dienophiles react with dienes in the cisoid conformation[83].

At 170°C penta-1,2,4-triene undergoes analogous cyclisation to methylenecyclobutene (CV):[85]



(I) (CV)

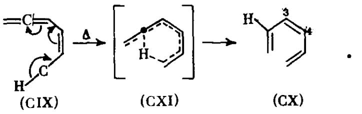
However, the content of the cyclic hydrocarbon (CV) in the reaction mixture does not exceed 10%. The main pathway in the thermal transformation of enallene (I) is its dimerisation, leading to the formation of at least seven hydrocarbons having the composition $C_{10}H_{12}$. Only three have been specified as the most interesting[85]—compounds (CVI), (CVII), and (CVIII):



(I) (CVI) (CVII) (CVIII)

(c) Sigmatropic Rearrangements

Apart from the intramolecular cyclisation discussed above, the thermal transformation of an enallene can involve a sigmatropic rearrangement to a conjugated triene accompanied by a [1,5]-H-shift:

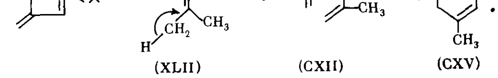


(CIX) (CXI) (CX)

Since this process involves three electron pairs, the synchronous migration of hydrogen takes place suprafacially[86].

The sigmatropic rearrangement of the enallene system (CIX) to the conjugated triene system (CX) is believed to take place[87] as a result of a rearrangement of the orbitals in the six-centre transition state (CXI). The latter is possible only provided that the initial enallene has the *cis*-configuration of the α-ethylenic bond. The experimental observation that the 3,4-bond in the resulting triene (CX) is a *cis*-C=C bond confirms the cyclic process mechanism.

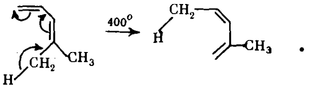
The sigmatropic rearrangement of 5-methylhexa-1,2,4-triene (XLII) takes place similarly[33], the compound being rapidly converted into *cis*-2-methylhexa-1,3,5-triene (CXII) at 135°C:



(XLII) (CXII) (CXV)

A methylenecyclobutene derivative is not formed under these conditions. The above process has an activation energy of 24.6 kcal mole^{-1} and proceeds at an anomalously low temperature.

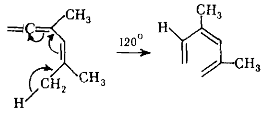
The analogous thermal rearrangement of acyclic conjugated dienes requires much more severe conditions. Thus the sigmatropic rearrangement of 4-methylpenta-1,3-diene (CXIII) to *cis*-2-methylpenta-1,3-diene (CXIV) proceeds at a temperature not less than 400°C (E_a = 32.8 kcal mole^{-1}):[88]



(CXIII) (CXIV)

The thermal transformation of the enallene (XLII) at 330°C leads to the exclusive formation of the cyclohexadiene derivative (CXV), which is a consequence of the intramolecular cyclisation of the hexatriene (CXII), having the *cis*-configuration which favours the electrocyclic process.

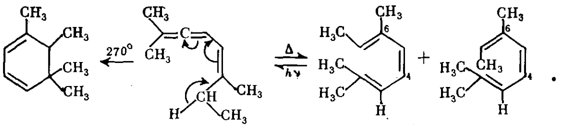
The conjugated enallene (CXVI) rearranges to the conjugated triene (CXVII) at the instant of distillation[33,55]:



(CXVI) (CXVII)

It is of interest to compare the thermally controlled transformation of conjugated enallenes into conjugated trienes with the opposite process which is photochemically controlled. Thus 2,6-dimethylocta-2,3,5-triene (LIII), obtained by the photochemical [1,5]-sigmatropic rearrangement of 2,6-dimethylocta-2,4,6-triene (LII), was reconverted into the initial triene (LIII) after heating for 8 min at 112–114°C as a result of a thermal [1,5]-H-shift (degree of conversion 93%).[42,43] The triene (LII) is formed as a mixture of the 4-*cis*-6-*cis*- and 4-*cis*-6-*trans*-isomers, the latter greatly predominating owing to favourable steric factors. As already mentioned above, the *cis*-configuration of the central double bond of the triene (LII) is a consequence of a cyclic mechanism of the rearrangement.

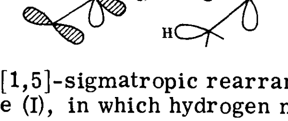
As expected, at a higher temperature (270°C) the enallene (LIII) is converted into the cyclohexadiene (CXVIII):



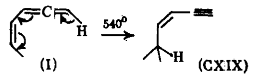
(CXVIII) (LIII) (LII)

It has been established[43] that the 4-*trans*-6-*trans*- and 4-*trans*-6-*cis*-isomers of the hydrocarbon (LII) are formed when the enallene (LIII) is stored for several years at room temperature.

It has been suggested[33] that the unusual ease with which the thermal sigmatropic rearrangement of conjugated enallenes takes place (compared with conjugated dienes) can be accounted for by the specific influence of the allene group. In the case of a [1,5]-H-shift in the enallene the hydrogen atom migrates to the C atom in the *sp* state, which is more electronegative than the C atom in the sp^2 state to which the hydrogen atom migrates in the diene. Furthermore, the sigmatropic rearrangement of the enallene results in the dissociation of the C_{sp^3}–H bond and the formation of a stronger C_{sp^2}–H bond. These effects lead to an appreciable decrease of the process activation energy. The stabilisation of the transition state during the rearrangement of the enallene to a conjugated triene can take place as a result of the partial involvement in the conjugation of the π orbitals of the terminal C=C bond of the allene group:

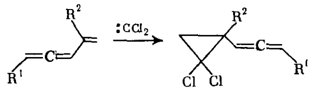


A new type of [1,5]-sigmatropic rearrangement of penta-1,2,4-triene (I), in which hydrogen migrates from the terminal carbon atom of the allene group to the terminal carbon atom of the α-ethylenic bond, was established recently[85]. The rearrangement, occurring at a very high temperature (540°C), results in the formation of pent-2-en-4-yne (CXIX):



(d) Cheletropic Reactions

Conjugated enallenes react with carbenes. This reaction, which belongs to the class of non-linear cheletropic processes[38], has been investigated in relation to the interaction of dichlorocarbene with penta-1,2,4-triene (I)[89] and 2-methylocta-1,3,4-triene (CXX).[90] It was carried out with an equimolar enallene–dichlorocarbene mixture, the dichlorocarbene being generated from t-BuOK and chloroform. It was shown that in both cases the dichlorocarbene attacks the α-ethylenic bonds of enallenes, which shows that it has more pronounced nucleophilic properties than the C=C bonds in the allene group:



(I): $R^1=R^2=H$; (CXXI): $R^1=R^2=H$;
(CXX): $R^1=n\text{-}C_3H_7$, $R^2=CH_3$; (CXXII): $R^1=n\text{-}C_3H_7$, $R^2=CH_3$.

The selective addition of CCl_2 to the α-ethylenic bonds of enallenes (I) and (CXX) resulted in the synthesis of new derivatives of *gem*-dichlorocyclopropane, (CXXI) and (CXXII), containing an allene group conjugated with the cyclopropane ring.

The more marked nucleophilic properties of the α-ethylenic bond of enallene (I), manifested in its reaction with dichlorocarbene, have also been confirmed by the results of the epoxidation of this hydrocarbon with *p*-nitroperbenzoic acid.

3. CATALYTIC HYDROGENATION

Selective stepwise hydrogenation of conjugated enallenes has not been studied. Exhaustive hydrogenation of these compounds proceeds smoothly in the presence of palladium and platinum catalysts, which has been used to demonstrate the structures of many conjugated enallenes[15,17,42,43].

Practical Applications of Cyclopentadienyl Complexes of Transition Metals

N.S.Kochetkova and Yu.K.Krynkina

The review is devoted to the main practical applications of metallocenes (dicyclopentadienylmetal complexes); the main practical applications of ferrocene and its derivatives are dealt with most widely. The practical utilisation of other cyclopentadienylmetal complexes is only beginning and the number of studies in this field is small. Investigations published in 1977 are considered.
The bibliography includes 162 references.

I. INTRODUCTION

The practical applications of dicyclopentadienylmetal complexes (metallocenes) have become possible owing to the successful development of synthetic research in this field. Ferrocene, which was discovered little more than 20 years ago, led to the foundation of the chemistry of metallocenes. Despite the fact that the cyclopentadienyl complexes of almost all the metals and many non-metals are known at present, the chemistry of the derivatives of metallocenes has so far been investigated most widely only for ferrocene[1,2]; that of osmocene and ruthenocene began to develop only comparatively recently and this is also true of cobaltocenium, nickelocenium, vanadocenium, etc. salts[2,3]. Derivatives of the dicyclopentadienyl complexes of titanium, zirconium, and to a lesser extent hafnium have been investigated in greater detail[4]. Among monocyclopentadienyl compounds, cyclopentadienylmanganese tricarbonyl (CMT) and cyclopentadienylrhenium tricarbonyl (CRT) have been most thoroughly investigated chemically[4].

The development of synthetic research on mono- and di-cyclopentadienyl derivatives of metals has served as the foundation on which the development of applied research in this field has been based. In the present review, which is devoted to the practical applications of metallocenes, attention is concentrated on the practical utilisation of ferrocene and its derivatives and studies associated with the cyclopentadienyl derivatives of other metals are only touched upon. The review constitutes a continuation of an earlier review[5], which was devoted to the practical applications of ferrocene and its derivatives.

A characteristic feature of the applications of metallocenes, which has become apparent recently, is the possibility of using them in various seemingly opposed fields; for example, ferrocene is used both as an inhibitor of the ageing of polymers and as a catalyst for their self-decomposition; or, for example, partly oxidised ferrocene derivatives are extremely effective semiconductors, while ferrocene serves at the same time as a successful additive in the manufacture of electrical insulators. The conditions used in the employment of metallocenes, their concentration, solvents, conditions of treatment, etc. apparently play a major role; for this reason, the application of such metal complexes requires an extremely careful adherence to the conditions developed for their utilisation. Wide scale studies on the properties of metallocenes involving all chemical and physicochemical methods are necessary; we may note that so far there have been virtually no quantitative investigations.

Studies on the mechanisms of the stabilisation of thermostable polymers under the influence of metal-containing inhibitors are only briefly mentioned in the review.

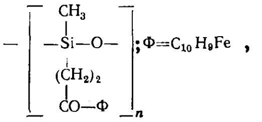
II. THERMO- AND PHOTO-STABILISERS

Effective photostabilisers for polymers, particularly *o*-hydroxybenzoylferrocene (I)[6,7], have been discovered comparatively recently and the possibility of coating spaceships with this compound has been mentioned[8]. The inhibiting effect of the ferrocenyl residue is apparently associated with the ability of compounds of this type to absorb light in both the visible and ultraviolet regions[9]. One cannot rule out the possibility that the effect is also enhanced by the aromatic component of the molecule, since benzoylbenzene derivatives are well known photostabilisers[10]. Other compounds containing the ferrocenyl fragment in the molecule, for example, phenylene substituted in the 4-position, can also serve as thermo- and photostabilisers[11]. Inhibitors of the light-induced ageing of polypropylene have been described[12].

The products of the interaction of diacetylferrocene with formaldehyde, which the authors called "diacetylferrocene-formaldehyde resins", have also been proposed for the modification of textile fibres based on poly(vinyl alcohol), for the improvement of their mechanical properties in spinning, and for the improvement of their resistance to the action of light[13]. The dimethyl ester of ferrocenedicarboxylic acid can likewise serve as a photostabiliser[14]. A decrease in mechanical fatigue strength in the spinning of fibre may be achieved by introducing into acetylcellulose 0.5-1 wt.% of formylferrocene[15], which also imparts resistance to radiation and increases the adhesion of polyamides to rubber[16,17].

Ferrocene has been proposed as a thermostabiliser for polyethylene: tests on shields 2 mm thick (involving heating to 100° C for three days) showed that the tensile strength decreases to 82.2% compared with 69.3% for the control specimen[18]. The addition of small amounts of ferrocene (0.5 wt.%) has a similar effect on ethylene–propene and diene rubbers[19]. A polyethylene film is stabilised in relation to ultraviolet radiation by the addition of 10% of the benzaldehyde–ferrocene copolymer in methylene chloride[20].

Polyferrocenylsiloxanes of the type

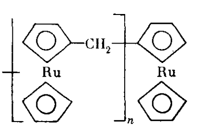


$$-\left[-\overset{\displaystyle CH_3}{\underset{\displaystyle (CH_2)_2-CO-\Phi}{Si}}-O-\right]_n ;\ \Phi = C_{10}H_9Fe\ ,$$

where the side chain contains the same ferrocenyl residue, have been described[5] as absorbers of ultraviolet light and photostabilisers.

Among other ferrocene derivatives proposed as thermostabilisers and antioxidants, *p*-aminoarylferrocenes have been mentioned[21]. Organosilicon derivatives of ferrocene in which the silicon atom is linked directly to the ferrocene ring constitute an interesting group of antioxidant stabilisers for polymers: $C_{10}H_4Fe[Si(CH_3)_3]_2$, $C_{10}H_8Fe[Si.(CH_3)_2OC_2H_5]_2$, $C_{10}H_8Fe[Si(CH_3)_2.OC_8H_{17}]_2$, $C_{10}H_8Fe[Si.(CH_3)_2OC_6H_5]_2$, and $C_{10}H_8Fe[Si(CH_3)_2N(C_2H_5)_2]_2$. In this series the most effective compounds are the diethylaminosilyl derivatives[22], which can be used as antioxidants for heat exchangers in refrigerators[23].

Polymers based on ruthenocene



proved to be resistant to heat and radiation[24]. They have been proposed as special protective coatings.

Two general ways of inhibiting polymer decomposition processes were examined in a recently published review[25]: (1) inhibition of chain processes by introducing into the system substances causing chain termination; (2) the removal from the system of chemical agents (present in the polymer composition or formed as a result of ageing), weak bonds, etc. It is shown in the same review that the deactivation of active centres under the influence of metal-containing inhibitors takes place as a non-chain inhibition process. The $M-C_5H_5$ bond dissociation energy probably constitutes a measure of the thermal stability of the compounds. Thermal decomposition can result in the formation of either pure finely dispersed metals or readily oxidisable products, which are involved in the chain termination reactions in the course of thermochemical degradation.

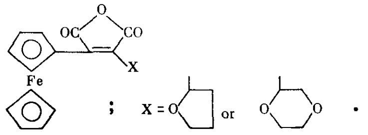
III. DYES AND PHOTOGRAPHIC MATERIALS

Few data on ferrocene dyes have appeared in the literature of recent years: this can be explained primarily by their low stability to light; early studies in this field have already been discussed[5].

Data have been published recently concerning the possibility of using organometallic compounds in photographic and particularly electrophotographic processes. Thus light-sensitive compositions containing organoelemental compounds, particularly cyclopentadienylmetal complexes, have been proposed[26]. An electrophotographic material is obtained by pouring compositions containing photoconductors, polyhalogeno-substituted compounds (for the formation of free radicals under the influence of light), the base form of the dye (for the formation of a sensitising dye under the influence of free radicals) and organoelemental additives onto conducting polyvinyl supports. After preliminary activation of these compositions by light or after pouring the same compositions onto polyvinyl supports and subsequent irradiation of the entire conducting polyvinyl layer with light, a positive image is formed. The material is then charged by a corona discharge source, irradiated with light from a tungsten lamp, and developed using a positive liquid developer, which yields the positive image. Tetraethyl-lead is used as an organometallic additive; cyclopentadienylmetal complexes have been mentioned as possible additives.

Photographic materials based on vinylferrocene, organic halides, and aromatic amines or their derivatives have been recently proposed[27] as photographic materials. A negative image has been obtained on paper following the illumination with light from a mercury lamp of a light-sensitive composition consisting of the styrene–vinylferrocene copolymer, tribromomethane, *p*-nitrophenyl sulphone, and diphenylamine.

Compounds containing the products of the condensation of maleic anhydride with tetrahydrofuran (THF), or 1,4-dioxan have been proposed as antidetonating agents and as inks soluble in organic solvents[28]:



IV. ADDITIVES TO FUELS AND OILS

Derivatives of ferrocene and cyclopentadienylmanganese tricarbonyl serve as regulators of various oxidation processes occurring in the fuel. They can be used as antismoke and anticoking agents, antidetonating agents, and regulators of the rate of combustion, can promote more complete oxidation of the fuel and decrease the amount of harmful exhaust gases resulting from combustion, and can even inhibit combustion processes, imparting fire resistance to the relevant substances. In view of the urgency of all the problems enumerated, the large scale manufacture of fuels of various types, and the importance of the problem of the protection of the environment, the possibility of using metallocenes in this field is of considerable practical interest.

1. Antismoke Additives

Ferrocene, diethylferrocene, tris(acetylacetonato)iron[29], CMT, and polymers based on vinyl-CMT and methyl-CMT have been proposed as antismoke additives to motor fuel[30].

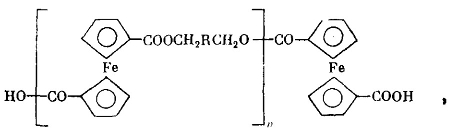
The successful use of organometallic antismoke additives is possible only in those cases where small amounts of the additive to the fuel (0.05–0.1 wt.%) can ensure a very effective increase of the degree of combustion of the fuel and a decrease of the amount of smoke. An increase in the amount of the antismoke additive can lead to other undesirable phenomena–the formation of a deposit on the working components of the engine, etc.

2. Antidetonating Agents

CMT† and ferrocene derivatives are effective antidetonating agents. However, fairly extensive deposit formation accompanying the use of ferrocene derivatives has so far precluded the practical employment of these compounds. Tests on the antidetonating properties of compounds of this class have shown[31,32] that ferrocenylmethyltrimethylammonium iodide, diferrocenylpropenone, and ferrocenylfluorophenylpropenone are most effective. Compounds containing a halogen and nitrogen form the smallest amount of deposit but it was not discovered whether nitrogen oxides are formed in the exhaust gases.

3. Regulators of the Rate of Combustion

Among new studies in this field, mention should be made of polymeric ferrocene-containing substances, for example, the products of the polycondensation of the heteroannular ferrocenedicarboxylic acid and diglycols (IX)[33,34], i.e.



(I)

the copolymers of isopropylferrocene or 1-divinylferrocene with butadiene, isoprene, and chloroprene[35], and the copolymers of butylferrocene with formaldehyde[36] and of vinylferrocene with butadiene[37] or chloroprene[38,39].

An involatile combustion catalyst, obtained by condensing t-butylferrocene with methylal[40] and added to a carboxylate butyl-rubber, the vulcanising agent, ammonium perchlorate, and dioctyl adipate, ensures an increase of the rate of combustion by a factor of 2–2.5.

Intensive research on the elimination of exhaust gases from air is proceeding in various countries. Thus it has been suggested that ferrocene be used as an additive to fuel (0.05 wt.%), which promotes the further combustion of CO to CO_2.[41] Compositions which yield less harmful substances on combustion have been obtained from poly(vinyl chloride), an aliphatic plasticiser, and $CaCO_3$ with small amounts of added ferrocene as well as lead stearate and sulphate.

4. Oxidation Inhibitors

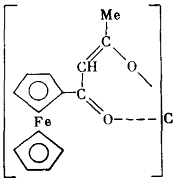
Ferrocene derivatives can serve not only as catalysts but also as inhibitors of oxidation. Thus fire-resistant compositions in which ferrocene and its derivatives are combined with halogen-containing polymeric materials have been proposed in a number of studies[42-44]. For example, fire-resistant shields (2 mm thick) are made from a composition containing polychlorovinyl-bis-(2-ethylhexyl) phthalate, lead sulphate and stearate, ferrocene, and $MgCO_3$. Such shields are also made from ferrocene-containing copolymers with anisyl aldehyde and *pp'*-benzoquinone dioxime combined with butyl-rubber and zinc oxide. Similar fire-resistant compositions, based on polyethylene with added ferrocene, have been proposed[42]. It may be that, oxidation inhibitors are formed from ferrocene and its derivatives on heat treatment in the presence of the components of the given fire-resistant compositions.

5. Accelerators of the Decomposition of Polymers

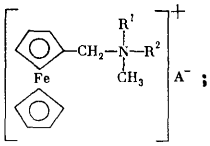
The problem of the contamination of the environment by waste products from the synthesis of polymers, which are difficult to decompose, is now becoming increasingly acute. Ferrocene and its derivatives proved not only to inhibit the ageing of polymers but also to catalyse their decomposition[44].

6. Antistatic Additives to Fuel

The transport of fuel over long distances and its storage for a fairly long time constitute an urgent problem. The necessity to find antistatic additives to fuel arises in this connection. Among ferrocene and CMT derivatives, salt-like compounds containing a chromium atom in addition to iron or manganese atoms have been proposed[45,46]:



It has recently been suggested[47] that alkylammonium salts of the dialkylaminomethylferrocene type be used as antistatic additives[47]:

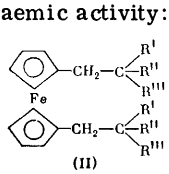


; $R^1 = C_nH_{2n+1}$ ($n = 1-5$), CH_2CH_2OH; $R^2 = C_nH_{2n+1}$ ($n = 1-18$); $A = Cl, Br, I, NO_3, SO_4, MeSO_4$, or ClO_4 .

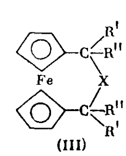
V. MEDICINAL SUBSTANCES

Ferrocene compounds proved to be effective agents in the fight against diseases caused by iron deficiency in the organism, i.e. against various types of anaemia.

Dialkylferrocenes (II)[48-51] and oxygen-containing[52,53] and sulphur-containing[54,55] ferrocenophanes of type (III) exhibit antianaemic activity:



(II)



(III)

; X=O or S .

The oxygen-containing compounds also exhibit a blood-liquefying activity.

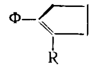
The sodium salt of *o*-carboxybenzoylferrocene (ferrocerone)[56-60] is the first ferrocene-containing medicinal preparation whose widescale use in medical practice is permitted. Its characteristic features are non-toxicity,

---

†This problem is discussed in detail in a monograph[30].

ready solubility in water, and rapid assimilation by the organism. Its application does not require the use of acids and it is therefore particularly suitable for administration to patients suffering from diseases of the gastro-intestinal system as well as children. It can be used in the treatment of various forms of anaemia and a severe disease of the nasopharynx—ozena, which hitherto has been virtually incurable.

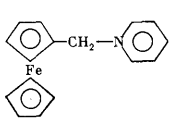
Substituted ferrocenylcyclopentenes have been proposed for the treatment of iron deficiency anaemia[61]:



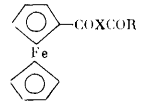
; R=Ph, $PhCH_2$, n-ClC_6H_4CO, or m-$CH_3C_6H_5CO$.

A complex medicine consisting of (1,1-diethyl-αα-thiobiscyclopentadienyl)iron and iron-dextran has been suggested recently[64]. It was found that the iron in this preparation, like that in ferrocerone[56-60], is absorbed in the liver.

Piperidinomethylferrocene exhibits a physiological activity[67]:

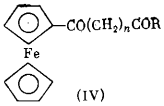


Ferrocene derivatives of the type

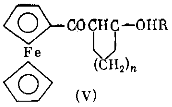


have been suggested for the treatment of disorders caused by iron deficiency in the organism. Here X is a saturated C_2–C_{10} hydrocarbon group and R is an alkyl group, a thiophen, furan, or benzene ring, or a benzene ring substituted by one or several halogen atoms or alkynyl groups.

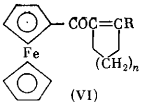
Monoketones (IV), diketones (V), and hydroxyketones (VI) of the type[63]



(IV)



(V)



(VI)

have also been suggested[63].

Molecules of the type

$$\begin{matrix}—HN\diagdown \\ \diagup CH(CH_2)_4NHXΦ \\ —CO\end{matrix} ;$$

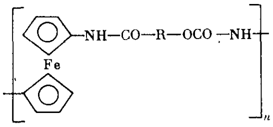
$X=CH_2$, CS—NH—CH_2, or $CO(CH_2)_2$.

based on ferrocenylacetic and ω-ferrocenylcaproic acids, have been obtained by grafting to the lysine residues in proteins[66]. Modified proteins of this type can be used in fluorescence microscopy; owing to their enhanced electron density, they are visible under the electron microscope.

Polymers obtained on the basis of ferrocenylenediacetic acid and diaminoferrocene can be used to study gas diffusion through membranes[67]:

;

R = $(CH_2)_4$, or $(CH_2)_6$



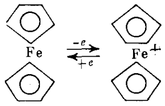
;

R = $(CH_2)_2$, $(CH_2)_4$, or $(CH_2)_6$.

They can also be used to study the following micro-organisms: *Candida pseudotropical*, *Mycobacteria BCG*, and *Mycobacterium foctuitum*. It has been noted[69] that compounds in which there is a possibility of ready elimination of a hydrogen halide showed the greatest bactericidal efficiency; there is a possibility of the formation of a double bond in the position conjugated to the CO group. It is striking that 3-chloropropionyl and 4-chlorobutyrylferrocenes are altogether ineffective.

VI. ION-EXCHANGE RESINS, REDOX SYSTEMS, SEMICONDUCTORS, AND INSULATORS

The use of ferrocene and its derivatives in various redox systems



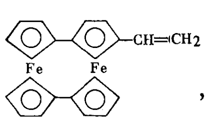
is based on their ability to undergo reversible oxidation to ferrocenium salts.

Electron-exchange resins based on ferrocene were first obtained by Nesmeyanov and coworkers[70,71]. A ferrocene electrode, ferrocene-containing polymers (redoxites), and liquid redox systems based on alkylferrocenes have been proposed[72-77]. Styrylferrocene–styrene copolymers exhibit electron-exchange properties[78]. Ion-exchange resins have been synthesised by grafting ferrocenyl residues (in the form of the amide of ferrocenedicarboxylic acid or formylferrocene) onto a fibre based on poly(vinyl alcohol)[81]. A biological redox system based on the reversible ferrocene–ferrocenium reaction at pH 7 has been used to convert cytochrome *c* into cytochrome *c* oxidase[80] and conversely.

Anion-exchange resins of a new type, based on cobaltocenium salts, have been suggested[81].

---o0o---

It has been shown that carefully purified polymers based on ferrocene do not exhibit paramagnetic properties[1,82,84]. Studies on partly oxidised ferrocene-containing polymers, which exhibit semiconducting properties, for example, polymers obtained from vinylferrocene and carbazole, constitute a new field in the chemistry of ferrocene[85]. Partial (to the extent of 60%) oxidation of the polymer obtained from vinylbis(fulvalene)iron



,

gives rise to a product which has the highest specific magnetic susceptibility among the known organic semiconducting materials[86]. It appears that there is at present a possibility of employing ferrocene and its derivatives as organometallic semiconductors; investigators in a number of countries are carrying out vigorous researches in this field[84,87,88].

Detailed studies on the physicochemical properties of bis(fulvalene)iron and its mono- and di-cations yielded evidence that the monocation is a delocalised resonance-stabilised ion[89,90]—a representative of the so called mixed valence compounds. Thus the role of the ferrocene–ferrocenium system in the generation of semiconducting properties is evident.

---o0o---

The study of partly oxidised ferrocene derivatives as semiconductors apparently stimulated research on the use of diamagnetic ferrocene compounds as insulators. Thus the addition of ferrocene (or its homologues) as well as polymers based on ketones and aldehydes derived from ferrocene to polyethylene increases the breakdown potential of the resulting dielectrics from 9.8 to 14.0 and 18.6 kV respectively[92]. An even more effective electrical insulator has been obtained from polyethylene, ferrocene, and isoprene GM.[93]

VII. FERROMAGNETIC MATERIALS BASED ON FERROCENE DECOMPOSITION PRODUCTS

On heating to 70–300°C with subsequent slow cooling to 25°C, ferrocene polymers[94] acquire ferromagnetic properties. Powders, solid materials, and thin shields made from these materials can be used in magnetic cores and in teleprinting and tele-reproducing devices and in magnetically shielded apparatus. The applications of organometallic compounds in electronics are described in greater detail in a monograph[95].

VIII. CHEMICAL REACTIONS INVOLVING METALLOCENES

1. Applications in Analytical Chemistry and in Methodological Chemical Research

Ferrocene has recently found increasing applications in analytical chemistry. The use of ferrocene in the potentiometric determination of molybdenum in metals, alloys, and steels[96] and the photometric determination of molybdenum in an aqueous organic medium[97] have been reported. The possibility of employing ferrocene in mixtures of glacial acetic and concentrated hydrochloric acids has been demonstrated in the direct amperometric oxidation-reduction titration of rhenium(VII) in aqueous organic media; many cations and anions do not interfere with the analysis[98].

Ferrocene has not become merely a generally accepted reagent of considerable importance in practice. Very recently it has come to be used as a methodological material for the training of students in procedures for the preparation of pure materials, the use of the infrared spectroscopic method in the determination of structure, in the gas–liquid chromatographic method, polarography, potentiometry, etc.[99]

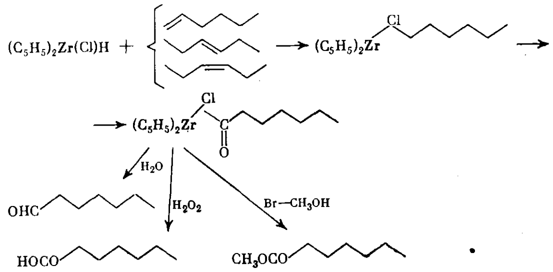
2. Catalysts of Chemical Processes

The oxidation of phenol by hydrogen peroxide in the presence of ferrocene or diacetylferrocene entails the formation of hydroquinone and catechol in proportions of 1 : 2.3 and in an almost quantitative yield[100]. Ferrocene–dichlorobenzene copolymers are capable of dehydrogenating and dehydrating alcohols[101].

When a solution of azulene is irradiated in the presence of sodium acetate and ferrocene in a carbon tetrachloride–ethanol mixture[102], the product is 1-ethoxycarbonylazulene. It has been noted that the irradiation of the same mixture in the absence of ferrocene or, conversely, in the presence of ferrocene derivatives with electron-donating (ethylferrocene) or electron-accepting (acetylferrocene) substituents does not yield satisfactory results.

Nickelocene $(C_5H_5Ni)_2$ catalyses many chemical processes. Thus a complex of the type $(C_5H_5)_2Ni.MX_n$ (where M = Al, Ti, or Nb; X = Cl; n = 3–5) polymerises butadiene with formation of polybutadiene containing *cis*-1,4-units[103,104]. Nickelocene in benzene or cyclohexane solution catalyses the hydrolysis of lignin to phenol[105]. The hydrolysis of lignin has become very important at the present time in connection with the problem of the elimination from the environment of the waste products of the cellulose industry. Reductive complex-formation reactions between phosphine sulphides and nickelocene have been described[106].

The hydrozirconation reactions in the presence of di(ηs-cyclo)pentadienyl(chloro)alkylzirconium hydride are being extensively investigated at the present time[107,108]. Carbon monoxide is inserted in the carbon–zirconium bond, olefins undergo oxidative hydrogenation, and, depending on the mode of the subsequent decomposition of the organozirconium compound, aldehydes, acids, or carboxylate esters may be obtained.



Cyclopentadienylzirconium(hafnium) dicarbonyls, $C_5H_5Zr(CO)_2$ and $C_5H_5Hf(CO)_2$, have been synthesised for the first time and tested as diphenylacetylene hydrogenation catalysts; their catalytic activity has been demonstrated. However, comparative analysis of the effect of equimolar amounts of these catalysts and cyclopentadienyltitanium dicarbonyl in the hydrogenation of phenylacetylene by hydrogen under a pressure of 3 atm showed that the latter is more effective[109].

Among organic derivatives of Group IV metals, mention should be made of dicyclopentadienyltitanium dichloride, which is widely used as a Ziegler–Natta catalyst in the polymerisation of ethylene and other mono- and poly-olefins[110,111]. Dicyclopentadienyltitanium dichloride in a 1 : 1 complex with triethylaluminium is also a hydrogenation catalyst: for example, it is used to convert oct-1-ene into n-octane[112]. The same complexes may be used as igniting agents for pyrotechnic compositions and as sources of free radicals[110].

The ability of dicyclopentadienyltitanium compounds to be reduced to compounds containing titanium in the lowest valence state, involving the intermediate formation of complexes with alkylaluminium halides, which ultimately leads to the appearance of free radicals, is believed[111] to be the main cause of the processes underlying the most important technological methods for the polymerisation of ethylene and other olefins.

Dicyclopentadienyltitanium dichloride also catalyses the fixation of molecular nitrogen[112-115]. Various systems are used in this process (for example $(\pi\text{-}C_5H_4)_2TiCl_2$, EtMgBr, $(\pi\text{-}C_5H_5)_2TiCl_2$, n-BuLi, etc.)

Vanadocene compounds proved to be active catalysts for the polymerisation of ethylene at room temperature[116]. The $(C_5H_5)_2VCl_2\text{–}CH_3AlCl_2$ and $C_5H_5VOCl_2\text{–}CH_3AlCl_2$ systems have been tested. In the first case polymerisation begins solely in the presence of oxygen as the initiator of chain transfer and termination. It has been suggested[116] that complexes of alkylated vanadium in the highest valence state are catalytically active.

An interesting report has been published recently concerning the use of cyclopentadienylcopper in the synthesis of acrylonitrile, methyl methacrylate, etc. polymers. The complex $C_5H_5Cu \leftarrow C{\equiv}N$-t-Bu is particularly effective in the polymerisation of acrylonitrile. The catalytic effect is appreciably enhanced in the presence of an excess (1 : 1) of t-BuCN and other ligands[117,118].

The use of cyclopentadienylmetal complexes in various chemical reactions constitutes a new rapidly developing field of homogeneous catalysis, which in the future may help us approach an understanding of the stereospecific processes occurring in the living organism at enormous rates at atmospheric pressure and at room or similar temperatures. The future applications of metallocenes will probably be found in this field, at the boundary between organic, organoelemental, and biological chemistry.

During the preparation of the manuscript for the press, a number of new reports were published on thermo- and photo-stabilisers[119-124], on photographic materials[125-131], on additives to fuels and oils[132-140], on medicinal substances[141-147], on semiconductors and insulators[148-154], on ferromagnetic materials[155], on applications in analytical chemistry[156-163], and on catalysts of chemical processes[164,165].

The Hydroperoxy-radical ($H\dot{O}_2$) in V.V.Voevodskii's Research and at the Present Time. Results and Problems

V.L.Tal'roze and A.I.Poroikova

The role of $H\dot{O}_2$ radicals in the kinetics of the gas-phase oxidation of hydrogen-containing substances is considered. It is shown that at a high concentration of active centres, for example, when the latter are generated under the influence of a fairly powerful radiation source, non-linear reactions of $H\dot{O}_2$ radicals, i.e. their interaction with one another and with other active species, become important. These processes play an important role in the following kinetic systems considered: at the second limit in mixtures of hydrogen with oxygen under the conditions of artificial chain initiation; in the region of Earth's ozone layer; in lasers based on the reactions between H_2 and F_2.
The bibliography includes 44 references.

I. INTRODUCTION

The ways of science are strange and unpredictable. Two different and sometimes opposite pathways converge unexpectedly. Similarly human beings following such pathways (if still alive) may meet or their memories may be juxtaposed and it would seem that everything could be predicted if one thought on these lines. This rare gift of prediction was to a large extent typical of Vladislav Vladislavovich Voevodskii.

Returning periodically to the study of $H\dot{O}_2$ radicals, mainly after Voevodskii's death, we realised how much Voevodskii foresaw in those cases where others saw only exercises in the solution of kinetic equations. Thirty years ago, at the time when one of the present authors was Voevodskii's Diploma Student, Voevodskii stated: "in this triatomic species ($H\dot{O}_2$ radical) are contained half of the future oxidation theories; it is a live radical, which is destroyed on the walls only in narrow tubes, and in all real instances it behaves as a truly reactive substance like hydrogen and oxygen atoms. If we learn to measure $H\dot{O}_2$ radicals, we shall obtain a key to oxidation mechanisms".

Thirty years have elapsed and these ideas, confirmed by extensive experimental data, have become generally accepted in the chemistry of the gas-phase oxidation of hydrogen-containing substances. It is now well known that $H\dot{O}_2$ radicals are formed in the oxidation of hydrogen, hydrocarbons, aldehydes, alcohols, ketones, ethers, and many other hydrogen-containing organic and inorganic substances.

The first hypothesis of the formation of $H\dot{O}_2$ in the gas phase was put forward in 1926 by Marshall[1] and independently by Taylor[2] in order to explain the results obtained in the oxidation of hydrogen photosensitised by mercury. The rate constant for the formation of $H\dot{O}_2$ radicals

$$\dot{H} + O_2 + M \rightarrow H\dot{O}_2 + M \tag{1}$$

was estimated in 1930[3] and at the same time Hinshelwood explained the second self-ignition limit in hydrogen-oxygen mixtures by chain termination in terms of reaction (1).[3,4] The $H\dot{O}_2$ radical appeared for the first time in 1937 in hypothetical hydrocarbon oxidation mechanisms when von Elbe and Lewis published a radical-chain mechanism for the oxidation of paraffinic hydrocarbons[5]. At the end of the 1940s, Voevodskii attempted to detect $H\dot{O}_2$ radicals on the basis of the gases evolved by frozen products in the study of the oxidation of hydrogen above the second limit. This investigation initiated a series of others, where the rate constant for the chain branching reaction was measured:

$$\dot{H} + O_2 \rightarrow \dot{O}H + \dot{O} \tag{2}$$

and the relative efficiency of the water molecules in reaction (1) was estimated[6,7]. The ratio $k_1^{H_2O}/k_1^{H_2} = 5$ obtained[6] still remains virtually unchanged.

The study of the oxidation of hydrogen at atmospheric pressure near the third limit in reactors treated with acids[7,8] led Voevodskii to the conclusion that at an early stage of the process hydrogen peroxide is the main product, in agreement with Kondrat'ev's preliminary data[9]. This feature of the oxidation of hydrogen in acid-treated reactors indicated the importance of the formation of hydrogen peroxide

$$2H\dot{O}_2 \rightarrow H_2O_2 + O_2 \tag{3}$$

together with the process

$$H\dot{O}_2 + H_2 \rightarrow H_2O_2 + \dot{H}\,. \tag{4}$$

(In the subsequent decades this idea was developed by Baldwin[10,11] and others.)

The measurement of the rate constant for reaction (4) is difficult because of the low rate of this process. In the study of the oxidation of hydrogen above the second limit Voevodskii was able to measure k_4,[6,7] which, together with the few available data obtained by other workers, served as a basis for the value recommended by Baulch[12].

Even when he became attracted to many new problems, Voevodskii continued to be interested in the reactions of $H\dot{O}_2$ radicals. Seventeen years after the first attempt to detect $H\dot{O}_2$, Panfilov, one of Voevodskii's students, successfully applied the EPR method to the determination of frozen $H\dot{O}_2$ radicals in hydrogen combustion products[13]. Soon afterwards, Nalbandyan and coworkers[14] converted the radical "freezing out" method with subsequent analysis of the EPR spectra into a quantitative procedure for the determination of $H\dot{O}_2$ and $R\dot{O}_2$ radicals in gas-phase oxidation and combustion reactions.

The regions corresponding to the combustion and slow oxidation of hydrogen were reinvestigated in order to study the characteristics of the accumulation of $H\dot{O}_2$ radicals. In particular, it was shown[14] that, in the region of the slow reaction between the second and third limits, the $H\dot{O}_2$ concentration is 10^{13} radical cm^{-3} and increases as the third limit is approached[14,15], as predicted by Voevodskii's calculations[7].

Using a modified method involving the freezing out of $H\dot{O}_2$ and $R\dot{O}_2$ radicals (fractionation) and analysing their EPR spectra, Nalbandyan and Mantashyan[14] established that the oxidation of hydrocarbons and lower aldehydes also involve the formation of $H\dot{O}_2$ radicals at a high concentration. The following processes serve as the sources of these active species:

$$\dot{C}_nH_{2n+1} + O_2 \rightarrow [\dot{C}_nH_{2n}O_2H] \rightarrow H\dot{O}_2 + C_nH_{2n},$$

$$\dot{C}_nH_{2n+1} + O_2 \rightarrow H\dot{O}_2 + C_nH_{2n},$$

$$H\dot{C}O\ (\text{from aldehydes}) + O_2 \rightarrow H\dot{O}_2 + CO,$$

$$CO + \dot{O}H \rightarrow CO_2 + \dot{H} \xrightarrow{+O_2+M} H\dot{O}_2 .$$

On passing from the low-temperature to the higher-temperature region in the oxidation of hydrocarbons[5], the ratio $[H\dot{O}_2]/[R\dot{O}_2]$ increases appreciably[14]. This finding confirms the earlier hypothesis concerning the change in the mechanism of the oxidation of hydrocarbon on passing through the region corresponding to a negative temperature coefficient of the reaction and the involvement of $H\dot{O}_2$ radicals in chain propagation reactions in the higher-temperature oxidation region[14].

Whereas in the low-temperature oxidation region the formation of $H\dot{O}_2$ radicals leads to chain termination, on raising the temperature chain propagation reactions become important:

$$H\dot{O}_2 + RH \rightarrow H_2O_2 + \dot{R}, \qquad (5)$$

$$H\dot{O}_2 + R'CHO \rightarrow H_2O_2 + R'\dot{C}O, \qquad (6)$$

and the decomposition of the hydrogen peroxide formed leads to degenerate branching. Thus it was found that, in agreement with Voevodskii's views, in the higher-temperature oxidation region the $H\dot{O}_2$ radical is an active intermediate—a chain carrier.

For a quantitative description of the oxidation of hydrocarbons at a high temperature, it is necessary to know the rate constants for reactions (5) and (6), the few available values for which are listed in Table 1. The rate constants for the interaction of $H\dot{O}_2$ radicals with paraffinic hydrocarbons, presented in Lloyd's review[3], were measured by Baldwin and coworkers at a single temperature (500°C). Assuming that the activation energy for C_2H_6 is 14 kcal $mole^{-1}$ and that the difference between the enthalpies of reaction (5) enters into the activation energy with a coefficient of unity (according to the Semenov–Polanyi rule, with a coefficient of 0.75 for endothermic reactions[17]), Lloyd[3] obtained the Arrhenius parameters of reactions (5) listed in Table 1.

The products of the interaction of $H\dot{O}_2$ radicals with olefins are unknown[3,18]. The rate constants have been estimated[18].

We examined the pathways followed in the "linear" reactions of $H\dot{O}_2$ in the oxidation of hydrogen and hydrocarbons, i.e. the reactions of $H\dot{O}_2$ radicals with stable substances. These processes are important, because they lead to the third chain limit in the oxidation of hydrogen[7] and to the characteristics of the higher-temperature oxidation of hydrocarbons mentioned above.

However, nowadays non-linear reactions of $H\dot{O}_2$ radicals and their reactions with active species are attracting the attention of investigators to an increasing extent. We shall demonstrate three examples of the importance of non-linear processes involving $H\dot{O}_2$ radicals. We shall consider only situations in which the initial reactions where the species are generated are associated with the effect of radiation on reactive gaseous mixtures: (1) the influence of modern sources of ionising radiation (isotopes, nuclear reactors, accelerators) on the ignition limits associated with a branched chain mechanism; (2) the reactions of $H\dot{O}_2$ radicals in Earth's ozonosphere; (3) the reactions of $H\dot{O}_2$ radicals in common chemical lasers. As classical examples, we shall consider a mixture of hydrogen and oxygen for the first case and the working mixture in the laser whose operation is based on the reaction between H_2 and F_2 (the mechanism of this reaction was discovered at the Institute of Chemical Physics[19,20] and the most important chemical lasers in existence at the present time are based on it) for the third case.

Table 1. The rate constants for reactions (5) and (6) $[k = A\exp(-E/RT)]$.

RH	C_2H_6	C_3H_8	n-C_4H_{10}	iso-C_4H_{10}	CH_2O*
ΔH_i, kcal $mole^{-1}$	8.36	4.84	4.97	1.27	—0.9
E, kcal $mole^{-1}$	14.0	10.5	10.5	7.0	10.4
lg A (cm^3 $mole^{-1}$ s^{-1})	12.0	11.3	11.7	11.0	13.0

*k was measured in the temperature range 773–793 K [16]; for the remaining RH, estimates taken from Ref. 3 are quoted.

II. NON-LINEAR REACTIONS OF $H\dot{O}_2$ RADICALS ASSOCIATED WITH THE OXIDATION OF HYDROGEN

The problem of the influence of radiation and of other physical methods for the generation of active species on the reaction of hydrogen with oxygen is the problem of the positive interaction of chains. The idea, logic, and initial method are due to Semenov[17] and the first postwar experiments, on the basis of which Semenov derived the mechanism, were carried out by Dubovitskii and Nalbandyan[21]. According to Semenov's calculation[17], when one begins with the rate of generation of oxygen atoms in Nalbandyan's photochemical experiments and one assumes that $H\dot{O}_2$ radicals are destroyed on the reactor wall and the chains interact solely via the reaction

$$\dot{H} + H\dot{O}_2 \rightarrow 2\dot{O}H,$$

then a rate constant of 10^{-11} cm^2 $molecule^{-1}$ s^{-1} must be attributed to the latter reaction in order to account for the observed limiting increase of pressure. Since that time the reaction between $\dot{H}$ and $H\dot{O}_2$, which was found to proceed via the three channels

$$\dot{H}+H\dot{O}_2 \begin{cases} \longrightarrow 2\dot{O}H, & (7) \\ \longrightarrow H_2+O_2, & (8) \\ \longrightarrow H_2O+\ddot{O}, & (9) \end{cases}$$

has been the subject of numerous investigations. Table 2 presents the experimental data accumulated hitherto. If Westenberg's results (which are probably erroneous[22,31]) are rejected, then, despite the quantitative discrepancy, all these data confirm a single main idea: the reaction between $\dot{H}$ and $H\dot{O}_2$ involves chain branching and not chain termination, in agreement with Semenov's hypothesis, because $k_8 < k_7 + k_9$.

Table 2. The ratios of the rate constants for the chain termination and propagation channels in the reaction between $\dot{H}$ and $H\dot{O}_2$.

T, K	$\frac{k_8}{k_7+k_9}$	Method	Refs.
773	0.17	Computer calculation, IInd limit in $H_2 + O_2$ reaction	22
900	0.15	Rate of $H_2 + O_2 + N_2$ flame propagation, computer calculation	23—25
293	0.50	Extrapolation of high-temperature data	23—25
291	0.51±0.2	Discharge flow, measurement of H and H_2O concentrations; $p = 2$ mmHg	26
291	0.75±0.25	Discharge flow, EPR; $p = 50–250$ mmHg	27
291	0.76	Diffusion cloud, mass spectrometry; $p = 20$ mmHg	28
291	1.6	Discharge flow, EPR; $p \leqslant 2.5$ mmHg	29
293	0.41	Discharge flow, EPR; $p = 10$ mmHg	30

As a result of the studies by Baldwin[11] and other investigators[32], it is known that the mechanism of the oxidation of hydrogen at the second ignition limit depends to a large extent on the treatment of the reaction vessel walls. In vessels treated with oxides and certain metal chlorides the active centres are destroyed at a higher rate on the reactor surface. The principal characteristics observed at the first and second ignition limits can then be accounted for in terms of a reaction mechanism involving only linear reaction processes:

$$H_2+O_2 \rightarrow 2\dot{O}H, \qquad (10)$$

$$\dot{O}H+H_2 \rightarrow H_2O+\dot{H}, \qquad (11)$$

$$\dot{H}+O_2 \rightarrow \dot{O}H+\ddot{O}, \qquad (2)$$

$$\ddot{O}+H_2 \rightarrow \dot{O}H+\dot{H}, \qquad (12)$$

$$\dot{H} \xrightarrow{\text{wall}} (H)_w,$$

$$\ddot{O} \xrightarrow{\text{wall}} (O)_w,$$

$$\dot{O}H \xrightarrow{\text{wall}} (OH)_w,$$

$$\dot{H}+O_2+M \rightarrow H\dot{O}_2+M, \qquad (1)$$

$$H\dot{O}_2 \xrightarrow{\text{wall}} (HO_2)_w.$$

The opposite case of the "fully reflecting" surface is that of the surface of reactors treated with acids[32] and primarily with boric acid[10,11]. Here the probability of the destruction of $H\dot{O}_2$ radicals on the wall is low ($\leqslant 10^{-4}$)[33] and the non-linear processes (7)–(9) and (3) make a considerable contribution to the mechanism of the oxidation of hydrogen near the second limit. Experiments show that in acid-treated vessels the second limit occurs at a higher pressure, which also indicates the dominance of the positive chain interaction processes (7) and (9).

The problem of the possible influence of ionising radiation on the ignition region has been examined[34]. After the essential features of the interaction of ions with molecules were established a quarter of a century ago and the corresponding rate constants were estimated, it became possible to convert the fluxed and doses of ionising radiation into the absolute rates of initiation of chemical reactions by such radiation[35]. The *EFDC* plot of the logarithm of the radiation dose rate against the reciprocal of temperature in Fig. 1, taken from Tal'roze[34], shows the dose rates for which the effect of radiation is significant. The region of an appreciable effect by the radiation is limited by plots corresponding to the following four criteria proposed for the analysis of the problem of the radiation-induced initiation of chain processes[34].

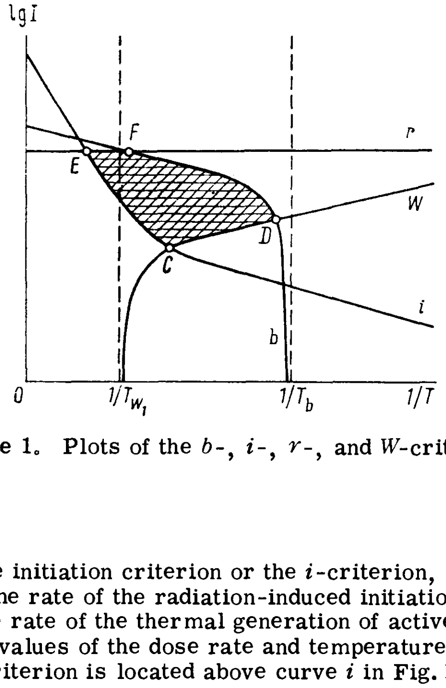

Figure 1. Plots of the b-, i-, r-, and W-criteria.

1. The initiation criterion or the i-criterion, according to which the rate of the radiation-induced initiation must exceed the rate of the thermal generation of active centres; the set of values of the dose rate and temperature satisfying this criterion is located above curve i in Fig. 1.
2. The branching criterion or b-criterion, requiring that the reaction should be self-accelerating under isothermal conditions. This characteristic of the process should be observed to the left of curve b.
3. The absolute rate or W-criterion, according to which it is necessary that the overall reaction rates should exceed a value selected on the grounds of practical considerations. This criterion is satisfied to the right of curve W.
4. The criterion concerning the presence of a source of sufficient intensity or the r-criterion. It is satisfied below the horizontal straight line r corresponding to the maximum dose rate which may be established in the reaction mixture using a particular type of ionising radiation source.

On the basis of the plots in Fig. 1, one may expect that radiation affects the ignition limits for a hydrogen–oxygen mixture only in the range of dose rates corresponding to the region *EFDC*. The calculations of Poroikova et al.[36] do indeed show that the ionising radiation from the available sources can alter the position of the second ignition limit in hydrogen–oxygen mixtures.

Fig. 2 presents the results of calculations in terms of plots of the dimensionless pressure at the second limit against the logarithm of the ratio of the rate of artificial initiation and the rate of thermal chain generation [the calculation was performed for the following conditions: stoichiometric mixture, 723 K, cylindrical vessel with a radius of 2 cm, and the ratio $k_8/(k_7 + k_9) = 0.15$]. The limit is appreciably displaced when the rate of artificial initiation corresponds to a dose rate of 10^{14}–10^{17} eV cm^{-3} s^{-1}, which requires the use of powerful radiation sources.

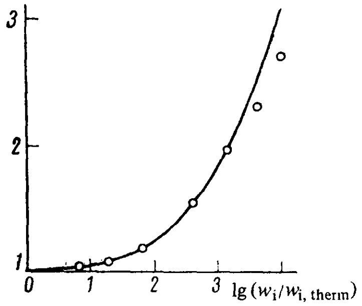

Figure 2. Dependence of the pressure at the second limit on the rate of artificial initiation; p_{II}—pressure at the limit; $p_{II, therm}$—pressure at the limit corresponding to thermal chain initiation; W_i—rate of artificial initiation; $W_{i, therm}$—rate of thermal generation of active centres.

The circles in Fig. 2 present the results of the calculation by the equation obtained for the second limit taking into account reactions (1)–(4) and (7)–(12), while the continuous line represents the results of the calculation of the second limit on a computer taking into account a more complex mechanism, including the consumption of the initial substances, the self-heating of the reacting mixture, the formation and consumption of hydrogen peroxide, and a number of other non-linear processes[33,36].

Evidently the results of the two calculations agree over a wide range of artificial initiation rates. The limit is controlled by processes (1) and (2) (as for a linear mechanism) and by the quadratic reactions (3) and (7) to (9). At higher rates of initiation there is an additional displacement of the limit (the continuous line passes above the circles) owing to the self-heating of the mixture[33,36].

Thus the four non-linear processes (3) and (7)–(9) involving $H\dot{O}_2$ radicals determine the position of the thermal limit in acid-treated vessels and the displacement of the limit following artificial chain initiation. In order to calculate the limit, it is necessary to know both the overall rate constant for the reaction between H and $H\dot{O}_2$ and the ratio of the rate constants for the chain propagation and termination channels and their temperature dependence. Values of the above ratio obtained by various workers are listed in Table 2. All the low-temperature results refer to the system where H atoms were obtained from a discharge and the overall pressure in the reaction vessel was several mmHg. In his analysis of causes of the discrepancies between the results, Lloyd[3] points to the possible contribution of excited $H\dot{O}_2^*$ species to the reaction with H atoms [the heat of reaction (1) is 47 kcal mole^{-1}]. It has been shown[37] that an even more important source of errors is the formation in the discharge of excited hydrogen molecules whose interaction with $\dot{O}H$ radicals takes place with a low activation energy. The corresponding increase in the concentration of $\dot{H}$ atoms and the decrease in the concentration of $\dot{O}H$ radicals may lead[37] to unduly low values of k_7 and of the overall rate constant for the reaction between $\dot{H}$ and $H\dot{O}_2$ (in the available data[22–30], the values of the overall rate constant vary by a factor of 3).

The high temperature results, quoted by Baldwin et al.[22] and by Dixon-Lewis and coworkers[23–25] for only one temperature, were obtained by comparing the experimental position of the second limit and the rate of propagation of the hydrogen-oxygen flame with a very complex oxidation mechanism. The values obtained are thus based on certain numerical rate constants for a whole series of other processes. The rate constants for reactions (7)–(9) and the corresponding activation energies quoted by Hampson and Garvin[38] must therefore be regarded as estimates.

The rate constant for reaction (3) has been measured by many investigators[12]. The activation energy for this process is unknown but is probably small[3]. According to Lloyd's estimates[3], k_3 at 700–800 K is known within the limits of a factor of 2.

It follows from the foregoing data that reliable measurements of the rates of reactions (3) and (7)–(9) are necessary over a wide temperature range.

III. REACTIONS OF $H\dot{O}_2$ RADICALS IN EARTH'S OZONOSPHERE

Earth's ozonosphere is a giant photochemical reactor in the ultraviolet part of the spectrum. Until recently it was believed that the photochemistry of the ozone layer is limited to Chapman's oxygen cycle[38]:

$$O_2 + h\nu \rightarrow 2\ddot{O}, \tag{13}$$

$$\ddot{O} + O_2 + M \rightarrow O_3 + M, \tag{14}$$

$$O_3 + h\nu \rightarrow \ddot{O} + O_2, \tag{15}$$

$$\ddot{O} + O_3 \rightarrow 2O_2, \tag{16}$$

in which reactions (14) and (15) are rapid. Reaction (13) involves the generation of active substances comprising the so called odd oxygen (oxygen atoms and ozone molecules), while reaction (16) involves their destruction.

At least three more groups of chain reactions opposing the tendency of sunlight to generate odd oxygen, are known at the present time. These groups are the hydrogen, nitrogen, and chlorine ozone decomposition cycles. The reactions in these cycles, together with processes (13) and (16) control the steady-state concentration of ozone (in the ozone layer the concentration of oxygen atoms is much smaller than the concentration of ozone).

The active species in the hydrogen cycle, the so called odd hydrogen ($\dot{H}$ atoms, $\dot{O}H$ and $H\dot{O}_2$ radicals, and H_2O_2 molecules), are formed from the H_2O, H_2, and CH_4

molecules arriving from Earth's surface. The most important processes in the hydrogen cycle are the following reactions in which the $\dot{O}H$ and $H\dot{O}_2$ radicals behave as catalysts of the decomposition of odd oxygen:

$$\begin{aligned} O_3 + \dot{O}H &\rightarrow H\dot{O}_2 + O_2\ , \\ H\dot{O}_2 + \ddot{O} &\rightarrow \dot{O}H + O_2\ , \\ O_3 + H\dot{O}_2 &\rightarrow \dot{O}H + 2O_2\ , \\ \dot{O}H + \ddot{O} &\rightarrow \dot{H} + O_2\ , \\ \dot{H} + O_2 + M &\rightarrow H\dot{O}_2 + M\ . \end{aligned}$$

These processes involve the termination of odd oxygen chains, while in relation to the substances constituting odd hydrogen they are chain propagation reactions (the interaction of the hydrogen and oxygen cycles).

Examples of other important chain propagation reactions are presented below:

$$\begin{aligned} 2H\dot{O}_2 &\rightarrow H_2O_2 + O_2, \\ H_2O_2 + h\nu &\rightarrow 2\dot{O}H, \\ H\dot{O}_2 + NO &\rightarrow \dot{O}H + NO_2, \\ H\dot{O}_2 + CH_3\dot{O}_2 &\rightarrow CH_3O_2H + O_2, \\ CH_3O_2H + h\nu &\rightarrow CH_3\dot{O} + \dot{O}H. \end{aligned} \tag{17}$$

Here Eqn. (17) represents the interaction of the hydrogen and nitrogen cycles (the substances constituting odd nitrogen are NO, NO_2, NO_3, N_2O_5, HNO_3, and HNO_2). The last two processes are associated with the oxidation of natural methane.

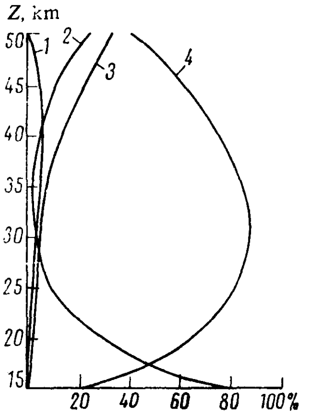

Figure 3. Contribution of the cycles to the rate of decomposition of ozone (%): 1) ClO_X; 2) HO_X; 3) O_X; 4) NO_X.

The relative contribution of the hydrogen cycle to the decomposition of ozone and the relative roles of other ozone decomposition cycles, which we recently calculated[39], are presented in Fig. 3. Evidently the chain reaction involving $H\dot{O}_2$ makes different contributions to the decomposition of ozone and in the lower ozonosphere this contribution may reach 2/3. We chose the chain length ν, equal to the number of odd oxygen molecules decomposed by one molecule of the cycle catalyst, as a measure of the efficiency of cycles in the decomposition of odd oxygen. The ozone decomposition chain length in each cycle, calculated by Tal'roze et al.[39], is presented in Fig. 4. Evidently the chain length in the hydrogen cycle has the smallest dependence on the height above sea level (Z) and amounts on average to several hundreds of units.

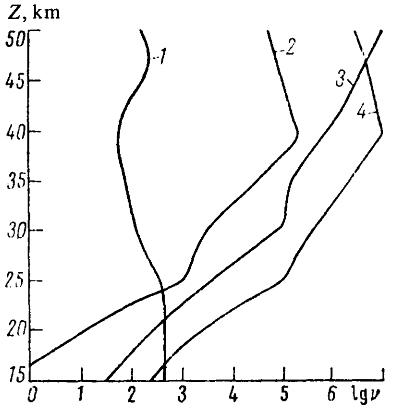

Figure 4. Odd oxygen chain lengths in different cycles: 1) HO_X; 2) ClO_X; 3) NO_X; 4) BrO_X.

Thus the key position of $H\dot{O}_2$ in the chemistry of the ozonosphere is determined to a large extent by its involvement in the "mixing" of different groups of chemical reactions, i.e. in non-linear interactions with active species of other cycles. Apart from the chain propagation reactions described above, the following interactions between the cycles are important:

$$\left.\begin{array}{l} H\dot{O}_2 + \dot{O}H \rightarrow O_2 + H_2O \\ H\dot{O}_2 + NO_2 \rightarrow O_2 + HNO_2 \\ H\dot{O}_2 + NO + M \rightarrow M + HNO_3 \\ H\dot{O}_2 + \dot{C}l \rightarrow O_2 + HCl \\ \\ H\dot{O}_2 + CH_3\dot{O} \rightarrow O_2 + CH_3OH \end{array}\right\} \begin{array}{l} \text{(chain termination in the } HO_X \text{ cycle)} \\ \text{transfer, washing out by rain } \rightarrow \\ \rightarrow \text{termination in both cycles} \\ \xrightarrow{+\dot{O}H} H_2O + NO_x, ClO_x \text{ (partial termination} \\ \text{in } HO_X \text{ cycle)} \\ \xrightarrow{+h\nu} \text{ regeneration of cycles} \end{array}$$

These processes largely lead to chain termination, but there also exists a chain propagation channel (photochemical decomposition).

Chain termination in the nitrogen and chlorine cycles takes place via the diffusion of acid species (HNO_X and HCl) to the troposphere and their subsequent washing out by rain. The rate of this process may be calculated with the aid of vertical turbulent diffusion coefficients, which have been estimated by many workers[39-41]. Compared with the rate of transfer, the chemical chain termination reaction

$$H\dot{O}_2 + \dot{O}H \rightarrow O_2 + H_2O \tag{18}$$

takes place at a high rate in the stratosphere. This explains the relatively small length of the ozone decomposition chain in the hydrogen cycle. Thus reaction (18) is one of the key elementary processes influencing ozone in the lower stratosphere. Many investigators have been devoted to the measurement of the rate constant for reaction (17). Its reliable measurements are difficult in view of the complexity of the systems in which $\dot{O}H$ and $H\dot{O}_2$ radicals may be obtained simultaneously. Hampson and Garvin[38] recommend values of k_{17} in the range from 2×10^{-11} to 2×10^{-10} cm^{-3} mol.$^{-1}$ s^{-1}, but the scatter of the literature data exceeds this range.

IV. THE $H\dot{O}_2$ RADICAL IN THE LASER BASED ON THE REACTION BETWEEN H_2 AND F_2†

The emission from these lasers is in the infrared because the elementary reactions

$$\dot{H} + F_2 \rightarrow HF + \dot{F},$$
$$\dot{F} + H_2 \rightarrow HF + \dot{H}$$

lead to the generation of inverted populations of vibrationally excited HF molecules. Despite the outward simplicity of the system, it is difficult to control the active process in the chemical laser. In the first place, when one is dealing with pulsed lasers, it is necessary to mix the initial substances under a considerable pressure. Shilov, Chaikin, and coworkers[19,20] found a simple solution to this problem: oxygen is added and the stabilisation process, which produces a second ignition limit in the fluorine–hydrogen mixture under the conditions of vigorous branching, is

$$\dot{H} + O_2 + M \rightarrow H\dot{O}_2 + M. \qquad (1)$$

The question arises of the subsequent fate of the $H\dot{O}_2$ radicals and whether or not it is important. This problem has been inadequately analysed and we shall point to only one of its aspects.

A pulsed chemical laser operates effectively under the conditions of intense initiation of the chain reaction. The initiation is achieved by some kind of influence on the fluorine–hydrogen mixture which leads to the appearance of fluorine atoms. The intensity of the initiation is usually such that, after a short period, the concentration of fluorine atoms reaches 0.1–1% of the initial concentration of molecules. It is noteworthy that, in a mixture having a nearly stoichiometric composition, the "slow" active centre is the hydrogen atom and the number of hydrogen atoms is virtually equal to the number of generated fluorine atoms. This factor distinguishes significantly the conditions in the pulsed reaction between fluorine and hydrogen from those in the thermal reaction and also from the reaction between hydrogen and oxygen in the initial stages of self-ignition. Indeed the $H\dot{O}_2$ radicals formed can no longer be regarded as relatively inactive, because the mixture contains a substance (hydrogen atoms) the concentration of which is sufficient to react rapidly with $H\dot{O}_2$ radicals. The hydroxy-radicals formed in this process can react with molecular hydrogen to generate hydrogen atoms. The rate constant for this reaction can be in principle very large and close to the collision number, since the $\dot{O}H$ radicals formed have an average excitation energy of 20 kcal mole^{-1}. Thus the situation of "an infinite chain length" is created.

Such are the three kinetic systems, outwardly so different and yet identical as regards the important role of $H\dot{O}_2$ radicals, to the understanding of which Voevodskii's fundamental ideas have made a significant contribution.

---

†For the description of chemical lasers employing the reaction between H_2 and F_2, see Refs. 42–44.

Infrared Photochemistry

V.N.Panfilov and Yu.N.Molin

The characteristics of chemical reactions under the influence of infrared radiation and the conditions under which they occur in the absence of equilibrium between the vibrational and other degrees of freedom of the reacting species are examined. Studies on isotopically selective reactions, on the role of various types of energy (namely vibrational and translational energy), and on the overcoming of the activation barrier in chemical reactions are analysed.
The bibliography includes 226 references.

I. INTRODUCTION

The vigorous development of laser techniques in recent years has greatly extended the scope of photochemistry. The application of lasers with ultrashort (picoseconds) pulses made it possible to investigate ultrafast processes which previously had not been susceptible to direct experimental investigation. High radiation densities (megawatts and gigawatts per square centimetre) made it possible to achieve readily multiquantum processes. The highly monochromatic nature of laser radiation has led to selective photochemical reactions (including reactions selective with respect to isotopes).

Whereas in the visible and ultraviolet regions (i.e. in the regions of electronic transitions) the appearance of lasers significantly extended the scope of photochemistry, in the infrared region (i.e. in the region of vibrational transitions) photochemical research has become in general possible only after lasers became available. Until then there had been no sources of infrared radiation with a sufficiently high intensity to be capable of generating in a single, not necessarily very narrow, part of the spectrum excited species at a higher rate than in thermal equilibration processes. Infrared spectroscopy existed but not infrared photochemistry. One can point to only one study of the pre-laser period[1] whose author investigated the *cis*–*trans* isomerisation of nitrous acid in a low-temperature matrix (at 20 K) under the influence of infrared radiation isolated by filters from the emission spectrum of a heated body.

Numerous studies have now been published on infrared laser photochemistry. Some of them have been analysed in review articles on the chemical action of laser emissions[2-16] and the laser method for isotope separation[17-21] as well as a number of popular articles[22-25]. Most of the reviews have dealt with processes occurring under the influence of laser radiation over the entire spectral range and comparatively little attention has been devoted to the infrared region. Only brief reviews have been devoted to problems of infrared laser photochemistry[5,13].

We shall now formulate the fundamental distinctive features of infrared photochemistry, i.e. the photochemistry of vibrationally excited molecules, in relation to the photochemistry in the ultraviolet and visible regions, i.e. the photochemistry of electronically excited states.

The primary step in photochemical processes under the influence of ultraviolet and visible radiation is the formation of electronically excited species, which then usually decompose or isomerise. The large electronic excitation quanta make the contribution of the thermal reaction pathway insignificant compared with the photochemical pathway. When an infrared quantum is absorbed, vibrationally excited species are formed in the ground electronic state. Owing to the smallness of the infrared quanta, the population of the corresponding vibrationally excited state corresponding to thermal equilibrium is not as a rule negligibly small compared with the population induced by the radiation. For this reason, one of the distinctive features of infrared photochemistry is methodological difficulties associated with the competition between the photochemical and thermal reaction pathways. These difficulties are eliminated mainly by reducing the pressure and temperature. A decrease of pressure retards the deactivation of excited molecules, which is determined by vibrational relaxation in collisions with other species, while a decrease of temperature diminishes the thermal population of the vibrationally excited states. Thus infrared photochemistry is mainly the photochemistry of low pressures and temperatures.

Chemical reactions under the influence of ultraviolet and visible radiation are determined as a rule by the reactivity of the excited state formed in the primary light absorption step. In the infrared region this situation is rarely encountered. It is prevented by intramolecular vibrational energy transfer between different vibrational degrees of freedom, which is very rapid in complex molecules. For this reason, chemical reactions under the influence of infrared radiation may be determined by the reactivity of not only the directly excited bond but also of others. Furthermore, in the infrared region intermolecular energy transfer also plays a relatively major role. As a result, other more reactive species react instead of the molecule excited by infrared radiation; thus infrared photosensitisation must be a fairly common phenomenon.

One of the characteristics of infrared photochemistry is associated with the fact that the reactivity of vibrationally excited molecules increases sharply with increase in the amount of vibrational energy. For a fairly large amount of energy, other processes, such as the dissociation and ionisation of the molecule, also become possible. Multiquantum processes, i.e. processes involving highly excited states, therefore play an extremely important role in the infrared region.

Finally we may note that in the infrared region the quantum yields are usually low, whereas in electronic excitation they frequently approach unity. This is associated primarily with the relatively high rates of deactivation processes compared with the rate of reaction. On the other hand the faster multiquantum processes, such as multiquantum dissociation processes, show quantum yields much less than unity by virtue of the very nature of the process.

In the light of the characteristics of infrared photochemistry formulated above, one may specify three types of chemical reactions, with different degrees of complexity, under the influence of infrared radiation. Firstly, these are reactions under conditions where there is no equilibrium between the vibrational and translational degrees of freedom. One of the main scientific problems in these investigations involves the study of chemical reactions under non-equilibrium conditions, which is very important not only for laser photochemistry but also for plasma chemistry, chemical combustion, and other problems of practical importance. Whereas it is evident that in unimolecular decomposition reactions the vibrational energy is in fact responsible for overcoming the activation barrier, in bimolecular and other reactions the problem is more complex. One of the tasks in infrared laser photochemistry is the elucidation of the role of various types of energy (particularly vibrational energy) in the overcoming of the activation barrier in chemical reactions. A practical aspect of the studies under consideration is a more economical utilisation of the energy required to carry out the chemical reactions. In this case the energy is consumed in "heating" only the vibrational degrees of freedom of the reacting species and not of the entire substance. The high efficiency of modern infrared lasers (particularly the CO_2 laser) permits one to hope that they may be used in practice to achieve processes of this kind.

The second task—the selective involvement in the reaction of molecules having similar chemical properties, particularly isotopic molecules—is more complex. The high rates of exchange of vibrational energy between them make it possible to carry out such processes only in gases at low pressures or in the condensed phase at low temperatures under the conditions of matrix isolation of the excited molecules. Still greater difficulties arise in the solution of the third problem—the achievement of reactions via a selected pathway by "exciting" the corresponding vibrations as a result of the absorption of infrared radiation. Rapid intramolecular transfer of vibrational energy between different degrees of freedom in complex molecules prevents this.

Most studies on infrared laser photochemistry refer to processes in gases at low pressures. They can be divided into two groups. The first involves the study of the dissociation of polyatomic molecules as a result of multiphoton excitation by the action of powerful and short radiation pulses of infrared lasers (particularly the CO_2 laser) and the second involves the study of reactions with atoms and free radicals of molecules whose degree of vibrational excitation is comparatively low. Furthermore, there have been numerous studies where chemical reactions under the influence of infrared laser radiation were due to equilibrium thermal heating. These are mainly processes in gases at comparatively high pressures (tens and hundreds of mmHg) under the influence of continuous laser radiation. The number of studies on chemical reactions in the condensed phase or on solid surfaces has been much smaller owing to the high rates of relaxation of vibrational energy in liquids and solids.

Accordingly, in Section II we examine the competition between the thermal and photochemical mechanisms of reactions under the influence of infrared radiation and analysed studies at high pressures. Strictly speaking, a considerable proportion of these studies cannot be regarded as photochemical (or "laser-chemical"), but laser heating leads to characteristic features in the kinetics compared with the equilibrium heating by the wall. For this reason, the inclusion of these studies in the present review appears useful. Section III is devoted to the reactions of weakly excited molecules with atoms and free radicals. Section IV deals with the results of studies on the selective dissociation of polyatomic molecules under the influence of the pulsed radiation of infrared lasers. The rates of transformation of vibrational energy into translational and rotational energy and the rates of transfer of vibrational energy between different molecules and different vibrational degrees of freedom of one molecule are very important in all reactions involving vibrationally excited species. Numerous experimental and theoretical studies on this problem are now available in the literature and their analysis requires a special review. For this reason, we confine ourselves to an examination of relaxation processes in molecules whose reactions under the influence of infrared radiation have been investigated in greatest detail (Section V). Section VI is devoted to reactions in the condensed phase and on the surface.

The review does not deal with chemical reactions occurring on evaporation of condensed substances and following electrical breakdown in gases under the influence of infrared radiation. Nor do we consider processes involving multistage dissociation and ionisation, where the infrared laser radiation is used solely in the first stage, and processes associated with a change in properties of vibrationally excited molecules other than their reactivity.

II. COMPETITION BETWEEN THE THERMAL AND PHOTOCHEMICAL MECHANISM OF REACTIONS UNDER THE INFLUENCE OF INFRARED RADIATION

Irradiation of a substance by infrared light is inevitably accompanied by equilibrium thermal heating owing to vibrational-translational ($V-T$) relaxation. The problem therefore arises of the cause of the chemical reaction under the influence of infrared radiation: equilibrium thermal heating or the involvement of more reactive vibrationally excited species generated by the laser radiation.

The competition between the thermal and photochemical mechanisms of the transformation of the given substance under the influence of pulsed laser radiation has been examined in a study[26] where the criteria for the selection of the duration of the laser pulse and its intensity where the reaction proceeds via a non-thermal pathway were formulated. Analysis of the thermal and radiation-induced populations of the excited states when the substance is acted upon by continuous laser radiation[27,28] led to the conclusion that there is a critical pressure above which the radiation-induced population cannot exceed the thermal population whatever the power of the laser emission. This critical pressure depends on the size of the infrared quantum, temperature, thermal conductivity of the mixture, the rate of $V-T$ relaxation, and the ratio of the diameters of the reaction vessel and the laser beam. For processes under the influence of the emission of the CO_2 laser at room temperature and for molecules of moderate complexity, the critical pressure does not exceed 1 mmHg.

The thermal and radiation-induced populations of vibrationally excited states have been analysed[26-28] in terms of a two-level approximation, i.e. without taking into account the vibrational–vibrational ($V-V$) relation processes. In reality these processes lead to a redistribution of vibrational energy among different degrees of freedom of the excited molecules. Since the rate of $V-V$ relaxation usually greatly exceeds the rate of $V-T$ relaxation, the energy undergoes equilibrium distribution among the vibrational degrees of freedom, which may be characterised by the vibrational temperature (different from the translational temperature). The criteria governing the "discrepancy" between the vibrational and translational temperatures and the possibility of carrying out chemical reactions under such conditions have been examined[29-31]. However, this analysis was carried out without taking into account the equilibrium thermal heating due to the infrared radiation. We may note that a complicating factor in the consideration of complex molecules is the high probability of $V-T$ relaxation from high vibrational levels. A general theoretical treatment of the distribution of excited species with respect to different vibrational states is not available in the literature for this case.

The first observations of chemical reactions under the influence of infrared laser emissions were made by French investigators[32-35], who recorded the glow of ammonia, ethylene, ethyl chloride, and their decomposition products under the influence of the emission from a continuous CO_2 laser on the gases at a pressure of several hundred mmHg. The authors themselves attributed the observed chemical reactions to equilibrium thermal heating. Subsequently a number of studies were made on the laser pyrolysis of ethylene[36-39], ammonia[40,41], and other compounds which effectively absorb the radiation generated by the CO_2 laser[42-51]. Analysis of the secondary infrared emission spectra under such conditions shows that they are caused by the heating of the gases in the region of laser irradiation[52-54]. The study of the bimolecular reactions of PF_5 with SO_2[55] and of SF_6 with H_2 and O_2[56] under the influence of the radiation from the CO_2 laser operating under quasi-continuous conditions (with pulses lasting $10^{-2}-10^{-3}$ s) showed that they also proceed via the thermal mechanism.

However, the authors of a number of studies dealing with chemical reactions under the influence of infrared laser radiation under conditions similar to those described above (i.e. at pressures of tens and hundreds of mmHg) hold a different view and attribute the reactions under these conditions to the non-equilibrium population of highly vibrationally excited states of the molecules irradiated by infrared light. These are the reactions of tetrafluorohydrazine with nitrogen oxides, hydrogen, methane, etc.[57-66], the bromination of pentafluorobenzene[67], the reaction of HBr with carboranes[68,69], the decomposition of Freons[70,72], the interaction of diborane with isobutene[73] and hydrogen sulphide[74], the interaction of boron trichloride with tetrachloroethylene[75] and trimethylboron[76], and the pyrolysis of acetylene[77].

One of the principal arguments of the authors of the majority of these studies in support of a non-thermal mechanism of the chemical reactions is higher rates and differences in the composition of the products of chemical reactions under the influence of infrared radiation compared with reactions under the conditions of ordinary heating to the corresponding temperatures. However, the difficulties in the direct measurements of the temperature rise induced by the laser radiation make it necessary to estimate the temperature by calculation, which hinders the comparison of the results corresponding to laser and thermal initiation of the reactions.

Another argument is the observation of threshold phenomena, i.e. a sharp dependence of the reaction rates on the intensity of the laser radiation when the latter is above a threshold value and the virtually complete absence of reactions below the threshold. According to the authors, the presence of the threshold may show that the rate of reaction is determined by the concentration of highly excited species with an energy much higher than the energy of the absorbed quantum. The probability of their formation in $V-V$ relaxation processes depends strongly on the intensity of the infrared radiation, the dependence being described by a power function. If the equilibrium temperature rise due to the infrared radiation is insignificant, the occurrence of threshold phenomena is indeed a serious argument in support of a photochemical process mechanism. However, the occurrence of an equilibrium temperature rise in the irradiated volume may lead to the same behaviour both in consequence of the pronounced exponential temperature dependence of the rates of the majority of chemical reactions and as a result of the initiation of thermal or chain explosion, so that experiments of this kind require careful analysis.

A number of studies have been devoted to detailed analysis of threshold phenomena in reactions under the influence of infrared radiation[60-63]. One should note that in most instances threshold phenomena have been observed in exothermic reactions. The given substance undergoes virtually complete conversion on irradiation with a single pulse despite the fact that only part of the reactor volume is irradiated. Evidently the pulse of infrared radiation initiates the reaction in the irradiated volume, after which it is propagated throughout the reactor. The explosive decomposition of ethyl iodide under the influence of the radiation of a continuous CO_2 laser has been explained[78] within the framework of the theory of thermal explosion initiated by the laser radiation. In the thermally neutral decomposition of monosilane[61] threshold phenomena have been observed less distinctly and the latter can also be accounted for within the framework of a thermal reaction mechanism: the exponential dependence of the rate of reaction on temperature (the temperature increases with increasing radiation intensity) can simulate effectively threshold phenomena. Thus the threshold phenomena cannot themselves serve as an unambiguous demonstration of a photochemical mechanism of reactions under the influence of infrared radiation.

At first sight non-ambiguous evidence for a non-thermal reaction mechanism at high temperatures was obtained in a study[70] where the decomposition of Freon (CF_2Cl_2) was investigated at a pressure of 100 mmHg under the influence of the radiation of a continuous CO_2 laser. We shall consider this study in greater detail. It involves the investigation of the decomposition of Freon mixed with SF_6. The infrared absorption bands of CF_2Cl_2 and SF_6 are separated by 17 cm^{-1}. When the laser is tuned to a frequency of 948 cm^{-1}, corresponding to the absorption maximum of SF_6, Freon does not absorb the infrared radiation and, conversely, when the laser is tuned to $\nu_{max} = 931$ cm^{-1} for CF_2Cl_2, SF_6 does not absorb. The SF_6 and CF_2Cl_2 pressures (4.4 and 100 mmHg respectively) were chosen so that the absorption of the infrared radiation by the mixture was the same in the above two experiments, which should have led to identical temperature distributions. If the reaction mechanism is thermal, the nature of the transformations should be independent of whether SF_6 or CF_2Cl_2 absorbs. It was shown experimentally that, when the laser is tuned to the SF_6 absorption, frequency the reaction does not occur (SF_6 is itself stable up to very high temperatures), whereas, on tuning the laser to the absorption frequency of CF_2Cl_2, the latter decomposes. The authors[70] conclude that the decomposition of Freon is due to its vibrational excitation and not to the temperature rise.

Although this conclusion is outwardly self-evident, detailed analysis has shown[43] that it is not unambiguous. In these experiments the absorption coefficients on which the calculation of the SF_6 and CF_2Cl_2 pressures necessary to equalise the absorptions was based were determined at room temperature with the aid of a low-power CO_2 laser. On passing to more powerful infrared radiation, where the gas is appreciably heated, the infrared absorption spectra change owing to the appearance of "hot" bands. Furthermore, it is easy to show[43] that the SF_6 absorption maximum undergoes a bathochromic shift under these conditions. This leads to a greater temperature rise in the mixture when the laser is tuned to 931 cm^{-1}, which is sufficient for the decomposition of Freon by a thermal mechanism. The results of the above study[70] as well as those of other investigations of chemical reactions under the influence of infrared radiation at high pressures have been analysed in detail[43] and it has been concluded that the evidence for a non-thermal mechanism of the laser-chemical reactions under these conditions is not sufficiently established.

As regards the differences in the composition of the products of laser-chemical reactions at high pressures, it has been shown[43] that they can be due to the exclusion of heterogeneous processes, because the reactor walls remain cold on laser heating. A number of studies involving the pyrolysis of ethane[44,45], formic acid[46], formaldehyde[47], methanol[48], and other compounds as well as the interaction of boron trichloride with acetylene[49], the bromination of pentafluorobenzene[50,67], and other reactions[51] have been devoted to the problem of the characteristic features of chemical reactions on laser heating[43-51]. Since not all substances absorb infrared radiation, they are frequently sensitised by compounds which absorb effectively the radiation of the CO_2 laser, mainly SF_6. In the majority of investigations it is emphasised that laser heating makes it possible to carry out reactions under rigorously homogeneous conditions. This permits the determination of the rate constants and activation energies for the reactions, which under the conditions of ordinary heating are complicated by heterogeneous side reactions[43,46-48,50].

The exclusion of heterogeneous processes in the laser heating of gases at high pressures is apparently one of the main factors responsible for the unusual products of the chemical reactions. (The formation of mercaptoboranes[74], the reactions of tetrafluorohydrazine[57,58,64], the alkylation of diborane[73], etc.) Thus analysis of the experimental data for gas-phase reactions at pressures of tens and hundreds of mmHg under the influence of continuous and quasi-continuous (with pulses lasting 10^{-3}–10^{-2} s) laser irradiation shows that under these conditions chemical reactions take place mainly via a thermal mechanism. Laser heating can then lead to an alteration of the mechanisms of complex chemical reactions owing to the exclusion of heterogeneous processes. This can be used both for preparative purposes and for the investigation of quantitative kinetic relations governing the homogeneous stages of complex chemical reactions.

In order to avoid the influence of thermal heating on the rate of chemical reactions in systems acted upon by the radiation of continuous infrared lasers, it is necessary to carry out the processes at low pressures[27,28]. This has been confirmed experimentally by a study[79] in which the influence of the radiation of a continuous CO_2 laser on the induction period in the chain decomposition of chlorine dioxide was studied. At pressures more than 1 mmHg the induction period was shortened, i.e. the reaction was accelerated, due to the equilibrium thermal heating as a result of the absorption of the infrared radiation. However, at pressures below 1 mmHg, the induction period for the decomposition of ClO_2 increased under the influence of the laser radiation, which was explained by the acceleration of the $ClO + ClO_2 \rightarrow Cl_2O_3$ elementary stage owing to the vibrational excitation of the ClO_2 molecule; this leads to an increase of the induction period.

Low pressures limit the range of reactions susceptible to such investigations. It is necessary that the reaction should occur at a sufficient rate at low pressures (below 1 mmHg). The activation energy for such a reaction must be fairly low. Among molecular reactions satisfying this requirement, mention may be made of the decomposition of limonene at low pressures[42] and the decomposition of H_3BPF_3 under the influence of the radiation of a continuous CO_2 laser[80,81]. When the latter reaction was carried out at pressures in the range 10^{-3}–10^{-2} mmHg, the authors were able to observe isotopic selectivity with respect to both hydrogen and boron.

III. REACTIONS OF VIBRATIONALLY EXCITED MOLECULES WITH ATOMS AND FREE RADICALS

Reactions with low activation energies are convenient for the investigation of infrared photochemistry for two reasons. Firstly, their high rates make it possible to carry them out at low pressures, which permits investigations under conditions uncomplicated by equilibrium thermal heating. Secondly, for low activation energies, comparable with the energies of the infrared quantum, it is possible to ensure conditions where only vibrationally excited molecules, formed in the primary radiation absorption step, are involved in the reaction and the role of higher vibrationally excited states, arising in $V-V$ relaxation processes, is insignificant. One can then expect a high process selectivity owing to the differences between the infrared absorption spectra of the excited molecules.

The most common processes with low activation energies are those of atoms and free radicals with molecules. One of the problems in the study of the influence of infrared radiation on these reactions is that of the role of vibrational energy in overcoming the activation barrier. Here it is necessary to distinguish two situations. At very low concentrations of the absorbing gas, where the $V-V$

relaxation is slower than that $V-T$ relaxation and the reaction, it is possible to obtain information about the reactivities of individual excited states. At higher concentrations (which are nevertheless sufficiently low to rule out equilibrium thermal heating), where equilibrium is established between all the vibrational degrees of freedom and one can postulate vibrational heating, one may investigate the influence of vibrational temperature on the reaction at a fixed translational temperature.

A promising practical application of these studies involves chemical reactions which are selective with respect to isotopes. The isotopic selectivity may be not only the aim of the investigation but can also serve as a test of the reactivity of the excited isotopic molecule. In view of the high rates of exchange of vibrational energy between the isotopic molecules, the concentrations over which such processes are possible will be fairly low.

One of the first studies which demonstrated experimentally the increase of reactivity under the conditions of laser infrared excitation was that of Brooks and coworkers[82]. They recorded an increase by two orders of magnitude of the cross-section of the K + HCl → KCl + H reaction in a molecular beam on excitation of HCl by the radiation of a chemical HCl laser. The study of the role of translational energy in this reaction showed[83] that the reaction cross-section increases only by a factor of five for a corresponding increase in translational energy.

The rate of reaction of a vibrationally excited HCl molecule ($v = 1$), generated by a chemical HCl laser, with hydrogen and oxygen atoms has been measured[84,85]. The infrared fluorescence of HCl ($v = 1$) was recorded and at the same time measurements were made of the concentrations of H and O atoms. The study of the simultaneous decrease of fluorescence intensity yields the sum of the rate constants for relaxation by atoms, namely $O + HCl (v = 1) \rightarrow O + HCl (v = 0)$, and for the reaction $O + HCl (v = 1) \rightarrow OH + Cl$, while the measurement of the decrease in the concentration of atoms makes it possible to determine the reaction rate constant. The overall rates of disappearance of vibrationally excited HCl molecules ($v = 1$) have been measured[84] and it has been shown that, following interaction with hydrogen atoms, the rate of the reaction $H + HCl (v = 1) \rightarrow H_2 + Cl$ is negligibly small compared with the rate of relaxation, whereas following interaction with oxygen atoms its contribution is appreciable. Detailed measurements have shown[85] that the rate of reaction of HCl ($v = 1$) with oxygen atoms is lower by a factor of 20 than the rate of relaxation and that the reaction rate constant is $(1.1 \pm 0.3) \times 10^{11}$ cm^3 mole^{-1} s^{-1}. This made it possible to calculate the ratio of the rate constants for the reaction of oxygen atoms with an HCl molecule in the first vibrationally excited and ground states, which amounts to 300 ± 100. It is noteworthy that in this instance the HCl excitation energy (8.2 kcal mole^{-1}) greatly exceeds the activation energy for the reaction with oxygen atoms (4.5 kcal mole^{-1}), so that the maximum expected increase of the rate constant for a vibrationally excited molecule (at 300 K) is by a factor $\exp(4500/RT) = 1.8 \times 10^4$. The measured increase of the rate constant (by a factor of 300) shows that in this reaction the vibrational energy is not fully utilised to overcome the activation barrier.

The measurement of the rate constants for the reactions of vibrationally excited species is greatly simplified if one of the reaction products is also an excited species. In this case it is possible to use the highly sensitive and rapid technique involving the recording of its luminescence. The reactions of vibrationally excited ozone molecules with NO and SO have been studied[86-93]. They lead to the formation of electronically excited NO_2 (in the $^2B_1$ and $^2B_2$ states) and SO_2 ($^1B_1$) molecules, the luminescence of which was recorded. The vibrational excitation of ozone was achieved by means of the radiation of a continuous CO_2 laser which was modulated by a chopper. The luminescence signal of the electronically excited reaction products was also found to be modulated. At the same time the decrease in signal intensity is determined by the sum of the rate constants for relaxation and the reaction and the degree of modulation is determined by the rate constant for the reaction of the vibrationally excited molecules. The rate constants for the reactions of the vibrationally excited ozone molecules with NO and SO measured under these conditions exceed the corresponding values for the non-excited ozone molecules by factors of 5.6 and 2.5. Such low factors can probably be accounted for by the markedly exothermic nature of these reactions. It is not clear whether the acceleration of the reactions should be attributed to the reactivity of the excited state of the ozone molecule (ν_3 antisymmetric stretching vibration) or to the redistribution of the absorbed energy over all the vibrational states of O_3 under the conditions of these experiments.

The reaction of O_3 with NO is of interest because the NO molecule can also be vibrationally excited ($v = 1$) by the radiation of the CO laser (1884 cm^{-1}). Such experiments[94] led to an increase of the reaction rate constant by a factor of 5.7 after the vibrational excitation of NO. In this case one may confidently speak of the reactivity of the NO molecule in the first vibrationally excited state.

An analogous method (with excitation by a CO_2 laser) has been used to investigate the reactions of vibrationally excited O_3 with oxygen in the $^1\Delta_g$ state[90] and also to investigate the reactions of atomic oxygen with vibrationally excited C_2H_4 and OCS molecules[95]. In the latter case both direct excitation of the molecules by the radiation of the CO_2 laser and excitation via sensitisers (molecules with high absorption coefficients for the laser radiation, in the present instance CH_3F and CH_2F_2) was achieved.

The use of the rapid luminescence technique for the recording of reaction rates is difficult in reactions leading to the formation of non-excited products. The study of the decrease of the infrared luminescence signal due to a vibrationally excited molecule yields the sum of the rates of reaction and relaxation. The determination of the reaction rate from these data involves considerable experimental difficulties and becomes impossible if the rate of relaxation is much higher than the rate of reaction (see, for example, Refs. 84 and 85). In endothermic reactions, where one may expect a considerable influence of the vibrational excitation, the products are usually non-excited. The most direct way of investigating such reactions involves the direct measurement of the relative increase in reaction rates under the influence of the radiation of continuous lasers. Mass spectrometry is a convenient method for the measurement of reaction rates. Low pressures in the reactor make it possible to connect it via a leak valve to the ion source and to record the change in the concentration of the initial substances and reaction products directly in the course of the process.

This method has been used to investigate the influence of the vibrational excitation of methane on its reaction with atomic chlorine[96]. The methane molecule was excited by the radiation of a continuous He–Ne laser at a wavelength of 3.39 μm, the corresponding frequency being the same as that of the antisymmetric stretching vibration of CH_4. The comparatively low power of the laser (up to 80 MW) nevertheless made it possible to obtain a concentration of the vibrationally excited molecules higher than the equilibrium value by a factor of several units at room temperature and by several orders of magnitude at 150 K. However, no increase was recorded in the reaction rate under the influence of infrared radiation, within the limits of experimental accuracy. Hence it was concluded that the vibrational energy is relatively ineffective in overcoming the activation barrier in this virtually thermally neutral reaction. The low isotope effect (~ 3% with respect to bromine) in the analogous CH_3Br chlorination reaction under the influence of the radiation of the CO_2 laser is probably associated with the same factor[97].

The above method has also been applied to the study of the endothermic reaction of bromine atoms with CH_3F.[98,99] The vibrational excitation was achieved by the radiation of a continuous CO_2 laser having a power up to 20 W. An increase in the reaction rate by a factor of several units at CH_3F pressures amounting to tenths and hundredths of mmHg was recorded in these experiments. Special experiments showed that under these conditions the increase in reaction rate is not associated with equilibrium thermal heating but is caused by the superequilibrium concentration of the vibrationally excited molecules generated by the laser radiation. The study of the dependence of the rate of reaction on the power of the laser emission has shown that at low CH_3F pressures it is linear, but, as the pressure rises, the rate increases more rapidly with increase in the power. Hence one may conclude that, under linear conditions, the lowest vibrationally excited states of the CH_3F molecule (with an energy of ~3 kcal mole^{-1}) are responsible for the increase of the reaction rate. An increase in pressure increases the role of higher vibrationally excited states formed when the species initially generated by the laser emission collide with one another; this leads to a more pronounced dependence of the reaction rate on the power. As the pressure in an equimolar mixture of $^{12}CH_3F$ and $^{13}CH_3F$ was reduced to values for which there is insufficient time to establish vibrational equilibrium between the excited and non-excited isotopic molecules (~10^{-2} mmHg), a doubling of the rate of formation of the reaction product containing the carbon isotope present in the CH_3F molecule excited by the laser emission was recorded[99].

The bromination of CH_3F is of interest also because, depending on the wavelength of the light causing the dissociation of the Br_2 molecule into atoms, the latter are formed in both ground (${}^2P_{3/2}$) and excited (${}^2P_{1/2}$) states with an excitation energy of ~10.5 kcal mole^{-1}. At low pressures the atoms in both states make comparable contributions to the reaction. It has been shown[100] that electronic excitation of the bromine atom reduces the activation energy for its reaction with CH_3F by the excitation energy, with a simultaneous decrease of the pre-exponential factor by 2.6 orders of magnitude. Photobromination of CH_3F under the influence of ultraviolet light at different wavelengths and study of the influence of infrared radiation on the reaction showed that the vibrational energy is effectively utilised in the endothermic reaction of the bromine atom in its ground state and has no influence whatever on the virtually thermally neutral reaction of the electronically excited bromine atom[101].

It is noteworthy that the low efficiency of the utilisation of the vibrational energy in overcoming the activation barrier in exothermic and thermally neutral reactions is consistent with data on the formation of vibrationally excited species in exothermic reactions. Such processes underlie the operation of chemical lasers and are the converse of those discussed in the present section.

Reactions involving the formation of vibrationally excited species with energies greater than the heats of reaction are at present virtually unknown[102]. It follows from the principle of detailed balancing that in the reverse processes the vibrational energy plays a significant role in overcoming only the endothermic part of the activation barrier, while the remaining energy must be translational or rotational. Theoretical calculations of the rate constants for model interactions of atoms with diatomic molecules[103] also showed that vibrational energy should play a significant role in endothermic reactions and a much smaller role in thermally neutral reactions and, particularly, exothermic reactions, where the barrier must be overcome mainly by translational energy. Analysis of the available experimental data for the reactivity of vibrationally excited molecules[104,105] shows that in the vast majority of instances vibrational energy is not fully utilised in overcoming the activation barrier. The attempts to relate the fraction of the vibrational energy effectively employed in overcoming the activation barrier of the reaction to the size of the barrier, the heat of reaction, or the size of the vibrational quantum[104] have not as yet established any empirical relations. It appears that the number of reliable experimental rate constants for the elementary reactions of vibrationally excited molecules is still insufficient. The most reliable of the available experimental data, obtained by infrared laser photochemical methods, are presented in Table 1.

Table 1. Reactions of vibrationally excited molecules with atoms and free radicals.

Reaction	ΔH, kcal mole^{-1}	E, kcal mole^{-1}	hν, kcal mole^{-1}	$\left(\frac{k^*}{k}\right)_{calc}$	$\left(\frac{k^*}{k}\right)_{expt}$	Refs.
$HCl^*(v=1)+O \rightarrow OH + Cl$	0.8	4.5	8.2	$1.8\cdot10^4$	300	85

$CH_3F^*(\nu_{3,6}) + Br(^2P_{3/2}) \rightarrow HBr + CH_2F$	12.0	14.6	3.0	56 (373 K)	30	98
$CH_3F^*(\nu_{3,6}) + Br(^2P_{1/2}) \rightarrow HBr + CH_2F$	1.5	4.5	3.0	56 (373 K)	1	101

Note. $(k^*/k)_{calc} = \exp(h\nu/RT)$ for $h\nu < E$ and $\exp(E/RT)$ for $h\nu > E$, ΔH is the heat of reaction, and E and $h\nu$ are respectively the activation and excitation energies.

A number of studies on the effect of infrared laser emission on the reactions of atoms with molecules were undertaken specially to achieve chemical reactions selective with respect to isotopes. One of the first attempts to achieve such a process was undertaken by Mayer et al.[106] A mixture of CH_3OH, CD_3OD, and Br_2 at 70 mmHg was exposed to the emission of a continuous HF laser with a power of 90 W, which is selectively absorbed by the CH_3OH molecule, while CD_3OD does not absorb such emission. After irradiation for 1 min, 90% of CH_3OH was converted into CH_2O, while CD_3OD hardly reacted under these conditions. The rate-limiting step of the process is the reaction of the bromine atom with CH_3OH, the activation energy for which is 6.2 kcal mole^{-1}. Since the energy of the quantum of the HF laser (10.4 kcal mole^{-1}) exceeds the above value, the authors concluded that they observed the reaction of a vibrationally excited CH_3OH molecule with a bromine atom, which thus proceeds without activation energy, in contrast to the non-excited CD_3OD molecule. This leads to a high isotopic selectivity of the given reaction. However, the above conclusion is doubtful, because at the high pressures employed (i.e. for high rates of $V-T$ relaxation) it is difficult to expect appreciable deviations of the populations of the vibrationally excited molecules from the equilibrium values and the results may be accounted for by a kinetic isotope effect. Special experiments on the chlorination of a mixture of CH_4 and CD_4 by the emission of a continuous CO_2 laser, carried out at the same pressures as in the study of Mayer et al.[106], showed[107] that mainly CH_4 molecules are involved in the reaction, although the laser emission is absorbed by the CD_4 molecule. Detailed measurements of the quantum yield of the reaction in a methanol–bromine mixture under the influence of infrared radiation[108] also failed to confirm the conclusions of Mayer et al.[106]

More evident successes in carrying out an isotopically selective reaction were achieved by Arnoldi et al.[109] and Leone et al.[110] By exciting an $H^{35}Cl$ molecule to the second vibrational level using the emission of a pulsed chemical HCl laser[109] and a parametric oscillator[110], it was possible to carry out a $Br + H^{35}Cl \rightarrow HBr + {}^{35}Cl$ reaction selective with respect to chlorine isotopes. However, rapid secondary radical processes precluded an isotopic enrichment of the final reaction product.

The chlorination of CH_3Br [97] (selectivity with respect to bromine isotopes) and the bromination of CH_3F [99] (selectivity with respect to carbon isotopes) are examples of processes in which isotope enrichment was achieved in the final products under the influence of the emission of a continuous CO_2 laser.

IV. SELECTIVE DISSOCIATION OF POLYATOMIC MOLECULES UNDER THE INFLUENCE OF PULSED INFRARED RADIATION

The selective dissociation of molecules (as well as other reactions with high activation energies), requiring the absorption of many infrared photons, initially appeared to be virtually impossible to achieve. Indeed when the infrared laser emission is absorbed, the products are molecules with a low degree of excitation which are incapable of absorbing radiation at the same frequency owing to vibrational anharmonicity. Higher vibrationally excited states may arise on collision of the initially excited molecules with one another, i.e. in a $V-V$ relaxation process. At high emission intensities this can lead to specific reactions, but the selectivity attainable in the primary absorption step must be lost in the course of the $V-V$ processes.

Letokhov and Ambartsumyan observed that the above difficulties may be overcome by employing a powerful pulsed infrared emission. This discovery greatly extended the likely applications of infrared lasers both in carrying out isotopically selective chemical reactions and in the development of vibrational photochemistry.

The first evidence for the possibility of multiphoton absorption was obtained in studies[111,112] where luminescence was observed in the visible and infrared regions of the spectrum, due to the rapid dissociation of NH_3, SiF_4, and CCl_2F_2 molecules under the influence of the focussed emission of a powerful pulsing CO_2 laser. Later analogous results were obtained also in studies of the dissociation of other compounds[113-116]. The study of the luminescence kinetics showed[117-119] that two stages are observed: a rapid stage arising immediately after the pulse of the infrared radiation and a slow stage due to collisions. It has been shown[120-122] that, when many compounds are irradiated by powerful pulses from a CO_2 laser, not only dissociation but also ionisation takes place.

Ambartsumyan et al.[118] showed for the first time that dissociation in the field of the emission from a powerful pulsed CO_2 laser is isotopically selective. The luminescence due to the ^{10}BO and ^{11}BO radicals, formed as a result of the irradiation of BCl_3 having the natural isotope composition in an oxygen atmosphere, was recorded, the enrichment coefficient in the BO intermediate reaching 10 under these conditions. Soon the above method led to isotope enrichment of the final products of the dissociation of SF_6,[123,124] BCl_3,[125] OsO_4,[126] and CCl_4.[127] Subsequently such experiments on the isotopically selective dissociation of polyatomic molecules were reproduced in many laboratories for the same and a number of new systems [128-134] and many experimental and theoretical studies, devoted to the detailed investigation of the mechanism of this phenomenon, were published[135-169].

The fundamental feature of these investigations was the elucidation of the problem of compensating the vibrational anharmonicity, which must lead to the breakdown of the conditions for the resonance absorption of infrared radiation after the absorption of the first quantum. The initial explanations reduced to the Stark broadening of the frequencies of vibrational transitions in the strong field of the infrared radiation[118-124]. However, calculations showed[169] that this requires a much higher radiation intensity than those for which selective dissociation is observed. Next the hypothesis was put forward that compensation of the anharmonicity is required only for a few of the lowest vibrational transitions (3–4 for molecules such as those of SF_6, BCl_3, etc.), where the vibrational spectrum has a discrete structure, while in higher vibrational transitions the density of the levels increases so much that they form a quasi-continuum[138,141]. Experiments on two-frequency dissociation[138-141], in which molecules were excited by resonance infrared radiation to a few of the initial levels and dissociation was achieved by means of non-resonance infrared radiation absorbed in the quasi-continuum, confirmed this view. According to the proposed hypothesis[138,141], the vibrational anharmonicity in the lowest transitions is compensated as a result of rotational energy; the first, second, and third quanta of infrared radiation are resonance-absorbed by one of the rotational lines of the P-, Q-, and R-branches of the vibrational transition respectively. The dependence of the probability of dissociation on the frequency of the resonance infrared radiation is consistent with this hypothesis.

However, only some of the molecules in specific rotational states are involved in vibrational energy accumulation processes when this mechanism operates. On the other hand, measurements of the number of molecules dissociating under the influence of infrared radiation have shown that in the region of the focus of the light beam virtually all the molecules are dissociated by a single pulse. For this reason, in the latest studies on this problem the anharmonic splitting of overtones[147], the removal of the degeneracy of the vibrational levels in symmetrical molecules[154,164], and forced transitions between various rotational levels[153] were additionally invoked to account for the compensation of the vibrational anharmonicity in the lowest transitions.

One of the causes of the loss of selectivity (for fairly large isotopic shifts) is $V-V$ relaxation processes, so that a high selectivity in multiphoton dissociation is achieved only at low pressures (below 1 mmHg). Another cause may be secondary radical reactions, lowering the selectivity of the primary dissociation step. For example, it has been shown that the formation of active species such as fluorine atoms in the primary dissociation step may lead to a decrease of selectivity[170,171]. For this reason, the study of the chemical mechanism of the primary dissociation step is of great interest.

The discovery of multiphoton absorption of intense infrared radiation "without collisions" leads to new interesting possibilities in the study of the unimolecular decomposition of molecules with a large excess of energy. Among these, mention should be made in the first place of the possibility of observing non-statistical unimolecular decomposition of vibrationally excited species and decomposition in states whose energy greatly exceeds the dissociation threshold. Bimolecular reactions involving such highly excited molecules may also be of great interest. At the present time the number of studies published on the mechanisms of reactions of highly vibrationally excited molecules is much smaller than the number of studies on isotopically selective dissociation. Among these, mention should be made of the decomposition of alkyl halides [172], the reactions of methyl halides with halogens[173,174], and the *cis-trans* isomerisation of $C_2H_2Cl_2$ [175] and deuterohexadienes[176]. The dissociation due to vibrational excitation proceeds by no means in all cases via fundamentally new chemical reaction pathways. Thus it has been shown[177] that, when pulsed infrared radiation acts on mixtures of SF_6 with hydrocarbons, the latter react with the fluorine atoms formed on dissociation of SF_6. The chemical reactions of molecules which do not absorb the infrared laser emission are of great interest. In this case the reaction may be achieved as a result of the transfer of vibrational energy from molecules which effectively absorb the infrared emission. An examples of such a process may be the decomposition of 1,2-dihydroxytetramethylethane into two acetone molecules as a result of the transfer of vibrational energy from a CH_3F molecule, excited by the emission of a pulsed CO_2 laser, to a molecule of 1,2-dihydroxytetramethylethane[178].

The processes examined may also be of preparative interest. The synthesis of $BHCl_2$ from BCl_3 and H_2 was achieved[179] on irradiating a mixture of the latter two substances by the pulses of a CO_2 laser. It has been stated[180] that it is likely to be useful to dissociate small amounts of impurities in order to achieve a high degree of purification of the main substance; arsenic trichloride was freed in this way from 1,2-dichloroethane and carbon tetrachloride.

The vast majority of processes considered in this section have been achieved with the aid of the emission from a CO_2 laser. This is the most powerful, economical, and simplest gas laser to operate. It can operate on different lines in the range 9.4–10.6 μm (the use of isotopic modifications of CO_2 such as $^{13}CO_2$ or $^{12}C^{18}O^{16}O$ extends this range to 8.5–10.6 μm). However, not all the molecules which are of theoretical or practical interest have absorption lines in this region. Diatomic homonuclear molecules such as H_2, N_2, O_2, and others cannot be vibrationally excited by infrared radiation at all. The phenomenon of stimulated Raman scattering (SRS) may be used to excite such molecules. When a pulse of laser emission in the ultraviolet, visible, or near infrared range is passed through a cuvette with a gas at a high pressure, then a Stokes component, the energy of the quantum of which is lower than the energy of the initial quantum by the energy of the vibrational quantum of the substance in the cuvette, appears at the exit together with the transmitted emission. The interaction of these two types of emission, having different frequencies, with the same substance in the following cuvette leads to its vibrational excitation.

The idea of using SRS for isotope separation has been suggested[181]. This process was achieved experimentally in the formation of NO by the reaction of N_2 or O_2.[182] The vibrational excitation of N_2 was achieved with the aid of SRS in liquid nitrogen. The absorption coefficient with respect to nitrogen-15 reached 10^2 under these conditions. The same result was also obtained in the excitation of a mixture of N_2 and O_2 in a pulsed electric discharge[183]. The authors[182] explained it by the establishment of different vibrational temperatures of $^{14}N_2$ and $^{15}N_2$ under the conditions of the experiment described. However, in analogous experiments in a discharge tube an enrichment of 21% with respect to nitrogen-15 was attained[184]. In order to resolve this discrepancy, additional studies are necessary.

At the same time, using SRS it is possible to achieve the vibrational excitation of molecules which do not absorb infared radiation. This technique permits an alteration of the laser frequency and its displacement to the regions where sufficiently powerful infrared lasers are not available. Hydrogen-based SRS has been used to dissociate SF_6 in the region of the $\nu_4 + \nu_5$ combination band[185], which made it possible to increase the process selectivity.

V. RELAXATION AND VIBRATIONAL ENERGY TRANSFER PROCESSES

The main processes competing with the reactions of vibrationally excited molecules are the $V-T$ and $V-R$ relaxation processes leading to the loss of vibrational energy and the $V-V$ relaxation processes leading to its redistribution between different molecules and between vibrational degrees of freedom within the same molecule. In most cases the vibrationally excited species react more slowly than they relax, so that the rate of the relaxation processes must be compared with the rate of generation of vibrationally excited species (proportional to the intensity of the infrared radiation and the absorption coefficient) in order to determine the conditions under which a non-equilibrium population of the corresponding excited state is possible. Before lasers became available, the main sources of information about the relaxation of vibrational excitation were experiments in shock tubes and by acoustic methods as well as kinetic spectroscopy. When infrared laser became available, the above possibilities were greatly extended. The problems of the relaxation of vibrational excitation have been described in a number of review articles and monographs[186-190].

The method of infrared luminescence induced by the laser emission, first used to measure the vibrational relaxation of CO_2,[191] and the double resonance method employed for the measurement of the rates of transfer of vibrational energy in SF_6,[192] BCl_3,[193] and CH_3F [194-196] are most widely employed to investigate the relaxation and vibrational energy transfer processes. The first method involves the observation of the time dependence of the luminescence originating from different vibrational levels and arising after the excitation of the molecule by an infrared pulse. In order to record the spectral dependence of the luminescence, different infrared detectors, cooled to low temperatures, are used. The luminescence originating from different vibrational states is isolated by means of combinations of interference filters. In addition, the filters protect the infrared detector from scattered laser emission, the intensity of which greatly exceeds the luminescence intensity. The recorded signal is usually weak, but the high frequency of the pulses from modern infrared lasers (mainly the CO_2 laser and optical parametric oscillators) makes it possible to use signal accumulation techniques in order to improve the signal to noise ratio.

The double resonance method involves the observation of the changes in the infrared absorption at a fixed frequency when the molecule is excited by an infrared pulse at another frequency. The possibility of using long absorption cells (in contrast to the infrared luminescence method) and hence of reducing the pressure of the gas investigated makes this procedure preferable in the study of rapid processes such as the resonance transfer of vibrational energy between isotopic molecules.

The rates of relaxation processes in a large number of molecules have been investigated in detail with the aid of the above methods. The rate constant for the $V-T$ and $V-V$ relaxation processes for SF_6, BCl_3, HCl, O_3, and CH_3F molecules, the laser-induced chemical reactions of which have been studied in greatest detail, are presented in Table 2. Analysis of the available experimental data shows that the $V-T$ relaxation involving the molecules takes place comparatively slowly and usually requires 10^2-10^5 collisions. The rate-limiting stage of the $V-T$ relaxation is the deactivation of the lowest vibrationally

Table 2. The relaxation and vibrational energy transfer processes for molecules whose reactions under the influence of infrared radiation have been investigated in greatest detail (k is the rate constant and n the number of collisions).

excited state. Hence it follows that the simplest type of non-equilibrium in vibrational excitation may be a "discrepancy" between the vibrational and translational temperatures. This discrepancy may arise at low pressures under the conditions of continuous irradiation or at higher pressures under the conditions of pulsed irradiation. It is noteworthy that the rate of relaxation of the vibrational energy is determined by the deactivation of the lowest vibrational level only under the conditions of comparatively weak optical pumping. *V*–*T* relaxation processes involving higher vibrational levels, the rates of which is higher than that of relaxation involving the lowest level, play an appreciable role at high concentrations of vibrationally excited molecules[209].

The *V*–*V* relaxation processes are much faster, usually requiring between 10 and 100 collisions. For this reason it is much more difficult to achieve the vibrational "heating" of a specified degree of freedom, particularly since intramolecular vibrational energy transfer processes, occurring over periods shorter than the period between collisions, are possible in complex molecules[210]. The transfer of vibrational energy between isotopic molecules, involving virtually a resonance mechanism, is even faster than the collision processes involved in *V*–*V* relaxation. Less than ten collisions are required for this purpose[192–196].

Whereas the *V*–*T* relaxation of vibrationally excited molecules by inert gas molecules and atoms is comparatively slow, the rate of the *V*–*T* relaxation by free atoms is much higher and approaches the rate of the *V*–*V* processes. A large number of direct experimental measurements of the rate constants for these processes have been made in recent years; some of these have been examined in reviews[105,189,211]. The results of some of the latest measurements of the rate constants for the above processes are presented in Table 2. Comparison of the rate constants for the *V*–*T* relaxation of vibrationally excited molecules by inert gas molecules and atoms with the constants for relaxation by chemically active atoms showed that the rates of the latter are greater by 2–3 orders of magnitude. This implies that in real reacting systems, where the relative concentrations of atoms may exceed 10^{-3}–10^{-2} (for example, in flash photolysis or in processes occurring in an electric discharge), the relaxation of vibrationally excited molecules at such species must be taken into account.

VI. REACTIONS OF VIBRATIONALLY EXCITED MOLECULES IN THE CONDENSED PHASE AND ON THE SURFACES

Whereas in the gas phase superequilibrium concentrations of vibrationally excited molecules may be obtained at low temperatures even under the influence of the emission of continuous infrared lasers of comparatively low power (watts per cm^2), on passing to a condensed phase this requires a much greater radiation density—megawatts and gigawatts per cm^2.[31,212] Such radiation densities are attainable only in pulsed lasers. Furthermore, when energy with such a high density is incident on a given substance, considerable heating, leading to its evaporation, is inevitable. For example, it has been shown[213] that the interaction of the radiation from a pulsed CO_2 laser (energy per pulse 1 J, duration of pulse 80 ns) with water and chloroform leads to the formation of a shock wave as a result of the rapid evaporation of the liquid and the increase of pressure over the surface. Such interactions of infrared radiation with a given substance are undoubtedly of chemical interest. An apparatus has been described[214] for the synthesis of organometallic compounds by the interaction between the metals evaporated by the laser beam and the vapours of organic compounds. However, the discussion of processes beginning with a change in the phase state of the relevant substance under the influence of infrared radiation is outside the scope of the present review.

In view of the experimental difficulties mentioned above, the number of studies on the infrared photochemistry of the condensed phase is much smaller than the number of corresponding studies in the gas phase. The effect of the emission of a CO_2 laser on adenosine triphosphate and ammonium pyrophosphate, prepared in the form of potassium bromide discs, has been studied[215]. It was established that, after exposure to the pulsed radiation (with pulses lasting 100 ns), molecular structure are produced with an increased angle between the P–O–P bonds, while quasi-continuous irradiation (with pulses lasting 0.1–1 s) causes the same changes as thermal heating. A displacement of the complex-formation equilibrium under the influence of the pulsed radiation of a CO_2 laser incident on the interface between aqueous and organic uranyl nitrate solutions has been observed[216,217].

The above reactions are most likely to be due to the purely thermal effect of the laser emission, since the *V*–*T* relaxation times under these conditions should be short. Experiments at low temperatures, where the rates of the relaxation processes may be greatly reduced, are therefore more promising. For example, a study of the infrared fluorescence of the CO molecule in solid argon and neon matrices at 10–30 K established that, after the excitation of the $^{12}C^{16}O$ molecule to its lowest excited vibrational level by the second harmonic of the radiation from a pulsed CO_2 laser, signals appear due to the fluorescence of $^{12}C^{16}O$, $^{13}C^{16}O$, and $^{12}C^{18}O$ molecules in vibrational states up to $v = 8$.[218] The times during which the corresponding signals increase, determined by the rate of the *V*–*V* relaxation of CO, amounted to tens and hundreds of microseconds in these experiments (depending on the degree of dilution of CO by argon or neon), while the times during which the signal intensities decrease, determined by the rate of the *V*–*T* relaxation of the vibrationally excited CO molecules at Ar and Ne species and the emission of radiation, amounted to 15–20 ms. The comparatively low rates of relaxation in low-temperature matrices suggest that the effect of infrared laser emissions on such systems may exhibit a high isotopic and stereochemical selectivity. The behaviour of iron tetracarbonyl $Fe(CO)_4$, isolated in a methane matrix at 20 K, has been investigated[219]. $Fe(CO)_4$ was obtained by the ultraviolet irradiation of the matrix containing $Fe(CO)_5$. Heating to 35 K led to the regeneration of the pentacarbonyl; black body infrared emission (Nernst glower) induced the reaction $Fe(CO)_4 + CH_4 \rightarrow [Fe(CO)_4.CH_4]$, which does not occur when the matrix is heated. The influence of the radiation from a continuous CO laser (power 400–650 mW, intensity <1 W cm^{-2}) on $Fe(CO)_4$ enriched in carbon-13 (34%) initiated the same reaction but, depending on the radiation frequency, only isomers with a specific number and distribution of ^{13}CO groups reacted.

Isotopically selective dissociation of SF_6 in a low-temperature matrix under the influence of the pulsed radiation of a CO_2 laser has been observed[220]. Isotopically-selective evaporation of BCl_3, on irradiation by a continuous CO_2 laser of a film obtained by freezing boron trichloride at 77 K on a solid support, has been reported[221].

The study of the role of vibrational excitation in heterogeneous-catalytic reactions is of great interest. Such processes may be investigated at gas pressures which are sufficiently low to enable the vibrationally excited molecules generated by the laser emission in the bulk phase to reach the surface without losing vibrational energy by collisions. The influence of the vibrational excitation of N_2O molecules, due to the radiation from a continuous electric-discharge N_2O laser (with a power up to 90 mW) in the reaction $N_2O + Cu \rightarrow N_2 + CuO$ at pressures of approximately 1 mmHg, has been investigated[222] and it has been established that the probability of the reaction increases as a result of vibrational excitation by a factor of 5×10^3 (from 2.9×10^{-11} to 1.5×10^{-7}). This cannot be explained solely in terms of the reactivity of the vibrationally excited state of the N_2O (001) molecule with an energy of approximately 3 kcal mole^{-1}. An increase of reaction probability by a factor greater than $\exp(h\nu/RT)$, which does not exceed 60 at the experimental temperature (363 K), is impossible under these conditions. It appears that under the given experimental conditions higher vibrationally excited states are also populated, i.e. N_2O undergoes vibrational "heating" to a temperature greatly exceeding the translational temperature. Analogous studies were made in another investigation[223], where the stimulation of the heterogeneous ammonia decomposition reaction on the surface of platinum by the radiation from a CO_2 laser was observed.

Adsorption processes involving vibrationally excited molecules generated by continuous infrared radiation have been investigated in a number of studies[224-226]. The recorded isotope effects in the adsorption of BCl_3 and when the latter is filtered through finely dispersed sodium chloride exceed the equilibrium isotope effects.

Table 3. Characteristics of the infrared lasers used in photochemical research (studies on relaxation are not included).

Type of laser	Range of generation, cm^{-1}	Energy of quantum, kcal mole^{-1}	Power, W	Energy of pulse, J	Duration of pulse, s	Number of published studies
CO_2 *	900—1100	2.6—3.1	to 650	—	—	70
CO_2	900—1100	2.6—3.1	—	to 10	$3 \cdot 10^{-8}$—$1 \cdot 10^{-6}$	66
CO *	1500—2000	4.3—5.7	3,0	—	—	2
N_2O *	900—970	2.6—2.8	0,09	—	—	1
HF *	3500—3800	9.5—11.0	90	—	—	1
HCl	2500—2900	7.2—8.6	—	0.01	10^{-6}—10^{-5}	3
Neodymium	9400	27.0	—	to 10	10^{-3}	1
Neodymium + H_2SRS	1100—1200	3.2—3.5	—	0.5	$2 \cdot 10^{-8}$	1
Ruby + N_2 SRS	2330	6.7	—	0.8—1.4	$3 \cdot 10^{-8}$	1
Parametric $LiNbO_3$ oscillator	2800—18 300	8.2—52.9	—	10^{-5}	10^{-7}	1

---

* Continuous operating conditions; pulsed conditions were employed in the remaining instances.

In conclusion we may note that the scope for the formulation and interpretation of laser-chemical studies in the condensed phase is significantly restricted by the scarcity of experimental data for vibrational relaxation under these conditions.

VII. CONCLUSION

Numerous experimental studies published in recent years are evidence for the vigorous development of infrared laser photochemistry. A characteristic feature of the initial stage of the development of this research field was a distinctly applied bias of many of the investigations, associated with the prospect of developing new isotope separation methods. The considerable possibilities of infrared lasers in carrying out selective chemical processes were demonstrated and the difficulties and unsolved problems arising in this connection were described. The proportion of studies directed to the solution of fundamental chemical kinetic problems has begun to increase in recent years: the characteristics of reactions under non-equilibrium conditions, the influence of various forms of energy on reactivity, the competition between the reaction and relaxation, and others.

The development of infrared photochemistry will undoubtedly depend on the progress in laser engineering. Analysis of published studies (Table 3) shows that most of them have been carried out with the aid of pulsed and continuous CO_2 lasers. The lack of commercial infrared lasers operating in other frequency ranges restricts the range of systems susceptible to experimental photochemical investigation. This restriction arises not only because the spectra of many molecules lack absorption lines falling within the range of CO_2 lasers but also because of the small energy of the emitted quanta of such lasers, which hinders the competition between the radiation-induced and thermal processes involving the generation of vibrationally excited molecules. Another factor which narrows the range of systems suitable for experimental study is the difficulty of a smooth adjustment of the infrared frequency of lasers. However, these difficulties are not insurmountable, since tunable lasers, covering virtually the entire infrared range (at least in the pulsed version), already exist in physics laboratories. One may hope that the use of this new laser technique will promote the successful development of infrared photochemistry.

Long-range Tunnelling Electron Transfer in Chemical Reactions

K.I.Zamaraev and R.F.Khairutdinov

We have generalised recent experimental and theoretical results on a process which is uncommon in classical chemistry: long-range tunnelling electron transfer. These reactions play an important role in various areas of chemistry and biochemistry, and they offer new pathways for controlling the direction of chemical change. 94 references.

I. INTRODUCTION

It has long been thought self-evident that bimolecular reactions can occur only when the interacting molecules are in direct contact, i.e. when the approach distance is equal to the sum of the gas-kinetic or crystallographic radii. However several reactions between particles separated by much larger distances (up to many tens of Ångstroms) have recently been discovered. The reacting species are separated either by molecules of the medium (condensed phase) or by a vacuum (gas phase).

These are the so-called tunnelling (or sub-barrier) long-range electron transfer reactions. During these reactions an electron passes (tunnels) through the energy barrier separating the reactants, which can be much higher than the intrinsic energy of the electron (several electron-volts). These transitions contravene the rules of classical mechanics, but they are permitted in quantum mechanics.

The quantum-mechanical tunnelling of particles through potential barriers was first postulated in physics to explain the ionisation of atoms in a strong electric field[1], the cold emission of electrons from metals[2], and the α-decomposition of atomic nuclei[3,4]. A simple formula was obtained[3] for the transition probability w per unit time of a particle of energy E below a potential barrier of height $U(x)$:

$$w = \nu_0 \exp\left(-\frac{2}{\hbar}\int_0^r |p|\,\mathrm{d}x\right). \tag{1}$$

In this formula ν_0 is the collision frequency of the particle with the potential barrier, $p = \{2m[U(x) - E]\}^{1/2}$, m is the mass of the particle, and $\hbar$ is Planck's constant. Eqn. (1) can be written more simply

$$w = \nu_0 \exp(-2r/a), \tag{2}$$

where $a = \gamma\hbar/[2m(U_{\max} - E)]^{1/2}$, $U_{\max}$ is the maximum value of $U(x)$ (the barrier height), $\gamma \simeq 1$ is a numerical coefficient depending on the shape of the barrier, and the distance r corresponds to the width of the barrier (see Fig. 1). It is evident from formula (2) that the probability of the tunnelling transition decreases exponentially as the mass of the particle increases. Hence the most effective tunnelling transitions can be expected in reactions involving the lightest of all chemical particles: the electron.

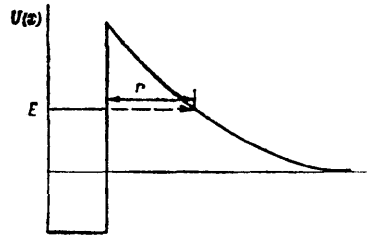

Figure 1. Tunnelling electron transfer through an energy barrier.

There have been many attempts to estimate the maximum distance through which an electron can tunnel in chemical reactions[5,6] (see also Ref. 7). All these calculations were based on formula (2), assuming a frequency ν_0 equal to the characteristic frequency of the motion of electrons in atoms ($\nu_0 \simeq 10^{15}-10^{16}$ s^{-1}), and a barrier height $U_{\max}$ equal to the ionisation potential of the donor particle. These estimates are too approximate to confirm or deny with any reliability the hypothesis of long-range tunnelling transitions of electrons in chemical reactions. Their most serious shortcoming is that formula (2) was obtained for processes in which the particles can tunnel into a region of space possessing a continuous spectrum of energies: strictly speaking, this formula is not applicable to chemical reactions, in which the electron is transferred between states with discrete energy levels. Hence the concept of long-range electron transfer in chemical reactions did not gain wide acceptance until direct experimental evidence of the reality of this process became available.

The most convincing evidence of long-range electron tunnelling was obtained in studies of the low-temperature oxidation and reduction of solids. Typical of these processes are the reactions of trapped electrons (e_{tr}^-) with various acceptors (organic or inorganic molecules, ions, ion-radicals, and transition metal complexes). The rates of many of these reactions were found to be temperature-independent and much higher than the rate of diffusion-limited collisions between reactants.

Examples of long-range electron transfer reactions in the liquid phase include the reaction of hydrated electrons (e_{aq}^-) with various inorganic anions (CrO_4^{2-}, MnO_4^-, etc.) in dilute solutions. The effect of the electrostatic repulsion between like charges on the rate of these reactions is abnormally low, suggesting a large separation between the charges at the moment of reaction.

Typical gas-phase reactions involving a long-range electron transfer step are the reactions between alkali metal atoms and halogen molecules, for example

$$K + I_2 \rightarrow K^+ + I_2^- \rightarrow KI + I.$$

Measurements by the molecular beam method have shown that the interaction radii for these reactions can exceed the gas-kinetic radii by a factor of two.

II. HISTORICAL ACCOUNT OF THE DISCOVERY AND STUDY OF LONG-RANGE TUNNELLING ELECTRON TRANSFER REACTIONS

The reactions of alkali metal atoms with halogen molecules in the gas phase are the first reported example of chemical reactions at long range. Reaction cross-sections somewhat greater than the gas-kinetic cross-sections were observed in a study[8] of diffusion flames published in 1932. The correctness of this observation was confirmed by later, more precise measurements by the molecular beam method[9-11] carried out in the 1950's and 1960's. The following mechanism was proposed[12]: initially the reactants approach to within a distance such that the difference between the ionisation potential I_M of the metal atom and the electron affinity A_{X_2} of the halogen molecule is equal to the energy of the interacting unit charges, i.e.

$$I_M - A_{X_2} = e^2/r_c. \tag{3}$$

At this instant the electron passes under the barrier from M to X_2. Immediately after the electron transfer the long-range Coulombic forces between M^+ and X_2^- begin to operate, making the particles approach each other until the ordinary chemical forces can break the X–X bond and form an M–X bond.

Table 1. Interaction radii r_e, distances r_c,[10] and sums of gas-kinetic radii of the reactants $r_M + r_{I_2}$ for the reactions between alkali metals and iodine (Na* is an excited sodium atom).

M	r_e, Å	r_c, Å	$r_M + r_{I_2}$, Å
K	6.3	5.26	4.2
Pb	7.3	5.63	4.4
Cs	7.6	6.43	4.6
Na	7.9	4.07	3.8
Na *	8.2	—	3.8

The interaction radii r_e calculated from the measured cross-sections for a series of reactions are compared in Table 1 with the distances r_c calculated by formula (3) and with the sums of the gas-kinetic radii of the reactants $r_M + r_{X_2}$. It can be seen that both r_e and r_c are greater than $r_M + r_{X_2}$, i.e. the electron transfer step occurs at distances beyond the range of chemical (exchange) forces.

The next important step was the discovery[13-16] of anomalously large rate constants for the diffusion-controlled reactions of hydrated electrons with various inorganic anions in aqueous solutions. Table 2 lists the highest observed rate constants (k_e) for reactions between e_{aq}^- and inorganic anions and cations, and also the theoretical diffusion-limited rate constants (k_D) for the same reactions, calculated by the Debye formula[17] from the known radii and diffusion coefficients of the reactants[16]

$$k_D = 0{,}004\pi ND\sigma\,(z_A e^2/\varepsilon kT\sigma)\,[\exp(z_A e^2/\varepsilon kT\sigma) - 1]^{-1}. \tag{4}$$

Table 2. Maximum reported values of the rate constants k_e and of the diffusion constants k_D for the reactions of e_{aq}^- with anions and cations[16] (en is ethylenediamine, EDTA is the ethylenediaminetetra-acetate ion).

Acceptor	$10^{10}k_e$, litre mole^{-1} s^{-1}	$10^{10}k_D$, litre mole^{-1} s^{-1}
$Co(NO_2)_6^{3-}$	3.2—5.8*	0.27
$Co(C_2O_4)_3^{3-}$	1.3	0.27
$Co(CN)_5Cl^{3-}$	1.8*	0.19
$Cr(C_2O_4)_3^{3-}$	1.8*	0.25
$Cr(EDTA)^-$	2.6*	1.2

*Experimental value; the k_e values for all the other acceptors in the Table are extrapolated to zero ionic strength in the solution.

In this formula $z_A e$ is the charge on the acceptor, $D = D_A + D_e$ refers to the diffusion coefficients of the acceptor and of e_{aq}^-, σ is the distance between the reactants at the instant of electron transfer, $\epsilon = 81$ is the dielectric constant of water, N is Avogadro's number, k is Boltzmann's constant, and T is the temperature. In the calculation of k_D it was assumed that electron transfer occurs by direct collision between the reactants i.e. that $\sigma = r_A + r_e$ where r_A and r_e are the radii of the reactants. It is clear from Table 2 that the largest values of k_e for the reactions of e_{aq}^- with anions are similar to the k_e values for the reactions of e_{aq}^- with cations, and much greater than the k_D constants calculated by formula (4). The relative insensitivity to electrostatic repulsion effects of the rate of the reaction of e_{aq}^- with anions was taken as evidence that fast reactions of this type take place at distances in excess of the sum of the radii of the reactants.

Nevertheless the experimental evidence for long-range electron transfer in liquids and gases was too limited for a wide recognition of the importance of long-range interactions in chemistry. In view of the complexity of the molecular beam method, the observed difference between the interaction radii and the sum of the gas-kinetic radii ($r_M + r_{X_2}$) did not seem unduly large for the gas-phase reactions examined. In the reactions of e_{aq}^- with anions a weak electrostatic repulsion effect on the rate of the association of charged particles with their counter-ions could not be totally excluded.

Decisive proof of the existence of long-range tunnelling electron transfer processes was obtained only recently, from studies of oxidation–reduction reactions in solid matrices at low temperatures, i.e. under conditions where the diffusion of reactants and their mutual approach to within short distances can be rigorously excluded. Under these conditions long-range tunnelling electron transfer becomes the only possible mechanism for the reaction, and it can be observed and investigated unambiguously.

In 1965 it was found[18] that the trapped electrons (e_{tr}^-) formed by the γ-radiolysis of 2-methyltetrahydrofuran (2-MTHF) disappear slowly at 77 K. The decay of the e_{tr}^- species was ascribed[19] to a tunnelling reaction with hole centres, and a tunnel mechanism was proposed[20] for the disappearance of e_{tr}^- in an aqueous alkali glass containing additives. The Gamow formula (2) has been used[19,21] to calculate the distances to which electrons can tunnel in low-temperature radiation-chemical reactions (several tens of Ångstroms).

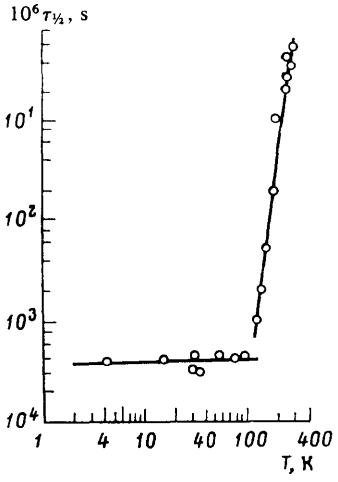

Figure 2. Characteristic time $\tau_{1/2}$ against temperature for the transfer of an electron from the reduced form of cytochrome *c* to the oxidised form of chlorophyll in *Chromatium D* bacteria.

However none of these results[18-20] definitely excluded the possibility of a diffusional mechanism for the disappearance of e_{tr}^-, or of a reaction with acceptors in direct contact with the trapped charge. Furthermore the use of Gamow's formula raises some objections (as was pointed out above). Nevertheless the work[19-21] stimulated further research in this area.

The first definitive formulation of the importance of tunnelling processes appeared in a paper by Chance and DeVault[22], who studied the temperature dependence of the characteristic time $\tau_{1/2}$ for the transfer of electrons from the reduced form of cytochrome *c* to the oxidised form of chlorophyll in *Chromatium D* bacteria over a wide range of temperature (300–4.2 K). They found a normal Arrhenius dependence at the higher temperatures ($T > 130$ K), but at $T < 130$ K $\tau_{1/2}$ was independent of temperature (see Fig. 2). Hence a diffusion-limited mechanism could be rigorously excluded, at least at $T < 130$ K. A detailed theoretical analysis of the electron transfer process in this system is given in a later paper[23]. However, as before, direct contact between the active centres of cytochrome *c* and those of chlorophyll in the bacteria at the instant of reaction could not be entirely excluded.

A tunnel mechanism for the electron transfer process was proposed also to explain[24-26] the temperature-independent luminescence produced by electron–hole recombination in γ-irradiated alkali halide crystals. The model[27,28] proposed to explain similar effects assumes that the recombination of donor–acceptor pairs in semiconductors also takes place by a tunnel mechanism. However the distance to which the electron is transferred in real systems was, again, unknown.

The first direct experimental demonstration[29] of a reaction between donors and acceptors a large distance apart was the reaction between e_{tr}^- and the anion-radical O^-. Both particles are formed, in equal yield, by the low-temperature radiolysis of frozen aqueous alkaline solutions, and they can be monitored through their characteristic optical (e_{tr}^-) and ESR (e_{tr}^- and O^-) spectra. It was possible to show from the width of the ESR spectral line that the distance between the reacting particles could not be less than 20 Å for most of the reacting pairs[30]. Also, the e_{tr}^- and O^- species were found to decay at the same rate even at very low temperatures. The kinetic curves for different temperatures are indistinguishable within experimental error over a wide range of time (five orders of magnitude), and they are linearised in an unusual set of coordinates (concentration against logarithm of time, see Fig. 3). A diffusion-limited mechanism for this process is excluded by the coincidence of the kinetic curves for different temperatures, and the distance between the reactants confirms the reality of the long-range electron transfer process. The unusual type of kinetic equation was simply explained by the distribution of distances $e_{tr}^- \ldots O^-$ between the reacting pairs (see below).

Temperature-independent kinetics (at T = 77.66 and 4.2 K) were reported shortly afterwards[31] for the luminescence quenching process involving the recombination of e_{tr}^- with a biphenyl cation in a methylcyclohexane glass.

A detailed analysis[32] of the effect of added acceptors on the yield of ionic radiolysis products (e_{tr}^- and anion-radicals) revealed satisfactory agreement with the tunnelling electron transfer mechanism for the formation and disappearance of these particles. In particular it was found that the disappearance of e_{tr}^- in 2-MTHF doped with naphthalene (Nh) is accompanied by the formation of the Nh^- anion-radical in corresponding amounts (by the reaction $e_{tr}^- + Nh \rightarrow Nh^-$). The kinetic curves for this reaction at 77 and 87 K were indistinguishable.

Because of the logarithmic time-dependence of the concentration of reactants quantitative kinetic studies of tunnelling electron transfer reactions in solid matrices must extend over very long periods. For example, the reaction between e_{tr}^- and O^- had to be monitored over 5 orders of magnitude of time (see Fig. 3). Hence the development of pulsed techniques for measuring the kinetics of low-temperature reactions between active intermediates in radiolysis over many orders of magnitude, including very short times (from 10^{-6} to 10^2 s), has played a very important role in subsequent studies of tunnelling electron transfer reactions[32]. Pulsed apparatus has been used to measure the kinetics of the reaction of e^-_{tr} with many different acceptors[32,33]. By combining measurements made in this apparatus with more traditional measurements over long periods the kinetics of the reaction

$$e^-_{tr} + Cu\,(en)_2^{2+} \rightarrow Cu\,(en)_2^{+} \qquad (5)$$

(where en is ethylenediamine) have been studied quantitatively over time intervals between 10^{-6} and 10^6 s.[34,58]

The next important stage in the study of long-range electron transfer reactions was the development of special kinetic equations[35-47], including equations for paired[35,39,46], random[37-39], and arbitrary[35,36,46] distributions of reactants in the absence of diffusion, and also in the presence of diffusion for a random[40-42,44] or an arbitrary[43,45,47] distribution of reactants. It was shown that these equations give an accurate description of the observed kinetics of tunnelling reactions over the whole range of reaction times[58]. As an example we show in Fig. 4 the experimental (points) and the theoretical (lines) kinetic curves for the reaction between e^-_{tr} and $Cu(en)_2^{2+}$ at different concentration of $Cu(en)_2^{2+}$. This agreement between theory and experiment provides an important confirmation of the tunnel mechanism of the reaction.

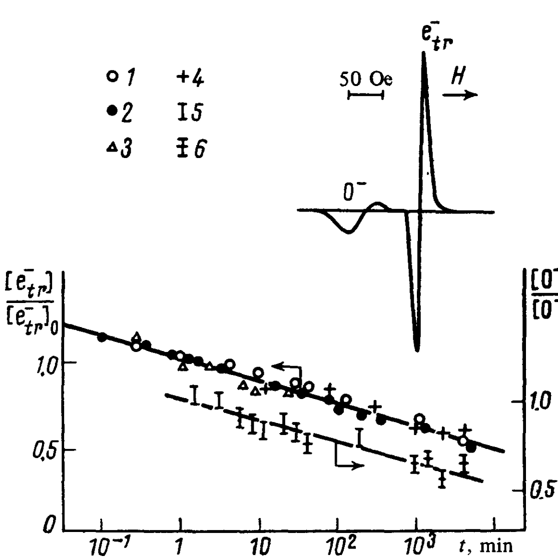

Figure 3. ESR spectra and decay curves for e^-_{tr} and O^- in 10 *M* aqueous NaOH; $[e^-_{tr}]_0$ and $[O^-]_0$ are the concentrations at $t_0 = 1$ min; *1*), *2*), *3*), and *5*) β-radiolysis, *4*) and *6*) γ-radiolysis; *D* values *1*) 3×10^{19}, *2*) 3.6×10^{20}, *3*)–*6*) 1.2×10^{20} eV cm^{-3}; *1*), *2*), *5*), *6*) 77 K, *3*) 120 K, *4*) samples stored at 4.2 K but irradiated and measured at 77 K.

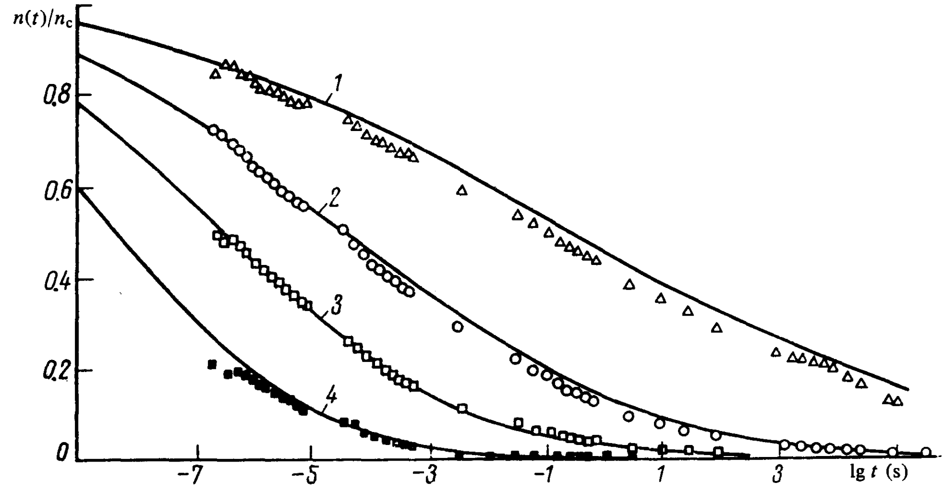

Figure 4. Kinetic curves for the reaction between e^-_{tr} and $Cu(en)_2^{2+}$ in 10 *M* aqueous NaOH solution at 77 K for different concentrations of $Cu(en)_2^{2+}$: *1*) 0.005, *2*) 0.01, *3*) 0.05, *4*) 0.1 *M*. The points are experimental, the curves are theoretical calculations by Eqn. (26) with the values $\nu = 10^{15.2}$ s^{-1} and $a = 1.83$ Å.

As long as long-range electron transfer had been observed only in the low-temperature reactions of e^-_{tr} there remained a doubt that the mechanism could be specific for this particle only, and that an alternative explanation could be delocalisation of e^-_{tr} (as in the case of polarons) over a large number of centres in solid matrices. Therefore the discovery of charge transfer over large distances in the low-temperature reactions of ordinary chemical species (inorganic anion-radicals and transition metal compounds) was the next important step[48,49]:

$$O^- + Fe(CN)_6^{4-} \rightarrow O^{2-} + Fe(CN)_6^{3-}, \qquad (6)$$

$$SO_4^- + FeSO_4 \rightarrow SO_4^{2-} + FeSO_4^+, \qquad (7a)$$

$$SO_4^- + AgNO_3 \rightarrow SO_4^{2-} + AgNO_3^+. \qquad (7b)$$

The list of reactions of this type grew rapidly, and it now includes electron transfer processes from inorganic anion-radicals to organic molecules[50,51], from electronically excited molecules to various acceptors[52-54], between compounds of metals of variable valency[49,55], and from F-centres to hole centres in crystals[56] (see also Refs. 24-26).

The logical extension of this work was a quantitative analysis of the accumulated kinetic data[57,58] and a detailed theoretical discussion of the mechanism of the elementary act of the long-range tunnelling electron transfer process in solids[23,58-60].

Thus significant progress has been made in the study of long-range tunnelling electron transfer reactions. In this review we shall examine the theory of these processes, and we shall analyse existing kinetic data uniquely from the standpoint of this theory.

III. MODELS OF THE ELEMENTARY ACT OF LONG-RANGE ELECTRON TRANSFER

The simplest model used to describe long-range electron transfer reactions involves the tunnelling of an electron from a potential well through an energy barrier $U(x)$ (see Fig. 1). This model leads to formulae (1) and (2) for the variation of the transition probability per unit time with distance. According to this model the frequency ν_0 in Eqn. (2) is the characteristic frequency of the motion of electrons in atoms, i.e. $\nu_0 \simeq 10^{16}$ s^{-1}. The model also assumes that the parameters ν_0 and a are fully determined by the initial state of the system, i.e. the properties of the electron donor and those of the medium, and are independent of the final state, i.e. the properties of the electron acceptor. However both these predictions of the model were found to be incompatible with experimental results, since both ν_0 and a in practice depend on the nature of both the donor and the acceptor. For example, ν_0 can vary from 10^6 to 10^{21} s^{-1} for different reactions[58] (see Tables 3 and 4. But in spite of these shortcomings of the model formula (2) in general gives a correct qualitative description of the variation of w with r.

More exact models of tunnelling electron transfer between particles A^- and B in a solid,

$$A^- + B \rightarrow A + B^- \qquad (8)$$

have been proposed[23,58-60]. The qualitative difference between these models and the previous model is the inclusion of the interaction (important in principle) between electronic and nuclear degrees of freedom in the molecules of the reactants and of the medium. As a result of this interaction the transition probability is substantially influenced by the motion of the nuclei of the reacting molecules and of the intervening molecules of the medium. Energy conservation is preserved by the transformation of the energy set free by the electron transfer into vibrational energy of the nuclei.

The newer models[23,58-60] differ in the type of nuclear motion assumed. Some workers[23,59,60] use the harmonic approximation to the vibration of the nuclei, whereas we have allowed for strong anharmonicity of the nuclear motion[58]. The model proposed in Ref. 58 gives a fuller physical description of long-range tunnelling electron transfer, and is fully consistent with all available experimental data. The transition probability of an electron per unit time is expressed as

$$w = \sum_i \sum_f p_i w_{if}\,. \qquad (9)$$

The summation is taken over all the initial (i) and the final (f) states of the nuclear motion. In this expression p_i is the probability of an initial state i of energy E_i:

$$p_i = e^{-E_i/kT} / \sum_i e^{-E_i/kT}, \qquad (10)$$

and w_{if} is the probability of a transition from the initial state i to the final state f. The variation of w_{if} with distance is given, as before, by the simple exponential function

$$w_{if} = \nu_{if} \exp(-2r/a_{if}). \qquad (11)$$

This dependence arises, as in the case of the simplest model of tunnelling, from the exponential damping of the electronic wave functions in a classically inaccessible region of space. The ν_{if} values for different i or f in formula (11) should be different, in general. The a_{if} values are identical for all states of nuclear motion corresponding to the same electronic energy level, and they can vary only as a result of a change in electronic state. Hence in transfer processes not involving excited states Eqn. (9) simplifies to a form identical to Eqn. (2), i.e.

$$w = \nu \exp(-2r/a), \qquad (12)$$

where $\nu = \sum\limits_i \sum\limits_f p_i \nu_{if}$.

However the parameters a_{if} and ν_{if} have a physical significance entirely different from that of the parameters a and ν_0 used in the simplest model. The parameter a is the half-sum of the Bohr radii of the electron in the initial (a_{A^-}) and the final (a_{B^-}) state in a medium of dielectric constant ϵ:

$$a = \frac{1}{2}(a_{A^-} + a_{B^-}), \qquad (13)$$

which can also be written

$$a = \frac{1}{2}\varepsilon^{1/2}(a^0_{A^-} + a^0_{B^-}), \qquad (14)$$

where $a^0_{A^-}$ and $a^0_{B^-}$ are the Bohr radii of the centres A^- and B^- in a vacuum. The subscripts i and f have been omitted in Eqns. (13) and (14). It can be seen from Eqn. (14) that the parameter a is symmetrically dependent on the properties of both the initial and the final state of the system, and also on the properties of the medium.

The parameter ν is a complex combination of the characteristics of electronic and nuclear motions in the system, and cannot be interpreted simply as the collision frequency of the electron with the potential barrier. According to our calculations ν can be vanishingly small under unfavourable conditions, and under favourable conditions it can exceed the characteristic frequency of the motion of electrons in atoms and be as high as 10^{22} s^{-1}.[58]

We note from Eqn. (9) that at low temperatures (when only the lowest initial state i is populated) the rate of an exothermic electron transfer reaction is independent of temperature:

$$w = \sum_f w_{0f}. \tag{15}$$

However at higher temperatures w can depend on T: depending on the relative probabilities of electron transfer from the ground state and from an excited state, w can either increase or decrease with increase of T.[58,61] The quantity

$$\tau = [w(r)]^{-1} = \nu^{-1}\exp(2r/a) \tag{16}$$

is the characteristic time for the tunnelling of the electron to a distance r. Eqn. (16) leads to the following expression for the average distance R_t to which the electron can tunnel in time τ:

$$R_t = (a/2)\ln \nu\tau. \tag{17}$$

Because of the exponential dependence of w on r the transition probability of the electron in time τ is almost unity for $r < R_t$ and close to zero for $r > R_t$.

IV. FORMAL KINETICS OF TUNNELLING ELECTRON TRANSFER REACTIONS

According to formula (12) the probability of a tunnelling transition for the electron decreases rapidly as the distance r between the reacting particles increases. In a typical situation (condensed medium) there is a distribution of the distance r between the reactants, leading to an unusual type of overall reaction kinetics: the variation of concentration $n(t)$ with time t is described by complex functions having $\lg t$ as their argument (see below). The specific form of these functions depends on the spatial distribution of the reactants and on the relative rates of tunnelling transitions and of diffusion.

A fruitful approach in the development of kinetic equations for tunnelling reactions was the use of equations for the normal concentrations of donors $n(r,t)$ and acceptors $N(r,t)$: the concentrations of donors $n_i(r,t)$ and acceptors $N_i(r,t)$ at a distance r from an arbitrarily chosen (i-th) acceptor (or donor) particle averaged at time t over the ensemble of particles of the opposite kind[62,63]:

$$n(r,t) = \sum_{i=1}^{N(t)} n_i(r,t), \tag{18}$$

$$N(r,t) = \sum_{i=1}^{n(t)} N_i(r,t). \tag{19}$$

In these expressions $n(t)$ and $N(t)$ are the volume average concentrations of donors and acceptors. The nominal and the volume average concentrations are related by the expressions[62]

$$n(t) = \lim_{r\to\infty} n(r,t), \tag{20a}$$

$$N(t) = \lim_{r\to\infty} N(r,t), \tag{20b}$$

$$n(t)\cdot N(r,t) = N(t)\cdot n(r,t), \tag{21}$$

$$n(0) - n(t) = N(0) - N(t), \tag{22}$$

where $n(0)$ and $N(0)$ are the average concentrations of donors and acceptors at zero time.

By assuming that each donor can react with an arbitrary acceptor, and that diffusional approach between the reactants can take place in parallel with the direct tunnelling transition, we arrive at the following equation for the nominal and the average concentrations as a function of time[45]

$$\frac{\partial}{\partial t}n(r,t) = -\left[w(r) + \int_0^\infty w(\rho)4\pi\rho^2 N(\rho,t)\,\mathrm{d}\rho\right]n(r,t) + \frac{D}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial n(r,t)}{\partial r}\right), \tag{23a}$$

$$\frac{\partial}{\partial t}N(r,t) = -\left[w(r) + \int_0^\infty w(\rho)4\pi\rho^2 n(\rho,t)\,\mathrm{d}\rho\right]N(r,t) + \frac{D}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial N(r,t)}{\partial r}\right), \tag{23b}$$

$$\frac{\mathrm{d}}{\mathrm{d}t}n(t) = -\int_0^\infty w(\rho)4\pi\rho^2 N(\rho,t)\,\mathrm{d}\rho\, n(t), \tag{24a}$$

$$\frac{\mathrm{d}}{\mathrm{d}t}N(t) = -\int_0^\infty w(\rho)4\pi\rho^2 n(\rho,t)\,\mathrm{d}\rho\, N(t). \tag{24b}$$

The general analytic solution of the system (23)–(24) is very cumbersome[45], but a much simpler solution is obtained by ignoring the diffusional mechanism:

$$\frac{n(t)}{n(0)} = \frac{1 - N(0)/n(0)}{1 - [N(0)/n(0)]\exp\left\{[1 - n(0)/N(0)]\int_0^t\int_0^\infty w(\rho)\exp[-w(\rho)t]\,N(\rho,0)\,4\pi\rho^2\,\mathrm{d}\rho\,\mathrm{d}t\right\}}. \tag{25}$$

For the most important case (in practice) of a random distribution of reactants, when $N(r,0) = N(0)$, we obtain from (12) and (25)

$$n(t)/n(0) = \exp[-(\pi a^3/6)N(0)\ln^3 \nu t] \tag{26}$$

in the case of $N(0) \gg n(0)$, and

$$n(t)/n(0) = [1 + n(0)(\pi a^3/6)\ln^3 \nu t]^{-1} \tag{27}$$

in the case of $N(0) = n(0)$.

The physical significance of Eqns. (26) and (27) is clear. The quantity $R_t = (a/2)\ln \nu t$ is the average distance to which the electron can tunnel in time t (see above). Hence the quantity $\exp[-(\pi a^3/6)N(0)\ln^3 \nu t] \equiv \exp[-(4\pi/3)N(0)R_t^3]$ in the right-hand side of Eqn. (26) is the probability of finding a donor particle outside the effective reaction volume $V_t = (4/3)\pi R_t^3$ surrounding an arbitrary acceptor particle, i.e. the probability that the particle will not disappear as a result of a tunnelling reaction at time t.

Eqn. (27) can be rewritten

$$1/n(t) - 1/n(0) = (4/3)\pi R_t^3. \tag{28}$$

This equation expresses the fact that the increase in time t of the mean volume associated with a single donor particle, $\Delta V = [n(t)]^{-1} - [n(0)]^{-1}$, is $(4/3)\pi R_t^3$.

Most experiments on the kinetics of tunnelling reactions have been made in glassy solutions, in which the spatial distribution of reactants was approximately random and the concentration of one of the reactants was usually much greater than that of the other. The results agree well with Eqn. (26), as shown by the experimental and the calculated kinetic curves for reaction (5) which are compared in Fig. 4. The calculated curves were obtained by Eqn. (26), the parameters a and ν being chosen so as to optimise the agreement between calculation and experiment. It is clear from Fig. 4 that the kinetics of reaction (5) can be described quantitatively over a wider range of time (12 orders of magnitude) and at concentrations $N(0) = 0.1$–0.01 M $\mathrm{Cu(en)}_2^{2+}$ by selecting only two parameters. This means that Eqn. (26) correctly describes the quantitative dependence of the concentration $n(t)$ both on time t and on the concentration of the other reactant $N(0)$. The optimum values of the parameters ($a_{\text{opt}} = 1.83$ Å and $\nu_{\text{opt}} = 10^{15\cdot 2}$ s^{-1}) are entirely reasonable in the light of other theoretical considerations.

Another practically important case is that of a paired distribution of reactants. Kinetic equations for tunnelling reactions between isolated donor–acceptor pairs cannot be obtained from Eqns. (23) and (24) because the concept of a nominal concentration is meaningless for isolated pairs. Kinetic equations for the tunnelling recombination of isolated pairs were obtained[29] by assuming a rectangular distribution of the pairs with respect to distance r, and also by assuming an arbitrary distribution[35].

If the distribution of the pairs in distance is described by the function $f(r)$ the change with time of the number $dn(t)$ of pairs separated by a distance between r and $r + dr$ is given by

$$\frac{\delta}{\delta t}[dn(t)] = -w(r) \cdot dn(t). \tag{29}$$

Integrating Eqn. (29) with respect to time and using the initial condition $dn(0) = n(0)\cdot f(r)\cdot dr$ (where $n(0)$ is the total number of pairs at $t = 0$) we obtain

$$dn(t) = n(0)\exp[-w(r)t] \cdot f(r) \cdot dr. \tag{30}$$

Integration of Eqn. (30) with respect to r gives an expression for the time-change of the number of donor–acceptor pairs $n(t)$:

$$n(t)/n(0) = \int_0^\infty \exp[-w(r)t] \cdot f(r) \cdot dr. \tag{31}$$

For a rectangular distribution of the pair separations we have

$$f(r) = \begin{cases} (r_{\max} - r_{\min})^{-1} & \text{for} \quad r_{\min} \leqslant r \leqslant r_{\max}, \\ 0 & \text{for} \quad r > r_{\max}; \ r < r_{\min}. \end{cases} \tag{32}$$

Under the conditions $\ln \nu t \gg 1$ and $r_{\max} \gg R_t \gg r_{\min}$ we obtain from Eqns. (32) and (31)

$$n(t)/n(0) = [r_{\max} - (a/2)\ln(\nu t)]/(r_{\max} - r_{\min}). \tag{33}$$

Like Eqns. (26) and (27), Eqn. (33) has a clear physical meaning. It expresses the fact that for a rectangular distribution in r the fraction of the particles which do not undergo recombination at time t is $(r_{\max} - R_t)/(r_{\max} - r_{\min})$.

As shown in Fig. 3, Eqn. (33) accurately describes the kinetics of the recombination of the e_{tr}^- and O^- particles formed in equal yield during the radiolysis of aqueous alkaline glasses.

1. Effect of an Electric Field on the Kinetics of Tunnelling Recombination

Formula (12) applies for an isotropic configuration of the function $w(r)$. However $w(r)$ can become anisotropic in the presence of an electric field: the energy barrier opposing electron transfer is raised in the direction of the field and lowered in the opposite direction. Under these conditions the parameter a in Eqn. (12) is smaller for transfer in the direction of the field than in the opposite direction. In principle the parameter ν also can be altered by the shift in the energy levels of the initial and the final state produced by the application of the field. However, in practice, we only need to be concerned with the effect of the field on the parameter a. The following formula for the transition probability in a constant electric field E has been proposed[46] to replace Eqn. (12) when the parameter a is asymmetric:

$$w(r) = \nu \exp[(2r/a_0) - (r^2 eE\cos\theta)/(2a_0V_0)], \tag{34}$$

where a_0 is the value of a in the absence of the field, e is the electronic charge, θ is the angle between the direction of electron transfer and that of the field, and V_0 is a parameter which characterises the binding energy of the electron to the centres A and B. In the derivation of Eqn. (34) it is assumed that the change in the interaction energy of the electron with the electric field produced by the transfer from the donor to the acceptor is small in comparison with V_0.

By inserting Eqn. (34) into (25) or (31) we obtain kinetic equations for tunnelling reactions in the presence of a field. In this way expressions were obtained[46] for the change with time of the luminescence intensity produced by the tunnelling recombination of donors and acceptors in paired

$$I(t) = A\{f[(a_0/2)\ln(\nu t)]/4\ln b\} \cdot (1/x\tau) \cdot \ln[(1 + bx)/(1 + x/b)] \tag{35}$$

or in unpaired arbitrary distributions

$$I(t) = AN[(a_0/2) \cdot \ln(\nu t), 0] \cdot (\pi a_0^3/2x\tau) \cdot [\ln^2(\nu\tau)/2\ln b] \times \\ \times \ln[(1 + bx)/(1 + x/b)] \cdot [n(t)/n(0)] \cdot [N(t)/N(0)]. \tag{36}$$

In these expressions (which apply for $t > \tau$) the parameter τ is the time between the beginning of the tunnelling reaction and the application of the electric field, $f(r)$ is the initial distribution function of the distance between particles in a pair, $N(r, 0)$ is the initial arbitrary concentration of acceptors, $x = (t - \tau)/\tau$, and

$$b = \exp[(a_0Ee/8V_0)\ln^2(\nu t)].$$

It can be seen from Eqns. (35) and (36) that the kinetics of luminescence quenching by the application of a field are entirely determined by the spatial distribution of the reactants and by the parameter b, which can be evaluated from the discontinuous change in luminescence intensity at the instant when the field is applied[46].

Eqn. (35) has been used[46] to analyse results[64] on the influence of a field on the quenching kinetics of the luminescence due to the paired tunnelling recombination of e_{tr}^- with its counter-ion (the cation of tetramethyl-p-phenylenediamine) in glassy 3-methylpentane. The distribution function of the electron to counter-ion distances found in this way.

2. Kinetic Equations for Tunnelling Reactions in the Presence of Diffusion of Reactants

Diffusion can influence the kinetics of these reactions because it affects the spatial distribution of the reactants.

A general solution of the system of equations (23)–(24) has been obtained[45]. In the practically important case of a random distribution of reactants and $N(0) \gg n(0)$ the solution has a simple form for the two limiting cases of $t \gg \tau_D$ and $t \ll \tau_D$ (where $\tau_D = a^2/D$ is the time for the diffusion of the reactants to a distance of the order of a). For $t \ll \tau_D$ (slow diffusion) the kinetics of the tunnelling reactions are described by Eqn. (26), and for $t \gg \tau_D$ (fast diffusion) by the equation

$$n(t)/n(0) = \exp\left[-\frac{4}{3}\pi R^3N(0) - 4\pi RDN(0)t\right], \tag{37}$$

where $R = \frac{1}{2}a\ln(\nu\tau_D)$ is the tunnelling distance in time τ_D.

As can be seen from Eqn. (37) the disappearance of the donors in this situation is described by the ordinary kinetic law for first-order reactions (the second term in the exponential). The two terms in the exponential of Eqn. (37) correspond to two possible mechanisms for the disappearance of reactants at time t. Thus, for a donor and an acceptor particle at a distance $r < R$ we have $[w(r)]^{-1} < \tau_D$, and electron transfer is the faster process, whereas for $r > R$ we have $[w(r)]^{-1} > \tau_D$, and the diffusional approach of the reactants is faster than the direct tunnelling mechanism. Hence donors and acceptors separated by a distance $r < R$ disappear by direct tunnelling transfer [described by the term $4/3\pi R^3N(0)$ in the kinetic equation (37)], and particles for which $r > R$ approach each other to a distance R and then react by the tunnelling mechanism [term $4\pi RDtN(0)$]. Thus the distance $R = \frac{1}{2}a \ln(\nu\tau_D)$ plays the role of a collision diameter in tunnelling reactions involving diffusion of the reactants.

We note from Eqn. (37) that, as predicted[57], the effective initial concentration of donors $n_{\text{eff}}(0) = n(0)\cdot\exp[-4/3\pi R^3N(0)]$, formally determined by extrapolating $\ln[n(t)]$ to $t = 0$, is lower than the real concentration by the number of donors which are initially within a sphere of radius R surrounding the acceptors, and which disappear by diffusionless direct tunnelling within a time τ_D from the beginning of the reaction. The activated nature of diffusion in condensed media is responsible for the monotonic increase of R with decrease of temperature.

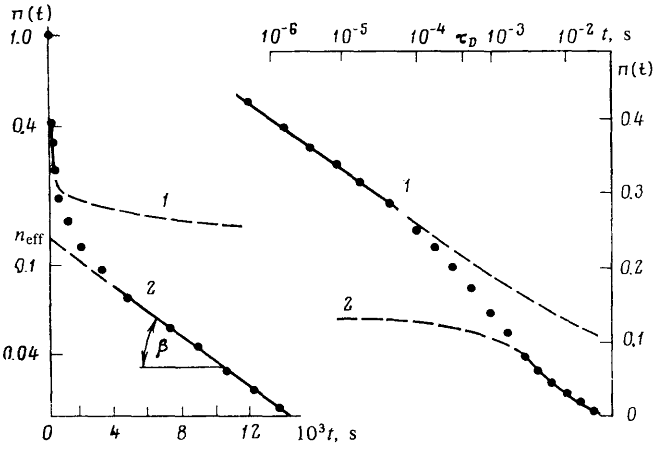

Figure 5. Kinetic curve for the reaction between e_{tr}^- and CrO_4^{2-} (2.5×10^{-2} *M*) in a 6 *M* aqueous solution of NaOH at 178 K. The points are experimental, the lines are theoretical curves calculated by Eqn. (26) (curve *1*) and Eqn. (37) (curve *2*) for $R = 31$ Å, $D = 2.2 \times 10^{-12}$ cm² s⁻¹ ($\tan\beta = 4\pi RDN$).

Miller[33] studied the kinetics of several reactions between e_{tr}^- and acceptors in an aqueous alkaline glass at relatively high temperatures under conditions such that $N(0) \gg n(0)$. By extending his measurements over a wide range of time (from 10^{-6} to 1 s) he was able to observe a change in kinetic law corresponding qualitatively to the transition from a tunnelling ($t \ll \tau_D$) to a diffusion mechanism ($t \gg \tau_D$).

We shall show that these results are described quantitatively by Eqns. (26) and (37). The experimental results[33] are compared in Fig. 5 with calculations by formulae (26) and (37). It can be seen that the initial portion of the kinetic curve is accurately described by formula (26) (curve *1*), whereas the final portion agrees with formula (37) (curve *2*). The numerical values of the diffusion coefficient ($D = 2.2 \times 10^{-12}$ cm² s⁻¹) and of the tunnelling distance ($R = 31$ Å) corresponding to curve *2* were obtained by linearising the final portion of the experimental kinetic curve in coordinates of $\ln[n(t)/n(0)]$ against t (Fig. 5). It can be seen from Fig. 5 that the value $\tau_D = a^2/D \simeq 4 \times 10^{-4}$ s corresponds to the transition from the kinetic regime described by Eqn. (26) to that described by Eqn. (37).

In principle the spatial distribution of reactants can alter not only as a result of thermal diffusion but also as a result of tunnelling diffusion through vacancies such as ionised donor particles or empty electron traps (in the case of e_{tr}^-). Kinetic equations for tunnelling reactions under conditions of tunnelling diffusion of electrons have been obtained by Khairutdinov[43], who showed that for short observation times $t \ll J^{-1}$ (where J is the probability of electron transfer by tunnelling diffusion from a donor to a vacancy in unit time), and when the concentration of acceptors in vacancies is much greater than the concentration of donors, the kinetics of the tunnelling reaction are described by Eqn. (26). In the opposite case ($t \gg J^{-1}$) the kinetics are described by an expression analogous to Eqn. (37) in which the quantity $D = \frac{1}{3}R^2/J^{-1}$ plays the role of a diffusion coefficient and R is the distance at which the probability of direct tunnelling recombination between the donor and the acceptor is comparable to the probability of a tunnelling diffusion jump.

An important consequence of that work[43] was the realisation that the kinetic equations for the direct tunnelling transfer of an electron from a donor to an acceptor and for the transfer of an electron by a series of tunnelling jumps into randomly distributed vacancies are quite different. This allows the two mechanisms to be distinguished. For example, the good agreement over a wide range of time between the experimental kinetic curves and those calculated by Eqn. (26) for the reaction of e_{tr}^- with $Cu(en)_2^{2+}$ suggests that this reaction involves direct electron tunnelling rather than the tunnelling diffusion of electrons along traps.

We have reviewed the kinetic equations for tunnelling reactions which can be used directly to analyse existing experimental data. Among the work which has not been discussed we should note a derivation[43] of the kinetic equations for tunnelling reactions under conditions of light-induced electron diffusion and an attempt[40,47,65] to allow for the effect of electrostatic interactions on the tunnelling recombination of charged particles in the presence of diffusion.

V. METHODS OF CALCULATING THE KINETIC CHARACTERISTICS OF TUNNELLING REACTIONS FROM EXPERIMENTAL DATA

The fundamental kinetic characteristics of tunnelling reaction are the parameters a and ν of Eqn. (12) for the probability of tunnelling in unit time. If a and ν are known we can calculate the probability $w(r)$ and the characteristic time $\tau(r) = w^{-1}$ for the tunnelling transfer of an electron to various distances, or the distance R_t to which the electron will tunnel in various times.

The parameters ν and a can be obtained from kinetic data on tunnelling reactions in solids only if the spatial distribution of the reactants is known. This requirement is met by reactions in glassy solutions under conditions such that one of the reactants (say, the acceptor A) was introduced before freezing the solution at a concentration much greater than that of the other reactant (the donor D). By preparing the samples in this way a random distribution of A particles in space can often be achieved[34,66]. It can be seen from Eqn. (26) that under these conditions the spatial distribution of the donors has no effect on the kinetics of the tunnelling reaction.

Kinetic curves are usually obtained by measuring the time dependence of the intensity $I(t)$ of lines in the optical or ESR spectra of the reactant present at lower concentration. The corresponding decrease in the intensity of the spectrum of the second reactant[29] or increase in the intensity of the spectrum of the reaction product[51] can also be monitored. From these measurements we obtain the ratio

$$n(t)/n(t_0) = I(t)/I(t_0),$$

where $n(t)$ is the time-dependent concentration of reactant, and $n(t_0)$ and $I(t_0)$ are the concentration of reactant and the spectral intensity at the beginning of the measurement. However the concentration term in Eqn. (26) is not $n(t_0)$ but $n(0)$, i.e. the concentration at time $t = 0$. Since the concentrations of reactants vary by an approximately logarithmic law in tunnelling reactions, $n(t_0)$ and $n(0)$ can be very different even for very short values of t_0. Direct measurement of $n(0)$ is impossible, and therefore $n(0)$ is usually replaced by the concentration n_c in control samples not containing the second reactant but otherwise identical in every respect with the experimental samples:

$$n(t)/n(0) = n(t)/n_c = I(t)/I_c; \tag{38}$$

where I_c is the spectral intensity of the control sample. The concentration of particles in the control sample is sometimes found to vary with time as a result of side reactions. In this case the ratio $n(t)/n(0)$ is replaced by $I(t)/I_c(t)$.[50,51]

In kinetic studies of tunnelling processes the reactant whose concentration is monitored is usually generated within the sample by radiolysis or photolysis so as to minimise the possibility of reaction during sample preparation. Under these conditions the assumption $n(0) = n_c$ is legitimate only if the tunnelling reaction between D and A is the only process by which the concentration of D can decrease in the presence of A. However in practice we cannot exclude *a priori* the possibility of a reaction of A with the precursors of D during radiolysis or photolysis. For example, the concentration of trapped electrons could decrease in the presence of acceptors not only as a result of the tunnelling reaction of e_{tr}^- itself, but also through the reaction of A with the precursors of e_{tr}^- (the so-called dry electrons[67]). As a result of such reactions the true initial concentration of donors $n(0)$ in the presence of A can be smaller than n_c (the concentration of D in the control samples not containing A). The quantities $n(0)$ and n_c are related by the expression

$$n(0) = n_c \exp[-\alpha N(0)]. \tag{39}$$

The parameter α characterises the efficiency with which the precursors of D are captured by the acceptor A. From Eqns. (26), (38), and (39) we obtain

$$I(t)/I_c = n(t)/n_c = \exp\left[-\alpha N - \frac{\pi a^3}{6} N \ln^3(\nu t)\right] \tag{40}$$

or

$$I(t)/I_c = n(t)/n_c = \exp\left(-\alpha N - \frac{4}{3}\pi R_t^3 N\right). \tag{41}$$

Thus if $N = N(0)$ is fixed the variation with time of $n(t)/n_c$ is determined by three independent parameters. These parameters can be evaluated by optimising the fit of Eqn. (40) to experimental data. The most obvious criterion of optimum fit is a minimum in the mean-square deviation of the experimental points from the theoretical curve plotted by using Eqn. (40).

Several methods of calculating the optimum values of ν, a, and α have been proposed[58]. In the simplest of these each parameter is varied in turn to give the best linearisation of the experimental kinetic curve in the coordinates which should give a linear plot according to Eqn. (40) or (41).

One of the methods of calculation depends on varying the parameter ν. Eqn. (40) can be written as

$$N^{-1} \ln [n_c/n(t)] = \alpha + (\pi a^3/6) \ln^3(\nu t). \tag{42}$$

It can be seen from this equation that after choosing the value of ν which gives the most linear kinetic plot of $N^{-1}\ln[n_c/n(t)]$ against $\ln^3(\nu t)$ we can find the best value of a from the slope, which is $\pi a^3/6$, and the best value of α from the intercept on the vertical axis.

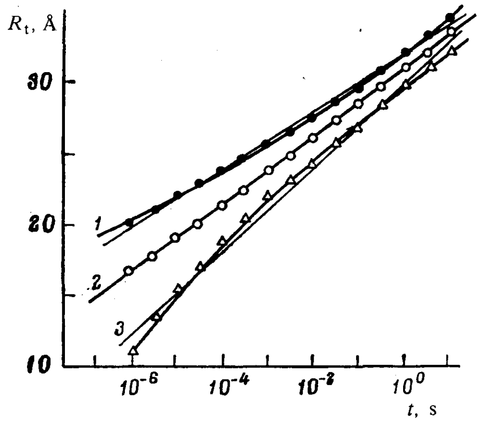

Figure 6. Kinetic plots of R_t against $\ln t$ for the reaction between e_{tr}^- and $K_3Fe(CN)_6$ (0.025 *M*) in 6 *M* aqueous NaOH at 77 K: *1*) $\alpha = 0$, *2*) $\alpha = \alpha_{opt} = 8.7$ M^{-1}, *3*) $\alpha = 2\alpha_{opt}$. Values of R_t calculated by formula (43) from the results of Ref. 33.

In another method of calculation the parameter α is varied. From Eqn. (41) we have

$$R_t = \{(3/4\pi N)[\ln(n_c/n(t)) - \alpha N]\}^{1/3}. \tag{43}$$

On the other hand, according to Eqn. (17), R_t should vary linearly with the logarithm of time. By choosing the best value of α we optimise the linearity of the experimental kinetic plot of R_t against $\ln t$. As before, the best value of a is obtained from the slope of the resulting straight line, which according to Eqn. (17) is $a/2$, and the best value of ν from the intercept on the vertical axis, which is $(a/2) \ln \nu$ (see Fig. 6).

A detailed analysis of these and other methods of calculating the parameters ν, a, and α can be found in Ref. 58, where it is shown that the results obtained by different methods are acceptably consistent (see, for example, Table 3). However, because of the logarithmic dependence of the concentration of reactants on time, the kinetic measurements must encompass a very wide range of observation times (not less than five orders of magnitude) for a reliable determination of the kinetic parameters of tunnelling reactions.

Table 3. Parameters ν and a calculated[58] by varying $\lg \nu$ (*1*) and α (*2*) from experimental curves for the decay of e^-_{tr} by reactions with different acceptors in aqueous-alkaline glasses at T = 77 K.

Acceptor	$\lg \nu$, [s^{-1}]		a, Å	
	1	*2*	*1*	*2*
BrO_3^-	11.0	11.2	1.30	1.29
$Co(NH_3)_6^{3+}$	10.9	12.1	2.24	2.05
$Fe(CN)_5NH_3^{2-}$	11.1	10.7	1.65	1.70
MoO_4^{2-}	12.5	11.8	1.41	1.48
$Fe(CN)_6^{3-}$	12.8	13.1	2.10	2.05
$Ni(CN)_4^{2-}$	13.9	13.9	1.31	1.31
IO_3^-	14.1	15.1	1.18	1.12
$Cr(CN)_6^{3-}$	14.9	16.0	2.02	1.92
ReO_4^{2-}	15.2	16.2	1.59	1.51
Np(VII)	15.5	12.9	2.29	2.65
Picrate	15.9	13.5	2.0	2.29
$Co(en)_3^{3+}$	15.7	15.8	1.91	1.90
$Co(CN)_6^{3-}$	17.9	18.4	1.39	1.35
NO_2^-	18.8	19.0	1.03	1.025
$ClAc^-$	20.3	19.6	0.35	0.36
Acrylamide	20.3	22 1	0.72	0.67
NO_3^-	18.6	18.4	0.98	1.02
$Cu(en)_2^{2+}$	15.5	15.0	1.79	1.87
CrO_4^{2-}	19.1	19.1	1.69	1.68

Eqn. (26) assumes that the parameters ν and a are the same for all pairs of reactants. The validity of this assumption has been demonstrated in Ref. 58 for tunnelling reactions in glassy matrices.

VI. KINETIC CHARACTERISTICS OF LONG-RANGE TUNNELLING ELECTRON TRANSFER REACTIONS

The most detailed studies of long-range tunnelling electron transfer are those devoted to the reactions of e^-_{tr} [18,20,29,31-35,57,68-76]. Currently known values of the parameters ν and a for reactions of e^-_{tr} are summarised in Table 3. These values were calculated[58] by analysing experimental data obtained[33,34,58] in kinetic studies of tunnelling reactions of e^-_{tr} extending over a sufficiently wide range of observation times (10^{-6}–10^2 s in Ref. 33 and 34, 10^{-6}–10^6 s in Ref. 58). As Table 3 shows, ν can vary over the very wide range from 10^{11} to 10^{21} s^{-1} depending on the nature of the acceptor, while a varies between 0.4 and 2.5 Å. The ranges of ν and a are very much greater than the experimental error in the determination of these parameters from the kinetic curves (not more than 15%).[58]

Table 4. Parameters ν and a for reactions of particles other than e^-_{tr}.

No.	Donor	Acceptor	Matrix	T, K	$\lg \nu$, [s^{-1}]	a, Å	Reference
1	NO_3^{2-}	CrO_4^{2-}	10 M $NaOH+H_2O$	77	20	0.9	77
2	$AgNO_3$	SO_4^-	6 M $H_2SO_4+H_2O$	77	6	1.3	49
3	$FeSO_4$	SO_4^-	ditto	4.2—77	7	1.8	48
4	$K_4Fe(CN)_6$	O^-	6.5 M $NaOH+H_2O$	4.2—77	12	1.8	48
5	$(C_6H_5)_2^-$	$C_{10}H_8$	ethanol + ether	77	7	1.7	50
6	$(C_6H_5)_2^-$	3-phenylethylene 0.01 M	ethanol	77	12.5*	1.98*	51
7	$(C_6H_5)_2^-$	3-phenylethylene 0.03 M	ethanol	77	13.8*	1.84*	51
8	$C_{10}H_8^*$	CCl_4	ethanol	77—140	—	—	53
9	Cd(I)	$Cr_2O_7^{2-}$	6 M $H_2SO_4+H_2O$	77	12	1.4	55
10	Cd(I)	MnO_4^-	6 M $H_2SO_4+H_2O$	4.2—77	14	1.3	55
11	Ni(I)	MnO_4^-	6 M $H_2SO_4+H_2O$	77	12	1.2	49

*Here $\lg \nu$ and a are the mean values of the parameters calculated[58] by varying $\lg \nu$ and α.

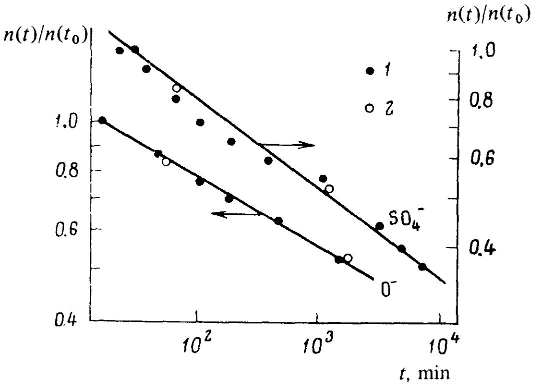

Figure 7. Kinetic plots of $n(t)/n(t_0)$ against $\lg t$ ($t_0 = 10^3$ s) for reactions (6) and (7a) at 77 K (points *1*) and 4.2 K (points *2*). The concentrations of $FeSO_4$ and $K_4[Fe(CN)_6]$ are 0.05 and 0.3 M respectively.

An outline of the reactions of particles other than e^-_{tr} is given in Table 4, which lists the kinetic characteristics of these reactions. For processes No. 6 and 7 the values of ν and a were obtained[58] by analysing kinetic curves extending over a wide (10^{-6}–10^2 s) range of time[51]. For the other reactions the kinetic curves were determined over a more limited range of time (not more than three orders of magnitude). As an example we show in Fig. 7 the kinetic curves for reactions (6) and (7a). From data of this type the parameters ν and a can be evaluated only if the parameter α is known from independent measurements[58]. Hence the ν and a values given in Table 4 were obtained by assuming α = 0 (except in the case of processes No. 6 and 7). These values, therefore, are an upper limit of the true value of ν and a lower limit of the true value of a.[58] As Table 4 shows, the range over which the parameters ν and a can vary in the different reactions is similar to the range of variation of these parameters for the reactions of e^-_{tr}.

We should note also that the values of ν and a (Tables 3 and 4) agree well with theoretical calculations[58] (see Chapter III).

Table 5. Temperature dependence of the parameters ν and a for the reactions between e_{tr}^- and various acceptors, calculated[58] from kinetic data[33] by varying lg ν (*1*) and α (*2*).

Acceptor	T, K	lg ν, [s^{-1}]		a, Å	
		1	*2*	*1*	*2*
$Co(en)_3^{3+}$	77	15.7	15.8	1.91	1.90
$Co(en)_3^{3+}$	143	11.1	13.1	2.5	2.2
CrO_4^{2-}	77	19.1	19.1	1.69	1.68
CrO_4^{2-}	147	10.0	10.9	2.97	2.74
NO_3^-	77	18.6	18.4	0.98	1.02
NO_3^-	143	10.6	10,6	1.69	1.49
BrO_3^-	77	11.0	11.2	1.30	1.29
BrO_3^-	143	13.0	11.5	1.02	1.13

The few data so far available on the temperature dependence of the parameters ν and a are summarised in Table 5. It can be seen that at least for the reactions of e_{tr}^- with CrO_4^{2-} and NO_3^- the parameter a increases very significantly with temperature. One possibility is that in these cases a new reaction path becomes available on raising the temperature, involving the excited electronic levels of the reaction products. In parallel with an increase of a we observe a decrease of ν, but overall the velocity of the reaction increases with temperature. On the other hand the variation of ν and a for the reaction of e_{tr}^- with BrO_3^- lies within experimental error, and for the reaction of e_{tr}^- with $Co(en)_3^{3+}$ is close to the limits of experimental error.

Conversely, the rate of the reaction of e_{tr}^- with biphenyl in 2-MTHF[78] and with benzyl chloride in C_2H_5OH [79] apparently increases as the temperature is lowered. As shown in the original papers, the influence of the acceptors on the radiation yield of e_{tr}^- decreases as the temperature increases from 4.2 to 77 K.

Thus the range of ν values in these tunnelling reactions extends from 10^6 to 10^{21} s^{-1}, and the range of a values extends from 0.4 to 2.5 Å. Both parameters depend on the nature of the electron donor and the electron acceptor, and they can decrease, increase, or stay constant when the temperature is increased. All these experimental findings are fully consistent with the theoretical model of long-range tunnelling electron transfer proposed in Ref. 58.

VII. CHEMICAL REACTIONS INVOLVING LONG-RANGE ELECTRON TRANSFER

Electron transfer reactions play an important rolè in various chemical situations. Many redox reactions in liquids or on solid surfaces, and also many electrochemical, radiation-chemical, photochemical, and biochemical changes include an electron transfer step.

The long-range electron transfer reaction allows chemical change to take place when the reactants are separated by a relatively large distance, thus offering interesting new possibilities in the organisation of chemical changes at the molecular level and in the control of these changes. These possibilities are fully utilised in the living world, for example in respiration and in photosynthesis[80]. The substances which take part in these complex biochemical processes are often immobilised in membranes, thus being prevented from undergoing undesirable side-reactions by collision processes. Nonetheless these substances can exchange electrons by a tunnelling mechanism[22,23,59,60,81-89]. The resulting oxidised and reduced forms can initiate chains of chemical reactions within their own region of the membrane.

We may assume that natural photosynthetic systems are able, by virtue of this type of organisation of chemical changes, to avoid fast recombination of the electrical charge pairs produced by the absorbed radiation, thus ensuring efficient photosynthesis. Separation of charges probably occurs by fast tunnelling electron transfer from the photo-excited chlorophyll (Chl) to the so-called primary acceptor (A):

$$\mathrm{Chl} \xrightarrow{h\nu} \mathrm{Chl}^* \xrightarrow{A} \mathrm{Chl}^+ + A^-.$$

The species Chl^+ and A^- initiate further chemical changes, leading ultimately to the evolution of oxygen from water and to the formation of carbohydrates from CO_2. The reverse electron transfer from A^- to Chl^+ is much slower. A possible explanation is the rapid conversion into heat of some of the energy stored in Chl^+ and A^- (the conditions which favour tunnelling electron transfer may be disturbed by lowering the energy levels); alternatively, the separation of the reactants may be increased by fast conformational changes in the membrane produced by the forward reaction. The fast recombination of light-separated charges is known to be the major obstacle to the design of artificial solar energy converters. By analogy with natural photosynthesis, the use of tunnelling processes would seem a promising way of overcoming these difficulties.

Table 6. Rate constants k_e for the reactions of e_{tr}^- with various acceptors in liquid solutions at 25° C and characteristic times τ for the reactions of e_{tr}^- with the same acceptors in solid aqueous-alkaline glasses at 77 K.

Acceptor	$10^{-10}k_e$, litre mole^{-1} s^{-1}	τ, s		
		R=10 Å	R=15 Å	R=20 Å
$ClAc^-$	0.12	$10^{4,6}$	10^{17}	—
NO_3^-	0.85	$10^{-9,9}$	$10^{-5,6}$	$10^{-1,3}$
$Cu(en)_2^{2+}$	1.8	10^{-10}	$10^{-7,5}$	10^{-5}

Tunnelling processes can be used to control the selectivity of redox reactions. This has not yet been achieved in practically important situations, however the possibility (in principle) of this type of control is shown by Table 6, in which we compare the rate constants for the reactions of hydrated electrons with three different acceptors in a liquid at 25° C and the characteristic times τ for the reactions of trapped electrons with the same acceptors in solid aqueous alkaline glasses at 77 K. It can be seen that in liquids, where the reactants can approach each other by diffusion (direct collisions), the rate constants for all three reactions are similar and very large. On the other hand in solids, where diffusion is negligible and the reactions take place by a tunnel mechanism, the characteristic times of the reactions vary with distance to different extents because of the differences in ν and a. For the reaction of e^-_{tr} with $Cu(en)_2^{2+}$ we obtain $\tau = 10^{-5}$ s even for $R = 20$ Å, and $\tau = 10^{-10}$ s for $R = 10$ Å. On the other hand the τ value for the reaction of e^-_{tr} with $ClAc^-$ is 14–15 orders of magnitude greater with $R = 10$ Å. This difference in the distance dependence of the time τ suggests the possibility of exploiting the tunnel effect for generating selectivity in redox reactions by creating barriers against direct collisions between the reactants. The gain in selectivity would be achieved at the cost of a loss in speed, but this could be unimportant in many fast electron transfer processes.

In solids there is practically no possibility of direct collisions between the reactants, and therefore the distance of the tunnelling transition (and hence the time τ) can be controlled by controlling the concentration of the reactants. In the case of liquids close approach between the reactants could be prevented by surrounding them with a shell of inert molecules (large ligands, or micelles). Experimental confirmation of the differences in tunnelling electron transfer behaviour between particles inside and outside a micelle has recently been obtained[90,91].

Long-range tunnelling electron transfer processes play an important role in radiation chemistry and in photochemistry. They enable many oxidation–reduction reactions in irradiated solid matrices to take place at rates well in excess of the diffusion-limited rate.[57] The tunnelling recombination of positive and negative ions can set a limit to the steady-state concentration of these particles in radiolysis[21], and it can produce time-changes in the radiation-chemical yield[57].

Long-range electron transfer can be important also in the protection of materials from radiation damage and photo-degradation[92,57]. By using the tunnel mechanism the photochemical changes of some organic materials in solids can be made to occur by a one-photon rather than a two-photon process, i.e. with a smaller energy input[52].

Tunnelling electron transfer is very relevant also in oxidation–reduction catalysis, including enzyme reactions. Thus it has been shown[93] that the two-electron reduction of molecular oxygen to hydrogen peroxide by Cu^+ ions immobilised in blue (copper-containing) oxidases is thermodynamically unfavourable. Hence we may assume that molecular oxygen is reduced directly to water when complexed with the active centres of these enzymes[94]:

$$4Cu^+ + O_2 + 4H^+ \rightarrow 4Cu^{2+} + 2H_2O.$$

It appears that two electrons are transferred from copper ions directly bound to oxygen in the complex, and two additional electrons are transferred from more remote copper ions in the enzyme molecule.

Radical Pairs in the Study of Elementary Chemical Reactions in Solid Organic Substances

O.E.Yakimchenko and Ya.S.Lebedev

Methods for the investigation of elementary chemical reactions and molecular motions on the basis of the EPR spectra of radical pairs are examined. The results of the study of the stereochemistry and kinetics of processes involving radical pairs are used to discuss the nature of the characteristic features of the elementary solid-phase reactions: the existence of a broad spectrum of the frequencies of the reactions and molecular motions, the reaction mechanisms at low temperatures, and the influence of intra- and inter-molecular motions on the rates of chemical reactions.

The bibliography includes 92 references.

I. INTRODUCTION

Studies on elementary chemical processes in solid organic substances, which were initiated to a large extent in the research of Academician V.V.Voevodskii[1], are developing vigorously at the present time. These studies are fundamentally closely related to fields of modern science such as the physical chemistry of polymers, molecular biology, and radiation chemistry. In contrast to elementary gas-phase reactions, where energy transfer, excitation, and excited state relaxation processes are most significant (and responsible for the rate of the chemical reaction), in the solid state an analogous role is apparently played by phenomena of a quite different type: translational and rotational motions, conformational rearrangements of molecules, etc.

In the study of reactive species in condensed media spectroscopic and microwave spectroscopic methods are of greatest importance. However, it is difficult to use even these methods to investigate elementary processes of the above type, because rotation and conformational transitions usually have only a weak influence and translational displacements have no influence at all on the spectra of individual species. The aim of the present review is to show that, in relation to radical reactions which play an important role in the chemistry of solid organic substances, considerable progress may be achieved by investigating radical pairs, i.e. radicals separated by a "molecular" distance (3–10 Å). Such radical pairs are, as it were, "entropically excited" intermediates in dissociation-recombination and disproportionation reactions. The high sensitivity of the EPR spectra of radical pairs to a relative displacement of the reaction centres has proved to be most significant, and makes it possible to obtain in many instances detailed information about the elementary processes in solids.

It has been shown a comparatively long time ago that, when stable radicals adjoin one another, the interaction between unpaired electrons greatly alters the spectrum. This permits the determination of the distance between the electrons[2]. There was a growth of interest in the "chemical" applications of this phenomenon after the discovery of the possibility of detecting metastable radical pairs, consisting of active radicals formed as a result of the decomposition of molecules in the solid phase[3]. Since 1966–1967, studies in this field have led to the detection and investigation of radical pairs in many chemical systems; these investigations have been surveyed in monographs[4,5] and reviews[6,7]. However, the above reviews were devoted mainly to problems of the formation of radical pairs and the analysis of their EPR spectra. As far as we are aware, the present review is the first attempt to survey new data on the kinetics of elementary physical and chemical processes obtained in the study of radical pairs. We hope that this survey will make it possible to formulate more clearly the possibilities arising as a result of the development of this field of research.

II. METHODS FOR THE INVESTIGATION OF RADICAL PAIRS

The theory of the EPR spectra of radical pairs has been described in detail in reviews[8,9] and monographs[10,11]. Here we shall consider the main theoretical conclusions directly applicable to the study of elementary reactions in the condensed phase.

1. EPR Spectra of Radical Pairs

A pair of radicals separated by distance $r \leqslant 10$ Å constitutes a system with two interacting electrons having an overall spin $S = 1$ and hence a multiplicity $2S + 1 = 3$. The dipole–dipole interaction between the electrons removes the degeneracy of the levels in the "zero field". The energy of the states and the transitions in the case of axial symmetry, where the energies of the T_1 and T_{-1} states in the zero field are the same, are illustrated in Fig. 1. When the magnetic field H_0 is scanned using a fixed frequency, it is possible to observe two allowed $\Delta M_S = 1$ transitions corresponding to the reversal of a single spin in the magnetic field. The splitting in this instance is

$$D = \frac{\xi g\beta}{r_{\text{cp}}^3}(3\cos^2\alpha - 1) \quad , \tag{1}$$

where r_{av} is the length of the appropriately averaged vector connecting the unpaired electrons of the free radicals, α the angle between the interelectron vector $\vec{r}_{av}$ and the direction of the permanent magnetic field H_0, g the spectroscopic splitting factor, assumed to be isotropic, β the Bohr magneton, and ξ a numerical coefficient equal to 3/4 for resonance spins (having the same Larmor precession frequency) and 1/2 for non-resonance spins.

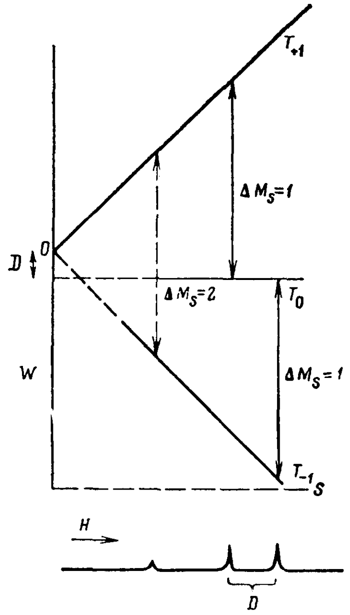

Figure 1. Energies of the states and transitions responsible for the EPR spectrum of the radical pair in a single crystal.

In the absence of axial symmetry, the degeneracy is fully removed in the zero field. The energies are then usually formulated in terms of two independent parameters D and E:

$$T_1 = 1/3D - E + g\beta H_0,$$
$$T_{-1} = 1/3D + E - g\beta H_0,$$
$$T_0 = -2/3D.$$

For radical pairs, $E \ll \frac{1}{3}D$ in most cases, and the difference between T_1 and T_{-1} in the zero field may be neglected without a significant loss of accuracy[12].

2. Determination of Spectroscopic Parameters

Determination of the fine structure parameters. The quantity $D_{\parallel}$ (i.e. D corresponding to $\alpha = 0$), the average distance between the unpaired electrons r_{av}, and the orientation of the interelectron vector of the radical pair relative to the crystallographic axes can be determined from the dependence of the fine splitting in the pair D on the orientation of the single crystals in the magnetic field.

The quantity $D_{\parallel}$ may be measured also on the basis of the EPR spectra of randomly oriented systems, which can be established experimentally in polycrystalline and vitrified specimens. The calculated line form for axial symmetry and on the assumption of a small line width is presented in Fig. 2. In the case of large line width and poorly resolved EPR spectra the rules obtained with the aid of model calculations of the line form[13] must be used in the determination of $D_{\parallel}$. When there is a significant deviation from axial symmetry, the intense "perpendicular" peaks illustrated in Fig. 2 are split by an amount $3|E|$. This usually makes it possible to determine both spectroscopic parameters (D and E). The same parameters can be found when the single crystal is rotated about two perpendicular axes after finding the principal values and directional cosines of the experimental splittings tensor in a zero field[10]. The $\Delta M_S = 1$ transition is frequently not observed in radical pairs owing to the considerable extent of the spectrum, the broadening of the lines caused by the scatter of the distances r_{av}, or very frequently, owing to the superposition of the intense signal due to isolated radicals. In this case one investigates the weak signal of the "forbidden" $\Delta M_S = 2$ transitions (Fig. 1), formally corresponding to the simultaneous reversal of two spins. The finite probability of the "forbidden" transition is due to the mixing of the T_0 and T_{+1} levels as a result of the dipole–dipole interactions; for the usual formulation of the experiment (EPR in perpendicular fields), it is given by[8]

$$\varphi = 2\frac{D_{\parallel}^2}{H_0^2}\sin^2 2\alpha = 2\left(\frac{3g\beta}{2r_{cp}^3 H_0}\right)^2 \sin^2 2\alpha; \tag{2}$$

when $D_{\parallel} \simeq 10^2$ G and $H_0 = 3 \times 10^3$ G, we have $\varphi \lesssim 10^{-3}$.

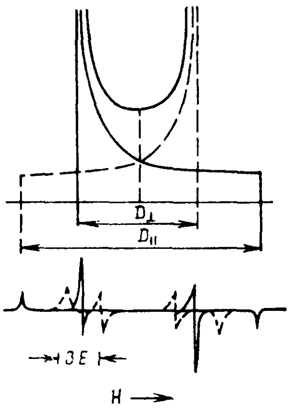

Figure 2. Theoretical EPR spectrum of polyoriented radical pairs (absorption corresponding to infinitesimal line width and the derivative of the absorption curve obtained taking into account the finite line width) for an axially-symmetrical tensor D. The additional splitting of the lines in the absence of axial symmetry ($D_{\parallel} = 2D_{\perp}$) is shown below by dashed lines.

However, the observation of "forbidden" transitions becomes possible when the line width is smaller and a higher microwave power is used[14]. The position of the centre of the $\Delta M_S = 2$ transition is determined by the condition

$$H^2 = 1/4H_0^2 - 1/3\,(D^2 - 3E^2),$$

i.e., when $D \ll H_0$, the position of the line virtually coincides with $H_0/2$; the shift $\delta H \simeq D^2/6H_0$ of the line may be used to determine D, but it is usually impossible to measure it.

Another method for the determination of D, proposed by Grinberg et al.[15], is based on the measurement of the shift of the saturation curves, i.e. the dependence of the signal intensity I on the amplitude of the microwave field H_1. If the spin–lattice relaxation times of the radicals and radical pairs are the same, then the I–lg H_1 saturation curves are displaced by an amount $\Delta = \lg \varphi$ (for a single-crystal), which makes it possible to determine φ and D. For polyoriented specimens, the analysis is more complicated but the simultaneous measurement of the shift Δ of the relative signal intensity $I_{\Delta M_S=2}/I_{\Delta M_S=1}$ frequently permits the determination of φ and D.[15]

Determination of the hyperfine structure parameters. The hyperfine interaction in the radical pairs leads to additional splitting of the levels of the triplet state ($S = 1$; $M_S = 1, 0, -1$):

$$T_1 = g\beta H_0 + 1/3D + \sum A_i M_{Ii},$$

$$T_{-1} = -g\beta H_0 + 1/3D - \sum A_i M_{Ii},$$

$$T_0 = -2/3D,$$

where the summation is carried out over all the interacting nuclei of the radical pair. Although the electronic spin moment in the triplet state is the moment of two bound electrons ($S = 1$), on average only half of this moment interacts effectively with the nuclei of each individual radical. Two electrons cannot be present in the same orbital and for this reason they occupy different normalised molecular orbitals,

$$\psi_1 = 1/\sqrt{2}\{\psi(R_1) + \psi(R_2)\},$$

$$\psi_2 = 1/\sqrt{2}\{\psi(R_1) - \psi(R_2)\},$$

formed by the combination of the orbitals of the unpaired electrons of the isolated radicals R_1 and R_2. Consequently the resulting spin density for each radical in the pair is the same as for the isolated radicals. Since the distance between the radicals is large, the magnetic cross-interaction of the nuclei of R_1 with the electrons in R_2 is negligibly small. Ultimately the splitting of the $M_S = \pm 1$ energy levels is the same as for $M_S = \pm 1/2$. For the allowed $\Delta M_S = 1$ transition, the hyperfine interaction constants for the radical pairs are equal to half the hyperfine interaction constants for the isolated radicals (Fig. 3). The same situation obtains for $\Delta M_S = 2$ transitions when the hyperfine interaction constants are expressed in magnetic field units[8].

It is noteworthy that the hyperfine interaction constants measured in "perpendicular" or "parallel" components of the spectrum of the radical pairs (Fig. 3) may refer to quite different orientations of the hyperfine interaction tensor in the magnetic field. This makes it possible to determine the orientation of the radical fragments relative to the axis of the pair.

Extent of the exchange interaction. In considering the EPR spectra we have hitherto assumed that the system is in the triplet state. In reality the triplet state of radical pairs is usually separated from the nearest singlet state by an energy gap which is very small compared with kT. All four levels are equally populated, so that 1/4 of the radical pairs do not give rise to an EPR signal. Yet another interesting case arises when the singlet–triplet splitting $E_T - E_S = J$ is greater than kT but is nevertheless fairly small and the triplet becomes thermally attainable without a significant mixing of the states. In this case it is possible to determine the exchange integral from the temperature dependence of the EPR signal intensity of the triplet state, because the signal intensity $I_{\Delta M_S=1} \simeq 3T^{-1}\exp(-J/kT)$. The latter

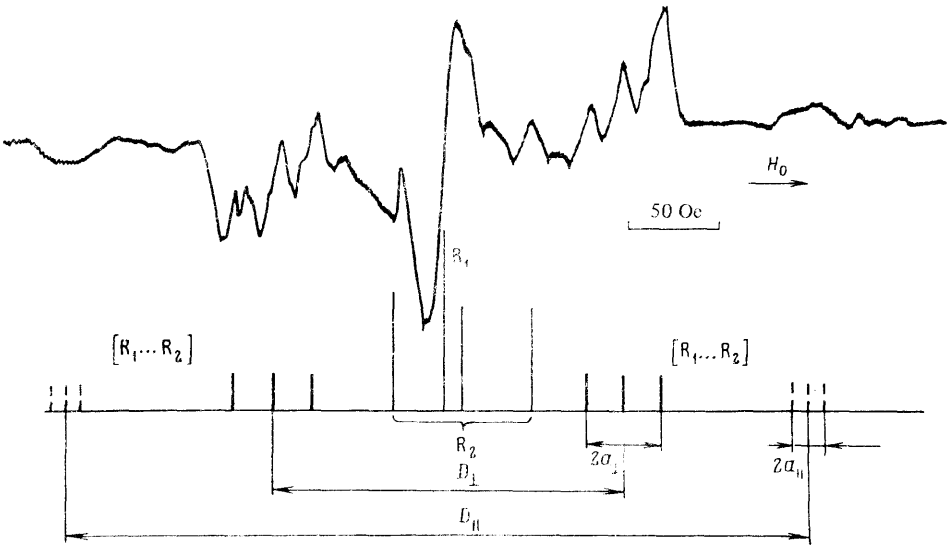

Figure 3. The real EPR spectrum of the "iminoxy–phenoxy"-radical pair and the isolated radicals in γ-irradiated polycrystalline o-nitrophenol and the conditions used in the interpretation of the spectrum. Evidently the hyperfine splitting in the spectrum of the radical pair is smaller by a factor of two than in the spectrum of the isolated radicals and is different for parallel and perpendicular orientations.

is of particular interest for chemistry, since the dependence of J on r_{av} determines the magnetic effects in chemical reactions[16]. The quantity J has been determined[17,18] for different values of r_{av} in radical pairs. Effects arising from the distortion of the hyperfine structure, caused by the mixing of the T_{+1} (or T_{-1}) and S_0 levels, have been used for this purpose[19,20] and not the temperature dependence of the EPR signal intensity.

3. Determination of Structural Parameters

In those cases where the point dipole approximation is valid, the dipole–dipole interaction leads to fine splitting of D in the spectrum of the radical pair described by formula (1). This formula may be replaced by an equivalent expression which is convenient for the interpretation of experimental data:

$$D=\frac{1}{2}D_{\parallel}(3\cos^2\theta\cdot\sin^2\psi-1), \quad (3)$$

where θ is the angle between the projection of the interelectron vector and the direction of the magnetic field H_0, ψ the angle between the interelectron vector and the axis of rotation of the crystal, and $D_{\parallel}=55\,600/r_{av}^3$ (for resonance spins); D and $D_{\parallel}$ are expressed in gauss and r_{av} is expressed in angstroms. The crystallographic axes are selected as the axes of rotation of the single crystals. Fig. 4 presents the experimental[21] relations between D and the angle θ for pairs of iminoxy-radicals. In order to determine the positions of the detected radical pairs in the unit cell of the dimethylglyoxime crystal, parameters characterising the structures of all possible pairs of iminoxy-radicals with $r_{av} \leq 6$ Å were calculated. It was assumed[8] that the spin density is localised at the NO bond, that the electron densities at the atoms are $\rho_O = 0.67$ and $\rho_N = 0.33$, and that the same spin density distribution is maintained approximately in all the radical pairs.

The theoretical relations are compared in Fig. 4 with the experimental relations; their agreement shows quite clearly that irradiation results in the formation of all the possible types of pairs and that the distances between them are close to those in the undisrupted crystal lattice. In determining the orientations of pairs of radicals with delocalised electrons, account must be taken of the degree of delocalisation. Thus allowance for delocalisation in a pair of diphenylnitrogen radicals in tetraphenylhydrazine[18] gave values of r_{av} differing by ~1 Å from those calculated in terms of the point dipole approximation. However, in these calculations no account was taken of the form of the orbitals of the unpaired electrons. A calculation of r_{av} with allowance for the form of the orbitals has been carried out[22], which made it possible to determine the structure of the complex from which radical pairs are formed as a result of subsequent phototransfer of a proton.

4. Measurement of the Concentration of Radical Pairs

Since radical pairs have an effective spin $S = 1$ and stable radicals with $S = 1/2$ are used as the standards in EPR, account must be taken of the difference between the transition probabilities for systems with different spins. The EPR signal intensity (I) in the absence of saturation is proportional to the number of species N and to the square of the magnetic moment $\mu^2 = g^2\beta^2S(S+1)$, i.e.

$$I \propto NS(S+1).$$

If the specimen contains N radical pairs, then only 3/4 of them populate the magnetic (triplet) levels T_0 and $T_{\pm1}$ (Fig. 1), and for this reason we have $I \simeq \frac{3}{2}N$ when $S = 1$. For N_R isolated radicals with $S = 1/2$, the intensity $I \simeq \frac{3}{4}N_R$. Thus, in the standard determination of concentration from EPR spectra, one obtains twice the number of radical pairs, i.e. the number of radicals combined into pairs. If no account is taken of this, one can make an error by a factor of two in the calculation of the concentration.

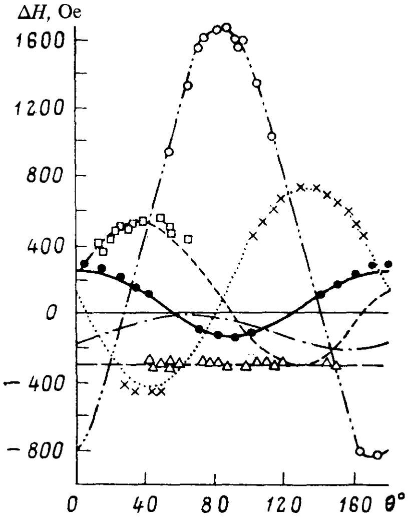

Figure 4. Experimental (circles) and theoretical (lines) angular relations for the hyperfine splitting constant D corresponding to the rotation of a dimethylglyoxime single crystal about the crystallographic a axis for five types of pairs with $r_{av} \leqslant 6$ Å. Comparison of the experimental points and the calculated curves makes it possible to identify the positions of the radical pairs in the unit cell of the crystal[21].

When account is taken of the differences between the transition probabilities described, the determination of concentrations from EPR spectra does not differ from the usual procedure, i.e. one compares the areas of the EPR signals of the test and reference specimens. The following useful relation has been obtained for the estimation of the area under the absorption line (s), recorded as a derivative line[23]:

$$s = kI'_{\perp}(3/2D_{\perp})^{1/2}\delta_{\perp}^{3/2},$$

where $I'_{\perp}$ and $\delta_{\perp}$ are the intensity and the apparent width of the "perpendicular" component (Fig. 5), while the shape coefficient $k \simeq 1/2$ for a Gaussian form of the individual line and $k \simeq 2$ for a Lorentzian form. A relation of the same type (but with different coefficients) makes it possible to express the area in terms of the intensity of the "parallel" component. A more accurate but cumbersome method of determining the area under the EPR signal consists in double integration or evaluation of the first moment of the experimental line.

If the usual $\Delta M_S = 1$ transition is not observed and only "forbidden" $\Delta M_S = 2$ signals are recorded, the problem of the determination of the concentration of radical pairs becomes significantly more difficult, because absolute calculations require the knowledge of the transition probability φ defined by Eqn. (2). A method has been proposed[15] for measurements based on the shift of saturation curves. In fact, for polyoriented radical pairs it is also necessary to average $\varphi(r, \alpha)$ with respect to orientations; nevertheless joint measurement of the $\Delta M_S = 2$ signal intensity and of the shift of its saturation curve relative to the signal of the radicals makes it possible to determine the concentration of radical pairs and the distance between the unpaired electrons[15].

In conclusion of the methodological part of the review, one must emphasise that the simultaneous determination of the hyperfine interaction constants and the fine structure constants, of the distance between the radicals (to within 0.1 Å), and of the orientation of the pair makes it possible to determine almost ambiguously the structure of the active centre and its position in the matrix. By studying the variation of these parameters during the course of a reaction, we have a unique possibility of investigating the "stereometry" of an elementary chemical process in a solid matrix.

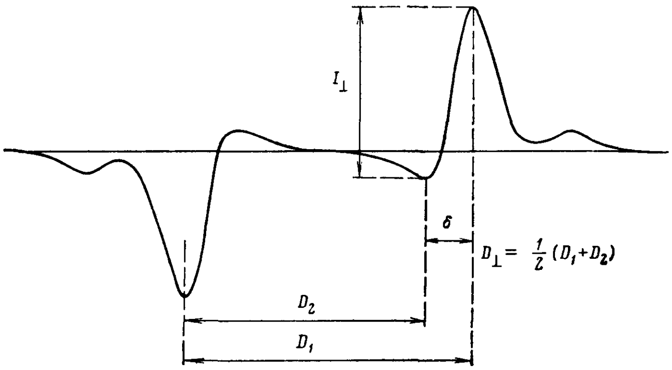

Figure 5. EPR spectrum of randomly oriented radical pairs with a large width of the individual lines and the parameters used to analyse the poorly resolved spectra[13,23].

III. THE PRIMARY STAGES IN RADIOLYSIS AND PHOTOLYSIS

In conformity with the principle of the conservation of valence, any process involving the formation of radicals from neutral molecules should proceed via a radical pair formation stage. Direct detection of radical pairs should naturally yield valuable information about the mechanisms of the reactions leading to the formation of the active centres—free radicals in solid matrices. In particular, the structure of metastable radical pairs, their orientation, and other characteristics may be used to elucidate the mechanisms of the reactions in solids under the influence of light and ionising radiation.

1. Photodissociation in the Solid Phase. Primary Steps of Photolysis

As already mentioned, in the photolysis of many solid organic compounds it is possible to detect metastable radical pairs[3,18,24]. Interesting data on the mechanism of the primary steps of photolysis have been obtained by magnetophotoselection of radical pairs. The effect of the steric selection of triplet molecules under the influence of polarised visible light is comparatively little known[25]. The magnetophotoselection effect of this kind was observed for the first time[26-28] in the formation of radical pairs under the influence of linearly polarised ultraviolet light.

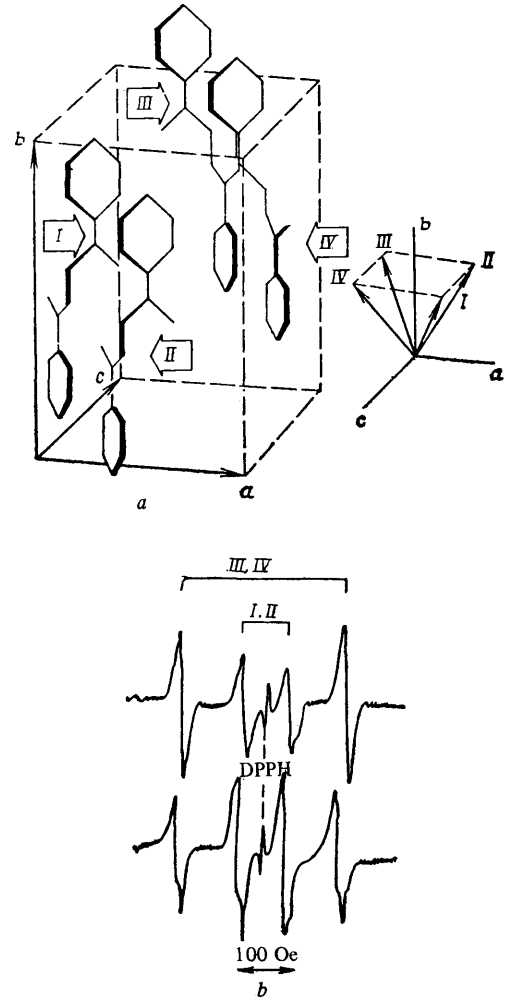

Figure 6. *a*) Schematic illustration of the orientation of different types of radical pairs in the unit cell of a benzoyl peroxide crystal; the arrows indicate the positions of the CO_2 groups evolved on photolysis[28]; *b*) selective accumulation of the EPR signals of radical pairs on photolysis with linearly polarised light: above—electric field strength $e \parallel (1,\bar{1},0)$; below—$e \parallel (1,1,0)$. The spectra were recorded for the $H_0 \parallel (1,\bar{1},0)$ orientation.

The formation of radical pairs in acridine–acridan single crystals under the influence of linearly polarised light has been studied by EPR.[27] The directions of the dipole moments of the transitions were found from the dependence of the quantum yield of radical pairs on the angle between the electric field strength vector **e** and the crystallographic axis. In the range 250–400 nm the dipole moment of the transition is in the plane of the acridine molecule and is directed along the *c* axis; in the range 380–540 nm the component of the dipole moment of the transition is perpendicular to the plane of the molecule and is directed along the *b* axis. These results are consistent with data showing the anisotropy of the absorption of polarised light by the acridine molecule[29] and illustrate the advantages of the EPR study of the anisotropy of the absorption of light in single crystal specimens.

For benzoyl peroxide[28], the transition in the range 300–330 nm corresponds to electron transfer along the C–O bond (O is the oxygen of the peroxide bridge). The existence of four radical pairs with non-equivalent orientations in the benzoyl peroxide single crystal (Fig. 6) and the distance between the radicals, which is 5.4 Å, indicate the formation of the $PhCO_2^{\bullet}$ and $Ph^{\bullet}$ radicals on photolysis. One of the two symmetrical CO_2 groups, oriented in different ways in the cell, can be selectively abstracted by polarised light, i.e. the primary excitation is localised at one of the two symmetrical benzoxy fragments. This permitted the conclusion that there is no rapid transfer of excitation between the two equivalent fragments of the benzoyl peroxide molecule.

The analysis of the EPR spectra of polyoriented systems is more complex; nevertheless, by studying the angular distribution of the primary photolysis products (radical pairs), it is possible to determine the direction of the transition moment and the nature of the photodissociation step. Thus, for the dissociation of tetraphenylhydrazine,[26] the best agreement between the theoretically calculated EPR spectra of partly oriented radical pairs and experimental spectra was observed when the transition moment coincided with the direction of the N–N bond in the molecule and for an angle of 62° ± 3°C. It has been found analogously[30] that the vector of the electronic transition moment, excited by polarised light in 3,6-di-t-butyl-*o*-benzoquinone, is at an angle of 70° ± 5°C relative to the plane of the molecule. In both cases the polarisation of the transition corresponds to the electron transfer from the heteroatom to the benzene ring (an $l-\pi^*$ transition) and the observed directions of the vectors agree with the ideas concerning the geometry of the wave functions in complex organic molecules.

The whole of the information about the structure of the radical pair and about the nature of the excitation step suggests also a mechanism for the photoinitiation of radical pairs. Thus it has been shown[27,30] that selectively excited molecules in the singlet state abstract hydrogen atoms from neighbouring molecules, forming radical pairs.

2. The Mechanism of the Radiolytic Generation of Radical Pairs

The mechanism of radiolysis is of special interest for the chemistry of elementary radical reactions, because it determines the initial steric distribution of radicals.

A large series of studies on radical pairs[12,31-36] made it possible to approach from new standpoints an understanding of the mechanism of the formation of radicals in radiolysis. However, there is no final view concerning these problems. The situation is similar as regards the question of whether the same mechanism operates in the formation of isolated radicals and radicals stabilised in a matrix in pairs and separated by short distances. Radical pairs may be formed in different ways[12,31,32]:

$$\begin{array}{rl}
\text{I.} & R_1{-}R_2 \rightsquigarrow [R_1R_2]\ ,\\
\text{II.} & [RH \ldots RH] \rightsquigarrow [RH^+RH^-] \to [R \ldots RH_2]\ ,\\
\text{III.} & [RHRH] \rightsquigarrow [RH \ldots RH]^* \to [R \ldots R] + H_2\ ,\\
\text{IV}\,a. & RH \rightsquigarrow RH^+ + e^-\ ,
\end{array}$$

$$\begin{array}{rl} b. & RH^+ + e^- \to \\ c. & RH + H \to \end{array}\left[\begin{array}{c} R \\ R \end{array}\right]\begin{array}{l} + H\ ,\\ + H_2\ ,\end{array}$$

$$\text{V}\,a.\ RH \rightsquigarrow RH^+ + e^-\ ,$$

$$\begin{array}{rl} b. & RH^+ + RH \to \\ c. & RH_2^+ + e^- \to \end{array}\left[\begin{array}{c} R \\ R \end{array}\right]\begin{array}{l} + RH_2^+\ ,\\ + H_2\ .\end{array}$$

According to a number of data[24,31,32,37-43], it is seen that radical pairs at concentrations comparable to or greater than those of isolated radicals are generated in compounds capable of forming complexes in solutions and containing functional groups giving rise to hydrogen bonds. A probable mechanism of the formation of radical pairs may be pathway II–III, where the complex decomposes with charge transfer or excitation of the complex. A characteristic feature of this pathway is the stereospecificity in the formation of pairs, since a complex may be formed only from molecules oriented in a particular manner relative to one another in the solid phase.

The formation of radical pairs at concentrations lower by 1–2 orders of magnitude than those of isolated radicals takes place in the radiolysis of paraffins, polyolefins, and other polymers which do not contain active functional groups (for example in polyethylene[32], acrylic polymers[44], n-eicosane[45], vinyl monomers[46], etc.). This results in the formation of several types of pairs[12,35,47]. In the given instance one should consider only mechanisms IV and V, because the relaxation of molecular excitation in the condensed phase is very effective and ion-molecule processes play the main role. It has been shown[32] that the introduction of bromodecane into n-decane lowers the yield of radical pairs. The replacement of hydrogen in n-decane by deuterium has a similar influence[34]. This points directly to mechanism V. Reaction Vc may not in fact lead to the formation of an alkyl radical. If it entails the formation of RH and H, the isolated radical is stabilised by reaction IVc.

Many new characteristics of the mechanism of the formation of radical pairs have been observed in the latest studies of the low-temperature radiolysis of olefins and polymers[12,35]. It has been found that, when the radiolysis takes place at lower temperatures (1.5–4 K), then the yield of pairs exceeds that of isolated radicals and virtually all types of radical pairs which can be formed in the crystal cell are in fact formed at concentrations proportional to their statistical weight. The random formation of pairs is in poor agreement with mechanism V, where the third stage is undoubtedly stereospecific and sensitive to the distance over which H^+ or D^+ is transferred. The increase in the yield of radical pairs following the replacement of H and D and with increased length of straight-chain hydrocarbons, functioning as boundary lines limiting the free migration of H or D, also supports mechanism IV. However, the mechanism of the temperature dependence of the migration of H and D following irradiation remains incomprehensible. Similarly, it has been deduced[12,36] that there is a specific mechanism of the formation of compact pairs on the basis of the observation that the yield of pairs with a small distance between the radicals exceeds the random yield.

It has been shown[36] that irradiation with large doses at 77 K is characterised by yet another interesting feature. Despite the high overall concentration of radicals, randomly formed radical pairs are absent from the system. The concentration of pairs increases synchronously with increase of the concentration of radicals, while the formation of radical pairs should have led to the observation of a quadratic relation at higher concentrations. A "protective" mechanism begins to operate, preventing the formation of new radicals within a sphere having a radius of 10 Å around a radical which has been stabilised. In frozen solutions of stable radicals at the same concentration randomly formed pairs are stabilised at concentrations corresponding to normal statistics.

3. Steric Distribution of Radicals on Radiolysis

Data for the formation of radical pairs on radiolysis can be used to determine the complete picture of the steric distribution of radicals in irradiated solids. Studies of the role of track effects in the steric distribution of radicals, carried out by the electron spin echo method[47,48], have shown that on γ-radiolysis the overlapping of tracks begins for very low doses (~0.1 Mrad). Consequently, for the usually employed doses of 1-100 Mrad, the role of track effects may be neglected and the distribution of species throughout the specimen may be regarded as uniform. On the other hand, the data presented in the previous section demonstrated the appreciable role of pair stabilisation in the steric distribution of active centres. Furthermore, it has been shown[12,35] that, when the radiolysis is carried out at 1.5 and 4.2 K, 91% of the radicals in $C_{10}D_{10}$ are stabilised in pairs. All possible types of pairs are formed with equal probabilities from 26 nearest adjoining molecules, i.e. the distribution with respect to distances is virtually rectangular:

$$\frac{dc}{dr}=\begin{cases}0 \text{ when } r<2.5\text{Å} \text{ and } r>30\text{Å}\\ \dfrac{c}{r_{\max}-r_{\min}} \text{ when } 2.5\text{Å}<r<30\text{Å}\end{cases}, \tag{4}$$

where $r_{\min}$ and $r_{\max}$ determine the set of possible distances r_{av} between arbitrarily selected nearest C-H bonds. In other words, there is a random distribution in pairs. The form and width of their distribution depends on the irradiation temperature and on the isotopic concentration of the substance: with increase of temperature and following the replacement of $C_{10}D_{10}$ by $C_{10}H_{10}$, the width increases. Furthermore, in all cases the formation of pairs is accompanied by destruction and valence migration reactions[12,35] which necessitate a correction to the initial distribution. The distribution widens in the direction of higher values of r_{av} and there is partial "annealing" of pairs with small values of r_{av}. It is of interest that in polyethylene and in $C_{10}H_{10}$ the form of the distribution is independent of the dose up to 330 Mrad. The situation is different in the γ-radiolysis of dimethylglyoxime,[49] where the distribution of isolated radicals changes with increasing dose, which is manifested by an increase in the order of the recombination reaction from first to second. Thus, on low-temperature radiolysis, the radicals are initially distributed at random in pairs.

4. Conditions Governing the Stabilisation of Radical Pairs in the Matrix

The formation of radical pairs involves primarily the generation of non-equilibrium defects. Their relative stability is determined by the partial rearrangement of the molecule and the matrix. The recombination of radicals in the pair is activated even in those cases where the radical centres are nearest neighbours. The rearrangement of the matrix, stabilising the radical pairs, should seemingly cause a scatter of the parameters of the radical pairs (the distance r_{av} and orientation). However, the EPR spectra of radical pairs described in the literature indicate a surprising constancy of the distance between the radicals. For the $\mathrm{Ph^{\bullet}...CH_3^{\bullet}}$ pair, it is possible to record a hyperfine splitting of the β-protons of the phenyl radical with a constant of 3 G.[24] This implies that the scatter of the parameters should be less than 3 G, i.e. less than 3% and the scatter of r_{av} should be less than 1%, i.e. 0.06 Å. A similar situation obtains if one assumes also a greater scatter of r_{av} but with a sharp extremum at r = 6.2 Å.

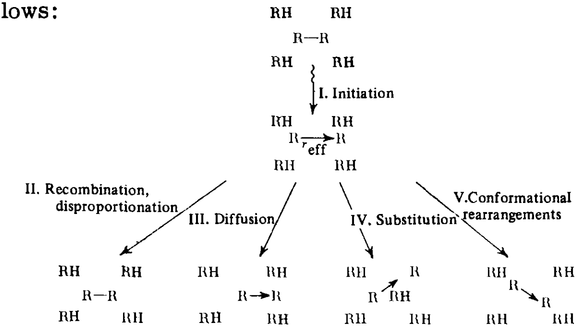
The pairs of iminoxy-radicals arising in dimethylglyoxime single crystals on radiolysis at 77 K have structural parameters close to those in the undamaged structure of the crystal[21]. Even when "large" water molecules are evolved in the formation reaction[50], the scatter of the distances is less than 1%. However, in this case a broad background line is generated and probably includes the spectra of the radical pairs stabilised in the defect regions with several different distances between the radicals, i.e. a distribution with respect to r_{av} with a sharp extremum is observed. In glassy solutions the stabilisation conditions must reflect the inhomogeneity of the matrix structure. Thus the EPR spectra of allowed transitions in frozen solutions of certain acyl peroxides[51] are more broadened, apparently owing to the presence of a distribution with respect to r_{av}. Tetraphenylhydrazine, where radical pairs with fixed distances between the radicals are observed even in frozen solvents, is an interesting example. The sterically branched tetraphenylhydrazine molecules probably generate a solvent structure in their vicinity. On the other hand, in the decomposition of "ribbon" molecules, which generate a solvent structure less effectively, a distribution with respect to r_{av} is generated.

An intermediate case between pair formation in the decomposition of a single molecule, on the one hand, and the formation of pairs from two neighbouring molecules is pair generation from "weak" binary complexes[52]. In this case a rectangular distribution [Eqn. (4)] is observed with respect to the distances between the radicals in the pair with $\Delta r = r_{\max} - r_{\min}$ = 0.2 Å. This feature of pair stabilisation has been used to investigate the geometry of the formation of binary complexes—the precursors of radical pairs. The structure of the binary complex of 3,6-di-t-butyl-*o*-quinone with 2,4,6-tri-t-butylphenol, formed on mixing these compounds, has been determined[22] from the EPR spectra of the radical pairs formed on photolysis. The pair stabilisation conditions determine the stereochemistry and kinetics of thermal radical reactions, which are considered in the next section of the review.

IV. THE KINETICS OF ELEMENTARY REACTIONS IN THE "CAGE"

One of the most significant features of solid-phase reactions is the limited mobility of the reacting species or species formed as a result of the reaction. For this reason, the solid may be represented, with an adequate degree of approximation, as a body consisting of compartments ("cages") containing immediately adjoining molecules; the compartments do not interact with one another and for this reason do not average out the properties of the system. The data at present available for the kinetics of solid-phase radical reactions show that virtually all the characteristics of the processes are already manifested on a scale corresponding to a single cage. A radical pair trapped in the cage serves as the ideal probe for the direct measurement of the kinetic constants of elementary reactions in the solid phase. This section reviews the results of such measurements and discusses certain specific conclusions concerning the mechanisms of solid-phase reactions based on them.

The overall mechanism of processes occurring in the cage on formation of radical pairs can be represented as follows:



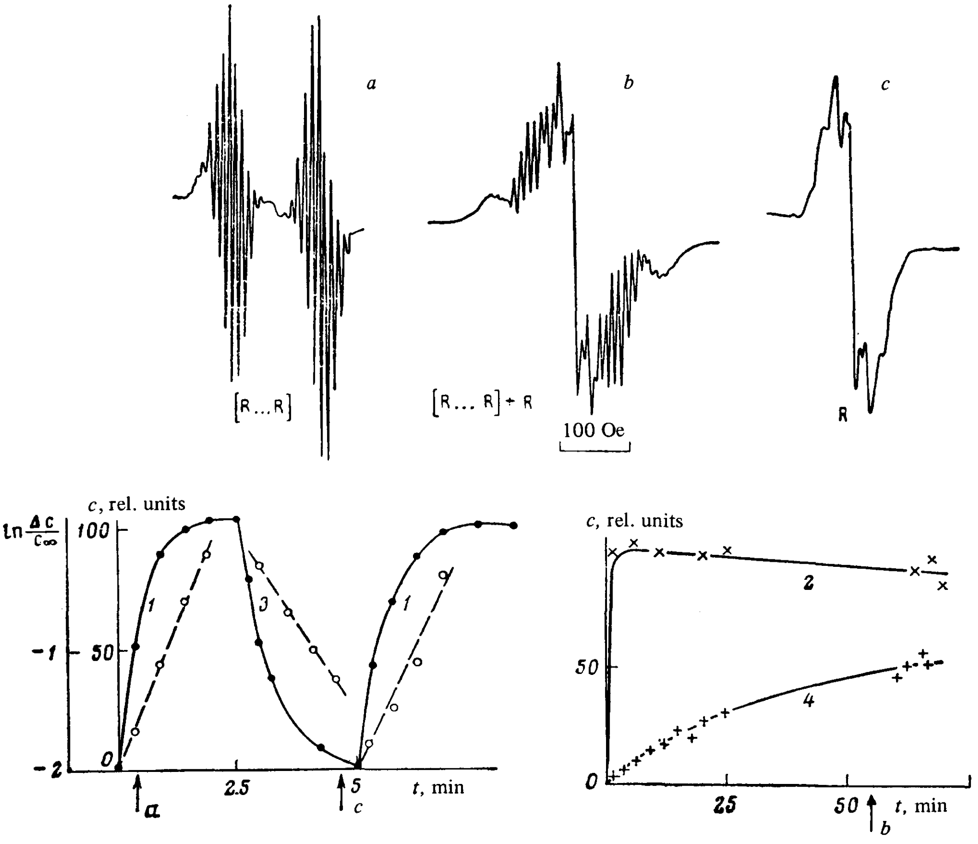


Figure 7. Kinetics of the accumulation (curves *1* and *2*) and destruction (curve *3*) of radical pairs and the accumulation of radicals (curve *4*) in the photolysis of azobisisobutyronitrile at 77 K. The linear forms of the kinetic curves are illustrated by dashed lines in terms of the variables corresponding to an exponential radical destruction law: above—EPR spectra at the instants indicated by arrows on the abscissa axes.

Depending on the ratio of the rate constants for different steps, a particular reaction pathway obtains in each specific system. On photolysis the radical pairs formed largely recombine or disproportionate in the cage and a simplified reaction mechanism can be represented as follows:

$$\begin{tikzcd} M \arrow[r, squiggly, "k_0"] & {[R_1 \ldots R_2]} \arrow[r, "k_2"] \arrow[d, "k_1"'] & R_1+R_2 \\ & M' & \end{tikzcd} \quad . \qquad (5)$$

The radical pairs produced on radiolysis are usually stable at the initiation temperature and on heating it is possible to investigate independently processes II, IV, V. When pairs of stable radicals are used, it is convenient to investigate diffusion processes III.

1. Recombination and Liberation from the Cage

The study of "live" metastable radical pairs, formed on photodecomposition of unstable organic compounds, is of considerable interest for understanding the mechanism of initiation in the solid phase.

On the basis of the simplest mechanism (5) of the photodissociation of molecules in the cage, it is easy to obtain the following expressions from the kinetics of the accumulation of radical pairs (without taking into account the subsequent reactions of isolated radicals):

$$c_{RR} = c_\infty \{1 - \exp[-(k_1+k_2)t]\},$$

$$c_R = \frac{k_2}{k_1+k_2} c_\infty [(k_1+k_2)t - \{1 - \exp[-(k_1+k_2)t]\}], \qquad (6)$$

where $c_\infty = k_0 c_M/(k_1 + k_2)$. It follows from Eqns. (6) that an induction period, approximately equal to the lifetime of radical pairs, should be observed in the accumulation of radicals and that a steady radical accumulation rate should be established subsequently:

$$w_R = k_0 c_M k_2/(k_1+k_2) = f k_0 c_M,$$

where f is the probability of liberation from the cage. Since the initial rate of accumulation of radical pairs $w_{R\ldots R} = k_0 c_M$, it is possible to find the probability of liberation from the cage on the basis of the ratio of the slopes of the linear sections of the experimental curves, while measurements of the absolute rate and the analysis of the radical pair accumulation or destruction curve make it possible to determine all the kinetic constants in Eqns. (5). Experiments of this type have been carried out on the photodecomposition of solid organic initiators—azobisisobutyronitrile,[3,53] azobis-3-methyl-2-phenylbutane,[54,55] tetraphenylhydrazine,[18,24] and a number of acyl peroxides[24,51] At low temperatures (77–100 K, sometimes up to 150 K) EPR spectra can be recorded for crystalline substances and frozen solutions. Some of the results of the kinetic studies are illustrated in Fig. 7. The signal intensities in Fig. 7 are quoted in relative units but account is taken of the shape coefficients of the spectra, so that the values of c_R and $c_{R\ldots R}$ are proportional to the true concentrations. We thus find from Fig. 7 that $f = 2 \times 10^{-2}$ at 77 K for crystalline azobisisobutyronitrile. This value is much less than that obtained from kinetic measurements in solution ($f = 0.5$ according to Kulitski et al.[56]), but is in good agreement with $f = 3 \times 10^{-3}$ calculated for the initiation of polymerisation in the solid phase[57].

Fig. 7 shows that the radical pair accumulation and destruction kinetic curves can be expressed in a satisfactory linear form in terms of semilogarithmic coordinates, i.e. the destruction of radical pairs is indeed a first-order reaction. The rate constant for the destruction of radical pairs in the "cage" in crystalline azobisisobutyronitrile has been measured[58] over the range 63–77 K. Further measurements have been made in tetraphenylhydrazine single crystals. The constants are compiled in the Table.

Kinetic curves for radical pairs and radicals formed in the photolysis of acetylbenzoyl peroxide have been published[51]. The radical accumulation curve shows a distinct inflection associated with the lag in the formation of radicals, in conformity with Eqn. (6). This implies that radical initiation precedes the appearance of isolated (in the given instance methyl) radicals, but the induction period is clearly shorter than the time required for the establishment of a steady-state concentration of radical pairs, i.e. the reaction mechanism is apparently more complex than that described by Eqns. (5).

In the study of processes of the type described the problem naturally arises whether the recombination reactions and the reactions involving liberation from the cage are thermal or whether they are also associated with photoexcitation. In the case of azobisisobutyronitrile the time constants for photoaccumulation and destruction in the dark are the same (Fig. 7), which indicates a thermal mechanism of the recombination reaction. On the other hand, in the case of acyl peroxides, direct data have been obtained indicating the influence of light on the liberation from the cage. For example, when peroxydisuccinic acid is irradiated with light at wavelengths in the range 240 to 400 nm, radicals and radical centres accumulate rapidly, but only pairs are produced in the presence of light corresponding to the 330–570 nm band[51]. The radical pairs in peroxydisuccinic acid are converted into radicals even under the influence of visible light[51]. The kinetics of the destruction of radical pairs formed in the low-temperature photolysis (77 K, 300–400 nm) of mono- and poly-crystalline tetraphenylhydrazine specimens and frozen solutions of tetraphenylhydrazine in toluene have been studied in detail[59,60]. In single crystals the destruction of radical pairs obeys the equation for first-order kinetics. In powders and vitrified solutions the kinetics are of the "stepwise" type, which corresponds to a set of kinetic constants (see Table) with a rectangular distribution with respect to E having a width $\Delta E = 2.3 \pm 1$ kcal mole^{-1} and $\lg k_0 = 12.1 \pm 3$ s^{-1}. Vitrified solutions of tetraphenylhydrazine are interesting in view of the similarity of the experimental conditions to those which really obtain when compounds of this class are used as initiators. It has been shown[60] that the probability of the liberation of radicals from the cage and hence the efficiency of the initiator are negligibly small in the vitrified crystalline state and that the probability is close to unity in the region corresponding to the devitrification of the solution.

In those cases where the reactions take place in the region remote from the phase transition temperatures, the reaction in the cage becomes strongly stereospecific. A set of studies in this field was undertaken by McBride and coworkers[53–55,61]. When asymmetric fragments recombine, the composition of the products is not random but depends on the structure of the cage. Thus in the case of crystalline azobisisobutyronitrile 95% of the photolysis products are formed via radical pairs in undisrupted regions of the crystal and only ~5% may be formed on defects, giving rise to other compounds[61]. In the liquid phase the ratio of product yields is reversed. A study of the photolysis of acetylbenzoyl peroxide has shown that even at low temperatures the products are not just a pair of benzoyloxy- and methyl radicals but also (as a result of decarboxylation) a "phenyl-methyl radical" pair. This gives rise to a large set of recombination products which may be formed in the cage. However, the structure of the cage facilitates the interaction of the methyl radical with oxygen forming part of the peroxide chain before decomposition, which leads to the selective formation of products[51].

2. Substitution and Disproportionation Reactions in the Cage

At low temperatures, where the diffusional mobility of large molecules is frozen, reactions of the type

$$R + RH \rightarrow RH + R, \qquad (7)$$

which are capable of ensuring the migration of the valence over considerable distances, acquire particular importance. Such reactions may occur both on heating and under the influence of light. However, direct measurement of the kinetic constants for reaction (7) became possible only when radical pairs were used, because there is no change in chemical structure during the reaction and only the coordinate of the active centre is altered. Reactions of type (7) were first investigated in detail in γ-irradiated dimethylglyoxime and $\{[D_2]$dimethylglyoxime [31,62]$\}$. The rate constants, the kinetic isotope effects, the direction of migration, and hydrogen migration distances were measured. The experimental results are presented in Fig. 8 and in the Table. A characteristic feature of the thermal valence migration reactions is their stereospecificity—the anisotropy of the directions of valence migration. The sensitivity of reactions to weak intermolecular interactions is a no less interesting feature. Thus it has been observed[31] that at low temperatures (77–120 K) intramolecular migration of hydrogen via one of two pathways, equivalent as regards the direction in the crystal, the distance traversed, and the chemical structure of the radical fragments, is observed. It is apparently due to the ability of iminoxy-radicals to form hydrogen bonds with the molecules of the medium or with one another.

In those cases where there are no interactions of this kind or their energy is low compared with the activation energy for the migration reaction, a dynamic equilibrium is observed between two positions of the active centre. In dimethylglyoxime[31] such migration reactions are observed at higher temperatures (270–320 K). There is intermolecular migration of a hydrogen (deuterium) atom, which can be located in two closely adjacent positions with equal probabilities; this is manifested when the EPR spectra of two types of radical pairs are recorded. A similar behaviour has been observed in studies[30,52] of the photolysis of frozen solutions of 2,4,6-tri-t-butylphenol and 3,6-di-t-butyl-*o*-benzoquinone, which form a weak complex (see Section III). The transfer of a hydrogen atom from phenol to quinone leads to the formation of radical pairs of two types, which arise owing to the intramolecular exchange between the two carbonyl groups of *o*-quinone.

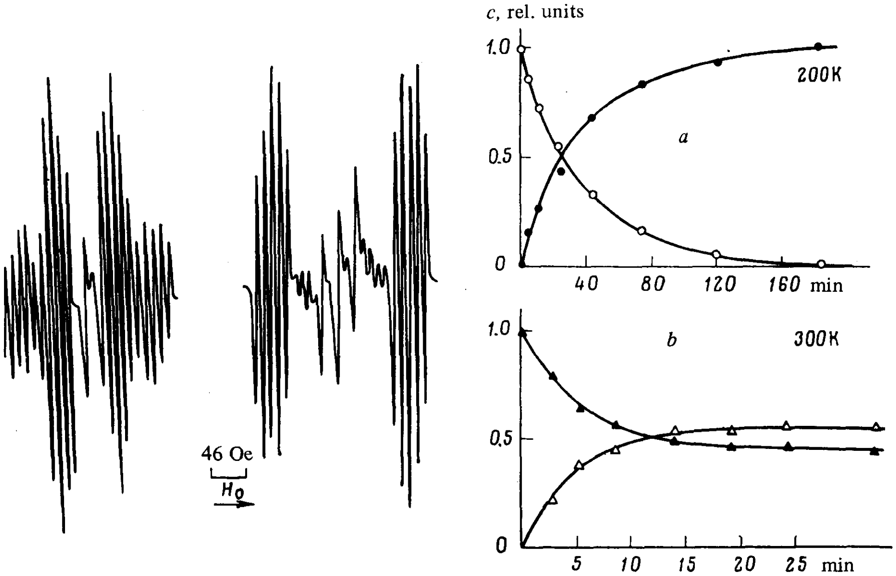

Figure 8. Kinetics of intramolecular (*a*) and intermolecular (*b*) substitution reactions (R...HR) → (RH...R) in γ-irradiated $[D_2]$dimethylglyoxime (*a*) and non-deuterated dimethylglyoxime (*b*): on the left—transformation of the EPR spectra of the radical pairs in the course of the intramolecular substitution[31].

Notation: r_1 and r_2 are the distances between the radicals before and after the process, E (kcal mole^{-1}) and k_0 (s^{-1}) are the Arrhenius parameters of the rate constant, f is the probability of liberation from the cage, ΔT is the temperature range, and E_1, k_{01}, E_2, and k_{02} are the parameters for low and high degrees of conversion respectively.

Under the influence of ultraviolet light, migration reactions are also observed in γ-irradiated dimethylglyoxime crystals at 77 K.[63] However, they are non-stereospecific and proceed via several pathways simultaneously. Irradiation with light apparently leads to electronic excitation of the radicals, which react in the excited state either with a neighbouring radical (destruction of the pair) or with a neighbouring molecule (valence migration).

Disproportionation reactions have much in common with valence migration reactions of type (7). As a rule, they exhbiit a kinetic isotope effect[31,52,62]. The stereochemistry of the disproportionation of radical pairs has been examined[57] and it has been shown that the pathway followed in the transfer of hydrogen from the quinone radical to the phenone radical during "annealing" does not coincide with the channel in phototransfer or during formation. The rate of reaction is then extremely sensitive to the distance traversed and a distribution with respect to distances leads to a distribution with respect to rate constants.

3. Characteristics of the Kinetics of Elementary Reactions in the Cage

The kinetic constants found from the EPR spectra of the radical pairs are compiled in the Table. Evidently even in those cases where the reaction is elementary, i.e. the kinetics satisfy a first-order equation, the Arrhenius parameters differ sharply from the "usual" values for analogous reactions in the gas and liquid phases. In vitrified and powdered matrices the reaction kinetics are "polychromatic" and are described by a spectrum of kinetic constants. These features are in general characteristic of the kinetics of radical reactions in solids[59,64-67] and are apparently of key importance for the understanding of their mechanism. For radical pairs, it is possible to achieve the closest approach to the elementary stages of the process. It will be shown below that in many instances this has made it possible to understand the nature of the observed phenomena.

Tunnel transfer of hydrogen. From the kinetic point of view, rapid thermally activated migration reactions, occurring in dimethylglyoxime at low temperatures, are of particular interest. The measured dependence of the rate constants on temperatures obeys the Arrhenius equation. However, the pre-exponential factors for unimolecular reactions vary over a wide range, from several reciprocal seconds (for a reaction at the temperature of liquid nitrogen) to normal values of 10^{13} s^{-1} at 300 K, and there is a linear compensation relation between $\lg k_0$ and E. The migration reactions investigated are characterised by considerable kinetic isotope effects. Low pre-exponential factors for the low-temperature reactions and the anomalously large kinetic isotope effect indicate a tunnel reaction mechanism. If the rate of the process is estimated in terms of the reaction [RH...R] → [R...HR] for a continuous distribution of the vibrational levels of the bond being ruptured, then the experimental points corresponding to a barrier half-width $d_{1/2}$ = 0.6 Å, E_H = 15 kcal mole^{-1}, and E_D = 16 kcal mole^{-1} fit satisfactorily on theoretical curves (Fig. 9). In order to illustrate the relation between the true and apparent activation energies, "Arrhenius" straight lines have been drawn through the experimental rate constants in Fig. 9. Evidently the unjustified linear extrapolation yields in this case unduly low values of E and k_0 and for deuterated dimethylglyoxime higher pre-exponential factors correspond to higher values of E, i.e. a compensation effect is observed. Subsequently the occurrence of hydrogen transfer via a tunnel mechanism at low temperatures was confirmed by numerous experimental investigations (see the review of Lebedev et al.[69]).

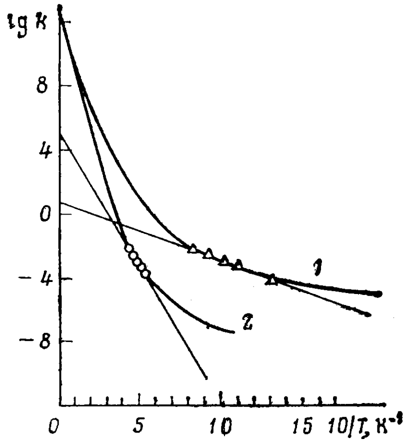

Figure 9. Calculated and experimental temperature dependences of the rate constants for the reaction (R...RH) → (RH...R) in dimethylglyoxime (curve *1*) and [D$_2$]dimethylglyoxime (curve *2*). The calculation was carried out taking into account the tunnel transitions for the quasi-continuous distribution of the vibrational levels of the dissociating bond corresponding to a barrier half-width $d_{1/2}$ = 0.6 Å and barrier heights E = 15 and 16 kcal mole^{-1} respectively[62]. Evidently in the temperature range of the measurement it is possible to draw straight lines through the experimental points, whose slope yields the apparent activation energy $E_{\text{eff}} \ll E$.

Polychromatic reactions. In most radical reactions occurring in the solid phase at low temperatures, a kinetic arrest of the reaction (i.e. a sharp reduction of its rate) is observed for a certain degree of reaction. The stepwise nature of the recombination is usually accounted for by the fact that the reacting centres are non-equivalent and that a set of reaction rates obtains. Several hypotheses explaining such distribution of properties have been put forward[64-67,69]: (a) structural inhomogeneity of the specimen; (b) the presence of a distribution with respect to the distances between the reacting species; (c) an increased local concentration of radicals at the sites of defects; (d) thermal chain recombination†. The last two possibilities are known to be negligible for radical pairs. The distribution of properties in the case under consideration may be due either to the structural inhomogeneity of the specimen or to the stabilisation of radicals separated by different distances.

---

†Thermal chain recombination is the chain destruction of free radicals activated by the energy liberated in the elementary recombination step.

A correlation has been observed[34] between the distance in the radical pair obtained on γ-radiolysis of $C_{10}D_{22}$ and their destruction temperature. It has been possible to establish directly[52] the relation between the rate constant (activation energy) for the reaction and the distance between the reacting radicals in the cage. In frozen solutions of quinones and phenols a change in the parameter D, i.e. in the distance between the radicals, was observed in the course of the stepwise "annealing" of radical pairs, associated with the disproportionation of radicals in the cage. An increase of D by 0.2 Å corresponded to an increase of the activation energy for the reaction by 3.3 kcal $mole^{-1}$. In polycrystalline n-decane the variation of the distance between the radicals in the course of their recombination was investigated by the method involving the saturation of forbidden transitions (Fig. 10). It has been shown[36] that the activation energy for recombination increases approximately linearly with distance in the range 6–8 Å.

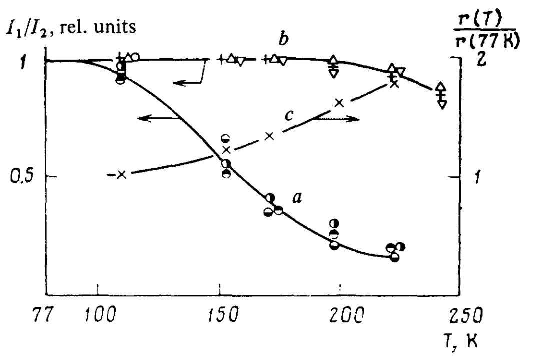

Figure 10. "Annealing" of the EPR signals of radical pairs (a) and isolated radicals (b) in γ-irradiated polycrystalline n-decane; c) variation of the minimum distance between the radicals during "annealing". Analysis of curves a and b shows that the effective activation energy for the recombination reaction increases linearly with distance[36].

However, the scatter with respect to distances is not the only cause of the existence of a set of rate constants for the reaction in the cage. In many instances the stepwise reaction is not accompanied by a change in the parameter D. This implies the existence of kinetically non-equivalent cages owing to a difference in the immediate environments of the reacting molecules. The direct influence of the inhomogeneity of the matrix on the reaction kinetics has been demonstrated[67,70]. It has been shown that in oriented polyethylene the kinetics of the destruction of a radical pair with r_{av} = 5.3 Å, studied on the basis of the spectrum of an allowed transition, are distinctly "stepwise" and the scatter of the constants is very wide. This observed feature has been followed consistently in experiments using tetraphenylhydrazine[59,60] where the recombination of pairs with the same distances between the radicals in single crystals obeys a simple first-order law, while in vitrified and crystallised solutions and in crystalline tetraphenylhydrazine powder the destruction kinetics become stepwise (Fig. 11). The results described demonstrated probably for the first time that the stepwise kinetics of solid-phase reactions are due to the scatter of the properties of the medium at the level of the kinetic cage.

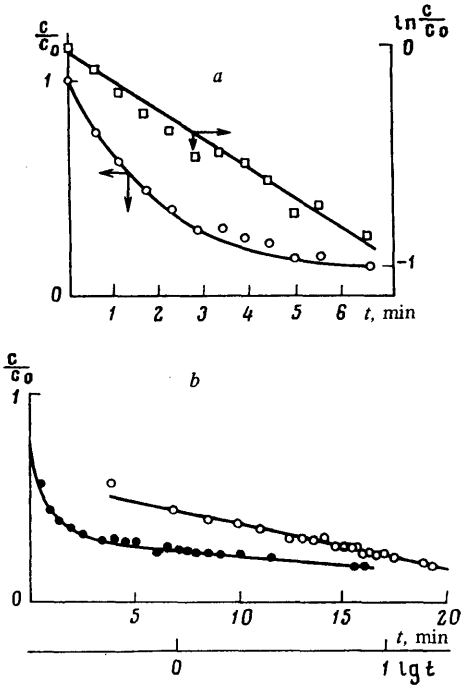

Figure 11. Kinetics of the "merging" of the radical pairs in single crystals (a) and in a polycrystalline solution of tetraphenylhydrazine in toluene (b). In the former case the kinetic curve is described by an exponential function and in the latter by a linear relation with lg t, which indicates the existence of a broad spectrum of rate constants[59].

The existence of cages with different immediate environments in vitrified solutions is not particularly surprising. However, the stepwise nature of the destruction of radical pairs in powdered specimens requires special consideration. The four types of radical pairs formed in the decomposition of four molecules with different orientations are magnetically non-equivalent in tetraphenylhydrazine crystals. In polycrystalline specimens the pairs are spectroscopically identical, but the exponential kinetics of the destruction of radical pairs of each type are characterised by different rate constants[59]. By measuring the overall concentration of pairs of all types, we can observe complex first-order kinetics—stepwise destruction. An analogous behaviour has been observed in the "annealing" of radical pairs in 2,4-dinitrophenol. Analysis of the spectra revealed two sets of magnetically non-equivalent radical pairs and the destruction kinetics in powders became satisfactorily linearised on the assumption that there are two exponential destruction rate constants. Thus the EPR spectra of radical pairs in crystalline solids allow the resolution of kinetically non-equivalent states of radical pairs (with a fixed distance). This makes it possible to investigate the relation between the structure of the cage and its dynamic properties.

V. CONFORMATIONAL AND MOLECULAR MOBILITY IN SOLID MATRICES

The data described above confirm that the reactions in solid matrices are controlled by or at least depend strongly on molecular motions in the cage. For this reason, the simultaneous investigation of elementary molecular motions (translational displacement, rotation, reorientation, and conformational rearrangements) and chemical reactions is a very important task. The spin probe method[71–73] is not very effective for such purposes, since in most cases the reactions are "unfrozen" at very low frequencies of molecular motions when the EPR spectra of the paramagnetic label of the probe do not yet show any changes. The recombination-kinetic method[65] permits the detection of slow molecular motions but it yields only indirect information about the elementary motions, since it is based on the measurement of the rate of the overall recombination of radicals. The use of radical pairs as two-spin probes in the matrix leads to the possibility of the direct investigation of the dynamics and stereochemistry of slow molecular motions.

1. The Study of Phase and Structural Transitions

For compact radical pairs, the recombination of active centres does not require translational diffusional displacements and pair labels are presumably extremely sensitive to local molecular motions. It has been shown[74] that the different stabilities of radical pairs in polymers are of interest from the standpoint of the detection of phase and structural transitions (Fig. 12). Fig. 12 shows that the heating curve for $\Delta M_S = 2$ signals has inflections indicating structural changes in the polymer, i.e. phase transitions slightly "modulate" the curve for the distribution of the pair recombination activation energies. Inferences can be drawn about the structural and phase transitions by measuring the distances between the radicals r_{av} over a wide range of temperatures for any type of pairs which are stable at high temperatures. In the absence of transitions a dependence reflecting simply the linear expansion of the crystal will be obtained[75].

2. Translational Mobility

The frequency of translational motion can be determined directly from the EPR spectra of radical pairs because the liberation of the radical from the cage and its migration over a distance corresponding to one cage diameter lead to the disappearance of the spectrum of the radical pair and to the appearance of signals due to the isolated radicals. The kinetics of the liberation of the diphenylnitrogen radical from the cage have been investigated[60] for the devitrification of frozen solutions in toluene. The characteristic times of the liberation of the radical from the cage $\tau \simeq 10$ s makes it possible to estimate the frequency of translational motion in the liquid phase $\nu_{tr} \gtrsim 10^{-1}$ s^{-1}. To refine the estimate, the EPR spectra of frozen solutions of the stable 2,2,6,6-tetramethyloxopiperidin-1-yloxy-radical in toluene were recorded. Since a change in the form of this spectrum was not observed on devitrification, the upper limit to the rotational frequency is $\nu_{tr} < 10^8$ s^{-1}.

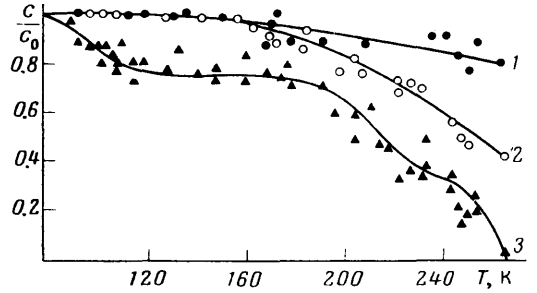

Figure 12. Heating curves for alkyl radicals (curve *1*), a mixture of alkyl and peroxy-radicals (curve *2*), and radical pairs (curve *3*) in polyethylene. The inflection points in the range 160–260 K correspond to structural transitions in the crystalline phase[74].

Yet another interesting possibility of investigating elementary translational motions arises when one employs the stable radical pairs formed as a result of the random entry of radicals into a single cage on dissolution of nitroxy-radicals at high concentrations (0.01–0.1 M).[76] The $\Delta M_S = 2$ transitions at half field (see Section II) are then distinctly observed despite the existence of a more intense $\Delta M_S = 1$ signal due to the isolated radicals.

When the translational mobility is "unfrozen", the number of pairs of chemically stable radicals remains unchanged and is statistically determined, though the lifetime of an individual pair diminishes, since it is determined by the average residence time of the radical in a "settled" position, i.e. the correlation time for translational motion τ_{tr}. This leads to the modulation of the values of r_{av} and α, and, in conformity with Eqn. (2), to the modulation of the intensity of the $\Delta M_S = 2$ transition with a frequency τ_{tr}^{-1}. As a result, the EPR line should become broadened by an amount $1/\gamma_{tr}$, i.e. it becomes possible to measure the frequencies of the translational jumps executed by the radical[76]. A rigorous calculation of the line form fully confirmed this simple picture[77].

A study has been made[76] of the EPR spectra of solutions of 2,2,6,6-tetramethylpiperidinyl-1-oxy-radicals in liquid paraffin and toluene at a concentration of (1–5 (1–5) $\times 10^{19}$ cm^{-3}. The temperature variation of the EPR signal is illustrated in Fig. 13. Evidently the intensity of the forbidden transition diminishes, but the line width hardly increases. Such behaviour of the line cannot be accounted for within the framework of relaxation theory[77] and indicates the existence of a set of very different frequencies of translational motions τ_{tr}^{-1}. In this case the $\Delta M_S = 2$ signal represents, as it were, a superposition of lines with very different widths; only the narrowest line, corresponding to the signal due to cages where the jump frequency is a minimum, is recorded. Thus polychromatic kinetics are characteristic not only of chemical reactions but also of elementary motions in the solid. This agrees well with the model of kinetically non-equivalent cages, which is nowadays resorted to for the interpretation of a wide variety of processes in the solid phase[65-67,69].

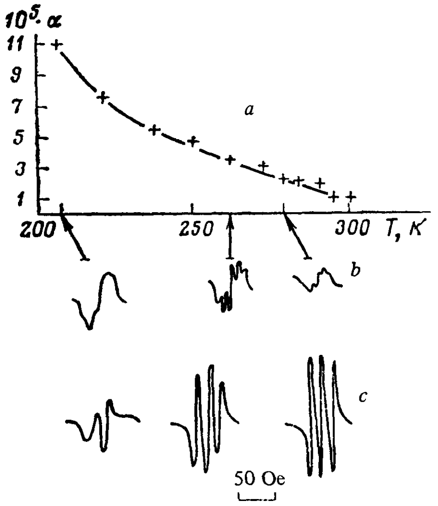

Figure 13. Temperature dependence of the relative intensity (*a*) and form of the EPR spectrum (*b*) for the $\Delta M_S = 2$ transition involving stable radical pairs in liquid paraffin; *c*) EPR spectra of single crystals ($\Delta M_S = 1$). The decrease of the $\Delta M_S = 2$ signal intensity without an increase in line width indicates the presence of a broad spectrum of frequencies of the translational displacements of radicals[76].

3. Rotational Mobility

If a two-spin system is sufficiently rigid (biradicals, triplet molecules, radical pairs formed from complexes), then effects completely analogous to those described above will be observed as a result of rotational mobility[76]. The orientational spin probe method is of particular interest in this instance[78]. Signals due to species where the tensor axis D is oriented mainly in one direction can sometimes be isolated with the aid of the magnetophotoselective effect described in Section III or as a result of strong magnetic fields[79]. This makes it possible, in principle, to investigate the kinetics of the rotational disorientation of species with very long correlation times[76]. Measurements performed by this method have also shown that, in vitrified solutions and in polymers, the rotational motions of molecules are polychromatic, i.e. take place with different frequencies in different cages. One of the important problems which investigators have attempted to solve in this manner consists in the choice between two types of elementary motion: rotation in very small random jumps (rotational diffusion) or rotation in large non-correlation jumps. Two different models of elementary processes in the solid phase correspond to these two types of motion: the quasi-crystalline and free-volume models[80]. However, it has not so far been possible to make a final choice (based on experimental data).

4. Conformational Rearrangements

Since the orientation of the reactive groups in molecules is specified by the matrix structure, the study of the dynamics of intra- and inter-molecular rearrangements in the crystal is an essential stage in the investigation of the mechanisms of elementary solid-phase reactions. Fundamentally new possibilities arise in the study of the EPR spectra of radical pairs. In this case the second radical plays the role of a paramagnetic label and a change in the orientation of the radical (or its fragment) leads to a change in the radius-vector of the radical pair r_{eff} and to a marked alteration of the magnetic parameters of the EPR spectrum.

We investigated in detail the structural transformations of iminoxy-radicals in a γ-irradiated 2,4-dinitrophenol matrix at 77 K (Fig. 14),[41,81] and showed that radicals and radical pairs are formed in non-equilibrium conformations with different magneto-relaxation characteristics and thermal stabilities. When the specimens are heated, structural relaxation of two types is observed. In the first, structural transition, there is an appreciable change in the geometry of the CNO fragment due to the difference between the C–N–O angles in the nitrophenol molecule and the iminoxy-radical. The hyperfine interaction constants are also altered and two types of radical pairs are formed with $r_{\text{av}} = 4.8$ Å, differing in the orientation of the inter-electron vector in the cell by 5°. On further heating, the radical changes its orientation in the crystal cell slightly, the structure of the fragment being retained. The kinetics of the structural transitions in radicals are consistent with a first-order reaction. The reactive groups are displaced abruptly over small distances (~0.2 Å). The rearrangements give rise to structurally non-equivalent states, which affects the kinetics of the recombination of radicals in the pairs. The kinetics are more complex—the kinetic curve for powders can be fitted by two exponential functions (see Table).

Thus even a small difference in the structure causes a marked alteration of the recombination rate constant. This characteristic is of interest primarily because the occurrence of a large number of intermediate elementary rearrangements can be the reason for the polychromatic kinetics of the recombination reactions. A characteristic feature of the processes investigated is the presence of kinetic isotope effects in the entire chain of transformations, although conformational transitions and recombination involve radicals which do not contain H or D. This demonstrates the major role of the matrix and particularly of hydrogen bonds in the mechanism of radical reactions in 2,4-dinitrophenol. Thus, when the hydroxyl proton is replaced by a deuteron, the rate of the second transition, consisting in the rotation of the molecule as a whole, increases. This may be accounted for by a decrease of the stability of the crystal in parallel with the decrease of the energy of hydrogen bonds when a hydroxyl hydrogen atom is replaced by a deuterium atom in the nitrophenol. The large isotope effect in the recombination reaction (see Table) may be caused by the formation of intermediate complexes of the radicals with the water molecule evolved on radiolysis and captured by the matrix.

The existence of a definite analogy between the conformational relaxation processes considered here and the mechanism of the functioning of complex molecular systems (protein enzymes) is noteworthy[82]. For protein enzymes, it is assumed that, after the formation of a substrate-enzyme complex, rapid relaxation of the active centre takes place directly and is followed by a slow relaxation of the macromolecule. Presumably the behaviour of the hydrogen-bonded molecules in the nitrophenol crystal is to some extent analogous to that of protein macromolecules. Since a molecular crystal is a significantly simpler system than protein, it is possible to interpret in detail the relaxation transitions in this instance.

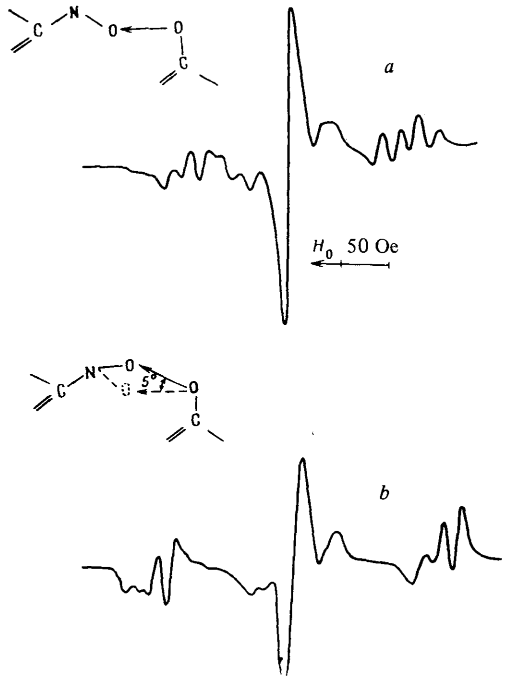

Figure 14. Variation of the EPR spectrum of the "iminoxy–phenoxy"-radical pair in γ-irradiated 2,4-dinitrophenol due to the relaxation of the structure of the CNO fragment. Spectra *a* and *b* were recorded at 77 K and after heating for 10 min at 190 K respectively. Their interpretation is analogous to that illustrated in Fig. 3. In spectra *a* and *b* the C–N–O angle corresponds to the structure of the undamaged molecule and to the equilibrium structure of the iminoxy-radical respectively[81].

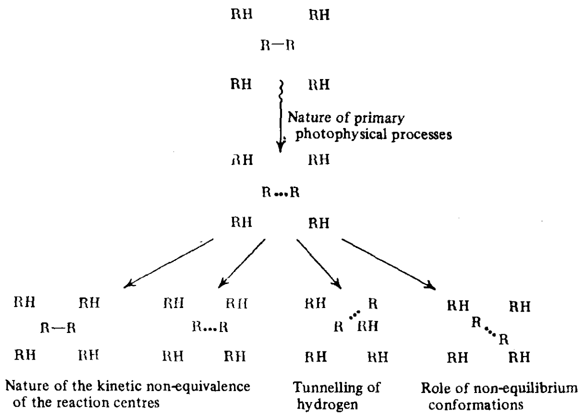
oOo

During the decade since the detection of metastable radical pairs, kinetic studies in this field have greatly extended our ideas about the physicochemical foundations of the kinetics of solid-phase reactions. On the basis of the reaction scheme presented at the beginning of Section IV for radical pairs, the most important results of this research can be formulated as follows:



We believe that the demonstration of the kinetic non-equivalence of radicals at the level of the cage, the demonstration of the role of tunnel transitions and conformational changes in solid-phase reactions, and the development of methods for the investigation of the "stereometry of reactions", based on the unique sensitivity of the EPR spectra of radical pairs to changes in the inter-radical vector, are of greatest value. One may hope that further studies in these fields will help to formulate the fundamental characteristics of chemical processes in solid organic substances at least at the level already attained for reactions in the gas phase and dilute solutions.

A completely new field in research on short-lived radical pairs has been initiated recently[83,84]. The results of the latest studies on the structures and spectroscopy of radical pairs, which were not specially considered in this review, may be found in other publications[85-92].

Dynamics of Degenerate Tautomerism in Free Radicals

N.N.Bubnov, S.P.Solodovnikov, A.I.Prokof'ev, and M.I.Kabachnik

The theoretical principles of the application of the EPR method in the study of the kinetics of exchange processes involving free radicals and radical-anions are described and the results of studies by the EPR method of the tautomeric transformations in radicals and radical-anions, accompanied by the migration of atoms, cations, and organic and organoelemental fragments, are examined.

The bibliography includes 73 references.

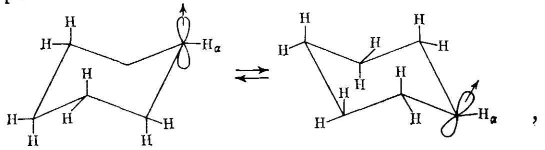
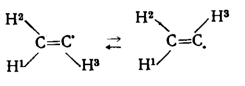
I. INTRODUCTION

In the present review an attempt is made to survey the results of kinetic studies by the EPR method of tautomeric transformations in free radicals and radical-anions or more precisely the reversible intramolecular migrations of atoms and organic or organoelemental fragments between equivalent (or almost equivalent) positions in the molecule and of the cations in pairs formed with radical-anions. Such migration is accompanied by a synchronous redistribution of the unpaired electron density, which leads to a change in the EPR spectra of the species investigated. The application of the EPR method to the study of phenomena of this kind is based on the analysis of the line width in the hyperfine structure (HFS) of the EPR spectra, which frequently proves to be extremely sensitive to changes in the rates of tautomeric transitions. When applied to such processes, the EPR method provides unique possibilities for the investigation of the kinetics of many rapid transitions, the characteristic times of which are in the range between 10^{-6} and 10^{-10} s. There are several types of effects leading to a change in line width, but, for the problems discussed in this review, the most valuable information can be obtained by analysing the so called alternation of line widths in EPR spectra. This effect was observed in 1962 by Bolton and Carrington[1] and independently by Freed and Fraenkel[2]. In the Soviet Union, one of the first investigators to understand this phenomenon was V.V.Voevodskii, under whose supervision research was carried out at the beginning of the 1960s on the inversion isomerisation of the cyclohexyl radical of the chair–chair type[3]:



the *cis–trans* isomerisation of the vinyl radical[4]:



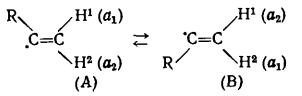
and the delocalisation of the unpaired electron in bridged radical-anions[5] $[\mathrm{Ar{-}X{-}Ar}]^{\overline{\cdot}}\mathrm{M}^{+}$. By analysing the alternation of line widths, it is possible to obtain extremely valuable information about the kinetics of various processes with participation of paramagnetic species. During recent years the method of analysis of line widths in EPR spectra has been closely applied in the study of processes such as the isomerisation of radicals, conformational transitions, electron and proton exchange reactions, and the tautomerism of free radicals and radical-ions.

Before discussing the results of these studies, we shall consider briefly the theoretical principles of the application of the EPR method to the study of the kinetics of exchange processes involving free radicals.

II. THEORETICAL PRINCIPLES

1. Qualitative Considerations

The alternation of line widths in EPR spectra is interpreted on the hypothesis that the hyperfine interaction (HFI), caused by some intermolecular or intramolecular processes, is modulated. We shall consider initially the simplest case where the radical contains only two nuclei with a spin $I = 1/2$. As an example we shall consider the vinyl radical:



Suppose that the HFI constant $a_2 > a_1$. If the radical does not isomerise or the rate of isomerisation is very low, the EPR spectrum corresponds to the picture presented in Fig. 1*a*, where the positions of lines relative to the centre of the spectrum and the spin states of the protons H^1 and H^2 are represented in a conventional manner.

We shall examine the change in the spectrum with increase of the rate of mutual transitions between forms (A) and (B). At first sight, it may appear that both forms of the radicals are identical and therefore there should be no change in the spectrum on transition from one form to the other. However, when account is taken of the spin state of the protons, this is not found to be the case. On passing from form (A) to form (B), the constants a_1 and a_2, corresponding to HFI with the H^1 and H^2 protons in the initial form, correspond in form (B) to HFI with the H^2 and

H^1 protons or, in other words, the protons as it were change places. If the constants a_1 and a_2 in the expressions $\pm\frac{1}{2}(a_2 \pm a_1)$, which characterise the positions of the lines in the spectrum, are made to change places, then it is readily seen that the extreme lines remain in the same positions, while the inner, central components change places or frequency exchange is said to take place. From this very simple picture follows a very important rule, according to which only lines corresponding to identical overall projections $[M_I(H^1) + M_I(H^2)]$ of proton spins undergo frequency exchange.

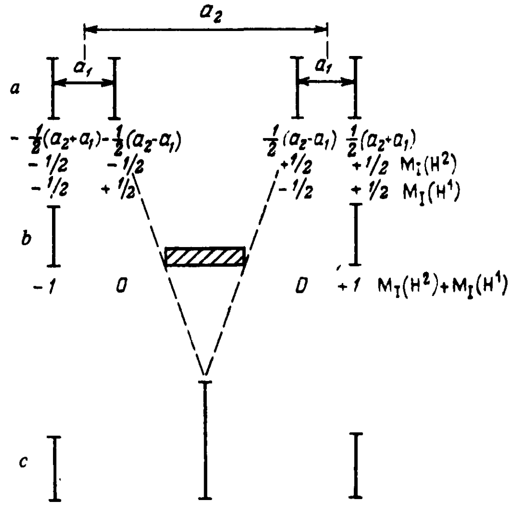


Figure 1. Schematic illustration of the EPR spectrum of an R-substituted vinyl radical: *a*) slow exchange; *b*) intermediate exchange; *c*) fast exchange.

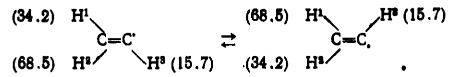
If the rate of isomerisation is not too high, such frequency exchange leads to the broadening and merging of the central components, which is indicated in Fig. 1*b* by the shaded rectangle. In the limiting case of rapid exchange so-called exchange narrowing takes place and the spectrum consists of a triplet with intensity ratios of 1 : 2 : 1 (Fig. 1*c*). A necessary condition for the above picture of the changes in the EPR spectrum as a function of the frequency of the isomeric transition to be valid is antiparallel changes in the two HFI constants a_1 and a_2, i.e. it is necessary that they should be anticorrelated. Indeed this condition holds for the given radicals. While HFI with the H^1 proton becomes more intense, that with the H^2 proton is weakened. As we shall see subsequently, this situation is very frequently encountered in practice.

On the basis of the behaviour of the EPR lines, analysed above, in the spectrum of an R-substituted vinyl radical, it is easy to understand the variations in the EPR spectrum of the unsubstituted vinyl radical under different conditions in the recording of the spectrum. If the radical is obtained at 77 K by the reaction of a hydrogen atom with acetylene[4], an eight-line spectrum (illustrated in Fig. 2*a*) is observed, in agreement with the hypothesis that there are three non-equivalent HFI constants: a_2 = 68.5 G, a_1 = 34.2 G, and a_3 = 15.7 G.



If the same radical is obtained in the liquid phase[6], then the spectrum shows only four lines corresponding to the extreme lines of the low-temperature spectrum. Such transformation of the spectrum can be understood if it is assumed that the two isomeric forms of the radical are involved in rapid interconversion in solution, which leads to the antiparallel modulation of the HFI constants for the H^1 and H^2 protons. For the radicals where the orientations of the nuclear spins of the H^1 and H^2 protons are the same ($\alpha_1\alpha_2$ or $\beta_1\beta_2$), the transition from one tautomeric form to another does not entail a line shift, and for this reason the extreme lines remain narrow. The lines corresponding to the $\alpha_1\beta_2$ or $\beta_1\alpha_2$ state will be displaced and, for a certain rate of transformation, may become broadened to such an extent that they cannot be observed at all (Fig. 2*b*).

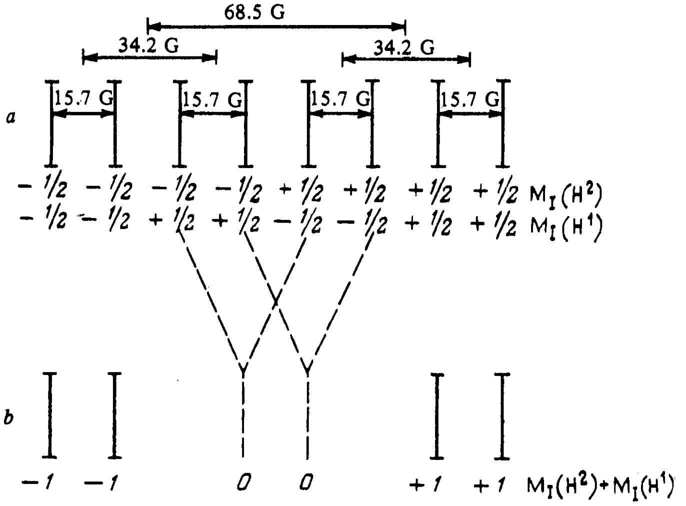


Figure 2. The influence of the rapid interconversion of the tautomeric forms of the vinyl radical on the EPR spectra at 77 K: *a*) spectrum of the radical in a rigid matrix; *b*) spectrum of the radical in the liquid phase.

2. Relation Between Line Width and Kinetics of the Exchange

The graphical description of the broadening of certain components of the EPR spectrum discussed above provides a clear qualitative picture of the influence of transitions between tautomeric forms of the radical on the spectrum. The quantitative relation between the broadening of the components and the frequencies of the intramolecular transformations, on the basis of which it is possible to obtain detailed kinetic information, is examined below.

It is possible to distinguish two main types of effects determining line width: effects associated with the lifetime of the given spin state and effects leading to the fluctuation of the energies of these states. Effects of the first type are determined by the characteristic spin–lattice relaxation time T_1 and those of the second type are determined by the spin–spin relaxation time T_2'. In chemical applications it is reasonable to restrict the treatment to the line widths determined by the reciprocal of the time T_2, which is related to T_1 and T_2' as follows:

$$\frac{1}{T_2}=\frac{1}{T_2'}+\frac{1}{2T_1}. \tag{1}$$

The main task of the theory is to find a quantitative relation between line width $(1/T_2)$ and the kinetic parameters of radical exchange reaction. There are two fundamental approaches to this problem. According to the first, the changes in line width as a result of chemical exchange processes can be described with the aid of modified Bloch equations[7,8], which make it possible to describe the spectra over a wide range of exchange frequencies—from the fully averaged spectrum to the spectrum corresponding to two individual forms of the radical. The second approach, based on the analysis of the relaxation matrix[9], yields a satisfactory agreement with experiment only at high frequencies. We shall consider further the main corollaries arising from the solution of the modified Bloch equations, which are necessary for the interpretation of the experimental data.

The physical significance of the broadening of the lines in EPR spectra is that the reciprocal transitions of the radical from one form to the other alter the local fields in which the unpaired electron is located, which entails a shortening of T_2 and a broadening of the corresponding lines.

Consider a free radical which may exist in two different forms A and B to which correspond different EPR spectra. We shall assume for simplicity that the concentrations of the two forms are identical and that only one EPR line corresponds to each. If there is exchange between forms A and B in this system, the spectrum will depend significantly on the rate of the exchange process, or, in other words, on the lifetimes of forms A and B. The theory usually involves the time τ which is related to the average lifetimes τ_A and τ_B in the following manner:

$$\tau=\tau_A\tau_B/(\tau_A+\tau_B). \tag{2}$$

It is seen from this expression that, when $\tau_A=\tau_B$, the average lifetime of each form, A or B, is 2τ. It is usual to divide exchange processes into three main types depending on their rates: slow exchange, rapid exchange, and intermediate exchange. We shall consider the theoretical form of the spectrum for each specific case.

(a) Slow exchange. If the rate of interconversion of forms A and B is low, then τ is large compared with the difference between the resonance frequencies $(\omega_A-\omega_B)$, and the spectrum consists of two individual signals with an intrinsic width $1/T_{2,0}$ (Fig. 3*a*). With increase of the rate of interconversion, both components are broadened, the broadening in the case of slow exchange being related to the lifetime τ in the following manner:

$$\Delta(1/T_2)=1/2\tau\gamma_e, \tag{3}$$

where γ_e is the gyromagnetic ratio for the electron.

(b) Rapid exchange. With increase of the exchange frequency, the lines are displaced towards the centre of the spectrum and merge into a single exchange-narrowed line (Fig. 3*d*), whereupon the frequency of chemical exchange becomes much greater than the frequency difference $(\omega_A-\omega_B)$, i.e. $\frac{1}{2}\tau \gg (\omega_A-\omega_B)$. For very rapid interconversions, the line broadening is given by the following expression[10]:

$$\Delta(1/T_2)=(\omega_A-\omega_B)^2\tau/4=\gamma_e(H_A-H_B)^2\tau/4, \tag{4}$$

where H_A and H_B are the resonance values of the magnetic field for forms A and B. When the rate of interconversion of forms A and B reaches the upper limit, the central line is again narrowed to its intrinsic width $1/T_{2,0}$ (Fig. 3*e*).

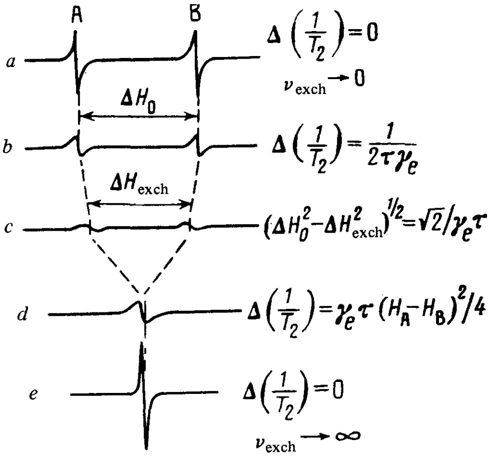

Figure 3. Schematic illustration of the influence of the rate of interconversion of the A- and B-forms of the radical on the EPR spectrum.

If the probabilities of the formation of each form of the radical involved in the exchange are P_A and P_B, the lines are displaced towards a weighted-mean position:

$$\langle H\rangle=(P_AH_A+P_BH_B)/(P_A+P_B). \tag{5}$$

This situation is reflected in Figs. 3*c* and 3*d*. The line broadening is in this case expressed by the relation[10]

$$\Delta(1/T_2)=\gamma_e\tau P_AP_B(H_A-H_B)^2. \tag{6}$$

(c) Intermediate exchange. Fig. 3 shows that, with increase of the frequency of the exchange, the lines are displaced towards the centre of the spectrum and become broadened. This shift is unambiguously related to the lifetime of the forms involved in the exchange by the following expression[10]:

$$(\Delta H_0^2-\Delta H_{exch}^2)^{1/2}=\sqrt{2}/\gamma_e\tau, \tag{7}$$

where ΔH_0 and ΔH_{exch} are the distances between the lines in the absence and presence of exchange respectively.

The two lines begin to merge into a single line when the exchange frequency is close to the frequency difference $(\omega_A-\omega_B)$. For this reason, the order of magnitude of the exchange frequency may be estimated also from the instant when the two lines merge. The relation

$$1/2\tau=(\omega_A-\omega_B)/4\sqrt{2} \tag{8}$$

corresponds to this so called intermediate exchange condition. If the frequency units are replaced by magnetic field units in oersteds, it is easy to show that

$$\nu_{\text{exch}} = 1/2\tau = 6.25 \cdot 10^{-8}(H_A - H_B). \qquad (9)$$

Thus the theory establishes an unambiguous relation between the experimental parameters of the spectrum (the widths and distance between the lines) and the kinetic parameters of the system investigated (ν_{exch} or τ).

The above relations were obtained for the simplest model where two identical EPR lines with the resonance values of the magnetic field H_A and H_B correspond to the two forms of the radical (A and B). However, in practice cases are more frequently encountered where chemical exchange entails exchange between definite HFS components within the complex EPR spectrum. The simplest instance of such exchange was examined qualitatively above in relation to the vinyl radical. The quantitative relation between the exchange frequency and the broadening of the HFS components involved in the exchange in the region of rapid and slow chemical exchange is given by the following expressions[10]:

$$\nu_{\text{exch}} = \frac{\gamma_e (\Delta a)^2 (\Delta M_I)^2}{8\Delta (1/T_2)} \text{ (rapid exchange)}, \qquad (10)$$

where Δa is the difference between the HFS constants for the forms involved in the exchange and ΔM_I the difference between the projections of the linear spins;

$$\nu_{\text{exch}} = \Delta (1/T_2)\, \gamma_e \text{ (slow exchange)}. \qquad (11)$$

If the probabilities of the formation of A and B are different and equal to P_A and P_B respectively, then Eqn. (10) is transformed into

$$(\nu_1 + \nu_{-1}) = \frac{\gamma_e P_A P_B (\Delta a)^2 (\Delta M_I)^2}{\Delta (1/T_2)}, \qquad (12)$$

where ν_1 and ν_{-1} are the rates of the forward and reverse reactions.

In practice the broadening of the HFS lines due to exchange is estimated from the amplitude of the lines, which is inversely proportional to the square of the width and is thus extremely sensitive to changes in the exchange frequency.

III. DYNAMIC EFFECTS OF THE REDISTRIBUTION OF THE UNPAIRED ELECTRON DENSITY IN RADICAL-ANIONS (CATIONOTROPISM)

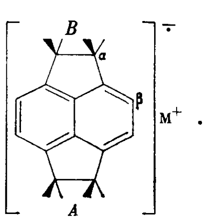
The phenomenon of the dynamic redistribution (depending on the external conditions) of the unpaired electron density between chemically equivalent parts of the molecule is frequently observed in bifunctional radical-anions. The main cause of such redistribution is cationotropism—the transfer of the cation from one functional group to another. In most organic solvents the radical-anions form ion pairs which are weakly dissociated into the free ionic species. In bifunctional radical-anions the cation is located in the vicinity of one of the two functional groups and the symmetrical distribution of unpaired electron density characteristic of the free radical-ion is thus disturbed.

The rate of cationotropic migration determines the form of the EPR spectrum to the extent that it corresponds to the conditions of rapid or slow exchange. The rate of cationotropic migration is determined in its turn by several factors: the chemical nature of the anion and cation, the solvating capacity of the solvent, and temperature.

In the study of a specific radical-anion it is usually possible to alter, within certain limits, the influence of these factors on the rate of the process and to observe how this is manifested in the EPR spectra.

Studies of this kind made it possible to put forward definite hypotheses concerning the mechanism of the dynamic delocalisation of the unpaired electron in bifunctional radical-anions. The term dynamic delocalisation is adopted to emphasise the molecular nature of the motions leading to the redistribution of the unpaired electron density between functional groups. Dynamic delocalisation is in a certain sense equivalent to a chemical reaction the only result of which is the transfer of the cation and electron density between functional groups. Analysis of the specific broadening of EPR lines makes it possible to obtain the kinetic characteristics of chemical reactions of this type.

The dynamic manifestations of cationotropism in the EPR spectra of radical-anions were observed for the first time by de Boer and Mackor[11] in relation to pyracene:



Using various solvents 1,2-dimethoxyethane (DME), tetrahydrofuran (THF), and 2-methyltetrahydrofuran (2-MeTHF), metals (Li, Na, and K), and temperatures, de Boer and Mackor found that the form of the spectra, the line widths, and the constants for the hyperfine interaction with the metal cations depend markedly on the conditions used in the observations. In DME, the solvating properties of which are more pronounced than those of THF and 2-MeTHF, spectra characteristic of the "free" pyracene radical-anion with a symmetrical distribution of the unpaired electron density relative to the symmetry axes of the molecule were observed for all the cations employed. Indeed the structure of the ion pair in DME appears to be that of a solvent-separated ion pair. In 2-MeTHF a strong interionic interaction is observed, being manifested by a breakdown of the symmetry of the spin density distribution. The constants for the hyperfine interaction of the unpaired electron with the protons of the CH_2 groups and aromatic β-protons localised in the vicinity of position A differed somewhat from the constants for the protons in the vicinity of position B. When sodium was used as the reducing agent in 2-MeTHF, hyperfine interaction with the sodium nucleus was observed in addition to the proton hyperfine structure, which indicates unambiguously the formation of a contact ion pair. When potassium was used in THF, a pattern involving the alternation of line widths was observed, which was attributed to the migration of the cation between positions A and B in the pyracene molecule. In this case there was splitting due to the interaction with the potassium nucleus, which made it possible to assign the above phenomenon unambiguously to the migration of the cation within the ion pair and to rule out intermolecular interactions.

The data discussed in this section have been classified in accordance with the nature of the functional groups.

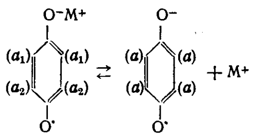
1. Semiquinones

The phenomena of ion association and cationotropism have been widely investigated in relation to semiquinone radical-anions. The use of ethereal solvents and alkali metals as reducing agents made it possible to follow and investigate quantitatively the kinetics of cationotropic migration.

Lucken[12] observed that the lithium salt of *p*-benzosemiquinone in anhydrous t-butyl alcohol gives rise to an EPR spectrum which in no way resembles that obtained previously[13]. Instead of five lines with binomial intensity ratios, Lucken recorded a spectrum comprising nine lines with the intensity ratios 1 : 2 : 2 : 1 : 4 : 1 : 2 : 2 : 1. This implies that the protons in the *p*-benzosemiquinone radical-anion have become non-equivalent in pairs; the relations between the HFS constants are as follows:

$$a_1 \neq a_2 \text{ and } a_1 \neq a,\ (a_1+a_2)/2 = a.$$

The breakdown of symmetry in the distribution of the unpaired electron density is associated with the formation of ion pairs in which the cation is linked to one of the oxygen atoms:



It has been observed[14] that, depending on the conditions, apart from the nine- and five-line spectra, other spectra are also recorded and can be used to follow the smooth transition between the extreme states of the ions; the alternation effects are clearly manifested in these intermediate spectra. Initially there were two views concerning the nature of the phenomena responsible for the alternation of line widths in the spectrum of the *p*-benzosemiquinone radical-anion. Khakhar et al.[15] believed that the alternation is associated with the equilibrium between ion pairs separated by solvent molecules and contact ion pairs and not with the dynamics of the migration of the cation. They attributed the observed alternation pattern to a superposition of the spectra of different ion pairs. Careful analysis of the line form showed subsequently[16] that the observed line width alternation pattern is in fact due to the migrations of the cations between oxygen atoms.

Oakes and Symons[17] investigated the influence of the solvent, the cation, and temperature on the EPR spectra of *p*-benzosemiquinone, durosemiquinone, and different 2,6-disubstituted semiquinones. The solvents employed were t-pentyl alcohol, t-butyl alcohol, DME, and THF, and the counterions were H^+ (hydroxy-radical), Li^+, Na^+, K^+, Rb^+, Cs^+, and $(n\text{-}Bu)_4N^+$. No migration of hydrogen between the oxygen atoms was observed for the hydroxy-radicals derived from *p*-benzosemiquinone and durosemiquinone, and in all the solvents a static pattern was found. In alcohols the lithium cation associated with *p*-benzosemiquinone and durosemiquinone radical-anions migrates at a rate corresponding to slow exchange (the lifetime of the cation near one of the oxygen atoms is $\tau = 5 \times 10^{-7}$ s). The rates of migration of the Li^+ cation in DME and THF correspond to a static pattern ($\tau = 10^{-6}$ s). In alcohols the Na^+ cation migrates at a rate corresponding to the intermediate case ($\tau = 10^{-7}$ s). Depending on the temperature, situations corresponding both to the intermediate case (+25°C) and to the static case (−60°C) are observed in ethers. The frequencies of the migration of the K^+ cation proved to be higher in all the solvents than those for Li^+ and Na^+ and, depending on the conditions, correspond to rapid, intermediate, and slow exchange processes. Oakes and Symons[17] note that the rate of migration of the cation between the oxygen atoms depends strongly on the substituents in the semiquinone:

$$2,3,5,6H \simeq 2,3,5,6\text{-Me} < 2\text{-Me} < 2,6\text{-di-Me} < 2,6\text{-di-t-Bu}.$$

The lifetimes of the cation in the vicinity of one of the oxygen atoms can be arranged in the same sequence and the migration frequencies fall in the opposite sequence. The introduction of substituents makes the oxygen atoms significantly non-equivalent, which leads to the preferential localisation of the cation in the vicinity of one of them and to a decrease of the exchange frequency.

The study of the EPR spectra at different temperatures made it possible to examine the effect of the cation and the solvent on the activation energy for the migration of the metal cation. Fig. 4 illustrates two spectra of K-*p*-benzosemiquinone[18] in DME at two temperatures; the alternation of line widths is seen at −30°C. The contributions of the cation exchange process to line width may be estimated by analysing the line intensities, and the exchange rate constants[19] and activation energies may be calculated (E = 3.4 ± 1 kcal mole^{-1}, $\lg A$ = 9.5 ± 0.5). The activation energy for cation migration varies within wide limits. Table 1 presents kinetic data for the intramolecular migration of the cation in the ion pair formed by the durosemiquinone radical-anion[20,21]. The quantity $\Delta a_H(CH_3)$ (the difference between the two observed HFI constants in the static configuration) increases with temperature, while the mean of the two HFI constants remains unchanged (1.94 ± 0.03 G). For a given series there is a linear relation between the change in the free energy of activation $\Delta G^{\neq}$ and $\Delta a_H(CH_3)$. The negative activation entropy shows that the degree of order in the activated state is greater than that in the reactants and that the activated complex is more solvated than the ion pair.

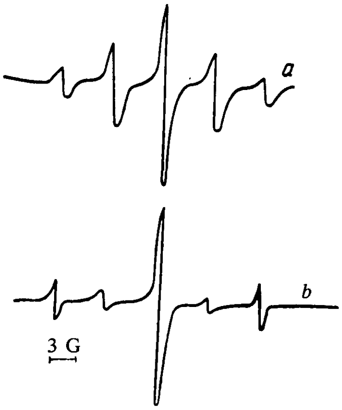


Figure 4. The EPR spectrum of the ion pair comprising the *p*-benzosemiquinone radical-anion and the potassium cation in DME different temperatures (°C): *a*) 20°; *b*) −30°C.[18]

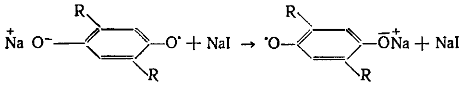
The migration of the cation from one oxygen atom to the other in the semiquinone radical-anion may occur as a bimolecular process. Line width alternation effects in the EPR spectrum of the Na–2,5-di-t-butyl-*p*-benzosemiquinone radical-ion pair were observed[22] following the addition of NaI to a solution in THF. The authors found from the temperature dependence of the rate constant for the process



(R = t-butyl).

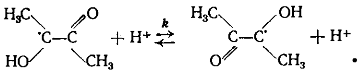
that the activation energy is 2.5 kcal mole^{-1} and the pre-exponential factor is 5.6 × 10^{10} litre mole^{-1}s^{-1}.

Table 1. The activation energies and pre-exponential factors for the cation migration in durosemiquinone radical-anions (D).

Ion pair	Solvent	E, kcal mole^{-1}	$10^{-10}A$, s^{-1}
Na-D	DME	3.57±0.20	0.12
Na-D	THF	5.61±0.23	0.47
K-D*	DME	5.27	14
K-D*	THF	7.39±0.52	470
Cs-D	DME	4.46±0.27	54
Cs-D	THF	4.82±0.28	660
Cs-D	MeTHF	3.70±0.25	6.9
K-D	DME	5.05±0.34	52
K-D	THF	6.2±0.20	270

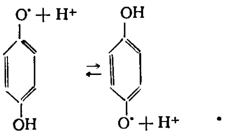
*Data from Prahananda et al.[21]

A similar mechanism has been proposed to explain the acid-catalysed proton transfer in the monoprotonated *trans*-semidione radical[23]. The authors obtained it in a water flow system at 23°C by one-electron reduction of diacetyl. At pH 0.5 they observed a spectrum consisting of a binomial septet (a_H = 8.3 G); at pH 1 appreciable line width alternation was observed in the spectrum. At pH 2 the pronounced alternation converts the septet into a 1 : 9 : 9 : 1 quartet with an HFI constant of 16.6 G. At pH 3 the two methyl groups become non-equivalent and a splitting due to the one proton of the OH group appears: $a_H(CH_3)$ = 12.8 G; $a_H(CH_3)$ = 3.8 G; $a_H(OH)$ = 2.0 G. This result was attributed to acid-catalysed proton transfer between oxygen atoms:

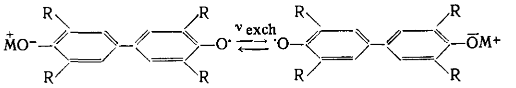


The rate constant is 4.53 × 10^9 litre mole^{-1}s^{-1}.

Smith and Carrington[24] observed a dependence of the line width on pH in the spectrum of the monoprotonated *p*-benzosemiquinone radical-anion (the 4-hydroxyphenoxy-radical), which they attributed to the process



There exists yet another factor which may influence the exchange frequency. It is the distance between the oxygen atoms, which may be altered by employing quinones of different structures. We investigated[25] the EPR spectra of the radical-anions derived from 3,3′,5,5′-tetra-t-butyldiphenylquinone (TBDP). The observed line width alternation patterns made it possible to measure the cation exchange frequencies:

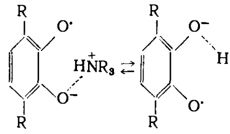


(R = t-butyl).

The order of magnitude of the values of ν_{exch} for the TBDP radical-anion corresponds to that of the cation migration frequencies in *p*-benzosemiquinones, although the cation localisation centres in the radical-anion which we investigated are separated by a much greater distance. The cause of this phenomenon is apparently the fact that the cation migration frequency is determined mainly by the depth of the energy minima on the potential curves corresponding to the limiting structures and by the distance between these minima. The minima for *p*-benzosemiquinone are fairly close. The energy minima for the "limiting" structures of TBDP are much further apart, although their depth is smaller owing to the extensive conjugation system and this leads to the same cation migration frequencies as in benzosemiquinones.

The *o*-benzosemiquinone radical-anions are systems in which the oxygen atoms are much closer to one another. The EPR spectra of 3,6-di-t-butyl-*o*-benzosemiquinone radical-anions[26] in different solvents, at different temperatures, and in the presence of different metal cations always exhibit a symmetrical unpaired electron density distribution. This implies that the cations either occupy a symmetrical position in relation to the oxygen atoms or migrate at a high frequency.

The use of alkylammonium cations in an ion pair incorporating the 3,6-di-t-butyl-*o*-semiquinone anion leads to effects associated with a dynamic redistribution of the unpaired electron density, which was attributed to the migration of the hydrogen bond between oxygen atoms[27]:

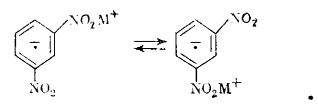


(R = t-butyl).

2. Cationotropism in Ion-Pairs Formed by Dinitrobenzene Radical-Anions and in Certain Other Bifunctional Radical-Anions

Line width alternation effects have been found in ion pairs formed by *o*-, *m*-, and *p*-dinitrobenzene radical-anions[28–33]. The alternation is caused by the migration of the cations between the nitro-groups. Symons and coworkers[18,19] [wrong references?] obtained the *p*-dinitrobenzene radical-anions by the photolysis of a methanol solution containing sodium methoxide. The addition of solvents promoting the formation of ion pairs caused line width alternation. In the *o*-dinitrobenzene radical-anion the sodium cation migrates at room temperature at a frequency corresponding to the rapid exchange conditions. A decrease of temperature to −60°C causes the appearance of the alternation effect. The slow exchange situation is not observed. A similar behaviour has been observed for potassium cations[33]. For caesium cations, only rapid exchange is observed at all temperatures.

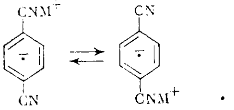
Slow exchange is observed in the sodium salt of the *m*-dinitrobenzene radical-anion at all temperatures. In the potassium salt at low temperatures there is slow exchange but at 0° C alternation effects appear. In the EPR spectra of the caesium and rubidium salts a transition is observed from slow exchange at low temperatures to a distinct line width alternation pattern at room temperature:



The formation of ion pairs comprising the pyrazine radical-anion and the sodium cation has been investigated[34]:

At room temperature the EPR spectrum reveals hyperfine interactions with the two nitrogen nuclei ($a_N = 7.14$ G), with the four protons ($a_H = 2.70$ G), and with the sodium nucleus ($a_{Na} = 0.55$ G). At lower temperatures alternation effects associated with the migration of the cation appear. The process activation energy is $E_a = 7.1 \pm 0.5$ kcal mole^{-1} and $A = 2 \times 10^{13}$ s^{-1}. The activation energy for the caesium cation proved to be much higher: $E_a =$ 15 kcal mole^{-1}.

Nakamura[35] investigated the exchange of the sodium cation in the terephthalonitrile radical-anion:



The activation energy in THF proved to be $E_a = 5 \pm 1$ kcal mole^{-1} for sodium and $E_a = 3.7 \pm 0.5$ kcal mole^{-1} for potassium.

3. The Radical-Anions of Bridged Compounds

Numerous studies have been devoted to the distribution of the unpaired electron density in systems having the general structure $[\text{Ar–X–Ar}]^{\bar{\cdot}}\text{M}^+$, where Ar are either aromatic radicals or π-electron functional groups and X are isolating bridges of different lengths and structures[36]. The interest in these systems is due to the hypothesis that the study of the distribution of their unpaired electron density can yield information about the ability of the X groups to "transmit" the unpaired electron from one aromatic fragment to the other. However, later studies showed that this simplified electron transfer mechanism, which depends only on the transmittivity of the –X– bridge, does not take into account the formation of ion pairs. Studies of the EPR spectra of the radical-anions $[\text{Ar–X–Ar}]^{\bar{\cdot}}\text{M}^+$ showed that the nature of the solvent and temperature have a strong influence on the distribution of the unpaired electron density and on the frequency of electron transfer between the aromatic fragments.

The hypothesis that the migration of the metal cation plays a decisive role in the dynamic delocalisation of the electron in the radical-anions of bridged compounds was not immediately demonstrated experimentally. The clearest example is provided by the study of Gerson and Martin[71], who investigated the EPR spectra of diphenylmethane and *p*-deuterodiphenylmethane in DME and showed that the unpaired electron is delocalised over the two benzene rings. It is believed[72,73] that the annular 1,3-interaction between the benzene rings determines the mechanism of the electron transfer between them. However, this idea conflicts with data which the same authors obtained in a study of the EPR spectrum of the diphenylmethane radical-anion in MeTHF.[72] A static picture, corresponding to the localisation of the unpaired electron in one benzene ring, was observed, which is inconsistent with the concept of the decisive role of annular 1,3-interactions.

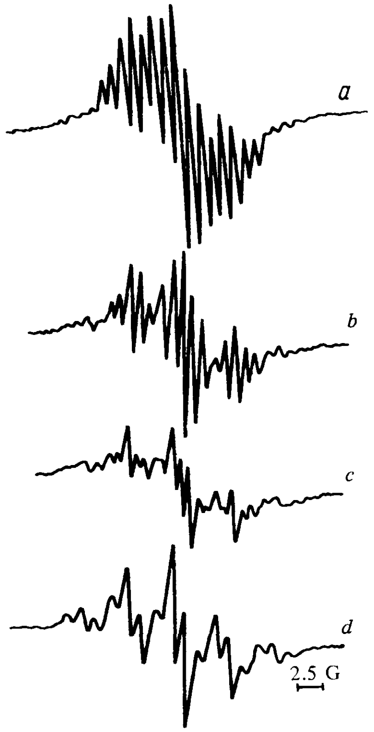


Figure 5. The EPR spectrum of the ion pair comprising the diphenylmethane radical-anion and the potassium cation in a mixture of diethyl ether and 10% of hexamethylphosphoramide at different temperatures (°C): *a*) –70; *b*) –100; *c*) –110; *d*) –127.

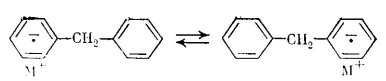
The authors of the present review investigated the exchange of the unpaired electron in the diphenylmethane radical-anion in various solvents and at various temperatures[37-40]. The rapid exchange condition holds in DME (K^+ cation) over the entire temperature range. In a 1 : 1 DME : THF mixture at –70° C there is also a rapid exchange. When the temperature is reduced to –100° C, alternating line width effects appear. As a result, the relatively complex EPR spectrum is converted into a spectrum in which five principal lines are distinctly visible; EPR spectra of this type usually arise from the radical-anions of alkylbenzenes[36]. Analysis of the hyperfine structure of the spectrum showed that the exchange frequency corresponds to the intermediate case in relation to the hyperfine interaction with the *ortho*- and *meta*-protons; the rapid exchange condition holds in relation to *para*-protons. The exchange frequency is $\nu_{exch} = 10^{12} \exp(-4000/RT)(s^{-1})$. The slow exchange condition was achieved[40] when ethyl ether containing 10% of hexamethylphosphoramide was used as the solvent. Fig. 5 presents the EPR spectra corresponding to the conditions of the rapid (*a*), intermediate (*b*) and (*c*) and slow (*d*) exchange processes, the exchange frequency being given by $\nu_{\text{exch}} = 2.3 \times 10^{13} \exp(-4300/RT)$.

The nature of the influence of the solvent and temperature shows convincingly that the solvating capacity of the solvent determines the mobility of the metal cation on which the fulfilment of rapid or slow exchange conditions depends. A distinctive feature of the diphenylmethane radical-anion compared with the systems discussed above is the separation of the functional groups (benzene rings) by a considerable energy barrier due to the methylene group. As a result of this feature, the unpaired electron is fully transferred from one benzene ring to the other:



In *p*-benzosemiquinone radical-anions the migration of the cation causes only a partial redistribution of electron density between oxygen and carbon atoms within the limits of the common π-electron system.

Similar effects of temperature and the solvent were observed for other radical-anions—those of $\alpha\alpha'$-dinaphthylmethane and 1,2-di(α-naphthyl)ethane[37]. A similar situation has been observed in a study of exchange via the $>\mathrm{Si}(C_2H_5)_2$ group in the radical-anion $Ph_2Si(C_2H_5)_2^{\overline{\cdot}}K^+$ in THF:[41] $\nu_{\text{exch}} = 10^9 \exp(-2800/RT)$ (s^{-1}).

Apart from the "two-well" systems discussed above, more complex systems have been investigated—"three-well" (triphenylmethane radical-anions)[42] and "four-well" systems (tetraphenylsilane radical-anions)[41]. Fig. 6 presents the EPR spectrum of the tetraphenylsilane radical-anion in THF (K^+ cation). The spectrum at −40°C (*a*) consists of the principal quintet arising due to four *para*-protons (a_p = 2.2 G). Each line of the quintet is split into nine lines due to the eight *ortho*-protons (a_0 = 0.8 G). At −140°C the spectrum is converted into a poorly resolved doublet with a splitting of 8 G, which indicates the localisation of the unpaired electron in one benzene ring only.

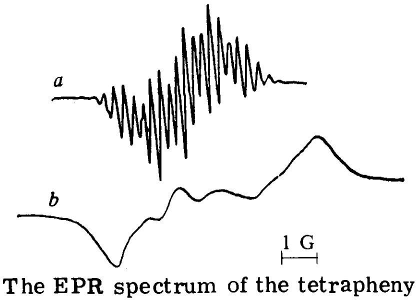


Figure 6. The EPR spectrum of the tetraphenylsilane radical-anion in THF at different temperatures (°C): *a*) −40; *b*) −140.

The systems considered hitherto have equivalent cation localisation centres. In the *p*-dibenzylbenzene radical-anion the two extreme benzene rings are structurally different from the central ring and the probability of finding the metal cation near the centre of the molecule should be different from the probability of finding the cation at its edges[43]. This should be the case primarily in the region of slow exchange, where the spectrum corresponds to the localisation of the cation near one of the benzene rings:

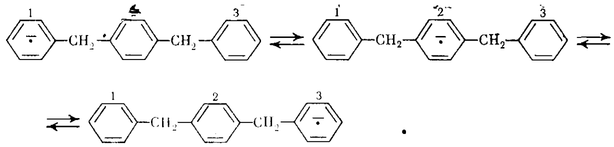

Fig. 7 illustrates one of the spectra recorded in THF, DME, and their mixtures (potassium cation) at −60° and −70°C. A decrease of temperature and the addition of ethyl ether cause a transformation of this fairly complex spectrum into a quintet characteristic of *p*-dialkylbenzenes. Analysis of the spectrum shows that at a low temperature the cation is localised near the central benzene ring. The principal quintet splitting of 4.67 G is due to the interaction with the four protons of the central benzene ring and the additional splitting (1.14 G) is due to the interaction with the four protons of the two methylene groups. Analysis of the line width alternation effects showed that the potassium cation migration frequency at −60° and −70°C between benzene rings *1*, *2*, and *3* and the corresponding unpaired electron delocalisation frequency are within the following limits (s^{-1}): $10^7 > \nu^{1-3} > 3 \times 10^6\ s^{-1}$; $\nu^{1-2} = \nu^{2-3} > 10^7\ s^{-1}$. At −100°C the exchange frequency is $\nu^{1-2} = \nu^{2-3} > 10^7\ s^{-1}$.

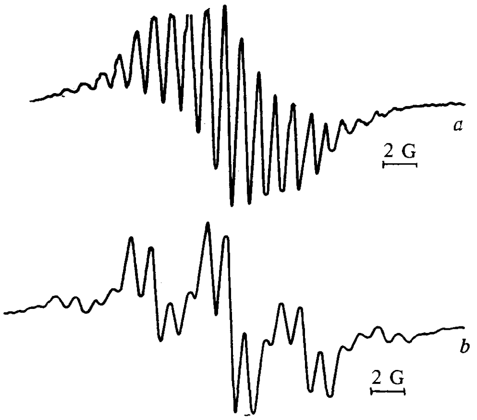

Figure 7. The EPR spectrum of the ion pair comprising the *p*-dibenzylbenzene radical-anion and the potassium cation in THF, DME, and their mixture at −60° and −70°C (*a*) and in a mixture of 90% of diethyl ether and 5% of hexamethylphosphoramide at −100°C (*b*).

Non-aromatic bridged systems have also been investigated. Syrkin et al.[44] found that in the electrochemical generation of difluorodinitromethane anions there is rapid electron exchange between the nitro-groups. On the other hand, a static picture involving the localisation of the unpaired electron in one of the nitrated aromatic components of the molecule is observed in the di-$\alpha\alpha$-difluoro-di-(4-nitrophenyl)methane[45]. A static picture is also characteristic of the dibenzyl[46] and di-(4-nitrophenyl)methane radical-anions[47].

4. The Mechanism of the Dynamic Delocalisation of Electrons in Bifunctional Radical-Anions

Before considering the mechanism of the dynamic delocalisation of the electron (cationotropism), it is necessary to examine the causes responsible for the asymmetric disposition of the cation in the ion pairs formed by bifunctional radical-anions. If the exchange interaction is fully disregarded, then the nature of the bond between the anion and the cation in the ion pair reduces exclusively to electrostatic forces. A simple calculation shows that the Coulombic interaction energy between the cation and anion increases if the cation is located near one of the functional groups, to which an excess (compared with the free ion) negative change density is drawn under the influence of the electric field of the cation. Thus an asymmetric structure of the ion pair formed by a radical-anion having two functional groups is energetically more favourable than the symmetrical disposition of the cation. An asymmetric distribution of the unpaired electron density leads to some loss of exchange energy but in the case of bridged compounds the latter is apparently small; in other cases the loss may be appreciable. It appears that for this reason it is impossible to ensure the location of the unpaired electron in a single benzene ring of the biphenyl radical-anion by selecting appropriate conditions. It is quite likely that in this case the loss of exchange energy owing to the separation of the π-electron systems of the benzene rings is not compensated by the gain in Coulombic energy. The degree of redistribution of the unpaired electron density in a particular radical-anion as a function of the nature of the cation and the solvent is a qualitative measure of the bond strength in the ion pair.

Several models have now been proposed for the description of the dynamic delocalisation of the unpaired electron. McConnell[48] considered the delocalisation of the unpaired electron in the radical-anions of $\alpha\omega$-diphenylalkanes. The interaction with the medium was taken into account with the aid of the formal effect involving the self-localisation of the charge without taking into account the structure of the ion pairs. McConnell analysed the ability of $(-CH_2-)_n$ bridges of different lengths to transmit an electron.

Claxton[49] considered the exchange of the cation between the nitrogen atoms of the pyrazine radical-anion and postulated the liberation of the cation from the solvent cage containing the radical-anion. After the cation leaves the cage, the radical-anion rotates in the latter independently of the cation. This rotation ensures the migration of the cation when it re-enters the solvent cage. By studying the reaction coordinate, Claxton found that the cation moves from one atom to another, deviating from the plane of symmetry of the molecule.

It is noteworthy that both models considered do not take into account the specific structure of ion pairs. Presumably the mechanisms of the dynamic delocalisation of the unpaired electron in bifunctional aromatic radical-anions and in bridged compounds have common features. These features are associated with the decisive role of the mobility of the cation. The difference between them is that in bifunctional aromatic radical-anions there are no energy barriers preventing the delocalisation of the electron, since the positions of the cations are linked by the common π-electron system. At the present time the mechanism of the dynamic delocalisation cannot be treated in isolation from modern ideas concerning the structure of ion pairs. We believe that the dynamics of the migration of the cation is indissolubly linked to the interconversions between contact ion pairs and ion pairs separated by solvent molecule.

Evidently the Coulombic interaction between the radical-anion and the cation in a solvent-separated ion pair is much weaker than the interaction in a contact ion pair. The cation in a solvent-separated ion pair is less able to distort the distribution of the unpaired electron over the radical anion. Thus for the interconversions of ion pairs having different structures to play a significant role in the dynamic delocalisation mechanism, they must take place with frequencies of approximately 10^7–10^8 s^{-1}. Such frequencies are indeed observed in the reactions of ion pairs[50]. There is a complete parallelism between the influences of the nature of the cation and the solvent on the rate of dynamic electron delocalisation and on the interconversions of ion pairs. In solvents such as THF and diethyl ether (DEE), where the formation of contact ion pairs takes place more readily than in DME, dynamic delocalisation processes are much slower than in DME. Analysis of experimental data showed that the activation energy for the migration of the cation is determined by the nature of the ion pair.

Presumably the conversion of a contact ion pair into a solvent-separated one is the initial stage in the cation migration processes. Furthermore, it is necessary that during the lifetime of the solvent-separated ion pair there is sufficient time for the cation to pass to a new location in the radical-anion. The influence of the solvent and the cation on processes associated with the dynamic delocalisation of the unpaired electron in a specific radical-anion reduces mainly to a change of bond strength in the ion pair. On the other hand, in considering different radical-anions, one must take into account the geometrical factors in the locations of the cation. A large distance between them or an unfavourable conformational disposition may increase the time taken for the transfer of the cation to such an extent (static case) that the application of the EPR method to the estimation of the kinetic parameters of the cationotropic migration becomes ineffective.

In the majority of the bifunctional aromatic radical-anions considered above, the functional groups are fairly close and the rate-limiting stage is apparently merely the dissociation of the bond in the ion pair. In the radical-anions derived from bridge compounds, increase of the distance between the locations of the cation leads to a decrease of the delocalisation frequency owing to the longer migration of the cation[39,51].

An unambiguous answer to the question of the ability of bridge groups to transmit an electron cannot be obtained from EPR data, because the delocalisation frequency depends on the mobility of the cation. One can only assume that, in the presence of a small number of units in the bridge group, an exchange interaction (with an intensity corresponding to approximately 10^{-5}–10^{-7} eV), which is necessary to ensure the "intrinsic" exchange frequencies in the "free" radical-anion (approximately 10^9–10^7 s^{-1}), takes place.

The phenomenological picture considered above reflects only the most general features of the exchange processes. In a quantitative treatment of the experimental data for the rates of exchange or the constants for equilibria involving ion pairs of radical anions one frequently encounters additional effects associated with the dependence of the properties of the solvent on temperature[25,52]. Over a wide temperature range, the dielectric constants of solvents vary within broad limits, which leads to appreciable additional shifts in the equilibria between ion pairs having different structures. Change in the properties of the solvent frequently leads to appreciable deviations from the Arrhenius relation for the rate and equilibrium constants. For this reason, all the activation energies and rate constants for exchange processes as a rule refer to narrow temperature ranges.

IV. DYNAMIC DELOCALISATION OF THE UNPAIRED ELECTRON IN FREE RADICALS

The examples considered in the previous section, which illustrate the cationotropisms in ion pairs formed by radical-anions, constitute the type of tautomerism of radicals which has been investigated in greatest detail and which differs from the classical tautomerism by the migration of ionic and not covalent bonds. The tautomerism of radicals, accompanied by the migration of organic or organoelemental fragments between equivalent positions in radicals and the synchronous redistribution of the unpaired electron density in such species, is considered below.

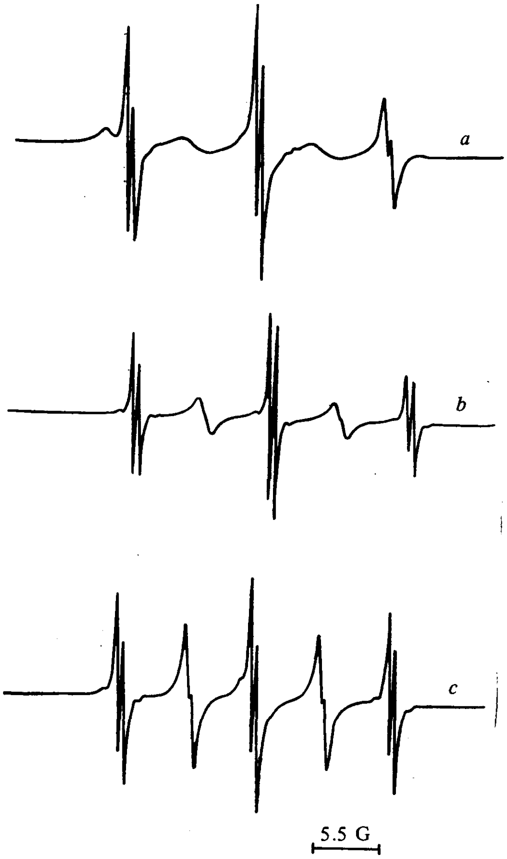

Figure 8. The EPR spectra of radical (I) at different temperatures (°C): *a*) −80; *b*) 0; *c*) 60.

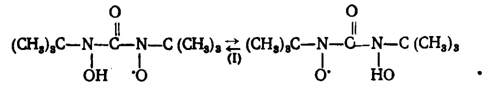
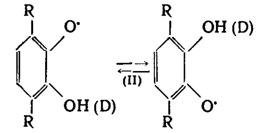
1. Migration of Hydrogen and Deuterium

The simplest examples of this type of tautomerism are the intramolecular migration of hydrogen and deuterium atoms. Analysis of the line width in the EPR spectra[53] demonstrated the possibility of the migration of the hydrogen atom in radical (I) having the following structure:



$$(CH_3)_3C-\underset{OH}{N}-\overset{O}{\overset{\|}{C}}-\underset{\cdot O}{N}-C(CH_3)_3 \underset{(I)}{\rightleftarrows} (CH_3)_3C-\underset{O\cdot}{N}-\overset{O}{\overset{\|}{C}}-\underset{HO}{N}-C(CH_3)_3$$

At low temperatures (−90° C) the EPR spectrum of this radical is a triplet due to the interaction of the unpaired electron with the nitrogen nucleus (a_N = 10.4 G), each component of which is split into a doublet by the proton of the hydroxy-group [a_H(OH) = 0.5 G] (Fig. 8). With increase of temperature, the spectrum is transformed into a quintet (owing to the two equivalent nitrogen atoms) with an HFI constant smaller by a factor of two than the constant due to one nitrogen atom. The energy barrier to the migration of hydrogen is 2.7 ± 0.3 kcal mole^{-1}. The authors of the present review demonstrated almost simultaneously[54,55] the occurrence of the intramolecular migration of hydrogen and deuterium atoms in the 3,6-di-t-butyl-2-hydroxyphenoxy-radical (II):



(R = t-butyl).

Fig. 9*a* illustrates the EPR spectrum of this radical at 60° C.

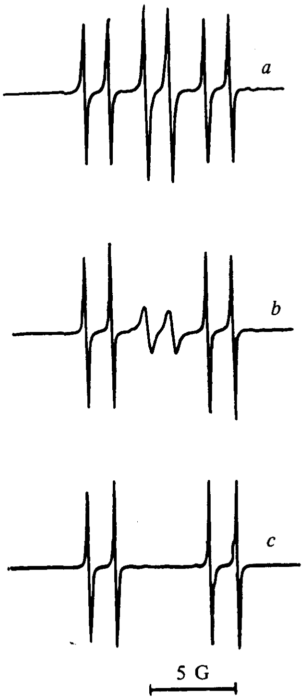


Figure 9. The EPR spectra of radical (II) in toluene at different temperatures (°C): *a*) 60; *b*) 0; *c*) −60.

The triplet (a_H = 3.92 G) is due to the interaction of the unpaired electron with the "equivalent" ring protons; each component of the triplet is split into a doublet by the proton of the hydroxy-group [a_H(OH) = 1.6 G]. In the spectrum of the analogue of radical (II) deuterated at the hydroxy-group each component of the triplet consists of three lines owing to the interaction of the unpaired electron with the deuterium nucleus [a_D(OD) = 0.26 G] (Fig. 10*a*). With increase of temperature, the central component of the triplet is broadened (the breakdown of the "equivalence" of the ring protons), indicating the inhibition of the intramolecular migration of hydrogen (deuterium) atoms between the oxygen atoms in radical (II).

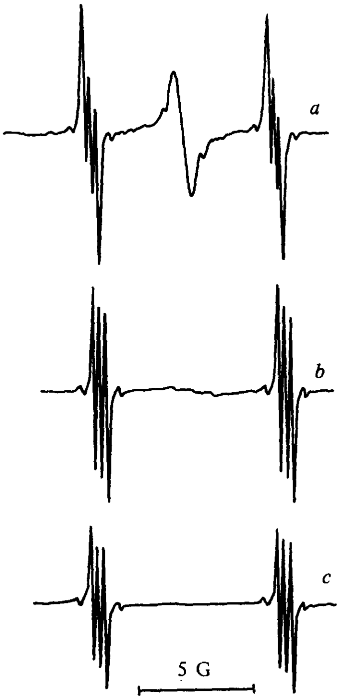

Figure 10. The spectra of radical (II), deuterated in the hydroxy-group, in toluene at different temperatures (°C): *a*) 60; *b*) 0; *c*) −60.

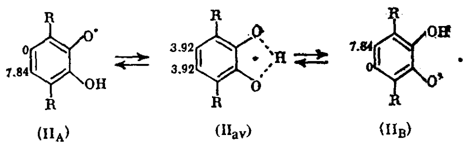
At fairly low temperatures (below −60°C) migration ceases on the EPR time scale (~ 10^{-7} s) and a spectrum corresponding to one of the "frozen" structures (II_A) or (II_B) is observed (Figs. 10*c* and 11*c*). The HFI constants for structures (II_A) and (II_B) (slow exchange) as well as (II_{av}) (rapid exchange) are given below for greater clarity:



(R = t-butyl).

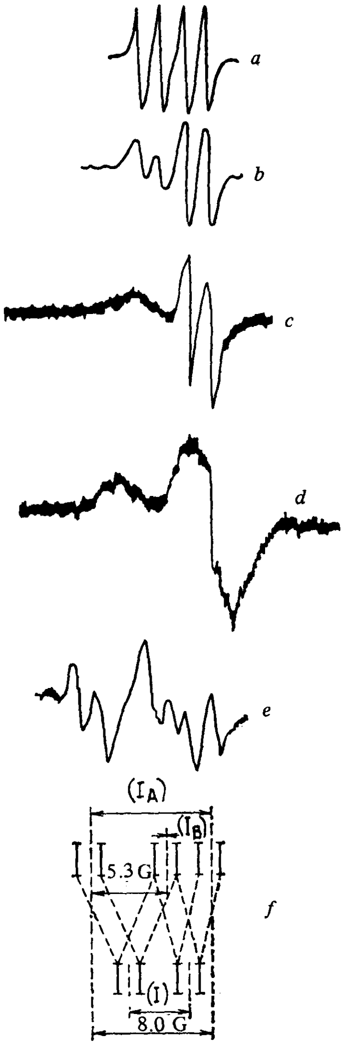


Figure 11. The EPR spectra of radical (V) in diethyl ether at different temperatures (°C): *a*) 100; *b*) 20; *c*) 0; *d*) −20; *e*) −100; *f*) schematic representation of the spectra of radical (V) under slow exchange conditions.

Analysis of the line widths made it possible to determine the kinetic parameters of the migration of hydrogen and deuterium atoms and to estimate the kinetic isotope effect. The frequencies of the intramolecular migration of hydrogen (ν_H) and deuterium (ν_D) atoms in radical (II) are listed below (solvent—heptane):

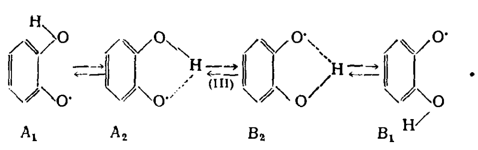
t, °C	$10^{-9}\nu_H$, s^{-1}	$10^{-9}\nu_D$, s^{-1}	ν_D/ν_H (expt.)	ν_D/ν_H (calc.)
20	3.2	0.3	0.08	0.09
60	5.5	0.75	0.14	0.12
80	6.3	1.0	0.16	0.14
120	10.0	2.2	0.22	0.17

Activation energies of 2.9 and 4.5 kcal $mole^{-1}$ respectively were determined from the temperature dependence of ν_H and ν_D. The experimental isotope effect agrees well with the value calculated theoretically from the following expression:

$$\frac{\nu_D}{\nu_H} = \exp\left\{\frac{hc}{2kT}(\tilde{\nu}_{OD} - \tilde{\nu}_{OH})\right\}, \qquad (13)$$

where $\tilde{\nu}_{OD}$ and $\tilde{\nu}_{OH}$ are the stretching vibration frequencies of the OD and OH bonds determined from the infrared spectra of sterically hindered phenols. It has been shown[56] that solvents capable of forming hydrogen bonds inhibit the migration of hydrogen in radical (II). The complete set of results obtained made it possible to conclude that the migration of hydrogen atoms has a homolytic mechanism and is in essence an intramolecular radical substitution reaction.

Later Loth et al.[57] observed an analogous effect in the unsubstituted 2-hydroxy-phenoxy-radical (III), the EPR spectra of which exhibit a specific broadening of the lines—a hyperfine structure. However, analysis of the spectra is complicated in this instance by the hindered rotation of the OH bond and the occurrence of the conformers A_1, A_2, or B_1, B_2, which differ in their structures and thermodynamic stabilities:



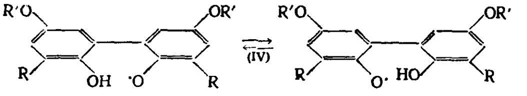
The hydrogen migration frequencies (ν_H) and deuterium (ν_D) in radical (III)[57] are listed below:

t, °C	$10^{-5}\nu_H$, s^{-1}	t, °C	$10^{-5}\nu_D$, s^{-1}
22	191	72	21.4
5	96.1	58	14.8
−25	16.0	38	5.12
−55	1.62	18	1.78

The activation energies are 8.2 ± 0.1 and 9.5 ± 0.5 kcal $mole^{-1}$ respectively. Owing to the possibility of the existence of the above conformers, the migration frequencies of hydrogen and deuterium in radical (III) are much lower than those in radical (II), where the presence of the bulky t-butyl groups prevents the rotation of the OH group, and the radical exists in a form where the hydrogen atom is virtually in the plane of the aromatic ring (of type A_2 or B_2). The sharply reduced migration frequencies in radical (III) may be due to the fact that the rate-limiting stage in the intramolecular transfer is not the dissociation of the OH or OD bonds, but the stage defined by the lifetime of the conformers A_2 or B_2, simulating the transition state in the transfer of hydrogen and deuterium. Analysis of the planar conformers (A_2, B_2) showed that the difference between the O–H and O...H bond lengths is small and amounts to only 0.3 Å.

The authors explain the anomalous kinetic isotope effect (approximately 100) for radical (III) by the fact that, apart from the stretching vibrations of the OH and OD bonds, account must be taken of the contributions of all the vibrations characteristic of the COOH fragment.

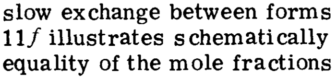
The EPR spectra of radicals (IV),



(R = t-butyl).

were observed quite recently[58]. The HFI constants of the ring protons and α-hydrogen atoms of the alkoxy-substituents are equivalent in pairs and in the temperature range from −50° to 25°C there is no alternation of line widths. This led the authors to the conclusion that rapid intramolecular processes take place in radicals of this type. It is noteworthy that the HFI constants for the ring protons ($a_H^{3,3'} = 1.4$ G) and the protons in the alkoxy-substituents [$a_H(OCH_3) = 0.83$ G] are small and that in this case the rapid exchange condition may be fulfilled for the usual exchange frequencies (~ 10^7–10^8 s^{-1}).

The examples discussed above illustrate the simplest instances of degenerate tautomerism—the migration of hydrogen and deuterium atoms between equivalent positions in the radical. The intramolecular migration of hydrogen and deuterium atoms in the 3,5-di-t-butyl-2-chloro-6-hydroxyphenoxy-radical (V), which constitutes the simplest example of non-degenerate tautomerism:



(V_A) (V_B)

(R = t-butyl).

has been investigated[59]. In diethyl ether at low temperatures the EPR spectrum of radical (V) is a doublet (a_H = 3.3 G) due to the interaction of the unpaired electron with a ring proton; each component of the doublet contains two lines (a_H = 1.5 G) owing to the hydroxyl proton (Fig. 11*a*). With decrease of temperature, the downfield component of the ring proton doublet is broadened, virtually disappearing at 0°C (Figs. 11*b* and 11*c*). On further decrease of temperature, the hydroxyl doublet coalesces (Fig. 11*d*) and at −100°C the observed spectrum consists of a superposition of two signals with slightly different *g* factors (Fig. 11*e*): a doublet with a_H = 8.0 G, each component of which is split in two (a_H = 1.5 G), and a second doublet a_H = 1.5 G.

The above changes in the spectra are fully reversible when the temperature is altered and indicate the occurrence of dynamic effects due to the intramolecular migration of a hydrogen atom between oxygen atoms. At higher and lower temperatures respectively the conditions for rapid and slow exchange between forms (V_A) and (V_B) obtain. Fig. 11*f* illustrates schematically these two instances for equality of the mole fractions of forms (V_A) and (V_B). This interpretation of the EPR spectra is confirmed by the comparative analysis of the spectrum of the deuterated analogue of radical (V). The doublet with a_H = 8.0 G refers to the (V_B) form, while the spectrum without HFI due to the ring proton refers to the (V_A) form. Analysis of the temperature dependence of the HFI of the ring proton in the high-temperature spectra (rapid exchange) made it possible to estimate the constant for the equilibrium between forms (V_A) and (V_B), from the expression

$$K_p = \frac{\alpha}{1-\alpha} = \frac{\tilde{a}}{a_{V_A} - \tilde{a}}, \qquad (14)$$

where $\tilde{a} = \alpha a_{V_A} + (1 - \alpha) a_{V_B}$, α is the mole fraction of form (V_A), and a_{V_A} = 8.0 G and a_{V_B} = 0 G are respectively the HFI constants for the ring proton in the corresponding forms. The thermodynamic parameters obtained in this way are $K_p(20°) = 0.83$ and $\Delta H = -0.33$ kcal $mole^{-1}$ (toluene). The greater thermodynamic stability of form (V_A) follows from the fact that the electrons in the outer shell of the chlorine atom, located in this form in the *ortho*-position relative to the univalent oxygen atom, interact more effectively with the unpaired electron of radical (V), increasing its stabilisation energy.

The thermodynamic data obtained and analysis of the broadening in the EPR spectra made it possible to obtain the rate constants (k_1 and k_{-1}) for the reversible proton transfer between forms (V_A) and (V_B). The hydrogen and deuterium migration frequencies for radical (V) in toluene are listed below:

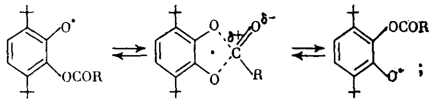
t, °C	$10^{-8}k_1(H)$, s^{-1}	$10^{-7}k_1(D)$, s^{-1}	$k_1(D)/k_1(H)$ (expt.)	$k_1(D)/k_1(H)$ (calc.)
20	4.1	3.0	0.07	0.09
40	6.5	5.6	0.09	0.11
60	9.5	9.6	0.10	0.12
80	19	25.0	0.13	0.14

The activation energies are respectively 4.1 ± 0.5 and 5.7 ± 0.5 kcal mole^{-1}. As for radical (II), the kinetic isotope effect is described satisfactorily by Eqn. (13). In solvents capable of forming hydrogen bonds (for example in diethyl ether) the constants K_p hardly change, but the rate constants k_1 and k_{-1} decrease appreciably, which makes it possible to observe the spectra of the individual species at low temperatures corresponding to the slow exchange conditions.

2. Migration of Fragments with Group IV Elements

In the search for further examples of the tautomerism of radicals, the authors of the present review turned to radicals containing substituents with Group IV elements (carbon and tin). The migration of the methyl group between oxygen atoms in the 3,6-di-t-butyl-2-methoxyphenoxy-radical (VI)† was not observed up to 200°C. The hyperfine structure of the EPR spectrum of this radical does not exhibit a specific broadening of the lines over the entire temperature range; the spectrum consists of a doublet of doublets due to the interaction of the unpaired electron with the *para*-proton (a_H = 8.65 G) and the *ortho*-protons (a_H = 1.0 G) of the aromatic ring; each component being a quartet owing to the protons of the methyl group [$a_H(CH_3)$ = 1.37 G].

The intramolecular migration of carbon-containing groups with EPR frequencies has been observed for acylotropic migration in 2-acyloxy-3,6-di-t-butylphenoxy-radicals[60,61]:



R = $COCH_3$ (VII), COC_2H_5 (VIII), $COCH_2Br$ (IX), $COCH_2C_6H_5$ (X), or $COCH(C_6H_5)_2$ (XI) .

The EPR spectrum of radical (VII) is illustrated in Fig. 12. The doublet with a_H = 10.2 G is due to the interaction of the unpaired electron with the ring proton in the *para*-position relative to the "univalent" oxygen atom. Each component of this doublet is split into two lines due to the *meta*-proton of the aromatic ring (a_H = 1.95 G). The above interpretation of the spectrum is fully consistent with the unpaired electron density distribution characteristic of phenoxy-radicals: an appreciable positive spin density is observed in the *para*-position of the phenoxy-ring and the HFI constant is between −8 and 10 G, while in the *meta*-position the spin density is negative and the HFI constant is between 0.5 and 2.2 G. The EPR spectra of radicals (VIII)–(XI) are analogous to the spectrum of radical (VII).

With increase of temperature (to 120°C) a distinct broadening of the extreme HFS component is observed in the EPR spectra of radicals (VII)–(X) (Fig. 13) due to the migration of the acyl group between the oxygen atoms. It is noteworthy that the broadened lines are not displaced, i.e. the slow exchange condition is fulfilled. Under the rapid exchange condition, which does not obtain in the given experiment, the EPR spectra of radicals (VII)–(X) should consist of a triplet, due to the "equivalent" ring protons, with an HFI constant of (10.2−1.95)/2 = 4.1 G. In the case under consideration, corresponding to slow exchange, the spectral lines with overall nuclear spin projections $M_I(+1/2, +1/2)$ and $M_I(-1/2, -1/2)$ hardly change their positions, while the lines with $M_I(+1/2, -1/2)$ and $M_I(-1/2, +1/2)$, should be converted into the line with $M_I(0)$ in the spectrum corresponding to rapid exchange. The opposite signs of the nuclear spin projections of the aromatic ring protons are due to the opposite signs of the spin intensities at the corresponding carbon atoms, which leads to the broadening of the extreme HFS components[60].

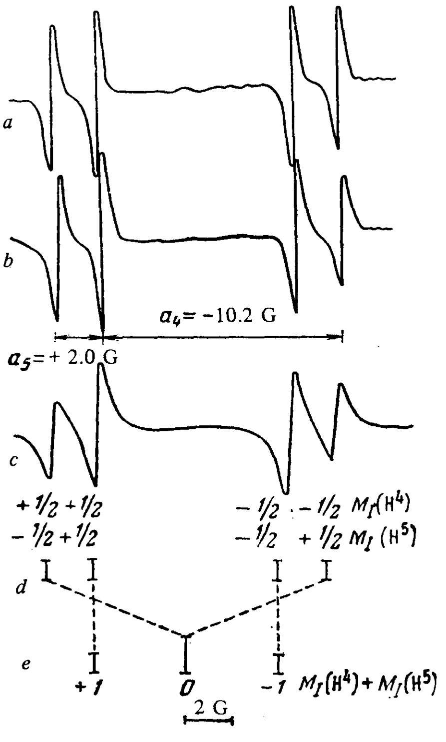


Figure 12. The EPR spectra of radical (VII) in benzene at different temperatures (°C): *a*) 80; *b*) 100; *c*) 120; *d*) and *e*) schematic representation of the spectra under the conditions of slow and fast exchange respectively.

The kinetic parameters of the acylotropic migration in radicals (VII)–(XI) were calculated on the basis of the analysis of the line width[61]. The influence of the substituent on the kinetic parameters of the acylotropic migration

---

† A.I. Prokof'ev, T.I. Prokof'eva, N.N. Bubnov, S.P. Solodovnikov, I.S. Belostotskaya, V.V. Ershov, and M.I. Kabachnik, Dokl. Akad. Nauk SSSR (in the Press).

in radicals (VII)–(XI) (solvent—toluene) is illustrated below:

Radical	Acyl	$10^{-4}\nu(20°)$, s^{-1}	$10^{-12}\nu_0$, s^{-1}	E_{act} ± 1.0, kcal mole^{-1}
(VII)	$COCH_3$	1	9.0	11.4
(VIII)	COC_2H_5	1	11.0	13.0
(IX)	$COCH_2Br$	26	21.0	10.7
(X)	$COCH_2C_6H_5$	10	0.6	9.15
(XI)	$COCH(C_6H_5)_2$	3	2.3	10.7

Evidently, as the electron-accepting properties of the substituents in the acyl group become more pronounced, the exchange frequencies increase and the energy barriers diminish. The data for radicals (X) and (XI) show that the mass of the migrating fragment plays a definite role. The results suggest that the facilitation of the migration of the acyl group following the enhancement of the electron-accepting properties of the substituents is due to the electron deficiency arising at the carbonyl carbon atom, which favours the formation of a polar transition state. The migration of acyl groups apparently proceeds via this state. The above mechanism of acylotropic migration is supported by positive acid catalysis. It has been shown for radical (VII)[61] that in the presence of one mole of trifluoroacetic acid the energy barrier decreases by a factor of two, and the frequency of migration of the acyl group increases by a factor greater than 100. The electron deficiency at the carbonyl carbon atom occurs as a result of the protonation of the carbonyl group in the acid–radical complex.

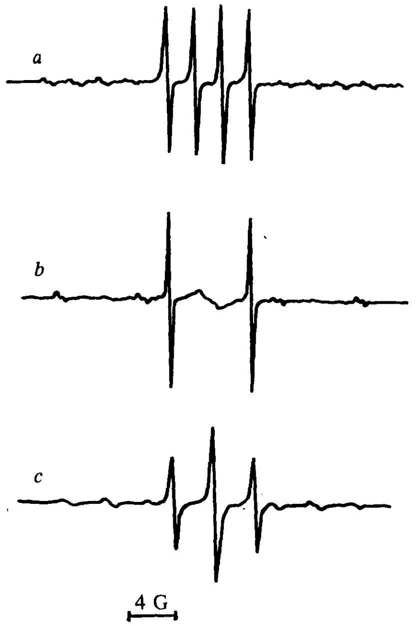

Figure 13. The EPR spectra of radical (XIII) in THF at different temperatures (°C): *a*) −70; *b*) 0; *c*) 110.

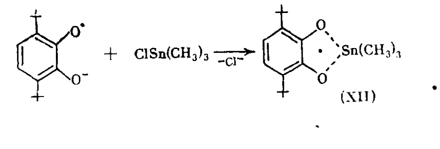
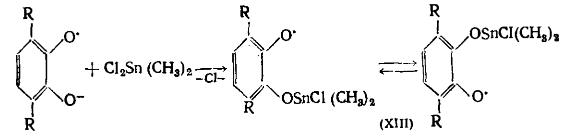
Radicals containing the trimethylstannyl group have been obtained by the reaction of 3,6-di-t-butyl-*o*-semiquinone radical-anions with chlorotrimethylstannane[62]:



The EPR spectrum of this radical is a triplet with a_H = 3.6 G due to the equivalent ring protons. In addition, the lines due to the paramagnetic tin isotopes are observed ($a_{^{117}Sn}$ = 12.8 G and $a_{^{119}Sn}$ = 13.3 G). Variation of temperature does not lead to a specific broadening of the spectral lines, which indicates either a stationary symmetrical disposition of the tin-containing group or its rapid migration (relative to the EPR time scale) between the oxygen atoms.

Stannotropic transitions, revealed by EPR spectra, have been observed in radical (XIII), obtained by the interaction of the semiquinone radical-anion with dichlorodimethylstannane[62]:



(R = t-butyl) .

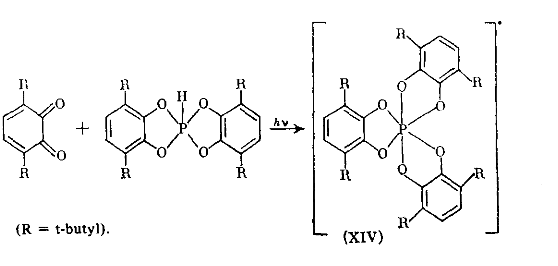
Fig. 13 shows that, as the temperature is reduced from 110° to −70°C, the EPR spectra of radical (XIII) reveal a transition from the triplet with a_H = 3.6 G, due to the HFI of the equivalent aromatic ring protons, to a doublet of doublets (a_H = 5.2 G, a_H = 2.6 G), which indicates the breakdown of the "equivalence" of the ring protons. An alternation of line widths, due to the intramolecular migration of the tin-containing fragment, is observed in the intermediate temperature range. The kinetic parameters of the tautomerism of radicals (VI), (XII), and (XIII) in THF are presented below:

Migrating radical	$\nu(20°)$, s^{-1}	$10^{-12}\nu_0$, s^{-1}	E_{act} ± 0.5 kcal mole^{-1}
(VI) $-CH_3$	0	—	—
(XII) $-Sn(CH_3)_3$	10^9	—	—
(XIII) $-Sn(CH_3)_2Cl$	$9 \cdot 10^6$	50	9.1

The data presented permit a quantitative comparison of the migration frequencies of fragments containing Group IV elements. The increase of migration frequency on passing from carbon to tin [radicals (VI), (XII), and (XIII)] illustrates the decisive role of the coordination unsaturation of the central atom of the migrating fragment in tautomeric transitions.

3. Free Radicals with a Six-Coordinated Phosphorus Atom

The above examples constitute "two-well" tautomeric systems (migration of fragments between two oxygen atoms). We shall now examine more complex instances of degenerate tautomerism, where the free valence migrates between six or four oxygen atoms ("wandering" valence). Such radicals have been obtained as a result of the interaction of 3,6-di-t-butyl-*o*-quinone with tetra-t-butylspirophosphorane under the influence of ultraviolet radiation. This interaction can be represented as follows[63]:



(R = t-butyl).

At high temperatures the EPR spectrum of radical (XIV) is a doublet due to the interaction of the unpaired electron with the ^{31}P nucleus (a_P = 4.1 G). Each component of the doublet contains seven lines (a_H = 1.45 G), the intensity ratios of which indicate unambiguously the interaction of the unpaired electron with six "equivalent" ring protons (Fig. 14*a*). With decrease of temperature, the HFS components with the proton nuclear spin projections $M_I = \pm 2$, ± 1 are broadened (Figs. 14*b*, 14*c*, and 14*d*) and at fairly low temperatures (−80° C) a spectrum is recorded in which each component of the phosphorus doublet contains three lines (a_H = 4.35 G) (Fig. 15*e*) corresponding to the interaction of the unpaired electron with two equivalent protons in a single ring. The above changes in the spectra are fully reversible with respect to temperature; the constant for hyperfine interaction with the ring protons is smaller by a factor of three in the high-temperature spectra than in those at low temperatures (Fig. 14).

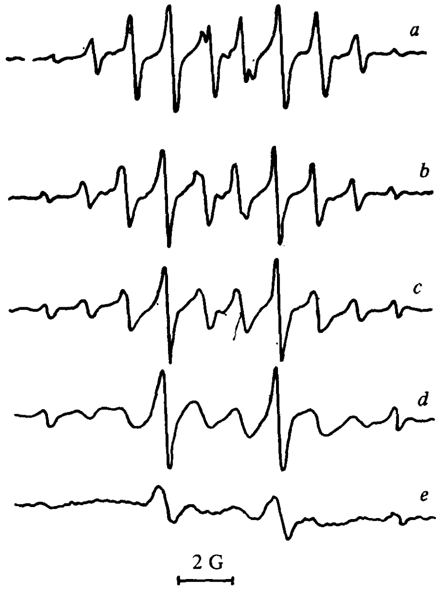


Figure 14. The EPR spectra of radical (XIV) in toluene at different temperatures (°C): *a*) 0; *b*) −20; *c*) −40; *d*) −60; *e*) −80.

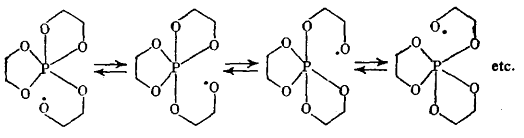
In interpreting the results one must bear in mind that the high-temperature spectra indicate the presence of six equivalent protons in radical (XIV). Since a specific broadening of the components of the septet, indicating the occurrence of dynamic effects, is observed when the temperature is reduced, presumably the "equivalence" of the six protons at high temperatures is achieved as a result of rapid exchange of the free valence and a bond in the system:



The free valence then "runs round" all six oxygen atoms of the catechol ligands and, in terms of the EPR scale, the phosphorus atom has a coordination number of six.

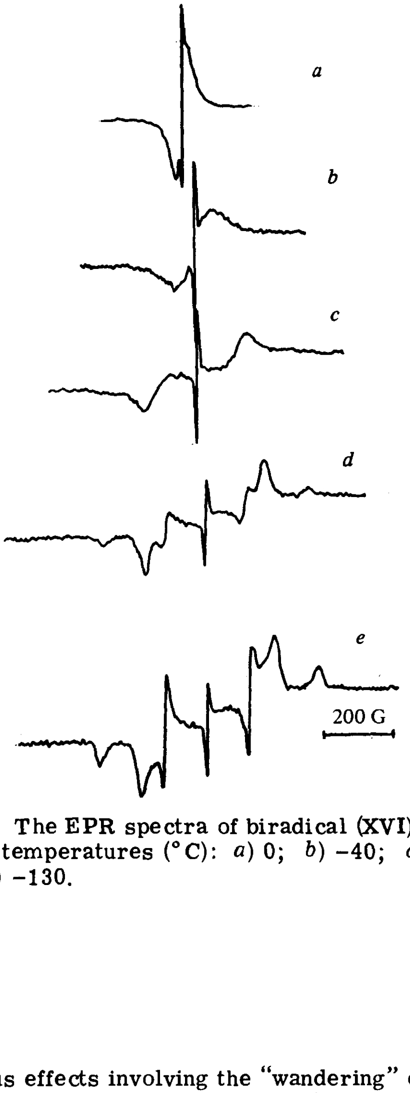


Figure 15. The EPR spectra of biradical (XVI) in toluene at different temperatures (°C): *a*) 0; *b*) −40; *c*) −80; *d*) −100; *e*) −130.

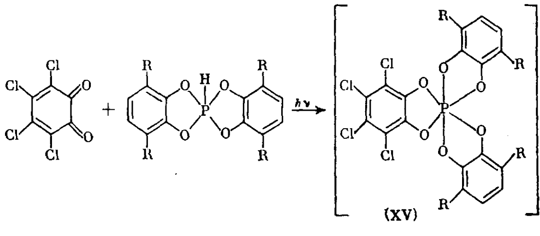
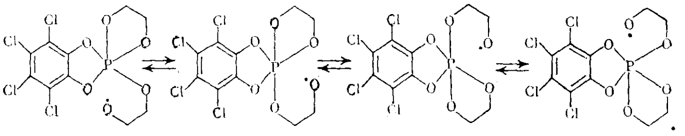
Analogous effects involving the "wandering" of the free valence have been obtained for radical (XV):



(XV)

At high temperatures each component of the phosphorus doublet contains five lines owing to the four protons of the two 3,6-di-t-butylcatechol ligands, which indicates the exchange of the unpaired electron and a bond between these ligands. The delocalisation of the unpaired electron over the two catechol ligands makes the HFI constant for the ring protons greater by a factor of 1.5 than in radical (XV) and indicates the absence of the exchange of the unpaired electron and a bond in the *o*-chloranil ligand:



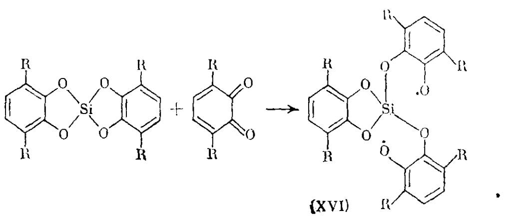
Analysis of line widths made it possible to estimate the energy parameters of the "wandering" of the free valence, the general expressions for which are as follows in the case of radicals (**XIV**) and (**XV**):

$$\nu_{\text{XIV}},\ (\text{s}^{-1}) = 3{,}4\cdot 10^{12}\exp[-(4{,}3 \pm 0{,}5)/RT],$$
$$\nu_{\text{XV}},\ (\text{s}^{-1}) = 0.9\cdot 10^{12}\exp[-(3.6 \pm 0.5)/RT].$$

At 20° C the frequencies of the "wandering" of the free valence in these radicals are similar and amount to 2×10^9 s^{-1}.

4. Free Radicals with a Six-Coordinated Silicon Atom

The effects associated with the intramolecular exchange of an electron and a bond in multiwell systems, which we have referred to as the "wandering" of the free valence, have been observed for free radicals with a six-coordinated silicon atom. Such radicals have been obtained by the interaction of silicon bis-3,6-di-t-butylcatecholate with 3,6-di-t-butyl-*o*-quinone, which leads to the formation of biradicals[64]:



(XVI)

The EPR spectra obtained for frozen solutions of these species are characteristic of biradical systems (Fig. 15) with an effective spin–spin interaction of two unpaired electrons, manifested by the presence of the zero splitting constants *D* and *E*. On raising the temperature, the spin–spin interaction is averaged out and the EPR spectrum of the liquid phase consists of a single broad line, which narrows on raising the temperature (Fig. 15). The line width between the points of maximum slope at 20° C is 25 G. Such a change in the spectra is characteristic of stable biradicals of the phenoxy-type and confirms the proposed structure of the species formed[23]. At half-field (g = 4) an intense absorption is observed (in frozen solutions), corresponding to a transition with $\Delta m = \pm 2$ and persisting down to −80° C.

Analysis of the main spectrum (Fig. 15*e*) gave the zero splitting parameters $D = 322$ G and $E = 24$ G. The non-zero value of *E* indicates the absence of axial symmetry in the unpaired electron distribution in biradical (XVI). The constant *D* characterises the average distance between the spins and, in terms of the point dipole approximation, is defined by the expression $D = g\beta r_{\text{av}}^{-3}$. One must bear in mind that the unpaired electrons are delocalised over the conjugated bond system of the catechol rings and, for small distances between the radical centres, comparable with the unpaired electron delocalisation regions, the point model may prove to be inapplicable to the estimation of distances between the interacting spins.

The parameter *D* depends greatly on r_{av}, so that one may assume that the main contribution to *D* comes from the spin density ρ_0 at the oxygen atoms of biradical (**XVI**) capable of maximum mutual approach. The estimate of the distribution of spin density in the 3,6-di-t-butyl-2-hydroxyphenoxy-radical[65], whose structure is similar to that of the radical fragments of biradical (XVI), suggests that $\rho_0 = 0.3$, so that $r_{\text{av}} = 3$ Å. If biradical (XVI) has a "quasi-octahedral" configuration owing to the coordination of the unpaired electrons to the vacant orbitals of silicon, then the univalent oxygen atoms may be either in the *cis*- or *trans*-positions relative to one another. The *trans*-positions for normal SiO bonds are separated by a distance of 3.3 Å. For coordinate bonds, these distances are apparently greater, and one may therefore assume that the distance $r = 3$ Å in biradical (XVI) corresponds to the *cis*-positions of the "univalent" oxygen atoms. This is confirmed by the absence of axial symmetry ($E \neq 0$) in the spectra of frozen solutions.

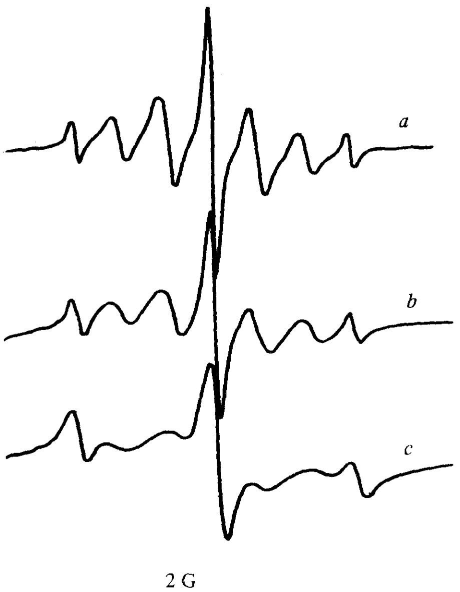


Figure 16. The EPR spectra of radical (XVII) in THF at different temperatures (°C): *a*) −40; *b*) −60; *c*) −80.

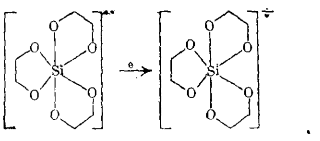
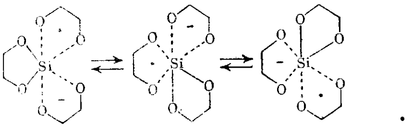
The main evidence for the structure of biradical (XVI) was the spectroscopic detection of the radical-anion (XVII), obtained by the electrochemical reduction of biradical (XVI):



(XVI) (XVII)

Fig. 16 presents the EPR spectrum of radical-anion (XVII) in THF, which consists at low temperatures (−80° C) of three lines due to the interaction of the unpaired electron with two protons in a single catechol ligand ($a_{\text{H}} = 3.75$ G).

With increase of temperature, additional broad lines appear in the spectrum, becoming narrower on further heating (Figs. 16*a* and 16*b*) and indicating the interaction of the unpaired electron with six "equivalent" protons and three catechol rings (a_H = 1.25 G). The above changes are fully reversible when the temperature is altered and indicate intramolecular processes. These reduce to the "wandering" of the free valence and the charge in accordance with the mechanism



The electronic structure of radical-anion (XVII) differs from that of the usual radical-anions obtained on reduction of neutral organic compounds. In the ion pairs formed by the latter compounds the motion of the cation is indissolubly linked to the synchronous redistribution of the charge and spin intensities of the unpaired electron over the system of conjugated bonds (for example in semiquinone radical-anions, see Section III). In ion pairs formed by radical-anion (XVII) the charge and spin densities are in principle separate and localised in different ligands. Under these conditions, the migration of the cation (and the redistribution of charge density) may take place to some extent independently of the exchange of the free valence and a bond, as can be seen from an examination of the "instantaneous" structures of ion pairs formed by radical-anion (XVII):

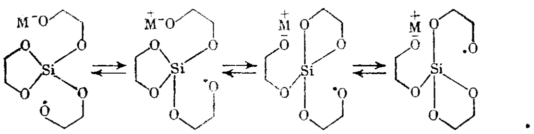


Table 2. The kinetic parameters of the interligand electron exchange in ion pairs comprising radical-anion (XVII).

Cation	Solvent	10^{-6} ν (20°), s^{-1}	$10^{11}\nu_0$, s^{-1}	E_{act} ± 0.5 kcal mole^{-1}
TBA^+	THF	10^3	10	4.1
Na^+	THF + crown	$4\cdot10^2$	10	4.6
Na^+	THF	2.5	7.4	7.4
Na^+	DME	2.2	22	8.1
K^+	THF	1.8	1.5	6.6
K^+	DME	1.2	7	7.9
Li^+	THF	0.6	$3\cdot10^{-4}$	2.3
Li^+	DME	1.1	0.12	5.5

Note. TBA^+ is the tetrabutylammonium cation and crown stands for 18-crown-6 (0.01 M).

The characteristics of the structure of ion pairs formed by radical-anion (XVII) are clearly manifested in the variation of the frequency of the exchange (ν_{exch}) of the unpaired electron and a bond as a function of temperature, the nature of the cation, and the solvating properties of the medium (Table 2). In the free radical-anions (XVII) (tetrabutylammonium cation) and in alkali metal salts of radical-anion (XVII) in the presence of crown-ethers, which are powerful solvating agents, the kinetic parameters of the exchange are large and close to the values for radical (XIV) with a six-coordinated phosphorus atom, which has a similar structure but no negative charge. This supports the view that the rate-limiting stage of the interligand electron exchange in these species is the exchange of the free valence and a bond, i.e. an intramolecular radical substitution reaction.

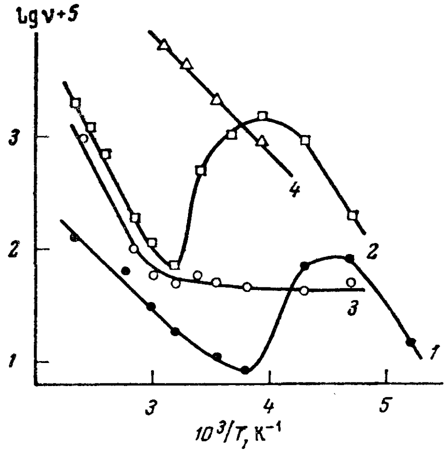

Figure 17. Dependence of the exchange frequency in radical-anion (XVII) on $1/T$ in DME for different cations: 1) Li^+; 2) Na^+; 3) K^+; 4) t-butylammonium.

Table 2 shows that in contact ion pairs formed by radical-anion (XVII) (alkali metal cations, weakly solvating solvents) ν_{exch} is appreciably lower and its temperature dependence in terms of Arrhenius coordinates is non-linear (Fig. 17). The rate-limiting stage of the exchange in contact ion pairs is the migration of a cation from ligand to ligand and a non-linear Arrhenius temperature dependence of ν_{exch} is due to the competition of two processes: the solvation of the cation by solvent molecules, responsible for the approach to the properties of free ions and the acceleration of the exchange frequency (low temperatures), and to the increase with temperature of the fraction of contact ion pairs in which the exchange frequency is much lower than in the solvated complexes. This competition in fact leads to the observed results: with increase of temperature, the exchange frequency initially falls and then increases again at very high temperatures (Fig. 18).

A characteristic feature of the exchange of the free valence and a bond in radical-anion (XVII) is the transition from the intraligand exchange immediately to the three-ligand exchange, bypassing the two-ligand exchange stage, which can be formally postulated on the basis of the above examination of the "instantaneous" structures of radical-anion (XVII). This can be explained by the fact that in contact ion pairs formed by radical-anion (XVII), where the unpaired electron is localised in one ligand, the cation tends to assume a symmetrical disposition relative to the other two catechol rings, determined by the coordination of the lone electron pairs of the oxygen atoms in the field of the cation (by analogy with crown-ethers). Such coordination prevents the involvement of the "vacant" ligand in the two-ligand exchange and creates conditions for the involvement of all three ligands at once in the exchange process. This also explains why the migration of the cation is rate-limiting in the exchange of the free valence and a bond in contact ion pairs[66].

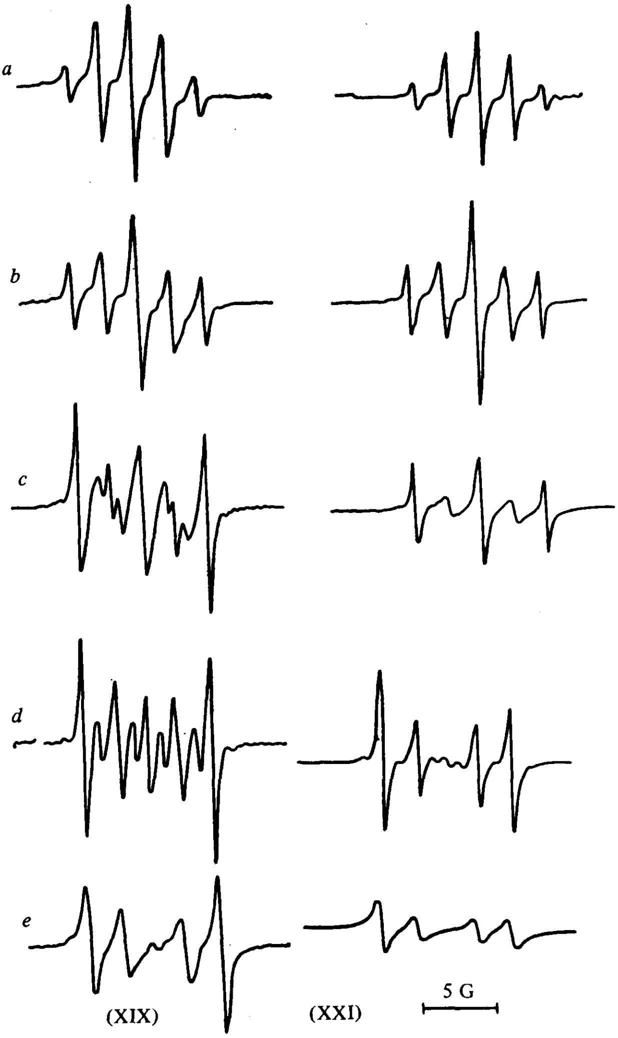

Figure 18. The EPR spectra of radicals (XIX) and (XXI) in pentane at different temperatures (°C): *a*) 80; *b*) 40; *c*) -40; *d*) -80; *e*) -110.

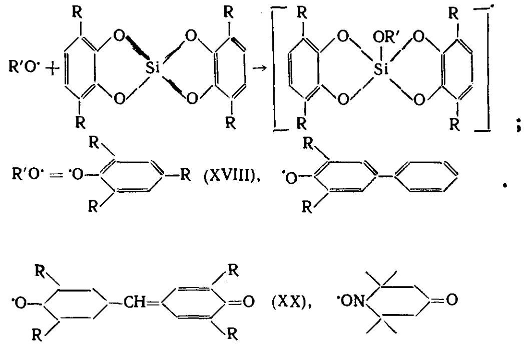
5. Free Radicals with a Five-Coordinated Silicon Atom

The two-ligand exchange of the unpaired electron and a bond has been investigated in detail in relation to free radicals with a five-coordinated silicon atom, obtained by the interaction of stable phenoxy- and iminoxy-radicals with silicon bis-(3,6-di-t-butylcatecholate) (SC)[67]:



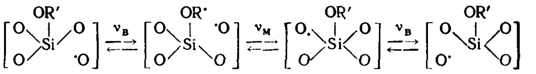
(XIX)

(XXI)

The kinetic parameters of the exchange between the electron and a bond in radicals with a five-coordinated silicon atom in pentane are listed below:

Radical	$10^{-8}\nu(20°)$, s^{-1}	$10^{-11}\nu_0$, s^{-1}	$E_{act} \pm 0.5$, kcal $mole^{-1}$
(XVIII) — (XX)	22	44	4.5
(XXI)	4.5	4.2	4.1

At high temperatures (80°C) the spectra of these radicals consist of a quintet (Fig. 18), due to the interaction of the four "equivalent" protons of the two catechol rings (a_H = 2.19 G), the silicon atom has a coordination number of five in terms of the EPR time scale, and the unpaired electron "runs round" the four oxygen atoms in the two catechol rings with a high frequency ("wandering" valence):



In other words, the rapid exchange condition is fulfilled; ν_B and ν_M are the frequencies of the exchange of the unpaired electron and a bond within a single ligand and between ligands respectively.

It is striking that the exchange does not involve the Si–OR bond, where it is possible to specify formally a state corresponding to the initial reactants (RO· and SC). It has been shown for radical (XXI) that at high temperatures (in excess of 100°C) this state does exist, but it corresponds simply to the reverse dissociation of radical (XXI) and the EPR spectra show a decrease of the intensity of the (XXI) lines and the appearance of the spectrum of the initial iminoxy-radical. At lower temperatures the equilibrium is wholly displaced towards radical (XXI) and the exchange takes place only between the catechol ligands and within them (the quintet due to the four "equivalent" protons of the two catechol rings). The alternative hypothesis of the possible ionic character of the Si–OR bond is unlikely, because the ultraviolet spectra of radicals (XVIII)–(XXI) obtained lack bands characteristic of the RO^- anion.

With decrease of temperature, the components of the quintet with M_I = 0, ±1, are broadened, which indicates inhibition of the exchange (Figs. 18*b* and 18*c*). At low temperatures (-110°C) the spectrum consists of a doublet (a_4^H = 6.37 G), each component of which is split into two lines (a_5^H = 2.37 G) (Fig. 18*e*) and corresponds to the structure with the localisation of the unpaired electron at one oxygen atom of the catechol ligand (slow exchange condition fulfilled)[67]. The HFI constants were assigned on the basis of the generally accepted ideas, according to which the maximum HFI is due to the proton in the *para*-position relative to the univalent oxygen atom.

The kinetic parameters of the exchange of the unpaired electron and a bond were estimated from the broadening of the central component of the quintet (relative to the extreme components) and reflect the change in the exchange frequency as a function of the nature of the added radical and the solvent. In pentane the frequencies and the energy barriers estimated in this way are similar for all radicals (see above).

In the intermediate exchange frequency range ($\nu_B, \nu_M \simeq \gamma_e\Delta a$) the alternation of line widths in the EPR spectra of radicals (XVIII)–(XXI) has its characteristic features. Firstly, the central component ($M_I = 0$) and lines with $M_I = \pm 1$ in the quintet are broadened non-uniformly and their intensity ratios change from 4 : 6 : 4 (high temperatures) to 1 : 2 : 1 (when the temperature is reduced—Figs. 18*a*, 18*b*, and 18*c*), and in certain cases even as far as 1 : 3 : 1.[67] On further reduction of temperature, the central component becomes less intense than the lateral ones ($M_I = \pm 1$) and additional lines appear, vanishing as a result of a further reduction of temperature accompanied by the formation of a doublet of doublets (Figs. 18*c*, 18*d*, and 18*e*).

Before analysing these features, it is necessary to examine the individual contributions to the line widths taking into account the intra- and inter-ligand exchange processes as the intermediate stages in the inhibition of the overall exchange in the course of the localisation of the unpaired electron at one of the oxygen atoms (Fig. 19). From this standpoint, the radicals investigated may be regarded as "four-well" systems with potential energy minima for each of the four oxygen atoms. This system can be formally divided into two types of "two-well" subsystems, in the first of which the exchange of the electron and a bond takes place in a single ligand [intraligand exchange (ν_B)]. For this exchange, the EPR spectrum should consist of a triplet due to the interaction of the unpaired electron with the two "equivalent" protons of a single catechol ring; the HFI constant for this triplet is equal to half the sum of the HFI constants for the limiting structure (Fig. 19). The second type involves exchange between the oxygen atoms of different ligands [interligand exchange (ν_M)]. This case should give rise to a spectrum consisting of a triplet due to the presence of two *para*-protons (the 4-position relative to the univalent oxygen atom); its HFI constant is equal to half the HFI constant for the *para*-proton in the limiting structure. Each component of this triplet contains three lines due to the *meta*-protons (the 5-positions in the two-ligands) with an HFI constant equal to half the constant for the *meta*-proton in the limiting structure (Fig. 19).

One can imagine that the inhibition of the overall exchange (the conversion of the quintet into a doublet of doublets) proceeds via preliminary stages involving complete inhibition of one of the types of migration: type I with $\nu_B \gg \nu_M$ and type II with $\nu_B \ll \nu_M$. In these cases the spectrum should vary in accordance with the schemes in Fig. 19 with the intermediate formation of a triplet and a triplet of triplets respectively. However, the experimental spectra are complex (Fig. 18), which necessitates the hypothesis that both types of migration occur simultaneously in radicals (XVIII)–(XXI).

To test this hypothesis, the contributions to the width of the quintet $\Delta(T_2^{-1})$ were calculated for the two cases considered[67]. Evidently, whereas the broadening of the central component of the triplet is the same for both types of inhibition of the exchange, for the components with $M_I = \pm 1$ the broadening is different in each case. We calculated these contributions using the HFI constants for the limiting structures of the radicals investigated. Table 3 (type I) shows that four lines of the central component make a minimal contribution (16 G) compared with the lines having $M_I = \pm 1$ (35 G). This explains the non-uniform broadening of the components, mentioned above. The sharp decrease of the intensity of the central component on further reduction of temperature may be due to the predominance of the type II inhibition ($\nu_B \ll \nu_M$). Indeed in this case the minimal contribution to the broadening comes from the lines with $M_I = \pm 1$ (9.6 G) compared with the central component (16 G). This is also supported by the appearance of additional lines (the formation of a nine-line spectrum) on further reduction of temperature (Figs. 18*c* and 18*d*), which may be attributed to the intermediate formation of a triplet of triplets (cf the scheme in Fig. 19). The discrepancy between the intensities may be due to the non-rigorous fulfilment of the rapid exchange condition for the individual components at a particular exchange frequency (different contributions to the width) and also to the presence of an intermediate spectrum of the exchange inhibition type (a triplet, Fig. 19).

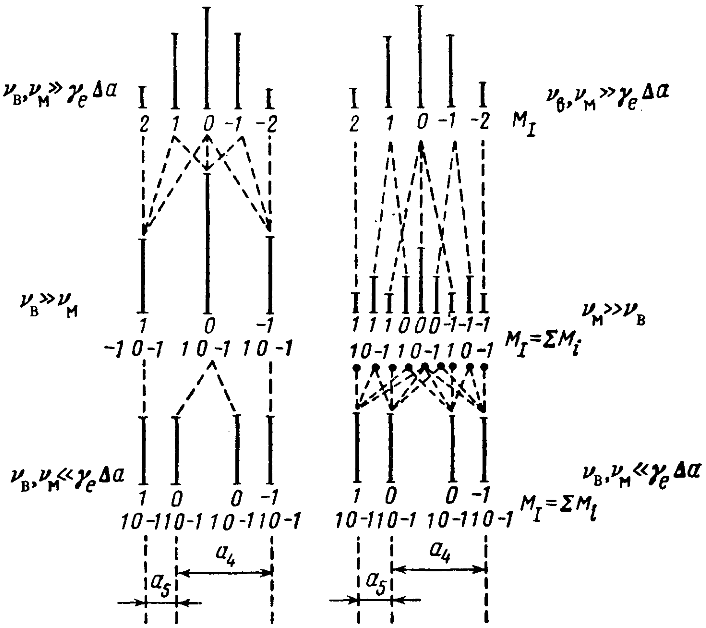


Figure 19. Schematic representation of the spectra of radicals (XVIII)–(XXI) under the conditions of the inhibition of the interligand exchange (type I) and the intraligand exchange (type II).

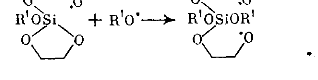
The increase of the thermodynamic stability of radicals (XVIII)–(XXI) after their formation suggests that they can combine with yet another initial radical to form the corresponding biradicals. Such species are produced when SC is made to react with an excess of the initial radicals:



Under these conditions, the EPR spectra shows signals characteristic of biradical systems; analysis of the spectrum makes it possible to determine the zero splitting constants for the biradicals (D = 335 ± 8 G, E = 21 ± 2 G). Estimates of the distances between the unpaired electrons yield 2.9 Å, which indicates the coordination of the unpaired electrons to the vacant orbitals of silicon. In frozen solutions signals at half-field (g = 4) are also recorded and at the usual temperatures signals in the form of single broad lines have been observed.

Table 3. The contributions $\Delta(T_2^{-1})$ to the width of the components of the quintet in the spectra of radicals (XVIII)-(XXI) under conditions of the inhibition of the exchange of the unpaired electron and a bond. (The numerical contributions were obtained with the following HFI constants: a_4^H = 6.37 G and a_5^H = 2.37 G).

Fast exchange				Intermediate exchange			
				type I exchange, $\nu_B \gg \nu_M$		type II exchange, $\nu_B \ll \nu_M$	
M_I	degeneracy	$M_I = \Sigma M_i$	degeneracy	$\Delta(T_2^{-1})$	$\Delta(T_2^{-1})$, G²	$\Delta(T_2^{-1})$	$\Delta(T_2^{-1})$, G²
±2	1	±1, ±1	1	0	0	0	0
±1	4	±1, 0	2	$^1/_4(a_4+a_5)^2+(a_4-a_5)^2$	35	$^1/_4(a_4-a_5)^2+a_5^2$	9.6
		0, ±1	2	$^1/_4(a_4+a_5)^2+(a_4-a_5)^2$	35	$^1/_4(a_4-a_5)^2+a_4^2$	44.5

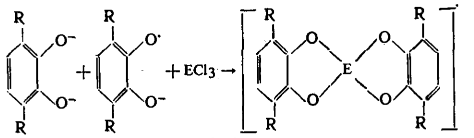
*The magnetic moments are expressed in terms of the NMR frequencies for a constant field of 21.14 kG.

6. Free Radicals with Four-Coordinated Boron and Aluminium Atoms

The effects associated with the "wandering" of the free valence have been observed also for radicals with four-coordinated boron and aluminium atoms, obtained as a result of the following reaction[68]:



;

E = B (XXII), or Al (XXIII) .

The EPR spectrum of the boron-containing radical (XXII) is a quartet (Fig. 20), due to the interaction of the unpaired electron with the main paramagnetic ^{11}B isotope (Table 4).

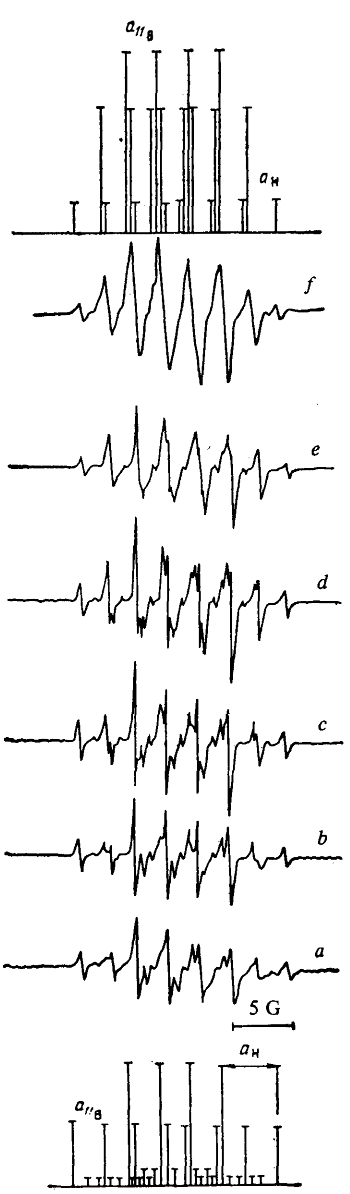


Figure 20. The EPR spectra of radicals (XXII) in THF at different temperatures (°C): a) −100; b) −80; c) −60; d) −40; e) −20; f) 20; data obtained from the reconstruction of the spectra corresponding to high and low temperatures and obtained with the HFI constants listed in Table 4.

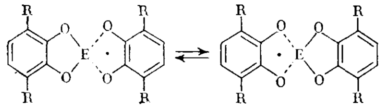
Each component of this quartet consists at low temperatures (−100° C) of a triplet (1 : 2 : 1) due to two protons of a single catechol ring (Fig. 20a). In addition, lines due to the ^{10}B isotope can be observed in the spectra at low temperatures. The ratios of the constants for the interaction of the unpaired electron with paramagnetic boron isotopes ($a_{^{11}\mathrm{B}}/a_{^{10}\mathrm{B}} = 3$) and the intensity ratio of the corresponding lines ($I_{^{11}\mathrm{B}}/I_{^{10}\mathrm{B}} = 7.5$) agree satisfactorily with the values calculated theoretically on the basis of the analysis of the magnetic moments of the nuclei and the natural abundances of the two isotopes (3 and 7.6 respectively).

When the specimen is heated, additional broad lines, narrowing on further increase of temperature (Figs. 20*b*, 20*c*, and 20*d*), are observed. At 20° C and above, each component of the boron quartet is transformed into a quintet with binomial intensity ratios (Fig. 20*e*) due to the interaction of the unpaired electron with the four equivalent protons of the two catechol rings. The changes in the spectra are fully reversible with respect to temperature and the HFI constant for the quintet is smaller by a factor of two than for the triplet at low temperatures.

Analogous changes occur in the EPR spectra of radical (XXIII), which has a central aluminium atom. Its spectra are illustrated in Fig. 21 and confirm the proposed structure. Six lines are due to the ^{27}Al nucleus (Table 4) and each component of the sextet consists of a triplet (low temperatures, Fig. 21*a*) or a quintet (high temperatures, Fig. 21*e*) due to the interaction of the unpaired electron with the protons of one or two catechol rings respectively.

The observed dynamic effects in the EPR spectra of radicals (XXII) and (XXIII) indicate rapid exchange of the free valence and a bond in these radicals:



.

At high temperatures the free valence "runs round" the four oxygen atoms and the B and Al atoms have tetrahedral configurations in terms of the EPR time scale. As for the free radicals with a six-coordinated phosphorus atom, the barriers to the transition within a single ligand are overcome at low temperatures and the unpaired electron interacts with the protons of a single ring[68].

Analysis of line widths made it possible to estimate the kinetic parameters of the "wandering" of the free valence, the general expressions for which are of the following form in the case of radicals (XXII) and (XXIII):

$$\nu_{\mathrm{XXII}},\ (\mathrm{s}^{-1}) = 1{,}8\cdot 10^{13}\exp[-(4200 \pm 300)/RT],$$

$$\nu_{\mathrm{XXIII}},\ (\mathrm{s}^{-1}) = 3.2\cdot 10^{11}\exp[-(3000 \pm 300)/RT].$$

At 20°C we have $\nu_{\mathrm{XXII}} = 2 \times 10^{9}\ \mathrm{s}^{-1}$ and $\nu_{\mathrm{XXIII}} = 1.25 \times 10^{10}\ \mathrm{s}^{-1}$.

Thus the spectroscopic data obtained constitute convincing evidence in support of the structures proposed for the radicals under consideration and illustrate the existence in the latter of a "wandering" valence in the presence of four-coordinated boron and aluminium atoms. The differences between the frequencies and the exchange of the free valence and a bond in these radicals are apparently due to the difference between the types of element–oxygen bonds.

The processes associated with degenerate tautomerism considered above can serve, depending on the type of migrating species, as models of heterolytic (cationotropism) and homolytic (intramolecular radical substitution) reactions. The study of the ion pairs formed by radical-anions, cationotropic processes, and the solvation of ions has greatly extended our ideas about the occurrence of ionic processes in organic solvents.

The conclusion that the mobility of the cation plays an important role in intramolecular electron transfer processes we believe to have a more general importance, going outside the limits of the chemistry of radical-anions. The idea that certain reactions proceed via an electron transfer stage is being developed at the present time[69,70]. In those cases where compounds containing alkali or other metal cations, for example, organometallic compounds, alkoxides, radical-anions, etc. serve as electron donors it is necessary to take into account the role of dissociative processes, without which it is impossible to describe correctly the electron transfer processes.

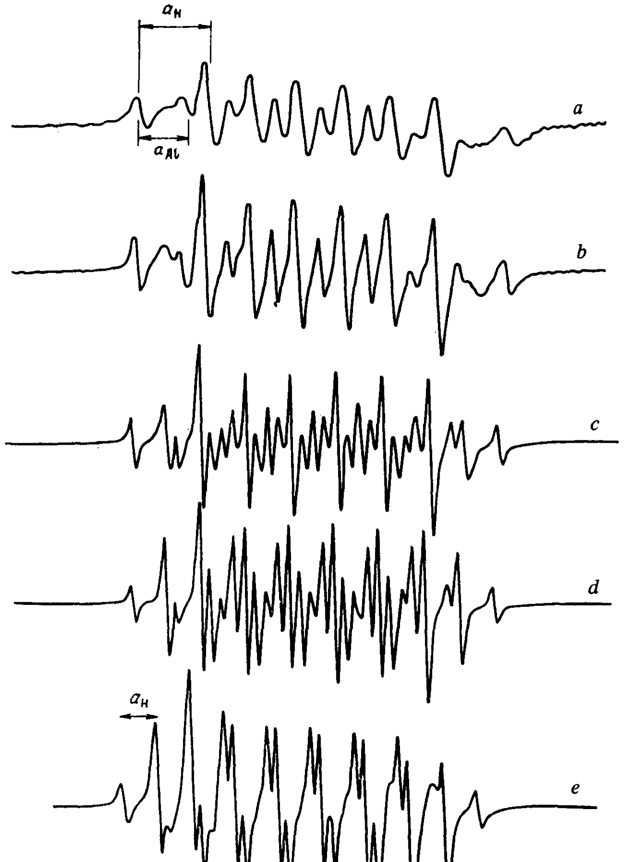


Figure 21. The EPR spectra of radical (XXIII) in THF at different temperatures (°C): *a*) −110; *b*) −100; *c*) −80; *d*) −40; *e*) 0.

The above examples of the tautomerism of radicals illustrate a type of tautomeric transformation new to organic chemistry, which constitute in essence intramolecular radical substitution reactions and permits certain generalisations concerning factors influencing the frequency of the transfer of the migrating fragments. In the simplest instances (migration of hydrogen and deuterium) it is evident that the formation of an intramolecular hydrogen bond intensifies the tendency of these atoms to assume a symmetrical disposition relative to the oxygen atoms of the catechol ring (the difference between the lengths of the normal and hydrogen bonds for the planar disposition of the O...HO fragment is only 0.3 Å[57]). The introduction of solvents capable of forming hydrogen bonds inhibits the migration of hydrogen owing to the competitive effects involving the formation of intermolecular hydrogen bonds by these solvents with the proton of the hydroxy-group.

In all the remaining cases considered the electron deficiency at the central atom of the migrating fragment promotes the coordination of the "univalent" oxygen to the vacant orbitals of this atom, which leads to high frequencies of the tautomeric transitions observed by the EPR method (10^6-10^{10} s^{-1}).

The tautomeric transformations in free radicals with four-, five-, and six-coordinated atoms of Group III, IV, and V elements ("wandering" valence) constitute in essence a new type of delocalisation of the unpaired electron namely delocalisation with bond dissociation. The data obtained suggest that analogous effects should be observed in the corresponding diamagnetic anions and should be associated with the "wandering" of the charge at a frequency which depends significantly on the state of the ion pairs involving these anions.

Solid-phase Radical Reactions and Mechanism of Oxidation of Carbon-chain Polymers

E.T.Denisov

Analysis of recent results on the kinetics of the oxidation of model hydrocarbons and carbon-chain polymers in solution and in the solid phase emphasises the common character of the oxidation mechanisms in liquid and solid phases. Detailed consideration is given to specific features of the solid-phase oxidation of polymers consequent on their high molecular mass, inhomogeneity in the solid state, the influence of molecular mobility on the kinetics of radical reactions, and the migration of free electrons. A list of 104 references is included.

I. INTRODUCTION

The history of science contains many examples of how, with the development of theory and experiment, research workers pass from studying comparatively simple to increasingly complicated systems, a tendency that can be traced in the kinetics of chain oxidations. Semenov's theory of branched and degenerate chain reactions was based on the gas-phase oxidation of simple molecules[1]. The oxidation of hydrocarbons and aldehydes in the gas phase occupied a central position in kinetic research during the 1930s and 1940s.[2] Advance into the liquid-phase oxidation of hydrocarbons was a feature of kinetic investigations during the 1950s,[3] which was subsequently applied to diverse organic compounds[4]. During the past decade the interest taken by research workers in the mechanism of the oxidation of polymers has grown considerably, both in our own country[5,6] and abroad[7-9]. The number of publications devoted to oxidation and radical reactions in polymers approaches the number on liquid-phase oxidation and far exceeds the annual number on gas-phase oxidation. Some of the apparent reasons for this change in the direction of research are enumerated below.

Firstly, the theory of the oxidation of polymers forms the scientific basis for their stabilisation and for predicting the durability of polymeric materials.

Secondly, the oxidation of polymers relates to a complicated, interesting, and hitherto largely unsolved scientific problem—the kinetics of radical reactions in the solid phase—and thus to the radiation chemistry of polymers and solid-phase polymerisation.

Thirdly, quantitative kinetic methods, developed earlier in the study of the liquid-phase oxidation of hydrocarbons, have been more and more widely used in research on the oxidation of polymers. Results obtained by these methods permit in several cases a quantitative comparison with the liquid-phase oxidation of model hydrocarbons.

Fourthly, very valuable results have recently been obtained on the oxidation of polymers in solution. Electron spin resonance has been widely used to measure the rate constants of radical reactions[10,11]. It has revealed the polychromatic kinetics of radical reactions in the solid phase[11] and the dependence of the rate of the primary step on the rigidity of the polymer matrix[12].

Comparison of experimental results obtained during recent years on the oxidation of polymers with data on the liquid-phase oxidation of model hydrocarbons indicates the similarities and differences between solid-phase and liquid-phase oxidation, together with possible reasons for such differences. These aspects will be covered in the present Review.

II. OXIDATION OF POLYMERS IN SOLUTION

The liquid-phase chain oxidation of hydrocarbons[3] and other organic compounds[4] involves the following primary stages

$$\text{Initiation In} \xrightarrow{k_i} \text{r}^{\cdot} \xrightarrow{\text{RH}} \text{R}^{\cdot} \tag{i}$$

$$\text{Chain progagation} \quad \text{R}^{\cdot} \xrightarrow{\text{O}_2} \text{RO}_2^{\cdot} \xrightarrow{\text{RH}} \text{ROOH} + \text{R}^{\cdot} \tag{1, 2}$$

$$\text{Self-initiation} \quad \text{ROOH} \rightarrow \quad \text{Free radicals} \quad (\text{R}^{\cdot}) \tag{3}$$

$$\text{Chain termination} \quad \text{R}^{\cdot}\,(\text{RO}_2^{\cdot}) + \text{R}^{\cdot}\,(\text{RO}_2^{\cdot}) \rightarrow \quad \text{Molecular products} \tag{4—6}$$

With a practically constant rate of initiation, when $k_\text{i}[\text{In}] \gg k_3[\text{ROOH}]$, and a sufficiently high concentration of dissolved oxygen ($k_1[\text{O}_2] \gg k_2[\text{RH}]$) the rate of liquid-phase oxidation is described by a formula which for long chains becomes

$$W_{\text{O}_2} = a\,[\text{RH}]\,W_i^{1/2},$$

where W_i is the rate of initiation. The reason for the first order with respect to RH is that chain propagation is limited by the reaction $\text{RO}_2^{\cdot} + \text{RH}$, the order 0.5 with respect to the initiator is due to bimolecular (quadratic) chain termination, and the zero order with respect to oxygen is connected with preferential chain termination by reaction (6) between two peroxy-radicals. At low RH concentrations the oxidation chains are short, so that absorption of oxygen must be taken into account even in the act of initiation, and the rate of such absorption in the steady state is

$$W_{O_2} = 1/2W_i + a\,[\mathrm{RH}]\cdot W_i^{1/2}, \quad a = k_2\cdot k_6^{-1/2}.$$

This formula is valid for peroxide initiators, such as cumenyl, t-butyl, and benzoyl peroxides, whose decomposition yields alkoxy- or acyloxy-radicals that do not react with oxygen but attack the hydrocarbon. When initiators that generate alkyl radicals are used, such as azoisobutyronitrile, reaction of the initiator radical $r^{\cdot}$ with oxygen

$$\mathrm{r}^{\cdot} \xrightarrow{O_2} \mathrm{rO}_2^{\cdot} \xrightarrow{RH} \mathrm{R}^{\cdot} + \mathrm{rOOH}$$

must also be taken into account, so that

$$W_{O_2} = 3/2W_i + a\,[\mathrm{RH}]\cdot W_i^{1/2}\ .$$

With sufficiently long chains $W_{O_2} \simeq [\mathrm{RH}]W_i^{1/2}$: i.e. the reaction has the first order with respect to the hydrocarbon, and 0.5 with respect to the initiator, in agreement with experimental results (Table 1, cumene).

The equation of the above type for polymers PH in solution is[13]

$$W_{O_2} = 2W_i + a\,[\mathrm{PH}]\cdot W_i^{1/2}\ ,$$

For the oxidation of polystyrene in the presence of azoisobutyronitrile in benzene and in chlorobenzene a is respectively 3.6×10^{-4} and 5.0×10^{-4} $\mathrm{M^{-1/2}\ s^{-1/2}}$ at 333 K (activation energy $E = 74.2$ kJ mole^{-1}). The solvent may take part in the oxidation, which is apparently why the coefficient of W_i is 2, not $1\frac{1}{2}$, while the coefficient a has different values in the two solvents. Table 1 shows that the dependence of the rate of the initiated oxidation of polyethylene, polypropylene, and polystyrene on the initiator and polymer concentrations differs from the corresponding relation for a hydrocarbon [Eqns. (I) and (II), and data for cumene in Table 1]: the order with respect to the initiator always exceeds 0.5 and is close to unity. The first order has been established for polyethylene and polypropylene in chlorobenzene[14], which indicates the linear character of chain termination in the oxidation of polymers in solution. This is because the recombination of two peroxy-macroradicals $\mathrm{PO}_2^{\cdot}$ in solution takes place slowly owing to the slowness of the diffusion of one coiled macromolecule into another, so that chain termination results from reaction between a macroradical and molecules of low molecular weight arising from attack by radicals on solvent molecules.

Chlorobenzene is not absolutely inert[14], but slowly oxidises when cumenyl peroxide decomposes. Its rate of oxidation is described by Eqn. (I) with the coefficient $a = 3.85 \times 10^5 \exp(-68/RT)$. Oxidation is due to the ability of aromatic molecules to add radicals with subsequent generation of $\mathrm{HO}_2^{\cdot}$ and $\mathrm{HO}^{\cdot}$:

$$\mathrm{ROOR} \to 2\mathrm{RO}^{\cdot}$$

$$\mathrm{RO}^{\cdot} + \mathrm{ArH} \to \mathrm{RO\dot{A}rH}$$

$$\mathrm{RO\dot{A}rH} + \mathrm{O_2} \to \mathrm{ROAr} + \mathrm{HO}_2^{\cdot}$$

$$\mathrm{HO}_2^{\cdot} + \mathrm{ArH} \to \mathrm{ArOH} + \mathrm{HO}^{\cdot}$$

$$\mathrm{HO}^{\cdot} + \mathrm{ArH} \to \mathrm{HO\dot{A}rH}$$

$$\mathrm{HO\dot{A}rH} + \mathrm{O_2} \to \mathrm{ArOH} + \mathrm{HO}_2^{\cdot}\ .$$

When a polymer is oxidised in such a solvent, the $\mathrm{HO}_2^{\cdot}$ radicals diffuse rapidly and react with $\mathrm{PO}_2^{\cdot}$, thus effecting chain termination, the rate of which is directly proportional to the rate of reaction of $\mathrm{RO}^{\cdot}$ with the solvent, i.e. the rate of initiation W_i. The order of oxidation with respect to the polymer is always less than unity (Table 1); for polystyrene of number-average molecular mass 100 000 the kinetic order is zero[18].

When azoisobutyronitrile (AIBN) is used as initiator, it is improbable that 1-cyano-1-methylethylperoxy-radicals formed from the initiator in the presence of oxygen will attack the solvent (benzene) molecules. At low polymer (PH) concentrations in such systems ($\mathrm{ArH{-}[CN.C(CH_3)_2.N{:}]_2{-}O_2{-}PH}$) a peroxy-radical of the initiator apparently reacts with the peroxy-macroradical. At sufficiently high PH concentrations $\mathrm{HO}_2^{\cdot}$ radicals, formed after $\mathrm{RO}^{\cdot}$ and $\mathrm{HO}^{\cdot}$ radicals appearing in the system have interacted with the solvent, may be involved in termination.

The primary reason for the diminished order with respect to the oxidisable compound on passing from a hydrocarbon to a polymer is that oxidation in the latter takes place predominantly within each coiled macromole-

Table 1. Kinetics of the oxidation of polymers in solution (I = light intensity).

*AIBN = azoisobutyronitrile.

cule. As soon as all the initiator radicals have reacted with the polymer to form P$^\cdot$ radicals (for which a minimum concentration $[PH]_{min}$ is required), further oxidation as a sequence of steps (1) and (2) takes place within a single macromolecule, resulting in a lower order of oxidation with respect to the polymer. Comparison of the photoinitiated oxidation of cumene, 2,4-diphenylpentane, and polystyrene (Table 1) leads to the same conclusion: whereas for cumene the kinetic order with respect to PH is unity, diphenylpentane undergoes appreciable intramolecular isomerisation of $RO_2^\cdot$ and the order with respect to RH is 0.8, while in polystyrene having $\overline{M}_n = 10^4$ the order with respect to PH is 0.6.[18]

Convincing evidence that in solution chain oxidation develops within a single macromolecule is provided by a comparison[14] of the rates of initiated oxidation of the n-decane–2,2,4-trimethylpentane and polyethylene–polypropylene systems. In the former case the rate of oxidation passes first through a maximum and then through a minimum with change in composition of the hydrocarbon mixture, such variation being due to the different activities of secondary and tertiary peroxy-radicals in chain propagation and termination[19]. In the latter case the rate of oxidation varies linearly with the composition of the polymer mixture, which indicates the absence of cross propagation and termination, possible only when the chain oxidation develops inside each separate coiled molecule.

Thus the kinetics of the oxidation of polymers in solution differs significantly from that of the oxidation of hydrocarbons in the participation of simple initiator or solvent radicals in chain termination, while chain oxidation develops within each macromolecule. Both circumstances result in slower oxidation of a polymer than of the model hydrocarbon.

III. REACTIVITY OF POLYMERS AND MODEL HYDROCARBONS

Since polymers and hydrocarbons differ in the kinetics of their initiated oxidation (Table 1), comparison of their rates of oxidation under similar conditions will not give a correct idea of the reactivities of carbon–hydrogen bonds in polymers and in model hydrocarbons. An example is provided by data on the oxidation of polypropylene and 2,2,4-trimethylpentane (RH) in the presence of 0.01 M azocyclohexanecarbonitrile in chlorobenzene at 363 K:[20] for the hydrocarbon the ratio $W_{O_2}/[RH]W_i^{1/2} = 4.1 \times 10^{-5}$ $M^{-1/2}$ $s^{-1/2}$, whereas the corresponding ratio for the polymer (per gram-equivalent of the monomer unit) is some hundredfold greater, i.e. 1.5×10^{-3}. We shall see below that the reactivity of a tertiary carbon–hydrogen bond in polypropylene is closely similar to that for 2,2,4-trimethylpentane.

During recent years rate constants have been measured for the reactions of peroxy- and alkoxy-radicals with carbon–hydrogen bonds in polymers and in model hydrocarbons. Cumene (RH) and polyethylene (PH) were oxidised together, and the quantities of ROOH and POOH were determined[21]. The ratio [POOH]/[ROOH] gave the ratio of the rate constants k_2^{PH}/k_2^{RH}, and k_2 was calculated for the reaction of the cumenylperoxy-radical with a carbon–hydrogen bond in polyethylene in solution. The rate of oxidation of polypropylene was measured in the presence of an initiator and t-butyl hydroperoxide[20], reaction with which caused rapid exchange of $PO_2^\cdot$ by $(CH_3)_3COO^\cdot$ radicals, so that the rate of oxidation of polypropylene was

$$W_{O_2} = (k_2/\sqrt{k_6}) \cdot [PH] \cdot [(CH_3)_3COO^\cdot]$$

from which k_2 could be calculated when k_6 was known. Peroxy-radicals of polystyrene (ps) recombine rapidly, so that its addition to cumene tended to inhibit oxidation of the latter[22]. The ratio k_2^{ps}/k_2^{RH} was found from the dependence of W_{O_2} on the concentration of polystyrene, and hence k_2^{ps} was calculated[22]. Rate constants for the abstraction of hydrogen from PH and RH by t-butoxy-radicals were measured by a method of competing reactions[23]. The results of these investigations are summarised in Table 2.

A comparison of polyethylene and polypropylene with model hydrocarbons shows that carbon–hydrogen bonds in a polymer and in the corresponding model have similar reactivities (differing not more than twofold, within the limits of error in the calculation of absolute rate constants). However, a marked (tenfold) difference in reactivity is observed between polystyrene and the model hydrocarbon cumene[22,25]. The most probable reason why a carbon–hydrogen bond is attacked more slowly in polystyrene when in cumene is steric hindrance by neighbouring phenyl rings. Detachment of hydrogen from such a

Table 2. Rate constants k* for reactions of peroxy- and alkoxy-radicals with C–H bonds in polymers and model hydrocarbons.

Oxidisable compound	Radical	Solvent	T, K	k, M^{-1} s^{-1}	Ref.

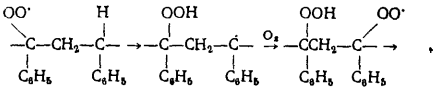
---

*Values of k calculated from k/k_d ratios, where $k_d = 10^{13.5}\exp(-69/RT)$ s^{-1} is the decomposition rate constant of the t-butoxy-radical (it has the values 100 and 140 s^{-1} at 313 and 318 K respectively)[27].

bond in cumene produces a cumenyl radical, which is stabilised by interaction of the p orbital of the unpaired electron with π orbitals of the phenyl ring. In polystyrene such stabilisation, which requires coplanarity of the phenyl ring and adjacent carbon–carbon bonds, is made difficult by neighbouring phenyl rings, which prevent such coplanarity. This explanation is supported by a comparison of the rate constants for reactions of the t-butoxy-radical with cumene, 2,4-diphenylpentane, and polystyrene (Table 2): rates of attack on a carbon–hydrogen bond are 5 times as rapid in diphenylpentane as in polystyrene, and ~10 times as rapid in cumene as in diphenylpentane. It is also interesting that the rate constant for chain propagation in polystyrene is $10^6 \exp(-33/RT) = 12.5\ M^{-1}\ s^{-1}$, which is hundredfold the rate constant for reaction of the cumenylperoxy-radical with a carbon–hydrogen bond in polystyrene[13]. If no experimental error is involved in the measurement of k_6 (which together with the ratio $k_2/k_6^{1/2}$ was used to calculate k_2), this can be explained by intramolecular chain propagation:



$$-\underset{C_6H_5}{\overset{OO^\cdot}{C}}-CH_2-\underset{C_6H_5}{\overset{H}{C}}- \rightarrow -\underset{C_6H_5}{\overset{OOH}{C}}-CH_2-\underset{C_6H_5}{\dot{C}}- \xrightarrow{O_2} -\underset{C_6H_5}{\overset{OOH}{C}}CH_2-\underset{C_6H_5}{\overset{OO^\cdot}{C}}- \rightarrow\ ,$$

Thus carbon–hydrogen bonds in a polymer exhibit the same reactivity towards free radicals as do those in a model hydrocarbon, provided that neighbouring groups do not create steric hindrance, as occurs in polystyrene.

IV. SIMILARITY OF THE MECHANISMS OF OXIDATION OF LIQUID HYDROCARBONS AND SOLID POLYMERS

Solid carbon-chain polymers, like liquid hydrocarbons, are oxidised by a chain mechanism involving alkyl and peroxy-radicals. This is demonstrated by investigations on the initiated oxidation of polymers, in which $W_{O_2} \gg W_i$ at not very high rates of initiation, and the chain length usually varies over the range $\nu = 5-200$ monomer units. Rate constants for initiation and for the decomposition of several initiators in polymers are given in Table 3. The liquid-phase chain oxidation of hydrocarbons involves alkyl and peroxy-radicals, the latter recorded by electron spin resonance[3]. The oxidation of solid polymers also is accompanied by formation of peroxy-radicals, detected by e.s.r. both in low-temperature radiation-chemical oxidation[43] and in oxidation in the presence of initiators at ~373 K (see Section VI).

During recent years important data on the mechanism of the oxidation of solid carbon-chain polymers have been obtained by the use of initiated oxidation, in which a known fixed rate of generation of free radicals enables the dependence of rate of oxidation on reactant concentrations and on rate of generation to be examined, the length of the chain to be calculated, and a quantitative measure of the oxidisability of a substance to be obtained as the overall constant in the formula

$$W_{O_2} = \text{const}\,[RH]^{n_1}\cdot[O_2]^{n_2}\cdot W_i^{n_3}\ .$$

The rate of the initiated oxidation of solid polymers, like the liquid-phase oxidation of hydrocarbons, is proportional to $W_i^{1/2}$ (Table 4). Hence in both solid and liquid phases chain termination results from the encounter and loss of two active centres (bimolecularly). As in the liquid phase, the rate of oxidation is independent of the partial pressure of oxygen when the latter is "high" (~1 atm).[38]

It is interesting to compare the rates of oxidation of polymers and model hydrocarbons. For polyethylene the ratio $W_{O_2}/W_i^{1/2} = 0.9 \times 10^{-5}$ per methylene group at 373 K (Table 4 [40]); but for a methylene group in cyclohexane[44] $k_2k_6^{-1/2} = 7.6 \times 10^{-5}$, an almost tenfold difference. On the other hand, polypropylene and isopentane are closely similar in oxidisability: $W_{O_2}/W_i^{1/2} = 6.4 \times 10^{-4}$ for one monomeric group in the polymer (Table 4 [38]) and $k_2k_6^{-1/2} = 4.5 \times 10^{-4}$ for isopentane (373 K).[24] The fact that, in the absence of an inhibitor, the rate of oxidation of a polymer in the solid phase is directly proportional to $W_i^{1/2}$ proves that chain termination always occurs by a bimolecular

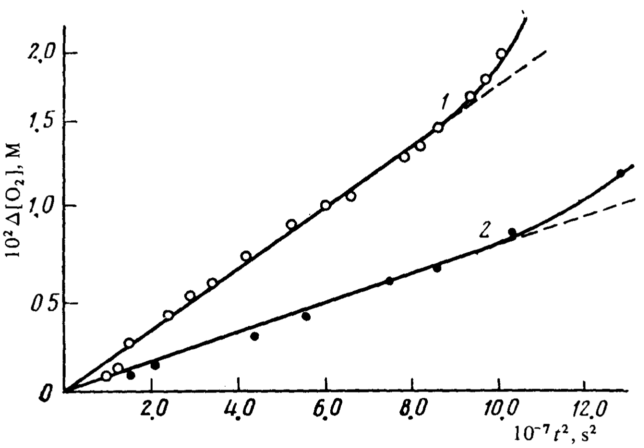

Figure 1. Kinetic curves for the autoxidation of polypropylene at 387 K under different oxygen pressures: 1) 1 atm; 2) 0.6 atm.

The uninitiated oxidation (autoxidation) of hydrocarbons and polymers is characterised by autocatalysis[3,7,48] due to the accumulation of hydroperoxide, an intermediate product that breaks down into free radicals. Both in liquid and in solid phases, therefore, oxidation is a self-initiated chain reaction (a chain reaction with degenerate branching of the chains). Since chains are terminated by a bimolecular reaction, the rate of autoxidation of a hydrocarbon is described by the equation[4]

$$d\Delta[O_2]/dt \cong k_2 k_6^{-1/2}\cdot[RH]\cdot(k_3[ROOH])^{1/2}$$

or

$$\Delta[O_2] \cong \frac{1}{4}(k_2 k_3^{1/2} k_6^{-1/2}\cdot[RH])^2\cdot t^2$$

provided that the rate of generation of chains is small ($W_{i0} \ll k_3[ROOH]$ almost throughout the experiment) and the whole of the oxygen absorbed is converted into hydroperoxide. The parabolic kinetic law, $\Delta[O_2] \propto t^2$ is due to the fact that self-initiation is a first-order reaction, whereas chain termination has a bimolecular mechanism. Both factors apply also to the oxidation of polymers in the solid phase, which therefore is also described (Fig. 1) by the kinetic law

$$\Delta[O_2]^{1/2} = b\cdot t\ .$$

In view of the above considerations use of the kinetic law $\Delta[O_2] \propto e^{\varphi t}$ (e.g. Ref. 48) for the uninhibited oxidation of solid polymers is evidently incorrect.

Thus oxidation both of liquid hydrocarbons and of solid carbon-chain polymers is a self-initiated chain reaction involving alkyl and peroxy-radicals with bimolecular chain termination. Within the framework of such a definition we can speak of a single radical–chain mechanism for the oxidation of liquid hydrocarbons and solid polymers. It is interesting that the gas-phase oxidation of hydrocarbons falls outside the scope of such a definition and has a different mechanism[49], in which not only $R^{\bullet}$ and $RO_2^{\bullet}$ but also alkoxy-radicals play an important part in chain propagation, and the reaction between two $RO_2^{\bullet}$ radicals involves not termination but propagation: $2RO_2^{\bullet} \rightarrow 2RO^{\bullet} + O_2$.

V. PRIMARY RADICAL REACTION IN A POLYMER MATRIX

In a condensed phase (liquid or solid) a bimolecular reaction between freely diffusing reactants takes place in two stages, with diffusion of two particles into the same cage followed by their collision and reaction in the cage[50]:

$$A + B \underset{k'_D}{\overset{k_D}{\rightleftarrows}} A\cdot B \xrightarrow{k} \text{Products}\ .$$

Depending on the relation between k and k'_D reactions are divided into slow ($k \ll k'_D$) and rapid or diffusion-controlled ($k \geqslant k'_D$). In a solution the cage walls consist of molecules undergoing quite rapid rotation (10^9–10^{11} s^{-1}) and translation (a molecular diameter in 10^{-9}–10^{-10} s). In the liquid phase, therefore, the form of the cage changes rapidly, and in the absence of orientational interactions between the molecules the cage walls can be regarded as an isotropic viscous medium surrounding the pair of reacting particles. In such a cage it may be expected that all mutual orientations of the particles will be equivalent, and that the steric factor for the bimolecular reaction will be closely similar to that for a gas-phase reaction.

An amorphous polymer phase resembles a liquid with regard to molecular motion, but displacements and rotations of segments and molecules are comparatively slow owing to the great length of the macromolecular chains and the large energy of intermolecular interaction of the chains. As a consequence, the shape of the cage formed by segments of the macromolecule changes slowly in the amorphous phase when compared with the liquid, the relaxation time of the form of the cage in the polymer is long, and the cage can be regarded as a kind of "bag" with rigid walls surrounding the pair of reactant particles[51]. In such a "rigid" cage by no means all the mutual orientations of the reactant particles are energetically equivalent. If an orientation required the consumption of energy is necessary for a primary step, the steric factor P for such a reaction will be smaller in the polymer than in the liquid phase, and will depend on the temperature: $P = P_0 e^{-E_{or}/RT}$, where E_{or} is the activation energy of orientation of the particles due to the energy consumed in overcoming the action of the rigid polymer matrix, i.e. in orienting the particles. Such a model of a rigid cage (a cage with slow relaxation of its shape and size) leads to the qualitative conclusions outlined below[51].

1. The rate constant for species requires a precise orientation before they can react should be smaller in a solid polymer matrix than in the liquid phase. This conclusion is supported by comparison of the rate of such reactions as the oxidation of dinaphthyl-*p*-phenylenediamine by a hydroperoxide (k_*/k_{sd} = 7.4 in polypropylene at 373 K [52]), the reaction of tri-t-butylphenoxyl with POOH (43 in polypropylene at 295 K [53]), and the action of the nitroxyl radical on 2,6-di-t-butylphenol[54] (14 in polyethylene at 313 K).
2. The activation energy of a bimolecular reaction should be greater in the solid phase than in solution. This conclusion is consistent with data on termination reactions: for the reaction of 2,4,6-tri-t-butylphenoxyl with POOH in benzene and in polypropylene the activation energy is respectively 45.5 and 67 kJ mole^{-1};[53] the corresponding values for the action of the nitroxyl radical on 2,6-di-t-butylphenol are 42 and 75 kJ mole^{-1}.[54]
3. Introduction of a simple compound into a polymer, by increasing the molecular mobility and making the cage more elastic (shortening the relaxation time of its shape), should accelerate a bimolecular reaction. Benzene actually has such an effect on the above two reactions[53,54].
4. Since both the mutual orientation of species and the rotation of a species in a cage involve overcoming forces of repulsion due to "neighbours", a parallelism can be expected in the variation of the rate constant of a bimolecular reaction and the frequency of rotation of a species, e.g. a stable nitroxyl radical, with change in the polymer matrix. Such parallelism has been demonstrated[12,53,54]. It is interesting that the activation energy of rotation E_ν and the difference in activation energy of the reaction in solid and liquid phases are then closely similar (respectively 40 and 33 kJ mole^{-1}).[53,54]
5. Rise in temperature is accompanied by an increase in molecular mobility in the polymer, a shortening of the relaxation time of the cage shape, and an increase in the elasticity of the cage. As a consequence, the orientation of the reactant species necessary for the primary step is more easily attained, and E_{or} is lowered. Thus, since in the solid phase the total activation energy $E_\Sigma = E_{or} + E$, while E_{or} decreases with rise in temperature, it follows that E_Σ is an effective quantity that decreases with rise in temperature.

Termination in the solid phase may also be retarded by a possible delay between the abstraction of hydrogen and rehybridisation of *p* orbitals of the carbon atom under attack[55]. However, the difference between the rate constants for abstraction of a hydrogen atom by peroxy-radicals in solution and in the solid phase (see below) is small, so that delay in rehybridisation is not evident here. At the given temperatures the molecular mobility of the macromolecular segments is apparently sufficient to ensure rehybridisation of orbitals immediately on accomplishment of the primary step.

Another substantial difference between a solid polymer and a liquid is the inhomogeneity of a polymer as a medium. Firstly, a polymer (polyethylene, isotactic polypropylene, ethylene–propylene copolymers, etc.) comprises crystalline and amorphous phases. If the former is more densely packed than the latter, dissolution and interaction of the reactants will occur predominantly in the amorphous phase. Electron spin resonance has shown[53] that nitroxyl radicals dissolve only in the amorphous phase. Secondly, the amorphous phase of a polymer is itself non-uniform, consisting of a series of zones differing in molecular mobility. This leads to so called polychromatic kinetics both of radical reactions and of physical processes, e.g. diffusion in a polymer[56–60]. With rise in temperature the polychromatism disappears, apparently because of increasing mobility of the molecules and more rapid migration of density fluctuations along the polymer (the amorphous phase approaches a liquid in molecular mobility). Thus a polymer differs from a liquid as a medium in its more rigid cage structure (the shape of the cage changes slowly) and in inhomogeneity. These two features affect the kinetics of radical reactions in a polymer.

Table 5. Specific rates of generation of chains in polymers and model hydrocarbons.

Oxidisable compound	T, K	k_{i0}, M^{-1} s^{-1}	E_{i0}, kJ mole^{-1}	Ref.

*Here calculation of k_{i0} per monomer unit was based on the amorphous phase.

VI. CHAIN GENERATION AND PROPAGATION

Generation of Chains

In hydrocarbons undergoing oxidation, chains are generated by reactions involving oxygen. Most often generation occurs by the bimolecular reaction[61]

$$RH + O_2 \rightarrow R^{\cdot} + HO_2^{\cdot},$$

whose activation energy approximates to its endothermicity. In compounds having weak carbon–hydrogen bonds (bonding energy < 330 kJ mole^{-1}) chains are generated mainly by the termolecular reaction[3]

$$2RH + O_2 \rightarrow 2R^{\cdot} + H_2O_2 \ .$$

The reaction

$$C_6H_5CH_2CH_3 + 2O_2 \rightarrow C_6H_5CH\dot{C}H_2 + 2HO_2^{\cdot}$$

has been demonstrated[62] for ethylbenzene.

In the only study of chain generation in polymers (polyethylene, polypropylene)[63] the rate of formation of radicals was measured by an inhibitor method from the consumption of 1-naphthol and *NN'*-dinaphth-2-yl-*p*-phenylenediamine. Chain generation was shown to involve oxygen, which in effect dissolves only in the amorphous phase, so that generation was concentrated therein. In the solid phase the specific rate of chain generation $k_{i0} = W_{i0}/\alpha[O_2][PH]$ (in which α is the fraction of the amorphous phase) is significantly higher than in solution (Table 4) and higher than in model hydrocarbons by several orders of magnitude. In a polymer chains are probably generated by reaction between oxygen and residues of the catalyst. The higher specific rate in the solid phase than in solution (Table 5) can be explained by the presence of "weak" carbon–hydrogen bonds in deformed segments of the macromolecular chains. A relatively high rate in polymers must be taken into account in the use of inhibitors for the stabilisation of polymers and in interpretation of the results of experiments with inhibitors. In particular, the high value of W_{i0} in polypropylene casts doubt on the legitimacy of applying the theory of critical phenomena in inhibited oxidation, since quite a high k_3/W_{i0} ratio is then necessary[66].

Reaction $P^{\cdot} + O_2 \rightarrow PO_2^{\cdot}$

The addition of oxygen to alkyl radicals is very rapid, its rate being limited by diffusion of the gas into the polymer. For example, the rate constant for addition of oxygen to the methyl radical in water is 5×10^9 M^{-1} s^{-1}.[19] The kinetics of the $P^{\cdot} + O_2$ reaction in polymers has been studied by low-temperature e.s.r. with radiation-chemical generation of $P^{\cdot}$ (Table 6). Owing to the non-uniformity of the polymer and differences in the diffusion coefficients of oxygen in different zones, the reaction with alkyl radicals is described by a polychromatic kinetic equation with an activation-energy particle distribution (every zone has its own activation energy for the diffusion of oxygen). Table 6 gives values of $E_{\min}$ and $E_{\max}$ calculated for a linear energy distribution of $P^{\cdot}$. Earlier measurements of k_1 and E_1 have been given in a review[5].

Table 6. Rate constants of the reaction $P^{\cdot} + O_2$ in polymers.

Polymer	T, K	E, kJ mole^{-1}	lg (A, M^{-1} s^{-1})	Ref.
Isotactic polypropylene, powder	373	—	6.4*	34
Isotactic polypropylene, film	100—140	$E_{\min}$=33; $E_{\max}$=44	14	67
Atactic polypropylene, film	100—140	$E_{\min}$=19; $E_{\max}$=25	9	67
Polystyrene	90—120	$E_{\min}$=29; $E_{\max}$=35	13	68
Polystyrene	94—140	$E_{\min}$=22.5; $E_{\max}$=27	12	69

*Value of lg (k, M^{-1} s^{-1}).

Since diffusion in a polymer is due to segmental mobility, while rise in temperature produces an abrupt release of degrees of freedom, it follows that $E_{\text{diff}} = E_1$ changes from one temperature range to another. Therefore the extrapolation of k_1 to the comparatively high oxidation temperatures will give incorrect estimates. The only estimate of k_1 for 373 K (oxidation temperature) was based[34] on the dependence of rate of oxidation on partial pressure of oxygen (the ratio $k_1/k_4^{1/2}$ was found) with the value $k_4 = 2.7 \times 10^6$ M^{-1} s^{-1} measured by e.s.r.

The Reaction $PO_2^{\cdot} + PH \rightarrow POOH + P^{\cdot}$

Reaction rate constants for peroxy-radicals in polymers have been studied by electron spin resonance—at low temperatures (below room temperature) from the kinetics of the disappearance of $PO_2^{\cdot}$, and under oxidation conditions from the rate of oxidation at the steady-state concentration of peroxy-radicals ($k_2 = W_{O_2}/[PO_2^{\cdot}]$)—and the results are listed in Table 7. The activation energy for the $PO^{\cdot} + PH$ in polyethylene[70] seems to be greatly underestimated. It must be expected that in the solid phase $E > E_{\text{liq}}$. For the reaction of cumenylperoxy-radicals with n-decane $E_2 = 73$ kJ mole^{-1} (Table 2), whereas in polyethylene $E_2 = 39$ kJ mole^{-1} (Table 7). Furthermore, a carbon–hydrogen bond in polyethylene is more stable than a tertiary bond in polypropylene, so that E_2 should be higher in the former than in the latter polymer, whereas the opposite situation has been observed[70]. On the other hand, E_2 is higher in deuterated than in ordinary polyethylene, which indicates the loss of $PO_2^{\cdot}$ by reaction with a C–H (C–D) bond.

Table 7. Rate constants of $PO_2^{\cdot} + PH$ reactions in solid polymers calculated per monomer unit.

*For maximum value of k_2.

**For minimum value of k_2.

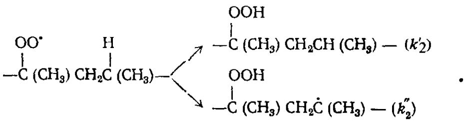
***Value of k.

Values of k_2 must be expected to be smaller in the solid phase than in solution (see above and Tables 2 and 7). In solution at 388 K the cumenylperoxy-radical attacks a carbon–hydrogen bond in polyethylene with $k_2 = 0.12$ M^{-1} s^{-1}. In the solid phase extrapolation of k_2 to 388 K gives 0.0012 M^{-1} s^{-1} per bond (Table 7): i.e. in the solid phase abstraction of a hydrogen atom by the peroxy-radical is slower by a factor of 100.

We reach a similar conclusion if we compare $k_2 = 0.05$ M^{-1} s^{-1} in poly(methyl methacrylate) [monomeric unit $-CH_2\overset{|}{C}(CH_3)COOCH_3$] at 360 K with the rate constant $k_2 = 24$ M^{-1} s^{-1} for reaction of the cumenylperoxy-radical with methyl propionate at the same temperature[4]. At first glance a different conclusion is reached from a comparison of k_2 for polypropylene in solution and in the solid phase: the t-butylperoxy-radical attacks a tertiary carbon–hydrogen bond in polypropylene with $k_2 = 0.98$ M^{-1} s^{-1} at 338 K (Table 2), whereas in solid atactic polypropylene $k_2 = 0.7$ M^{-1} s^{-1} (Table 7).[35] However, these constants represent different processes. In the oxidation of polypropylene in the presence of a hydroperoxide in solution k_2 relates to the reaction

$$(CH_3)_3COO^{\cdot} + PH \rightarrow (CH_3)_3COOH + P^{\cdot} ,$$

Chain propagation in such oxidation in the solid, like the oxidation of hydrocarbons with neighbouring tertiary carbon–hydrogen bonds in the β position[3], occurs by intermolecular and intramolecular mechanisms:



For oxidation in the solid phase, therefore, $k_2 = k_2' + k_2''/[PH]$. For 2,4-dimethylpentane $k_2''/k_2' = 90$ at 373 K if k_2' relates to a single tertiary carbon–hydrogen bond[74]. Assuming the same relation for polypropylene, with the use of $k_2 = 0.7$ and $[PH] = 22$ M, we obtain $k_2' = 0.18$ M^{-1} s^{-1}, about one-fifth of the value in the liquid phase.

Thus reaction of a peroxy-radical with a carbon–hydrogen bond takes place more slowly in a solid polymer than in the liquid phase. This is due to the effect of the rigid cage of the polymer matrix on the probability of achieving the mutual orientation of radical and bond required for the reaction. This is consistent also with the polychromatic reaction kinetics of peroxy-radicals in polystyrene[72], which cannot be explained by hindrance to translational or rotational diffusion of segments, since in this case we are dealing with a slow reaction not controlled by such diffusion of species.

Breakdown of Macroradicals

The oxidation of polymers is accompanied by degradation of the macromolecules and a fall in the molecular mass of the polymer. The mechanism of this process still remains obscure. Since alkoxy-radicals tend to break down, but are formed by the decomposition of hydroperoxides, it was natural to attribute degradation of the macromolecules to breakdown of POOH:[48]

$$POOH \rightarrow HO^{\cdot} + PO^{\cdot} \rightarrow \text{decomposition.}$$

However, experiments on the initiated oxidation of polymers have shown that degradation begins with the appearance of peroxy-radicals long before a hydroperoxide has accumulated and begun to break down at an appreciable rate[37,75].

Tobolsky found[37] that the rate of degradation of polypropylene $W_S \propto W_i$ (with benzoyl peroxide as initiator at 363–378 K). Since in a steady state rate of initiation and of loss of radicals are equal, while tertiary peroxy-radicals also react to form alkoxy-radicals $2PO_2^{\cdot} \rightarrow 2PO^{\cdot} + O_2$, degradation was attributed to the generation of $PO^{\cdot}$ radicals and their subsequent decomposition. However, the relation $W_S \propto W_i^{1/2}$ is observed[75] in the oxidation of polyethylene (at 115°C): i.e. W_S is directly proportional to the concentration of peroxy-radicals, and rupture of a carbon–carbon bond is a first-order reaction with respect to $PO_2^{\cdot}$. By analogy with the breakdown of $PO_2^{\cdot}$ in the gas phase[2] it is suggested[75] that such rupture is effected by the reaction

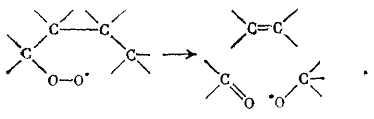
$$-CH_2-\overset{OO^{\cdot}}{\overset{|}{C}}H-CH_2 \rightarrow -CH_2CHO + {}^{\cdot}OCH_2- \ .$$

With the oxidation of methane as example, however, it has recently been convincingly demonstrated[49] that degradation in gas-phase oxidation has the mechanism

$$2RO_2^{\cdot} \rightarrow 2RO^{\cdot} \rightarrow \text{decomposition.}$$

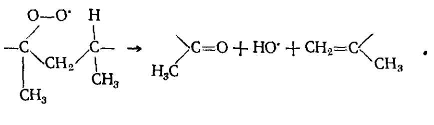
Hence there are no grounds for the first mechanism of degradation.

Marchal suggests[76] the mechanism



However, such intramolecular incorporation of oxygen of the peroxy-radical (radical substitution) is improbable, since the activation energy of this process followed by decomposition would be very high.

The most probable mechanism is breakdown of the peroxy-radical by degradative isomerisation:



VII. RELAY MECHANISM OF MIGRATION OF A FREE ELECTRON IN A POLYMER

In liquid free radicals ($R^{\cdot}$, $RO_2^{\cdot}$) migrate by diffusion, and chain termination either occurs with a diffusion rate constant ($R^{\cdot} + R^{\cdot}$, $R^{\cdot} + RO_2^{\cdot}$) or is determined by the rate of interaction of radicals ($RO_2^{\cdot} + RO_2^{\cdot}$). In a solid polymer a macroradical hardly diffuses at all[77], but segments of the macromolecule (macroradical) are displaced by thermal motion. In polymers undergoing oxidation, chains can in general be terminated by one of three mechanisms.

The first mechanism is segmental diffusion: a segment carrying the free electron, as it moves, encounters another segment, a radical, with which it interacts. Segmental diffusion provides a satisfactory explanation of the kinetics of the loss of alkyl macroradicals at low temperatures, and notably the "stepwise" character of their disappearance, which is due also to the non-uniformity of the polymer. Segmental diffusion is a slow process: e.g. in an ethylene–propylene copolymer (mol. wt. 200 000) $D = 4 \times 10^{-17}$ cm^2 s^{-1} at 220 K.[78] Displacement of a segment is restricted to an effective distance l. At the temperatures of oxidation (350–450 K) the loss of radicals is far more rapid than could be due to segmental diffusion, so that another hypothesis was required.

A second hypothetical mechanism of chain termination involved the formation of simple radicals, their rapid diffusion, and their recombination with macroradicals[79]. This hypothesis is open to several objections. Firstly, radicals of low molecular weight should appear at a rate exceeding the rate of initiation, but they can be formed only in the slow endothermic decomposition of radicals. On the assumption that termination is limited by the rate of such decomposition, it should be linear, whereas in oxidation termination is always bimolecular (Section IV). Secondly, if such active radicals as $HO^{\cdot}$ and $RO^{\cdot}$ are formed, they will react rapidly with carbon–hydrogen bonds in the polymer and, because of the low steady-state concentration, will be unable to participate in chain termination. For example, t-butoxy-radicals abstract hydrogen from tertiary carbon–hydrogen bonds in aliphatic hydrocarbons with $k = 80\,000$ M^{-1} s^{-1} at 408 K,[19] and in polypropylene with a rate of formation $rO^{\cdot} = 10^{-6}$ M s^{-1}

their steady-state concentration is ~10^{-12} M; with $[P^\cdot] = 10^{-6}$ M and $k_D = 10^8$ M^{-1} s^{-1} we obtain $W_{P^\cdot + rO^\cdot} \simeq 10^{-10}$. Substantial difficulties arise when an attempt is made to write down specific decomposition reactions. A terminal alkyl radical usually breaks down to form a monomer and a macroradical [polyethylene, polypropylene, polystyrene, poly(methyl methacrylate), etc.]; and a central alkyl macroradical mostly decomposes into a macromolecule and a macroradical. Therefore chain termination involving radicals of low molecular weight in hydrocarbon polymers undergoing oxidation is improbable in the absence of compounds of low molecular weight.

A mechanism of migration of a free electron in the form of simple radicals may develop when the polymer contains a highly active simple compound that reacts rapidly with the macroradicals. Introduction of cumenyl hydroperoxide, for example, retards the initiated oxidation of polypropylene and arrests the oxidation of polyethylene [80] by means of the reaction

$$PO_2^\cdot + rOOH \rightarrow POOH + r\dot{O}_2$$
$$r\dot{O}_2 + PO_2^\cdot \rightarrow \text{Molecular products} \ .$$

Rapid diffusion of $rO_2^\cdot$ ensures comparatively rapid termination of chains. Simple compounds such as the lower aldehydes and hydroperoxides are formed in the later stages of the oxidation of polymers as a result of the degradation of POOH, and may also be involved in transmitting free electrons along the polymer [79]. However, such a mechanism of chain termination cannot develop in the early stages of oxidation of a high polymer unless special additives are present.

Table 8. Effective $PO_2^\cdot$ loss rate constants in solid polymers at $p_{O_2} = 1$ atm.

Polymer	T, K	k_6, M^{-1} s^{-1}	Ref.
Isotactic polypropylene	383	$4 \cdot 10^5$*	71

---

*Calculated from published data [71] by means of the formula $k_6 = W_i/[PO_2^\cdot]$, with $W_i = W_{O_2}^2/a^2$, in which $a = W_{O_2} W_i^{-1/2}$, taken from Ref. 38 (Table 4).

**Calculated for the amorphous phase.

A third possibility is that the free electron may migrate as a macroradical in the polymer by the so called relay mechanism [81]: the fragment of the macromolecule bearing the free electron moves by segmental diffusion, which is followed by chemical transfer of the electron to another segment, and so on, until two radicals meet and react. A relay mechanism of free-electron migration along a polymer during its oxidation is convincingly supported by the following facts. (i) The irradiation of polymers in the presence of oxygen yields free radicals, whose loss in the absence of an initiating effect is accompanied by the absorption of oxygen [43]. Several oxygen molecules are absorbed per $PO_2^\cdot$ radical lost: i.e. disappearance of the radicals is accompanied by the chain reaction

$$PO_2^\cdot \xrightarrow{PH} P^\cdot \xrightarrow{O_2} PO_2^\cdot \longrightarrow \ldots,$$

and the encounter and loss of radicals result from their relay migration. (ii) Introduction of a chemically inert solvent into the polymer increases segmental mobility and also the average distance l through which the segment carrying the free electron moves during its lifetime. Thus the "relay distance" is increased and hence also the effective rate constant of recombination of the radicals. Addition of benzene to polypropylene and polystyrene produces a very considerable increase (by factors of 10–100) in the corresponding constant for bimolecular loss of $PO_2^\cdot$. [83] (iii) Since relay migration of the free electron involves a step of chain propagation, the inequalities $E_6^{PH} > E_6^{RH}$ and $E_6^{PH} > E_2^{PH}$ (the superscripts PH and RH denote media in which E_6 has been measured for peroxy-radicals of similar structure). This is consistent with experiment: values of 48 and 52 kJ $mole^{-1}$ have been obtained for E_6 in amorphous polypropylene, and 119 in the isotactic polymer (Table 8), while for cumenylperoxy-radicals in cumene $E_6 = 25$ kJ $mole^{-1}$, [19] so that $E_6^{PH} > E_6^{RH}$; since in isotactic polypropylene $E_2 = 88$ kJ $mole^{-1}$, we have $E_6^{PH} > E_2^{PH}$. (iv) The inhibiting effect of cumenyl hydroperoxide on the initiated oxidation of polyethylene and polypropylene [80] is also consistent with a relay mechanism, since inhibition can be explained by substitution of more rapid diffusion for the comparatively slow relay mechanism.

Table 9. Segmental movement (relay distance l) in the loss of free radicals in polymers.

Polymer	Valency-transfer reaction	T, K	$10^6 l$, cm	Δt, s	Ref.
Polyethylene	$P^\cdot + PH$	363	0.5	—	90
Polypropylene	$P^\cdot + PH$	373	1.7	0.015	34
Poly(methyl methacrylate)	$P^\cdot + PH$	311	0.55	—	90
Poly(methyl methacrylate)	$P^\cdot + PH$	328	0.15	—	90
Polyethylene	$PO_2^\cdot + PH$	363	0.35	—	90
Polypropylene	$PO_2^\cdot + PH$	292	0.75	—	90
Polypropylene	$PO_2^\cdot + PH$	323	0.37	—	89
Polypropylene	$PO_2^\cdot + PH$	383	2.4	0.12	71
Polypropylene	$PO_2^\cdot + PH$	383	1.7	0.21	82
Polypropylene	$PO_2^\cdot + PH$	383	4.7	0.14	35

Two parameters—the relay distance l and the specific rate of transfer of the free electron to another segment by chemical reaction—determine the effective rate constant with which two radicals meet. In the absence of oxygen transfer of the free electron takes place by the reaction

$$P^\cdot + PH \xrightarrow{k_1'} PH + P^\cdot \ .$$

The distance l can be estimated from experimental data in three ways.

Firstly, the bimolecular rate constant for the loss of radicals in the polymer can be used. In the amorphous phase of isotactic polypropylene, for example, $k_4 = 2.7 \times 10^6$ M^{-1} s^{-1} at 373 K.[34] With a relay mechanism $k_4 = 4 \times 10^{-3} \pi N l^3 k'_1 [\mathrm{PH}] \alpha_4$ M^{-1} s^{-1}, where N is Avogadro's number, l is expressed in centimetres, and α_4 is the probability of reaction between two P$^\bullet$ radicals $< 2l$ apart. On the assumption that the reaction P$^\bullet$ + PH takes place in PH with the same rate constant as the reaction $CH_3^\bullet + CH_4$ in the gas phase, where the rate constant is 3 M^{-1} s^{-1} at 373 K,[88] we find with [PH] = 22 M, $\alpha_4 = 1$, and $k_4 = 2.7 \times 10^6$ that l = 17 nm.

Secondly, the distance l can be identified with the radius of the "cage" in which two macroradicals meet as a consequence of segmental diffusion[78]. This radius can be estimated from experimental data on the kinetics of the loss of P$^\bullet$ in the polymer by means of the equation

$$t^{-1}([\mathrm{P}^\bullet]^{-1} - [\mathrm{P}^\bullet]_0^{-1}) = k_4(1+2\sqrt{\tau/t})$$

(where $\tau = l^2/\pi D$ and $k_4 = 4 \times 10^{-3} \pi N l D$, in which D (cm^2 s^{-1}) is the diffusion coefficient and values of l are given in Table 9), describing the kinetics of the diffusion loss of P$^\bullet$ and allowing for the initially non-stationary character of the process[78]. In the presence of oxygen the relay migration of a free electron is also a chain reaction accompanied by the absorption of oxygen. This is used to estimate l (cm) from the relation between the quantity of P$^\bullet$ that has disappeared and the oxygen absorbed[89] (Table 9):

$$\Delta[\mathrm{O_2}] = l^{-3} \ln([\mathrm{P}^\bullet]/[\mathrm{P}^\bullet]_0]$$

where $\Delta[O_2]$ is expressed in mol.cm^{-3}.

When $[O_2]$ is sufficiently high and P$^\bullet$ radicals are converted rapidly into $PO_2^\bullet$, so that relay transfer is limited by the reaction $PO_2^\bullet$ + PH, we can estimate l also from the rate constants k_2 and k_6. In polypropylene chain propagation takes place both intra- and inter-molecularly at the respective rates $k''_2[PO_2^\bullet]$ and $k'_2[PH][PO_2^\bullet]$, but only the latter process is involved in the relay mechanism. By analogy with 2,4-dimethylpentane[74] we can put $k''_2/k'_2 = 90$ at 373 K and $k'_2 = 0.2k_2$, where k_2 is the overall propagation rate constant. Hence for polypropylene we obtain $k_6/k_2 = 8 \times 10^{-4} \pi N l^3 \alpha_6$, which enables l_{min} to be estimated with $\alpha_6 = 1$. Table 9 shows that segmental movements are quite large—of the order 10^{-7}–10^{-6} cm in 0.1–0.01 s—i.e. at a mean speed of 10^{-6}–10^{-4} cm s^{-1}, while $L_{\mathrm{segm}} = 10^{-12}$–$10^{-10}$ cm^2 s^{-1} at around 373 K. The comparatively high segmental mobility also ensures relatively rapid migration and meeting of free electrons during the oxidation of such polymers as polyethylene and polypropylene. Since a polymer is non-uniform, with zones differing in segmental mobility, polychromatic kinetics is observed in the recombination of radicals at low temperatures[56-59].

The relay mechanism of migration of the free electron explains also why oxidation of a solid polymer is local in character, i.e. why each chain develops and terminates within a small volume. Because of the comparatively short relay distance the displacement of the free electron during such development is around $l\nu^{1/2}$, where ν is the length of the chain; with $\nu = 30$ and $l = 10^{-6}$ cm this displacement is $\sim 5 \times 10^{-6}$ cm. Therefore a mixture of polymers, e.g. polyethylene and polypropylene, is oxidised additively[38]: $W_\Sigma = W_{\mathrm{pe}} V_{\mathrm{pe}} + W_{\mathrm{pp}} V_{\mathrm{pp}}$, where W_{pe} is the rate of the initiated oxidation of polyethylene, while V_{pe} is the fraction of polyethylene by volume. Under the same conditions the rate of oxidation of copolymers of ethylene and propylene varies non-additively with composition[38]:

$$W_\Sigma \neq W_{\mathrm{pe}} \cdot [\mathrm{-CH_2-CH_2-}] + W_{\mathrm{pp}} \cdot [\mathrm{-CH_2CH(CH_3)-}],$$

just as for a mixture of n-decane and iso-octane, because of the different activities of secondary and tertiary peroxy-radicals in acts of chain propagation and termination.

VIII. REACTIONS OF ALKYL MACRORADICALS IN POLYMERS UNDERGOING OXIDATION

1. Diffusion and Kinetic Régimes of Oxidation

The oxidation of a polymer is preceded by the dissolution of oxygen in it. In a steady state, when the rates of oxidation and dissolution are equal, the process is described by the diffusion equation

$$d^2[\mathrm{O_2}]/dx^2 = W_{\mathrm{O_2}}/D,$$

where D is the diffusion coefficient for oxygen in the polymer and x the distance from the surface. Several studies have been made at low oxygen concentrations[91,92], when the rate of oxidation $W_{\mathrm{O_2}} = \beta[O_2]$, where $\beta = k_1 k_4^{-1/2} W_{\mathrm{i}}^{1/2}$. For a film $2l$ thick the depth x distribution of oxygen is given by

$$[\mathrm{O_2}] = \gamma p_{\mathrm{O_2}} \frac{\cosh[(l-x)\sqrt{\beta/D}]}{\cosh[l\sqrt{\beta/D}]},$$

in which γ is the Henry coefficient. The formula

$$\overline{[\mathrm{O_2}]} = \gamma p_{\mathrm{O_2}} l^{-1} (D/\beta)^{1/2} \tanh[l \cdot \sqrt{\beta/D}]$$

gives the average concentration of dissolved oxygen across the film.

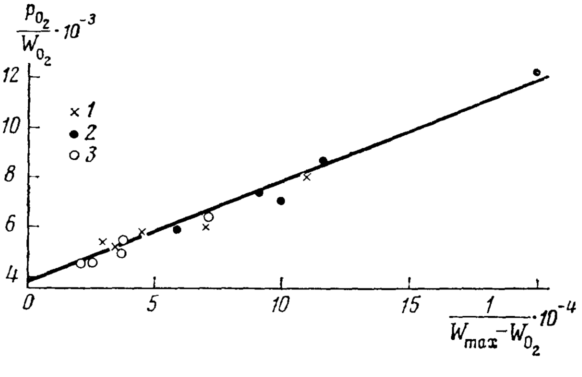

Figure 2. Dependence of $p_{\mathrm{O_2}}/W_{\mathrm{O_2}}$ on $(W_{\mathrm{max}} - W_{\mathrm{O_2}})^{-1}$ for the oxidation of polypropylene under different oxygen pressures at 371 K and initiated by different quantities (mole kg^{-1}) of benzoyl peroxide: 1) 0.031; 2) 0.062; 3) 0.1.

At small values of $l < (D/\beta)^{1/2}$ oxidation takes place in the kinetic range. Under these conditions $[O_2] = \gamma p_{\mathrm{O_2}}$ and $W_{\mathrm{O_2}} = k_1 k_4^{-1/2} W_{\mathrm{i}}^{1/2} \gamma p_{\mathrm{O_2}}$: i.e. the rate of oxidation is independent of film thickness and is proportional to $W_{\mathrm{i}}^{1/2}$. When l is large, oxidation occurs in the diffusion range, is concentrated in a thin layer $l^* = (D/\beta)^{1/2}$, and occurs at the rate $W_{O_2} = \gamma l^{-1} p_{O_2} (\beta D)^{1/2}$: i.e. it depends on D and l, and is proportional to $W_i^{1/4}$. In general the rate of oxidation is given by the formula

$$W_{O_2} = \gamma l^{-1} p_{O_2} \sqrt{\beta D} \tanh [l \sqrt{\beta / D}] \ .$$

With variation in the partial pressure of oxygen over a wider range account must be taken of the non-linear dependence of rate of oxidation on oxygen concentration, described with good approximation by the formula [34]

$$W_{O_2} = W_{max}(1 + b/[O_2])^{-1}, \ W_{max} = k_2 k_6^{-1/2} [RH] W_i^{1/2},$$
$$b = 2k_2 k_4 k_1^{-1} k_5^{-2} [PH] (\sqrt{1 + 12 k_4 k_5^{-2} k_6} - 1)^{-1}.$$

In a steady state the equation

$$\frac{p_{O_2}}{W_{O_2}} = \frac{b}{\gamma} (V_{max} - W_{O_2})^{-1} + \frac{1}{\varkappa \gamma}; \ \varkappa = 2D/l^2$$

represents the rate of oxidation in both kinetic and diffusion ranges [34]. It agrees well with experimental results (Fig. 2), and enables both diffusion and kinetic parameters κ and b to be determined. For powdered polypropylene of particle radius 10–15 μm we have κ = 0.2–0.3 s^{-1} and $b = 3 \times 10^{-5}$ M. [34]

2. Lifetime of Alkyl Radicals in an Oxidising Polymer

In a hydrocarbon or a polymer undergoing oxidation alkyl radicals ($R^{\cdot}$, $P^{\cdot}$) are interconverted into peroxy-radicals ($RO_2^{\cdot}$, $PO_2^{\cdot}$). With sufficiently long chains the rates of the two processes are almost equal. Since in the liquid phase alkyl radicals react very rapidly with oxygen ($k_1 \approx 10^8$ M^{-1} s^{-1}), it follows that $[R^{\cdot}]/[RO_2^{\cdot}] \ll 1$. In isopentane with p_{O_2} = 1 atm at 373 K ($k_2[RH] = 5$ s^{-1} [24]), for example, $[R^{\cdot}]/[RO_2^{\cdot}] = 5 \times 10^{-6}$, while the lifetime of $R^{\cdot}$ radicals is only 10^{-6} s. Under these conditions alkyl radicals have time to react only with oxygen.

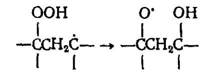
Oxygen diffuses more slowly in a polymer than in a liquid (stirring is absent, and the diffusion coefficient is smaller), so that the reaction of $P^{\cdot}$ with oxygen is far slower. In polypropylene with p_{O_2} = 1 atm at 373 K, for example, $k_1 \approx 10^6$ M^{-1} s^{-1}, [34] $\gamma = 10^{-3}$ mole kg^{-1}, [93] and the lifetime of an alkyl macroradical under these conditions is 10^{-3} s, a thousandfold the lifetime in a hydrocarbon, while the ratio $[P^{\cdot}]/[PO_2^{\cdot}] = 0.02$ on the assumption that $k_2[PH]$ = 5 s^{-1} as in isopentane. As a consequence, alkyl radicals in a polymer undergoing oxidation have time not only to react with oxygen but also to undergo other reactions.

3. Role of Alkyl Macroradicals in Chain Termination

It has been shown that in polypropylene undergoing oxidation $[P^{\cdot}]/[PO_2^{\cdot}]$ = 0.01–0.1 when p_{O_2} = 0.1–1 atm. A comparatively high relative concentration of alkyl macroradicals is present in polymers during inhibited oxidation. Inhibitors—acceptors of alkyl radicals—have a very slight effect on the oxidation of hydrocarbons [3], but inhibit that of polymers considerably more effectively [94]. For example, even at a concentration of 1mM p-benzoquinone inhibits the oxidation of polypropylene (p_{O_2} = 1 atm at 388 K), but begins to affect the oxidation of isooctane (1 atm at 353 K) only at concentrations exceeding 30mM. Moreover, such inhibitors as anthracene and 2,6-dinitrophenol, which react only with peroxy-radicals in inhibiting liquid-phase oxidation [3], terminate chains by reaction both with $PO_2^{\cdot}$ and with $P^{\cdot}$ in the oxidation of polypropylene [94]. A stable nitroxyl radical reacts with a $P^{\cdot}$ radical in polypropylene at 387 K and a rate constant of 35 000 M^{-1} s^{-1} (calculated from the ratio $k/k_1 \gamma$ [94] with $k_1 = 1.1 \times 10^6$ M^{-1} s^{-1} and $\gamma = 10^{-3}$ M atm^{-1}). Reactions of alkyl radicals play a very important part in the formation and transformation of hydroperoxy-groups (Section IX).

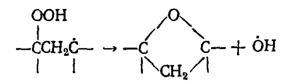
IX. FORMATION AND BREAKDOWN OF HYDROPEROXY-GROUPS

In the chain oxidation of hydrocarbons all the oxygen absorbed initially forms a hydroperoxide [3]: i.e. all the $RO_2^{\cdot}$ radicals are converted into ROOH. In polymers a discrepancy is often observed between the quantity of oxygen absorbed and the hydroperoxide formed [46,95–97]. It has been suggested [97] that in polypropylene this is due to isomerisation of the type



$$-\overset{OOH}{\overset{|}{\underset{|}{C}}}CH_2\dot{\underset{|}{C}}- \rightarrow -\overset{O^{\cdot}}{\overset{|}{\underset{|}{C}}}CH_2\overset{OH}{\overset{|}{\underset{|}{C}}}-$$

or [74]



Since the reaction $P^{\cdot} + O_2$ competes with isomerisation, fall in the oxygen pressure should be accompanied by decrease in the proportion of absorbed oxygen that is converted into hydroperoxide. This is supported by experiments [34] on the oxidation of polypropylene at different oxygen pressures, in which such a decrease is observed (Fig. 3). A decrease is observed also when a specimen of polypropylene is stretched and thus undergoes orientational cross-linking [98–100]. Kinetic data give for isomerisation of the peroxy-radical a rate constant of 1500 s^{-1} in polypropylene at 373 K. [34]

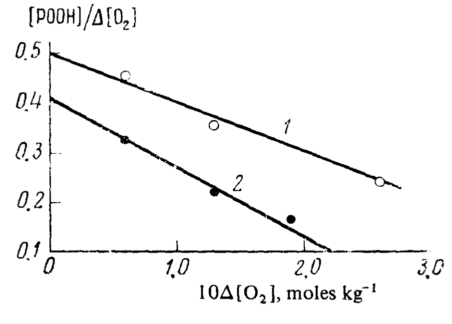


Figure 3. Dependence of $[POOH]/\Delta[O_2]$ on extent of oxidation $\Delta[O_2]$ of polypropylene initiated by benzoyl peroxide (0.064 mole kg^{-1}) at 365 K under different oxygen pressures: 1) 1 atm; 2) 0.26 atm.

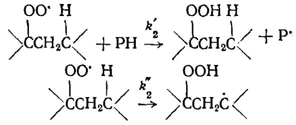
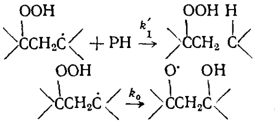
Propagation of an oxidation chain in polypropylene, as in model hydrocarbons, is effected by two mechanisms—intermolecular and intramolecular—which lead to the respective formation of single and block (adjoining) hydroperoxy-groups:



Predominantly block groups are formed in the polymer, as has been demonstrated[101] by several methods. Preferential isomerisation of peroxy-radicals characterises not only polypropylene but also hydrocarbons containing several tertiary carbon–hydrogen bonds in β positions. Thus in 2,4-dimethylpentane at 373 K the ratio $k_2'[\mathrm{RH}]/k_2'' = 0.25$.[74] In polyethylene, in contrast, single hydroperoxy-groups are formed, as a consequence of the low probability of intramolecular isomerisation in n-alkanes. For example, in n-pentane at 373 K the corresponding ratio is 25,[102] a hundred times the value in 2,4-dimethylpentane. In a polymer the lifetime of an alkyl radical is much longer than in a liquid, and provides time for the reaction



Therefore the ratio between single and block groups (POOH and POOH′) depends on the oxygen pressure:

$$\frac{[\mathrm{POOH}]}{[\mathrm{POOH}]'}=\frac{k_2'}{k_2''}[\mathrm{PH}]+\frac{(k_2'[\mathrm{PH}]+k_2'')(k_0+k_1'[\mathrm{PH}])}{k_1[\mathrm{O_2}]}\ .$$

The proportion of block groups increases with rise in this pressure, but since they break down more rapidly into radicals, this leads to an increase in the effective rate constant of radical generation[103].

Thus through the concentration of oxygen in the polymer (polypropylene) the oxygen pressure has different effects on oxidation. Firstly, it affects the relation between the quantities of absorbed oxygen converted into POOH and into other groups:

$$\Delta[\mathrm{O_2}]/[\mathrm{POOH}]=1+k_0k_1^{-1}[\mathrm{O_2}]^{-1}.$$

Secondly, the ratio between the quantities of single and block POOH groups depends on the oxygen concentration and hence pressure, and this in turn affects the rate of self-initiation, since $k_{3\Sigma} = k_3[\mathrm{POOH}]/[\mathrm{POOH}]_\Sigma + k_3'[\mathrm{POOH}']/[\mathrm{POOH}]_\Sigma$. Fig. 1 shows that the higher the oxygen pressure the more rapidly does oxidation develop.

Hydroperoxy-groups are unstable, undergoing decomposition into radicals that either escape into space or undergo recombination inside the cage (with relative probabilities e and $1 - e$), as well as[34] induced chain decomposition. This last process has been demonstrated in polypropylene by an experiment involving introduction of an inhibitor and an initiator, respectively retarding and accelerating such decomposition[34]. The rate of induced chain decomposition conforms to the formula

$$W_\nu=\mathrm{const}\cdot[\mathrm{POOH}]\cdot W_i^{1/2}$$

and is consistent with the reaction scheme

$$\begin{gathered}\mathrm{POOH}\xrightarrow{k_3}\quad\text{Free radicals}\quad\xrightarrow{\mathrm{PH}}\mathrm{P\cdot}\\ \mathrm{P\cdot}+\mathrm{POOH}\xrightarrow{k'}\mathrm{POH}+\mathrm{PO\cdot}\\ \mathrm{PO\cdot}+\mathrm{PH}\rightarrow\mathrm{P\cdot}+\mathrm{POH}\ \text{(rapid)}\\ \mathrm{P^{\cdot}}+\mathrm{P\cdot}\xrightarrow{k_4}\text{Chain termination}\ .\end{gathered}$$

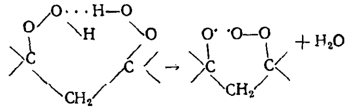
The rate of the chain decomposition of POOH will then be $k'k_4^{-1/2}W_i^{1/2}[\mathrm{POOH}]$; when the hydroperoxide itself is the source of radicals, $W_i = k_3[\mathrm{POOH}]$ and $W_\nu = k'k_4^{-1/2}k_3^{1/2}$.$[\mathrm{POOH}]^{3/2}$, which agrees with experiment[34]. In polypropylene at 365 K the coefficient $k'k_4^{-1/2} = 0.02\ \mathrm{M^{-1/2}\ s^{-1/2}}$; using the value $k_4 = 2.7\times10^6\ \mathrm{M^{-1}\ s^{-1}}$,[34] we obtain $k' = 50\ \mathrm{M^{-1}\ s^{-1}}$. Under oxidising conditions induced decomposition also takes place[34], although alkyl radicals disappear rapidly by reaction with oxygen (which is proved by comparing the rate of decomposition of POOH under oxidising conditions with its rate of decomposition into radicals).

Induced decomposition must be allowed for in calculating the probability e of the escape of radicals into space. By definition $e = k_3/2k_r$, where k_r is the rate constant of breakdown into radicals. But the total rate of decomposition of POOH is $k_r[\mathrm{POOH}] + k_\nu[\mathrm{POOH}]^{3/2}$, where $k_\nu = k'k_4^{-1/2}k_3^{1/2}$. Calculation of e from the ratio $k_3/2k_\Sigma$ will therefore give an underestimate, since $k_\Sigma > k_r$. Hence the formula $e = k_3/2(k_\Sigma - k_\nu[\mathrm{POOH}]^{1/2})$ must be used, in which k_Σ is the overall rate constant of decomposition of POOH. In polypropylene at 365 K block hydroperoxy-groups decompose with a probability $e = 0.11$ that the radicals formed will escape into space[34]; but in polyethylene at the same temperature $e = 0.5$ for the decomposition of single OOH groups[34]. Two methods—inhibitors[103] and chain oxidation[34,103]—are used to measure the formation of radicals from POOH: in the former the rate of consumption of an inhibitor W_{InH} is determined, and $W_i = fW_{\mathrm{InH}}$ if the inhibitor is consumed only by reaction with free radicals and "captures" all the free radicals; the latter method involves measuring the rate $W_{\mathrm{O_2}}$ of the POOH-initiated oxidation, when $k_i = W_{\mathrm{O_2}}^2/a^2[\mathrm{POOH}]$, in which $a = W_{\mathrm{O_2}}W_i^{-1/2}$ measured in an experiment with an initiator under the same conditions. Closely similar results are obtained by the two methods. If the inhibitor reacts directly with POOH, this can be taken into account in calculating k_i, but in such cases it is preferable to determine k_i from $W_{\mathrm{O_2}}$, since this will give more reliable results.

Table 10. Decomposition rate constants for hydroperoxy-groups in polyethylene and polypropylene.

Polymer	Oxidation conditions	T, K	k_i, $\mathrm{s^{-1}}$	Ref.
Polyethylene	in chlorobenzene at 388 K	351—403	$1.6\cdot10^{14}\ \exp(-146/RT)$	103
Polyethylene	benzoyl peroxide at 363 K	365	$5.0\cdot10^{-6}$	34
Polypropylene	in cumene at 388K	388	$5.0\cdot10^{-6}$	103
Polypropylene	in chlorobenzene at 383 K	383—413	$2.4\cdot10^{6}\ \exp(-79/RT)$	103
Polypropylene	benzoyl peroxide, 363 K, 1 atm $\mathrm{O_2}$	365	$5.0\cdot10^{-6}$	34
Polypropylene	benzoyl peroxide, 363 K, 1 atm $\mathrm{O_2}$	387	$2.8\cdot10^{-5}$	34
Polypropylene	AIBN, 358 K, 1 atm $\mathrm{O_2}$	322—370	$3.1\cdot10^{11}\ \exp(-119/RT)$	31

Table 10 gives values of k_i for POOH groups obtained by oxidising polypropylene and polyethylene. Comparison of k_i for the oxidation of polypropylene in cumene and in chlorobenzene, in which single and block hydroperoxy-groups respectively predominate, indicates that the latter type decompose far more rapidly[103], which is explained by the involvement of both OOH groups. By analogy with the bimolecular breakdown of POOH in the liquid phase the most probable mechanism is



which energetically is far more advantageous that unimolecular decomposition with rupture of a single O–C bond. Furthermore, such bimolecular decomposition occurs in the liquid phase in preference to the reaction

$$ROOH + RH \rightarrow RO^{\cdot} + H_2O + R^{\cdot}$$

owing to formation of a hydrogen bond between two ROOH groups.

The mechanism of the breakdown of single hydroperoxy-groups is still obscure. Two possibilities are unimolecular decomposition at the peroxy-bond and reaction of POOH with a carbon–hydrogen bond. If radicals are generated by the latter reaction, it must be expected that $k_3^{pe} < k_3^{pp}$, since carbon–hydrogen bonds are more stable in polyethylene than in polypropylene. However, closely similar values are obtained: $k_3 = 10^{-5}$ s^{-1} in polyethylene and 0.6×10^{-5} s^{-1} for single hydroperoxy-groups in polypropylene at 398 K.[103] For a unimolecular reaction, on the other hand, k_3 should not depend on the length of the alkyl substituent and should have similar values in gaseous and condensed phases. However, it is substantially larger (hundredfold at 393 K) in liquid and solid than in the gas phase[104]. Therefore further investigation is required on the mechanism of the breakdown of POOH and ROOH in solid and liquid phases respectively.

X. CONCLUSION

As we have become convinced, the oxidation of carbon-chain polymers in the solid phase and of hydrocarbons in the liquid phase has a single mechanism—a self-initiated chain reaction involving propagation of alkyl and peroxy-radicals with bimolecular chain termination—characterised by certain kinetic features: under conditions of initiated oxidation $W_{O_2} \propto W_i^{1/2}$; at low oxygen pressures $W_{O_2} \propto p_{O_2}$ under both kinetic and diffusion régimes of oxidation; W_{O_2} is independent of sufficiently high oxygen pressures; and in the initial stage of autoxidation $\Delta[O_2] \propto t^2$. Furthermore, a solid polymer as medium in which oxidation is developing has several important characteristics, leading to the following features of chain oxidation typical only of solid-phase oxidation.

1. The free electron (as a $P^{\cdot}$ or $PO_2^{\cdot}$ macroradical) moves along the polymer in a chain oxidation mostly by a *relay mechanism* involving segmental diffusion and transfer of the electron from one segment to another by the reactions

$$P^{\cdot} + PH \rightarrow PH + P^{\cdot} \text{ и } PO_2^{\cdot} + PH \rightarrow POOH + P^{\cdot} .$$

2. As the cage walls in a polymer are formed by *slowly moving segments of macromolecules* and the form of the cage relaxes slowly, a *polymer matrix* differs from a non-polar liquid in influencing the rate of primary steps involving radicals: the more rigid the matrix, i.e. the slower are molecular displacements in it, the lower the rate of the primary step.

3. Because of the comparatively slow diffusion of oxygen in the polymer and its lower solubility *alkyl macroradicals* live for a relatively long time in the polymer, and undergo together with $P^{\cdot} + O_2$ various other reactions, such as isomerisation, interaction with an adjacent carbon–hydrogen bond, reaction with POOH, and reactions with inhibitors effecting chain termination.

4. As a consequence of the *inhomogeneity of a polymer* different regions are oxidised at different rates. In polyethylene and polypropylene, for example, oxidation affects the amorphous phase almost alone, while the crystalline phase is oxidised only slightly.

5. Because of the *high molecular mass of a polymer* the comparatively rare (slow) *acts of rupture* of a carbon–carbon bond, which are almost imperceptible in the oxidation of the lower hydrocarbons, appear at an early stage in the oxidation of polymers.

Effect of Mobility of Medium on Formal Kinetics of Chemical Reactions in a Condensed Phase

O.N.Karpukhin

Chemical kinetics is examined under conditions such that the medium is quite mobile (classical kinetics), when it can be regarded as immobile throughout the process (i.e. with kinetic non-equivalence of reactant species), and also under intermediate conditions of kinetic non-equivalence maintained only during the lifetime of the leading active species. Methods for studying the kinetics of variation in reactivity due to change in the local properties of the medium are discussed, and reasons for the levelling of reactivity in a series of structurally different molecules on passing from liquid to solid media are analysed. The bibliography contains 37 references.

I. INTRODUCTION

In a condensed phase every species is subject to the time-variable influence of the surrounding molecules of the medium. This affects the probability of occurrence of primary steps of chemical conversion. Herein lies the chief cause of the qualitative difference between a primary chemical step in a condensed phase and the corresponding step in the gas phase. In the study of, for instance, a bimolecular reaction in the latter it is sufficient to examine the interaction of the two reactants in a vacuum, for the remaining species have no appreciable effect on this process.

A substantially different situation obtains in a condensed phase, in which molecules of the medium influence all stages of chemical interaction. The properties of the molecules govern transport of reactant species towards each other and the probability of their meeting. The medium has a considerable effect also on the actual chemical reaction: surrounding molecules may prevent rearrangement of reactant species, the electromagnetic field due to the medium changes the relation between different possible primary reaction paths, and considerable exchange of energy takes place between medium and reactants. Thus the medium plays a part in organising the primary step of chemical conversion[1]. The molecular motion of the medium produces continuous change in its local properties in the immediate environment of the reactants. The formal kinetics of a chemical process depends on the rapidity of variation in these local properties influencing the reactivity of the reactants.

The present Review examines the influence of the dynamics of the variation in these local properties of the medium on the kinetics of a chemical process, and discusses qualitative differences between the description of reaction kinetics in a condensed medium and the classical kinetics of gas-phase reactions. The problem of which local properties cause the variation in reactivity is almost completely ignored. Nor are more complicated aspects of the influence of the medium on chemical kinetics considered (the structure and the reasons for the formation of more or less stable complexes of the reactants with the medium, or solvate sheaths, the influence of the supermolecular structure of the medium on the process, etc.). Consequently the Review regards a condensed phase as a macroscopically homogeneous medium, non-uniformity in which can arise only at a cellular level, i.e. at distances of the order of the dimensions of the reactant molecules.

II. FORMAL KINETICS OF REACTIONS IN A CONDENSED PHASE

Two main approaches are usually made to the kinetics of chemical reactions in the gas phase. If the process is sufficiently slow, the reactants have enough time to exchange energy with the medium, so that they are in a nearly equilibrium distribution with respect to energies, rates, and distances apart. Under these conditions the law of mass action is used to describe the formal kinetics: the rate of a given primary process is proportional to the product of the reactant concentrations. The coefficient of proportionality is a measure of the rate constant; its temperature dependence is given by the Arrhenius equation.

In the other extreme case, in which chemical interaction produces either a chemically unstable species or a highly reactive species, i.e. one that undergoes further chemical changes only through several collisions with other molecules, the kinetic description is based neither on the law of mass action nor on the concept of the reaction rate constant but on the probability of involvement of the species in a particular reaction after its formation.

In a condensed phase the probability of chemical reaction may be influenced not only by the properties of the reactants but also by the local properties of the medium. In general, therefore, the rate constant of a chemical reaction occurring in a condensed phase is a function of some parameter u representing such local properties. We shall not now specify the physical nature of u, since various media may have different effects on various primary chemical processes. The parameter may represent the formation of specific complexes, the effect of the electromagnetic field of the medium, steric hindrance, direct involvement of molecules of the medium in the chemical reaction. In general, if the local properties governing the probability of chemical reaction depend on several parameters, u is a vector.

On the above approach the kinetics of the variation in the macroscopic concentration of a substance A involved e.g. in a simple unimolecular reaction is described by the integrodifferential equation

$$\frac{d[A]}{dt}=\int\frac{dA(u)}{dt}\,du=\int k(u)\,A(u)\,du, \qquad (1)$$

where $A(u)$ is the distribution function of the concentration of A in terms of the parameter u, and $k(u)$ is a function relating the effective rate constant of chemical conversion of A to u. Equation (1) leads to the usual exponential law of variation of [A], known as the first-order kinetic equation, in only two cases—(i) if the rate constant varies little with the local properties of the medium, i.e. if

$$k(u)=\text{const}, \qquad (2)$$

and (ii) if these local properties vary so rapidly in comparison with the rate of chemical reaction that $k(u)$ can be replaced throughout the process by a mean value and removed from the integral on the right-hand side of Eqn. (1).

Thus the rate of variation in the local properties of the medium, i.e. the relationship between three temporal parameters—the characteristic time of chemical conversion τ_x, the lifetime of the active centre effecting the process τ_e, and the correlation time between the reactants over all states in the medium τ_c—must be taken into account in order to describe the kinetics of a process in a condensed phase. Here τ_x is a macroscopic parameter of the process, representing the time for significant change in composition of the reactants; it can be characterised by the reciprocal of the relative rate of change in concentration of the reactants. For a unimolecular reaction τ_x is then the reciprocal of the rate constant k_1:

$$\tau_x=1/k_1,$$

For a bimolecular reaction it is given by the reciprocal of the product of the rate constant k_2 and the instantaneous concentration c:

$$\tau_x=1/k_2c.$$

The quantity τ_e may represent the time from the instant of formation of an active centre until its destruction or conversion into another active centre. For molecular decomposition τ_e is of the order of the time of rearrangement of the molecule during decomposition, i.e. the vibration period of the atoms in the molecule. It will be considerably longer when the molecule breaks down into active species, e.g. radicals. Thus for radicals that have escaped into the bulk of the specimen

$$\tau_e=1/k_t\,[R],$$

where k_t is the rate constant of such loss. The lifetime of an oxidation chain may also correspond to τ_e:

$$\tau_e=1/\sqrt{w_ik_t},$$

where w_i is the rate of formation of active centres in the system. Different values of τ_e may apply to different primary steps in the same composite process. For example, τ_e is considerably shorter for active centres that recombine in the cage in which they were formed than for those that have escaped from the cage and recombine in the bulk of the specimen.

The correlation time τ_c between species in a medium is the time during which a reactive species is able to exist in all possible states in which it has different reactivities. It is determined by how rapidly those properties of the reactant species that determine reactivity change as a result of the relative motion of the species and the molecules of the medium. The magnitude of τ_c can be judged to some extent from the correlation time of a paramagnetic probe or the time of depolarisation of luminescence. There is some analogy between τ_c and the time of establishment of thermal equilibrium between the species and the medium. In this sense we can speak of a correlation time even in gas-phase systems. Since energy is exchanged in the gas phase by collisions between particles, the correlation time for energy is of similar order of magnitude to the time between two collisions. In a condensed phase any particle is almost always in a state of collision with some particle of the medium, and τ_c is then very short—around a few picoseconds—for energy. Correlation times with other characteristics of reactant species therefore have greater practical value.

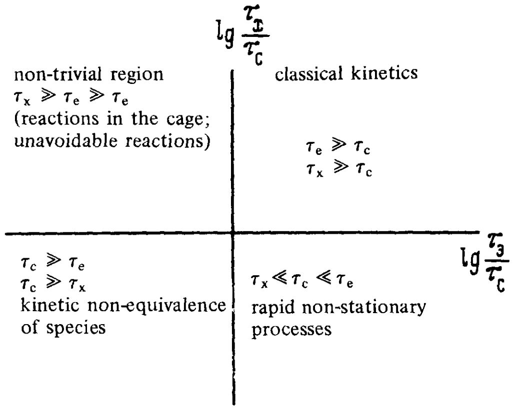

Figure 1. Qualitative variation in kinetics of chemical processes with the relationship between the characteristic times of their occurrence and the correlation time of the species in the medium.

The formal kinetics of chemical processes are qualitatively different depending on the relationship between the above three characteristic times. If in a plane $\lg(\tau_e/\tau_c)$ is plotted as abscissa, and $\lg(\tau_x/\tau_c)$ as ordinate (Fig. 1), every specific chemical process can be represented by a point in this plane†. The upper right-hand corner contains processes for which the correlation time is the shortest of the three:

$$\tau_c\ll\tau_x;\ \tau_c\ll\tau_e. \qquad (3)$$

---

† The three characteristic times (primarily τ_x) may vary during change in the composition of the system due to the chemical process. In the plane, therefore, the chemical reaction is represented by a segment of a curve. For the sake of simplicity, however, we shall henceforward neglect the linear dimensions of this segment: more precisely, we shall consider only those processes during which change in the relation between the characteristic times is insignificant.

All the primary steps then occur under the same conditions, so that the kinetic description is formally analogous to that in the gas phase. The effective rate constants of the primary reactions will equal the average values of the primary constants over all possible values of *u* realisable in the given medium under the given conditions. This part of the coordinate plane is the region in which all the classic concepts of chemical kinetics are valid.

The lower left-hand corner contains processes for which the correlation time is the longest of the characteristic times:

$$\tau_c \gg \tau_x;\ \tau_c \gg \tau_e. \tag{4}$$

This means that the process occurs as if in a completely "frozen" medium, with the reactant species under unchanged conditions throughout the process, but these conditions may differ for different species, so that the species may be kinetically non-equivalent. Under these conditions the rate of a chemical process is not proportional to the macroscopic concentration of the reactant species, but depends on how the latter are initially distributed with respect to the parameters determining their reactivity in the condensed medium, and how this distribution varies with time. The kinetics of such processes are often termed *polychromatic*[2], since, in contrast to the usual monochromatic processes, the rate of each primary reaction is then defined not by a single rate constant but by a set of rate constants governed by the local conditions. Since the medium is "frozen", the condition of each species remain unchanged throughout the process: i.e. it appears to "remember" its conditions when the process began. The equations of classic kinetics then describe not the variation in the macroscopic concentration of the reactants but that of the density of distribution among various local conditions $A(u)$.

In the above example of a unimolecular reaction $k(u)$ may differ for different $A(u)$ functions. The kinetics of the variation in $A(u)$ will therefore be described for each value by the exponential relation

$$A(u) = A(u)_0 e^{-k(u)t}, \tag{5}$$

but the exponent will differ for different values of *u*. The variation in the macroscopic concentration of the substance A, given by the equation

$$[A] = \int A(u)_0 e^{-k(u)t} du \tag{6}$$

may thus not be exponential in character. A common feature of reactions under these conditions (4) is the kinetic non-equivalence of species of the same chemical structure, which remains unchanged throughout the process.

As we move upwards from the lower left-hand corner of the plane (Fig. 1), we may enter a range of processes in which τ_X is comparable with τ_C. In describing them we must bear in mind that the density of distribution of concentration may vary with *u* as a consequence not only of chemical change but also of the mobility of the medium. In the case of a unimolecular reaction the kinetics of the variation in $A(u)$ will thus be determined by a more complicated equation than if the law of mass action were formally obeyed:

$$\frac{dA(u)}{dt} = -k(u)A(u) + \frac{\partial A(u)}{\partial u}\frac{\partial u}{\partial t}. \tag{7}$$

Under these conditions it is obviously not always possible to obtain an exponential variation of $A(u)$ with time.

Still higher, in the top left-hand corner of the plane, are situated processes for which the correlation times have intermediate values:

$$\tau_x \gg \tau_c \gg \tau_e. \tag{8}$$

When condition (8) is satisfied, the process takes place under a peculiar quasi-stationary régime. Any reactant species may initiate chemical conversion independently of its state at the start of the process: i.e. the rate of variation of the macroscopic concentration of a reactant, as in classical kinetics, is proportional to its instantaneous macroscopic concentration.

Another large region comprises complicated processes for which $\tau_X < \tau_e$. They lie on the plane to the right and below the 45° line through the origin. This is a region of so called non-stationary processes, for which the lifetimes of the active centres are comparable with the times required for large degrees of conversion. Certain branched-chain reactions can evidently be included here. The present Review will not discuss processes of this kind: it may merely be noted that, when the relations between the characteristic times correspond to the lower half of the plane, their description must allow for the possible kinetic non-equivalence of the reactant species.

III. KINETICS WITH COMPLETE KINETIC NON-EQUIVALENCE OF REACTANT SPECIES

Under conditions such that reactant species of the same chemical structure are completely equivalent kinetically ($\tau_C \ll \tau_e$, $\tau_C \ll \tau_X$) the kinetics of a chemical process does not differ fundamentally from that of a gas-phase process, as already mentioned. Departures from classical views arise only in the description of very fast processes, whose rates are controlled by diffusion. Rate constants of such processes vary with time in conformity with Waite's equation[3,4]. However, deviations of this kind occur both in condensed-phase and in gas-phase reactions. Therefore the present Review will not survey the kinetics of such chemical processes, occurring under conditions of actual kinetic equivalence of species.

If the process occurs under the directly opposite conditions, i.e. if the correlation time is much shorter than the other characteristic times, the kinetic description differs qualitatively from that for a gas-phase process, since reactant species of the same chemical structure may be kinetically non-equivalent. It is not altogether a simple matter to realise such a process: on the one hand, it is necessary that the local properties of the matrix should remain unchanged throughout the process: on the other hand, a chemical process is usually caused by some changes in properties in the immediate vicinity of a molecule of the starting material or is due to the transport of reactant species towards each other. These difficulties probably explain why heterogeneous processes at a gas-solid interface were the first to be examined in terms of kinetic non-equivalence: species on a non-uniform solid surface are under kinetically non-equivalent conditions with respect to species arriving from the gas phase and therefore kinetically equivalent.

During the 1930s Ya. B. Zel'dovich, M. I. Temkin, and S. Z. Roginskii made a large number of studies on such chemical reactions, the results of which were summarised in a monograph[5]. They developed mathematical methods for describing the kinetics, and showed how the form of distribution of reactants among non-equivalence parameters could influence the process, as well as how the form of distribution could be estimated from kinetic data.

Ideas on the kinetic non-equivalence of reactant species involved in macroscopically homogeneous processes were first used in the 1950s to early 1960s to describe the kinetics of the annealing of radiation defects[6,7] and of the loss of free radicals at low temperatures[2,8,9]. The kinetics of such processes could be described in terms of the so called polychromaticity of the rate constant (Section II).

However, the loss of active centres in a solid matrix is not an altogether convenient process for studying the kinetic non-equivalence of reactant species, since the mechanism of their mutual approach is not always entirely clear. For example, a simple mechanism of free diffusion towards one another in the solid polymer cannot be assumed for such large species as macromolecular radicals. Therefore discussion of the kinetic non-equivalence of radicals has been widely accompanied by that of the mechanism of migration of an active centre, e.g. a valence, through a polymer matrix[10], the possible role of relatively simple impurities in this process[11], possible dimensions for microheterogeneities that might explain the observed rules without recourse to ideas on the kinetic non-equivalence of species in a macroscopically homogeneous medium. For example, a model has been suggested involving fluctuations of the free volume in a solid matrix[12]; in fact it could explain the results in terms of the kinetic equivalence of reactant species. Serious consideration has been given also to a model of controlled diffusion of the process in a homogeneous medium[13,14], providing a formally rigorous explanation of the kinetics of the initial stage of loss of free radicals, but yielding overestimates of the radii of interaction between active centres.

The main evidence for kinetic non-equivalence of species in processes of this kind is provided by the peculiar form and the temperature dependence of the kinetic curves for the variation in reactant concentrations. With change in temperature the process almost ceases after not very large changes in reactant concentrations, although no products capable of inhibiting the reaction have accumulated in the system. Nor is such cessation due to the establishment of any equilibrium. Actually, the process is not completely arrested, but undergoes a so called kinetic termination. The semi-logarithmic form of the kinetic curve, with $[A]/[A]_0$ plotted against $\ln t$, is a straight line extending to high degrees of conversion.

The above form of kinetic curve can easily be explained on the assumption of a first- or second-order reaction whose rate constant k has a wide distribution ($k_{max}/k_{min} \gg 1$), and that the reactants are initially uniformly distributed with respect to the non-equivalence parameter s, which is exponentially related to the rate constant and varies from zero to some value S:

$$k = k_{max}\,e^{-s} \quad (0 \leqslant s \leqslant S). \tag{9}$$

The kinetics of the variation in the macroscopic concentration of the initial substance A under these conditions is governed by an equation analogous to (6):

$$-\frac{d[A]}{dt} = \frac{1}{S}\int_0^S k_{max}\,e^{-s}A^n(s)\,ds, \tag{10}$$

where $1/S$ is a normalising factor, and n the order of the primary reaction, while the density of distribution $A(s)$ changes with time in conformity with the equation

$$-\frac{dA(s)}{dt} = k_{max}\,e^{-s}A^n(s) \tag{11}$$

If n is not too large and the initial distribution is uniform ($A(s) = [A]_0/S$ at $t = 0$), Eqns. (10) and (11) can be solved[15] quite accurately in the form

$$[A] \simeq -\frac{[A]_0}{S}[\ln(k_{max}[A]_0^{n-1}) - S + \ln t] \tag{12}$$

with $1 < k_{max}[A]_0^{n-1}t < e^S$. For $n = 1$ the more exact solution

$$[A] = -\frac{[A]_0}{S}[\ln(1.76k_{max}) - S + \ln t] \tag{13}$$

was obtained[16].

The specific experimental procedure, i.e. kinetic study of the loss of active centres at different temperatures, made it natural to assume that kinetic non-equivalence of species was due to different heights of the energy barrier opposing chemical reaction. This corresponded formally to a distribution of rate constants according to activation energies:

$$S = \frac{E_{max} - E_{min}}{RT}. \tag{14}$$

However, no evidence was found to support this hypothesis. Similarly, for a long time only kinetic evidence was available for the view that the peculiar kinetics of such chemical processes in a solid phase might be due to kinetic non-equivalence of species in a macroscopically homogeneous medium.

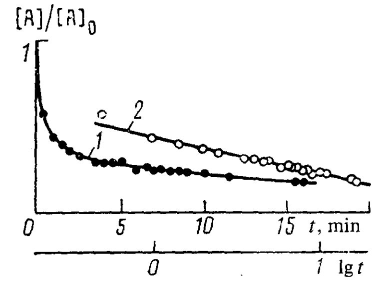

Figure 2. Destruction at 116 K of radical-pairs formed by the low-temperature (77 K) photolysis (300–400 nm) of frozen solutions of tetraphenylhydrazine in toluene: 1) kinetic curve; 2) semi-logarithmic transform (Eqn.12).

Direct evidence for such views was obtained only when effectively unimolecular processes, uncomplicated by a mechanism of approach of reactant species, began to be examined in terms of kinetic non-equivalence, and also when it became possible to halt a chemical reaction by different methods, and during the period of arrest to change the reactivity distribution of species without any change in the chemical composition of the system. The change in the effective rate of the process after such interruption served both as evidence of the validity of the model of kinetic non-equivalence of species and as a measure of the change in their reactivity distribution.

The first effectively unimolecular process examined from this point of view was the destruction of radical-pairs[15]. Electron spin resonance showed that pairs of radicals 3–6 Å apart can be generated in solutions of certain organic compounds. For example, pairs with the radicals 4 ± 0.2 Å apart have been recorded in a solution of tetraphenylhydrazine in toluene. The destruction of such radical-pairs obeys "stepwise" kinetics corresponding to Eqn. (13).

Fig. 2 shows an example of a kinetic curve for the destruction of radical-pairs and its transform plotted in the variables of Eqn. (12). These results can be explained on the assumption that the width of the distribution of the rate constants exceeds a thousandfold. Accepting in conformity with formula (9) a rectangular distribution with respect to s for the species whose decay is plotted in Fig. 2, we find that $S = 10$. It was suggested[15] that the distribution of rate constants was due solely to the distribution of activation energies and found that $\delta E = 2.3 \pm 1$ kcal mole^{-1}. Because of the narrow temperature range (100–120 K) in which the kinetics of pair destruction could conveniently be recorded, it could not be established whether the distribution of rate constants was determined by the activation energy or the pre-exponential factor. Nevertheless, since the distance between the radicals in a pair is small and almost the same for all pairs, the observed kinetics cannot be explained by peculiarities in the mutual approach of radicals. In fact a pseudounimolecular reaction takes place, whose efficiency can be influenced only by the local environment of the reacting species. It was thus shown[15] that chemical reactions could actually occur under conditions of kinetic non-equivalence of the reactant species when the time during which the local properties of the medium remain constant exceeds significantly the other characteristic times of the process.

However, kinetic non-equivalence of reactant species could be observed especially clearly in photochemical reactions, the first example being the photo-oxidation of fused-ring hydrocarbons (anthracene, naphthacene, rubrene)[16,17]. This reaction involves singlet oxygen formed on interaction between a hydrocarbon molecule in a triplet state and a molecule of ordinary triplet oxygen. The product—a transannular peroxide—can be formed by reaction of singlet oxygen either with the same hydrocarbon molecule or with another, to which it diffuses through the medium. Singlet oxygen is a relatively small molecule, probably differing little in mobility from an ordinary oxygen molecule. Therefore the character of the diffusion of this active species in any medium is known, and in quantitative descriptions use can quite confidently be made of data on diffusion coefficients of diatomic gases, which have been measured in many media.

The kinetic scheme of the photo-oxidation of a fused-ring hydrocarbon can be written

$$\begin{gathered}
\mathrm{A} + h\nu \rightarrow \mathrm{A}^* \rightarrow \mathrm{A}^{\mathrm{T}}, \\
\mathrm{A}^{\mathrm{T}} + {}^3\mathrm{O}_2 \xrightarrow{k_0} \mathrm{A} + {}^1\mathrm{O}_2, \\
\mathrm{A}^{\mathrm{T}} + {}^3\mathrm{O}_2 \xrightarrow{k_{r0}} \mathrm{AO}_2, \\
\mathrm{A} + {}^1\mathrm{O}_2 \xrightarrow{k_r} \mathrm{AO}_2, \\
\mathrm{Q} + {}^1\mathrm{O}_2 \xrightarrow{k_q} {}^3\mathrm{O}_2, \\
{}^1\mathrm{O}_2 \xrightarrow{k_d} {}^3\mathrm{O}_2,
\end{gathered} \tag{15}$$

where A, A*, and A^{T} are molecules of the oxidisable compound in ground, excited, and triplet states, ${}^3\mathrm{O}_2$ and ${}^1\mathrm{O}_2$ are oxygen molecules in the triplet ground and the singlet states, Q is the quenching agent, and AO_2 is the transannular peroxide; the symbols above the arrows denote the corresponding rate constants.

According to the law of mass action, under quasi-stationary conditions with respect to singlet oxygen, the rate of change of the concentration of the oxidisable compound should be given by the equation

$$\frac{\mathrm{d}[\mathrm{A}]}{\mathrm{d}t} = \alpha\left[1 - \gamma\left(1 - \frac{(k_r/k_d)\cdot[\mathrm{A}]}{1 + (k_r/k_d\cdot[\mathrm{A}] + (k_q/k_d)[\mathrm{Q}]}\right)\right][\mathrm{A}], \tag{16}$$

where α is the product of the probability of absorption of a light quantum by an oxidisable molecule in unit time and the quantum efficiency η of formation of singlet oxygen, while $\gamma = k_0/(k_0 + k_{r0})$ is the probability of the escape of singlet oxygen into space.

However, Eqn. (16) describes the kinetics right up to high degrees of conversion only when photo-oxidation takes place in a sufficiently fluid medium. In solid polymers at temperature considerably below the glass point it describes satisfactorily only the initial stage: at later stages the process slows down significantly more rapidly than is required by Eqn. (16). Yet no data have been obtained on the occurrence in the system of any primary steps other than those listed in scheme (15). The kinetics of the variation in the concentration of the oxidisable compound is determined solely by the quantity of light incident on the specimen, independent of its intensity. This indicates that no two-quantum processes occur, interaction between intermediate species is absent, and a sufficient quantity of oxygen diffuses into the specimen. Reactant concentrations can be recorded during the process both from the variation in the absorption spectra and from the change in intensity of fluorescence of the initial substance. Hence no quenching agents are formed during the process.

The observed kinetics was explained on the hypothesis of a non-equivalent environment of the oxidisable molecules. Because of the relative immobility of the polymer matrix the relative proportion of molecules in an environment favourable for oxidation diminishes during the process, and hence also the effective overall quantum efficiency. This hypothesis has been confirmed by direct experiment[17,18]. It was found that photo-oxidation takes place significantly more efficiently if the process is periodically interrupted and the specimen is heated in the dark to temperatures close to the glass point. This affects neither the concentration of the oxidisable substance, its absorption and fluorescence spectra, nor the quantum efficiency of fluorescence. However, after such thermal activation the process conforms to Eqn. (16) until high degrees of conversion are reached, provided that the thermal activation is conducted at a sufficiently high temperature for a sufficiently long time, sufficiently frequently, and after equal periods of illumination.

Such a result was obtained in various polymer matrices with thermal activation at ~20 deg below the glass point for 10–20 min. In polypropylene and BMK-5 (a copolymer of methacrylic acid and butyl methacrylate having $T_{\mathrm{gl}} = 40\,^\circ\mathrm{C}$) at room temperature the process satisfies Eqn. (16), and is uninfluenced by thermal activation. The explanation for these results is that the thermal activation increases the mobility of the polymer matrix, permitting restoration of the original reactivity distribution of the reactants. In polypropylene and BMK-5 the initial distribution remains unchanged throughout the process because the molecular mobility of the matrix is adequate at temperatures close to or above the glass point.

For a quantitative description of the results a model was proposed in which the kinetic non-equivalence of the oxidisable molecules was attributed to differences in permeability to singlet oxygen of the surrounding cage walls. Permeability can be characterised by the parameter u_0 occurring as a factor in the primary formation and decomposition rate constants k_1 and k_2 of the "singlet oxygen–oxidisable substance" pair. Provided that spontaneous breakdown of $^1O_2$ molecules in the cage can be neglected, k_r and γ will then be given by the formulae

$$k_r = \frac{k_1 k_3 u_0}{k_2 u_0 + k_3}, \qquad (17)$$

$$\gamma = \frac{k_2 u_0}{k_2 u_0 + k_3}, \qquad (18)$$

where k_3 is the oxidation rate constant in the pair.

The parameter u_0 has different values for different molecules of the oxidisable substance, but remains unchanged throughout the process in the absence of thermal activation. On such a model the form of the kinetic curve for consumption of the oxidisable compound is determined not only by the magnitude of the kinetic parameters but also by the kinetics of the change in the distribution function $\rho(u_0)$ of oxidisable molecules among cages differing in permeability. Assuming that the initial form of distribution is independent of the macroscopic concentration of the oxidisable compound, while the local concentration of singlet oxygen corresponds to its average concentration in the specimen, we obtain for the kinetics of variation in the concentration of the oxidisable substance, instead of (16), the equation

$$\frac{d[A]}{dt} = -(\alpha I_1 + k_1 I_2 [^1O_2]) k_3 [A], \qquad (19)$$

in which

$$I_1 = \int \frac{\rho(u_0)\, du_0}{k_2 u_0 + k_3}; \quad I_2 = \int \frac{u\rho(u_0)\, du_0}{k_2 u_0 + k_3}.$$

The distribution $\rho(u_0)$ is normalised only at zero time: $\rho(u_0)du_0 = 1$ at $t = 0$.

If the concentration of singlet oxygen $^1O_2$ is quasi-stationary, we find that

$$[^1O_2] = \frac{\alpha k_2 I_2 [A]_0}{k_1 k_3 I_2 [A]_0 + k_d}. \qquad (20)$$

Substitution of (20) in (19) yields the equation

$$\frac{d([A])/[A]_0)}{dt} = -\alpha k_3 I_1 - \frac{\alpha k_1 k_2 k_3 I_2^2 [A]_0}{k_1 k_3 I_2 [A]_0 + k_d} \qquad (21)$$

which describes the variation in concentration of the oxidisable substance right until high degrees of conversion are reached.

We can make a similar approach to the more general case, taking into account the quenching of $^1O_2$ molecules in the pair with rate constants k'_d and a possible difference in probability of chemical interaction in pairs formed after absorption of a light quantum and in those formed after an encounter between $^1O_2$ and an oxidisable molecule. With rate constants and parameters corresponding to pairs of the former type primed, the appropriate equation is

$$\frac{d([A]/[A]_0)}{dt} = -\alpha\left(k'_3 I'_1 + \frac{k_1 k'_2 k_3 I_2 I'_2 [A]_0}{k_1 (k_3 + k'_d) I_2 [A]_0 + k_d}\right), \qquad (22)$$

in which

$$I'_i = \int \frac{u_0^{i-1}\rho(u_0)\, du_0}{k_3 + k'_d + k_2 u_0}.$$

The time dependence of the distribution $\rho(u_0)$ normalised at zero time conforms to an equation analogous to (19):

$$\frac{d\rho(u_0)}{dt} = -\alpha \frac{k_3}{k_2 u_0 + k_3}\left(1 + \frac{k_1 k_2 u_0 I_2 [A]_0}{k_1 k_3 I_2 [A]_0 + k_d}\right). \qquad (23)$$

The complexity of the solution of (23) is due to the variation of the integral I_2 with time. At low concentrations of the oxidisable substance terms containing I_2 can be neglected, and (23) can be solved similarly to (11). Assuming that the probability of chemical interaction in a pair is related exponentially to some parameter s_0 distributed uniformly between 0 and S_0[‡]

$$\frac{k_3}{k_2 u_0 + k_3} = e^{-s_0}, \qquad (24)$$

we obtain instead of (23) the equation

$$\frac{d\rho(s_0)}{dt} = \frac{1}{S_0} \alpha e^{s_0} \rho(s_0) \qquad (25)$$

which is analogous to (11).

If we neglect also diffusion of oxidisable molecules through cages having different values of s_0, the kinetics of the variation in the concentration of the oxidisable compound will be described by an equation analogous to (13):

$$[A] = [A]_0 \left(1 - \frac{1}{S_0} \ln(1.76\alpha t)\right). \qquad (26)$$

At high concentrations of A we find an approximate solution analogous to (12):

$$[A] = [A]_0 \left[1 - \frac{1}{S_0} \ln\left(Z_1 \alpha t \frac{Z_2}{1 + Z_2 - \alpha t}\right)\right], \qquad (27)$$

where $Z_2 = k_d/k_1 k_3 I_2[A]_0$ and Z_1 is a factor exceeding unity (but in the present case probably not exceeding 2) characterising the form of the $\rho(u_0)$ kinetic curve. The initial rate under these conditions is given by

$$\left(\frac{d([A]/[A]_0)}{dt}\right)_{t=0} = -\alpha Z_1 \left[\frac{1 - e^{-S_0}}{S_0} - Z_2 \left(1 + \frac{1 - e^{-S_0}}{S_0}\right)\right]. \qquad (28)$$

With a sufficiently wide distribution Eqn. (28) can be simplified to

$$\left(\frac{d([A]/[A]_0)}{dt}\right)_{t=0} = -\alpha Z_1 \left(\frac{1}{S_0} - Z_2\right). \qquad (29)$$

In the study of the destruction of free radicals it is usually difficult to determine the initial rate, since the specimen heats up during the reaction, so that the initial stage takes place at a lower temperature than the process as a whole. Such difficulties do not arise with a photochemical process, which begins almost without inertia. Comparison of data on its initial rate with the kinetics of variation in concentration at later stages can therefore be used for quantitative verification of the above ideas[17,18].

Thus ideas on the kinetic non-equivalence of reactant species have provided a kinetic description of photo-oxidation, which is formally more complicated than the destruction of free radicals. However, photo-oxidation of hydrocarbons can be conducted under conditions such that the kinetics are simpler. At low concentrations of the oxidisable substance, when reactions of singlet oxygen that has escaped from the cage in which it had been formed

---

[‡] If the ratio $k_2 u_0/k_3 \gg 1$ for all u, the significance of S_0 is a quantity proportional to the free energy of activation of the chemical reaction: $S_0 = \Delta G/RT = \Delta S/R + E/RT$.

can be neglected, photo-oxidation takes place within a single cage: i.e. it is formally a unimolecular reaction, uncomplicated by transport of the reactant species to each other. Furthermore, it is a photoreaction, which can be arrested or restarted by switching the radiation off or on. This advantage has opened up new technical possibilities—of studying the kinetics of the variation in reactivity of a substance in the absence of chemical change.

IV. KINETICS OF VARIATION IN REACTIVITY

The first kinetic studies of the variation in the reactivity of molecules located in a solid matrix (Section III) showed[16,17] that the initial reactivity of fused-ring hydrocarbons towards photo-oxidation could be restored by heating the specimens to temperatures 10–30 deg below the glass point of the matrix for a few minutes. This provided estimates of the temperature and time scales required to restore the original reactivity distribution of the molecules.

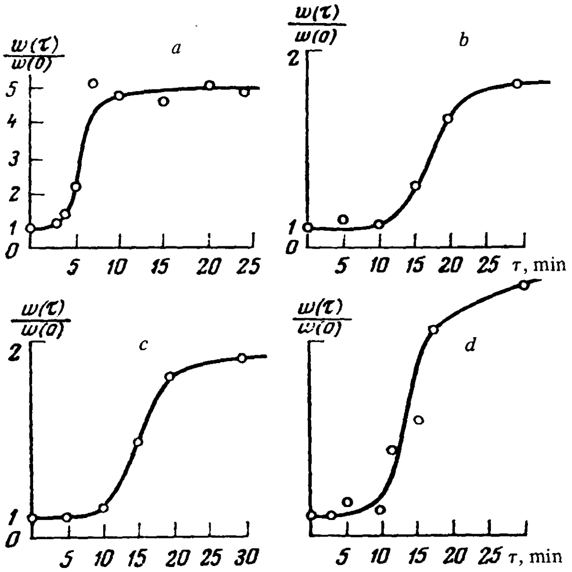

Figure 3. Dependence of relative rate of photo-oxidation $w(\tau)/w(0)$ on duration of thermal activation: *a*) 1.36 mM naphthacene in polystyrene (activated at 70°C, conversion 80%); *b*) 1.36 mM naphthacene in poly(methyl methacrylate) (52°C, 40%); *c*) 5.6 mM anthracene in polystyrene (70°C, 40%); *d*) 3.1 mM naphthacene in polystyrene (60°C, 60%).

In a more detailed study[19] fused-ring hydrocarbons were subjected in polymer films to photo-oxidation at 20°C until a specified degree of conversion was attained. The specimen was then heated in the dark at a fixed temperature T for a certain time τ. After this the specimen was again exposed at 20°C, and the rate of change in the concentration of the oxidisable substance during the second exposure was recorded. The variation in the rate of the process with different times of heating provided a measure of the variation in reactivity of the oxidisable compound during heating. Fig. 3 illustrates the dependence of the relative rate of the second photo-oxidation $W(\tau)/W(0)$ on the time of heating τ at different temperatures. As could have been expected, rise in the temperature of thermal activation accelerates restoration of the equilibrium rate of oxidation; the range of variation in the rate expands with increase in the initial degree of conversion.

A striking feature of Fig. 3 is the sigmoid form of the dependence of rate of photo-oxidation on time of thermal activation at sufficiently high degrees of primary conversion. From simple considerations it might have been expected that maximum rate of change of reactivity would occur with short times of thermal activation, when the reactivity distribution of the species would be most remote from equilibrium. This might have occurred if the change in reactivity had resulted from movement of fluctuations of the free volume through a macroscopically homogeneous specimen[12]. On such a model any molecule can change its reactivity abruptly on thermal activation, passing into a state corresponding to equilibrium. The probability of such a jump is independent of the state of the molecules before thermal activation.

On the other hand, a sigmoid dependence can be observed only if the initial reactivity of the molecule has a significant influence either on the sequence of states through which it passes during thermal activation or on the probability of a change in reactivity. This type of dependence may be expected, for example, if thermal activation involves continuous "diffusion" of molecules from a non-equilibrium to an equilibrium reactivity distribution. We postulate that molecular reactivity χ is determined by a parameter u_1 characterising the state of the molecule in the given medium. Under equilibrium conditions there exists a certain distribution of species according to this parameter $\rho_0(u_1)$. During the first photo-oxidation, when thermal diffusion among states can be neglected, the equilibrium distribution is disturbed by occurrence of the chemical reaction, so that

$$\rho(u_1, t) = \rho_0(u_1)\exp(-\chi(u_1)t), \tag{30}$$

where t is the time of photo-oxidation.

During thermal activation continuous diffusion through states differing in u_1 value will be described by the equation

$$\frac{\partial\rho}{\partial\tau} = D\frac{\partial^2\rho}{\partial u_1^2}, \tag{31}$$

where τ is the time of thermal activation and D the corresponding diffusion coefficient. The boundary conditions for Eqn. (31) correspond to absence of diffusion beyond the extreme values of u_1:

$$\left.\frac{\partial\rho}{\partial u_1}\right|_{u_{1\,\min},\tau} = \left.\frac{\partial\rho}{\partial u_1}\right|_{u_{1\,\max},\tau} = 0. \tag{32}$$

With certain forms of the distribution $\rho_0(u_1)$ the solution of Eqn. (31) enables a sigmoid dependence to be obtained. This occurs, for example, with D constant and independent of u_1, i.e. with the uniform distribution $\rho_0(u_1)$ = const, when

$$\chi(u_1) = -k_0\ln\left(\sin\frac{u_1}{2}\right);\quad 0\leqslant u_1\leqslant\pi, \tag{33}$$

and at degrees of conversion during the first photo-oxidation exceeding 50%.

The above results do not give the reasons for the non-equivalence of reactant species. However, they must be taken into account in constructing models to explain this phenomenon.

V. KINETICS WITH PARTIAL KINETIC NON-EQUIVALENCE OF REACTANT SPECIES

As noted above, under conditions such that the correlation time τ_c of reactant species over all possible states in the medium is intermediate between the time τ_x of significant change in concentration of the reactant species and the lifetime of an active centre τ_e, i.e. when

$$\tau_x \gg \tau_c \gg \tau_e, \tag{34}$$

the variation in macroscopic concentration obeys the usual kinetic laws, while kinetic non-equivalence of the species merely disturbs classical ideas on the relative rates of different possible reactions.

Conditions for such partial kinetic non-equivalence of reactant species can be realised especially easily in photochemical processes. If the light is not too intense, such a process comprises a series of consecutive or parallel physical or chemical changes lasting a relatively short time after absorption of a quantum (usually $\tau_e \ll 1$ s). Each such process usually proceeds until a certain stage is reached, independently of the occurrence of other primary processes initiated by the absorption of other light quanta. Therefore the time τ_e for development of a primary photochemical process is independent of the light intensity. Yet τ_x does depend on the intensity, and usually exceeds τ_e considerably, amounting to minutes, hours, or longer. Evidently, therefore, it is not difficult to find a medium and a photochemical process for which the condition (34) of partial kinetic non-equivalence of reactant species will be satisfied.

A photochemical process can be influenced relatively easily by the introduction of additives that quench excited states. Under conditions of partial kinetic non-equivalence of excited species the intensity of luminescence and the rate of the photochemical process will then vary in different ways.

As example we can consider results for so called unstoppable photochemical processes, which cannot be completely inhibited when the luminescence of the leading species has been extinguished[20]. Phenomena of this type have been known for some time[21,22]. The most common class of photochemical processes involves species in the triplet state, and cannot be completely inhibited by the introduction of quenchers for such states. This is usually explained by the involvement of single excited molecules[23], but this hypothesis is fairly difficult to substantiate. Therefore an alternative explanation of unstoppable processes, based on the kinetic non-equivalence of reactant species, seems quite permissible.

The quenching of excited states by any mechanism can be described approximately by the Stern–Volmer equation[24]: the concentration of molecules in an excited state S^* is

$$[S^*] = \frac{w}{k_d + k_f + k_r + k_q[Q]}, \tag{35}$$

where w is the rate of formation of excited molecules, k_d and k_f are the rate constants of spontaneous and radiative deactivation of excited molecules, k_r is the rate constant of their chemical reaction in the given medium, and k_q is the rate constant of the quenching of S^* by a quencher molecule Q. If, however, the excited molecules are kinetically non-equivalent, Eqn. (35) represents the effect of the quenching agent on the concentration of only one species. Then the total macroscopic concentration of excited species will be described by the integral over all possible local properties that can be effective in the given medium:

$$[S^*] = \int \frac{w\rho(u)\,\mathrm{d}u}{k_d + k_f + k_r + k_q[Q]}, \tag{36}$$

where u is a parameter representing these properties and $\rho(u)$ the density of distribution of concentration with respect to this parameter. In general all the other quantities in (36) are also functions of u.

The quantum efficiencies of luminescence η and of the photochemical process φ will be given by analogous formulae:

$$\eta = \alpha' \int \frac{k_f\rho(u)\,\mathrm{d}u}{k_d + k_f + k_r + k_q[Q]} \tag{37}$$

$$\varphi = \alpha' \int \frac{k_r\rho(u)\,\mathrm{d}u}{k_d + k_f + k_r + k_q[Q]} \tag{38}$$

From these expressions we find that quenchers of excited states have different effects on the intensity of luminescence and on the rate of the photochemical process:

$$\frac{\varphi}{\varphi_0} \neq \frac{\eta}{\eta_0}.$$

Equations (37) and (38) have been subjected[25] to detailed analysis for the case in which the kinetic non-equivalence of the excited molecules is due to the effect of the local properties of the medium on k_r. The character of the $\rho(u)$ distribution is examined by comparing the efficiency of the quenching of luminescence and of the inhibition of the photochemical process by small additions of the quenching agent

$$Z = \left(\frac{\partial(\eta/\eta_0)}{\partial[Q]}\right)_{[Q]=0} \Bigg/ \left(\frac{\partial(\varphi/\varphi_0)}{\partial[Q]}\right)_{[Q]=0} \tag{39}$$

with the type of deviations from the Stern–Volmer equation of the variation of the quantum efficiencies η and φ with the quencher concentration. It was shown that only one of the variations in quantum efficiency—either of the photochemical process or of luminescence—can be expected to diverge considerably from the equation. Quenching agents are always more effective in quenching luminescence than in inhibiting a photochemical process ($Z \leqslant 1$). If a uniform distribution is assumed for the entropy factor S of the chemical reaction rate constant, as is done by many authors in discussing processes with complete kinetic non-equivalence of species (9), considerable deviations from the Stern–Volmer equation appear to be possible only at sufficiently small ratios Z. To explain such departures when Z is large we must postulate other types of distribution, in particular bimodal, based on the presence of two kinds of local conditions, under which excited molecules have significantly different reactivities.

This last hypothesis has been used[28] to explain the effect of oxygen on the photodecomposition and the phosphorescence of benzophenone in poly(methyl methacrylate). Plots of the quantum efficiencies show (Fig. 4) that oxygen is almost twice as effective in quenching phosphorescence as in retarding photodecomposition ($Z \simeq 0.6$), and the Stern–Volmer equation does not describe the inhibition of the photochemical process. These results can be understood on the hypothesis that $\rho(u)$ is bimodal: the lifetimes of triplet benzophenone molecules corresponding to different local conditions differ more than fourfold; and the probability of chemical reaction for species possessing shorter lifetimes exceeds 0.75, while the probability of formation of such species is ~0.4.

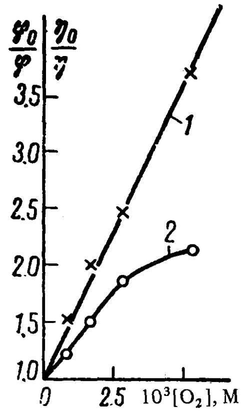

Figure 4. Effect of oxygen on quantum efficiency in 0.29 M benzophenone in poly(methyl methacrylate) exposed to light of wavelength 365 nm and intensity 10^{17} cm^{-2} s^{-1}: 1) phosphorescence; 2) photochemical conversion.

VI. INFLUENCE OF MOBILITY OF MEDIUM ON EFFICIENCY OF PRIMARY CHEMICAL REACTIONS

On passing from liquid-phase systems to solid solutions we find not only the above kinetic features of solid-phase reactions but also a qualitative change in the relative reactivities of species differing in chemical structure. In viscous solutions, especially media that can be regarded as solid, when effective chemical reaction rate constants are remote from diffusion constants, i.e. when encounter between reactant species cannot be the rate-determining stage, a considerable levelling is observed in the activities of chemically different species.

A method for measuring the relative efficiencies with which inhibitors differing in structure act on peroxy-radicals in a solid polymer matrix is based[26,27] on a study of the influence of the inhibitors on the initial rate of consumption of stable quinoline or di-*p*-methoxyphenylnitroxide radicals ($R_{quin}\cdot$ or $R_{dmpn}\cdot$) during initiated oxidation of the polymer. Table 1 shows that the rate constants for interaction of different valency-saturated inhibitors with peroxy-radicals are almost the same in solid polystyrene, whereas they differ hundredfold in the liquid phase. The observed levelling of inhibitor activity cannot be explained by diffusion limiting reaction in the solid phase, with the limiting value of the constant representing the diffusion mobility of the reactants. Such a suggestion is contradicted by the fact that the activity of stable radicals exceeds by factors of 10–20 the "limiting" activity of valency-saturated inhibitors. Since there are no data indicating an abnormally high diffusion coefficient for stable radicals, the result suggests that the levelling effect is not merely a restriction on translational mobility, but has a more complex nature and probably depends on the type of reaction.

Table 1. Effect of polymer matrix on antiradical activity of antioxidants at 70°C.

Antioxidant	$10^{-4}k_7$, M^{-1} s^{-1}	
	ethylbenzene	polystyrene*
stable radicals		
$R_{quin}\cdot$	124	51

$$\left(HO-C_6H_2R_2-CH_2-\overset{O^-}{\underset{O}{P}}-OC_2H_5\right)_2$$

A similar effect has been found for the rate constants in the quenching of singlet oxygen by various substances and its reaction with aromatic hydrocarbons (Table 2).[28-30] Here the levelling is still more clearly defined: in the liquid phase the difference in relative quenching rate constants reaches 10^5, but in the solid it does not exceed factors of 200–300. Such parallel variation in rate constants on passing from the liquid to the solid phase occurs only with reactions of the same type: rate constants for different types of reactions vary differently. Thus the rate constant for reaction between molecular oxygen and rubrene in the liquid phase exceeds those for the quenching of oxygen by almost all substances other than β-carotene and nickel dithiocarbamate, but in solid polystyrene it becomes smaller than those for the action of oxygen on any of the quenching agents investigated. Change in reactivity leading to the levelling effect takes place at temperatures above the glass point of the medium[29]. A study of the efficiency of inhibitors in the thermal oxidation of polyalkenes revealed a levelling phenomenon at temperatures of ~100°C, more than 100 deg above the glass point[31].

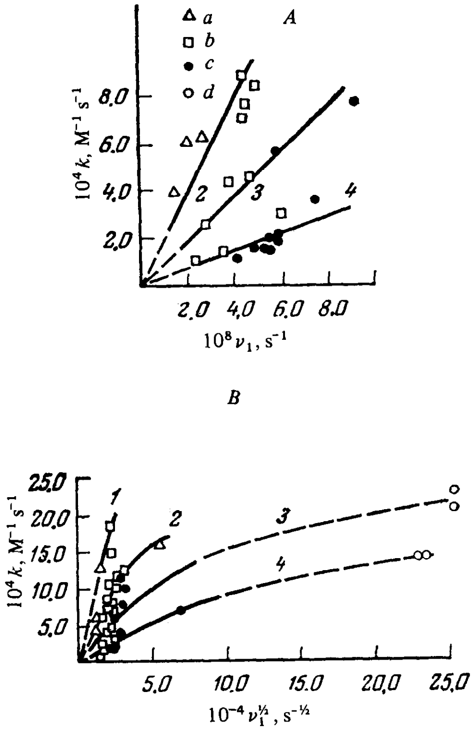

Figure 5. Dependence of rate constant k for reaction of $\rangle$NO with phenol on frequency of rotation of paramagnetic probe: A) at low frequencies; B) over a wide frequency range in various media: a) polystyrene; b) polypropylene; c) polyethylene; d) benzene at different temperatures (°C): 1) 70; 2) 60; 3) 50; 4) 40.

Yet another phenomenon characteristic of reactions in a polymer matrix—the dependence of the reaction rate constant, not limited by diffusion, on the mobility of the medium—has been observed[32-36] in the same matrix at about the same temperature. The reaction of 2,4,6-tri-t-butylphenoxyl with hydroperoxy-groups in polyalkenes exhibits a correlation between its rate constant and the frequency of rotation of a stable nitroxyl radical in the same polymer matrix[32,34]. This correlation was interpreted as due to the effect of the cage on the probability and the rate of change of the mutual orientation of the species in the cage[35]. Rate constants for this reaction[32,34] and for that between the nitroxyl radical 4-benzoyloxy-2,2,6,6-tetramethylpiperidino-oxyl (>NO·) and 2,6-di-t-butylphenol[36] are determined by the change in the frequency of rotation of a paramagnetic probe, and are independent of the nature of the matrix in which the reaction occurs (Fig. 5). Hence the differences in activation energy of these reactions in different media are governed by the difference in the activation energy of rotational mobility in them.

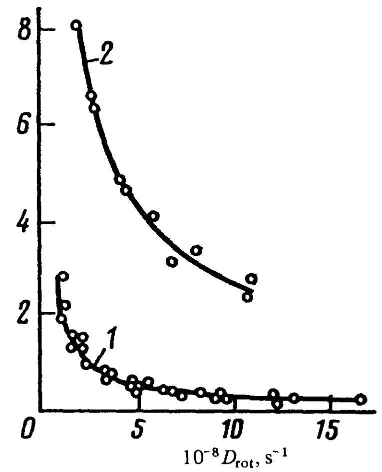

Figure 6. Influence of mobility of medium on ratio of times of translational and rotational diffusion ($n = \tau_{rot}/\tau_{tr}$, with $\tau_{tr} = x/2D_{tr}$ (x = 5 Å) and $\tau_{rot} = 1/6D_{rot}$, where x is the translational displacement of the probe, and D_{tr} and D_{rot} are the coefficients of translational and rotational diffusion) in rubbers at different temperatures: 1) polyenes; 2) polybutyl rubbers.

Both phenomena—levelling of the activity of structurally different species involved in reactions of the same class and the effect of the mobility of the medium on reactions not limited by diffusion—probably have the same origin, change in character of the motion of the species on passing from a liquid to a solid medium. Evidence in support of this suggestion is provided by the fact that the ratio of the correlation time of a paramagnetic probe to the characteristic time of its translational mobility increases with the viscosity of the medium (Fig. 6).[37] Increase in viscosity is probably accompanied by an increase in the number of rotations by the molecule relative to the walls before it escapes from the cage. This tends to increase the probability of chemical reaction when the reactant molecules meet. On passing to more viscous media, therefore, we must evidently expect not only a diminished probability of chemical reaction between species due to the diminished mobility of the medium, and hence also a lower probability that particles will meet, but also an increased probability of chemical reaction resulting from the longer lifetime of reactant species in the same cage.

To examine this last suggestion in greater detail we postulate that two molecules A and B meet, assuming for simplicity that B is considerably smaller than A and that their relative motion can be represented as the movement of a point (B) over the surface of a sphere (A). When the point B enters some reactive region of area s on the spherical surface of A, reaction takes place without energy of activation. In the liquid phase the probability of reaction on the collision of A and B will be given by the ratio of s to the whole spherical surface area S_0, so that the rate constant of this reaction k_{liq} is related to the encounter rate constant $(k_D)_{\mathrm{liq}}$ by the equation

$$k_{\mathrm{liq}} = (k_D)_{\mathrm{liq}}\,\frac{s}{S_0}\,. \tag{40}$$

In the solid phase the probability of reaction in an encounter P_{sd} is increased by movement of the point on the spherical surface during the lifetime of the pair. If $s \ll S_0$ and the path L traversed by the point on the surface is not too long, this probability will be given by the formula

$$P_{\mathrm{sd}} = \frac{s}{S_0} + \frac{L}{\chi\sqrt{s}}\cdot\frac{s}{S_0}\,, \tag{41}$$

in which χ is a coefficient around unity, whose value depends on the configuration of the reactive region.

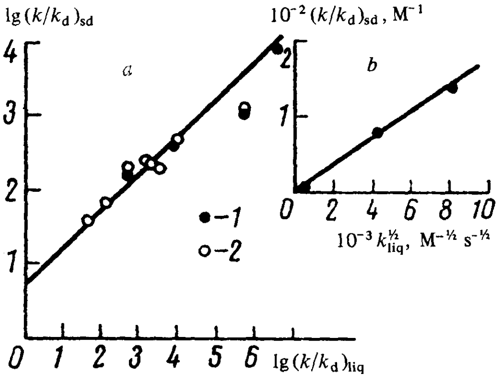

Figure 7. Comparison of rate constants for processes occurring in liquid and solid phases (k_{liq} in methylene dichloride and k_{sd} in: 1) polystyrene; 2) BMK-5: *a*) quenching of singlet oxygen; *b*) chemical interaction with $^1O_2$.

From Eqn. (40) it is easy to obtain a relation between the rate constants of the same reaction in liquid and solid phases:

$$\left(\frac{k}{k_D}\right)_{\mathrm{sd}} = \left(\frac{k}{k_D}\right)_{\mathrm{liq}} + \frac{L}{\chi\sqrt{S_0}}\left(\frac{k}{k_D}\right)_{\mathrm{liq}}^{1/2}. \tag{42}$$

Since all the arguments have been conducted for a case in which the reaction rate constant is far from diffusion-controlled, the formula simplifies to

$$\left(\frac{k}{k_D}\right)_{\mathrm{sd}} = \varphi\left(\frac{k}{k_D}\right)_{\mathrm{liq}}^{1/2}, \text{where } \varphi = \frac{L}{\chi\sqrt{S_0}}, \tag{43}$$

i.e. the reaction rate constant in the solid phase is proportional to the square root of the rate constant of the corresponding liquid-phase reaction. Fig. 7*a* shows that Eqn.(43) describes satisfactorily the results[30] in Table 2 on the quenching of singlet oxygen by various agents: the formula is satisfied for a variation in the reactivity of quenching agents in the liquid phase by factors $>10^5$.

The above reasoning is consistent also with the reactivities of valency-saturated inhibitors and stable radicals towards peroxy-radicals[26,27] (Fig. 8) and with data on the chemical interaction of singlet oxygen with fused rings[28,29] (Fig. 7*b*).

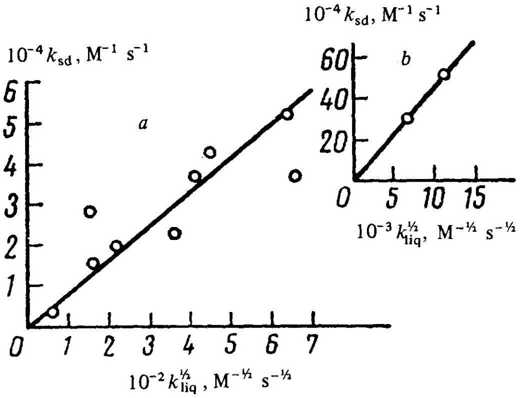

Figure 8. Comparison of rate constants in liquid and solid phases (k_{liq} in ethylbenzene and k_{sd} in polystyrene) for interaction of peroxy-radicals with: *a*) valency-saturated inhibitors; *b*) stable radicals.

The parameter φ has been estimated[30] from the deactivation rate constant k_d and the diffusion coefficient of singlet oxygen. The active centre traverses on the surface of the larger molecule a path of the order of the length of a great circle. This result tends to validate the approximation of a relatively short path made in deducing formula (41).

The models discussed above are evidently extremely rough approximations. However, the experimental results can be explained on the hypothesis that steric factors of the rate constants of chemical reactions in liquid and solid phases are interrelated by the above formulae. The essence of the models is that variation in reactivity is determined by significant change in character of the motion of the reactant species. In the liquid phase this merely involves the meeting or collision of two species; but in the solid phase comparatively lengthy relative motion in the pair is involved.

---o0o---

It has been thus been shown above that the main kinetic features of solid-phase reactions can be explained in terms of the single concept of a difference between solid and liquid phases in the character of the motion of reactant species in them. Transition from an ideal liquid to an ideal solid involves a sequence of qualitative changes in chemical kinetics. In a relatively mobile medium (at temperatures above the glass point) the relation between the reactivity of chemically different species changes, and their activities level off within a given class of reactions. Roughly under the same conditions the mobility of the medium begins to influence significantly the rate constants of the primary reactions. In more rigid matrices (below the glass point) the relative immobility of the medium does not allow "mixing" of relative species among all possible states in the given medium, which entails the appearance of unusual chemical kinetics.

Several aspects of practical importance—the causes of kinetic non-equivalence of species in structurally different cages, the nature of the relation between the kinetics of variation in cage structure and the kinetics of molecular motions of the matrix, the properties of the medium governing the influence of the motion of species in a cage on their reactivity—remain open questions. The last problem is especially important, since there are indications[36] that a transition from "liquid-phase" to "solid-phase" reactivity occurs in polyalkenes at temperatures above 100°C, more than 100 deg above the glass point, and thus under conditions such that the medium can no longer be regarded as a solid but as a very viscous liquid. It is therefore possible that certain kinetic features of solid-phase reactions can be observed even in ordinary liquid-phase processes.

Thermochemistry of Halogenomethanes

V.P.Kolesov

Data on the thermochemistry of halogenomethanes are surveyed. The most reliable enthalpies of formation of 17 compounds have been selected by analysing the literature results and the "key" values adopted in recent years. The scope of modern methods for the approximate calculation of the enthalpies of formation of halogenomethanes is examined. Values are recommended for the enthalpies of formation of all 70 halogenomethanes and their reliability is estimated.
The bibliography includes 111 references.

I. INTRODUCTION

The great importance of organic halogeno-compounds in modern chemistry and technology is due to their extensive and rapidly growing applications. Halogenoderivatives of lower aliphatic hydrocarbons, particularly those of methane, occupy an especially important place among such substances.

The thermochemistry of halogenomethanes is of great interest from both theoretical and practical points of view. The theoretical interest is related to the specific influence of the successive introduction of halogen atoms on the energetic properties of the molecule, which is manifested, for example, by unusual thermochemical reactions[1,2]. The practical interest arises primarily from the necessity to carry out thermodynamic calculations for technical purposes.

Nevertheless the thermochemistry of halogenomethanes has been investigated inadequately and the published data for the enthalpies of formation are contradictory[3-9]. This is caused primarily by the difficulty of the experimental determination of the enthalpies of formation of organic halogeno-compounds, particularly polysubstituted compounds[2,5]. Critical analysis of the available data has shown that this is why reliable enthalpies of formation have been obtained experimentally only for a comparatively small number of halogenomethanes. In many cases the results obtained by different investigators or by different methods show appreciable discrepancies and the choice between them is difficult. Frequently, having at their disposal the same set of initial data, different workers selected "best" values differing by 10–15 kcal mol^{-1}.[5,9,10] Another source of the contradictions in the recommended enthalpies of formation is associated with the necessity to employ methods of approximate calculation, because among the 70 halogenomethanes experimental data are available for a comparatively small number of compounds (not more than 20).

Thus using 17 "reference" values of ΔH_f° which they selected, Yudin and Khachkuruzov[5] estimated the enthalpies of formation of other halogenomethanes by approximate methods. A handbook[3] quoted data for 46 compounds based on their investigation, and still constitutes the most complete compilation of thermochemical constants in the field under consideration. Bernstein[9] estimated the enthalpies of formation of 35 compounds having the composition $CH_nCl_mBr_pF_{4-m-n-p}$ by the method which he proposed. However estimates of the enthalpies of formation by approximate methods involve an even greater arbitrary factor than the choice between experimental values. The results of such estimates generally depend both on the selection of "reference" ΔH_f° values and on the choice of the method of estimation. The estimates of the enthalpies of formation of halogenomethanes by Yudin and Khachkuruzov[5] and Bernstein[9] cannot be regarded as successful for certain groups of compounds. Thus Yudin and Khachkuruzov's[5] enthalpies of formation of chlorofluoromethanes (CH_2FCl, $CHFCl_2$, and CHF_2Cl) proved to deviate appreciably from the true values mainly as a result of the incorrect selection of "reference" ΔH_f° values for fluoromethanes (CH_3F, CH_2F_2, and CHF_3) and also owing to a non-critical application of computational methods[10]. The choice of ΔH_f° in Bernstein's paper[9] for CBr_4, which serves as a basis for the calculation of the enthalpies of formation of other bromo-derivatives, gives rise to appreciable doubts.

The handbooks published in recent years[4,7,8,11] contain carefully selected enthalpies of formation of halogenomethanes, but they include only a comparatively small number of results found experimentally.

This review presents a compilation of the enthalpies of formation of all 70 halogenomethanes. Different experimental methods are described concisely and their possibilities are compared; the difficulties arising in the study of this group of compounds and the methods which can be used to overcome them are discussed. The experimental data are analysed and a value is recommended for each substance. The regularities in the enthalpies of formation of halogenomethanes are considered. The literature methods for the approximate calculation of the enthalpies of formation of halogenomethanes and their theoretical foundations are analysed; recommendations are made concerning the use of these methods.

The enthalpies of formation of the 70 halogenomethanes are recommended on the basis of critically selected most reliable available enthalpies of formation (17 values), the complete set of methods of approximate calculation, and the observed regularities in ΔH_f°. All the recommended values of ΔH_f° have been recalculated on the basis of the key data adopted in 1972–1975 by the International CODATA Commission[12,13].

II. METHODS FOR THE DETERMINATION OF THE ENTHALPIES OF FORMATION OF HALOGENOMETHANES

The most general method for determining the enthalpies of formation of solid and liquid organic compounds is based on the measurement of their enthalpies of combustion in oxygen at an elevated pressure[14,15]. This procedure, developed by Berthelot and known as the bomb calorimetric method, is the most reliable for very many organic compounds of comparatively simple combustion ($C_aH_bO_cN_d$), but its application to organic halogeno-compounds involves considerable difficulties, associated mainly with the complex composition of the combustion products and their highly corrosive nature[2,14,15]. These difficulties may be overcome by employing rotating bombs, auxiliary reducing agents (for organic chloro- and bromo-compounds) and other complications and improvements in the method[14,15]. In the determination of the enthalpies of combustion of liquid and solid organic halogeno-compounds an accuracy to within approximately ±0.01–0.02% can be achieved nowadays, which usually corresponds to the determination of the standard enthalpy of formation with an error not exceeding several tenths of kcal mol^{-1}.[14,15] However, this accuracy can be achieved only when many additional conditions are observed; high purity of the test substances, rapid and complete reduction of the free halogens to hydrogen halides, careful analysis of the solution in the bomb calorimeter and of the gaseous reaction products with subsequent application of reliably determined thermal corrections, etc. The actual discrepancies between the results obtained by different workers amount in many instances to several kcal mol^{-1} and the choice between such values is frequently not evident.

The method involving the determination of enthalpies of combustion in a stream of oxygen under a pressure close to atmospheric has been used successfully for gaseous organic compounds[14,16]. The method is applicable to halogeno-derivatives with a low halogen content, as a rule to monohalogeno-derivatives[16]. The determination of the enthalpies of formation of gaseous compounds with a high halogen content or compounds containing different halogens is more difficult. Their enthalpies of formation are sometimes determined by combustion in oxygen in a bomb calorimeter[2,17,18]. In this case careful analysis of the combustion products is necessary, because the combustion of the gases in the bomb does not as a rule go to completion.

The experimental difficulties encountered in the determination of the enthalpies of combustion of halogenomethanes in oxygen led to the development of many new procedures, usually less universal but having definite advantages in the study of individual groups of compounds. In order to determine the ΔH_f° for gas-phase catalytic reactions, Lacher and coworkers designed a novel isothermal calorimeter of the compensation type[14,19,20]. They used it most often to measure the enthalpies of reactions involving addition to a double bond (chlorination, bromination, hydrobromination, etc.). However, in certain cases, the enthalpies of hydrogenation of organic halogeno-compounds with complete or partial substitution of the halogen by hydrogen were determined[21–23]. These studies made it possible to calculate the standard enthalpies of formation of individual halogenoalkanes, particularly halogenomethanes.

The choice of the catalyst and the reaction conditions is very important for the determination of the enthalpies of gas-phase reactions. The reproducibility of the results of measurements is as a rule fairly high (0.1–0.2 kcal mol^{-1}), but in certain cases there are significant discrepancies with data obtained by other methods[16]. Thus the discrepancy for methyl chloride amounts to ~1 kcal mol^{-1} and is probably associated with failure to take into account the systematic errors in the determination of $\Delta H°$ for the catalytic reaction (for example, owing to the insufficient inertness of the catalyst[16]).

In order to determine the enthalpies of formation of chlorofluorocarbons, particularly chlorofluoromethanes, a method[24-30] based on the measurement of the enthalpies of the reactions of these compounds with alkali metals has been used:

$$CF_nCl_{4-n} + 4M \rightarrow C + n\,MF + (4-n)\,MCl\ ; \quad M = Na \text{ or } K. \tag{1}$$

This reaction is initiated by an electric arc, the energy of which must therefore be accurately measured. It usually results in the formation of amorphous highly dispersed carbon. Since the enthalpies of formation of different specimens of amorphous carbon may differ, it is desirable to determine them experimentally for each series of experiments. In order to prevent side reactions, it is very important to make sure that, when reaction (1) is carried out in a calorimeter, the gaseous substance investigated reacts in its entirety[31]. To make sure that the reaction goes to completion and proceeds unambiguously, it is necessary to carry out numerous measurements and analyses: measurement of the residual pressure in the bomb, analysis of the contents of the bomb for fluoride and chloride ions, weighing of the initial gas, weighing of the alkali metal, and determination of the amount of metal which has not reacted. The accuracy of the results is determined ultimately by the accuracy of these measurements and analyses and also by the accuracy of the measurement of the energy of the arc and of the enthalpy of combustion of the carbon. The enthalpies of reactions with alkali metals can be determined only for a limited range of substances. In terms of accuracy, this method is much inferior to the determination of the enthalpies of combustion in oxygen. Its use for chlorofluoromethanes is justified by the fact that more accurate thermochemical procedures are as a rule inapplicable to this group of compounds[31].

Other methods are still more specific. The application of the method of combustion in fluorine, which has been used successfully in recent years to determine the enthalpies of formation of fluorides and certain other classes of compounds, is restricted in the case of halogenomethanes by the need to determine the enthalpy of formation of carbon tetrafluoride[32,33].

The method based on the measurement of the enthalpies of reduction of halogeno-derivatives by lithium tetrahydroaluminate has been used successfully for certain methane derivatives[34]. The reduction is carried out in ethereal solution in the presence of an excess of lithium hydride. Lithium tetrahydroaluminate is regenerated under these conditions and the reaction may be represented by the equation

$$RX + LiH \xrightarrow[\text{in ethereal soln.}]{LiAlH_4} RH + LiX\ , \tag{2}$$

where X is the halogen (bromine or iodine). The enthalpies of formation of LiH, RH, and LiX are known, so that the calculation of the enthalpies of formation of RX presents no difficulties. The method is mainly applicable to monohalogeno-derivatives. In certain cases the enthalpies of formation of halogenomethanes were determined by measuring the enthalpies of their thermal decomposition reactions[17,35]. The enthalpies of formation of certain chlorofluoromethanes have been measured by the method involving explosion in a spherical bomb[37,38]. The last three methods are applicable solely to a small group of substances and has not as yet been adequately investigated. Their use must be accompanied by particularly careful chemical control of the relevant process.

Apart from the procedures described, there exist also calorimetric methods which have been used only in individual and exceptional cases. Their possibilities are briefly described below in connection with the assessment of specific literature data.

Together with direct measurements, the method involving the determination of the enthalpies of reaction from chemical equilibrium data is frequently used in the thermochemistry of halogenomethanes. Measurement of the equilibrium constants makes it possible to calculate the Gibbs free energy of reaction:

$$\Delta G_T^0 = -RT\ln K_p,$$

or the enthalpy of reaction may be calculated from the equation

$$\Delta H_T^0 = -RT\ln K_p + T\Delta S_T^0 . \tag{3}$$

ΔH_T^0 may be calculated from Eqn. (3) by two procedures. Usually ΔH_T^0 is calculated from the temperature dependence of K_p assuming that ΔS_T^0 is constant. On the other hand, when the values of ΔS_T^0 for the given reaction may be calculated by an independent method, it is possible to evaluate ΔH_T^0 directly. The latter method is more accurate, but is applicable only when the entropies of all the reactants are known (for example, have been calculated on the basis of the Third Law of Thermodynamics).

The calculation of the enthalpies of reaction from equilibrium data does not always lead to reliable results. An essential condition for the successful application of this method is a high accuracy of the measurement of K_p, the attainment of equilibrium over the entire temperature range, and the absence of side reactions. This is particularly important in the calculation of ΔH_T^0 from the temperature variation of K_p.

In a series of careful studies in recent years[39-46], undertaken to investigate equilibria involving halogenomethanes, a high accuracy of the measurement of K_p was achieved as a result of the employment of sensitive instruments for the measurements of pressure and concentration and careful investigation of the equilibrium conditions over a wide temperature range. In terms of the accuracy of the calculation of ΔH_T^0, some of these studies can compete successfully with the measurements of ΔH_T^0 by direct calorimetric methods.

Apart from the equilibrium method, other non-calorimetric procedures are sometimes used. Thus enthalpies of formation have been estimated[5] using the results of the experimental determination of the bond dissociation energies (for example, by the electron impact method). However, this method is much less accurate than those described above. The determination of dissociation energies is usually associated with the measurement of the appearance and ionisation potentials and the accuracy of such measurements is comparatively low (see Yudin and Khachkuruzov[5], Table 3). Furthermore, in order to calculate ΔH_f^0 for compounds in terms of the dissociation energy, it is necessary to know the ΔH_f^0 for the groups involved; these values are also as a rule not accurate. For this reason, the calculation of ΔH_f^0 in terms of dissociation energies can be usefully employed only in the absence of more accurate data and only in those cases where even a rough estimate of the thermochemical quantities is sufficient.

III. KEY VALUES AND UNITS OF MEASUREMENT

To ensure the mutual consistency of all the recommended thermochemical data, the single system of key values developed and adopted by the Committee on Data for Science and Technology (CODATA) is used in the present review. In calculating the enthalpies of formation of halogenomethanes, the following key values of ΔH_f°(kcal mol^{-1}) were used: −68.315 ± 0.010 (H_2O, liq.); −94.051 ± 0.031 (CO_2, gas); −80.15 ± 0.16 (F^-_{aq}); −39.933 ± 0.021 (Cl^-_{aq}); −29.039 ± 0.35 (Br^-_{aq}); 7.388 ± 0.026 (Br_2, gas); −8.695 ± 0.041 (HBr, gas); −57.433 ± 0.015 (Na^+_{aq}); −60.271 ± 0.025 (K^+_{aq}); −22.063 ± 0.031 (HCl, gas); 6.30 ± 0.19 (HI, gas); 14.919 ± 0.019 (I_2, gas).[12,13,47] All the values of ΔH_f° quoted in this review refer to the standard states of the substances and 298.15 K.

The most significant difference between the adopted system of key values and those employed in the most widely used handbooks[4,7] consists in the revision of ΔH_f° (F^-_{aq}). The remaining quantities have remained unchanged or have been changed very insignificantly.

In many instances, apart from the quantities listed above, others (enthalpy of evaporation, enthalpy of dilution, etc.) are needed to calculate the enthalpies of formation of halogenomethanes. These auxiliary quantities were taken from handbooks[4,7] and other publications[48,49]. In calculating the enthalpies of reaction from equilibrium constants, revised values of the thermodynamic functions were used[50].

The enthalpies of formation of compounds in the vast majority of thermochemical studies are expressed in kcal mol^{-1}. To facilitate the comparison of the results, these units were used also in the present review. However, the final data in the Table of recommended values are also expressed in kJ mol^{-1}, which corresponds to the International "SI" system of units adopted by the XIth General Conference on Weights and Measures in 1960.[51,52]. These units are related: 1 cal = 4.184 J.[14] The atomic weights were adopted from Ref. 53.

IV. ANALYSIS OF EXPERIMENTAL THERMOCHEMICAL DATA FOR HALOGENOMETHANES AND SELECTION OF RECOMMENDED ENTHALPIES OF FORMATION

Methane

The bibliography of the determinations of the enthalpy of combustion of methane up to 1970 is given by Glushko[4]. Rossini's study[54] is the most accurate. After applying corrections for the adjustment of the gas to the ideal state[55] and for the modification of atomic weights, these data[54] lead to ΔH_f° (CH_4, gas) = −17.88 ± 0.08 kcal mol^{-1}.[3,4] In 1972 Pittam and Pilcher[56] redetermined the enthalpy of combustion of gaseous methane in an improved calorimeter with a burner[16] and obtained ΔH_f° (CH_4, gas) = −17.80 ± 0.10 kcal mol^{-1}. Pittam and Pilcher had at their disposal a purer methane specimen than in Rossini's work, but, since they calibrated the calorimeter on the basis of the heat of combustion of hydrogen, their results depend on the latter. Since the discrepancy between the values in Refs. 54 and 56 is small, it is desirable to adopt the mean as the recommended value of ΔH_f° (CH_4, gas), i.e.

$$\Delta H_f^\circ(CH_4, \text{gas}) = -17.85 \pm 0.06 \text{ kcal mol}^{-1}.$$

Difluoromethane

Neugebauer and Margrave[57] determined the enthalpy of combustion of difluoromethane in a rotating bomb calorimeter. Since the solubilities and heats of solution of CO_2 and O_2 in HF solution were unknown, the calorimeter was calibrated in three series of experiments: under standardised conditions, with the bomb containing 50 cm^3 of water, and with the bomb containing 50 cm^3 of the HF solution. This procedure enabled the authors[57] to apply a correction for the standard state and also to exclude a secondary thermal effect associated with the corrosion of the walls of the bomb. Mass-spectrometric analysis of the combustion products showed that no substance other than CO_2 and HF were obtained on combustion. Only a small amount of uncombusted difluoromethane was detected. The enthalpy of combustion of CH_2F_2 via the reaction

$$CH_2F_2(\text{gas}) + O_2(\text{gas}) \rightarrow CO_2(\text{gas}) + 2HF \text{ (soln; 2.4 } N)$$

which the present author calculated from the results of individual experiments quoted by Neugebauer and Margrave[57], is −139.83 ± 0.20 kcal mol^{-1}. ΔH_f° (CH_2F_2, gas) = −108.09 ± 0.42 kcal mol^{-1} corresponds to this value.

Trifluoromethane

Neugebauer and Margrave[57] determined the enthalpy of combustion of CHF_3 by the same method as for CH_2F_2 (see above). Their results lead to the following value when account is taken of the key quantities adopted above: ΔH_f° (CHF_3, gas) = −166.47 ± 0.90 kcal mol^{-1}.

The equilibrium in the reaction

$$Br_2 + CHF_3 \rightleftarrows HBr + CBrF_3 \qquad (4)$$

has been investigated[42,58]. Calculation based on the Third Law of Thermodynamics using revised values of thermodynamic functions[50] yielded $\Delta H^\circ(4)$ = −4.26 ± 0.11 kcal mol^{-1} for this reaction. Coomber and Whittle[41] also investigated the equilibrium in the reaction

$$C_2F_6 + Br_2 \rightleftarrows 2CF_3Br \qquad (5)$$

and their results lead to $\Delta H^\circ(5)$ = 3.287 ± 0.075 kcal mol^{-1}.

The equilibria in reactions (4) and (5) were attained from both directions. The results of the measurement of $\Delta H(4)$ and $\Delta H(5)$ make it possible to establish the relation $\Delta H_f^\circ(C_2F_6) - 2\Delta H_f^\circ(CHF_3)$ = 12.193 ± 1.2 kcal mol^{-1}, whence, using $\Delta H_f^\circ(C_2F_6$, gas) = −321.03 ± 1.30 kcal mol^{-1},[50] we obtain ΔH_f° (CHF_3, gas) = −166.97 ± 0.90 kcal mol^{-1}.

The values of ΔH_f° obtained by the two different methods agree within the limits of experimental error. The recommended value is the weighted mean of those quoted above:

$$\Delta H_f^\circ(CHF_3, \text{gas}) = -166.72 \pm 0.64 \text{ kcal mol}^{-1}.$$

Carbon Tetrafluoride

The example of CF_4 shows particularly clearly how difficult is a reliable determination of the enthalpies of formation of organic halogeno-compounds with a high halogen content. In the 15 studies carried out during the period between 1933 and 1965 different methods were used to determine ΔH_f°: combustion of carbon in fluoride[59,60], combustion of methane in fluorine[61], reaction between CF_4 and potassium[24,25] and sodium[27], thermal decomposition of tetrafluoroethylene[17,35], combustion of polytetrafluoroethylene[62,63] and docosafluorobicyclohexyl[64] in oxygen under conditions leading to markedly different CF_4 contents in the combustion product, explosion in a spherical bomb[37,38], etc. However, the results were not very accurate and the maximum discrepancy between them reached more than 70 kcal mol^{-1} (the results range from -162 kcal mol^{-1} [59] to -235 kcal mol^{-1} [24]).

The most reliable results were obtained in recent years by the direct measurement of the enthalpy of fluorination of graphite[32,33]. Domalski and Armstrong[32] combusted a mixture of graphite and Teflon in fluorine. Greenberg and Hubbard[33] achieved a high degree of combustion of graphite by a successful choice of the reaction initiator (silicon powder). The combustion products were carefully analysed in both cases; the amounts of the C_2F_6 and C_3F_8 admixtures in the products were very small and the values of $\Delta H_f^\circ(CF_4$, gas) obtained agree extremely well: -222.87 ± 0.38 kcal mol^{-1} [32] and -223.05 ± 0.20 kcal mol^{-1}.[33] Similar results were also obtained[65] from the measurement of the heat of combustion of Teflon in fluorine: $\Delta H_f^\circ(CF_4$, gas) = -222.0 kcal mol^{-1}, and from a determination[66] of the enthalpy of reaction between dicyanogen and nitrogen trifluoride: $\Delta H_f^\circ(CF_4$, gas) = -223.23 ± 0.5 kcal mol^{-1}. The following value has been adopted[4] on the basis of the results in Refs. 32 and 33:

$$\Delta H_f^\circ(\mathrm{CF_4, gas}) = -223.0 \pm 0.4 \text{ kcal mol}^{-1},$$

This is a key value in the thermochemistry of organic fluoro-compounds and one of the most reliable among the known enthalpies of formation of halogenomethanes.

Chloromethane

The enthalpy of combustion of gaseous chloromethane was determined by Berthelot[67] and Thomsen[68], but the accuracy of their results is low. The enthalpy of the hydrogenation of CH_3Cl to methane was determined in later investigations[21-23], the results leading to $\Delta H_f^\circ(CH_3Cl$, gas) = -20.6 kcal mol^{-1}.[4] Very similar values of ΔH_f° were obtained in a number of compilations[3,6,8] from the results in Refs. 21 and 22. Somewhat later Fletcher and Pilcher[69] determined the enthalpy of combustion of chloromethane in a calorimeter with a heater. Their results lead to the following value:

$$\Delta H_f^\circ(\mathrm{CH_3Cl, gas}) = -19.58 \pm 0.16 \text{ kcal mol}^{-1},$$

which we recommend bearing in mind the reliability of the apparatus and method used[69]. A similar value, ΔH_f°.(CH$_3$Cl, gas) = -19.32 kcal mol^{-1}, was adopted in Ref. 7.

Dichloromethane

The determination of the enthalpy of combustion of CH_2Cl_2 by Berthelot and Ogier[70] is only of historical interest. Smith et al.[71] determined the enthalpy of combustion of CH_2Cl_2 in a stationery bomb calorimeter. Their value of ΔH_c°, adjusted to 25°C, corresponds to ΔH_f°.(CH$_2$Cl$_2$, liq.) = -28.74 kcal mol^{-1}. Taking into account the enthalpy of evaporation, which is 6.90 ± 0.03 kcal mol^{-1},[4] we find $\Delta H_f^\circ(CH_2Cl_2$, gas) = -21.84 kcal mol^{-1}. Lacher et al.[72] measured the enthalpy of the gas-phase hydrogenation of dichloromethane to methane and hydrogen chloride at 250°C. After adjustment to 25°C, their data leads to $\Delta H_f^\circ((CH_2Cl_2$, gas) = -22.92 kcal mol^{-1}. Hu and Sinke[73] redetermined in 1969 the enthalpy of combustion of liquid dichloromethane using a rotating bomb calorimeter and a very pure CH_2Cl_2 specimen. Their results yield $\Delta H_f^\circ(CH_2Cl_2$, liq.) = -29.66 ± 0.07 kcal mol^{-1} or $\Delta H_f^\circ(CH_2Cl_2$, gas) = -22.76 ± 0.08 kcal mol^{-1}. The last value is the most reliable and agrees very well with the data of Lacher et al.[72].

Trichloromethane

The accuracy of the determinations of the enthalpy of combustion of trichloromethane in Refs. 68, 74, and 75 is not high. The data of Smith et al.[71] for the enthalpy of combustion of $CHCl_3$ lead to $\Delta H_f^\circ(CHCl_3$, liq.) = -31.65 kcal mol^{-1} after adjustment to 25°C. Kirkbride[76] measured the enthalpy of the reaction between liquid trichloromethane and gaseous chlorine and his result makes it possible to establish only the relation $\Delta H_f^\circ(CHCl_3$, liq.) = $\Delta H_f^\circ(CCl_4$, liq.) + 0.24 kcal mol^{-1}. The most reliable data are those of Hu and Sinke[73], who determined the enthalpy of combustion of an extremely pure trichloromethane specimen in a rotating bomb calorimeter. Their results[73] lead to $\Delta H_f^\circ(CHCl_3$, liq.) = -32.04 ± 0.35 kcal mol^{-1} or, taking into account $\Delta H_{v298.15}^\circ(CHCl_3$, liq.) = 7.5 ± 0.1 kcal mol^{-1},[4] to $\Delta H_f^\circ(CHCl_3$, gas) = -24.54 ± 0.37 kcal mol^{-1}.

Carbon Tetrachloride

The determination of the enthalpy of combustion carried out by Berthelot[74] and Thomsen[68] are less accurate than the values obtained in later studies. Bodenstein et al.[77] determined the enthalpy of the gas-phase reaction of CCl_4 with hydrogen involving the formation of hydrogen chloride and amorphous carbon. ΔH_f° for amorphous carbon may vary appreciably; having adopted its value from the paper of Neugebauer and Margrave[17], Yudin and Khachkuruzov[5] obtained the following value from the data of Bodenstein et al.[77]: $\Delta H_f^\circ(CCl_4$, gas) = -24.7 kcal mol^{-1}. Baibuz and Medvedev[37,38] found $\Delta H_f^\circ(CCl_4$, gas) = -24.6 ± 1.9 kcal mol^{-1} by an explosion method. Neugebauer[78] measured the enthalpy of the reaction of carbon tetrachloride with magnesium and obtained $\Delta H_f^\circ(CCl_4$, liq.) = -32.3 ± 1.5 kcal mol^{-1}. Smith et al.[71] determined the enthalpy of combustion of CCl_4 in oxygen in the presence of a large amount of an auxiliary substance—only 4% of the measured heat corresponded to CCl_4. After adjustment to 25°C, their data lead to $\Delta H_f^\circ(CCl_4$, liq.) = -29.03 kcal mol^{-1}. Lord and Pritchard[79] studied the equilibrium

$$\mathrm{CO_2(gas) + CCl_4(gas) \rightarrow 2COCl_2(gas)} \qquad (6)$$

and found $\Delta H_{298}^\circ(6) = 16.8 \pm 0.5$ kcal mol^{-1}. Depending on the enthalpy of formation of phosgene adopted, this value leads to $\Delta H_f^\circ(CCl_4$, gas) = -29.75 ± 1.1 or $\Delta H_f^\circ(CCl_4$, gas) = -27.4 ± 0.7 kcal mol^{-1}. In their study of the equilibrium

$$\mathrm{Br_2 + CCl_4 \rightleftarrows BrCl + CBrCl_3,} \qquad (7)$$

Mendenhall et al.[43] obtained $\Delta H^\circ_{298}(7) = 8.84 \pm 0.3$ kcal mol^{-1}; recalculation of this value using revised thermodynamic functions[50] yields $\Delta H^\circ_{298}(7) = 8.37 \pm 0.30$ kcal mol^{-1}. Sullivan and Davidson[80] found $\Delta H^\circ_{298}(8) = -1.44 \pm 0.10$ kcal mol^{-1} for the reaction

$$Br_2 + CHCl_3 \rightleftarrows HBr + CBrCl_3 \quad , \qquad (8)$$

which, together with the previous result, yields the difference $\Delta H^\circ_f(CCl_4, \text{gas}) - \Delta H^\circ_f(CHCl_3, \text{gas}) = 2.44 \pm 0.35$ kcal mol^{-1}. Using the value $\Delta H^\circ_f(CHCl_3, \text{gas}) = -24.54 \pm 0.37$ kcal mol^{-1} adopted above, we obtain $\Delta H^\circ_f(CCl_4, \text{gas}) = -22.10 \pm 0.51$ kcal mol^{-1}.

The most reliable study is that of Hu and Sinke[73], who determined ΔH° for the combustion of a pure carbon tetrachloride specimen in a rotating bomb calorimeter. Their data lead to $\Delta H^\circ_f(CCl_4, \text{liq.}) = -30.61 \pm 0.16$ kcal mol^{-1} or, taking into account the enthalpy of evaporation $\Delta H^\circ_{V298.15}(CCl_4, \text{liq.}) = 7.75 \pm 0.01$ kcal mol^{-1},[4] the result is $\Delta H^\circ_f(CCl_4, \text{gas}) = -22.86 \pm 0.16$ kcal mol^{-1}.

Chlorotrifluoromethane

The values of $\Delta H^\circ_f(CF_3Cl, \text{gas})$ calculated from ΔH° for the reactions of CF_3Cl with potassium[25,26] or sodium[29,30] diverge appreciably: -176.2 kcal mol^{-1} [25]; -167.0 kcal mol^{-1} [26]; -176.7 kcal mol^{-1}.[29,30] These discrepancies are probably a consequence of numerous complications arising in the determination of the heats of reaction with alkali metals (see above). Mears and Stahl's measurements[81] of the enthalpy of the disproportionation reaction lead to -20.85 kcal mol^{-1} for the reaction

$$3HF + CCl_4 \rightarrow CF_3Cl + 3HCl$$

at 573 K, which on recalculation yields $\Delta H^\circ_f(CF_3Cl, \text{gas}) = -172.6$ kcal mol^{-1}. Baibuz and Medvedev[37,38] found $\Delta H^\circ_f(CF_3Cl, \text{gas}) = -167.7 \pm 2.2$ kcal mol^{-1} by an explosion method in a spherical bomb. Lord and coworkers[82,83] studied the equilibria

$$CF_3Cl + I_2 \rightleftarrows CF_3I + ICl \quad , \qquad (9)$$

$$CF_3H + I_2 \rightleftarrows CF_3I + HI \quad . \qquad (10)$$

When revised thermodynamic functions[80] are used, their data lead to $\Delta H^\circ_{298}(9) = 17.22 \pm 0.11$ kcal mol^{-1} and $\Delta H^\circ_{298}(10) = 17.29 \pm 0.15$ kcal mol^{-1}.[82] Hence we obtain $\Delta(\Delta H) = \Delta H^\circ_f(CF_3Cl, \text{gas}) - \Delta H^\circ_f(CF_3H, \text{gas}) = -2.07 \pm 0.30$ kcal mol^{-1}. The quantity $\Delta(\Delta H)$ may also be calculated from Coomber and Whittle's data[42,84] for the equilibria

$$CF_3Br + Cl_2 \rightleftarrows CF_3Cl + BrCl \quad , \qquad (11)$$

$$CF_3Cl + Br_2 \rightleftarrows CF_3Br + BrCl \quad , \qquad (12)$$

$$CF_3H + Br_2 \rightleftarrows CF_3Br + HBr \quad . \qquad (13)$$

They obtained $\Delta H^\circ_{298}(11) = -10.69 \pm 0.30$ kcal mol^{-1}, $\Delta H^\circ_{298}(12) = 10.49 \pm 0.40$ kcal mol^{-1}, and $\Delta H^\circ_{298}(13) = -4.26 \pm 0.11$ kcal mol^{-1}. $\Delta(\Delta H) = -2.75 \pm 0.50$ kcal mol^{-1} when $\Delta H^\circ(11)$ and $\Delta H^\circ(13)$ are used, and $\Delta(\Delta H) = -2.84 \pm 0.53$ kcal mol^{-1} follows from $\Delta H^\circ(12)$ and $\Delta H^\circ(13)$. The average value of the difference $\Delta(\Delta H)$ based on the results in Refs. 42 and 82–84 is -2.55 ± 0.50 kcal mol^{-1}. Since $\Delta H^\circ_f(CHF_3, \text{gas}) = -166.72 \pm 0.64$ kcal mol^{-1}, we obtain

$$\Delta H^\circ_f(CF_3Cl, \text{gas}) = -169.27 \pm 0.81 \text{ kcal mol}^{-1}.$$

Bearing in mind the satisfactory agreement between the three values of $\Delta(\Delta H)$, the last value of the enthalpy of formation appears to be the most reliable.

Dichlorodifluoromethane

The values of $\Delta H^\circ_f(CF_2Cl_2, \text{gas})$ calculated from the ΔH° for the reactions of CF_2Cl_2 with potassium[25,26] or sodium[29,30] agree satisfactorily: -115.6 kcal mol^{-1} [25]; -114.6 kcal mol^{-1} [26]; -115.0 kcal mol^{-1}.[29,30] Mears and Stahl[81] quote $\Delta H^\circ_{573}(14) = -10.97$ kcal mol^{-1} for the reaction

$$2HF + CCl_4 \rightarrow CF_2Cl_2 + 2HCl \, , \qquad (14)$$

which leads to $\Delta H^\circ_f(CF_2Cl_2, \text{gas}) = -119.8$ kcal mol^{-1}. Petersen and Pitzer[85] measured K_p for the reaction

$$2CF_3Cl + CCl_4 \rightleftarrows 3CF_2Cl_2 \quad . \qquad (15)$$

According to their data, $\Delta H^\circ_{298}(15) = 7.64$ kcal mol^{-1} and $\Delta H^\circ_f(CF_2Cl_2, \text{gas}) = -117.9$ kcal mol^{-1}. Mears and Stahl[81] published no information about the experiment and Petersen and Pitzer[85] noted the occurrence of side reactions. We therefore recommend the mean of the three values obtained in Refs. 25, 26, 29, and 30, i.e. $\Delta H^\circ_f(CF_2Cl_2, \text{gas}) = -115.1$ kcal mol^{-1}. The error of this quantity probably does not exceed ± 2 kcal mol^{-1}.

Trichlorofluoromethane

The values of $\Delta H^\circ_f(CFCl_3, \text{gas})$ calculated from the ΔH° for the reaction of $CFCl_3$ with potassium differ significantly: -72.0 kcal mol^{-1} [25] and -64.6 kcal mol^{-1}.[26] Mears and Stahl's data[81] lead to values which vary from -64.7 to -70.2 kcal mol^{-1} depending on the selected method of calculation. Petersen and Pitzer[85] measured K_p for the reaction

$$CF_3Cl + 2CCl_4 \rightleftarrows 3CFCl_3 \, , \qquad (16)$$

and according to their data $\Delta H^\circ_{298}(16) = 10.56$ kcal mol^{-1} and $\Delta H^\circ_f(CFCl_3, \text{gas}) = -68.1$ kcal mol^{-1}. They noted the occurrence of side reactions between chlorofluoromethanes and the catalyst ($AlCl_3$). Baibuz and Medvedev[37,38] found $\Delta H^\circ_f(CFCl_3, \text{gas}) = -67.5$ kcal mol^{-1} by an explosion method in a spherical bomb. Neugebauer[36] measured ΔH° for the reaction of $CFCl_3$ with magnesium and obtained $\Delta H^\circ_f(CFCl_3, \text{gas}) = -66.2$ kcal mol^{-1}. Recalculation of this result on the basis of the system of key quantities adopted in the present review is impossible owing to the lack of information about the experiment in Neugebauer paper[36]. The choice of the recommended value of ΔH°_f is difficult, but the available set of data suggests that it lies in the range between -65 and -70 kcal mol^{-1}. The average value $\Delta H^\circ_f(CFCl_3, \text{gas}) = -67.5 \pm 2.5$ kcal mol^{-1} is recommended.

Bromomethane

Berthelot[67] and Thomsen[68] measured ΔH° for the combustion of bromomethane, but the accuracy of their measurements is low. Bak[86] investigated the equilibrium in the gas-phase reaction

$$CH_3Br + HCl \rightleftarrows CH_3Cl + HBr \tag{17}$$

and $\Delta H^\circ_{298}(17) = -2.41 \pm 0.10$ kcal mol^{-1} and $\Delta H^\circ_f(CH_3Br$, gas) = −8.62 ± 0.19 kcal mol^{-1} were calculated from his data. Hartley et al.[87] determined the enthalpy of the reaction

$$Hg(CH_3)_2(liq.) + 2Br_2(liq.) \rightarrow HgBr_2(cryst.) + 2CH_3Br\ (gas) \tag{18}$$

and found $\Delta H^\circ_{298}(18) = -72.15 \pm 0.61$ kcal mol^{-1}. Together with the ΔH° for the combustion of dimethylmercury,[88] these data lead to $\Delta H^\circ_f(CH_3Br$, gas) = −8.6 kcal mol^{-1}. Fowell et al.[23] determined the enthalpy of the hydrogenation of CH_3Br to methane and their results yield $\Delta H^\circ_f(CH_3Br$, gas) = −8.97 ± 0.34 kcal mol^{-1}.

Adams et al.[89] determined the energy of the reaction of bromomethane with lithium hydride in lithium tetrahydroaluminate, whence they found $\Delta H^\circ_{298}(19) = -3.3 \pm 0.3$ kcal mol^{-1} for the reaction

$$CH_3Br(liq.) + \tfrac{1}{2}H_2(gas) \rightarrow CH_4(gas) + \tfrac{1}{2}Br_2(liq.). \tag{19}$$

We obtain from these data $\Delta H^\circ_f(CH_3Br$, liq.) = −14.55 ± 0.31 kcal mol^{-1} or, taking into account the enthalpy of evaporation $\Delta H^\circ_{V298}(CH_3Br$, liq.) = 5.64 ± 0.10 kcal mol^{-1}, we have $\Delta H^\circ_f(CH_3Br$, gas) = −8.91 ± 0.32 kcal mol^{-1}. Ferguson et al.[90] investigated the equilibrium in the gas-phase bromination of methane with formation of HBr and CH_3Br; calculation from their results based on the Second Law of Thermodynamics yields $\Delta H^\circ_{298} = -8.63$ kcal mol^{-1} for the bromination reaction, while calculation based on the Third Law gives rise to $\Delta H^\circ_{298} = -6.26 \pm 0.10$ kcal mol^{-1}. The latter result corresponds to $\Delta H^\circ_f(CH_3Br$, gas) = −8.03 ± 0.12 kcal mol^{-1}, but conflicts with the results of the majority of other studies. The most probable value is the mean of those obtained in Refs. 23 and 89, i.e. $\Delta H^\circ_f(CH_3Br$, gas) = −8.94 ± 0.30 kcal mol^{-1}.

Bromotrifluoromethane

The enthalpy of reaction (4) and the value of $\Delta H_f(CHF_3$, gas) adopted above lead to $\Delta H^\circ_f(CF_3Br$, gas) = −155.22 ± 0.65 kcal mol^{-1}. Lord et al.[82] investigated the equilibrium

$$CF_3Br + I_2 \rightleftarrows CF_3I + BrI \tag{20}$$

and according to their data $\Delta H^\circ_{298}(20) = 9.55 \pm 0.04$ kcal mol^{-1}. Together with the enthalpy of reaction (10), this yields $\Delta H^\circ_f(CF_3Br$, gas) = −155.55 ± 0.70 kcal mol^{-1}. The following average value is recommended:

$$\Delta H^\circ_f(CF_3Br, gas) = -155.38 \pm 0.65\ kcal\ mol^{-1}.$$

Bromotrichloromethane

Equilibrium (8) was investigated by Sullivan and Davidson[80] and their results made it possible to calculate $\Delta H^\circ_f(CCl_3Br$, gas) = −9.90 ± 0.40 kcal mol^{-1}. The data of Mendenhall et al.[43] for reaction (7) lead to $\Delta H^\circ_f(CCl_3Br$, gas) = −10.65 ± 0.35 kcal mol^{-1}. The mean of the two values quoted, i.e. $\Delta H^\circ_f(CCl_3Br$, gas) = −10.28 ± 0.35 kcal mol^{-1}, may be adopted as the most probable value.

Iodomethane

Berthelot[67,91] and Thomsen[68] measured ΔH° for the combustion of iodomethane, but these studies are only of historical interest. Carson et al.[92,93] determined ΔH° for the reaction of dimethylcadmium with iodine in ether and their results lead to $\Delta H^\circ_f(CH_3I$, liq.) = −3.4 ± 0.8 kcal mol^{-1}.[87] Hartley et al.[87] determined the enthalpy of the reaction

$$Hg(CH_3)_2(liq.) + 2I_2(cryst.) \rightarrow HgI_2(cryst.) + 2CH_3I(liq.) \tag{21}$$

and obtained $\Delta H^\circ_{298}(21) = 44.11 \pm 0.44$ kcal mol^{-1}. These data, together with ΔH° for the combustion of dimethylmercury[88], lead to $\Delta H^\circ_f(CH_3I$, liq.) = −2.3 kcal mol^{-1}. Mackle and Ubbelohde[94] and later Nichol and Ubbelohde[95] measured ΔH° for the reaction of the Grignard reagent with I_2 and HI in solutions in ether and *p*-xylene; the data[95] for the reaction

$$CH_3I(gas) + HI(gas) \rightarrow CH_4(gas) + I_2(gas) \tag{22}$$

lead to $\Delta H^\circ_{291}(22) = -11.04 \pm 1.33$ kcal mol^{-1}, whence it follows that $\Delta H^\circ_f(CH_3I$, gas) = −1.7 kcal mol^{-1}. Carson et al.[34] measured ΔH° for the reduction of iodomethane by lithium tetrahydroaluminate in ether and obtained $\Delta H^\circ_{298}(23) = -15.0 \pm 0.4$ kcal mol^{-1} for the reaction

$$CH_3I(liq.) + \tfrac{1}{2}H_2(gas) \rightarrow CH_4(gas) + \tfrac{1}{2}I_2(cryst.), \tag{23}$$

whence it follows that $\Delta H^\circ_f(CH_3I$, liq.) = −2.85 ± 0.4 kcal mol^{-1}; these are apparently the most accurate measurements for liquid iodomethane.

The most accurate studies on gaseous iodomethane were those of Goy and Pritchard[39] and Golden et al.[40]. They dealt with the equilibrium in the reacton

$$CH_4(gas) + I_2(gas) \rightleftharpoons CH_3I(gas) + HI(gas), \tag{24}$$

and led to $\Delta H^\circ_{298}(24) = 12.61 \pm 0.04$ kcal mol^{-1} [40] and 12.63 ± 0.03 kcal mol^{-1}.[39] These values correspond to $\Delta H^\circ_f(CH_3I$, gas) = 3.38 ± 0.21 kcal mol^{-1} [40] and 3.40 ± 0.21 kcal mol^{-1},[39] which agree very well, but those of Goy and Pritchard[39] are somewhat superior, since the latter investigated a wider temperature range, the reproducibility of the values of K_p was more satisfactory, and the enthalpies ΔH° calculated on the basis of the Second and Third Laws of Thermodynamics agree better. Taking into account the enthalpy of evaporation $\Delta H^\circ_{V298}(CH_3I$, liq.) = 6.6 ± 0.3 kcal mol^{-1}, we obtain $\Delta H^\circ_f(CH_3I$, liq.) = −3.16 ± 0.37 kcal mol^{-1}, in satisfactory agreement with the results of Carson et al.[34] Bearing in mind the difficulty of accurate thermochemical measurements using lithium tetrahydroaluminate, preference must be given to the value of $\Delta H^\circ_f(CH_3I$, liq.), calculated from Goy and Pritchard's data[39] and ΔH°_V.

Di-iodomethane

Berthelot[91] measured ΔH° for the combustion of di-iodomethane and on the basis of his results Glushko[4] obtained $\Delta H^\circ_f(CH_2I_2$, gas) = 28.5 kcal mol^{-1}. More reliable data were obtained by Furuyama et al.[44], who investigated the equilibrium in the reaction

$$2CH_3I \rightleftarrows CH_4 + CH_2I_2 \tag{25}$$

and obtained $\Delta H^\circ_{298}(25) = 4.24 \pm 0.63$ kcal mol^{-1}. This result leads to $\Delta H^\circ_f(CH_2I_2$, gas) = 28.9 ± 0.7 kcal mol^{-1}.

Trifluoroiodomethane

It follows from $\Delta H^\circ_{298}(10)$ that $\Delta H^\circ_f(CF_3I, \text{gas}) = -140.8 \pm 0.7$ kcal mol^{-1}.

V. METHODS FOR THE APPROXIMATE ESTIMATION OF THE ENTHALPIES OF FORMATION OF HALOGENOMETHANES

A whole series of methods have been proposed for the estimation of the enthalpies of formation of organic compounds; a fairly complete bibliography is given in Refs. 96–101. Most of the methods are based on the representation of the energy of formation of the molecule by the sum of the contributions due to its structural elements.

One of the simplest and most widely used additive computational schemes is based on the hypothesis that the average thermochemical bond energies are constant[5,10]. When this procedure is applied to a series of halogenomethanes of the type $CX_{4-n}Y_n$, where X and Y are hydrogen or a halogen, a linear relation between ΔH°_f and n is postulated. Generally speaking, bond energies can vary markedly, particularly in those cases where there is a sharp alteration in the environment of the bond. For this reason, the method of average bond energies as a rule makes it possible to estimate the required quantities only to a rough approximation. This is seen also in relation to certain series of the type $CX_{4-n}Y_n$; thus the experimental enthalpies of formation of compounds of the $CH_{4-n}F_n$ or $CH_{4-n}I_n$ series can be in no way represented by a linear function of n. However, the method of average bond energies may yield entirely satisfactory results when it is used for comparatively small groups of substances of a similar type or for series where the dependence of the bond energies on their environment is believed to be small.

The method proposed by Kharasch[107] also leads to a linear relation between ΔH°_f and n in series of the type $CX_{4-n}Y_n$.[10]

Among the methods where account is taken of the bond environment, only Bernstein's method[9,102], in which account is taken of the interaction of all the atoms, both linked directly and not linked at all, may be widely applied to halogenomethanes. Allowance for pair interactions only leads to a quadratic relation between $\Delta H^\circ_f(CX_{4-n}Y_n)$ and n.[102] On the other hand, the introduction of triple as well as pair interactions leads to a cubic relation[9]. Thus, in order to calculate the enthalpies of formation of compounds in the $CX_{4-n}Y_n$ series, it is necessary to know three[102] or four[9] constants, i.e. to know three or four quantities of the five to be determined.

Other computational schemes taking into account the interactions of bonds or atoms cannot be used owing to the insufficiency of experimental data. Some of these, for example Allen's scheme[98], are used in a few instances to establish relations between the enthalpies of formation of related compounds[103].

Apart from additive schemes, other approximate methods are frequently used, for example, the methods of comparative calculation developed by Karapet'yants[97]. Here it is most convenient to employ the equation

$$F_{II} = AF_I + B, \tag{26}$$

which establishes the relation between the numerical values of the parameter F (for example, ΔH°_f) in two similar series of compounds (I) and (II). The methods of comparative calculation usually yield satisfactory results[97]; in the case of halogenomethanes the greatest difficulty is associated with the selection of the appropriate reference series. Where it is necessary to take into account the structural analogy of the series, the chemical similarity of the fragments by which they differ, and the observed thermochemical regularities (the increase of the C–F bond energy as H is substituted by F,[1,2] the decrease of the C–I bond energy in the analogous substitution, etc.), i.e. series (I) and (II), resembling one another as regards the dependence of ΔH°_f on composition, must be selected.

Estimates of the enthalpies of formation of halogenomethanes by approximate methods are given below. In those cases where the amount of experimental data was sufficient, an additive scheme taking into account the bond environment was used (Bernstein's method[9,102]; Allen's scheme[98,103]). In other cases the ΔH°_f were estimated by methods of comparative calculation[97] using variable reference series, and the method of average bond energies was used for individual small groups of substances.

VI. ESTIMATION OF THE ENTHALPIES OF FORMATION OF HALOGENOMETHANES

Fluoromethanes

No calorimetric determinations have been made for this substance. The accuracy of the mass-spectrometric determinations of $\Delta H^\circ_f(CH_3F, \text{gas})$ in terms of the appearance potential of the CH_3^+ ion or the ionisation potential of the CH_3 radical[104,105] is very low; the results vary from −59 to −79 kcal mol^{-1}.[3]

A more reliable result may be obtained by calculation. Since reliable values of ΔH°_f are available for all the compounds of the $CH_{4-n}F_n$ series except CH_3F, the relevant quantity may be calculated using comparatively accurate computational methods: Allen's scheme[98] and Bernstein's cubic equation[9].

Application of Allen's scheme leads to the relation[103]

$$\Delta H^0_f(CH_3F) = 1/4\,[\Delta H^0_f(CH_4) + \Delta H^0_f(CF_4)] + 3/2\Delta H^0_f(CH_2F_2) - \Delta H^0_f(CHF_3),$$

which yields $\Delta H^\circ_f(CH_3F, \text{gas}) = -55.6$ kcal mol^{-1}. Bernstein's cubic equation gives the same result.

The $CH_{4-n}Br_n$ Series

Reliable values of ΔH°_f are available for CH_4 and CH_3Br in this series. Kaboukov and Perel'man[75] determined ΔH° for the combustion of liquid $CHBr_3$, but their results are very unreliable owing to the incomplete reduction of free bromine, poor reproducibility of the experimental data, and insufficient purity of the specimen.

The difference between the enthalpies of formation of gaseous $CHBr_3$ and CBr_4 may ve calculated from the results of the study of the equilibrium

$$Br_2 + CHBr_3 \rightleftarrows CBr_4 + HBr\ . \tag{27}$$

Strong and Pease[106] obtained $\Delta H^\circ_{298}(27) = -1.0$ kcal mol^{-1} for reaction (27). More accurate measurements[45] lead to $\Delta H^\circ_{298}(27) = -1.66 \pm 0.09$ kcal mol^{-1}. $\Delta H^\circ_f(CBr_4, \text{gas}) - \Delta H^\circ_f(CHBr_3, \text{gas}) = 14.42 \pm 0.10$ kcal mol^{-1} follows from these data.

The available set of data makes it possible to apply Bernstein's quadratic equation, which takes into account the pair interactions between atoms[102], to the calculation of ΔH°_f in the $CH_{4-n}Br_n$ series. The calculation leads to the following values: $\Delta H_f^\circ(CH_2Br_2, \text{gas}) = 1.77$ kcal mol^{-1}, $\Delta H_f^\circ(CHBr_3, \text{gas}) = 14.33$ kcal mol^{-1}, and $\Delta H_f^\circ(CBr_4, \text{gas}) = 28.73$ kcal mol^{-1}. These results are larger than the values adopted in the literature[3,4], because the latter estimates were based on the average bond energies without taking into account the interaction of non-bonded atoms.

The $CH_{4-n}I_n$ Series

The experimental values of ΔH_f° for CH_4, CH_3I, and CH_2I_2 are quoted above. The enthalpy of combustion of crystalline iodoform was determined by Berthelot in 1900[91]; these data were adopted as the basis for the calculation of $\Delta H_f^\circ(CHI_3)$ in a number of compilations[3,4,6,7]. When account is taken of the enthalpies of sublimation, they lead to a value of $\Delta H_f^\circ(CHI_3, \text{gas})$ between 50.3 and 51 kcal mol^{-1}. However, this value appears to be too low: if it is adopted, it is found that the enthalpy of formation varies non-systematically in the $CH_{4-n}I_n$ series and, on passing from CH_2I_2 to CHI_3, the second difference between the ΔH_f° changes sign.

Calculation by Bernstein's quadratic equation[102] using the CH_4, CH_3I, and CH_2I_2 data leads to a significantly different result: $\Delta H_f^\circ(CHI_3, \text{gas}) = 58.7$ kcal mol^{-1}. Analogous calculation for CI_4 yields $\Delta H_f^\circ(CI_4, \text{gas}) = 92.7$ kcal mol^{-1}. The values of $\Delta H_f^\circ(CI_4, \text{gas})$ estimated[3,4] from the average bond energies are approximately 20 kcal mol^{-1} lower. However, comparison of the ΔH_f° data adopted above for CH_4, CH_3I, and CH_2I_2 shows clearly that the dependence of ΔH_f° on n in the $CH_{4-n}I_n$ series is non-linear; for this reason, calculation based on the average bond energies is unjustified in this instance[44].

The $CBr_{4-n}F_n$ Series

Three values of ΔH_f° are known in this series; for CF_4, CF_3Br, and CBr_4 (see above). This makes it possible to use Bernstein's equation[102] for the calculation of the enthalpies of formation of the remaining two compounds. The calculation yields

$$\Delta H_f^\circ(CF_2Br_2, \text{gas}) = -90.9 \text{ kcal mol}^{-1};$$
$$\Delta H_f^\circ(CFBr_3, \text{gas}) = -29.5 \text{ kcal mol}^{-1}.$$

The $CI_{4-n}F_n$ Series

Three values of ΔH_f° are also known in this series: for CF_4, CF_3I, and CI_4. Calculation by Bernstein's equation[102] leads to

$$\Delta H_f^\circ(CF_2I_2, \text{gas}) = -60.8 \text{ kcal mol}^{-1};$$
$$\Delta H_f^\circ(CFI_3, \text{gas}) = 17.0 \text{ kcal mol}^{-1}.$$

The $CBr_{4-n}Cl_n$ Series

Three values of ΔH_f° are known in the CCl_4–CBr series: for CCl_4, CCl_3Br, and CBr_4 (see above). Calculation by Bernstein's equation[102] leads to

$$\Delta H_f^\circ(CCl_2Br_2, \text{gas}) = 2.5 \text{ kcal mol}^{-1};$$
$$\Delta H_f^\circ(CClBr_3, \text{gas}) = 15.5 \text{ kcal mol}^{-1}.$$

The $CCl_{4-n}I_n$ Series

Since only two values of ΔH_f° are known in this series (for CCl_4 and CI_4), it is impossible to estimate the missing quantities by Bernstein's method. They can be estimated from the average bond energies or by the method of comparative calculation[97]. Calculation based on average bond energies yields

$$\Delta H_f^\circ(CCl_3I, \text{gas}) = 6.0 \text{ kcal mol}^{-1};$$
$$\Delta H_f^\circ(CCl_2I_2, \text{gas}) = 34.9 \text{ kcal mol}^{-1};$$
$$\Delta H_f^\circ(CClI_3, \text{gas}) = 63.8 \text{ kcal mol}^{-1}.$$

When the method of comparative calculation is used, it is possible, in principle, to select as a reference any of the eight series of the type $CX_{4-n}Y_n$ examined above; the numerical data obtained for three compounds of the $CCl_{4-n}I_n$ series vary appreciably under these conditions (in the range from 6 to 9 kcal mol^{-1}). The $CH_{4-n}I_n$ and $CH_{4-n}Br_n$ series are probably closest to the $CCl_{4-n}I_n$ series as regards their thermochemical properties. This can be justified as follows: (1) the replacement of an H atom by Cl entails a very small thermochemical effect—thus the first differences between the ΔH_f° in the $CH_{4-n}Cl_n$ series is only approximately 2 kcal mol^{-1}; (2) the non-linear dependence of ΔH_f° on n in the $CH_{4-n}I_n$ and $CH_{4-n}Br_n$ series is probably due to some destabilisation of the compound as the I or Br atoms accumulate (for example, owing to steric hindrance). Presumably this effect also persists in the $CCl_{4-n}I_n$ series. The method of comparative calculation using the $CH_{4-n}I_n$ and $CH_{4-n}Br_n$ series yields very similar results. Data obtained with the aid of the $CH_{4-n}I_n$ reference series are listed below:

$$\Delta H_f^\circ(CCl_3I, \text{gas}) = -0.6 \text{ kcal mol}^{-1};$$
$$\Delta H_f^\circ(CCl_2I_2, \text{gas}) = 26.0 \text{ kcal mol}^{-1};$$
$$\Delta H_f^\circ(CClI_3, \text{gas}) = 57.1 \text{ kcal mol}^{-1}.$$

If a reference series is chosen in which the dependence of ΔH_f° on n is close to linearity, for example $CCl_{4-n}Br_n$, then the result naturally agrees with that calculated from the average bond energies. Since by virtue of the causes mentioned above there are no grounds for the hypothesis that there is a linear relation for the $CCl_{4-n}I_n$ series, preference must be given to the calculation by the comparative method based on the $CH_{4-n}I_n$ series.

The $CBr_{4-n}I_n$ Series

In this series too only two values of ΔH_f° were selected: for CBr_4 and CI_4. The difference between the ΔH_f° for CBr_4 and CI_4 is much smaller than in the case of CCl_4 and CI_4. The choice of a reference series for the calculation of ΔH_f° in the $CBr_{4-n}I_n$ series is therefore less important than in the $CCl_{4-n}I_n$ series. The values of ΔH_f° for the three missing compounds, calculated from the average bond energies and by the comparative method (four reference series), vary in the range of 4 to 5 kcal mol^{-1}. In view of the similarity of the properties of Br and I atoms, the dependence of ΔH_f° on n in the $CBr_{4-n}I_n$ series should presumably be closer to linearity than in the $CH_{4-n}I_n$ and $CH_{4-n}Br_n$ series. The best of the calculated values should therefore lie in the range between those obtained by the Karapet'yants method[97], based on series with a distinct quadratic relation, and those found from the average bond energies. It is useful to employ a reference series in which the quadratic relation is weak, for example $CBr_{4-n}F_n$. Then the method of comparative calculation yields the following data:

$$\Delta H_f^\circ(CBr_3I, gas) = 43.5 \text{ kcal mol}^{-};$$
$$\Delta H_f^\circ(CBr_2I_2, gas) = 59.1 \text{ kcal mol}^{-1};$$
$$\Delta H_f^\circ(CBrI_3, gas) = 75.5 \text{ kcal mol}^{-1}.$$

Chlorofluoromethane, Chlorodifluoromethane, and Dichlorofluoromethane

Among these compounds, experimental data are available only for CHF_2Cl. Edwards and Small[108] investigated the equilibrium

$$2CHF_2Cl \rightleftarrows C_2F_4 + 2HCl \qquad (28)$$

by measuring the pressures of the components at 600°C. They noted the formation of side products and obtained K_p by extrapolation. It follows from their data that $\Delta H_{298}^\circ(28) =$ 28.75 kcal mol^{-1} [11] and $\Delta H_f^\circ(CHF_2Cl, gas) = -115.5$ kcal mol^{-1}. A more reliable value of ΔH_f° may be obtained by the method of comparative calculation based on the $CF_2H_{2-n}Cl_n$ and $CF_{4-n}Cl_n$ (reference) series, where $0 \leqslant n \leqslant 2$:

$$\Delta H_f^\circ(CHF_2Cl, gas) = -111.6 \text{ kcal mol}^{-1}.$$

The compounds CH_2FCl and $CHFCl_2$ may be regarded as members of the $CFH_{3-n}Cl_n$ series, where the enthalpies of formation of the extreme members are known. Calculation by the comparative method using the $CH_{4-n}Cl_n$ reference series (where $0 \leqslant n \leqslant 3$) yields the following results:

$$\Delta H_f^\circ(CH_2FCl, gas) = -58.8 \text{ kcal mol}^{-1};$$
$$\Delta H_f^\circ(CHFCl_2, gas) = -64.7 \text{ kcal mol}^{-1}.$$

In both series considered, $CF_2H_{2-n}Cl_n$ and $CFH_{3-n}Cl_n$, the difference between the values of ΔH_f° for the extreme members of the series is very small, so that the result of the calculation by the comparative method is relatively insensitive to the selection of the reference series. Similar results are also obtained if the constancy of the bond energies in the given series is assumed.

Bromofluoromethane, Bromodifluoromethane, and Dibromofluoromethane

The compounds CH_2BrF and $CHBr_2F$ may be regarded as members of the $CFH_{3-n}Br_n$ series in which the values of ΔH_f° for CFH_3 and $CFBr_3$ are known. Calculation by the comparative method using the $CH_{4-n}Br_n$ reference series (where $0 \leqslant n \leqslant 3$) yields

$$\Delta H_f^\circ(CH_2FBr, gas) = -48.4 \text{ kcal mol}^{-1};$$
$$\Delta H_f^\circ(CHFBr_2, gas) = -39.7 \text{ kcal mol}^{-1}.$$

The value of $\Delta H_f^\circ(CHF_2Br, gas)$ may be obtained by the method of comparative calculation based on the $CF_2H_{2-n}Br_n$ and $CBr_{2-n}F_{2+n}$ (reference) series:

$$\Delta H_f^\circ(CHF_2Br, gas) = -99.7 \text{ kcal mol}^{-1}.$$

Fluoroiodomethane, Difluoroiodomethane, and Fluorodiiodomethane

The choice of the reference series in the calculation of ΔH_f° for the above three substances by the comparative method is particularly important, because the enthalpies of formation of fluoroiodomethanes vary very markedly with composition. Presumably the dependence of ΔH_f° on n for series of the type $CF_{4-m-n}I_nH_m$ with constant m should be close to the variation of these quantities in the $CF_{4-n}I_n$ series. The compounds CHF_2I and $CHFI_2$ may be regarded as members of the $CHF_{3-n}I_n$ series in which the values of ΔH_f° for CHF_3 and CHI_3 are known. Calculation by the comparative method using the $CF_{4-n}I_n$ reference series (where $0 \leqslant n \leqslant 3$) yields

$$\Delta H_f^\circ(CHF_2I, gas) = -89.5 \text{ kcal mol}^{-1};$$
$$\Delta H_f^\circ(CHFI_2, gas) = -14.4 \text{ kcal mol}^{-1}.$$

The value of $\Delta H_f^\circ(CH_2FI, gas)$ may be obtained by the method of comparative calculation involving comparison of the $CH_2F_{2-n}I_n$ and $CF_{4-n}I_n$ (reference) series, where $0 \leqslant n \leqslant 2$:

$$\Delta H_f^\circ(CH_2FI, gas) = -38.7 \text{ kcal mol}^{-1}.$$

Bromochloromethane, Dibromochloromethane, and Bromodichloromethane

By considering the $CBrH_{3-n}Cl_n$ series, in which the values of ΔH_f° for CH_3Br and CCl_3Br are known, and the $CH_{3-n}Cl_{1+n}$ reference series, we obtain

$$\Delta H_f^\circ(CH_2ClBr, gas) = -10.2 \text{ kcal mol}^{-1};$$
$$\Delta H_f^\circ(CHCl_2Br, gas) = -11.0 \text{ kcal mol}^{-1}.$$

The values of ΔH_f° for CH_2Br_2 and CCl_2Br_2 in the $CBr_2H_{2-n}Cl_n$ series are known. Using the $CBr_{4-n}Cl_n$ reference series, where $0 \leqslant n \leqslant 2$, we find

$$\Delta H_f^\circ(CHClBr_2, gas) = 2.1 \text{ kcal mol}^{-1}.$$

We may note that the replacement of H by Cl in the $CBr.H_{3-n}Cl_n$ and $CBr_2H_{2-n}Cl_n$ series entails a very slight change in the values of ΔH_f°. Within the limits of these series, it is possible to use successfully the method of average bond energies; the values of ΔH_f° calculated by this method are very close to those quoted above.

Chloroiodomethane, Dichloroiodomethane, and Chlorodiiodomethane

By considering the $CClH_{3-n}I_n$ series, in which the values of ΔH_f° for CH_3Cl and CI_3Cl are known, and the $CH_{4-n}I_n$ reference series, where $0 \leqslant n \leqslant 3$, we obtain

$$\Delta H_f^\circ(CH_2ClI, gas) = 1.7 \text{ kcal mol}^{-1};$$
$$\Delta H_f^\circ(CHClI_2, gas) = 27.2 \text{ kcal mol}^{-1}.$$

The quantity $\Delta H_f^\circ(CHCl_2I, gas)$ can be readily obtained by considering the $CCl_2H_{2-n}I_n$ series, in which the values of ΔH_f° for CH_2Cl_2 and CI_2Cl_2 are known. Using the $CH_{4-n}I_n$ reference series, where $0 \leqslant n \leqslant 2$, we find

$$\Delta H_f^\circ(CHCl_2I, gas) = -0.6 \text{ kcal mol}^{-1}.$$

In the case under consideration the difference between the enthalpies of formation of the corresponding compounds in the test and reference series is comparatively small (only 2–4 kcal mol^{-1}), which ensures a fairly accurate estimate of ΔH_f° by the comparative method.

Bromoiodomethane, Bromodi-iodomethane, and Dibromoiodomethane

The values of ΔH_f° for $\mathrm{CH_3I}$ and $\mathrm{CBr_3I}$ are known in the $\mathrm{ClH_{3-n}Br_n}$ series. Using the $\mathrm{CH_{3-n}Br_{1+n}}$ reference series, we obtain the following values for $\mathrm{CH_2BrI}$ and $\mathrm{CHBr_2I}$:

$$\Delta H_f^\circ(\mathrm{CH_2BrI, gas}) = 14.8\ \mathrm{kcal\ mol^{-1}};$$
$$\Delta H_f^\circ(\mathrm{CHBr_2I, gas}) = 28.2\ \mathrm{kcal\ mol^{-1}}.$$

The value of $\Delta H_f^\circ(\mathrm{CHBrI_2}$, gas) may be obtained by comparing the $\mathrm{CI_2H_{2-n}Br_n}$ series with the $\mathrm{CH_{2-n}Br_{2+n}}$ reference series:

$$\Delta H_f^\circ(\mathrm{CHBrI_2, gas}) = 43.0\ \mathrm{kcal\ mol^{-1}}.$$

The selection of the reference series for the estimation of the ΔH_f° for the three compounds considered is determined by the similarity of the properties of the Br and I atoms. The latter is manifested particularly in the similarity of the dependence of ΔH_f° on n in the $\mathrm{CH_{4-n}I_n}$ and $\mathrm{CH_{4-n}Br_n}$ series.

Bromochlorodifluoromethane, Bromodichlorofluoromethane, and Dibromochlorofluoromethane

The enthalpies of formation of $\mathrm{CFCl_2Br}$ and $\mathrm{CFClBr_2}$ may be calculated by considering the $\mathrm{CFCl_{3-n}Br_n}$ and $\mathrm{CCl_{4-n}Br_n}$ (reference) series, where $0 \leqslant n \leqslant 3$:

$$\Delta H_f^\circ(\mathrm{CFCl_2Br, gas}) = -55.0\ \mathrm{kcal\ mol^{-1}};$$
$$\Delta H_f^\circ(\mathrm{CFClBr_2, gas}) = -42.4\ \mathrm{kcal\ mol^{-1}}.$$

The value of $\Delta H_f^\circ(\mathrm{CF_2ClBr}$, gas) can be obtained by comparing the $\mathrm{CF_2Cl_{2-n}Br_n}$ series with the $\mathrm{CCl_{4-n}Br_n}$ reference series, where $0 \leqslant n \leqslant 3$:

$$\Delta H_f^\circ(\mathrm{CF_2ClBr, gas}) = -103.1\ \mathrm{kcal\ mol^{-1}}.$$

Similar values of ΔH_f° are obtained, for example, also by considering the $\mathrm{CClF_{3-n}Br_n}$ and $\mathrm{CF_3Br_{1+n}}$ (reference) series or the $\mathrm{CBrF_{3-n}Cl_n}$ and $\mathrm{CF_{4-n}Cl_n}$ (reference) series for $0 \leqslant n \leqslant 3$.

Bromodifluoroiodomethane, Dibromofluoroiodomethane, and Bromofluorodi-iodomethane

By comparing the $\mathrm{ClF_{3-n}Br_n}$ series, in which the values of ΔH_f° for $\mathrm{CF_3I}$ and $\mathrm{CBr_3I}$ are known, with the $\mathrm{CF_{3-n}Br_{1+n}}$ reference series, we obtain:

$$\Delta H_f^\circ(\mathrm{CF_2BrI, gas}) = -76.3\ \mathrm{kcal\ mol^{-1}};$$
$$\Delta H_f^\circ(\mathrm{CFBr_2I, gas}) = -14.8\ \mathrm{kcal\ mol^{-1}}.$$

The value of $\Delta H_f^\circ(\mathrm{CFBrI_2}$, gas) can be obtained by considering the $\mathrm{CI_2F_{2-n}Br_n}$ and $\mathrm{CF_{2-n}BR_{2+n}}$ (reference) series:

$$\Delta H_f^\circ(\mathrm{CFBrI_2, gas}) = 0.7\ \mathrm{kcal\ mol^{-1}}.$$

Similar values of ΔH_f° are obtained also, for example, by comparing the $\mathrm{CBrF_{3-n}I_n}$ and $\mathrm{CF_{3-n}I_{1+n}}$ (reference) series or the $\mathrm{CFBr_{3-n}I_n}$ and $\mathrm{CBr_{4-n}I_n}$ (reference) series, where $0 \leqslant n \leqslant 3$.

Chlorodifluoroiodomethane, Dichlorofluoroiodomethane, and Chlorofluorodi-iodomethane

The values of ΔH_f° for $\mathrm{CF_2ClI}$ and $\mathrm{CFClI_2}$ can be found by considering the $\mathrm{CClF_{3-n}I_n}$ and $\mathrm{CF_{4-n}I_n}$ (reference) series, where $0 \leqslant n \leqslant 3$:

$$\Delta H_f^\circ(\mathrm{CF_2ClI, gas}) = -91.7\ \mathrm{kcal\ mol^{-1}};$$
$$\Delta H_f^\circ(\mathrm{CFlI_2, gas}) = -16.3\ \mathrm{kcal\ mol^{-1}}.$$

Comparison of the $\mathrm{CCl_2F_{2-n}I_n}$ and $\mathrm{CCl_{2+n}F_{2+n}}$ series yields

$$\Delta H_f^\circ(\mathrm{CFCl_2I, gas}) = -42.3\ \mathrm{kcal\ mol^{-1}}.$$

Similar values of ΔH_f° are obtained by comparing other similar series, for example, the $\mathrm{ClF_{3-n}Cl_n}$ and $\mathrm{CF_{4-n}Cl_n}$ (reference) series or the $\mathrm{CFCl_{3-n}I_n}$ and $\mathrm{CCl_{4-n}I_n}$ (reference) series, where $0 \leqslant n \leqslant 3$.

Bromodichloroiodomethane, Dibromochloroiodomethane, and Bromochlorodi-iodomethane

The values of ΔH_f° for $\mathrm{CCl_2BrI}$ and $\mathrm{CClBr_2I}$ are obtained by comparing the $\mathrm{ClCl_{3-n}Br_n}$ and $\mathrm{CCl_{3-n}Br_{1+n}}$ (reference series):

$$\Delta H_f^\circ(\mathrm{CCl_2BrI, gas}) = 13.8\ \mathrm{kcal\ mol^{-1}};$$
$$\Delta H_f^\circ(\mathrm{CClBr_2I, gas}) = 28.5\ \mathrm{kcal\ mol^{-1}}.$$

By comparing the $\mathrm{CI_2Cl_{2-n}Br_n}$ and $\mathrm{CCl_{2-n}Br_{2+n}}$ (reference) series, we find

$$\Delta H_f^\circ(\mathrm{CClBrI_2, gas}) = 42.4\ \mathrm{kcal\ mol^{-1}}.$$

Similar values of ΔH_f° are also obtained by comparing the $\mathrm{ClCl_{3-n}Br_n}$ and $\mathrm{CCl_{4-n}Br_n}$ (reference) series, where $0 \leqslant n \leqslant 3$, or the $\mathrm{CI_2Cl_{2-n}Br_n}$ and $\mathrm{CI_{2+n}Cl_{2-n}}$ (reference) series, where $0 \leqslant n \leqslant 2$.

Bromochlorofluoromethanes

By considering the $\mathrm{CFClH_{2-n}Br_n}$ and $\mathrm{CH_{4-n}Br_n}$ (reference) series, where $0 \leqslant n \leqslant 2$, we find

$$\Delta H_f^\circ(\mathrm{CHFClBr, gas}) = -51.4\ \mathrm{kcal\ mol^{-1}}.$$

A similar value of ΔH_f° (CHFClBr, gas) is obtained by applying the method of average bond energies to the $\mathrm{CFBrH_{2-n}Cl_n}$ series, in which the replacement of H by Cl entails a comparatively small alteration of the enthalpies of formation.

Chlorofluoroiodomethane

Application of the method of comparative calculation to the $\mathrm{CFIH_{2-n}Cl_n}$ and $\mathrm{CH_{4-n}Cl_n}$ (reference) series, where $0 \leqslant n \leqslant 2$, yields

$$\Delta H_f^\circ(\mathrm{CHFClI, gas}) = -40.0\ \mathrm{kcal\ mol^{-1}}.$$

The replacement of an H atom by Cl in the $\mathrm{CFIH_{2-n}Cl_n}$ series entails a comparatively small change in ΔH_f°, so that the result of the calculation of ΔH_f°(CHFClI, gas) depends little on the choice of the reference series. Application of the method of average bond energies to the $\mathrm{CFIH_{2-n}Cl_n}$ series also yields a similar value.

Bromofluoroiodomethane

By considering the $CFIH_{2-n}Br_n$ and $CH_{4-n}Br_n$ (reference) series, where $0 \leqslant n \leqslant 2$, we obtain

$$\Delta H_f^\circ(\mathrm{CHFBrI, gas}) = -27.8\ \mathrm{kcal\ mol^{-1}}.$$

Similar values are obtained using the $ClH_{3-n}Br_n$ or $CFH_{3-n}Br_n$ (for $0 \leqslant n \leqslant 2$) reference series.

Bromochloroiodomethane

The variation of ΔH_f° in the $CBrIH_{2-n}Cl_n$ series is very slight: $\Delta H_f^\circ(CH_2BrI, gas) = 14.8$ kcal mol^{-1} and $\Delta H_f^\circ(CCl_2.BrI, gas) = 13.8$ kcal mol^{-1}. Using the $CBr_2H_{2-n}Cl_n$ reference series, we obtain the following value for the middle member of the series:

$$\Delta H_f^\circ(\mathrm{CHClBrI, gas}) = 14.3\ \mathrm{kcal\ mol^{-1}}.$$

The use of other reference series as well as the method of average bond energies leads to very similar results.

Bromochlorofluoroiodomethane

Comparison of the $CClBrI_{2-n}F_n$ and $CHBrI_{2-n}F_n$ (reference) series leads to the following value:

$$\Delta H_f^\circ(\mathrm{CFClBrI, gas}) = -29.8\ \mathrm{kcal\ mol^{-1}}.$$

In this case the differences between the ΔH_f° for the corresponding members of two similar series are very slight, which improves the reliability of the estimate of ΔH_f° by the comparative method. Similar results are also obtained when other series are used, for example, $CBr.ICl_{2-n}F_n$ and $CI_2Cl_{2-n}F_n$ (reference) series.

VII. CONCLUSION

The recommended enthalpies of formation of all 70 halogenomethanes are listed in the Table. The error of the values chosen as the most reliable experimental data is expressed in terms of 95% confidence intervals (in addition, account was taken of the errors of the determination of all the auxiliary quantities). The only exceptions are CF_2Cl_2 and $CFCl_3$, for which the errors were estimated using the entire set of experimental data obtained and the estimate has no rigorous statistical basis owing to the inadequacy of the experimental methods employed.

The errors of the quantities found by methods of approximate estimation are not quoted in the Table. For the majority of the compounds, they probably do not exceed 3-5 kcal mol^{-1}, which may be supported by the following arguments:

1. The estimates were made by different methods and the discrepancies between the results were comparatively small, as stated above.
2. For certain series of experimental data it was found sufficient to employ additive schemes taking into account the environment of the atoms (Allen's[98] and Bernstein's[9,102] schemes).
3. In calculations by the comparative method, both the test and reference series were varied widely. For each quantity estimated, apart from that quoted in the text, a further 6-8 versions of the calculation were performed; when the series compared were sufficiently "similar", the results differed insignificantly.
4. The calculations by the method of average bond energies were performed only for narrow groups of compounds—mainly in series comprising three members and with a not unduly great variation of the enthalpy of formation. Under such conditions, even estimates carried out by this comparatively rough method could not lead to major errors.

Enthalpies of formation of halogenomethanes.

Compound	$\Delta H^0_{f;\,298,\,15}$ (gas)		Compound	$\Delta H^0_{f;\,298,\,15}$ (gas)

CBr_3I	43.5	182.0	$CFClBrI$	−29,8	−124.7
CBr_2I_2	59.1	247.3			

However, in certain instances the error of the estimated ΔH_f° may be much greater. This applies particularly to carbon tetraiodide whose enthalpy of formation was obtained by the extrapolation of the experimental data available for the first three numbers of the $CH_{4-n}I_n$ series. Owing to the accumulation of errors, the error in the estimated $\Delta H_f^\circ(CI_4$, gas) may be 10-12 kcal mol^{-1}. For the same reasons, the error in the calculated value of $\Delta H_f^\circ(CBr_4$, gas) may reach 5-6 kcal mol^{-1}. The foregoing applies to a lesser extent to all the tri-iodo- and tribromo-substituted methanes whose enthalpies of formation were estimated.

Although experimental data are available only for a comparatively small number of halogenomethanes and the reliability of the estimated values is limited, nevertheless certain thermochemical regularities are evident for this type of compound. In the first place there is no doubt that in the general case the dependence of the enthalpy of formation of n in series of the type $CX_{4-n}Y_n$ is not linear. For the $CH_{4-n}F_n$ series, an increase of n entails a faster increase of this function compared with the increase that would be expected on the basis of a linear equation. Within the framework of the model of atom—atom interactions, this implies that the bond energies are not constant in the $CH_{4-n}F_n$ series. The additional stabilisation of the molecules arising when the H atoms are replaced successively by F may be associated, for example, with the interaction of fluorine atoms which are not bonded directly[9,102]. Stabilisation as fluorine atoms accumulate is also observed in the $CF_{4-n}Cl_n$, $CF_{4-n}Br$, and $CF_{4-n}I_n$ series, but it is less marked.

In the $CH_{4-n}Cl_n$ series trichloromethane has the maximum absolute enthalpy of formation. Thus in this instance the experimental data cannot be described correctly by any of the proposed computational schemes. Since the experimental enthalpies of formation of all the five compounds in this series are fairly reliable, presumably the computational schemes[9,98,102] take into account inadequately the interaction of the non-bonded atoms. We may note that a similar behaviour is observed also in other organic chloro-compounds, for example, among the chloroethanes investigated the absolute enthalpy is a maximum for 1,1,2,2-tetrachloroethane[4]. It appears that, as the chlorine atoms accumulate at a single carbon atom, the energy of the interaction of the non-bonded atoms does not remain constant; as a result, the slight stabilisation of the chloromethanes which are the first members of the $CH_{4-n}Cl_n$ series is replaced by destabilisation after complete chlorination.

In certain studies it was concluded previously that in the series of halogenomethanes the enthalpy of formation varies linearly with composition[109,110]. This conclusion is a natural consequence of the unsuccessful selection of reference quantities. Papulov and coworkers[109,110] used the most reliable experimental determinations and the data from Glushko's handbook[3] as such quantities; computational methods based on a linear relation were used widely to obtain data of this kind[10].

Analysis of the data obtained by Stull et al.[6] leads to the conclusion that they are frequently mutually contradictory. As an example, it is sufficient to quote the following series[6]:

	CH_2F_2	$CHClF_2$	CCl_2F_2
ΔH_f°, kcal mol	—108.24	— 119.9	—115.0

The contradictory nature of certain numerical data in the above book[6] is due to the fact that the authors used without recalculation a fairly large number of ΔH_f° values obtained by Maslov[111]. The value of $\Delta H_f^\circ(CHClF_2$, gas), which deviates strongly in the above series, was also taken from Maslov's work[111]. Maslov and Maslov[111] estimated ΔH_f° solely on the basis of a simple additive scheme in which the bond energies in all halogenomethanes were assumed to be constant and equal to the bond energies in the tetrahalogeno-derivatives. The choice of reference data in their study[111] is now obsolete and differs strongly from that in the book by Stull et al.[6]

In order to refine further the thermochemical properties of halogenomethanes, it is necessary to increase the number of reliable ΔH_f° reference data. On the one hand, this would make it possible to revise the estimates of ΔH_f° based on the existing computational schemes and, on the other, one could investigate in greater detail the dependence of ΔH_f° for halogenomethanes on composition and the real possibilities of the computational schemes.

The Interaction of Hydrogen Atoms with Solid Organic Substances

A.M.Dubinskaya

The mechanisms and kinetics of reactions occurring when solid organic compounds of different structures (low-molecular- and high-molecular-weight substances) are acted upon by "thermal" hydrogen atoms are examined. Models and kinetic schemes proposed for the description of the interaction of solid organic substances with gaseous atomic hydrogen are analysed. The majority of the results summarised in the review refer to the path and rate of the primary chemical step in the interaction. Particular attention has been devoted to reactions of the type $H + RH \rightarrow H_2 + R$, the kinetic constants of which have been measured only in recent years. These data are treated on the basis of the hypothesis of a tunnel mechanism for the transfer of a hydrogen atom at a low temperature. The review also deals with the results of studies of the low-temperature reactions of free radicals with hydrogen atoms and with one another.

The bibliography includes 103 references.

I. INTRODUCTION

The study of the interaction of atomic hydrogen with solid organic substances was initiated in 1958 by Klein and Scheer[1,2], who established that hydrogen atoms add to frozen olefins at a high rate at 77 K. More than 100 studies devoted to the paths and rates of the reactions of atomic hydrogen with solid organic substances have already been published. They are important for the determination of the nature of the elementary steps in the free-radical processes and for the elucidation of the rules relating the structures of the reactants to their reactivities. Furthermore, the study of the reaction of hydrogen atoms with solid organic substances is essential for the understanding of the kinetics and mechanisms of low-temperature chemical reactions as well as heterogeneous processes in systems, frequently encountered in practice, which comprise atomic species in the gas phase and a solid substance.

The knowledge of detailed mechanisms and characteristics of the elementary reactions between the atomic hydrogen and solid organic substances plays a particularly important role in the solution of problems arising in the study of the action of high-energy radiation on such substances. Under the influence of ionising radiation, C–H bonds are ruptured in organic compounds and the reactions of the resulting hydrogen atoms influence the yields of radiolysis products and the radiation stability of the substances.

The reactions of atomic hydrogen with solid organic substances are studied by a wide variety of methods: monitoring of the changes in the pressure of molecular hydrogen, chromatographic or mass-spectrometric analysis of reaction products, and study of the exchange between the gas and solid phases during the interaction of hydrogen isotopes (deuterium and tritium) with frozen hydrocarbons. Lomanov et al.[3] developed the method of kinetic calorimetry for the simultaneous measurement of the heat evolved in the reaction layer and of the amount of hydrogen absorbed. EPR spectroscopy is widely used in the study of reactions of atomic hydrogen with solid organic substances. The free-radical reaction products are identified and their concentration and the concentration of hydrogen atoms are determined by EPR.

Another microwave spectroscopic method is based on the use of a hydrogen maser, the sensitivity of which is higher by approximately 4 orders of magnitude than that of an EPR spectrometer. This makes it possible to investigate reactions in the presence of a very low concentration of atomic hydrogen. It has been suggested[4] that the hydrogen maser be used under pulsed conditions to investigate not only chemical reactions but also the steps preceding them, namely the physical and chemical adsorption of atomic hydrogen on the surface of a solid (from the change in the hyperfine state of the hydrogen atom).

Atomic hydrogen is usually obtained either in the gas phase or is generated directly in the solid substance. The most suitable methods for the generation of atomic hydrogen in the gas phase are thermal decomposition and the dissociation of molecular hydrogen in the gas discharge. The latter procedure is more convenient and effective. The generation of hydrogen atoms in an electrodeless high-frequency or ultrahigh frequency discharge is particularly common. The methods for the generation of hydrogen in the gas phase and the procedures for the measurement of their concentration have been examined in a review[5].

Radiation and photochemical methods are used to generate hydrogen atoms directly in the solid. Among the latter procedures, the method involving the ultraviolet irradiation of frozen aqueous solutions of acids (H_2SO_4 and H_3PO_4) containing small amounts of $FeSO_4$ has come to be most widely used[6,7]. Ultraviolet irradiation of such systems leads to the oxidation-reduction reaction

$$Fe^{2+} + H_2O + h\nu \rightarrow Fe^{3+} + OH^- + H^{\cdot} \quad .$$

The hydrogen atoms produced are stabilised at 77 K, but, on raising the solution temperature to 90–120 K, they become mobile and can react with the solute.

The methods available for the investigation of the interaction of atomic hydrogen with solid organic substances have made it possible to establish fairly reliably the paths of the reactions and in certain cases also to measure their rates. The review presents results referring solely to thermalised hydrogen atoms. The extensive literature on the radiolysis of solid organic substances, from which data for the reactions of atomic hydrogen may be obtained, is not dealt with because radiolysis may entail the formation of "hot" hydrogen atoms.

II. PROCESSES IN SYSTEMS H(GAS) + SOLID ORGANIC SUBSTANCE

1. Models for the Description of Processes

The chemical interaction of hydrogen atoms with organic compounds can be described by the following fundamental equations:

$$\mathrm{M+H} \xrightarrow{k_1} \mathrm{R}, \tag{1}$$

$$\mathrm{RX+H} \xrightarrow{k_2} \mathrm{R+HX}, \tag{2}$$

$$\mathrm{R+H} \xrightarrow{k_3} \mathrm{RH}, \tag{3}$$

$$\mathrm{R+H} \xrightarrow{k_4} {>}\mathrm{C{=}C}{<} + \mathrm{H_2}, \tag{4}$$

$$\mathrm{R+R} \xrightarrow{k_5} \mathrm{R{-}R}, \tag{5}$$

$$\mathrm{R+R} \xrightarrow{k_6} {>}\mathrm{C{=}C}{<} + \mathrm{RH}, \tag{6}$$

$$\mathrm{H+H} \xrightarrow{k_7} \mathrm{H_2}, \tag{7}$$

where M and RX are molecules of unsaturated and saturated compounds respectively. Depending on the structure of the initial molecules, the primary step in the interaction is either the addition reaction (1) or reaction (2) involving the abstraction of an atom or groups of atoms. The transfer of a hydrogen atom (X = H) constitutes a special case of reactions of the second type. For certain compounds with complex structures, there is a possibility of the simultaneous occurrence of reactions (1) and (2) (see Section III). The free radicals generated in the primary step react further with hydrogen atoms [reactions (3) and (4)] and with one another [reactions (5) and (6)]; these secondary reactions of free radicals proceed via recombination [reactions (3) and (5)] or disproportionation [reactions (4) and (6)] mechanisms. Reactions (4) and (6) lead to the formation of molecules with double bonds.

Since the reactant is in the solid phase, physical processes such as diffusion, dissolution or adsorption of hydrogen atoms, and elementary steps involving the migration of the reacting solid-phase species (molecules and free radicals), in the first place their translational diffusion, play an important role in the kinetics. One should also bear in mind that many parameters, for example, diffusion coefficients, may vary as the reaction proceeds, owing to the change in the structure of the initial substance. The fundamental differential equations describing the interaction of hydrogen atoms with an unsaturated compound are presented below [a one-dimensional model is considered; it is assumed that reactions (4) and (6) result in the formation of unsaturated compounds having the same structure as the initial substance]:

$$\frac{\partial [\mathrm{H}]}{\partial \tau} = D_{\mathrm{H}} \frac{\partial^2 [\mathrm{H}]}{\partial x^2} - k_1 [\mathrm{M}] [\mathrm{H}] - (k_3 + k_4) [\mathrm{R}] [\mathrm{H}] - k_7 [\mathrm{H}]^2, \tag{8}$$

$$\frac{\partial [\mathrm{M}]}{\partial \tau} = D_{\mathrm{M}} \frac{\partial^2 [\mathrm{M}]}{\partial x^2} - k_1 [\mathrm{M}] [\mathrm{H}] + k_4 [\mathrm{R}] [\mathrm{H}] + k_6 [\mathrm{R}]^2, \tag{9}$$

$$\frac{\partial [\mathrm{R}]}{\partial \tau} = D_{\mathrm{R}} \frac{\partial^2 [\mathrm{R}]}{\partial x^2} + k_1 [\mathrm{M}] [\mathrm{H}] - (k_3 + k_4) [\mathrm{R}] [\mathrm{H}] - (k_5 + k_6) [\mathrm{R}]^2, \tag{10}$$

where k_1, k_2, k_3, etc. are the rate constants for the above reactions, [H], [M], and [R] are respectively the concentrations of hydrogen atoms, reacting molecules, and free radicals, and D_{H}, D_{M}, and D_{R} are the diffusion coefficients of these species. In the general case the concentrations and diffusion coefficients are functions of the distance x from the surface of the specimen (Fig. 1) and the time τ.

The above equations must be supplemented by the analogous material balance equations for the molecular hydrogenation products (RH and R–R). The solution of the complete system of equations is difficult, but it is quite feasible with the aid of a computer. Thus Rappe et al.[8] calculated on a computer the time variation of the quantity $\partial[\mathrm{H}]/\partial\tau$ for frozen (77 K) isobutene, taking into account reactions (1), (3), (4), (6) and (7), which occur in this system, and the diffusion of all the reacting species (hydrogen atoms, isobutene molecules, isobutyl radicals, isobutane molecules), and in the first version of the calculation it was assumed that the diffusion coefficients are constant throughout the hydrogenation process. The calculated variation of $\partial[\mathrm{H}]/\partial\tau$ with τ agrees with the experimental variation along the initial section; at more advanced stages of the reaction the measured rate decreases faster than would follow from the results of the calculation. In order to account for the discrepancy, the authors suggested that the presence of isobutane leads to a decrease of either (1) the rate of diffusion of hydrogen atoms and of all the solid-phase reacting species or (2) the solubility of hydrogen atoms. When either of these possibilities was taken into account, satisfactory agreement between the experimental and calculated data was achieved. However, one should note that the reaction rate constants and diffusion coefficients used in the calculation have not been measured experimentally in most cases and are not always reliable. For this reason, the results must be treated with a certain amount of caution.

It is seen from the above example that the correct description of the interaction of hydrogen atoms with solid organic substances requires the knowledge of many constants for chemical and physical processes. In practice, in order to simplify the problem, use is made of approximate models. Among all the transport phenomena, commonly only the diffusion of atomic hydrogen is taken into account, while the diffusion of molecules and free radicals is neglected (the H-diffusion model[8-10]).

It is usually assumed that $\partial[\mathrm{H}]/\partial\tau = 0$. Then

$$D_{\mathrm{H}} \frac{\partial^2 [\mathrm{H}]}{\partial x^2} = k_1 [\mathrm{M}] [\mathrm{H}] + k_3 [\mathrm{R}] [\mathrm{H}] + k_4 [\mathrm{R}] [\mathrm{H}] + k_7 [\mathrm{H}]^2. \tag{11}$$

The distribution of the concentration of atomic hydrogen in the layer of the given substance, where a whole series of reactions take place simultaneously, is complex. We shall confine ourselves to an examination of two special cases which are encountered in practice.

(a) The distribution of the concentration of atomic hydrogen determined by the rate of recombination of hydrogen atoms [reaction (7)]. One can state *a priori* that this mechanism should obtain for saturated compounds (such as alkanes) at very low temperatures (< 80 K):

$$D_{\mathrm{H}} \partial^2 [\mathrm{H}]/\partial x^2 = k_7 [\mathrm{H}]^2, \tag{12}$$

$$[\mathrm{H}] = \{[\mathrm{H}]_0^{-1/2} + (k_7/6D_{\mathrm{H}})^{1/2} x\}^{-2}, \tag{13}$$

where $[\mathrm{H}]_0$ is the concentration of atomic hydrogen on the surface of the specimen for $x = 0$.

(b) The consumption of atomic hydrogen is determined by reaction (1) or (2) (depending on the structure of the initial substance). This special case corresponds to compounds reacting with atomic hydrogen at a high rate. These include in the first place unsaturated and many saturated compounds at temperatures ⩾ 100 K (see Section VI). Eqn. (11) transforms into

$$D_H \partial^2 [H]/\partial x^2 = k_1 [M] [H], \tag{14}$$

$$[H] = [H]_0 \{ch (k_1 [M]/D_H)^{1/2} x - th (k_1 [M]/D_H)^{1/2} l \cdot sh (k_1 [M]/D_H)^{1/2} x\}. \tag{15}$$

The measured parameters are usually the rate of change of the pressure of molecular hydrogen (when the reactions proceed in a closed system) and the rate of formation of free radicals. The corresponding equations for the rate of addition are

$$-2 \frac{d H_2}{d \tau} = \int_0^l \{k_1 [M] [H] + (k_3 - k_4) [R] [H]\} s\, d x, \tag{16}$$

$$\frac{d N}{d \tau} = \int_0^l \{k_1 [M] [H] - (k_3 + k_4) [R] [H] - (k_5 + k_6) [R]^2\} s\, d x, \tag{17}$$

where H_2 is the total number of hydrogen molecules in the system, N the number of free radicals in the specimen, s the surface area of the specimen, and l its thickness. On substituting the expressions for [H] [Eqns. (13) and (15)] in these equations, it is possible to obtain the dependence of the rates of the processes on $[H]_0$ and D_H for the two cases considered.

We shall deal with the more interesting case (b). The initial rate of consumption of molecular hydrogen is

$$2 \left(\frac{d H_2}{d \tau}\right)_0 = \int_0^l k_1 [M] [H] s\, d x = (D_H k_1 [M])^{1/2} [H]_0 s\, th (k_1 [M]/D_H)^{1/2} l. \tag{18}$$

It is assumed that $[H]|_{x=0} = [H]_0$ and $\partial[H]/\partial x|_{x=l} = 0$. For a very thin layer, we have

$$-2 \left(\frac{d H_2}{d \tau}\right)_0 = k_1 [H]_0 [M] s l. \tag{19}$$

An analogous expression is obtained for the initial rate of accumulation of free radicals:

$$(d N/d \tau)_0 = k_1 [H]_0 [M] s l. \tag{20}$$

Thus the initial rate of reaction for thin-layer specimens is proportional to their thickness, the concentration of hydrogen atoms, and the concentration of the reactant. For a thick-layer specimen, Eqn. (18) becomes

$$-2 \left(\frac{d H_2}{d \tau}\right)_0 = [H]_0 s (D_H k_1 [M])^{1/2}, \tag{21}$$

i.e. the initial rate of change of the pressure of molecular hydrogen is independent of the thickness of the specimen and is proportional to the concentration of atomic hydrogen and the square root of the concentration of the reactant.

The model involving the diffusion of hydrogen atoms is suitable for the description of the interaction with solid organic compounds, whose molecules have no mobility or their mobility is restricted. For low-molecular-weight compounds, the temperature range in which it is possible to employ the H-diffusion model depends on the melting point (T_m) and usually includes temperatures $T \leqslant T_m/2$. For high-molecular-weight compounds, the upper limit of this temperature range is approximately T_g − 20°, where T_g is the glass point of the amorphous polymer, or is close to the melting point of the crystalline polymer.

The given model is sometimes applicable also to hydrocarbons with a low melting point, such as, for example, propene and isobutene. The foregoing refers to thin films of olefins. Thus it has been found that[8] the initial rate of absorption of molecular hydrogen by isobutene ($l \leqslant 0.5$ m) at 77 K varies linearly with the concentration of atomic hydrogen in the gas phase and with film thickness. The linear dependence of $dH_2/d\tau$ on l has also been observed for propene[9]. For thick films of olefins (~ 1 μm), the rate ceases to depend on film thickness, approaching a constant value[9].

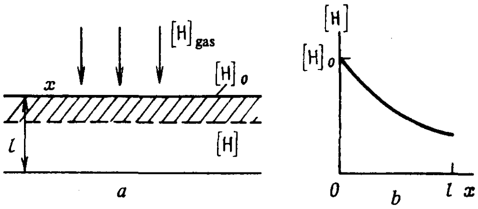

Figure 1. Schematic representation of the interaction of hydrogen atoms (gas) with a solid (*a*) and variation of the concentration of hydrogen atoms in a layer with a thickness l (*b*).

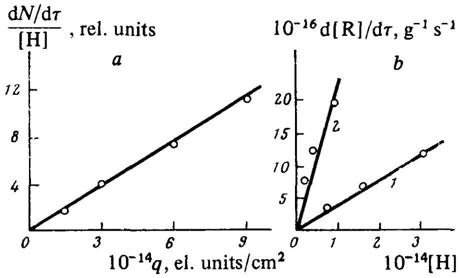

Figure 2. Dependence of the initial rate of formation of free radicals in polyisobutylene adsorbed on aerosil (s_{sp} = 200 m^2 g^{-1}) on the number of elementary units (q) of the polymer (*a*) and the concentration of atomic hydrogen in the gas phase (*b*): *a*) T = 100 K, the number of radicals and the number of elementary units are referred to unit surface of aerosil; *b*) $q = 6 \times 10^{14}$ elementary units per cm^2, T = 115 K (line *1*) and 163 K (line *2*).

However, studies of the interaction of atomic hydrogen with thick propene films established a whole series of facts, which could not be explained within the framework of the H-diffusion model and indicated a high diffusion coefficient of the olefin. It was found that (1) the initial rate of reaction is proportional to [M] and not $[M]^{1/2}$, as would follow from Eqn. (21),[1] (2) the rate depends on the type of matrix in which the olefin is located[11], the consumption of molecules in rigid matrices being proportional to $\tau^{1/2}$ and not τ, and (3) when the hydrogenation is interrupted and the supply of atomic hydrogen is then resumed, the rate of reaction increases significantly[12]. The low concentration of free-radical products of propene and isobutene hydrogenation, which cannot be measured by EPR ($\leqslant 6 \times 10^{17}$ g^{-1}) also constitutes indirect indication of the mobility of olefins. The surface reaction model has been put forward to account for the observed phenomena[8,11]. It is suggested that the reaction proceeds on the surface where the concentration of hydrogen atoms is $[H]_0$, while the concentration within the layer is zero. The model takes into account the diffusion of the reacting substance from the bulk of the layer onto the surface, and it is assumed that the diffusion coefficient is independent of the composition of the layer and the duration of the process. According to the model, the initial rate of absorption of hydrogen is independent of the thickness of the layer and is proportional to the concentration of the reactant and hydrogen atoms:

$$-2\left(\frac{dH_2}{d\tau}\right)_0 = k_1 [H]_0 [M] s \quad . \tag{22}$$

At more advanced stages of the process there is a possibility of two limiting cases where the rate is determined by (a) the chemical reaction [(1) or (2)] on the surface and (b) the diffusion of the reactant. If the rate of the process is limited by that of the reaction, Eqn. (22) is applicable, and, when it is limited by the rate of diffusion, we have

$$\Delta H_2 \simeq (D_M \tau/\pi)^{1/2}. \tag{23}$$

The model agrees satisfactorily with experimental data for thick films at advanced stages in the hydrogenation of propene in different matrices[11].

Systems where the reacting molecules are adsorbed on the surface of an inert carrier constitute the simplest case[13-15]. When such specimens are used, all the reactions take place on the surface and one may disregard the diffusion of hydrogen atoms and the reacting species.

The adsorbent is usually aerosil (SiO_2) with a high specific surface ($\geqslant 200$ m^2 g^{-1}); it is a non-porous fine-grained powder (particle size between 4 and 40 nm), which readily adsorbs organic substances. The specific surfaces of the specimens are the same as the specific surface of the initial aerosil when the adsorbed amounts correspond to approximately 1–2 molecular layers (5–10 μmole m^{-2}). The reaction kinetics may be described by Eqns.(19) and (20), which are valid for a very thin layer of reactant (in this case the average thickness of the layer l corresponds to only 1–2 molecular diameters).

For low surface coverages of aerosil, the amount of free radicals formed varies linearly with the amount of adsorbed polymer (Fig. 2*a*). For high coverages, the linearity breaks down. Fig. 2*b* shows that the initial rate of accumulation of radicals for the polymer adsorbed on a thin layer of aerosil, as well as for olefin films, is proportional to the concentration of hydrogen atoms in the gas phase.

2. The Mechanisms of Elementary Chemical Reactions for Certain Compounds

The compositions of the molecular hydrogenation products have been analysed for the simplest olefins and the mechanisms of chemical reactions leading to hydrogenation have been fairly reliably established[8,9,11,12,16-22]. When propene is acted upon by atomic hydrogen, mainly propane and dimethylbutane are formed. In soft matrices (propene, propene + propane, propene + n-butane), reactions (1), (5), and (6) take place and of the two reactions of isopropyl radicals with each other disproportionation is the dominant process[9,11,20-23]. The rates of reactions (3) and (4) are insignificant, but their role increases in rigid matrices, where the probability of the interaction of free radicals with one another is reduced. Thus in solid mixtures of propene with isopentane[24] and *cis*-butene[11] and in propene adsorbed on quartz[18] isopropyl free radicals are destroyed mainly via reactions (3) and (4).

In order to determine the sequence of the elementary processes occurring in the hydrogenation of olefins, some investigators[21,24-26] studied the deuterium–hydrogen exchange between the gas and solid phases. It was found that, when propene is acted upon (at 77 K) by deuterium atoms, hardly any HD is formed[25]. On the other hand, when butene, isobutene, 2-methylbut-1-ene, and 3-methylbut-1-ene are bombarded by atomic deuterium, H–D exchange takes place at a high rate[25,27]. Its rate for isobutene is close to the rate of absorption of deuterium. The isotope exchange may be caused by the two reactions:

$$R + D \rightarrow \text{olefin} + HD + 60 \text{ kcal mole}^{-1}, \tag{24}$$

$$R + D \rightarrow R_D + H + 0 \text{ kcal mole}^{-1}. \tag{25}$$

Here R_D is a free radical containing a D atom.

The simultaneous study of heat evolution and the amount of absorbed deuterium in the case of isobutene showed[25] that the H–D exchange must be due to a thermally neutral process, i.e. reaction (25). The authors therefore believe[25,27] that the mechanism involving reactions (1)–(7), occurring when solid olefins are acted upon by atomic hydrogen, should be supplemented by the exchange between free radicals and hydrogen atoms. However, the possibility of such an energetically unfavourable process requires further experimental confirmation.

The interaction of atomic hydrogen with many high-molecular-weight [polyisobutylene, polypropylene, poly-(methyl acrylate), etc.] and low-molecular weight (n-hexadecane, malonic acid) compounds at a fairly low temperature may be described by reactions (2)–(4). This conclusion is based on the results of kinetic studies by EPR[14,15,28]. The curves representing the variation of the concentration of free radicals in the substances enumerated above are described by the equation

$$\frac{d[R]}{d\tau} = k_2 [H][RH] - (k_3 + k_4)[H][R]. \tag{26}$$

Similarly the rate of formation of free radicals in unsaturated compounds may be represented by the expression

$$\frac{d[R]}{d\tau} = k_1 [H][M] - (k_3 + k_4)[H][R]. \tag{27}$$

A simultaneous study of the rate of accumulation of free radicals and of the rate of change of pressure in the system makes it possible to determine which of the two reactions [(3) or (4)] predominates. For unsaturated compounds, the rate of absorption of hydrogen is

$$-2\frac{dH_2}{d\tau} = k_1 [H][M] + (k_3 - k_4)[H][R]. \tag{28}$$

Under the conditions of a steady-state concentration of free radicals, we have

$$-\frac{dH_2}{d\tau} = \frac{k_1 k_3}{k_3 + k_4}[H][M]. \tag{29}$$

Two extreme cases are possible:

$$\text{when } k_3 \gg k_4 \qquad -dH_2/d\tau = k_1 [H][M] \, ,$$
$$\text{when } k_3 \ll k_4 \qquad -dH_2/d\tau \approx 0 \, .$$

The nature of the kinetic curves for polystyrene[29] (Fig. 3) shows that in this instance $k_3 \gg k_4$, i.e. the interaction of atomic hydrogen with polystyrene includes only two chemical reactions [(1) and (3)].

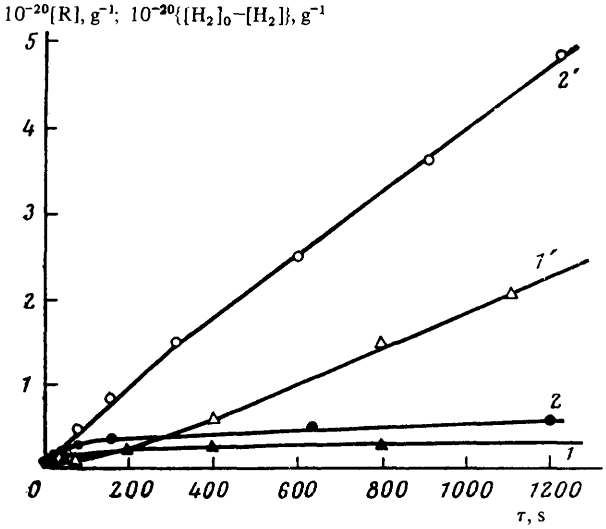

Figure 3. Kinetic curves for the variation of the concentration of free radicals (lines *1* and *2*) and the absorption of molecular hydrogen (lines *1′* and *2′*) in the interaction of atomic hydrogen with polystyrene at 123 K (lines *1* and *1′*) and 163 K (lines *2* and *2′*).[29] The amounts of free radicals and H_2 molecules are referred to unit mass of the polymer.

3. The Depth of Penetration of Hydrogen Atoms into a Layer of a Solid Organic Substance

The relation between the rates of diffusion and chemical reactions in the layer of reactant determines the depth of penetration of atomic hydrogen δ into this substance. Thus δ depends on the chemical structure of the reactants, their physical properties, and, finally, temperature. It can be measured by various experimental methods, including EPR. Since in thick layers hydrogen atoms penetrate only into a layer with a thickness δ, free radicals are likewise formed only in this layer. The average concentration of radicals in such specimens therefore differs from the local concentration in the δ layer: $[R]_{av} = [R]_{loc} s\rho\delta$ (here s is the specific surface of the specimen and ρ its density). Knowing the average and local concentrations of free radicals, it is possible to determine δ. $[R]_{av}$ is measured directly by EPR, while $[R]_{loc}$ is found by studying the broadening of EPR spectra with increasing amount of free radicals, which is due to the dipole–dipole spin interaction. The width of an individual line in the EPR spectrum usually varies linearly with the concentration of radicals (Fig. 4) and $[R]_{loc}$ can be calculated from the equation[30]

$$\Delta H = \Delta H_0 + 5 \cdot 10^{-20} [R]_{loc}, \qquad (30)$$

where ΔH_0 is the intrinsic width of the individual spectral line and ΔH the width of the same line increased owing to the dipole–dipole interaction.

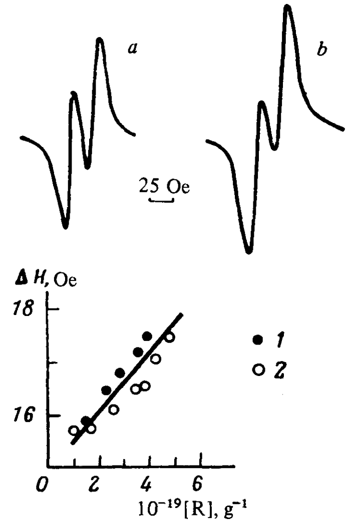

Figure 4. Dependence of the width of an individual line in the EPR spectrum of polyisobutylene radicals on the concentration of the latter[33]. Reaction temperature 145 K (*1*) and 123 K (*2*). The upper part of the figure represents the EPR spectra of free radicals at 145 K. Duration of exposure to the action of hydrogen atoms: *a*) 40 s; *b*) 400 s.

Table 1. The depth of penetration by hydrogen atoms into certain solid organic substances.

Substance	T, K	$10^5\delta$, cm	References
Propane	77	10	1
Propene	77	1—10	1
Propene	77	0.2	27
Polystyrene	295	1	31
Thymine	295	2—3	32
Poly(methyl methacrylate)	100	0.2	33
Poly(vinyl acetate)	120	0.1—0.2	33

Table 1 presents the values of δ for certain organic substances. Those for thymine and poly(methyl methacrylate) were determined by the method described above.

The depth of penetration by atomic hydrogen in solid organic substances of different chemical structures in the temperature range 77–300 K is 10^{-6}–10^{-5} cm (Table 1). Only for propane is δ greater (10^{-4} cm), which can be accounted for by the high rate of diffusion of atomic hydrogen in this substance compared with the rate of destruction of hydrogen atoms on recombination and chemical interaction with propane.

In estimating the values of δ for propene at 77 K the authors of the first investigations[1] did not take into account the possibility of the diffusion of the olefin to the surface of the film, which led to unduly high values of δ. In a later study[11], where an olefin-diffusion model was considered, the estimated δ amounted to only a few molecular diameters.

III. THE PRIMARY CHEMICAL STEP IN THE INTERACTION OF ATOMIC HYDROGEN WITH ORGANIC COMPOUNDS OF DIFFERENT CLASSES

1. The Paths of Reactions (1) and (2)

The path of the chemical reaction can be determined from the EPR spectra of free radicals (Fig. 5) and by analysing molecular products. In most cases the hyperfine structure of EPR spectra is susceptible to elucidation and the directions of reactions (1) and (2) have been established reliably. Since this information is given in a monograph[34] and it is only briefly discussed in the present review, emphasis is laid on the results obtained after the publication of the book by Pshezhetskii et al.[34]

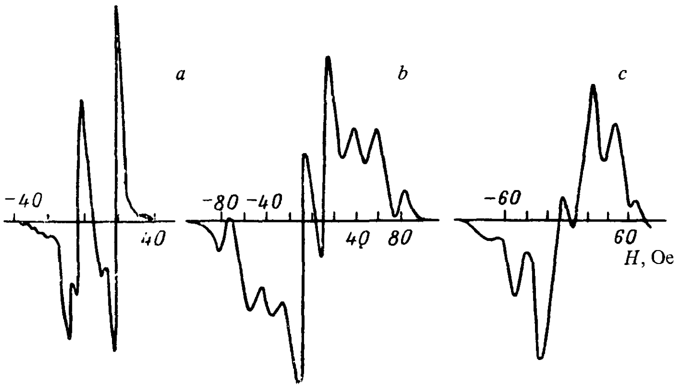

Figure 5. EPR spectra of the free radicals arising as a result of the reaction $H + RH \rightarrow H_2 + R$ at 110–115 K: *a*) malonic acid; *b*) n-hexadecane; *c*) polypropylene.

The principal data for addition reactions (1) are summarised in Tables 2–4. Hydrogen atoms add at 80–140 K to multiple bonds of different types: $C{=}C$, $C{\equiv}C$, $C{=}O$, $C{\equiv}N$, $N{=}O$, $N\begin{smallmatrix}/\!\!/O\\ \diagdown O\end{smallmatrix}$, $N{=}C{=}O$ (Table 2). For olefins and monomers of the vinyl type (methyl methacrylate, vinyl acetate, etc.), the energy of a C–H bond involving a primary carbon atom is greater by several kilocalories than for a bond involving a secondary carbon atom, and hydrogen atoms add mainly to a terminal carbon atom (in conformity with the empirical Markovnikov rule).

Analysis of the molecular olefin hydrogenation products made it possible to determine the relative reactivities of two carbon atoms linked by a double bond. Table 3, which presents data for certain olefins at 90 K, shows that the rate of addition of a hydrogen atom to a primary carbon atom (propene) exceeds by a factor of approximately 100 the rate of addition to a secondary carbon atom. The difference between the rates of addition to primary and tertiary carbon atoms is greater still—it is illustrated by the example of isobutene. Data for the relative reactivities at other temperatures can be found below in Table 8, which also presents values obtained in the study of the effect of atomic deuterium on olefins.

Nitro- and nitroso-groups behave as active acceptors of hydrogen atoms. The addition to a nitro-olefin (nitroethylene, isonitropropene) is selective: virtually only the N=O bonds react. The interaction of the $N{=}C{=}O$ and $N{=}C{=}S$ groups with hydrogen atoms entails the rupture of the $N{=}C$ bond and the site of addition (the nitrogen or carbon atom) depends on the nature of the substituent at these bonds[45].

Hydrogen atoms react very readily with benzene and its derivatives: toluene, biphenyl, phenol, hydroquinone, anisole, etc., with formation of radicals of the cyclohexadienyl type[36,38,46–54]. The EPR spectra of the free radicals arising in these substances are usually poorly resolved and it is not always possible to determine their structure. However, the available data nevertheless permit the conclusion that hydrogen atoms add to the majority of benzene derivatives in the *ortho*- and *para*-positions relative to the substituent (Table 4). 1,3-Disubstituted benzenes react with hydrogen atoms more readily than the 1,2- or 1,4-substituted derivatives[50]. Heterocyclic compounds with aromatic properties, such as furan, thiophen, and their derivatives (Table 4), combine with hydrogen atoms in the 2-position.

Table 3. The relative reactivities of carbon atoms in olefins at 90 K (k_1 and k_1' are the rate constants for the addition of a hydrogen atom to carbon atoms shown to the left and to the right of the double bond respectively)[37].

Olefin	k_1/k_1'
$CH_2=CH-CH_3$	126
$CH_2=C(CH_3)_2$	1000
$CH_3-CH=C(CH_3)_2$	115

Many compounds are involved in hydrogen atom transfer reactions when they interact with atomic hydrogen (Table 5). The free radicals arising in aniline[47], thiophenol[47], allyl alcohol[38], and other compounds as a result of the dissociation of the N-H, S-H, and C-H bonds are to a large extent stabilised owing to conjugation and the reactions therefore proceed at a high rate even at low temperatures. The C-H bonds in other compounds, particularly paraffins, are comparatively strong and the activation energy for a reaction of the type $H + RH \rightarrow H_2 + R$ is 6-9 kcal mole^{-1}.[60] For this reason, it is frequently claimed (see, for example, Refs. 34 and 61) that such reactions cannot be detected at low temperatures (near the boiling point of nitrogen).

However, studies carried out by the EPR method in recent years revealed the abstraction of hydrogen atoms at a low temperature (in many instances down to 77 K) from a wide variety of compounds, such as cyclohexane, malonic acid, glucose, mannose, and other monosaccharides, tetrahydrofuran, etc. (Table 5). This reaction was observed when many polymers, for example, polyethylene, polypropylene, polyisobutylene, etc. were acted upon by atomic hydrogen[42]. As was to be expected, the site of attack is determined by the weakest C-H bond.

For certain compounds with a complex structure, containing several functional groups, there is a possibility of competition between different modes of reaction. For example, the addition of atomic hydrogen to the aromatic ring and the abstraction of a hydrogen atom from the substituent take place simultaneously in thiophenol, mesitylene, benzyl alcohol, etc.[47,49] When but-2-ene is acted upon by atomic hydrogen, secondary butyl (addition to the double bond) and methylallyl (abstraction of a hydrogen atom from the terminal methyl group) radicals are formed in proportions of 40 : 60.[62] Very many similar examples may be quoted.

Numerous studies have been devoted to the interaction of atomic hydrogen with compounds of biological interest: amino-acids and purine and pyrimidine bases (see the monograph of Pshezhetskii et al.[34] and other reports[32,57,63-73]).

There are numerous data on the modes of reaction of atomic hydrogen with macromolecules. Atomic hydrogen adds to the benzene rings of polymers such as polystyrene, polymethylstyrene, poly(ethylene terephthalate), polyphenylalanine, etc.,[29,31,42,53,54,68] and to the nitrile group of polyacrylonitrile[42]. As already mentioned, atomic hydrogen is abstracted from the main polymer chain in polyethylene, polypropylene, poly(methyl acrylate), poly(methyl methacrylate), polyisobutylene, and certain other polymers[42]. Bombardment of the polymers with hydrogen atoms sometimes leads to the dissociation of C-C bonds with elimination of the side group (poly-L-lysine, poly-L-serine), C-N bonds (poly-L-alanine, poly-L-proline), and C-S bonds (poly-L-methionine)[68,69].

Table 4. The interaction of atomic hydrogen with aromatic compounds [reaction (1)].

Thus at a low temperature atomic hydrogen enters into a wide variety of reactions with the molecules of solid organic substances. It has been established for many compounds that the structures of the free radicals obtained on bombardment with hydrogen atoms and under the influence of high-energy radiation are the same[34,39,41,50,57]. One must therefore suppose that many free radicals, arising in the radiolysis of solid organic substances and responsible for the alteration of their properties, are formed via reactions involving atomic hydrogen.

2. Kinetic Constants for Reactions (1) and (2)

The rate constants for all the elementary reactions (1)–(7) have not as yet been determined. The majority of the available kinetic data refer to reactions (1) and (2); the most reliable results have been obtained in studies of the interaction of hydrogen atoms with thin films of olefins[8,9] and with substances adsorbed on the surface of aerosil[13-15,28,29]. The latter method is particularly promising, because it makes it possible to eliminate completely all kinds of diffusion-dependent complications and to measure directly the rate of reaction (1) or (2).

The rate constants for reactions (1) and (2) are calculated from the initial rate of any one of the following processes: absorption of hydrogen, accumulation of free radicals, alteration of the concentration of the initial compound. In all cases it is assumed that $[H]_0 = [H]_{gas}$, i.e. that the concentration of atomic hydrogen in the surface layer of the substance is equal to its concentration in the gas phase—$[H]_{gas}$ is usually determined by EPR.

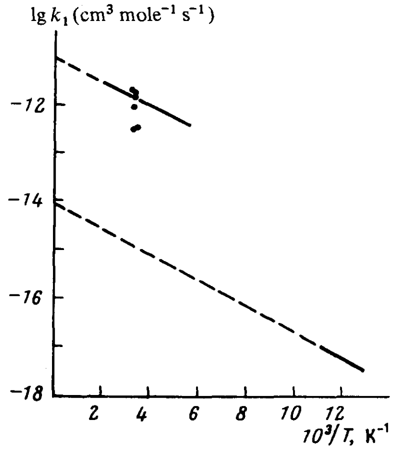

Figure 6. Temperature dependence of the rate constant k_1 for the reaction $H + C_3H_6 \rightarrow C_3H_7$ (for explanation, see text).

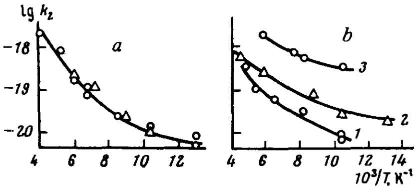

Figure 7. Temperature dependence of the rate constant k_2 for the reaction $H + RH \rightarrow H_2 + R$[14,28]: *a*) polyisobutylene, the triangles denote the values of k_2 for the reaction $D + RH \rightarrow HD + R$; *b*) [1) poly(methyl methacrylate); 2) poly(methyl acrylate); 3) polypropylene]. The constants are referred to a single reacting C–H bond.

Kinetic data for reaction (1) are presented in Table 6 and in Fig. 6 and those for reaction (2) are in Table 7 and in Figs. 7 and 8. For thin films and substances adsorbed in an approximately monomolecular layer on aerosil, the effective activation energy represents the difference between the activation energy for the reaction and the heat of adsorption of atomic hydrogen:

$$E_{\text{eff}} = E - Q_{\text{ads}}. \qquad (31)$$

It has not so far been possible to measure Q_{ads}, but one may suppose that it is small for solid organic substances and that the reactions on the surface proceed with participation of hydrogen atoms arriving directly from the gas phase. In this case $E_{\text{eff}} \simeq E$.

For thick films (acetylene, methylbutene, etc.) and for powders with a small specific surface (thymine, dihydrothymine, etc.), the energy E_{eff} characterises a fairly complex process, including diffusion and dissolution of atomic hydrogen in the given substance. According to the model described by Eqn. (21),

$$E_{eff} = [(E + E_{dif})/2] - Q_{ads}. \qquad (31')$$

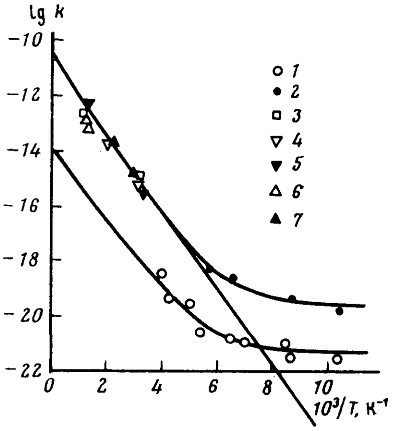

Figure 8. Temperature dependence of the rate constants for different reactions: 1) $H + CH_2(COOH)_2 \rightarrow H_2 + \dot{C}H(COOH)_2$; 2) $H + n\text{-}C_{16}H_{34} \rightarrow H_2 + n\text{-}C_{16}H_{33}$ (Dubinskaya and Yusubov[15]); 3)–7) $H + n\text{-}C_4H_{10} \rightarrow H_2 + n\text{-}C_4H_9$ (Kondrat'ev[60]). The constants refer to a single methylene group.

Table 6 shows that the values of k_1 calculated for propene at 77 K from the rate of change of its concentration agree with one another, but differ from the values determined by another method—from the decrease in the H_2 pressure.

It is noteworthy that in the determination of k_1 from the change in the initial concentration of the reactant, the relative rates of the subsequent reactions (3)–(6) are used. However, analysis has shown that a change by a large factor in the ratio of the rate constants for these reactions has little effect on the calculated k_1. For this reason, the possible inaccuracies in the determination of the role of secondary free-radical reactions can be the cause of the differences between the values of k_1 found by these two methods.

The rate constants for the reaction of atomic hydrogen with solid propene at low temperatures are compared in Fig. 6 with the values measured in the gas phase at elevated temperatures. The upper continuous straight line (177–434 K) was plotted using the results of Kurylo and Preston[75]. The constants at 177–300 K are trustworthy, because they were measured under conditions excluding possible errors associated with side reactions (the abstraction of hydrogen atoms from propene, the decomposition of excited propyl radicals, etc.). The data of other workers at room temperature (circles), summarised by Jones et al.[5] and Kondrat'ev[60], are also presented. The lower straight line refers to the reaction of atomic hydrogen with solid propene and was plotted using the following values: $E_1 = 1.5$ kcal mole^{-1} and $k_1(77\ K) = 3 \times 10^{-18}$ cm^3 s^{-1}, which we believe to be the most trustworthy. Fig. 6 shows that the activation energies in the gas and solid phases are similar, but the pre-exponential factor in the Arrhenius equation for the reaction with solid propene is appreciably lower (by three orders of magnitude).

The values of k_1 for polystyrene at a low temperature, determined by two different methods (from the initial rate of formation of free radicals and from the decrease of the

pressure of molecular hydrogen) agree satisfactorily (Table 6). The dependence of the rate constant for the addition of atomic hydrogen to polystyrene on temperature in the range 77–163 K may be represented by the expressions $k_1 = 10^{-15.8\pm0.4} \exp[(-1300 \pm 200)/RT]$ cm^3 s^{-1}.[29] These data refer to polystyrene adsorbed in an approximately monomolecular layer on the surface of aerosil ($s_{sp} \simeq 200$ m^2 g^{-1}) and the measured kinetic constants presumably characterise the rate of the chemical reaction itself.

***Aerogels; in the remaining cases the substance was adsorbed on aerosil.

It is of interest to compare the constants k_1 for different compounds at a single temperature; unfortunately only a limited number of such data are available. Table 6 shows that the rate constants for the addition of atomic hydrogen to propene and isobutene (77 K) are approximately the same and exceed the corresponding constant for the addition to the benzene rings of polystyrene by two orders of magnitude. The ratio of the rates of addition of atomic hydrogen at 90 K to the $CH_2 = CH-$ (propene and but-1-ene) and $-CH=CH-$ (*trans*-but-2-ene) bonds is ten[37]. An approximately the same ratio of the rates is observed for the addition of atomic hydrogen to the terminal and inner double bonds in hexa-1,4-diene[37].

Interesting results were obtained in a kinetic study of reaction (2): $H + RH \rightarrow H_2 + R$ (Table 7 and Figs. 7 and 8). The rate of reaction and the concentration of hydrogen atoms (in the gas phase) were in all cases measured by EPR. The majority of kinetic data refer to substances adsorbed in a thin layer (not more than 5–10 μmole m^{-2}) on aerosil with a specific surface of 200 m^2 g^{-1}.

The principal characteristic feature of the low-temperature reaction $H + RH \rightarrow H_2 + R$ is the absence of a linear dependence of $\lg k_2$ on $1/T$. The plot of $\lg k_2$ against $1/T$ is a concave curve[14,15,28], i.e. the rate constant diminishes much more slowly than would follow from the Arrhenius law as the temperature is reduced. The concave shape of the curves is pronounced in those cases where it was possible to investigate the reaction over a comparatively wide range of temperatures, for example, for polyisobutylene (Fig. 7*a*) and malonic acid (Fig. 8, curve *1*).

The rate constants for reactions at a low temperature are high [thus the values of k_2 at 77 K for n-hexadecane, poly(methyl methacrylate) and polyisobutylene are in the range 10^{-21}–10^{-20} cm^3 s^{-1}] and exceed by many orders of magnitude the values which would be expected if the Arrhenius law held. Fig. 8 compares the rate constants for the reactions of atomic hydrogen with the methylene groups of n-hexadecane (solid phase, 77–188 K) and n-butane (gas phase, 300–500 K).

The plot shows that the rate constant for the reaction at 77 K exceeds the extrapolated value by ten orders of magnitude. At 77–120 K the reaction rate is almost independent of temperature. The effective activation energy in this temperature range is < 1 kcal mole^{-1}.

3. Isotope Effects in Reactions (1) and (2)

As mentioned at the beginning of Section III, the ratio of the rate constants for the addition of atomic hydrogen in the two possible positions relative to the $\rangle C=C \langle$ double bond [reactions (1) and (1′)] depends on the nature of the substituents at the carbon atoms (Table 3). The ratio increases when the olefin is acted upon by atomic deuterium; under these conditions, the greater the ratio k_1/k_1', the greater the isotope effect (Table 8)[37]. It has been established[37] that, when atomic hydrogen reacts with propene and deuteropropene, the relative rates of reactions (1) and (1′) are the same, i.e. there is no isotope effect.

Table 8. The isotope effects in reactions involving the addition of hydrogen and deuterium atoms to olefins[37] (k_1 and k_1' are the rate constants for the addition of hydrogen or deuterium atoms to carbon atoms shown to the left and to the right of the double bond respectively).

Olefin	T, K	$(k_1/k_1')_H$	$(k_1/k_1')_D$	$\frac{(k_1/k_1')_D}{(k_1/k_1')_H}$
$CH_2=CH-CH_3$ or $CD_2=CD-CD_3$	90	126	398	3.1
	77	167	575	3.4
$CH_3-CH=CH-CH_2-CH_3$ (cis)	90	1.48	1.46	1.0
$CH_3-CH=C(CH_3)_2$	77	115	234	2.0
	90	115	233	2.0
	113	102	155	1.5
	143	53	75	1.4

The rate of the reaction $H + RH \rightarrow H_2 + R$ hardly changes when hydrogen atoms are replaced by deuterium[77]. The rate constants for the reactions in these two instances are plotted in Fig. 7*a*. Evidently all the points lie on a single curve. On the other hand, the rate of the hydrogen atom transfer reaction is very sensitive to isotope substitution in the structure of the reacting molecule[28,77]. Fig. 9 presents data for the kinetic isotope effects in the reactions of atomic hydrogen with poly(methyl methacrylate) and deuteropoly(methyl methacrylate) (all the hydrogen atoms have been replaced by deuterium atoms and the deuterium content in the isotope-substituted position is 98.9%). The measured isotope effects (curve *1*) are compared with the values calculated from the equation $k_H/k_D \simeq \exp(0.15\, h\nu_{C\text{-}H}/kT)$ (Here $\nu_{C\text{-}H} = 9 \times 10^{13}$ s^{-1} is the stretching vibration frequency of the C–H bonds, h the Planck constant, and k the Boltzmann constant)[78]. Fig. 9 shows that the experimental values exceed the calculated data over the entire temperature range (165–300 K), the discrepancy increasing at low temperatures. The calculated isotope effect at 165 K is 45, while the experimental value is $\geqslant 260$.

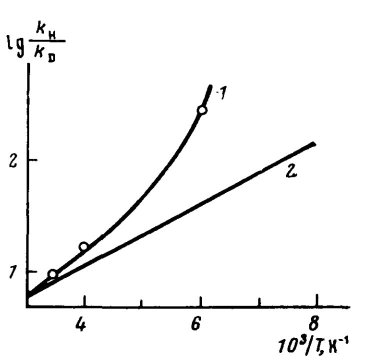

Figure 9. Temperature dependence of the isotope effect k_H/k_D for the reactions of hydrogen atoms with poly(methyl methacrylate) and deuteropoly(methyl methacrylate)[28]: 1) experimental values; 2) linear plot based on calculated values (see text).

Thus kinetic isotope effects of two types were observed—those associated with the replacement of (1) atomic hydrogen by atomic deuterium and (2) of H atoms by D atoms in the structure of the reacting molecule. Isotope effects of the first type are characteristic of addition reactions where the second effect is absent, while the situation is reversed in hydrogen atom transfer reactions.

IV. QUANTUM-MECHANICAL EFFECTS IN LOW-TEMPERATURE REACTIONS

The possible role of the tunnel effect in chemical kinetics has been frequently discussed theoretically[79-82]. It has been shown experimentally that tunnelling must be taken into account in a whole series of reactions involving electron transfer (oxidation-reduction reactions and radiation-chemical and photochemical processes). The mass of the hydrogen atom exceeds that of the electron by a factor of 1841, which reduces sharply the probability of the passage of H through the barrier. For this reason, the tunnel effect in reactions involving the transfer of a proton or a hydrogen atom can be manifested distinctly only at low temperatures. A number of kinetic consequences arise from the possible tunnel migration of a hydrogen atom through the barrier: deviations from the Arrhenius law, extremely large isotope effects when the H atom in the structure of the reacting molecule is replaced by a D or T atom (k_H/k_D or k_H/k_T), a nonlinear relation between $\lg(k_H/k_D)$ and $1/T$, etc. These facts were established in a study of the interaction of hydrogen atoms with solid organic substances at low temperatures, namely $H + RH \rightarrow H_2 + R$. The tunnel mechanism of this reaction is confirmed by calculations of the dependence of the reaction rate constant on temperature, taking into account the passage through the barrier.

The reaction rate constant can be represented in the usual Arrhenius form:

$$k = A\gamma \exp(-V/RT), \tag{32}$$

where V is the height of the potential barrier in the reaction, A the pre-exponential factor, and $\gamma = w_{qu}/w_{cl}$ the correction for tunnelling or the "tunnel" correction (w_{qu} and w_{cl} are the "quantum" and "classical" reaction rates).

An exact calculation of the "tunnel" correction is impossible without knowing the potential surface for the reaction. Simplified models are used in approximate calculations. It is assumed to a rough approximation[79,82] that the activation barrier is one-dimensional and that the system is in thermal equilibrium. For such a system, we have:

$$\gamma = \exp\frac{V}{kT}\int_0^\infty \frac{1}{kT}\, G(W)\exp\left(-\frac{W}{kT}\right)\mathrm{d}W, \tag{33}$$

where W is the energy of the reacting species, $G(W)$ the probability of the tunnel reaction or the permeability of the barrier, which depends only on its width and height when its shape is specified, and k is the Boltzmann constant.

The experimental data for the reaction $H + RH \rightarrow H_2 + R$ at low temperatures agree satisfactorily with the results of the calculation carried out in accordance with this model[13,15,83]. In the calculations the barrier was assumed to have the parabolic shape; Bell[80] obtained an exact solution of the integral Eqn. (33) for such a barrier:

$$\gamma = \frac{e^{\alpha}}{\beta-\alpha}\left(\beta e^{-\alpha} - \alpha e^{-\beta}\right). \tag{34}$$

Here

$$\alpha = V/kT,\ \beta = \frac{2\pi^2}{h} d \cdot (2mV)^{1/2},$$

where d is the effective half-width of the barrier, m the reduced mass of the tunnelling species, and h the Planck constant.

The rate constants calculated for the reactions involving malonic acid and n-hexadecane (continuous curves) are compared in Fig. 8 with the measured values (designated by circles). The parameters of the barrier and the pre-exponential factors used in the calculation are listed in Table 9. It is striking that the rate constants for the reactions involving n-butane and n-hexadecane (per methylene group) fit on a single smooth $\lg k - 1/T$ curve, which satisfies the parameters listed in Table 9 for the reaction

$$H + C_nH_{2n+2} \rightarrow H_2 + C_nH_{2n+1}.$$

Thus the temperature dependence of the rate of this reaction may be accounted for over a very wide range (100–1000 K) on the assumption that the potential surface for the reaction remains unchanged on passing from the gas phase (330–1000 K) to the solid phase (100–173 K) and that the deviation from the Arrhenius law is due to the tunnel mechanism of the reaction at a low temperature.

Table 9 also presents the parameters of the activation barrier for a number of other reactions for which the appropriate calculations have been made[83]. In all cases the calculated and experimental results agreed satisfactorily. The effective half-widths of the barriers in these reactions are in the range 0.5–0.65 Å (Table 9) and are comparable with the values calculated by Caldin[82] for proton transfer in the liquid phase.

Table 9. Certain parameters adopted in the calculation of the "tunnel" correction (parabolic barrier)[83].

Reaction	T, K	V, kcal mole^{-1}	d, Å	A, cm^3 s^{-1}
$\dot{H} + -(CH_3)_2C-CH_2-C(CH_3)_2- \rightarrow H_2 + -(CH_3)_2C-\dot{C}H-C(CH_3)_2-$	100—180	6.0	0.65	$5\cdot10^{-11}$
$\dot{H} + -CH_2CH_2O- \rightarrow H_2 + -CH_2\dot{C}HO-$	100—150	6.7	0,57	$5\cdot10^{-11}$
$\dot{H} + C_nH_{2n+2} \rightarrow H_2 + C_nH_{2n+1}$	100—1000	7.0	0.58	$3\cdot10^{-11}$
$\dot{H} + CH_2(COOH)_2 \rightarrow H_2 + \dot{C}H(COOH)_2$	100—250	6.1	0.51	10^{-14}

Thus calculations carried out in terms of a rough approximation showed that the rate constants for the reaction $H + RH \rightarrow H_2 + R$ and the form of the temperature dependence of lg k_2 can be satisfactorily explained on the assumption of tunnelling.

Calculations of the ratios k_1/k_1' for the addition of atomic hydrogen to olefins have been carried out taking into account tunnelling (Table 8).[37] It was assumed in these calculations that the addition to two carbon atoms can be described by two one-dimensional barriers, taking into account the asymmetry of the barriers. The parameters of each barrier were varied as follows: the height from 1.2 to 4.5 kcal mole^{-1} and the effective half-width from 0.25 to 0.75 Å. The authors[37] were unable to achieve the agreement of all the experimental k_1/k_1' ratios at different temperatures with the calculated values whatever the combination of the quantities characterising the height and width of the barrier (the calculations were performed for rectangular and Eckart forms of the barrier). Nevertheless one may agree with the authors' conclusions that tunnelling is the only mechanism which permits an explanation of the isotope effects observed in the addition reaction. The discrepancies between the experimental and calculated values are probably associated with the fact that the one-dimensional barrier model is relatively unsuitable for the description of the reaction in the present instance.

V. REACTIONS OF FREE RADICALS WITH HYDROGEN ATOMS AND WITH ONE ANOTHER AT A LOW TEMPERATURE

Hydrogen atoms react with free radicals at a low temperature via recombination [reaction (3)] and disproportionation [reaction (4)] mechanisms. The elementary constants k_3 and k_4 for low-molecular-weight free radicals have not been measured, but attempts have been made[22,24] to estimate the ratios of these constants for certain systems. The few available data for reactions of the type R + H are summarised in Table 10, which shows that the disproportionation reaction predominates for alkyl radicals at a low temperature. This conclusion applies also to isotope-substituted radicals, without hydrogen atoms, such as C_3D_6T.

The overall rate constants for the reaction with atomic hydrogen ($k_3 + k_4$) were measured in the range 77–220 K for polymeric free radicals of different structures[28]. To a first approximation, the temperature dependence of $k_3 + k_4$ obeys the Arrhenius law. The activation energies for the reactions are in the range 0.4–0.9 kcal mole^{-1} and the pre-exponential factors are in the range $10^{-14.3}$–$10^{-15.6}$ cm^3 s^{-1} (Table 11), i.e. are smaller by 2–4 orders of magnitude than the collision numbers Z for the systems investigated ($Z \simeq 10^{-11}$ cm^3 s^{-1}).

Table 10. The ratios of the rate constants for the disproportionation and recombination reactions.

Reactions	T, K	k_4/k_3	References
$H + s\text{-}C_4H_9$	90	1.9	22
$T + iso\text{-}C_3H_6T$	63	3,55	24
$T + C_3D_6T$	63	3,05	24

Table 11. Parameters of the Arrhenius equation for the reaction between R(ROO) and atomic hydrogen[28,29].

Polymeric free radicals	Temp. range, K	E, kcal mole^{-1}	$-\lg A$ (cm^3 s^{-1})
$-C(CH_3)_2-\dot{C}H-C(CH_3)_2-$	77—163	0.4	~15.6
$-C(CH_3)(COOCH_3)-\dot{C}H-C(CH_3)(COOCH_3)-$	96—203	0.9±0.3	14.7±0.3
$-CH_2-\dot{C}(COOH_3)-CH_2-$	77—223	0,5±0.2	15.5±0.3
$-CH_2-\dot{C}(CH_3)-CH_2-$	96—173	0.5±0.3	14.4±0.5
$-CH_2-C(C_6H_5)-CH_2-$	77—163	0,8±0,1	14.3±0.3
ROO· poly(vinyl acetate)	113—173	1.2±0,1	14,8±0.1

These values were obtained from the analysis of kinetic curves for the accumulation of free radicals, which does not allow the separate determination of k_3 and k_4. In order to discover which reaction predominates—recombination or disproportionation—additional measurements are necessary using other methods (analysis of molecular products, the study of the deuterium-hydrogen exchange, monitoring of the pressure variation, etc.). It has been possible to establish for polystyrene[29] that free radicals (of the cyclohexadienyl type) interact with hydrogen atoms (at 123–163 K) via a recombination mechanism, which leads to partial hydrogenation of the aromatic rings. Presumably this reaction is the cause of the appearance of cyclohexadiene rings, which were detected by infrared spectroscopy in polystyrene irradiated by fast electrons[84].

The free radicals arising as a result of reactions (1) and (2) can react not only with hydrogen atoms but also with one another. The rate of reaction of the radicals in the solid phase is usually limited by their mobility. The kinetics and mechanism of the destruction of free radicals in the solid phase constitute an independent problem and numerous studies have been devoted to it. We shall consider only the question of the relative rates of the reactions leading to the destruction of free radicals when they interact with one another: the recombination [reaction (5)] and disproportionation [reaction (6)] reactions. The ratios k_{disp}/k_{rec} (k_6/k_5) for the free radicals formed when solid organic compounds are acted upon by hydrogen or tritium atoms are listed in Table 12, which also includes the values for the free radicals obtained by other methods. Analysis of these data reveals the following fundamental features.

(1) The ratio k_{disp}/k_{rec} depends on the structure of the radicals. For primary alkyl radicals (methyl–ethyl, ethyl–ethyl), the ratio is small and amounts to 0.2–0.3 at 80–90 K, i.e. the recombination reaction predominates. For secondary radicals (isopropyl, s-butyl, s-pentyl, cyclohexyl), the ratio k_{disp}/k_{rec} increases and is in the range 2–11 according to different data. The difference between the relative rates of disproportionation and recombination is even greater for tertiary butyl and pentyl radicals. The disproportionation reaction is virtually the only pathway to the destruction of these radicals at a low temperature.

Table 12. The ratios of the rate constants for the disproportionation and recombination reactions in the solid-phase interaction of certain free radicals with one another.

[a] The free radicals were generated by exposing the corresponding olefin or diene to hydrogen or tritium atoms; in the instances denoted by asterisks the free radicals were obtained by the photodecomposition of azo-compounds.

In contrast to alkyl radicals, allyl radicals are destroyed exclusively via a recombination mechanism (Table 12).

(2) The ratio k_{disp}/k_{rec} is sensitive to the nature of the matrix in which the free radicals are present. The physical state of the substance in which the radicals are distributed plays an important role under these conditions. Thus the ratios and the rates of recombination and disproportionation are different in vitreous and crystalline matrices[92].

(3) The ratio k_{disp}/k_{rec} increases as the temperature is reduced, which indicates a higher activation energy for the recombination reaction than for the disproportionation reaction. It follows from the data in Table 12 that the difference $E_{rec} - E_{disp}$ usually amounts to several hundreds of cal mole^{-1}.

Similar features, albeit not quite so pronounced, are also observed for the reactions of free radicals with one another in the liquid phase[93,94]. The ratio k_{disp}/k_{rec} also depends in this case on the structure of the reacting radicals and on the type of solvent, increasing as the temperature is reduced.

Thus fairly extensive experimental data concerning the nature of the interaction of free radicals with one another in the solid phase, analysis of which is useful in the study of the mechanisms of solid-phase reactions and for the elucidation of the structure of the transition complex in recombination and disproportionation reactions, have now accumulated. It has been suggested at one time that these two reactions have a common transition complex, which aroused controversy and stimulated a number of investigations[94]. The dependence of k_{disp}/k_{rec} on the nature of the matrix and temperature (Table 12) shows that the hypothesis of two types of transition complex is more correct. This problem is discussed in greater detail in a special review[94].

VI. DIFFUSION AND RECOMBINATION OF HYDROGEN ATOMS IN SURFACE LAYERS

Data on the diffusion, solubility, adsorption, and recombination of hydrogen atoms in solid organic substances are important for understanding the mechanism of the interaction of gaseous atomic hydrogen with such substances. Unfortunately there is almost no information of this kind, mainly owing to the lack of direct methods of measurement. For this reason, this last section represents merely an attempt at a compilation in one place of the scattered values which are sometimes rough estimates based on indirect data.

Table 13. The diffusion coefficients D and rate constants for the recombination of hydrogen atoms (k_7) in frozen hydrocarbons at 77 K.

Hydrocarbon	D, cm^2 s^{-1}	k_7, cm^3 s^{-1}
Propene	$3\cdot10^{-7}$ (27)	$2\cdot10^{-14}$
Propane	$2\cdot10^{-4}$	$\sim10^{-11}$
n-Butane	$5\cdot10^{-4}$ (9)	$3\cdot10^{-11}$
Isobutene	$2\cdot10^{-8}$ (8)	$1\cdot10^{-10}$ ($2\cdot10^{-12}$ (8))

Note. Figures in round brackets denote references (Ed. of translation).

The diffusion coefficients of hydrogen atoms in certain frozen hydrocarbons are listed in Table 13. The estimates of D are based on the H-diffusion model where no account was taken of the mobilities of other reacting species (see Section II), so that the tabulated values do not correspond entirely to real systems.

The recombination rate constants k_7 for hydrogen atoms in a layer of frozen hydrocarbon (Table 13) were calculated on the hypothesis that each collision leads to interaction and that the rate of reaction (7) is limited by the diffusion of hydrogen atoms. Then

$$k_7(\mathrm{cm^3\,s^{-1}}) = 4\pi\rho D\,, \tag{35}$$

where ρ is the collision radius of the hydrogen atom, assumed to be 0.5 Å in the calculations.

Table 13 also lists the value $k_7 = 2 \times 10^{-12}$ proposed for isobutene[8].

The values of D and k_7 for propane were estimated from calorimetric measurements[3,27]. The heat evolved in a layer of propane amounts to 6% of that evolved in a layer of propene with the same thickness. Assuming that the evolution of heat is caused in the first case by hydrogenation and in the second by reaction (7) (as will be shown below, this is apparently true), one can write

$$w_7/w_{\mathrm{hydr}} = 0.06\ Q_{\mathrm{hydr}}/Q_7 = 0{,}08$$

where w_7 and Q_7 are the rate and heat of recombination of hydrogen atoms in propane and w_{hydr} and Q_{hydr} are the rate and heat of hydrogenation of propene. Under the experimental conditions, we have

$$w_{\mathrm{hydr}} \simeq 2k_1[\mathrm{H}][\mathrm{C_3H_8}],\ w_7 = k_7[\mathrm{H}]^2.$$

Hence

$$k_7 \sim \frac{2k_1[\mathrm{C_3H_8}]}{[\mathrm{H}]} \cdot \frac{w_7}{w_{\mathrm{hydr}}} \simeq \frac{2k_1[\mathrm{C_3H_8}]}{[\mathrm{H}]} \cdot 0{.}08 \simeq \frac{0{,}16k_1[\mathrm{C_3H_8}]}{[\mathrm{H}]}\,.$$

When $[\mathrm{H}] = 10^{14}$ cm^{-3}, we have $k_7 \simeq 10^{-11}$ cm^3 s^{-1}.

D for propane, calculated by Eqn. (35), is 2×10^{-4} cm^2 s^{-1} and is close to the diffusion coefficient in n-butane.

We shall now trace the fate of hydrogen atoms in a solid reacting substance. The destruction of hydrogen atoms is possible in the course of reactions (1)–(4) and (7). We shall denote by w_{add} the rate of destruction of hydrogen atoms as a result of the chemical reaction with an unsaturated compound M and by w_{abs} the rate of destruction due to the reaction with a saturated compound RH. At a steady-state concentration of free radicals, we have

$$w_{\mathrm{add}} \simeq 2k_1[\mathrm{H}][\mathrm{M}],\ w_{\mathrm{abs}} \simeq 2k_2[\mathrm{H}][\mathrm{RH}].$$

Then

$$w_7/w_{\mathrm{add}} = \frac{k_7[\mathrm{H}]}{2k_1[\mathrm{M}]}\ \text{and}\ w_7/w_{\mathrm{abs}} = \frac{k_7[\mathrm{H}]}{2k_2[\mathrm{RH}]}\,.$$

Thus the ratio of the rates of the corresponding processes is determined by the constants k_7 and k_1 (k_2) and the concentration of atomic hydrogen in the layer of the reacting substance. For frozen olefins (propene, isobutene), k_7(77 K) = 10^{-12} cm^3 s^{-1}, which is probably close to the real value. The constant $k_1 \simeq 10^{-18}$ cm^3 s^{-1} (Table 6). Hence $w_7/w_{\mathrm{add}} \simeq 10^{-16}[\mathrm{H}]$. Since $[\mathrm{H}] \leqslant 10^{14}$ cm^{-3} under the experimental conditions, it follows that $w_7 \simeq 10^{-2} w_{\mathrm{add}}$, i.e. hydrogen atoms are destroyed preferentially as a result of the hydrogenation of the olefin.

For the hydrogen atom transfer reaction $\mathrm{H + RH \rightarrow H_2 + R}$ (polyisobutylene), k_2(77 K) = 5×10^{-21} cm^3 s^{-1}. If the value of k_7 is the same as in the previous example, then $w_7/w_{\mathrm{abs}} = 10^{-14}[\mathrm{H}]$. Hence we obtain $w_7 \simeq w_{\mathrm{abs}}$ for $[\mathrm{H}] = 10^{14}$ cm^{-3} and $w_7 < w_{\mathrm{abs}}$ for $[\mathrm{H}] < 10^{14}$ cm^{-3}. Thus under the real experimental conditions the rate of recombination of hydrogen atoms in polyisobutylene at 77 K is comparable to the rate of their destruction via chemical interaction with the polymer. At low concentrations of atomic hydrogen, the destruction of radical species in reactions (2)–(4) predominates.

The heterogeneous recombination of hydrogen atoms on the surfaces of certain organoelemental polymers has been studied in a number of investigations[5,95,101,102]. The rate of destruction of atoms on any surface is characterised by the probability of recombination ϵ, which is defined as the ratio of the rate of heterogeneous recombination to the frequency of the impacts by atoms on the surface. It is usually believed[5] that the rate of recombination of hydrogen atoms on the surfaces of polymeric films obeys (as for Pyrex) first-order kinetics, but this conclusion requires further confirmation and ϵ may depend on the concentration of atomic hydrogen in the gas phase. The probabilities of the recombination of atomic hydrogen on the surfaces of certain polymers at room temperature are listed below:

Polymer	ε	Literature
Polytetrafluoroethylene	10^{-4}	95
	$\sim 10^{-6}$	101
Polychlorotrifluoroethylene	$4 \cdot 10^{-4}$	95
Chloromethylsilane polycondensation products (Drifilm)	$4 \cdot 10^{-4}$	95
	$2 \cdot 10^{-5}$	102

The rate of hydrogenation of propene hardly changes when it is coated by a thin film of propane[1,3,27], which indicates a low rate of recombination of hydrogen atoms in the propane layer. According to Ponomarev's estimate[27], the probability of the recombination of atomic hydrogen on the surface of propane (at 77 K) is 6×10^{-5}.

There are no other more detailed literature data for the rates and mechanisms of the recombination of hydrogen atoms on the surfaces of solid organic substances. We believe that research on the heterogeneous recombination of atomic hydrogen at low temperatures, where its rate still depends on the heat of the physical adsorption of hydrogen atoms on the surface of the substance, is urgently required. One may hope that such research will make it possible to estimate the heats of adsorption of various compounds and to approach more closely the mechanisms of the chemical reactions of atomic hydrogen with solid organic substances.

VII. CONCLUSION

The interaction of thermal hydrogen atoms with a wide range of solid organic substances has been investigated. The mechanisms of the reactions leading to the formation of free radicals have been unambiguously established for the vast majority of the compounds. The mode of these reactions is determined by the chemical structure of the reactant and is as a rule the same in the gas and liquid phases. However, in those cases where there is a possibility of two or more reaction pathways, the low-temperature reaction in the solid phase proceeds via the pathway which requires the lowest activation energy. For example, the main pathway in the reaction of atomic hydrogen with toluene at 113 K involves addition to the aromatic ring[49]: $\mathrm{H + C_6H_5CH_3 \rightarrow C_6H_6CH_3}$, whereas in the gas phase at high temperatures hydrogen atoms are abstracted from the methyl group[96] and the reaction $\mathrm{H + C_6H_5CH_3 \rightarrow C_6H_6 + CH_3}$ takes place[97].

The ratio of the rate constants for the addition of hydrogen atoms in two different positions relative to the double bond of the olefin increases as the temperature is reduced. Thus the ratio for propene increases from 21 (300 K, gas phase) to 189 (63 K, solid phase)[37]. These two examples therefore show that the reactions are more selective at a low temperature.

The specific features of the solid phase and low temperatures affect the kinetics of the individual stages of the interaction of atomic hydrogen with solids; they are manifested in two ways. On the one hand, the mechanism of the chemical reactions is simplified, since many secondary free-radical processes occurring in the gas phase do not take place in the solid phase at fairly low temperatures owing to the limited mobility of the molecules and free radicals. Furthermore, vibrationally excited species are formed in the gas phase, while the solid phase promotes their effective deactivation. For this reason, reactions involving the decomposition of excited species as well as possible reactions of hot radicals[5,61,98,99] are ruled out when the kinetics of solid-phase processes are considered.

On the other hand, the occurrence of the reactions in the solid phase and at low temperatures complicates the determination of their elementary rate constants. Under these conditions, the process kinetics depend on the rates of a number of physical stages, primarily diffusion, adsorption, and the dissolution of hydrogen atoms in the solid substance. In a more detailed approach one must take into account also the molecular motions in the solid phase; translation, rotations, etc.

The kinetic data obtained hitherto make it possible to infer the rate of interaction of hydrogen atoms with solid organic compounds as a whole and the rates of its individual stages. The kinetics of the reactions of atomic hydrogen at a low temperature are characterised by specific features associated with the manifestation of quantum effects. At low temperatures below a critical value T_{cr}, the rate of the reactions via the tunnel mechanism exceeds by a large factor the rate of the classical Arrhenius reaction. T_{cr} is proportional to the square root of the height of the potential barrier[79], so that at $T > 77$ K the tunnel effect is manifested most distinctly by reactions with large activation energies—the hydrogen atom transfer reactions. The following characteristics, which are the kinetic consequences of the transfer of a hydrogen atom via the tunnel mechanism, have been established for the $\mathrm{H} + \mathrm{HR} \rightarrow \mathrm{H_2} + \mathrm{R}$ reaction at 77–220 K: high rate constants at 80–100 K (10^{-19}–10^{-22} cm^3 s^{-1}), low effective activation energies at these temperatures ($<$ 1 kcal mole^{-1}), failure to obey the Arrhenius law, extremely large kinetic isotope effect when RH is replaced by RD, and a non-linear dependence of $\lg(k_{\mathrm{H}}/k_{\mathrm{D}})$ on $1/T$. One should note that the deviation from the Arrhenius law, due to the effect of the tunnel transfer of a hydrogen atom on the rate of the given reaction, is observed also at higher temperatures in the gas phase. However, the deviation at high temperatures is insignificant and can be observed only when kinetic data are analysed over an extended temperature range (300–1800 K)[100]. At a low temperature, the $\lg k - 1/T$ curves are distinctly concave (Figs. 7 and 8).

For reactions of atomic hydrogen with unsaturated compounds, the ratio of the rate constants for addition in two possible positions relative to the double bond of the olefin increases when hydrogen atoms are replaced by deuterium atoms. This isotope effect also indicates a tunnel mechanism of the addition reaction at a low temperature. Other kinetic manifestations of tunnelling, analogous to those described above, for hydrogen atom transfer reactions are to be expected at temperatures below 77 K, because the activation energy and hence also T_{cr} are lower for the addition reactions.

The studies of the kinetics of the interaction of atomic hydrogen with solid organic substances have established certain facts, which indicate a specific character of the chemical process in the solid phase. Thus the pre-exponential factor in the Arrhenius equation for reactions involving the addition of hydrogen atoms to unsaturated compounds (propene, polystyrene) and H + R reactions are smaller by 3 – 4 orders of magnitude than the collision number. Interesting data have been obtained concerning the pathways in the reactions of alkyl radicals with one another. Although recombination is energetically more favourable than disproportionation, alkyl radicals are destroyed in the solid phase mainly via a disproportionation mechanism and the ratio $k_{\text{disp}}/k_{\text{rec}}$ depends very markedly on the structure of the matrix.

After the manuscript had been sent to the printers, Ovchinnikova[103] published a study, in which the probabilities of tunnelling in the reaction $\mathrm{H} + \mathrm{H} - \overset{|}{\underset{|}{\mathrm{C}}} - \rightarrow \mathrm{H_2} + \overset{|}{\underset{|}{\dot{\mathrm{C}}}}-$ were calculated for a three-dimensional barrier. The exact quantum-mechanical solution of the problem was replaced by approximate calculations based on the classical S-matrix method. Comparison of the tunnelling probabilities for vibrational-adiabatic one-dimensional and three-dimensional barriers established that non-adiabatic effects significantly increase the probability of the tunnel reaction. Parameters of the model were selected for which the experimental data[28] (the dependence of the rate constant for the hydrogen transfer reaction on temperature and the isotope effects) agree with the results of the calculation.

The α-Effect in the Chemistry of Organic Compounds

A.P.Grekov and V.Ya.Veselov

The anomalously high reactivity of compounds with one or several lone electron pairs at the atom adjoining the reaction centre (the α-effect) is discussed in relation to reactions involving nucleophilic substitution at the carbon atom in various valence states. The manifestation of the α-effect is noted for nucleophilic addition to a carbon atom; other examples of the α-effect in the chemistry of organic compounds are quoted. The possible causes of the effect are discussed, and a quantitative estimate of the latter is made.
The bibliography includes 234 references.

I. INTRODUCTION

The report[1] describing the manifestation of the α-effect was published in 1955, but 1962, when Edwards and Pearson[2] first introduced the term "α-effect" and formulated its general characteristics, must be regarded as the date when research on this phenomenon began.

The α-effect is the term given to the anomalously high nucleophilic reactivity of many compounds having one or more pairs of lone electrons at an atom adjoining (i.e. in the α-position) a nucleophilic centre. Such compounds are hydrazine and its derivatives, hydroxylamine, hydroxamic acids, peroxide anions, the hypochlorite ion, etc. Epstein et al.[3] suggested that substances of this type can be referred to as α-nucleophiles and they are sometimes referred to in the literature as hypernucleophiles[4]. The α-effect is manifested as an appreciable positive deviation from the relation described by the Brønsted equation[5-7]:

$$\lg k = \beta\,pK + C\ .$$

The α-effect continues to attract the unflagging interest of chemists. The lack of a clear-cut understanding of the source of the high reactivity of α-nucleophiles led to numerous studies of reactions of different types, including reactions involving unsaturated and saturated carbon atoms[14-17]. The manifestation of the α-effect at nitrogen, phosphorus, sulphur, and peroxide oxygen atoms is being vigorously investigated[13,17-20]. A few years ago two reviews devoted to the α-effect were published[12,13], but they suffer from significant deficiencies: firstly, the numerous examples of the manifestation of the α-effect in organic chemistry are insufficiently covered, and, secondly, the reviews are somewhat obsolete, difficult to get hold of, and do not include the work of Soviet investigators.

The aim of the present review is to give a systematic account of the experimental observations of the α-effect in various processes in the chemistry of organic compounds, to discuss the possible causes of its manifestation, and to estimate it quantitatively. The review covers the literature up to 1976, that for 1977 is only partly included.

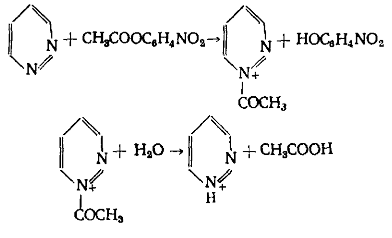
II. MANIFESTATION OF THE α-EFFECT IN THE CHEMISTRY OF ORGANIC COMPOUNDS

1. Nucleophilic Substitution Reactions at a Carbonyl Carbon Atom

Extensive data confirming the manifestation of the α-effect involving nucleophilic substitution reactions at a carbonyl carbon atom have now accumulated. In the reactions discussed below the α-effect has been studied in greatest detail.

(a) Reactions with carboxylate esters. Reactions involving the nucleophilic substitution of carboxylate esters by nucleophiles of different types have been investigated in fair detail; considerable factual data have accumulated concerning the manifestation of the α-effect, particularly in reactions with participation of aryl acetate esters[5,16,17,20-23]. Oximate anions[24] and hydroxamic[26-28] and *trans*-cinnamohydroxamic acid[29] exhibit an anomalously high reactivity in their reactions with 4-nitrophenyl acetate. The α-effect has also been observed in the reactions of 4-nitrophenyl thioloacetate with hydrazine in acetonitrile[30]. Analogous high reactivities have been noted in the interaction of benzohydroxamic acids and their *N*-methyl-substituted derivatives with phenyl acetate in 12% aqueous ethanol[31]. The ClO^- anion reacts with 4-nitrophenyl acetate twice as fast as the hydroxide ion, despite the fact that the latter is 10^9 times more reactive[16].

An anomalous reactivity is shown by certain heteroaromatic nitrogen-containing nucleophiles (pyridazine, phthalazine, and quinoline)[24,32]. Pyridine bases and diazines react with 4-nitrophenol acetate via a mechanism involving nucleophilic catalysis, which consists in the addition of a nucleophile to the substrate with formation of the *N*-acyl intermediate, which then rapidly hydrolyses[33,34]:



.

In contrast to pyrazine, pyrimidine, and thiazole, pyridazine and isothiazole exhibit the α-effect in the interaction with 2,4-dinitrophenyl acetate[24,32]. The high reactivity of benzohydroxamic acids in reactions with 4-nitrophenyl benzoate and 4-nitrophenyl-4-nitrobenzoate has been demonstrated[35]. The α-effect has been noted in the hydrazinolysis and hydroxylaminolysis of the esters 8-acetoxyquinoline, 6-acetoxyquinoline, and 4-(2-acetoxyphenyl)imidazole[27].

In contrast to the aminolysis of esters[5,11,16,17,21], the reactions of hydrazine derivatives with arenecarboxylate esters are characterised by the absence of a catalytic effect both by a second molecule of the hydrazine derivative and by the reaction products[36-38]. The interaction of hydrazine derivatives with esters is greatly accelerated in the presence of small amounts of added carboxylic acids, amides, and tertiary amines; the rate constants for the reactions are linearly related to the catalyst concentration[37-40].

Table 1. The rate constants *k* (mole litre^{-1} s^{-1}) for the reactions of nucleophiles with chloroformates (in benzene at 25° C)[47-53].

Nucleophile	p*K*	Ethyl chloroformate	Phenyl chloroformate
$C_6H_5NH_2$	4.60	0.00374	0.183
$C_6H_5NHNH_2$	5.27	0.175	3.36
$C_6H_5N(C_2H_5)NH_2$	—	—	0.172
$C_6H_5CONHNH_2$	3.05	0.0510	1.33
$C_6H_5CON(CH_3)NH_2$	—	0.00576	0.174
$C_6H_5CSNHNH_2$	5.50	0.00410	0.0749
$C_6H_5CSN(CH_3)NH_2$	7.35	0.000721	0.150
$C_6H_5OCONHNH_2$	2.92	0.00752	0.196
$CH_3CONHNH_2$	3.24	0.0235	0.679
4-$CH_3C_6H_4SO_2NHNH_2$	1.41	—	0.00529
4-$CH_3C_6H_4SO_2N(n\text{-}C_3H_7)NH_2$	1.35	—	0.00114
$(CH_3)_2C{=}NO^-$	12.40	8.35	—

(b) Reactions with carboxylic acid anhydrides and chlorides. The study of the kinetics of the reactions of aroylhydrazines with carboxylic acid anhydrides and chlorides in benzene has revealed a high nucleophilic reactivity of aroylhydrazines compared with amines of the same basicity[41-46]. The interaction of acylhydrazines with carboxylic acid anhydride is complicated by the autocatalytic influence of the carboxylic acids evolved during the reaction[42-44]. An exception is the reaction of butyrylhydrazine with succinic acid anhydride; the product of this reaction is quantitatively separated from the reaction mixture and has no catalytic effect[44].

Amidoximes, which are hydrazine derivatives, exhibit the α-effect in reactions with chloroformates (chlorocarbonic acid chlorides) (Table 1), whereas in the reactions of arylamines with chloroformates an anomalous enhancement of nucleophilic reactivity has not been observed[53,54]. The reactions of chloroformates with hydrazine derivatives follow second-order kinetic equations for irreversible processes; the rate constants calculated from these equations remain satisfactorily constant during the process and are independent of the concentrations of the initial reactants[51,52,55-57]. Sulphonic acid hydrazines show a high reactivity in reactions with acryloyl chloride[58].

Separate Brønsted relations have been established for α-nucleophiles (hydrazine, acetylhydrazine, semicarbazide, thiosemicarbazide, hydroxylamine, and methoxyamine), on the one hand, and amines which do not show the α-effect, on the other, in reactions of nitrogen-containing nucleophiles with carbon dioxide[59].

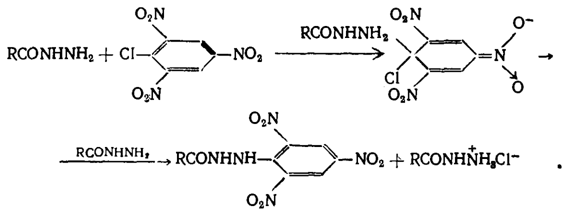
(c) Reactions with carboxylic acids. In the study of the kinetics of the reactions of hydrazine with glacial acetic acid at 25° C, Harris and Stone[60] established that the acylation of hydrazine is much faster than that of amines of similar basicity. The interaction of hydrazine and its substituted derivatives with certain carboxylic acids in oleum takes place via a series of transformations with formation of 2,5-disubstituted derivatives of 1,3,4-oxadiazole[61]; when hydrazine reacts with dibasic carboxylic acids in equimolar proportions, polyoxadiazoles are formed[62]. The condensation reactions of hydrazine and acylhydrazines take place satisfactorily only with aromatic carboxylic acids containing strong electron-accepting substituents (NO_2, COOH, etc.) in the ring[62,63]. The reaction with acids containing electron-donating groups is complicated by the sulphonation of the benzene ring by oleum[64,65].

In the condensation of acylhydrazines with carboxylic acids in *m*-cresol at 120–180° C the rate-determining stage is the slow formation of a cyclic complex between the reactants in the transition state, which decomposes with liberation of water and the formation of the corresponding acyl hydrazine[66-69]. The condensation of diacylhydrazines with dibasic acids takes place similarly and subsequently leads to the formation of polymers[64,65].

2. Nucleophilic Substitution Reactions at a Saturated Carbon Atom

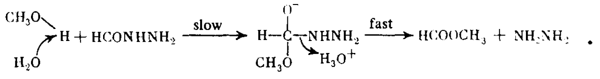
The first report of the α-effect in compounds with saturated carbon atoms is apparently that of Pearson and Edgington[14], who noted that benzyl bromide reacts with the HOO^- anion forty times faster than with HO^-. Benzyl bromide also exhibits a high reactivity in the reaction with neutral forms of amidoximes and *N*-methylhydroxamic acid[70]. The study of the reactivities of hydrazine, methoxyamine, and a number of different amines in relation to 1-halogeno-2,4-dinitrobenzenes in various solvents showed that hydrazine and methoxyamine exhibit small positive deviations from the Brønsted plot[71-74]. The halogen in 1-halogeno-2,4-dinitrobenzenes is quantitatively substituted by various amines, including α-nucleophiles; in terms of their reactivity, the halogens can be arranged in the sequence F > Cl > Br > I.[71-73] The reactivity of the hydrazine derivative diminishes with enhancement of the electron-accepting properties of the substituent. The same rule holds also in the reactions of picryl chloride with carboxylic and diarylphosphinic acid hydrazides[46,75].

The reactions of acylhydrazines with picryl chloride in benzene follow second-order kinetics. A mechanism has been proposed for the reactions involving the formation in the slow stage of an addition product (a quinonoid intermediate), which interacts with a second molecule of the initial hydrazine and is converted into the reaction product[76]:



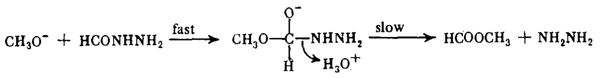
The absence of the α-effect in the reactions of hydrazine and hydroxylamine with alkyl iodides has been firmly established. However, the α-effect is manifested in the reaction of 1,8-naphthyridine with methyl iodide. In this case it is apparently necessary to take into account the geometrical disposition of the diamine heteroatoms (the nitrogen atoms with lone electron pairs are in the *peri*-positions) as a possible cause of the anomalous nucleophilic reactivity of 1,8-naphthyridine[32].

Formylhydrazine is more reactive in methanolysis than amides, which do not exhibit the α-effect[77]. At pH ≤ 5 methanolysis consists in the interaction of the reactants with the rate-determining formation of a tetrahedral intermediate, which then decomposes with the preferential formation of an ester and an amine:



$$\underset{H_2O}{\overset{CH_3O}{H}} + HCONHNH_2 \xrightarrow{slow} H-\underset{CH_3O}{\overset{O^-}{C}}-\underset{\searrow H_3O^+}{NHNH_2} \xrightarrow{fast} HCOOCH_3 + NH_2NH_2 \;.$$

This reaction undergoes general base catalysis. At pH > 9 the methanolysis of formylhydrazine involves the rate-determining decomposition of the intermediate into the reaction products[77]:



$$CH_3O^- + HCONHNH_2 \xrightarrow{fast} CH_3O-\underset{H}{\overset{O^-}{C}}-\underset{\searrow H_3O^+}{NHNH_2} \xrightarrow{slow} HCOOCH_3 + NH_2NH_2 \;.$$

An appreciable α-effect has been noted in the reactions of Malachite Green (tetramethyl-4-diaminotriphenylmethane) with hydrazine, methoxyamine, and CN^- and HOO^- ions.

3. Nucleophilic Substitution Reactions at a Phosphorus Atom

Systematic studies on the reactions of phosphate esters have revealed the α-effect for ClO^- and HOO^- ions, hydrazine, and hydroxylamine[82-86]. Isoproyl methylphosphonofluoridate ("Sarin", nerve gas) reacts with the HOO^- ion fifty times faster than with the HO^- ion[86,87-90] despite the fact that their basicity constants differ by a factor of 10^4 (Table 2). It has been noted that hydrazine and hydroxylamine exhibit an anomalous reactivity in the reaction with methyl 4-nitrophenylphosphate[91-93], 4-nitrophenyl phosphate[94], and 2,4-dinitrophenyl methyl phosphate[84,85] anions. The high reactivity of the methyl 4-nitrophenyl phosphate anion in the reactions with hydroxylamine and its *N*-alkyl substituted derivatives supports the occurrence of *O*-substitution and for certain compounds there is a possibility of the formation of a hydrogen bond with the phosphoryl oxygen, which is confirmed by the disappearance of the isotope effect[93].

Hydroximates are nucleophiles with an unusual reactivity in reactions with organophosphorus compounds[86,87,95]. The reactivity of various hydroximates and oximates in reactions with certain organophosphorus anticholinesterases is much higher than has been suggested on the grounds of their basicities[86].

Table 2. The rate constants k (litre $mole^{-1}$ min^{-1}) for the reactions of certain nucleophiles with phosphate esters[85,86].

Nucleophile	p*K*	Zarin	Tetraethyl pyrophosphate	2,4-Dinitrophenyl methyl phosphate
HO^-	15.27	2000	21	0.0505
HOO^-	11.60	94000	2180	10.4
ClO^-	7.4	600	267	—
NH_2OH	6.2	2.6	26	0.053
$C_6H_5CH_2NHO^-$	8.8	1020	160	—

4. Nucleophilic Addition Reactions

(a) Reactions with isocyanates. Nucleophiles can be arranged in the following sequence in terms of the rates of their reactions with isocyanates[96]: $AlkNH_2 > ArNH_2 > AlkOH > s\text{-}AlkOH \simeq H_2O > ArOH > RSH > RCOOH$; the position of *N*-substituted hydroxylamines in this series has not been established. It is known that the compounds RNHOH (R = Alk or Ar) react readily with isocyanates via the nitrogen atom, but, with increase of the electronegativity of the substituent, a tendency appears towards simultaneous *N*- and *O*-addition; *N*-substituted hydroxylamines are much more reactive than the corresponding amines in reactions with isocyanates[97]. This is due to the repulsion of the lone electron pairs of the adjacent electronegative atoms in hydroxylamines.

Phenyl isocyanate reacts with hydrazine derivatives in accordance with the following equation[98-109]:

$$R{-}NHNH_2 + O{=}C{=}N{-}R' \rightarrow R{-}NHNHCONH{-}R',$$
$$R = Ar,\ ArCO,\ AlkCO,\ ArSO_2,\ (Ar)_2PO,\ \text{or}\ (Ar)_2PS,\ R'{=}Ar.$$

It has been established that neither the initial reactants nor the products (substituted semicarbazides) influence the rate of reaction of hydrazine derivatives with phenyl isocyanate. The influence of substituents of different electronic types on the reactivity of hydrazine derivatives in reactions with phenyl isocyanate is described by the Hammett–Taft equation. In reactions of phenyl isocyanate with aliphatic acylhydrazines a separate correlation is observed for hydrocarbon groups and hydrogen, on the one hand, and the electronegative substituents, on the other, which is due to the different mechanisms of the effects of these substituents[99].

The enhanced reactivity of hydrazine derivatives in reactions with phenyl isocyanate (Table 3) is associated with the effect of the nitrogen atom of the imino-group adjoining the nucleophilic centre. It is believed that the α-effect in these reactions is due to the appreciable shift of the lone electron pair of the imino-nitrogen in the transition state and that an essential condition for the manifestation of the α-effect is the participation of the hydrogen atom of the imino-group in the formation of a hydrogen bond with the oxygen atom (or another electronegative atom) of the isocyanate[98-102,108]. The lower reactivity of hydrazine derivatives in reactions with phenyl isothiocyanate is apparently due to the difficulty of the formation of a hydrogen bond of the imino-group hydrogen–sulphur atom type in the transition state[108,109].

Kinetic studies of the synthesis of urea in the reactions of amines with cyanic acid showed that hydrazine is at least ten times more reactive than was believed on the grounds of its basicity and polarisability[110].

Table 3. The rate constants k (litre mole^{-1} s^{-1}) for the reactions of nucleophiles with phenyl isocyanate and phenyl isothiocyanate (in benzene at 25° C)[50,99-106].

Nucleophile	pK	Phenyl isocyanate	Phenyl isothiocyanate

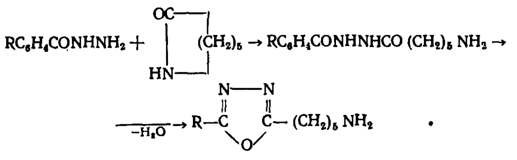
*Measured in 50% aqueous ethanol.
**Quoted for comparison.

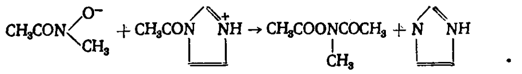
(b) **Reactions with ϵ-caprolactam.** The reactions of aroylhydrazines with ϵ-caprolactam at 160–270°C in *m*-cresol, decalin, and in the absence of solvents takes place via the following mechanism[111,112]:



The reactions of aroylhydrazines with ϵ-caprolactam in *m*-cresol solution are described by second-order kinetic equations for irreversible processes[111]. The interaction of benzoyl hydrazide, phenylhydrazine, semicarbazide, and carbohydrazide with ϵ-caprolactam in *m*-cresol take place in 10–20 h at 250° C, while in the presence of aniline appreciable changes are not observed even after 100 h.[113] The introduction of small amounts of primary and tertiary amines as well as carboxylic acid derivatives does not affect the rate of reaction of ϵ-caprolactam with benzoylhydrazine, while carboxylic acids themselves, which behave as bifunctional catalysts, accelerate the process[111,112].

5. Other Instances of the Manifestation of the α-Effect

NN-Dialkylhydroxylamines react faster with t-butyl peroxide than do other dialkylamines, which is used in the synthesis of nitrenes[114]. The rate constants for the reactions of hydrazine and hydroxylamine with 4-nitrophenyl sulphate are several times greater than those for the reactions with amines of similar basicity[117]. The α-effect has been observed in the reaction of *N*-acetyl-*N*-methylhydroxylamine with acetylimidazole[115]:



The anomalous reactivity of acetylimidazole in the hydrazinolysis[116-118] and methoxyaminolysis of *N*-acetyltriazole[116] and of 2-acetyl-3,4-dimethylthiazolium iodide in the reaction with hydroxylamine (in contrast to imidazole, which has a similar basicity but is relatively unreactive) has been pointed out[119]. The inapplicability of the Brønsted relation between the logarithm of the reaction rate constant and the basicity/acidity of the catalyst to the acid- and base-catalysed hydrolysis of 4-tolyl *NN*-dimethylacetimidate has been demonstrated[116].

The reactions of δ-thiovalerolactone with hydrazine and morpholine undergo general acid and base catalysis[120]. The hydrazinolysis of δ-thiovalerlactone is much faster than the morpholinolysis of the same thiester, which is due to the α-effect[121].

Two-centre nucleophiles (hydrazine, hydroxylamine, and their derivatives) exhibit an enhanced reactivity in reactions with heterocycles containing polar double bonds ($C = X$, where $X = O$, S, N, or P) compared with one-centre nucleophiles (ammonia, primary amines, 1,1-disubstituted hydrazines, and sulphide and hydroxide ions, for example)[122]. The α-effect can have a significant influence on the rate-determining stage of the recyclisation reaction and can affect the mode of the rearrangement; furthermore, two-centre nucleophiles can react via one or two heteroatoms in the ring rearrangement process[122].

The α-effect has been noted in reactions involving the nucleophilic addition of aliphatic 1,1-dinitrocarbanions to methyl acrylate and methyl vinyl ketone in water and 50% aqueous dioxan (the Michael reaction)[123,124]. The virtual equality of the Brønsted β-constants for the addition reactions involving methyl acrylate and methyl vinyl ketone and the recombination of the carbanion with a proton as well as the identical enthalpies of activation for the above reactions indicate the existence of a common stage associated with the localisation of the charge at the carbon atom of the dinitro-carbanion when the hybridisation of this atom changes from sp^2 to sp^3.[124] The rate of the Michael reaction in water at 30°C is 3400 times higher (4200 times higher in 50% aqueous dioxan) for carbanions with $R = F$ than for carbanions with $R = CH_3$ or C_2H_5, which is apparently due to the repulsion of lone pairs of p electrons of the fluorine atom and the carbanion carbon (i.e. the destabilisation of the sp^2-hybridised carbon by the fluorine atom in the α-position)[124].

A series of carbanions derived from *N*-substituted 1,1-dinitroacetamides, i.e. $RNHCOCH(NO_2)_2$, are characterised by an anomalous reactivity in nucleophilic addition to methyl vinyl ketone via the Michael reaction in water and methanol in the temperature range 10–50° C; the operation of the α-effect in these reactions is demonstrated by the authors by the analysis of the influence of various structural factors on the nucleophilic properties in terms of the linear free energy equations[125].

The rate of ferrocenylmethylation of aliphatic 1,1-dinitrocarbanions in 50% aqueous methanol at 45–60° C is independent of the basicity of the anions derived from 1,1-dinitroalkanes[126]. The high rate of ferrocenylmethylation and the absence of *O*-alkylation of dinitro-carbanions are probably due to the influence of the α-effect. The study of the kinetics of the reactions of ferrocenylmethylpyridinium salts with mono- and di-nitro-carbanions permitted a soundly based approach to the selection of the optimum conditions for the preparative synthesis of β-nitro- and $\beta\beta$-dinitro-alkyl derivatives of ferrocene.

The interaction of platinum(II) complexes with hydrazine, hydroxylamine, acid anions, ammonia, and pyridine takes place in two stages; the first stage is slow and rate-determining[127,128]:

$$trans\text{-}[PtL_2Cl_2] + Y \xrightarrow{\text{slow}} trans\text{-}[PtL_2ClY] + Cl^-,$$

$$trans\text{-}[PtL_2ClY] + Y \xrightarrow{\text{fast}} trans\text{-}[PtL_2Y_2] + Cl^-,$$

where L is an organic ligand, which may be pyridine, piperidine, or $P(C_2H_5)_3$, and Y is a nucleophile. The nucleophilic reaction constants for bivalent platinum in the reactions with hydrazine and hydroxylamine are much higher than in the reactions of the complexes with pyridine, ammonia, and NO_2^- and N_3^- ions; the latter implies that the α-effect is responsible for the much greater reactivity of α-nucleophiles compared with other nitrogen-containing compounds[127,128].

Hydrazine, hydroxylamine, and the HOO^- ion show a much greater reactivity than have been suggested in reactions with the octahedral tris(acetylacetonato)silicon(IV) cation[129]. The high reactivity of such nucleophiles is attributed to the influence of the α-effect, which is manifested by the fact that the lone electron pairs stabilise the transition state, compensating thereby the loss of electrons by the nucleophilic atom[1]:

$$HOO^- + -\overset{|}{\underset{|}{Si}}-X \rightleftarrows H-\ddot{O}-\ddot{O}-Si-X\ .$$

The interaction of the reactants is promoted by the high positive charge on the silicon atom and the unfilled outer *d* orbitals of the tris(acetylacetonato)silicon(IV) cation[129]. Sander and Jencks[130] pointed out the extremely high reactivity of the HOO^- ion in its reactions with acetaldehyde and formaldehyde.

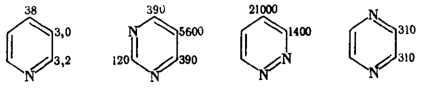
The experimental data on the reactivities of α-carbofunctional compounds of Group IVB elements, the "mesoids" $\gt M-\overset{|}{\underset{|}{C}}-X$ (where M = Si, Ge, or Sn, i.e. elements having atoms with vacant *d* orbitals; H = Hal, N, O, or S), as well as studies by infrared, NMR, and NQR spectroscopy and other physical methods indicate the anomalous behaviour of the above compounds[131,132]. The ^{35}Cl frequencies in the NQR spectra of mesoids confirm that the mechanism of the transmission of the electronic influences for M = Si, Ge, or Sn differs appreciably from the purely inductive effect for M = C; together with the inductive effect, there is intramolecular coordination between M and X atoms[132]. If M has vacant *d* orbitals, the ^{35}Cl frequency is higher than for the corresponding organic analogue (i.e. for M = C).[133] If M is an atom with lone-pair electrons, then the ^{35}Cl frequency proves to be lower. A more detailed analysis of the NQR spectra of compounds of this type led to the conclusion that the regularity in the variation of the frequencies is associated primarily with the electronegativity of the M atom. The ^{35}Cl NQR spectra of all chloroderivatives of nitrogen-containing heterocyclic compounds exhibit the above regularity[134]. The appreciably different ^{35}Cl frequencies of the NQR spectra when the chlorine atoms are in the α-positions relative to the nitrogen atoms of the pyridine and pyrrole types in 3-substituted 5-chloro-1,2,4-triazoles are due to the electronegativity of the nitrogen atoms[135].

The high reactivity of the halogen atom (chloromethyl) in alkyl esters compared with the corresponding alkyl halides has been frequently interpreted from the standpoint of the electronic theory. The anomalously low ^{35}Cl frequencies are attributed[136] either to the interaction between the lone electron pair of the oxygen atom and the σ electrons of the C–Cl bond (I) or to the formation of an intramolecular three-centre bond (II):

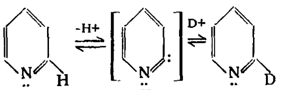
(I)

(II)

Zoltewicz et al.[137] demonstrated the non-equality of the rates of isotopic H–D exchange for different positions in the heteroaromatic pyridine, pyrimidine, pyridazine, and pyrazine rings (the numerals indicate the second-order rate constants at 164.6° C, multiplied by 10^6, measured in a CH_3OD-CH_3ONa medium):



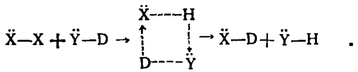
Positions which are either adjacent to the nitrogen atom or are located between two nitrogen atoms show the smallest capacity for H–D exchange. The base-catalysed deuterium exchange involving pyridine takes place most readily in the 4-position[138], although, according to calculations of the charges by the Hückel method, the 2-position, should be the most "acid".[137] Calculations by the extended Hückel method show that the 2-carbanion of pyridine is destabilised by the influence of the lone-pair electrons[138]. The loss of stability by the heterocycle is due to the intermediate (or transition) state (III), the formation of which accompanies proton transfer from a position adjoining the nitrogen atom[13]:



(III)

The reduced reactivity of α-carbon atoms in isotope exchange reactions is the result of the operation of two factors: the decrease of the *s*-character of the hydrogen bond with the carbon atom adjoining the nitrogen atom of the nucleophile and the repulsion between the electron pairs of the nitrogen and the carbanion generated[137,141].

Mention should be made of the α-effect in the exchange of hydrogen for the deuterium of heavy water in ammonia, ammonium salt, and sucrose solutions[142]. The capacity of hydrogen for exchange depends on the nature of the bond; in hydrogen bonds with halogens, oxygen, nitrogen, sulphur, selenium, and other elements having lone-pair electrons the exchange takes place very readily and in many instances instantaneously. The exchange of hydrogen in C–H bonds is as a rule very difficult and may be accelerated only in the presence of strong bases, which promote the abstraction of a proton, in the presence of strong acids, which facilitate the transfer of deuterium, or, finally, in the presence of suitable substituents which weaken the C–H bond. Deuterium exchange takes place in the reaction complex (**IV**) formed via hydrogen bonding ($\ddot{X}$ and $\ddot{Y}$ are atoms or parts of molecules):



$$\ddot{X}-X+\ddot{Y}-D \rightarrow \begin{matrix}\ddot{X}\text{----}H\\ \uparrow \quad\quad \downarrow\\ D\text{----}\ddot{Y}\end{matrix} \rightarrow \ddot{X}-D+\ddot{Y}-H \quad .$$

(IV)

The maximum rate of the alkaline hydrolysis of the haloforms CHX_3 (X = Hal) is a phenomenon common to all halogenomethanes[143,144]. For example, the rate of hydrolysis of $CHCl_3$ is one thousand times higher than that of CH_2Cl_2 and the rate of hydrolysis of bromine-containing haloforms is higher by approximately three orders of magnitude compared with CH_2ClBr or CH_2Br_2. Carbenes are intermediates in the alkaline hydrolysis of haloforms; 1,1-elimination takes place via the mechanism involving unimolecular elimination from the conjugate base:

$$CHX_3+HO^- \rightleftarrows CX_3^- + H_2O \quad ,$$
$$CX_3^- \rightleftarrows :CX_2+X^- \quad ,$$
$$:CX_2+H_2O \xrightarrow{HO^-} CO+HCOO^-+X^- \quad .$$

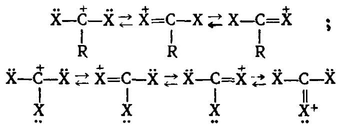
The introduction of a fluorine atom into the haloform has the most appreciable kinetic effect compared with other halogens. Difluoromethanes (CHF_2Cl, CHF_2Br, CHF_2) are hydrolysed much faster, which conflicts with the suggested mechanism. Hine[143-145] interprets these results on the hypothesis of a single-stage bimolecular 1,1-elimination mechanism:

$$HO^-+H-CF_2X \rightarrow H_2O+CF_2+X^- \quad ,$$
$$CF_2+H_2O \xrightarrow{HO^-} CO+HCOO^-+F^- \quad .$$

The electron shift from the heteroatom to the electron-deficient carbene carbon has a significant influence on the reactivity of carbenes containing α-heteroatoms with lone-pair electrons. If the heteroatom is linked by a double bond to the carbene carbon, then the shift of electron density leads to the formation of stable compounds such as isonitriles and derivatives of fulminic acid and carbon monoxide[145]; these compounds do not exhibit electrophilic properties and behave as more or less reactive nucleophiles. The carbene ions are stabilised by the lone-pair electrons of the heteroatom X in the α-position relative to the cationic centre[46-148]:

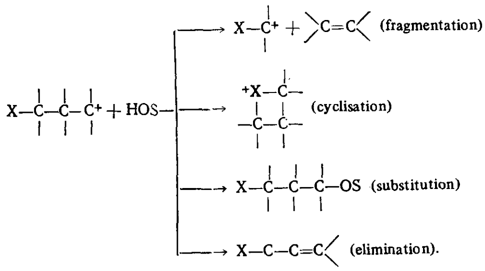
$$R_2\overset{+}{C}-\ddot{X} \rightleftarrows R_2C=\overset{+}{X},\ X=\text{Hal, N, O, S, or Se} \quad .$$

The stabilising effect increases sharply if the electron-deficient carbon atom is linked to two or even three electron-donating heteroatoms X[147]:



$$\ddot{X}-\underset{R}{\overset{+}{C}}-\ddot{X} \rightleftarrows \overset{+}{X}=\underset{R}{C}-X \rightleftarrows X-\underset{R}{C}=\overset{+}{X} \quad ;$$
$$\ddot{X}-\underset{\ddot{X}}{\overset{+}{C}}-\ddot{X} \rightleftarrows \overset{+}{X}=\underset{\ddot{X}}{C}-\ddot{X} \rightleftarrows \ddot{X}-\underset{\ddot{X}}{C}=\overset{+}{X} \rightleftarrows \ddot{X}-\underset{\ddot{X}^+}{\overset{}{C}}-\ddot{X} \quad .$$

The stability of the carbonium ion formed in the solvolysis of precursor carbonium ions is exceptionally high in those cases where the atom adjoining the carbonium centre has lone-pair electrons, the symmetry of the orbitals of which is favourable for overlapping with the vacant *p* orbital of the carbonium centre. Solvolysis of carbonium ions containing α-substituents with lone-pair electrons is accompanied by mutually competing reactions[149,150] (HOS is the solvent):



III. DEPENDENCE ON THE NATURE OF THE REACTANTS

Since the dependence of the α-effect on the nature of the reactants has been analysed in detail in a review[13], in this section we shall consider examples where the α-effect loses its force (vanishes). Epstein et al.[3] suggested a close relation between the manifestation of the α-effect and the nature of the nucleophile and the substrate involved in the reaction. Together with the above examples of the reactions where the α-effect has been noted for hydrazine and its derivatives, data have been obtained on reactions in which hydrazine does not show an enhanced reactivity[151,152]. Thus, whereas the α-effect is possible in the interaction of 4-nitrophenyl acetate with hydrazine and methylhydrazine, *NN*-dimethylhydrazine does not exhibit a high reactivity; the point corresponding to the above nucleophile fits on the linear Brønsted plot for primary and secondary amines[8].

The α-effect has been demonstrated for reactions of hydrazine, hydroxylamine, sulphides, and other nucleophiles with methyl iodide in methanol[126]; on the other hand, an anomalous reactivity of this substrate has not been observed in the interaction with hydrazine, hydroxylamine, and their monomethyl derivatives in an aqueous medium[15]. Gregory and Bruice's paper[15] was perhaps the first report on the α-effect in the reaction of neutral nucleophiles with saturated substrates. The α-effect has not been observed in the reactions of alkyl iodides with hydrazine in acetonitrile[152], methyl iodide does not exhibit an enhanced reactivity in reactions with heteroaromatic nitrogen-containing nucleophiles (including pyridines, diazines, and their analogues) in dimethyl sulphoxide at 23°C.[32] Hydrazine and methoxyamine react with 1-chloro-2,4-dinitrobenzene, showing very insignificant α-effects[71].

Systematic studies on the nucleophilic reactions of phosphate esters revealed the α-effect for hydrazine and hydroxylamine[84,85]. However, there is no α-effect in the reactions of the monoanion of 4-nitrophenyl methylphosphonate with hydrazine; other nucleophiles show a very insignificant α-effect in their reactions with this substrate[91-93]. The differences between the reactivity of hydrazine, which behaves as a neutral reactant in these processes, and those of other α-nucleophiles are extremely insignificant[88]; the α-effect has not been noted in the hydrazinolysis of phosphate esters[94].

α-Nucleophiles incapable of participating in the formation of a transition state characteristic of the push-pull mechanism have the "normal" reactivity[8,16,153]. Certain amidoximes react very slowly with Sarin and di-isopropyl phosphorofluoridate; *N*-triphenylmethylhydroxylamine does not react with these substrates at all[154]. The α-effect has not been observed in the interaction of nitroethane with hydrazine, methylhydrazine, hydroxylamine[151], and alkyl iodides[32,153]; this demonstrates in the first place, a close relation between the α-effect and the type of transition state (more precisely Brønsted's β constant). By analogy with proton transfer reactions[15,155], the high values of β should be attributed largely to the intense bond formation in the transition state. However, according to Hammond's postulate[156], this analogy is not altogether correct.

There is no α-effect in the reactions of *NN*-dimethylhydrazine with 2-phenyl-L-4-benzyloxazolone[10], which can be accounted for by the impossibility of the formation of a hydrogen bond with the carbonyl oxygen.

In the deprotonation of t-butylmalononitrile all nucleophiles (including hydrazine, hydroxylamine, methoxyamine, and peroxide ions) show the "normal" reactivity and fit on a single common Brønsted linear plot[155,157]. The α-effect has not been noted in the reaction of 1-chloro-2,4-dinitrobenzene with hydrazine and methoxyamine[46] and of picryl chloride with carboxylic acid hydrazides[50], *N*-alkyl-*N*-arylhydrazines[50], and phosphorus acid hydrazides and their *N*-ethyl-substituted derivatives[104].

The cause of the absence of the α-effect in the reactions of 2,4-dinitrophenyl acetate with pyridine and pyridazine at 25°C in water is not clear[5,33,158]. This example is particularly surprising, since strong interaction of the unpaired electrons of the two nitrogen atoms in the above nucleophiles has been demonstrated and confirmed by molecular orbital calculations[159] and photoelectron spectra[160].

The above example makes it clear that the α-effect depends both on the type of substrate and on the nature of the nucleophile. Fairly convincing experimental data have now accumulated, showing that the α-effect of the substrate depends primarily on the valence state of the carbon atom and can be arranged in the following sequence: $sp > sp^2 > sp^3$. This behaviour is illustrated quantitatively by the ratios $k_{\mathrm{HOO^-}}/k_{\mathrm{HO^-}}$ and the rate constants for the reactions with bromophenylacetic acid, 4-nitrophenyl acetate, and benzonitrile, which indicate different values of the α-effect due to the carbon atoms in different valence states[161]. It is suggested that the α-effect of the carbon atom is enhanced with increasing *s*-character of the bonding orbitals[152].

IV. THE POSSIBLE CAUSES OF THE α-EFFECT

The possible causes of the α-effect have now been established and analysed[8,128], the main ones being as follows: destabilisation of the ground state of the nucleophile due to the electrostatic repulsion between the electrons of adjacent electronegative atoms[32,162]; stabilisation of the transition state owing to the overlapping of the lone-pair electron orbitals[12,13]; reduced solvation of α-nucleophiles compared with reactants which do not exhibit the α-effect[15,163,164]; stabilisation of the reaction products (this factor also stabilises the transition state[79,115,165]); polarisability of the transition state[163]. During recent years several new causes of the α-effect have been added to the above list[4]. Certain probable causes of the α-effect are discussed in detail below, but any one of them in isolation does not fully account for the nature of this phenomenon.

1. Destabilisation of the Ground State

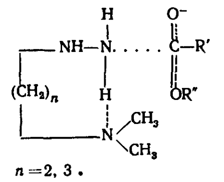
The first hypothesis of the destabilisation of the ground state of the nucleophile as a possible cause of the anomalous reactivity was put forward as early as 1962.[162] The α-effect in hydrazine derivatives may be due to the difference between the free energies of the ground states of the initial reactants and the reaction products[32,79,166]. The energy of the ground state increases owing to the electrostatic repulsion between the electrons of adjacent electronegative atoms[8,162]. This conclusion is confirmed by the photoelectron and EPR spectra of substituted hydrazines[167-170]. The repulsion of the lone-pair electrons in molecules of the type H_2O_2, NH_2NH_2, HClO, and ClF[171-174] introduces serious errors into estimates of the enthalpies of reaction and heats of dissociation of the adducts of Lewis acids and bases by the Drago–Wayland equation and leads to values of these quantities which are appreciably too low[175,176]. The repulsion of the electron pairs is responsible for the inaccurate prediction of the bond lengths and heats of formation of α-nucleophiles; the calculated bond lengths are too small and the heats of formation evaluated from the incorrect bond lengths are negative[177].

The increase of the energy of the ground state acts in the same direction as the decrease of the activation energy, which leads to an increase of the rate constants; however, the repulsion of the lone-pair electrons should also lead to an increase of basicity. The simultaneous increase of the rate constants and basicity should not apparently result in the appreciable lack of correspondence between basicity and reactivity observed experimentally[8]. In hydrazine and its derivatives the electrostatic repulsion between the lone-pair electrons of the nitrogen atoms diminishes in the transition state owing to the decrease of the charge of the nitrogen atom of the amino-group, the lone-pair electrons of which are involved in conjugation with the bond being formed, stabilising thereby the transition state[178,179]. Furthermore, such conjugation is the cause of the increase of the ability of the NH bridge group in monosubstituted hydrazines to transmit electronic influences in reactions with carbonyl-containing substrates ($z_{\mathrm{NH}} \simeq 1$).[51,99,104] The low N–X, O–X, and F–X bond energies are attributed to the influence of the repulsion of the lone-pair electrons in the ground state (X is an electronegative atom), the weakening of the above bonds becoming more pronounced with increase of the electronegativity of X.[180]

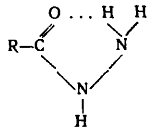
2. Stabilisation of the Transition State

The stabilisation of the transition state may be due to general intramolecular base catalysis and resonance interaction. Epstein et al.[3] proposed acid–base mechanisms for reactions involving nucleophilic attack on esters (particularly with formation of hydrogen bonds); similar mechanisms are discussed in later communications[158,182,183]. Bifunctional catalysis and resonance stabilisation have been examined by Jencks[158].

(a) General intramolecular base catalysis. The rate constants for the reactions of 2-dimethylaminoethylhydrazine and 3-dimethylaminopropylhydrazine with phenyl acetate are one thousand times higher than would be expected on the grounds of their basicity[184]. The high reactivity of dimethylaminoalkylhydrazines is due to the general intramolecular base catalysis [see formula (V)]:



(V)



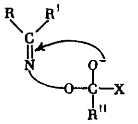
(VI)

;

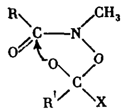
The occurrence of the catalysis illustrated by formula (V) is confirmed by the dependence of the rate constants on the concentration of the dimethylamino-group in the form of the free base[184].

The increased reactivity of carboxylic acid hydrazides in reactions with carbonyl-containing substrates can be explained by general intramolecular base catalysis involving the formation of an intramolecular hydrogen bond of type (VI). The formation of such intramolecular bonds is indicated by the shift of the ν(C=O) and ν(N–H) stretching vibration frequencies in the infrared spectra of carboxylic acid hydrazides[185,186], the measured dipole moments[187], and the study of the structure of the hydrazide group by the CNDO/2 method[188]. The replacement of the oxygen atom of the carbonyl group by the less electronegative sulphur atom leads, on the one hand, to an increased basicity of the amino-group and, on the other hand, to a decrease of the mobility of the hydrogen atoms of the amino-group, which hinders the formation of an intramolecular hydrogen bond; the latter is the most likely cause of the reduced reactivity of thiobenzoylhydrazine[32,48]. Phenoxycarbonylhydrazine, in which an intramolecular hydrogen bond of type (VI) has not been observed[185], exhibits a much lower reactivity compared with benzoylhydrazine despite the similarity of their basicity constants[48,99]. Evidently general intramolecular base catalysis has some effect on the reactivity of hydrazine and its derivatives. However, on the basis of this hypothesis, it is impossible to explain the lower reactivity of N-benzoyl-N-methylhydrazine in the reactions with ethyl chloroformate[48], phenyl chloroformate[50-52,55], and esters[38] as well as the absence of an increase in the reactivity of hydrazine derivatives in reactions with picryl chloride[46,75]; general intramolecular base catalysis should operate in the above reactions, because the presence of N-methyl groups does not apparently affect its occurrence[184].

The manifestation of the α-effect in the acylation of neutral amidoximes[57] and oximate anions with 4-nitrophenyl acetate (VII) can be accounted for by general intramolecular base catalysis[9]. The α-effect in N-methylhydroxamic acids has been explained by a similar mechanism (VIII):[189]



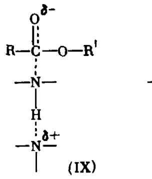
(VII)



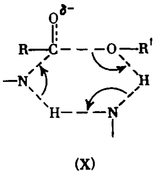
(VIII)

.

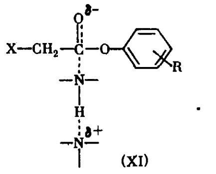
Bruice et al.[183] showed that the aminolysis of esters can also involve general base catalysis (IX–XI):



(IX)



(X)



(XI)

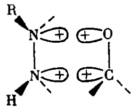
.

The delocalisation of the negative δ-charge on the carbonyl oxygen atom corresponds to scheme (IX), a cyclic proton transfer corresponds to scheme (X), and the localisation of the δ-charge on the phenolic oxygen atom corresponds to scheme (XI).

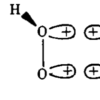
The high reactivity of hydrazine in reactions with the esters 4-(2-acetoxyphenyl)imidazole, 6-acetoxyquinoline, and 8-acetoxyquinoline is due to the fact that the adjoining imidazole group promotes a high rate of reaction of the reactants, behaving as a general intramolecular base catalyst; under the same conditions, phenyl acetate reacts with hydrazine forty times more slowly than with 6-acetoxyquinoline[27].

(b) The formation of an aromatic transition state. Liebman and Pollack[190] proposed an explanation of the α-effect based on allowance for the interaction of the electron pair orbitals in the transition state, which does not occur either in the initial reactants or in the products. This interpretation of the α-effect takes into account the fact that a high reactivity is observed only for substrates with π orbitals and provides a much better interpretation of the increase of reactivity than could be achieved by analysing the stability of the reaction products.

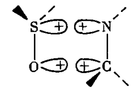
By means of this approach, it has been shown that the addition of hydrazine to the carbonyl group leads to the formation of a six-electron aromatic transition state (XII); a transition state of an analogous type is probably formed as a result of the addition of the peroxide ion to benzonitrile (XIII) and of bisulphite to oximes (XIV)[177]:



(XII)



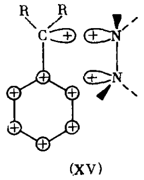
(XIII)



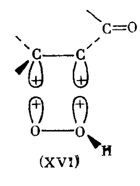
(XIV)

.

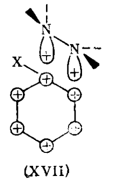
The α-effect in reactions involving the addition of α-nucleophiles to Malachite Green[78,79] can be explained by the formation in the course of the reaction of a cyclic transition state with aromatic properties. If Malachite Green is regarded as a substituted benzyl cation, then (XV) can be treated as a transition state incorporating ten electrons, as a result of which the system acquires aromatic properties[190]:



(XV)



(XVI)

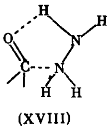


(XVII)

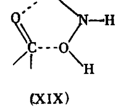
.

The addition of peroxide ions in the Michael reaction[121,122] and the transition states in aromatic nucleophilic substitution reactions are illustrated in structures (XVI) and (XVII)[190].

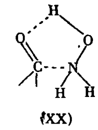
Hydrazine and its derivatives are capable of bifunctional (electrophilic-nucleophilic) interaction with carbonyl-containing substrates (esters, acid halides, acylureas, anhydrides, and oxazolinone). The transition states in the above reactions are illustrated by scheme (XVIII)–(XXI)[10]:



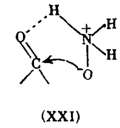
(XVIII)



(XIX)



(XX)

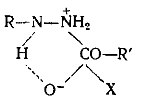


(XXI)

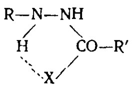
.

The reaction of oxazolinone with hydroxylamine involves competition between the oxygen and nitrogen atoms in which there is a bifunctional attack on the neutral hydroxylamine molecule [(XIX)–(XX)]. In addition one cannot rule out the possibility of attack by the oxygen atom in the form of the zwitter-ion (XXI); the last scheme explains the formation of a considerable amount of *O*-acyloxazolinone[10]. Epstein et al.[89] describe the appearance of stable transition states in the reactions of Sarin and the ClO^- ion with various phosphorus-containing substrates.

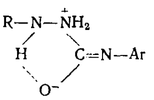
An aromatic transition state in the reactions of monosubstituted hydrazines with carbonyl-containing substrates is formed via a hydrogen bond between the oxygen atom (or another electronegative atom) and the hydrogen atom of the imino-group and via a new bond between a carbon atom of the substrate and the amino-group of the nucleophile. The transition state is of type (XXII) for reactions of monosubstituted hydrazines, of type (XXIII) for reactions with benzoyl chloride[41,50], phenyl chloroformate[51,52], and carboxylate esters[38], and of types (XXIV) and (XXV) for reactions with phenyl isocyanate[99,100]:



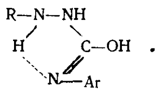
(XXII)



(XXIII)



(XXIV)



(XXV)

The formation of structures (XXII)–(XXV) is favoured by the disposition in a single plane of the hydrogen atom of the imino-group and the lone-pair electrons of the amino-nitrogen[191]. Furthermore, the aromatic transition state promotes a more complete shift of electron pair from the nucleophilic centre and is energetically the most favourable[190,192]. Convincing arguments involving cross-correlation analysis have been put forward for the possibility of the formation of transition states of types (XXII) and (XXIII) in the acylation of carboxylic acid hydrazides by aryl chloroformates and aroyl chlorides[41,52,55].

The hypothesis of the formation of transition states of type (XXII)–(XXV) in reactions of monosubstituted hydrazines with carbonyl-containing substrates is also supported by the kinetic parameters of the reactions with *NN*-disubstituted hydrazines. The replacement of a hydrogen atom in the imino-group by an alkyl substituent eliminates the possibility of the formation of an aromatic transition state, which leads to a decrease of the reactivity of *NN*-disubstituted hydrazines[50,104]. It is clear from the foregoing that, when monosubstituted hydrazines react with carbonyl-containing substrates, there is a possibility of the formation of transition states (XXII)–(XXV) with a high stability. Consequently the α-effect is shown by hydrazine derivatives on interaction with substrates containing π orbitals; the transition states in these reactions are aromatic and contain $4n + 2$ electrons.

By virtue of the specific features of the nucleophilic substitution at an aromatic carbon atom, the formation of transition states (XXII)–(XXV) is impossible in reactions with picryl chloride; the mechanism of such reactions involves the formation of intermediates having quinonoid structures[75]. Presumably this factor is the main cause of the low reactivity of hydrazine derivatives in reactions with picryl chloride.

3. Differences in Solvation Effects

Solvation is not one of the main causes of the α-effect, but the accumulated factual data do not allow neglect of this factor[165,193,194]. It is suggested that α-nucleophiles are much less solvated than other nucleophiles, which do not show the α-effect. This question has not been completely worked out in detail, the interpretation of certain solvation effects still does not fit satisfactorily within the framework of generally accepted theories, and experimental results are difficult to account for in many instances. Furthermore, solvation is one of the destabilising factors which should alter both the basicity and the nucleophilic reactivity of the compound[158]. The nucleophilic properties of hydrazine in acetonitrile in the reaction with 4-nitrophenyl acetate, for example, are much more marked than would follow from the pK value and this is why in an aprotic solvent, such as acetonitrile, hydrazine exhibits the α-effect[15].

Benzamidine (pK = 11.6) reacts with 4-nitrophenyl acetate in chlorobenzene approximately 15 000 times faster than does n-butylamine (pK = 10.6) despite the small differences between the basicity constants[192]. In a study of the reactions of peroxide ions with benzonitriles, Wiberg[163] stated that the HOO^- ion is approximately 10^4 times more reactive than the HO^- ion. The differences between the reactivities cannot be attributed to the low enthalpies of activation and differences between the entropies of activation; this fact should probably be explained by the influence of the solvent (a 50% aqueous acetone solution was used). The reactions of peroxide ions with benzonitriles, which have been studied in detail[161,195], are greatly influenced by solvation[196].

Table 4. The rate constants k (litre $mole^{-1}$ s^{-1}) for the reactions of phenyl isocyanate with certain nucleophiles in various solvents at 25° C[102,103,107] (*DN* is the donor number of the solvent[198]).

Solvent	*DN*	Diphenylphosphinic acid hydrazide	4-Tosylhydrazine	4-Toluidine
Hexamethylphosphoramide	38.8	—	—	0.436
Pyridine	33.1	8.84	—	—
Diethylacetamide	32.2	7.11	—	—
Dimethyl sulphoxide	29.8	7.24	3.57	0.164
Dimethylacetamide	27.8	5.50	1.88	0.0784
Dimethylformamide	26.6	4.90	1.64	0.0601
Tetrahydrofuran	—	3.00	1.25	—
Dioxan	—	2.74	0.923	—
Diethyl ether	19.2	2.63	0.723	0.0347
Ethyl acetate	17.1	2.14	—	0.0315
Methyl acetate	16.5	2.07	—	—
Acetonitrile	14.1	1.72	—	—
Nitrobenzene	4.4	0.727	0.163	0.00697
Benzene	0	0.449	0.0539	0.00397

A parallel relation between the logarithms of the rate constants and the donor numbers (*DN*) of the solvents (Table 4), described by Eqn. (1) for reactions with diphenylphosphinic acid hydrazide[197] and by Eqn. (2) for reactions with tosylhydrazine[103,199], has been demonstrated for the reactions of phenyl isocyanate with certain hydrazine derivatives:

$$\lg k = -0.294 + 0.0372\,DN \quad (r = 0.997), \tag{1}$$

$$\lg k = -1.12 + 0.049\,DN \quad (r = 0.989)\ . \tag{2}$$

For the reactions of phenyl isocyanate with 4-toluidine (which does not exhibit the α-effect), the influence of solvents on the reactivity of nucleophiles should be described by the following equation:

$$\lg k = -2.67 + 0.050\,DN \ (r = 0.987) \ . \qquad (3)$$

The study of the influence of donor solvents in a mixture with benzene on the rate of reaction of phenyl isocyanate with hydrazine derivatives showed that even small amounts of added donor solvents increase significantly the rate of reaction. A linear relation, described by Eqn. (4) for diphenylphosphinic acid hydrazide[197] and by Eqn. (5) for tosylhydrazine[103], holds between the logarithms of the catalytic rate constants and the donor numbers of the solvents:

$$\lg k = -0.577 + 0.0725\,DN \ (r = 0.996), \qquad (4)$$

$$\lg k = -1.91 + 0.106\,DN \ (r = 0.997). \qquad (5)$$

Donor solvents solvate the initial hydrazine, the transition state, and the substrate. The catalytic activities of dimethylformamide, dioxan, and pyridine in reactions of tosylhydrazine and diphenylphosphinic acid hydrazide with phenyl isocyanate and picryl chloride show that the solvation of the substrate does not play a significant role; the different influences of the above solvents are probably a result of the solvation of either the transition state or the initial hydrazine. The approximately same efficiencies of catalysis by donor solvents in reactions of diphenylphosphinic acid hydrazide with phenyl isocyanate and picryl chloride as well as the absence of catalysis in the reactions of *N*-ethyl-*N*-diphenylphosphinylhydrazine and *N*-methyl-*N*-tosylhydrazine[103,197] confirm quite convincingly that solvation involves the hydrogen atom of the imino-group in the initial hydrazide. Consequently the influence of donor solvents in reactions of phenyl isocyanate with phosphorus acid hydrazides and sulphonic acid hydrazides, which leads to an increase of the rate, is most probably associated with the specific solvation of the transition states in these reactions. The effectiveness of the catalysis by donor solvents depends both on the structure of the nucleophile and on the type of substrate employed[197,199].

4. Stabilisation of the Reaction Products

The parallel variation of the thermodynamic stability of the reaction products and the deviations from the reactivity–basicity relation have been demonstrated for the interactions of 4-nitrophenyl acetate with alcohols, peroxides, amines, hydrazines, and hydroxylamines[78]. However, the observed deviations show that this type of correlation is not general, particularly when the reactivities of different atoms are compared. The thermodynamics of the stabilisation of the reaction products is important in the interaction of hydrazine and methoxyamine with the carbonium ion of Malachite Green[79,164]. It has been recognised that factors promoting the stabilisation of the reaction products stabilise also the transition state[8,79,80,200-202].

5. Orbital Splitting

The high reactivity of nucleophiles with a lone electron pair at the α-atom can be explained[4,202] in terms of the theories of reactions controlled by the charge and the disposition of the boundary molecular orbitals of the reactants, i.e. the highest occupied orbital (HOMO) and the lowest unoccupied orbital (LUMO). The free energy of the reaction between a nucleophile and a substrate is determined by an equation whose first term describes the electrostatic interaction of the charges of the reactants in the course of the reaction and the second describes the formation of a covalent bond in the transition state[203]. The use of this equation in the study of the interaction of the ClO^- and HO^- ions with the same substrate permitted the conclusion that the former is more nucleophilic despite its lower basicity constant; the theoretical postulates have been confirmed by experimental data[4].

The lone-pair electrons in hydrazine, hydroxylamine, disulphides, and the ClO^- ions are oriented, relative to the electron pair interacting with the electrophile to form a covalent bond, in a manner which leads to the splitting of the orbitals[9,203]. Such splitting can be detected in photoelectron spectra[205,206]. The splitting of the orbitals increases the HOMO orbital energy, which affects the physical properties of the α-nucleophile: the ionisation potential, the redox potential, and the polarisability[9,207,208]. The occupied π^* orbital interacts more strongly with the "electronic" σ^* orbital compared with the unperturbed π orbitals of the usual nucleophiles; there is then a possibility not only of allowed $\pi \rightarrow \pi^*$ transitions but also of transitions of the type $\pi^* \rightarrow \sigma^*$ (Fig. 1). The latter factor is responsible for the increased reactivity[4,209]. The atom adjoining the lone-pair electrons in (XXVI) is more electronegative than the carbon or hydrogen atom in (XXVII), giving rise as a result to a positive inductive effect and reducing thereby the charge on the nucleophilic atom[5,209]. All these factors reduce the extent of the interaction with the approaching substrate:

$$\underset{\text{(XXVI)}}{R{-}\underset{\cdot\cdot}{\ddot{O}}\leftarrow\underset{\cdot\cdot}{\ddot{O}}\!:} \qquad \underset{\text{(XXVII)}}{R{-}CH_2{-}\underset{\cdot\cdot}{\ddot{O}}\!:} \ .$$

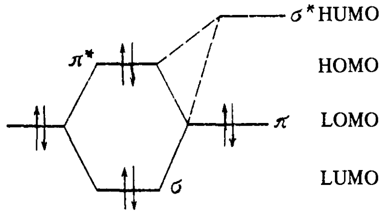


Figure 1. Energy levels of the molecular orbitals of α-nucleophiles: HUMO—highest unoccupied molecular orbital; HOMO—highest occupied molecular orbital; LOMO—lowest occupied molecular orbital; LUMO—lowest unoccupied molecular orbital.

In such cases the change in nucleophilic properties opposes the effect of the change in p*K*; indeed the CH_3COO^- ion is $10^{4.6}$ times more basic than the $CH_3CH_2O^-$ ion[5], while H_2O_2 is 10^4 times stronger as an acid than H_2O.[209]

Comparison of the energy levels of the ClO^- and HO^- ions shows that in the ClO^- ion there is interaction between the p,π orbitals of the oxygen and chlorine atoms, resulting in the splitting of the energy levels (Fig. 2). Because of this, the HUMO level in the ClO^- ion lies far above the corresponding energy level in the HO^- ion[4]. Fig. 2 shows that the ClO^- ion requires a smaller expenditure of energy ($\Delta E_1 > \Delta E_2$) and is therefore more reactive than the HO^- ion. The intermediate thus produced is stabilised by a three-orbital covalent bond and its loosening and dissociation are considerably hindered owing to the absence of an effect by the approaching group. The validity of the above treatment is confirmed by the fact that the α-effect is shown by nucleophiles with partial overlapping of the lone electron pair orbitals[4].

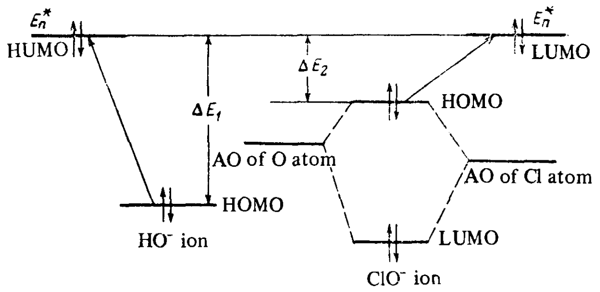

Figure 2. Diagram of the orbital energy levels of the HO^- and ClO^- ions in nucleophilic attack on the *n*th substrate: AO—atomic orbital; E_n^*—energy level of the LUMO of the substrate. The remaining symbols have the same significance as in Fig. 1.

The relation between the proposed explanation of the α-effect and the description of an acid–base type interaction may be analysed within the framework of Edwards' equation[210]:

$$\lg (k/k_0) = \alpha E + \beta H,$$

where α characterises the ability of the substrate to accept electrons and form a covalent bond and β characterises the capacity of the substrate for coordination[4]. For α-nucleophiles, $\alpha > 0$ and $\beta \leqslant 0$, in contrast to ordinary nucleophiles, which do not exhibit an anomalous reactivity (for the latter, $\alpha = 0$ and $\beta \simeq 1$). The ratio α/β then becomes a measure of the factor controlling the reaction: if α/β is large, the reaction is controlled by boundary molecular orbitals; for low values of α/β, the course of the reaction is determined by the charges of the reactants, which should lead to a relation between the α-effect and the redox potentials. If the latter hypothesis is correct, it is to be expected that hydrazine should be oxidised more readily than ammonia, and its redox potential should be higher owing to the higher HUMO energy E^*_n. Experimental data confirm this: the redox potential of hydrazine is higher than that of ammonia[5].

The involvement of an anionic nucleophile in the reaction is accompanied by a decrease of the p,π- p,π electron orbital interaction, because one of these orbitals forms a σ bond. The interaction between p,π and σ orbitals is on the whole less intense than the p,π–p,π interaction; the latter entails an increase of the reactivity of the nucleophile. The foregoing considerations lead to the following conclusion: the positive α-effect is induced by the decrease in the course of the chemical reaction of the overlap integral of the orbitals containing lone-pair electrons; hence one may conclude that the manifestation of the α-effect is determined by the conformation of the α-nucleophile. On this basis, α-nucleophiles can be divided into two groups[5]:

(a) Nucleophiles of the type ROO^-, ClO^-, and RSS^-, which have high p,π orbital repulsion energies in the ground state. Such nucleophiles should exhibit an enhanced reactivity in reactions with both saturated and unsaturated substrates.

(b) The conformation of nucleophiles of the type NH_2NH_2, NH_2OH, and RSSR is such that the p,π–p,π (or sp^3–sp^3) repulsion in the ground state is reduced to a minimum; under these conditions, the orbital splitting is zero.

The conformations of the ground state and the rotational barriers in peroxides[211–213], disulphides[214], F_2O_2,[215] NH_2NH_2,[216,217] NF_2NF_2,[173,218,219] NH_2OH,[174] diarsines[220], and diphosphines[221] have been studied in detail and may be accounted for in terms of a simple rule, described above, concerning the relation between the α-effect and the overlap integral of orbitals with lone-pair electrons. Fig. 3 illustrates examples of these α-nucleophiles in the form of idealised Newman projections[5]. Their molecules should not exhibit the α-effect due to the repulsion of the p,π orbitals; the increase of nucleophilic reactivity noted in certain reactions should be attributed to other causes. For example, the anomalous reactivity of amidoximes in reactions with benzyl bromide is attributed to general intramolecular base catalysis[14].

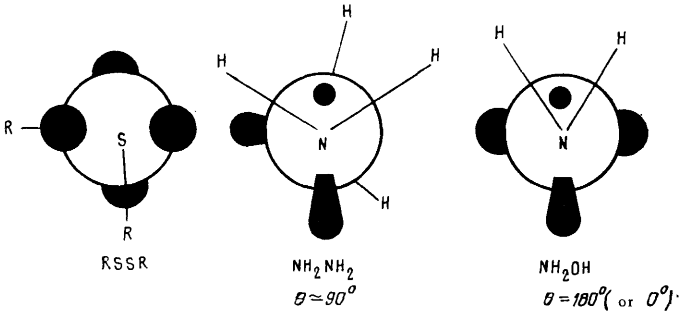

Figure 3. Idealised Newman projections for disulphides RSSR ($\theta = 90°$), hydrazine NH_2NH_2 ($\theta \simeq 90°$), and hydroxylamine NH_2OH ($\theta = 180°$ or $0°$). θ is the torsional angle.

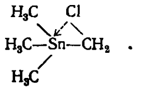
However, one should note that the explanation of the α-effect based on the repulsion of the lone-pair electron orbitals suffers from a significant disadvantage. This is the assumption that the splitting of the energy level necessarily leads to an increase of the HUMO[190]. Quantum-chemical calculations and their thermodynamic analysis have shown, however, that the α-effect for NH_2NH_2 [190,222] and the ClO^- ion[190] cannot be explained solely by taking into account the orbital splitting.

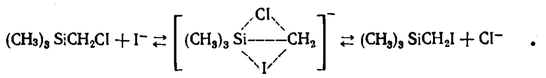
6. Intramolecular Coordination

The anomalous behaviour of "mesoids" (α-carbofunctional compounds of Group IVB elements) is due to the effect of the intramolecular electronic interaction between M and Hal atoms; for example, the effect in chloromethyl(trimethyl)tin (XXVIII) is apparently due to the transfer of the lone-pair electrons of the chlorine atom to the vacant *d* orbital of the Sn atom[223]:



(XXVIII)

However, NQR data for "mesoids" with Ge, Si, and Sn atoms show that, together with the inductive effect of the substituents, there is intramolecular coordination between the atom of the Group IVB element and the halogen. The reactivity of $(CH_3)_3MCH_2Cl$ with respect to nucleophiles increases for different M in the sequence C < Si < Ge < Sn.[131] The latter shows that the site of nucleophilic attack is not only the carbon atom of the CH_2 group but also the M atom of the mesoid. For this reason, the relatively high reactivity of chloromethyl(trimethyl)silane has been explained[132] by the stabilisation of the transition state (XXIX) owing to the simultaneous interaction of the approaching halide ion with the carbon atom and the vacant 3*d* orbitals of the silicon atom:

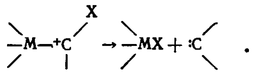


$$(CH_3)_3SiCH_2Cl + I^- \rightleftarrows \left[(CH_3)_3Si\overset{Cl}{\underset{I}{\cdots}}CH_2\right]^- \rightleftarrows (CH_3)_3SiCH_2I + Cl^- \ .$$

(XXIX)

The outgoing Cl^- ion may interact with silicon and carbon atoms; a similar mechanism has been postulated for the reactions of chloromethyl(trimethyl)silane with SCN^- and $C_2H_5O^-$ ions.

The rearrangements involving the cleavage of the M–C bond and the migration of the substituent X from the carbon atom to the M atom constitute fairly convincing evidence for intramolecular coordination between the M and X atoms of mesoids:



$$\rangle M-{}^{+}\overset{X}{C}\langle \ \rightarrow \ \rangle MX + {:}C\langle \ .$$

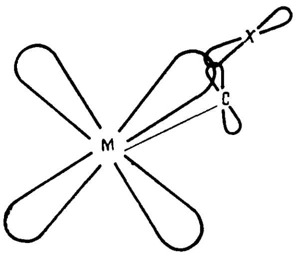


Figure 4. The formation of a three-centre bond of the "closed" type in "mesoids" (α-carbofunctional compounds of Group IVB elements).

The coordination interaction between the M and X atoms takes place with transfer of the σ electrons of the X atoms involved in the C–X bond to the vacant *d* orbitals of the M atom. This leads to the formation of a three-centre bond of the "closed" type[132] (Fig. 4) due to the overlapping of the *p*, σ orbitals of the X atom, the sp^3-hybridised orbitals of the carbon atom, and the vacant *d* orbitals of the M atom. The axes of these orbitals are directed to the interior of a non-equilateral triangle formed by the M, C, and X atoms. The occurrence of intramolecular coordination in mesoids has been questioned[224] in view of the very low coordination capacity of the M atom. The decreasing basicity of amino-derivatives of mesoids is pointed out in support of this view, while the Ge > Sn > Si series corresponds to the generally accepted electronegativity scale of the M atoms[224].

The ^{35}Cl NQR frequencies for alkyl chloromethyl ethers, which are appreciably lower than for alkyl chlorides, are attributed to the interaction between the lone-pair electrons of the oxygen atom and the σ electrons of the C–Cl bond in α-halogeno-ethers[225]. Voronkov[136,226] believes that the most likely explanation of the anomalous properties of the halogen atoms in α-halogeno-ethers is the direct interaction of the oxygen atom with the C–Cl bond and the formation of an intramolecular three-centre bond of the "closed" type (Fig. 5). This bond is formed between the O, C, and Cl atoms with participation of the sp^3-hybridised orbitals of the carbon atom, the *p*, σ orbitals of the chlorine atom, and the lone-pair electrons of the oxygen atom.

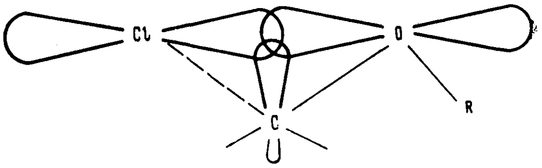

Figure 5. The formation of an intramolecular three-centre bond of the closed type in α-halogeno-ethers.

V. QUANTITATIVE ESTIMATE

Together with the qualitative description of the α-effect, it is of interest to consider the quantitative criteria for the assessment of this phenomenon. The increase of nucleophilic reactivity (i.e. the magnitude of the α-effect) has been estimated in terms of the ratio of the rate constants for reactions of α-nucleophiles and compounds which do not exhibit the α-effect (reference standards) when the basicities of both are the same; the α-effect varies significantly as a function of the type of nucleophiles used as the reference standards[79,164,166]. The latter were usually the HO^- ion, NH_3, glycine, and glycylglycine (Table 5). The α-effects in heteroaromatic compounds have been estimated as the ratios of the rate constants for the reactions of diazines and pyridine bases[32]. The ratios of the rate constants for the reactions of oximate and phenoxide (or alkoxide) ions of the same basicity were adopted as the α-effects in the reactions of 4-nitrophenyl acetate with oximate anions in water[9]. The α-effects in reactions with hydroxamic acids has been estimated as the ratios of the rate constants for the reactions of hydroxamic acids and phenoxide ions derived from phenols having the same p*K* values as the acids[189].

$RCOOH \rightleftharpoons RCOO^- + H^+$	0.61^{155}	—	—	—	1.02^{155}			

[a] $pK(HOO^-) = 11.60$. [b] $pK(HO^-) = 15.27$. [c] $pK(NH_2NH_2) = 8.11$. [d] $pK(NH_2O^-) = 6.20$. [e] $pK(ClO^-) = 7.10$. [f] $pK(CF_3CH_2O^-) = 12.36$. [g] pK(glycylglycine) = 8.25. [h] pK(glycine amide) = 8.10. [i] $pK(NH_3) = 9.21$.

One must note that the ratios $k(HOO^-)/k(HO^-)$ and $k(HOO^-)/k(NH_3)$ should be used with much caution as quantitative estimates of the α-effect, because the points on the Brønsted plots for HO^- and NH_3 very frequently lie below the straight line for primary amines and alkoxide ions; this finding apparently has nothing in common with the enhanced nucleophilic properties of the reactants due to the α-effect[71]. This probably explains the appreciable variation of the α-effect in reactions of aryl acetate esters (Table 5) and Malachite Green, for which Dixon and Bruice[79,164] estimated the α-effects as the ratios of the nucleophile/glycine, nucleophile/glycylglycine, and nucleophile/hydroxide ion rate constants.

The relative α-effects in the acylation reactions of hydrazine derivatives may be estimated as the ratios of the rate constants for the reactions of benzoylhydrazine and aniline with the same substrate[233]. Shevchenko[233] showed that the nucleophilic addition reactions (reactions with phenyl isocyanate) are the most sensitive to the α-effect and are followed, in this respect, by nucleophilic substitution at the carbonyl carbon atom (interaction with benzoyl chloride, ethyl chloroformate, phenyl chloroformate, and benzoic and acetic anhydrides). Substitution at an aromatic carbon atom (reactions of picryl chloride) exhibits an extremely insignificant α-effect. From our point of view, the ratio of the rate constants for the reactions of the given α-nucleophile and a primary arylamine of the same basicity must be regarded as a more correct estimate of the α-effect in hydrazine derivatives[104,234]. Table 6 presents quantitative estimates of the α-effect obtained using in certain cases the rate constants calculated by the Brønsted equations for the reactions of arylamines with phenyl chloroformate[234], phenyl isocyanate[234], phenyl thioisocyanate[104], benzoyl chloride[234], and picryl chloride[104]. In terms of the sensitivity to the α-effect, the substrates investigated can be arranged in the following sequence: phenyl isocyanate > benzoyl chloride > phenyl thioisocyanate > phenyl chloroformate > picryl chloride (Table 6). In reactions involving the hydrazides of phosphorus acids, those involving nucleophilic addition also exhibit the greatest α-effect; N-ethyl-substituted derivatives of these compounds show an α-effect smaller by a factor of 5–20 under the same conditions (Table 6).

Many workers have suggested a close relation between the α-effect and the β constant in the Brønsted equation[79,164,166]. A linear correlation has been noted between the magnitude of the α-effect and the β constant[166]. For hydrazine derivatives, correlations of this type are characterised by an appreciable scatter of the points, which can probably be accounted for by the fact that the basicity constants of hydrazine derivatives and the rate constants for the reactions were measured in different media.

The linear correlation between $k(HOO^-)/k(HO^-)$ and the product $\alpha\beta$ of the coefficients of Edwards' equation for reactions employing ethyl acetate, 4-nitrophenyl acetate, 4-nitrophenyl methylphosphonate, 1-chloro-2,4-dinitrobenzene, α-bromo-4-toluic acid, and bromoacetic acid, which was noted by Behrman and coworkers[161], is promising for the quantitative estimation of the α-effect.

Table 6. Estimated α-effects in various reaction series involving hydrazine derivatives[104,123].

Hydrazine derivative	Phenyl chloroformate	Phenyl isocyanate	Picryl chloride	Hydrazine derivative	Phenyl chloroformate	Phenyl isothiocyanate	Picryl isocyanate
$RC_6H_4NHNH_2$	80	235	0	$(C_6H_5)_2PONHNH_2$	2772	331	32
$RC_6H_4N(C_2H_5)NH_2$	0	42	0	$(C_6H_5)_2PON(C_2H_5)NH_2$	565	173	37
$C_6H_5N(Alk)NH_2$	29	95	0	$(C_6H_5O)_2PONHNH_2$	1783	204	8
$RC_6H_4CONHNH_2$*	192	20 000	3	$(C_6H_5O)_2PON(C_2H_5)NH_2$	83	64	7
$RC_6H_4SO_2NHNH_2$	62	—	—	$(C_6H_5O)_2PSNHNH_2$	967	182	10
$AlkCONHNH_2$	—	3 600	—	$(C_6H_5O)_2PSN(C_2H_5)NH_2$	158	110	8

*In reactions with benzoyl chloride, the α-effect amounts to 7600.

Thus the foregoing findings show that a high reactivity (α-effect) is manifested by compounds with one or several lone-pair electrons at an atom adjoining the reaction centre. There are a wide variety of causes responsible for the α-effect, but none of them can fully explain its manifestations. In considering the α-effect in specific systems, one should probably take into account simultaneously a wide variety of factors which could explain this phenomenon.

It is noteworthy that an enormous amount of experimental data associated with the observation of the α-effect has accumulated largely as a result of the application of kinetic methods. Unfortunately there have been almost no studies on the nature of the α-effect by physical methods, and quantum-chemical procedures for calculations on reactions involving α-nucleophiles have also been inadequately used.

Despite the fact that the problem of the α-effect in organic compounds requires further systematic study and development, the relevant available information can already be used in analytical chemistry, in fine chemical organic syntheses on an industrial scale, and in the manufacture of physiologically active preparations and polymeric materials.

Oxidative Coupling of Aromatic Systems under the Influence of Transition Metal Compounds

I.V.Kozhevnikov and K.I.Matveev

Liquid-phase reactions involving the oxidative coupling of aromatic systems (including heteroaromatic systems and aryl derivatives of the elements) to the corresponding biaryls under the influence of transition metal compounds are examined. Attention is concentrated on reactions under the influence of palladium(II) salts and complexes, which constitute the group of the most important reactions of this class. Oxidative coupling under the influence of other oxidants, including strong one-electron oxidants such as cobalt(III), manganese(III), cerium(IV), iron(III), etc., is considered for comparison. The bibliography includes 124 references.

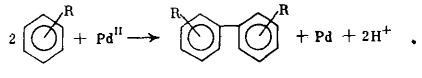
III. Coupling under the influence of other metals 660

I. INTRODUCTION

Oxidative coupling reactions with formation of a C–C bond have been known for a long time. Interest in them increased considerably after the development of the Wacker process for the oxidation of olefins[1] and particularly in the last ten years in connection with the discovery of the coupling of aromatic compounds to biaryls under the influence of palladium salts[2].



The rapid publication of the relevant patent literature (see, for example, Refs. 3–16) indicates the potential importance of this reaction for the development of a single-stage method of synthesising biaryls, which are valuable intermediates in organic synthesis. Until recently the most universal method for the synthesis of biaryls was the technologically complex two-stage Ullmann reaction[17]. Coupling under the influence of palladium(II) salts proceeds under milder conditions via a non-radical mechanism, which creates conditions for a high selectivity. Furthermore, coupling may be achieved catalytically as a result of the regeneration of palladium(II) by means of oxidants, including O_2.

The early studies on this reaction, published before 1969, have been examined in previous reviews[1,18–20] and have been briefly discussed in other publications[21,22]†. Further research into the oxidative coupling of the aromatic systems, including heteroatomatic systems and aryl derivatives of the elements, greatly extended the applications of the reaction and deepened the understanding of its mechanism. Significant advances have been achieved in the development of oxidative coupling catalysts based on palladium(II). Numerous studies have been published recently on the oxidative coupling of aromatic compounds under the influence of other oxidants, in the first place strong one-electron oxidants such as cobalt(III), manganese(III), cerium(IV), iron(III), etc. These data are extremely useful for the understanding of the mechanism of coupling under the influence of palladium(II). Such problems are in fact the subject of the present review. which covers the literature published up to the middle of 1976. It is noteworthy that, together with the term "oxidative coupling", the terms "oxidative dimerisation", "oxidative dehydrodimerisation", and "oxidative pairing" are used in the literature. The first term is used in the review because in the author's view it is the most accurate and embraces not only symmetrical but also asymmetric coupling reactions. Stern's[18] and Moritani and Fujiwara's[23] reviews may be recommended to those who wish to become acquainted with the related oxidative coupling and olefin arylation reactions under the influence of palladium(II).

II. OXIDATIVE COUPLING UNDER THE INFLUENCE OF PALLADIUM(II) COMPOUNDS

1. AROMATIC (CARBOCYCLIC) COMPOUNDS

In 1965 Van Helden and Verberg[2] reported for the first time the oxidative coupling of aromatic compounds to biaryls under the influence of palladium(II) in acetic acid:

$$2RH + Pd^{II} \rightarrow R{-}R + Pd^0 + 2H^+ .$$

Subsequent studies showed that the composition of the products of the reaction depends on the conditions. The coupling of benzene derivatives has been most fully investigated (see Table). Compounds of the naphthalene series and probably other aromatic condensed systems also enter into this reaction.

Depending on the substrate, when aromatic hydrocarbons are acted upon by $PdCl_2$ + NaOAc in acetic acid, biaryls are formed in yields of 25–81% [here and henceforth the yields are quoted relative to the initial amount of palladium(II)][2]. In the absence of sodium acetate the reaction does not occur. Davidson and Triggs found that, when palladium(II) is used in the form of $Pd(OAc)_2$, products resulting from the acetoxylation of the ring and the

---

† During the preparation of this paper for the Press, the following reviews were also published: R. A. Sheldon and J. K. Kochi, Adv. Catalysis, **25**, 274 (1976); I. I. Moiseev, Zhur. Vses. Khim. Obshch. im. Mendeleeva, 22, 30 (1977); H. W. Krause, R. Selke, and H. Pracejus, Z. Chem., **16**, 465 (1976).

side chain are formed together with the coupling products[24,25,27] (for further details about the acetoxylation, see Refs. 22 and 26). Thus biphenyl (66%) and phenyl acetate (16%) were obtained from benzene in acetic acid. Benzyl acetate (40–45%) was the main product from toluene. In the presence of $HClO_4$ in acetic acid the reaction is sharply accelerated and the yield of coupling products increases as a result of the suppression of the acetoxylation reaction[24,27]. The addition of alkali metal acetates also accelerates the overall reaction, but under these conditions there is an increase in the yield of acetoxylation products[24,28]. The acetoxylation of benzene and toluenee by palladium(II) acetate in acetic acid is almostly completely suppressed when the reaction is carried out under oxygen at a pressure of 50 atm.[29] when mainly coupling products are formed. When benzene was allowed to interact with $Pd(OAc)_2$ in benzene solution and with $PdSO_4$ in 20% aqueous sulphuric acid solution, only coupling products were obtained[24,27].

The oxidative coupling of aromatic systems to biaryls under the influence of palladium(II).

Catalytic reactions. 3. Oxidation by oxygen in the presence of a catalyst							
Benzene	$PdSO_4$	H_2O—HOAc	84	3	Biphenyl	1600^d	99
Toluene	$Pd(OAc)_2$	H_2O—HOAc	70	2	Bitolyl (2,4'—21%; 3,4'—31%; 4,4'—22%)	1800^d	99
Toluene	$Pd(OAc)_2$	H_2O—HOAc, $Hg(OAc)_2$	70	2	Bitolyl (3,4'—36%; 4,4'—36%)	1900^d	99
Toluene	$PdCl_2$, $H_4SiW_{10}V_2O_{40}$, O_2 (1.5 atm)	H_2O—HOAc	84	3	Bitolyl	920	99
Toluene	$Pd(OAc)_2$	sulpholane	70	3	Bitolyl (3,4'—35%; 4,4'—48%)	610^d	99
Chlorobenzene	$Pd(OAc)_2$	H_2O—HOAc	90	—	Dichlorobiphenyl (2,4'—29%; 3,4'—26%; 4,4'—21%)	$—^d$	100
Chlorobenzene	$Pd(OAc)_2$	H_2O—HOAc, $Hg(OAc)_2$	90	—	Dichlorobiphenyl (2,4'—15%; 3,4'—34%; 4,4'—36%)	$—^d$	100

Table (contd.)

Substrate	Oxidant	Medium	T, °C	Time, h	Product R – R	Yield, % Pd	Refs.
o-Xylene	$Pd(OAc)_2$	H_2O—HOAc	50	2,5	Bixylyl (3,4,3′,4′—92%)	1300[d]	99
Durene	$PdSO_4$	H_2O—HOAc	84	4	Biduryl	670[d]	99

---

[a] Analogous products were obtained in a yield of 70–80% in the reaction of *p*-tolyl-, *p*-anisyl-, and *m*-nitrophenylmercury(II) acetates.

[b] Reaction carried out in the substrate undergoing oxidation in the presence of acetylacetone under a pressure of 150 atm of a 1 : 1 $O_2 + N_2$ gas mixture.

[c] Reaction carried out in the presence of $Fe(ClO_4)_3$ and $HClO_4$ under O_2 pressure (1 atm).

[d] Reaction carried out in the presence of HPA-2 having the composition $H_5PMo_{10}V_2O_{40}$ under O_2 pressure (1.5 atm).

It has been established[30] that substituted phenols in acetic acid in the presence of $PdCl_2$ and sodium acetate undergo oxidative coupling with formation of a C–C bond. This process yielded biphenols (1%) and products of their subsequent oxidation–biphenoquinones (17–25%). Phenol coupling products involving the formation of a C–O bond, which are frequently produced in other catalytic systems[18], were not detected.

When $PdBr_2$ and PdI_2 are used in acetic acid solution, oxidative coupling of aromatic compounds does not occur[2]. Palladium(II) nitrate interacts with aromatic compounds in acetic acid to form acetoxylation, nitration, and oxidative coupling products[31]. Thus phenyl acetate (39%), nitrobenzene (14%), and biphenyl (4%) were obtained from benzene. The addition of water, $HClO_4$, and iron(III) sulphate increases the yield of the coupling products.

Clark et al.[32] (see also Gol'dshleger et al.[33]) found that, under the influence of palladium(II) trifluoroacetate in trifluoroacetic acid at room temperature, aromatic compounds give rise to coupling products together with a small amount of phenols, which are probably formed on hydrolysis of the corresponding aryl trifluoroacetates during the separation of the reaction mixtures. The mode of coupling depends on the nature of the aromatic substrate. Benzene and its monosubstituted derivatives give rise preferentially or exclusively to biaryls. This is also observed with *o*- and *m*-xylenes and 1,2,3-trimethylbenzene. Apart from biaryls, alkylbenzenes yield diarylmethanes (mesitylene and durene give rise exclusively to diarylmethanes in 60% yield). Arylmethylation is characteristic of strongly acid media. Similarly phenyltolylmethane was obtained in the reaction of toluene with $Pd(OAc)_2$ in acetic acid in the presence of $HClO_4$.[27]

According to Fujiwara et al.[34], the $(olefin.PdCl_2)_2$ complexes cause the effective coupling of aromatic compounds in the presence of added silver(I), mercury(II), and copper(II) salts or oxides. Best results are obtained in the presence of the $(C_2H_4.PdCl_2)_2$–$AgNO_3$ (1 : 1) system. In the absence of the palladium(II) complex, silver(I) nitrate is inactive. Gaseous products (ethylene, nitrogen dioxide, and HCl) are evolved during the reaction. The yield of biphenyl in the coupling of benzene decreases in the following sequence of palladium(II) complexes: $(C_2H_4.PdCl_2)_2 > (styrene.PdCl_2)_2 > PdCl_2 > (cyclo\text{-}C_6H_{10}.PdCl_2)_2$. It is suggested that the role of $AgNO_3$ is cooperation in the substitution of the olefin for RH in the palladium(II) complex. In addition, the nitrate ion is involved in the reaction as an oxidant, which is indicated by the evolution of nitrogen dioxide.

The influence of substituents in the aromatic substrate shows that oxidative coupling under the influence of palladium(II) has the characteristics of electrophilic substitution in the aromatic ring[2]; electron-donating substituents facilitate the reaction, while electron-accepting substituents retard it. Monosubstituted benzene derivatives give rise to all six theoretical biaryl isomers[2,27]. 2,2′-Isomers are usually formed in an insignificant amount, probably owing to steric hindrance. In the reactions involving monoalkylbenzenes the main coupling products are the 3,4′- and 4,4′-isomers of biaryls. *o*-Xylene gives a mixture of the three possible isomers of bixylyl, in which the 3,4,3′,4′-isomer predominates (more than 60%)[2]. The proportions of the biaryl isomers are almost independent of added acids, salts, (for example NaOAc), and complex-forming agents. It has been shown[35] that the addition of mercury(II) salts significantly increases the yield of 4,4′-isomers in the coupling of alkylbenzenes. In this case the reaction proceeds via the intermediate formation of mercury derivatives of the aromatic compounds (see below). The proportions of the isomers depend strongly on temperature. Thus, when toluene is coupled in acetic acid under the influence of $PdCl_2$ + NaOAc at 25°C, 2,4′- and 2,3′-bitolyls are formed preferentially (in yields of 44 and 24% respectively), while at 200°C the main products are the 3,4′- and 4,4′-isomers (35 and 21%)[35].

Steric effects play a significant role in oxidative coupling. This is indicated by the inertness of the $PdCl_2$ + NaOAc system in acetic acid in relation to *p*-di-isopropylbenzene, *p*-di-(t-butyl)benzene, and mesitylene[2]. It is noteworthy that in trifluoroacetic acid polysubstituted benzene derivatives (mesitylene and durene) show the highest reactivity compared with benzene and its monosubstituted derivatives in the arylmethylation reaction and not the coupling reaction[32]; the reaction mechanism is in this case different (see below).

The coupling of benzene in acetic acid in the presence of $PdCl_2$ and NaOAc proceeds in accordance with the kinetic equation[2].

$$v = k[Pd^{II}][C_6H_6] \tag{1}$$

It is remarkable that the rate of reaction v is independent of the sodium acetate concentration, although in the absence of the latter the reaction with $PdCl_2$ does not occur[2]. This is probably because the relevant measurements were made[2] at a fairly high sodium acetate concentration (approximately 1 M) under saturation conditions.

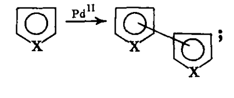
Eqn. (1) is also valid for the coupling of benzene in acetic acid[27] and in aqueous acetic acid[36] in the presence of $Pd(OAc)_2$. The replacement of C_6H_6 by C_6D_6 leads to a marked isotope effect: $k(H)/k(D) = 5.0$.[27] The rate of the reaction in acetic acid falls when water and chloride ions are added[36].

It has been established[27] that, when benzene is coupled in the presence of palladium(II) acetate at 50°C in acetic acid containing 0.5 M $HClO_4$, metallic palladium is not precipitated. The explosive red complex $[Pd(C_6H_6).(H_2O)(ClO_4)]_n$, in which the formal oxidation state of palladium is +1, was isolated instead. The complex decomposes in solution with formation of zero-valent palladium and biphenyl on heating *in vacuo* to 100°C. When chloride ions are added to the solution, palladium(I) disproportionates to bivalent and zero-valent palladium; molecular oxygen, bromine, and $KMnO_4$ oxidise palladium(I) to palladium(II). The role of the palladium(I) complex in the oxidative coupling has not so far been elucidated. The complex probably contains simultaneously bivalent and zero-valent palladium and the latter is stabilised by the benzene molecule. A complex containing palladium in the formal +1 oxidation state and having the composition (quinone).$Pd_2SO_4.3H_2O$ has been isolated in the oxidation of olefins to carbonyl compounds[37]. The zero-valent palladium formed in this reaction is stabilised in solution as a result of the formation of a complex with the olefin, for example $Pd(C_2H_4)_2$. We have suggested the involvement of palladium(I) in the coupling of benzene with ethylene under the influence of $Pd(OAc)_2$.[39]

2. HETEROAROMATIC COMPOUNDS

Like benzene and naphthalene derivatives, aromatic heterocycles undergo oxidative coupling smoothly under the influence of palladium(II). The coupling of five-membered heterocycles of the furan and thiophene series has now been investigated in detail (see Table). Presumably other heteroaromatic systems with various heteroatoms and ring sizes, which do not form inert complexes with palladium(II), would also undergo the coupling reaction. Heteroaryls differ from benzene derivatives by their higher reactivity. The coupling conditions in the heterocyclic series are on the whole analogous to those in the aromatic coupling. Limitations are imposed by the specific properties of the particular classes of heterocyclic compounds. Thus the tendency by furan derivatives to undergo solvolytic ring opening[40] restricts the application of aqueous solvents and rules out the possibility of adding inorganic acids. The coupling of thiophen is less complicated and shows the greatest similarity with the reaction of benzene.

Products of the coupling of five-membered heterocycles were detected when an attempt was made to acetoxylate thiophen[41] and to carbonylate thienyl- and furyl-mercury(II) derivatives[42] under the influence of palladium(II). The oxidative coupling of thiophen and furan derivatives has been studied[43-47]; the reaction proceeds under very mild conditions with formation of a mixture of 2,2'- and 2,3'-biheteroaryls and a small amount of the 3,3'-isomer[44]:



X = O or S.

The coupling of thiophen proceeds in both organic and aqueous solutions, including strongly acid solutions. The yield of bithienyls increases following the addition of mercury(II) salts. The coupling of furan takes place in a wide range of organic solvents[44,45] and in basic aqueous solutions, for example, in H_2O–dimethyl formamide (DMF) mixtures. In acetic acid the yield of biheteroaryls increases after the addition of sodium acetate[44,45]. Thiophen acetoxylation products were not detected under these conditions[41]. The isomeric composition of biheteroaryls depends on the reaction conditions. In acetic acid the ratio of the yields of 2,2'- and 2,3'-bithienyls—the main reaction products—increases after the addition of sodium acetate and water and after the reduction of temperature[44,46]. The ratio of the 2,2'- and 2,3'-isomers of bithienyl increases sharply when aqueous media are used and mercury(II) is added[44].

The reactivity of 2-substituted furan derivatives in the coupling reaction under the influence of $Pd(OAc)_2$ varies as follows in the presence of various substituents: H, CH_3, CHO > $COOCH_3$, $COOC_2H_5$, $CH(OOCCH_3)_2$ > COOH.[45] The sequence was established for electrophilic substitution reactions involving all five-membered aromatic heterocycles[40].

The joint coupling of furan and thiophen makes it possible to obtain in a single stage furylthiophens mixed with bithienyl and bifuryl[44]. The main product is 2-(2'-furyl)-thiophen and a small amount of 3-(2'-furyl)thiophen. It is noteworthy that the synthesis of furylthiophens by other methods is very complex[48,49].

The interaction of benzofuran with $Pd(OAc)_2$ in a benzene–acetic acid mixture yielded 2,2'-bibenzofuryl (68%), 2-phenylbenzofuran (12%), and biphenyl (4%).[50] The ratio of the reaction products indicates a much higher reactivity of benzofuran compared with benzene. A similar result was obtained with 5-methylbenzofuran[50].

Pyrrole chars rapidly on interaction with $Pd(OAc)_2$ in acetic acid, DMF, and heptane[44] and only traces of 2,2'-bipyrrolyl are formed (1%). It may prove useful to protect the pyrrole ring by *N*-alkylation, because *N*-methylpyrrole is smoothly vinylated by olefins under the influence of palladium(II).[51] Pyridine does not undergo the coupling reaction[44], because it forms a very stable complex with palladium(II).[52]

The kinetics of the coupling of heterocycles have been studied in relation to the reaction of thiophen[46]. The coupling of thiophen under the influence of $Pd(OAc)_2$ in acetic acid proceeds in accordance with the equation

$$v = k[Pd^{II}] \cdot [C_4H_4S]/(1 + K[C_4H_4S]), \qquad (2)$$

which differs from Eqn. (1) by the presence of the denominator $1 + K[C_4H_4S]$, which indicates the formation of an intermediate palladium(II) complex of thiophen with a stability constant, $K = 0.2$ litre $mole^{-1}$ at 70°C. In benzene a similar complex is less stable, the difference between the coordination capacities of benzene and thiophen in relation to palladium(II) being manifested. It is suggested[46] that palladium(II) forms a complex with thiophen via the sulphur atom. The kinetic isotope effect in the coupling of [2,5-D_2]thiophen in acetic acid is $k_2(H)/k_2(D) = 1.8$ [k_2 is the rate constant for the attack by palladium(II) on the 2-position in thiophen][46]. In aqueous solution the rate of reaction of thiophen with $PdCl_2$ is given by the equation[47]

$$v = k[Pd^{II}][C_4H_4S]/[H^+]^a \; [\bar{Cl}]^b,$$

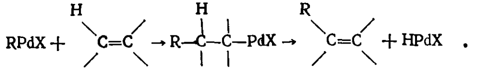
where $a \leqslant 1$ and $2 < b < 3$. A similar kinetic equation holds[1] for the oxidation of olefins by an aqueous solution of $PdCl_2$.

3. ORGANOELEMENTAL COMPOUNDS

The oxidative coupling of aryl derivatives of metals and non-metals [for example, mercury(II), thallium(II), boron(III), etc.] to biaryls under the influence of palladium(II) is discussed in this section. The coupling of organoelemental compounds takes place as a rule very readily and, in contrast to the coupling of hydrocarbons, makes it possible to obtain a unique biaryl isomer and not a mixture of isomers, the structure of the isomer depending on the organoelemental compound (see Table). These reactions proceed via the mechanism involving the substitution of the element by palladium(II), [18,19] which has been well established in the chemistry of palladium, and for this reason are of fundamental importance for the understanding of the mechanism of aromatic coupling under the influence of palladium(II).

Heck was the first to show[53, 60] the considerable preparative possibilities of such reactions in relation to the arylation of olefin and acetylene derivatives. Mercury(II) compounds proved to be the most effective. Tin(IV), lead(IV), etc. compounds have also been used. It is suggested[53-60] that the short-lived intermediate RPdX plays a decisive role in the reaction:

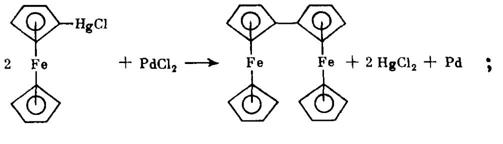
$$\mathrm{RHgX + PdX_2 \rightarrow RPdX + HgX_2} \quad ,$$

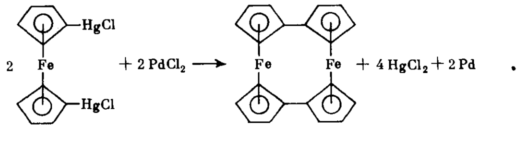


In the absence of unsaturated compounds RPdX gives rise to oxidative coupling products:

$$\mathrm{2RPdX \rightarrow R{-}R + PdX_2 + Pd} \quad .$$

Oxidative coupling of RHgX derivatives (R = phenyl, *p*-tolyl, *p*-cumenyl, *m*-nitrophenyl, *m*-carboxyphenyl, etc.) takes place at 25°C with high yields of the corresponding biphenyl derivatives[5]. A new C–C bond is then formed almost exclusively at the site of the initial addition of mercury(II). The coupling of (*p*-tolyl)HgOAc in acetic acid under the influence of $(\mathrm{PdOAc})_2$ is fairly slow, but is sharply accelerated by the addition of $\mathrm{HClO_4}$; $(p\text{-tolyl})_2\mathrm{Hg}$ reacts instantaneously also in the absence of $\mathrm{HClO_4}$.[35] Heterocyclic mercury(II) derivatives react analogously[42]. The reaction with ferrocene gave a high yield of biferrocenyl[61, 62]:





Arylthallium(III) derivatives react with $\mathrm{PdCl_2}$ in acetic acid in the presence of sodium acetate to form biaryls [Eqn. (3)][63]. As in the coupling of mercury(II) derivatives, the C–C bond is formed at the site of the initial addition of thallium(III); a small amount of side products comprising hydrocarbons RH and RCl is formed. The reaction proceeds with substitution of thallium(III) by palladium(II) in RTl(III).[63] Here $\mathrm{PdCl_2}$ is active also in the absence of NaOAc, but the addition of the latter accelerates the reaction. The inorganic products of the reaction are zero-valent palladium and thallium(I). Thallium(III), formed by reaction (3), probably oxidises metallic palladium to palladium(II), which makes the reaction catalytic in relation to palladium(II):

$$\begin{gathered}\mathrm{2RTl\,(III) + Pd\,(II) \rightarrow R{-}R + Pd + 2Tl\,(III)}\ , \\ \mathrm{Tl\,(III) + Pd \rightarrow Tl\,(I) + Pd\,(II)}\ . \end{gathered} \tag{3}$$

On reaction with palladium(II) salts, Grignard reagents give rise to coupling products with intermediate substitution of magnesium(II) by palladium(II):[64]

$$\begin{gathered}\mathrm{C_6H_5MgX + PdX_2 \rightarrow C_6H_5PdX + MgX_2}\ ; \\ \mathrm{2C_6H_5PdX \rightarrow (C_6H_5)_2 + PdX_2 + Pd}\ . \end{gathered}$$

A similar reaction takes place smoothly with aromatic and heterocyclic compounds also under the influence of copper(II), silver(I), iron(III), cobalt(II), nickel(II), ruthenium(IV), rhodium(III), etc. salts; iridium, osmium, and platinum compounds are less active[64].

The coupling of organic derivatives of non-metals (boron and sulphur) also involves the substitution of these elements by palladium(II). Benzene- and 3-methylbenzeneboronic acids give rise to biphenyl and 4,4′-bitolyl respectively after interacting for several minutes with $\mathrm{Pd(OAc)_2}$ in acetic acid in the presence of $\mathrm{HClO_4}$:[27]

$$\mathrm{2C_6H_5B\,(OH)_2 + Pd\,(II) + H_2O \rightarrow (C_6H_5)_2 + 2B\,(OH)_3 + Pd + 2H^+}\ .$$

Arenesulphinic acids and their salts are converted into biaryls in the presence of palladium(II) with liberation of $\mathrm{SO_2}$ [Eqn. (4)][65]. The reaction takes place in aqueous and organic media and the addition of mercury(II) salts catalyses the coupling reaction. Similar reactions may also be expected for aryl derivatives of silicon, because phenylation of olefins by trimethylphenylsilane in the presence of palladium(II) is known[66]. For the same reason, there is probably also a possibility of aromatic coupling via a stage involving the substitution of phosphorus in triphenylphosphine and of antimony in triphenylstibine for palladium(II), since the above compounds are capable of arylating styrene with a high yield [Eqn. (5)][23]:

$$\mathrm{2\,(}p\mathrm{\text{-}CH_3C_6H_4)\,SO_2Na + Pd\,(II) \rightarrow 4,4'\text{-}(C_6H_4CH_3)_2 + Pd + 2SO_2 + 2Na^+}\ ; \tag{4}$$

$$\mathrm{(C_6H_5)_3P + CH_2{=}CHC_6H_5 \xrightarrow{Pd(OAc)_2}}\ trans\text{-}\ \mathrm{C_6H_5CH{=}CHC_6H_5}\ . \tag{5}$$

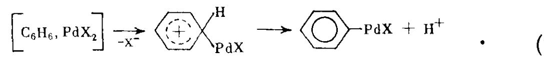
4. THE OXIDATIVE COUPLING MECHANISM

The oxidative coupling of aromatic, heteroaromatic, and organoelemental compounds under the influence of palladium(II) includes a slow stage in which the aromatic ring undergoes electrophilic substitution and proceeds via the intermediate formation of σ-arylpalladium(II).[18,19] This is preceded by the rapid formation of an intermediate arene–palladium(II) complex in accordance with Eqn. (6); this complex has been detected by kinetic methods in the thiophen coupling reaction[46]:

$$\mathrm{C_6H_6 + PdX_2 \rightleftarrows [C_6H_6,\ PdX_2]}\ . \tag{6}$$

The involvement of a σ-arylpalladium(II) is confirmed by the following data: (1) the acceleration of the reaction by electron-donating substituents and its inhibition by electron-accepting substituents: (2) the formation of coupling products when organoelemental compounds containing an aryl–element σ bond interact with palladium(II); (3) the marked kinetic isotope effect in the coupling of $\mathrm{C_6D_6}$ and [2,5-$\mathrm{D_2}$]thiophen; (4) the first order of the reaction with respect to palladium(II) and the substrate; (5) the acceleration of the coupling by the addition of alkali metal acetates, which promotes the abstraction of H^+; (6) other data.

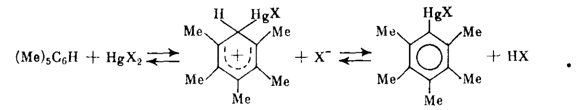
It is usually believed[67] that electrophilic substitution in the aromatic ring proceeds via mechanism(7) in two stages with formation of a cyclohexadienyl intermediate. The marked kinetic isotope effect in the oxidative coupling shows that the rate-limiting stage in reaction (7) is the abstraction of a proton from the cyclohexadienyl intermediate[27,46]:



(7)

Similar behaviour has been observed in the mercuration of aromatic compounds[67]. According to Yatsimirskii et al.[36], the anion bound to palladium(II) cooperaties in the abstraction of H^+ in reaction (7). The absence of deuterobenzene when the coupling is carried out in D_2O and DOAc shows that reaction (7) is irreversible[27]. Reaction (7) does not involve hydride transfer, because 2,2′-bibenzofuryl, obtained on coupling [2-D]benzofuran, does not contain dueterium[50].

The cyclohexadienyl intermediate in reaction (7) is an analogue of stable arenonium ions formed as intermediates in many reactions involving the electrophilic substitution of a hydrogen atom in an aromatic ring[68-70]. Nitration and halogenation of aromatic compounds, alkylation of aromatic compounds by olefins in the presence of Lewis acids, and the numerous reactions involving the migration of substituents in the aromatic molecule and their intermolecular transfer, investigated by Koptyug and coworkers[71], belong to this group of reactions. Reaction (7), involving the formation of a σ-arylpalladium(II), is analogous to the familiar reactions of arenonium ions[71], for example:



Here the cyclohexadienyl intermediate was detected by ultraviolet and ^1H NMR spectroscopy[72].

The subsequent fate of the σ-arylpalladium(II) (RPdX) is less definite. Van Helden and Verberg[2] rule out a radical decomposition of RPdX, because in an oxygen atmosphere phenol is absent from the reaction products; futhermore, the reaction is not affected by inhibitors of free radicals. The formation of coupling products at the instant of the liberation of zero-valent palladium from diarylpalladium(II) (RPdR) [Eqn. (9)] appears to be most likely:

$$RPdX + RPdX \rightarrow RPdR + PdX_2\ , \qquad (8)$$

$$RPdR \rightarrow R{-}R + Pd\ . \qquad (9)$$

This hypothesis is based on the exceptional ease of formation of coupling products from diarylmercury(II) derivatives under the influence of palladium(II).[35] The synthesis and reactions of σ-aryl derivatives of nickel(II), palladium(II), and platinum(II) of the type $RM(C_6H_4F)(PEt_3)_2$, where R = Ph or Me, constitutes a direct model of reaction (9).[73] The above nickel(II) and palladium(II) compounds decompose in solution with formation of coupling products and the zero-valent metal:

$$RPd(C_6H_4F)(PEt_3)_2 \rightarrow R{-}C_6H_4F + Pd + 2PEt_3\ .$$

The complex $NiBr(C_6H_5)(PEt_3)_2$ decomposes rapidly in toluene at 80°C with a quantitative yield of biphenyl; it has been suggested[73] that the reaction proceeds via a disproportionation stage:

$$2NiBr(C_6H_5)(PEt_3)_2 \rightleftarrows Ni(C_6H_5)_2(PEt_3)_2 + NiBr_2(PEt_3)_2\ , \qquad (10)$$

$$Ni(C_6H_5)_2(PET_3)_2 \rightarrow (C_6H_5)_2 + Ni(PEt_3)_2\ . \qquad (11)$$

The pathway leading to the formation of RPdR from RPdX has not been elucidated; we believe that it involves the disproportionation stage (8), similar to reaction (10). It has been suggested in a number of studies[22,32] that the substrate molecule is attacked by RPdX in accordance with the equation

$$RPdX + RH \rightarrow RPdR + HX\ . \qquad (12)$$

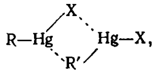
Reaction (12) does not conflict with data on the influence of the ring substituent and on isotope effects, but it is inconsistent with kinetic data. Since the electrophilic activity of RPdX must be lower than that of PdX_2, reaction (12) cannot be faster then reaction (7). One should therefore expect that stage (12) becomes rate-limiting and that the overall oxidative coupling process is of second order with respect to RH. This is inconsistent with experiment and necessitates the abandonment of the hypothesis of stage (12). Reaction (8) must be fast despite the low concentration of RPdX in the reaction mixture. There is no direct experimental confirmation of this, but numerous data for exchange reactions involving organometallic derivatives of beryllium, magnesium, cadmium, mercury, lead, zinc, and other metals have shown that reactions of type (8) are frequently very fast (for further details, see Reutov et al.[74]). In view of the profound analogy between the reactions of mercury(II) and palladium(II) with unsaturated compounds[19,74], the results for mercury(II) compounds are the most instructive. The kinetics and mechanisms of the exchange reactions of alkyl and aryl derivatives of mercury(II) have been studied in detail; the available data[74] show that such reactions proceed fairly readily, which may be an indication of the involvement of stage (8) in oxidative coupling.

Thus the principal features of the mechanisms of the oxidative coupling of aromatic compounds under the influence of palladium(II) can be represented by the sequence of reactions (6)–(9), among which reactions (7) and (8) determine the isomeric composition of the coupling products. It is possible to calculate the ratio of the rate constants for attack by palladium(II) on various positions in the substrate and to find the statistical proportions of the isomeric biaryls [i.e. the proportions obtained when the probabilities of reactions (8) are the same for different RPdX isomers]. By comparing the statistical and experimental proportions of the isomers, it is possible to obtain information about the rate of the exchange reaction (8) for different RPdX isomers. Fine polar effects of the group R in reaction (8) can be discovered in this way.

As an example, we shall consider the coupling of thiophen. When this reaction is carried out in acetic acid under the influence of $Pd(OAc)_2$ at 70°C with $[C_4H_4S]$ = 2.0 M, the experimental ratios of the 2,2′-, 2,3′-, and 3,3′-bithienyls are 6.4 : 13.8 : 1 (Kozhevnikov et al.[46]), while the statistical ratios are 3.2 : 3.6 : 1. Thus reaction (8), which leads to the asymmetric 2,3′-isomer, is much faster than the analogous reactions giving rise to the symmetrical 2,2′- and 3,3′-isomers. The concerted influence of the 2-thienyl and 3-thienyl groups, which have different electropolar properties, is probably manifested here. This effect is known for the "symmetrisation" reactions of RHgX:[74]

$$RHgX + R'HgX \rightarrow RHgR' + HgX_2\ . \qquad (13)$$

It has been established that reaction (13), involving the formation of asymmetric mercury derivatives, is faster than the fastest of the reactions where the symmetrical derivatives R_2Hg and R'_2Hg are formed from RHgX and R′HgX. This synergistic effect indicates the occurrence of reaction (13) [and in the case which we are considering also of reaction (8)] via the cyclic transition state



which corresponds to the S_Ei mechanism[74]. The preferential formation of asymmetric bithienyls in the reaction of thiophen with $Pd(OAc)_2$ may serve as confirmation of the occurrence of reaction (8) in oxidative coupling. More reliable conclusions require a broad analysis, for which the available data are as yet insufficient.

The mechanism discussed above refers to oxidative coupling in non-acid and moderately acid media. Coupling in strongly acid media (trifluoroacetic acid[32], acetic acid with added $HClO_4$ [27]) may proceed via a different mechanism. When alkylbenzenes are coupled in strongly acid media, diarylmethanes are formed together with biaryls. Under these conditions, polyalkylbenzenes (mesitylene, durene) yield mainly diarylmethanes[32]. Analogous products are formed when very strong oxidants [cobalt(III), cerium(IV), manganese(III), etc.)] act on alkylbenzenes. In this case coupling proceeds via a radical mechanism involving a stage in which an electron is transferred from RH to the oxidant (see Section III). In view of the similarity of the coupling products, a radical mechanism cannot be ruled out also in the case of coupling under the influence of palladium(II) in strongly acid media, particularly for reactions of polyalkylbenzenes. It is noteworthy that even thallium(III), which usually reacts with aromatic compounds via an electrophilic substitution mechanism, is capable of abstracting an electron from RH in trifluoroacetic acid with formation of a radical-cation[75] (Section III).

5. CATALYTIC REACTIONS

Catalytic oxidative coupling reactions are of greatest practical interest. For these to occur, palladium(II) must be regenerated from zero-valent palladium under the influence of an oxidant. The oxidants employed are O_2, copper(II), iron(III), vanadium(V), heteropolycompounds, etc. The most suitable industrial oxidant is oxygen; other oxidants may be used in laboratory practice, for example, the salts of metals in the highest oxidation states, hydrogen peroxide, or organic peroxides. Coupling under the influence of molecular oxygen, catalysed by palladium(II), can be divided into processes of two types: (1) those in which zero-valent palladium is oxidised by molecular oxygen and (2) those in which zero-valent palladium is reversibly oxidised by the effective oxidant, which plays the role of an agent transferring electrons from zero-valent palladium to oxygen‡; these reactions are considered separately below. Examples of catalytic reactions are presented in the Table. In the discussion of the catalytic coupling of aromatic compounds attention has been concentrated on fundamental research and only a selection of the patent literature is covered.

(a) General Discussion

Oxidative coupling under the influence of palladium(II) results in the formation of inactive zero-valent palladium, which is then converted into metallic palladium. In order to achieve the catalytic process, it is therefore necessary to oxidise zero-valent palladium to active palladium(II):

$$2RH + Pd(II) \rightarrow R{-}R + Pd(0) + 2H^+ , \qquad (14)$$

$$Pd(0) + Ox \rightarrow Pd(II) + Red. \qquad (15)$$

Depending on the conditions, any of the reactions (14) and (15) may be the rate-limiting stage of the catalytic process; hence follows the necessity for finding the optimum conditions. This problem was first solved successfully for the liquid-phase oxidation of olefins to carbonyl compounds[76,77] and has been examined in detail for these reactions in a number of reviews[1,18,78]. The principles underlying the selection of catalytic systems for the oxidation of olefins are largely applicable also to oxidative coupling reactions when account is taken of the specific features of the latter.

The choice of oxidants based on the oxidation potential is restricted at the lower limit by the requirement for a fairly high oxidation potential in order to regenerate palladium(II) and at the upper limit by the requirement for chemical inertness with respect to the organic substrate being oxidised. When a reversibly acting oxidant is used, the upper limit to its oxidation potential is set by the potential of molecular oxygen. The quantity $E_0[Pd_{met}/Pd(II)]$—the standard oxidation potential of the $Pd_{met}/Pd(II)$ pair whose values have been measured in various media—is usually employed as a criterion for the selection of oxidants[79]. However, this criterion is not entirely correct, because in real catalytic systems the reduced palladium is not precipitated and remains in solution in the form of zero-valent palladium complexes[78]. Such complexes, having the composition $Pd(olefin)_2$, have been detected in the oxidation reactions of ethylene and propene in aqueous palladium(II) solutions[37]. $E_0[Pd(0)/Pd(II)]$—the potential of the Pd(0)/Pd(II) pair, where Pd(0) does not refer to metallic palladium but to a zero-valent palladium complex in solution—must be regarded as a more accurate criterion[37,78]. The accurate oxidation potential of the Pd(0)/Pd(II) pair is not available, but there is not doubt that this potential is less negative than that of the $Pd_{met}/Pd(II)$ pair. For this reason, oxidants (for example, *p*-benzoquinone in the absence of Cl^- ions[37]) weaker than those which might have been thought suitable on the basis of the value of $E_0[Pd_{met}/Pd(II)]$ are also suitable for the regeneration of palladium(II). Together with the oxidation potential, an important characteristic of the oxidant is its ability to form zero-valent palladium complexes in the catalytic system[37].

The optimum reaction conditions for the given oxidant are usually selected by introducing ligands with definite coordination properties in relation to the Pd^{2+} ion[78]. The standard oxidation potential of the $Pd_{met}/Pd(II)$ pair depends significantly on the ligands present in the reaction system. In the absence of ligands capable of forming stable complexes with the Pd^{2+} ion (for example, in dilute solutions of palladium perchlorate or sulphate), the standard oxidation potential of the electrode process $Pd_{met} = Pd^{2+} + 2e^-$ is very high ($E_0 = 0.987$ V). In the presence of

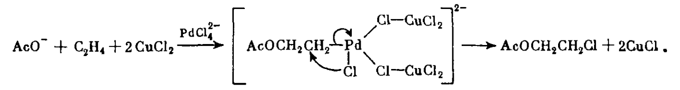
---

‡ Here and henceforth the term reversibly acting oxidant is understood to imply an oxidant whose oxidised form (Ox) can be rapidly regenerated by treating the reduced form (Red) with molecular oxygen under the reaction conditions.

ligands binding Pd^{2+} into fairly stable complexes (for example, Cl^-, Br^-, CN^-, etc.), the absolute value of the standard oxidation potential of the $Pd_{met}/Pd(II)$ pair diminishes. For example, $E_0 = 0.632$ V for the electrode process $Pd_{met} + 4Cl^- = PdCl_4^{2-} + 2e^-$.[79] Hence it follows that, for the same oxidant, the introduction into the reaction system of ligands forming stable complexes with Pd^{2+} should increase the rate of reaction (15) and reduce that of reaction (14), while exclusion of the ligands from the reaction mixture should lead to the opposite consequences. Since palladium(II) complexes are extremely labile, these thermodynamic predictions are indeed observed in practice.

The use of an oxidant with a higher potential should accelerate reaction (15), which, however, does not always happen owing to kinetic difficulties. An example is provided by molecular oxygen. The standard electrode potential of the process $2H_2O = O_2 + 4H^+ + 4e^-$ is 1.228 V.[79] Consequently direct oxidation of zero-valent palladium by oxygen is thermodynamically feasible in the presence of any ligand. However, in reality this process is very slow and requires severe conditions. The oxidation of zero-valent palladium by oxygen is significantly facilitated in the presence of reversibly acting oxidants, which are capable of effecting rapid electron transfer from zero-valent palladium to oxygen[78]. Copper(II) salts are usually employed as oxidants of this kind. The number of compounds suitable as reversibly acting oxidants in homogeneous catalysis is small. The discovery of the ability of copper salts to function as reversibly acting oxidants in relation to zero-valent palladium made it possible to achieve the catalytic oxidation of olefins to carbonyl compounds and stimulated the development of a whole series of related catalytic oxidation processes, including oxidative coupling reactions[1]. We therefore believe that it is very important to seek new reversibly active oxidants, the application of which will make it possible to extend significantly the scope of homogeneous metal-complex catalysis in partial oxidation reactions.

Before discussing studies on the catalytic oxidative coupling reactions, certain comments must be made concerning the mechanisms of the oxidation of organic compounds by palladium(II) salts in the presence of oxidants. This process was discussed above within the framework of the multistage mechanism (14)–(15) with the intermediate formation of zero-valent palladium. There is no doubt about the possibility of a multistage process, since reactions (14) and (15) may be carried out independently. At the same time it has been suggested that there is a possibility of a concerted mechanism of the oxidation process in which there is no intermediate formation of reduced palladium and electrons are transferred directly from the organic substrate to the oxidant via palladium(II),[37] the Pd^{2+} ion behaving as a bridge under these conditions. There are as yet no reliably established examples of reactions via the concerted mechanism, but many experimental data indicate its feasibility. They include the influence of the oxidant on the composition of the reaction products. Thus at a high $CuCl_2$ concentration in the oxidation of ethylene in water and acetic acid, saturated chloro-derivatives are formed as side products—ethylene chlorohydrin[80] and β-chloroethyl acetate[81] respectively. Since this happens only in the presence of $CuCl_2$, it has been suggested[81] that the reaction proceeds via the heterolytic cleavage of the C–Pd bond with transfer of the ligand:



Saturated β-halogeno-substituted coupling products were obtained similarly in the reaction of phenylmercury(II) with ethylene[82]. It has been shown[83] that in the reaction of benzene, alkylbenzenes, or their mercury derivatives with palladium(II) in the presence of acetate, chloride, etc. anions, the introduction of an oxidant (for example, $K_2Cr_2O_7$) results in substitution in the aromatic ring. In the absence of the oxidant, only oxidative coupling takes place. Thus the concerted mechanism can promote substitution in the aromatic ring or arylmethylation via the formation of R^+ in the heterolysis of RPdX induced by the oxidant. However, the involvement of the oxidant in reaction (9) leads to coupling. Presumably the former is more likely in the case of strong oxidants and the latter in the case of moderately strong oxidants. This problem requires special study.

Conclusions based on the above thermodynamic consideration of the influence of oxidants and ligands are independent of the reaction mechanism. They are valid also for the concerted mechanism. However, in the concerted mechanism the ability of the ligands to form bridge bonds between palladium(II) and the oxidant, at least in the case of cationic oxidants, is important together with the coordination properties of the ligand in relation to the Pd^{2+} ion.

(b) Oxidation by Metal Salts

The possibility of the regeneration of palladium(II) by copper(II) and iron (III) salts was already noted in the first patent of Van Helden et al.[3] Copper(II) salts are effective as oxidants for zero-valent palladium in the coupling reactions of very reactive aromatic systems, such as the thiophen and furan heterocycles and organoelemental compounds. Benzene and its derivatives are much less reactive in relation to coupling reactions under the influence of palladium(II). This is the reason for the limited applicability of copper salts as oxidants for the coupling reactions of these compounds. The Pd(II)/Cu(II) catalytic system is stable only in the presence of high concentrations of ligands forming stable complexes with palladium(II) and (or) copper(I) (these are usually Cl^- ions)[78]. The optimum concentration of Cl^- in the catalytic solution in water is approximately 1 M,[84] while in non-aqueous solutions it is less but still remains high. Under these conditions, the rate of reaction (14) is fairly high only for very reactive aromatic systems. Benzene and the majority of its derivatives are not included among these. The presence of Cl^- ions induces an appreciable side reaction involving the chlorination of organic compounds and intense corrosion of the apparatus, which also restricts the applications of the Pd(II)/Cu(II) system.

In the presence of palladium(II) as the catalyst, $CuCl_2$ effectively oxidises aryl derivatives of mercury(II) [5] and arenesulphinic acids[65] to biaryls in yields up to 800% [here and henceforth the yields are quoted in relation to palladium(II)]. The coupling of benzene in trifluoroacetic acid under the influence of copper(II) acetate is very slow[32].

The palladium(II)-catalysed oxidative coupling of furan, thiophen, and their derivatives under the influence of copper salts proceeds very readily and may be used as a convenient preparative method for the synthesis of the corresponding bifuryl, bithienyl, and furylthiophen derivatives[44,45,47,85]. Copper salts do not have a significant influence on the isomeric composition of the coupling products. The reaction proceeds in both aqueous and organic solvents (DMF, acetic acid, etc.) in yields up to

9000%. The coupling of furfural to 5,5′-diformyl-2,2′-bifuryl takes place smoothly in furfural and the yield and purity of the products increase after the addition of inert adsorbents to the system, for example, of activated charcoal[45].

The use of iron(II) salts as oxidants in palladium(II)-catalysed coupling of thiophen in aqueous solution makes it possible to obtain bithienyl in yields exceeding 700%.[44,47] The isomeric composition of bithienyl depends significantly on the presence of chloride ions in the reaction medium[47]. 2,2′-Bithienyl is formed in chloride systems with a selectivity up to 90%. In the absence of chloride ions in acid sulphate and perchlorate media 2,3-bithienyl is formed with a selectivity of about 90%, while its synthesis by other methods is extremely complex[86]. An increase of the concentrations of H^+ and Fe^{3+} increases the yield of the 2,3′-isomer, but lowers the catalytic activity. The influence of H^+ has been explained[47] by the protonation of thiophen at the sulphur atom, which entails the deactivation of the aromatic system, particularly in the 2-position of the thiophen ring. The analogous influence of the Fe^{3+} ion is probably due to its coordination to the sulphur atom. It may be that the latter favours the coupling of thiophen via the concerted mechanism[47]. The competitive influence of the Cl^- ion on the rates of stages (14) and (15) leads to an extremum in the dependence of the catalytic activity on $[Cl^-]$. In chloride-free systems the addition of mercury(II) salts sharply accelerates the reaction and leads to the exclusive formation of 2,2′-bithienyl[47]. Apart from Fe^{3+}, V_2O_5 is suitable as an oxidant in the coupling of thiophen in aqueous solution[47]. Iron(III) and vanadium(V) salts have been used as oxidants in the coupling of benzene, naphthalene, and their derivatives in sulphuric acid[6].

Palladium(II) may be regenerated also by thallium(III) compounds. This is indicated by the formation of biphenyl (in a yield of approximately 400%) when an excess of $C_6H_5Tl(OAc)ClO_4$ reacts with palladium(II)[63].

(c) Oxidation with Oxygen

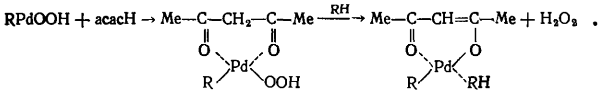
The possibility of the regeneration of palladium(II) by oxygen without cocatalysts was already noted in the first studies[2,29] on the oxidative coupling of aromatic compounds. Davidson and Triggs reported that the coupling of benzene in acetic acid in the presence of $Pd(OAc)_2$ takes place catalytically at an O_2 pressure exceeding 50 atm,[25,29] but the yield of biphenyl under these conditions is low (160% after 8 h at 100°C)[25]. In the presence of $Pd(OAc)_2$ in acetic acid bubbled with O_2 naphthalene gives very slowly (after 400 h) catalytic yields of a mixture of isomeric binaphthyls (1600%) and naphthalene oligomers ranging from the trimer to the hexamer (1500%).[41]

$Pd(ClO_4)_2$ catalyses the coupling of benzene under the influence of oxygen (1 atm) in aqueous acetic acid in the presence of $HClO_4$.[87] The yield of biphenyl increases linearly with time (220% after 8 h at 68°C) and depends on the $HClO_4$ concentration {the yield is a maximum when $[HClO_4] = 2-4$ M}. The activity of palladium(II) depends appreciably on the anion: $Pd(ClO_4)_2$ is twice as active as $Pd(OAc)_2$. The addition of $Fe(ClO_4)_3$ in an amount corresponding to $[Fe^{3+}]/[Pd^{2+}] = 90-200$ has a strong promoting influence. In the presence of Fe^{3+} the yield of biaryls decreases in the sequence toluene > *p*-xylene > *o*-xylene > *m*-xylene > benzene > chlorobenzene. 3,4,3′,4′-Bixylyl is formed preferentially from *o*-xylene, while toluene yields mainly 3,4′-bitolyl. The Fe^{3+} ion behaves as an oxidant in this reaction rather than as a cocatalyst, because there are no data showing the absorption of oxygen and yields of biaryls exceeding 100% (relative to Fe^{3+}) have not been achieved.

The oxidative coupling of benzene and naphthalene derivatives catalysed by palladium(II) carboxylates takes place very effectively in the substrate undergoing oxidation at an elevated temperature and a partial O_2 pressure of about 25 atm. This interesting reaction was discovered by Japanese workers, who investigated it extensively in relation to many aromatic compounds. The influence of conditions on the yield of coupling products[88,89], the relative activities of the aromatic compounds[90], and isotope effects[91] were investigated and the mechanism of the coupling reaction was considered[92,93]. The reaction is usually carried out at 150°C using a 1 : 1 $O_2 + N_2$ mixture in order to exclude the formation of explosive mixtures of organic vapours and oxygen[88]. The yield of coupling products increases with the pressure of the gas mixture up to 50 atm and then ceases to depend on the pressure[89]. The catalytic activity of palladium(II) decreases with increase of the $Pd(OAc)_2$ concentration, although the absolute yield of biaryls increases under these conditions[91]. The yield rises when β-diketones (acetylacetone is best) and EDTA are added to the reaction mixture. The addition of polar solvents, inorganic acids, alkali metal acetates and ligands such as triphenylphosphine, bipyridyl, pyridine, chloride ions, dienes, etc. reduces significantly the yield of oxidative coupling products[89]. The catalyst exhibits a high activity for a long time. Thus, in the coupling of toluene in the presence of $Pd(OAc)_2$ and acetylacetone the yield of bitolyl was 20 600% after 16 h.[88] The influence of the substituent in the benzene ring on the yield of biaryls is typical of electrophilic substitution in the aromatic ring: toluene > *o*-xylene > *m*-xylene > *p*-xylene > mesitylene[89]. The reaction mechanism is not yet entirely clear. A scheme has been proposed for the catalytic process in which oxygen both regenerates palladium(II) and abstracts a hydrogen atom from the molecule of the aromatic compound[92,93]:

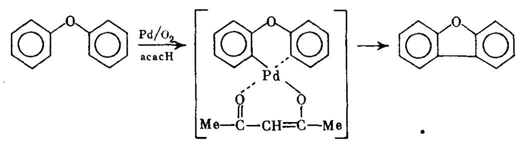
$$\begin{gathered}\mathrm{Pd(OAc)_2 + 2RH \rightarrow RPdR + 2HOAc}\ ,\\ \mathrm{RPdR \rightarrow R{-}R + Pd}\ ,\\ \mathrm{Pd + O_2 + RH \rightarrow RPdOOH}\ ,\\ \mathrm{RPdOOH + acacH \rightarrow RPd{-}acac + H_2O_2}\ ,\\ \mathrm{RPd{-}acac + RH \rightarrow RPdR + acacH}\ .\end{gathered} \tag{16}$$

It is suggested that acetylacetone (acacH) promotes the reaction by forming a stable *cis*-diarylpalladium(II) complex, which then readily gives rise to coupling products[92]:



$$\mathrm{RPdOOH + acacH \rightarrow Me{-}C(=O){-}CH_2{-}C(=O){-}Me \xrightarrow{RH} Me{-}C(=O){-}CH{=}C(O){-}Me + H_2O_2}\ .$$

It is of interest that diphenyl ether undergoes an intramolecular coupling reaction, which has been explained[92] by the possibility of the formation, in the first place, of an energetically favourable transition state with a six-π-electron system:

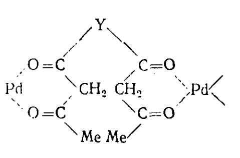


The favourable initial orientation, in one plane, of the benzene rings of the diphenyl ether (owing to conjugation via the oxygen atom) is apparently also important.

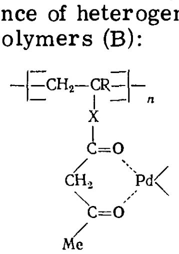
It has been suggested that this reaction may resemble the oxidation of triphenylphosphine and alkyl isocyanides by oxygen, which proceeds via zero-valent palladium complexes of molecular oxygen[94]. In this connection it has been postulated[91] that reaction (16) proceeds via a zero-valent palladium complex of O_2:

The involvement of free radicals in the reaction is probably ruled out because the coupling reaction is unaffected by inhibitors of free radicals[92].

There are data in the patent literature[8-15] concerning the possible practical achievement of the oxidative coupling of aromatic hydrocarbons at elevated temperatures and under O_2 pressure. The problem of separating the catalyst from the involatile oxidative coupling product is most complex when such processes are employed. In this connection mention should be made of the very important patent of Krause and Doebler[16] for the synthesis of biphenyl derivatives in the presence of heterogeneous palladium catalysts of type (A) or polymers (B):



(A)



(B)

where Y = alkylene, arylene, etc., R = alkyl or aryl, and X = arylene of a single bond. These catalysts are in essence palladium(II) complexes of diketones fixed on the solid surface. The catalysts are chemically equivalent to the homogeneous catalysts based on $Pd(OAc)_2$ and acetylacetone, which were discussed above; this is manifested by the similarity of the conditions in the corresponding reaction. The fundamental difference is the heterogeneous nature of the catalysts, which makes it possible to separate them readily from the reaction products and return them to the cycle.

Methods for attaching metal-complex catalysts to the surface of a solid carrier have been widely developed recently[95] and are extremely promising for the improvement of the technology of oxidative coupling processes. This applies particularly to the coupling reactions discussed in this section, which take place in the substrate undergoing oxidation, in the absence of polar solvents which significantly complicate the use of fixed metal complexes.

(d) Oxidation by Oxygen in the Presence of the Cocatalyst

Direct oxidation of zero-valent palladium by oxygen requires fairly severe conditions. The process may be significantly facilitated by the introduction of a cocatalyst—a reversibly acting oxidant, capable of effecting rapid electron transfer from zero-valent palladium to O_2. The use of classical reversibly acting oxidants-copper(II) salts—in oxidative coupling reactions is limited for reasons partly indicated above. Furthermore, there exist kinetic limitations, which hinder the formation of copper salts: in aqueous solutions the oxidation of copper(I) by oxygen is very rapid, but in organic media, where oxidative coupling is usually carried out, this reaction is very slow owing to the low solubility of CuCl.[96]

Matveev and coworkers suggested that heteropolyacids (HPA) be used as new reversibly acting oxidants, suitable for employment in palladium(II)-catalysed liquid-phase oxidations of olefins[97,98], oxidative coupling of aromatic compounds[99,100], etc. It has been established[99] that many molybdenum and tungsten HPA, which have a sufficiently high potential for the oxidation of zero-valent palladium to palladium(II), can be used for this purpose, including HPA with phosphorus, silicon, arsenic, boron, etc. heteroatoms. However, the most effective compounds of this series are those in which molybdenum or tungsten are partially substituted by vanadium, for example, compounds of the type $H_{3+n}PMo_{12-n}V_nO_{40}$ (henceforth designated by HPA-*n*, $n = 1$–8). Vanadium-containing HPA-*n* have the properties of reversibly acting oxidants and therefore permit the use of molecular oxygen as the oxidant in coupling reactions. The corresponding process may be represented by Eqns. (17)–(19), in which $H_2(HPA)$ is the reduced form of HPA:[99,100]

$$2RH + Pd(II) \rightarrow R{-}R + Pd + 2H^+ \ , \tag{17}$$

$$Pd + HPA + 2H^+ \rightarrow Pd(II) + H_2(HPA) \ , \tag{18}$$

$$\frac{H_2(HPA) + 1/2O_2 \rightarrow HPA + H_2O \quad ,}{2RH + 1/2O_2 \rightarrow R{-}R + H_2O \quad .} \tag{19}$$

It is noteworthy that reaction (19) in organic solvents proceeds faster than the corresponding reaction of copper(I) owing to the higher solubility of $H_2(HPA)$ compared with CuCl.

HPA are of great interest as components of catalysts for oxidative coupling and other partial oxidation reactions. This is due to the comparatively simple methods for their synthesis, ready solubility in both aqueous and organic solvents, and the possibility of varying over a wide range their compositions and hence their oxidation-reduction properties. The latter possibility is at the present time just beginning to be investigated. It is very significant that, in contrast to copper salts, HPA are capable of oxidising palladium in the absence of chloride ions. This makes it possible to achieve a much higher activity of palladium(II) and to eliminate the side reaction involving the chlorination of aromatic compounds, which takes place in the presence of chloride ions. There are reviews[101,102] and a special monograph[103] on the methods of synthesis and properties of HPA. The oxidation-reduction properties of HPA have not as yet been widely discussed in connection with their employment in catalysis. Matveev and coworkers investigated the spectra[104], thermodynamics[105], and kinetics[106] of oxidation-reduction reactions of the HPA-*n*. However, a detailed discussion of these studies is outside the framework of the present review.

The yields of the products of the oxidative coupling of benzene derivatives under the influence of oxygen, catalysed by the Pd(II)/HPA-2 oxidation-reduction system, have been widely studied[99,100]. The reaction proceeds in aqueous acetic acid under an O_2 pressure of 1.5 atm. The yield of biaryls relative to absorbed O_2 in the coupling of benzene, toluene, *o*-xylene, and durene (characterised by the selectivity of the reaction) reaches 70–93%.[99] The yield calculated relative to palladium(II) exceeds 4400% in a single catalytic cycle. The catalytic coupling of aromatic compounds in the presence of HPA-2 as well as the corresponding stoichiometric reaction have the characteristic features of electrophilic substitution in the aromatic ring. The alkylbenzene activity series benzene < toluene and *o*-xylene > durene, determined by the polar and steric influences of the substituents, are consistent with the results of earlier studies on the stoichiometric reaction, Neither HPA-2 nor oxygen affect the composition of the coupling products. As in the stoichiometric reaction, mercury(II) has a marked influence on the proportions of the biaryl isomers. For monosubstituted benzenes, the addition of mercury(II) increases the yield of the 4,4′- and 3,4′-isomers. Thus in the coupling of toluene the yield of 4,4′-bitolyl increases from 22 to 41% with increase of the concentration of $Hg(OAc)_2$ from zero to 0.1 M. In the coupling of *o*-xylene the yield of the 3,4,3′,4′-isomer increases in the presence of mercury(II). It is interesting that the replacement of acetic acid as a solvent by sulpholane has a similar effect on the proportions of the isomeric biaryls[99].

The kinetic data obtained for the coupling of benzene derivatives in the presence of HPA-2 [100] are also consistent with the interpretation of this reaction as electrophilic aromatic substitution: electropositive substituents [OCH_3, $N(CH_3)_2$, OC_6H_5, alkyl] accelerate the reaction, while electronegative substituents (Cl, COOH, CF_3) inhibit it. The influence of chain length (toluene–ethylbenzene > isopropylbenzene > propylbenzene) and of the number of substituents (*o*-xylene > 1,2,4-trimethylbenzene > mesitylene > durene) on the reaction rate corresponds to the usually observed steric influence in electrophilic substitution reactions involving the aromatic ring. The rate of coupling increases after the addition of mercury(II) and reaches saturation at an $Hg(OAc)_2$ concentration of 0.1 M. The orders of the reaction with respect to O_2 and HPA-2 are close to unity, while the order with respect to palladium(II) is less than unity (more precisely 0.4–0.6). These data show that the rate-limiting stage of the oxidative coupling of aromatic compounds under the influence of oxygen, catalysed by Pd(II)/HPA-2, is reaction (19), involving the oxidation of $H_2(HPA)$ to HPA by oxygen[100].

It is very significant that coupling in the presence of HPA proceeds under very mild conditions: at 50–90°C and an O_2 pressure of 1.5 atm. This is an advantage of this process over the palladium(II)-catalysed oxidative coupling in the absence of a reversible oxidant, which takes place at an oxygen partial pressure of about 25 atm.

III. COUPLING UNDER THE INFLUENCE OF OTHER METALS

Apart from palladium(II) compounds, the compounds of many other metals, usually in high oxidation states, may be used for the coupling of aromatic systems. The preparative importance of the coupling reaction involving compounds of these metals is small. Depending on the nature of the metal and the oxidation state, which determines its oxidising properties, coupling may occur via two mechanisms: by electrophilic substitution in the aromatic ring, like the majority of the reactions in the presence of palladium(II), or via electron transfer from RH to the oxidant with formation of a radical-cation. The mechanism of oxidative coupling depends also on the nature of RH, the acidity of the medium, and other factors. The ability of the oxidant to form aryl derivatives is an essential but not sufficient condition for the reaction via the electrophilic substitution mechanism. An increase of the oxidation potential of the oxidant and of the acidity of the medium as well as a decrease of the ionisation potential of RH favour the reaction via the electron transfer mechanism with formation of a radical-cation.

1. COUPLING VIA THE ELECTROPHILIC SUBSTITUTION MECHANISM

The mechanism of these reactions has been little studied, so that only preliminary conclusions may be reached. More complete information is available about coupling under the influence of platinum(II) and platinum(IV): these reactions are very similar to coupling under the influence of palladium(II). Platinum(II) acetate interacts with benzene in an excess of the latter and with benzeneboronic acid in HOAc to form biphenyl[27]. Toluene reacts with $Pt(OAc)_2$ in acetic acid in the presence of $HClO_4$ to form phenyltolylmethane[27]. Chloroplatinic acid is active in the coupling of furan to bifuryl[45] and also readily induces the coupling of toluene in acetic acid in the presence of $Hg(OAc)_2$ and $HClO_4$ to form mainly 4,4′-bitolyl[35]. The degree of reduction of platinum(IV) depends on the $HClO_4$ concentration. In a weakly acid medium platinum(IV) is reduced to platinum(II), while in a strongly acid medium it is reduced to zero-valent platinum[35]. In the last case two moles of biaryl are formed per mole of platinum(IV). It is suggested[35] that the addition of $HClO_4$ increases the electrophilic acitivity of platinum(II) [$PtCl_2$ (Ed. of Translation)] owing to the formation of $Pt(ClO_4)_2$ [which may be more dissociated (Ed. of Translation)]. The coupling of benzene under the influence of H_2PtCl_6 proceeds with a low selectivity in relation to biphenyl in water and aqueous acetic acid[107]; the main product is chlorobenzene. Platinum(IV) is reduced under these conditions to platinum(II) and the reaction proceeds autocatalytically, since platinum(II) catalyses the coupling reaction with participation of platinum(IV).[107] A mechanism has been proposed for the coupling of benzene with the intermediate formation of σ-phenylplatinum(II).[107] The occurrence of aromatic coupling in the presence of platinum(II) via the electrophilic substitution mechanism is also indicated by the well known ability of platinum(II) to catalyse the H–D exchange involving aromatic compounds[107].

Very little is known about coupling under the influence of compounds of other noble metals and data on the mechanisms of these reactions are altogether lacking. Gold(III) sulphate causes slow coupling of benzene in aqueous sulphuric acid, while treatment of toluene with Au_2O_3 in acetic acid in the presence of $HClO_4$ results in the formation of bitolyl[27]. When benzene is coupled under the influence of gold(III) in D_2O, the deuteration is not observed, as in the case of palladium(II)[27]. Ruthenium(IV) and ruthenium(III) compounds are relatively ineffective in the coupling of benzene[30] and furan[45].

As already mentioned, copper, silver, iron, cobalt, nickel, ruthenium, rhodium, iridium, osmium, and platinum as well as palladium(II) compounds interact with Grignard reagents to form coupling products[64]. Recently biaryls were obtained in a high yield from a Grignard reagent under the influence of thallium(I)[108]. The course of the reaction may be represented by the equations

$$RMgBr + TlBr \rightarrow RTl + MgBr_2 \ ,$$

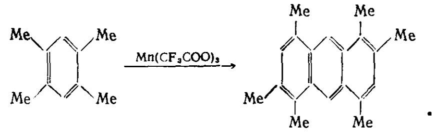
$$2RTl \rightarrow R{-}R + 2Tl \ .$$

However, the formation of a small amount of arylthallium(III) derivatives and aryl bromides indicates a more complex reaction mechanism.

2. COUPLING VIA THE ELECTRON TRANSFER MECHANISM

This class of reactions includes primarily coupling under the influence of strong one-electron oxidants in strongly acid media. These reactions have been studied in detail and their radical mechanism has been demonstrated quite reliably in many instances.

Cobalt(III), manganese(III), and cerium(IV) trifluoroacetates oxidise aromatic hydrocarbons RH in trifluoroacetic acid at room temperature with formation of a mixture of biaryls, diarylmethanes, and aryl trifluoroacetates[109,110]. The composition of the products depends on the nature of RH and the [RH]:[Me] ratio. For the ratio [RH]:[Co(III)] = 0.5, benzene gives a quantitative yield of phenyl trifluoroacetate[109]; in the presence of an excess of benzene, biphenyl was found among the products. However, its yield is insignificant, because biphenyl itself is oxidised by cobalt(III) much faster than benzene[109]. Benzene reacts similarly with cerium(IV)[111]. Toluene and *p*-xylene give rise to benzyl trifluoroacetates, diarylmethanes, and higher oligomers; anisole yields mainly 4,4′-dimethoxybiphenyl (30%). The oxidation of mesitylene results in the preferential formation of bimesityl together with diarylmethane. Durene yields diarylmethane and only traces of a biaryl. When durene was treated with cobalt(III) or manganese(II) trifluoroacetates, hexamethylanthracene was obtained in addition to biarylmethane[110]:



Under these conditions, naphthalene gives a low yield of 1,1′-binaphthyl[110]. The reactions of cobalt(III), manganese(III) and cerium(IV) with aromatic hydrocarbons exhibit considerable qualitative similarities despite certain quantitative differences between the reactivities and product ratios[110].

The heterogeneous oxidation of polymethylbenzenes by iron(III) chloride in non-polar media takes place similarly to oxidation by cobalt, manganese, and cerium compounds[112,113]. In this case chloro-derivatives of the aromatic compounds and polymers are formed together with biaryls and diarylmethanes. Alkylbenzenes react similarly with $SbCl_5$.[114]

It is of interest that the reactions of aromatic perfluorocarbonium ions in $SbCl_5$ solution also lead to coupling products—perfluoropolyaryls. For example, perfluoro-1,3,5-triphenylbenzene was obtained by the reaction between perfluorohexadiene and pentafluorobenzene (80%)[115].

The reactions of aromatic compounds with strong oxidants exhibit a low selectivity in relation to coupling and give many products, as a result of which they are not usually of synthetic value. However, certain reactions can be of preparative importance. For example, the coupling of naphthalene with mesitylene in the presence of $FeCl_3$ makes it possible to isolate 1-(2,4,6-trimethylphenyl)naphthalene in 35% yield[113].

It can be regarded as established that the reactions of aromatic compounds with strong one-electron oxidants proceed via a radical mechanism involving a slow stage in which an electron is transferred from RH to the oxidant[109–113]. This is indicated by the following data. The reactivity of RH increases in the sequence benzene < toluene < *p*-xylene < mesitylene < durene. The ionisation potential of RH diminishes in the same sequence. The above reactions are fully analogous to the electrochemical oxidation of RH, which takes place via electron transfer. The oxidation of benzene and toluene by cobalt(III) trifluoroacetate is of first order with respect to RH and cobalt(III) and there is no kinetic isotope effect. Finally aromatic radical-cations were detected directly by EPR in the reaction of RH and cobalt(III)[109,116]. The reaction mechanism may be represented by the following equations[109–113]:

$$Me^{n+} + RH \rightleftarrows [RH, Me^{n+}] \rightleftarrows [RH^{\dot{+}}, Me^{(n-1)+}] \rightarrow RH^{\dot{+}} + Me^{(n-1)+} ,$$

$$RH^{\dot{+}} + RH \rightarrow [HR\text{—}RH]^{\dot{+}} \xrightarrow[-e,\ 2H^+]{Me^{n+}} \text{biaryl},$$

$$RH^{\dot{+}} \xrightarrow[-H^+]{} R^{\cdot} \xrightarrow[-e]{Me^{n+}} R^+ ,$$

$$R^+ + RH \rightarrow [R\text{—}RH]^+ \xrightarrow[-H^+]{} \text{diarylmethane},$$

$$R^+ + CF_3COOH \rightarrow ROOCCF_3 + H^+ .$$

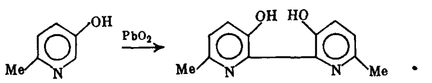
Electron transfer takes place in the molecular complex $[RH.Me^{n+}]$, the decomposition of which yields the $RH^{\dot{+}}$ radical-cation, Subsequently $RH^{\dot{+}}$ may attack the RH molecule with formation of the coupling products or it may lose a proton and an electron under the influence of the base and Me^{n+} may be converted into the carbonium ion R^+. The latter gives rise to substitution and arylmethylation products.

Depending on the conditions, the two-electron oxidants thallium(III) and lead(IV) may react with aromatic compounds via electrophilic substitution in the aromatic ring or via a radical mechanism involving electron transfer[110].

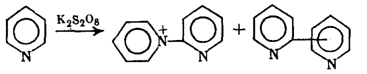
Benzene and toluene are coupled to biaryls under the influence of thallium(III) in aqueous $HClO_4$ and in acetic acid, the reaction being slow and having a low yield[117,118]. The addition of palladium(II) increases sharply the yield of biaryls as a result of the substitution of thallium(III) by palladium(II) in aryl derivatives of thallium(III)[117]. It is well known that thallium(III) usually reacts with aromatic compounds via the electrophilic substitution mechanism[119]. Numerous arylthallium derivatives have been isolated and characterised satisfactorily. However, Elson and Kochi reported[75] that they succeeded in detecting by EPR the durene and 4,4′-bitolyl radical-cations under the conditions of the substitution of thallium in durene and toluene by thallium(III) trifluoroacetate. This demonstrated the possibility of reactions of thallium(III) via a radical mechanism involving electron transfer from RH to thallium(III).

Lead(IV) readily oxidises aromatic compounds to biaryls, diarylmethanes, and aryl ethers with formation of aryllead(IV) derivatives as side products[120,121]; the composition of the product depends on the reaction conditions. In trichloroacetic acid lead(IV) gives products resulting from the metallation of RH, for example *p*-methoxyphenyl-lead(IV) was obtained from anisole in 50% yield[120]. Under more severe conditions (in trifluoroacetic acid), the reaction of lead(IV) with methylbenzenes proceeds via a radical mechanism[121], similar to that of the reactions with one-electron oxidants examined above. These data for thallium(III) and lead(IV) show that even the well-established ability of the metal ion to form aryl derivatives may prove to be an inadequate criterion for the selection of the reaction mechanism. One must also take into account the acidity of the medium and the nature of the ligands and the substrate. In this connection, Nyberg and Wistrand suggested[110] that in media more acid than trifluoroacetic acid reactions with aromatic compounds via electron transfer are not ruled out even in the case of mercury(II).

The coupling reactions of heterocyclic compounds of the pyridine series can be carried out under the influence of strong radical oxidants. Substituted 3-pyridinols react with PbO_2 in benzene solutions to give 2,2′-bipyridyl derivatives, which are remarkable because of their fluoroescence in the visible region under the influence of ultraviolet radiation[122]:



Pyridine is oxidised by potassium persulphate in aqueous solution with formation of the pyridylpyridinium cation and a mixture of bipyridyl isomers[123]:



The ratio of the reaction products depends on the pH of the medium; in acid media the pyridylpyridinium cation is formed preferentially (90%), while in alkaline media the product is 40% of bipyridyl. The addition of silver(I) in an alkaline medium increases the yield of bipyridyl. The radical mechanism of this reaction has been reliably established by detecting the pyridinium radical-cation using EPR.

The oxidative coupling of aromatic systems has a fairly broad universality. The coupling takes place in series of aromatic, heterocyclic, and organoelemental compounds in the presence of a large range of oxidants. Naturally, with such wide variation of the conditions, the reaction mechanism does not remain the same. Having arranged the oxidants effecting the coupling reaction in order of decreasing oxidation potentials, it is possible to observe quite clearly a continuous change in this series from the radical coupling mechanism (via electron transfer with intermediate formation of an aromatic radical-cation) to electrophilic substitution in the aromatic ring and participation of an organometallic intermediate. The selectivity of the conversion of the substrate into the coupling products increases in the same sequence. Oxidative coupling under the influence of palladium(II) salts and complexes is the most important reaction among those in the above class. This is associated with its high selectivity and the possibility of its being catalytic. The latter is a decisive advantage of palladium(II) over other oxidants.

The synthetic possibilities of the reactions are fairly extensive for a wide range of aromatic systems. Among these, the coupling of benzene and its derivatives has been studied in greatest detail. The coupling of benzene to form biphenyl has no significant advantages over the non-catalytic vapour-phase pyrolysis of benzene. However, the coupling of benzene derivatives is really promising as an effective method for the preparation of the corresponding polyfunctional biphenyl derivatives, which are of interest as monomers for polycondensation[124], the synthesis of plasticisers, etc. Oxidative coupling of heterocyclic compounds, where this reaction makes it possible to obtain readily biheteroaryls whose synthesis by other methods is extremely difficult, is extremely promising. The useful properties of biheteroaryls have as yet been inadequately elucidated owing to the difficulty of their synthesis.

The most complex problem, constituting an obstacle to the practical utilisation of catalytic oxidative coupling, is the separation of the catalyst from involatile coupling products. This is a specific disadvantage of homogeneous catalytic processes. The development of metal-complex catalysts deposited on the surface of a solid carrier can probably become the most promising trend in the solution of this problem.

Topological Principles of the Analysis of Binary Statistical Copolymerisation

V.A.Myagchenkov and S.Ya.Frenkel'

The criteria for the estimation of the characteristics of binary statistical copolymerisation, namely composition, curves for distribution with respect to composition, chemical structure of macromolecules, and parameters of the quantitative estimate of inhomogeneity with respect to composition, are examined on the basis of the most general model of such a process. It is suggested that all copolymeric systems be divided into four classes: (1) classical; (2) classical subject to certain boundary conditions; (3) "unusual" systems of the first kind; (4) "unusual" systems of the second kind ("anomalous" systems). The principles described are illustrated by the analysis of a number of specific models (heterophase copolymerisation, copolymerisation of ionogenic monomers in ionising media, copolymerisation of partly complexed monomers, copolymerisation complicated by reactions involving chain transfer to macromolecules or by depolymerisation reactions, etc.). The bibliography includes 136 references.

I. INTRODUCTION

A specific alteration of the properties of the final products can be achieved in many instances by replacing homopolymers by copolymers, and the correct choice of the modifying units in the copolymer macromolecules makes it possible to alter in the required direction the rheological, thermomechanical, and physicochemical parameters of materials[1,2]. For many multicomponent systems, an appreciable effect is achieved by the introduction of small amounts of a second monomer, but the contribution of the second component to the resulting property can be by no means always predicted *a priori* and even less so calculated on the assumption of additivity[3]. According to modern ideas, the principal properties of materials (such as thermal stability, chemical stability, tensile strength, residual deformation, modulus of elasticity, radiation stability, and ageing parameters) are determined by the main component of the copolymer, while other properties, for example, surface and volume conductivity, colourability, vulcanisability, surface hardness, adhesion, and ion-exchange capacity, are determined to a significant extent by the nature of the modifying component. Furthermore, the most important parameters of materials based on copolymers are not determined only by the chemical nature of the monomeric units, the average molecular weight, and the average composition, depending no less on the method of introduction of the second component (block, graft, or static copolymers), the chemical structure of the macromolecules, and the characteristics of the distributions with respect to composition and molecular weight[4].

The continuously increasing number of studies devoted to different aspects of copolymerisation (the current bibliography includes more than 100 000 items) faces investigators with the necessity for devising a general classification of the relevant processes. Such classification would promote a more rigorous and well-founded approach to the selection of a realistic detailed copolymerisation model as well as a method and apparatus for the investigation. The employment of such a classification is extremely desirable also for the systematic arrangement and compilation of the existing copolymerisation data. The principal requirements in creating this type of classification may be formulated as follows: firstly, it must be based on the most general copolymerisation model; secondly, the criteria for the estimates must take into account the main specific characteristics of the process; thirdly, the use of the classification should promote the development of a specific experimental programme.

This review deals only with problems concerning binary statistical copolymerisation. Our aim was not to write an exhaustive survey of literature (one of the reasons being the availability of systematic reviews of different branches of copolymerisation[1,4-9]) and we confined ourselves to examining studies where copolymerisation was analysed without the *a priori* assumption of the applicability of the Mayo–Lewis scheme. One should note particularly that the easiest and most widely used method for the interpretation of experimental data employing the average composition of the copolymer increment as the "key" parameter is insufficiently sensitive and reliable to draw final influences about the characteristics of the copolymerisation process. On the other hand, analysis of the complete distribution curves with respect to composition makes it possible to infer much more reliably the process characteristics, particularly when a specific copolymerisation is assigned to classical or "unusual" systems[4,10].

In a series of studies by the present authors the current problems in the statistical theory of copolymerisation are critically analysed. Having examined mainly the "anomalies" of binary copolymerisation, we showed that the classical Mayo–Lewis theory and the widely used schemes which follow from it, for example, the Alfrey–Price scheme, are exceptions to the rule rather than the rule itself. This third and concluding review, constitutes an attempt at a classification of binary copolymerisation processes in terms of topological features, with the principles of kinetic and statistical analyses which follow from it. Naturally, we do not in any way suggest that this is a final classification, but we hope that it will assist investigators working in the field of copolymerisation in developing analytical schemes which are more flexible and realistic than the "classical" schemes mentioned above.

II. FUNDAMENTAL PRINCIPLES OF THE CLASSIFICATION OF BINARY STATISTICAL COPOLYMERISATION PROCESSES

The statistical theory of copolymerisation can be justifiably treated as an independent branch of physical chemistry for three reasons.

(1) The synthesis of copolymers result in the formation of macromolecules with a predetermined configuration; in the general case the composition of the macromolecules depends not only on the composition of the initial monomer mixture but also on the degree of conversion Ψ and the nature of the reaction medium[11].

(2) The principal characteristics of the synthesis of copolymers cannot be described within the framework of the general relations of homopolymerisation processes[1, 12-14].

(3) The properties of copolymers and compositions based on them are in most cases related in a complex manner to the characteristics of the *ensemble* of macromolecules (particularly to the composition[15] and the distribution functions with respect to composition[7,16]) and, in order to obtain even estimates of the corresponding parameters, it is necessary to know at least the mechanism of such copolymerisation.

It is already clear from the foregoing that the technique for the investigation of copolymeric systems must itself be to a large extent specialised and must differ significantly from that for the investigation of homopolymers. Since the most important differences between copolymers and homopolymers are associated with the presence in the macromolecules of fragment of the second monomer (on the nature of the components and their proportions depend also other more complex characteristics of the *ensemble* of the copolymer macromolecules, such as molecular polymorphism, the nature of selective interactions at the intra- and inter-molecular levels, etc.), we selected the composition, the distribution functions with respect to composition, and the stereochemical configuration of the macromolecules as the fundamental criterial parameters in the development of a general classification for the analysis of binary statistical copolymerisation.

We shall examine, for example, a general scheme for the synthesis of macromolecules of statistical copolymers, which includes, as usual, three stages—initiation (I), propagation (II), and termination of kinetic chains (III):

$$\left.\begin{array}{r}\theta \xrightarrow{k_{\mathrm{i}}} q^{*}\ ,\\ q^{*}+\mathrm{A} \xrightarrow{k_{\mathrm{iA}}} q\,\mathrm{A}^{*},\\ q^{*}+\mathrm{B} \xrightarrow{k_{\mathrm{iB}}} q\,\mathrm{B}^{*},\end{array}\right\} \qquad (\mathrm{I})$$

$$\left.\begin{array}{r}
q\mathrm{A}^{*}+\mathrm{A} \underset{k'_{1\mathrm{AA}}}{\overset{k_{1\mathrm{AA}}}{\rightleftarrows}} q\mathrm{AA}^{*}\ ,\\
q\mathrm{A}^{*}+\mathrm{B} \underset{k'_{1\mathrm{AB}}}{\overset{k_{1\mathrm{AB}}}{\rightleftarrows}} q\mathrm{AB}^{*}\ ,\\
q\mathrm{B}^{*}+\mathrm{A} \underset{k'_{1\mathrm{BA}}}{\overset{k_{1\mathrm{BA}}}{\rightleftarrows}} q\mathrm{BA}^{*}\ ,\\
q\mathrm{B}^{*}+\mathrm{B} \underset{k'_{1\mathrm{BB}}}{\overset{k_{1\mathrm{BB}}}{\rightleftarrows}} q\mathrm{BB}^{*}\ ,\\
\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\\
q\,\mathrm{A}_{n_1}\mathrm{B}_{n_2}\mathrm{AA}^{*}+\mathrm{A} \underset{k'_{n\mathrm{AAA}}}{\overset{k_{n\mathrm{AAA}}}{\rightleftarrows}} q\,\mathrm{A}_{n_1+1}\mathrm{B}_{n_2}\mathrm{AA}^{*}\ ,\\
q\,\mathrm{A}_{n_1}\mathrm{B}_{n_2}\mathrm{AA}^{*}+\mathrm{B} \underset{k'_{n\mathrm{AAB}}}{\overset{k_{n\mathrm{AAB}}}{\rightleftarrows}} q\,\mathrm{A}_{n_1}\mathrm{B}_{n_2+1}\mathrm{AB}^{*}\ ,\\
q\,\mathrm{A}_{n_1}\mathrm{B}_{n_2}\mathrm{BA}^{*}+\mathrm{A} \underset{k'_{n\mathrm{BAA}}}{\overset{k_{n\mathrm{BAA}}}{\rightleftarrows}} q\,\mathrm{A}_{n_1}\mathrm{B}_{n_2+1}\mathrm{AA}^{*},\\
q\,\mathrm{A}_{n_1}\mathrm{B}_{n_2}\mathrm{BA}^{*}+\mathrm{B} \underset{k'_{n\mathrm{BAB}}}{\overset{k_{n\mathrm{BAB}}}{\rightleftarrows}} q\,\mathrm{A}_{n_1}\mathrm{B}_{n_2+1}\mathrm{AB}^{*},\\
q\,\mathrm{A}_{n_1}\mathrm{B}_{n_2}\mathrm{BB}^{*}+\mathrm{A} \underset{k'_{n\mathrm{BBA}}}{\overset{k_{n\mathrm{BBA}}}{\rightleftarrows}} q\,\mathrm{A}_{n_1}\mathrm{B}_{n_2+1}\mathrm{BA}^{*},\\
q\,\mathrm{A}_{n_1}\mathrm{B}_{n_2}\mathrm{AB}^{*}+\mathrm{A} \underset{k'_{n\mathrm{ABA}}}{\overset{k_{n\mathrm{ABA}}}{\rightleftarrows}} q\,\mathrm{A}_{n_1+1}\mathrm{B}_{n_2}\mathrm{BA}^{*},\\
q\,\mathrm{A}_{n_1}\mathrm{B}_{n_2}\mathrm{BB}^{*}+\mathrm{B} \underset{k'_{n\mathrm{BBB}}}{\overset{k_{n\mathrm{BBB}}}{\rightleftarrows}} q\,\mathrm{A}_{n_1}\mathrm{B}_{n_2+1}\mathrm{BB}^{*},\\
q\,\mathrm{A}_{n_1}\mathrm{B}_{n_2}\mathrm{AB}^{*}+\mathrm{B} \underset{k'_{n\mathrm{ABB}}}{\overset{k_{n\mathrm{ABB}}}{\rightleftarrows}} q\,\mathrm{A}_{n_1+1}\mathrm{B}_{n_2}\mathrm{BB}^{*},
\end{array}\right\} \qquad (\mathrm{II})$$

$$\left.\begin{array}{r}
q\,\mathrm{A}_{p_1}\mathrm{B}_{p_2}\mathrm{A}^{*}+\lambda \xrightarrow{k_{\mathrm{t}}(1)} \mathrm{L}(1)\ ,\\
q\,\mathrm{A}_{p_1}\mathrm{B}_{p_2}\mathrm{B}^{*}+\lambda \xrightarrow{k_{\mathrm{t}}(2)} \mathrm{L}(2)\ ,\\
q\,\mathrm{A}_{p_1}\mathrm{B}_{p_2}\mathrm{A}^{*}+q\,A_{m_1}\mathrm{B}_{m_2}\mathrm{A}^{*} \xrightarrow{k_{\mathrm{t}}(3)} \mathrm{L}(3)\ ,\\
q\,\mathrm{A}_{p_1}\mathrm{B}_{p_2}\mathrm{A}^{*}+q\,\mathrm{A}_{m_1}\mathrm{B}_{m_2}\mathrm{B}^{*} \xrightarrow{k_{\mathrm{t}}(4)} \mathrm{L}(4)\ ,\\
q\,\mathrm{A}_{p_1}\mathrm{B}_{p_2}\mathrm{B}^{*}+q\,\mathrm{A}_{m_1}\mathrm{B}_{m_2}\mathrm{B}^{*} \xrightarrow{k_{\mathrm{t}}(5)} \mathrm{L}(5)\ ,\\
q\,\mathrm{A}_{p_1}\mathrm{B}_{p_2}\mathrm{B}^{*}+q\,\mathrm{A}_{m_1}\mathrm{B}_{n_2}\mathrm{A}^{*} \xrightarrow{k_{\mathrm{t}}(6)} \mathrm{L}(6)\ .\\
q\,\mathrm{A}_{p_1}\mathrm{B}_{p_2}\mathrm{A}^{*}+\mathrm{A}_{n_1}\mathrm{B}_{n_2} \xrightarrow{k_{\mathrm{t}}(7)} (\mathrm{A}_{n_1}\mathrm{B}_{n_2})^{*}+q\,\mathrm{A}_{p_1}\mathrm{B}_{p_2}\ ,\\
q\,\mathrm{A}_{p_1}\mathrm{B}_{p_2}\mathrm{B}^{*}+\mathrm{A}_{n_1}\mathrm{B}_{n_2} \xrightarrow{k_{\mathrm{t}}(8)} (\mathrm{A}_{n_1}\mathrm{B}_{n_2})^{*}+q\,\mathrm{A}_{p_1}\mathrm{B}_{p_2+1}\ .
\end{array}\right\} \qquad (\mathrm{III})$$

Here q^{*} is the active polymerisation centre, the nature of which will henceforth be of little interest to us, i.e. it can be an anion, a cation, a radical, a biradical, etc. and L(3) and L(4), L(5), and L(6) are inactive molecules, the reactions with the rate constants $k_{\mathrm{t}}(3)$, $k_{\mathrm{t}}(4)$, $k_{\mathrm{t}}(5)$, and $k_{\mathrm{t}}(6)$ occurring in systems where copolymerisation proceeds via a radical mechanism; λ is the kinetic chain "terminating agent". The remaining symbols are self-evident and do not require additional explanation. In describing the termination of kinetic chains with the rate constant $k_{\mathrm{t}}(3)$, $k_{\mathrm{t}}(4)$, $k_{\mathrm{t}}(5)$, and $k_{\mathrm{t}}(6)$, we deliberately did not specify in a concrete form the corresponding reactions (recombination or disproportionation) in order to maintain a unique treatment, because this is unimportant for the subsequent description of the data.

This formulation of the copolymerisation mechanism (I)–(II)–(III) takes into account, in principle, the following factors: (1) the occurrence of reversible processes[17]; (2) the influence of the nature of the preterminal units on the propagation rate constants[18] (the mechanism can be extended without much difficulty by taking into account the influence of the nature of four- and five-unit sequences of monomeric fragments on the kinetic constants[19,20]); (3) the chain transfer reactions with the rate constants $k_{\mathrm{t}}(7)$ and $k_{\mathrm{t}}(8)$; nor does one exclude the possible influence of the degree of polymerisation and composition of macroradicals (or macroions) on the rate constants for the individual reactions in stage (II). Naturally, the characteristics of the synthesis via mechanism (I)–(II)–(III) depend significantly on a number of other factors, such as the active parameters of the reaction medium R_{i}, the temperature of the synthesis T, and a whole series of other parameters (they will be designated by P_{r}). It is already seen from mechanism (I)–(II)–(III) that in the synthesis of an *ensemble* of copolymer macromolecules the following parameters vary in the general case: the composition of the macromolecules α_{A}; the configuration of the macromolecules characterised by the composition parameter γ_{AB}; the average degree of polymerisation. It is noteworthy that the molecular weight and the nature of the molecular weight distribution[21,22] are not specific criterial parameters of binary statistic copolymerisation (naturally the choice of parameters is based on emphasising the differences between copolymerisation and homopolymerisation) and for this reason we shall henceforth use these parameters only when necessary.

Thus the fundamental (criterial) parameters of statistical polymerisation are assumed to be the "instantaneous" values of α_A and γ_{AB}, the distribution curves with respect to composition (w_{α_A}) and structure (configuration) ($w_{\gamma_{AB}}$) for the *ensemble* of the copolymer macromolecules with finite values of ψ. Naturally α_A, γ_{AB}, w_{α_A}, and $w_{\gamma_{AB}}$ are statistical characteristics and depend on many "instantaneous" parameters of the system. In particular, for copolymerisation processes which obey the (I)–(II)–(III) mechanism, we have

$$\begin{gathered}\alpha_A = F_1(\beta_A^0, R_i, P_r, T, k_{1AA}, k'_{1AA}, k_{1AB}, k'_{1AB}, k_{1BA}, k'_{1BA}, k_{1BB}, k'_{1BB} \,..\\ \ldots\, k_{nAAA}, k'_{nAAA}, k_{nBAA}, k'_{nBAA}, k_{nAAB}, k'_{nAAB}, k_{nBAB}, k'_{nBAB}, k_{nBBA},\\ k'_{nBBA}, k_{nABA}, k'_{nABA}, k_{nBBB}, k'_{nBBB}, k_{nABB}, k'_{nABB}\ ,\end{gathered} \tag{1}$$

where β_A^0 is the content of component A by weight in the initial monomer mixture and, when the expression in round brackets is denoted by $M_{B,i,m}$, we have

$$\gamma_{AB} = F_2(M_{P,i,m}), \tag{2}$$

$$w_{\alpha_A} = F_3\{M_{P,i,m}, \psi, k_t(7), \ k_t(8)\ \}, \tag{3}$$

$$w_{\gamma_{AB}} \doteq F_4\{M_{P,i,m}, \psi, k_t(7),. \ k_t(8)\ \}, \tag{4}$$

$$w_{\alpha_A, \gamma_{AB}} = F_5\{M_{P,i,m}, \psi, k_t(7), \ k_t(8)\ \}. \tag{5}$$

Eqns. (3)–(5) have been formulated for systems where interchain exchange reactions[22] or reactions involving kinetic chain transfer to macromolecules, particularly with rupture of the latter[23], take place. One should note that the functions F_3, F_4, and particularly F_5 contain incomparable more information about the copolymerisation process than the functions F_1 and F_2, because F_3, F_4, and F_5 take into account the influence of the polymer formed during the reaction (this is formally taken into account by introducing Ψ). The determination of the functions F_1 and F_2 and even more so F_3, F_4, and F_5 in an explicit form makes it necessary to overcome major technical difficulties even for the simplest copolymerisation models and, when the process becomes more complex, the difficulty of determining functional relations of type (1)–(5) increases significantly. There is no doubt that the determination of F_1, F_2, F_3, F_4, and F_5 in an analytical form is by no means possible, in principle, for all copolymerisation models.

Another method of analysing the copolymerisation process (which does not involve the determination of F_1, F_2, F_3, F_4, and F_5 in an explicit form), where a comparative analysis of experimental relations of the type $\alpha_A = f(\beta_A^0)$ and $\gamma_{AB} = f_1(\beta_A^0)$ is carried out in conformity with the characteristics of the "blank" (classical) system, is therefore more promising[4]. Naturally analysis of copolymerisation at the level of distribution curves with respect to composition for different β_A^0 and ψ is laborious and complex, but the reliability of such analysis is incomparable greater than that of the analysis of composition diagrams of the chemical structure of macromolecules for $\psi \to 0$,[4,24-26] which makes up for all the difficulties in the corresponding experiments. At any rate (both in the interpretation of data for distribution with respect to composition and in the analysis of the average compositions for different polymerisation increments[22]) the necessity for comparing the experimental results with data for the "blank" (classical) system immediately gives rise to a self-evident requirements—an integral part of the analysis must be a comprehensive study of various characteristics of the copolymerisation of classical systems.

III. TOPOLOGICAL SCHEMES FOR BINARY STATISTICAL COPOLYMERISATION

In analysing experimental data for copolymerisation, it is useful to distinguish four types of systems[4,8]: classical systems; classical systems subject to definite boundary conditions; "unusual" systems of the first and second kind.

1. Classical Systems

Assuming that the quasi-steady-state condition holds, Mayo and Lewis[27] and somewhat later Wall[28] derived a relation between the composition of the initial monomer mixture and the composition of the macromolecules formed in terms of two copolymerisation constants:

$$r_A = k_{AA}/k_{AB} \text{ and } r_B = k_{BB}/k_{BA}:$$

$$\frac{M_A}{M_B} = \frac{m_A}{m_B} \cdot \frac{r_A m_A + m_B}{r_B m_B + m_A}, \tag{6}$$

where M_A, M_B, m_A and m_B are the molar concentrations of monomers A and B in the copolymer macromolecules and in the initial mixture respectively. We may recall that Mayo and Lewis quite correctly referred to r_A and r_B as activity ratios and the name copolymerisation "constants" was given to them later. However, this seemingly purely terminological nicety later led to serious confusion in both the kinetic and statistical copolymerisation theories let alone applications such as the synthesis of copolymers "with specified properties". In 1944 Eqn. (6) was obtained by Goldfinger and Kone[29] without postulating the quasi-steady-state condition. On conversion to weight concentrations, the Mayo–Lewis equation [Eqn.(6)] becomes

$$\frac{g\alpha_A\,(1-\beta_A^2)}{(1-\alpha_A)\,\beta_A^2}\,r_B - r_A = \frac{1-\beta_A}{\beta_A}\left(g - \frac{\alpha_A}{1-\alpha_A}\right), \tag{7}$$

where $\alpha_A = 1 - \alpha_B$, $\beta_A = 1 - \beta_B$, and g is the ratio of the molecular weights of components A and B. In the first place, one should note that Eqns. (6) and (7) are by no means valid for all copolymerisation models[4,8] and, when the process takes place within the framework of classical relations (r_A = const. and r_B = const.), it is necessary that many special conditions should be fulfilled. We shall formulate them here, because they are important:

(1) the chain propagation reactions must be fully irreversible, i.e.

$$\begin{gathered}k'_{AA} = k'_{AB} = k'_{BB} = k'_{BA} \ \ldots\ = k'_{nAAA} = k'_{nBAA} =\\ = k'_{nAAB} = k'_{nBAB} = k'_{nABA} = k'_{nBBB} = k'_{nABB} = 0;\end{gathered}$$

(2) the monomers A and B must be capable of polymerising via only one mechanism, i.e. a one-centre copolymerisation process must take place:

(3) the propagation rate constants must be independent of the composition of the initial monomer mixture, i.e.

$$\begin{gathered}k_{nAA} \neq \mathrm{f}(\beta_A^0),\ k_{nBB} \neq \mathrm{f}(\beta_A^0);\ \ k_{nAB} \neq \mathrm{f}(\beta_A^0);\\ k_{nBA} \neq \mathrm{f}(\beta_A^0);\end{gathered}$$

(4) the copolymerisation process must be homophase with respect to all β_A^0 and ψ;

(5) the propagation rate constant must be independent of the degree of polymerisation, i.e.

$$k_{1AA} = k_{2AA} = \ldots k_{nAA};\; k_{1BB} = k_{2BB} = \ldots k_{nBB};$$
$$k_{1AB} = k_{2AB} = \ldots k_{nAB};\; k_{1BA} = k_{2BA} = \ldots k_{nBA};$$

(6) the propagation rate constants must be independent of the composition of the macroradical (macroion), in particular the propagation rate constants must be independent of the nature of the preterminal, pre-preterminal and more remote units, i.e.

$$k_{nBAA} = k_{nAAA};\; k_{nBAB} = k_{nAAB};$$
$$n_{nABB} = k_{nBBB};\; k_{nBBA} = k_{nABA};$$

(7) the polymer formed must not influence the parameter of the interactions of macroradicals (macroions) with the monomers A and B, i.e.

$$k_{nAA} \neq f(\psi);\; k_{nAB} \neq f(\psi);\; k_{nBA} \neq f(\psi);\; k_{nBB} \neq f(\psi);$$

(8) the reactions involving the transfer of the kinetic chain to the macromolecules, i.e.

$$k_t(7) = k_t(8) = 0;$$

must not occur during the synthesis;

(9) the lifetimes of the individual macroradicals must be much shorter than the times of formation of the polymerisation increment[20], i.e. there should be no long-lived active centres in the system and hence bimolecular termination reactions with the constants $k_t(3)$, $k_t(4)$, $k_t(5)$, and $k_t(6)$ [see the mechanism (I)–(II)–(III)] must be ruled out in the case where $p_1/p_2 \neq m_1/m_2$;

(10) the system must be free from active ingredients (in the simplest case complex-forming additives) which bind part of the monomer A or B; this condition can be represented schematically as follows:

$$aA + Q \not\rightarrow a'\overset{+}{A} + (a - a')A,$$
$$bB + Q \not\rightarrow b'\overset{+}{B} + (b - b')B,$$
$$aA + bB \not\rightarrow a'(AB)^+ + (a - a')B + (b - a')B;$$

It is postulated that the relative activities of A and B, on the one hand, and A^+, B^+, and $(AB)^+$, on the other, in copolymerisation reactions differ significantly from one another;

(11) it is assumed that the copolymerisation process should involve the formation of products with fairly high molecular weights; at any rate the degree of copolymerisation is such that the influence of the terminal units may be neglected;

(12) a microsubstrate with the composition β'_A, different from that of the macroscopic composition β_A, must not be formed around the macroradicals (or macroions); in other words, in the system there must be no selective macroradical–monomer A (or B) interactions responsible for the appearance of microheterophase properties[30-33].

When all twelve necessary conditions are fulfilled, the copolymerisation process is greatly simplified, but the main bulk of the information about the system may be obtained using only two parameters, namely r_A = const. and r_B = const. In conformity with the aim of the present review, it is appropriate to list at this point the decisive features of classical polymerisation which make it possible to distinguish a classical process from an unusual process.

1. In order to obtain relations (1)–(5) in an explicit form, it is in principle sufficient to operate with two process parameters, namely r_A = const. and r_B = const.

2. There is an unambiguous relation between α_A and β_A for any β^0_A and ψ. In an analytical form the relation $\alpha_A = f(\beta^0_A)$ is determined by the Mayo–Lewis equation (6) or (7). Fig. 1 illustrates schematically the relation between α_A and β_A for systems with and without an azeotropic point. For classical systems, a single rigorously defined value of α_A corresponds to each β_A, i.e. we have $\beta'_A \longleftrightarrow \alpha'_A(1)$, $\beta''_A \longleftrightarrow \alpha''_A(1)$, and $\beta'''_A \longleftrightarrow \alpha'''_A(1)$ for curve *1*, $\beta'_A \longleftrightarrow \alpha'_A(2)$, $\beta''_A \longleftrightarrow \alpha''_A(2)$, and $\beta'''_A \longleftrightarrow \alpha'''_A(2)$ for curve *2*, and $\beta'_A \longleftrightarrow \alpha'_A(3)$, $\beta''_A \longleftrightarrow \alpha''_A(3)$, and $\beta'''_A \longleftrightarrow \alpha'''_A(3)$ for curve *3*.

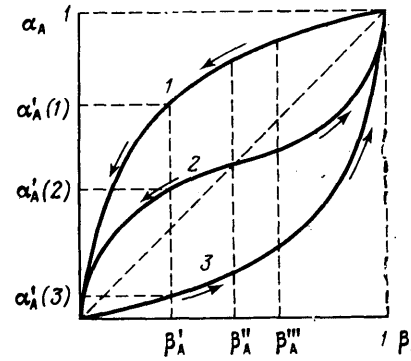

Figure 1. Schematic composition diagrams for systems with (curve *2*) and without (curves *1* and *3*) azeotropic points: 1) $r_A(1) > 1$, $r_B(1) < 1$; 2) $r_A(2) < 1$, $r_B(2) < 1$ or a less probable version of the synthesis with $r_A(2) > 1$, $r_B(2) > 1$; 3) $r_A(3) < 1$, $r_B(3) > 1$.

3. For each point on the composition diagram, it is possible to predict the direction of the development of the process, i.e. the increase or decrease of α_A when ψ increases. Thus, for the process described by curve *1* in Fig. 1, α_A diminishes, while that for the process described by curve *3* increases with increase of ψ. The above relations are valid for any fixed β^0_A = const. As regards systems with an azeotropic point (curve *2*), it is necessary to distinguish three regions: the first region, involving a decrease of α_A for $\beta_A < \beta''_A$, the second, involving an increase of α_A when $\beta_A > \beta''_A$, and the third, where $\alpha_A = \alpha''_A(2) \neq f(\psi)$ for $\beta_A = \beta''_A$; in all cases the analysis is carried out on the assumption of a continuous increase of ψ. To make the analysis complete, we may also note the special case where $r_A = r_B = 0$.[12,34] Naturally, in such systems the compositions of the macromolecules formed are the same for all β^0_A and ψ and for this reason no particular direction of process development can be specified and we are dealing in essence with a homopolymer $(AB)_n$ for any β^0_A and ψ.

4. It can be shown (this is done most simply using a model composition diagram) that for classical systems any interpretation of data in terms of the $\alpha_A = f(\beta_A)$ relation leads to the same values of r_A and r_B.[35,36]

5. The relative errors in the determination of r_A and r_B (i.e. $\Delta r_A/r_A$ and $\Delta r_B/r_B$) are objective characteristics of the copolymerisation process and depend mainly on the

experimental technique; the method of determination itself and the absolute values of r_A and r_B have less effect[10,26].

6. Using two copolymerisation constants (r_A and r_B), it is possible to plot theoretical integral distribution curves with respect to composition (IDCC) for classical systems whatever the values of β_A^0 and ψ, both by the Skeist method[37] and, with the aid of analytical expressions for $1-\psi$, by the Meyer and Lurry method[38] (for molar IDCC) or its analogue for the derivation of weight distribution functions with respect to composition[39]. As an illustration, Fig. 2 presents calculated and experimental IDCC for one of the systems[40]. One should note a characteristic property of classical IDCC—for each individual point corresponding to fixed α_A^0, it is possible to determine β_A^0 and ψ^0, provided that the overall ψ is known for the IDCC.

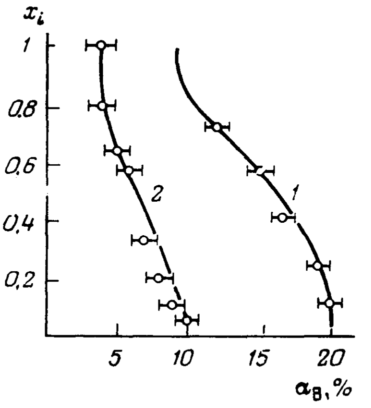

Figure 2. Theoretical and experimental IDCC for the vinyl acetate (A)–vinylcaprolactam (B) system; the theoretical IDCC are indicated by continuous lines[40]: 1) $\beta_A^0 = 0.16$; 2) $\beta_B^0 = 0.05$; x_i is the integral proportion by weight of the ith fraction.

7. For classical systems, operation (6) is reversible, i.e. using IDCC it is possible to determine r_A and r_B by an appropriate treatment of data (for example, in terms of the variables[41]

$$\frac{\beta_A}{1-\beta_A}\left(g-\frac{1-\alpha_A}{\alpha_A}\right)-\frac{\beta_A^2(1-\alpha_A)}{\alpha_A(1-\beta_A)^2},$$

where g is the ratio of the molecular weights of component A and B). It is of interest that, in order to derive r_A and r_B from IDCC, only one distribution curve with respect to composition is in principle sufficient. Fig. 3 presents an example of the determination of r_A and r_B from IDCC for the acrylamide–sodium fumarate system with added NaCl; according to the data in Fig. 3, $r_A = 10$ and $r_B = 0$.

8. There is an unambiguous relation between all the distribution curves with respect to composition within the given "family"[43] (i.e. for the set of IDCC, where r_A = const. and r_B = const.), which makes it possible to apply the principle of extrapolation and superposition in analysing the set of IDCC for different β_A^0 and ψ.

We shall consider this in greater detail, since the extrapolation and superposition principles mentioned above are common to classical systems and their breakdown can serve as direct evidence for the appearance of "unusual" relations in the system. We shall assume a system without an azeotropic point (Fig. 4, curve *2*); in this case the content of the second component decreases with increase of ψ. Accordingly, the copolymerisation process may be characterised statistically by a family of monotonically varying distribution functions with respect to composition. The principle of the interrelation of the distribution curves with respect to composition was first clearly formulated by Markert[44,45], who illustrated such an interrelation by analysing the differential distribution curves with respect to composition (DDCC). However, in the comparative analysis of distribution curves with respect to composition it is much more convenient to employ IDCC rather than DDCC and to carry out the corresponding analysis using weight distribution functions with respect to composition. Evidently in the case of IDCC there is an unambiguous relation between the individual curves of a single "family". The fundamental condition for the existence of such a relation is that fractions having the same composition may be obtained for different compositions of the initial monomer mixture at different copolymerisation stages.

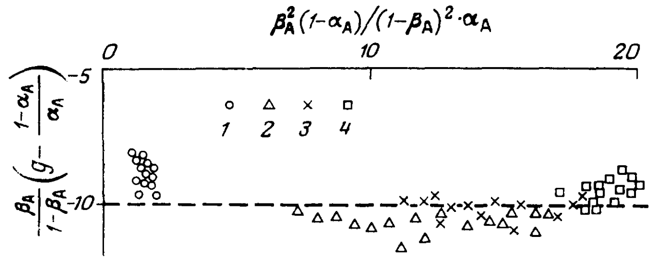

Figure 3. Dependence of $[\beta_A(1-\beta_A)][g-(1-\alpha_A)/\alpha_A]$ on $\beta_A^2(1-\alpha_A)/\alpha_A(1-\beta_A)^2$ for the acrylamide–sodium fumarate system with added 10% NaCl;[42] β_B^0: 1) 0.1; 2) 0.4; 3) 0.5; 4) 0.67.

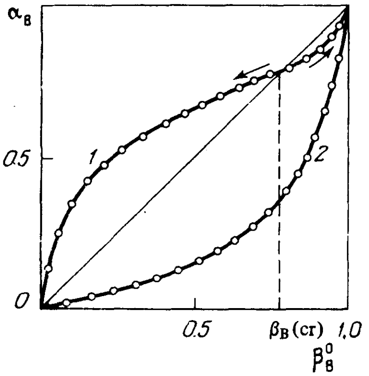

Figure 4. Composition diagrams for copolymerisation models: 1) $r_A = 0.1$, $r_B = 0.7$, $g = 0.8$; 2) $r_A = 7.0$, $r_B = 0.09$, $g = 1.63$.[43]

The interrelation between the individual IDCC of a single "family" can be most simply illustrated using as an example the dependence of $1 - \psi$ on β_A. Analytical weight functions relating $1 - \psi$ to r_A, r_B, g and β_A have been obtained[39]. Fig. 5 presents the calculated relations[43] between $1 - \psi$ and β_A for two copolymerisation models, whose composition diagrams are illustrated in Fig. 4. Simple comparison of the curves in Fig. 5 already shows that there is a simple relation between individual curves. It is easy to establish in an explicit form also the nature of the relations between the individual curves in Figs. 5*a* and 5*b*.[43]. Thus curves *2–6* in Fig. 5*b* as it were describe the part of the copolymerisation process illustrated by curve *1*; similarly curves *3–6* constitute, as it were, part of curve *2*, etc. Curve *2*, for example, describes the same process as curve *1* after the attainment of a definite degree of conversion $\psi_a = 0.27$; similarly curves *3–6* are part of curve *1* after the attainment of values of ψ_a of 0.44, 0.58, 0.73, and 0.76 respectively. Thus, after the attainment of ψ_a, the curves of one "family" differ only by a scale factor, which in the given instance is ψ. The validity of such comparison of the IDCC of a single family is confirmed by the satisfactory correspondence between the individual calculated points and curves evaluated directly from an analytical expression for $1 - \psi$.[39]

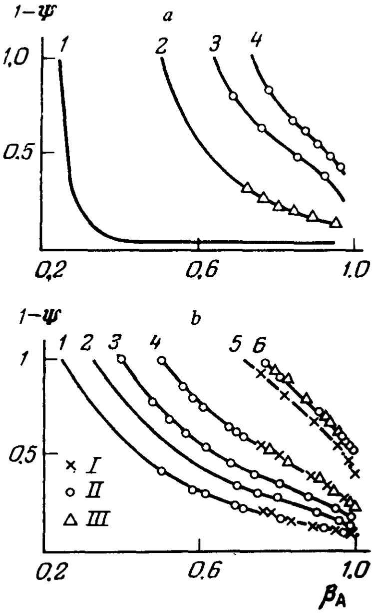

Figure 5. Dependence of $1 - \psi$ on β_A for blank systems[43]: *a*) $r_A = 0.1$, $r_B = 0.7$, and $g = 0.8$ (Lewis and Young[46]) for $\beta_A^0 = 0.25$ (curve *1*), 0.5 (curve *2*), 0.65 (curve *3*), and 0.75 (curve *4*); *b*) $r_A = 7.0$, $r_B = 0.09$, and $g = 1.63$ for $\beta_A^0 = 0.75$ (curve *1*), 0.68 (curve *2*), 0.6 (curve *3*), 0.5 (curve *4*), 0.27 (curve *5*), and 0.25 (curve *6*). Points I, II, and III were obtained using different computational formulae.

Clearly the correlation between the individual curves for the dependence of $1 - \psi$ on β_A inevitably implies the existence of an unambiguous relation also between the IDCC. This may be illustrated by Fig. 6. The individual points in the figure were obtained using the extrapolation and superposition principles for the comparison of the IDCC.[43] Evidently the correspondence of the IDCC obtained by the Skeist method and by the application of the extrapolation and superposition relations[43] is entirely satisfactory. This factor, demonstrating the particular advantage of the application of the superposition principle, may be employed for the rapid construction of IDCC for classical systems. The principles described are extremely important also in the comparative analysis of the set of experimental IDCC for which there can be no simple correlation between the individual curves, which may be an indication of the "unusual" nature of the process.

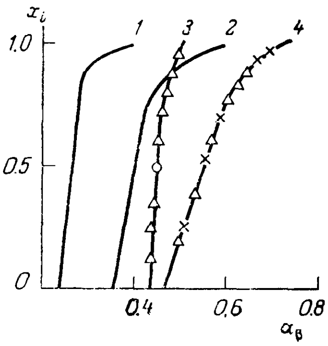

Figure 6. The IDCC for the system with $r_A = 0.1$, $r_B = 0.7$, and $g = 0.8$ (Myagchenkov and Frenkel'[41]); β_A^0: 1) 0.25; 2) 0.5; 3) 0.67; 4) 0.75. The continuous curves were obtained by the Skeist method and the individual points were obtained using the extrapolation and superposition relations between the IDCC.[42]

9. For classical systems, the chemical structure of macromolecules (it can be regarded as known, provided that the probabilities of the occurrence of various sequences of the monomeric fragments A and B are known[47–49]) is determined unambiguously by the values of r_A and r_B.

10. Knowing the chemical structures for different β_A^0, it is possible to calculate r_A and r_B for classical systems.

11. There is no doubt about the existence of an unambiguous relation between IDCC and the stereochemical configuration of the copolymer macromolecules.

12. For classical systems, there is an unambiguous relation between the IDCC, the chemical structure of the *ensemble* of macromolecules, and the quantitative parameters of the inhomogeneity with respect to composition[50].

13. For classical systems, the specimen should be monodisperse with respect to composition at the azeotropic point $\beta_A^0 = \beta_A(\text{az.})$, i.e. $\alpha_A = \beta_A(\text{az.})$ in the region $0 \leq \psi \leq 1$.

Thus an unambiguous relation between β_A, α_A, the chemical structure (configuration) of the macromolecules, the IDCC, and the quantitative parameters of the inhomogeneity with respect to composition is characteristic of classical systems. The breakdown of the correspondences 1–13 already constitutes indirect evidence for the lack of validity of the description of the copolymerisation process with the aid of two copolymerisation constants r_A = const. and r_B = const.

2. Systems Which Reduce to Classical Systems when Definite Boundary Conditions are Fulfilled

In such systems none of the twelve conditions necessary for the classical process are fulfilled, but the nature of the process itself remains such that one may expect the fulfilment of all thirteen features of a classical process, enumerated above, for a definite range of β_A^0 and ψ values. We shall consider several systems of this kind.

1. All the conditions necessary for a classical process are fulfilled with the exception of the seventh condition and the influence of the polymer formed on the rate constants for the propagation of macromolecules may be traced only after the attainment of a certain value ψ_{cr}, which depends on β_A^0. Suppose that $\beta_A^0(1)$, $\beta_A^0(2)$, $\beta_A^0(3)$ ... $\beta_A^0(p)$ correspond to $\psi_{cr}(1)$, $\psi_{cr}(2)$, $\psi_{cr}(3)$, ..., $\psi_{cr}(p)$ and that $\psi_{cr}(1) < \psi_{cr}(2) < \psi_{cr}(3) < \ldots \psi_{cr}(p)$, while the values of $\beta_A^0(1) - \beta_A^0(p)$ cover virtually the entire range of β_A^0 from 0 to 1; in this case the system may be regarded as classical for the degrees of conversion $\psi < \psi_{cr}(1)$.

2. All the conditions necessary for a classical process hold with the exception of the tenth condition, but the concentration of active ingredients is such that the entire monomer A (or B) is converted into A^+ (or B^+), i.e. $mA + Q \rightarrow mA^+$ (or $mB + Q \rightarrow mB^+$). In this case the copolymerisation reaction takes place between B and A^+ (or A and B^+) and one may expect a change in the copolymerisation constants $r_A \rightarrow r_{A^+}$ or $r_B \rightarrow r_{B^+}$, but such changes do not entail the failure of even one of the thirteen features of a classical process.

3. The separation of the system into separate phases occurs only for certain values of $\beta_A \geq \beta_A(\text{cr.})$. Complications of this kind in the copolymerisation process can be readily traced in the copolymerisation of acrylamide with hydrophilic non-ionogenic monomers (solvent—water)[50-54].

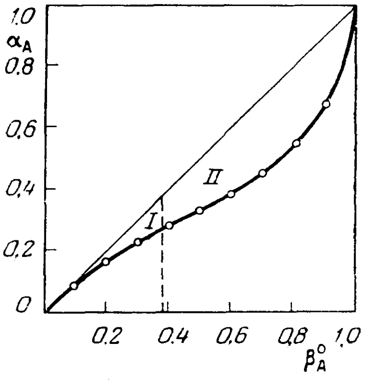

Figure 7. Composition diagram for statistical acrylonitrile–hydroxymethylmethacrylamide copolymers[54].

Fig. 7 presents a typical composition diagram for the acrylonitrile (A)–hydroxymethylmethacrylamide (B) system[54]. There are two characteristic regions in the diagram: region I where the copolymerisation process takes place in a single phase and region II where the copolymerisation takes place in a two-phase system. Clearly in region I (i.e. for $\beta_A \leq 0.39$) the system can manifest all the features characteristic of a classical process and in the region $0 \leq \beta_A \leq 0.39$ it is possible to calculate r_A and r_B. On the other hand, in region II the system is known to be non-classical and it is therefore erroneous to operate with the values of r_A and r_B found for region I; in general for region II one can speak in this instance only of apparent copolymerisation "constants" r_A^* and r_B^* [8,55]. One must bear in mind that systems where the copolymerisation process takes place in a single phase only within a certain region of β_A values are encountered fairly frequently in practice[1].

4. An analogous limitation may be observed also when reactions involving chain transfer to macromolecules occur in the system. If ψ_{cr} is a minimum value of ψ (for different compositions of the initial polymer mixture) after the attainment of which reactions involving the transfer of kinetic chains to macromolecules are observed, then the system may be regarded as classical in the region $0 \leq \psi \leq \psi_{cr}$. However, the extension of the observed relations (for example, the use of values of r_A and r_B found for the region $0 \leq \psi < \psi_{cr}$) to the region $\psi_{cr} \leq \psi \leq 1$ is known to be illegitimate and may lead to serious errors in the estimates of the characteristics of the statistical copolymerisation process.

3. Unusual Systems of the First Kind

One or several of the necessary conditions for a classical process do not hold for such systems, but there is an unambiguous relation between β_A and α_A for all the β_A^0 and ψ. The nature of the $\alpha_A = f(\beta_A)$ relation is more complex than the Mayo–Lewis equation; at any rate, this relation cannot be described in terms of only two copolymerisation constants. In the majority of cases it is possible to plot calculated distribution curves with respect to composition for unusual systems of the first kind (and hence it is possible to evaluate the quantitative parameters of the inhomogeneity with respect to composition) and to find analytical expressions for the functions characterising the structure of the macromolecules, but these relations are much much complex than the corresponding relations for classical systems. Naturally, not all of the thirteen enumerated features of classical polymerisation hold for unusual systems of the first kind. There is no doubt that the study of the relations $\alpha_A = f(\beta_A)$ can serve only as a first approximation in the analysis of the process characteristics for unusual systems of the first kind; for a more accurate assessment of the process, it is necessary to compare theoretical and experimental IDCC and to analyse the chemical structure of the copolymer macromolecules.

(1) The fulfilment of all the necessary conditions for classical copolymerisation with the exception of the sixth condition, i.e. that the reactivity of the macroradical depends on the nature of the free terminal and more remote units, is characteristic of the system[1,18-20,56,57]. A number of workers[1,18-20,56,57] explained the deviation of the $\alpha_A = f(\beta_A^0)$ relations from the classical relations (6) and (7) by the fact that r_A and r_B do not reflect fully the specific features of the interaction in the macroradical (macroion)–monomer system. When account is taken of the influence of the pre-terminal units, the following relation must be formulated instead of the Mayo–Lewis equation:

$$\frac{M_A}{M_B} = \frac{1 + (r'_A m_A/m_B)(r_A m_B/m_A + 1)/(r'_A m_A/m_B + 1)}{1 + (r'_B m_B/m_A)[(r_B + m_A/m_B)/(r'_B + m_A/m_B)]}, \qquad (8)$$

where

$$r_A = k_{AAA}/k_{AAB};\quad r'_A = k_{BAA}/k_{BAB};$$
$$r_B = k_{BBB}/k_{BBB};\ r'_B = k_{ABB}/k_{ABA}.$$

For the pre-terminal model, Eqn.(8) becomes even more complex and the relation between α_A and β^0_A is expressed in terms of eight copolymerisation constants:

$$r_A = k_{AAAA}/k_{AAAB};\quad r_B = k_{BBBB}/k_{BBBA};$$
$$r'_A = k_{BAAA}/k_{BAAB};\quad r'_B = k_{ABBB}/k_{ABBA};$$
$$r''_A = k_{ABAA}/k_{ABAB};\quad r''_B = k_{BABB}/k_{BABA};$$
$$r'''_A = k_{BBAA}/k_{BBAB};\quad r'''_B = k_{AABB}/k_{AABA}.$$

Analytical expressions have been obtained[20] for the relation $\alpha_A = f(\beta^0_A)$ taking into account also more remote interactions (via four- and five-unit sequences of monomer fragments). Thus, according to Barb[58], $r_A = 0.0084$, $r'_A = 0.01$, $r''_A = 0.0275$, and $r'''_A = 0.063$ for the styrene–maleic anhydride system; this set of constants describes satisfactorily the experimental relation $\alpha_A = f(\beta^0_A)$. We may note that a set of constants of the type r_A, r'_A, r''_A, r'''_A, r_B, r'_B, r''_B, r'''_B may be regarded as resembling variational parameters which establish the correspondence between the experimental points on the composition diagram. It is appropriate to note here that the use of a large set of such constants makes it possible, in principle, to describe satisfactorily very complex relations $\alpha_A = f(\beta^0_A)$, but the lack of reasonable correlations between r_A, r'_A, r''_A, r'''_A, on the one hand, and r_B, r'_B, r''_B, r'''_B, on the other, is an indication of the inaccuracy and arbitrary nature of such an approach. We believe that the region of the applicability of the pre-terminal model must be clearly defined—this model must not be misused when difficulties arise in finding an explanation for the sharp differences between the values of r_A and r'_A, on the other hand, and r_B and r'_B, on the other.

It is necessary to consider yet another question. It has been shown[59] that analysis of IDCC and of the variance of the distribution with respect to composition in relation to analysis of the function $\alpha_A = f(\beta^0_A)$ makes it possible to infer with much greater certainty which model (classical or pre-terminal) is valid in each specific case of copolymerisation.

(2) Systems where all the necessary conditions for classical copolymerisation hold with the exception of the tenth condition, but the reactivities of the activated [A^+ (or B^+)] and non-activated specimens [A (or B)] monomers do not differ sufficiently to entail the appearance of an ambiguity in the relation $\alpha_A = f(\beta^0_A)$. Without infringing the generality of the description, we shall assume that the activated monomer (in the simplest case a monomer bound in a complex) is monomer A. In such a system the copolymerisation process may be described by the Alfrey–Goldfinger scheme[60] for a three-component mixture of monomers:

$$\begin{aligned}
&A_{n-q-1}B_qA^\bullet + A \xrightarrow{k_{AA}} A_{n-q}B_qA^\bullet;\\
&A_{n-q-1}B_qA^\bullet + A^+ \xrightarrow{k_{AA+}} A_{n-q}B_q(A^+)^\bullet,\\
&A_{n-q-1}B_qA^\bullet + B \xrightarrow{k_{AB}} A_{n-q}B_qB^\bullet,\\
&A_{n-q-1}B_q(A^+)^\bullet + A \xrightarrow{k_{A+A}} A_{n-q-1}B_qA^+A^\bullet,\\
&A_{n-q-1}B_q(A^+)^\bullet + A^+ \xrightarrow{k_{A+A+}} A_{n-q-1}B_qA^+(A^+)^\bullet,\\
&A_{n-q-1}B_q(A^+)^\bullet + B \xrightarrow{k_{A+B}} A_{n-q-1}B_qA^+B^\bullet,\\
&A_{n-q-1}B_qB^\bullet + A \xrightarrow{k_{BA}} A_{n-q-1}B_{q+1}A^\bullet,\\
&A_{n-q-1}B_qB^+ + A^+ \xrightarrow{k_{BA+}} A_{n-q-1}B_{q+1}(A^+)^\bullet,\\
&A_{n-q-1}B_qB^\bullet + B \xrightarrow{k_{BB}} A_{n-q-1}B_{q+1}B^\bullet.
\end{aligned}\qquad (9)$$

The composition equation becomes

$$\begin{aligned}
\mathrm{d}M_A : \mathrm{d}M_B : \mathrm{d}M_{A^+} = M'_A\left[\frac{M'_A}{r_{A^+A}r_{BA}} + \frac{M_B}{r_{BA}r_{A^+B}} + \frac{M_A - M'_A}{r_{A^+A}r_{A^+B}}\right]\times\\
\times\left[M'_A + \frac{M_B}{r_{AB}} + \frac{M_A - M'_A}{r_{AA^+}}\right] : M_B\left[\frac{M_A}{r_{AB}r_{A^+A}} + \frac{M_B}{r_{AB}r_{BA^+}} + \right.\\
\left. + \frac{M_A - M'_A}{r_{A^+B}r_{AA^+}}\right]\left[M_B + \frac{M'_A}{r_{BA}} + \frac{M_A + M'_A}{r_{BA^+}}\right] : (M_A - M'_A)\times\\
\times\left[\frac{M'_A}{r_{AA^+}r_{BA}} + \frac{M_B}{r_{BA^+}r_{AB}} + \frac{M_A - M'_A}{r_{AA^+}r_{BA^+}}\right]\times\\
\times\left[(M_A - M'_A) + \frac{M'_A}{r_{A^+A}} + \frac{M_B}{r_{A^+B}}\right],
\end{aligned}$$

where M'_A and M_A are respectively the molar concentration of the monomer A not bound in the complex and the overall concentration of the same monomer A in the system (it is implied that M_A and M'_A are known) and $\mathrm{d}M_A$, $\mathrm{d}M_B$, and $\mathrm{d}M_{A^+}$ are the numbers of molecules of A, B, and A^+ in the copolymer macromolecule:

$$r_{AB} = \frac{k_{AA}}{k_{AB}};\quad r_{AA^+} = \frac{k_{AA}}{k_{AA^+}};\quad r_{BA} = \frac{k_{BB}}{k_{BA}};$$
$$r_{BA^+} = \frac{k_{BB}}{k_{BA^+}};\quad r_{A^+A} = \frac{k_{A^+A^+}}{k_{A^+A}};\quad r_{A^+B} = \frac{k_{A^+A^+}}{k_{A^+B}}.$$

Naturally Eqn.(10) is applicable to the analysis of copolymerisation under the conditions of complex formation in the system only when there are definite relations between M_{A^+} and M'_A (in particular, when the concentration of A^+ is limited by the concentration of the complex-forming agent in the system). In order to determine r_{AB}, r_{AA^+}, r_{BA}, r_{BA^+}, r_{A^+B}, and r_{A^+A}, it is necessary to analyse the composition diagrams for the binary systems (AA^+, AB, BA^+). It is fairly difficult to carry out such analysis for the AA^+ system, but even in its absence it is clear that the copolymerisation process in a system with the monomer partly bound in a complex cannot be described by the classical Mayo–Lewis equation. For this reason, the values of r_A and r_B obtained by the usual treatment of the data (without taking into account the complex-formation steps) are apparent process characteristics, which has been shown[61] in relation to the copolymerisation of acrylic and methacrylic acids with vinylpyrrolidinone. In the same report it is correctly noted that calculation of the parameters Q and e in the Alfrey–Price equation for the above systems lacks significance. In principle, any instance of polymerisation where the monomers A and B form a complex (AB) which behaves in the copolymerisation reaction as an "individual monomer" can be reduced to a relation of type (10).

(3) Systems with weak depolymerisation reactions, i.e. those where there is a specific breakdown of the necessary first condition. In this case the relation $\alpha_A = f(\beta_A)$ cannot be described in terms of two copolymerisation constants r_A = const. and r_B = const. It is implied that depolymerisation is not sufficiently intense to cause the breakdown of the unambiguous nature of the relation $\alpha_A = f(\beta_A)$.

(4) Systems where all the necessary conditions for classical copolymerisation are fulfilled with the exception of the eleventh condition, i.e. in such systems the synthesis results in the formation of copolymer macromolecules with an average degree of polymerisation < 100. Such systems may be regarded as "defective" classical systems or, more precisely, as systems obtained by random degradation from quasi-infinite copolymer macromolecules for the same values of r_A, r_B, β^0_A, and ψ.[12] The breakdown of the classical relations between IDCC and the

chemical structure of the macromolecules is due to two causes: the statistical nature of the reactions involving the rupture of macromolecules and the necessity for the introduction of revised values of α_A and α_B taking into account the influence of terminal groups on these parameters. Naturally the distribution functions with respect to composition depend on n. There have been obtained in an analytical form [62,63] and the following most general formulation is possible:

$$w_{n,M_A} = A(1 - f + nf/B)\,n^{3/2}e^{-n/B}\exp[-n(M_A - \overline{M}_A)^2/D], \qquad (11)$$

where w_{n,M_A} is the weight fraction of macromolecules with the degree of polymerisation n and the composition, M_A, $\overline{M}_A = \sum_{i=1}^{k} N_i M_{Ai} / \sum_{i=1}^{k} N_i$ is the arithmetical mean composition of the statistical *ensemble* of k fractions of macromolecules, B the arithmetical mean degree of polymerisation, A and D are constants which depend on r_A and r_B, and f is the probability of recombination steps in the termination of kinetic chains ($f = 1 - f_1$, where f_1 is the probability of the occurrence of disproportionation reactions in the termination of kinetic chains).

(5) Systems with a varying reactivity of the monomers A and B; here the relation $\alpha_A = f(\beta_A)$ remains unambiguous for all β_A^0. Many of such systems can be reduced to non-steady-state systems of the type

$$r_A = c_0 + R\beta_A, \qquad (12)$$

$$r_B = c_0' + R'\beta_A, \qquad (13)$$

where c_0, c_0', R, and R' are constants. It can be shown that, for systems of type (12) and (13), it is possible to calculate the IDCC,[64] the parameters of the quantitative estimate of the inhomogeneity with respect to composition, and the probabilities of various sequences of AB units in the macromolecules for different β_A^0, and ψ.

We shall consider further specific instances of copolymerisation in systems where the reactivity of the monomers is variable. Systems where one of the monomers contains ionogenic groups are of greatest interest in this respect; the reactivity of the medium is then such that the ionogenic groups exist in partly or fully ionised states [65-67]. The characteristics of the copolymerisation of ionogenic monomers must be considered in greater detail for three reasons: (1) the great practical importance of polyelectrolytes [9,68], (2) the fact that such systems are convenient models for the analysis of non-steady-state versions of copolymerisation, and (3) the fact that the characteristics of the copolymerisation of ionogenic monomers have so far been inadequately investigated [4,9,69].

In the first place we may note that many complications arise even in the homopolymerisation of ionogenic monomers, due to the presence of charged groups in the macroradical and in the monomer [69-72]. Thus in the homopolymerisation of ionogenic monomers in ionising media the overall rate of the process [73], the activation energy, the molecular weight [9,74,75], the degree and nature of stereoregularity [47,74], and the order of the reaction with respect to the monomer [76] depend on pH and the ionic strength of the solution. The order of the reaction with respect to the monomer varies in ionising media as the dielectric constant [77] and the ionic strength of the solution [78] are altered. Presumably, on passing from high to very low concentrations of the ionogenic monomer, the order of the reaction with respect to the monomer does not remain constant. In addition, one may expect also the variability of the individual elementary "constants" when the concentration of the monomer is varied within wide limits. Indeed $k_p/k_0^{1/2} = f(c_A) \neq$ const., where k_p and k_0 are propagation and termination rate constants, was obtained [79] for concentrations of the ionogenic monomer (2-sulphoethylmethacrylate) $c_A < 2\%$. This implies that k_p and k_0 are variable for $c_A < 2\%$ and depend on the internal ionic strength set up by the ionogenic monomer A. The results of the above study [79] are important for a correct assessment of the mechanism of the polymerisation of ionogenic monomers.

Naturally, in the copolymerisation of monomers with ionogenic groups the above polymerisation anomalies must be manifested to an even greater extent. There are in addition new anomalies associated directly with the greater complexity of the copolymerisation mechanism. Indeed, even when the specific features of the macroradical (the nature of the ionisation of the terminal, pre-terminal, and pre-pre-terminal units and the overall charge of the macroion) are disregarded, the copolymerisation mechanism becomes

$$\begin{aligned}
&A_nB_m\dot{A} + A \xrightarrow{k_{AA}} A_nB_mA\dot{A},\\
&A_nB_m\dot{A} + (A) \xrightarrow{k_{A(A)}} A_nB_mA(\dot{A}),\\
&A_nB_m\dot{A} + B \xrightarrow{k_{AB}} A_nB_mA\dot{B},\\
&A_nB_m\dot{A} + A \xrightarrow{k_{BA}} A_nB_mB\dot{A},\\
&A_nB_m\dot{A} + (A) \xrightarrow{k_{B(A)}} A_nB_mB\dot{A},\\
&A_nB_m\dot{B} + B \xrightarrow{k_{BB}} A_nB_mB\dot{B}.
\end{aligned} \qquad (14)$$

where A is the ionised unit A. Clearly mechanism (14) is not equivalent to the Mayo–Lewis mechanism in view of the differences between the values of $k_{A(A)}$ and k_{AA}, on the one hand, and between $k_{B(A)}$ and k_{BA}, on the other. Together with the usual property (i.e. the property of the monomer) of an unsaturated compound, the ionised monomer forms a cloud of counterions (the Debye–Hückel "ionic atmosphere" [80,81]) around the ionised macroradical and, as ψ increases, the monomer A passes from the ionic atmosphere to the chain of the copolymer macromolecule. It is then necessary to take into account the fact that γ_{ion}'—the effective degree of ionisation of the A monomer fragment within the macromolecule—is by no means identical with γ_{ion}—the effective degree of ionisation of the monomer A. This is because within the macromolecule the strong electrostatic field of the counterions (we may state that within the macromolecule their concentration is much higher than the average concentration of the counterions in the bulk of the solution) lowers the effective ionisation constant, so that $\gamma_{ion}' < \gamma_{ion}$. If (A) is a univalent ion and an electrolyte maintaining a constant ionic strength is absent from the copolymerising system, one can show [10] that the effective ionic strength I_{eff} for $\psi = \psi_1$ is

$$I_{eff}(\psi_1) = ac_A\{\gamma_{ion}(1 - \psi_1) + \gamma_{ion}'\psi_1\}. \qquad (15)$$

For $\psi = 0$, we have

$$I_{eff}^0 = a\gamma_{ion}c_A, \qquad (16)$$

where $a = 500/M_0$ and M_0 is the molecular weight of the monomer A. If

$$R \equiv I_{eff}(\psi_1)/I_{eff}^0 = [\gamma_{ion}(1 - \psi_1) + \gamma_{ion}'\psi_1]/\gamma_{ion}, \qquad (17)$$

when it follows from Eqns. (15) and (17) that I_{eff} and R diminish with increase of ψ. It can be readily shown that I_{eff} depends on $\beta_A^0 = c_A^0/(c_A^0 + c_B^0)$. Indeed, if the overall concentration of monomers A and B is constant, i.e. $c_A^0 + c_B^0 =$ const., then

$$\frac{I_{eff}(\psi_1)}{I_{eff}(\psi_2)} = \frac{\beta_A(1)}{\beta_A(2)} \simeq \frac{c_A(1)}{c_A(2)}.$$

Thus the copolymerisation of ionogenic monomers is not isoionic for two reasons: (1) a change in β_A^0 automatically leads to a change in the ionic strength (for $c_A^0 + c_B^0$ = const., the increase of β_A^0 entails an increase of I_{eff}, while its decrease reduces I_{eff}); (2) the increase of ψ (for fixed values of β_A^0) is accompanied by a decrease of I_{eff}.

The very fact that I_{eff} changes implies that the propagation rate constants $k_{A(A)}$ and $k_{B(A)}$ are in essence variable quantities. This follows immediately from the analysis of the expression for the rate constants for the interaction between charged species[82,83]:

$$\lg k = \lg k_0 + q_D q_C I_{eff}^{1/2} + (b_D - b_C - b^+) I_{eff}, \tag{18}$$

where k_0 is the reaction rate constant in the absence of low-molecular-weight salts, q_D, and q_C are the charges of the corresponding species D and C, and b_D, b_C, and b^+ are the empirical constants for the D and C species and the activated complex DC.

It is seen from Eqn. (18) than an increase of I_{eff} leads either to an increase (when the charges of the D and C species are of the same sign) or to a decrease (when the charges are of different sign) of the rate constant k.[84] Since the charges of the macroradical and the ionised monomer A are always of the same sign for the instance of copolymerisation in which we are interested, one may expect an increase of $k_{A(A)}$ and $k_{B(A)}$ with increase of I_{eff} [or β_A^0 in the case where $c_A^0 + c_B^0$ = const.]. Since $k_{A(A)}$ and $k_{B(A)}$ are not constants, it follows that the copolymerisation of the ionogenic monomers cannot be described in terms of the two constants r_A and r_B.

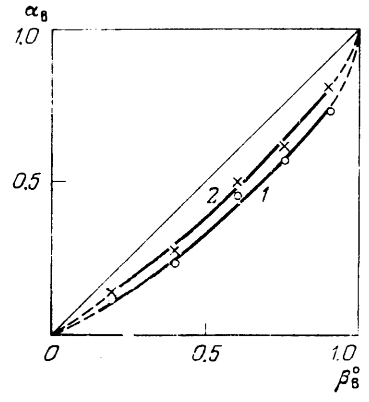

Figure 8. Composition diagram for the acrylamide–potassium *N*-vinylsuccinamate system[95]; concentration of aqueous solution (%): 1) 2; 2) 15.

These considerations have been confirmed experimentally[64,85-90] in relation to a whole series of systems (acrylamide–maleic acid[88], acrylamide–sodium maleate[89], and, in aqueous methanol solutions, acrylonitrile–3-methyl-*N*-vinylimidazolium methyl sulphate[90], acrylamide–sodium fumarate[42], etc.). Somewhat later, interesting results were obtained in a study[91] where the dependence of the composition and the chemical structure of the macromolecules of the copolymers of acrylamide with the lithium, sodium, and potassium salts of acrylic acid on the nature of the counterion was determined (naturally, the comparative analysis was carried out for fixed values of β_A^0 and ψ). When an external electrolyte (NaCl) was introduced into the acrylamide–sodium maleate[92] and acrylamide–sodium fumarate[64] copolymeric systems, the kinetic copolymerisation parameters, the average composition of the macromolecules formed, and the inhomogeneity with respect to composition changed. The last factor can be most simply detected from the change in the parameter

$$y_1 = \{(\bar{\alpha}_A)_z - (\bar{\alpha}_A)_b\}\,(\bar{\alpha}_A)_b = \\ = \left(\sum_{i=1}^{k} w_i \alpha_{Ai}^2 \Big/ \sum_{i=1}^{k} w_i \alpha_{Ai} - \sum_{i=1}^{k} w_i \alpha_{Ai}\right) \sum_{i=1}^{k} w_i \alpha_{Ai} \tag{19}$$

after the introduction of NaCl into the system (for fixed values of β_A^0 and ψ). Here $(\bar{\alpha}_A)_z$ and $(\bar{\alpha}_A)_b$ are respectively the z-average and weight-average compositions of the copolymer; the averaging is carried out with respect to component A. The decrease of y_1 after the addition of NaCl for all values of β_A^0 indicates simpler relations in the synthesis when the process is virtually isoionic[41,93,94] compared with non-isoionic synthesis, so that the inhomogeneity with respect to composition in a non-isoionic process is significantly greater than in an isoionic process.

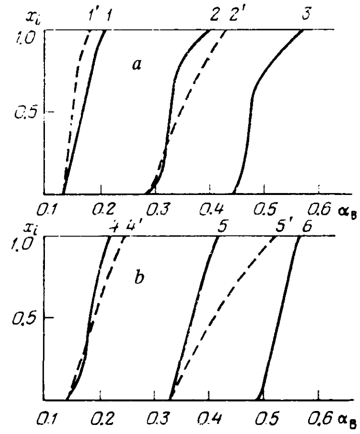

Figure 9. Integral acrylamide–potassium *N*-vinylsuccinamate distribution curves with respect to composition for 2% (*a*) and 15% (*b*) aqueous solutions[95]; β_B^0: 1) and 4) 0.2; 2) and 5) 0.4; 3) and 6) 0.6; ψ: 1) 0.45; 2) 0.76; 3) 0.41; 4) 0.72; 5) 0.73; 6) 0.57; derivative IDCC are shown by dashed lines.

The effect of concentration in the copolymerisation of acrylamide with potassium *N*-vinylsuccinamate has been demonstrated[95]: the composition of the resulting macromolecules depends not only on β_A^0 but also on the overall monomer concentration (Fig. 8). This effect does not occur in classical copolymerisation and is wholly caused by the presence in the system of the ionised monomer, i.e. potassium *N*-vinylsuccinamate. More important information compared with the data derived from the composition diagram (Fig. 8) may be obtained by analysing the experimental IDCC. Fig. 9 shows that the IDCC for statistical copolymers synthesised in 2 and 15% aqueous solutions differ appreciably, namely the IDCC for the 15% solutions are displaced to the right compared with the corresponding IDCC for the 2% solutions. Hence it follows that, on passing from the 2% to the 15% solutions, the relative activity of the salt component in the copolymerisation increases. The failure of the system to obey classical relations is also indicated by the lack of correspondence between the experimental IDCC and their derivatives[43]. The basic IDCC curves from which the derivatives (shown dashed) were obtained were curve *2* for *1*, curve *3* for *2*, curve *5* for *4*, and curve *6* for *5*. An additional illustration of the non-classical nature of the copolymerisation process in the acrylamide–potassium *N*-vinylsuccinamate system may be provided also by the data in Fig. 10, which were obtained by the appropriate treatment[43] of the experimental IDCC in Fig. 9. The form of the relations between $[\beta_B/(1-\beta_B)][g-(1-\alpha_B)/\alpha_B]$ and $\beta_B^2(1-\alpha_B)/(1-\beta_B)^2\alpha_B$ permits the conclusion that the parameters of the interaction of the ionised monomer and the macroradical containing the ionogenic unit not only at the end of the chain but also at a considerable distance from the latter are variable. Fig. 11 demonstrates the difference between the effective[13] sizes of the macromolecular copolymer coils in media where the copolymerisation in 2 and 15% solutions is simulated.

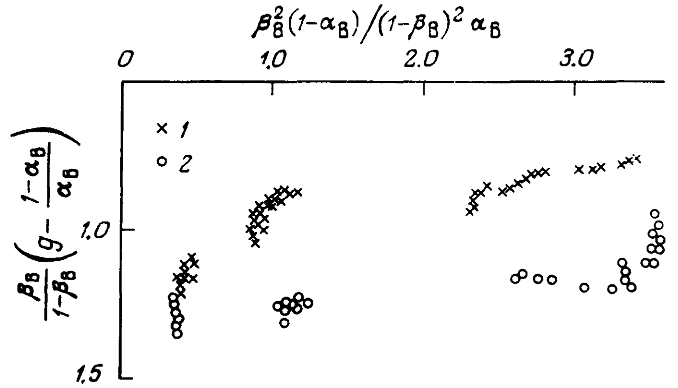

Figure 10. Dependence of $[\beta_B/(1-\beta_B)][g-(1-\alpha_B)/\alpha_B]$ on $\beta_B^2(1-\alpha_B)/(1-\beta_B)^2\alpha_B$ for the acrylamide–potassium vinylamidosuccinate system[95]; concentration of aqueous solution (%): 1) 15; 2) 2.

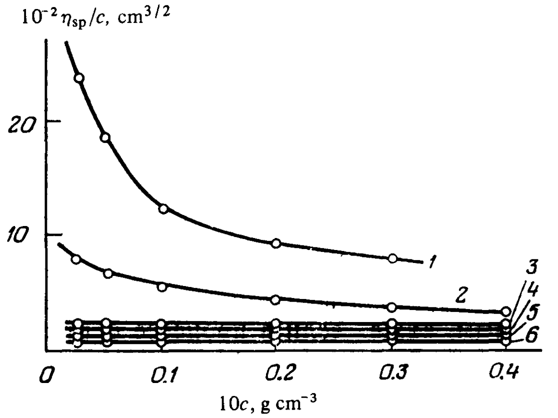

Figure 11. Dependence of the viscosity numbers on concentration for fractions of the acrylamide–potassium vinylamidosuccinate copolymer[95]; $\bar{\alpha}_B = 0.17$ and $\beta_B^0 = 0.2$ for 2% solutions (curves *1*, *3*, and *5*) and $\bar{\alpha}_B = 0.516$ and $\beta_B^0 = 0.6$ for 15% solutions (curves *2*, *4*, and *6*): 1) and 2) in pure water; 3)–6) in the presence of added ionogenic monomer [amount of added ionogenic monomer (%): 3) 0.33; 4) 2.93; 5) 1; 6) 8.8]; η_{sp} = specific viscosity of the solution.

Many of the most important parameters (in the first place the degree of ionisation, the potential of the intramacromolecular interactions between the ionised units, and the conformational parameters of the macromolecules) for polyelectrolytes may be altered by passing from aqueous media to water–organic component mixed solvents[10, 96–98]. Naturally in the copolymerisation process the use of mixed solvents makes it possible to vary within wide limits the rates of the individual reaction stages [mainly $k_{A(A)}$ and $k_{B(A)}$]. It has been shown[99] in relation to the copolymerisation of maleic acid with acrylamide in aqueous dioxan mixtures that, by changing φ (the weight concentration of water in the binary solvent), it is possible to alter specifically the degree of ionisation of the ionogenic units and hence also I_{eff}. It is interesting to note that both in water and in dioxan the copolymerisation is of an unusual type: in water because the process in non-isoionic and in dioxan because the synthesis is a two-phase process[99]. In both instances the experimental IDCC are found to be "anomalously" diffuse. With decrease of φ, the IDCC are shifted to the right (i.e. α_A increases), which may be attributed to the decrease of the effective ionisation constant of maleic acid with increase of dioxan concentration in the binary water–dioxan mixture. The considerable diminution of the anomalous features of the copolymerisation process over a certain range of values of φ merits particular attention. It is associated with two factors: the decrease of the role of polyelectrolyte interactions on passing from purely aqueous to mixed water–dioxan solutions and the fact that the process takes place in a single phase (φ is not sufficiently small to cause the separation of the system into two phases).

(6) An interesting case of "unusual" copolymerisation of the first kind was examined in a study[100] of the copolymerisation of styrene with methacrylic acid (MAA). The "unusual" nature of the copolymerisation was a consequence in the presence in the substrate of the dimeric and non-dimeric forms of the acid. Naturally the relative reactivities of these two forms of methacrylic acid in copolymerisation are different, so that the changes in β_A^0 and ψ automatically entail a change in the relative reactivity of one of the copolymers. The authors confirmed these conclusions by comparing the experimental and blank

(for $r_A = 0.7$ and $r_B = 0.15$) distribution curves with respect to composition.

4. Unusual Systems of the Second Kind ("Anomalous" Systems)

These systems include those where the copolymerisation process is accompanied by such marked deviations from the classical Mayo–Lewis mechanism that the unambiguous relation between β_A and α_A breaks down. This has the automatic consequence that the characteristics of the classical copolymerisation process (or at least the main ones) do not hold for unusual systems of the second kind. Naturally, the correct analysis of "anomalous" systems requires the most complete information possible about the distribution with respect to composition and about the characteristics of the chemical structure of the copolymer macromolecules.

(1) Suppose that the copolymerisation takes place as a heterophase process. It has been shown[8,101] that, depending on the conditions of the synthesis, the resulting distribution with respect to composition is bi- or tri-modal. Naturally, in this instance one cannot always reach the correct conclusion about the conditions under which a particular fraction with the composition α_{Ai} is obtained, even if r_A = const. and r_B = const. in the synthesis. As an example, Fig. 12 presents experimental composition diagrams for copolymers of methyl methacrylate (A) with methacrylic acid; the synthesis was carried out in mixed water–dioxan solvents with variable compositions[102]. In region *LR* (shown schematically by dashed lines) the unambiguous relation between m_A and M_A breaks down. The region *QR* is particularly interesting, because in the latter M_A should increase with increase of ψ, while in the remainder of the composition range M_A decreases with increase of ψ.

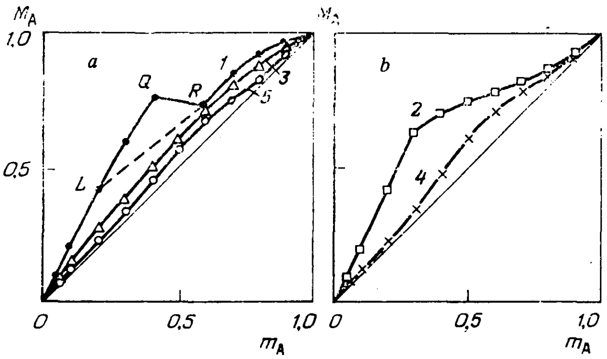

Figure 12. Composition diagrams for methyl methacrylate (A)–methacrylic acid (B) copolymers for different water : dioxan ratios: 1) 100 : 0; 2) 80 : 20; 3) 50 : 50; 4) 30 : 70; 5) 0 : 100.[102]

Consider another system—the copolymerisation of acrylamide (A) with potassium *N*-vinylsuccinamate (B).[103] The greatest amount of information about the process can be obtained by comparing the IDCC found separately for each phase (naturally, one is dealing with a heterophase process). The necessity for the separate comparison of the IDCC for copolymers isolated from phases 1 and 2 arises from the fact that, without preliminary calibration experiments, it is impossible to establish in which particular phase the specific copolymer fractions have been obtained[8]. Fig. 13 presents the IDCC for the A–B copolymers synthesised in binary water–dioxan and water–methanol solvents. We may note that the copolymeric A–B system investigated is "anomalous" not only in consequence of the heterophase nature of the synthesis but also because of the variability of the relative reactivities of monomers A and B in copolymerisation[104].

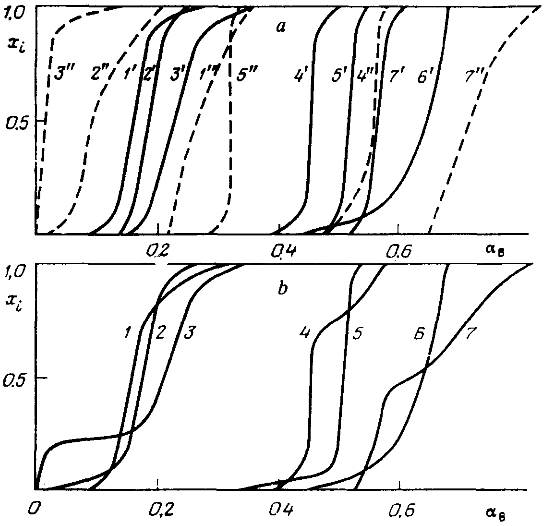

Figure 13. Integral distribution curves with respect to composition for acrylamide–potassium *N*-vinylsuccinamate copolymers[103]: *a*) separately for concentrated and dilute phases; the IDCC for specimens isolated from the dilute phase (curves *1″*–*7″*) are shown by dashed lines, while continuous lines represent the curves for the specimens isolated from the concentrated phase (curves *1′*–*7′*); *b*) overall IDCC for specimens isolated simultaneously from the dilute and concentrated phases (curves *1*–*7*). Reaction medium: 1), 1′), and 1″) water : methanol = 1 : 3; 2), 2′), and 2″) water : dioxan = 1 : 1; 3), 3′) and 3″) water : dioxan = 1 : 2; 4), 4′), 4″), 7), 7′), and 7″) water : methanol = 1 : 5; 5), 5′), 5″), 6), 6′), and 6″) water : dioxan = 1 : 3; β^0_B: 1), 1′), 1″), 2), 2′), 2″), 3) 3′), and 3″) 0.2; 4), 4′), 4″), 5), 5′), 5″) 0.6; 6), 6′), 6″), 7) 7′), and 7″) 0.8.

Labile hydrogen bonds[105] as well as the nature of the heterogeneous equilibrium in the multicomponent system[106,107] can also complicate the copolymerisation process. However, even a qualitative comparison of the IDCC (Fig. 13) permits the important conclusion that, depending on the nature of the precipitant employed, the copolymer in the concentrated phase is enriched (dioxan) or depleted (methanol) in component B relative to the copolymer in the dilute phase. The explanation is that the homopolymer B and copolymers with a high content of B are soluble in methanol, which is a very effective precipitant for polyacrylamide. Dioxan does not behave as a precipitant either for homopolymers or for copolymers of different compositions. After the attainment of a critical degree of conversion ψ_{cr}, the "displacement" of the monomeric component B from the solution to the concentrated phase is much less pronounced than in the water–dioxan system according to the Langmuir rule. Thus in heterophase synthesis a kind of fractionation of the copolymer with respect to composition between dilute and concentrated phases take place already during the formation of macromolecules, the choice of the solvent–precipitant system determining in many respects the properties of the reaction products. In this connection it is appropriate to mention that the IDCC are much more reliable "indicators" of different types of interphase interactions than molecular weight distribution curves.

An interesting case of "anomalous" copolymerisation in a precipitant was examined by Slavnitskaya et al.[108] In conformity with the general mechanism of heterophase copolymerisation[101], the experimental IDCC were trimodal. Comparative analysis of the individual branches of the overall IDCC led Slavnitskaya et al.[108] to important conclusions about the copolymerisation mechanism, particularly about the intensity of the kinetic chain propagation and termination process in individual phases of the system.

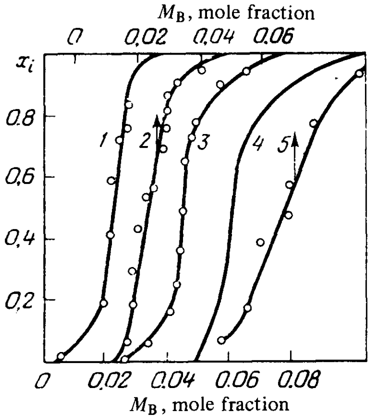

Figure 14. Integral distribution curves with respect to composition for ethylene (A)–triethylvinylsilane (B) copolymers with different average contents $\bar{\alpha}_B$ of component B: 1) 0.018; 2) 0.03; 3) 0.41 (Samoilov et al.[109]); 4) 0.069 (Samoilov et al.[109]); 5) 0.066.

(2) Copolymerisation complicated by intense depolymerisation processes. The breakdown of the unambiguous nature of the relation $\alpha_A = f(\beta_A)$ may be expected when the rate constants for the depolymerisation of the first and second components differ appreciably. This apparently happened in a study[109] of the radical copolymerisation of ethylene with trimethyl- and triethyl-silanes at 160°C and 1400 atm using di-t-butyl peroxide as the initiator. On the basis of the composition diagram and the analysis of the results in terms of the Feinman–Ross coordinates, the authors reached the well argued conclusion that the Mayo–Lewis equation is inapplicable to the system. This is also clearly indicated by data for polydispersity with respect to composition for the same copolymers (Fig. 14). In view of a number of indirect pieces of evidence, the authors[109] fully rule out a heterophase copolymerisation mechanism, but in our view (bearing in mind the form of curves *1*, *2*, and *4* in Fig. 14) the partial heterophase nature of the system may make a definite contribution to the "abnormality" of the system apart from the depolymerisation processes.

The principal characteristics of copolymerisation when polymerisation and depolymerisation processes occur simultaneously was examined in detail in a review[110]. In particular, the review deals with the influence of the ratio of the rate constants for the forward and reverse (depolymerisation) processes on the composition of the macromolecules formed. It is shown that the composition diagrams differ significantly when the relative contribution of the depolymerisation process to the overall copolymerisation reaction balance is varied (Fig. 15), which is achieved most simply by altering the temperature of the copolymerisation process.

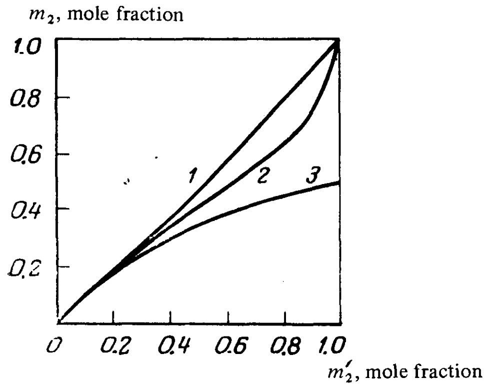

Figure 15. Composition diagrams in the presence of the depolymerisation process at different temperatures (°C): 1) 0; 2) 50; 3) 100; m_2 and m_2' are the mole fractions of the second component in the copolymer and in the mixture of monomers respectively.

(3) The ambiguity of the $\alpha_A = f(\beta_A)$ relation in two-centre copolymerisation was demonstrated experimentally[111] for the copolymerisation of N-butylidenecyclohexylamine with acrylonitrile.

(4) The "anomalous" nature of the system is due to intense reactions involving kinetic chain transfer to macromolecules. Such systems have been examined[112] in relation to the copolymerisation of styrene with dioxolan and elsewhere[113] for the copolymers of oxacyclobutane with β-propiolactone. In the latter study[113] the "anomalous" nature of the copolymer was demonstrated by direct analysis of its chemical structure. The main theoretical principles of copolymerisation complicated by chain transfer reactions with rupture of the macromolecules were formulated by Enikolopov[23]. One should note that, in the polymerisation of cyclic compounds, many parameters of the final product (particularly the nature of the molecular

weight distribution) depend on the degree of departure of the reaction from equilibrium[20,114].

We shall consider in greater detail the copolymerisation of cyclosiloxanes, because, according to literature data[115], intense interchain exchange reactions at the stage of the synthesis are to be expected for polymers of this class. On the other hand, the occurrence of various secondary reactions should affect to the greatest extent the distribution curves with respect to composition. Fig. 16 presents the IDCC for copolymers of dimethyl- and methylphenyl-siloxanes[116] (analogous relations were obtained also for SKTNF rubber[117]). We may not in the first place that, whereas the difference between the compositions of the fractions detected during fractionation without employing selective solvent–precipitant mixtures[5,118–120] exceeds only slightly the limit of the sensitivity of the method (under somewhat different fractionation conditions, no differences between the compositions of the fractions were noted at all in another study[121]), in fractionation employing selective solvent–precipitant systems sensitive to the composition of the macromolecules the difference between the compositions of the isolated fractions greatly exceeds this value. The very difference between the compositions of the fractions (Fig. 16) permits the conclusion that the interchain exchange processes do not suppress completely the main process involving the synthesis of the macromolecules of a copolymer having a definite structure, in conformity with the relative reactivities of the monomers and their concentrations. Indeed if depolymerisation and chain transfer to macromolecules played the main role, one should expect a high degree of homogeneity of the fractions with respect to composition, which conflicts with experimental data in Fig. 16. On the other hand, since $\psi \geqslant 0.9$ for all the specimens, one might expect a greater polydispersity of the fractions with respect to compositions on the assumption that the Mayo–Lewis scheme applies. The conclusion that the scheme does not apply is consistent with those reached by investigators[122] who studied the copolymerisation of octamethyl- and octaphenylcyclotetrasiloxanes.

The following most probable chain transfer reactions may be considered[114,115]:

$$\sim R_1R_2SiO^- + \sim SiR_1R_2OSiR_1'R_2' \sim \xrightarrow{k_1'} \sim R_1R_2SiOSiR_1R_2 \sim + \sim R_1'R_2'SiO^-,$$

$$\sim R_1R_2SiO^- + \sim SiR_1'R_2'OSiR_1'R_2' \sim \xrightarrow{k_2'} \sim R_1R_2SiOSiR_1'R_2' \sim + \sim R_1'R_2'SiO^-,$$

$$\sim R_1'R_2'SiO^- + \sim SiR_1'R_2'OSiR_1R_2 \sim \xrightarrow{k_3'} \sim R_1R_2SiO^- + \sim R_1'R_2'SiOSiR_1'R_2' \sim,$$

$$\sim R_1'R_2'SiO^- + \sim R_1R_2SiOSiR_1R_2 \sim \xrightarrow{k_4'} \sim R_1'R_2'SiOSiR_1R_2 \sim + \sim R_1R_2SiO^- . \tag{20}$$

The fact that for certain compositions of the initial mixture of cyclosiloxanes the copolymerisation cannot be regarded *a priori* as a homophase process after the attainment of ψ_{cr} may also have a significant influence on the copolymerisation reaction, particularly on the distribution curves with respect to composition[122]. The lack of information about the relative reactivities of different cyclic monomers in the copolymerisation reaction[123] and about the composition of the mixture of monomers during the synthesis precludes a quantitative assessment of the degree of departure from equilibrium and of the role of the chain transfer reactions in the copolymerisation. However, the results already obtained do indicate the necessity for careful studies on these lines with the obligatory involvement of data for the distribution of copolymers with respect to composition.

Naturally, the "anomalous" nature of the system persists also when the principal necessary conditions for the classification of the process break down simultaneously (for example, when depolymerisation accompanies the process under heterophase conditions, when reactions involving chain transfer to the polymer are accompanied by two-centre copolymerisation, etc.). It is quite unreasonable to use the copolymerisation "constants" r_A and r_B for all "anomalous" systems. For such systems, even the available information about the distribution with respect to composition within the specimen for different values of β_A^0 and ψ is insufficient in certain instances for the estimation of the characteristic features of the copolymerisation process and it is necessary to resort to data for the real chemical structure of the macromolecules (for example, in heterophase copolymerisation with intense interphase recombination interactions or in the presence of intense kinetic chain transfer reactions between the phases, etc.).

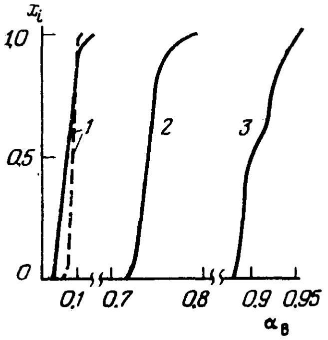

Figure 16. Integral distribution curves with respect to composition for SKDFV-803 (curves *1* and *2*) based on fractional dissolution (curve *1*) and fractional precipitation (curve *2*) data for copolymers of methylphenyl- and dimethyl-siloxanes with ratios of the initial monomers of 3 : 2 (curve *2*) and 4 : 1 (curve *3*).[116]

IV. METHODOLOGICAL RECOMMENDATIONS

Thus binary statistical copolymerisation may be classical, classical in a certain range of β_A^0 and ψ, and unusual (of the first and second kind). However, the answer to the question whether a specific process is classical or unusual is far from trivial. The point is that it is extremely difficult to state *a priori* whether a particular condition necessary for a classical process holds; on the other hand, successive tests of the validity of all twelve conditions formulated above are too cumbersome. For this reason, a simpler analytical scheme is necessary in which a conclusion concerning the topology of the copolymerisation process is reached on the basis of a comparison of the individual features of the specific copolymerisation system and a classical system.

In this sense the following analytical procedure is most promising. In the first stage one analyses the $\alpha_A = f(\beta_A^0)$ relation and, when the latter is not unambiguous, the system is known to be "anomalous" (unusual system of the first kind). For such systems, it is erroneous to calculate the apparent copolymerisation "constants" [obtained by the formal treatment of the $\alpha_A = f(\beta_A^0)$ relations]: it is necessary to analyse the IDCC and the chemical structure of the specimens for different β_A^0 and ψ. When the $\alpha_A = f(\beta_A^0)$ relation is ambiguous, it is necessary to determine whether it can be described in terms of two copolymerisation constants ($r_A \pm \Delta r_A$ and $r_B \pm \Delta r_B$) or whether the function $\alpha_A = f(\beta_A)$ is more complex. Several approaches are possible in order to obtain an answer to the last question.

The first involves the comparative analysis of the experimental values $(\Delta r_A/r_A)_{exp}$ and $(\Delta r_B/r_B)_{exp}$ together with the calculated values $(\Delta r_A/r_A)_{calc}$ and $(\Delta r_B/r_B)_{calc}$. If $(\Delta r_A/r_A)_{exp} \gg (\Delta r_A/r_A)_{calc}$ and $(\Delta r_B/r_B)_{exp} \gg (\Delta r_B/r_B)_{calc}$, then unusual copolymerisation is indicated[19,26].

In the second procedure the formal values of r_A and r_B may be used to plot theoretical IDCC[124,125] which are then compared with the experimental curves. The conclusion whether or not the process is unusual or classical can be reached on the basis of the positions, widths, and shapes of the experimental and theoretical IDCC.[4,26]

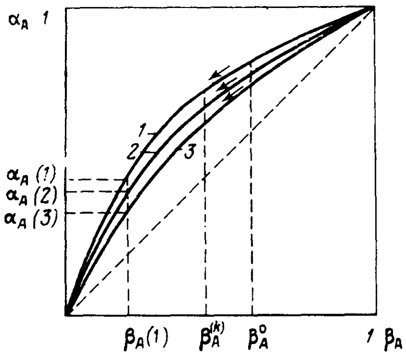

Figure 17. Schematic composition diagrams for different ψ = const.: 1) ψ_1; 2) ψ_2; 3) ψ_3; $\psi_1 < \psi_2 < \psi_3$.

In the third procedure conclusions are reached about the unusual or classical nature of the process from a comparison with experimental curves of the theoretical IDCC plotted on the basis of data derived from the composition diagram (without calculating r_A and r_B). We shall consider in greater detail the plotting of theoretical IDCC by this method, because it is extremely important from the practical point of view. Suppose that we do not know the form of the $\alpha_A = f(\beta_A)$ function and have at our disposal only empirical data of the type of composition diagrams. Suppose further that $\alpha_A < \beta_A$, which means that α_A increases with increase of ψ (Fig. 17). If

$$\beta_A|_{\psi=0} = \beta_A^0 = c_A|_{\psi=0}/(c_A|_{\psi=0} + c_B|_{\psi=0}) \text{ and}$$
$$\beta_A^{(k)} = \beta_A|_{\psi=\psi_k} = c_A|_{\psi=\psi_k}/(c_A|_{\psi=\psi_k} + c_B|_{\psi=\psi_k});$$
$$c_A|_{\psi=0} + c_B|_{\psi=0} - c_B|_{\psi=\psi_k} - c_B|_{\psi=\psi_k} = \Delta c_A + \Delta c_B;$$

then the average weight content of component A in the copolymer is

$$\bar{\alpha}_A = \Delta c_A|_{\psi=\psi_k}/(\Delta c_A|_{\psi=\psi_k} + \Delta c_B|_{\psi=\psi_k}),$$

and

$$\psi_k = (\Delta c_A + \Delta c_B)/(c_A + c_B)|_{\psi=0} .$$

Without infringing the generality of the approach, we put $(c_A + c_B)|_{\psi=0} = 1$. In order to plot the weight IDCC, the entire $\Delta c_A = |c_A|_{\psi=\psi_k} - c_A|_{\psi=0}|$ section must be divided into a polymerisation increments[22] (smooth relations between $\psi^{(i)}$ and $\alpha_A^{(i)}$, which are necessary for accurate IDCC plots, can be achieved when $a \simeq 20$). For the first polymerisation increment, we have

$$\beta^1_{(A)} = \frac{\beta_A|_{\psi=0} - \Delta c_A/a}{1-\psi^{(1)}};\ \bar{\alpha}_A^{(1)} = \frac{\Delta c_{A/a}}{\Delta c_A/a + \Delta c_B^{(1)}} = \frac{\Delta c_A}{a\psi^{(1)}};$$
$$\beta_A^{(1)}(1-\psi^{(1)}) = \beta_A|_{\psi=0} - \bar{\alpha}_A^{(1)}\psi^{(1)}.$$

Hence $\psi^{(1)} = \Delta c_A/a + \Delta c_B^{(1)} = (\beta_A^{(1)} - \beta_A^0)/(\beta_A^{(1)} - \bar{\alpha}_A^{(1)})$. $\psi^{(2)}, \psi^{(3)}, \ldots$ can be calculated similarly, but one must recall that a proportion of the monomers are consumed in preceding polymerisation increments, so that

$$\psi^{(2)} = \frac{\beta_A^{(2)} - \beta_A^{(1)}}{\beta_A^{(2)} - \bar{\alpha}_A^{(2)}}[1-\psi^{(1)}];\ \psi^{(3)} = \frac{\beta_A^{(3)} - \beta_A^{(2)}}{\beta_A^3 - \bar{\alpha}_A^{(3)}}[1-\psi^{(1)}][1-\psi^{(2)}],$$

etc. After calculating all the $\psi^{(p)}$ for $p \leqslant a$, it is easy to convert the result into the integral weight fraction of the increment and then plot the weight IDCC. Similarly it is not difficult to calculate the molar IDCC; in this case one must employ a molar composition diagram. Conclusions whether or not the copolymerisation process is unusual or classical can also be reached by other indirect methods. Some of these are indicated below.

(1) Suppose that the copolymerisation process takes place in a solvent. For a classical process, α_A is determined by the values of $\bar{\beta}_A$ and ψ and is independent of the overall monomer concentration ($c_A^0 + c_B^0$). The appearance of a dependence of α_A on $c_A^0 + c_B^0$ shows unambiguously that the process is unusual. We examined this case in detail previously in relation to the copolymerisation of ionogenic monomers in ionising media.

(2) The study of the distribution with respect to composition for $\beta_A = (\beta_A)_{az}$. For classical systems, the specimen should be monodisperse and the parameter y_1 [see Eqn. (19)] should be zero also when $\psi \to 1$ (it is assumed that the degree of polymerisation is fairly high and that the "instantaneous" component of the inhomogeneity with respect to composition may be neglected). On the other hand, if y_1 differs appreciably from zero to $\beta_A = (\beta_A)_{az}$, the implication is that the copolymerisation process has an unusual mechanism. In this case unusual distribution curves with respect to composition may be expected for specimens obtained by heterophase copolymerisation—one branch of the curve should be convex and the other should be concave with respect to the abscissa axis.

(3) In many instances the conclusion that the nature of the copolymerisation process is unusual may be arrived at by comparing the values of y_1 for model and experimental IDCC.[36,43]

It is necessary to note yet another important factor—the points on the composition diagrams must be analysed for the same values of ψ. As shown schematically in Fig. 17, the values of α_A for the same β_A may differ appreciably for different ψ. The analysis where values of α_A are determined as a function of ψ for different β_A^0 and the results are used to find $\bar{\alpha}_A$ for the required values of $\psi = \psi_A$ is most suitable for a practical study. If ψ varies within wide limits under these conditions, then the above type of analysis yields an amount of information intermediate between that derivable from the analysis of the IDCC and the analysis of the composition diagrams.

In conclusion of this section, a few words must be said about the Alfrey–Price $Q-e$ scheme[126,127]. In the first place one must understand that the scheme is in principle applicable solely to the analysis of classical systems. The Alfrey–Price scheme is empirical and can be useful only in a comparative analysis of the binary statistical copolymerisation of A and B, A and B′, A and B″, etc. monomers, where B, B′, B″, ... are vinyl monomers differing in the group R, but the copolymerisation conditions must be identical. It is illegitimate to apply the Alfrey–Price scheme to the estimation of the reactivities of 1,1- and 1,2-disubstituted ethylenes, because the scheme does not take into account the role of the steric factor[128,129]. The difficulties arising in the application of the Alfrey–Price scheme are hardly resolvable if the relative reactivities of the monomers depend on the parameters of the reaction medium. Indeed, in this case Q_A, Q_B, e_A, and e_B cease to be unambiguous and the Alfrey–Price scheme itself becomes arbitrary. The attempt to employ the Alfrey–Price scheme in the analysis of systems where for even one of the monomer pairs [part of the Russian text appears to be missing at this point] (the copolymerisation is an unusual process of the first or second kind) is known *a priori* to be unsatisfactory. We have to consider these self-evident matters because many workers, while realising the limited nature of the Alfrey–Price scheme, contradict themselves by employing it.

The question of the much greater complexity of the characteristics of the copolymerisation of a large class of systems compared with the characteristics of the copolymerisation of classical systems is no longer controversial. Naturally, the increase in the complexity of the copolymerisation mechanism requires the formulation of more complicated experiments and a more complicated method of interpretation of the experimental data[130] (compared with classical systems). The employment of data for distribution with respect to composition[131] and also the derivation of information about the chemical structure (configurational inhomogeneity) or macromolecules are not only desirable but also necessary[8,10]. This review deals only with the principal criteria for the estimation of the characteristics of binary statistical copolymerisation and the most general copolymerisation model has been adopted for the treatment. The general principles described are illustrated by the analysis of the characteristics of copolymerisation for a number of specific models.

Further progress in the development of a general statistical copolymerisation theory will be evidently associated with an intense development of research on the following lines: (1) the discovery and development of new reliable methods for the determination of the statistical parameters of copolymerisation, in the first place the IDCC and the chemical structure of the macromolecules. Together with the high-resolution NMR method[132], the degradation method[133] is in many cases promising for the estimation of structure. The degradation method is particularly effective in the absence of a depolymerisation process and for a sharp difference between the degradation rate constants k_g for components A and B. In particular, analysis of the molecular weight distribution (MWD) curves for degradation products permits important inferences about the characteristic features of the synthesis of copolymers. Thus unimodal and bimodal MWD curves for the products of the ozonolysis of statistical copolymers of isobutene (A) and butadiene (B) $[k_g(A) \ll k_g(B)]$ indicate homophase[134] and heterophase[135] synthesis of copolymers. The determination of quantitative relations between MWD and the Schultz parameters for the degradation products, on the one hand, and the IDCC and the parameters of dispersion with respect to the composition of the copolymer, on the other, appears quite realistic; (2) the accumulation of experimental data on the characteristics of the copolymerisation of unusual systems; (3) the development of theories which establish a relation between the statistical parameters and the process mechanisms for specific unusual (of the first and second kind) copolymerisation models[136]; (4) the development of the most complete classification scheme for the analysis of binary statistical copolymerisation based on a general copolymerisation model.

Thin-layer Chromatography of Polymers

E.S.Gankina and B.G.Belen'kii

A new method for the investigation of the polydispersity of polymers in terms of molecular weight, composition, regularity, and stereoregularity—the thin-layer chromatography of polymers—is described. The theoretical principles of the method, quantitative analysis, and its application to the study of various classes of polymers and oligomers are considered. The bibliography includes 102 references.

I. INTRODUCTION

A major advance in the development of thin-layer chromatography (TLC) has been its application to the analysis of high polymers. The first studies on the TLC of statistical copolymers were carried out in 1968 simultaneously at the Analytical Laboratory of the Institute of Macromolecular Compounds of the USSR Academy of Sciences[1] and in Inagaki's laboratory at Kyoto University[2]. Since then the following principal trends have been established in this new field of chromatography[3-6]: the study of the heterogeneity of polymers [molecular weight distribution (MWD) and inhomogeneity with respect to composition]; identification (diagnosis) of polymers differing in microstructure; analysis of MWD and the functionality of oligomers.

Depending on the nature of the interactions in chromatographic systems, the following types of TLC of polymers are possible: (a) adsorption TLC of polymers (ATLC) in which differences in the adsorption activity of polymers are used, the differences increasing with increase of the molecular weight (MW) and the fraction of adsorption-active polar groups in the copolymer or oligomer; (b) thin-layer gel-permeation chromatography (TLGPC) based on the use of the molecular sieve effect, in which the separation of polymers is associated with the differences between the relative dimensions of the macromolecule and the dimensions of the pores in the adsorbent; (c) precipitation TLC of polymers (PTLC) based on differences between the solubilities of polymers having different molecular weights and different chemical structures; (d) extraction TLC (ETLC), in which polymers of different types are selectively dissolved in the initial spot on the "all or nothing" principle. These versions of the TLC of polymers can be usefully combined into two groups, differing in the mechanism of the fractionation of macromolecules: (1) adsorption methods (ATLC) with positive adsorption and TLGPC with negative adsorption; (2) methods based on differences between the solubilities of polymers (PTLC and ETLC).

At the present time TLC is used widely in the study of high-molecular-weight substances. Here one may point out that TLC is used successfully in the quantitative analysis of polymers: for the analysis of the molecular weight distribution (MWD) of homopolymers (ATLC, PTLC), statistical copolymers (PTLC), and oligomers (ATLC), the inhomogeneity of block and statistical copolymers with respect to composition (ATLC), the functionality of oligomers (ATLC), and the functionality of polymers (with $M < 5 \times 10^4$) having terminal adsorption-active groups (ATLC, ETLC). TLC is also employed for the quantitative analysis (diagnosis) of the branching of homopolymers and oligomers (ATLC) and the microstructure of polymers: the regularity of polybutadiene and polyisoprene (ATLC, ETLC), the stereoregularity of poly(methyl methacrylate) and polystyrene (ATLC, PTLC, ETLC), statistical, alternating, and block copolymers (ATLC) and two- and three-block copolymers (ATLC), and the analysis of the purity and homogeneity of polymer fractions, the admixture of homopolymers in block and graft copolymers (ATLC, PTLC, ETLC), and the side chains split off from graft copolymers and the corresponding homopolymers (ATLC). TLC is also used in combination with other chromatographic techniques [gel permeation (GPC) and pyrolytic gas chromatography (PGC)] in the analysis of complex polymer systems where the problems enumerated above are solved with the aid of TLC.

II. THIN-LAYER CHROMATOGRAPHY OF POLYMERS BASED ON ADSORPTION

1. Adsorption TLC (ATLC) of Copolymers

ATLC was the first version of the TLC of polymers developed by ourselves[1,7-9] and Inagaki[2] for the fractionation of statistical ST–MMA and ST–MA copolymers† with respect to composition. Eluent systems consisting of chlorinated hydrocarbons and solvents and adsorption-active oxygen compounds as displacing agents were used for the TLC of ST–MMA copolymers; they can be arranged in the following eluotropic series: ethyl ether < EMK < acetone < THF < dioxan; chlorobenzene < dichloroethane < chloroform. The copolymers were chromatographed in sandwich chambers (S-chambers), where a concentration gradient of the displacing agent was set up by its gradual evaporation into the air space within the chamber while flowing along the plate. High gradients were used to separate copolymers with large differences in composition (Fig. 1‡). ST and MMA copolymers, the elemental compositions of which are virtually indistinguishable, can be fractionated by high-resolution TLC with a weak displacing agent concentration gradient; for example, it is possible to observe differences in the polydispersity of copolymers having an azeotropic composition (with 54 mole % ST), obtained for different conversions. It was observed[3,7] that the R_f (relative migration) of the copolymer depends not only on the composition, but also on its molecular weight (for MW < 10^5). Similar results for the TLC of ST–MA statistical polymers were obtained in a study[2] where gradient TLX was used with addition of methyl and ethyl acetates to chloroform.

The distribution and inhomogeneity with respect to composition of many other statistical copolymers (styrene–butadiene, styrene–acrylonitrile, incompletely substituted cellulose nitrates and acetates, and α-amino-acid copolymers) were investigated with the aid of ATLC—see Appendix (Table 1).

Inagaki established[10] that the chromatographic mobility of ST–MMA copolymers is related to their structure. Thus the R_f for these copolymers in the chloroform–ethyl acetate system increase in the following sequence: block copolymers < alternating copolymers < statistical copolymers; the values of R_f for block copolymers vary as a function of the number of blocks incorporated in them[11,12].

2. ATLC of Homopolymers

The considerable possibilities of ATLC for the separation of homopolymers on the basis of their molecular weights have been demonstrated[13]. Fig. 2 illustrates chromatograms for narrowly disperse polystyrenes ($M_w/M_n \leqslant 1.2$) on KSK silica gel plates in the cyclohexane–benzene–acetone system.

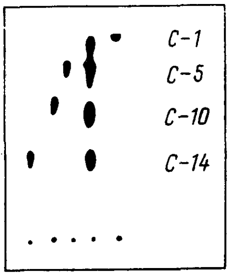

Figure 1. TLC of statistical ST–MMA copolymers on KSK silica gel in the 12 : 2.2 chloroform + acetone system in an S-chamber: C-14 (22% ST, $M_w = 2.3 \times 10^5$); C-10 (31% ST, $M_w = 8.8 \times 10^4$); C-5 (54% ST, $M_w = 8 \times 10^4$); C-1 (80% ST, $M_w = 1.2 \times 10^5$).

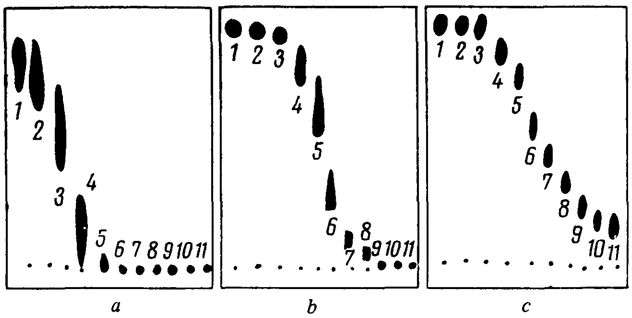

Figure 2. TLC of polystyrenes ($M_w/M_n \leqslant 1.2$) on KSK silica gel in the cyclohexane + benzene + acetone system: *a*) 13 : 3 : 1; *b*) 12 : 4 : 0.4; *c*) 12 : 4 : 0.7; 1) $M_n = 10^3 \times 0.9$; 2) $M_n = 10^3 \times 2.03$; M_w/M_n; 3) 5/4.5; 4) 10.3/9; 5) 19.85/19.65; 6) 51/49; 7) 98.2/96.2; 8) 173/164; 9) 411/392; 10) 867/773; 11) 2145/1780.

If solvents with relatively low adsorption activity, for example, a mixture of cyclohexane and benzene, are used for the ATLC of polystyrene, then polystyrenes with MW > 10^5 do not form compact spots and are smeared over the plate, which is due to the low rate of the adsorption-desorption processes involving high-molecular-weight polymers in such systems.

It has also been possible to resolve PMMA by adsorption TLC in the 5 : 95 methanol–chloroform system[14,15] and PEO in the ethylene glycol–methanol system on silica gel and the methanol–DMF system on alumina on the basis of their molecular weights[16].

---

†The following abbreviations have been adopted in this review: ST = styrene, PS = polystyrene, MMA = methyl methacrylate, MA = methyl acrylate, PMMA = poly(methyl methacrylate), EO = ethylene oxide (epoxyethane], PEO = poly(ethylene oxide), PB = polybutadiene, BD = butadiene, P-α-methylstyrene, AN = acrylonitrile, PI = polyisoprene, CTA = cellulose triacetate, PVA = poly(vinyl acetate), ETP = ethylene terephthalate, PETP = poly(ethylene terephthalate), PPG = poly(propylene glycol), EMK = ethyl methyl ketone, THF = tetrahydrofuran, and DMF = dimethylformamide.

‡Fig. 1 and other figures represent contact photographs of thin-layer chromatograms.

3. Thin-Layer Gel-Permeation Chromatography of Polymers (TLGPC)

The possibility of separating polymers with the aid of TLC on the basis of the molecular sieve mechanism was first established by Halpaap and Klatyk[17], and the feasibility of its application to the analysis of TLGPC was first studied by Belenkii et al.[3] This form of TLC of polymers has also been studied in other investigations[18,19]. In order to reveal the molecular-sieve effect in TLC, it is necessary to suppress the adsorption activity of silica gel and to fill the adsorbent pores with the solvent before the start of elution. This can be achieved in two ways: with the aid of so-called pre-elution, i.e, by passing the solvent along the plate before depositing the sample[18], or by capillary condensation involving the preliminary saturation of the chromatographic layer on the plate with solvent vapour[3,13]. It has been shown[18] that the effectiveness of TLGPC in the separation of polymers on the basis of their molecular weights depends on the degree of saturation with the solvent of the adsorbent pores and of the space between the particles of the chromatographic layer. This is the reason for the differences in the effectiveness of TLGPC as a function of the thickness of the adsorbent layer and the direction of motion of the eluent (upwards or downwards) along the plate. For this reason, column GPC is more effective than TLGPC, where the packing density of the adsorbent is lower.

4. Fundamental Characteristics of Adsorption TLC Methods for Polymers (ATLC and TLGPC)

The adsorption of polymers has been studied in many theoretical and experimental investigations[20]. The most notable achievement in this field has been the prediction[21-24] of the phase transition occurring after the attainment of a critical value ϵ_{cr} in the energy of the interaction of the polymer unit with the adsorption surface (ϵ). In this transition all the properties of the adsorbed macromolecule change: its size, the fraction of adsorbed segments, and the sign of the free energy change (there is a transition from negative to positive adsorption), i.e. $-\Delta F = 0$ when $-\epsilon = -\epsilon_{cr}$. It has been shown theoretically[24] that these features are characteristic of the adsorption of isolated macromolecules both on a planar surface and within pores.

The chromatographic experiments made it possible to investigate the adsorption behaviour of macromolecules in the absence of concentration effects, i.e. one can study experimentally the behaviour of isolated macromolecules. These features of the adsorption behaviour of macromolecules have been tested experimentally[25] by TLC on silica gels in the hydrogen-form ensuring the energetic equivalence of the surfaces of silica gel adsorbents of different porosities[26]. Narrowly disperse PS were chromatographed in the 40 : 16 : x cyclohexane–benzene–acetone system, where changes in the acetone content (x) regulated the energy of the interaction ($-\epsilon$) of the macromolecular segment with the adsorbent surface. The quantity $-\epsilon$ (in units of kT) can be expressed in the form $-\epsilon = \epsilon_{pa} - \epsilon_{sa}$, i.e. as the difference between the energies of the adsorption interactions of the polymer segment (ϵ_p) and the solvent (ϵ_{sa}). Since ϵ_p remains constant when the solvent composition is altered, ϵ is determined in terms of the quantity ϵ_s, which may be calculated by Snyder's method[27].

Fig. 3 presents PS chromatograms on KSK silica gel (pore diameter 100 Å).[25] Evidently, with increase of the acetone content and hence with decrease of $-\epsilon$, there is a gradual transition from adsorption to molecular sieve chromatography. The chromatograms illustrated in Fig. 3 have the following features: (1) with increase of $-\epsilon$ (i.e. with increase of x) in the region of the preferential operation of the molecular sieve effect (MSE), where negative adsorption is observed (Figs. 3*d*–3*f*), the R_f for the large PS macromolecules diminish; the macromolecules are, as it were, "drawn into" previously inaccessible pores, i.e. the limit corresponding to the exclusion of macromolecules from the pore space is determined not only by the MSE (the ratio of the dimensions of the macromolecules and pores) but also by the adsorption in the pores; (2) there exists a composition of the eluent for which the energy of the interaction of the molecular segments with silica gel is close to the critical value $-\epsilon_{cr}$ (Fig. 3*c*); PS molecules with different molecular weights then exhibit identical values of K_d and R_f and the macromolecules are, as it were, insensitive to the pore dimensions (zero adsorption); (3) on further decrease of x (on increase of $-\epsilon$), there is a transition to the region of positive adsorption (ATLC—Figs. 3*c* and 3*a*), where an increase of the molecular weight of the polymer entails a decrease of its R_f.

The free energies of the adsorption ($-\Delta F$) of the macromolecules can be readily evaluated from the thin-layer chromatograms. For this purpose, one may use the equation

$$R_f = \left(1 + \frac{V_p}{V_0} K_d\right)^{-1}, \tag{1}$$

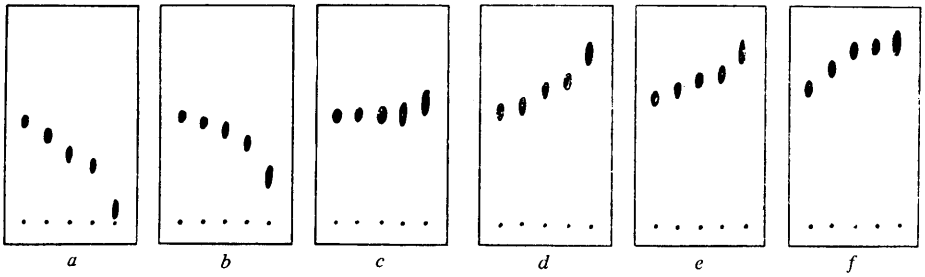

Figure 3. TLC of polystyrenes *5–9* (see Fig. 2) from left to right on KSK silica gel in the 40 : 16 : x cyclohexane + benzene + acetone system; x: *a*) 1.5; *b*) 1.8; *c*) 2.0; *d*) 2.2; *e*) 2.5; *f*) 2.8; with preliminary saturation of the plate in solvent vapour for 2 h.

where V_p/V_0 is the ratio of the volumes of the pore and interparticle spaces in the adsorbent, as well as the expression

$$K_d = \exp\left(-\frac{\Delta F}{kT}\right). \qquad (2)$$

Eqns.(1) and (2) make it possible to determine the ratio V_p/V_0, since we have $-\Delta F = 0$, $K_d = 1$, and

$$\frac{V_p}{V_0} = \left(\frac{1-R_f}{R_f}\right)_{-\varepsilon=-\varepsilon_{cr}} \qquad (3)$$

when $-\epsilon = -\epsilon_{cr}$.

Fig. 4[25] illustrates the experimental relation between $-\Delta F/kT$ and $-\epsilon$, calculated by Eqns. (1) and (2) for silica gels of different porosity. The observed relation is similar to the theoretical relation[23]. Fig. 4 shows clearly the presence of two energy regions corresponding to the adsorption of macromolecules with energies smaller and greater than $-\epsilon_{cr}$ (the regions of negative and positive adsorption). The experimental relations for PS with different molecular weights then make an intercept on the abscissa axis at the same point, corresponding to $-\epsilon_{cr}$. At this point the entropy losses ΔS by the macromolecule on adsorption are fully compensated by the increase of the enthalpy ΔH:

$$\Delta F(-\varepsilon) = \Delta F(-\varepsilon_{cr}) = \Delta H - T\Delta S = 0 \ .$$

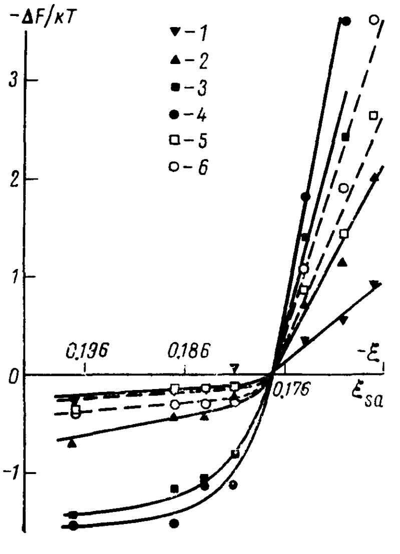

Figure 4. Dependence of the change in the free energy of PS macromolecules ($-\Delta F/kT$) on entering pores on the energies of the interaction of the macromolecular segment ($-\epsilon$) and solvent molecules (ϵ_{sa}) with the surface of the pores. Curves *1–4* represent data for KSK silica gel (pore diameter 100 Å) and curves *5* and *6* represent data for silochrome K-80 (pore diameter 500 Å); molecular weight of polystyrenes M_w: 1) 1.98×10^4; 2) 5.1×10^4; 3) and 5) 1.11×10^5; 4) and 6) 1.73×10^5.

It is possible to show with the aid of TLC on silica gels of different porosity using eluents of the same composition for the same values of $-\epsilon$) that, as the pore size increases, the TLGPC of polystyrene is transformed into ATLC at high acetone concentrations, i.e. with increase of pore size $-\epsilon_{cr}$ diminishes. The observation that, for high values of $-\epsilon$, the macromolecules enter small KSM silica gel pores and are adsorbed in the latter more strongly than in the large KSK and K-80 silica gel pores is of considerable interest[25]. This fundamentally new result conflicts with the results of a number of investigations[20] carried out in non-chromatographic concentration ranges, but is fully consistent with the theory[24].

Experiments[3] on the TLC of PS yielded a linear relation between $-\Delta F/kT$ and the number of segments (i.e. M_w) of the polymer (Fig. 5), which is consistent with the relation predicted by the theory[25]:

$$K_d = \exp(-\lambda_\varepsilon N), \qquad (4)$$

where λ_ϵ is the change in the free energy of the macromolecule per unit and N the number of polymer units. Using Eqn. (4), we can formulate an expression for R_f in the case of adsorption TLC of polymers:

$$R_f = \left(1 + \frac{V_p}{V_0}\exp(-\lambda_\varepsilon N)\right)^{-1}. \qquad (5)$$

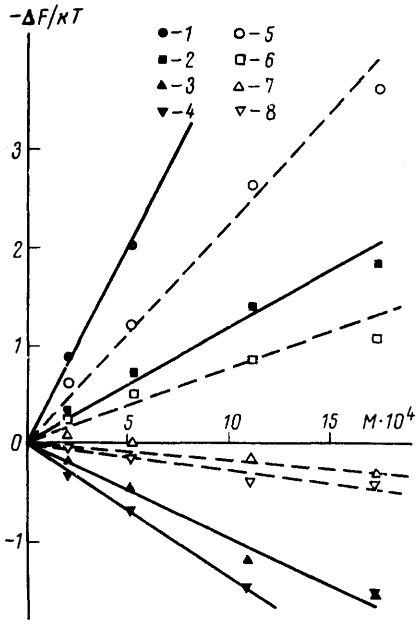

Figure 5. Dependence of the change in the free energy ($-\Delta F/kT$) of PS macromolecules on entering KSK silica gel (curves *1–4*) and silica gel K-80 (curves *5–8*) pores on the molecular weight. ϵ_{sa}: 1) and 5) 0.167; 2) and 6) 0.173; 3) and 7) 0.181; 4) and 8) 0.197.

Having differentiated Eqn. (5) with respect to N and λ_ϵ, we find that the sensitivity of R_f to the molecular weight of the polymer ($\partial R_f/\partial N$) decreases with increase of N and the dependence of $\partial R_f/\partial N$ on $-\lambda_\epsilon$ passes through an extremum near ϵ_{cr}. For each molecular weight there is a characteristic extremum in λ_ϵ, i.e. near the eluent composition;

consequently the region of the maximum sensitivity of TLC to the molecular weight of the polymer in each range of M_w values is characterised by the particular eluent composition, as can be seen in Fig. 2. The variation of the influence on R_f of the chemical composition of the polymer, characterised by λ_ϵ, i.e. of $\partial R_f/\partial\lambda_\epsilon$, also passes through a maximum. It follows from studies of ATLC that the sensitivity of R_f to the copolymer composition persists at least up to $M_w \simeq 5 \times 10^5$.

It has been suggested in the literature[18,28-30] that in ATLC polymers are fractionated on the basis of their chemical compositions and not their molecular weights. In reality, when a binary or ternary mixture of solvents, preferably containing an adsorption-active component, is used instead of a pure solvent, it is always possible to obtain the value of $-\epsilon$ necessary for the separation of polymers over a fairly broad range of molecular weights, with R_f in the range 0.1–0.8. The upper limit to the molecular weights in the separation of polymers by the ATLC method is set by the low rates of adsorption and desorption processes involving high-molecular-weight polymers. However, by introducing an adsorption-active component into the eluent, for example acetone, it is possible to increase this limit significantly (Fig. 2*c*).

III. THIN-LAYER CHROMATOGRAPHY BASED ON DIFFERENCES BETWEEN THE SOLUBILITIES OF POLYMERS

Inagaki and coworkers[14,28] proposed precipitation TLC as the main method for the separation of polymers on the basis of their molecular weights. Precipitation TLC has been used successfully by these and other investigations in the fractionation of homopolymers[14,28,31,32] and statistical copolymers[30] in terms of their molecular weights, for the separation of atactic and syndiotactic PMMA[15], for the fractionation of ST–MMA block copolymers[32], and for the separation of block copolymers of this type and PMMA.[33]

1. Characteristics of the Precipitation and Extraction TLC of Polymers

The elementary step in precipitation TLC involves the separation of the polymer solution into a dilute phase and a concentrated gel phase, which is precipitated on the surface of the adsorbent particles; the dilute phase is removed with the solvent stream and the chromatographic process is thus achieved. In order to carry out precipitation TLC (PTLC), it is necessary to suppress the adsorption of the polymer. Hence arise two requirements which must be met by eluents: they must be adsorption-active and must at the same time be poor solvents for the polymer (the latter may be assessed with the aid of the Flory–Huggins solubility parameter[34] χ, which is defined as the change in free energy, in units of kT, on transferring a solvent molecule from the pure solvent to the polymer solution). When $\chi > 0.5$, the solubility of the polymer falls and the formation of the gel phase begins.

According to the Flory-Huggins theory[34], the phase separation of the polymer solution (at a constant temperature) can occur under the influence of two factors: (1) with increase of χ, i.e. when $\chi > 0.5$ or (2) with increase of the polymer concentration in solution φ_p (for $\chi \simeq 0.5$). χ may be increased by raising the content of the precipitant in the eluent composition, while the bulk-phase concentration of the polymer may be increased by altering the phase ratio r (the ratio of the volume of the eluent to the weight of the adsorbent). Since the removal of the dilute polymer phase with the stream of eluent is accompanied by the formation of a gel phase in equilibrium with it only when χ and φ_p are varied, an essential condition for PTLC is the creation of a solvent concentration gradient (i.e. χ) and (or) the establishment of the given phase ratio r on the plate. Two procedures are used for this purpose: (1) by the reduction of the solubility of the polymer, as the eluent rises along the plate, owing to the evaporation of the solvent in the unsaturated chromatographic chamber and by its frontal separation on the adsorbent layer (intrinsic PTLC); (2) by applying to the chromatographic plate an eluent in which the content of the solvent is increased (the extraction version of PTLC).

Figure 6. TLC of PMMA on silica gel in the 29 : 71 chloroform + methanol system. Molecular weight of PMMA M_w: 1) 4.3×10^4; 2) 1.14×10^5; 3) 1.65×10^5; 4) 4.12×10^5.

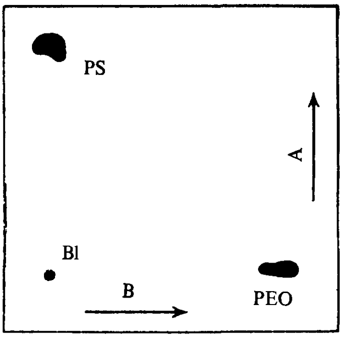

Figure 7. Two-dimensional TLC of a 50 : 50 ST-OE [EO?] block copolymer (Bl) on KSK silica gel in the 12 : 4 : 2 cyclohexane + benzene + acetone system in the *A* direction and in the 3 : 9 pyridine + water system in the *B* direction.

TLC based on the solubilities of polymers includes ETLC, where polymers with appreciably different solubilities are separated with the aid of a gradient-free eluent at the starting point on the "all or nothing" principle.

Examples of the extraction version of PTLC are provided by the separation of PS on the basis of their molecular weights following the addition to acetone of acetone–chloroform and acetone–toluene mixtures[31] and the separation of PMMA in the chloroform (solvent)–methanol (precipitant) system[14] (Fig. 6). An example of PTLC proper is the separation of PS in the 5 : 3 : 6 : 4 benzene–EMK–acetone–ethanol system, where the first two components are solvents and the last two are precipitants. Examples of ETLC are provided by the separation of isotactic and atactic PS and of the ST–EO block copolymer and the PS and PEO present in it[3] (Fig. 7). It has been stated in the literature that the effectiveness of fractionation on the basis of molecular weights is greater in ATLC and PTLC respectively in the regions where $M_w < 10^5$ and $M_w > 10^5$.[18,28-30] A combination of these methods is used in the study of the distribution in the polymer on the basis of its composition (ATLC) and its molecular weight (PTLC). For example, it has been used to separate statistical ST–BD copolymers in ethyl acetate and in the THF–methanol system[30]. The dependence of R_f on M_w and the mole fraction of ST is then determined by the equation $R_f = A + B[\mathrm{ST}] - C_2 \lg M_w$, where A, B, and C_2 are constants. Similarly PS with terminal COOH groups are separated on the basis of their functionalities following successive elution with benzene and chlorobenzene (ATLC) and on the basis of the molecular weights in the 1 : 10 THF–acetone system to which THF has been added (PTLC).[36] Other examples of the employment of precipitation TLC in the analysis of polymers are given in the Appendix (Table II).

It is noteworthy that the main application of the PTLC of polymers involves fractionation on the basis of the molecular weights and determination of the molecular weight distribution. The molecular weight distributions of polystyrene found with the aid of PTLC and by the GPC method in columns have been compared[16,37]. The results agreed satisfactorily, but there is no doubt that the TLC method is inferior to GPC as regards the speed and accuracy of analysis. In the fractionation of polymers on the basis of their molecular weights, it is desirable to employ two-dimensional PTLC with the simultaneous analysis of the inhomogeneity of the polymers with respect to composition by means of ATLC.

The decrease of the solubility of the polymer in the presence of the support[19], while the chemical nature of the adsorbent and its porosity have no effect on the separation of polymers with the aid of PTLC (i.e. the precipitation of the polymer takes place on the outer surface of the adsorbent grain[35]) is important for the understanding of the PTLC mechanism.

2. The Formation of False Chromatographic Bands in Precipitation TLC of Polymers

In TLC in a solvent–precipitate system where the solvent does not exhibit adsorption activity while the precipitant does possess it (for example, in the chloroform–methanol system for PMMA[14]) there are two methanol concentration ranges where its content is less than 5% (ATLC) and more than 70% (PTLC) and R_f for the polymer changes from 0 to 1 (Fig. 8). This finding explains the formation of double chromatographic spots on plates in the PTLC of polymers (Fig. 9).[33] A PMMA chromatogram has been obtained (Fig. 9) with the starting spots applied to the plate along the diagonal. Evidently, with increase of the distance of the starting zones from the line along which the plate is immersed in the solvent, the substance is, as it were, pumped from the starting spot to the upper spot, moving with the eluent surface. The essential feature of this phenomenon consists in the frontal separation of the eluent into the chloroform and chloroform–methanol zones. On reaching the starting point, the diffuse front of the second zone dissolves PMMA until the methanol concentration rises above 80%. Naturally, the lower the flow rate of the eluent, i.e. the higher the position of the polymer starting zone on the plate, the greater the proportion of the polymer which is able to dissolve and pass to the upper chromatographic spot and the lower the residual amount of the polymer at the starting point.

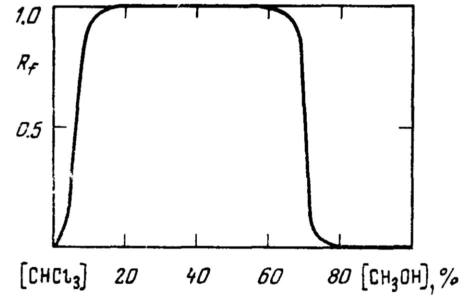

Figure 8. Dependence of R_f for PMMA with $M_w = 4.1 \times 10^5$ on the composition of the chloroform + methanol mixture in TLC on silica gel.

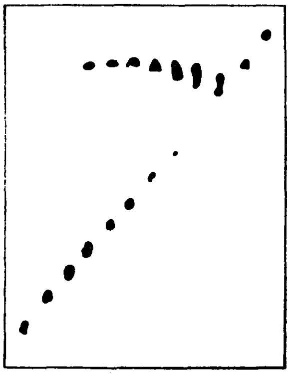

Figure 9. TLC for PMMA with $M_w = 10^5$ in the 6 : 16 chloroform + methanol system on KSK silica gel in an S-chamber (samples deposited along the diagonal of the plate).

IV. CONCENTRATION DEPENDENCE OF THE SHAPE OF THE CHROMATOGRAPHIC SPOT IN THE THIN-LAYER CHROMATOGRAPHY OF POLYMERS

The shape of the chromatographic spot is determined by the type of the adsorption isotherm (Fig. 10).[3] A concave isotherm is characteristic of weak adsorbability ($R_f \rightarrow 1$) and with increase of the concentration of the substance the chromatographic spot is extended towards the rear (Fig. 10*c*). A convex isotherm is characteristic of strong adsorbability ($R_f \rightarrow 0$) and with increase of concentration the chromatographic spot is extended forward (Fig. 10*a*). When $R_f \simeq 0.5$, the adsorption isotherm is close to linearity and the shape of the chromatographic spot depends little on the concentration of the substances (Fig. 10*b*). Two-dimensional spreading in TLC leads to additional concentration effects. Along the sides of the chromatographic zone, the concentration of the substance diminishes and hence the velocity of the zone is determined by a partition coefficient different from that in the central zone. As a result, the spot assumes a sharper shape: in the front and in the rear it is characteristic of convex and concave adsorption isotherms respectively. In precipitation TLC the higher the polymer concentration in the chromatographic spot, the lower the precipitant concentration corresponding to the polymer solubility threshold and the spot is more extended in the direction opposite to that of the motion of the polymer on the plate.

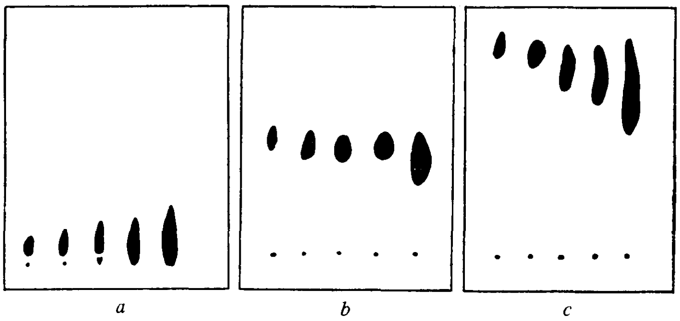

Figure 10. Concentration dependence of the shape of the chromatographic spot in TLC of PS with $M_w = 4 \times 10^5$ in cyclohexane + benzene + acetone systems: *a*) 12 : 4 : 0.25; *b*) 12 : 4 : 0.5; *c*) 12 : 4 : 1. 2, 5, 10, 20 and 40 μg of PS deposited from left to right.

The shape of the chromatographic spot in the TLC of polymers depends also on the characteristics of the viscous flow of the polymer solution along the plate. In the centre of the spot, where the polymer concentration is high, the velocity of the solvent is a minimum. In the peripheral regions it increases and reaches a maximum in the gaps between the chromatographic spots. As a result, the spot assumes a drop-like shape (Fig. 11)[4] characteristic of the streams formed when a viscous liquid flows past obstacles[38]. Under these conditions, the rear boundary of the spot undergoes additional sharpening by the incoming flow of liquid, which prevents the diffusional spreading of the spot, while in the front section of the zone the velocity of the diffusing molecules and the flow rate of the stream are added together[39]. These processes lead to instability of the chromatographic zone. It can assume an irregular shape and can actually be split into several spots moving separately.

V. TLC STUDY OF THE MICROSTRUCTURES OF POLYMERS

1. The Study of the Stereoregularity of Polymers

Inagaki and coworkers[15] showed that the separation of stereoregular polymers may be based on the differences between their solubilities. Using ethyl acetate as the eluent, Inagaki and coworkers succeeded in separating by ETLC [40] isotactic (*i*) PMMA, which remained in the starting spot, from syndiotactic (*s*) and atactic (*a*) PMMA, which moved with the solvent front. When the elution is carried out with acetone[41], *i*-PMMA is also desorbed, but the 1 : 1 stereocomplex of *i*-PMMA and *s*-PMMA remains at the starting point; thus 2 : 1 and 1 : 2 mixtures of these polymers appear on the chromatogram as two spots—at the starting point and near the solvent front. The lower spot represents the 1 : 1 stereocomplex and the upper spot corresponds to *i*-PMMA or *s*-PMMA respectively. Stereoblock PMMA with a high content of iso- and syndio-tactic triads can also be separated with the aid of TLC.[40]

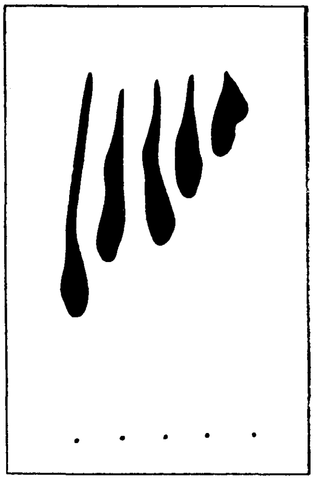

Figure 11. The "viscous" form of the chromatographic spot of PS with $M_w = 8.7 \times 10^5$ in TLC on KSK silica gel in benzene; 100, 40, 30, 20 and 10 μg of PS deposited from left to right.

We obtained analogous results[4] in the TLC of polystyrene (Fig. 9). It was shown that *a*-PMMA and *s*-PMMA may be separated[41] with the aid of ATLC in the ethyl acetate–isopropyl acetate system and with the aid of PTLC in the acetonitrile–methanol system. Under these conditions, R_f is found to depend not only on the content of syndiotactic triads (Ts) but also on M_w: $R'_f = 1.73\,[\mathrm{Ts}] - 0.51 \lg M_w - 2.2$ in the acetonitrile–methanol system and $R''_f = -1.74\,[\mathrm{Ts}] - 0.08 \lg M_w + 6.0$ in the ethyl acetate–isopropyl acetate system. [Ts] and M_w for PMMA may be determined to within approximately 10% with the aid of the above equations.

The conditions found for the isolation of *i*- and *s*-PMMA by ATLC were used for preparative isolation of *i*-PMMA from their mixture by adsorbing *i*-PMMA on silica gel from solution in chloroform. The *i*-PMMA obtained in this way was 80–90% pure[42].

2. The Study of the Regularity and Isomerism of Polybutadienes and Polyisoprenes

1,4-*trans*-, 1,4-*cis*-, and 1,2-Polybutadienes can be separated by ATLC in tetrachloroethane and by ETLC in pentyl chloride on silica gel and alumina plates[43]. This method may be used to test the homogeneity of the so-called equibinary PB in which 1,4-*cis*- and 1,2-vinylbutadiene units are present. In TLC in tetrachloroethane these polymers move with the solvent front; on the other hand, when the specimen is a mixture of 1,4-*cis*- and 1,2-PB, they are separated into the corresponding zones on the plate.

It has been shown[44] that 3,4-vinyl-PI can be separated from 1,4-*cis*- and 1,4-*trans*-PI with the aid of ATLC in tetrachloroethane, while in the 20 : 80 cyclohexane–*p*-xylene system 3,4-vinyl- and 1,4-*trans*-PI can be separated from 1,4-*cis*-PI.

3. TLC of Block Copolymers

The possibility of separating two-block and three-block ST–MMA copolymers with the aid of ATLC in gradient-free tetrachloroethane–EMK systems to which EMK is added has been demonstrated[32]. Under these conditions, R_f is independent of the molecular weight of the copolymer. Fig.12 shows[32] that R_f for ST–MMA copolymers having the same composition increases in the sequence statistical < three-block < two-block copolymers. ST–BD block copolymers can be separated by ATLC in the 9 : 1 cyclohexane–chloroform system with gradual addition of chloroform[11]. R_f for ST–BD copolymers increases in the following sequence: two-block (ST–BD) < three-block (ST–BD–ST) copolymers (i.e. two- and three-block ST–BD copolymers move on the plate in a sequence different to that of the analogous ST–MMA copolymers). In this chromatographic system R_f for the ST–BD copolymers is independent of their molecular weight. When PTLC is used in the 3 : 2 chloroform–methanol system with addition of methanol, the ST–BD block copolymers can be separated on the basis of their molecular weights.

The application of these chromatographic systems made it possible to establish with the aid of two-dimensional TLC that the Kraton 1101 industrial block copolymer consists of three components: two three-block copolymers having the same composition but different molecular weights and PS with $M_w = 10^4$. These data agreed with the results of GPC analysis using two detectors (refractometric and spectrophotometric), which permitted a direct determination of the compositions of the copolymers chromatographed.

The conditions found for the ATLC of ST–MMA copolymers, where R_f depends only on the copolymer composition, enabled Inagaki and coworkers[45] to suggest a method for the determination of the inhomogeneity of these copolymers with respect to composition (Section VII, 3), based on the densitometry of thin-layer chromatograms at two wavelengths: $\lambda_1 = 225$ nm (where the ST and MMA units absorb) and $\lambda_2 = 265$ nm, where only the ST units absorb. The distribution of two- and three-block ST–MMA copolymers with respect to composition, investigated by this method, showed that it corresponds fully to the distribution obtained by cross-fractionation and calculated on the assumption of a random mechanism of the coupling of the blocks in anionic polymerisation.

In the TLC of block copolymers one can use the precipitation mechanism instead of the adsorption mechanism. In a solvent which is ineffective in relation to one of the blocks the block copolymer enriched in this particular block then frequently undergoes selective precipitation. Thus, in order to separate PMMA from the ST–MMA block copolymer, a chloroform–methanol gradient system may be employed. Since PS is initially precipitated in this system and then PMMA, as the chloroform content is reduced, in the PTLC of PMMA and the ST–MMA block copolymer in an S-chamber, one can employ a system having a composition (with 72–80% of methanol depending on the molecular weight of PMMA) such that the copolymer remains at the start. $R_f < 1$ for PMMA under these conditions, since the concentration of methanol in the eluent becomes sufficient for the precipitation of PMMA at a certain height as a result of the gradual evaporation from the plate.

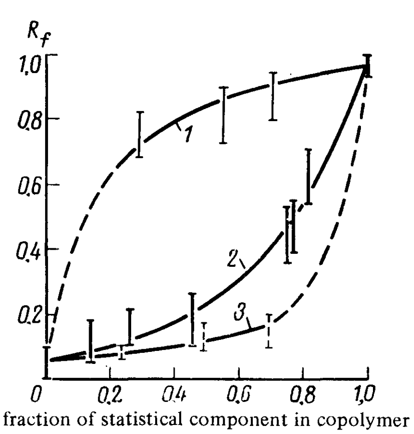

Figure 12. Separation of statistical (curve *1*), three-block (MMA–ST–MMA) (curve *2*), and two-block (curve *3*) ST–MMA copolymers using EMK gradients ranging from 0 to 2.5 in the EMK + carbon tetrachloride system.

In the study of block copolymers the determination of the admixture of homopolymers plays an important role. In this type of analysis of the EO–ST block copolymer use was made of two-dimensional ETLC [3] (Fig.7), which makes it possible to separate the corresponding homopolymers from the EO–ST block copolymer. This copolymer may be subjected to analogous analysis by one-dimensional TLC on microcrystalline cellulose in the 9 : 1 ethyl acetate–methanol system[46]. Under these conditions, PS moves with the solvent front, the block copolymer passes to the centre of the plate, and PEO remains at the start. Wesslen and Nansson[46] developed a preparative method for the isolation of the block copolymer by column chromatography: PS was separated by elution with ethyl acetate, the block copolymer was then eluted with a 4 : 1 mixture of ethyl acetate and methanol, and finally PEO was eluted with methanol; the column chromatography was checked by TLC.

4. TLC of Graft Copolymers

In the analysis of graft copolymers TLC is used to determine their purity, to detect the presence of homopolymers corresponding to the main and side chains, and to separate the polymers forming their grafted side chains (after the cleavage of the main chain of the graft copolymer) and the homopolymers present in the graft copolymer (Section VIII, 3).

The use of TLC for the solution of the first problem was first demonstrated[3] in the separation of the ST–MMA graft copolymer, PS, and PMMA. Methods have been proposed[47] for the separation of copolymers of PS grafted on CTA, PVA, PETP, and polyamide, and of PMMA grafted on PVA from the corresponding homopolymers with the aid of flow ATLC. The separation conditions discovered made it possible to proceed to preparative adsorption chromatography on columns, whereupon a PS–CTA graft copolymer contains less than 0.5–1% of impurities was obtained in quantitative yield.

It is of interest to use TLC in the study of impact-resistant PS. Here ETLC in EMK on silica gel[44] was employed to separate PS from the PS–PBD graft copolymer (see Appendix, Table III).

VI. THIN-LAYER CHROMATOGRAPHY OF OLIGOMERS

1. Principal Characteristics of the TLC of Oligomers

The TLC of many classes of oligomers has been described: polyols[48-58], polyethers[59-63], polyolefins[64], and polyamides[65]. Most of the studies demonstrated the possibility of separating oligomers differing in the number and structure of terminal groups. Many investigators[48-50, 58,61] demonstrated the independence of the chromatographic behaviour of oligomers of their molecular weights, while the differences in the R_f values are determined solely by the number of functional groups present in the oligomers. This makes it possible to achieve an extremely important form of the analysis of oligomers—the determination of their functionality[66], which is responsible for the quality of the high polymers obtained from oligomers, for example, polyurethane. On the other hand, substituted polyoxyethylenes can be separated on the basis of their molecular weights, with isolation of the individual polymer homologues in terms of the degree of polymerisation[12-15]. It has been shown[57] that the efficiency of the separation of polyols on the basis of their molecular weights is related to the type of substituent blocking the hydroxyl in the terminal units. The more hydrophobic the substituent (i.e. apparently the greater the bulk of the hydrocarbon group of the substituent and hence the lower the adsorbability of the terminal units), the greater the efficiency of the separation of the oligomers into individual homologues.

The characteristics of the adsorption of oligomers are associated with the presence of terminal functional groups. These terminal units as a rule show a greater adsorption activity than the central units of the oligomer and the change in the free energy of the latter on adsorption is determined mainly by the adsorption of the terminal groups. The free energy of adsorption ($-\Delta F$) of oligomers is associated with the decrease of the entropy ΔS, owing to the decrease of the number of possible conformations of the oligomer on adsorption, and with the increase of the enthalpy of the system $-\Delta H$ on formation of contacts between the units of one mole of the oligomer and the adsorbent surface:

$$-\frac{\Delta H}{RT}=N_A[(-\varepsilon_t)N_t+(-\varepsilon_c)(N-N_t)], \tag{6}$$

where $-\epsilon_t$ and $-\epsilon_c$ are the energies of the interaction of the terminal and central units with the adsorbent surface in units of kT, N and N_t are the total number of units and the number of terminal units in the oligomer molecule, and N_A is the Avogadro number. The partition coefficient in adsorption is expressed as follows:

$$K_d=\exp\left(-\frac{\Delta F}{RT}\right)=\exp\left(-\frac{N_A\Delta F_M}{RT}\right)=\exp\left(-\frac{\Delta F_M}{kT}\right), \tag{7}$$

where $-\Delta F_M$ is the free energy of adsorption of one molecule of the oligomer. One can specify an energy $-\epsilon_0$ such that the enthalpy of adsorption fully compensates the decrease of entropy and $-\Delta F_M = 0$. Then $-\Delta F/kT$ for the oligomer undergoing adsorption is

$$-\frac{\Delta F}{kT}=[(-\varepsilon_t)-(-\varepsilon_0)]N_t+[(-\varepsilon_c)-(\varepsilon_0)](N-N_t). \tag{8}$$

We shall consider the influence of the relative values of $-\epsilon_c$ and $-\epsilon_0$ (in TLC, we always have $-\epsilon_c > -\epsilon_0$) on the R_f of oligomers in ATLC: $R_f = 1/[1 + (V_p/V_0)\exp(-\Delta F_M/kT)]$. There can be three instances of the dependence of R_f on N (i.e. on the molecular weight of the oligomer):

(1) $(-\epsilon_c) > (-\epsilon_0)$; $-\Delta F/kT = [(-\epsilon_t) - (-\epsilon_0)]N_t + [(-\epsilon_c) - (-\epsilon_0)](N - N_t)$, where R_f decreases with increase of N;

(2) $(-\epsilon_c) < (-\epsilon_0)$; $-\Delta F/kT = [(-\epsilon_t) - (-\epsilon_0)]N_t - [(-\epsilon_c) - (-\epsilon_0)](N - N_t)$, where R_f increases with increase N;

(3) $(-\epsilon_c) = (-\epsilon_0)$; $-\Delta F/kT = [(-\epsilon_t) - (-\epsilon_0)]N_t$, where R_f is independent of N and is determined by the number of terminal groups N_t.

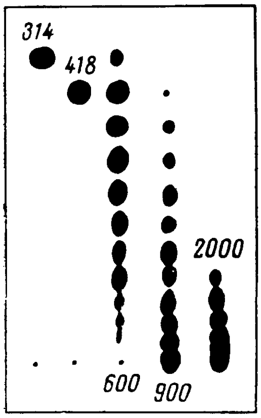

Figure 13. TLC of oligomers: PS with M_n = 314, 418, 600, 900, and 2000 in the 14:3 cyclohexane + benzene system on KSK silica gel.

It is noteworthy that in the absence of functional groups ($N_t = 0$) only the dependence of the first type can be observed. Fig. 13 illustrates chromatograms of PS oligomers of this type[67,68]. Clearly the dependence of R_f on the molecular weight of oligomers with $N_t = 0$ will be manifested to the greatest extent. On the other hand, when the oligomer contains functional groups, the dependence of R_f on the molecular weight becomes less marked with increase of the differences between $-\epsilon_t$ and $-\epsilon_c$.

Fig. 14 illustrates the TLC of poly(ethylene oxide) with M_n = 300, 400, and 600 in chromatographic systems where the dependence of R_f on the molecular weight is of the first, second, and third type[67]. Attention should be drawn to the correspondence of the polymer homologues in poly-(ethylene oxides) with different molecular weights. The dependence of R_f on the molecular weight of poly(ethylene oxide) shown in Fig. 14*b* is characteristic of the molecular sieve effect, but the mechanism of TLC is in this case different since the oligomers investigated begin to be excluded from the pore space of these adsorbents when the molecular weight exceeds 10^4. The moon shape of the chromatographic spot is associated (see above) with the convex adsorption isotherms for polyols. It is noteworthy that an effective separation on the basis of molecular weights of oligomers with weakly adsorption-active central units (for example, polydimethylsiloxanediols) is impossible without blocking the terminal groups. However, even when the terminal hydroxyls are blocked, (for example, by the dinitrobenzoic acid residue) only the second type of dependence of R_f on the molecular weight can be obtained.

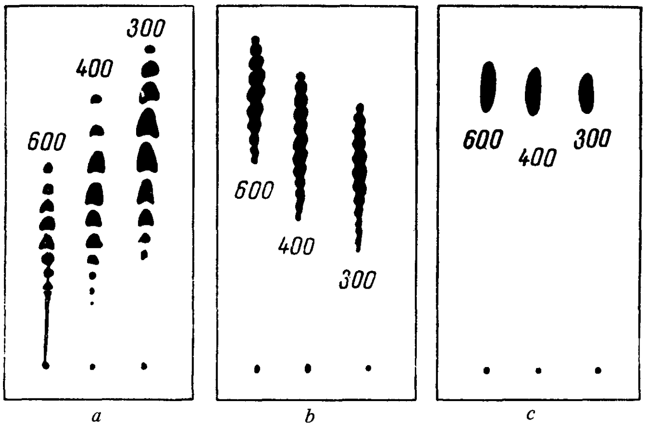

Figure 14. TLC of poly(ethylene oxides) with M_n = 300, 400, and 600: *a*) on KSK silica gel in the 0.1 : 10 pyridine + water system; *b*) on alumina in the 10 : 1 chloroform + ethanol system; *c*) on KSK silica gel in the 5 : 1 chloroform + pyridine system.

2. Separation of Oligomers on the Basis of Their Functionality

The separation of oligomers on the basis of their functionality in the absence of a dependence of R_f on the molecular weight (third type of dependence of R_f for the oligomer on the molecular weight) is of great practical interest. The possibility of separating mono-ols, diols, and triols over a wide range of molecular weights is illustrated in Fig. 15 in relation to polyoxypropylenepolyols (POPP).[68] This method for the determination of the functionality of oligomers makes it possible to separate linear and branched oligomers differing in the number of terminal functional groups. The separation of linear and branched oligomers with the same molecular weight is of great analytical interest, because it has been established[69] that in GPC they emerge with the same retention volumes. Thus the molecular weight distribution of oligoethers obtained with the aid of GPC may be significantly supplemented by information about the distribution of branched polyfunctional oligoethers in the specimen analysed.

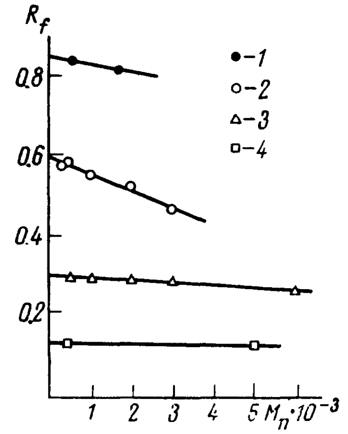

Figure 15. Dependence of R_f for polyoxypropylenepolyols (POPP) on their molecular weight and functionality on KSK silica gel in ethyl acetate saturated with water and containing 2% EMK: 1) mono-ols; 2) diols; 3) triols; 4) pentols.

VII. DETERMINATION OF POLYMER MOLECULAR WEIGHT AND COMPOSITION DISTRIBUTIONS FROM THIN-LAYER CHROMATOGRAPHIC DATA

1. Quantitative Interpretation of Thin-Layer Chromatograms of Polymers

Two fundamentally different methods for the quantitative analysis of thin-layer chromatograms are known[70]. The first is based on the extraction of the substance from the layer of adsorbent on the chromatographic plate with its subsequent determination, and the second involves the analysis of the substance directly in the chromatographic spot *in situ* from the distribution of the concentrations of the compounds in the spot[71,72] or from its size[73,74], the second method being more accurate and sensitive. For quantitative calculations on chromatograms of polymers from the distribution of concentrations or from the size of the spot, it is necessary to be able to view the chromatogram in visible light (i.e. it must be made visible), photographed, and then scanned to determine the distribution of the polymer concentrations in the chromatographic spot, or or to obtain with the aid of high-contrast photography the image of the polymer zone with distinct boundaries and, having measured the distance between the latter, to find the distribution of the spots with respect to size. Having at one's disposal more sophisticated methods and equipment, for example, luminescence and ultraviolet photographic techniques and scanning ultraviolet densitometers and fluorimeters, it is possible to reduce the number of stages required for quantitative analysis. Each stage introduces its own error into the result, but in certain cases the more complex procedure has advantages over the simpler method. For example, the linear relation between the blackening occurring when the spot is made visible by means of a corroding reagent and the polymer concentration in the spot is retained up to a concentration of 200 μg cm^{-2} in photodensitometry in the visible part of the spectrum, which is much higher than in the direct densitometry in the ultraviolet[2,3,7,16,40]. Furthermore, direct densitometry is possible only when the polymer contains chromophores strongly absorbing ultraviolet light, for example, styrene units. In this case the linear dependence of the signal on the amount of substance is maintained up to 100 μg cm^{-2}. Direct densitometry (particularly in reflected light) suffers also from other disadvantages, associated with the mutual influence of the monomer units of the polymer on their extinction and the preferential accumulation of the polymer in the lower layer of adsorbent adjoining the glass support. On the other hand, direct densitometry in the ultraviolet made it possible to suggest an absolute method for the determination of the inhomogeneity of copolymers with respect to composition by scanning their chromatographic zones on the plate at two wavelengths.

An interesting and promising version of quantitative TLC of polymers when the latter are separated into discrete zones involves the use for this purpose of a flame-ionisation detector (FID), the quartz plate with the deposited layer of silica gel being drawn directly through the flame[72].

In the analysis of radioactive polymers by TLC the method of lumoautoradiography[73], which makes it possible to determine up to 10^{-9} c of tritium without using complex apparatus, may prove to be very useful.

It is possible to distinguish the following varieties of quantitative TLC: (a) in terms of the method used to detect the chromatographic spots (by making them visible, by direct photography, and by direct detection on scanning); (b) in terms of the photographic process (photography in the visible or ultraviolet regions, lumoautoradiography, luminescence photography, equidense photography and ultrahigh-contrast photocopying); (c) in terms of the type of scanning (direct scanning of the chromatogram or of its photographic image); (d) in terms of the type of detecting system (detection using photometry, fluorimetry, radiometry, or a flame-ionisation detector); (e) in terms of the method used to carry out calculations on the chromatograms (based on the distribution of the concentrations of the given substance and the dimensions of the spot).

Evidently different combinations of these processes make it possible to obtain a multiplicity of different versions of quantitative TLC, about which the following comments may be made: methods based on procedures for rendering the chromatograph visible and direct photography consist of many stages and are therefore very time consuming. However, these methods, particularly those involving calculations on chromatograms based on the size of the spot, do not require expensive equipment. On the other hand, such equipment (scanning ultraviolet densitometers, fluorimeters, radiometers, FID) makes it possible to employ high-speed methods for the direct scanning of thin-layer chromatograms with an improved accuracy of the analysis. Methods involving ultraviolet and luminescence photography of chromatograms and lumoautoradiography occupy an intermediate place (as regards the speed of analysis and the complexity of equipment). Less expensive photometers, scanning in the visible region of the spectrum, are used in this case.

Methods for calculations on chromatograms, based on scanning and the determination of the size of the chromatographic zone, are considered below in relation to the analysis of the polydispersity of polymers.

As can be seen from the foregoing considerations, in order to determine the distribution of the molecular weights or compositions from TLC data, it is necessary (a) to make the polymer zone visible on the chromatogram (by dyeing it)§, (b) to determine the dependence of R_f for the polymer on the fractionating **X** (the molecular weight of the polymer) or on the composition of the copolymer, i.e. $R_\mathrm{f}(X)$ must be found, (c) to measure the dependence of the sensitivity of the detection (the ratio of the surface concentration of the given substance c to the colour intensity i) on R_f, i.e. to determine $(\mathrm{d}c/R_\mathrm{f})\mathrm{d}i$, (d) to measure the distribution of the colour intensity in the section of the chromatographic spot along the y axis, in the direction of motion of the spot, as a function of R_f, i.e. $I = I(R_\mathrm{f})$, where $I(R_\mathrm{f}) = \int\limits_{-\infty}^{+\infty} i(R_\mathrm{f}, y)\mathrm{d}y$, (e) to determine the distribution of the polymer in the chromatographic spot along the x axis, i.e. $Q(R_\mathrm{f}) = I(R_\mathrm{f})\colon (\mathrm{d}c/R_\mathrm{f})\mathrm{d}i$, where $\mathbf{Q}\int\limits_{-\infty}^{+\infty} c(y)\mathrm{d}y$, and finally (f), knowing $R_\mathrm{f}(x)$, to obtain the normalised differential distribution of the molecular weights of the polymer or the compositions of the copolymer:

$$P(X) = \tilde{Q}(R_f)\cdot\left|\frac{\mathrm{d}R_f}{\mathrm{d}X}\right|, \tag{10}$$

where $\tilde{\mathbf{Q}}(R_\mathrm{f})$ is the normalised distribution $Q(R_\mathrm{f})$:

$$\tilde{Q}(R_f) = Q(R_f)\Big/\int\limits_0^1 Q(R_f)\,\mathrm{d}R_f,$$

$$\int\limits_0^1 \tilde{Q}(R_f)\,\mathrm{d}R_f = 1.$$

In the study of narrowly disperse polymers it is necessary, in addition, to correct $Q(R_\mathrm{f})$ for chromatographic spreading—for example by means of two-dimensional chromatography (Fig. 16). The chromatogram of the polymer along the first direction, which is homogeneous with respect to the molecular weight (composition) along the spot diameter, may be regarded as the starting zone for chromatography in the second direction.

The difference between the dispersions of the zones at the finish and at the start in the direction of the second chromatographic process constitutes the dispersion of the chromatographic spreading. The correction may be applied in the simplest way by substracting the dispersion

---

§A 1% solution of iodine in methanol[2], a saturated solution of Thymol Blue in 50% aqueous ethanol with subsequent treatment with 3 N H_2SO_4,[37] a 5% solution of $KMnO_4$ in concentrated H_2SO_4,[3] and, for oxygen-containing polymers, Dragendorff reagents[3] and iodine vapour[46] are most frequently used for this purpose. It is possible to detect PS on plates from the extinction of the luminescence due to a phosphor introduced into the chromatographic layer and excited with ultraviolet radiation at 254 μm.

of the chromatographic spreading from the dispersion of the distribution, or by a more complex and rigorous procedure, as in the analysis of the molecular weight distribution of polymers by the GPC method[75].

The normalised integral distribution $P(X) = \int_0^x F(X')\,\mathrm{d}X'$ and the weight-average quantity $\bar{X} = \int_0^\infty XF(X)\,\mathrm{d}X$ may be obtained from the weight distribution of the polymer $P(X)$ [Eqn. (10)].

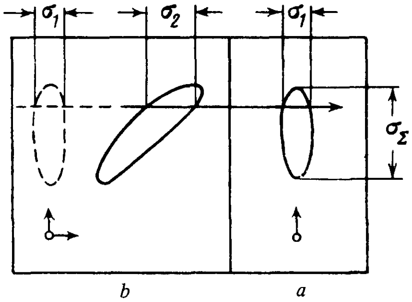

Figure 16. Determination of the chromatographic spreading in TLC: *a*) chromatogram along the first direction; *b*) two-dimensional chromatogram.

2. Photometric Method for Quantitative TLC of Polymers

In the photometric scanning of the polymer zone along the chromatographic axis (x), multistep scanning with an accurate light probe and integration of the signal with respect to the y axis, perpendicular to the chromatographic axis, is necessary in order to obtain accurate results. These integral properties represent the distribution $I(R_f)$ with an accuracy which is inversely proportional to the size of the step Δx. In order to determine the distribution of the compositions of the copolymers (provided that R_f for the copolymer is independent of its molecular weight), the method based on the scanning of the chromatographic plate at two wavelengths (265 and 225 nm), at which the molar extinction coefficients of the copolymer components differ markedly, has been proposed[45]. The absorption I at point x, corresponding to the fraction X of ST in the copolymer is then given by $I'(x) = X\epsilon'_{\mathrm{ST}}W(x)$ for $\lambda' = 265$ nm and $I''(x) = [X\epsilon''_{\mathrm{ST}} + (1 + X)\epsilon''_{\mathrm{MMA}}]W(x)$ for $\lambda'' = 225$ nm, where $W(x)$ is the amount of polymer in the region $(x \pm \Delta x)/2$ and ϵ is the molar extinction coefficient.

Having determined the areas A' and A'' under the densitograms of the polymer, using $I'(x)$ and $I''(x)$, and knowing $(\epsilon''_{\mathrm{ST}}/\epsilon''_{\mathrm{MMA}})$ and $(\epsilon'_{\mathrm{ST}}/\epsilon''_{\mathrm{MMA}})$, it is then possible to calculate the following characteristics of the copolymer:

(a) the normalised weight distribution of the copolymer $\tilde{P}(X)$:

$$\tilde{P}(X) = \frac{W(x)}{\sum\limits_i W_i(x)} = \frac{[1-(\varepsilon''_{\mathrm{ST}}/\varepsilon''_{\mathrm{MMA}})]\,I'(x) + (\varepsilon'_{\mathrm{ST}}/\varepsilon''_{\mathrm{MMA}})\,I''(x)}{[1-(\varepsilon''_{\mathrm{ST}}/\varepsilon''_{\mathrm{MMA}})]\,A' + (\varepsilon'_{\mathrm{ST}}/\varepsilon''_{\mathrm{MMA}})\,A''}; \tag{11}$$

(b) the calibration relation $X(x)$:

$$X(x) = \frac{I'(x)}{[1-(\varepsilon''_{\mathrm{ST}}/\varepsilon''_{\mathrm{MMA}})]\,I'(x) + (\varepsilon'_{\mathrm{ST}}/\varepsilon''_{\mathrm{MMA}})\,I''(x)}; \tag{12}$$

(c) the average composition of the copolymer $\bar{X}$:

$$\bar{X} = \frac{A'}{[1-(\varepsilon''_{\mathrm{ST}}/\varepsilon''_{\mathrm{MMA}})]\,A' + (\varepsilon'_{\mathrm{ST}}/\varepsilon''_{\mathrm{MMA}})\,A''} \tag{13}$$

without using reference copolymer specimens for the calibration of $X(x)$. The parameters $\epsilon'_{\mathrm{ST}}/\epsilon''_{\mathrm{MMA}}$ may be determined by Eqn. (12) from the known values of $\epsilon''_{\mathrm{ST}}/\epsilon''_{\mathrm{MMA}}$ and the average composition of the copolymer $\bar{X}$ determined independently.

3. Analysis of the Distribution of a Polydisperse Polymer Along the Width of the Chromatographic Zone

Since the distribution of the substance along the y axis in TLC is always described by a Gaussian curve, it is possible to determine the amount of substance in the given section (ith along the x axis) of the polymer zone on the chromatographic plate, having measured the width of the zone at a specific boundary (limiting detectable) concentration C_{b}. For a Gaussian distribution of the substance, we have

$$C_{\mathrm{b}} = C_{m,i}\exp\left(-\frac{y_i^2}{8\sigma_{y,i}^2}\right), \tag{14}$$

where $C_{\mathrm{m,i}}$ and $\sigma^2_{\mathrm{y,i}}$ are the concentration of the polymer at the maximum and the variance of the distribution in the ith (along the x axis) section of the zone and y_{i} is the distance along the y axis between the points C_{b} (the width of the zone in the ith section). The amount of substance in the ith section with the width Δx is then expressed as follows:

$$W_i = \sqrt{2\pi}\,\bar{C}_{m,i}\bar{\sigma}_{y,i}\,\Delta x = \sqrt{2\pi}k_iD_{\mathrm{b}}\,\sigma_{yi}\,\Delta x\exp\left\{\frac{\bar{y}_i^2}{8\bar{\sigma}_{y,i}^2}\right\}; \tag{15}$$

where the width of the zone $\bar{y}_{\mathrm{i}}$ and the variance $\bar{\sigma}^2_{\mathrm{y,i}}$ are averaged with respect to Δx and C_{b} is replaced by the corresponding optical density D_{b} ($C_{\mathrm{b}} = k_{\mathrm{i}}D_{\mathrm{b}}$, where k is a coefficient, which is constant for a homopolymer and which depends on the composition for a copolymer). In order to be able to use Eqn. (15), it is necessary to determine $\bar{\sigma}_{\mathrm{y,i}}$ having expressed it in terms of the experimental width of the chromatographic zone $\bar{y}_{\mathrm{i}}$. For this purpose, one can employ two procedures: (a) two chromatograms of the polymer containing different amounts of the substance, Q_1 and Q_2, are obtained, whereupon in each ith section in the two chromatographic zones the ratio of the amounts of the substance $W'_{\mathrm{i}}/W''_{\mathrm{i}} = Q_1/Q_2$, or (b) the polymer chromatogram is photographed with two different exposures, so that the contour of the spot corresponds to different values of C_{b} (i.e. D_{b}) and the ratio $D'_{\mathrm{b}}/D''_{\mathrm{b}}$ is determined.

The corresponding formulae for the calculation of the distribution $\tilde{P}_{\mathrm{i}} = W_{\mathrm{i}}/\sum\limits_{\mathrm{i}} W_{\mathrm{i}}$ by methods (a) and (b) are as follows:

$$\text{(a)}\ \tilde{P}_i = \frac{[ka^{1/2}b^{y_1^2/a}]_i}{\sum\limits_i [ka^{1/2}b^{y_1^2/a}]_i\Big|_{b=e}} = \frac{[ka^{1/2}\exp(y_1^2/a)]_i}{\sum\limits_i [ka^{1/2}\exp(y_1^2/a)]_i}, \tag{16}$$

$$a = y_1^2 - y_2^2,\quad b = Q_1/Q_2;$$

$$\text{(b)}\ \tilde{P}_i = \frac{[k(a')^{1/2}c^{(y')^2/a'}]_i}{\sum\limits_i [k(a')^{1/2}c^{(y')^2/a'}]_i},$$

$$a' = (y')^2 - (y'')^2,\quad c = D'_{\mathrm{b}}/D''_{\mathrm{b}}. \tag{17}$$

If method (a) is used to determine $\tilde{P}_i$, it is convenient to employ chromatograms on which polymers have been deposited in proportions $Q_1/Q_2 = e$, whereupon Eqn. (16) for $\tilde{P}_i$ simplifies.

As already stated, k = const. in the TLC of homopolymers or copolymers with narrowly disperse compositions and may be omitted from Eqns. (16) and (17). In the analysis of copolymers with polydisperse compositions, it is necessary to take into account the dependence of k on the composition of the copolymer (or R_f) and P_i must be calculated from Eqns. (16) and (17).

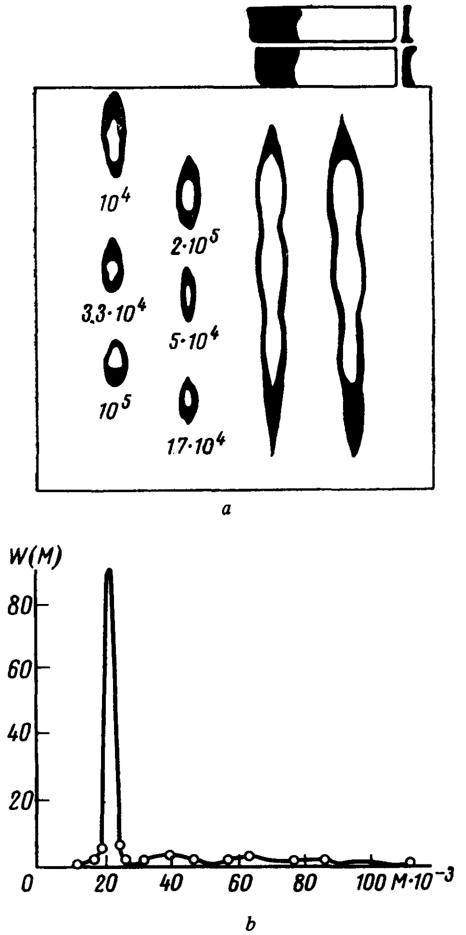

Figure 17. Determination of the molecular weight distribution in polystyrene by the equidense method: *a*) equidense representation of the chromatograms of PS specimens at two concentrations in the 12 : 4 : 0.9 cyclohexane + benzene + acetone system (on the left—chromatograms of reference PS specimens; above—image of optical wedge); *b*) molecular weight distribution in polystyrene.

Among the equations presented for the calculation of P_i, Eqn. (17) is of great interest, since its application requires only one chromatogram and there are no errors associated with the inaccuracy in the deposition onto the plate of calculated amounts of the polymers, Q_1 and Q_2, and with concentration effects distorting the shape of the chromatographic spot. In order to employ Eqn. (17), it is necessary to know D_b. An equidense method of obtaining the images of the chromatographic spot, based on the Sabatier phenomenon, which is well known in photography[76] (consisting in the complete or partial reversal of a briefly developed image under the influence of secondary illumination), was devised for this purpose[4]. An equidense image is achieved if a print is obtained, with a certain exposure, from the object for which photometric measurements are being made (the negative, in our case the thin-layer chromatographic plate), on a high-contrast photographic material, is developed for a short time, and, without fixation, is re-exposed to uniform secondary illumination. After redevelopment, the images of the chromatographic spots (equidense images) consist of pale contours of the spots against a dark background. The optical density D of the given equidense image of the object is determined by the duration of the first exposure. By varying this duration, it is possible to obtain equidense images corresponding to different optical densities $D_b^{(i)}$, which can be readily determined by photographing a calibrated optical wedge together with the object for which photometric measurements are made. In order to increase the contrast of the image, it is useful to photocopy the equidense image on an ultrahigh-contrast photographic material, which yields black equidense images against a light background.

The accuracy of the equidensitometric method of quantitative analysis discussed above was tested[4] by determining on the chromatograms the ratios of two polymers whose mixture had been deposited on the plate in proportions Q'/Q''. The ratios of 2.48 and 0.592 obtained agree satisfactorily with the ratios Q'/Q'' of the polymers in the samples (2.5 and 0.6). Fig. 17 illustrates an example of the analysis of the molecular weight distribution of PS by the equidensitometric method[4]. It is noteworthy that, owing to the relatively low sensitivity of the width of the chromatographic spot to the amount of substance it contains, the method described is inferior as regards accuracy to densitometric scanning methods in quantitative analysis. On the other hand, by virtue of the enhanced dependence of y on q on the wings of the curve, which is characteristic of a Gaussian distribution, the proposed method is particularly sensitive to the determination of microimpurities.

4. Determination of the Distribution of the Molecular Weights of Oligomers Using Equidense Images of Thin-Layer Chromatograms

A characteristic feature of the TLC of oligomers is the discrete nature of the chromatographic zones of individual polymer homologues up to $N \leqslant N'$, where $N' = 10-12$. Polymer homologues with higher molecular weights ($N > N'$) are chromatographed in the form of a continuous zone, which may be analysed in the same way as the chromatograms of high-molecular-weight polymers. If the limiting detectable concentration of the substance on the chromatograms is denoted by C_b, then the equation of the ellipse surrounding the chromatographic spot (x_b, y_b) is[77]:

$$C_b = \frac{q}{2\pi\sigma_x\sigma_y}\exp\left[-\frac{1}{2}\left(\frac{x_b^2}{\sigma_x^2}+\frac{y_b^2}{\sigma_y^2}\right)\right], \qquad (18)$$

where q is the amount of substance in the chromatographic spot and σ_x^2 and σ_y^2 are the variances of the distribution of the substance along the x and y axes. By denoting the half-axes of the ellipse by x_0 and y_0 (for $y = 0$ and $x = 0$ respectively), we obtain from Eqn. (18)

$$\frac{x_0^2}{\sigma_x^2} = \frac{y_0^2}{\sigma_y^2}. \qquad (19)$$

Using Eqn. (18) with $x_b = x_0$ and $y = 0$, and replacing σ_y with the aid of Eqn. (19), we have

$$q = 2\pi C_b \sigma_x^2 \frac{y_0}{x_0} \exp\left[\frac{1}{2}\frac{x_0^2}{\sigma_x^2}\right] = 2\pi k D_b \sigma_x^2 \frac{y_0}{x_0} \exp\left[\frac{1}{2}\frac{x_0^2}{\sigma_x^2}\right]. \qquad (20)$$

If two equidense images of the chromatogram with optical densities D'_b and D''_b are used, it is possible to obtain with the aid of two corresponding equations of type (20) an expression for q which includes only the experimentally determined quantities D_b, x_0, and y_0, obtained for two exposures:

$$q = 2\pi k D'_b \frac{(x''_0)^2 - (x'_0)^2}{2\ln\left[\frac{D'_b}{D''_b}\cdot\frac{y'_0/x'_0}{y''_0/x''_0}\right]} \cdot \frac{y''_0}{x''_0}\left(\frac{D'_b}{D''_b}\cdot\frac{y'_0/x'_0}{y''_0/x''_0}\right)^{\frac{x'_0}{(x''_0)^2-(x'_0)^2}}. \qquad (21)$$

It is also possible to find the amount of substance in the unresolved spots on the chromatograms (where $i > N'$). Using the $R_f(i)$ calibration relation in the form of a second-degree polynomial $R_f(i) = a + bi + ci^2$, where the coefficients a, b, and c are obtained by the method of least squares, we find the values of R_f for $i > N'$. Next, linear extrapolation (valid for $R_f < 1/3$) yields the values of x'_i, x''_i, y'_i, and y''_i for $i > N'$, using the values of the above quantities for $i = N'$ and $i = N' - 1$.

5. Quantitative Determination of Low-Functional Impurities in Polyoxypropylenepolyols with the Aid of TLC

A method based on the dependence of the mobility of the chromatographic spot on its oligomer content is used for the quantitative determination of low-functional components in polyoxypropylenepolyols[69]. The chromatographic spots of polyoxypropylenepolyols have a sharpened forward "tip" with a sharply defined leading boundary, while the rear front is diffuse. As stated above, this shape of the chromatographic zone is due to the concentration effects associated with a convex adsorption isotherm. It is natural to employ the chromatographic mobility of the "tip" of the chromatographic spot, which is related to the polymer concentration; R_f for the tip may be measured accurately in order to determine the amount of oligomer which it contains (under conditions such that R_f is independent of the molecular weight). An experimental test showed that this type of relation does exist (Fig. 18).[69] It is linear and retains a constant slope in a concentration range corresponding to two orders of magnitude, the slope of the straight line being related to the molecular weight of polyoxypropylenepolyol and the distance traversed by the substance on the chromatographic plate. A similar relation may be obtained theoretically on the basis of a simplified model of the ATLC of oligomers, where the adsorption is characterised by the Freundlich equation.

The proposed method for the quantitative analysis of thin-layer chromatograms is distinguished by its extreme simplicitiy; its error does not exceed 2–3%. Admixtures ($\leq$ 1–2%) of the mono-ol and diol in the specimens of polyoxypropylenepolyols can be determined by the above procedure[69].

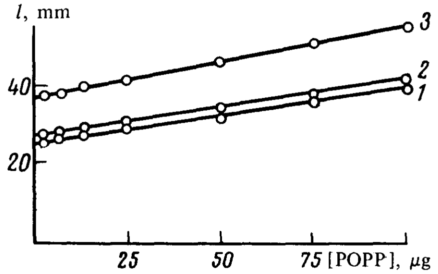

Figure 18. Dependence of the length of the chromatographic spot l on the amount of POPP with different M_n 1) 10^3; 2) 425; 3) 10^3 (40% EMK was added to the system) in TLC on silica gel in ethyl acetate saturated with water and containing 2% EMK.

6. The Use of a Scanning Flame-Ionisation Detector for the Quantitative TLC of Polymers with Separation of the Components into Individual Zones

The employment of a TLC–FID combination for the quantitative analysis of polymers, separated into individual zones, i.e. for the investigation of mixtures of fairly heterogeneous polymers has been described. The system described by Padley[72], where TLC is carried out on a quartz rod 0.45 mm in diameter coated by a layer of silica gel 75 μm thick, is used for this purpose; the polymer is deposited in an amount of several μg. After the completion of chromatographic process, the quartz rod is drawn through an FID during several tens of seconds.

The TLC–FID combination[44] has been used to determine the PS impurity in a copolymer obtained by grafting PS on to CTA, PS being separated by flow ETLC in EMK, and for the analysis of the functionality (the content of COOH and OH groups) of low-molecular-weight rubbers using the 100 : 1 carbon tetrachloride–THF system, in which PB molecules were separated into bifunctional molecules ($R_f = 0$), monofunctional molecules ($R_f = 0.3$), and molecules without functional groups ($R_f = 1.0$).

VIII. COMBINED CHROMATOGRAPHIC METHODS FOR THE ANALYSIS OF COMPLEX POLYMER SYSTEMS INVOLVING THIN-LAYER CHROMATOGRAPHY

In the synthesis of complex polymer systems, such as block copolymers, graft copolymers, and branched homopolymers the corresponding linear homopolymers are obtained together with the main product, which is characterised by its polydispersity with respect to molecular weight and composition (type of branching). The study of such polydisperse systems has constituted hitherto an extremely complex and laborious task and frequently could not be achieved at all by the classical methods for the analysis of polymers. Important results in this field may be obtained by using a combination of chromatographic methods for the analysis of polymers, GPC for the micropreparative fractionation of polymers involving the determination of the hydrodynamic radii R_s of the fractions obtained, TLC for the qualitative and quantitative analysis of the structural and chemical heterogeneity of the fractions, and pyrolytic gas chromatography (PGC) for the determination of their overall composition. The PGC method is unequalled under these conditions as regards the sensitivity of the analysis (it requires an amount of substance of the order of several μg) and as regards the accuracy of the determination of the composition of copolymers with a component ratio less than 1/20–1/50.[78]

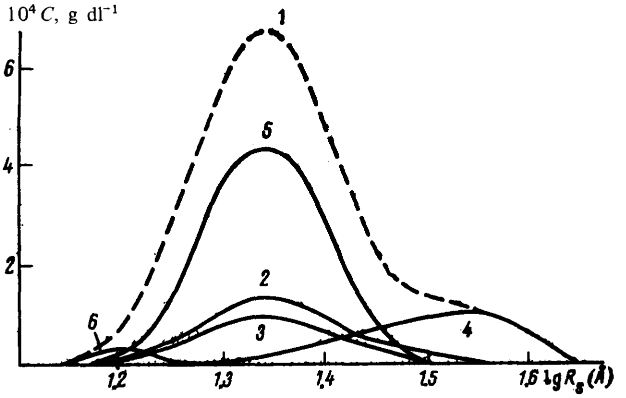

Figure 19. Concentration distribution curves for a PS specimen (curve *1*) and its components (curves *2–6*) as a function of the logarithm of the hydrodynamic radius lg R_S.

1. The Study of Mixtures of Linear and Branched Polymers by Gel-Permeation and Thin-Layer Chromatographic Methods

The possibility of studying a mixture of linear and branched PS using GPC and TLC has been demonstrated[79]. The micropreparative fractionation of the PS investigated has been achieved by means of GPC with determination of the hydrodynamic radius R_s of each fraction. For this purpose, use was made of the calibration relation obtained for linear PS specimens. Next, the GPC fractions were studied by ATLC methods in the 12 : 4 : γ cyclohexane–benzene–acetone system on KSK silica gel plates. In each fraction several components were detected with different dependences of R_f on the acetone content in the system (γ).[78] Some of these components behave similarly to the linear PS standards; they were identified as linear PS. Others show a weaker dependence of R_f on γ; these components were identified as branched PS and it was suggested that the differences between the adsorbabilities of linear and branched PS must increase with increase of the degree of branching. The GPC fractions were analysed quantitatively with the aid of a densitometer[79], which made it possible to obtain the distribution of the linear and branched components in the PS specimen, illustrated in Fig. 19.[78] In conformity with the $R_f(\gamma)$ relation, these PS components were identified as branched (components 1 and 2), weakly branched (component 3), and linear (components 4 and 5). Assuming that the PS components form a continuous series ranging from linear to strongly branched, it was possible to conclude that the fifth component is true linear PS, while the fourth, third, second, and first components are respectively branched PS with one, two, three, and four units. It is now possible to employ the familiar relation[80] between R_s and the molecular weights of branched polymers, which is of the following form for PS: $R_s = 0.255\, hM^{1/2}$, where h is the branching factor and M the molecular weight. Since the PS investigated were synthesised with polystyryl-lithium as the initiator, they should have a comb-like structure. The corresponding values of h were selected for this model[81], which made it possible to obtain the molecular weights of the main and side chains of this branched polymer. Table 1[79] presents the results of a similar analysis of one of the PS specimens. It is noteworthy that 2 mg of the polymer was sufficient for such detailed analysis of the narrowly disperse PS specimen (with $M_w/M_n < 1.1$). The molecular weights of linear (found with the aid of TLC and PGC) and branched specimens and their branching parameters were determined, and component 5, whose content in the specimen analysed was 1–4%, was characterised.

Table 1. Results of the analysis of a polystyrene specimen (comb-like model).

Parameters	Component				
	branched			linear	
	1	2	3	4	5
R_s, A	20.5	21.5	32.5	22.5	16.5
MW of polymer	10 500	10 600	19 500	10 500	5500
MW of backbone	5 000	5 000	—	—	—
MW of branch	1 400	1 900	—	—	—
Content of component, %	23	15	16	42	4

2. Determination of the Polydispersity of Styrene–Methyl Methacrylate Block Copolymers with the Aid of Gel-Permeation, Thin-Layer, and Pyrolytic Gas Chromatography

The determination of the polydispersity of block copolymers includes the analysis of the distribution of their molecular weights, compositions, and admixtures of the corresponding homopolymers. It has been shown[33] that the polydispersity of block copolymers can be effectively studied with the aid of a combination of chromatographic methods with the following sequence of chromatographic operations. After the preliminary fractionation of the macromolecules in terms of size (by the GPC method), the fractions obtained are again chromatographed (this time by TLC), with respect to composition, and the block copolymer is separated from the admixture of homopolymers; finally, using PGC,[78] the compositions of the fractions obtained by the GPC and TLC methods are determined. The above procedure was used to investigate a block copolymer of the ABA type (where A = PMMA and B = PS).

The PGC method makes it possible to determine to within 1–2% the overall compositions of fractions containing the ST and MMA polymers, regardless of their molecular weight and chemical structure. The amount of specimens sufficient for analysis is 0.1–5 μg, and the method can therefore be used both for the analysis of the GPC fractions and the fractions separated with the aid of TLC. Interesting possibilities arise from a comparison of the compositions of the complete fraction and its separated components. It is easily shown that, when the compositions of two fractions, obtained with the aid of TLC, namely $x = m_1'/m_2'$ and $y = m_1''/m_2''$, and of the initial fraction (obtained by GPC), namely $z = m_1'''/m_2'''$, are known, then the ratio of the components separated by TLC ($\omega = q_1/q_2$) may be determined by the equation

$$\omega = \frac{(z-x)(1+y)}{(1+x)(y-z)}\,. \tag{22}$$

The block copolymer analysed was fractionated with the aid of GPC[33] in DMF on styrogel columns calibrated with respect to the R_S, and PMMA was fractionated simultaneously on similar columns. The fractions were analysed by PTLC in the chloroform-methanol system containing 80–72% of methanol as a function of R_S of the GPC fraction analysed (the molecular weight of PMMA). In this system PMMA moved along the plate, while the block copolymer remained at the start. Analysis of the GPC and TLC fractions by PGC made it possible to calculate by Eqn.(22) the content of the block copolymer in each fraction and, knowing the composition of the fraction and the increments in the refractive indices for PS and PMMA, to obtain (taking into account the additivity of the refractive indices in the copolymer solution[82]) the distribution in the block copolymer specimen analysed of the PS and PMMA components and the composition of the block copolymer as a function of R_S, as shown in Fig. 20.[33]

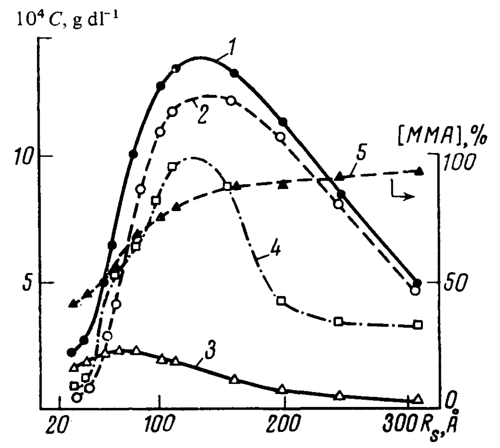

Figure 20. Distribution of PMMA–PS–PMMA block copolymers and PS and PMMA homopolymers as a function of R_S according to GPC, TLC, and PGC data: 1) initial polymer; 2) PMMA; 3) PS; 4) block copolymer; 5) PMMA content in block copolymer.

An interesting application of the combination of the two-detector (refractometer, spectrophotometer) GPC of an ST–BD block copolymer (with the simultaneous determination of its molecular weight distribution and compositions) and TLC for the investigation of the sequence of blocks in the copolymer has been demonstrated[83]. Since TLC established that the entire copolymer is of the three-block type, it was concluded that its bimodal distribution in GPC is associated with the presence of two types of three-block copolymers having different molecular weights.

3. Investigations of Graft Cellulose Copolymers with the Aid of Gel-Permeation and Thin-Layer Chromatography

In the study of gel copolymers it is usually necessary to establish whether the corresponding free homopolymers are present. TLC may be used for this purpose, as shown in relation to a PS–PMMA graft copolymer[3]. Another type of study of graft cellulose copolymers is based on the disruption of the cellulose base by acid hydrolysis or acetolysis and the determination of the molecular characteristics of the liberated graft homopolymer. However, difficulties are encountered here in the separation of the graft homopolymer and the homopolymer present as an admixture in the copolymer. A version of this method, proposed[84] for the study of a cellulose–styrene graft copolymer, consists in the acid hydrolysis of the copolymer, the separation of the free and grafted PS by adsorption TLC, and the determination of the molecular weight distribution of its PS by GPC. The polystyrene chains split off in the acid hydrolysis of the graft copolymer contain polysaccharide units at their ends, which exhibit a high adsorption activity. This, at first sight striking, high sensitivity of ATLC to the terminal glucosidic group of PS with $M = 10^5$ is co-related with the observed[36] sensitivity of ATLC in the separation of PS with $M = 5 \times 10^4 - 10^5$ and different numbers of terminal carboxy-groups.

Table 2. Results of the GPC analysis of polystyrene in the copolymer obtained by grafting PS on cellulose.

Specimen	$10^{-5}M_n$	$10^{-5}M_w$	M_w/M_n
PS after hydrolysis—PS_{tot}	2.8	13.0	4.65
Grafted PS—PS_{gr} (lower spot in TLC)	1.9	5.8	3.0
Free PS–PS_{fr} (upper spot in TLC)	4.9	17.0	3.5

Thus the free and grafted PS may be separated with the aid of ATLC on silica gel plates using THF as the eluent. The lower (starting) spot consists of grafted PS and the zone moving with the solvent front is free PS. If the chromatogram is developed by gradual spraying with a saturated solution of Thymol Blue in 50% aqueous ethanol and 3 N H_2SO_4, then the intensity of the blackening of the upper and lower spots makes it possible to determine the fraction of grafted PS (P_g) in the total amount of PS. Polystyrene was extracted from the plate with the aid of THF and its molecular weight distribution was determined by GPC on styrogel columns in THF. The observed values of M_w and M_n are listed in Table 2.[71] These data make it possible to determine the frequency index of the graft (F_g)—the ratio of the average number of polystyrene chains to the average number of cellulose chains in the graft copolymer: $F_g = [AP_g/M_n.(PS_{tot})][100/M_n\ (\text{cellulose})]$, where A is the increase in the weight of cellulose after PS has been grafted (expressed as a percentage)[71].

oOo

The thin-layer chromatography of polymers is a universal method for the study of the polydispersity of polymers and the diagnosis of different types of regularity and stereoregularity. This method combines all the useful features of TLC: simple apparatus, high sensitivity and speed of analysis, and comparative ease of selection of separating systems. At the same time the TLC of polymers also suffers from limitations: a relatively low reproducibility and the necessity to use in many instances reference polymer specimens (which may be obtained and characterised with the aid of GPC): however, the high sensitivity of TLC results in an economical use of such reference specimens.

Further progress in the TLC of polymers will involve the standardisation of analytical methods, in the first place quantitative methods, and the extension of the applications of this method to new classes of polymers and types of polydispersity. There is no doubt that the present development of the TLC method permits its effective employment both in the study of new polymers and in the industrial control of manufactured polymeric materials.

IX. APPENDIX

Table I. The use of adsorption chromatography in the study of polymers (on silica gel as the adsorbent). The following notation has been adopted: (MWD) = quantitative determination of MWD; (IC) = quantitative determination of inhomogeneity with respect to composition; an arrow represents the eluent gradient.

PS	Separation of 4-pointed star from PS with MW = 10^5–10^6	chloroform + acetone (10:1), chloroform	4	44,86
PS	Separation w.r.t. MW of polymers with terminal COOH groups (1.1×10^4–5×10^4 and 2.3×10^4–1.2×10^5)	THF + acetone (10:1) → THF	4	
PMMA	w.r.t. MW (4×10^4–4×10^5)	chloroform + methanol (29 : 71)	2	
PMMA	w.r.t MW (1.6×10^5–4.12×10^5)	benzene + acetone (2 : 8), isopropyl alcohol + methyl acetate (100 : 62), ethyl acetate + methyl acetate (100 : 23)	2	
PMMA	Separation of *s*- and *a*-PMMA and w.r.t. MW	acetonitrile + methanol (20 : 40, 46 : 54)	2	
PEO	w.r.t. MW (1.5×10^3–6×10^3)	ethylene glycol + methanol (80 : 20)	2	15
PEO	w.r.t. MW (1.5×10^3–2.8×10^4)	methanol → methanol + DMF (80 : 20)	2	31
PB	Separation of *cis*-1,4- and 1,2-PB from *trans*-1,4-PB	pentyl chloride	3	43

Table II (cont'd.).

Polymer	Polydispersity investigated	Eluent	Method of development	Refs.
	Copolymers (co)			
Poly(ST-co-BD)	w.r.t. MW (6.1×10^4–1.4×10^5)	THF → methanol	4	84
Poly(ST-block-MMA)	Separation of PMMA	chloroform + methanol (6 : 16–4 : 16)	1	33
Poly(ST-block-BD)	Separation w.r.t. MW, separation of low-molecular-weight PS	chloroform + methanol (3 : 2) → methanol	3	84
Poly(BD-gr-ST)	Separation of PS	EMK	3	44

---

*For the methods of development and the significance of abbreviations, see Table I of the Appendix.

**Adsorbent— Al_2O_3.

***Method of development— $ZnSiO_3$.

Table III. The use of TLC in the study of oligomers* (adsorbent– silica gel).

Oligomer	Polydispersity investigated	Eluent	Method of development	Refs.
Polyisoprene	w.r.t. MW (700–2100), M_n = 1780	benzene + acetone (17.43 : 28.57)**	1	64
Polybutene	w.r.t. MW, M_n = 300	hexane	2	102
Poly-1,2-butadiene	w.r.t. functionality (COOH and OH groups)	*p*-xylene, carbon tetrachloride + THF (100 : 1)	3	44
	Non-functional, mono- and bi-functional	cyclohexane + benzene (14 : 3)	4	67
PS	w.r.t. MW (n = 3–9), M_n = 900	carbon tetrachloride + heptane (2 : 1)	4	67
Poly-α-methylstyrene	w.r.t. MW (n = 3–10)	ethyl acetate + isopropyl alcohol + acetone + methanol + water (50 : 15 : 15 : 4 : 16), isopropyl alcohol + ethyl acetate + water*** (30.5 : 55 : 14.5)	5	56
Polyglycerols	(1) w.r.t. MW (n = 1–4) (2) separation of linear and branched oligomers			
PEG	w.r.t. MW (n = 1–3) (M_n = 200–2000)	chloroform + ethanol (92 : 8)***	1	50
PEG (3,5-dinitrobenzoates)	w.r.t. MW (M_n = 200–2800)	EMK sat. with water	6	51
PEG (dichloro-derivatives)	w.r.t. MW (up to n = 21)	EMK sat. with water	1	94
PEG (dichloro-derivatives, triphenylmethyl derivatives)	w.r.t. MW (n = 13.2) (n = 17.2)	EMK sat. with water	1	95
PEG (3,5-dinitrobenzoates	w.r.t. MW (M_n = 200–4000) (MWD)	EMK sat. with water	7	53
PEG	w.r.t. MW (M_n = 600)	pyridine + water (0.1 : 10), chloroform + ethanol (10 : 1)*****	6	67
PPG	w.r.t. functionality	hexane + di-isopropyl ether + ethanol + water (5 : 10 : 5 : 3)	8	61
PPG	w.r.t. MW (M_n = 150–2000)	ethyl acetate + acetic acid (97.5 : 2.5)	1,9, 10	53
PPG	w.r.t. functionality (monools, diols, triols, and pentols) M_n = 500–5000)	ethyl acetate sat. with water	6	48
Mixture of PPG and PEG	Separation	chloroform + white spirit (85 : 15)	7	53
Mixture of PPG, PEG, and poly-THF	Separation (M_n = 2000)	chloroform + ethanol (92 : 8)	1	50
PEG–nonyl ether	w.r.t. MW (n = 9)	EMK sat. with water	11	59
PEG and its derivatives ($-O-CH_2CH_2SR$, where R = phenyl, n-hexyl, n-octyl, or n-decyl; $-O-CH_2CH_2Cl$ and $-OR$, where R = phenyl or triphenylmethyl)	w.r.t. MW (up to n = 13)	EMK and EMK sat. with water	1	57

Table III (cont'd.)

Oligomer	Polydispersity investigated	Eluent	Method of development	Refs.
PEG and its derivatives R–O(CH_2CH_2O)$_n$R', where R = R' = H, R = R' = phenyl, or R = *p*-t-nonylphenyl and R' = H	w.r.t. MW (up to *n* = 17) *n* = 6.5 *n* = 7.3 *n* = 5.4	EMK, EMK + water (9:1); EMK + water (95:5); EMK sat. with water	1	2
PEG–*p*-t-nonyl phenyl ether	w.r.t. MW (*n* = 6.5–12.9)	EMK sat. with water	1	60
Surfactants based on PEG	w.r.t. MW (up to *n* = 8.6)	EMK sat. with water	1	96
Surfactants based on PEG of the type RO(CH_2CH_2.O)$_n$, where R = alkylphenyl or alkyl	w.r.t. MW	EMK sat. with water	1	97
Products of condensation of PEG with aliphatic acids, alcohols, amines, phenols, and amides	w.r.t. MW and degree of hydroxyethylation (up to 1:20)	EMK + water (1:1)—upper phase, EMK + 2.5% aqueous ammonia (1:1)—upper phase, butanol + acetic acid + water (4:1:5)	6	49
Esters of PEG and adipic acid	Separation of linear and branched oligomers (M_n = 1000–3000)	benzene + ethanol (3:1)		
Poly(methylene-2-hydroxybenzoate)	w.r.t. MW (138–1100)	benzene + acetic acid + water (2:2:1)	12	98
ε-Caprolactam and its cyclic oligomers	w.r.t. MW (*n* = 1–8)	THF + petroleum ether (100–120°C) + water (80:14:10); 1-butanol + acetic acid + water (10:2:5); 2-butanol + formic acid + water (7.5:1.5:1); 1-butanol sat. with water; isopropyl alcohol + methanol + water (1:1:1); 1-butanol + conc. HCl + water (10.2:3.8)	6	65
Poly(ethylene terephthalates)	Separation w.r.t. functionality	benzene + ethyl acetate (85:15, 55:45) → ethyl acetate	13	63
Diethylene glycol in poly(ethylene terephthalate)		Dichloromethane + 25% aqueous ammonia + methanol (8:3:17)	14	100
Polydimethylsiloxanediols	w.r.t. MW (*n* = 1–20)	benzene + ethyl acetate (10:0.1)	15	67

Methods of development: 1) I_2 vapour; 2) 1% vanillin and 10% $HClO_4$ with subsequent heating at 110°C for 1 h; 3) 14.7% H_2SO_4 with subsequent heating to 100°C; 4) 3% $KMnO_4$ in concentrated H_2SO_4 with subsequent heating to 180°C; 5) 0.5% Thymol Blue in 95:5 ethanol–H_2SO_4 mixture with subsequent heating at 120°C for 1 h; 6) Dragendorff reagent; 7) acetic acid solution of $KMnO_4$; 8) cobalt thiocyanate; 9) 0.05% ethanol solution of rhodamine B; 10) 2% $KMnO_4$ in 2 *N* H_2SO_4; 11) 1% I_2 in methanol; 12) u.v. irradiation at 366 nm; 13) Methyl Red, Bromothymol Blue, and formaldehyde in 95% ethanol; 14) 0.5% $KMnO_4$ and $K_2S_2O_8$; 15) luminescence of background at 365 nm.

*For the notation employed, see Table I.

**Al_2O_3 (17% of water), neutral unfixed layer.

***Mixture of kieselguhr and silica gel.

****Al_2O_3 with first degree of activity, unfixed layer.

*****Adsorbent—Al_2O_3.

The Problems of the Selectivity of Chemical Reactions

N.M.Emanuel'

The review discusses the problem of the selectivity of chemical processes of different classes. Mathematical expressions are given for the selectivity of reactions of simple types and for radical-chain processes and a relation is demonstrated between the selectivity and the kinetic parameters of the reaction. Factors controlling the selectivity by influencing the mechanism of the process and its kinetics are considered—chemical and physical factors (catalysing, inhibiting, and complex-forming additives, factors associated with control of the reaction by carrying it out at low temperatures, by employing laser radiation and magnetic and electric fields, etc.).
Data on reaction selectivity and ways of improving it are considered in relation to specific examples of oxidation, polymerisation, cracking, and halogenation reactions involving organic substances.
The bibliography includes 102 references.
