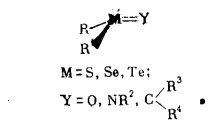
The replacement of one of the fluorine atoms by a dialkylamino-group [155,156] or transition to tetra-arylsulphuranes [157] leads to an appreciable decrease of the rate of exchange, which is extremely sensitive to catalytic influences of the impurities. The latter factor indicates a significant role of the intermolecular mechanism of ligand exchange in the polytopic rearrangement (XVI) ⇌ (XVII). Various possibilities of associative, dissociative, and catalytic mechanisms have been examined [158-162]. In dilute solutions and in the gas phase truly intramolecular processes can compete with intermolecular processes [162]. The wide variety of mechanisms of such reactions is still greater than in the series of trigonal bipyramidal structures of Group V elements. Calculations on the pathways followed in the topomerisation of various model sulphuranes, carried out by the CNDO/2 and extended Hückel methods, led to the isolation of two more mechanisms specific to bisphenoid structures: the lever and pyramidal mechanisms, each of which is due to the non-synchronous motion of the ligands involved in the exchange, in contrast to Berry's pseudorotation mechanism [141].

The calculations [141] predict an interesting dependence of the energy to topomerisation in MX_4 molecules via the lever mechanism (the motion of a single axial ligand, while the skeleton made up of the remaining bonds remains stationary). In agreement with experiment, the topomerisation barrier for fluorides decreases on passing from sulphuranes to telluranes. However, for less negative substituents X the situation may be reversed.

In the series of σ-telluranes (except TeF_4) there is yet another experimental indication of a rapid polytopic rearrangement of the type (XVI) ⇌ (XVII). Hellwinkel and Fahrbach [106] explained their observation of the equivalence of all the methyl groups in the spirotellurane (XVIII) as a consequence of Berry's pseudorotation (other mechanisms are hindered by the spiran structure).

(XVIII)



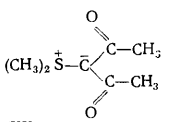
In view of the possible random isochronic nature of the protons of the methyl group (very remote from the chiral centre) the possibility of pseudorotation in structures of type (XVIII) requires further tests.

2. THE STEREOCHEMISTRY OF π-TELLURANES

There are no literature data for the molecular structure of π-telluranes obtained by direct methods. However, it had been concluded earlier on the basis of the results of thermal analysis that the configurations of diaryltellurium and diarylselenium oxides are identical [110].

Like the corresponding sulphonium [163,164] and selenonium ylids [165-167], telluronium ylids should evidently have the structure of a trigonal pyramid with a tellurium atom at the apex. Proof of the high stability of the tellurium pyramid in the dimedone ylids synthesised previously [117] has been obtained [118] by ^1H NMR (using a chiral shift reagent).

Recent theoretical calculations of the inversion and rotational barriers and on the mechanism of the topomerisation of the oxides, ylids, and imides of Group VI elements of type (XIX) [168] revealed definite tendencies in the above series:

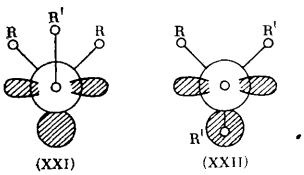


M = S, Se, Te;
Y = O, NR^2, $C\begin{matrix}R^3\\R^4\end{matrix}$.

(XIX)

1. The barriers to the pyramidal inversion of the central atom M in all compounds of type (XIX) with identical Y increase in the sequence S < Se < Te. This justifies the assertion that selenium and tellurium oxides can be resolved into highly stable enantiomers of type (XIX) (M = Te, $R \neq R'$). The methods of synthesis and reactions of these compounds are being studied in detail at the present time [101,102]. Correspondingly, selenium and tellurium imides and ylids with different substituents at the central atom can also exist as stable optically active compounds.

2. The stability of the pyramid of the central atom M and the barrier to pyramidal inversion depend markedly on the nature of Y. In agreement with experimental data, the barrier to inversion in the oxides is highest.



3. On passing from S and Se to Te, the barriers to rotation in the imides and ylids decrease. In the sulphonium ylid of type (XX) (M = S) the barrier to rotation about the C=S bond has been estimated as 12 kcal mole^{-1} [169] on the basis of the broadening of the signals due to the methyl groups in the ^{1}H NMR spectrum on cooling:

(XX)

Such broadening is observed also in the spectra of selenium ylids but at lower temperatures (−60°C),[166] which corresponds to a lowering of the rotation barrier. Presumably in telluronium dimedone ylids the rotation about the Te=C bonds is characterised by particularly high rates.

4. The stable molecular conformation of the imides and ylids of type (XIX) satisfies, according to the calculations, the *gauche*-rule and corresponds to conformation (XXI):

(XXI) (XXII)

This makes it possible to reject conformation (XXII), postulated by Claus and Gycydilik [170] to explain the observed isochronic nature of the signals due to the protons of the methyl groups in aryldimethylsulphimines.

3. THE ELECTRONIC STRUCTURE AND PHYSICAL PROPERTIES OF TELLURANES

(a) The Electronic Effects of Tellurium-Containing Substituents According to Dipole Moment Measurements and ^{19}F NMR

The dipole moments of compounds of the type $RC_6H_4TeX_2C_6H_4R'$ have been determined in a number of studies [67,171-173]. The appreciably higher dipole moments of diphenyltellurium dihalides compared with the corresponding dimethyl derivatives show (taking into account the direction of the C–Te bond moment) that the lone electron pair of the tellurium atom in diphenyltellurium dihalide molecules is not involved in conjugation with the π electrons of the aromatic rings. On the other hand, this difference between the dipole moments can be a consequence of the opposed electronic effect, of which the tellurium atom is capable in principle (d,π conjugation). The inductive and resonance components of the σ constants of the substituents $RTeX_2$ (R = Me or Ph), obtained from the ^{19}F NMR spectra of methyl (and phenyl) derivatives of *p*- (and *m*-)fluorophenyltellurium dihalides [174] with the aid of the Taft equations [175-177] (Table 4), do indeed show that the $RTeX_2$ groups do not exhibit electron-donating mesomeric properties. The σ_C constants of these groups are comparatively small compared with σ_I and, remaining virtually invariant when the halogen is altered, amount to ~ 10% of the overall σ_n constant of the substituent. The σ_I constants increase steadily on passing from chlorine-containing to iodine-containing compounds. Comparison of the values of σ_I and σ_C shows that the above groups interact with the π-electron system of the benzene ring mainly via an inductive mechanism.

When the values of σ_I, σ_C, and σ_n are examined for a series of substituents CH_3TeX_2, it is seen that the increase of the last constant is determined mainly by the increase of the σ_I constant and the values of the σ_n constants of the CH_3TeX_2 groups in the series Cl, Br, I increase on passing from chlorine-containing to iodine-containing compounds. An analogous increase of the σ constants is observed also in the $C_6H_5TeX_2$ series. Here the σ_I constants are greater than for the CH_3TeX_2 groups, evidently owing to the more pronounced inductive properties of the phenyl group compared with the methyl group. Thus one may speak of the preferential inductive mechanism of the interaction of the $RTeX_2$ groups with the π-electron system of the benzene ring. However, as for tellurides [178], when there is an active π-donor substituent (the dimethylamino-group) in the *p*-position relative to the TeX_2 group, there is a possibility of a sharp enhancement of the electron-accepting properties of the tellurium-containing group, probably owing to the population of the vacant *d* orbitals of the Te atom. The experimental dipole moments of aryl(*p*-dimethylaminophenyl)tellurium dihalides greatly exceed the values calculated by the vector scheme [173], the direction of the dipole moment coinciding with the direction expected for d,π conjugation.

In the series of similarly substituted diorganotellurium dihalides the dipole moment increases steadily, like the σ_I and σ_n constants, on passing from the difluorides to the di-iodides. To explain this, it has been suggested [172] that, under the influence of electronegative axial halogen atoms, the lone electron pair of tellurium undergoes contraction to different extents, which leads to a change in the dipole moment and the moment of the molecule as a whole.

A more rigorous explanation in terms of the resolution of the overall moment into the charge and hybridised components [144] was obtained as a result of calculations by the CNDO/2 method with inclusion in the basis set of the *d* orbitals of the central atom of the molecules of dimethylchalcogen dihalides $(CH_3)_2MX_2$. An increase of the dipole moment in the series X = F, Cl, or Br and M = S or Se can be accounted for by the simultaneous increase of the point component and the decrease of the *pd*-hybridised component (the *sp* components remain almost constant).

The problems of the electronic properties of TeX_3 groups have been investigated by ^{1}H and ^{19}F NMR [148,174] and by the dipole moment method [148].

The ^{1}H NMR spectra of *p*-substituted aryltellurium trihalides show that the *o*,*o'*- and *m*,*m'*-protons are isochronous and the barrier to rotation about the Te–Ar bonds is therefore small. The chemical shifts of the *o*-protons of aryltellurium trichlorides, which occur in a very weak field, indicate a strong deshielding effect of the trichlorotelluro-group, whose magnitude (δ_0^H = −1.0 ± 0.1 p.p.m.) is comparable to the analogous effect of the nitro-group. The value of δ_M^H for the $TeCl_3$ group has been calculated from the chemical shifts of the *m*-protons (satisfactorily correlated with the substituent constants δ_0^H),[148] as −0.23 p.p.m., which almost agrees with the corresponding value for the nitro-group. These data agree with the strong negative inductive effect of the $TeCl_3$ group.

The chemical shifts of the *o*-protons of the tribromides and *p*-substituted trichlorides are almost identical and the chemical shifts of *m*-protons are displaced upfield by

0.15–0.25 p.p.m., which indicates a smaller negative inductive effect of the tribromotelluro-group compared with the trichlorotelluro-group.

The σ_C constants of the TeX_3 groups, determined from ^{19}F NMR data [174], amount to 15% of the overall electronic effect of the substituent, which indicates a predominantly inductive nature of the interaction of these substituents with the π-electron system of the ring. In the Cl, Br series, the σ_n constants of the TeX_3 groups diminish, which is consistent with the overall ^1H NMR spectroscopic data.

The dipole moments of aryltellurium trichlorides calculated by the usual vector scheme agree satisfactorily with the experimental values. The vector of the dipole moment of the $TeCl_3$ group, equal to that of the dipole moment of phenyltellurium dichloride, makes an angle of 115° with the Ph–Te bond, which agrees closely with the direction of the equatorial Te–Cl bond. The absence of the moment of the interaction of the $TeCl_3$ group and the nitro-group in the benzene ring indicates the localisation of the lone electron pair and the similar dipole moments of phenyl- and methyl-tellurium trichlorides confirm the absence of an appreciable mesomeric electron-accepting effect of the $TeCl_3$ group.

The results of the calculation of orbital populations and examination of the nature of the highest bonding and lowest vacant molecular orbitals explain the causes of the observed characteristics of the electronic properties of the trichlorotelluro-group. The π-electron system of the benzene ring is only slightly affected by substituent influences and retains six electrons. The large positive charge on the tellurium atom is due to the merging of its p_Z orbital with a combination of suitable orbital symmetry, of the p_X and p_Z orbitals of the chlorine atoms in the π molecular orbital [148].

(b) The Basicity and Dipole Moments of π-Telluranes

The thermodynamic basicity constants of diorganotelluronium dimedone ylids in anhydrous acetonitrile and the correlation of the pK_a values with the σ constants of the substituents have been investigated [118]. Ylids of this type are fairly strong bases (Table 3), comparable in strength with aromatic amines. In the series of dicarbonyl-stabilised ylids of Group VI elements, having structures of the same type, the basicity increases in the sequence S < Se < Te, i.e. increases with decrease of the electronegativity of the 'onium atom and with increase of its size (an analogous relation obtains also for the ylids of Group V elements [179]). The pK_a values of the ylids investigated are best correlated with the σ^0 constants of the substituents ($r = 0.983$; $\rho = 0.958$), which indicates a predominantly inductive effect of the interaction of the aryl rings with the 'onium tellurium atom.

The ylids examined above have relatively low dipole moments compared with the usual values for ylids (Table 3), lying in the range 2–5 D. Such relatively low dipole moments of the ylids, compared, for example, with the dipole moments of diorganosulphonium dicyanomethylides [180] and the fact that they are comparable to the dipole moments of the structurally related arylmethylsulphonium 1,3-indandion ylids (3–5 D) [181] can be explained by the fact that the $Te^+–C^-$ bond moments in telluronium dimedone ylids and the group moment of the dimedone fragment are directed to opposite sides and to a large extent cancel out. In most cases the dipole moments calculated on the basis of a fragmentary vector scheme and determined experimentally agree fairly satisfactorily. The only exception is the *p*-dimethylamino-derivative, where the effect of the direct polar conjugation of the dimethylamino-group with the vacant *d* orbitals of tellurium is evidently manifested.

---o0o---

During the period when the review was dealt with by the editors a number of new studies were published.

Methods of synthesis of mono-organo-derivatives of tellurium (IV). The interaction of 4-halogeno-substituted diphenyl ethers with tellurium tetrachloride, which proceeds via a stage involving the formation of 2-trichlorotelluro-derivatives and leading ultimately to 10,10-dichlorophenoxatellurins, has been investigated [184,185]. Berry et al. [186] established that, when acetic anhydride reacts with $TeCl_4$, bis(trichlorotelluro)methane is indeed formed and its reduction by potassium metabisulphite yields cyclo-1,4-dimethylenetetratellurium $\overbrace{CH_2–Te_4–CH_2}$. It has been shown [187] that organotin compounds of the type R_3SnBr and R_4Sn react with $TeBr_4$ (there is no reaction with TeI_4 or the yields are extremely low) to form organotellurium tribromides or diorganotellurium dibromides. An earlier report [57] of the synthesis of phenyltellurium triacetate on oxidation of diphenyl ditelluride with lead tetra-acetate was not subsequently confirmed. Although the presence of $C_6H_5Te(OCOCH_3)_3$ in solution was demonstrated by NMR, [188,189] attempts to isolate this compound in a pure form yielded only a substance of unknown structure. Aryltellurenyl halides ArTeX (X = Br or I), obtained by the reaction of diaryl ditellurides with one equivalent of a halogen in non-polar solvents [190,191], are unstable compounds, particularly in the case of bromine, which disproportionates to diaryltellurium dihalides and elemental tellurium [192]. Use of these compounds in the synthesis of asymmetric diaryl tellurides and selenotellurides has been described by Petragnani [193].

Methods of synthesis of diorgano-derivatives of tellurium (IV). Diphenacyl- and arylphenacyl-tellurium dichlorides have been obtained by the reaction of the trimethylsilyl ether of the enolic form of acetophenone with $TeCl_4$ and aryltellurium trichlorides [194]. Symmetrical and asymmetric diaryltellurium dichlorides have been obtained by treating sodium (or potassium) tellurophenoxides with arene-diazonium tetrafluoroborates in ethanol with subsequent chlorination [195] or by the arylation of diaryl ditellurides with arenediazonium chlorides in the presence of copper(II) salts [196]. A new class of diorgano-derivatives of tellurium(IV)—diaryltellurium di-isocyanates $Ar_2Te(NCS)_2$—have been synthesised by the oxidation of diaryl tellurides with free thiocyanogen [197,198] or by the interaction of diaryltellurium dichlorides with ammonium thiocyanate in methanol [198]. A series of studies have been devoted to methods of synthesis and the investigation of the properties of diaryltellurium diacylates. Petragnani [199] obtained these compounds by treating diaryltellurium dichlorides with carboxylic acids in the presence of silver oxide and Pant [189] synthesised them by oxidising diaryl tellurides with lead tetra-acetate and by the double decomposition of diaryltellurium dichlorides with silver salts of carboxylic acids. In order to obtain diaryltellurium diacylates, including derivatives of dicarboxylic acids, Tamagaki et al. [200] used the reaction, described previously by the present authors [100,101], of diaryltellurium oxides with carboxylic acid anhydrides and the acids themselves. It is of interest to note that dicarboxylic acid anhydrides, for example, phthalic anhydride, give rise to

monomeric compounds on reaction with diaryltellurium oxides, while, according to the results of Dance and McWhinnie[201], the reaction of diaryltellurium dichlorides with sodium salts of phthalic acids yield dimeric diaryltellurium diacylates. The infrared spectra of diaryltellurium diacylates, investigated by Pant et al.,[188] indicate the non-equivalence of the carboxylate groups in certain diaryltellurium diacylates, although according to ^{1}H NMR data both the arene rings and the carboxylate groups are completely equivalent[161]. The mass spectra of diaryltellurium diacylates and certain diaryltellurium dichlorides have been investigated[202,203]. The synthesis of previously unknown esters derived from diorganotellurium dioxides $R_2Te(OR')_2$, based on the interaction of dialkyl- or diaryltellurium dihalides with sodium alkoxides, as well as some of their properties have been described[204].

The synthesis of π-telluranes. Diaryltelluronium ylids have been obtained by refluxing diaryltellurium oxides with active methylene compounds (dimedone, indandione, and nitroacetic and malonic esters) in benzene with simultaneous distillation of the water formed[205]. When tellurium tetrahalides TeX_4 (X = F or Cl) interact with hexamethyldisilamides of acetic and arenesulphonic acids, the products are *N*-substituted halogeno-derivatives of iminotelluryls and tellurium *N*,*N'*-diacyldi-imides[206].

The structure of organic derivatives of tellurium(IV). Crystallographic data have been obtained recently for the compounds *o*-$HCOC_6H_4TeX$ (X = Cl, Br, or I)[207] and a complete X-ray diffraction analysis of di-(*p*-anisyl)telluronium dimedone ylid was carried out[208]. The electronic effects of the tellurium-containing substituents $-Te(CH_3)F_2$, $-Te(C_6H_5)(NCS)_2$, and $-Te(C_6H_5)F_2$ have been investigated[209] with the aid of ^{19}F NMR. Studies have been made on the Mössbauer[210-213] and ^{125}Te NMR[214] spectra of various organotellurium compounds, including σ-telluranes.

The Stability of Colloid Systems (Theoretical Aspects)

B.V.Deryagin

After a brief description of the development of ideas concerning the nature of the stability of colloids, the main factors (ionic-electrostatic and molecular forces) whose balance determines the resistance of colloids to aggregation, are examined. An account is given of calculations of the free energy of charged particles in an electrolyte solution. The influence of the dense layer of adsorbed ions on the stability of colloids is discussed. The phase transitions in colloid systems, particularly coacervation and the formation of periodic colloid structures, are considered. The problem of thermodynamically stable colloid systems is analysed in connection with the properties of micellar solutions. A brief description is given of the problem of the stability of liquid layers and of the phenomenon of heterocoagulation.
The bibliography includes 281 references.

I. INTRODUCTION

Colloidal systems or colloids became the object of systematic study in the middle of the XIXth century. At that time they were considered as ordinary solutions of special glue-like substances—hence the origin of the term "colloidal solution". Only when the fundamental differences between colloid systems and glue solutions became understood, the science of colloids was established as an independent discipline. Traditionally it is still referred to as colloid chemistry, because of the earlier view that all the differences between colloidal and normal solutions are determined by the nature of "colloidal substances" and also because studies on such systems have been made mainly by chemists. However, in the course of development of the relevant research, the differences between normal and colloidal solutions were discovered and began to be investigated. These differences are largely physical and sometimes physicochemical. It is not fortuitous that the most important work in the study of colloid systems has been carried out by physicists: Helmholtz, Einstein, de Boer, Langmuir, Gibbs, Bernal, Onsager, Kirkwood, Rayleigh, Perrin, Smoluchowski, Gouy, Chapman, Debye, and others. The traditional term "colloid chemistry" has therefore now become, in essence, obsolete and the term "colloid science" is being increasingly used.

The principal difference between colloid systems and glue solutions is that the kinetic units in the former (colloid particles) consist in the general case of a large fairly indefinite number of molecules, and exhibit to a first approximation the properties of a phase separated from the adjoining phase (dispersion medium) by a very large interface. Hence the enormous role of surface phenomena at the boundary between particles of the disperse phase and the dispersion medium becomes understandable: the formation of an ionic double layer and ion exchange, electrokinetic phenomena, and adsorption. Without the consideration of the role of surface phenomena, the science of colloids would have been completely without theoretical foundation†. A distinction is frequently drawn between colloid and coarsely disperse systems: suspensions and emulsion. However, this difference is extremely arbitrary and depends on the particle size or on the area of interface and is largely qualitative.

All the foregoing considerations make it possible to define colloid science as the physical chemistry of disperse systems or systems with a large interface indissolubly linked to the physical chemistry of surface phenomena. In contrast to the science of solutions, the fundamental problem in this science is that of stability. Its importance is determined by the fact that colloid systems are in the main not in a state of thermodynamic equilibrium and an adequate stability of the colloid system constitutes a condition for its existence as such.

In contrast to solutions, the state of a colloid system can change in two significantly different ways—either by the dissolution of some particles and the growth of others, which are relatively more stable, or by the sticking together but not coalescence of the "primary" particles and the formation of aggregates with or without layers of the dispersion medium between the particle. A condition for equilibrium in a colloid system with respect to processes of the first type, i.e. the condition for the stability (constancy) of the composition of the disperse phase, is minimum free energy of the system relative to the distribution of particles with respect to size—the condition for thermodynamic equilibrium.

---

†The role of surface phenomena in colloid science is indicated by the names of the international journals and semiperiodical publications as well as institutes: Journal of Colloid and Interface Science; Advances in Colloid and Interface Science; Institute of Colloid and Interface Science (USA); Surface and Colloid Science (Edited by E. Matijević).

The condition for equilibrium in the system relative to processes of the second type (stability in relation to aggregation) requires the existence of repulsion forces between particles approaching each other, which are capable of interfering with their cohesion under the influence of molecular attraction forces. A general condition for thermodynamic equilibrium may not in fact be fulfilled in this case. A characteristic of stability towards aggregation or of aggregation equilibrium in the system is constancy of the distribution of aggregates with respect to the number of "primary" particles in them. In the simplest case equilibrium can correspond to the absence of aggregates.

In mists and "unprotected" emulsions unhindered cohesion of particles may or may not be accompanied by coalescence. In the former case one should speak of the breakdown of the stability of the composition of the dispersion medium and not of stability with respect to aggregation.

The condition for the thermodynamic equilibrium of particles surrounded by electrical double layers was examined for the first time by March[1]. However, we incorrectly formulated the problem of thermodynamic equilibrium in relation to the changes in the degree of dispersion without the breakdown of monodispersity, i.e. with retention of identical surface curvatures by all the particles. Furthermore, when account is taken of the influence of the difference between the curvatures of the particles on their chemical potential, such a state (at any rate for particles containing one component soluble in the dispersion medium) is labile. On the other hand, it is pointless to consider the possibility or impossibility of a process in which such lability is maintained. This is entirely equivalent to considering from the standpoint of thermodynamics the possibility of the rolling of a sphere along a tightrope. A second error in March's work was failure to understand that the main thermodynamic condition which he considered has a bearing solely on the stability of the composition of the disperse phase and not on stability with respect to aggregation.

When the general condition for thermodynamic equilibrium in relation to changes in the composition of the disperse phase of the system holds, the possibility of the formation of aggregates whose particles are separated from one another by thin layers of the dispersion medium is not ruled out. However, whether this possibility does arise and, if it does, the state of the system (metastable, stable, or labile) are problems which must be solved for each specific case by a more detailed examination.

Thus it is necessary to distinguish two specific forms of stability of colloid systems, which are absent in glue solutions: the stability of the composition of the disperse phase and the stability of the aggregate composition or stability with respect to aggregation. Naturally if aggregation is accompanied by the coalescence of particles, then instability with respect to aggregation entails the instability of the composition of the disperse phase. The existence of two types of stability of colloid systems is one of the manifestations of the fundamental qualitative difference between them and true solutions for which the concept of the stability of the composition of the disperse phase and of stability with respect to aggregation lack significance. At the same time it is possible to consider also a third type of stability, which is common to true solutions and colloids. This is the stability with respect to the separation of the system into two phases or, in the case of colloids, quasi-phases, which differ in the concentrations of the kinetic units—molecules or colloidal particles—and also, possibly, in their distribution‡.

In the present review attention is concentrated on the stability with respect to aggregation, the changes in which are usually faster than the changes in the composition of the disperse phase and are therefore of practical importance. The nature of the stability of the aggregate composition is also important. If the condition of the constancy of the composition of the disperse phase does not hold but varies extremely slowly, the constancy of the composition of the aggregate may be referred to as partial equilibrium, since only some of the conditions for equilibrium are then maintained. Aggregation equilibrium can in this case be only temporary and will inevitably change as the composition of the disperse phase changes in direct functional relation to the latter. An exception is provided by a system where there are no aggregates owing to the operation of strong repulsion forces. Equilibrium in such systems can be maintained also during the variation of the disperse phase composition, at least until the size of the particles approaches molecular dimensions, which makes it easier for them to overcome the repulsion forces arising from other particles. At any rate aggregation stability can be considered independently of the possible instability of the disperse phase composition, ignoring the changes in the latter, provided that they are sufficiently slow.

With this stipulation, the aggregation stability can be of two kinds. Firstly it can be due to the slowness of the coagulation process (or the slowness of the decomposition of aggregates) and its nature is then purely kinetic. The aggregation quasi-equilibrium can be referred to in this instance as the relaxation of frozen or hindered non-equilibrium states (but not metastable equilibria). Secondly, a rigorous constancy of the aggregate composition can obtain when aggregation processes are balanced by the opposed deaggregation processes. As will be shown below (Section V), equilibria of this kind can break down also in consequence of the formation of larger aggregates; in this case one can speak of a metastable equilibrium.

Critical emulsions and micellar solutions (see Section VIII), which are colloid systems in complete thermodynamic equilibrium where the conditions of a constant disperse phase composition and the absence of aggregates are maintained, must be treated as a special case.

Equilibrium periodic colloid structures, formed, for example, by the tobacco mosaic virus or by spherical latex particles, merit a special discussion. This will be done later (see Section VII), where the problem of equilibria in colloid systems of the type of phase equilibria in the usual solutions is considered.

The foregoing considerations are based on the most general postulates and are used merely to throw light on the problem of the concept of stability of colloid systems. It is, however, impossible to reach fairly concrete conclusions about the nature of stability and its characteristics, solely on the basis of general considerations of this kind; concrete conclusions make it necessary to specify in greater detail the physical formulation of the problem, perhaps even at the expense of abandoning the generality of the conclusions. Colloid science entered this fruitful

---

‡In considering the different types of stability of colloid systems, we are not concerned with kinetic or sedimentation stability, which is manifested by the presence of a sedimentation-diffusion equilibrium in the system.

path about forty years ago, which led to the development and general recognition and application of the physical theory of the stability of lyophobic colloids.

II. IONIC-ELECTROSTATIC AND MOLECULAR FORCES OF THE INTERACTION BETWEEN COLLOID PARTICLES

We shall now describe briefly the path traversed by colloid science and shall consider the factors which are either little known or have been incorrectly described in many monographs and articles to the detriment of the priority due to Soviet scientists§.

The sensitivity of many colloid systems, for example, metal sols, to electrolytes was noted a long time ago[2-5]. The concentrations of electrolytes for coagulating such systems are low, and decrease sharply with the increasing charge of the counterion[6-8]. Colloid systems of this class have been called lyophobic or electrocratic. Colloid systems which coagulate only at high electrolyte concentrations (of the order of several units on the molar scale), which depend little on the type of counterions, have been assigned to another class. A considerable proportion of such systems, referred to as lyophobic colloids, proved subsequently to be true solutions of polymers, whose particles (macromolecules) do not form an interace with the solvent. They ceased to be classified as colloid systems, because a fundamental feature of the latter is the existence of an interface. However, there remained many colloid systems, which, while not true solutions, are nevertheless fairly stable towards electrolytes. It must be emphasised that the same colloid may lose or acquire sensitivity to electrolytes depending on the state of the surface of its particles, which is determined by the absorption of surface-active molecules or ions[9,10]. It is therefore perhaps more correct to speak of the lyophobic or lyophilic state of colloid systems rather than lyophobic and lyophilic colloid systems. There also exist colloid systems, for example polysilicic acid hydrosols, which do not contain surface-active molecules or ions, and are at the same time relatively insensitive to electrolytes.

It was noted long ago that the stability of lyophobic colloids is as a rule correlated with the electrophoretic mobility of the particles, indicating their charge[11-15]. In considering the repulsion forces between charged particles as the cause of their aggregation stability, some workers attempted, following Freundlich[16], to explain the action of electrolytes by a decrease of the charge under the influence of the adsorption of ions of opposite sign. Together with this idea, Kruyt introduced the hypothesis of solvation as the second stability factor[17,18], apart from the charge, which explains the properties of lyophilic colloids. All these ideas, which remained largely qualitative, were completely inadequate for the creation of a full fledged theory of the stability of colloids with clearly formulated physical principles.

A breakthrough for this problem occurred when, firstly, a narrower problem was formulated: the elucidation of the mechanism of the stability and coagulation of lyophobic systems and, secondly, when the balance between molecular attraction and electrostatic repulsion forces between particles was adopted as a basis. In a qualitative form these forces, considered as responsible for the stability of lyophobic colloids, were examined by Kallmann and Willstatter[19]. The attempt to proceed to a quantitative allowance for such forces is due to Hamaker[21,22]. The latter (and independently de Boer[20]) summarised the London expressions for the energy of the pair interaction between all the molecules of two plates or spheres, as well as the dispersion medium, and found an expression for the energy of the molecular interaction between colloid systems as a function of their radii and the thickness of the layer separating them. However, Hamaker's calculations did not lead to the establishment of a theory of stability, because his empirical formula[23-25] for the energy of electrostatic repulsion was not subsequently confirmed theoretically.

A theoretically well founded method for the calculation of the force and energy of the interaction between colloid species, which depends on the overlap of their diffuse ionic atmospheres, is due to the author of the present review[26-29]. He based the calculation on the expression for the ponderomotive pressure P applied to a unit area of the surface of the colloid particle:

$$P = -\frac{\varepsilon}{8\pi} E^2 + p = -\frac{\varepsilon}{8\pi} |\operatorname{grad}\varphi|^2 + p, \qquad (1)$$

where ϵ is the dielectric constant, φ the electric potential, E the projection of the electric field strength vector at the surface of the particle on to the normal to the latter, and p the hydrostatic pressure at the surface in excess of the hydrostatic pressure in the region where there is no electric field¶. The pressure p at any place satisfies the equation for hydrostatic equilibrium taking into account the electric force acting on the space charge (allowance for the polarisation of the medium causes little change in the final results):

$$\operatorname{grad} p + \rho \operatorname{grad}\varphi = 0. \qquad (2)$$

According to the Boltzmann equation, the concentration of ions and hence the space charge density ρ are a function of the local potential φ:

$$\rho = \rho(\varphi). \qquad (3)$$

Therefore it follows from Eqn. (2) that

$$p = A - \int_0^{\varphi} \rho \, d\varphi, \qquad (4)$$

where the integration constant A is independent of the coordinates and is zero according to the definition of p. When a potential $\varphi = \varphi_0$ has been specified on the surface of the particles, it is the same at all sections of the surface, both internal and external. The force balancing the hydrostatic pressure on each particle is therefore zero regardless of the shape of the latter and the force balancing the ponderomotive forces is determined by the summation of the vector-Maxwell tensions $(\epsilon/8\pi)E^2 = f'$ applied to different sections of the surface. The Maxwell tension f' must be supplemented by the electrostriction number f'':

$$f'' = \frac{1}{8\pi} E^2 \frac{\partial \varepsilon}{\partial \rho} \rho. \qquad (5)$$

However, it is known from electrostatics[32] that this addition does not alter the total ponderomotive force acting on bodies immersed in a liquid or gaseous medium. The explanation is that the electrostriction terms should be

§ For example, in the well known book[85] edited by Kruyt.

¶ Langmuir[30] called this excess pressure the excess osmotic pressure. Verwey and Overbeek[31] point out that it is more rational to call it the excess hydrostatic pressure, with which one must agree.

introduced at the same time into Eqn. (2) and should cause a change in the electrostatic pressure p, acting in the vicinity of the surface, such that it compensates exactly the Maxwell tension. This demonstrates the gross error of Babchin's work [33], where an attempt was made to alter the principles of the theory of the stability of lyophobic colloids by introducing electrostriction terms. This work has been criticised by the present author [34,35] and by Levin [36].

If the surface charge densities have not been specified, the values of E at various sections of the surface of the particles must be determined (for a symmetrical electrolyte) by integrating the Poisson–Boltzmann equation:

$$\frac{4\pi}{\varepsilon}\rho = \Delta\varphi = a \operatorname{sh} \alpha\varphi, \tag{6}$$

where

$$a = \frac{8\pi}{\varepsilon} zec, \tag{7}$$

$$\alpha = \frac{ze}{kT}, \tag{8}$$

Here e is the electronic charge, c the electrolyte concentration (in equiv. cm^{-3}) outside the limits of the ionic double layers, k the Boltzmann constant, T the absolute temperature, z the ionic charge, and Δ the Laplace operator, indicating that the sum of the second derivatives of φ with respect to coordinates is considered:

$$\Delta\varphi = \frac{\partial^2\varphi}{\partial x^2} + \frac{\partial^2\varphi}{\partial y^2} + \frac{\partial^2\varphi}{\partial z^2}.$$

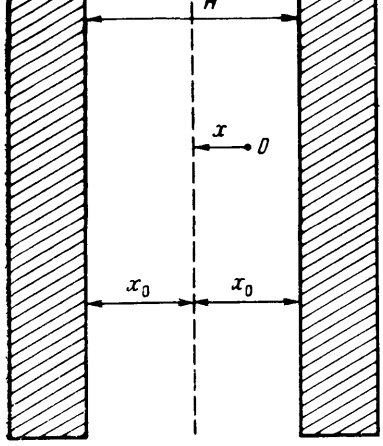

Figure 1. The distribution of potential in the electrolyte layer.

In this general formulation the calculation of the ionic-electrostatic interaction forces between the particles presents enormous mathematical difficulties even for two identical spherical particles.

The present author [26–29] examined initially the simpler case of the interaction of two parallel plates, whose dimensions are so much greater than the gap H separating them that the edge effects may be neglected (Fig. 1). The treatment was restricted initially to the case of low potentials satisfying the condition

$$\frac{ze\varphi}{kT} \ll 1. \tag{9}$$

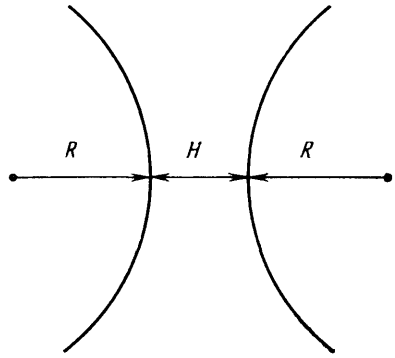

Figure 2. The interaction of two equal spheres.

In this case Eqn. (6) can be written approximately in the form

$$\Delta\varphi = \varkappa^2\varphi, \tag{10}$$

where κ is the reciprocal of the effective thickness d of ionic atmospheres and is given by

$$\varkappa = \frac{1}{d} = \sqrt{a\alpha} = \sqrt{\frac{8\pi}{\varepsilon}\frac{e^2z^2c}{kT}}. \tag{11}$$

In the general case of an arbitrary ionic composition cz^2 must be replaced by the ionic strength $\frac{1}{2}\Sigma z_i^2 c_i$, where c_i is the concentration (in gram-ion cm^{-3}) of the ions having the charge z_i. In the integration of Eqn. (10) it was assumed that a constant potential φ is maintained on the surfaces of the plates regardless of the thickness of the electrolyte layer H:

$$\varphi = \varphi_0, \tag{12}$$

The distribution of the potential between the plates has the following form:

$$\varphi = \varphi_0 \frac{\cosh \varkappa x}{\cosh \varkappa x_0}, \tag{13}$$

where x is the distance from the symmetry plane within the intervening layer to the zero point, where the potential has the required value φ, and $x_0 = H/2$.

Outside the plate, the distribution of the potential is

$$\varphi = \varphi_0 e^{-\varkappa x'}, \tag{14}$$

where x' is the distance from the outer surfaces of the plates. It follows from Eqns. (1), (13), and (14) that the Maxwell tension acting on sections of the inner surfaces of the plates is

$$f_t = \frac{\varepsilon}{8\pi}\varkappa^2\varphi_0^2 \tanh^2 \varkappa x_0, \tag{15}$$

while that on the sections of the outer surface is

$$f_0 = \frac{\varepsilon}{8\pi}\varkappa^2\varphi_0^2. \quad (16)$$

The difference between these tensions is directed to the outside and is equal, according to the foregoing considerations, to the repulsion force N between the plates per unit area:

$$f_0 - f_l = N = \frac{\varepsilon}{8\pi}\varkappa^2\varphi_0^2 \cdot \frac{1}{\cosh^2 \varkappa x_0}. \quad (17)$$

Integration of both parts of Eqn. (17) with respect to x_0 can yield the energy of the interaction between the plates per unit area:

$$U_e = \frac{\varepsilon}{4\pi}\varkappa\varphi_0^2\left[1 - \tanh\left(\varkappa\frac{H}{2}\right)\right]. \quad (18)$$

When applied to the one-dimensional case under consideration, Eqn. (2) becomes

$$\frac{dp}{dx} + \rho\frac{d\varphi}{dx} = 0. \quad (19)$$

Having replaced ρ by $-(\epsilon/4\pi)(d^2\varphi/dx^2)$ and having integrated Eqn. (19), we obtain

$$p = \frac{\varepsilon}{8\pi}E^2 + C, \quad (20)$$

where C is the integration constant.

According to Eqn. (1), the repulsion pressure can be calculated, even if the potential of the surface of the plate changes when the two plates approach one another, by considering the differences between the constants C corresponding to the region between the plates and to the region outside, where $C = 0$. It is therefore sufficient to find the difference between the values of C for the region between the two plates. It is simplest to consider a point in the symmetry plane between the plates where $E = 0$. Then

$$N \equiv C = p_m = -\int_0^{\varphi_m}\rho\, d\varphi, \quad (21)$$

where φ_m is the potential in the symmetry plane.

Thus the force of repulsion between the plates (the "wedging" pressure of the layer between them) is equal to the excess hydrostatic pressure in the symmetry plane. On substituting in Eqn. (21) the expression found with the aid of the Poisson–Boltzmann equation [Eqn. (6)] instead of $\rho(\varphi)$, we find that p_m is equal to the excess osmotic pressure of the ions if it is assumed that the van't Hoff law applies (without the Debye–Hückel correction). In the analogous case of wetting films this led Langmuir to identify N with the excess osmotic pressure of ions at points where $E = 0$. However, as stated before, this is in essence incorrect, because formula (21) is essentially equal to the excess osmotic pressure only for extremely low electrolyte concentrations.

However, for identically charged surfaces, the wedging pressure can be expressed in terms of the potential φ_m, which has many mathematical advantages. The extension of Eqn. (21) to the interaction of spherical particles with the same absolute charges, but different signs of the latter, will be described below.

The transition from the interaction of planar particles to the interaction of spherical particles has been achieved[26–29] with the aid of the transformation proposed earlier by the present author[37]:

$$K = GU(H), \quad (22)$$

where K is an interaction force of any kind (belonging to the class of conservative forces) between convex surfaces, whose radii of curvature are much greater than the effective radii of action of the force (in the present instance twice the thicknesses of the ionic double layers), G a geometrical factor which depends on the radii of curvature of the normal sections of the surfaces near the region of the mutual approach of the particles, and U the energy of the interaction of planar surfaces of the same kind, separated by a plane-parallel layer of the same medium having a thickness H equal to the shortest distance between the convex surfaces under consideration (Fig. 2).

In the simplest case of two identical spheres with a radius R we have

$$G = \pi R. \quad (23)$$

Here it follows from Eqns. (15), (16), and (18) that

$$K = \frac{\varepsilon}{4}R\varkappa\varphi_0^2\left[1 - \tanh\left(\varkappa\frac{H}{2}\right)\right]. \quad (24)$$

Hence integrations with respect to H yields an expression for the energy of the interaction of spherical particles:

$$U(H) = \int_H^\infty K\, dH = \frac{\varepsilon}{2}R\varphi_0^2\ln(1 + e^{-\varkappa H}). \quad (25)$$

In order to estimate the extent to which the calculated repulsion is capable of stabilising the colloid, the present author used the formula for the rate of slow coagulation derived by Fuchs[38] in order to take into account the influence of charges on the rate of coagulation of aerosols:

$$\nu = \frac{4\pi Dc^2}{\int_0^\infty \left[e^{\frac{U(H)}{kT}}/(2R + H)^2\right]dH}, \quad (26)$$

where ν is the number of aggregation steps per unit volume per unit time, D the coefficient of Brownian diffusion of the colloid particles, and c their numerical concentration. In the derivation of Eqn. (26) it was postulated that the mutual approach up to contact leads to irreversible aggregation, and molecular long-range forces were neglected. Hence the stabilisation coefficient introduced by the present author is described by the expression

$$J = \frac{\nu_0}{\nu} = \int_0^\infty e^{\frac{U(H)}{kT}}\frac{2R}{(2R + H)^2}\, dH, \quad (27)$$

where ν_0 is the value of ν for $U(H) = 0$, i.e. in the absence of repulsion forces. Later J was called the retardation coefficient.

Eqn. (25) was supplemented[39,40] by a term defining the energy of attraction of the particles via van der Waals forces and assumed the following form:

$$U(H) = \frac{\varepsilon R\varphi_0^2}{2}\ln(1 + e^{-\varkappa H}) - \frac{AR}{12H}, \quad (28)$$

where A is the Hamaker constant. Analysis of Eqn. (28) showed[39,40] that, for values of the dimensionless parameter

$$m = \frac{1}{6}\frac{A\varkappa}{\varepsilon\varphi_0^2} < 0.3 \quad (29)$$

the function $U(H)$ has a shallow minimum and to the left of it a maximum whose height increases on further decrease of the parameter m (Fig. 3).

On substituting Eqn. (28) in Eqn. (27), it can be shown that the coefficient J is large, provided that

$$\frac{\varepsilon\varphi_0^2}{A\varkappa} > 1. \quad (30)$$

This criterion was introduced for $R \gg d$ and for low electrolyte concentrations where Eqns. (6) and (10) are applicable, subject to the condition that the dimensionless potential of the surface of the particles, corresponding to the coagulation threshold, is fairly small, i.e. that Eqn. (9) holds.

Inequality (30) is a modification and a refinement of the empirical rule of Eilers and Korff[41,42]. It agrees well with Powis's work[43], where observations on stability were accompanied by measurements of the electrokinetic potential ζ.

The substitution of the electrokinetic potential ζ instead of φ_0 in Eqn. (30) is permissible to a first approximation at low electrolyte concentrations. Inequality (30) in a modified form[44,45] proved to be applicable also to the determination of the limits of floatability of natural hydrophobic minerals[46-48].

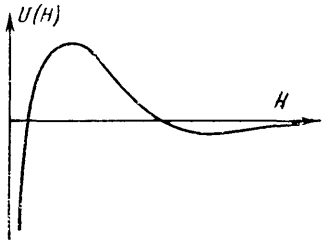

Figure 3. Dependence of the interaction energy between two particles U on the distance H.

An inconvenient aspect of the practical application of inequality (30) is that it includes, apart from the concentration (which determines the values of κ), a second unknown φ_0, which is difficult to measure accurately.

The present author[26-29] also considered another limiting case of the stability of lyophobic colloids corresponding to the condition

$$R \ll d, \tag{31}$$

which obtains either for highly disperse systems or at a very low ionic strength. If the van der Waals interaction is taken into account, then, instead of inequality (30), one must formulate the stability criterion [the condition for the maximum on the $U(H)$ curve] in the following form:

$$\frac{\varepsilon R \varphi_0^2}{A} > 1. \tag{32}$$

In order to ensure that the $U(H)$ maximum is much larger than the energy of the Brownian motion, it is necessary that an additional condition be fulfilled:

$$\frac{\varepsilon R \varphi_0^2}{kT} > 20, \tag{33}$$

which is infringed sooner for low values of A than condition (32).

Either condition [(32) and (33)] should be inevitably infringed for low values of K, i.e. for highly disperse systems, as observed in practice. Barriers preventing both the aggregation and deaggregation of particles are gradually lowered on passing from colloidally disperse systems to true solutions in which they are of the order of magnitude of the energy of Brownian motion or less.

III. THE FREE ENERGY OF CHARGED PARTICLES IN AN ELECTROLYTE SOLUTION

The first studies by the author of this review on the theory of stability were restricted to condition (9), i.e. to the condition where the potential φ_0 is small. The removal of this limitation and replacement of Eqn. (10) by the unsimplified Eqn. (6) was associated merely with computational conditions and was the subject of further studies[49-53]. However, the determination of the correct physical principles for calculations of the interaction between particles when their ionic double layers overlap and rigorous allowance for the van der Waals forces proved to be by no means trivial tasks, as shown by the errors in the 1939 publications by Levine[54-57] and Corkill and Rosenhead[58].

These workers adopted as their next task the calculation of the free energy of colloid particles. Knowing the dependence of the free energy on the distance between the particles, the interaction forces can also be found with some approximation by evaluating the derivative of the free energy with respect to distance. Many followers of these investigators concentrated initially on the calculation of the free energy of the system of charged particles in electrolyte solutions. In order to justify the advantages of this method of calculation on the interaction between colloid particles, Verwey and Overbeek wrote[59] "Serious difficulties arise in the subsequent integration (of the repulsive force) with respect to distance even for planar double layers. Indeed the force in the latter case is not a simple function of distance between the plates and it must therefore be integrated by numerical or graphical methods. In view of these difficulties, we investigated another simpler procedure: the determination of the free energy.... "

One cannot agree with these views, in the first place because the integration of the interaction force can be carried out analytically in terms of very general postulates, in particular when the potential is independent of the distance between the surfaces and when the density of the surface charge of the particles is independent of this distance[60-62]. If it were impossible to integrate analytically the expression for the force, it would also be impossible to obtain this expression in terms of the derivative of the free energy. The fundamental advantages of the "force method" are as follows:

1. The expression for the interaction force can be obtained very simply and rigorously from general and rigorous postulates of electrostatics and hydrostatics, using the familiar expression for the ponderomotive forces in an electric field.
2. The expression is independent of the type of variation of the potential for the surface charge with the distance between the particles and is therefore more general and fundamental.
3. It is easier to introduce corrections into this expression, taking into account the influence of dielectric saturation, the dense ionic layer, the mirror forces and the discrete nature of the ions, and the penetration of electric field into the bulk of the particles.

The history of the calculations of the free energy of the double layers surrounding particles showed that the establishment of the physical principles of these calculations involved considerable difficulties of both fundamental and mathematical kinds, and was fraught with many errors and obscurities. Apart from this, the expression for the free energy, in contrast to the expression for the interaction force, depends on the mechanism of the charging of

the surface particles and is of a different type, for example, in the two limiting cases where either the potential of the particles or the density of the surface charge is independent of the thickness of the intervening layer. It is particularly difficult to calculate the free energy in the case where the surface becomes non-isopotential as the particles approach one another, and the electric field penetrates into the bulk of the colloid particles.

It is therefore superfluous to calculate the free energy of the system in the theory of the interaction of colloid particles and the theory of the stability of colloids based on it, and it is incomparably simpler to employ directly the repulsion forces between particles.

However, the free energy of particles or electrodes immersed in an electrolyte solution is of independent interest. The history of the development of its calculation is extremely instructive and merits a critical consideration.

As stated above, the papers by Levine[54-57] and Corkill and Rosenhead[58] contain an incorrect expression for the free energy of ionic double layers and hence for the energy of the interaction between the particles when their ionic atmosphere overlap. It follows from the formulae derived that identically charged particles should attract one another over long distances, i.e. a qualitatively incorrect result was obtained.

The present paper[63,64] (1940) discovered the root cause of the error and indicated two correct methods for the determination of the free energy of charged particles in an electrolyte solution leading to the same expressions for the interaction forces as those found in his earlier studies[26,27].

The first, purely thermodynamic method is based on the expression for the differential of the free energy of the system of charged spheres immersed in an electrolyte solution. For simplicity, we shall assume that the surface of each sphere is isopotential and that each carries a charge e_i, which does not change in consequence of the ideal polarisability of the surface. Subsequently it will be shown that the combination of the requirements for an isopotential surface and the constancy of the overall charge can only apply approximately†. In a more rigorous treatment it is assumed that a constant potential has been specified on the surface of each particle and that the charge can vary when the ionic atmospheres overlap as the particles approach one another. This treatment corresponds to a different limiting case—the case of ideal non-polarisability of the surfaces of the particles, and obtains approximately if the potential is determined by the adsorbed ions for an extremely high specific energy of adsorption. Thus we can formulate an expression for the free energy of the system:

$$\mathrm{d}\Phi = \sum \varphi_i \mathrm{d}e_i - \sum (X_i \mathrm{d}x_i + Y_i \mathrm{d}y_i + Z_i \mathrm{d}z_i), \tag{34}$$

where φ_i and e_i are respectively the potential and the charge of the ith spherical particle, x_i, y_i, and z_i are its coordinates, and X_i, Y_i, and Z_i are the components of the external forces acting on it. The charges and coordinates of the particles, determining the state of the system when it is in equilibrium, constitute a complete set of its generalised coordinates provided that the surface of each particle is isopotential and non-polarisable.

Terms corresponding to the charges of the ionic atmospheres should not be introduced into Eqn. (34) as was done by Levine, because the coordinates of the ions forming the ionic atmospheres are dependent quantities, in contrast to the coordinates of the particles in the present author's approach, and are established as a result of thermal equilibrium. By integrating Eqn. (34) for fixed positions of the particles, we obtain

$$\Phi = \Phi_0 + \sum \int_0^{e_i} \varphi_i \mathrm{d}e_i, \tag{35}$$

where Φ_0 is the free energy corresponding to the state of the system with uncharged and non-interacting particles and therefore independent of the coordinates. Consequently the part of the free energy associated with the interaction forces is

$$F_e = \sum \int_0^{e_i} \varphi_i \mathrm{d}e_i. \tag{36}$$

The derivatives of F_e with respect to the distances between the particles for e_i = const. give rise to forces of interaction between them and the work performed in the mutual approach of the particles from infinity is given by the following expression according to Eqn. (36):

$$A = F_e - F_\infty = \sum \int_0^{e_i} (\varphi_i - \varphi_\infty) \mathrm{d}e_i. \tag{37}$$

For low potentials, when φ_i and e_i are proportional to one another, we obtain instead of Eqn. (36)

$$F_e = \frac{1}{2} \sum \varphi_i e_i. \tag{38}$$

The free energy F_e can be expressed in terms of the electric fields in the ionic atmospheres. On differentiating Eqn. (36) for constant values of φ_i and ϵ and expressing $\mathrm{d}e_i$ in terms of the value of $\partial\varphi/\partial n$ at the surface‡, we obtain

$$\mathrm{d}F_e = \frac{\varepsilon}{4\pi} \int \varphi \, \mathrm{d}\left(\frac{\partial\varphi}{\partial n}\right) \mathrm{d}S, \tag{39}$$

where n is the coordinate along the normal to the surface of the ith particle, and $\mathrm{d}S$ is an element of the surface; the integration is extended to the surface of all the particles.

Next, on transforming this expression with the aid of Green's theorem and Poisson's equation, we obtain

$$\mathrm{d}F_e = \frac{\varepsilon}{4\pi} \int \left[\frac{\partial\varphi}{\partial x} \mathrm{d}\left(\frac{\partial\varphi}{\partial x}\right) + \frac{\partial\varphi}{\partial y} \mathrm{d}\left(\frac{d\varphi}{\partial y}\right) + \frac{\partial\varphi}{\partial z} \mathrm{d}\left(\frac{\partial\varphi}{\partial z}\right)\right] \mathrm{d}n - \int \varphi \, \mathrm{d}\rho \, \mathrm{d}v; \tag{40}$$

the integration is carried out with respect to the entire volume of the electrolyte (where φ or grad φ are non-zero). Integration of Eqn. (40) yields

$$F_e = \frac{\varepsilon}{8\pi} \int |\mathrm{grad}\,\varphi|^2 \mathrm{d}v - \int_0^{\rho} \int \varphi \, \mathrm{d}\rho \, \mathrm{d}v. \tag{41}$$

The integral $\int_0^{\rho} \varphi \mathrm{d}\rho$ in the second term on the right-hand side of Eqn. (41) can be readily evaluated using the dependence of ρ on φ expressed by the Poisson–Boltzmann equation [Eqn. (6)]. When simplified Eqn. (10), used for low potential, is employed, Eqn. (41) becomes

$$F_e = \frac{\varepsilon}{8\pi} \int |\mathrm{grad}\,\varphi|^2 \mathrm{d}v + \kappa^2 \int \varphi^2 \mathrm{d}v. \tag{42}$$

†Incidentally the results depend also on where the surface separating the surface charge from the diffuse ionic atmosphere is drawn.

‡It is assumed that there are no fields within the particles, for example, by virtue of the isopotential nature of the surfaces.

The second term, introduced by the present author[63], is absent from Levine's equation[54,55], which explains why Levine obtained an incorrect expression for the interaction forces. It was also shown[63] that the free energy of the charged particles satisfies the Gibbs–Helmholtz equation:

$$F_e - T\frac{\partial F_e}{\partial T} = U_e = \left(\varepsilon + T\frac{\partial \varepsilon}{\partial T}\right)\frac{\int |\operatorname{grad}\varphi|^2}{8\pi} d v, \tag{43}$$

where U_e is the total internal energy—the increment in the total electrochemical energy which depends on the electric field. We shall now describe the derivation of Eqn.(43) for the simplest case of conducting particles whose charges have been specified. Denoting the temperature-dependent variation of the quantities by δ and applying Poisson's equation and Green's theorem, we obtain from Eqn. (41)

$$\delta F_e = \frac{\delta\varepsilon}{8\pi}\int |\operatorname{grad}\varphi|^2 d v - \frac{1}{4\pi}\int \varphi\varepsilon\delta\Delta\varphi\, d v - \tag{44}$$
$$- \int \varphi\delta\rho\, d v - \int d v \int_0^{\rho} \delta\varphi_\rho\, d\rho\, \frac{1}{4\pi}\varphi \int \varepsilon\delta\left(\frac{\partial\varphi}{\partial n}\right) d S$$

where $\partial\varphi/\partial n$ is the derivative with respect to the external normal to the surface of the particle and dS is an element of its surface. In the penultimate term on the right-hand side the integrand $\delta\varphi_\rho$, where φ_ρ is a function of ρ and T, corresponds to a constant value of ρ. We obtain from the Poisson equation

$$\frac{1}{4\pi}\delta(\varepsilon\Delta\varphi) + \delta\rho = 0. \tag{45}$$

The condition of a constant total charge on each particle yields

$$\int \delta\left(\varepsilon\frac{\partial\varphi}{\partial n}\right) d S = 0. \tag{46}$$

With the aid of Eqns. (45) and (46), the expression for δF_e can be put in the following form:

$$\delta F_e = \frac{\delta\varepsilon}{8\pi}\int |\operatorname{grad}\varphi|^2 d v + \frac{\delta\varepsilon}{4\pi}\int \varphi\Delta\varphi\, d v - \int d v \int \delta\varphi_\rho\, d\rho + \frac{\delta\varepsilon}{4\pi}\int \varphi\frac{\partial\varphi}{\partial n} d S.$$

Application of the Green's theorem yields

$$\delta F_e = -\frac{\delta\varepsilon}{8\pi}\int |\operatorname{grad}\varphi|^2 d v - \int d v \int \delta\varphi_\rho\, d\rho; \tag{47}$$

whence

$$\frac{d F_e}{d T} = -\frac{d\varepsilon}{d T}\cdot\frac{1}{8\pi}\int |\operatorname{grad}\varphi|^2 d v - \int d v \int \frac{d\varphi_\rho}{d T} d\rho. \tag{48}$$

The Boltzmann equation relates ρ and φ by an expression of the type

$$\rho = \omega\left(\frac{\varphi}{T}\right). \tag{49}$$

where ω is a function of φ/T. Consequently

$$\varphi = T\omega^{-1}(\rho), \tag{49'}$$

whence

$$\varphi - T\frac{d\varphi_\rho}{d T} = 0. \tag{49''}$$

Taking into account Eqn. (49), we obtain Eqn. (43) from Eqns. (41) and (48).

We shall now show that F_e, as given by Eqn. (41), is also obtained by an artificial procedure based on the consideration of an imaginary ion charging process and applied by Debye to the calculation of the electrical component of the free energy of strong electrolytes. The correct§ application of the Debye method for particles surrounded by ionic atmospheres has been described[63,64]. An analogous derivation (with certain differences) was described by Casimir[65]. The Debye method involves the consideration of the work of an imaginary process in which all the ions are charged simultaneously and at each instant the charges of the ions and of the particles are equal to the real charges multiplied by a parameter λ, which varies in the charging process from 0 to 1, but is independent of the coordinates of the given ion. As a result, the charge densities of the ionic atmosphere should vary in proportion to this parameter.

It is easy to show that, in calculations on the work of the charging process, which depends on the charges of the particles, it is sufficient to take into account only the macroscopic field around the charges (i.e. the average force potential), neglecting the microfields of the atmospheres around the individual ions, which are considered in the Debye theory of strong electrolytes. The elemental work dA of the charging process, corresponding to the increment $d\lambda$ in the parameter λ, is then given by

$$d A = \sum \varphi_i e_i d\lambda + \int \varphi_\lambda \rho_\lambda \frac{d\lambda}{\lambda} d v, \tag{50}$$

where e_i are the charges of the particles; the subscript λ shows that the corresponding quantities refer to the instant of charging, corresponding to the given value of the parameter λ. If the surfaces of the particles are not isopotential, e_i denotes the charges of elementary sections of their surfaces, and the summation sign Σ should be replaced by the integration sign with respect to the surfaces of all the particles. The charges of the particles play a role analogous to the charges of the ions, i.e. the surfaces of the particles behave during the charging process as ideally polarisable electrodes and their charges cannot vary as a result of adsorption.

One can therefore write

$$e_i d\lambda = e_{i\lambda}\frac{d\lambda}{\lambda} = d e_{i\lambda}. \tag{51}$$

On the other hand, one cannot put

$$\rho_\lambda \cdot \frac{d\lambda}{\lambda} = d\rho_\lambda \tag{52}$$

as in Levine's work[54-56], since the increment in the charge density in the ionic atmosphere with increasing λ takes place not only in consequence of the increase by $d\lambda/\lambda$ of the charges of the ions forming part of the ionic atmosphere at a given instant, but also in consequence of a redistribution of the ions between the atmosphere and the bulk of the solution. This redistribution takes place with increase of λ owing to the change in the constants a and α which depend on the ionic charge and relate in accordance with the Boltzmann equation the concentration of the ions in the double layer and the potential φ.

We shall now prove the relation

$$d A = d F_{e\lambda}, \tag{53}$$

where $F_{e\lambda}$ is the value of F_e in a hypothetical fictitious case, where the charges are reduced by a factor λ. In calculating $dF_{e\lambda}$ one must bear in mind that the relation

---

§An incorrect use of the Debye method in this case[54-56] led to a value of F_e different from that of the present author and agreeing with the value obtained when only the first term is retained on the right-hand side of Eqn.(41).

$\varphi(\rho)$ is also modified by virtue of the change in the constants a and α, which depend on λ.

We obtain from Eqn. (40) [the derivation is the same as that of Eqn. (44) but it is now assumed that $d\epsilon = 0$]:

$$dF_{e\lambda} = -\frac{\varepsilon}{4\pi}\int \varphi_\lambda d\Delta\varphi_\lambda dv - \int \varphi_\lambda d\rho_\lambda dv - \\ -\int dv \int_0^{\rho_\lambda} d\varphi_\lambda d\rho_\lambda - \frac{\varepsilon}{4\pi}\int \varphi_\lambda d\left(\frac{\partial\varphi_\lambda}{\partial n}\right) dS, \quad (54)$$

or, taking into account the Poisson and Gauss equations

$$dF_{e\lambda} = -\int dv \int_0^{\rho_\lambda} d\varphi_\lambda d\rho_\lambda + \sum_i \varphi_{i\lambda} de_{i\lambda}. \quad (55)$$

Taking into account the identity

$$\left(\frac{\partial\varphi_\lambda}{\partial\lambda}\right)_{\rho_\lambda} = -\left(\frac{\partial\varphi_\lambda}{\partial\rho}\right)_\lambda \cdot \left(\frac{\partial\rho_\lambda}{\partial\lambda}\right)_{\varphi_\lambda}, \quad (56)$$

we obtain instead of Eqn. (55)

$$dF_{e\lambda} = \sum_i \varphi_{i\lambda} de_{i\lambda} + \int dv \int_0^{\varphi_\lambda} d\lambda \left(\frac{d\rho_\lambda}{d\lambda}\right)_{\varphi_\lambda} d\varphi_\lambda. \quad (57)$$

According to Eqn. (6), ρ depends on the ionic charge z and hence also on λ via the coefficients a and α in the equation

$$\rho = af(\alpha\varphi). \quad (58)$$

which are proportional to the ionic charge. One can therefore easily demonstrate the identity

$$z\left(\frac{\partial\rho_\lambda}{\partial z}\right)_\varphi = \lambda\left(\frac{\partial\rho_\lambda}{\partial\lambda}\right)_\varphi = \frac{\partial\rho_\lambda\varphi_\lambda}{\partial\varphi_\lambda}. \quad (59)$$

On substituting Eqn. (59) in Eqn. (57) and integrating the latter, we obtain finally,

$$dF_{e\lambda} = \sum \varphi_{i\lambda} de_{i\lambda} + \int \rho_\lambda\varphi_\lambda \frac{d\lambda}{\lambda} dv. \quad (60)$$

The validity of Eqn. (53) follows from a comparison of Eqn. (60) with Eqns. (50) and (51). On integrating the latter in the range from 0 to 1, we obtain

$$A = F_e. \quad (61)$$

Thus the correct generalisation of the Debye method leads to the same correct Eqn. (36) for the free energy of the particles in the electrolyte solution.

The function F_e, specified by Eqn. (36) is, by virtue of Eqn. (7), the potential of the interaction of the particles in the electrolyte solution at a constant charge on each particle. However, Eqn. (41) can be used to find F_e, integrating with respect to the volume of the dispersion medium only, subject to the condition that there is no field within the particles when their surfaces are isopotential. However, on the sections of the surfaces whose ionic atmospheres overlap with the atmospheres of neighbouring particles, the isopotential condition is incompatible with the condition of a constant surface charge density[66,67]. Because of this, the constancy of the overall charge of the particle can be maintained when it approaches another particle only as a result of a change in the charge density on the sections of the surface remote from the overlap zone. However, on these sections, the local surface charge density, which is a function of the local potential, cannot vary as a function of the situation on the sections of the surface remote from it. Thus we conclude that in the case of real colloid systems with an electrolyte solution as the dispersion medium, in which we are interested, where the function F_e should be used in the calculation on the interaction arising following the overlap of the ionic atmospheres, it is impossible to reconcile the conditions of a constant charge and a constant potential. This constitutes the profound difference between this case and classical electrostatics where conducting particles immersed in a liquid dielectric are considered.

In the absence of isopotential conditions, part of the work expended on the charging of the surface of the particles, which is equal to F_e, is consumed in creating an electrostatic field within the particles. In this case appropriate corrections must be applied to Eqns. (39) and (42). Eqns. (43) and (61) remain unchanged, but their derivation must be modified by taking into account the presence of the field within the particles. The cases with a constant potential and a constant charge have been compared[68].

We shall now consider the interaction potential F_φ of the particles at a constant potential (but not charge) of each, which applies particularly to metallic particles with a polarisable surface. The work performed to alter the configuration of the system for constant potentials φ_i is coupled with the work necessary to alter the charges and performed against forces maintaining a constant potential. Consequently we must write instead of Eqn. (37)

$$A_\varphi = \sum \varphi_i^0 (e_i^\infty - e_i^0) = \sum \int_0^{e_i^0} (\varphi_i)\, d e_i - \sum \int_0^{e_i^\infty} \varphi_i d e_i, \quad (62)$$

where the superscripts ∞ and 0 denote the states of the system where the particles are separated by distances for which the ionic atmospheres do not and do overlap respectively, and φ_i^0 is the constant potential applied to the ith particle. On transforming Eqn. (62), we obtain instead of Eqn. (37)

$$A_\varphi = -\sum \int_0^{\varphi_i^0} (e_i^0 - e_i^\infty)\, d\varphi_i = F_\varphi^0 - F_\varphi^\infty. \quad (63)$$

whence it follows that the free energy of the system for a constant potential of the particles is

$$F_\varphi = -\sum \int_0^{\varphi_i} e_i\, d\varphi_i. \quad (63')$$

On differentiating this expression and carrying out transformations analogous to those used in the derivation of Eqn. (39), we obtain

$$dF_\varphi = -\frac{\varepsilon}{4\pi}\int \frac{\partial\varphi}{\partial n} d\varphi\, dS. \quad (64)$$

Application of Green's theorem yields

$$dF_\varphi = -\frac{\varepsilon}{4\pi}\int \left(\frac{\partial\varphi}{\partial x} d\frac{\partial\varphi}{\partial x} + \frac{\partial\varphi}{\partial y} d\frac{\partial\varphi}{\partial y} + \frac{\partial\varphi}{\partial z} d\frac{\partial\varphi}{\partial z}\right) dv - \frac{\varepsilon}{4\pi}\int \Delta\varphi\, d\varphi\, dS, \quad (65)$$

or, taking into account Poisson's equation and integrating, we obtain

$$F_\varphi = -\frac{\varepsilon}{8\pi}\int |\operatorname{grad}\varphi|^2 dv + \int dv \int_0^{\varphi} \rho\, d\varphi. \quad (66)$$

Here ρ is a function of φ, specified by the Boltzmann equation (3) or Eqn. (58).

Eqns. (64) and (66) differ from Eqns. (39) and (41), which express the free energy of the electric field in the electrolyte, because they take into account, apart from the energy of the field, the energy of the source of the charge used to maintain a constant potential of the surfaces of the particles.

We shall now prove that Eqn.(41) or (66) is equivalent to the system of tensions of the Maxwell electric field tensor to which an excess isotropic hydrostatic pressure has been added:

$$p = \int_0^{\varphi} \rho \, d\varphi. \tag{67}$$

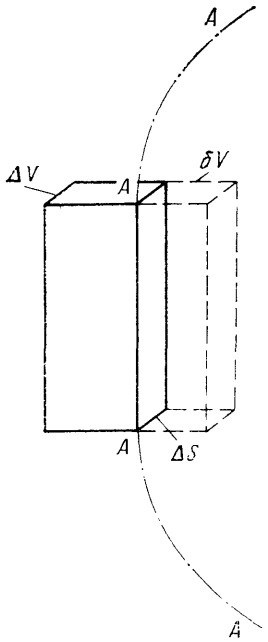

Figure 4. Derivation of the pressure tensor in an electrolyte surrounding charged particles.

We isolate from the total volume of the electrolyte a volume element Δv (Fig.4) and consider the virtual work performed in its expansion as a result of the displacement of a small section of its surface ΔS by a distance δh into the bulk of the remaining volume. The work expended in this process is converted into an increment of the free energy δF_{φ} of the remaining part of the system, in relation to which the volume V plays the role of the external medium:

$$\delta A = P\delta V = \delta F_{\varphi}, \tag{68}$$

where P is the total (including the corresponding component of the Maxwellian tensor) pressure on the given section of the surface of the volume and $\delta V = \Delta S \delta h$ is the volume increment ΔV when a section ΔS of its surface is displaced. The variation of δF_{φ} is given by the sum of two terms:

$$\delta F_{\varphi} = \delta_1 F_{\varphi} + \delta_2 F_{\varphi}. \tag{69}$$

The first term expresses the change in F_{φ} as a result of the loss of the field element δV and is therefore equal to

$$\delta_1 F_{\varphi} = +\frac{\varepsilon}{8\pi} |\operatorname{grad}\varphi|^2 \delta V - \int_0^{\varphi} \rho \, d\varphi \delta V. \tag{70}$$

The second term in Eqn.(69) expresses the change in F_{φ} occurring owing to the change in the potential φ over the entire volume of the system due to the shift of a section ΔS of the outer surface. The change $\delta_2 F_{\varphi}$ would be zero if, following the shift of the surface, its potential, having changed, acquires the value which existed hitherto at its new location, having received thereby the increment

$$\delta\varphi = \frac{\partial\varphi}{\partial n} \delta h, \tag{71}$$

where $\partial\varphi/\partial n$ is the derivative of φ with respect to the normal to the surface at the point under consideration.

However, the applicability of Eqn.(68) is determined by the maintenance on all the boundaries of the solution of the electrolyte AAAA (Fig.4) of a constant potential (this is recalled by the subscript φ in F_{φ}); in reality there is therefore no increment in the potential φ defined by Eqn. (71) and the new values of the potential at the new site on the surface S are reduced compared with the previous ones by an amount

$$\delta\varphi = -\frac{\partial\varphi}{\partial n} \delta h. \tag{72}$$

We can find from Eqn.(66) the change in F_{φ} caused by this factor:

$$\delta_2 F_{\varphi} = -\frac{\varepsilon}{4\pi} \int (\operatorname{grad}\varphi \cdot \operatorname{grad}\delta\varphi) \, dv + \int \rho\delta\varphi \, dv. \tag{73}$$

Application of Green's theorem yields

$$\delta_2 F_{\varphi} = \int \left(\frac{\varepsilon}{4\pi}\Delta\varphi + \rho\right)\delta\varphi \, dv + \frac{\varepsilon}{4\pi}\int \frac{\partial\varphi}{\partial n}\delta\varphi \, dS. \tag{74}$$

Taking into account Poisson's equation and Eqn.(72), we obtain

$$\delta_2 F_{\varphi} = -\frac{\varepsilon}{4\pi}\int \left(\frac{\partial\varphi}{\partial n}\right)^2 \delta h \, dS = \frac{-\varepsilon}{4\pi}\left(\frac{\partial\varphi}{\partial n}\right)^2 \delta V. \tag{75}$$

Finally, we find from Eqns.(75), (70), (69), and (68)

$$P = \frac{\varepsilon}{8\pi}|\operatorname{grad}\varphi|^2 - \frac{\varepsilon}{4\pi}\left(\frac{\partial\varphi}{\partial n}\right)^2 - \int_0^{\varphi} \rho \, d\varphi. \tag{76}$$

The last term on the right-hand side of Eqn.(76) expresses the excess isotropic hydrostatic pressure which is due to the electric field within the framework of the applicability of the Boltzmann equation and which depends on the field potential φ in accordance with the equation

$$p = -\int_0^{\varphi} \rho \, d\varphi = kT \sum c_i (e^{-\alpha_i\varphi} - 1), \tag{77}$$

which is applicable to any electrolyte including an asymmetric electrolyte.

The sum of the first two terms in Eqn.(76) expresses the pressure of the electrostatic field, which follows from the Maxwell tensor.

In the specific case of a plane parallel to the lines of force of the field, we have

$$P_{\parallel} = \frac{\varepsilon}{8\pi}|\operatorname{grad}\varphi|^2 + p. \tag{78}$$

The formula corresponding to a plane at right angles to the field vector is

$$P_{\perp} = -\frac{\varepsilon}{8\pi}|\operatorname{grag}\varphi|^2 + p. \tag{79}$$

It is important to emphasise that the values of the pressure P obtained are independent of the conditions governing the maintenance of the potential or charge when the surfaces

are displaced. Eqns.(78) and (79) can be undoubtedly obtained also by considering the function F_e.

Eqn.(79) agrees with Eqn.(1) which we used previously and confirms it.

According to its derivation, Eqn.(76) is applicable to any plane selected within the bulk of the electrolyte. This makes it possible to calculate the interaction forces between two particles by the summation of the pressure, expressed by Eqn.(76), over all the sections of any surface incorporating one of the particles or with respect to any infinite plan BB′ separating them (Fig.5). Indeed, according to Stevin's solidification principle, equilibrium cannot be infringed if part of the liquid, included between this surface and the particle which it incorporates, "solidifies" (without change in charge density and distribution). The condition for equilibrium in the solidified part requires that the forces balancing the pressures on the outer and inner surfaces bounding this region should be equal since the introduction of the Maxwell tensor excludes from consideration the long-range electrical forces applied to the charges of the ionic atmospheres. However, the force balancing the pressure on the inner surface is equal to the force acting on the particle itself. Mathematically it is most convenient to select the symmetry plane normal to the line passing through the centres of two identical spherical particles (BB′ in Fig.5) as the separating surface for two such particles. In this case one must integrate with respect to this plane the pressure expressed by Eqn.(78), which was done by the present author [63,64] and by Dukhin et al. [69].

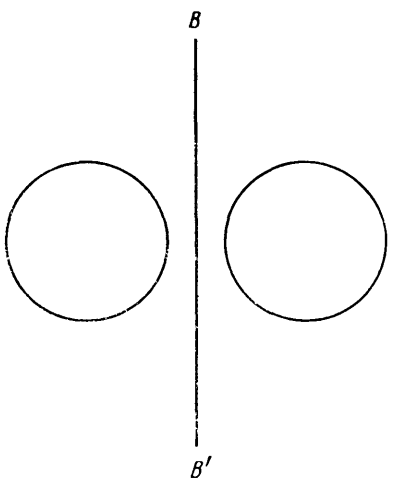

Figure 5. Calculation of the degree of interaction between spherical particles.

It follows from Eqn.(78) that the interaction of a sphere with a plane, which remains uncharged under all conditions, is the same as its interaction with another identical sphere. In addition one must take into account the fact that the boundary conditions in these problems are such that the distribution of the potential is the same in both instances. For two spheres charged to potentials which are equal but of opposite sign, it is possible to apply Eqn.(79) having put $p = 0$. Since the potential is zero at all points on the symmetry plane and p depends on φ in accordance with Eqn.(4) or (77), Eqn.(79) with $p = 0$ is also applicable to the calculation of the attraction is an electrolyte solution of a charged particle to the surface of a conductor with a zero potential. This case obtains, for example, in the electrophoretic coatings. We may note that Ikeda [70] arrived at the same expressions for the free energy and hence for the interaction forces of the particles in electrolyte solutions on the basis of a rigorously statistical method.

In conclusion of this section, we shall indicate a method for the calculation of the interaction forces between parallel plates in an electrolyte solution [72], which is based on a generalisation of the Gibbs–Duhem equation [71] in combination with the Poisson–Boltzmann equation. This method employs the most general postulates of thermodynamics and statistics, does not require the introduction of any additional assumptions, and does not use the Maxwell tension tensor and the distribution of the hydrostatic pressure in ionic double layers. For this reason, this is the most rigorous and general method, being at the same time very simple mathematically.

Further application of the above principles to the theory of the stability of lyophobic colloids has been described by the present author and Landau [52,53]. In contrast to previous reports, they calculated the repulsion forces from exact formulae obtained without linearising the Poisson–Boltzmann equation. At the same time, as in earlier studies [39,40], account was taken of the dispersion type attraction forces. For the interaction between plates separated by a plane-parallel layer of electrolyte, this implies that the wedging pressure of the layer [73–78] is considered as the sum of two terms—electrostatic and molecular (negative), which is characteristic of lyophobic systems. The degree of interaction between spherical particles was calculated on the basis of the interaction between plane surfaces by the integration method proposed previously [37].

It was shown that in the general case the curves describing the potential interaction energy can have, as before [26,29,39,40] (Fig.3), a potential barrier, which prevents particles from entering the potential well.

The present author and Landau [52,53] examined the limiting case of highly charged species and found conditions under which the potential and force barriers separating them vanish. The calculations were performed both for a symmetrical electrolyte and for electrolytes of the 1-2 and 2-1 valence types (the first numeral indicates the charge of the counterion). It was demonstrated by these examples that the charge of the coion has little effect on the stability of the sol. On the other hand, the charge of the counterion ez_1 determines the coagulation concentration m in accordance with the formula

$$m = C\frac{\varepsilon^3 (kT)^5}{A^2 e^6 z_1^6}, \qquad (80)$$

where A is the Hamaker constant and C a numerical coefficient, which depends only slightly on the valence of the coion. Thus the Hardy-Schulze rule, which states that the valence of the counterion has a dominant and a strong influence on the coagulation threshold, was explained.

The coagulation criterion (80), derived theoretically by the present author and Landau, is in good agreement with many experimental data which have accumulated in the last thirty years [79,80]. For convenience, it is frequently formulated in the form:

$$m \propto z_1^{-6}. \qquad (81)$$

In many instances deviations are observed, which can be accounted for by the lack of validity of the postulates underlying the derivation of this criterion: for example, the solvation of the surfaces of the particles and the failure of the condition that the Debye length is small compared with the radius of the particles. It is more difficult to explain why condition (80) is valid even when the dimensionless potential of the particle

$$\omega = \frac{z_i e\psi}{kT} \tag{82}$$

is small, so that one of the main conditions underlying its derivation does not hold. This question was considered particularly by Muller[81]. Glazman and Dykman[82,83] formulated the condition governing the applicability of the "law" defined by Eqn.(81) for moderate values of ω; this condition, which is of the form

$$\omega \propto z_i\varphi = \text{const}, \tag{83}$$

involves an inverse proportionality between the potential of the particle and the charge of the counterion. Us'yarov[84] demonstrated in relation to extensive experimental data that this condition holds satisfactorily in practice, and interpreted it theoretically.

It is noteworthy that the correct formulae for the repulsion forces between particles with a specified charge, separated by plane-parallel layers of electrolytes at any potential, have been developed by Bergmann et al.[49] in an attempt to explain the formation of the so-called "schiller" layers¶. These layers are formed after the sedimentation of lamellar particles of certain minerals in an electrolyte solution. The thicknesses of the layers separating the particles at different electrolyte concentrations can be determined from the interference colours visible in the light reflected from them. These thicknesses proved to agree more or less with theoretical calculations in which the pressure on the layer was calculated from the weight of the particles located above them. The effect of van der Waals forces was not taken into account, which apparently did not introduce a significant error. Bergmann et al.[49] confirmed experimentally the theory of the repulsion forces in electrolyte layers, but did not claim to have established a general theory of the stability of lyophobic colloids. The theory of the stability of lyophobic colloids was developed further by Verwey and Overbeek[31]. Their investigations were based on the principles described above. Apart from publication of a monograph on the subject, they can be credited with the study of the following problems:

1. The use of formulae for the repulsion forces between colloid particles charged to any potential.
2. The elucidation of the influence of the Stern correction, which takes into account the formation of a dense monolayer of adsorbed ions on the stability of colloids.
3. A theoretical determination of the principal characteristics of peptisation process.
4. Examination of the influence of the secondary (remote) potential well, first observed by the present author[39], on the aggregation and thixotropy of suspensions.

¶The name of these layers originates from the German word *schillern*, meaning to iridesce, which has apparently been long forgotten. On the erroneous assumption that this name is derived from the name of a scientist, they have come to be called Schiller layers.

IV. ALLOWANCE FOR MONOLAYER ADSORPTION

A correction taking into account the monolayer adsorption on the basis of the Stern or some other theory is of the most fundamental importance for the refinement of the theory of the stability of lyophobic colloids. On the basis of the Stern theory in a simplified form, Verwey and Overbeek arrived at the following conclusions.

In the Stern layer AA'SS' (Fig.6) there is a sharp decrease of potential (continuous UU' curve), which forces the potential of the diffuse layer to assume a Stern potential U' significantly smaller than the potential of the surface of the particle itself. This decrease of the potential eliminates objections to the employment in the theory of stability of the Boltzmann equation for potentials at which an unrealistically high concentration of ions is obtained. Furthermore, the introduction of the Stern correction improves the agreement between the theory and experiment, since it makes it possible to explain the dependence of the coagulating action of the counterions having the same charge on their chemical nature (their position in the lyotropic series). The Stern correction makes it possible to eliminate also a number of other contradictions, but some inconsistencies between theory and experiment nevertheless remained. Thus the Deryagin–Landau–Verwey–Overbeek (DLVO) theory explains the linear dependence of the logarithm on the concentration of the added indifferent electrolyte[86]. However, the experimental dependence of the slope of the plot of this function against the radius of the particles and the valence of the counterion does not agree with this theory[87].

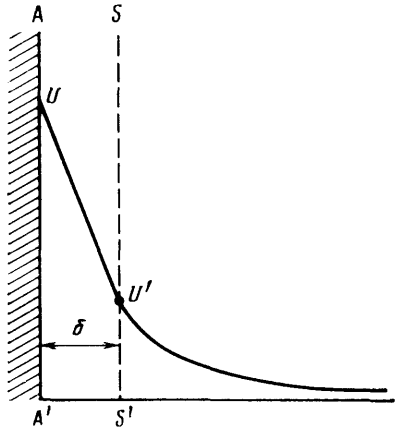

Figure 6. Distribution of the potential in the double layer near a charged surface.

An attempt to improve the DLVO theory by taking into account additional factors has been made by Martynov and Muller[88,89]. Their calculations include the earlier hypothesis that the presence of a molecular condenser shifts the plane corresponding to the beginning of the diffuse layer by a distance equal to its thickness δ relative to the interface (in their calculations the authors assumed that $\delta = 4$ Å). Thus the distance, inversely related to the van der Waals interaction, increases by 2 δ. The author's calculate that this can cause the near-by potential well to vanish

before the potential barrier under the influence of uni-univalent electrolytes. At a Stern potential exceeding 25–50 mV and at fairly high electrolyte concentrations, the near-by potential well disappears for similar values of the parameters for both planar surfaces and for spherical particles.

This conclusion conflicts with a multiplicity of experimental studies[6], which have firmly established the existence of two potential wells for electrolytes of different valence, including uni-univalent electrolytes, and for low concentrations and high potentials. The presence of a near-by potential well, protected by a potential barrier, has been observed particularly clearly in a study of the intracrystalline swelling of montmorillonite saturated beforehand by ion exchange with lithium, sodium, or potassium cations.[90] The problem has been studied theoretically by Serebrovskaya et al.[91] Comparison of the calculations with experiment showed that the quantitative discrepancies may be accounted for by the shear strength of the interlayer aqueous layers. Another possible cause, which reduces the thicknesses of the aqueous layers observed at low ionic strengths is, according to Van Olphen[92], adhesion of small crystals to the edges of other small crystals. Both explanations require further tests. There have also been a number of studies[93] indicating unambiguously the existence in various colloid systems of two wells separated by a barrier. For periodic colloid structures, the transfer of particles from the remote potential well to the near-by well is examined by direct microscopic observations[94,127].

The inconsistency between the conclusions in the literature[88,89] and experimental data is not surprising when the principles from which they were derived are examined more deeply. In the first place the concept of a molecular condenser whose charges are uniformly "smeared" over parallel planes is applicable in the introduction of a correction to the distribution of the potential (and hence to the repulsion forces) only at distances from the interfaces significantly exceeding the distance between neighbouring ions in the adsorption monolayer. Furthermore, the distance of the near-by potential well is known not to satisfy this necessary condition, particularly at electrolyte concentrations for which a barrier-free coagulation mechanism is said[88,89] to operate, because at these concentrations ($c \simeq 0.1$–0.15 M) the effective Debye thickness of the double layers becomes less than 10 Å. Furthermore, the limit of the applicability of the Poisson–Boltzmann equation, used for the double layer, is reached, since the distance between the surfaces and the near-by potential well becomes of the same order of magnitude as the distance between neighbouring ions of the molecular condenser, but with the thickness of the latter doubled. For this reason the use in this case of the concept of a molecular condenser with an arbitrary thickness in order to infer whether or not a near-by potential well is present is not justified.

This does not imply that the problem of the presence of the potential well cannot be the subject of theoretical calculations, but they must be performed differently taking into account in the first place the discrete nature of the structure of the monolayer of the adsorbed ions.

The last comment is of extremely general importance. The discrete nature of the adsorbed layer, made up of individual ions, must be taken into account also in other instances, for example, when the height of the potential barrier is considered at high electrolyte concentrations. The influence of the discrete structure of the surface charge on the interaction of the planes separated by a layer of electrolyte was taken into account for the first time by Yalamov[95], who used Levine's charging method as corrected by the present author. Using the same method, similar results were obtained recently by Richmond[96]. It was assumed in the above studies that ions are distributed on the surfaces in a strictly periodic arrangement among the sites of identical lattices, i.e. there is a rigorous correlation between the positions of the ions on both planes.

In contrast to these calculations, Deryagin and Muller[97] carried out an approximate stochastic calculation of the influence of the discrete nature of the structure of the dense part of the double layer on the interaction of parallel surfaces at short distances on the assumption that the correlation between the relative positions of the ions adsorbed on opposite surfaces are determined exclusively by the energy of the interaction of these ions in accordance with the Boltzmann equation. In other words, either the ions are adsorbed in a non-localised manner or the positions of the centres of adsorption on a single surface are in no way correlated with the positions of the centres of adsorption on the other surface.

Calculations performed on the assumption that the adsorption energy is small showed that the discrete but disordered distribution of adsorbed ions can reduce sharply the repulsion forces between surfaces over short distances and can thereby deepen the near-by potential well.

It is also important to take into account the discrete structure of the adsorption layer in the calculation of its influence on the Stern potential, i.e. on the potential in the plane from which the diffuse part of the double layer begins. Evidently this transition from the discrete lattice of the adsorption layer to the diffuse layer (treated in macroscopic terms), whose properties depend solely on one coordinate—the distance to the interface—cannot occur abruptly, especially directly on the surface of the outer plate of the condenser. Thus there should be a transitional layer between the molecular condenser and the diffuse ionic atmosphere with a thickness greater than that of the condenser itself. Its existence should alter the calculations of the potential outside its limits and in the diffuse double layer, especially within the transition layer. The thinner the layer of electrolyte, the greater the error in calculations where the effect of the discrete nature of the structure is ignored.

Without taking into account the discrete nature of the Stern layer, it is also impossible to devise a genuine quantitative theory of peptisation processes which, however, did not prevent a qualitative treatment of this phenomenon by Verwey and Overbeek[31] in accordance with experiments and a correct elucidation of its mechanism. Overbeek wrote later[98], "Quantitative studies in this field are lacking, which is to be regretted, since the peptisation phenomenon might yield information about the region of potential curves least accessible to study, corresponding to short distances between particles."

V. THE REVERSIBLE NATURE OF LONG-RANGE AGGREGATION

In their consideration of the problem of the role of the secondary (remote) potential well, Verwey and Overbeek[31] drew attention to the fact that it can be the cause of the formation of aggregates from primary particles only when the radius of the particle is approximately 1 μm and above, i.e. in suspensions. Only then is the depth of the remote

potential well sufficiently large compared with the energy of Brownian motion. Aggregation in the remote well is readily reversible owing to the absence of a barrier hindering the decomposition of aggregates. The aggregation process in the remote well is therefore rapidly balanced by the opposed deaggregation process and the authors used the Boltzmann equation in the following form in order to determine the degree of aggregation:

$$\Delta b = n_0 \int 4\pi a^3 s^2 e^{-V/kT} \, ds, \qquad (84)$$

where Δb is the fraction of aggregated particles, n_0 their total number, $s = d/2R$ (d is the distance between the centres of the particles and R their radius), and V is their interaction energy.

The authors [85] used $\Delta b \geqslant 0.1$ as the aggregation condition. On the basis of Eqn.(84), Martynov and Muller[88,89] found that rapid coagulation takes place when $\Delta b \gg 10$. However, they attribute a completely different significance to the concept of "rapid coagulation" in contrast to that associated with the kinetics of barrier coagulation. The degree of aggregation has been characterised[88,89] by the value of Δb, which depends significantly not only on the depth of the secondary potential well but also on the numerical concentration of the particles. We shall return to the problem of the role of the remote potential well in subsequent discussion of the question of quasi-equilibrium and equilibrium systems in which the particles are interrelated owing to these wells.

In principle, Eqn.(84) is applicable to the calculation of the degree of aggregation also due to the near-by potential well. The difference between the short-range aggregation and long-range aggregation consists in the fact that the corresponding equilibrium is established over a period the duration of which can be very large if the potential barrier is many times greater than the energy kT. Another, less fundamental difference is that the calculation of the interaction energy of the particles in the vicinity of the near-by potential well, for not unduly high electrolyte concentrations when the electrostatic interaction can influence its position and depth, is extremely difficult—one can actually say that so far it is virtually impossible. However, without such calculation, Eqn.(84) cannot be used for quantitative conclusions.

The calculation of the potential barrier and of the conditions for its disappearance is much easier. The results of our calculations, which have been introduced into Fuch's formula[26,38], made it possible to calculate the rate of slow coagulation. In order to test the theory, it is sufficient to measure the number of particles (including primary particles and aggregates) as a function of time. However, until recently these measurements were hindered by the lack of a sufficiently accurate, rapid, and convenient method for counting particles. The method based on the ultramicroscope counting of particles in a stationary volume is relatively unsuitable for this purpose. A number of new methods[99,100] are inconvenient because, owing to the low upper limit to the measurable concentrations, the measurement must be preceded by a high dilution of colloid systems with an optically clear solvent.

New possibilities arose after the development by the present author and Vlasenko of flow ultramicroscopy, initially for counting particles in aerosols[101-103]. Flow ultramicroscopes based on the same principle, for colloid systems with a liquid dispersion medium, have been developed by the present author and Kudryavtseva[104,105]. A series of studies on the kinetics of slow and rapid coagulation of red and blue gold sols have been carried out with the aid of a flow ultramicroscopic method[106,107] at different electrolyte concentrations; a version of the method using a laser has been published[108].

The results obtained permit the following conclusions.

At fairly high electrolyte concentrations the rate of coagulation expressed in terms of the variables $1/n$ and t, where n is the numerical concentration of the particles and t the time elapsed from the onset of coagulation, is expressed, in conformity with Smoluchowski's theory, by a straight line with a slope fairly close to the theoretical value. The deviations from theory can be explained in some cases by the operation of van der Waals forces and in others by deviations from Stokes' law when the particles which have approached one another to distances less than their radii move towards one another[109-111].

With decrease of the electrolyte concentration, the rate of coagulation not only falls but, "in conflict with both the Smoluchowski and Fuchs theories", the dependence of $1/n$ on t deviates increasingly from linearity, the curve becoming S-shaped. Fig. 7 illustrates examples of such relations. At a fairly low electrolyte concentration the reciprocal of the concentration of particles $1/n$, having increased with time by a factor of 2 or more, reaches fairly rapidly a value which remains constant for a long time. This time can increase to many days as the electrolyte concentration is reduced. After the elapse of a certain time, the quantity $1/n$ again begins to increase with t (at any rate for not unduly low electrolyte concentrations) and the curve rises more steeply. Towards the end, the slope of the curve tends to a more or less constant value.

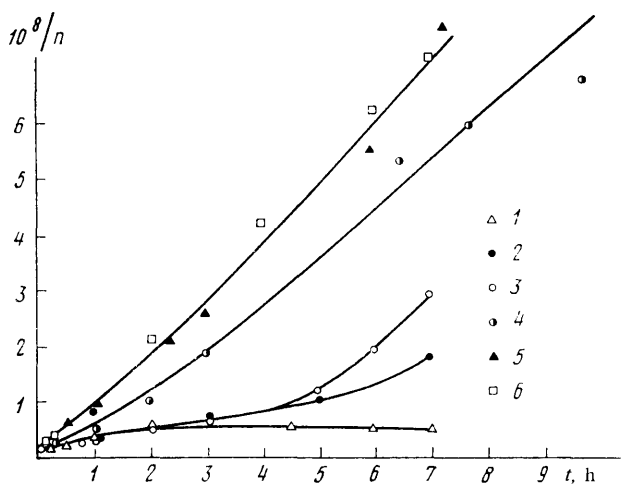

Figure 7. Relation between the reciprocal of the numerical concentration n and the time t. Silver iodide sol; $BaCl_2$ electrolyte; molar electrolyte concentration: *1*) $1.5 \cdot 10^{-3}$; *2*) $1.8 \cdot 10^{-3}$; *3*) $1.9 \cdot 10^{-3}$; *4*) $2.0 \cdot 10^{-3}$; *5*) $2.15 \cdot 10^{-3}$; *6*) $3.0 \cdot 10^{-3}$.

In order to explain this shape of kinetic coagulation curves, the present author and Kudryavtseva took into account the superposition of a deaggregation process on the aggregation process leading to the pairing of particles[106,107]. As a result, the kinetics of this stage of the

coagulation process become similar to those of a reversible bimolecular reaction and obey the differential equation

$$\frac{dn}{dt} = -kn^2 + l(n_0 - n), \quad (85)$$

where n_0 and n are respectively the number of particles at the initial instant and after time t and k and l are constants. The reasons why the equilibrium between the two process breaks down may be twofold:

1. At a certain instant an aggregate may be formed where the energy of the bonds between particles is greater than the energy of the bonds in the remaining aggregates as a result of a kind of collective interaction. For example, if each particle in an aggregate of three particles is linked to two others, then, as a result of the decreased probability of decomposition, the number of particles in the aggregate may subsequently increase rapidly. The growth of the aggregate may acquire the properties of an avalanche is each new particle added to the aggregate forms more than a single bond with any one particle in its condensation. The new state of aggregation equilibrium, at extremely low concentrations of individual particles, may be attained after a very long time.

2. Initially the pairing of particles may occur in the remote potential well. After some time they may pass to the near-by potential well, which sharply increases the bond energy. This facilitates the formation and growth of larger aggregates. It is noteworthy that the depth of the remote potential well for highly disperse sols is so small that the probability of such two-stage process is low.

The formation after a more or less prolonged "latent" period of larger aggregates, which serve, as it were, as effective coagulation nuclei, is clearly confirmed by visual observations in a flow ultramicroscope.

We may add that the cardinal difference between coagulation processes and typical processes involving the formation of new condensed phases consists in the possibility of bonds between particles in an aggregate corresponding to either the primary or secondary (remote) potential minimum. In the former case the barrier mechanism has no adequate analogue in condensation processes. Thus the activation energy for chemical condensation is not determined by the need to overcome repulsion forces as a result of thermal motion, but is caused by the low probability of collisions leading to the activated complex. This difference must be specially emphasised, since any attempt to minimise the fundamental differences between colloid and true solutions interferes with the development of colloid science as an independent discipline and with the discovery of its characteristics.

As stated at the beginning of this review, another characteristic difference between colloid systems and molecular solutions is the existence of two different types of equilibrium—the aggregation equilibrium and the equilibrium of the disperse phase composition. Kudryavtseva et al.[113] reported observations of equilibrium between the coagulant and single gold particles at a numerical concentration of the latter of the order of 10^6 cm^{-3}. However, this does not allow any general conclusions about the reversibility of hydrophobic sols, because, in view of the characteristics of the method developed by Sigmund for the preparation of the red gold sols, a certain degree of hydrophilisation of the surface of its particles due to the adsorption of organic molecules is probable. Owing to the high degree of dispersion of the gold sol, even when reversibility is observed, its aggregation under these conditions occurs after the passage through the barrier to the near-by potential well, including the process under the influence of univalent electrolytes. In other cases metal sols apparently coagulate virtually irreversibly.

An important further development of the theory of the stability of lyophobic colloids involves its application to a mixture of electrolytes. In view of lack of space, we refer the reader to the relevant literature[114-121].

VI. LANGMUIR'S THERMODYNAMIC CONCEPT OF COACERVATION AND COAGULATION PROCESSES

We shall now consider Langmuir's interesting attempt[122] at a thermodynamic approach to changes in the state of highly disperse colloid systems such as colloidal electrolytes. By analogy with the phase equilibria in molecularly disperse systems, for example, solutions, Langmuir considered temperature, numerical concentration, and osmotic pressure as the thermodynamic parameters of such systems. The expression borrowed from the Debye–Hückel theory of strong electrolytes is used for the osmotic pressure p:

$$p = kT\sum n_i - \frac{e^2\varkappa}{6\varepsilon}\sum_i n_i z_i^2, \quad (86)$$

where n_i is the concentration of ions with a valence z_i. The second term on the right-hand side of the equation expresses the decrease of the osmotic pressure caused by collective electrostatic interaction forces of all the charged particles and ions in which the influence of attraction forces predominates, which accounts for the sign of this term (because $\Sigma n_i z_i^2 > 0$).

Thus Langmuir treats colloid particles as large multicharged ions with a fixed charge. At the same time he considers the limiting case where no ions other than counterions are present in solution. However, Langmuir assumes that, with increase of the concentration of colloid particles, their charge falls owing to the conditions of a constant potential on the surface of the particles. As a result, Langmuir concluded that the dependence of the osmotic pressure on concentration is analogous in form to the van der Waals equation for real gases. From this, it follows immediately that, as the concentration of the sol increases, it may separate into two sols at different concentrations, which are in equilibrium. Langmuir postulates that one can explain in this way not only the coacervation of proteins but also the coagulation of lyophobic sols.

Langmuir's theory was subjected to a serious criticism in the book of Verwey and Overbeek[123], which was not answered. In particular, it was noted that, with increase of the charge of any ion, the applicability of the linearised Debye–Hückel equation is impaired. On the other hand, for the particles of a sol or a colloidal electrolyte, this equation leads to completely incorrect results. When Langmuir's theory is applied to ordinary electrolytes to determine their solubility, the ascending section of the $p(n)$ curve is determined by Born forces and not by the operation of ionic-electrostatic interaction forces.

The following may be added to Verwey and Overbeek's criticism of Langmuir's theory. Coagulation is a process in which a colloid system passes from one state to another under significantly non-equilibrium conditions and is characterised either by the aggregation of particles or by a decreased degree of dispersion as a result of their coalescence. The thermodynamic approach based on the

concentration dependence of the osmotic pressure cannot therefore be adopted for the determination of the rate of coagulation and for predicting its practical feasibility (when the rate is not unduly low).

Calculations on coagulation, according to Smoluchowski and Fuchs, must be based on a procedure taking into account the pair interaction forces between colloid particles approaching one another. In such approach of two particles the distances between the counterions surrounding them and between the counterions and colloid particles do not in any way change in the same proportions as in the phase transitions considered by Langmuir. The deformations of the ionic atmospheres around both particles are determined on the basis of the Boltzmann–Poisson equation taking into account the electrical interaction. In the approach of two identical colloid particles surrounded by ionic atmosphere repulsion is therefore never replaced by attraction.

The difference between the signs of the interaction in Langmuir's theory and in the theory of the pair interaction between particles can be explained by the fact that in the former case the interaction is regarded as a collective effect while in the latter it is a pair effect. The interaction force between particles in the former case is obtained by differentiating the Gibbs free energy of the system, for a constant volume of the dispersion medium, with respect to the concentration (or volume) of the entire system of particles including counterions. The interaction force in the latter case is obtained by the partial differentiation of the free energy of the system with respect to the distance between two isolated particles, assuming that the concentration of the surrounding particles and counterions is unchanged. Thus the difference between the signs of the two effects is not a contradiction. Hence it follows that Langmuir's approach is in principle inapplicable to the development of the theory of the coagulation of colloids. Despite this, Langmuir's work is valuable because he was the first to draw attention to the problem of phase equilibria and transitions in colloid systems. Consequently, it is appropriate to formulate the question of the existence not only of the aggregation equilibrium or equilibrium disperse phase composition, but also of the phase equilibrium, which may break down without a change in the degree of aggregation or dispersion owing to a change in the numerical concentration of particles—an increase in their density.

VII. THE FORMATION AND STABILITY OF PERIODIC COLLOIDAL STRUCTURES†

If one disregards the defects pointed out Verwey and Overbeek, Langmuir's thermodynamic approach can apparently be applied not only to the treatment of coacervation, i.e. the separation of a colloid system into two "phases" with different concentrations, but also to a number of other processes, for example, processes such as the formation of certain periodic colloidal structures (PCS). The question of the conditions governing the formation and stability of PCS is very complex and has been inadequately worked out. We shall therefore confine ourselves to the folowing general considerations without a detailed discussion, the reader being referred to the relevant literature[93,124-127].

†This chapter was written jointly with I. F. Efremov.

The fundamental characteristics of the formation and behaviour of different types of PCS were established as a result of the extension of the DLVO theory to processes involving the conversion of sols, suspensions, and emulsions into gels[128-130]. It was shown that, as a result of the interaction between micro-objects over long distances, different (depending on the conditions) regular structures are generated.

Periodic Colloidal Structures Filling the Entire Volume of the System

Their quasi-crystallinity has been confirmed by numerous experimental data, including direct observations of coexisting hexagonal and cubic lattices in concentrated latexes[131]. In these systems the repulsion forces between the particles, which are stable in relation to direct adhesion to one another, usually exceed the attraction forces[132-134]. Thus "constrained" conditions arise in the system, under which the average distance between the surfaces of the particles is smaller than that corresponding to the second minimum on the potential curve for their pair interaction[124].

The spontaneous transition of individual particles from the secondary to the primary minimum can gradually cause the breakdown of the regularity of the structure (Fig.8) up to the complete disappearance of "crystallinity". However, for very high potential barriers (of the ionic-electrostatic or solvation type), the state of the system approaches equilibrium, which is the reason for the prolonged maintenance of order in it.

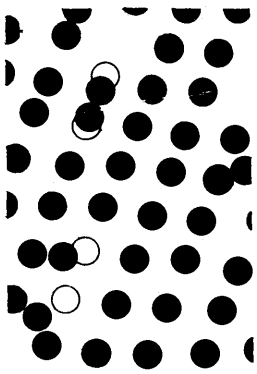

Figure 8. Defects in the periodic lattice of polystyrene particles with a radius of 950 Å caused by the transition of the particles through the potential barrier to the primary minimum.

Periodic Colloidal Structures Filling Part of the Volume of the System

These are tactoids—gel-like deposits. Under appropriate conditions, the local ordered structure in such formations coexists with a "phase" in which the particles are distributed at random, as in an ordinary dispersion medium (a sol or a suspension), but with a definite homogeneous numerical concentration. In some cases this

concentration is not much less than the numerical concentration of the PCS, while in others it is much less and sometimes becomes virtually zero.

The formation of local ordered structures is possible in two cases: when the attraction forces predominate over repulsion forces and when constrained conditions arise.

Owing to the predominance of attraction forces over repulsion forces at long distances and the maintenance of a force (potential) barrier, in the former case the particles may remain fixed for a long time relative to one another owing to the remote potential well. The fixation of micro-objects at the secondary minimum (long-range aggregation) has been observed a comparatively long time ago by numerous investigators and has been confirmed by the results of a large number of studies published recently and undertaken to investigate the influence on long-range aggregation by electrolytes, the size, shape, and concentration of colloid particles, and external electric and magnetic fields, which enhance the attraction forces between the particles [126]. The distribution of particles between the ordered and amorphous "phases" depends on the concentration and valence of ions, the concentration, size, and shape of the particles, the nature of the medium, etc.

The experimental data obtained by various investigators confirm the theoretical conclusions. In particular, the following law holds satisfactorily:

$$nz^{\chi}=\text{const},$$

where n and z are the concentration and valence of the counterions, expressing the influence of electrolytes on the aggregation threshold at the secondary minimum. The theoretical and experimental power exponents χ for both rapid coagulation ($\chi = 6$) and for long-range aggregation ($\chi = 2.5-3.5$) are in good agreement [127].

In the latter case the ordering of the structure takes place under the influence of external, including electrical, forces owing to the appearance of constrained conditions at some place in the stable dispersion, which is associated with the increase of the local concentration of colloid particles. Such PCS include "schiller" layers, gel-like deposits, formed in certain disperse systems, and also cream. In practice, such conditions are generated by the wide-scale application of centrifugal fields to dispersions [135, 136]. To a first approximation, one can assume that these fields do not alter the magnitude of the forces acting between surfaces which have approached one another. The structures arising under these conditions are analogous to the PCS with a limited volume of the medium and accordingly exhibit a ready reversibility; they can serve as model systems in the study of the formation and properties of PCS under constrained conditions.

It is of interest to investigate the distribution of particles between the ordered and disordered "phases" in the field of centrifugal forces as a function of the properties of the system and the field parameters. Concentrated "phases" (for example, electrophoretic coatings) with the required densities and other properties are obtained similarly with the aid of electrical and magnetic fields.

The possibility of equilibrium between a quasi-crystalline "phase" and an "amorphous phase" at a lower concentration has been demonstrated theoretically by Kirkwood [137] and confirmed by the results of the computer experiments of Alder et al. [138] According to these studies, a model system made up of identical solid spheres (or discs), between which there are no long-range forces (attraction or repulsion) of any kind, forms a periodic quasi-crystalline lattice when the volume of the system is half filled. According to Kirkwood's theory, this ordering is a paradoxical consequence of the purely random motion of individual particles. The authors noted that this quasi-crystalline "phase" can exist in equilibrium with the "amorphous phase" at a somewhat lower concentration.

Some investigators have used the purely statistical Kirkwood–Alder approach to explain the formation of quasi-crystalline structures in latexes. Thus aqueous dispersions of polystyrene with a volume fraction of the solid polymer less than 0.4 were found to separate into "phases" in the presence of an electrolyte [139]; in benzene dispersions of poly(methyl methacrylate), which swell appreciably in benzene, such layer formation occurred at a volume fraction of polymer particles of 0.1–0.2. [140] Finally, a highly concentrated polystyrene latex was obtained by the ultrafiltration (under a press) of the initial latex stabilised by surfactants and subsequent addition of large amounts of the electrolyte. At a KCl concentration of approximately 1 M an ordered "phase" with an effective volume fraction of the polymer of approximately 0.5 is formed. It is believed [141] that the results of these experiments confirm the validity of the Kirkwood–Alder theory.

Unfortunately the authors of these in general interesting studies [139–141] characterised a dispersion only to a very slight extent (the potential of the surface of the particles in dispersions with a low concentration of ions, the electrical conductivity of the medium, the degree of swelling of the particles, etc. are not indicated). Nor are there any data showing how the concentration of the disordered "phase" varies with time. A doubt therefore arises as to the reliability of the explanation of the results given by the authors on the assumption that there is no force interaction. Furthermore, in the presence of a lower electrolyte concentration, that of the quasi-crystalline phase diminishes. The authors nevertheless believe it possible to apply the Kirkwood–Alder theory to the systems investigated when the true volume of the particles is replaced by their "effective" volume, which exceeds the former owing to repulsion forces due to diffuse ionic layers.

This cannot be accepted, since the Kirkwood–Alder theory was derived for solid spheres in the absence of repulsion forces with a finite radius of action. Cases where the distances between neighbouring particles significantly exceed the distances indicated by the theory as a consequence of the ionic-electrostatic repulsion should evidently be interpreted in terms of another theory where the structure forming factor is the repulsion forces as well as molecular attraction forces. Such comparatively dilute periodic colloidal structures have been known for a long time [94, 125] and have been observed by the authors [143] themselves. Bernal and Fankuchen [142] observed in an early study, for example, that the average distance between the particles of the tobacco mosaic virus increases steadily with decrease of the electrolyte concentration, which is a consequence of the increasing radius of action of repulsion forces. They assume that in these periodic structures each particle executes an oscillatory Brownian motion about positions in which the repulsion forces, arising from neighbouring particles, are in mutual balance. Evidently particles located at the boundary with another much less concentrated "phase" cannot be in balance if they are acted upon only by repulsion forces from the side of neighbouring particles. The equal force opposing them will expel particles located on the boundary to the outside, i.e. to the less concentrated phase. However, equilibrium is possible if long-range attraction

forces operate together with repulsion forces. Quantitative calculations on conditions for such equilibrium, taking into account the theory of electrostatic repulsion forces and molecular attraction forces, have been described[127]. The separation into phases in the coacervation of sols consisting of rod-like particles, leads to the appearance of an anisotropic phase (tactoids) analogous to nematic liquid crystals. An example is provided by the quasi-crystals of the tobacco mosaic virus[142,144].

A theory of this phenomenon was described by Onsager[145], who also began with the calculation of the osmotic pressure and the chemical potential of the colloid system. This treatment is based on the general expression taken from statistical mechanics:

$$p = kT\frac{\partial \ln B}{\partial V}, \qquad (87)$$

where V is the volume of the system and B is given by

$$B(N, V, T) = \frac{1}{N}\int \exp\left(-\frac{W_N}{kT}\right)\prod_{i=1}^{i=N}(\mathrm{d}q_i); \qquad (88)$$

here N is the number of particles and W_N the potential energy of the interaction of the particles, which depends on their configuration, determined by the generalised coordinates q_i.

In contrast to Langmuir, Onsager considers the case of non-spherical particles, in particular rods and discs. In the calculation of the function B Onsager uses the Mayer–Mayer method[146], neglecting, like Langmuir, the van der Waals forces and also, at the beginning of his exposition, the ionic-electrostatic repulsion forces, but he does take into account the repulsion forces arising on direct contact between the particles. At the end of fairly complex calculations, Onsager found that the system can separate into two stably coexisting "phases": isotropic and anisotropic. At equilibrium the concentration of the latter is higher than that of the former by a factor of 1.34, which is close to the experimental data. For such separation to occur, the volume fraction of the sol particles must be higher than a definite limit where the influence of the effective volume of the particles on the osmotic pressure becomes sufficiently significant. An important result of the Onsager theory is that the greater the deviation of the particle from the isometric shape (for which the effective volume is equal to four times the intrinsic volume of the particles), the lower the volume fraction of the particles in the system for which separation into "phases" is observed. Thus, for rod-like particles, the critical volume fraction, above which the differentiation of an anisotropic phase with oriented particles is observed, is inversely proportional to the ratio of the length of the particles to their diameter. The ability of a sol with extended particles to form tactoids was thus explained.

Later in his communication[145] Onsager takes into account the influence of the ionic-electrostatic repulsion forces, which he neglected at the beginning. For sols with rod-like particles, this leads to the conclusion that, in the calculation of the critical concentration for the onset of coacervation, the effective diameter of the particles must be increased by an amount δ, which is approximately proportional to the thickness of the ionic atmospheres. As a result, the "effective" volume fraction of particles increases to the critical theoretical value for a lower actual volume fraction. This effect, facilitating coacervation in systems with rod-like particles as the electrolyte concentration decreases, has also been observed experimentally.

This effect, discovered by Onsager, should depend, on the one hand, on the influence of the rotational Brownian motion of anisometric particles on the osmotic pressure and, on the other, it should depend on their orientation. Nevertheless, there is no quantitative agreement between the theory and experiment in terms of certain data[147]. Isachara developed the theory for systems with spherical particles[148,149].

It must be emphasised that colloidal quasi-phases, analogous to ordinary phases, constitute an unusual special case. Its manifestation requires primarily the maintenance of approximate monodispersity and certain concentration and temperature ranges. Its occurrence does not constitute a reason for underestimating the fundamental differences between disperse, typically heterogeneous systems, with the characteristic variability of the degree of dispersion and the decisive role of surface phenomena at interfaces, and ordinary single-phase systems.

VIII. MICELLAR SOLUTIONS

The fundamental difference between colloidal and true or molecular solutions noted above does not rule out the existence of semicolloid systems, occupying an intermediate position. These include micellar solutions. They are quite stable thermodynamically and at the same time exhibit a definite degree of dispersion, which can vary as the temperature and composition are altered. The micelles exhibit a certain scatter with respect to the molecular (more correctly micellar) weight, although it is frequently very small. In connection with the existence of micellar solutions, it is appropriate to consider the general problem of the possibility and conditions for the existence of thermodynamically stable disperse systems. This problem has been formulated in the following simplified form[150–153]. It is required to satisfy the conditions for the existence of a minimum in the free energy of a monodisperse system in relation to a virtual change in the latter such that the size of the particles is altered but the monodispersity is maintained. Naturally, this type of equilibrium has nothing in common with the equilibrium of periodic structures. Evidently the required conditions are necessary but not sufficient, since there remains the possibility of a spontaneous breakdown of monodispersity.

One of the conditions isolated by Kachanova et al.[161] is

$$\sigma \ll \frac{\gamma kT}{R^2}, \qquad (89)$$

where σ is the free energy per unit interface between particles with a radius R and the dispersion medium and γ is a numerical coefficient.

The significance of this condition is that, for fairly low values of σ, there is no tendency for the degree of dispersion in the system to decrease during ageing, since the decrease of the free surface energy in such a process is compensated by the increase of entropy. However low (but finite) is the value of σ, condition (89) can hold only if the radius of the particles is smaller than a certain value. The spontaneous dispersion of an arbitrarily coarse phase can therefore occur only as a result of the separation from the latter of sufficiently small particles, which can occur, in particular, as stated by Rebinder and coworkers[152,153], owing to internal stresses, the liberation of the energy of which makes it possible to overcome the activation energy barrier, which prevents such "colloidal dissolution".

However, it has been noted[151,154] that condition (89) must be supplemented by another condition, which, in contrast to the first, might hinder an unlimited increase of the degree of dispersion up to the formation of a true solution. This condition has been formulated[154] as follows:

$$-\frac{\partial \ln \sigma}{\partial \ln R} > 2. \qquad (90)$$

We shall consider the problem of the kind of systems for which this condition can hold. According to Shcherbakov[155] (see also Tolman[156]), the dependence of the free surface energy on the radius of spherical particles for one-component systems satisfies the relation

$$-\frac{\partial \ln \sigma}{\partial \ln R} = -1, \qquad (91)$$

which is incompatible with condition (90). At the same time this incompatibility with condition (90) may not obtain for three reasons. Firstly, condition (91) is valid only in the asymptotic case where $R \to \infty$. Secondly, both conditions may be modified in multicomponent systems. Thirdly, condition (91) has been derived for molecules interacting on the basis of central forces and is presumably inapplicable to diphilic molecules (for example, the molecules of soaps), the opposite ends of which exhibit affinity for phases of different polarity.

It is noteworthy that the derivation of equilibrium conditions was not accompanied by the analysis of the problem of the particular systems for which these conditions can be realised. This question is undoubtedly very difficult to resolve but is also the most important. We shall therefore now return to experimental results.

Only two types of fully (thermodynamically) stable colloidally disperse systems have now been firmly established—critical emulsions and micellar solutions. The theory of critical emulsions was first described by Volmer[157-159] and was improved by other workers[150,160,161]. However, the instability of the droplets of such emulsions has more in common with associated species in polar liquids than with stable colloid particles. Critical emulsions can therefore be hardly classified as colloid or even semicolloid systems.

Micellar solutions, to which soap solutions‡ belong, for example, are of great practical importance, being extremely varied and usually consisting of two or more components, at least one of which exhibits a high surface activity.

The literature devoted to micellar solutions is extremely extensive and contains many theoretical studies. In this review we are unable to discuss them and we shall confine ourselves solely to remarks of a general nature on the problem of the stability of disperse systems. Micelles are known to have different shapes, usually spherical, cylindrical, or lamellar[162]. The surface of cylindrical micelles is non-isotropic (has no circular symmetry) and the properties of the directions along the generatrices of the cylinder differ from those of the directions along the tangents to the perimeters of the normal sections. This can be explained in many instances by an orientation of the dipolar molecules on the surface such that the projection of the dipole moment of the molecules onto the surface of the micelle§ coincides with one of these two directions. For highly extended micelles, these projections should be tangential to the perimeters of sections of the cylindrical surface, according to the conditions for the free energy minimum[164], forming closed chains, and for this reason the external electrostatic field is extremely weak. At the same time if it is assumed by analogy with formula (90) that the formation of a micellar solution from a molecular solution is associated with the dependence of σ on the surface curvature, then, in order to apply Eqn.(91) to cylindrical micelles, it must be generalised by introducing the derivatives of the free interfacial energy with respect to the principal radii of surface curvature, one of which is zero and the other is equal to $1/r$ (r is the radius of the micelle).

IX. THE FORMATION AND STABILITY OF LIQUID FILMS

It is well known that many micellar solutions form liquid-crystal, for example smectic, phases in a particular range of concentrations and temperatures[167,168]. Such systems resemble a layer cake (Fig. 9). Some layers (*W*) consist of the polar, in most cases aqueous, phase, while others (*C*) consist of the hydrocarbon phase; at the interface there are layers of diphilic surface-active molecules oriented with the polar end towards the aqueous phase. The layers of hydrocarbon phase are frequently absent and only oriented bimolecular layers of diphilic molecules (analogous to lipid membranes) are located between adjoining layers of the aqueous phase. The system as a whole has a one-dimensional periodic structure.

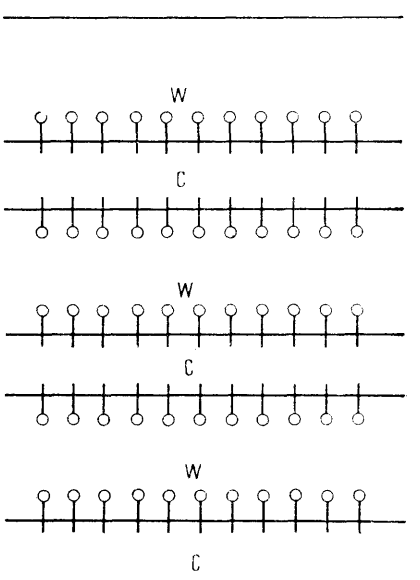

Figure 9. Schematic illustration of a one-dimensional periodic micellar solution.

‡Attention has recently been concentrated on stable microemulsions. They are in essence a variety of micellar solutions.

§The existence of this type of inclination of dipole monolayers is well known and in addition follows from the electro-optical studies of Tolstoi and Spartakov[163,164]; the theory of this phenomenon has been described by Deryagin and Shulepov[165,166].

The same solutions are capable of forming stable thin symmetrical films of the type of foam[169], whose thickness at equilibrium differs, however, from the repeat period of the above liquid-crystal structures even when the latter do not contain non-polar layers[170].

Evidently the task of the theory is to explain the cause of the formation and stability of both smectic structures of this kind and of isolated symmetrical films. The thermodynamic stability of free films, ensured by equilibrium between capillary suction and the wedging pressure, was first demonstrated by Deryagin and Titievskaya[171,172]. In the first place the problem arises of the nature of the repulsion forces which balance the van der Waals component of the wedging pressure, tending to make the layers thinner, and ensure thereby an equilibrium polymolecular thickness of the aqueous layers. The equilibrium thickness of the so-called primary free films, observed at low electrolyte concentrations, is largely determined by ionic-electrostatic repulsion forces and amounts to several hundreds of Angstroms. The primary films are metastable and under certain conditions are either ruptured or are abruptly converted into secondary or Perrin films. Under certain conditions both types of behaviour can coexist, being separated by an interface (in the form of a circle or its arc) at which the thickness of the film changes abruptly[174,175,195]. The secondary films observed at high electrolyte concentrations, at which the electrostatic component of the wedging pressure is infective, have a thickness of approximately 20–60 Å.[173-178]

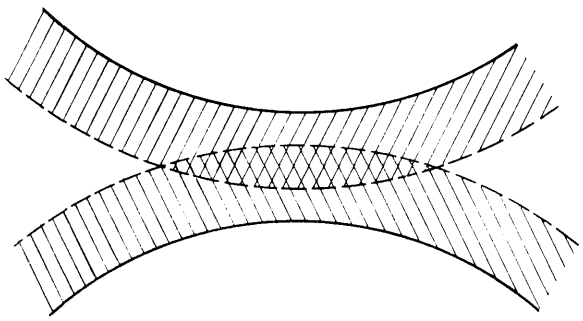

Figure 10. Schematic illustration of the overlap of surface layers.

In the light of the results of a series of experimental studies[179-182], one of the causes of aqueous layers retaining their thickness may be the structural component of the wedging pressure. In essence the same idea was put forward by Clunie et al.[183]. The origin of this component is as follows. The water layers at the interface between the aqueous phase and the hydrophilic surface or hydrophilic functional groups of the molecules adsorbed at the interface acquire under the influence of the latter a structure different from that in the bulk phase. The difference may consist, for example, in a modification of the network of hydrogen bonds and also in the polarisation of the molecular dipoles, which should be promoted by the oriented adsorption of diphilic molecules[184,185]. When the water layer becomes thinner, the boundary layers belonging to both surface layers may overlap (Fig. 10). This overlap should entail the disruption of the unusual structure of the peripheral parts of the boundary layers which leads to an increase in the amount of water with the properties of the bulk phase. This process initiates a change in the free energy of the system, which is inevitably associated with the generation of the wedging pressure. The role of the structural characteristics and the stability of secondary films is confirmed by the fact that aqueous solutions of surfactants, stabilising these films, are capable for forming liquid-crystal phases.

The secondary films are disrupted by the formation of a point break, or spontaneously, or under the influence of a spark, or on passing from α-rays.[169]

The theory of the rupture of secondary films, in the simplest case where the process is unaccompanied by local changes in thickness and takes place in only two dimensions, was developed by Gutop and Deryagin[197]. It is noteworthy that the assumption of a purely two-dimensional flow of all sections of the film during nucleation (the formation of a nuclear hole) constitutes a fairly rough first approximation. This approximation is altogether inapplicable to the primary thicker films, which greatly complicates the construction of a rigorous theory of their rupture or conversion into secondary films.

Theories permitting the calculation of the critical thicknesses and other conditions for the spontaneous conversion of primary films into secondary films have been developed in a number of studies[198-203], but these cannot be described here.

One of the important tasks of the theory of the stability of disperse systems consists in the development of a quantitative theory of the structural component of the wedging pressure. The main difficulty in this task is associated with the fact that the nature of the structure of water, even in the bulk phase, is controversial and cannot be regarded as reliably established.

Another example of a quasi-disperse system with a rigorously periodic structure in one direction is montmorillonite in the state of intracrystalline swelling[186]. The mechanism of the first stage of the swelling process, where the aqueous layer between elementary crystalline network layers, which has a thickness of the order of 10 Å, corresponding to a few molecular layers, may be compared with the formation of liquid-crystal smectic phases accompanied by the appearance of the components of the wedging pressure. At a low ionic strength of the surrounding solution, the second stage of the swelling process, referred to as osmotic, begins. Under the influence of the ionic-electrostatic component of the wedging pressure, aqueous layers can then be formed with an equilibrium thickness ranging from 10–20 to 300 Å, depending on the ionic strength[186]. Measurements of their thickness by X-ray diffraction may serve as a test (in terms of a model) of the theory of interaction of charged surfaces in electrolyte solutions and of the theory of the formation of colloid layer structures, including "schiller" layers.

For small thicknesses, the collective nature of the van der Waals interactions in closely spaced elementary crystalline layers (scales) constitutes in essence a complication, while for large thicknesses and low wedging pressures a complication arises from the mechanical jamming of the scales by the end faces of the adhering neighbouring scales[187]. The study of the state of equilibrium of free symmetrical films, first observed and investigated mainly by the present author and his coworkers[171-178], therefore has many advantages for model investigations. In this case it is possible to vary

the specified wedging pressure and to measure the thicknesses of the film and the aqueous layer by optical methods. A number of experimental studies made it possible to obtain a quantitative conformation of the theory of the electrostatic and van der Waals components of the cleaving pressure [189].

The most complete confirmation of this theory was obtained by Deryagin, Voropaeva, and Kabanov, who used crossed metallic wires in electrolyte solutions, whose potential could be varied by polarisation, as models of the interaction of particles in metal sols [190-194]. Apart from confirming the above theory, these measurements made it possible to determine the van der Waals interaction constant. At the same time lower values of the wedging pressure at the zero charge point and at high (of the order of several moles per litre) concentrations, which are not covered by the theory, were observed. Thus the theory of the wedging pressure of thin layers, which permits the calculation of their equilibrium thicknesses, has been confirmed in certain cases.

X. INTERACTION OF NON-IDENTICAL SURFACES

A theoretical treatment of the stability of disperse systems and thin films was described above for the interaction of surfaces of identical nature and having the same charge. The interaction of surfaces of different kinds and bearing different charges has been examined [204,205]. The following are the most significant theoretical conclusions.

The electrical component of the wedging pressure for surfaces bearing opposite charges is negative for all distances, i.e. corresponds to attraction. Surfaces charged to different potentials of the same sign alter the sign of the interaction from repulsion at long distances to attraction at short distances. The force barrier to mutual approach depends only on the potential of the surface which is charged to the lower potential. The van der Waals component of the wedging pressure of layers between bodies of different kinds may be positive (this conclusion was later confirmed [206,207] within the framework of the macroscopic theory of intermolecular forces). If the surfaces are simultaneously charged to very high potentials of different sign, then the inverse Hardy–Schulze rule is valid: the rapid coagulation threshold occurs as the concentration is decreased to a value inversely proportional to the ionic charge raised to the sixth power (for a symmetrical electrolyte).

This theory of heterocoagulation was developed further in other studies [208,209]. The case of surfaces with specified surface charge densities has also been examined [210-212]. Devereux and de Bruyn [213] published tables for the electrical components of the wedging pressure. Smilga [214] examined the case of an arbitrary mixture of electrolytes. The case of low potentials, examined initially by Deryagin and Levich [215], was later considered in greater detail [216,217].

The theory has received experimental confirmation in a number of studies; in particular, the inversion of the Hardy–Schulze rule was confirmed by Chernoberezhskii [218]. A rigorous quantitative comparison of experiment with theory is hindered mainly by the difficulty of determining the effective surface potential of the particles. Model experiments in which a study was made of the conditions for the mutual adhesion of two mercury drops polarised to different potentials [219, 220] as well as mercury and glass drops [221-223] are of interest in this respect. The mutual adhesion of mercury drops in a hydrocarbon medium was investigated by Srenge and Sonntag [224]. The wedging pressure of the electrolyte layer between the glass and the polarised mercury drop has also been investigated [225]. The theory of heterocoagulation was tested and confirmed [226,227] also by observing the adhesion of disperse particles to a rotating disc. It must be emphasised that heterocoagulation constitutes a wider range of phenomena than homocoagulation, which is its special case. Heterocoagulation constitutes the basis of such major problems as those of flotation [228-231], the purification of water in filters [232], dyeing, the adhesion of biological cells, etc. [233] The development, testing, and application of the heterocoagulation theory therefore undoubtedly merit further attention and efforts (see also Prieve and Ruckenstein [234]).

XI. CONCLUSION

The present review has shown that the theory of the stability of disperse systems and thin films is of the greatest importance for colloid science and for many fields involving surface phenomena. Despite the enormous literature on this problem, published during forty years, there is still much room for its further development and investigation, particularly as regards a quantitative test of the theory. It is also necessary to approach more rigorously the very definition of the concept of the stability of colloids, differentiating strictly its different varieties and aspects and avoiding a one-sided approach.

It must be emphasised that the development of the theory of the stability of colloids and the wedging pressure as its basis also led to progress in solving the purely physical problem of intermolecular forces and the electrochemical problem of the ionic double layer. This stimulating influence of the science of the stability of colloids merits its more detailed consideration in conclusion.

Although it had been known earlier that the molecular interaction in condensed media is non-additive, nevertheless up to 1955 it was generally accepted, following de Boer, Bradley, and Hamaker, that the degree of interaction between macro-objects should be found by integrating pair dispersion interactions with respect to their volumes. The first limitation of this procedure was pointed out by Casimir [235], who developed a more accurate quantum theory of dispersion interactions taking into account the finite rate of propagation of electromagnetic vibrations. As a result, molecular attraction over distances significantly greater than the characteristic length, where the electromagnetic lag is already fully manifested, begins to weaken more rapidly by a single power of the distance.

Casimir was also the first [236] to describe an example of a macroscopic theory of van der Waals forces, having devised it for the case of two metallic plates separated by distances over which the electromagnetic lag is fully manifested. The first study which demonstrated experimentally the inapplicability of the Hamaker method to the calculation of the attraction of macro-objects was that of Deryagin and Abrikosova [237-241]. The force of attraction of a glass (or quartz) lens to a similar plate was first correctly measured in their investigation as a function of the gap separating them¶. It was found that the experimental

¶ Owing to the incomplete elimination of random electrical charges, the measurements of Overbeek and Sparnay [242] published simultaneously were erroneous. They yielded attraction forces exceeding by a factor of thousands the true molecular attraction and were even greater than the value yielded by calculation without allowance for the electromagnetic lag.

attraction force in the range of gaps 500–5000 Å is much weaker than the value obtained when Hamaker's formula is applied. This result led Lifshits[243] to develop a macroscopic theory of van der Waals forces acting between macro-objects of any kind.

The experimental data agreed, within the limits of the error of the measurements, with data calculated from the formulae for the complete manifestation of the electromagnetic lag. Subsequently Deryagin and Abrikosova carried out measurements on another object (the quartz–chromium pair and the NaBr–NaI mixed crystal) and in all cases agreement between theory and experiment was demonstrated[244,245]. An analogous conclusion was arrived at later by experimenters using other methods. Recently it has been possible to extend the treatment also to the range of gaps for which the limiting laws neglecting the electromagnetic gap are valid[246,247]. In particular, measurements have been made for the first time on the molecular attraction between two metallic objects[248,249].

The reader is referred to reviews[250,277] of experimental studies and further theoretical developments, while here the following remarks will be made.

Dzyaloshinskii et al.[251] extended the theory to the case where the interacting plates are immersed in any medium, which is of particular interest for colloid science. Here it is important that the general formulae make it possible to calculate beforehand the interaction force, provided that the characteristic regions of the optical absorption spectra of both bodies and the medium are known. This possibility has been tested experimentally in many instances and is exceptionally valuable for the theory of the stability of disperse systems.

Recent studies, designed to develop further the theory of the electrical double layer (DL), took into account the influence of the intrinsic volume of ions and pair correlations on the DL structure[252], of the polarisation of DL on electrophoresis and diffusiophoresis[253], of adsorbed ions on the structure and polarisability of DL [254]; the problems of the discrete nature of DL [255], of the determination of the surface potential of spherical particles,[256] and of the comparison of the constant surface potential and constant surface charge conditions in the DLVO theory[257] have been examined. Furthermore, the results of studies of the interaction of DL of charged surfaces have been published: for a solution of a mixture of electrolytes[258], for planar particles in concentrated dispersions with a dispersion medium having a low dielectric constant[260], for constant surface charges[49,263], and for a constant potential of one surface and a constant charge of another[264,266].

In a number of studies an interesting attempt has been made at a unified treatment of the interaction energy (van der Waals attraction and electrostatic repulsion) of charged surfaces[267,268]; the low-frequency electromagnetic fluctuations and the statistical charge distribution between two plates have been examined jointly[269,270] and account has been taken of the influence of the dielectric constant of the medium on the energy of an ion near the interface[271]. The method of images has been used[272] to calculate the interaction energy of two different dielectrics separated by a layer of a third dielectric. The interaction of surfaces with energetic and geometrical inhomogeneities has been examined[273,274]. Reviews of the literature on the surface forces in disperse systems have been published[275–278]. The stability of black hydrocarbon films has been comprehensively examined in the monograph by Kruglyakov and Rovin[279]. Various questions of the stability of colloids have been discussed[280]. The wedging pressure of liquid-crystal films has been considered[281].

The Influence of Hydrogen Bonds and Ionic Interactions on the Properties of Carboxyl-containing Copolymers and Ionomers Based on Them

M.G.Marina, Yu.B.Monakov, and S.R.Rafikov

The changes in the properties of copolymers as a function of the introduction of units with carboxy- and salt groups into the macrochain are examined. Attention is concentrated on the analysis of the results of the study of copolymers in the acid and ionomeric forms in solutions. The decisive influence of ionic interactions on the properties of ionomers in bulk and on their hydrodynamic and conformational characteristics is demonstrated. The difference between hydrogen and ionic bonds in the sense of their effects both on the primary ordering of macromolecules within the chains in copolymers of the types indicated and on the interchain interaction processes is emphasised.
The bibliography includes 163 references.

IV. The influence of ionic interactions on the properties of monomers in bulk 393
V. The properties of solutions of copolymers with ionogenic salt groups 394

I. INTRODUCTION

One of the achievements in the regulation of the properties of polymers by the modification of their structure is the synthesis of ionomers. The term "ionomers" was first ascribed to ternary copolymers of ethylene with acrylic acids and their salts[1-6]; at the present time it is also used for other copolymers with ionogenic salt groups. The effective operational and technical properties of ionomers were already reported in the first studies, which attracted to them the continuous attention of specialists in many countries. The results of large-scale studies indicate some common features of ionomers of a wide variety of classes due primarily to the ionic and polar interactions in the macromolecular matrix.

Apart from the dispersion of dipole type interactions usual for all polymers, in the solid state ionomer macromolecules are also linked by ionic bonds, which are the strongest among those known; account must also be taken of the presence of hydrogen bonds between COOH groups. In dilute solutions the conformational characteristics of ionomers are in many respects determined by the same types of specific interactions, but this time at an intramolecular level. The differential approach to the assessment of these interactions and the determination of the dominant ones will permit a comparison of the properties of carboxyl-containing copolymers (CCC) in an acid form and copolymers with partial or complete neutralisation of the carboxy-groups by metal ions (ionomers). Since the properties of ionomers in the solid state are being investigated very vigorously at the present time and a number of reviews[7-16] deal very completely with the situation in this field, in the present review attention is concentrated on the result of the study of the CCC and ionomers in solution.

II. THE INFLUENCE OF HYDROGEN BONDS ON CERTAIN PROPERTIES OF CARBOXYL-CONTAINING COPOLYMERS IN BULK

The specific properties of solid carboxyl-containing copolymers and their solutions are to a large extent determined by the ability of the CCC to form hydrogen bonds which give rise to additional stronger contacts at intramolecular and intermolecular levels. The presence of an extensive system of such contacts leads to the appearance in solid CCC of a series of clear-cut effects. The characteristics of the formation and function of hydrogen bonds and the effects induced by them are being investigated by infrared spectroscopic[17-31] and calorimetric[18-20,23,25,31] methods; valuable information is provided by the study of the thermomechanical[18-20,23], viscoelastic[32,33], sorption[28,34,35], and other properties of the CCC.

The vast majority of the carboxy-groups in CCC are linked via hydrogen bonds to the dimeric complexes; the stretching vibration bands of the $>C=O$ groups at 1695 to 1705 cm^{-1} [17,20,21,23,25,29] and the 940 cm^{-1} band, attributed to the migrations of the out-of-plane OH group in the dimer[19,20], correspond to them. Below the glass point T_g, where there is no segmental motion of the chains, the intensity of the bands due to free carboxy-groups (1740 to 1750 cm^{-1}) is extremely insignificant[17,20,21,23,25,29], which indicates a low concentration of such groups in CCC. However, with increase in temperature there is some increase of the intensity of the free carboxyl band, which is particularly noteable near T_g.[17,23,28,29] The dissociation of hydrogen bonds in the styrene–methacrylic acid (MAA) copolymer (85:15) at 120°C leads to the appearance of an inflection in the curves describing the temperature variation of the intensity of the 1745 and 1700 cm^{-1} bands; this inflection corresponds to the glass point, which has been recorded at 120°C also by differential thermal analysis and by dynamic mechanical measurements[23].

The intial fraction of free COOH groups (α) in CCC is appreciably lower than after the heating–cooling cycle: in the range of temperatures above T_g the parameter α assumes its equilibrium value, which persists when the specimen is cooled[29]. The quenching of the structure thus formed leads to a closer packing of the macromolecules (an increase of density) of the hydrogen-bonded copolymer compared with the unannealed specimen[34,36].

The rupture of the main bulk of hydrogen bonds after the attainment of T_g can hardly be regarded solely as a consequence of the thermal lability of the corresponding cross links, since in this case one would have observed a steady shift of T_g towards higher temperatures with increasing content of COOH groups in the copolymer[17-20,23,29,37]. The

dissociation of hydrogen bridge bonds is apparently promoted, apart from temperature as such, also by the increased thermal motion of the chains. This apparently explains the dependence of the equilibrium constant for the formation of hydrogen bonds on the concentration of carboxyl-containing units in the copolymer[29]. The hypothesis that hydrogen bonds can be broken as a result of the active motion of macrochains is consistent with experimental data[25,28] concerning the stabilisation of the network of hydrogen bonds between carboxy-groups in partly neutralised CCC specimens (ionomers), because the appearance of strong hydrogen bonds increases the mobility of the chains. The fixed position of carboxylate ions in ionomers makes the relative intensity of the 1723 cm^{-1} absorption band (stretching vibrations of carboxy-groups involved in hydrogen bonds with carboxylate ions) unchanged even at temperatures above T_g.[28]

The observed changes in the T_g of CCC as a function of the number and type of hydrogen bonds are consistent with the view according to which certain transitions (of the T_g type) are interpreted[38] simply as a consequence of the disappearance of the different types of intermolecular (secondary) bonds in the solid polymer specimen.

Hydrogen bonds make an appreciable contribution to the enthalpy of the vitreous state, which is proportional to the content of carboxyl-containing units in the polymer[18]. The heat of dimerisation of carboxy-groups found for various CCC varies from 7.32 to 11.6 kcal $mole^{-1}$,[17,19-21,23,29], i.e. is very close to the value characteristic of low-molecular-weight compounds with COOH groups in non-polar solvents[39]. With increase of the degree of neutralisation of carboxy-groups in CCC, the enthalpy of the residual intermolecular hydrogen bonds increases[25] as a result of their strengthening.

The degree of crystallinity of polyethylene decreases after the introduction of acrylic acid units in consequence of the formation of hydrogen bridge bonds[19,20,21,40]. The crystallinity of such copolymers decreases linearly with increasing content of the acid and reaches zero when the content of acid unit is more than 8–9 mole %.[4,31] The dimerisation of carboxy-groups proceeds only in amorphous parts of the copolymer and the bulky acid groups are thereby excluded from the crystal lattice of the polyethylene[19,20,31]. This is also promoted by the tendency towards spontaneous aggregation of COOH groups in systems of this kind[32]. A certain incompatibility of hydrocarbon units and acrylic acid units, due to thermodynamic factors which is intensified owing to the presence of hydrogen bonds, is manifested to the greatest extent in graft copolymers. This has been shown for polypropylene with grafted polyacrylic acid chains in a study[41] where the presence of two phases was detected with the aid of transmission and scanning electron microscopy, indicating the microheterogeneity of the copolymer structure.

The presence of an extensive network of hydrogen bonds hinders the diffusion of solvent vapour into the bulk of the methyl methacrylate (MMA)–MAA copolymer, such hindrance to diffusion increasing with increase of the content of MAA units in the copolymer, i.e. with increasing density of the hydrogen bond network[34,35]. Analysis of the solvent sorption and desorption pattern and the observed distinct hysteresis demonstrate a redistribution of hydrogen bonds, an appreciable rearrangement of the steric structure of the network, and a change in the polymer–solvent interaction after the attainment of a certain degree of swelling of the polymer. Annealing of the specimens decreases the sorption capacity and causes the disappearance of a whole kinetic region of the sorption isotherms, which is regarded[34] as a critcal effect. The sorption characteristics of CCC depend significantly on the type of solvent–on its ability to compete in the formation of hydrogen bonds[28].

The decrease of swelling in benzene of the graft copolymers of natural rubber with acrylic polymers of methacrylic acid with increasing degree of grafting can apparently also be regarded as evidence for the formation in such copolymers of additional interchain contacts via hydrogen bonds; this tendency towards a decrease of swelling is most pronounced in copolymers with methacrylic acid[42]. The different contributions of COOH groups to the formation of hydrogen bonds as a function of the nature of the acid has also been observed (by infrared spectroscopy) in graft copolymers of starch with acrylic and methacrylic acids[27]. The difference between these acids is also manifested by the fact that the increase of T_g is more pronounced in the graft copolymer of cellulose with methacrylic acid compared with the copolymer with acrylic acid[43].

Although both intramolecular and intermolecular hydrogen bonds can be formed simultaneously in solid CCC, in some cases the interpretation of experimental data leads to the conclusion that interchain cross links are formed preferentially[19,21,23], while in others account is taken mainly of the presence of intramolecular dimeric complexes[17,24].

III. MANIFESTATION OF THE SPECIFIC INTERACTION BETWEEN THE CARBOXY-GROUPS OF COPOLYMERS IN SOLUTION

When we proceed from the consideration of solid carboxyl-containing copolymers to their dilute solution, it is possible to estimate the properties of an isolated macromolecule due to the presence of hydrogen bonds within a given chain only. These bonds can be formed between the carboxy-groups of the same macrochain, between a carboxy-group and another monomeric chain containing a hydrogen bond acceptor (for example in MMA copolymers with MAA), and also between a carboxy-group in the chain and a solvent molecule. However, interchain interactions also begin to be manifested in concentrated solutions.

The formation of intramolecular hydrogen bonds of the polymer–polymer type is not characteristic of polymeric acids, because they dissolve mainly in protic solvents (water, alcohols, and their mixtures). All these solvents ionise the carboxy-groups of the macrochain and in addition they can themselves form hydrogen bonds of the polymer–solvent type. The presence of a single C=O stretching vibration band at 1710 cm^{-1} in the infrared spectrum of the initial polyacrylic acid solution indicates a single type of hydrogen bonds in this system, namely COOH–H_2O bonds[44]. However, in an aqueous alcoholic solution of polymethacrylic acid infrared spectroscopy reveals the appearance of hydrogen bonds within the chains[45].

For CCC, it is possible to use organic solvents with a wide range of polarities and donor–acceptor capacities. By varying the composition of the solvent and the concentration of the polymer in the latter, it is possible to convert hydrogen bonds of one type into another, and thereby achieve a specific influence on the structure of CCC in solution. The presence of hydrogen bonds of all types alters the hydrodynamic characteristics of the CCC; the intensity of their formation is therefore usually inferred from viscometric data, which, together with the results of the study of CCC in solution by other methods, can yield detailed

information about the mechanism of the formation and dissociation of these bonds and about the extent to which they influence the conformational characteristics of CCC macromolecules.

The problem of the possible cross-linking of an isolated macromolecule has been considered theoretically by Kuhn and Balmer[46], who concluded that, when the ring intramolecular bonds are formed, the size of the macrocoil should diminish. Experimental data for the hydrodynamic properties of CCC having hydrogen bonds within the chain confirms this conclusion. MMA–MAA copolymers in which the MAA units are capable of forming stronger contacts, by virtue of the formation of hydrogen bonds, with all other units are interesting in this respect[47-61]; it has proved possible to regulate the effective density of such contacts by altering either the solvent or the relative content of MAA units in the copolymer. It has been shown for MMA–MAA copolymers[47-61] that selective interactions within the chains occur in dilute solutions in consequence of the formation of hydrogen bonds of the polymer–polymer type, which lead to additional contraction of the polymer coil in "inert" solvents (hydrocarbons, halogenated hydrocarbons, and other solvents, which cannot break the hydrogen bonds in the copolymer or which exhibit a very weak capacity for their formation with the carboxy-groups of CCC). In such solvents the macromolecules of the MMA–MAA copolymer undergo internal "vulcanisation" owing to the formation of a network of hydrogen bonds; because of these bonds, the points of contact involving groups which are remote in terms of their positions along the chain proved to be rigidly fixed: the so-called "frozen" conformation arises.

The disruption of the system of such contacts and transition to the state of the usual flexible statistical coil occur when a small amount (several per cent) of a substance actively competing for hydrogen bonds, for example dimethylformamide (DMF), is introduced into the inert solvent–copolymer system. This transition is indicated by the sharp (abrupt) changes in the hydrodynamic characteristics and conformations of the copolymer macromolecules. Since the thermodynamic quality of the solvent at a low DMF concentration in the latter hardly changes, all the effects observed following the addition of DMF are due to a change in the nature of the hydrogen bonds (hydrogen bonds within the chain of the polymer–polymer type are fully converted into bonds of the polymer–solvent type). This indicates an unambiguous correlation between the experimental parameters {particularly $[\eta]$} and the probability of the formation of stable contacts within the chain via hydrogen bonds.

The study of dilute solutions of MMA–MAA copolymers under the conditions of maximum formation of hydrogen bonds of the polymer–polymer type within the chains and when these bonds are broken by the addition of competing substances has shown that the values of $[\eta]$ for the copolymers increase after the introduction of competing substances by a factor of 2–5 and reach the intrinsic viscosities of poly(methyl methacrylate) with the same degree of polymerisation[51-54] or approach the values of $[\eta]$ of the copolymer in solvents where the formation of hydrogen bonds of the polymer–polymer type is impossible[58,60]. The equality of the values of $[\eta]$ and of the Huggins constant for the MMA–MAA copolymer and poly(methyl methacrylate) in a dichloroethane–DMF mixture indicates the similarity of the conformations of the MMA homopolymer macromolecules and the macromolecules of its copolymer with a low MAA content when the internal macrorings in the latter are liquidated[54].

It is significant that, when the hydrogen bonds within the chains are broken, the type of hydrodynamic homology also changes. For the MMA–MAA copolymer (with 7.6% of MAA) in dichloroethane, $[\eta] \propto M^{0.66}$, whereas following the addition of 5% of DMF the power exponent a increases to 0.87, i.e. becomes almost equal to the power exponent in dioxan ($a = 0.86$).[58,60] The intrinsic viscosity of a copolymer with a high content of MAA units (34%) in acetone is almost independent of the molecular weight (a is close to zero).[55,56,58,59] It is suggested that the copolymer macromolecule in acetone has the conformation of a quasi continuous coil highly "cross-linked" by hydrogen bonds, whose rupture as a result of the addition of DMF leads to an increase of a to 0.26.[59] The results illustrate the marked dependence of the conformation of the coil on the nature of the hydrogen bonds.

The efficiency of the formation of contacts via hydrogen bonds is determined primarily by the number of MAA units in the copolymer macromolecule and depends thus both on the composition of the copolymer and on the degree of its polymerisation[62,63]. In consequence of this there is (for a given solvent) a progressive "contraction" of the MMA-MAA copolymer coils as the molecular weight and the MAA content increase[53]. The critical DMF concentration at which the rupture of the network of hydrogen bonds within the chain occurs and $[\eta]$ of the copolymer approaches the value for poly(methyl methacrylate) depends only on the MAA content in the copolymer and is independent of its molecular weight. The contraction of coils via hydrogen bonding is therefore proportional to the number of MAA units in the copolymer and inversely proportional to the DMF concentration in the solvent[57,61].

Other conditions being equal, the efficiency of the formation of hydrogen bonds is also determined by the way in which the units are distributed, i.e. by the microstructure of the copolymer chain[64]. An appreciable difference has been observed between MMA–MAA copolymers having the same composition but obtained in different ways: by the hydrolysis of poly(methyl methacrylate) (statistical distribution of MAA units) or by radical copolymerisation (deviation from a rigorous statistical distribution because MAA units are grouped into diads, triads, etc. to a large extent). In the former case the contraction of coils is more pronounced owing to the greater density of cross linking via hydrogen bonds[57,61,64].

Since the contraction of the CCC macrocoil depends on the degree of polymerisation, the shape of the coils is to a large extent determined by the molecular weight. Strictly speaking even fractions of CCC with a homogeneous composition cannot be regarded as a polymer-homologous series under the conditions of the manifestation of selective interactions within the chain, because the ratio of the dimeric and monomeric forms of the carboxy-groups is determined (other conditions being equal) by the molecular weight of the fraction. In other words one can assume that the fractions, as it were, differ in composition. In this case the more effective formation of hydrogen bonds with increasing molecular weight will promote an anomalous decrease of the power exponent a in the equation $[\eta] = KM^a$; the rupture of hydrogen bonds within the chain owing to the addition of small amounts of a proton acceptor restores the normal value of the exponent. The above changes in a cannot be accounted for by an improvement or impairment of the thermodynamic quality of the solvent. One must therefore take into account the conventional nature of the results of the estimation of the parameters of equations of the Mark–Kuhn–Houwink type (for any hydrodynamic properties) and the unperturbed dimensions

of the CCC obtained by the Stockmayer–Fixman method when selective interactions within the copolymer chain take place[57,61].

Apart from the MMA–MAA copolymers, the presence of cross-links within the chain via hydrogen bonding and their influence on the hydrodynamic characteristics have been established also for other CCC of different compositions based on acrylic[58,65–72] and methacrylic[71,73–75] acids as well as monobutyl itaconate[76–80]. Different inert solvents (toluene, xylene, chlorobenzene, dichloroethane, carbon tetrachloride, bromoform, etc.) were used in the investigation; apart from DMF, other compounds capable of forming hydrogen bonds of the type polymer–solvent (acetic and methacrylic acids, methanol, dioxan, tetrahydrofuran, dimethyl sulphoxide, amines etc.) can also be used as competing additives. The experimental data obtained do not conflict with relations established for MMA–MAA copolymers, although in each specific case particular features of the test system can be manifested. This is associated primarily with the proton-accepting activity of the second component of the solvent, i.e. with its ability to compete with the polymer units in the formation of hydrogen bonds. On the other hand, the mechanism of the dissociation of the hydrogen bonds within the chain is apparently in all cases similar and is determined mainly by the preferential solvation of the carboxy-group by the competing additives.

In contrast to MMA–MAA copolymers, a characteristic feature of which is the formation of two types of hydrogen bonds within the chains, the copolymers of styrene and acrylic acid make it possible to investigate in the "purest" form the hydrogen bonds between the carboxy-group, although the presence of a weak hydrogen bond between the COOH group and the π electrons of the benzene ring has also been observed for systems of this kind[71]. A study of the copolymers of 4-vinylbenzoic (I), acrylic (II), and methacrylic (III) acids with styrene (IV) in carbon tetrachloride has shown that under these conditions the number of bonds of this type increases in the sequence of copolymers (I) – (IV) < (II) – (IV) < (III) – (IV).[71]

Apart from the effect of competing additive properties a study was also made of the effect of temperature on the intramolecular cross-links due to hydrogen bonds in CCC in inert solvents. It has been established that the intrinsic viscosity (which in the given case can be regarded as a measure of the effectiveness of various contacts between carboxy-groups within the chain) remains virtually unchanged over a wide temperature range up to 70 to 110°C; [53,54,58,60,73,80] nor is there any change in the Huggins constant. The constancy of $[\eta]$ in the above temperature range has been explained by the high energy of the hydrogen bonds, which exceeds the energy of the thermal motion of the chain units; this fact indicates indirectly the occurrence of intramolecular structure formation[58,60]. Since a marked temperature variation of the degree of decomposition of hydrogen bonds is characteristic of a model low-molecular-weight analogue (isobutyric acid, i.e. hydrogenated MAA), [73] one may say that the chain structure of CCC macromolecules introduces specific features into the mechanism of the formation and decomposition of these bonds. It has been suggested[73] that the equilibrium between the free and bound COOH groups in CCC solutions is determined by the effective concentration of active groups within the macromolecular coil, and not by their overall concentration in solution, as for hydrogenated MAA. The data showing the independence of the number of hydrogen bonds within the chain of temperature in CCC solutions are consistent with the results of the study of these copolymers in the solid state; the entire set of data obtained confirm the conclusion that the energy of polymer–polymer hydrogen bonds is fairly high.

The problem of the influence of the CCC concentration in solution on the nature of hydrogen bonds formed is of interest. Infrared spectroscopic data have shown[73,74] that only hydrogen bonds within the chain are observed for the styrene–MAA (3.1 wt.% MAA) copolymer in toluene and carbond tetrachloride at CCC concentrations up to 5%; under these conditions, the proportion of free carboxy-groups is 11% and the remaining groups form dimers[74]. The low probability of intermolecular association of the macromolecules of a hydrogen-bonded copolymer of mono- and di-butyl itaconate is indicated by infrared spectroscopic and osmometric data in dilute solutions[80]. The linearity of the variation of the intrinsic viscosity with CCC concentration up to 2.5% is evidence for the absence of interchain association of styrene – MAA (2–5% MAA) copolymer macromolecules in benzene[81].

The absence of interchain association of CCC macromolecules in dilute solutions is significant in connection with the problem of the determination of the CCC molecular weight. One must take into account the range of molecular weights: it has been established[82] that the association of polystyrene molecules containing terminal carboxy-groups is observed in toluene for low-molecular-weight specimens (3×10^4); on the other hand, specimens with a higher molecular weight in dilute solutions do not form such associated species owing to the reduced probability of contacts between COOH groups belonging to different macromolecules. The situation changes with increase of the concentration of the CCC solution. On passing from a very dilute CCC solution in an inert solvent to a concentrated solution, three different concentration ranges were discovered[83]: (1) the system contains individual macromolecules and small associated species (dilute solutions); (2) an incomplete fluctuation network, made up of interchain hydrogen bonds with a finite lifetime, is in equilibrium with associated species and individual macromolecules (moderately concentrated solutions); (3) there exists a fluctuation network incorporating all the macromolecules present (concentrated solutions). The significant differences between the regions are manifested by the fact that the introduction of a proton acceptor into dilute solutions leads to a dissociation of the hydrogen bonds within the chain and to an increase of the reduced or characteristic [intrinsic] viscosity of the CCC solutions, whereas in the second and third concentration ranges a decrease of the viscosity of the CCC solution is observed after the addition of the proton acceptor[69], because the viscosity of these solutions is determined primarily by the interchain contacts and the proton acceptor disrupts those which are due to hydrogen bonds. Even gel formation is possible in the absence of a proton acceptor[84].

The study of the concentration dependence of the Newtonian viscosity of the styrene–acrylic acid (4% of acrylic acid) copolymer under the conditions of maximum (toluene) and minimum (toluene + 20% DMF) formation of hydrogen bonds made it possible to discover[69] the concentrations characterising the critical conditions for the transition from a dilute to a moderately concentrated (c'_{crit}) solution and from a moderately concentrated to a concentrated solution (c_{crit}). At the concentration c'_{crit} the formation of a three-dimensional hydrogen bond network in the CCC solution begins, while at the concentration c_{crit} its formation is completed. It has been found for the above copolymer (degree of polymerisation 2.5×10^3) that $c'_{crit} = 4.36$ and $c_{crit} = 6.9$ g dl^{-1} in toluene, whereas in toluene

containing 20% DMF, these concentrations are 2.08 and 12.9 g dl^{-1} respectively.

The data presented show that the transitional region in which the formation of the complete three-dimensional network begins and is completed throughout the bulk of the solution becomes significantly extended under conditions of the minimum formation of hydrogen bonds of the polymer–polymer type, whereas in toluene this process takes place over a fairly narrow concentration range. The maximum rupture of hydrogen bonds within the chains between carboxy-groups promotes the unravelling of the coil; as a result of this, the network of interchain bonds in the copolymer in the toluene + DMF mixture begins to be formed at lower concentrations c'_{crit} than in pure toluene owing to the greater probability of the formation of interchain contacts. The probability of the formation of such contacts increases also with increase of the molecular weight of the CCC, which promotes a decrease of both critical concentration[69]. Thus the formation of a hydrogen bond network in fact determines the conditions for the transition from one concentration range to the other.

The study of the rheological properties of solutions of MMA–MAA copolymers established that the ability to form interchain hydrogen bonds is the fundamental cause of a whole series of observed effects. Thus the fluctuation network of the interchain hydrogen bonds hinders the disruption of the structure of the CCC solution in an inert solvent and causes its antithixotropic stabilisation both under the conditions of simple shear and for complex (predominantly longitudinal) flow deformations[49,51,52,54,63,83]. When this type of three-dimensional network is created, the transition from one thermodynamic state of equilibrium to another is hindered and the relaxation time τ_0 increases significantly[63,85]. The appearance of an excess heat of activation for the viscous flow of the CCC solutions is also regarded as a result of the same structure-formation effect[62,69,83,85–88] and the increment in the heat of activation ΔU depends both on the content of carboxy-groups in the copolymer (U increases in proportion to the logarithm of the molar content of MAA units[83,87,88]) and on the presence of added proton acceptors in an inert solvent. Experimental data indicate an unambiguous correlation between the heat of activation for viscous flow and the density of effective interchain contacts due to hydrogen bonds, which makes it possible to regard U in the region of moderately concentrated CCC solutions as a measure of the density of the three-dimensional fluctuation network formed[62]. In fairly dilute solutions a sharp increase of U with concentration is observed, but the formation of a complete hydrogen bond network throughout the bulk of the concentrated solution causes an asymptotic approach of U to a constant (for a given molecular weight and a given composition of the copolymer) value, which is virtually independent of the concentration of the copolymer in the inert solvent for $c > c_{crit}$.[69,83,87,88] The higher the molecular weight of the copolymer and the higher the molar content of the MAA units in it, the lower the critical concentration after the attainment of which U becomes constant. It has been suggested[87] that the independence of U of c in this concentration range is consistent with the idea that, for a fairly large number of bond nodes (contacts), U is independent of the number of nodes for the given copolymer and depends solely on their nature[89].

As in dilute solutions, the introduction of a small amount of a proton acceptor into an inert solvent causes the rupture of the polymer–polymer hydrogen bonds in CCC and to a large extent weakens or completely eliminates the effects mentioned above, which confirms that they are due to the selective interchain interactions between groups capable of forming a hydrogen bond.

Analogous relations, due to the presence of stronger interchain contacts, have been discovered also in the study of the viscous and relaxation properties of poly(methacrylic acid) solutions in methanol, ethanol, and ethylene glycol in the concentration range 9–20%.[90] In this case the dihydric alcohol behaves as a cross-linking agent forming hydrogen bond bridges between the macrochains. As a result of this, the "relaxation viscosities" and durations of the initial period of the relaxation of strain in poly(methacrylic acid) solutions in ethylene glycol are greater by approximately three orders of magnitude than in monohydric alcohols at the same polymer concentration.

Data for the dependence of a whole series of characteristics of CCC solutions on concentration over a wide range of the latter showed that the concentration of a real CCC solution as such cannot serve as a criterion of its being dilute or concentrated, because the limits of the existence of solutions with and without strengthened interchain contact are not absolute, are mobile, and are determined primarily by the composition of the copolymer and its molecular weight as well as the ability of the solvent to compete with the polymer in the formation of hydrogen bonds. For CCC, with their ability to undergo selective interactions, only analysis of the properties of a specific system can provide an answer to the question whether the macromolecules in the given solution are isolated from one another, or whether there are contacts of a definite type between them up to the formation of a complete fluctuation network throughout the bulk of the system[88].

IV. THE INFLUENCE OF IONIC INTERACTIONS ON THE PROPERTIES OF MONOMERS IN BULK

The neutralisation of some of the carboxy-groups in CCC by metal ions of different valence leads to the enrichment of the spectrum of the possible types of selective interactions and hence to the appearance of a series of specific properties in such polymers (ionomers) in both the solid state and in solutions.

The hydrogen bond joins together only two functional groups ($n = 2$) of the macrochain, whereas electrostatic forces, which are in addition capable of acting over a long distance, can lead to the formation of very large ionic associated species ($n \geq 2$). The preferred interaction of solvent groups with one another in ionomers is also caused by their definite incompatibility with the hydrocarbon chain units. The existence of ionic accumulations (clusters and multiplets) in the bulk of the monomer has been justified theoretically[91]; the concept of cluster formation constitutes the basis of the interpretation of the majority of experimental data in recent years, obtained in the study of ionomers in the solid state. To a first approximation, one may assume that the decrease of segmental mobility in consequence of strong ionic interactions is the main cause of the increase of mechanical moduli and the decrease of the elasticity of ionomers compared with the corresponding carboxyl-containing copolymers[15,32,33,92].

The replacement of acid groups by salt groups significantly retards crystallisation up to its complete disappearance in copolymers of ethylene with acrylic acids[4,5,31,93], the influence of the neutralisation of carboxy-groups on the crystallisation kinetics being shown to the greatest extent for copolymers containing 1–7 mole % of the acid. Internal structural rearrangement due to ionic cross linking lead to an appreciable increase of T_g for ionomers (in a

particular ion concentration range) compared with CCC[7-9,11,12,14,15,25,94-101]; additional transitions are also observed in ionomers. In the discussion of problems concerning the influence of ionic cross links on the transition temperatures, the following factors must be taken into account. In contrast to covalent cross links, whose position in the specimen is rigorously fixed, ionic cross links in ionomers exhibit a definite mobility owing to the ability of cations to migrate in the bulk of the specimen. The results of a study of a mixture of an ethylene copolymer with acrylic acid and its ionomer in which the degree of neutralisation is 70%[92] showed that in mixtures of this kind regions rich in ions act as ion donors for the entire system, which becomes identical as regards its properties with an ionomeric specimen having a degree of neutralisation of 35%.

The inc rease of the segmental mobility of the chains with temperature also gives rise to greater possibilities for the redistribution of ionic cross links in the bulk of the specimen. It cannot be ruled out that, when T_g and T_y are reached, ionic associated species of one kind break down (otherwise the specimen would not have softened and would not have passed into a fluid state) and ionic accumulations of a new type are generated; the appearance of such ionic inhomogeneities is opposed by the entropy factor. Since the degree of Coulombic interaction is independent of temperature, particular types of ionic associated species will be manifested in the ionomer specimen at any temperature. Infrared spectroscopic data for ionomers of different structure suggest[102,103] the existence of a whole set of ionic associated species of different structure, whose relative content varies with temperature.

The transition temperatures in ionomers are to a large extent determined by the content of acid groups in the copolymer and by the degree of their neutralisation[97]; in certain cases ionic cross links are so strong that they do not break even on heating to approximately 400°C (ionomers with a high degree of neutralisation based on graft ethylene–maleic anhydride copolymers). It was shown in the above study that[97] the nature of the cation also affects the transition temperatures: for the same degree of neutralisation, the softening and yield temperatures (T_s and T_y) for sodium ionomers based on statistical styrene–MAA (8 : 2) copolymers are greater than T_s and T_y for copolymers neutralised by rubidium ions. Thus the transition temperatures in sodium ionomers correspond to stronger ionic cross links formed by the Na^+ cation, which has a smaller radius than the Rb^+ cation.

It has been established for poly(acrylic acid) salts[104] and $T_g = 730\ (q/r) - 67$, where q is the charge of the cation and r the average distance between the centres of the charges of the cation and anion. This type of correlation between T_g and q/r id common to ionogenic polymers and is confirms the dependence of the transition temperatures of the electrostatic interactions in ionomers. Analysis of the available data shows[11] that one cannot rule out the possibility that the observed changes in the transition temperatures are caused by the possible operation in ionomers of a completely different flow mechanism than the segmental displacement occurring in the usual hydrocarbon polymers. The unusual nature of ionic cross links causes ionomers to behave at low temperatures as cross-linked polymeric materials, while at high temperatures they can melt[15].

The presence of additional stronger contacts between the ionomer macrochains owing to ionic interactions leads to a change of the kinetics and thermodynamic parameters of the sorption of solvent vapours. Neutralised CCC specimens, cross-linked by divinylbenzene, have appreciably lower swelling coefficients than the same copolymer in an acid form[105] and the introduction of urea into the system—an agent which actively breaks hydrogen bonds—entails an increase of the degree of swelling of the specimen also in a partly neutralised form. With increase of the degree of neutralisation of carboxy-groups in the ionomer, there is an increase in the resistance of the system to the action of a solvent capable of competing with the polymer in the formation of hydrogen bonds, as shown by the decrease of the rate of attainment of sorption equilibrium, the decrease of the diffusion coefficient of the solvent, and the corresponding increase of the activation energy for this process[28,106]. On passing to a significantly neutral solvent (toluene), it was observed[28] that the amount of sorbed solvent (in a state of equilibrium) in the styrene–acrylic acid (3.9% of acrylic acid) copolymer passes through a minimum and maximum when the degree of neutralisation (α) is 5–15% and 50% respectively. The authors[28] suggest that the increase of the resistance of the structure to the action of the solvent in the region of α = 5–15% is due to the strengthening of the existing fluctuation network of hydrogen bonds owing to additional interactions of the salt group. However, in the region α = 25–50% there is an "inversion of networks": a transition from hydrogen bonds to a lattice of ionic clusters. The imperfection of the network in this transitional region leads to the weakening of the interchain interactions in the ionomer, which is reflected in the experiment by an increase of the degree of sorption of toluene. For $\alpha > 50\%$, a kind of framework of clusters made up of metal ions, which significantly stabilises the ionomer structure, is formed.

Thus comparison of certain characteristics of CCC and their ionomers shows that the effects caused by the introduction of units with carboxy-groups into the hydrocarbon polymer chain change appreciable on partial neutralisation of these groups by metal ions. The characteristics of the properties of complex polymeric formations such as ionomers are in many respects caused by the superposition of the influences of hydrogen bonds and ionic interactions, the proportions of which are determined by the degree of neutralisation.

V. THE PROPERTIES OF SOLUTIONS OF COPOLYMERS WITH IONOGENIC SALT GROUPS

Whereas the physicochemical properties of ionomers in the condensed state are being investigated fairly vigorously, the number of studies on the conformation and transformations and behaviour of ionomers in solutions is not so great. Nevertheless certain common features in the variation of the conformational parameters of isolated CCC molecules on replacement of the protons of the carboxy-groups by various metal ions have been quite clearly demonstrated. The appearance of salt groups leads to sharp changes in interactions within the chains, the intensity of which in dilute solutions is inferred mainly from the intrinsic (characteristic of reduced) viscosity. The polarity of the solvent, its capacity to induce the dissociation of salt groups, exerts the primary influence on these interactions.

It is significant that, in contrast to neutralised homopolymeric acids, ionomers can be investigated (as a function of their composition) in solvents with a wide range of dielectric constants, although an organic solvent cannot be selected for some of them. The poor solubility of ionomers is caused by the extreme diphilic properties of their

macromolecules — the combination in one chain of a non-polar (hydrocarbon) unit and units with salt groups. It is therefore impossible to select for ionomers a solvent which will have the same or at least similar thermodynamic affinities for units of both types. The presence of inter-chain bond nodes in the form of ionic multiplets and clusters imparts to ionomers a high resistance to oil and motor fuel, because the action of organic products with a low dielectric constant cannot lead to the rupture of inter-chain ionic bonds.

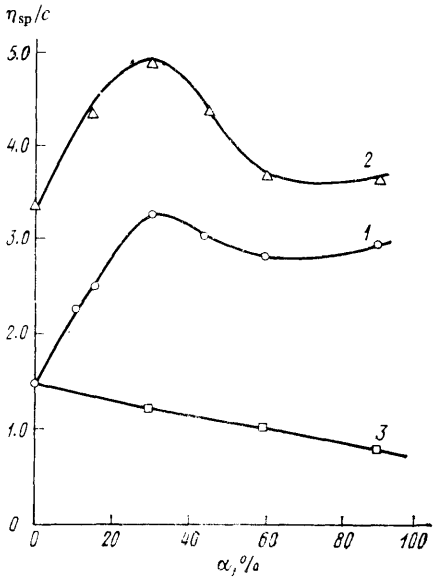

Figure 1. Dependence of the intrinsic viscosity ($c = 0.3\%$) on the degree of neutralisation of ionomers based on the styrene–methacrylic acid copolymer: *1*) Na-ionomers in DMF; *2*) Na-ionomers in DMF + 2% of water; *3*) Zn-ionomers in DMF. [75]

However, the same factors which ensure the notable physicomechanical properties of ionomers (including resistance to the action of solvents) complicate their study in solutions. In the first place the choice of solvent is made much more difficult and, what is most significant, in the study of a given ionomer it is usually impossible to use a wide range of different solvents. Another complication concerning the interpretation of data obtained in the study of the properties of ionomer solutions is due to the fact that, whereas hydrogen bonds of the polymer–polymer type can be completely destroyed by selecting a special solvent, electrostatic interactions in ionomer solutions always occur. By altering the nature of the solvent as a result of the introduction of various additives, it is possible to alter only the intensity of these interactions (both by changing the dielectric constant of the medium and by the solvation of ionic species). In solutions of ionomers a wide variety of intramolecular and intermolecular interactions (dipole–dipole, dipole–ionic, ionic, hydrogen bonds) can be manifested in principle. The real possibility of the manifestation and the intensities of particular interactions are determined by the specific nature of the ionomer and the solvent.

In a viscometric study in DMF ($\epsilon = 36$) the manifestation of polyelectrolyte swelling in the macromolecules of sodium ionomers, based on methacrylic acid copolymers, was noted[75,107–110]. The replacement of acid groups by salt groups, results in an increase of the ionogenic capacity in the region of dilute solutions. However, with increase of the concentration of the solution (up to 6%), the degree of ionisation falls appreciable[108]. The almost complete dissociation of salt groups with a univalent cation in ionomers based on the MMA–MAA copolymer (in DMF as the solvent) has been demonstrated also by electrochemical methods[111–113]. Bivalent metal ions interact with carboxylate groups of the ionomer chains so vigorously that the polyelectrolyte effect is as a rule not observed even in solvents with a fairly high polarity[75,114,115]. The study of electrolyte transfer in such systems also confirms the virtually complete absence of the dissociation of the salt groups of the macrochain, whereas the monomeric alkaline earth metal salts of methacrylic acid dissociate in DMF[111,116].

The macromolecules of ionomers based on acrylic acids containing univalent metal ions undergo a conformational transition in the course of ionisation in polar solvents[75,117]. The initial increase of intrinsic viscosity (Fig. 1) indicates a successive unravelling of the polyelectrolyte coil with increase of the number of ionogenic salt groups; the subsequent decrease of η_{sp}/c is due to the intense binding of sodium counterions and the consequent decrease of the effective number of charges on the chain. The onset of the conformational transition is determined by the content of the unsaturated acid in the copolymer. The occurrence of the conformational transition is confirmed also by potentiometric titration data[117]. Comparison of the viscometric behaviour of Na and Zn-ionomers based on the styrene–MAA (8:2) copolymer in the same solvent shows (Fig. 1) that there is no conformational transition in Zn-ionomers. This serves as yet another piece of evidence for the difference between the ionisation-dissociative processes in the methacrylate salt groups of ionomers in a polar solvent as a function of the nature of the metal.

When a highly polar solvent such as formamide ($\epsilon = 109$) is used, a sharp increase of the intrinsic viscosity of the sodium ionomer (degree of neutralisation $\alpha = 0.8$) is observed compared with the corresponding copolymer of ethyl acrylate and acrylic acid in an acid form[118]. Thus, in a medium with a fairly high dielectric constant, the macromolecules of ionomers with univalent cations exhibit the characteristic hydrodynamic and electrochemical features of polyelectrolytes.

However, the study of solutions of ionomers in weakly polar solvents is of great interest. A medium with a low dielectric constant imitates to a definite extent the environment of the ionomer macromolecule in bulk; furthermore, non-polar solvents in the majority of cases solvate ionic species very weakly. For this reason, in media of this kind the conditions for electrostatic interactions, which occur in solid ionomers and lead to the formation of ionic associated species, are established to the maximum extent. This ensures a direct relation between the results of a study of ionomers in weakly polar solutions and the results of their study in the condensed state. The transition to significantly non-polar solvents implies primarily an impairment of the solubility of the ionomer salt units and an intensification of electrostatic interactions. Such solvents exhibit a weak dissociating capacity; for $\epsilon < 10$ to 15, the dissociation of the solute hardly occurs and free ions are absent from the solution. Media with a low dielectric constant exhibit a characteristic tendency towards the formation of complex ionic species, such as

ion pairs, ion triplets, quadrupoles, and other higher-order aggregates[119]. The less polar the solvent the greater probability of the existence in the latter of contact ion pairs. All these factors, acting together, lead to a number of characteristics of the hydrodynamic properties and conformations of ionomer macromolecules in such solvents.

Judging from the experimental data[66,67,70,72,75,81,115,120-124] obtained using non-polar solvents or under the conditions of suppressed dissociation, in all cases a high degree of neutralisation of the carboxy-groups in CCC via metal ions is accompanied by the contraction of the macromolecular coil, as shown by the decrease of the intrinsic viscosity (or the specific or reduced viscosity at a low concentration) and by the increase of the diffusion coefficients of the ionomers compared with the corresponding copolymers in an acid form. The polyelectrolyte swelling in ionomers is not observed in this case. The contraction of the coil increases with increasing number of ionogenic salt groups in the macrochain (Figs. 2–4). The Huggins constant varies in opposition to $[\eta]$ with increase of the degree of neutralisation of carboxy-groups[66]. Although the conformation of the ionomer macromolecules in dilute solution is determined by the competing effects of forces of different kinds, experiment showed that forces drawing together the macromolecular coil predominate in this instance. The problem of their nature arises.

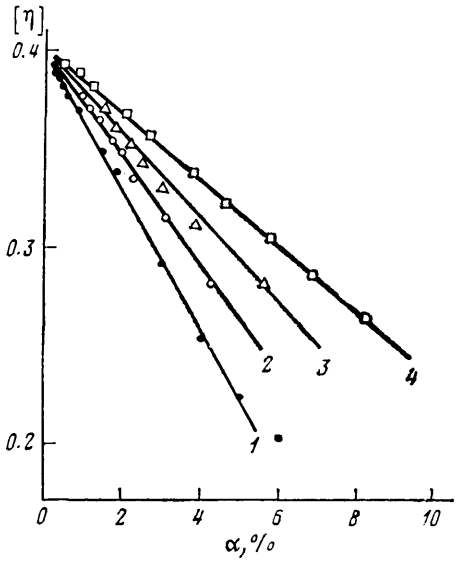

Figure 2. Dependence of the intrinsic viscosity in 1-octanol on the degree of neutralisation of Na-ionomers (line *1*), K-ionomers (line *2*), Cs-ionomers (line *3*), and Ca-ionomers (line *4*) based on the alternating maleic acid–hexadecyl vinyl ether copolymer[122].

The decrease in the size of the coil as a result of its contraction is associated primarily with the impairment of the thermodynamic quality of the solvent (non-polar solvents do not dissolve acrylate salts). This is also indicated by the increase of the Huggins constant on passing from the copolymer in an acid form to the ionomer. The thermodynamic factor promoting the aggregation of the ionomer salt groups within the chain is strengthened by electrostatic interaction forces between the ion pairs formed (here it is extremely significant that the Coulombic forces act over a long distance). The viscometric characteristics of the ionomers containing various metal ions constitute the most convincing evidence for the primary influence of ionic interactions on the conformational characteristics of their macromolecules. If the decrease of $[\eta]$ were caused solely by the impairment of the thermodynamic quality of the solvent, a clear cut dependence of $[\eta]$ on the nature of the cation introduced into the polymer would not have occurred (see Figs. 4–5 and literature data[81,107,110,112,115,121]). An increase of the radius of the cation leads to a weakening of the ionic interactions favouring the contraction of the coil. Accordingly, ionomers with a larger radius of the cation, introduced for the same charge of the latter, have a higher intrinsic viscosity.

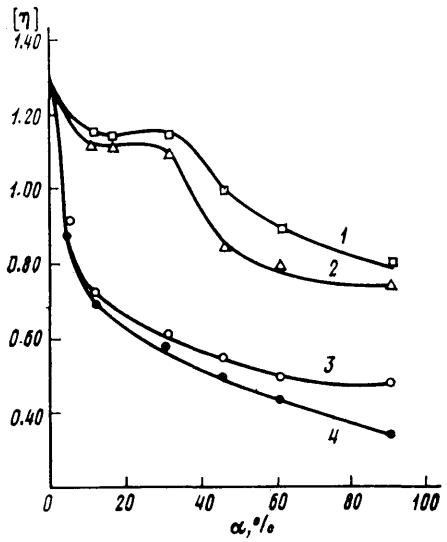

Figure 3. Dependence of the intrinsic viscosity in DMF + 0.05 M NaI on the degree of neutralisation of the Rb-ionomers (curve *1*), Na-ionomers (curve *2*), Ca-ionomers (curve *3*), and Zn-ionomers (curve *4*) based on the styrene–methacrylic acid copolymer[75].

The joint action of the thermodynamic factor and electrostatic interaction forces leads to the formation and stabilisation of ionic associated species of different degree of complexity, which can be regarded as stable bond nodes within the chains of ionomers in dilute solutions (the absence of interchain ionic interactions under these conditions has been confirmed by the equality of the molecular weights of the CCC before and after neutralisation[75,81,123]). An ionic quadrupole is formed in the simplest case under these conditions[81].

$$2\left\{\text{—COO}^{-}+\text{M}\right. \rightleftarrows \begin{matrix}\left\{\text{—COO}^{-}+\text{M}\right. \\ \left.\text{M}^{+}\text{-OOC—}\right\}\end{matrix}.$$

Such "cross linking" within the chain as a result of the interaction of two ion pairs does not differ in principle, as regards its effect on the size of the coil, from cross linking due to the formation of a dimeric hydrogen bond between carboxy-groups. However, experimental data show that the interaction between the salt groups of ionomers in non-polar solvents has a more effective influence on the contraction of the isolated coil than hydrogen bonds[70,72,81]. In the case of hydrogen bonds the number of cross-linked units is two. It has been found by infrared spectroscopy and viscometry for the sodium ionomer based on the styrene–acrylic acid (1.74% of acrylic acid) copolymer that the average number of ion pairs in ionic associated species is four[70,72].

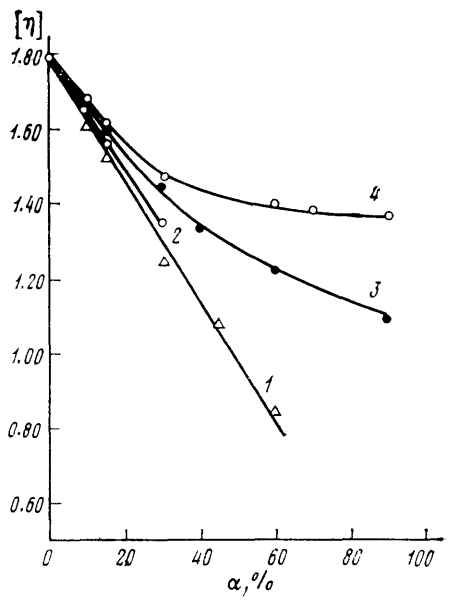

Figure 4. Dependence of the intrinsic viscosity in tetrahydrofuran on the degree of neutralisation of Na-ionomers (curve *1*), Rb-ionomers (curve *2*), Zn-ionomers (curve *3*), and Ca-ionomers (curve *4*) based on the styrene–methacrylic acid copolymer[75].

The set of data obtained for dilute solutions of sodium ionomers based on statistical styrene–MAA copolymers of different compositions suggests that the characteristics of the hydrodynamic behaviour and conformations of the ionomer macromolecules are determined by the formation of fairly large ionic associated species, which can behave as a disperse intramolecular microphase[124,125]. This type of microprecipitation phenomenon with all its consequence is characteristic only of block copolymers in selective solvents[126–130]. The observed specific feature of ionomers with a statistical distribution of units in the chain makes it possible to regard them as pseudo-block copolymers in solution. The intramolecular aggregation of ion pairs is not accompanied by the dissociation of interatomic bonds and a change in the sequence of units, i.e. the primary structure of the statistical copolymer chain is maintained. The secondary structure arising under these conditions imparts to the ionomer macromolecules a conformation more complex than that of the statistical coil.

One must bear in mind that the increased concentration of units with salt groups in the separate regions within the ionomer macrochain is a factor promoting an increase of the local electrostatic potential, enhanced binding of the metal cations, and the formation of ionic associated species with a size such that they begin to behave as a heterogeneous microphase. As an example of the influence of the mode of distribution of salt groups in the chain on the strength of the binding of counterions, one may refer to a study[131] where it has been shown that, for the same monomer ratio, aqueous solutions of sodium salts of the methyl acrylate–acrylic acid copolymer with salt units arranged in groups along the chain have a lower viscosity than solutions of the copolymer with a uniform (statistical) distribution of sodium acrylate units. Thus, even in aqueous solution, the arrangement of salt units in groups promotes an enhanced binding of counterions and the contraction of the coil; in a non-polar medium all these processes are additionally enhanced by the incompatibility of the salt groups and the solvent.

In this respect the hydrogen bonds in CCC are manifested in the opposite way[57,61,64]. The considerable concentration of unsaturated acid (or its salt) units in groups along the macrochain leads to a weakening of the influence of the hydrogen bonds and an enhancement of the influence of ionic interactions on the size and structure of the macrocoil in an inert non-polar solvent. Hydrogen and ionic bonds may prove to be comparable as regards the strength of their influence on the internal structure of the coil when the copolymer chain contains a small amount of statistically distributed units of the unsaturated acid or its salt; in this case both interactions are mainly pair interactions (the formation of large ionic associated species is unlikely) and the intrinsic viscosities of solutions of such copolymers in the acid and ionomeric forms are virtually the same[66,67,69].

It can be assumed that the selective interactions of the salt groups with one another, the formation of ionic associated species, and their segregation as a microphase occur in ionomer solutions for the same reasons as in the bulk of the ionomer (the incompatibility of the salt groups with the hydrocarbon part of the chain and electrostatic interactions). However, in solutions the formation of ionic associated species is also promoted by the thermodynamic incompatibility of the salt units with the weakly polar solvents usually employed for ionomers. The presence of a microphase in the form of ionic associated species determines the specific features of the behaviour of ionomers not only in the condensed state but also in dilute solutions.

The validity of the idea of the dominant role of ionic interactions within the chain and intense intramolecular processes as the most characteristic feature of isolated ionomer macromolecules in solution is confirmed by experimental data. All the methods for altering the strength of electrostatic interactions lead to an appreciable alteration of the conformation of the coil, which is usually observed by measuring the intrinsic viscosity. The strength of ionic interaction within the chain may be regulated by changing the charge density on the chain (i.e. the degree of neutralisation), by altering the radius and charge of the cation introduced into the ionomer and the dielectric constant of the medium (solvent), or by introducing into the solution small amounts of substances capable of active solvation of the cations. The data quoted

above reflect the influence of the majority of these factors on the strength of ionic interactions.

The interesting possibility of a specific influence on the order of ionomer macromolecules within the chain and on their solubility can be realised by taking into account the nature of solvation phenomena. The fact that the solvent exerts a significant influence on the strength of ionic interactions within the chain in ionomers precisely by virtue of its solvating activity has been confirmed by the following experimental data. In a salt solution in DMF ($\epsilon = 37.6$) ionomers based on the styrene–MAA copolymer containing univalent metal ions have appreciably lower values of $[\eta]$ than ionomers based on the same copolymer but containing bivalent metal cations[75] (Fig. 3). Bivalent metal cations are bound by the polymeric ion more effectively than univalent cations. However in tetrahydrofuran (THF) ($\epsilon = 7.4$) the opposite behaviour has been observed for the same specimens[75] (Fig. 4): ionomers with univalent cations have a lower intrinsic viscosity. This is apparently due to the formation in this non-polar solvent of contact ion pairs for ionomers with univalent metals and solvate-separated ion pairs for the macromolecules of ionomers with bivalent metals. A similar dependence of $[\eta]$ on the charge of the counterion has been observed (Fig. 2) for neutralised specimens of the alternating maleic acid–hexadecyl vinyl ether copolymer in 1-octanol ($\epsilon = 10.3$); the calcium ionomer dissolves in this solvent even for $\alpha = 40\%$, while the sodium ionomer dissolves only up to $\alpha = 10\%$.[122] However, it must be emphasised that for ionomers the nature of the dependence of $[\eta]$ on the valence of the metal introduced into them is determined, apart from the nature of the solvent, also by the characteristics of the structure of the macro-chain. Thus in a salt solution in DMF ionomers based on the alternating maleic acid–hex-1-ene copolymer have a high value of $[\eta]$ when the chain contains bivalent metal cations[132], in contrast to ionomers based on the statistical methacrylic acid polymer[75].

When a non-polar solvent is treated with small amounts (several per cent) of other solvents capable of solvating metal cations more actively, an appreciable increase of the size of the macrocoil, i.e. of $[\eta]$ of the ionomer, is observed[66,67,70,72,75], although both the thermodynamic quality of the solvent and its polarity are hardly affected thereby on the macroscopic scale. The unravelling of the coil under these conditions is due to the weakening of the ionic interactions and the possible breakdown of large ionic associated species, because a weaker electrostatic field is generated around the solvated cation and the energy of the Coulombic interaction diminishes under these conditions. When solvents appreciably more polar than the main solvent are added, account must be taken of the significant increase of the local dielectric constant of the medium owing to the selective solvation of ion pairs by the more polar component of the solvent (this effect is manifested to a particularly large extent when water is added to an organic solvent, which is accompanied, as can be seen from Fig. 1, by the enhancement of the polyelectrolyte unravelling of the ionomer coil).

However, the influence of solvation processes on the intensity of ionic interactions can be followed in the "purest" form[75] (Fig. 5) in relation to sodium ionomers using pyridine (5 vol.%) as an additive to THF. In this case both components of the solvent have similar polarities and both pure THF and THF with additives contain no "cross links" within the chains due to hydrogen bonds. Fig. 5 shows that the addition of pyridine ($\epsilon = 12.3$) to THF ($\epsilon = 7.4$) increases the intrinsic viscosity of the ionomeric specimens, because pyridine solvates sodium cations more actively and diminished thereby the intensity of the electrostatic interactions and the contraction of the coil. The weakening of ionic interactions within the chain in sodium ionomers in the presence of pyridine is manifested most clearly for $\alpha > 30\%$, i.e. in the region of the concentration of salt groups, for which the probability of the formation of large associated species increases. It is instructive that the ionomer with $\alpha = 90\%$ does not dissolve in THF, whereas in the presence of pyridine it does so. A similar improvement of the stability of ionomers is achieved by adding acetic acid[75] and methanol[121] to THF. Ionomers based on ethylene dissolve only in mixed solvents consisting of an organic solvent having a solubility parameter $\delta = 8$–9 and acetic acid[22].

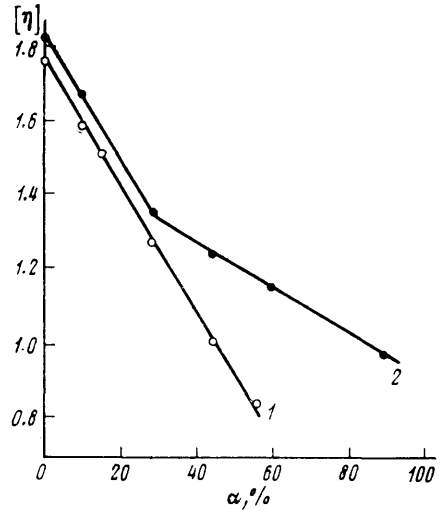

Figure 5. Dependence of the intrinsic viscosity on the degree of neutralisation of Na-ionomers based on the styrene-methacrylic acid copolymer; solvent: *1*) tetrahydrofuran; *2*) tetrahydrofuran + 5% of pyridine[75].

The choice of additives improving the solubility of ionomers is complicated by the fact that the main characteristics of the solvation of metal cations in non-aqueous media have still not been fully discovered, and comparative estimates of the solvating powers of solvents are not always correlated with their dielectric constants and dipole moments, because covalent σ and π interactions between the cation and the solvent molecule sometimes predominate over electrostatic (ion–dipole) interactions[133]. Significant changes in the solubility and hydrodynamic properties of ionomers can be expected when additives capable of forming complexes of the metal cations in the ionomeric are introduced into the inert solvent, particularly cations with *d* electron shells, whose high capacity of solvation is determined mainly by the donor–acceptor interactions with the solvent. This question still requires experimental tests.

In conformity with the concept of the dominant influence of ionic (electrostatic) interactions on the conformational characteristics of ionomer macromolecules, the size of the coil (for ionomers with univalent metal cations) is

independent of temperature in the range between -40° and +70°C, judging from viscometric data[107,120]. Furthermore, on passing to ionomers with bivalent metal cations, it has been noted[134] that the specific viscosity of their solutions decreases appreciably with increasing temperature. However, this finding not only does not conflict with the main concept but actually serves as one of its confirmations. The point is that an increase of temperature promotes the desolvation of cations, which is particularly pronounced for a bivalent metal cation, and this leads to an enhancement of their binding by the macrochain[135,136]. Under these conditions, the coil undergoes additional contraction, which is observed experimentally as a decrease of the viscosity of the ionomer solution[134]. In the discussion of the problem of the temperature dependence of the conformational parameters of the ionomer chain one must take into account the fact that the degree of desolvation is determined not only by the charge of the cation, but also by the nature of the solvent and the detailed mechanism of their interaction.

As shown above, the hydrodynamic properties of ionomers vary with the chemical nature of the cation introduced. The characteristics observed under these conditions are related in a definite manner to solvation phenomena and make it possible to determine the type of interaction between the counterion and the macrochain.

A definite view has now been formulated concerning the principal types of counterions in polyelectrolyte solutions. This problem has been dealt with in detail in reviews[137-145]. It is possible to distinguish three types of counterions: "free", "specifically bound", and "diffuse" or "atmospheric". Free counterions are not directly influenced by the electrostatic potential of the polymeric ion. The number of such counterions is fairly small even in aqueous polyelectrolyte solutions; their number in solutions with a reduced dielectric constant is even smaller, particularly in the case of bivalent counterions, as can be seen from the data presented at the beginning of this Section concerning the hydrodynamic and electrochemical properties of ionomer solutions.

The idea of the specific binding of counterions was first put forward in the study of aqueous solutions of polyacrylic acid salts[146,147]. Such counterions are associated with fixed ionic groups of the polymeric ion. As a result of this kind of binding in solution (even aqueous solutions), ion pairs and other more complex ionic formations and complex and chelate compounds are produced. The most important feature of the specific binding consists in the alteration of the solvent structure in the immediate vicinity of the polymeric ion and the counterion as a result of the desolvation or at least the reorganisation of the medium around the ion.

Diffuse or atmospheric counterions are subject to the influence of the electrostatic potential of polymeric ions, but they are not associated with the latter quite as strongly as specifically bound counterions. These ions form an ionic "atmosphere" around the polymeric ion and are retained in the vicinity of the latter exclusively by virtue of Coulombic interactions. Atmospheric counterions retain their solvation shells. The occurrence of specific binding does not eliminate the ionic atmosphere; the latter always exists to some extent around the polymeric ion.

The reversibility of the normal sequence of the binding of alkali metal ions by polycarboxylic acids in aqueous solutions can be regarded as direct evidence for occurrence of specific binding[148-157]. The normal binding sequence (from lithium to caesium) obeys the electrostatic interaction law, according to which the solvated ion with the minimum radius (Cs^+) is bound more strongly than the solvated ion with the maximum radius (Li^+). The opposite variation, observed for polycarboxylic acids, indicates the desolvation of counterions and hence their specific binding, which entails an increase of the viscosity of aqueous solutions of polycarboxylic acid salts in the sequence Li → Cs.

Water-soluble CCC salt exhibit a similar variation of the viscosities of the solutions as a function of the radius of the added cation: the intrinsic viscosity of such CCC salt solutions increases in the sequence Li < Na < K < Rb.[158,159]

As already mentioned above, the same type of variation of the viscosity for dilute solutions of ionomers is observed also when organic solvents are used[75,110,121,122]. Presumably the observed feature of carboxy-groups, which is manifested in the specific binding of the counterions and the formation of ion pairs in the macrochain of polycarboxylic acid salts even in an aqueous medium, should become still more pronounced for neutralised CCC in organic solvents with $\epsilon < 81$.

On passing from dilute solutions of ionomers to more concentrated solutions, there is a possibility of the formation of macromolecular associated species via interchain ionic cross links. Indeed ionomers (particularly ionomers with a bivalent metal) based on the styrene–MAA copolymer exhibit a sharp non-linear increase of the intrinsic viscosity in benzene ($\epsilon = 2.28$) with increase of the concentration above 1%, which is due to interchain association, whereas CCC itself (with MAA contents of 2 and 5%) in an acid form shows no deviations up to a concentration of 2.5%.[81] However, in dioxan ($\epsilon = 2.21$) the same monomers show no deviations from linearity up to a concentration of 2.25%. It is suggested that the relatively weak interaction between the ion pairs in this solvent can be a consequence of the solvation of the cations by dioxan. This example shows that, when solvents are compared from the standpoint of their influence on the intensity of electrostatic interactions within the chain and between different chains of ionomers, it is insufficient to take into account only the dielectric constants; one must also consider their solvating power.

In this connection one must emphasise that the selection of the solvent is particularly important in the determination of the molecular weights of ionomers. It has been found that the molecular weights of CCC and their sodium and barium ionomers with the same degree of polymerisation prove to be the same, when they are determined by light scattering in dioxan, whereas in benzene (working concentrations not in excess of 1%) the formation of interchain associated species in barium ionomers leads to an appreciable increase of the measured molecular weights[81].

The occurrence of interchain ionic interactions with increasing concentration causes such ionomer solutions (in the absence of dissociation in the given solvent) to have a higher viscosity than solutions with the corresponding copolymers in the acid form, wheras in dilute solutions ($c < 1\%$) the opposite relation is observed[75,81,121]. Similarly an increase in the degree of neutralisation (α) of carboxy-groups is accompanied by a decrease of $[\eta]$ and the viscosity of solutions of ionomers with a concentration of several per cent increases with increasing α.[75,121]

Whereas intramolecular and intermolecular association of the ionomer molecules in the presence of univalent cations takes place as a result of the ion pair interaction,

bivalent metal cations can give rise to ionic triplets of the type

$$\}\text{—COO}^-M^{2+}\ ^-\text{OOC—}\{,$$

which are much more stable than a quadrupole made up of two ion pairs, The interchain association processes of macromolecules with salt groups are therefore most instructive for solutions of ionomers containing bivalent metal cations[75,81,114,134,160]. The nature of the bivalent metal also plays an important role under these conditions: judging from measurements of the dynamic double refraction, the calcium ionomers based on the styrene–MAA (8 : 2) copolymer form in TMF rod-like aggregates containing several thousand macromolecules, while zinc ionomers give rise to molecularly disperse solutions under these conditions[115].

The interchain interactions in solutions of ionomers containing univalent and bivalent metal cations lead to structure formation and gel formation[69,114,115,120,134,160,161], the nature of the structures produced being determined (other conditions being equal) by the polymer concentration and, depending on this factor, there is a transition from the gel state to a true solution on high dilution, i.e. reversible gels are formed. The occurrence of such a transition, which is impossible in polymeric gel systems with covalent cross links, is a characteristic feature of polymers with ionogenic groups where interchain ionic cross links have a finite lifetime and exhibit a definite mobility, i.e. they can break down and reform. Similar reversible gels are produced by poly(methacrylic acid)[162] and its salts[163] in water.

The nodes of the network structure of ionomer gels in organic solvents with a low polarity consist of concentrations of salt groups (ionic associated species, ionic swarms), which leads to microlayer formation in the system[120]. The energetic non-equivalence of the nodes of the network structure of an ionomer gel has been established; this is due to the heterogeneity of the ionic associated species produced, the energy of which is between 2 and 11 kcal mole^{-1}.[120] Since the structural order in the gel state is to a large extent predetermined by the conformational characteristics of isolated macromolecules, presumably the conclusion that ionic associated species of different composition are formed and undergo microprecipitation applies equally to ionomer macromolecules in dilute solutions.

The mobility of ionic bonds in gels increases with temperature: the gel of a strontium ionomer, which is fully elastic at 20°C and is based on the MMA–MAA copolymer, passes to the viscoelastic state with increase of temperature in cyclohexanone (ϵ = 18) and at 100°C the specimen (α = 10%) acquires viscofluid properties[161]. Similar transitions have also been observed for gels of sodium monomers based on the same copolymer[120]. The transition of these systems to the viscofluid state is displaced towards higher temperatures with increasing degree of neutralisation of carboxy-groups; there is a corresponding increase also of the range of viscoelasticity and the maximum deformation in the viscoelastic state diminishes under these conditions[120,161]. In this case one may speak of a close analogy between the behaviour of ionomers in bulk and their gels under the influence of temperature, which is probably due to similar processes involving the decomposition and reorganisation of ionic associated species.

Continuing the consecutive comparison of ionic interactions and hydrogen bonds in terms of the strength of their influence on the properties of CCC and ionomers, we may note that the greatest strength of ionic bonds, compared with hydrogen bonds, is manifested most clearly in the range of concentrated solutions of the corresponding copolymers. The entire set of experimental data obtained confirm this. The results of a study[69] of the copolymer of styrene with 4 mole % of acrylic acid and its sodium ionomer (α = 25%) are very instructive in this respect. Although the intrinsic viscosities of the CCC and its ionomer in toluene are virtually the same, the transition to concentrated solutions made it possible to discover the following differences between these types of copolymers: (1) the critical concentration for the formation of a complete three-dimensional network of strengthened interchain contacts diminishes almost by a factor of two on passing from the CCC to its ionomer; (2) a high heat of activation for viscous flow has been observed in ionomer solutions; (3) in contrast to its neutralised specimen, the copolymer in the acid form does not form gels in toluene.

With increase of the ionomer concentration; even for a low content of salt groups in the macrochain, there is apparently an increase of the probability of the formation of large ionic associated species at the intermolecular level, and in such solutions there is a corresponding onset of segregation phenomena, i.e. a microphase appears. In contrast to this, in a dilute solution of an ionomer with a low content of salt groups (of the order of 1%) in the macrochain, mainly ionic quadrupoles are formed, which do not differ from the dimeric hydrogen bonds in CCC as regards their influence on the conformational characteristics of the coil.

* * *

Analysis of the results of the study of ionomers shows that the formation of ionic associated species (multiplets and clusters) is the key factor which determines the specific features of the properties of these complex polymeric structures in bulk and in solution. The results obtained suggest a particular sensitivity of the conformational parameters of ionomer macromolecules and of the internal structure of their coils to any types of influence on the intensity of ionic (electrostatic) interactions, because the latter predominate as regards the strength of their influence on the above characteristics of ionomers. However, one cannot fail to take into account also the strong selective interactions between the carboxy-groups of the copolymers. The understanding of the mechanism of the primary ordering processes within the chain (with allowance for the formation of ionic and hydrogen bonds) can lead to the discovery of methods for the specific regulation of these processes, which in many respects determine the structure and properties of the ionomeric specimen in the condensed state.

Nuclear Magnetic Resonance Study of Polymer-Low-molecular-weight Substance Systems

A.I.Maklakov and V.S.Derinovskii

The principles of the pulsed nuclear magnetic resonance method are briefly examined. A relation is demonstrated between the measured characteristics and the parameters describing molecular motion. The characteristic features of the derivation of information about molecules in the study of complex polymers-low-molecular-weight substance systems are considered. The principal results of investigations by the NMR method of solutions of polymers, plasticised polymers, polymer gels, and compositions consisting of low-molecular-weight substances adsorbed on polymers are presented. New possibilities in the application of the NMR method are indicated.
The bibliography includes 122 references.

I. INTRODUCTION

Polymer (P)-low-molecular-weight substance (LMS) systems are widely distributed in nature and technology. They include solutions of polymers, plasticised polymers, gels, and compositions consisting of small molecules adsorbed on a solid polymer. Various physical methods, one of which is NMR, are used to study such polymer systems. In many instances this method has unique possibilities. Thus it makes it possible to investigate the characteristics of the structure of complex polymeric compositions, the state of LMS molecules, the quality of the solvent, and the nature of molecular motion and helps to estimate the degree of completion of the incorporation of the LMS in the polymer, etc. However, frequently the possibilities of this method in the study of P-LMS systems are not fully appreciated and in many detailed monographs, devoted, for example, to the gel state of polymers[1] and plasticised poly(vinyl chloride) (PVC),[2] due importance is not attached to the results obtained by NMR.

The aim of the present review is (1) to describe the principal information about the pulsed NMR techniques, frequently used to investigate such compositions, (2) to examine the characteristic features of the derivation of information about molecules, (3) to describe the main results of studies on P-LMS systems, and (4) to indicate new possibilities in the application of NMR in the study of such compositions. It includes studies carried out in recent years (up to 1976) in which conclusions concerning the characteristics of the test systems have been reached from the molecular standpoint.

II. PRINCIPLES OF THE PULSED NMR METHOD

Three ways of observing NMR are used in the study of the structures and properties of matter: (1) high-resolution NMR; (2) broad-line NMR; (3) pulsed NMR. The general physical principles of the method have been described in detail in a number of monographs (for example, by Abragam[3] and Slonim and Lyubimov[4]) and will not be considered here. The characteristic features of the first method, which is one of the branches of microwave spectroscopy and makes it possible to investigate molecular structure including that of polymers, have been carefully dealt with[5,6]. The same may be said about broad-line NMR.[4,7] The most promising technique for the investigation of systems considered in this review is the pulsed NMR, the principles of which we shall describe briefly.

In order to observe the signal, the specimen is placed in a constant magnetic field H_0, at right angles to which a variable pulsed magnetic field H_1 is applied. It is generated by a pulsing microwave transmitter with a frequency $\omega_0 = \gamma H_0$, where γ is the gyromagnetic ratio of the resonating nuclei. The microwave pulse rotates the magnetisation vector $\mathbf{M}$ of the specimen by a definite angle, the magnitude of which depends on the duration of the pulse. Pulses rotating $\mathbf{M}$ by 90° ($\pi/2$ pulse) or 180° (π pulse) are usually employed. If a system of nuclei (usually protons) was at equilibrium before the application of the pulse, then $\mathbf{M}_0 \| \mathbf{H}_0$, where $\mathbf{M}_0$ is the equilibrium magnetisation of the system. After a time t has elapsed from the application of the pulse, for example, a $\pi/2$ pulse, the magnetisation vector has two components: a perpendicular component $M_\perp(t)$ and a parallel component $M_\parallel(t)$ in relation to the direction of $\mathbf{H}_0$. The nuclear relaxation process then consists in the approach of the value of $M_\perp(t)$ and of $M_\parallel(t)$ to M_0. The intensity of the signal obtained in pulsed NMR experiments as a function of the sequence and duration of the pulses is proportional to either $M_\parallel(t)$ or to $M_\perp(t)$.[8] The signal proportional to $M_\perp(t)$ is called the decrease of free induction (DFI), which is the Fourier transform of the absorption line obtained by stationary NMR methods.

Bloch suggested and it has been confirmed experimentally that

$$M_\parallel(t) = M_0[1 - \exp(-t/T_1)], \quad (1a)$$

$$M_\perp(t) = M_0 \exp(-t/T_2), \quad (1b)$$

where T_1 and T_2 are the longitudinal (spin–lattice) and transverse (spin–spin) nuclear relaxation times, which constitute additional useful information provided by the pulsed NMR method. If the NMR absorption line form is Lorentzian, then $M_\perp(t)$ is described by Eqn.(1*b*) and the line width δ is inversely proportional to T_2.

However, Eqns. (1*a*) and (1*b*) proved to be rigorously valid only for molecules containing a pair of nuclei and involved in rapid isotropic rotation. In other cases they may not hold. Thus the decreases of the values of $M_\parallel(t)$ and $M_\perp(t)$ for a three-spin anisotropically rotating system[9], four-spin systems[10], a number of polymer melts[11,12], and certain polymers in the viscoelastic state[13,14] are non-exponential, which makes it necessary to introduce effective relaxation times[11]. The spin–lattice relaxation times $T_{1\rho}$, expressed in a rotating coordinate system, are used nowadays in the study of polymer systems[8]. Studies on ^{13}C nuclear relaxation using specimens with the natural abundance of ^{13}C, have begun to develop very vigorously. The complete decoupling of the spin–spin interaction with protons, the increase of the sensitivity of pulse spectrometers, and the possibility of observing the relaxation in individual molecular fragments (CH_3–, $-CH_2-$, etc.) give rise to unique prospects for the investigation of complex polymer systems[15].

Another important characteristic of the systems, obtained with the aid of the pulsed NMR technique, is the self-diffusion coefficient D_S.[8] It is noteworthy that the method employed to measure D_S makes it possible to measure separately the translational mobility of the polymer and LMS molecules in the absence of a concentration gradient of the components.

1. Relation Between NMR Parameters and the Characteristics of Molecular Motion

The transverse and longitudinal nuclear magnetic relaxation times are magnetic parameters of the test systems and are not of independent interest in the study of polymers. However, if nuclear relaxation in polymer systems occurs as a result of the modulation of the nuclear dipole–dipole interaction of molecular motion (which occurs for the majority of polymers[4] except for polymers with conjugated bonds[16]), then it is possible to establish a relation between T_1 and T_2, on the one hand, and the characteristics of the molecular motion, on the other.

The intensity of molecular motion is characterised by the kinetic energy of the molecules E. Thus it follows from the kinetic theory that, for non-interacting molecules with a moment of inertia I', rotating about their axis with an angular velocity ω,

$$E = \frac{I'\omega^2}{2} = \frac{kT}{2}. \qquad (2)$$

If a correlation time τ_C, defined as the period of rotation of the molecule by an angle equal to one radian, widely used in NMR, is introduced in the description of molecular motion[17], then it follows from Eqn. (2) that $\tau_C^2 \propto I'/T$. Hence it is seen that, at a constant temperature, τ_C depends on the moment of inertia of the kinetic unit involved in the motion. We can therefore expect, for example, that in polymer solutions τ_C for the rotation of a segment must be greater than τ_C for the solvent molecules. If the magnetic relaxation times are related to τ_C, then there is a possibility of measuring the rate of relaxation of macromolecules and LMS molecules separately, which is in fact done in many instances.

The form of the dependence of T_1 and T_2 on τ_C is determined by the type of molecular motion of the kinetic unit and its structure. Thus we have for the isotropic rotation of molecules containing two nuclei[3]

$$T_1^{-1} = \frac{2}{5}\frac{\gamma^4\hbar^2}{r^6} I(I+1)\left(\frac{\tau_c}{1+(\omega_0\tau_c)^2} + \frac{4\tau_c}{1+(2\omega_0\tau_c)^2}\right), \qquad (3a)$$

$$T_1^{-1} = \frac{\gamma^4\hbar^2}{r^6} I(I+1)\left(\frac{3}{5}\tau_c + \frac{\tau_c}{1+(\omega_0\tau_c)^2} + \frac{2}{5}\cdot\frac{\tau_c}{1+(2\omega_0\tau_c)^2}\right), \qquad (3b)$$

where I is the nuclear spin, h the Planck constant, and r the distance between the nuclei. Analogous relations can be formulated also for the rate of relaxation determined by the translation motion of two-spin molecules[18]. If the molecular motion is described by a spectrum of correlation times, then Eqns. (3) become somewhat more complex. Expressions for T_1 and T_2, modified taking into account the τ_C spectrum, have been published by Connor[19] and Grigor'ev and Maklakov[20] respectively. It is noteworthy that equations of type (3) for relaxation occurring as a result of the segmental motion of macromolecules have been obtained only for very dilute solutions[21,22], although such equations are used frequently in the interpretation of experimental T_1 and T_2 results for block polymers or their concentrated solutions: this leads to incorrect results in many instances[23].

If the relaxation takes place via several mechanisms, then the overall relaxation time, for example, the transverse relaxation time, is of the form

$$T_2^{-1} = \sum_i T_{2i}^{-1}, \qquad (4)$$

where T_{2i} is the relaxation time corresponding to the ith mechanism.

2. Characteristics of Nuclear Relaxation in Multiphase Systems

The above discussion refers to single-phase systems, which are characterised by unique values of T_1 and T_2. It is readily seen that the polymer–low-molecular-weight substance systems are "multiphase" from the standpoint of NMR.[24] The term "phase" in NMR is usually understood as a set of magnetic nuclei characterised by a single relaxation time. The parameters of the ith phase are the relaxation times T_{1i} and T_{2i}, the population p_i, i.e. the fraction of nuclei referring to this phase, and the residence time τ_i of the nuclei in the given phase. If the nuclei pass from one phase to another, then one speaks of the occurrence of exchange in the system; the probability of the transition from the ith phase is then equal to τ_i^{-1}.

The decreases of the transverse and longitudinal magnetisations, which carry useful information about specimens consisting of n phases, can be formulated analytically[25] as follows:

(1) For "rapid" exchange, when $\tau_i \ll T_{1i}$ or T_{2i}:

$$M_\perp(t) = \exp(-t/T_{2m}), \qquad (5a)$$

where $T_{2m}^{-1} = \sum_{i=1}^{n} p_i T_{2i}^{-1}$, i.e. the transverse magnetisation of the specimen is described by a single exponential function with an average time T_{2m}.

(2) For "slow" exchange, when $\tau_i \gg T_{1i}$ or T_{2i}:

$$M_\perp(t) \sim \sum_{i=1}^{n} p_i \exp(-t/T_{2i}), \qquad (5b)$$

i.e. the decrease of magnetisation is described by the sum of the exponential functions and times characteristic of each phase. If the $M_\perp(t)$ curve is appropriately resolved[25], it is possible to obtain the values of p_i and T_{2i} for each phase.

(3) For "intermediate" exchange, when $\tau_i \simeq T_i$ or T_{2i}, calculation is possible only in the case of two-phase systems ($i = 1$ or 2):

$$M_\perp(t) \cong \sum_{i=1}^{2} p'_i \exp(-t/T'_{2i}). \qquad (5c)$$

The measured quantities p'_i and T'_{2i} in Eqn. (5*c*) differ from the true parameters p_i, T_1, and T_2 characterising the phase. For example:

$$T'_{2i} = f(T_{2i}, p_j, \tau_j), \qquad (5)$$

where $j = 1$ or 2 and the function f has been published by Zimmerman and Britten[25] and in Chernyshev's review[26] Eqns. (5) are valid if the resonance frequencies ω_0 of the nuclei in each phase are identical; otherwise the relations between the observed and true parameters of the phases become more complex[27].

3. Derivation of Information about the Molecules in Complex Systems from NMR Data

Examination of Eqns. (3) and (5) shows that the derivation of information about the molecular characteristics of P–LMS systems is complicated and consists of several stages. In order to obtain the parameters describing the kinetic state of systems, it is usual to proceed via the following steps: (1) the magnetic parameters (T'_{1i}, T'_{2i}, p'_i, etc.), which generally speaking can differ from the true values characterising each phase, are measured; (2) a relation is established between the measured magnetic quantities and the kinetic units responsible for them (a segment of the macromolecule, its side groups, solvent molecules, etc.); (3) the true magnetic parameters of each phase (T_1, T_{2i}, p_i) are calculated from Eqns. of type (5*c*); (4) a definite relaxation mechanism, which establishes the type and characteristics of the motion of each kinetic unit, are attributed to the system; (5) the correlation times of the molecular motions of the polymer and low-molecular-weight substance are determined.

The first stage does not require explanation: it involves the measurement of the magnetic parameters, the values of which may be distorted by the exchange processes[28] occurring in the test systems (translational displacement of molecules from "phase" to "phase", spin diffusion, proton exchange, etc.). Since the systems considered are characteristic by several transverse and longitudinal relaxation times, the second stage of the treatment involves the assignment of the measured quantities to a specific kinetic unit whose motion determines a particular relaxation time. This process requires particular caution, since it can lead to an incorrect treatment of the results. For a more reliable assignment of the times to kinetic units, one of the system components (usually the solvent) is deuterated and ^1H and ^2D resonance is observed[29]. Next the true values of T_{1i}, T_{2i}, p_i, etc. are calculated from one of Eqns. (5) (third stage). After that, on the basis of general considerations or using additional information, a definite mechanism (dipole–dipole, quadrupolar, and spin–rotational interaction) is assigned to each relaxation time and the type of motion of the kinetic units and its characteristics (continuous rotation, jumps by large angles, etc., the presence of a spectrum of τ_c values) are specified. This makes it possible to select a definite relation between the correlation times of the motions and the magnetic relaxation times [see, for example, Eqn. (3)] and one can then calculate the values of τ_c (fifth stage). An example of the sequence of steps in the analysis of NMR data is provided by studies on adsorption systems[30] and polymer solutions[31].

The specific results obtained in recent years as a result of the applications of NMR to the study of systems in which we are interested are examined below.

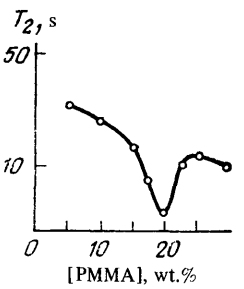

Figure 1. Concentration variation of T_2 for benzene in a solution of syndiotactic PMMA with a molecular weight of 2.2×10^6.[33]

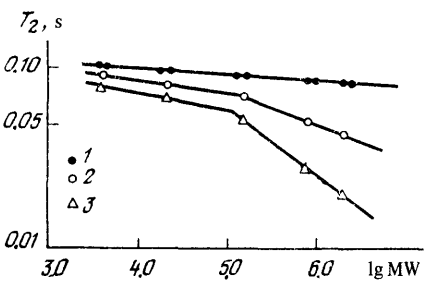

Figure 2. Variation of T_2 for the CH_3 group in the PIB–CCl_4 system with the molecular weight (MW) at 35°C; volume fraction of polymer: 1) 0.05; 2) 0.20; 3) 0.30.[34]

III. POLYMER SOLUTIONS

1. The Structure of the Solution

The measurement of the nuclear relaxation times of polymers yields information about the structure of solutions[4,32–34]. Thus the microscopic inhomogeneity of poly(methyl methacrylate) (PMM)—benzene systems has been investigated[33] and it was found that, depending on the polymer concentration, T_2 passes through a minimum (Fig. 1). The appearance of a minimum is a consequence of the diffusion of benzene molecules through the region of inhomogeneity of the solution. By means of a semiquantitative estimate of this effect, the authors found that the average size of the inhomogeneity is 200 Å, which roughly agrees with the radius of rotation of the polymer segment.

Characteristic breaks (Fig. 2), indicating the existence of a critical molecular weight or a critical concentration at which there is a sharp change in the properties of the system, have been observed in the study of polyisobutylene solutions (PIB) in CCl_4 on the curves relating T_2 to concentration or the molecular weight of the polymer [34]. According to the authors "hooked" formations are produced in the test solutions for polymer molecular weights and concentrations in excess of the critical values. It is suggested that these constitute the nodes of a fluctuation network made up of macromolecules and their supermolecular formations. The variation of local mobility, which determines T_2, with concentration is followed by observing the formation and density of this network.

The presence of empty cavities in concentrated solutions of atactic polystyrene in anisole, which are in a vitreous state, has been pointed out [35]. The LMS molecules in the cavities execute rotational and translational "jumps" at low temperatures. It has been found that LMS molecules then exhibit a tendency towards association [35,36]. The broadening of the ^{13}C NMR absorption lines in PIB solutions in CCl_4 [37] indicates a partial entanglement of the macrochains, which becomes more pronounced with increase of the molecular weight of the polymer and can be one of the causes of the formation of a three-dimensional network in solution.

The possibility of structural rearrangements in polymer solutions has been noted by Fedotov [38], who observed that the correlation time characterising the mobility of water molecules interacting with the macromolecules of poly(acrylic acid) (PAA) increases with increase of temperature from 10° to 80°C, while in a solution containing poly(methacrylic acid) (PMAA) it falls. The rearrangements are attributed to the uncoiling of the chains due to a redistribution of hydrogen bonds. It has also been found that the loose PAA macromolecule can be hydrated by twice as much water as the more rigid PMAA molecule. It is suggested that the presence of structures in macromolecules gives rise to steric hindrance to interaction between water and the macromolecule.

An attempt has been made to determine the fraction of macromolecules in helical and coiled conformations in aqueous solutions of serum albumin. [39,40] However, it is believed [41] that the information obtained in these studies [39,40] about the conformations of hydrated protein macromolecules is doubtful. Outhred and George [41] explained the same experimental results by assuming that the motion of the polymer macromolecules in solution is characterised by a spectrum of correlation times with a maximum at $\tau = 10^{-9.3}$ s.

Additional information about the structure of solutions has been obtained by studying the self-diffusion coefficient of both LMS molecules and macromolecules in aprotic solvents [42,50]. The results are usually interpreted by means of Fujita's free volume theory [51]. The parameters characterising the size of the "critical" regions for diffusional motion in solutions of natural rubber (NR), PIB, polystyrene (PS), and PMMA have been determined [42-44]. It was established that (1) in translational motion the greatest disruption of the packing of solvent molecules in the vicinity of macromolecules is observed for rigid-chain polymers and (2) that the self-diffusion of LMS molecules takes place as a result of the interchange of the kinetic units of the polymer and whole groups of solvent molecules.

A study of the self-diffusion of LMS in the PS–benzene and PS–cyclohexane systems showed [45] that the minimum free volume necessary for "jumps" by solvent molecules is greater by a factor of approximately 1.5 in the second system compared with the first. Analogous data have been obtained for PMMA solutions in benzene and acetone. [46] The temperature dependence of the free volume has been studied for these solutions and the coefficient of the expansion of the free volume in PMMA has been determined.

The study of D_S of the solvent with increasing concentration of polymers (PMMA, PS) [45,46] suggests the formation of cavities within entangled macromolecules which LMS molecules enter and are trapped. The cause of the inhibition of the translational motion of small molecules is believed to be [45,46,50] the formation of short-lived globules and small cavities in which solvent molecules are accommodated. Kosfeld and Goffloo [45] concluded that the self-diffusion of solvent molecules is determined by the motion of the macromolecules. The nature of the concentration variation of D_S for macromolecules permits a number of conclusions concerning the distribution of macromolecules in solution [42,44,47].

2. Estimation of the Quality of the Solvent

The quality of the solvent has a significant influence on the intermolecular interaction of the components in polymer solutions, which determines the molecular mobility. Since T_1, T_2, and D_S depend on the latter, the measurement of nuclear magnetic characteristics makes it possible to infer the quality of the solvent.

The first conclusions about the quality of the solvent based on the analysis of T_1 were put forward [52] in relation to the study of dilute PIB solutions in "good" (CCl_4) and "poor" (C_6D_6) solvents over a wide range of temperatures and polymer molecular weights. Comparison of the T_1 values for specimens corresponding to equal fractions of the solvent shows that relaxation in a good solvent is faster than in a poor one. It was also found that a minimum in T_1, caused by the rotation of the CH_3 group of the polymer, lies at a temperature 25°C lower in a good solvent than in a poor solvent and its value is smaller in the latter case. This finding apparently shows that the conformations of macromolecules in a good solvent are such that they give rise to less steric hindrance to the rotation of CH_3 groups.

It was later found that [53,54] the quality of the solvent has a similar influence on the intramolecular mobility also in moderately concentrated solutions. This conclusion was reached in a study of the temperature and concentration variation of the relaxation times T_1 and T_2 for PS and PMMA solutions in the aprotic solvents C_2Cl_4, C_6D_{12}, etc. Tanner et al. [47] observed that the translational motion of poly(ethylene oxide) macromolecules with a low molecular weight (approximately 1000) in a good solvent ($CDCl_3$) is more vigorous than in a poor solvent (CCl_4), while in the case of large macromolecules (with a molecular weight of approximately 870 000) the opposite relation holds. This has been explained [47] by taking into account the influence of the viscosity of the solvent and also of the solvation and shape of the macromolecules in solution.

3. The State of Solvent Molecules

The state of CH_2Cl_2 molecules in a solution of atactic PS in which the volume fraction of the solvent was 0.10 to 0.24 has been investigated [55]. The system is characterised by a weak P–LMS interaction. The calculated correlation

times of the solvent molecules surrounded by similar molecules (τ_{SS}) and in the vicinity of macromolecules (τ_{SP}) showed that $1 \leqslant \tau_{SP}/\tau_{SS} \leqslant 2$. According to the author[55], this showed that there is only one type of environment for LMS molecules in a PS–CH_2Cl_2 solution and that it is impossible to distinguish the "free" and "bound" solvent species. The inhibition of small molecules is more effective in a polymer with a larger molecular weight. The increased "lifetime" of the CH_2Cl_2 molecule in the "trap" with increase of the polymer concentration is caused exclusively by the influence of the macromolecular chains and not some special interactions between the π-electron system of the benzene ring and the CH_2Cl_2 molecule.

The state of solvent molecules in dilute polymer solutions has been thoroughly investigated[31,56-59]. Solutions with a strong intermolecular interaction (hydrogen bonds) were examined; the temperature and concentration variations of the nuclear spin–lattice relaxation times T_1 for protons, deuterons, and chlorine nuclei were investigated and the self-diffusion coefficients were measured. The behaviour of the solvent can be described with the aid of a simple model with two states:

$$A + M \rightleftarrows AM,$$

where the solvent molecule A can be either in a free state or in a bound state (as a solvate AM combined with the macromolecule M). It has been established for solutions of polyvinylpyrrolidinone (PVP) in chloroform, where a hydrogen bond is formed between the carbonyl group of the pyrrole ring and the deuterium atom of chloroform, that the "lifetime" of the hydrogen bond ($\sim 5 \times 10^{-11}$ s) is long compared with the rotational correlation time of the molecules of pure chloroform ($\sim 10^{-12}$ s), but is very short compared with the fastest motion of the macromolecule ($\sim 10^{-9}$ s).[31] In a PVP–pyrrole solution[59] the "lifetime" of the hydrogen bond is approximately twice as long as the lifetime of the corresponding bond in the PVP–chloroform system. The reorientation of the pyrrole ring about the C–H bond in the complex with the polymer is retarded by a factor of 10 compared with the reorientation of pure pyrrole, while the rotation of chloroform molecules in the complex with PVP is retarded only by a factor of 3. According to the authors, the "lifetime" of the hydrogen bond can be regarded as the "lifetime" of the polymer–solvent solvate.

Comparison of the results of studies on PS solutions in methylene dichloride[55] and of PVP in $CDCl_3$ [31] showed that the state of solvent molecules is determined to a large extent by the extent of the interaction between the polymer and LMS molecules. In systems with a strong interaction between the components there is a possibility of the subdivision of molecules into "bound" and "free".

The study of proton and deuteron relaxation in PMMA–benzene solutions[57] showed that, in the absence of a strong polymer–solvent interaction, the "lifetime" of the bond between the components is of the same order of magnitude as the rotational correlation time of the benzene molecule. At the same time the translational correlation time of benzene ($\sim 10^{-10}$ s) is longer almost by two orders of magnitude than the rotational correlation time.

As was to be expected, an increase of the polymer concentration in the solution leads to a decrease of the rotational and translational mobilities of the LMS molecules.[43,44] It is striking that the inhibition of the molecules, characterised by the ratio D_S/D_{S0}, depends very little on the nature of the polymer or on the type of LMS (Fig. 3). Nevertheless it is claimed[43] on the basis of a study of D_S for H_2O, CH_3COOH, CH_3OH, and CH_2Cl_2 molecules in PVP solutions that the stronger the polymer–solvent interaction the greater the inhibition of the [mobilities of the] latter.

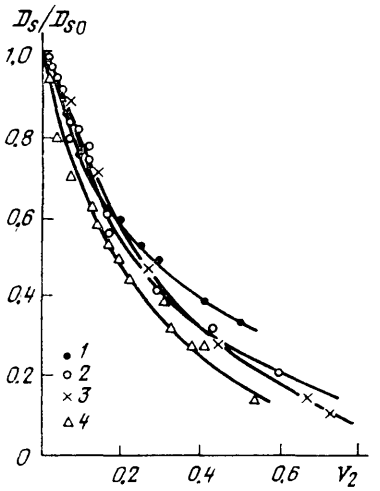

Figure 3, Dependence of the ratio of the self-diffusion coefficient of the solvent D_S in solution to the self-diffusion coefficient of the pure solvent D_{S0} on the volume fraction of the polymer in different systems: 1) natural rubber–benzene; 2) PIB–benzene; 3) PIB–toluene; 4) PMMA–toluene.[44]

The inhibition of [mobilities of] acetone molecules in solutions containing between zero and 20 wt.% PMMA has been studied over a wide temperature range[60] by the method of ^1H and ^{13}C spin–lattice relaxation. It was observed that the introduction of up to 10 wt.% of the polymer does not affect the translational and rotational diffusion of acetone molecules, but in the presence of 20 wt.% of the polymer the mobility decreases sharply. The sharp inhibition [of mobilities] of the solvent molecules over a narrow concentration range can be explained by the formation of an entangled network of macromolecules.

4. The Study of Selective Solvation

An independent field of research on complex formation in polymer solutions by NMR involves the study of the selective solvation by the polymer of one of the components in a mixture of two solvents[29,61-64]. The mixtures are chosen so that one component is a good solvent and the other a poor one. Liu observed for the first time[61] in a study of T_1 for the PIB + CCl_4 (C_6H_{12}) + CH_2Cl_2 and PMMA + CCl_4 + CH_3COCH_3 (CH_2Cl_2) systems that the spin–lattice relaxation time of one of the components of the mixture of solvents depends strongly on the type of added polymer, i.e. that the interaction of the polymer with this solution component is stronger than with the other one. In the systems indicated above CH_2Cl_2 is a good solvent for PMA but a poor one for PIB.

The study of the spin–lattice relaxation of C_6H_6 + C_6H_{12} + PS, C_6H_6 + CCl_4 + PMMA, $CHCl_3$ + CCl_4 + PMMA, and C_6H_6 + $CHCl_3$ + PMMA mixtures[62] with different ratios of the LMS components at a constant polymer concentration established that in mixtures with PS benzene (a good solvent) is solvated preferentially and that the polymer monomer unit combines with four C_6H_6 molecules. The numbers of benzene and chloroform molecules adsorbed on the PMMA monomer unit are respectively 5 and 4.

In solutions of PVP [29] in a mixture of solvents consisting of $CHCl_3$ (a good solvent) and C_6H_{12} (a poor solvent) the inhibition of the rotation of $CHCl_3$ molecules was observed as the polymer content was increased, while the mobility of C_6H_{12} remained unchanged. This finding can be explained by the preferential solvation of PVP by $CHCl_3$. Anallgous preferential solvation of PS by $CHCl_3$ had been observed in PS + $CHCl_3$ + CH_3COCH_3 mixtures[29].

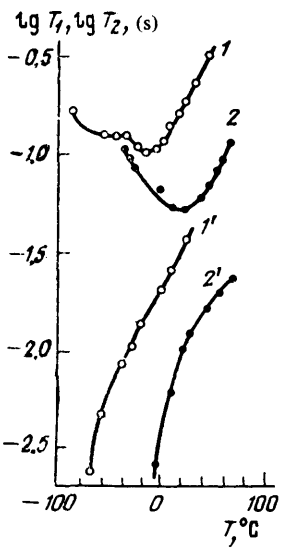

Figure 4. Temperature variation of $\lg T_1$ (curves *1* and *2*) and $\lg T_2$ (curves *1'* and *2'*) for solutions of PS in $C_6D_6CD_3$ at concentrations of 5 wt.% (curves *1* and *1'*) and 40 wt.% (curves *2* and *2'*).[53]

A novel approach to the study of the solvation equilibrium in a system with a mixed solvent, namely CCl_4 + PMMA + C_6H_6, at 31°C in the polymer concentration range from 0 to 100 g litre^{-1} has been described[63,64]. The author introduced the equilibrium constant K for the exchange of solvent molecules, which depends on the concentrations of molecules of both solvents—free and involved in solvate complexes with the polymer. In order to determine K, use was made of the measured T_1 for benzene protons at different polymer concentrations. It was found that in the system indicated above the exchange equilibrium constant obtained is $K = 2.5 \pm 0.5$; on the other hand, $K = 0$ in the C_6O_6 + PMMA + C_6H_6 system, where there is no selective solvation. Thus K is a convenient measure of the preferential solvation of one component (C_6H_6).

5. Phase Separation in Solutions

Information about the intermolecular interactions under conditions preceding the separation of the solution into layers has been obtained[53] in a study of PS solutions in aprotic solvents (CCl_4, $CDCl_3$, $C_6D_5CD_3$, and C_6D_{12}) at different concentrations. The amount of polymer was varied from 5 to 40 mole % and its molecular weight was varied from 10^4 to 10^6. The temperature variation of T_1 and T_2 for PS solutions in $C_6D_5CD_3$ is illustrated in Fig.4. The authors suggest that the stepwise variation of T_1 reflects the change in the state of the macromolecules, which involves the appearance of long-lived polymer–polymer contacts (associated species, aggregates), i.e. the separation of the solution into layers. Under these conditions, the observed relaxation time T_1 is a weight-average quantity referring to protons, highly mobile macromolecules, and macromolecules inhibited by the appearance of long-lived interchain contacts.

It has been observed[52] that the time T_2 in dilute solutions also changes when phase separation begins.

6. Characteristics of the Motion of Macromolecules

The mechanisms of the motion of PIB macromolecules in aprotic solvents have been investigated[52] and two forms of macromolecular motion have been found: (1) the low-temperature form involving the reorientation of the CH_3 groups and (2) the high-temperature form involving segmental motion. The addition of a low-molecular-weight substance facilitates the rotation of the CH_3 groups, whose motion is not free in the pure polymer.

The analogous problem of the study of the local forms of motion (rotation of CH_3 groups and reorientation of the Si–C bond) of macromolecules has been solved[65] in relation to solutions of PDMS [polydimethylsiloxane] having different molecular weights in protic (C_6H_6, C_6H_5Cl) and aprotic (C_6D_6, C_6D_{12}, CCl_4) solvents. The polymer concentration in solution varied from 1 to 20 g in 100 ml of the solvent. It is assumed that the inhibition of the rotation of the CH_3 groups increases with increasing molecular weight of the polymer at fairly high concentrations of the latter owing to steric hindrance.

In solutions of poly(ethylene oxide) in HCl, H_2O, D_2O, and DCl and pentachloroethane ($CHCL_2CCl_3$) the motions associated with conformational transitions around C–C bonds were investigated[66]. It was noted that the rotation of the molecule as a whole influences the relaxation in low-molecular-weight oligomers only, i.e. the mechanism of the motion of macromolecules changes from segmental to the rotation of the molecule as a whole as the molecular weight decreases.

The influence of the molecular weight of the polymer on the degree of inhibition of the translational motion of solvent molecules has been demonstrated[42,44,49]. New possibilities for the study of macromolecular motion arise in connection with the ^{13}C NMR method[37,67–73]. It has been observed that the motion of the carbon chain is almost isotropic in a 20% solution of PIB in $CDCl_3$.[37] The study of PS–tetrachloroethylene solutions at the same concentration showed that the rotation of the phenyl groups of the polymer is subject to a considerable steric inhibition, because their correlation time is appreciably longer than the effective correlation time for segmental motion[67]. It has been established that macromolecules with low molecular weights move as a whole and that these motions determine the observed T_1, while macromolecules with

high molecular weights exhibit predominantly an internal (segmental) motion of the polymer chain, which is fairly rapid[64-73].

Comparison of the activation energies for segmental motion in polyethylene (PE), polypropylene, and PIB solutions in *o*-dichlorobenzene showed[37] that the activation energy E increases on passing from PE to PIB. This is due to steric hindrance to the motion of methyl groups when the latter are introduced into the polymer as side units. The study of the relaxation of ^{13}C nuclei showed[73] that the motion of poly(propylene oxide) (PPO) molecules and PIB with a molecular weight of 2500 in $CDCl_3$ depends on the frictional forces acting from the side of the immediate environment. According to the author[73], the immediate environment consists of the first solvation shell, which is believed to be formed when the ratio of the number of $CDCl_3$ molecules to the number of monomer units is 5. It was established that the motion of CH_3 groups of PIB is strongly inhibited and that their orientation takes place co-operatively with neighbouring methyl groups. It is claimed that in PPO and PIB solutions, where the ratio of the number of solvent molecules to the number of monomer units exceeds 5, the correlation of the motion of the main chain disappears over a distance equal to 2–3 monomer units.

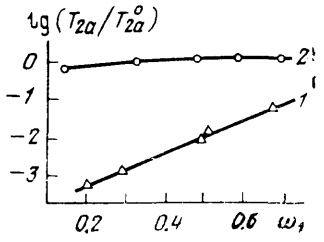

Figure 5. Dependence of $\lg (T_{2a}/T_{2a}^0)$ on the weight fraction ω_1 of the plasticiser in different systems: 1) PVC–DBP; 2) PVC–glycerol (at room temperature) [24].

IV. PLASTICISED POLYMERS

Plasticised polymer systems differ from solutions by the high content of the polymer and the consequent very high viscosity. The difficulty of the study of such objects by NMR is due to the fact that the plasticisers usually employed are high-boiling liquids whose molecules are bulky, have a complex structure, and possess a large number of internal degrees of freedom; the deuteration of such molecules is usually difficult. However, a series of results have been obtained recently showing the usefulness of NMR, particularly its pulsed version, in the study of such systems.

It has been established[24] that, from the standpoint of NMR, plasticised polymers are multiphase systems where exchange between the phases as a rule does not occur or is fairly slow. In this case the study of the decrease of transverse magnetisation[74], from which the nuclear relaxation time T_1 is determined by Eqn.5*b*, is most informative. Specimens with a moderate content of the plasticiser (up to 80 wt.%) are described by two times T_2 over a wide range of temperatures: a long time T_{2a} and a shorter time T_{2b}. The former characterises mainly the plasticiser protons and the latter the polymer protons[75].

1. Assessment of the Nature of the Plasticisation of Polymers

In the first studies[76,77] on plasticised PVC by the pulsed method it was shown that at room temperature T_{2a} for a molecular plasticiser introduced into the polymer is smaller by 2–3 orders of magnitude than T_{2a}^0 for the pure plasticiser, while in a polymer plasticised by a structural plasticiser $T_{2a} \simeq T_{2a}^0$. This feature makes it possible to deduce the type of plasticiser directly from the measured transverse relaxation time.

The concentration variation of $\lg (T_{2a}/T_{2a}^0)$ for a molecular plasticiser (Fig.5) is described by the equation[24]

$$\lg [T_{2a}/T_{2a}^0] = A\omega_1 + B$$

where ω_1 is the weight fraction of the plasticiser and A and B are constants which depend on the nature of the polymer–plasticiser interaction (high values of A and low values of B correspond to a strong interaction and low values of A and high values of B correspond to a weak interaction). In many systems (for example, in PVC plasticised with glycerol, ethyl stearate, castor oil, phthalates, and sebacates) the form and positions of the curves corresponding to this relation make it possible to determine the limits of the compatibility of the polymer and plasticiser and to introduce criteria for subdividing plasticisers into molecular and structural[78,79].

Analogous results were obtained for plasticised PS and polyvinylbutyral[80], which demonstrates the applicability of the parameter T_{2a}/T_{2a}^0 to the estimation of the nature of the plasticisation for a wide range of polymers. The characteristics of the plasticisation of vinyl chloride–vinyl acetate copolymers by phthalates have been investigated[81,82]. Thus dioctyl phthalate (DOP) is a molecular plasticiser for PVC and a structural plasticiser for poly(vinyl acetate). Examination of the concentration variation of T_{2a} made it possible to assess the compatibility of DOP with copolymers and to observe an inversion of the action of the plasticiser (a transition, depending on the content of vinyl acetate groups, from the molecular to the structural mechanism of plasticisation).

A broad-line NMR study of the nature of the polymer–plasticiser interaction in relation to rubbers plasticised by phthalates and sebacates has been undertaken[83]. The difference between the second moments of the absorption lines of the plasticised specimen, on the one hand, and the pure polymer and plasticiser taken in appropriate proportions, on the other, served as a characteristic of the interaction.

2. The Introduction of the Plasticiser into the Polymer

Measurements of T_{2a} make it possible to investigate the processes involved in the combination of the plasticiser with the polymer in the mixing and rolling stage, i.e. pulsed NMR can be used for purely technological purposes[80,84]. Thus the optimum time t_m for the mixing of PVC with phthalates and sebacates at 98°C in order to obtain a homogeneous mixture has been estimated (Fig.6). The time t_m was determined from the point of intersection of the tangents to the sharply descending and horizontal sections of the T_{2a}—mixing time curves. The mixing time

t_m increases for all plasticisers with increase of their concentration. It is a minimum for systems which are highly compatible. An analogous approach has been used to estimate the optimum rolling time for films of plasticised PVC. It was established [84] that, with increase of the temperature of the operation, the rolling time required for the preparation of homogeneous films diminishes. Analogous results have obtained in the study of the pressing of PVC specimens [80].

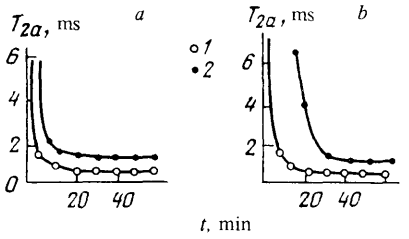

Figure 6. Dependence of T_2 on the mixing time of the components at 98°C for PVC–DBP (*a*) and PVC–DOP (*b*) systems containing 40 wt.% (curves *1*) and 50 wt.% (curves *2*) of the plasticiser [84].

3. The State of Plasticiser Molecules Introduced into the Polymer

The main aim of the plasticisation of polymers is to create the maximum molecular mobility in the polymer–plasticiser system [85]. It is therefore of interest to investigate the nature of the motion of small molecules introduced into the polymer, particularly since plasticiser molecules constitute a kind of "label" characterising the system as a whole[24].

(a) Plasticised PVC. The PVC–phthalate system with a low polymer content (< 10 wt.%) belongs to gels of type 1B.[1] However, at high PVC concentrations (> 50 wt.%) they can be treated as ordinary plasticised systems.

Measurements of the spin–lattice relaxation times in PVC plasticised by various phthalates and nitrophthalates in the range from −150°C to +70°C [86,87] made it possible to determine the nature of the motion executed by small molecules: the methyl groups are seen to rotate between −150°C and −120°C, while at approximately −50°C alkyl groups rotate as a whole at a frequency of approximately 10^7 Hz regardless of the concentration of the added plasticiser. However, a complete interpretation of the temperature variation of T_1 in such systems is difficult, since the measured quantities are as a rule distorted by exchange [74]. The study of the temperature variation of the transverse relaxation times proved to be more informative in this respect.

In the region of moderate plasticiser concentrations (≤ 60 wt.%) the PVC–DMF and PVC–DOP systems [74,75] are characterised, as mentioned above, by two relaxation times (Fig. 7). It was established that T_{2a} is determined by the rotational motion of the plasticiser molecules. The decrease of T_{2a} with increasing content of the polymer in the system relative to T_{2a}^0 over the entire experimental temperature and concentration ranges indicates a reduction of the rotational mobility of the phthalate molecules introduced into PVC. It has been noted that in the specimens investigated there is a distribution of correlation times for the reorientation of molecules. This makes it possible to regard the entire plasticiser introduced into the polymer as "bound" to different extents, provided that the degree of "binding" is estimated in terms of the degree of retardation of the rotational motion. The most probable correlation times for the rotational (τ_{r_0}) and translational (τ_t) motions of DMF molecules have been estimated.

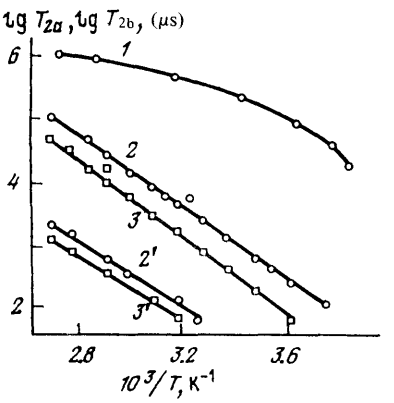

Figure 7. Temperature variation of lg T_{2a} (curves *2* and *3*) and lg T_{2b} (curves *2'* and *3'*) for PVC–DMF systems containing 24.2 mole % DMF (curves *2* and *2'*) and 13.3 mole % DMF (curves *3* and *3'*). Curve *1*—pure DMF. [75]

The NMR method permits a sounder approach to the determination of the lifetime of the polymer–plasticiser solvate. Thus in the PVC–DMF system it is most useful to select as the lifetime the correlation time τ_{r_0} for the rotational motion as the shortest time parameter characterising the system. However, since the correlation times for reorientations are characterised by a spectrum of values, one must assume that the lifetimes of various solvates present are different and have a wide range of values, which depend on the content of the plasticiser and the temperature of the measurement.

It has been established that the phthalate molecule interacts with the polar group of PVC, undergoes a reorientation during a period $\tau_t \geq \tau_r$, and then "jumps" to another site where it begins to rotate, etc. The PVC–dioctyl sebacate system has been investigated [88].

(b) Plasticised nitrocellulose. A study of the characteristics of the molecular motion of trinitroglycerol (TNG) plasticising nitrocellulose (NC) has been described [89]. Only T_{2a} was measured by high-resolution NMR. Various nitrocelluloses with nitrogen contents varying from 10.9 to 13.9 wt.% were investigated; the TNG concentration was in the range 30–60 wt.%. The solvation limit, which depends on the nitrogen content in NC, was estimated. The degree of nitration of cellulose was shown to influence the mobility of the plasticiser molecules. The linear relation between lg T_{2a} and $1/T$ makes it possible to determine the activation energies for

the motion of TNG. The values of E proved to be independent of the plasticiser content.

The analogous NC–TNG systems have been investigated[75,90] by pulsed NMR. Like the PVC–phthalates specimens, the above systems are characterised by two transverse relaxation times. The presence of a spectrum of correlation times for the motion of TNG molecules at $T < 60$°C was demonstrated. The pressure of a plateau on the $\lg T_{2a} = f(1/T)$ curves in the region of $T \geqslant 60$°C (Fig. 8) indicates the occurrence of exchange between the "quasi-free" and "bound" plasticiser species under these conditions. The rate of molecular exchange was estimated as ~10–10^2 Hz. The molecular motion in polystyrene plasticised by dibutyl phthalate has been investigated[91].

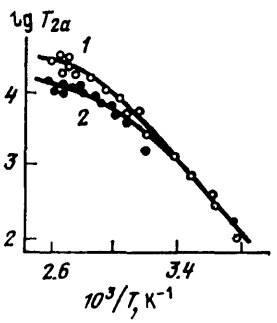

Figure 8. Temperature variation of lg T_{2a} for low-nitrogen (curve *1*) and high-nitrogen (curve *2*) nitrocellulose containing 50 wt.% of trinitroglycerol.[90]

The dynamic picture of the state of phthalate molecules introduced into PVC makes it possible to represent the overall picture of the transition of the plasticised system from the vitreous to the viscoelastic state. This transition is accompanied by a kind of "accelerated rocking" of the polymeric skeleton under the influence of the intense rotational and translational motion of the plasticiser molecules. The efficiency of this rocking depends on the number of internal degrees of freedom f of the plasticiser molecules and the amount of plasticiser. The condition for vitrification can be formulated as follows in this case:

$$\alpha f T_g \frac{Nm}{1-N} = E_p,$$

where N is the molar percentage of the plasticiser, m the number of monomeric units in the segment, E_p the minimum energy required to initiate segmental motion, α the proportionality coefficient, and T_g the glass point.

Ideas concerning the mobility of nitrocellulose macromolecules in plasticised specimens have been put forward[93].

V. THE GEL STATE OF POLYMERS

In the study of gels NMR has been used recently mainly to investigate aqueous polymer gels (agarose, gelatin, starch, carboxymethylcellulose, etc.). With some exceptions, the term LMS will therefore be understood below to imply water.

The majority of studies were carried out by pulsed NMR, gels containing a small amount of the polymer (2–3 wt.%) being characterised by unique values of T_1 and T_2 [94,95] or a one-component NMR absorption curve[96]. For a polymer content exceeding the above limit, there is a two-component absorption line. The broad component ($\delta \simeq 9$ Oe) is attributed to the polymer protons and the narrow component to the water protons[97].

1. The Formation, Fusion, and Ageing of Gels

Gels are known[98] to be characterised by gel (T_{gel}) and melting (T_m) points. The dependence of T_2 on the age of an aqueous agarose solution for T less than the gel melting point (Fig. 9) makes it possible to follow the gel formation process[95]. The curves illustrated in Fig. 9 suggest that an increase of the agarose content increases the rate of gel formation; the authors attribute this to the intensification of the nucleation stage. The decrease of T_2 in the course of the formation of the gel (Fig. 9) is accounted for by the decrease of the mobility of the macromolecules and of bound water. The T_2–agarose concentration curves indicate the formation of a macromolecular network. The temperature variation of T_2, measured in the course of the cooling of the specimen (curve *2'*, Fig. 10), shows a sharp break in the region of $T \simeq T_{gel}$ due to the loss of molecular mobility in the system. It is noteworthy that the $T_1(T)$ relations do not exhibit such anomalies. The decrease of T_2 with the duration of storage of the gel suggests the "ageing" of the system. Even a 3% solution of agarose at 40°C, i.e. above T_{gel}, "ages" in the course of 6 h without any visible signs of the formation of a network (T_2 diminishes).

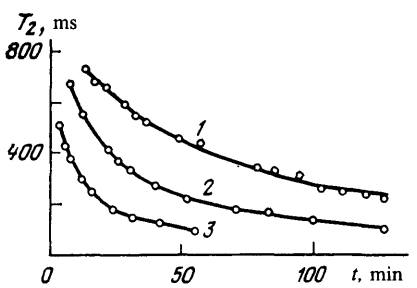

Figure 9. Dependence of T_2 on the gel formation time t at 34.7°C for different concentrations of agarose in solution (%) [95]: 1) 1.6; 2) 2; 3) 3.

The formation of the gel in a 0.5% solution of monodisperse α-gelatin with a molecular weight of 110 000 has been investigated[99]. The integral intensities J of lecithinyl, alanyl, prolyl, and arginyl lines were determined by high-resolution NMR in the course of the formation of the gel at 15°C. The form and positions of all the observed lines remain unchanged during the process, but the values of J diminish in accordance with the law

$$\frac{dJ}{J} = -K\,dt$$

with the same constant K for all the lines.

The decrease of J is attributed to the formation of helical molecules in which there is a sharp retardation of molecular motion, which entails a broadening of the line, precluding the possibility of its observation by high-resolution NMR. The same view has been expressed by Rouse and Gross[100]. This enabled Finer et al.[99] to reach conclusions about the possible conformational changes undergone by α-gelatin on formation of the gel. It is believed that gel formation is a multistage process in which the slow stage is described by the equation quoted above and involves the formation of the nuclei of the helix from the coil.

Gel formation in the poly(hexadecyl acrylate)–n-decane system has been investigated[101] with a polymer concentration varied from 1 to 100%. It was shown that at the temperature T_{gel} there are anomalies in the behaviour of T_1, the effective T_2, and the self-diffusion coefficient D_S. It was established that the formation of the gel is accompanied by a decrease of the mobility of the polymer molecules — the retardation of the rotational and translational motion of the molecules of the bound and non-solvated solvent.

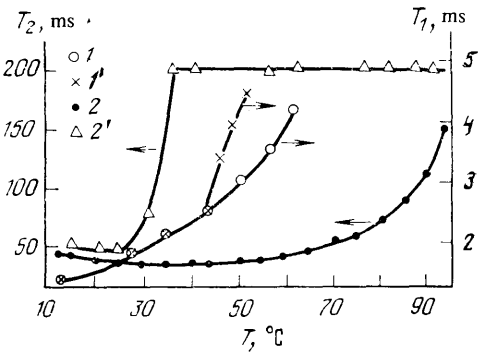

Figure 10. Temperature variation of T_1 obtained on heating (*1*) and cooling (*1'*) a 5% agarose gel and temperature variation of T_2 on heating (*2*) and cooling (*2'*) a 2% agarose gel.[95]

2. Hysteresis Phenomena in Gels

Hysteresis in agarose gels[94,95] consists in different positions of the curves representing the temperature variation of T_1 and particularly T_2 measured during the cooling and heating of the system (curves *1* and *1'* and *2* and *2'* in Fig. 10). It has been shown[95] that the form of the hysteresis loop depends on the maximum temperature to which the test specimen was heated during the measurement. The causes of the hysteresis have not been discussed, but presumably this effect is associated with the kinetic nature of the curves obtained. Another type of hysteresis is observed in the measurement of T_2 in a 3% agarose solution with alternation of the specimen heating and cooling cycles (Fig. 11).[95] The authors suggest that, with increase of temperature, the existing nodes break down and the mobility of the chains increases; however, on cooling to 60°C the nodes are restored to a different extent in each case, which leads to hysteresis.

3. The State of Water in Gels

Earlier studies (without the use of NMR) of the behaviour of water in gels led to the conclusion that the majority of water molecules are in a state intermediate between that of ordinary water and ice[102,103]. However, systematic study of the agarose–water system by NMR showed[94,104] that "free" water, having the mobility of ordinary bulk-phase water and "bound" water predominate in the gels. The degree of "binding" of water can be different and Sterling and Masuzawa[96] divided bound water into two parts: (1) simply "bound" water whose molecules exhibit a limited mobility and (2) "solid" water. Aizawa et al.[97], who investigated agarose gels in which the polymer content was varied within wide limits (from zero to 100%), suggest that the form of the curve for the concentration variation of the NMR absorption line width δ (Fig. 12) makes it possible to differentiate, apart from "free" and "bound" water, also a third type, namely "intermediate" water. Point A (Fig. 12) permits the determination of the amount of "bound" water. The independence of δ of polymer concentration along section AB indicates the existence of "intermediate" water, whose introduction is particularly necessary in the treatment of dilatometric and electrochemical data in such systems[105]. The sharp increase of δ in the region of 0°C indicates the existence of free water. Whereas bound water consists of molecules strongly interacting with the OH groups of agarose, the nature of the intermediate water is not clear.

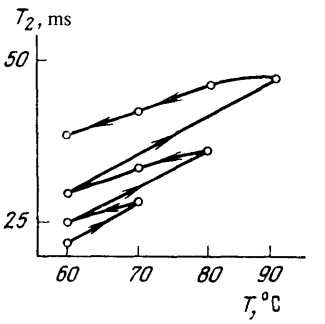

Figure 11. Temperature variation of T_2 for a 3% agarose solution recorded in the course of heating–cooling cycles.[95]

The use of pulsed NMR made it possible to determine the fraction of free water in gels (on the assumption that free and bound water exist in the system). Thus, a study of agarose gels containing 1–8 wt.% of the polymer showed[94] that more than two-thirds of the entire water is present in the free state. This is indicated by the closeness of the values of D_S for the water in gels ($D_S = 1.95 \times 10^{-5}$ cm^2 s^{-1}) and for pure water ($D_S = 2.25 \times 10^{-5}$ cm^2 s^{-1}) at room temperature. In the next study by the same authors[104], where a mixture of H_2O and D_2O with different component ratios was used as the solvent for agarose, it was shown that only 1% of the entire water is present in the bound state, in the gel containing 7–8 wt.% of agarose, while the remaining 99% is ordinary free water. With increase of polymer concentration, the fraction of bound water increases. Attention has been drawn to the small

difference between the values of D_S determined by NMR and the tracer atom method, which apparently indicates the existence in gels of "barriers" (various macromolecular structures) distributed at comparatively long distances from one another. A later study[106] established that 1 g of agarose retains 0.59 g of water, which is several times more than the amount of bound water determined by Woessner and Snowden[104]. However, the scheme proposed by Derbyshire and Duff[106] for the interpretation of relaxation data yields many anomalous results, which are difficult to explain from a physically significant standpoint.

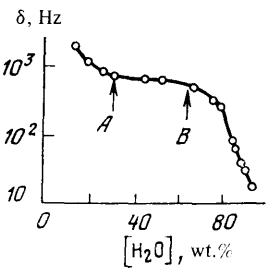

Figure 12. Dependence of the NMR absorption line width δ on the water content in agarose gels at 25°C.[97]

Ideas concerning the state of bound water have been put forward. In particular, it has been shown[104] that the rotational motion of its molecules should be anisotropic. At $T > 75$°C the bound molecules begin to rotate more vigorously, which can lead to the disruption of the water–agarose hydroxyls solvate. Agarose gels have been investigated[107] in the temperature range from −10° to −80°C, where free bulk phase water is frozen and the bound water exhibits some mobility (down to −80°C). The form of the temperature and concentration variations of T_1 permits the conclusion that the molecules of bound water have a different mobility and that their behaviour requires the introduction of a logarithmic normal distribution of the correlation times[108] for molecular motion.

VI. LOW-MOLECULAR-WEIGHT SUBSTANCES ADSORBED ON POLYMERS

1. The Interaction of Adsorbed Molecules with the Polymer

A few studies have been devoted to the NMR investigation of the adsorption of LMS by polymers. In most of them the substance adsorbed by the polymer was water. Thus a study has been made[109] of the interaction of H_2O molecules with oriented nylon 6,6 macromolecules. It was noted that the narrow component in the spectrum, corresponding to the molecules of adsorbed water, appears for a water content in excess of 1.4 wt.% and that its form is independent of the angle between the axis of the fibre and the direction of the magnetic field. For higher percentage moisture contents, water molecules decrease by 20–30°C the temperature of the transition associated with the motion in the crystalline regions of the polymer and lead to the appearance of a water phase with an intermediate mobility, due to motion in the amorphous parts of the polymer, and the "free" water phase. A study of the temperature variation of T_1 and T_2 in a polystyrene latex showed[110] that the presence of water decreases T_g for the polymer particles approximately by 10° and that its influence is somewhat greater in the presence of a concentrated electrolyte (0.1 M manganese sulphate). It has also been found that the penetration of the electrolyte into the polystyrene particles is restricted by a thin layer having a thickness of approximately 1 nm.

The interaction of adsorbed molecules with the polymer depends appreciably on its crystallinity[111]. The same conclusion was arrived at by the analysis of the temperature variations of the relaxation times for various celluloses. It has been found that the barrier to the diffusion of water molecules in cellulose of low crystallinity and based on cotton fibres is lower than in highly crystalline specimens.

The influence of ionic salts on the interaction of water molecules with collagen has been examined[112] on the basis of a ^2H NMR study. The decrease of the deuteron quadrupole splitting due to adsorbed water molecules in the presence of salts indicates a decrease of the fraction of water molecules bound to collagen fibres by hydrogen bonds. It is suggested that ions should either block certain sections of the chain, suitable for the formation of hydrogen bonds, or should alter slightly the conformation of the collagen molecules, hindering the binding of water.

Analysis of the NMR data for hydrated and oriented collagen fibres [113,114] suggests that water molecules diffuse rapidly between the polymer fibres. This motion is slightly anisotropic.

The study of the relaxation behaviour of water molecules adsorbed on keratin led to the hypothesis[115] that water molecules form clusters, whose number increases with increasing water content in the specimens. It has been established that water molecules have a continuous spectrum of correlation times for their motion and that, with increase in the amount of moisture in the specimens, the width of the spectrum diminishes.

In hydrated collagen only some of the adsorbed water molecules are linked to the collagen triple helix and are oriented. The remaining ("free") molecules are in a state of rapid reorientation. There is rapid exchange between the bound and free molecules. Examination of the NMR spectra led Fung and Traumann[112] to the same conclusion. It is believed that, in the presence of high water contents, excess water appears and is distributed on the surface of the specimen where it does not participate in exchange with water within the bulk of the specimen.

It has been reported[116] that 0.05–0.3 of all the cellulose protons are involved in exchange with water protons in celluloses or purified paper fabrics, silk yarn, and artificial silk in the presence of 7% of water.

The study of water adsorbed by specimens of cellulose acetate with different degrees of substitution at 20°C and a water concentration of approximately 10% showed[117] that the mobility of water molecules passes through a maximum for degrees of substitution in the range 0.5–0.6. The change in the mobility of water molecules is caused by redistribution of hydrogen bonds.

The NMR method makes it possible to determine the amount of water bound to the polymer. Thus it has been found[118] from ^2H NMR spectra that in oriented collagen fibres 1 g of the polymer binds 0.6 g of heavy water. The amount of water in celluloses of different types has been

determined[119] from measurements of spin–spin relaxation. Assuming that the bound water is distributed in a monomolecular layer, the authors[119] estimated the surface area of the specimens, the results agreeing satisfactorily with data obtained by other methods.

The relaxation analysis of ^1H NMR data for water adsorbed by lyophilized methaemoglobin crystals[120] showed that 1 g of the protein binds 16 mg of water. For a high moisture content in the compositions (up to 350 mg per g of the polymer) at −40°C a water phase is observed with correlation times intermediate between the values of τ_c for bound and ordinary liquid water.

However, despite the successful application of the NMR method to the determination of the number of bound water molecules by polymers and to the investigation of certain characteristics of their motion, it has been shown[121] for the relaxation of PAA in D_2O and H_2O that the difference between the rates of relaxation of the water associated by the polymer and unassociated water is small and yields no information about the behaviour of hydrated water molecules.

2. The "Freezing" of Adsorbed Water

A reduction of the temperature of the adsorbed mixture below 0°C does not lead to the appearance of breaks on the curves for the temperature variation of T_1 and T_2.[111] The signal amplitude is also constant and indicates a fairly high mobility of the adsorbed water molecules. On the other hand, the T_2–temperature plots for cotton cellulose show an inflexion in the region of 0°C. It has been suggested[111] that a certain amount of water on cotton cellulose behaves analogously to bulk-phase water. Below 243 K, the "freezing" of adsorbed water is observed in both systems and the NMR signal amplitude falls almost to zero at 223 K. The "freezing" process observed at low temperatures is not an indication of the formation of the ice lattice. A similar conclusion was arrived at[115] in a study of the relaxation times of keratin hydrates containing between 12 and 34 wt.% of water and in a study[122] of the relaxation of the water adsorbed in an amount of 33% by the walls of *Bacillus megaterium*.

It has also been discovered[115] that the correlation times of the water molecules adsorbed on keratin are approximately 10^3 times shorter at 270 K than in ice and that in the temperature range 273–240 K the above time is smaller by a factor of 100 than in the bulk-phase water. The authors believe[115] that the ice lattice is formed at high concentrations because some of the water molecules have "moved away" somewhat from the polymer surface and interact only slightly with the latter.

At high water concentrations, for example, in highly hydrated collagen containing more than 0.8 g of D_2O per g of the polymer, it was found that approximately 0.2 g of water is frozen at 0°C.[118]

o0o

The data presented show that the NMR method leads to extensive possibilities for the investigation of polymer–low-molecular-weight substance systems. These possibilities can be greatly expanded by employing ^{13}C NMR spectra and relaxation properties. The application of NMR to the study of such systems is based on the fact that the method makes it possible to assess the molecular mobility, which depends on the concentration of the components, their interaction, the phase state of the specimens, and other factors which determine the macroparameters of the system.

The Solvation of Mercury Ions and the Formation of Their Complexes in Water and Non-aqueous Solvents

L.N.Balyatinskaya

The characteristic features of the formation of mercury complexes in water and non-aqueous solvents are examined. A relation is established between the stability of the complexes and mercury solvates, on the one hand, and the properties of the solvents, on the other. pHg^{2+} mercury complex stability scales have been constructed on the basis of the concept of ionic activities and the possibility of predicting the activities of complex species, the disproportionation constants, and the solubility products of sparingly soluble mercury salts in non-aqueous media has been demonstrated. Correlations for a series of mercury complexes and solvato-complexes and the prospects for the employment of the quantitative characteristics of solvation in the chemistry of mercury complexes are discussed.
The bibliography includes 180 references.

CONTENTS

I. Introduction 418
II. The structure and properties of mercury atoms and ions 418
III. Characteristic features of the formation of mercury(II) complexes in water 421
IV. Mercury complexes in mixed and non-aqueous solvents 423

I. INTRODUCTION

There has been a considerable growth in recent years of the use of non-aqueous solvents as media for a wide variety of synthesis and analytical determinations. Non-aqueous solvents are being used in increasing amounts in industrial chemistry, which necessitates the study of non-aqueous systems. Investigation of the interaction of dissolved substances with the solvent, the most important of which is solvation, is of considerable interest. The determination of the thermodynamic characteristics of solvation makes it possible to predict properties of electrolytes in non-aqueous media (solubility, acidity, stability of complexes, standard potentials, etc.); the knowledge of the solvation characteristics permits a well-founded choice of solvents in the development of rational methods for non-aqueous titrimetry.

The development of the analytical chemistry of non-aqueous solutions follows a path designed to find stable and selective reagents, among which non-aqueous solutions of heavy metal salts, particularly those of mercury, are being used on an increasing scale. The reactions involving the formation of complex and sparingly soluble mercury compounds are widely employed in electrochemistry, analytical chemistry, and chemical engineering.

This review deals with the literature data for the stabilities of mercury complexes in aqueous and non-aqueous solutions published from 1940 until May, 1976: studies dealing with the chemistry of mixed mercury complexes and organomercury compounds are not considered in the review.

The study of the characteristic features of the solvation of mercury ions and the formation of their complexes makes it possible to discover which atoms and groups shows the greatest tendency towards a donor–acceptor interaction with mercury, to establish the nature of the influence of the solvents on the stability of mercury complexes and the solubility of sparingly soluble mercury compounds, and to estimate the degree of solvation of mercury complexes in order to predict their activities in reactions with organic compounds.

II. THE STRUCTURE AND PROPERTIES OF MERCURY ATOMS AND IONS

1. The Electronic Configuration of Mercury and Its Stable Compounds

The outer $6s$ sublevel of the mercury atom contains two electrons; this sublevel is preceded by the filled $5d$ sublevel and the $5f$ sublevel is unfilled. The Hg^{2+} ion is excited as a result of the transfer of one of the $6s$ electrons either to the $5f$ state or the $6p$ state; energetically the $6s^2 \rightarrow 6sp$ excitation is apparently more favourable. The state of the sp valence electrons determines the structure of mercury compounds [1].

It has been suggested that, in the low-temperature radiolysis [2] and low-temperature electrochemical oxidation [3] of mercury compounds, an unstable mercury(III) ion is produced.

Mercury(I) has formally a non-bonding $d^{10}s^1$ configuration, but in reality exists in the form of the dimer Hg_2^{2+}; one of the electrons in the $6s$ orbital is used to form a covalent Hg–Hg bond and the other is used for ionisation. The polyatomic cations Hg_n^{2+} ($n = 3-6$) have been obtained in reactions in melts and in liquid sulphur dioxide [4].

The Hg_2^{2+} ions exhibit a distinct tendency towards the formation of sparingly soluble compounds. The best known are mercury (I) halides; the fluoride hydrolyses in water, while the remaining mercury(I) halides are sparingly soluble. Mercury(I) perchlorate, sulphate, chlorate, bromate, and iodate are moderately soluble. The soluble mercury(I) salts are associated: their stability constants are as follows: $20(Hg_2SO_4)$; $250[Hg_2(SO_4)_2^{2-}]$; $0.9(Hg_2ClO_4^+)$ (Infeld and Sillén [5]); $1.05[Hg_2(NO_3)_2]$; $0.5(Hg_2NO_3^+)$ (Corbett [6]).

The small amount of data concerning mercury(I) complexes is associated with the weak tendency of Hg_2^{2+} towards the formation of coordinate bonds and with its disproportionation; the latter process takes place particularly vigorously in the presence of ligands forming stable mercury(II) complexes. Mercury(I) complexes can be obtained by introducing into the solution ligands which react to form

ionic bonds: oxalate, succinate, pyrophosphate, and triphosphate[7]. Aniline[8], phenanthroline[9], trifluorophosphine[10], diacetohydrazide[11], and triethanolamine[12] complexes of mercury(I) are known. The dimeric structure of mercury(I) persists in its complexes with arenes; in complexes with *m*-dinitrobenzene a bidentate coordination of NO_2 groups to Hg_2^{2+} was observed[13]. Mercury(I) complexes have one and more, rarely two, ligand molecules[10,14]. Only a few of the complexes—$Hg_2[Ph_3PO]_4(ClO_4)_2$ and $Hg_2[PhNO]_4(ClO_4)_2$—contain four ligand molecules[15].

The highly dissociated mercury(II) salts (perchlorate, nitrate, and sulphate) exhibit ionic properties; the association constants of $Hg(NO_3)_2.0.5H_2O$ are 1.28 (K_1) and 1.0 (K_2).[5] In contrast to the fluorides, the Hg–Hal bond in other halides is covalent. Like the halides, mercury(II) cyanide, oxalate, acetate, thiocyanate, and phosphate are partly or completely dissociated in water. Mercury(II) ions form a considerable number of complex compounds whose stability is characterised below.

The Stability of Aquo- and Solvato-Complexes of Mercury

Mercury ions exist in aqueous solutions in the form of diaquo-ions having the linear structure $Hg(H_2O)_2^{2+}$. The diaquo-complexes can be converted into coordination-saturated tetra-aquo- or even hexa-aquo ions[16]. The thermodynamic functions for the formation of hydrated mercury ions[17,18] are listed below:

	ΔG^0, kcal mole^{-1}	ΔH^0, kcal mole^{-1}	ΔS^0, e.u. (298 K)
Hg^{2+} (aq)	39.365 ± 0.025	40.67 ± 0.050	−8.66 ± 0.20
Hg_2^{2+} (aq)	36.713 ± 0.025	39.87 ± 0.050	15.72 ± 0.20

The enthalpy, energy, and entropy of hydration of the mercury(II) ion at infinite dilution are respectively $-\Delta H_h$ = 443 kcal g-ion^{-1}, $-\Delta G_h$ = 431 kcal g-ion^{-1}, and $-\Delta S_h$ = 40.9 e.u.[19]

The formation of aquo-complexes is complicated by the fact that the metal ion interacts vigorously with one of the ionic forms of the solvent. Mercury(II) hydroxide is an extremely weak base ($K_{diss} = 1.8 \times 10^{-22}$),[20] which exhibits amphoteric properties; this explains the appreciable influence of pH on the state of mercury salts in solution[21]. Thus mercury(II) chloride exists in solution as $HgCl_2$ at pH < 3, undergoes partial hydrolysis at pH 5–7, and at pH > 7 the entire mercury in solution is present as $Hg(OH)_2$.[22] The successive dissociation of hydrate complexes treated as diaquo-acids is characterised by the following negative logarithms of the equilibrium constants for mercury(II): $pk_1 = 2.8$ and $pk_2 = 3.5$;[23,24] for the diaquo-complex of mercury(I), $pk_1 = 4.0$–4.6.[25] The hydrolytic cleavage of mercury salts takes place in any proton-donating solvent; for mercury(II) perchlorate, the corresponding reactions

$$Hg^{2+} + H_2O \overset{k_1}{\rightarrow} HgOH^+ + H^+$$

$$Hg^{2+} + 2H_2O \overset{k_2}{\rightarrow} Hg(OH)_2 + 2H^+$$

are characterised by the constants $pk_1 = 3.70$ and $pk_2 = 6.30$.[26]

The formation of solvato-complexes of mercury is associated with the solvation of all the species involved in the reaction. Solvents (Solv) with appreciable electron-donating properties behave as competing ligands in relation to water[27] and are capable of displacing it from the inner coordination sphere of mercury aquo-ions:

$$[Hg_n(H_2O)_m]^{2+} + l\,Solv \rightleftarrows [Hg_n(Solv)_l(H_2O)_{m-l}]^{2+} + l\,H_2O\,.$$

This process can proceed up to the formation of solvato-complexes having the limiting coordination $[Hg_n(Solv)_m]^{2+}$. A comparative estimate of the stability of solvato-complexes can be made by employing the activity coefficients for the transfer of the corresponding ions; this quantity, designated by[28] $\gamma_t(M^{Z+})$ in accordance with an IUPAC recommendation, characterises the free energy ΔG of the transfer of the M^{Z+} ion from the standard solvent (usually an aqueous solution with unit activity of M^{Z+}) to the test solvent Solv:

$$-\Delta G = RT(\ln K_{[M(Solv)_m]^{z+}} - \ln K_{[M(H_2O)_m]^{z+}}) =$$

$$= zF({}^{H_2O}E^0_{M^{z+}/M} - {}^{Solv}E^0_{M^{z+}/M}) = RT \ln \gamma_t(M^{z+}).$$

** Extrapolation to infinite dilution.

Here $K_{[M(Solv)_m]^{Z+}}$ and $K_{[M(H_2O)_m]^{Z+}}$ are the stability constants of the solvato- and aquo-complexes of the ion M^{Z+} respectively, ${}^{H_2O}E^0_{M^{Z+}/M}$ and ${}^{Solv}E^0_{M^{Z+}/M}$ are the standard potentials of the M^{Z+}/M system in water and the non-aqueous solvent Solv respectively, and F is the Faraday. Thus the quantity $RT \ln \gamma_t(M^{Z+})$ represents the difference between the standard chemical potentials of the ion M^{Z+} in two different solvents.

The activity coefficients for the transfer of mercury(I) and mercury(II) ions from water to non-aqueous solvents of different types have been found[29–46] from electrochemical

and spectroscopic measurements and are listed in Table 1; the polarographic measurements have been carried out using a Strehlow ferrocene/ferrocenium reference electrode[47], the potentiometric measurements were carried out using hydrogen and rubidium reference electrodes, and spectrophotometric measurements were performed using calculations by the Asmus method. The donor–acceptor properties of solvents in relation to a particular ion are characterised by the stability of the corresponding solvato-complexes; such data for mercury(II) solvato-complexes[31] are presented in Table 2.

Table 2. The stabilities of mercury solvato-complexes with organic solvents at 25°C (according to ultra-violet spectroscopic data)[31].

*The designations of the solvents are the same as in Table 1.

In alcohols the solvation energy of mercury ions decreases compared with water; aliphatic monohydric alcohols are weak electron donors in relation to Pearson's "soft" acids[48]. Thus ΔG for the transfer of $HgCl_2$ from water to ethanol is −1.623 kcal mole^{-1} [49] according to solubility data[49].

Acetonitrile, nitromethane (and probably also sulpholane) constitutes a group of solvents whose dielectric constants and solvating capacities are high, while their electron-donating forces in relation to cations are weak (in the absence of specific interactions). In consequence of the weaker solvation of mercury ions, the mercurimetric oxidation of dihydroxybenzenes[50] and inorganic cations[51] as well as electrophilic addition of mercury(II) salts to unsaturated hydrocarbons[52–54] proceed faster in alcohols and acetic and trifluoroacetic acids. The specific interaction of mercury ions with dipolar aprotic solvents leads to the formation of stable solvato-complexes of mercury(I) and mercury(II) with dimethyl sulphoxide, dimethylformamide, dimethylacetamide, pyrrolidinone, and *N*-methylpyrrolidinone. The complexes with dimethyl sulphoxide are particularly stable: the solvent molecules have two electron-donating centres. The formula $3HgCl_2.2Solv$, with coordination via oxygen, has been attributed[55] to mercury(II) chloride complexes with sulphoxides. There is a possibility[56] of the coordination of mercury(II) nitrate to acetonitrile; the coordination number was found to be 3.5.[57] The hydrolysis of acetonitrile under the influence of traces of water in a solvent, catalysed by mercury(II) salts, proceeds with formation of acetamide complexes of mercury; in contrast to transition metal complexes, the latter involve coordination via the nitrogen atom[58,59].

The polarographic data presented in Table 1 were obtained on the hypothesis that $E_{1/2} \simeq E^0$; although the formal electrode potentials, measured in the presence of supporting electrolytes, do not reflect directly the changes in the free energy of formation of ions, they nevertheless give an idea about the solvating capacity of solvents. (Comparison of the half-wave potentials and the activity coefficients calculated with their aid is justified when the measurements are performed in identical supporting electrolyte solutions and when the same working hypothesis is used.)

*Notation: PN = propionitrile; BN = butyronitrile; iso-BN = isobutyronitrile; NB = nitrobenzene; BBCr(I) = bisbiphenylchromium(I) iodide reference electrode.

According to the anodic dissolution potentials for mercury[60], the solvation energy of mercury(I) ions and the stability of mercury(I) perchlorate in water are higher than in acetone or acetonitrile; in aromatic nitriles the solvation energy of mercury ions is greatly reduced compared with water. The decrease of the solvating capacity of solvents in relation to mercury ions proceeds in the

following sequence: dimethyl sulphoxide > *N*-methylpyrrolidinone > pyrrolidinone > dimethylformamide, dimethylacetamide > ethylene glycol > water > acetone > methanol > ethanol > propylene carbonate > propanol > acetic acid > nitromethane > acetonitrile.

3. Disproportionation and Standard Potentials of Mercury Systems

The energies of the mercury(I) disproportionation reactions are low; thus $\Delta H = 8$ kcal mole^{-1} and $\Delta G = 6.3$ kcal mole^{-1} for the reaction[81]

$$Hg_2Cl_2 \rightleftarrows HgCl_2 + Hg \cdot$$

It is possible to determine K_d indirectly via the standard potentials:

$$pK_d = \frac{E^0_{Hg^{2+}/Hg^0} - E^0_{Hg_2^{2+}/Hg^0}}{2.3RT/zF}, \quad (1)$$

where z is the number of electrons. The literature data for the standard and half-wave potentials of mercury systems are presented in Table 3 and the values of pK_d calculated by Eqn. (1) are in Table 4.

Table 4. The negative logarithms of the disproportionation constants of mercury(I) ions calculated from the values of E° on the ferrocene scale.

N-MP	−0.1±0.1	70	AN	2.7±2	77

Although comparison of the potentials measured on different scales is in fact difficult, it is nevertheless evident that the potentials of the mercury systems are more negative in dimethyl sulphoxide, dimethylformamide, dimethylacetamide, *N*-methylpyrrolidinone, and ethylene glycol than in water. The literature data[46] for acetic acid are probably erroneous; this solvent causes only slight solvation of inorganic cations[28]. Acetonitrile, propylene carbonate, and nitromethane weakly solvate mercury ions; in these solvents the oxidising properties of mercury ions should be manifested to a greater extent.

The values of K_d (Table 4) have been determined in many instances with a considerable error; nevertheless one can note that Hg_2^{2+} ions are stable in water (disproportionation takes place to the extent of 1%), propylene carbonate, and an acetic anhydride–acetic acid mixture (disproportionation to the extent of 5%).[83] The disproportionation of Hg_2^{2+} takes place partly in *N*-methylpyrrolidinone, dimethylformamide, and dimethylacetamide and almost wholly in ethanolamine[84], ethylenediamine, and *N*-methylacetamide[86].

Any significant weakening of the Hg–Hg bond promotes the disproportionation reaction; reagents which decrease the activity of Hg^{2+} as a result of the formation of complex or sparingly soluble mercury(II) compounds favour disproportionation.

It is to be expected that the solvation of both valence forms contributes to the change in the disproportionation constants; indeed, since

$$K_d = a_{Hg^{2+}}/a_{Hg_2^{2+}}$$

$$\text{and } K_d^{Solv} = K_d^{H_2O} \frac{\gamma_t(Hg^{2+})}{\gamma_t(Hg_2^{2+})},$$

one can write

$$pK_d^{Solv} = pK_d^{H_2O} + p\gamma_t(Hg^{2+}) - p\gamma_t(Hg_2^{2+}).$$

In a real process disproportionation of a sparingly soluble mercury(I) salt (in electrodes of the second kind, for example) is associated with the stability of the complexes formed in the reaction; for the reaction

$$Hg_2L_2 + mL^- \overset{K'_d}{\rightleftarrows} [HgL_{m+2}]^{m-} + Hg, \quad (2)$$

the negative logarithm of the disproportionation constant is

$$pK'_d = pK_d + pSP_{Hg_2L_2} + pK_{[HgL_{m+2}]^{m-}},$$

where $SP_{Hg_2L_2}$ is the solubility product of the salt undergoing disproportionation.

The change in the values of pK'_d on passing from water to the non-aqueous solvent Solv is associated with the nature of the solvation of all the compounds involved in equilibrium (2):

$$(pK'_d)^{Solv} = (pK'_d)^{H_2O} + p\gamma_t([HgL_{m+2}]^{m-}) - m \cdot p\gamma_t(L^-). \quad (3)$$

III. CHARACTERISTIC FEATURES OF THE FORMATION OF MERCURY(II) COMPLEXES IN WATER

1. The Electronic Structure of Mercury Complexes

The characteristic coordination numbers n of mercury(II) are 2 and 4; however, complexes with $n = 5$ are known[87]. The formation of octahedral complexes[88] is less typical; for example, hexa-aquo-complexes of mercury perchlorate are formed in water only at low salt concentrations[89]; an increase of the concentration leads to the formation of tetra-aquo-complexes.

Donor–acceptor complexes of mercury are formed as a result of the supply by the ligand electron-donor atom of a lone electron pair to an acceptor s or p orbital of mercury(II). The donor electrons fill the unoccupied s and p sublevels of the external level and form hybrid sp^3 orbitals; furthermore, the ligand itself can behave as an acceptor in relation to the electrons of the $5d$ sublevel of mercury.

Since the $5d$ sublevel is filled, stabilisation by the ligand field is not characteristic of mercury complexes; the stereochemistry of the complexes is determined exclusively by ion size, electrostatic forces, and the covalence of the bonds. The high stability of the mercury complexes has been explained[90] by the employment of the hybrid sp^3 orbitals of the metal and of the most stable tetrahedral configuration in coordination.

2. The Properties of Ligands and the Stability of Complexes

Mercury(II) is classified[91] as a typical representative of "soft" acids, the sequence of the changes in the stability of the complex species being identified with the sequence in the changes in the metal–ligand bond strength. Mercury ions form stronger complexes with the majority of ligands than other *d* elements; this applies to both acido-complexes and to ammines and complexonates. The stability of the complexes is determined to some extent by the nature of the polarisation of the ligands; the increase of the polarisability of the ligands in the series $Cl^- < Br^- < I^-$ (decrease of electron affinity[92]) is combined with an increase in the same sequence of the tendency of the ligands towards the formation of π bonds and with increase in stability of the complexes[62]. This sequence of the changes in the stability of mercury halide complexes indicates an appreciable role of the enthalpy component in complex formation[93].

A remarkable feature of the stereochemistry of mercury chloro-complexes is a tendency towards the retention of the linearity of the Cl–Hg–Cl group. The free energy of formation ΔG (kcal mole^{-1}) of hydrated complex ions varies as follows for halide[94-98] and cyanide[97,99] complexes: 22.1($HgCl_4^{2-}$); 29.5($HgBr_4^{2-}$); 41.3(HgI_4^{2-}); 54.8[$Hg(CN)_4^{2-}$]. The increased stability of the mercury cyanide complex is accounted for by the greater strength of the Hg–CN bond compared with Hg–Hal.[97]

The increase in the stability of the complexes is associated with the formation of a donor π bond[100]; correspondingly, complexes with electron-donating sulphur, selenium, and phosphorus atoms [$S{=}C(NH_2)_2$, $Se{=}C(NH_2)_2$, $HO(CH_2)_2$–S–$(CH_2)_2$–NH_2, Ph_2–$PC_6H_4SO_3^-$, and $HO(CH_2)_2PEt_2$] are extremely stable[101,102]. This also applies to mercury sulphide[103], thiocyanate[104], and selenocyanate[105] complexes.

A relatively low stability is characteristic of mercury complexes with "hard" ligands (Hal^-, NR_3, NH_3, N_3^-, OH^-, SO_4^{2-}, NO_2^-, NO_3^-, and $RCOO^-$); the formation of a donor–acceptor σ bond predominates in this case[101,106-108].

A decrease of the strength of the Hg–L bond in the series Se > S > N > O is characteristic of atoms with filled *d* orbitals, which are capable of forming $d_\pi - d_\pi$ bonds with atoms having vacant *d* orbitals[90]. The stability of amino-complexes exceeds that of carboxylate complexes approximately by 10 orders of magnitude; the Hg–N bond is 2–2.5 times stronger than the Hg–O and Hg–C bonds (the free energy of the latter is 24–36 kcal mole^{-1} [109]).

Mercury complexes with carboxylic acids[110-118] and hydroxyacids[113-115] usually have the 1:1 (rarely 1:2) composition and are characterised by a certain stability ($\lg K_{st} \leq 8$). The replacement of an oxygen atom in the ligand molecule by sulphur entails a sharp increase in the stability of the complexes, which is characteristic of thiocarboxylates[119-122] and unithiol derivatives[123,124].

The basicity of the nitrogen atom and the stability of complexes. The stability of the donor–acceptor bond between nitrogen and mercury atoms is determined by the density of the electron cloud at the nitrogen atom. The stability of mercury complexes with nitrogen-containing ligands is higher the greater the basicity of the ligands; this relation is maintained for ligands of different types[125-127] and can be represented by the following equations:

$$\lg K_{HgL} = 1.08\, p K_{HL} - 0.53 \text{ (ammines)};$$

$$\lg K_{HgL} = 0.91\, p K_{HL} + 1.81 \text{ (barbiturates)};$$

$$\lg K_{HgL} = 1.25\, p K_{HL} + 1.48 \text{ (sulphamides)};$$

$$\lg K_{HgL} = 0.73\, p K_{HL} + 1.01 \text{ (hydroxypyridines and hydroxypyrimidines)}.$$

Steric hindrance and the presence in ligands of functional groups capable of interacting with mercury(II) cause a deviation of plots of $\lg K_{HgL}$ from linearity. Analogous relations are characteristic also of mercury complexonates. The slope of these lines usually depends[128] on the ionisation potential of the central atom and the polarisation of the ligands by the metal ion. Such relations for aliphatic ammines have slopes close to unity; with intensification of the capacity of the metal ion for the formation of d_π bonds and with increase of the degree of stabilisation in the ligand field, the slopes increase. The linearity of these relations holds only for a series of ligands which are mutually similar structurally, form the same number of chelate rings, and have the same capacity for the formation of π bonds.

Pyrimidine derivatives interact with mercury(II) ions in three possible ways: by the coordination of the carbonyl oxygen of the mercury salt with the neutral ligand; by electrophilic attack with displacement of a proton and the formation of an Hg–C bond; by electrophilic attack with formation of an N–Hg bond[129]. Alkylamines[130-133], π-electron systems (pyridine[132] and aniline[134]), and amino-acids[135-137] bind mercury ions more weakly than other nitrogen-containing ligands (purines and pyrimidines, and imidazole).

Cyclisation and the stability of the complexes. The presence of three five-membered rings in the mercury(II) complex of EDTA is responsible for the highest stability of the complex[138]. Mercury complexes of triethylenediaminetetra-acetic[139], cyclohexane-1,2-diaminetetra-acetic[140], diethylenetriaminepenta-acetic[141], and triethylenetetraminehexa-acetic[142] acids have similar structures. The enhancement of the basic properties of these ligands compared with EDTA stabilises the mercury complexes.

The stability of mercury compounds with complexones having the general formula $(HOOCCH)_2$–$(CH_2)_X$–$(CH_2COOH)_2$ varies non-linearly with increasing x, reaching a minimum for six-membered rings ($x = 3$). A further increase of x leads to the stabilisation of the complexonates: with increase in the size of the ring, its strain, due to the bending of the *sp* orbitals of the mercury ion, diminishes[90].

Complexes with nitrilotriacetate[115], ethylenediaminedimalonic, ethylenediaminedisuccinic, and ethylenediaminediglutaric acids[142], propylenediaminetetra-acetic acid[143], dimethylethylenediaminetetra-acetic acid[140], ethylene disulphide diacetic acid[144] [data for this ligand are not in this reference (Ed. of Translation)], and other complexones[145,146] have low stability constants ($\lg K_{st} \leq 17$). Introduction of sulphur into the complexone molecule leads to a marked stabilisation of phthalyltetrathioacetic acid complexes: $\lg K_{st}[Hg(OH)_2L] = 45$.[147]

Olefin complexes. Many olefin reactions proceed via the formation of intermediate compounds of olefins with mercury atoms; the highest strength of the mercury–olefin bond is due to the involvement of both σ-donor and π-acceptor orbitals in complex formation. The activation of olefins by complexes of mercury and other metals[148] leads to the loosening and a decrease of the multiplicity of

the C=C bond and also to an increase of the positive charge on the carbon atoms owing to the formation of a three-membered ring in which the metal ion plays the role of a heteroatom. The stability constants of the ethylene, propene, and cyclohexene complexes of mercury are [149,150] respectively 1.4×10^4, 1.9×10^4, and 2.2×10^4.

IV. MERCURY COMPLEXES IN MIXED AND NON-AQUEOUS SOLVENTS

1. The Properties of the Solvents and the Stability of the Complexes

The formation of mercury complexes in non-aqueous solvents is determined by the nature of the solvation of mercury ions and the ligands: the stability of the complex species $[HgL_n]^{(2-nl)+}$ is greater than that of the solvato-complexes $[Hg(Solv)_m]^{2+}$ and $[L(Solv)_p]^{l-}$, and the ligands L^{l-} displace solvent molecules more or less readily from the inner coordination sphere of the solvato-complex of mercury:

$$[Hg(Solv)_m]^{2+} + n[L(Solv)_p]^{l-} \rightleftarrows [HgL_n]^{(2-nl)+} + (m + np)\,Solv \quad .$$

Otherwise the stability of the complexes $[HgL_n]^{(2-nl)+}$ is low. In the majority of mixed solvents the influence of the organic cosolvent on the stability of the complexes can be accounted for from the electrostatic standpoints described by the Born equation; indeed the relation between $\lg K$ and $1/\epsilon$ is linear for mercury halide, thiocyanate, and cyanide complexes in aqueous pyridine solutions [81], for cyanide complexes in water–ethanolamine and water–ethylenediamine mixtures [86], and for chloride complexes in aqueous methanol [151], ethanolamine, and ethanol [152] mixtures. The absence of such linearity for the *N*-methylacetamide–dimethylformamide system has been explained [44] by the appreciable electron-donating properties of *N*-methylacetamide in relation to mercury(II): the specific interaction of mercury ions with the solvent can make a significant contribution to the change in the stability of the complex when the composition of the medium is altered.

The introduction of donor-active solvents into aqueous solutions weakens hydration and increases the coordination number to $n > 4$. On the other hand, in pure non-aqueous solvents the solvation of ions can reduce their coordination capacity. Thus in aqueous methanol (up to 10 M MeOH) and aqueous ethanol (9 M EtOH) mixtures mercury thiocyanate complexes $[Hg(SCN)_n]^{(2-n)+}$ with $n = 5$ are formed, whereas in aqueous acetone (10M acetone) n is actually 6; [158] in pure ethanol and acetone n usually does not exceed 4. Similarly, in the formation of acetate complexes in water and methanol n does not exceed 3, while in ethanol and ethylene glycol n decreases to 2. [111,112]

The literature data on the stability of mercury complexes in non-aqueous solvents are numerous: they are available for halide and cyanide complexes in methanol [153-155], ethanol [152-154], acetone [153,154], ethylene glycol [156], pyrrolidone [43], *N*-methylpyrrolidone [70,71], dimethylformamide [39,72,154,157-161], dimethylacetamide [39,162], *N*-methylacetamide [44], ethylenediamine [85], ethanolamine [152], pyridine [41], liquid ammonia [163], acetonitrile [35,164-168], and dimethylsulphoxide [79,82,158-160]. The high stability of mono- and di-ethanolamine complexes of mercury in ethanol [152] and the dithizone, thiourea, and thioacetate complexes in dimethylformamide [39,169] has been noted.

The appreciable solvation of heavy metal ions in aprotic dipolar solvents [28,170] should have entailed a decrease of the stability of the mercury complexes in these media compared with their stability in water. Assuming that the electron-donating characteristics of dimethylsulphoxide, dimethylformamide, and dimethylacetamide are virtually the same, equal stabilities of the complexes in these solvents would be expected. However, the stability of the complexes is apparently determined not so much by the donor number (although the formation of the complexes is undoubtedly facilitated by a decrease of the donor numbers of the medium [172]) and the dielectric constant as by the solvation energies of the anions (ligands and complex species). The weak solvation of anions in aprotic dipolar solvents [173] leads to an increase of the stability of the coordination iodo-complexes in these media by 1–5 orders of magnitude and of the chloro- and bromo-complexes by 10–15 orders of magnitude compared with the stability of the same species in water. In aqueous solutions the stability of mercury complexes increases in the sequence $HgCl_2 < HgCl_4^{2-} < Hg(SCN)_2$, $HgBr_2 < HgBr_4^{2-} < HgI_2 < HgI_4^{2-}$. This series changes for aprotic dipolar solvents [4]; for example, in dimethyl sulphoxide and dimethylformamide it is $Hg(SCN)_2 < Hg(SCN)_4^{2-} < HgCl_2 < HgBr_2 < HgI_2 < HgCl_4^{2-} < HgBr_4^{2-} < HgI_4^{2-}$.

In alcoholic mercury halide solutions the complexes $HgHal_3^-$ and $HgHal_4^{2-}$ predominate [154,156] (a situation analogous to that in aqueous solutions [174]), but their stability is low: in methanol $K_{st} = (1.10-1.86) \times 10^4$ for HgI_3^-. [152] The presence of only $HgBr_3^-$ with $\lg K_{st} = 3.3$ was noted in acetone [154,175]. The stability of mercury iodide solvato-complexes with alcohols and acetone decreases in the sequence methanol > propanol > butanol > hexanol > acetone [176].

The heats of formation of mercury iodide complexes in amides and sulphoxides are independent of the radius of the outer-sphere cation [159]: the complexes HgI_3^- and HgI_4^{2-} are very stable. The logarithms of their stability constants are respectively 30.4 and 32.6 in dimethyl sulphoxide [80] and 33.3 and 37.3 in dimethylformamide [39]. The formation of mercury halide and thiocyanate complexes in these solvents is accompanied by an exothermic heat change; the heats of formation of complexes having analogous compositions are higher in dimethylformamide than in dimethyl sulphoxide [160]. The complexes are particularly stable in acetonitrile, where the species HgL_3^-, HgL_4^{2-} and $Hg_2L_5^-$ exist [164].

2. The Stability Scales of Mercury Complexes

The interpretation of the measurements and comparison of the stabilities of the complex species in various solvents become possible when the concept of ionic activity is used; the quantities $p\gamma_t(Hg^{2+})$ constitute a basis for the construction of scales characterising the relative affinities of the ligands for Hg^{2+} ions; some of these pHg^{2+} scales are illustrated in Fig. 1. The scales are displaced relative to the stability scale for mercury complexes in water by $p\gamma_t(Hg^{2+})$; [62] the beginning of each scale corresponds to $[Hg(Solv)_m^{2+}] = 1$ M. The greater the downward displacement of the pHg^{2+} scale in a solvent (Solv) the greater the ability of solvent molecules to displace the ligands L^{l-} lying higher in this series from the inner coordination spheres of the complexes. The logarithms of the exchange equilibrium constants correspond to the distance between the corresponding "ligand donor–acceptor" pairs on the

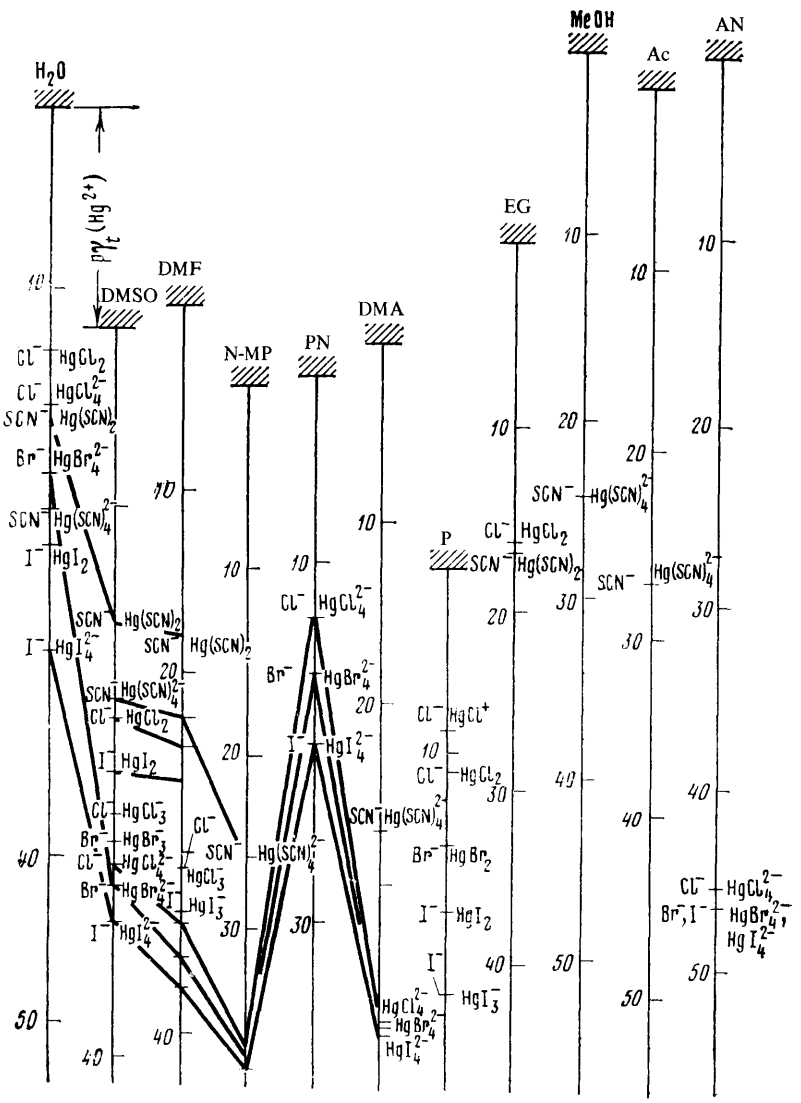

Figure 1. pHg^{2+} stability scales for mercury complexes in water and non-aqueous solvents. The designations of the solvents correspond to those in Table 1.

pHg^{2+} scale in terms of units of $\lg K$. Thus the reaction

$$HgCl_2 + 2SCN^- \overset{K}{\rightleftarrows} Hg(SCN)_2 + 2Cl^-$$

proceeds to the right in water ($\lg K = 3.6$), changes direction in dimethylformamide and dimethyl sulphoxide ($\lg K = -6.4$ and -5.1 respectively), and in *N*-methylpyrrolidone any halide displaces a thiocyanate ion from its mercury complex.

Evidently the removal of traces of water from solvents which weakly solvate Hg^{2+} cations (acetonitrile, nitromethane, and trifluoroacetic acid) is especially important: in aqueous acetonitrile mixtures water molecules occupy sites in the inner coordination sphere of the complex up to appreciable acetonitrile concentrations. On the other hand, the presence of even small amounts of amides in aqueous solutions of mercury compounds causes transolvation of the coordination sphere with replacement of water molecules (partial or complete) by the molecules of the organic cosolvent.

The positions of the complex species $[HgL_n]^{(2-nl)+}$ on the pHg^{2+} scale is determined by the solvation of all the species involved in the complex-formation reaction

$$p K^{Solv}_{[HgL_n]^{(2-nl)+}} = p K^{H_2O}_{[HgL_n]^{(2-nl)+}} + p\gamma_t(Hg^{2+}) + n \cdot p\gamma_t(L^{l-}) - p\gamma_t([HgL_n]^{(2-nl)+}). \quad (4)$$

Eqn. (4) has been used[54] to calculate the activity coefficients of mercury complexes. Aprotic dipolar solvents weakly solvate anionic complexes of mercury: for the chloride complex with the limiting coordination ($n = 4$), the values of $p\gamma_t$ are 8.8 in dimethylformamide, 7.7 in dimethyl sulphoxide, and 10.1 in dimethylacetamide. The weak solvation of cationic and molecular complexes of mercury in hydroxylated solvents leads to an increase of the activity of these complexes in reactions involving electrophilic addition to olefins.

The equation

$$pSP^{Solv}_{Hg_2L_2} = pSP^{H_2O}_{Hg_2L_2} + p\gamma_t(Hg_2^{2+}) + 2p\gamma_t(L^-) \quad (5)$$

for the solubility products of sparingly soluble mercury(I) compounds, which is analogous to Eqn. (4), makes it possible to calculate from the ionic activities and the known values of $SP_{Hg_2L_2}$ in water the solubilities of mercury(I) salts in non-aqueous solvents and to solve with the aid of Eqn. (3) the problem of the disproportionation of mercury halides in reference electrodes in measurements in non-aqueous media. Such calculations have demonstrated the absence of the disproportionation of sparingly soluble mercury(I) salts in the absence of an excess of ligands even in aprotic dipolar solvents. When there is an excess of ligands (which is typical for electrodes of the second kind) mercury halides are resistant to disproportionation in alcohols, formamide, and acetic acids [177].

3. Correlations in the Series of Mercury Complexes and Solvates

The experimental determination of the equilibrium constants for mercury systems in both water and non-aqueous solvents is complicated by solvolysis and disproportionation reactions. It is therefore of interest to follow the possibility of using methods of comparative calculation for predicting the stability of mercury(II) complexes and ionic activity coefficients.

The ratio of the constants for successive coordination stages. The successive equilibrium constants for individual stages involving many metal ion complexes with the same ligands usually decrease, as expected from an examination of statistical factors, steric effects, and Coulombic interaction [90]. According to Bjerrum [23,106], the stability of complexes corresponding to successive coordination stages is determined by the ratio

$$\frac{k_n}{k_{n+1}} = \frac{(N-n+1)(n+1)}{(N-n)\cdot n}, \quad (6)$$

where k_n and k_{n+1} are the stability constants of the nth and $(n+1)$th coordination stages and N is the maximum coordination number of the ion. However Eqn. (6) cannot fully characterise the stability of successively formed mercury(II) complex species: polarisation, statistical, and solvation effects are responsible for deviations of the experimental data from those calculated by the equation [92]

$$\frac{\lg K_n}{n} = \lg k_1 - \lambda(n-1). \quad (7)$$

The deviations are especially large for the second coordination stage in aqueous solutions and reach 1.9 lg K units [54]. This stage is characterised by a high stability of the complexes owing to the change in the structure of complex species in the course of their successive formation. Thus the complex $HgCl^+$ is a distorted tetrahedron with the mercury atom in the centre and the Cl^- ion and the three water molecules at the vertices; $HgCl_2$ is a flattened octahedron with chloride ions (in the *trans*-positions) and four water molecules (at the corners of the square) at the vertices; $HgCl_3^-$ is a distorted tetrahedron with a water molecule at a vertex; finally $HgCl_4^{2-}$ is a regular tetrahedron [178]. The highest exothermic heat change corresponds to the second coordination stage for mercury complexes in water. With increase of n, the degree of outer-sphere hydration of the complexes becomes more pronounced, which, when combined with structural changes, makes the heats of successive complex-formation stages less exothermic [178,179].

The dependence of $\lg K_n/n$ on n for mercury complexes in non-aqueous solvents is linear, which makes it possible to determine the approximate stability constants of the complexes HgL^+ in methanol, dimethylformamide, dimethyl sulphoxide, N-methylacetamide, and ammonia [54].

Relation between the electrochemical and spectroscopic manifestations of solvation. Numerous examples of the parallel variation of the electrochemical and spectroscopic characteristics of compounds have been described in the literature [180]. Indeed the oxidation-reduction potentials are proportional to the energies of the lowest unoccupied and highest occupied molecular orbitals and the long-wavelength absorption frequency in the electronic spectrum is equal to the difference between the energies of the two frontal mercury orbitals. In the series of mercury solvato-complexes there is [30,31,65] a linear correlation between the changes in the standard potential ΔE^0 (the half-wave potential $\Delta E_{1/2}$) and the solvatochromic effect; for protic and aprotic dipolar solvents, these relations are respectively

$$\Delta E^0 = -0.67(\Delta\lambda_{max}) + 6.33, \quad (8)$$

$$\Delta E_{1/2} = -2.20(\Delta\lambda_{max}) - 1.32. \quad (9)$$

The empirical Eqns. (8) and (9) can be used to predict certain spectroscopic properties on the basis of preliminary electrochemical measurements.

Correlations between the activity coefficients and properties of the solvents. The dependence of $\lg\gamma_t(Hg_n^{2+})$ on the reciprocals of the dielectric constant $1/\epsilon$ and the negative logarithms of the autoprotolysis constants pK_S of the solvents is usually non-linear [65]. The scatter of the points indicates an appreciable role of specific solvation: owing to the presence of unfilled 6*s* orbitals in mercury, there is a possibility of a donor–acceptor interaction of its ions with the lone electron pairs of solvent molecules. However, for solvents of the same type (aliphatic monohydric alcohols) distinct linear relations between $p\gamma_t(Hg_n^{2+})$ and $(1/\epsilon)pK_S$ are observed [29]. The dependence of $\lg\gamma_t(Hg_n^{2+})$ on the donor numbers DN of the solvents is linear [29] for $DN > 10$; the non-linearity of the relation in the region of low donor numbers can be attributed to ion association in media with low dielectric constants and low solvating capacity.

Correlation in the series of isoelectronic ions. The linearity of the relations between the enthalpies of complex formation by ions with isoelectronic structures and similar radii [101,106] suggests that the variation of the stabilities of the complexes is also linear. Such relations for mercury(II) and silver(I) ions in water, dimethyl sulphoxide, and dimethylformamide are described [54] by the equations

$$\lg K^{H_2O}_{AgX_2^-} = 0.67\lg K^{H_2O}_{HgX_2} - 4.7,$$

$$\lg K^{DMSO}_{AgX_2^-} = 0.57\lg K^{DMSO}_{HgX_2} - 0.75,$$

$$\lg K^{DMF}_{AgX_2^-} = 0.71\lg K^{DMF}_{HgX_2} - 0.52,$$

which can be used to estimate the stabilities of the molecular complexes of mercury from data for the analogous

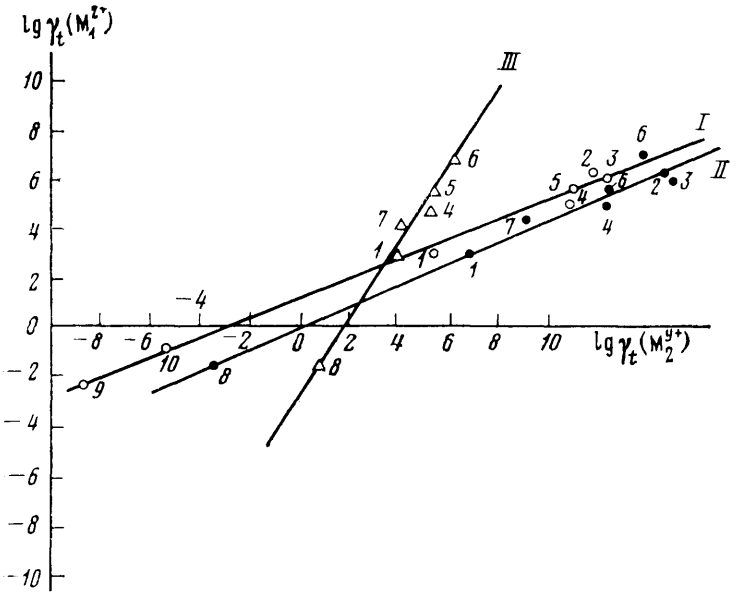

Figure 2. Dependence of $\lg\gamma_t(M_1^{z+})$ on $\lg\gamma_t(M_2^{y+})$ for ion pairs: I) Ag^+–Hg^{2+}; II) Ag^+–Hg_2^{2+}; III) Ag^+–Tl^+; solvent: 1) ethylene glycol; 2) pyrrolidone; 3) *N*-methylpyrrolidone; 4) dimethylformamide; 5) dimethylacetamide; 6) dimethyl sulphoxide; 7) *N*-methylacetamide; 8) propylene carbonate; 9) nitromethane; and 10) acetic acid.

silver complexes. Methods of comparative calculation can be used also for the approximate estimation of the activity coefficients for the transfer of Hg_n^{2+}, Ag^+, and Tl^+ ions. Some of these relations are illustrated in Fig. 2. The literature data are particularly numerous for silver ions; the use of relations analogous to those shown makes it possible to estimate not only the stability constants of the complexes and the ionic activity coefficients but also the stability constants of the solvato-complexes and the standard potentials of the mercury systems.

The results presented indicate an extremely vigorous development in recent years of the chemistry of mercury complexes. Apart from the wide-scale use of mercury compounds, this is associated with efforts directed towards the creation of a theory of solutions. With all the imperfection of the theoretical principles of non-aqueous titrimetry, there is no doubt that the use of quantitative characteristics of solvation processes (ionic activity coefficients) can serve as a reliable criterion for a well-founded choice of solvent. This approach to reactions involving the formation of mercury complexes leads to new possibilities, permitting the prediction of the equilibrium constants for reactions with participation of mercury compounds and the calculation of the activities of the reacting complex or simple forms of mercury.

A New Mechanism of Nucleophilic Substitution

I.P.Beletskaya and V.N.Drozd

A new radical-anionic chain mechanism of nucleophilic substitution at aliphatic, aromatic, and unsaturated carbon atoms is examined (the $S_{RN}1$ mechanism of nucleophilic substitution).
The bibliography includes 133 references.

CONTENTS

III.	$S_{RN}1$ nucleophilic substitution in aromatic compounds	440
IV.	$S_{RN}1$ nucleophilic substitution at an olefinic carbon atom	444
V.	General considerations concerning the mechanism	445

I. INTRODUCTION

According to the classification of Ingold and Hughes [1], nucleophilic substitution at a saturated carbon atom can take place via two mechanisms: the synchronous S_N2 mechanism and the two-stage S_N1 mechanism. However, in recent years it has become evident that between these limiting cases there is a possibility of a whole "spectrum" of mechanisms [2,3] and that different ionic intermediates can participate in each of these [4]. In nucleophilic aromatic substitution the specific features of the aromatic system are observed, being manifested primarily by the absence of the simple S_N2 mechanism. Nucleophilic aromatic substitution, which requires the presence of electron-accepting groups in the aromatic ring, usually takes place in stages and involves the formation of σ-anionic complexes. However, instances of S_N1 processes, leading to the formation of aryl cations, are also known.

A new type of nucleophilic substitution, involving a radical-anionic chain mechanism with formation of a substrate radical-anion and a nucleophilic radical, was discovered in 1966 in saturated systems and in 1970 in aromatic systems, and was called the $S_{RN}1$ mechanism (radical, nucleophilic, unimolecular substitution [5]). The term "radical" reflects the nature of the reaction and the term "nucleophilic" reflects its result. As regards the definition of the term "unimolecular", the authors see here an analogy (which, incidentally, is not supported by kinetic data) with S_N1 reactions, with the sole difference that the C–X bond is broken in a radical anion and not in a neutral molecule.

II. $S_{RN}1$ NUCLEOPHILIC SUBSTITUTION IN ALIPHATIC COMPOUNDS

The radical-anionic chain mechanism of nucleophilic substitution in aliphatic compounds was finally formulated in 1966 [6-9] (see the relevant reviews [10-12]) on the basis of previous (starting from the 1950s) vigorous studies on the chemistry of ambident ions. It was established that, although in principle the interaction of salts of aliphatic nitro-compounds with alkyl halides can involve alkylation

both at carbon and oxygen, the main result is the *O*-alkylation reaction[10,11]

$$RR'\bar{C}-NO_2 \leftrightarrow RR'C=NO_2^- \xrightarrow{R''CH_2X} \begin{cases} \longrightarrow RR'C(NO_2)CH_2R'' \\ \longrightarrow RR'C=N(O)OCH_2R'' \rightarrow (RR'C=NOH + R''CHO) \end{cases}$$

The nitronic esters formed subsequently decompose with formation of an oxime and an aldehyde.

However, somewhat unexpectedly, considerable amounts of *C*-alkylation products are formed in this reaction from *o*- and *p*-nitrobenzyl chlorides and also from 2,4-dinitrobenzyl chloride; thus, on interaction with the sodium salt of 2-nitropropane, *o*-nitrobenzyl chloride gives rise to 46% of the *C*-alkylation product and to 30% of the *O*-alkylation product, while the corresponding proportions of the two products obtained from the *p*-isomer are 83% and 1% (in alcohol at 30°C):[13,14]

$$p\text{-}NO_2C_6H_4CH_2Cl + (CH_3)_2\bar{C}NO_2 \cdot Na^+ \rightarrow p\text{-}NO_2C_6H_4CH_2C(CH_3)_2NO_2 .$$

In contrast to this, benzyl chloride itself, *m*-nitrobenzyl chloride, and p-$RC_6H_4CH_2Cl$ [R = CN, CF_3, $\overset{+}{N}(CH_3)_3$, $COCH_3$, $COOCH_3$, CH_3, or Br] react only via oxygen[14].

Later it was found that the ratio of the *C*- and *O*-alkylation products depends also on the nature of the substituted group X in the *p*-nitrobenzyl system p-$NO_2C_6H_4CH_2X$ (Table 1).[15] It is noteworthy that this effect of the leaving group is not observed for the unsubstituted benzyl system: the tosylate, chloride, bromide, and iodide give an 82–84% yield of benzaldehyde.

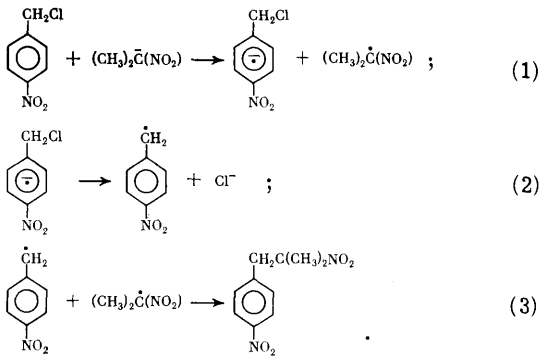

Table 1. Alkylation of the lithium salt of 2-nitropropane by the compounds p-$NO_2C_6H_4CH_2X$ in DMF at −16°C.[15]

X	Yield of product, %		Relative rate (unity for $C_6H_5CH_2X$)	X	Yield of product, %		Relative rate (unity for $C_6H_5CH_2X$)
	C-alkylation	*O*-alkylation			*C*-alkylation	*O*-alkylation	
$\overset{+}{N}(CH_3)_3Cl^-$	93	0	>100	p-$CH_3C_6H_4SO_2O$	40	32	8
C_6Cl_5COO	93	0	>100	Br	17	65	65
Cl	92	6	>100	I	7	81	3

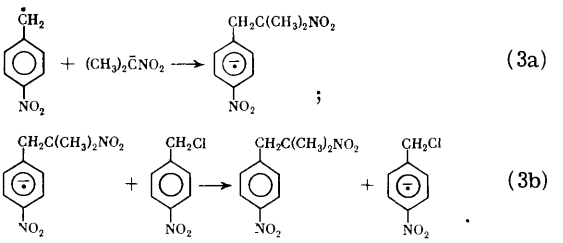
Furthermore, the *p*-nitro-group has only a slight influence on the rate of *O*-alkylation; thus *p*-nitrobenzyl iodide, which reacts mainly via oxygen, interacts with the lithium salt of 2-nitropropane only three times as fast as benzyl iodide. On the other hand, the *p*-nitrobenzyl derivatives, which react mainly via the carbon atom [X = Cl, C_6Cl_5COO, or $\overset{+}{N}(CH_3)_3.Cl^-$], react much more vigorously than the corresponding benzyl derivatives.

It was observed that the rate of *O*-alkylation of *p*-nitrobenzyl systems p-$O_2NC_6H_4CH_2X$ (X = Cl, Br, or I) in dimethylformamide (DMF) at 0°C depends to a much greater extent on the nature of the halogen X than the rate of *C*-alkylation (Table 2).[16,17] On this basis, it was suggested that *O*-alkylation constitutes a usual S_N2-substitution, which is involved in competition with *C*-alkylation via another mechanism when groups difficult to eliminate are present.

In 1964, Kornblum and coworkers proposed for the first time a radical-ionic *C*-alkylation mechanism[16,17]:

(1)

(2)



(3)

It is suggested that in the first stage an electron is transferred from the 2-nitropropane anion to *p*-nitrobenzyl chloride with formation of the radical-anion of *p*-nitrobenzyl chloride; next it decomposes with formation of the *p*-nitrobenzyl radical and the *p*-nitrobenzyl and 2-nitropropyl radicals recombine.

Table 2. Alkylation of the lithium salt of 2-nitropropane by nitrobenzyl halides in DMF at 0°C.[17]

X	Yield of product, %		Rate constant, litre mole^{-1} s^{-1}		
	C-alkylation	*O*-alkylation	overall	*C*-alkylation	*O*-alkylation
			p-$NO_2C_6H_5CH_2X$		
Cl	92	6	0.023	0.021	0.002
Br	20	80	0.34	0.068	0.27
I	8	86	1.9	0.15	1.8
			o-$NO_2C_6H_4CH_2X$		
Cl	31	52	0.0052	0.0016	0.0036
Br	1	98	0.33	0.004	0.032

Finally, in 1966 Kornblum and coworkers and independently Russell and Danen postulated a chain *C*-alkylation mechanism[6-9] having introduced stages (3a) and (3b) instead of stage (3):

(3a)

(3b)

The proposed mechanism was confirmed by a whole series of observations.

As already stated, the rate of *C*-alkylation is relatively insensitive to the nature of the leaving group, while the variation of the rates of *O*-alkylation in the Cl, Br, and I series is typical for substitution via the S_N2-mechanism[16,17].

Furthermore, it was known that aromatic nitro-compounds react with anions, including carbanions[18,19], to form radical-anions. Indeed, when the lithium salt of 2-nitropropane was added to a solution of nitrobenzene in DMF, a distinct EPR spectrum of the nitrobenzene radical-anion was produced. However, *p*-nitrobenzyl chloride at −50°C gave only an unresolved EPR signal with a width of 30 G.[16,17] Russell and Danen were able to generate *m*-nitrobenzyl chloride and *p*-nitrobenzyltrimethylammonium bromide radical-anions in ethylene by interaction with the 2-nitropropane anion under irradiation ($\lambda > 300$ nm); however, under these conditions *p*-nitrobenzyl chloride gave rise only to the EPR spectrum of the radical-anion of the reaction product—2-methyl-2-nitro-1-(*p*-nitrophenyl)propane[9].

The authors[6-9] of the proposed mechanism emphasised that stage (3a)—the interaction of the radical with the anion leading to the radical-anion—constitutes a fundamentally new type of reaction. In their discussion of the structure of the radical formed in this stage, Russell and Danen proposed an alternative structure with the localisation of the unpaired electron at the nitro-group of the side chain:

This radical-anion can isomerise rapidly to an aromatic radical-anion via an intramolecular or intermolecular mechanism, for example, as a result of the reversability of stage (3b), or it can enter stage (3b) directly before isomerising[9]. *o*-Nitrobenzyl chloride reacts via the radical-anionic mechanism with more difficulty; similarly, *o*-nitrotoluene undergoes one-elctron reduction with more difficulty than does *p*-nitrotoluene[20].

Table 3. The influence of added aromatic nitro-compounds on the interaction of *p*-nitrobenzyl chloride and the lithium salt of 2-nitropropylene in DMF at 0°C.[17]

An extremely important piece of evidence in support of the intermediate formation of the *p*-nitrobenzyl chloride radical-anion is the fact that the addition of aromatic nitro-compounds sharply inhibits *C*-alkylation, while the rate of *O*-alkylation hardly changes; thus the rate of reaction of *p*-nitrobenzyl chloride (0.01 M) with the lithium salt of 2-nitropropane (0.02 M) in DMF at 0°C diminishes after the addition of 0.01 M *p*-dinitrobenzene (*p*-DNB) by a factor of ten[17] (see also Table 3). This inhibiting influence can be explained by the fact that aromatic nitro-compounds react rapidly with *p*-nitrobenzyl chloride radical-anions, regenerating the initial *p*-nitrobenzyl chloride and thereby preventing *C*-alkylation. The inhibiting capacity varies in proportion to the electron affinity of the aromatic nitro-inhibitor (*p*-DNB > *m*-DNB > $C_6H_6NO_2$), which agrees with the series based on the relative reactivities of these compounds in electrochemical reduction: the polarographic reduction potentials in acetonitrile at 25°C are −0.69, −0.90, and −1.15 V for *p*-DNB, *m*-DNB, and nitrobenzene respectively[21].

Naturally, the inhibitors can react also with the radical-anions of the reaction products formed in stage (3a), blocking stage (3b) thereby and terminating the chain.

It is also known that aromatic nitro-compounds are effective inhibitors of free-radical chain processes[22,23] in which only neutral radicals participate, and, although the mechanism of such inhibition is not altogether clear, there is a possibility of the blocking of the proposed mechanism as a result of the interaction of the inhibitor with *p*-nitrobenzyl radicals. The inhibiting influence of hexaphenylethane is almost certainly due to the interaction of *p*-nitrobenzyl radicals with triphenylmethyl radicals[8,9].

C-Alkylation is fully inhibited in the presence of molecular oxygen; instead the 2-nitropropane anion is oxidised to acetone and the nitrite ion[24]:

$$(CH_3)_2\dot{C}(NO_2) + O_2 \rightarrow (CH_3)_2C(NO_2)-OO^{\cdot},$$
$$(CH_3)_2C(NO_2)-OO^{\cdot} + (CH_3)_2\bar{C}(NO_2) \rightarrow (CH_3)_2C(NO_2)-OO^{-} + (CH_3)_2\dot{C}(NO_2),$$
$$(CH_3)_2C(NO_2)-OO^{-} + (CH_3)_2\bar{C}(NO_2) \rightarrow 2(CH_3)_2C(NO_2)-O^{-},$$
$$(CH_3)_2C(NO_2)O^{-} \rightarrow (CH_3)_2CO + NO_2^{-}.$$

In the absence of *p*-nitrobenzyl chloride the 2-nitropropane anion is resistant to the action of oxygen.

The finding that the alkylation of the anion of 2-ethoxycarbonyl-3-coumaranone, which usually proceeds via the S_N2-mechanism and gives rise to considerable amounts of *O*-alkylation products, takes place almost exclusively as *C*-alkylation when *p*-nitrobenzyl chloride is used[6,7]:

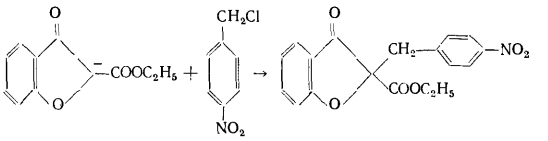

Table 4. Alkylation of the sodium salt of 2-ethoxycarbonyl-3-cumaranone by benzyl halides in DMF at 0°C.[6]

X	Yield of product, %		10^4k, litre mole^{-1} s^{-1}		
	C-alkylation	*O*-alkylation	overall	*C*-alkylation	*O*-alkylation
			$C_6H_5CH_2X$		
Cl	40	50	0.08	0.03	0.04

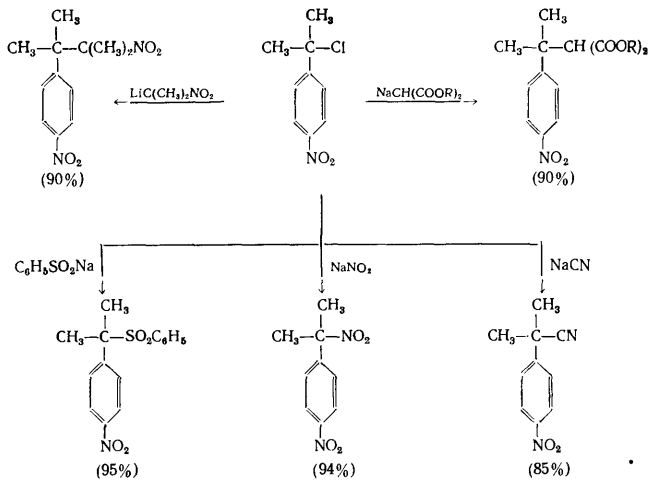
The ratios of the rates of *C*-alkylation for $C_6H_5CH_2X$, m-$O_2NC_6H_4CH_2X$, and p-$O_2NC_6H_4CH_2X$ are 1 : 4 : 4 when X = Br and 1 : 2 : 2 when X = I. On the other hand, when X = Cl, the rate of reaction for the *p*-nitrobenzyl system increases sharply and the ratios become 1 : 2 : 900 (Table 4).[6] Only this last reaction is suppressed by the addition



of *m*- and *p*-DNB (Table 5), while the addition of copper(II) chloride (6×10^{-6} mole) decreases the rate constant for alkylation by *p*-nitrobenzyl chloride from 3×10^{-3} to 5×10^{-5} litre mole^{-1} s^{-1} and alters the yield of the *C*- and *O*-alkylation products from 90 and 2% to 45 and 48% respectively[7].

Table 5. The influence of added inhibitors on the reaction of *p*-nitrobenzyl chloride with the sodium salt of 2-ethoxycarbonyl-3-cumaranone in DMF at 20°C.[6]

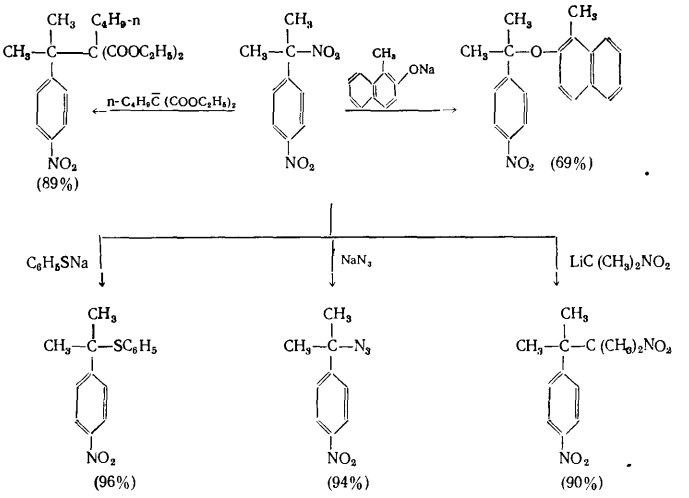
p-DNB (1)	46	49	6
p-DNB (2)	44	46	7



The successful study of the radical-anionic chain mechanism was continued by investigating substitution at a tertiary carbon atom in the *p*-nitrocumenyl system. This system has many advantages compared with the *p*-nitrobenzyl system. When tertiary halides are used, the competing S_N2-substitution mechanism is almost completely excluded. Also excluded is the side reaction of the bases with the fairly acidic products of the methylene group of the benzyl halide (for example, in the reaction of *p*-nitrobenzyl chloride with sodium 1-methyl-2-naphthoxide up to 40% of *p*,*p*′-dinitrostilbene is formed together with the *O*- and *C*-alkylation products).

It was found that *p*-nitrocumenyl chloride reacts exceptionally readily with various nucleophiles at room temperature in an inert gas atmosphere giving a high yield of the substitution product[25]:

Primary, secondary, and tertiary amines readily react with *p*-nitrocumenyl chloride to form alkylation products in high yields (Table 6)[26].

Such ease of substitution at a tertiary carbon atom is very striking. Even more surprising is the finding that α,*p*-dinitrocumene reacts easily with a wide variety of nucleophiles[27]:

Before Kornblum's investigation, no examples of the substitution of the nitro-group at a saturated carbon atom were known. Naturally, neither cumenyl chloride nor α-nitrocumene undergo these reactions.

Table 6. The reaction of *p*-nitrocumenyl chloride with amines (in DMSO, in the light, in N_2 atmosphere, ~35°C).[26]

Amine	Reaction time, h	Yield, %	Amine	Reaction time, h	Yield, %
Quinuclidine	10	90	Di-n-butylamine	88	34
Diazabicyclo-octane	36	85	Methylamine	5	91
Piperidine	18	91	Dimethylamine	5	96
Pyrrolidine	16	90	Trimethylamine	22	66
n-Butylamine	90	67	Ammonia	428	27

It is noteworthy that reactions of this type are relatively insensitive to steric hindrance and can be used successfully to synthesise sterically hindered compounds. In fact the first stage (electron transfer) involves only the aromatic nitro-component of the molecule. The second stage (conversion of the radical-anion into a radical as a result of the elimination of the leaving group) is also insensitive to the influence of steric factors. The third stage involves addition to the planar system of the radical; a combination of minimal steric requirements with a high reactivity of the radical ensures the ease of this stage also. Finally, the last stage (electron transfer from the aromatic nitro-radical-anion to the nitroarene) is very rapid and probably proceeds with minimal steric requirements[11].

Subsequent, detailed studies confirmed each stage of the proposed mechanism. At the beginning of these investigations the inhibiting influence of molecular oxygen was already noted[16-17,25-29] (Table 7). Thus the reaction of *p*-nitrocumenyl chloride with sodiomalonic ester in argon gives the *C*-alkylation product in 95% yield, while

in the presence of oxygen the alkylation is completely suppressed and *p*-nitrocumenyl alcohol is formed in 94% yield. Similarly the reaction of α,*p*-dinitrocumene with sodiobutylmalonic ester in argon gives a 98% yield of the *C*-alkylation product, while in the presence of oxygen *C*-alkylation proceeds to an extent of only 6% and *p*-nitrocumenyl alcohol is formed in 80% yield. In the absence of anions neither *p*-nitrocumenyl chloride nor α,*p*-dinitrocumene react with oxygen. Oxygen influences similarly the reaction of *p*-nitrocumenyl systems with amines[26].

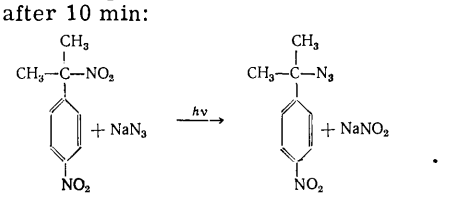
*** In HMPA.

When the reactions with sodium azide and piperidine are carried out in hexamethylphosphoramide (HMPA), it is possible to isolate *p*-nitrocumenyl hydroperoxide and not *p*-nitrocumenyl alcohol; thus the hydroperoxide is formed in 76% yield in the reaction of sodium azide with α,*p*-dinitrocumene in the presence of oxygen.

The mechanism of the inhibiting action of oxygen now becomes clear. Oxygen reacts with *p*-nitrocumenyl radicals, forming peroxy-radicals, which abstract hydrogen from the solvent and are converted into *p*-nitrocumenyl hydroperoxide. The anions (with the exception of the azide ion) rapidly reduce the hydroperoxide to the alcohol:



A^- represents an anion with reducing properties. In dimethylsulphoxide (DMSO) the solvent can also behave as the reducing agent[30].

The influence of the presence of traces of oxygen on the rate of reaction shows that it has a chain mechanism. Thus *p*-nitrocumenyl chloride reacts with sodium benzenesulphinate almost quantitatively with formation of the corresponding sulphone. In nitrogen at 25°C the reaction takes place over a period of 2 h, while in the presence of oxygen (1 mole %) only 10% of the substance reacts during this period. Analogous observations were made in the reactions with quinuclidine[26], sodiomalonic ester, the lithium salt of 2-nitropropane, and sodium azide[29].

As already stated above, the inhibiting influence of nitroarenes (*p*- and *m*-DNB) on the *C*-alkylation of the 2-nitropropane anion has been explained by the rapid electron transfer from the *p*-nitrobenzyl chloride radical-anion to the nitroarene, while the rate of *O*-alkylation via the S_N2-mechanism does not change under these conditions. *p*-Nitrocumenyl chloride cannot react via the S_N2 mechanism and the reaction is therefore simply retarded when nitroarenes are added. Thus the interactions of *p*-nitrocumenyl chloride with sodium azide, which takes place to an extent of 65% in 75 s, and with sodium nitrite, which is 93% complete after 20 min, are fully suppressed by the addition of *p*-DNB (10 mole %); the reaction with sodium benzene sulphinate, which takes place to an extent of 83% in 5 min, is only 19% complete after this period following the addition of *m*-DNB (10 mole %).[11] These results indicate the intermediate formation of radical-anions from the *p*-nitrocumenyl systems and a chain mechanism of the process.

Di-t-butylnitroxyl has also been used as a radical trap[31]. The reactions of *p*-nitrocumenyl chloride with the lithium salt of 2-nitropropane and quinuclidine, which proceed to an extent of 90% in 30 min and 61% in 5 h respectively, proceed to an extent of only 3–4% in the presence of 5 mole % of di-t-butylnitroxyl, while the reaction of α,*p*-dinitrocumene with sodium benzenesulphinate (20 min, 48%) is fully suppressed; galvinoxyl has a similar effect[11].

At the very beginning of studies on the radical-anionic chain mechanism the activating influence of illumination on the rate of the process was already established, diffuse daylight or the light of a fluorescent lamp being frequently sufficient[8,9,25–27]. Thus α,*p*-dinitrocumene does not react with sodium azide in the dark over a period of 2 days; under the influence of daylight, the extent of reaction after 30 min is 63% and under illumination by light from two 20-watt lamps at a distance of 15 cm the reaction is complete after 10 min:

The quantum yields of this reaction and the analogous reaction with *p*-nitrocumenyl chloride are 570 and 600, which undoubtedly indicates a chain mechanism of these processes. It is noteworthy that illumination is not always necessary for the reaction but frequently accelerates it. The study of the influence of the wavelength on the quantum yield shows that illumination promotes the formation of a charge-transfer complex of the nucleophile and the *p*-nitrocumenyl system [stage (1)].[11]

The hypothesis of the activating influence of light on stage (2) of the mechanism is less likely. Also unlikely is the following mechanism of stage (1): the nitro-compound undergoes $n \rightarrow \pi^*$ excitation under the influence of

light and abstracts hydrogen from the solvent, whereupon the base abstracts a proton with formation of a radical-anion [32-34]:

$$p\text{-}NO_2C_6H_4CR_2Cl \xrightarrow[\text{solvent}]{h\nu} [p\text{-}ClCR_2C_6H_4NO_2H^{\cdot}] \xrightarrow{B^-} p\text{-}ClCR_2C_6H_4NO_2^{\cdot-} .$$

The proposed reaction mechanism (see above) shows that the nucleophile plays a dual role in stages (1) and (3a) of the process. In stage (1) it plays the role of a one-electron reductant of the *p*-nitrobenzyl (*p*-nitrocumenyl) system. In stage (3a) the nucleophile, which propagates the reaction chain, adds to the *p*-nitrobenzyl (*p*-nitrocumenyl) radical. Presumably not only the anions which initiated the radical chain but also the anions which are not effective one-electron reductants of these systems react with radicals at this stage. In other words, the catalytic amount of the nucleophile capable of chain initiation is sufficient for the reaction between nucleophiles inactive in this respect and, for example, *p*-nitrocumenyl chloride or α,p-dinitrocumene. Indeed, this effect has been observed (Table 8). [35] Thus, whereas α,p-dinitrocumene does not react with sodium azide in the dark over a period of 48 h, the addition of 5 mole % of the lithium salt of 2-nitropropane leads to the formation of the corresponding azide in 97% yield after only 3 h. *p*-Nitrocumenyl chloride and sodium nitrite do not react in the dark over a period of 90 min; the addition of 5 mole % of the same initiator makes it possible to obtain 93% of α,p-dinitrocumene in 90 min. The reaction of *p*-nitrocumenyl chloride with quinuclidine is very slow in the dark, but the addition of 7 mole of the initiator makes it possible to obtained the corresponding salt in 63% yield after 36 h:

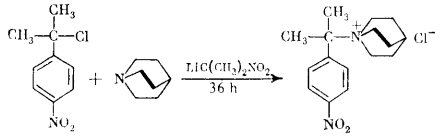


Table 8. Reactions of α,p-dinitrocumene with anions initiated by the lithium salt on 2-nitropropane (in HMPA in the dark) [35].

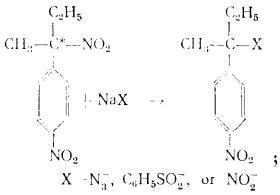

Anion	Amount of initiator, mole %	Reaction time, h	Degree of reaction, %	Product*	Yield, %

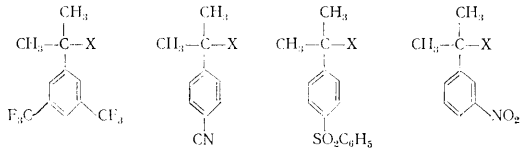
$\bar{C}H(COOC_2H_5)_2$	5	12	53	$RCH(COOC_2H_5)_2$	51

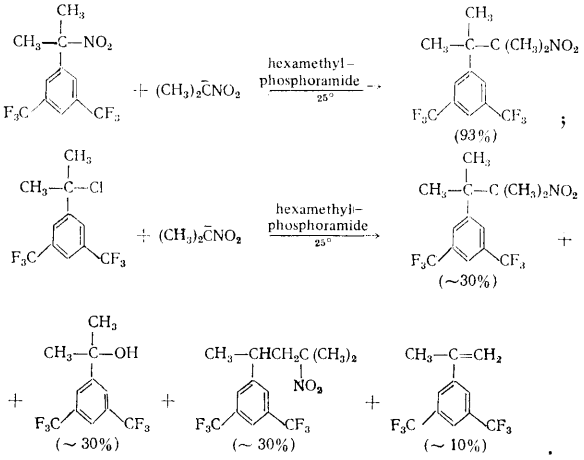
*R = *p*-nitrocumenyl.

Although the 2-nitropropane anion is a fairly effective initiator, other anions also have this capacity and the azide ion, which does not react with α,p-dinitrocumene in the dark, initiates the reaction with sodium benzenesulphinate in the light [35]. The observed series of induced reactions confirms the proposed mechanism and extends the synthetic scope of reactions via this mechanism.



It is quite natural that not only reducing nucleophiles, but also typical one-electron transferring agents can induce reactions with relatively inactive nucleophiles [11]. Thus the reaction between α,p-dinitrocumene and sodium azide in the dark is initiated by the addition of 5 mole % of sodionaphthalene, 3 mole % of sodium-trimesitylboron, and 4 mole % of a solution of sodium in HMPA (the yields of *p*-nitrocumenyl azide after 30 min are 97, 92, and 87% respectively). *p*-Nitrocumenyl chloride, which reacts slowly with sodium nitrite in the dark in HMPA (6% after 90 min), is converted into α,p-dinitrocumene during this period in yields of 89 and 85% after the addition of 12 mole % of sodionaphthalene and 20 mole % of a solution of sodium in HMPA ("solvated electron") respectively.

The radical mechanism of the reaction was confirmed in a study of the stereochemistry of the substitution: when optically active α-methylpropyl-α,p-dinitrobenzene reacts with sodium azide, benzenesulphinate, or thiophenoxide in HMPA, the racemic azide, sulphone, or thioether are formed. Naturally the interaction with sodium nitrite also leads to the racemisation of the initial compound [11]:



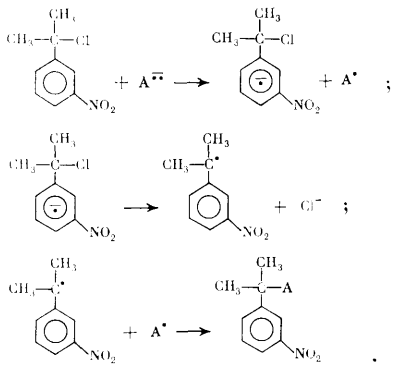
X = N_3^-, $C_6H_5SO_2^-$, or NO_2^-.

Vigorous attempts have now been made to extend the range of organic compounds capable of involvement in radical-anionic chain substitution reactions. Several cumenyl systems containing electron-accepting substituents in the benzene ring have been found [11]:

Although a whole series of synthetically valuable reactions have been observed for these systems, they are fairly frequently accompanied by side processes which do not occur with *p*-nitrocumenyl systems and this can be undoubtedly accounted for by the different stabilities of the corresponding radical-anions and radicals. This hinders routine applications of the radical-anionic chain substitution reactions for synthetic purposes:

Thus, whereas α-nitro-3,5-bis(trifluoromethyl)cumene smoothly alkylates the 2-nitropropane anion at a carbon atom with a yield of 93%, 3,5-bis(trifluoromethyl)cumenyl chloride gives the same product with a yield of only 30%. Two competing side reactions takes place: (a) *O*-alkylation via the S_N2 mechanism with subsequent formation of 3,5-bis(trifluoromethyl)cumenyl alcohol; (b) dehydrochlorination with formation of α-methyl-3,5-bis(trifluoromethyl)styrene and subsequent Michael addition to the latter of the 2-nitropropane anion [11].

Like the *p*-nitrocumenyl system, the *m*-nitrocumenyl system gives high yields of *C*-alkylation products in the reactions with sodium thiophenoxide, sodiomalonic ester, and sodiobutylmalonic ester, but in the reaction of *m*-nitrocumenyl chloride with ambident ions the formation of considerable amounts of *O*-alkylation products (S_N2 reaction) is observed [28]. Thus the reaction of *m*-nitrocumenyl chloride with sodium nitrite gives 52% of α,*m*-dinitrocumene and 27% of *m*-nitrocumenyl alcohol; under the same conditions, the *p*-isomer is converted to an extent of 92–95% into α,*p*-dinitrocumene. The reaction of the lithium salt of 2-nitropropane with *m*-nitrocumenyl chloride in HMPA leads to the formation of 33% of the *C*-alkylation product, 35% of *m*-nitrocumenyl alcohol, and 15% of *m*-nitromethylstyrene; the reaction with sodium benzenesulphinate gives 59% of the sulphone and 11% of *m*-nitrocumenyl alcohol, while *p*-nitrocumenyl chloride or α,*p*-dinitrocumene give rise only to the corresponding sulphone in 97% yield. Oxygen almost completely inhibits substitution via the radical-anionic mechanism in *p*-nitrocumenyl systems and leads to the formation of *p*-nitrocumenyl alcohol, whereas such inhibition of the reaction of *m*-nitrocumenyl chloride is not so pronounced and *m*-nitrocumenyl alcohol is formed in small amounts (Table 9) [28]. On the basis of these observations, it is suggested [28] that a non-chain radical "cage" mechanism can play an important role for *m*-nitrocumenyl chloride:



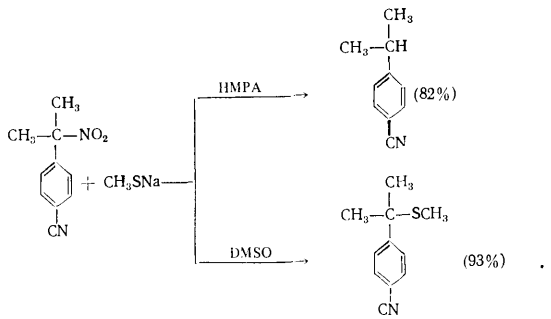


Table 9. The inhibiting influence of oxygen on the reaction of *m*-nitrocumenyl chloride with anions (in DMSO). [28]

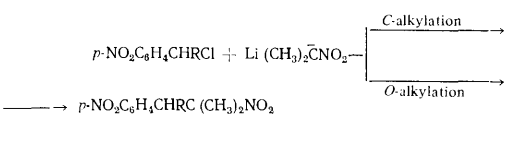
N_3^- *	O_2	76	0	14

* In HMPA.



Incidentally, the absence of selectivity in the alkylation of ambident anions by *m*-nitrocumenyl chloride can be explained with the aid of this mechanism.

The reaction of *p*-cyano-α-nitrocumene with sodium methanethiolate in DMSO gives the corresponding sulphide in 93% yield, while in HMPA the product is *p*-cyanocumene in 82% yield [11]:

In view of the similarity of the electron-accepting properties of the *p*-nitrophenyl and γ-pyridyl residues, 2-nitro-γ-pyridylpropane evidently interacts with the 2-nitropropane anion via a radical-anionic mechanism [11]. Light accelerates the reaction, while the addition of 5 mole % of *m*-DNB or di-t-butyl nitroxide fully inhibits it.

Although Kornblum [11] frequently emphasised and demonstrated the relative insensitivity of the *C*-alkylation via the radical-anionic mechanism to steric requirements (say in relation to *p*-nitrocumenyl systems), in 1976 Norris and Randles [36] showed that this is not always the case. By studying the interaction of α-alkyl-*p*-nitrobenzyl chlorides (R = CH_3, C_2H_5, iso-C_3H_7, or t-C_4H_9) with the lithium salt of 2-nitropropane, they showed, that, when R = CH_3 or C_2H_5, competing $S_{RN}1$ and S_N2 processes, leading to *C*- and *O*-alkylation products, take place. For more sterically hindered chlorides (R = iso-C_3H_7 or t-C_4H_9), the reaction proceeds exclusively as *O*-alkylation despite the clear $S_{RN}1$ mechanism and only the corresponding ketones *p*-$NC_2C_6H_4COR$ are formed as a result of the decomposition of nitronic esters (Table 10):

The hypothesis that in the last two cases the S_N2 mechanism operates is disproved by a whole series of observations: the reaction in the dark is much slower than in the light, oxygen and *p*-DNB have an inhibiting effect and, finally, α-isopropyl- and α-t-butyl-benzyl chlorides do not react under the conditions indicated. According to the authors [36], steric hindrance in stage (3a) of the radical-anionic chain mechanism provides the best explanation of the results. It also explains the decrease of the rate of interaction with increasing bulk of the group R (Table 10).

p-Nitrobenzylidene chloride also reacts with the lithium salt of 2-nitropropane via the radical-anionic chain mechanism with formation of 1-chloro-2-methyl-2-nitro-1-(*p*-nitrophenyl)propane [37–39]:

The reaction is inhibited by oxygen and *p*-DNB and is accelerated under illumination (Table 11).

However, perhaps the most interesting fact in this connection is that the authors [38,39] observed in their study of the reaction in the presence of an excess of the nucleophile a new type of elimination reaction with participation of a radical-anion—an $E_{RC}1$ reaction (radical-chain unimolecular elimination). The secondary interaction between the reaction product and the nucleophile leads to the formation of β,β-dimethyl-*p*-nitrostyrene and 2,3-dimethyl-2,3-dinitrobutane via the mechanism

$$p\text{-}NO_2C_6H_4CHClC(CH_3)_2NO_2 + 2(CH_3)_2\bar{C}NO_2 \rightarrow$$
$$\rightarrow p\text{-}NO_2C_6H_4CH{=}C(CH_3)_2 + (CH_3)_2C(NO_2){-}C(NO_2)(CH_3)_2 + Cl^- + NO_2^-$$

and not to double substitution. The reaction is initiated by light (in DMF in the dark at 5°C it proceeds to an extent of only 8%, while under illumination its extent is 96%) and is inhibited by *p*-DNB: in DMSO in the dark at 20°C the yield of β,β-dimethyl-*p*-nitrostyrene after 150 min is 90%, while in the presence of 20 mole % of *p*-DNB the yield falls to 18%. Benzylidene chloride itself does not undergo this reaction. The authors [38,39] proposed the following mechanism for this interaction:

$$ArCHClC(CH_3)_2NO_2 + (CH_3)_2\bar{C}NO_2 \rightarrow [ArCHClC(CH_3)_2NO_2]^{\cdot-} + (CH_3)_2\dot{C}NO_2;$$
$$[ArCHClC(CH_3)_2NO_2]^{\cdot-} \xrightarrow{\text{slow}} Ar\dot{C}HC(CH_3)_2NO_2 + Cl^-;$$
$$Ar\dot{C}HC(CH_3)_2NO_2 + (CH_3)_2\bar{C}NO_2 \rightarrow ArCH{=}C(CH_3)_2 + (CH_3)_2\dot{C}NO_2 + NO_2^-;$$

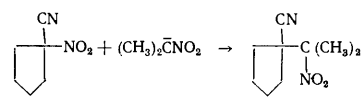
or

$$Ar\dot{C}HC(CH_3)_2NO_2 + A^- \rightarrow ArCH{=}C(CH_3)_2 + NO_2^- + A\cdot;$$
$$(CH_3)_2\bar{C}NO_2 + (CH_3)_2\dot{C}NO_2 \rightarrow [(CH_3)_2C(NO_2){-}C(CH_3)_2NO_2]^{\cdot-};$$
$$[(CH_3)_2C(NO_2){-}C(CH_3)_2NO_2]^{\cdot-} + ArCHClC(CH_3)_2NO_2 \rightarrow;$$
$$\rightarrow (CH_3)_2C(NO_2){-}C(NO_2)(CH_3)_2 + [ArCHClC(CH_3)_2NO_2]^{\cdot-}.$$

It is of interest to note that *p*-nitrobenzylidene acetate also interacts with the lithium salt of *p*-nitropropane, forming 2-methyl-2-nitro-1-(*p*-nitrophenyl)propyl acetate:

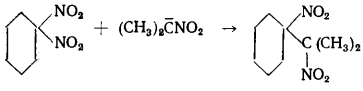
$$p\text{-}NO_2C_6H_4CH(OCOCH_3)_2 + (CH_3)_2\bar{C}NO_2 \rightarrow p\text{-}NO_2C_6H_4CH(OCOCH_3)C(CH_3)_2NO_2.$$

However, a completely different, ionic-chain (and not radical-chain) mechanism operates here: in the first stage the diacetate undergoes nucleophilic cleavage with formation of the free aldehyde [37,40]. The reaction is insensitive to light, oxygen, and *p*-DNB, and both benzylidene acetate itself and other $ArCH(OCOCH_3)_2$ undergo this reaction.



The reactions of (4-nitrobenzyl)- and (4-nitrophenyl)-methyl halides with the t-butoxide ion in t-butyl alcohol, which lead to high yields of 4,4′-dinitrostilbene and 4,4′-dinitrotetraphenylethylene respectively, also proceed via the radical-ionic chain mechanism [41]:

$$ArCH_2X + t\text{-}C_4H_9O^- \rightleftarrows Ar\dot{C}HX + t\text{-}C_4H_9OH;$$
$$ArCH_2X + t\text{-}C_4H_9O^- \rightarrow ArCH_2X^{\cdot-} + t\text{-}C_4H_9O\cdot;$$
$$ArCH_2X^{\cdot-} \rightarrow ArCH_2^{\cdot} + X^-$$
$$ArCH_2^{\cdot} + Ar\bar{C}HX \rightarrow [ArCH_2CHXAr]^{\cdot-}$$
$$[ArCH_2CHXAr]^{\cdot-} + ArCH_2X \rightleftarrows ArCH_2X^{\cdot-} + ArCH_2CHXAr$$
$$ArCH_2CHXAr + t\text{-}C_4H_9O^- \rightarrow ArCH{=}CHAr + t\text{-}C_4H_9OH + X^-.$$



The radical-ionic chain mechanism has been considered as one of the possibilities for the reaction of benzyl halides with sodium thiolates in which the formation of benzyl and thiyl radicals was demonstrated [42].

The range of substitution reactions involving radical-anions was extended in 1970 when Kornblum and coworkers found that the anions of nitro-compounds can react with α-nitrocarbonyl compounds (esters and ketones), α-nitronitriles, and α,α-dinitro-compounds, displacing the nitro-group [43,44]:

$$(CH_3)_2C(NO_2)COOC_2H_5 + (CH_3)_2\bar{C}(NO_2) \xrightarrow[\sim 20°]{DMSO} (CH_3)_2C(COOC_2H_5){-}C(NO_2)(CH_3)_2 \quad (95\%);$$
$$(CH_3)_2C(NO_2)COC_6H_5 + (CH_3)_2\bar{C}NO_2 \rightarrow (CH_3)_2C(COC_6H_5){-}C(NO_2)(CH_3)_2 \quad (82\%);$$

(84%);

(91%).

Further studies confirmed the radical-anionic chain mechanism of these reactions†. Thus light accelerates the reaction and, when the wavelength of the initiating

† It is of interest to note that the nitro-group can be substituted under the influence of the *p*-thiocresolate ion in primary and secondary nitro-compounds under the conditions of the usual S_N2 mechanism [45].

light is 400 nm, the quantum yield of ethyl α-nitroisobutyrate is 220; ethyl α-chloroisobutyrate does not react with the lithium salt of 2-nitropropane, while the α-bromoester gives rise to a complex range of products, from which the *C*-alkylation product was isolated in a yield of only 9%.[43,44]

Sodionaphthalene is an effective catalyst of the reaction of 2,2-dinitropropane with the anion of 2-nitropropane[46]:

$$(CH_3)_2C(NO_2)_2 + (CH_3)_2\bar{C}NO_2 \xrightarrow{C_{10}H_8Na} (CH_3)_2C(NO_2)-C(NO_2)(CH_3)_2 .$$

Inhibitors of radical processes strongly retard the reaction of ethyl α-nitroisobutyrate, α-nitroisobutyrophenone, and α,α-dinitrocyclohexane with the lithium salt of 2-nitropropane[44]. A complete analogy is observed in this case between the first two stages of the mechanism of the above reactions (one-electron reduction of α-nitrocompounds with subsequent decomposition of the resulting radical-anion into a radical and a nitrite ion) and the previously investigated behaviour of aliphatic nitro-compounds under the influence of more vigorous reductants, such as metallic sodium and the electric current[47,48].

The anions of nitroalkanes are not the only species which can displace the nitro-group from α,α-dinitrocompounds. Thus, 2,2-dinitropropane reacts at 25°C, albeit fairly slowly, with sodium benzenesulphinate to give the corresponding sulphone in 81% yield[49]:

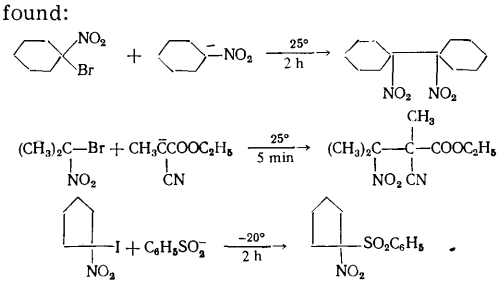
$$(CH_3)_2C(NO_2)_2 + C_6H_5SO_2^- \xrightarrow[25^\circ]{3\ days} (CH_3)_2C(NO_2)SO_2C_6H_5 .$$

The reaction is accelerated under illumination and is fully inhibited by the addition of 10 mole % of di-t-butylnitroxyl.

The reaction between 2,2-dinitropropane and sodioethylmalonic ester is accelerated by irradiation with light or by the addition of 15 mole % of the potassium derivative of nitrobenzene:

$$(CH_3)_2C(NO_2)_2 + C_2H_5\bar{C}(COOC_2H_5)_2 \xrightarrow{DMF} (CH_3)_2C(NO_2)-C(C_2H_5)(COOC_2H_5)_2 .$$

Irradiation also accelerates the reaction between 2,2-dinitropropane and sodioethylacetoacetic ester or sodiomethylacetylacetone[46].



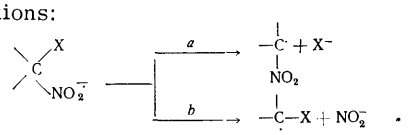
The mechanism of certain reactions between α-halogeno-α-nitro-compounds and nucleophiles, discovered previously, became understood in the light of these investigations. Thus, as early as 1940, Seigle and Hass[50] found that 2-halogeno-2-nitropropanes react with the sodium salt of 2-nitropropane to form 2,3-dimethyl-2,3-dinitrobutane:

$$(CH_3)_2C(NO_2)X + (CH_3)_2\bar{C}NO_2 \rightarrow (CH_3)_2C(NO_2)-C(NO_2)(CH_3)_2 ;$$
$$X = Cl, Br \text{ or } I.$$

The reaction between 2-chloro-2-nitropropane and sodioethylmalonic ester proceeds with a 68% yield[51]:

$$(CH_3)_2C(NO_2)Cl + C_2H_5\bar{C}(COOC_2H_5)_2 \rightarrow (CH_3)_2C(NO_2)-C(C_2H_5)(COOC_2H_5)_2 .$$

In recent years, mainly as a result of the efforts of Kornblum's[49,52] and Russell's[46] groups, new examples of the substitution of the halogen in α-halogen-α-nitro-derivatives via the radical-anionic chain mechanism have been found:



The reactions are catalysed by light and are inhibited by di-t-butylnitroxyl, *p*-dinitrobenzene, or triphenylmethyl radicals.

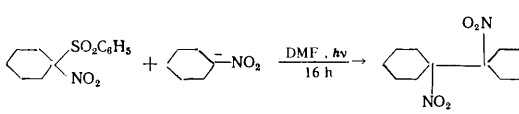
Reactions of this kind constitute the basis of the synthesis of α,β-unsaturated nitriles, ketones, and esters, where the first stage is the interaction of the sodium salts of $RCHYCOOC_2H_5$ (Y = CN, $COCH_3$, $COOC_2H_5$, or SO_2Ar) with α-halogeno-α-nitro-derivatives $R^1R^2CHalNO_2$ or the α,α-dinitro-derivatives $R^1R^2C(NO_2)_2$ in HMPA or DMF; subsequent heating of $R^1R^2C(NO_2)-CRYCOOC_2H_5$ in HMPA at 120°C leads to the formation of $R^1R^2C=CRY$;[53,54] the reduction of $R^1R^2C(NO_2)-CR(SO_2Ar)COOC_2H_5$ with sodium sulphide in DMF at room temperature yields $R^1R^2C=CRCOOC_2H_5$.[55]

Substitution of a sterically hindered nitro-group by hydrogen, including compounds synthesised via the $S_{RN}1$ mechanism, can be achieved by treatment with sodium methanethiolate in DMSO via the following mechanism[56]:

$$R_3C-NO_2 + CH_3S^- \rightarrow R_3C-NO_2^{\cdot-} + CH_3S^{\cdot} ;$$
$$R_3C-NO_2 \rightarrow R_3C^{\cdot} + NO_2^- ;$$
$$R_3C^{\cdot} + CH_3S^- \rightarrow R_3C-H + H_2\dot{C}-S^- ;$$
$$H_2\dot{C}-S^- + R_3C-NO_2 \rightarrow H_2C=S + R_3C-NO_2 .$$

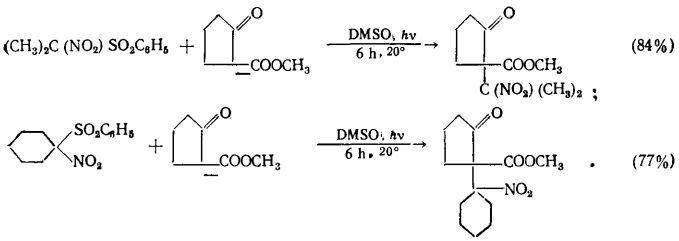
Thus the decomposition of the intermediate radical-anions of the α-nitro-compounds can proceed, in principle, in two directions:

Pathway *a* obtains for X = Cl, Br, or I and pathway *b* obtains for X = COOR, COR, CN, or NO_2.



Owing to their instability the 2-nitropropane[57,58] and 2,2-dinitropropane[59] radical-anions are not revealed by EPR spectroscopy. The driving force of the decomposition of the radical-anions via pathway *a* is the presence of a readily eliminated group X and the formation of a resonance-stabilised nitroalkyl radical. The radical-anions derived from nitroalkanes[60] and α-fluoronitroalkanes[58] are fairly unstable but can be detected by EPR spectroscopy.

Yet another example of pathway *a* is provided by α-nitrosulphones. In the reaction of α-nitroisopropyl-*p*-tolyl sulphone with the potassium[61] or lithium[31] salts of 2-nitropropane in DMSO at 20°C the product was 2,3-dimethyl-2,3-dinitropropane in 80% (15 min) or 96% (2.5 h) yields:



$$(CH_3)_2C(NO_2)SO_2C_6H_4CH_3\text{-}n + (CH_3)_2\bar{C}NO_2 \rightarrow (CH_3)_2C(NO_2)-C(NO_2)(CH_3)_2 .$$

Although the intermediate radical-anion of the initial sulphone was not detected in electrolysis in DMF or acetonitrile, all the results support the radical-anionic chain mechanism. The reaction is slower in the dark; when 5% of *p*-DNB is added it takes place to an extent of only 7% in 15 min, while in the presence of 5 mole % of di-t-butyl nitroxide its extent is only 1% after 4 h.

The reactions of α-nitrosulphones with other anions have also been studied[31]:

$$(CH_3)_2C(NO_2)SO_2C_6H_4CH_3\text{-}p + CH_3\bar{C}(COOC_2H_5)_2 \xrightarrow[2\ h]{DMSO,\ h\nu} (CH_3)_2C(NO_2)-C(CH_3)(COOC_2H_5)_2 ; \quad (82\%)$$

The reaction between α-nitroisopropyl-*p*-tolyl sulphone and the *p*-chlorothiophenoxide ion does not occur in the dark (DMSO, 2 h); under illumination by two 20-watt fluorescent lamps during the same period, the extent of the reaction is 95% and the corresponding sulphide is formed in 59% yield:

After 6 min, the extent of the reaction is 54%, while after the addition of 10 mole % of *m*-DNB it is only 13%; di-t-butylnitroxyl fully inhibits the reaction.

When α-nitroisopropyl phenyl sulphone is treated with six equivalents of sodium toluene-*p*-sulphinate in HMPA in the dark (20°C, 22 h) the reaction is not observed, while under illumination 25% of α-nitroisopropyl-*p*-tolyl sulphone is formed; the reaction is inhibited by the addition of 5 mole % of di-t-butylnitroxyl. The reverse reaction exhibits the same features:

$$(CH_3)_2C(NO_2)SO_2C_6H_5 + p\text{-}CH_3C_6H_4SO_2^- \rightleftarrows$$
$$\rightleftarrows (CH_3)_2C(NO_2)SO_2C_6H_4CH_3\text{-}p + C_6H_5SO_2^- \quad .$$

For the perfluoroalkylation of thiophenols [62,63], selenophenols [64], and sulphinic acids [65] by perfluoroalkyl iodides under illumination with ultraviolet light in liquid ammonia in accordance with the scheme:

$$ArXH + R_FI \xrightarrow[\text{liq. } NH_3]{h\nu} ArXR_F \ (X=S, Se, SO_2)$$

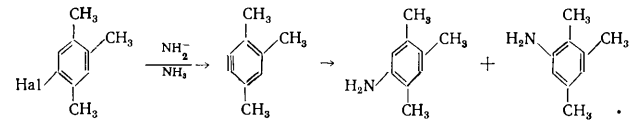
the authors propose the following radical-anionic chain mechanism:

$$ArS^- + R_FI \xrightarrow{h\nu} ArS^{\cdot} + R_FI^{\cdot -} \ ;$$
$$R_FI^{\cdot -} \rightarrow R_F^{\cdot} + I^- \ ;$$
$$ArS^- + R_F^{\cdot} \rightarrow [ArSR_F]^{\cdot -} \ ;$$
$$[ArSR_F]^{\cdot -} + R_FI \rightarrow ArSR_F + R_FI^{\cdot -} \ .$$

III. $S_{RN}1$ NUCLEOPHILIC SUBSTITUTION IN AROMATIC COMPOUNDS

Nucleophilic substitution in non-activated halogenobenzenes is known to proceed with much difficulty (if it occurs at all). The substitution of the halogen with a high yield can be achieved only in isolated reactions, for example, under the influence of lithium cuprates [66].

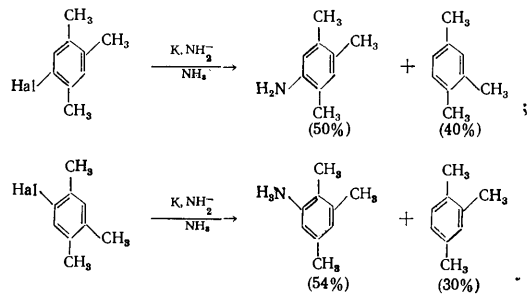
However, Bunnett and coworkers [67] showed that nucleophilic substitution in aryl halides or other aromatic compounds containing a group suitable for nucleophilic substitution can be readily achieved when metallic potassium (or sodium), which is an electron donor, is used as the catalyst, or under the influence of light. Naturally, activation by a metal in liquid ammonia is due to the solvated electron [68]. The amide ion, the thiophenoxide ion, carbanions such as the fluorenyl and cyanomethyl anions, and ketone enolates such as the acetonyl anion can function as nucleophiles [67].



A different mechanism was proposed for these reactions: the substrate is reduced with formation of the aryl radical, which can interact subsequently with the nucleophile (anion), forming a radical-anion; the latter gives up an electron to the initial molecule and is converted into the reaction product [5]:

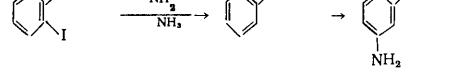
$$ArX + e \rightarrow [ArX]^{\cdot -} \text{ (chain initiation)}$$
$$\left.\begin{array}{l} [ArX]^{\cdot -} \rightarrow Ar^{\cdot} + X^- \\ Ar^{\cdot} + Y^- \rightarrow [ArY]^{\cdot -} \\ [ArY]^{\cdot -} + ArX \rightarrow [ArX]^{\cdot -} + ArY \end{array}\right\} \text{ (chain propagation)}$$
$$Ar^{\cdot} + RH \rightarrow ArH + R^{\cdot} \quad \text{(chain termination).}$$

Thus the new mechanism is based on the possibility of generating aryl radicals from ArX and on the hypothesis that a reaction takes place between Ar· and the anion. In other words, it is suggested that the anion behaves as "trap" for the aryl radical.



Liquid ammonia is usually employed as the solvent. The results depend on the experimental conditions, for example, on the way in which the carbanions are formed—by the action of KNH_2 or metallic potassium (whether or not the system contains an excess of electrons capable of reducing the aryl radical to the anion, i.e. $Ar^{\cdot} \rightarrow Ar^-$, depends on this). However, in most cases it is possible to select conditions ensuring a high yield of the nucleophilic substitution product.

The $S_{RN}1$ mechanism for reactions involving aromatic compounds was postulated for the first time in order to account for the results of the reaction of aryl halides (Hal = Cl, Br, or I) with the amide ion in liquid ammonia [5,69]. This reaction, involving 5- or 6-halogenopseudocumenes, proceeds via the aryne mechanism and leads to a mixture of isomers, whose composition is independent of the nature of the halogen for Hal = Cl or Br:



In the case of the more readily reducible ArI this mechanism is accompanied by another substitution reaction pathway, which leads to a different ratio of the isomers.

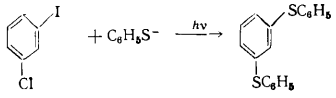
In the presence of metallic potassium, the aryne mechanism is suppressed, and the substitution proceeds wholly at the carbon atom linked to the halogen [69]:

o-Anisidine was obtained in 68% yield from *o*-iodoanisole, together with *m*-anisidine (17%) and anisole (8%). [69] The formation of *m*-anisidine is characteristic of the aryne mechanism:

The products of the substitution of the halogen for hydrogen (anisole or pseudocumene) are probably formed in the chain termination stage owing to the interaction of the aryl radical with the solvent.

In the presence of potassium reactions take place in the complete absence of the catalyst; thus iodobenzene reacts with potassium amide to form diphenylamine (19%) and *o*- and *p*-aminobiphenyls (11% of each)[69]. In acetonitrile, in the presence of potassium, chlorobenzene reacts with the cyanomethyl ion to form benzyl cyanide (36%) as well as benzene (26%) and toluene (18%). The latter might have been formed as a result of the decomposition of the radical-anion:

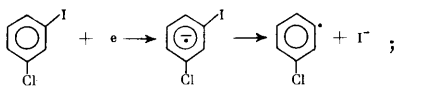
$$[C_6H_5CH_2CN]^{\cdot-} \rightarrow CN^- + C_6H_5\dot{C}H_2 \xrightarrow{RH} C_6H_5CH_3 .$$



Subsequently it was shown that the $S_{RN}1$ reactions are initiated also by radiation. Under these conditions, aryl iodides react with the anion Ar'S' with formation of asymmetric sulphides in 70–95% yield[70]:

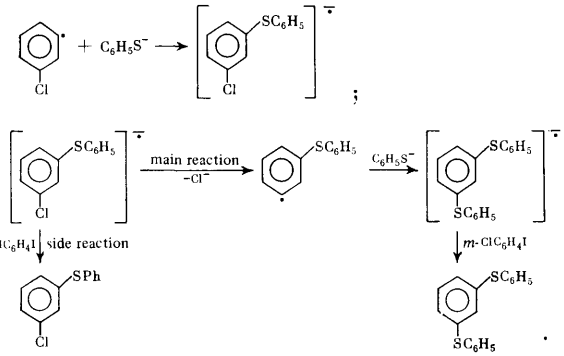
$$ArI + e \xrightarrow{h\nu} [ArI]^{\cdot-} ;$$
$$[ArI]^{\cdot-} \rightarrow Ar^{\cdot} + I^- ;$$
$$Ar^{\cdot} + Ar'S^- \rightarrow [ArSAr']^{\cdot-} ;$$
$$[ArSAr']^{\cdot-} + ArI \rightarrow [ArI]^{\cdot-} + ArSAr' .$$

The reaction constitutes a convenient method for the synthesis of diaryl sulphide, since for its occurrence it is sufficient to irradiate a solution of the reactants in liquid ammonia with light having $\lambda_{max} = 350$ nm. It has been noted that bromobenzene reacts much more slowly than iodobenzene. The absence of symmetrical sulphides from the reaction mixture implies that electron transfer is faster than the fragmentation of the radical-anion $[ArSAr']^{\cdot-}$ into an aryl radical and an arenethiolate anion. This conclusion is confirmed by the formation of the same sulphide (in 73–76% yield) in reactions of *p*-iodoanisole with $C_6H_5S^-$ and of iodobenzene with *p*-$CH_3OC_6H_4S^-$.[71]



However, the problem of the mechanism of the initiation stage still remains open; it is not clear whether irradiation promotes electron transfer from the anion to the aromatic substrate or whether the C–X bond undergoes homolysis under the influence of radiation. The first version appears more probable, although in the case of iodobenzene one cannot rule out the possibility that the activation in certain reactions proceeds as a result of the photolysis of the C–I bond.

When the *m*-dihalogeno-derivative is introduced into the reaction with $C_6H_5S^-$, then, apart from fluoro-derivatives, the product of the substitution of both halogens—di(thiophenoxy)benzene[72] (only traces of the monosubstituted compounds are obtained)—is formed in a high yield in all cases:



(91%)

The reaction of *m*-fluoroiodobenzene results in the formation of *m*-$FC_6H_4SC_6H_5$ (96%) only. The authors[72] believe that this result confirms the mechanism in which the rate of fragmentation of the radical-anion $[m\text{-}ClC_6H_4SC_6H_5]^{\cdot-}$ is higher than that of electron transfer:

;

Naturally, the only exception should be the radical-anion $[m\text{-}FC_6H_4SC_6H_5]^{\cdot-}$, since the carbon–fluorine bond is ruptured with difficulty and electron transfer predominates.

The photostimulated reaction with $C_2H_5S^-$ is much slower than that with ArS^-:

$$C_6H_5I + C_2H_5S^- \xrightarrow[NH_3]{h\nu} \underset{(30\%)}{C_6H_5SC_2H_5} + \underset{(44\%)}{C_6H_5S^-} + \underset{(3\%)}{(C_6H_5)_2S} .$$

The composition of the products of this reaction shows that radical-anion $[C_6H_5SC_2H_5]^{\cdot-}$ only partly gives up its electron to iodobenzene; most of it is able to fragment with formation of $C_2H_5^{\cdot}$ and $C_5H_5S^-$. Precisely this fragmentation pathway is observed in reduction with ArSAlk. The $C_6H_5S^-$ formed can interact with iodobenzene to give diphenyl sulphide (via the same $S_{RN}1$ mechanism).

Together with the C–N and C–S bonds, photostimulated aromatic nucleophilic substitution makes it possible to obtain the C–P bond. Thus the reactions of various aryl iodides with potassium dialkyl phosphites lead to the formation of arylphosphonates in a high yield (87–96%):[73, 74]

$$(RO)_2POK + ArI \xrightarrow[NH_3]{h\nu} ArP\underset{\underset{O}{\|}}{(OR)_2} .$$

1-Iodonaphthalene is converted after 2 h into the corresponding phosphonate in 93% yield (4% in the absence of radiation)[73]. The radical-anion of the aryl halide and the dialkyl phosphite radical are formed initially:

$$ArX + (RO)_2PO^- \xrightarrow[NH_3]{h\nu} [ArX]^{\cdot-} + (RO)_2PO^{\cdot} .$$

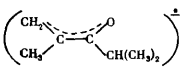
Next the reaction proceeds via the usual pathway involving the formation of $[ArPO(OR)_2]^{\cdot-}$. It is suggested that this radical-anion is more stable than $[ArSAr]^{\cdot-}$ owing to the more pronounced electron-accepting properties of the $OP(OR)_2$ group and for this reason it interacts with aryl halide instead of decomposing.

The ratio of the products of mono- and di-substitution was investigated as a function of the nature of the halogen in a series of studies on the substitution of halogens under the influence of $(RO)_2PO^-$ in dihalogenobenzenes under irradiation[75–77]. The authors of these studies state that the results agree solely with the $S_{RN}1$ mechanism.

The possibility of employing this reaction for the synthesis of aryl phenyl selenides in high yields has been demonstrated:

$$ArX + C_6H_5Se^- \xrightarrow[liq.\ NH_3]{h\nu} ArSeC_6H_5 .$$

This reaction proceeds only with halogeno-derivatives of phenanthrene, naphthalene, and biphenyl, but not benzene[78].



The new reaction involving the arylation of nucleophiles can be used to form carbon–carbon bonds. After initiation by an alkali metal or irradiation, various carbanions,

including ketone enolates, are arylated under the influence of ArX. Thus it has been shown that bromobenzene does not react with the potassium enolate of acetone in the dark, but, under illumination with near ultraviolet light (150 W), phenylacetone is formed in a high yield [79] with a small admixture of 1,1-diphenyl-2-propanone—the double phenylation product. In contrast to bromobenzene, iodobenzene undergoes this reaction also in the dark, but under irradiation it is appreciably accelerated (5–15% of the product is formed in the dark after 3 h, while the yield under irradiation is 67%). 3-Pentanone and 4-heptanone are phenylated in the α-position in 80% yield [80]. The radical chain mechanism is confirmed by the inhibiting effect of radical traps of the type of di-t-butylnitroxyl and also oxygen. Although the yield of the ketone phenylation products does not in general exceed the yields obtained by other methods (for example, in the phenylation of enolates by means of iodonium salts [81]), the proposed reaction is preparatively more convenient.

In the presence of sodium or potassium the reactions of aryl halides with acetone enolate give rise to a mixture of the ketone $ArCH_2COCH_3$ and the alcohol $ArCH_2CH(OH).CH_3$, with an overall yield up to 89%, as well as a certain amount of 1,1-diarylacetone [82]. Since the ketone is not reduced to the alcohol under these conditions but forms a ketyl, it is suggested that the radical-anion $[ArCH_2.COCH_3]^{\cdot-}$ is reduced and that this reaction proceeds simultaneously with its "oxidation" under the influence of ArX.

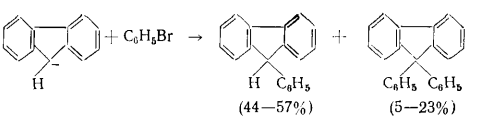
Bromo- and iodo-benzenes react similarly with the enolate ion derived from 2-butanone and 3-methyl-2-butanone [83]. Regardless of the method of initiation (by potassium or by illumination with light), 2-butanone gives rise to a mixture of phenylated ketones—$C_6H_5CH_2COCH_2.CH_3$ and $CH_3COCH(C_6H_5)CH_3$; the reaction of 3-methyl-2-butanone also results in a mixture of isomers, but the isomer $C_6H_5CH_2COCH(CH_3)_2$ predominates (81% yield).

When enolate ions derived from ketones such as di-isopropyl ketone are used as the anion in a photostimulated reaction with iodobenzene, benzene and a dimeric product (A) are formed together with the ketone arylation product. It is suggested that, apart from the usual reaction involving the radical-anion formed, the phenyl radical abstracts a β-hydrogen atom from the radical-anion. Since the radical-anion

formed is fairly stable, it is not involved in electron transfer, but is stabilised with formation of (A) or disproportionates to form a dianion and an unsaturated ketone [84]:

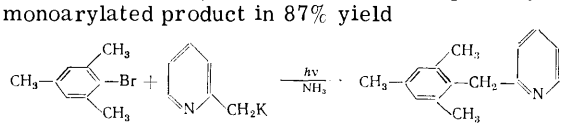
$$(CH_3)_2-\underset{\underset{O}{\|}}{C}-C(CH_3)_2-CH_2-C(CH_3)_2-\underset{\underset{O}{\|}}{C}-C(CH_3)_2 \quad (A)$$

The $S_{RN}1$ mechanism has also been resorted to in order to account for the causes of the formation of the dimeric product



$$(C_6H_5)_2C(CONR_2)-C_6H_4-C(C_6H_5)CONR_2$$

when 2-bromo-*N*,*N*-dimethyl-2-diphenylacetamide is acted upon by an excess of sodium methoxide in 2,2-dimethoxypropane [85].



The arylation of cyclic ketones (cyclobutanone, cyclopentanone, cyclohexanone, cyclo-octanone, and 2-indanone), initiated by radiation, takes place with excellent yields [80]. However, it has been shown in the same study that the reaction is not undergone by the monoanions of β-dicarbonyl compounds, although as can be seen from the first part of the review, alkyl radicals do react with these anions. It is suggested that arylation in such cases involves ready chain termination, although the true cause has not yet been established.

The influence of the nature of Ar in ArX on the yield of the product $ArCH_2COCH_3$ has been studied in relation to the photochemically initiated arylation of the acetone enolate ion [86]. The reactions of $2,4-(CH_3O)_2C_6H_3Br$, $2,4,6-(CH_3O)_3.C_6H_2I$, $2-\bar{O}OCC_6H_4Br$, and $2,5,6-(CH_3)_3C_6H_2I$ take place with with satisfactory yields. The reactions of compounds in which the benzene ring contains several bulky alkyl substituents take place much less effectively. After 1.5 h, the compounds $4-(C_2H_5)_2NC_6H_4Br$, $4-\bar{O}C_6H_4Br$, and $3-NO_2C_6.H_4Br$, i.e. compounds with any strong electron-donating or electron-accepting substituents, altogether failed to give an arylation product. 1- and 2-Iodonaphthalenes, 9-bromoanthracene, and 9-bromophenanthrene proved to be effective arylating agents.

The possibility of arylating "purely carbon" carbanions has also been demonstrated [86]. For example, the anion of penta-1,3-diene reacts with bromobenzene in the presence of potassium (NH_3, $-78°C$) to give a mixture of phenylated mono- and di-olefins. 3-Phenylindene (32%), 1-phenylindene (3%), diphenylindene (11%), and triphenylindene (4%) were obtained by the reaction of the indene anion with bromobenzene. The fluorene anion reacts similarly in the presence of potassium or sodium:

In those cases where the reaction of the carbanion with ArX proceeds also without a catalyst, for example, the interaction of α- and γ-picolinyl anions with bromo- or iodo-benzene [83], the yield can be increased by adding potassium or by irradiation. For example, the yield in the reaction with bromobenzene is 57% in the dark and 73% under irradiation, while the yield in the reaction with iodobenzene alone is 14% and 63% in the presence of potassium (the overall yield of the products of mono- and di-arylation is indicated); on the other hand, the reaction with chlorobenzene does not take place at all without initiation. The aryne mechanism has been proposed for the dark reaction, which has been confirmed by the absence of arylation in the case of bromomesitylene; however, the $S_{RN}1$ process takes place readily under the influence of irradiation and leads to the formation, in the case of the α-picolinyl anion, of a monoarylated product in 87% yield

The phenylation of α-cyano-carbanions in the presence of potassium is more complex [5,87]. Thus chlorobenzene reacts with the cyanomethyl anion in the presence of potassium in liquid ammonia to form phenylacetonitrile, toluene, benzene, and aniline. Significant amounts of 1,2-diphenylethane were obtained in the analogous reaction with iodobenzene together with the product already enumerated. It is noteworthy that the process itself takes place readily, in contrast to the photochemical reaction,

‡ It has been shown specially that benzyl radicals do not interact with anions.

which takes place appreciably less effectively than the reaction with the acetone enolate ion:

$$C_6H_5X + \bar{C}H_2CN \rightarrow [C_6H_5X]^{\cdot-} + {}^{\cdot}CH_2CN \quad ;$$

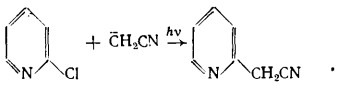
$$[C_6H_5X]^{\cdot-} \rightarrow C_6H_5^{\cdot} + X^- \quad ;$$

$$C_6H_5^{\cdot} + \bar{C}H_2CN \rightarrow [C_6H_5CH_2CN]^{\cdot-} \quad ;$$

$$CN^- + {}^{\cdot}CH_2C_6H_5^{\bullet} \leftarrow [C_6H_5CH_2CN]^{\cdot-} \xrightarrow{C_6H_5X} [C_6H_5X]^{\cdot-} + C_6H_5CH_2CN \quad ;$$

$$\downarrow +e_s$$

$$C_6H_5\bar{C}H_2CH_2C_6H_5 \quad C_6H_5\bar{C}H_2 \xrightarrow{NH_3} C_6H_5CH_3 + NH_2^- \quad ;$$



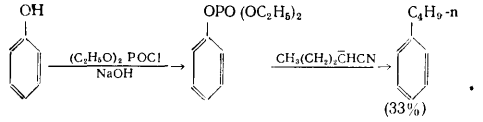
$$C_6H_5^{\cdot} + e_s \rightarrow C_6H_5^- \xrightarrow{NH_3} C_6H_6 + NH_2^- \quad ;$$

$$C_6H_5^{\cdot} + NH_2^- \rightarrow [C_6H_5NH_2]^{\cdot-} \xrightarrow{C_6H_5X} [C_6H_5X]^{\cdot-} + C_6H_5NH_2 \ .$$

The formation of all the products can be explained by a scheme postulating the ready interaction of $C_6H_5^{\cdot}$ with $\bar{C}H_2CN$ as well as the fragmentation of the resulting radical-anion. It is noteworthy that the elimination of the cyano-group from the benzyl cyanide formed can take place similarly under the influence of potassium [88]. The formation of hydrocarbons even in solvents from which the radical cannot abstract a hydrogen atom can be explained by the reduction of the radicals to the anions. Thus the reaction of $C_6H_5^{\cdot}$ with NH_3 is ruled out in view of the absence of benzene from the products of the reaction with acetone enolate ions, although the reaction was carried out in the presence of an effective hydrogen donor—the isopropoxide anion. The fraction of toluene and diphenylethane in the reaction product increases for fluorobenzene, which is reduced with difficulty under the influence of the radical-anion. The corresponding reaction with the anions obtained from other nitriles leads to the formation of different alkylbenzenes.

It has been shown recently [89] that, when a number of aryl halides other than C_6H_5X are used, the above reaction leads to the formation of α-aryl- or α-heteroaryl-acetonitriles in very satisfactory yields, and can therefore be of synthetic interest.

The arylation of the anion $\bar{C}H_2CN$ in liquid ammonia under irradiation, leading to $ArCH_2CN$ in nearly quantitative yields, has been achieved for 1- and 2-chloronaphthalene, 4-chlorobiphenyl, 4-bromobenzophenone, and 2-chloropyridine, for example:



(98%)

9-Bromophenanthrene reacts similarly (the yield of the arylation product is 60–70%). It is of interest to note that the reactivity of the anion $\bar{C}H_2CN$ in these reactions is approximately the same as that of the acetone enolate, i.e. the differences between the rates of these reactions with bromobenzene are determined by other stages.

The results were explained by examining the distribution of electrons in the resulting radical-anion using the molecular orbital perturbation theory [99]. However, in practice we are dealing with the greater stability of the radical-anion $[ArCH_2CN]^{\cdot-}$ compared with $[C_6H_5CH_2N]^{\cdot-}$.

It is of interest that, together with halogeno-derivatives of aromatic compounds, other aromatic compounds, containing groups capable of being fairly readily eliminated as anions, can be used in this reaction [91]. Thus $ArSC_6H_5$ (but not $C_6H_5SC_2H_5$) reacts under the influence of irradiation with the acetone enolate ion to form $ArCH_2COCH_3$, but the extent of the fragmentation of the radical-anion can be very great, depending on the nature of Ar. The relative contributions of the processes can be inferred from the ratio of the yields of the two ketones $C_6H_5CH_2COCH_3$ and $ArCH_2COCH_3$. An approximate estimate of the reactivities of ArX gives the following sequence: $I \simeq Br > SC_6H_5 \gg Cl > F \gg OC_6H_5$. [71,79] The sulphonium and ammonium salts $(C_6H_5)_3^{\bullet}SCl^-$ and $C_6H_5^{\bullet}N(CH_3)_3I^-$ are fairly reactive. Thus the reaction of $C_6H_5^{\bullet}N(CH_3)_3I^-$ with the α-picolinyl anion leads to the arylation products in 88% yield (3% of the diarylated derivative is also formed) [92].

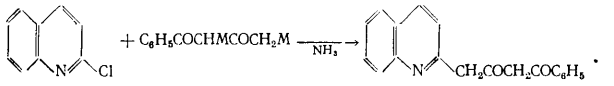
In some cases the $OPO(OC_2H_5)_2$ group proved to be particularly convenient for preparative purposes. The corresponding ester can be obtained in a high yield (87%) from phenol under the influence of $(C_2H_5O)_2POCL$ in the presence of alkali. Treatment of the resulting ester with, for example, the anion $CH_3(CH_2)_2\bar{C}HCN$ leads to n-butylbenzene in 38% yield. Thus the overall yield in this process is 33%; this reaction is of synthetic value, because it makes it possible to introduce an alkyl group into a specific position in the benzene ring and, in contrast to the Friedel–Crafts reaction, only the non-rearranged product can be obtained. Furthermore, in those cases where a nitrile is formed in the reaction, the cyano-group can be readily removed from the latter with formation of the same alkyl derivative:

The use of a phosphate ester for the conversion of phenols into anilines is of particular interest [93]. The yield of anilines in the reaction of aryl diethyl phosphate with potassium amide in liquid ammonia in the presence of potassium is 56–78%:

$$ArOPO(OC_2H_5)_2 + KNH_2 \xrightarrow[NH_3]{K} ArNH_2 \ .$$

(Ar = phenyl, 2,6-dimethylphenyl, or 2-methoxy-4-methylphenyl).

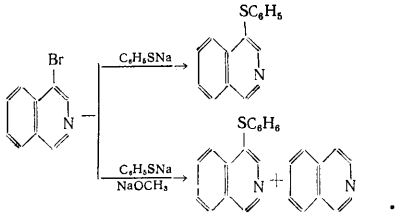
The $S_{RN}1$ mechanism has been proposed for the non-catalysed reaction of arenediazonium salts $ArN_2^{\bullet}X^-$ with potassium iodide in methanol [94,95], whose products are ArI, ArH, and formaldehyde. It is suggested that the first stage involves the reduction of the diazonium cation by the iodide ion with formation of $[ArN_2]^{\cdot}$, which decomposes to Ar$^{\cdot}$ (or R–⟨⊙⟩–⊕). The radical interacts with the iodide ion to form $ArI^{\cdot-}$, which reduces the initial cation.



It has been shown that DMSO can be used successfully in the $S_{RN}1$ reaction instead of ammonia [96–98]. The reactions of iodobenzene with diethyl phosphite, the thiophenoxide ion, and ketone enolate ions have been achieved in this solvent in high yields under the influence of irradiation. It is of interest that in the last case the $S_{RN}1$ process can be thermally induced. However, the authors [92,98] note difficulties in the interpretation of the kinetics observed in DMSO. The dimsyl ion is phenylated with high yields in DMSO under the influence of bromobenzene (80%) and iodobenzene (87%). [99] The authors of this study, who live in Madras, note that under their climatic conditions the reaction takes place simply under the influence of sunlight. An important advantage of DMSO compared with other solvents is its low reactivity as a donor of hydrogen atoms compared with phenyl radicals, although the reaction products can be more conveniently isolated from ammonia. Other promising solvents are DMF and acetonitrile, where the reaction of iodobenzene with $(C_2H_5O)_2POK$ has been shown to take place with high yields [96].

The possibility of $S_{RN}1$ processes in 50% aqueous t-butyl alcohol has been demonstrated in relation to the reaction of C_6H_5X (X = Cl, Br, or I) with sodium phenoxide catalysed by sodium amalgam [100]. The reaction leads to the formation of diphenyl ether and benzene, the former being the main product of the reaction with iodobenzene and the latter that of the reaction with chlorobenzene, which can be accounted for by the different rates of reduction of these halogenobenzenes. It is suggested that in the reaction with C_6H_5Cl, phenyl radicals are formed at a low rate but are able to diffuse into the solution and are reduced on the surface of the amalgam to anions. In conformity with the $S_{RN}1$ mechanism, the reaction does not occur in the absence of Na/Hg and is inhibited by oxygen.

Extremely fruitful results were obtained by carrying out $S_{RN}1$ reactions as well as other anionic processes under the conditions of interfacial catalysis [101-103]. Norris and coworkers [101] showed that, under these conditions, which make it possible to reduce the amount of the aprotic dipolar solvent, the reactions of nitroalkane anions take place with *p*- or *o*-nitro-substituted benzyl or benzylidene chlorides and also with *p*-dinitrobenzene to given excellent yields of products. 2-Nitro-2-(*p*-nitrophenyl)propane is formed in the reaction of the tetrabutylammonium salt of 2-nitropropane with *p*-dinitrobenzene in acetone or benzene in yields up to 76% after only 5 min, i.e. much faster than in the usual procedure in DMSO. [101,104]

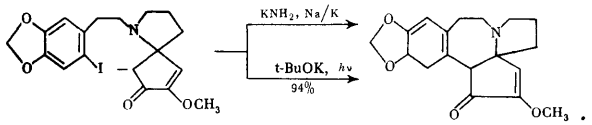


It has been shown recently for reactions of halogeno-derivatives of naphthalene, benzophenone, and benzonitrile with the thiophenoxide ion that substitution via the $S_{RN}1$ mechanism can be initiated electrochemically [105].

The $S_{RN}1$ mechanism was postulated for the first time for nucleophilic substitution in heterocyclic compounds in the reaction of the benzoylacetone dianion with 2-chloroquinoline [106]:

Since the reaction occurred without irradiation and in the absence of an alkali metal, the authors suggested that the reduction proceeds under the influence of the ambident anion itself. The radical chain mechanism was indicated by the powerful influence of inhibitors of the type of *p*-dinitrobenzene. The same workers showed that the interaction of 2-chloroquinoline with $LiCH_2COR$ (R = CH_3 or C_6H_5) in liquid ammonia (−33 °C) is sharply accelerated on irradiation with near ultraviolet light or in the presence of a small amount of added $C_6H_5COCH(Li)COCH_2Li$. [107] The reactions of potassium enolates of various ketones take place readily under the influence of irradiation; the ketone $R^1R^2CHCOCH_3$ then reacts not only with the primary but also with the tertiary carbon atom [108]. Under these conditions, 2-chloroquinoline exhibits a higher reactivity than iodobenzene. It is of interest that, as in the case of halogenobenzenes, the reaction does not take place with the monoanions of β-dicarbonyl compounds. The authors postulate the $S_{RN}1$ mechanism [109] for the reaction of 3-bromoquinoline with the superoxide ion, because bromine in the 3-position is usually relatively unreactive in nucleophilic aromatic substitution reactions.

4-Phenylthioisoquinoline is formed in the reaction of 4-bromoisoquinoline with sodium thiophenoxide in methanol via the usual ionic mechanism (addition-elimination). However, it has been shown [110,111] that in the presence of sodium methoxide the reaction mechanism changes to a radical chain mechanism, which leads to the formation of a reduction product (isoquinoline) together with the substitution product; according to the authors, isoquinoline is formed as a result of the interaction of Ar· with the solvent:



The remaining step is to postulate that, in contrast to the thiophenoxide ion, the methoxide ion behaves as an electron donor in this reaction. The possibility of the reduction of aryl halides under the influence of the methoxide ions is known. Thus it has been shown [111] that, in solution in CH_3OH-CH_3ONa (165 °C), 3-iodopyridine and 4-bromoquinoline give rise mainly to reductive dehalogenation products. The reaction proceeds via radicals, since deuterium is scarcely incorporated in the reaction product when CH_3OD is used. Although this is in fact a radical chain process, it does not have the $S_{RN}1$ mechanism, since there is no stage involving the addition of the anion to the radical. On the other hand, chain propagation proceeds in accordance with the following scheme:

$$CH_3O^- + ArX \rightarrow CH_3O^{\cdot} + ArX^{\cdot -} ;$$
$$ArX^{\cdot -} \rightarrow Ar^{\cdot} + X^- ;$$
$$Ar^{\cdot} + CH_3OH \rightarrow ArH + {}^{\cdot}CH_2OH ;$$
$$^{\cdot}CH_2OH + CH_3O^- \rightarrow CH_2O^{\cdot -} + CH_3OH ;$$
$$Ar^{\cdot} + CH_3O^- \rightarrow ArH + CH_2O^{\cdot -} ;$$
$$ArX + {}^{\cdot -}CH_2O \rightarrow ArX^{\cdot -} + CH_2{=}O .$$

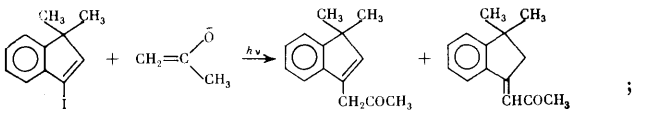
It has been shown recently that, under the classical conditions of the $S_{RN}1$ reaction (ammonia, irradiation), 2-bromo-, 3-bromo-, and 2,6-dibromo-pyridines readily interact with potassium enolates derived from ketones; thus 2-acetonylpyridine is obtained after 15 min in 95% yield [112]. It has been noted that promotion with a metal in the case of heteroaromatic compounds is much less successful than in the case of carboaromatic systems.

The substitution of the halogen in 2- and 3-halogeno-thiophens under the influence of the acetone enolate ion and the amide ion has been achieved in both versions, i.e. under the influence of sodium and irradiation [113].

The $S_{RN}1$ reaction has found a remarkable application in intramolecular cyclisation with formation of the cyclic system of cephalotaxine—the starting material for the synthesis of the anticancer antibiotic cephalotazinone [114, 115]—and also in other similar cyclic systems [116]:

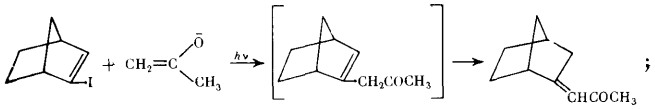
After the addition of the base and the formation of the carbonium ion, the reaction is initiated by an alkali metal or irradiation.

IV. $S_{RN}1$ NUCLEOPHILIC SUBSTITUTION AT AN OLEFINIC CARBON ATOM



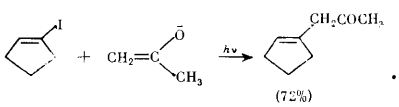
In 1976 the $S_{RN}1$ mechanism was extended to the reaction of vinyl halides [117]. It was found that β-bromostyrene reacts with potassium enolate of acetone under

irradiation (λ = 350 nm, 5 h) to form two isomeric unsaturated ketones (overall yield 82%) and a small amount of styrene (7%):



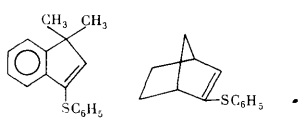
$$C_6H_5CH{=}CHBr + \bar{C}H_2COCH_3 \xrightarrow{h\nu,\,1} \underset{(48\%)}{C_6H_5CH{=}CHCH_2COCH_3} + \underset{(34\%)}{C_6H_5CH_2CH{=}CHCOCH_3} .$$

The reaction, initiated by metallic potassium, is accompanied by reduction, the saturated ketone $C_6H_5CH_2CH_2CH_2.COCH_3$ (63%) and the alcohol $C_6H_5(CH_2)_3CH(OH)CH_3$ (15%) being obtained.



The reactions with 1-iodo-3-dimethylindene§, 2-iodonorborn-2-ene, and 1-iodocyclopentene[117] take place similarly:

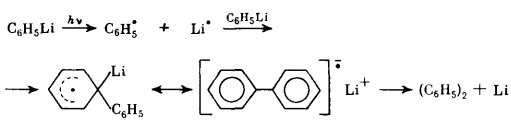
;



;

.

The reaction of the first two compounds with $C_6H_5S^-NH_4^+$ is slow, but also leads to substitution products:



.

It is noteworthy that the authors do not regard the $S_{RN}1$ mechanism as rigorously proved in the reaction described.

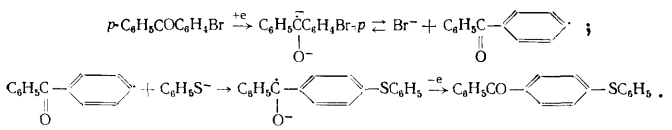
V. GENERAL CONSIDERATIONS CONCERNING THE MECHANISM

The usual reactions of radicals are known to involve dimerisation, disproportionation, or the abstraction of an atom, usually a hydrogen atom, from the solvent[118,119]. The $S_{RN}1$ mechanism under consideration postulates that under certain conditions the radical can interact with the anion to form a radical-anion. There exist data confirming the possibility of this type of radical reaction.

The hypothesis that the phenyl radical adds to the phenyl anion was put forward to account for the formation of biphenyl in the photolysis of phenyl-lithium in ethereal solution[120]:

.

The direct detection of the radical-anions formed is of greatest interest. Such data have been obtained, although their number is extremely small. Thus it has been shown by EPR that certain aryl radicals (obtained by the reduction of ArN_2^+ under the influence of Ti^{3+}) add to the nitrite ion in aqueous solution with formation of radical-anions[133]. The occurrence of this stage demonstrates the reality of the subsequent chain mechanism of the substitution of the diazonium group by a nitro-group via the Sandmeyer reaction:



$$ArN_2^+ + Cu \rightarrow Ar^\cdot + N_2 + Cu^+ \ ;$$
$$Ar^\cdot + NO_2^- \rightarrow [ArNO_2]^{-\cdot} \ ;$$
$$[ArNO_2]^{-\cdot} + Cu^+ \rightarrow ArNO_2 + Cu \ .$$

The addition of the nitrophenyl radical to the iodide ion has been reported[123], but, according to other data[112], the radical-anion formed readily dissociates into the initial components. The radical-anions are not formed by the reaction with chloride and bromide ions[123].

Another example involves the interaction of the cyanide ion with the *p*-nitrophenyl radical, which is generated by the electrochemical reduction of *p*-iodonitrobenzene in DMSO.[123] The formation of the *p*-nitrobenzonitrile radical-anion (in a yield greater than 90%) was established by cyclic volt-amperometric and EPR methods:

$$p\text{-}NO_2C_6H_4^\cdot + CN^- \rightarrow [p\text{-}NO_2C_6H_4CN]^{-\cdot} \ .$$

Analogous radical-anions have been obtained from *o*- and *m*-nitrophenyl radicals. The reaction of $NO_2C_6H_4^\cdot$ with $C_6H_5S^-$ could not be investigated by these methods owing to the rapid interaction of $NO_2C_6H_4I$ with $C_6H_5S^-$. However, the hypothesis of the possible addition of the phenyl radical to the thiophenoxide anion was confirmed in a study[124] of the electrochemical reduction of *p*-bromobenzophenone in the presence of $C_6H_5S^-$; as a result of the oxidation-reduction cycle, the authors obtained the nucleophilic substitution product[124]:

.

However, it has been shown recently[125] that the product of this reaction may be formed by the usual $S_{RN}1$ mechanism in which the initial compound abstracts an electron from the radical anion; the only difference is that in the given instance the electron in the radical-anion is localised in the side chain and not in the aromatic ring.

The problem of the structure of the radical-anion obtained by the interaction of aryl radicals with the cyanomethyl anion has been considered in a study[90] using the method of the molecular orbital perturbation theory; the relative stabilities of the radical-anions were estimated as a function of the distribution of their electron density:

$$[Ar]^{-\cdot} CH_2Z \rightleftarrows ArCH_2 [Z]^{-\cdot} \ .$$

The hypothesis that the alkyl radical can interact with the nitrite ion to form a radical-anion was put forward by the authors of a monograph[119] to account for experimental data[126] having observed that *gem*.-dinitro-compounds are formed in the electrolysis of aliphatic nitro-compound in an alkaline medium in the presence of nitrite ions.

Thus the possibility of a stage involving the addition of the radical to the anion in the $S_{RN}1$ mechanism gives rise to no doubts.

Another fundamental problem arising when the $S_{RN}1$ mechanism is considered concerns the source of electrons This applies particularly to reactions where no catalyst is introduced and to processes initiated by irradiation. When metallic potassium is introduced into the reaction, there

§ The reaction does not take place in the dark even in the presence of an excess of the enolate.

is no doubt about the possibility of the formation of $[ArX]^{\cdot-}$, since it is known that all aryl halides are capable of being reduced by the solvated electron or electrochemically[127]. In principle, it is possible to envisage the reduction of ArX under the influence of certain anions (or nucleophiles). Thus a one-electron transfer stage has been observed for certain nucleophilic substitution reactions using a fairly readily reducible substrate. For example, the reactions of iodonitrobenzenes (but not the chloro- and bromo-derivatives) with bulky amines give rise to a nitrobenzene together with substitution products and sometimes as the main product, i.e. reductive dehalogenation via a radical mechanism takes place[128]. Analogous reduction processes under the influence of CH_3O^- [110,111] were examined above.

However, the problem remains how irradiation promotes this process. In some instances one cannot rule out the possibility that irradiation leads to the rupture of the Ar–X bond, particularly in the case of aryl iodides[129-131]. The possibility of this reaction pathway (together with the photostimulated electron transfer) was rejected by Bunnett and coworkers[80], because the reactivities of bromo- and iodo-benzenes differ insignificantly.

Hoz and Bunnett[132] recently made a detailed study of the reaction of iodobenzene with the diethyl phosphite ion initiated by irradiation. They showed that the reaction is preceded by the formation of a charge-transfer complex. It was found that the reaction is inhibited by nitroxy-radicals but is insensitive to the presence of oxygen and copper chloride. Kinetic measurements showed that the quantum yield of the reaction is greater than unity and that chain termination is a first-order process, which is confirmed by the virtually complete absence of biphenyl from the reaction products. On the basis of these results, the authors concluded that the radical-anion propagating the chain in the $S_{RN}1$ mechanism is formed by one of the following pathways:

$$\text{I (a) } PhI \overset{h\nu}{\rightleftarrows} (PhI)^*\ ,$$

$$(PhI)^* + (EtO)_2PO^- \rightarrow [PhPO(OEt)_2]^{\cdot-} + I^\cdot\ ;$$

$$\text{(b) } (PhI)^* + (EtO)_2PO^- \rightarrow Ph^\cdot + I^- + (EtO)_2PO^\cdot\ ;$$

$$Ph^\cdot + (EtO)_2PO^- \rightarrow [PhPO(OEt)_2]^{\cdot-}\ ;$$

$$\text{II } PhI + (EtO)_2PO^- \rightleftarrows PhI\cdot(EtO)_2PO^-\ ;$$

$$PhI\cdot(EtO)_2PO^- \overset{h\nu}{\rightarrow} [Ph\cdot I^-\cdot OP(OEt)_2]^* \rightarrow PhPO(OEt)_2 + I^-\ ;$$

$$[Ph\cdot I^{\cdot-} OP(OEt)_2]^* + (EtO)_2PO^- \rightarrow [PhPO(OEt)_2]^{\cdot-} + I^- + (EtO)_2PO^\cdot\ .$$

Virtually no kinetic studies on the $S_{RN}1$ mechanism have been described in the literature hitherto. The first attempt at such an investigation was undertaken by Perez de Marquez et al.[133], who used a flow technique involving very rapid contact between a p-$XC_6H_4-C_6H_5$ solution (X = F, Cl, Br, or I) in a 2 : 1 tetrahydrofuran–dimethoxyethane mixture and the surface of a potassium mirror (at −135°C) and detected the radical-anion $[ArH]^{\cdot-}$ in the EPR spectrum. They showed that the rate of its disappearance in an excess of ArX is consistent with first-order kinetics. However, we believe that this study has no direct bearing on the $S_{RN}1$ mechanism.

It is quite evident that the new mechanism of nucleophilic substitution at the carbon atom under consideration is still in its formulation stage, and that its further development in both theoretical and practical respects will be achieved in the immediate future.

Electrochemistry of Metal Chelates in Non-aqueous Media

G.K.Budnikov and T.V.Troepol'skaya

A systematic account is given of experimental data on the electrochemical coordination reactions of compounds of metals with organic ligands in non-aqueous media. Attention is concentrated on the results of polarographic studies on the so-called inert chelate complexes. The influence of the nature of the metal and the ligand on the mechanism of the electrode reaction is discussed.
The bibliography includes 100 references

I. INTRODUCTION

Interest in the electrochemistry of coordination compounds in non-aqueous solutions is due to a number of causes. On the one hand, the vigorous development of inorganic chemistry and in the first place the chemistry of complex compounds requires tests on fundamental relations by various methods, including electrochemical methods. On the other hand, progress in electrochemistry, both theoretical (development of the theory of kinetic currents, mechanisms involving chemical reactions accompanied by charge transfer) and experimental (new apparatus permitting the recording of polarisation curves in solutions with a high ohmic resistance, new procedures for the detection of short-lived species at the electrode, etc.), has also stimulated the study of complexes in non-aqueous media by electrochemical methods. Many chelates are insoluble in aqueous media and the use of non-aqueous solvents therefore ensures suitable conditions for their investigation. From the practical point of view, studies in this field permit the solution of problems of electrocatalysis, electroplating, electrosynthesis of organometallic complexes (catalysts), and finally electroanalytical determination of metals.

Advances achieved hitherto in the polarography of organic compounds in aqueous and aqueous-organic media permit a more detailed examination of the effects accompanying the reduction of a complex species combined with an organic ligand. Virtually all organic substances are adsorbed to some extent on the surface of the mercury dropping electrode (m.d.e.), so that the shift of the half-wave potential ($E_{1/2}$) and the change in the slope of the reduction wave for the metal ion in solution in the presence of the organic ligand, on which conclusions concerning the stability of the complexes in solution and their composition are based, can be induced not only by complex formation but also by the inhibition of the reduction at the electrode, a change in the ψ' potential, etc. These effects are observed mainly when the region corresponding to the reduction of metal ions coincides with the region of the maximum adsorption of the organic ligand.

The study of complex formation processes by polarographic methods in non-aqueous media or in aqueous organic media with a high content of an organic solvent, where adsorption is considerably weakened and the above effects do not complicate the electrochemical reactions of complexes, is also promising in this connection. Furthermore, under these conditions, there is virtually no hydrolysis in solutions. The low dielectric constants of the majority of organic solvents have a significant influence on the behaviour of complexes at the electrode. Many metal ions, forming stable complexes in aqueous media, are highly solvated in organic solvents (for example, in ethylenediamine, formamides, acetonitrile, and dimethyl sulphoxide) and are characterised by high donor numbers. Problems of the solvation of metal cations have been reviewed recently in a collection of reports on non-aqueous electrochemistry[1]. The conditions governing the selection of a suitable solvent, supporting electrolyte, and reference electrode for the investigation of chelates are also discussed there.

Attention has been particularly concentrated recently on the use of aprotic solvents, for example, dimethylformamide (DMF). The usefulness of such solvents can be explained by the fact that the influence of protonation is weakened, the study of the mechanism of the electrode process is simplified, and it becomes possible to observe multistage electron transfer and the formation of complexes with the central atom in the lowest valence states, which are unstable under the usual conditions. Nor can one rule out the possibility of the selection on the basis of polarographic data of conditions for the electrochemical generation of these unstable species and the study of their chemical structure. Finally, in organic media it is possible to extend greatly the range of m.d.e. polarisation potentials.

In the present review an attempt is made to discuss the present state of electrochemical studies on metal chelates in non aqueous systems—to assess the fundamental achievements and prospects in this relatively new field.

II. ELECTROCHEMICAL REDUCTION OF METAL CHELATES WITH ORGANIC LIGANDS IN NON-AQUEOUS MEDIA

In order to elucidate the influence of the chemical structure of metal chelates on the mechanism of their electrochemical reduction, it is necessary to study a fairly wide range of coordination compounds with various types of chelate units, determined both by the nature of the central atom and by the properties of the donor atoms in the analytically useful functional groups and their steric disposition in the molecule of the organic reagent. The authors

realise that not all the series of coordination compounds have been considered in equal detail in this review, because a complete treatment of all chelating agents is impossible and is hardly desirable. Most attention has been devoted to the chelates of *d* elements with filled and unfilled *d* shells.

1. Electrochemical Reduction of Metal Dithiocarbamates at the Mercury Dropping Electrode

The polarographic reduction of dithiocarbamates (DTC) at the mercury electrode in DMF has been studied in a series of investigations[2-5]. Chelates having the general formula $(R_2NCS_2)_nM^{n+}$ [$(CH_2)_4ONCS_2$]$_n$ and [$(CH_2)_mNCS_2$]$_nM^{n+}$, where $M^{n+} = Zn^{2+}$, Cd^{2+}, Sn^{2+}, Tl^{+}, Pb^{2+}, Bi^{3+}, Cu^{2+}, Cr^{3+}, Mn^{3+}, Fe^{3+}, Co^{3+}, or Ni^{2+}, R = CH_3, C_2H_5, n-C_3H_7, or n-C_4H_9, and m = 4, 5, or 6, were investigated. It was found that, in terms of their electrochemical behaviour, they can be divided into two groups. The first includes the dithiocarbamates of metals with filled *d* shells: Zn^{2+}, Cd^{2+}, Sn^{2+}, Hg^{2+}, Tl^{+}, Pb^{2+}, Bi^{3+}, and Cu^{2+}. They give rise to waves, corresponding to the reduction of the central ion to the metal, on polarograms obtained in DMF in the presence of $(C_2H_5)_4NClO_4$ as the supporting electrolyte; the values of their $E_{1/2}$ vary in the range from −0.6 to −1.5 V. The reduction is nearly reversible (except for the Cd^{2+} and Zn^{2+} chelates):

$$M^{n+}(R_2NCS_2)_n + n\,e + Hg \rightleftarrows M^0(Hg) + nR_2NCS_2^-.$$

The nature of the ligand is reflected in the polarographic properties of the chelates. The greater stability of complexes with ligands having a stronger electron-donating group is the cause of the displacement of $E_{1/2}$ towards cathodic potentials (in the range 0.05–0.07 V) as R is varied in a homologous series. The standard rate constants for charge transfer k_S (based on oscillopolarographic data) are in the range $(1.2-2.6)\times10^{-2}$ cm s^{-1}. The form of the polarisation curves depends on the concentration of the complex, which is due to the adsorption activity of the DTC. The adsorbability is influenced by the nature of the solvent and R, which determine the solubility of the DTC. The reduction of this group of DTC takes place mainly in the range of E values close to the electrocapillary zero, where the adsorbability is manifested to the greatest extent.

Polarograms referring to the second group of complexes of the type $M^{n+}(R_2NCS_2)_n$, where $M^{n+} = Cr^{3+}$, Mn^{3+}, Fe^{3+}, Co^{3+}, or Ni^{2+}, consist of n plateaux corresponding to the successive transfer of n electrons. The reduction of Mn^{3+} chelates proceeds in two stages with the transfer of one and then two electrons. The product of the final irreversible stage is the metal on the mercury surface. The stepwise reduction of the DTC is complicated by the intervening dissociation of the intermediate complex species (the central atom in a low valence state) involving the formation of the $R_2NCS_2^-$ anion. The nature of the substituent at the nitrogen atom in the DTC molecule has some influence on the ease of reduction of complexes in DMF: an increase in the length of the aliphatic chain in the homologous series leads to a cathodic shift of $E_{1/2}$ for irreversible waves. The same shift occurs with increase in the size of the ring in heterocyclic derivatives. The lack of a simple correlation with the half-wave potentials of the one-electron reversible stage in the reduction of the dithiocarbamates of typical transition metals and the Taft constants of the substituents at the nitrogen atom can hardly be accounted for by the steric hindrance in the reduction reaction.

$E_{1/2}$ for the reversible one-electron process, characterising the energy of the lowest unoccupied molecular orbital, is apparently insensitive or only slightly sensitive to steric effects. The deviations of $E_{1/2}$ from the linear relation with the free energy are more likely to be due to a complex dependence of the adsorption of chelates on the nature of the groups involved and the influence of adsorbability on $E_{1/2}$.

Variation of the nature of the substituents R and R′ in the ligand fragment of iron(III) dialkyldithiocarbamates over a wide range made it possible to discover more refined factors influencing the reactivity of chelates of this type in the electrochemical reduction[6]. A study was made of the dependence of $E_{1/2}$ for the first reversible one-electron reduction stage on the energy difference between the ground and excited states. It was found that high-spin complexes are reduced more readily than low-spin complexes almost by 0.25 V. It was suggested[6] that the steric interaction with the sulphur atoms in low-spin complexes having bulky R and R′ groups leads to a non-planar structure of the fragment [C_2N-CS_2] and the electron pair of the atoms can be delocalised only within the limits of the chelate unit; the ligand field is therefore strengthened. For small substituents R and R′, a planar mesomeric structure (mesoionic form) of the type $C_2N^+ = CS_2$, with a shorter C–S bond, becomes preferable, so that the ligand field is weakened. To illustrate the influence of the steric effect of substituents on $E_{1/2}$, a comparison was made of the dithiocarbamates of the iron(III) complexes of pyrroline and 2,5-dimethylpyrroline[6].

Although in certain cases the reduction of chelates is in fact complicated by adsorption effects, the ease of reduction of dithiocarbamates of both groups at the m.d.e. is largely determined by the nature of the central atom, which is consistent with the "metallic" nature of the metal–ligand bond. However, the ease of reduction is apparently influenced in certain cases by the contribution of the mesomeric form of the ligand.

The results of a study of the electrochemical reduction of nickel dithiocarbamates by chronopotentiometry were published recently[7]. A study was made of the complexes with aliphatic straight-chain, branched, and alicyclic groups in DMF in the presence of 0.1 M $NaClO_4$ as the supporting electrolyte and platinum and stationary mercury electrodes. In all cases the authors[7] observed a single reduction wave, and not two, because the range of the possible polarisations of the electrodes in the presence of sodium perchlorate was insufficiently broad, i.e. the authors studied only the first stage of the reduction of the nickel chelates. It was found that the complexes are reduced irreversibly (with rare exceptions) and that the product $i\tau^{1/2}$ [where i is the current density and τ the duration of the arrest on the chronopotentiometric $E = f(t)$ curve] is independent of the current density. Consequently preceding dissociation of the complexes was not observed under the experimental conditions. It follows from these data[7] that the greater the stability of the chelates, the lower the charge-transfer rate constant. Having noted that in the series of complexes investigated the orbital to which an electron is transferred is mainly "metallic", the authors[7] believe that in certain cases there is a possibility of a shift of the location of the transferred electron from the metal to the ligand, for example, on passing from the dibenzyl derivative to the dicyclohexyl derivative. Comparison of the results of Budnikov and coworkers[3-5] and Ahmed and Magee[7] shows that the replacement of mercury by platinum leads to a significant change in the nature of the one-electron stage in the reduction of nickel

dithiocarbamates. The absence of a clear dependence of the ease of reduction at the platinum microelectrode on the structure of the ligand (with a large scatter of the peak potentials E_p along the potential axis) and the low rate of charge transfer apparently indicate a significant influence of the adsorption and kinetic contributions on the electrode process under these conditions[7].

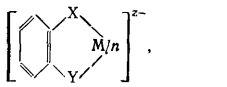
In connection with the problem of the elucidation of the biological role of metals in enzymes, the oxidation-reduction properties of certain molybdenum and vanadium complexes of a number of sulphur-containing ligands, which form the inner coordination sphere, including dithiocarbamates, were investigated by electrochemical methods[8,9]. These complexes were regarded as models of metalloenzymes. The formation of dinuclear dimers, which determine the mechanism of the behaviour at the electrode, is characteristic of molybdenum(V) dithiocarbamate chelate complexes. Dinuclear complexes with DTC were not observed for vanadium in different oxidation states[9]. The transfer of the first electron to $V(R_2NCS_2)_3$ at the platinum electrode is reversible. The reduction of $VO(R_2NCS_2)$ proceeds in a complex manner and involves the formation at one of the stages of a certain amount of the $V(R_2NCS_2)_3$ species apart from the main product V_2O_3. The reduction of $VO(R_2NCS_2)_3$ results in the formation of $VO(R_2NCS_2)_2$ and the ligand anion. In the molybdenum complexes the DTC ligands give rise to a more "electron saturated" environment around the central ion than other ligands, for example 8-hydroxyquinoline[8].

2. Mixed-Ligand Metal Complexes with Dithiocarbamates in Electrochemical Reactions

When complexes are formed with variable-valence transition metal ions, those with metals in a high oxidation state (Cr^{3+}, Mn^{3+}, Fe^{3+}, and Co^{3+}) are as a rule stabilised. The introduction into the chelate molecule of ligands exhibiting π-acceptor properties [2,2′-bipyridyl(Bipy) and 1,10-phenanthroline(Phen)] promotes the stabilisation of the low oxidation state of the central atom. An example is provided by manganese(II) and iron(II) complexes $M(R_2NCS_2)_2Bipy$ or $M(R_2NCS_2)_2Phen$.[10] When they are reduced in DMF at the m.d.e., the polarograms show four plateaux corresponding to one-electron transfers in accordance with the mechanism $M^{2+} \rightleftharpoons M^{+}$ and $M^{+} \rightleftharpoons M$ and the reduction of Bipy or Phen. Similar heteroligand complexes are also formed by Zn^{2+}. In contrast to simple zinc(II) dithiocarbamates, they are reduced in stages with formation of an intermediate species in which the central atom has a formally low valence state. The unpaired electron in the product of the reversible electron transfer to $Zn(R_2NCS_2)_2Bipy$ is delocalised over the Bipy ligand and occupies an antibonding π^* orbital. In the electrolysis of a solution of this complex at the potential of the limiting current of the first one-electron wave, the $Bipy^{\cdot-}$ radical-anion was detected by EPR.[11,12]

Nickel(II) dithiocarbamates do not form heteroligand complexes with Bipy. However, in the presence of Bipy or Phen an increase in the limiting current of the first reversible one-electron wave at the expense of the second and an anodic shift of both branches are observed. Similar phenomena are also observed for the chromium(III) and cobalt(III) dithiocarbamates when the above π-acceptors are added to the polarographed solution. The increased current is due to the kinetic contribution. The results indicate a chemical reaction of π-acceptors with the one-electron transfer product (ECE mechanism):

$$M^{(n+1)}(R_2NCS_2)_n + e \rightleftarrows [M^{n+}(R_2NCS_2)_n]^-$$



$$[M^{n+}(R_2NCS_2)_n]^- + Bipy(Phen) \xrightarrow{k} [M^{(n-1)}(R_2NCS_2)_{n-1}]Bipy(Phen) + R_2NCS_2^- .$$

The intermediates formed at the electrode in acetonitrile are more stable. The electrolysis of a solution of the chromium(III) complex at the potential of the limiting current of the first wave in the presence of Bipy exhibits a distinct spectrum of paramagnetic species containing lines due to splitting by the four nitrogen atoms. According to polarographic data, the heteroligand complex $Cr^{+}[(C_2H_5)_2NCS_2]Bipy$ is formed under these conditions. Since Cr^{3+}, having the d^5 electronic configuration, can form octahedral complexes, it follows that under the electrolysis conditions there is a possibility of the addition of yet another molecule and the formation of the complex species $Cr^{+}(C_2H_5)_2NCS_2(Bipy)_2$, whose signal is observed in EPR spectra[13].

Among other heteroligand complexes containing DTC, studies were made on compounds having the composition $[(Cp)_2VR_2NCS_2]^{+}$, where R = CH_3, C_2H_5, n-C_4H_9, or iso-C_3H_7, and Cp = cyclopentadienyl[14]. They are reduced in acetone in the presence of $(C_2H_5)_4NClO_4$ as the supporting electrolyte in two one-electron stages. The first reduction wave is fully reversible, while the second is irreversible. It is suggested that the reversible wave corresponds to the transfer of one electron to a non-bonding orbital of the vanadium atom with formation of a neutral vanadium(III) complex, tending to split off a free $R_2NCS_2^-$ anion. It was established by a.c. polarography that the dissociation is facilitated in the presence of oxygen. The free anion can oxidise metallic mercury to Hg^{+} at a potential more negative that $E_{1/2}$ for the first cathodic wave. The mechanism of the electrode process corresponding to the first wave has been described by an EC_1EC_2 scheme and is regarded as a special case of the ECE mechanism.

3. Dithiolates and Related Chelates

Dithiolate complexes, i.e. compounds with the chelate unit  , where M is a transition metal, have been the subject of numerous polarographic studies. The first investigations in this field are examined in two reviews[15,16]. The polarograms of complexes in this group have several waves, the first of which is as a rule reversible. The stepwise nature of the reduction process has been observed in a series of inner complexes in which the structure of the coordination shell is[17]

where M = Cu, Ni, Co, Pd, or Pt for $n = 2$ and V, Cr, Mo, or W for $n = 3$, with formation of species where $z = 1$ or 2 ($n = 2$) and $z = 1$, 2, or 3 ($n = 3$).

In methylene chloride the intermediate species are fairly stable. The influence of the donor atoms X and Y on the ease of transfer of the first electron was examined qualitatively in relation to nickel bis-complexes[18]. It was established that $E_{1/2}$ for the nickel chelates undergoes a "cathodic" shift in the following series of coordination cells:

$$[NiN_4] < [NiN_2S_2] < [NiS_4] \leqslant [NiO_2S_2].$$

In a subsequent study [19], these results were refined and in addition to the influence of the donor atoms in the chelate unit on $E_{1/2}$ was discussed in relation to the zinc, copper, palladium, and cobalt inner complexes with *o*-mercaptophenol, 1-mercapto-2-naphthol, and 1-hydroxy-2-pyridinethione.

Together with polarography, the EPR method was used in the studies under consideration [15-19]. The fact that the transfer of the first electron to the dithiolate is reversible with formation of a stable paramagnetic product in a suitable solvent permits the use of this electrode reaction for the electrochemical generation of such a product. Interest in the electrochemical generation of species of this kind is due primarily to the ease with which it can be followed. Application of the EPR method not only established the formation of paramagnetic species, but also yielded valuable information about the nature of these species, about the nature of the metal–ligand bond, etc.

Two studies have been published, in which cyclic voltammetry was used to investigate the mechanism of the one-electron transfer reactions involving cobalt [20] and nickel [21] maleonitriledithiolate (mnt) complexes. The method made it possible to study in detail the $[Co(mnt)_2]^{z-}$ ($z = 0$, 1, or 2) system in the absence and presence of pyridine (Py), to calculate the rate constant for the formation of heteroligand cobalt complexes with mnt and Py having the composition $[Co(mnt)_2Py]^-$ and $[Co(mnt)_2Py_2]^-$, and to propose a mechanism for the electrode process [20]. The triply charged anionic nickel complex with this ligand can be obtained by the reduction of the corresponding dianion at the electrode in acetonitrile or dimethoxyethane [21]. In the presence of traces of atmospheric oxygen this process takes place almost instantaneously. Analysis of the EPR spectra showed that the unpaired electron in the $[Ni(mnt)_2]^{3-}$ species is largely localised at the metal.

Polarography together with other methods has been used in the study of the dithiolene complexes of zirconium(IV), titanium(IV), and molybdenum in different valence states with toluene-3,4-dithiol in acetonitrile and methylene chloride [22]. Electrode transfer to the depolariser is irreversible in these processes.

4. Metal Diketonates in Electrochemical Reduction Reactions

The electrochemical behaviour of transition metal chelates with acetylacetone and certain dithiodiketones containing stable five-membered rings in their structure has been discussed in a review [23]. This section deals with studies carried out in recent years which are not included in the above review [23]. Thus interesting results were obtained in the investigation of the influence of substituents in the chelate ring in the series of trisdiketonate ruthenium(II) and ruthenium(III) complexes on the ease of reduction in DMF at a rotating platinum microelectrode [24]. Ruthenium complexes of this type, in both oxidation states, proved to be kinetically stable under the experimental conditions. The stage involving electron transfer to the ruthenium(III) chelate is reversible and uncomplicated by accompanying chemical reactions:

$$Ru(R_1COCHCOR_3)_3 + e \rightleftarrows Ru(R_1COCHCOR_3)_3^-.$$

$E_{1/2}$ varies over an unusually wide range (approximately 1.84 in DMF) as R_1 and R_2 are altered. The analogous range of variation of E was found to be at most 1.5 V in an earlier study [15] for a series of substituted chelates with a delocalised electronic structure of the type $M(S_2C_2R_2)_n$, where M is a transition metal (but not ruthenium). Electrochemical data for ruthenium(III) chelates of the type under consideration made it possible to employ the principle of the linearity of free energy in order to describe their reactivities in the one-electron transfer reaction. It has been stated [24] that cobalt(III) dithiocarbamate, for example, $Co[(C_2H_5)_2NCS_2]_3$, is reduced irreversibly in DMF at a platinum electrode with transfer of one electron. This finding is consistent with data for the reduction of nickel(II) dithiocarbamate under analogous conditions, discussed above [7].

The reduction of chromium(III) tris-β-diketonates was studied in dimethyl sulphoxide and 85% aqueous dioxan [25]. In the pure solvent the chelates CrL_3 (here HL = $R_1COCHR_2COR_3$; $R_2 = H$, $R_1 = R_3 = H$, CH_3, CF_3, or C_6H_5; $R_1 = H$, $R_3 = CH_3$, t-C_4H_9, or C_6H_5; $R_1 = CH_3$, $R_3 = CF_3$ or C_6H_5; $R_1 = CF_3$, $R_3 = C_6H_5$ or t-C_4H_9; $R_1 = R_3 = CH_3$, $R_2 = CH_3$, C_2H_5, or C_4H_9; $R_1 = C_6H_5$, $R_3 = CH_3$, $R_2 = CH_3$, C_2H_5, or C_4H_9; $R_1 = R_3 = C_6H_5$, $R_2 = CH_3$, C_2H_5, or C_4H_9) gave rise to one-electron waves, the first of which is associated with the reversible reduction

$$CrL_3 + e \rightleftarrows CrL_3^-.$$

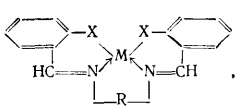
On the other hand, in a mixed solvent the process is less reversible and the polarograms show one wave. The values of $E_{1/2}$ are in the range from −0.4 to −1.8 V, depending on the nature of R_1, R_2, and R_3. The effects of substituents are additive and are determined by their polarity. There is no correlation between $E_{1/2}$ and the usual parameters characterising the ligand field, while the spherical potential of the ligand field varies in parallel with the ease of reduction of the chelate. It is suggested [25] that the dependence of $E_{1/2}$ on the nature of R_1, R_2, and R_3 is associated with changes in electron density at the oxygen atoms of the pseudoaromatic chelate ring.

Vanadyl acetylacetonate in acetonitrile is reduced at the mercury electrode via a complex mechanism involving two electrons. In the presence of a diketone the process is complicated by intervening chemical reactions of the intermediates in the reduction process with acetylacetone [26]. Nickel(II) bis-β-dithiodiketonate complexes are reduced with electron transfer in stages involving the formation of intermediate charged complex species [27].

A comparative study of the influence of the nature of the oxygen and sulphur donor atoms on the ease of reduction in the general case led to the same conclusions as for the similar nickel complexes with a five-membered chelate unit [18,19], i.e. the replacement of O by S facilitates the reduction. The greater the number of sulphur atoms in the coordination unit of nickel β-diketonate, the less negative are the potentials at which the reduction takes place and the higher the charge transfer rate constants. In terms of the ease of reduction, these chelates can be arranged in the sequence $NiS_4 > NiS_2O_2 > NiO_4$. The same series is in essence retained for the values of k_S: $NiS_4 \simeq NiS_2O_2 > NiO_4$. [27] As for ruthenium β-diketonates [24], the values of $E_{1/2}$ for the first stage in the reduction of nickel(II) bis-β-dithiodiketonates in acetone cover a fairly wide range [28]. However, the dependence of $E_{1/2}$ on $\Sigma\sigma^*$ is not linear, despite the fact that the reduction at this stage leads to the formation of a thermodynamically stable oxidation-reduction pair.

Palladium(II) acetylacetonate is reduced irreversibly in DMF with consumption of two electrons (to form the metal amalgam) [29], which agrees with data for alcohol–benzene solutions [30].

5. Complexes with Schiff Bases



One of the first studies on chelates of this type concerned cobalt complexes with ligands which are structural analogues of one of the fragments of vitamin B_{12}.[31,32] An electrochemical model of the reduction processes involving the cleavage of the cobalt–carbon bond was studied in relation to the reduction of cobalt complexes of the type RCo^{2+}, where R = C_6H_5 or CH_3, with N,N′-ethylenebis(salicylideneamine) (H_2A) and 1,3-bisdiacetylmonoximeiminopropane (HB) in DMF. The C_6H_5–CoA chelate gives rise to three one-electron waves on the polarograms. The first two are of a diffusional and reversible type. According to data derived from cyclic voltamperograms and electrolysis at a controlled potential, the product of the one-electron transfer $[C_6H_5–CoA]^-$ is fairly stable. The dianion $[C_6H_5–CoA]^{2-}$, formed in the second reduction stage, is unstable under these conditions. The chelate CH_3–CoA is reduced in the first stage to $[CH_3–CoA]^-$, decomposing at the electrode with formation of a number of products: Co, CoA^-, and CH_3^-.

The second and third stages are poorly reflected in the curves. The chelate $[C_6H_5–CoB]^+$ gives rise to two reversible one-electron plateaux on the polarograms; the product of the two-electron transfer is fairly stable and can be isolated after electrolysis at a controlled potential. The electrochemical reduction of the $[CH_3–CoB]^+$ species proceeds via the mechanism

$$[CH_3–CoB]^+ + e \rightleftarrows CH_3–CoB,$$
$$CH_3–CoB + e \rightleftarrows [CH_3–CoB]^-.$$

The neutral species disproportionates with formation of $(CH_3)_2CoB$ and CoB. The same products are formed as a result of the interaction of the initial species and the monoanion. The different types of electrochemical behaviour of the chelates $[C_6H_5–Co]^{2+}$ and $[CH_3–Co]^{2+}$ with the above ligands are due to weaker electron-donating properties of phenyl compared with methyl. The electrode reactions of these coordination compounds simulate to some extent the biochemical action of vitamin B_{12}.[32]

The redox properties of complexes having the structure[33]

where M = Co, Ni, or Cu, X = O or NH, and R = $CH_2–CH_2$, $(CH_2)_3$, or $CH(CH_3)CH_2$, were investigated at a platinum electrode in methylene chloride. The low-valence state of the central atom in the bis-complexes of the same metals with the Schiff bases obtained from acetylacetone and salicylaldehyde and amines is stabilised at the m.d.e. on reduction via the process $M^{2+} \rightleftarrows M^+$; the stabilisation can be explained by the square-planar structure of the initial ligands[34].

The electrochemical reduction of cobalt chelates having the general formula RCoLX,[35] where R = C_6H_5, CH_3, C_2H_5, or $CH{=}CH_2$, L = the monoanion of 1-diacetyl monoximatoimino-3-diacetylmonoximeiminopropane or a tetradentate dianion [*N*,*N*′-ethylenebis(salicylideneaminate), *N*,*N*′-ethylenebis-(7,7-dimethylsalicylideneaminate), or *N*,*N*′-ethylenebis(acetylacetoneiminate)] and X is the solvent, was investigated by polarography at the m.d.e. in DMF, pyridine, and dimethyl sulphoxide. The nature of the group R and the solvent X influences the stability of the one-electron transfer product. The complex of the first ligand gives rise to two one-electron plateaux on the polarogram, the second of which corresponds to the formation of a species in which the degree of oxidation of the central atom is +1. The complex $[C_6H_5–Co]^-$, obtained as a result of electrolysis at a controlled potential E, was identified spectrophotometrically. The species $[RCoL]^-$, derived from chelates with R = CH_3 or C_2H_5, reacts in the course of electrolysis with the initial depolariser, forming bis-complexes. The values of $E_{1/2}$ for the first plateaux are satisfactorily correlated with the pKa of acids of the type RH.

In another study[36] the same workers described the polarographic behaviour of cobalt complexes having the composition $[Co^{3+}YL_2]^+$ and $[Co^{2+}Y_2]^0$, where Y is an equatorial ligand—the dianion of an imine of the same type as in earlier investigations[35] and L is an axial ligand: methylamine, n-propylamine, benzylamine, aniline, pyridine, and similar amines. The complexes are reduced in 95% ethanol via two reversible one-electron stages corresponding to a formal change in the degree of oxidation of cobalt:

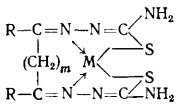
$$[Co^{3+}YL_2]^+ + e \rightleftarrows Co^{2+}YL_2 \text{ and}$$
$$Co^{2+}YL_2 + e \rightleftarrows [Co^{+}YL_2]^- ,$$

but only in the presence of an excess of the amine L. In the absence of the amine, the first reduction stage is irreversible, which was explained by the subsequent chemical stage in which L is split off. At a platinum microelectrode under the same conditions[36] oxidation takes place with the reversible transfer of one electron via the formal mechanism:

$$Co^{2+} - e \rightleftarrows Co^{3+}.$$

The values of $E_{1/2}$ for the first reduction stage of these chelates with various Y reflect the influence of the electronic structure of the tetradentate ligand. An increase in the degree of conjugation in the structure of Y causes an "anodic" shift of $E_{1/2}$. The observed correlation between $E_{1/2}$ for the first stage and the pKa of the amines indicates a transfer of electron density from L to Y. This correlation occurs only for ligands with the same electronic and steric configurations of the nitrogen donor atom. The small change of $E_{1/2}$ for the second stage as a function of the nature of L shows that the interaction of the amine with cobalt is only slight. The authors[36] suggest that $E_{1/2}$ for the first stage characterises the energy of the unoccupied molecular orbital.

The electrochemical reduction of 37 mononuclear and dinuclear copper(II) complexes with imino-ligands L (L = substituted β-ketoamines, β-iminoamines, or pyrrole-2-aldimines) in DMF in the presence of tetra-n-propylammonium perchlorate as the supporting electrolyte was investigated by electrochemical methods and ultraviolet spectroscopy[37]. The mononuclear complexes are reduced with consumption of one electron. The dinuclear chelates are reduced with transfer of two electrons in one of two consecutive stages as a function of the nature of L with formation of the corresponding copper(I) chelates. Complexes of this type, which have a non-planar structure, are reduced more readily than planar chelates. The ease of their reduction increases in the sequence rigid tetradentate (with N_4 units) < bidentate (with N_2O_2 units) < bidentate (with N_2S_2 units) ligands.



6. The Behaviour of Thio- and Seleno-semicarbazone Metal Complexes at the Mercury Dropping Electrode in DMF

The ligand in complexes of thio- and seleno-semicarbazones is in many cases the protonated form of the initial organic reagent. For this reason they exhibit different types of behaviour at the electrode[38-42]. Metal complexes with the thiosemicarbazones of acetone (Hthac), benzaldehyde (Hthbz), anthranilic aldehyde (Hthan), salicylaldehyde (Hthsa), and their selenium analogues give rise to different numbers of waves on polarograms in DMF in the presence of $(C_2H_5)_4NClO_4$ as the supporting electrolyte. The polarograms of copper(I) chelates with Hthac and Hthbz contain two waves. Their first one-electron waves are nearly reversible:

$$\underset{(L = \text{ligand})}{CuL} + e + Hg \rightleftarrows Cu(Hg) + L^- \ .$$

The second waves, at negative potentials, are due to the ligand liberated in the first stage. They are of the kinetic type and differ from the waves of the initial Hthac and Hthbz by their parameters owing to the deprotonation of the reactants on complex formation. The copper(II) chelate complex of H_2thsa gives rise to one two-electron wave on polarograms. The thio- and seleno-semicarbazones of anthranilic aldehyde react with Cu^{2+} to form complexes $Cu(HL)Cl_2$, i.e. without the displacement of hydrogen ions. They give rise to an extended irreversible wave on polarograms, corresponding to the reduction of the central ion, and a wave due to the reduction of the ligand with $E_{1/2}$ close to that of the initial Hthan or Hsesan.

The mechanism of the reduction of copper(II) complexes of bisthiosemicarbazones under the conditions corresponding to the first wave is probably analogous to the mechanism of the reduction of copper(I) chelate complexes of Hthac and Hthbz. The constant k_S for this stage is $(0.50 \pm 0.16) \times 10^{-2}$ cm s^{-1}. $E_{1/2}$ diminishes with increase of the number of methylene groups in the ligand fragment of the chelate. The structures of copper(II) complexes of bisthiosemicarbazones have in general three chelate rings[39]:

For $m = 0$ or 1, the middle ring is five- or six-membered, i.e. is the most stable, and this factor is responsible for the maximum chelating effect. With increase of m to three, the middle ring expands and makes no contribution to the stabilisation of the chelate structure. The possibility of forming complexes of this type promotes the stabilisation of the central atom in the +2 oxidation state. For $m = 4$, this does not happen: the bisthiosemicarbazone behaves similarly to Hthac or Hthbz, i.e. copper(II) is reduced to copper(I) with formation of the corresponding complex. The thiosemicarbazones of salicylaldehyde and anthranilic aldehyde (H_2thsa and Hthan) and their selenium analogues form the cobalt complexes $[Co(HL)_2]X$, in which the metal is in the +3 oxidation state. Their polarograms contain two waves. The first extended, irreversible wave (with $E_{1/2} \simeq -1.1$ V) formally corresponds to the reduction of the metal ion in the complex and the second at $E \simeq -1.5$–-2.0 V corresponds to the electrochemical reaction of the ligand anion.

The cathodic shift of $E_{1/2}$ on passing from cationic complexes of the type $[Co(Hthsa)_2]Cl$ to the anionic complexes $NH_4[Co(thsa)_2]$ can apparently be accounted for not only by the formation of a more stable complex in the latter case, but also by the sign of the charge of the species being reduced. The results of the investigation showed that $E_{1/2}$ is independent of or depends little on the nature of outer-sphere ion X.[41] Nickel ions react with reagents of this type to form complexes of two kinds: with and without substitution of the hydrogen atoms in the ligand. The complexes $[Ni(HL)_2]Cl_2$ give rise to two irreversible waves on the polarograms. The first diffusional stage formally corresponds to the process $Ni^{2+} \rightarrow Ni^0$, while the second is due to the ligand.

For nickel chelate complexes of bisthiosemicarbazones, the stepwise transfer of two electrons is observed. The stepwise mechanism of the reduction indicates the formation of intermediate complex species with a formally low-valence state of the central atom[42]:

$$NiL + e \rightleftarrows [NiL]^- + e \rightleftarrows [NiL]^{2-} \ .$$

The electrochemical behaviour of cadmium, lead, and nickel complexes with reagents of the above type has been described[40].

Comparison of the polarographic behaviour of metal chelate complexes (having structures of the same type) of various thiosemicarbazones reveals the following regularity. If the metal does not form an amalgam with mercury or its solubility in mercury is low, then the product of the two-electron transfer exists for a time at the electrode, which is the reason for the reversibility of the process (nickel chelates having the structure of the inner complex type). Subsequent electron transfer to the chelate dianion formed should apparently occur at very much higher negative potentials E, so that there are no waves due to the ligands. On the other hand, if the metal is readily soluble in mercury (for example, lead and cadmium), then the formation of an amalgam promotes the deactivation of the two-electron transfer product with formation of species differing from the initial thiosemicarbazone and being reduced at more "cathodic" potentials E. The difference between them can be explained by the fact that the ligand in the inner complex structure is a deprotonated thiol form of the thiosemicarbazone. In those cases where complex formation proceeds without the elimination of protons, the ligand and the initial thiosemicarbazone give rise to virtually identical waves on the polarograms.

7. Metal Chelate Complexes of Certain Hydroxyazo-Compounds in DMF

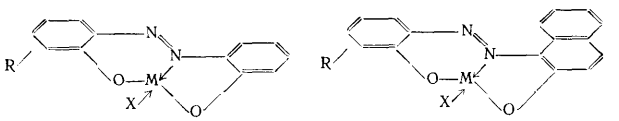
In terms of their electrochemical behaviour, these complexes like the metal complexes of dithiocarbamates and thiosemicarbazones can be divided into two groups, depending on the electronic configuration of the central atom[43-45]. Cadmium(II), lead(II), tin(II), and copper(II) complexes are reduced in DMF at the m.d.e. in two stages. The first stage corresponds to the transfer of two electrons and formally involves the electrochemical reduction of the central ion in the chelate. The second wave is due to the ligand L, liberated when the complex is reduced in the first stage. The parameters of the two waves differ from those of the initial azo-compounds.

The nature of the ligand is reflected in the polarographic properties of the chelates. The greater stability of complexes with ligands forming an additional coordinate bond due to the lone electron pair of the nitrogen atom in the heterocycle is the cause of the shift of $E_{1/2}$ towards more "cathodic" values. The introduction of a sulphur atom into the heterocycle reduces the electron-donating

properties of nitrogen in this ring and diminishes the strength of the M–L bond, which is reflected in the value of $E_{1/2}$.

The irreversibility of the second stage in the reduction of chelates in this group and its kinetic nature are evidently due to the decomposition of negatively charged complex species formed in the first stage, as in the reduction of chelate complexes of thio- and seleno-semicarbazones:

$$ML_n + 2e \rightleftarrows [ML_n]^{2-} + Hg \xrightarrow{k'} M^0(Hg) + nL^{(3-n)-};$$
$$n = 1, 2.$$



Manganese(II), nickel(II), and zinc(II) complexes, which constitute a second group of compounds, are reduced, in contrast to the previous compounds, via two irreversible one-electron stages, which are followed by a third irreversible wave. Comparison of the EPR spectra of the products of the one-electron reduction of nickel(II) and zinc(II) complexes with the EPR spectra of the products of the reduction of the initial azo-compound shows that the spin density of the transferred electron is localised at the ligand[46]. Taking into account the fact that the values of $E_{1/2}$ for chelates of this type with different metals differ insignificantly, presumably in this case the M–L bond is of the ligand type. Compared with the complexes of *o*-hydroxyazo-compounds, the chelate complexes of *o*,*o*′-dihydroxyazo-compounds are reduced at more negative potentials, since they form a more stable structure with metal ions, in which two pseudoaromatic rings are generated.

The limiting current of the first reduction wave of the nickel(II) and zinc(II) complexes of *o*,*o*′-dihydroxyazo-compounds exceeds the current of the second wave and the one-electron level. This is caused by the disproportionation of the products formed in the first stage. The disproportionation constants are in the range $(1-20) \times 10^4$ litre mole^{-1}s^{-1}. For certain rates of polarisation of the electrode, it is possible to eliminate almost completely the influence of the subsequent reactions and the electrode process can be regarded as reversible. For this range of rates, the equation of the linear relation between the free energy and the Hammett substituent constants can be put in the form

$$\Delta E_p' = \rho_\pi \sigma_R,$$

where $\Delta E_p'$ is the shift of the E peak on the oscillopolarograms under the influence of the substituents. This makes it possible to estimate the influence of substituents on the ease of the electrochemical reduction of the complexes, whose reduction under the conditions of classical polarography is complicated by the subsequent chemical reactions of the primary products of the reversible charge transfer[47].

The introduction of *m*- and *p*-substituents into the benzene ring of the ligand in chelates of the type

(where M = Ni, Zn, or Mn in the +2 oxidation state, X is the solvent, and R = *p*-NH_2, *p*-OH, *m*-Cl, *m*-Br, or *m*-I) alters E_p, but hardly influences other process parameters. The sensitivity of the reaction centre to the influence of substituents for zinc(II) complexes is somewhat smaller than for the analogous nickel(II) and manganese(II) chelates. The increase of $\rho_\pi(\rho_\pi^*)$ for chelates of the latter type can be accounted for by the increase of the electron density at the reaction centre owing to the involvement of the *d* electrons of the metals in the conjugation system. Owing to the characteristics of its electronic structure, the possibility of $p_\pi - d_\pi$ binding involving Zn^{2+} is smaller than for transition *d* elements, which is reflected in the sensitivity of the reaction centre to the influence of substituents[47].

8. Metal Complexes of 2,2′-Bipyridyl and 2,2′,2″-Terpyridyl in Electrochemical Reactions

Extensive studies on the polarographic behaviour of the chelates of typical transition metals have been carried out by Japanese investigators. Their earlier publications and those of other workers are discussed in a review[23]. Among the later studies on the polarography of bis-complexes, mention should be made of those concerning cobalt(II) and manganese(II) chelate complexes of bis-2,6-(2′-quinolinyl)pyridine[48], dicyanobispyridyl complexes of cobalt(III),[49] dichlorobispyridyl complexes of chromium(III),[50] and tungsten(V) and tungsten(IV) hexachloride complexes with Bipy in acetonitrile[51]. When the heteroligand complex $[Co(CN)_2(Bipy)_2]^+$ is reduced at the m.d.e. in dimethyl sulphoxide[48], three diffusion waves are observed. Each corresponds to the transfer of one electron, as for the cobalt(III) cyanide and bipyridyl complexes:

$$[Co(CN)_2(Bipy)_2]^+ + e \rightarrow Co(CN)_2(Bipy)_2 + e \rightarrow [Co(CN)_2(Bipy)_2]^- + e \rightarrow [CO(CN)_2(Bipy)_2]^{2-}.$$

In the concluding stage of the process, metallic cobalt is partly deposited, since the last complex is unstable under the experimental conditions. The formation of species with the central atom in the zero oxidation state has been confirmed oscillopolarographically.

In the presence of water, the one-electron reduction is accompanied by rapid disproportionation of the ligand and substitution by water molecules, which leads to the formation of an equimolar mixture of $[Co(CN)_4(Bipy)_2]^{2-}$ and $[Co(Bipy)_2(H_2O)_2]^{2+}$. The polarographic characteristics of the bipyridyl complexes in DMF can be found for ruthenium(III) in the paper of Patterson and Holm[37] and for osmium(IV) and iron in the paper of Misono et al.[52] Chelates with ligands of this type have been studied by electrically generated luminescence[53]. Its intensity depends on the stability of the intermediate species, which is determined in its turn by the nature of the ligand.

In the electrochemical studies examined above the metal in the initial depolariser was in the usual oxidation state, equal to two or three. Species with the central atom in a lower oxidation state arose at the electrode during electrochemical reduction; in certain cases they could be identified on the basis of their spectra.

For example, the absorption spectra of electrochemically generated unstable species were obtained in the reduction of bipyridyl complexes of cobalt(II) at a silver electrode in propylene carbonate[54].

There has been recently a renewed increase of interest in the study of electrode reactions of complexes of metals in a low oxidation state and in the determination of factors stabilising these complexes. The reversible one-electron reduction of heteroligand nitrosylbipyridylruthenium complexes having the overall formula $[Ru(Bipy)_2(NO)X]^{3+}$, where $X = Cl^-$, N_3^-, NO_2^-, NH_3, Py, or acetonitrile, was investigated by cyclic oscillopolarographic methods using a platinum electrode in acetonitrile[55]. It has been shown by EPR and infrared spectroscopy that the transfer of electrons is localised at the nitrosyl group.

Using the same methods as in the above study[55] and in addition the coulometric procedure, it has been shown[56] that the two consecutive one-electron stages in the reduction of diphenylbisbipyridylchromium(III) in acetonitrile and dimethyl sulphoxide occur at $E_{1/2} = 1.21$ and 1.64 V (relative to the saturated calomel electrode), regardless of the nature of the solvent and the material of the electrode, via the mechanism

$$[(C_6H_5)_2\,Cr\,(Bipy)_2]^+ + e \rightleftarrows [(C_6H_5)_2\,Cr\,(Bipy)_2]^0 + e \rightleftarrows [(C_6H_5)_2\,Cr\,(Bipy)_2]^-.$$

The higher degree of solvation of the depolariser in dimethyl sulphoxide compared with that observed in acetonitrile is reflected in the diffusion coefficient: 2.0×10^{-6} and 1.5×10^{-5} $cm^2 s^{-1}$ respectively.

A series of studies[57-62] devoted to the polarographic properties of transition metal complexes with different (ranging from +2 to −1) oxidation states of the central atom in the initial depolariser and also to the investigation of the kinetics of electron transfer in the corresponding oxidation-reduction pairs of the type $[M(Bipy)_3]^{n+}/[M(Bipy)_3]^{(n-1)+}$ arising at the electrode, have been published recently. The potentials $E_{1/2}$ of the first reversible one-electron stages in the reduction of Bipy, 4-methyl-2,2′-bipyridyl, 5-methyl-2,2′-bipyridyl and the corresponding iron(II), ruthenium(II), and osmium(II) complexes[67] in DMF have been compared. If it is assumed that the reduction of a chelate involves only the coordinated ligand, then there should be a linear relation between the electron affinity of the complex and that of the free ligand in the series of chelates of the same metal. Such a relation has been observed experimentally for iron, ruthenium, and osmium complexes with ligands of the same type:

$$E^{red}_{1/2,c} = E^{red}_{1/2,L} + C,$$

where the subscripts c and L refer to the $E_{1/2}$ of the complex and the free ligand and C is a constant. Since $E_{1/2}$ for complexes of metals M in the same oxidation state with any one ligand L varies by not more than 80 mV, for metals in the iron–ruthenium–osmium series, an electron is transferred to a molecular orbital of the π^*-ligand type.

The tris-complexes of chromium(I), chromium(0), vanadium(0), titanium(0), and molybdenum(0) have been studied by polarographic and cyclic voltamperometric methods[58] in DMF and tetrahydrofuran. Multiplateau waves are observed on the polarograms of these complexes in both the cathodic and anodic potential ranges, corresponding to multistage electron transfer. The half-wave potentials for reversible oxidation-reduction systems arising at the electrode have been determined. An empirical rule has been derived for the assessment of the nature of the orbital occupied by the electron transferred in the electrochemical reaction on the basis of $E_{1/2}$ for the complex with a methyl group introduced into the Bipy molecule. Thus, the transferred electron occupies an antibonding ligand orbital in the reduced forms of the redox pairs VL_3^-/VL_3^{2-}, CrL_3/CrL_3^-, CrL_3^-/CrL_3^{2-}, and CrL_3^{2-}/CrL_3^{3-}, where L = Bipy. In the corresponding VL_3^{2+}/VL_3^+ and VL_3^+/VL_3 complexes it occupies the t_{2g} orbital, which is of a metallic type. The difference between the energy levels of the orbitals of the complexes has been discussed quantitatively on the basis of the shift of their $E_{1/2}$ in relation to the $E_{1/2}$ of the free ligands. In the series of complexes $V(Bipy)_3^-$, $Cr(Bipy)_3$, and $Fe(Bipy)_3^{2+}$ the energy of the lowest unoccupied molecular π^* orbital is increased[58].

The values of k_S for trisbipyridyl chromium complexes have been determined by the method of the double galvanostatic pulse[59] at the m.d.e. and for analogous iron, ruthenium, osmium, chromium, titanium, vanadium, and molybdenum chelates[58] at a platinum electrode in DMF. In a series of these complexes k_S is independent (or depends little) of the oxidation-reduction potential of the corresponding redox pair, which varies from +1.03 to −1.54 V, of the degree of oxidation of the central atom in the oxidised form of the complex, of the nature of the solvent, and of the type of the electrode. This shows that the rate of charge transfer in the reduction of the complexes is largely determined by the electronic configuration of the reacting species. For species where the transferred electron is localised in the molecular orbital of the ligand π^* type, the values of k_S lie in the range 0.1 to 0.3 cm s^{-1}. For complexes in the reduction of which an electron is transferred to a molecular orbital of the metallic t_{2g} type, the values of k_S are in the range 0.8–1.3 cm s^{-1}. The constant k_S for the Bipy/$Bipy^-$ system is virtually the same as the value for the first group of the complexes investigated (~ 0.15 cm s^{-1}). On the basis of this finding, it has been suggested[58] that the contribution of the energy of reorganisation of the solvent† to the change in k_S is not as large as might have been expected. It is noteworthy that the values of k_S for the $[Fe(Bipy)_3]^{2+}/[Fe(Bipy)_2]^+$, $[Fe(Bipy)_3]^{3+}/[Fe(Bipy)_3]^{2+}$, and $[Cr(Bipy)_3]^+/[Cr(Bipy)_3]^0$ systems are close to the k_S for the Bipy/$Bipy^-$ redox system[58]. This difference can be accounted for by the fact that, in the oxidation of the $[Fe(Bipy)_3]^+$ species, an electron leaves a ligand π^* orbital, whereas in the reduction of the corresponding $[Fe(Bipy)_3]^{2+}$ species, an electron passes to a metallic t_{2g} orbital.

Information about the formation of bipyridyl complexes with a metal in a low oxidation state can be found for zerovalent vanadium[61], for Co^-,[63] for ruthenium in heteroligand nitrosoarene complexes with Bipy[64], and for manganese and chromium in complexes with certain aromatic tridentate ligands[65].

The overall mechanism of the reduction of metal bis-complexes with terpyridyl (Terpy) is similar to the mechanisms quoted above for reduction with stepwise electron transfer, for example, for chromium(III) chelates[65]:

$$[Cr(Terpy)_2]^{3+} + e \rightleftarrows [Cr(Terpy)_2]^{2+} + e \rightleftarrows [Cr(Terpy)_2]^{+}.$$

Manganese(II), cobalt(II), nickel(II), and europium(III) chelates of terpyridyl in acetonitrile have been investigated by different versions of the polarographic method[66]. Reversible electron transfer is observed for the first two stages in the reduction of manganese and cobalt complexes, but anions of the type $[Co(Terpy)_2]^-$ have not been detected. The reduction of the complex $[Eu(Terpy)_2]^{3+}$ involves the initial formation of $[Eu(Terpy)_2]^{2+}$. This species reacts further at the electrode with consumption of two electrons and the formation of zerovalent europium. The standard rate constant for this stage is 6.7×10^{-4} cm s^{-1}, which shows that it is clearly irreversible. The subsequent waves at the edge of the range of negative potentials are due to the reduction of the Terpy species. It has been concluded[66] that the d elements in the zero oxidation state exhibit a greater tendency towards complex formation than the f elements.

---

† In reactions of the complexes one distinguishes processes involving the reorganisation of the inner and outer coordination spheres. The latter includes also the reorganisation of the solvent in which the complex is dissolved.

Like bipyridyl, another heterocyclic ligand—1,10-phenanthroline—is capable of stabilising the low oxidation states of transition metals[67]. The electrochemical reactions of these complexes resemble processes with participation of bipyridyl analogues[67,68]. It has been suggested[69] that the significant involvement of the π binding of the metal in the lowest oxidation state to the ligand as well as the ability of phenanthroline and its alkyl-substituted derivatives to delocalise the charge on the central atom even in the presence of a tetrahedral environment (in bis-complexes) are factors stabilising the intermediate electrode products. The polarograms of the tris-complex of iron(II) of 4,7-diphenyl-1,10-phenanthroline contain six reversible one-electron plateaux, each of which corresponds to a successive stage in the oxidation state of the metal from 2+ to 4−, i.e. the final species obtained in the reduction of the tris-chelate has six electrons in excess of the number characteristic of the usual oxidation state[67]. This quantity Δ (in the given case Δ_6) is the maximum attained electrochemically for low-spin metal complexes.

9. Metal Complexes of Phosphines in Electrochemical Reduction Reactions

The metal complexes with substituted phosphines as one of the ligands have become much investigated by electrochemical methods in recent times. Interest in these compounds is because they can be extremely active homogeneous catalysts of reactions of unsaturated organic compounds. Furthermore, such complexes, with the central atom in a low oxidation state, can be used to bind carbon monoxide as well as nitrogen in an active form.

Using mainly classical polarography and cyclic voltamperometry, a group of Italian investigators carried out a series of studies on the electrochemistry of coordination compounds of this type in non-aqueous media[70-75]. Under an argon atmosphere, in a 50% mixture of toluene and acetonitrile containing a certain amount of triphenylphosphine, a study was made of *trans*-chlorocarbonyl-bis(triphenylphosphine)rhodium(I) $RhCl(CO)[P(C_6H_5)_3]_2$. Its reduction takes place with addition of two electrons in one stage and the formation of a complex anion with the metal in the formal 1-oxidation state. The anion reacts further with the depolariser, which leads to a species in which rhodium is in the zero oxidation state[70]. Rhodium(I) and iridium(I) complexes of bisdiphenylphosphinoethane $(C_6H_5)_2P-CH_2-CH_2-P(C_6H_5)_2$, another π-acceptor, have the composition ML_2Cl and the polarograms also exhibit a single two-electron reversible diffusion wave in acetonitrile[71]. The addition of water leads to the disappearance of anodic peaks from the cyclic curve. During electrolysis at a controlled potential in solutions of the complexes, the colour of the solution changes and precipitates are formed. Apart from bands characteristic of the ligand in L, bands corresponding to rhodium and iridium hydrides were identified in the infrared spectra of the electrolysis products. The authors[71] suggest the following mechanism of the reduction at the m.d.e. in the presence of proton donors:

$$(ML)_2^+ \overset{2e}{\rightleftarrows} (ML)_2^- \xrightarrow{\text{proton donors}} MHL_2.$$

Data for the oxidation-reduction behaviour of these compounds have been compared with the reactivities of the anionic complexes in which the metal is in the 1-oxidation state and which have the d^{10} configuration[71].

In contrast to rhodium and iridium complexes[71], the cobalt complexes of bisdiphenylphosphinylethane having the general formula CoL_2ClO_4 are reduced with the reversible transfer of two electrons in stages[73]. The product of electrolysis at a controlled potential E, corresponding to the limiting current of the first wave and isolated in the form of red crystals, was identified as CoL_2 in which the central atom is in the zero oxidation state. At the potential of the second wave the unstable species $[CoL_2]^-$ is formed at the electrode and reacts with the solvent, which leads to the formation of $CoHL_2$. Thus the stabilisation of low valence states of the metals in electrochemical reduction reactions can be attributed to the high π^*-acceptor capacity of ligands of the given type.

A parallelism between the results of kinetic measurements and polarographic data has been observed[74] in the study of the following platinum(II) complexes: in 1,2-dimethoxyethane at the m.d.e (L = piperidine): *trans*-$\{Pt[P(C_2H_5)_3]_2Cl_2\}$, *trans*-$\{PtL[P(C_2H_5)_3]Cl_2\}$, and *trans*-$[PtL_2Cl_2]$. The ease of reduction diminishes in the series of these compounds, i.e. the phosphine complex is reduced more readily than, for example, a heteroligand complex with piperidine. The authors suggest that the rate of nucleophilic S_N^2 substitution of the phosphine-complex is sensitive to changes in the nature of the entering group.

An irreversible two-electron diffusion wave is observed in the reduction of a tetrakis(triphenyl phosphite) complex of rhodium(I) at the m.d.e. It is suggested that it is highly solvated in acetonitrile[75]. The product of the addition of two electrons $[RhL_4]^-$, where L is triphenyl phosphite, was identified after electrolysis at a controlled potential. Platinum complexes of triphenylphosphine in DMF at the m.d.e are reduced with the consumption of two electrons and the formation of the corresponding zerovalent platinum complex[76]. In the presence of water the product of the two-electron reduction is converted into a hydride complex having the composition $Pt[(C_6H_5)_3P]_2H(Cl)$. Comparison of the values of $E_{1/2}$ for the above compound and the initial depolariser shows that the introduction of a hydride ion into the inner coordination sphere of this complex causes a marked hindrance of the charge-transfer process.

III. ANODIC REACTIONS OF METAL COORDINATION COMPOUNDS

Much less attention has been devoted to anodic processes in the electrochemistry of metal complexes with organic ligands than to reduction processes. The main reason for this is that in the case of the m.d.e. a comparatively limited range of polarisation potentials is available. On the other hand, the use of solid electrodes for these purposes began quite recently. There has been a growth of interest in recent times in the investigation of the anodic process involving a wide variety of complexes in organic and mixed solvents, including electrochemical oxidation at solid electrodes, particularly for compounds in which the central atom is in a low oxidation state.

In the anodic oxidation of metal complexes an electron may be abstracted both from the orbitals of the central atom and from molecular orbitals of the ligand type. The products exhibit different stabilities. Useful information about the structure of these species can be obtained by EPR. The dependence of the oxidation potentials on the ionisation potentials is frequently linear. This finding confirms the validity of the idea that the primary stage in

the oxidation of the complex involves the abstraction of an electron from the highest occupied molecular orbital.

The oxidation-reduction properties of typical transition metal dithiocarbamates have been studied for the first time comparatively recently at a platinum electrode in acetone as a function of the nature of the complex-forming ion and substituents R and R′ in the ligand fragment of the chelate[77]. Judging from the results, the majority of the electron transfer reactions are rapid. The products of one-electron oxidation of many dithiocarbamates in acetone have comparatively short lifetimes (determined from cyclic voltamperometric data). The nature of the substituents R and R′ affects the ease of oxidation of the metal dithiocarbamates. However, a simple Taft correlation between $E_{1/2}^{ox}$ and the sum of the Taft substituent constants was not found. According to the authors[77], this is associated with the steric effects of the alkyl groups in the one-electron transfer reactions. In the series investigated the complexes of all the metals with *N*,*N*-dicyclohexyldithiocarbamate are oxidised most readily, while the chelates with *N*,*N*-dibenzyldithiocarbamate are oxidised with the greatest difficulty. Diethyldithiocarbamate derivatives occupy an intermediate position. The opposite relation has been observed for the reduction of the same compounds. In the series of the metal dithiocarbamates investigated the values of $E_{1/2} = E_{1/2}^{ox} - E_{1/2}^{red}$ depend significantly on the nature of the metal atom:

M	Cr	Mn	Fe	Co	Ni	Cu
$E_{1/2}$, V	2.58	0.48	0.92	2.02	2.34	1.07

This demonstrates the predominantly metallic nature of the molecular orbital in which the electron transferred in the electrochemical step is localised.

The oxidation of nickel(II) diethyldithiocarbamate has been investigated in no less detail at a platinum electrode than in acetonitrile[78]. Like the corresponding copper and iron chelates[79,80], the nickel(II) compounds are oxidised electrochemically comparatively readily and this can serve as a basis of the synthesis of metal dithiocarbamates with a high oxidation state of the central atom. The first stage in the oxidation of nickel(II) dithiocarbamates is reversible abstraction of one electron. Coulometric measurements at the limiting one-electron oxidation current yield $n = 1.3$. In the presence of $(C_2H_5)_4NBF_4$ electrolysis at a controlled potential leads to two products: $Ni^{4+}[(C_2H_5)_2NCS_2]_3BF_4$, in which the formal oxidation state of the metal is 4+, and $Ni^{2+}(BF_4)_2$ with an oxidation state of 2+. Nickel(IV) chelates have been isolated and identified.

In the anodic reactions of chromium, molybdenum, and tungsten complexes having the composition $L_2M(CO)_2$, where L = bis(diphenylphosphino)methane, the stepwise abstraction of two electrons is accompanied by the isomerisation of the *cis*-cation in the complex to the *trans*-cation; the *trans*-isomers of complexes with this ligand L are oxidised more readily than the similar complexes with bis(diphenylphosphino)ethane[81]. Using cyclic voltamperometry, electrolysis at a controlled potential, EPR, the oxidation of cobalt(III) and rhodium(III) chelate complexes with derivatives of dimethylglyoxime and salicylideneaniline has been investigated[82,83] at a platinum electrode in acetonitrile, methylene chloride, and a mixture of the latter with toluene. The supporting electrolyte was a 0.1 M $(C_2H_5)_4NBF_4$ solution.

Previously unknown complexes with formally quadrivalent cobalt and rhodium, in which the metal–carbon σ bond is retained, were observed in the reversible one-electron oxidation of chelates of the type $RCoL_2Py$ (R = CH_3, C_2H_5, or $C_6H_5CH_2$; L = bisdimethylglyoximate dianion), RCoL [R = CH_3, C_2H_5, iso-C_3H_7, or n-C_4H_9; L = bis(salicylidenato)ethylenediamine dianion], and RRhLPy [R = CH_3, n-C_3H_7, or iso-C_3H_7; L = bis(salicylidenato)ethylenediamine dianion]. The lifetime of these species has been estimated as amounting to several minutes. The stability of the complex species with the metal in the 4+ oxidation state and the ease of the oxidation of the initial chelates increase as R is varied in the sequence $CH_3 < C_2H_5 <$ n-C_3H_7 < n-C_4H_9 < iso-C_3H_7. On the basis of these data, it is suggested that during oxidation at the electrode an electron is abstracted from the central atom or from the group R and not from the chelating ligand. The product of the oxidation of the complexes is an analogue of the carbonium ion R^+.[82]

It is fairly interesting to compare the oxidation potentials of the complexes and the frequencies of the charge-transfer bands in the ultraviolet spectra. Such a correlation has been drawn for the trisbipyridyl complexes of iron, osmium, ruthenium, cobalt, and chromium, in which the metal is in the 2+ oxidation stage[83]. It is known that the minimum energy corresponding to the frequency of the charge-transfer band can be represented by the difference $\nu = I_c - A_L^c$, where I_c is the vertical ionisation potential of the t_{2g} orbital in the metal complex and A_L^c is the electron affinity of the lowest antibonding π^* orbital in the coordinated ligand. It is suggested that, during the oxidation of the complex, an electron leaves the t_{2g} orbital. Furthermore, it is believed that there is a linear relation between the electron affinities of the coordinated ligand and the organic compound not bound in the complex, in a series of chelates of the same metal with different ligands, which is expressed by the following relation:

$$E_{1/2,c}^{ox} - E_{1/2,L}^{red} = \nu + C,$$

where *C* is a constant. A simple correlation between $E_{1/2,c}$ and ν has not been observed for the complexes $[FeL_3]^{2+}$, $[RuL_3]^{2+}$, $[OsL_3]^{2+}$, $[CrL_3]^{2+}$, and $[CoL_3]^{+}$.[84] However, if one uses the difference $E_{1/2,c}^{ox} - E_{1/2,L}^{red}$ instead of $E_{1/2,c}^{ox}$, then the former is linearly correlated with the energy corresponding to the frequency of the charge-transfer band.

Thus there is a linear relation between this energy characteristic and the oxidation potentials of the complexes corrected for the electron affinity of the π-acceptor ligand. If an electron leaves the t_{2g} orbital during oxidation, then $E_{1/2}^{ox}$ for the tris-complex of a transition metal with bipyridyl undergoes a cathodic shift in the following sequence when a methyl group is introduced into the ligand: Bipy < 5,5′-CH_3-Bipy < 4,4′-CH_3-Bipy. The empirical rule concerning the influence of substitution on $E_{1/2}$ is used as a criterion in the determination of the configurations of transition metal complexes of bipyridyl on the basis of electrochemical data[84].

Data have been published[27] on the oxidisability of nickel(II) chelates formed with dihydric *o*-phenols and their mono- and di-thio-analogues in acetone at a platinum electrode. In terms of the ease of their oxidation, these chelates can be arranged in the following sequence: $NiS_4 > NiO_2S_2 > NiO_4$. The irreversible one-electron oxidation in methylene chloride of complexes of the type $Ir(CO)XL_2$, where X = halide anion and L = tertiary phosphine, terminates with the formation of a dimer having a metal–metal bond, in which iridium is in the 2+ oxidation state[85].

IV. THE ROLE OF THE NATURE OF THE METAL AND THE STRUCTURE OF THE LIGAND IN THE MECHANISM OF THE ELECTROCHEMICAL REDUCTION OF CHELATES

The results of the electrochemical study of the coordination compounds of *d* elements with organic ligands in non-aqueous solvents make it possible to put forward general considerations concerning the influence of the nature of the central atom and the ligand on the nature of the electrode reactions. Depending on the electronic configuration of the complex-forming ion and the type of ligand, chelates are reduced in one or several stages. In terms of the nature of the first stage, electrochemical processes can be conventionally divided into two large groups. The metal chelates of the first group, which are of the inner complex type, undergo reversible reduction at the m.d.e. A slow electron transfer in the electrochemical stage proper is more characteristic of the second group. The conventional nature of this subdivision is due to the fact that in many instances, for example, with increased concentration of the depolariser, the process is complicated by the adsorption of the latter on the m.d.e. and becomes irreversible. For certain inner complexes, charge transfer is complicated by the subsequent chemical deactivation of the primary electron transfer product. The chelates of the second group are reduced irreversibly regardless of the duration of electrolysis in the course of the recording of the polarisation curve.

Among the electrochemical reactions of chelates in the first group, reversible one-electron processes, which can be regarded as purely electron transfer reactions, are of greatest interest. With rare exceptions, they are characteristic of metal chelates (including inner complexes), with unfilled *d* shells. In multistage reduction, with the transfer of one electron in each stage, intermediates are formed in which the central atom is in a formally low oxidation state. In such cases the electrochemical process can be represented as electron transfer to the lowest unoccupied molecular orbital; $E_{1/2}$ is a thermodynamic quantity and reflects the energy level of this orbital of the complex. The reaction centre to which an electron is transferred is delocalised and embraces a group of atoms with a common unoccupied molecular orbital, including the metal atom. When the electron occupies the lowest vacant molecular orbital, the activation barrier is apparently comparatively low[86].

In those cases where a rigorous correlation is observed between the half-wave potential and the $\Sigma\sigma$ of the substituents (the Hammett or Taft constants), the latter must be regarded as a consequence of the different sensitivities of the lowest unoccupied molecular orbital to the influence of substituents. The deviation of the values of $E_{1/2}$ from those predicted by the regression equation can have different causes: adsorbability of the components of the electrochemical reaction on the electrode surface, the influence of the subsequent chemical reaction, for example, with the solvent or impurities in the latter, etc. In this case the half-wave potential loses its rigorous thermodynamic significance, because it reflects not only the energy level of the lowest unoccupied molecular orbital of the complex, but also the influence of the subsequent chemical stage. The contribution of adsorption to the electrode process, which complicates the correlations, is particularly notable for complexes of sulphur-containing ligands.

The values of $E_{1/2}$ for reversible uncomplicated stages can be correlated with photoelectron spectroscopic data characterising the electron binding energies. Such correlations make it possible to predict the properties of hitherto unknown complexes.

The problem of the oxidation state of the central atom in the intermediate species formed is fairly complex. Quantum-chemical calculations of the populations of the atomic orbitals and of the degree of their overlap, which make it possible to discover the composition of the orbital to which an electron is transferred in the electrochemical stage proper as well as the most probable distribution of electron density in the one-electron transfer product, might be very useful. Such calculations have been made for certain types of coordination compounds. They showed, for example, that the molecular orbital to which an electron is transferred in the reduction of ruthenium(III) tris-β-diketonates is of the ligand type. This result implies that the contribution of the metallic t_{2g} (or e_a) orbital is much smaller than the contribution of the $\pi(\sigma+\pi)$ orbitals of the ligand to the common unoccupied molecular orbital of the complex. This is consistent with the considerable influence of the nature of the substituents on the ease of reduction[24]. However, for the majority of metal coordination compounds with different donor atoms, quantum-chemical data are not as yet available.

The unpaired electron in the one-electron reduction product can occupy one of the vacant *d* orbitals of the metal, so that the oxidation state of the latter is determined by the charge of the complex species. Its stability depends to a large extent on the π-acceptor properties of the ligand. π-Acceptor ligands are known to decrease the energy of the orbitals localised predominantly at the central atom and to increase the strength of the metal–ligand bond via the reverse dative bonding mechanism. This explains the fairly high stability of transition metal complexes of bipyridyl and terpyridyl with the central atom in a low oxidation state, which are formed in electrochemical reduction in non-aqueous media.

Analysis of literature data shows that the stabilisation of complexes with metals in low oxidation states depends on the nature of the ligands, the nature of their donor atoms, the number of rings formed, and the nature of the metal. In addition, account must be taken of the aromatic properties of the chelate rings formed. The formation of species with the metal in the 1+ oxidation state in the reduction of tris-complexes of iron(II) with aliphatic di-imines of the type $H_3C-N=C(R)-C(R)=N-CH_3$, where R = H or CH_3,[86] can be explained by the fact that the chelate units in these complexes and in the bipyridyl complexes are similar.

It is of interest that the apparent standard electron transfer rate constants lie in the narrow range of values $1\times10^{-2} - 2.5\times10^{-2}$ cm s^{-1} for a large group of metal chelates (thio- and bisthio-semicarbazones, dithiocarbamates, and complexes with *o*,*o'*-dihydroxyazo-compounds). The probable cause of this may be the similarity of the transition states in the charge-transfer reaction and of the factors which determine the magnitude of the energy barrier[87]. The dependence of k_S on the electronic configuration of the reacting species has been discussed[61–63]. If the metal orbital, for example t_{2g}, delocalised over the molecule and involved in the formation of an $M \rightarrow L\,\pi$ bond (in chelates with bipyridyl, terpyridyl[57,62], and the di-imines mentioned above[86]) makes the main contributions to the molecular orbital to which an electron is transferred, then the change in the geometry of the species formed as a result of the latter process can prove to be insignificant compared with the change in the geometry of the initial depolariser molecule. In other words, if the electrolysis product differs from the depolariser by not more than one electron, then the molecules with the metal in both oxidation states can have approximately the same configuration.

In this case the rate of electron transfer is fairly high, and, conversely, the activation energy for the reverse process is relatively small. An electron may be transferred to a molecular orbital made up of atomic orbitals of another type, for example, e_g, involved in the formation of an M–Lσ bond; under these conditions, electron transfer leads to appreciable changes of the length of the M–L bonds, and hence in the geometry of the molecules of the reduction products. Such a process requires a greater activation energy and the rate of charge transfer is therefore comparatively low. In general, k_S, determined experimentally by relaxation electrochemical methods, is frequently much lower than the theoretical value[62]. Apart from the factors mentioned above, k_S can be influenced by the range of potentials in which the complexes are reduced and by the charge of the complex species. Thus it has been concluded[88] that the formal charge has a significant influence on the rate of electron transfer (the heterogeneity of the process) and that the reorganisation of the solvent can play an important role. We may recall the Vlček rule, according to which the reduction potential is more negative the greater the degree of localisation of the orbital to which the first electron is transferred[89]. This is consistent with the data for bipyridyl complexes[62,90]. However, it is still unknown whether this conclusion is valid for metal chelates with sulphur-containing ligands[27].

Slow charge transfer in the electrochemical stage proper is characteristic of coordination compounds of cobalt, nickel, and copper and certain other metals with thio- and seleno-semicarbazones, formed without substitution of hydrogen atoms (the second group of complexes). They have the structure of chelates but the latter does not include cyclic $(pd)\pi$ systems, typical for inner complexes, which ensure the delocalisation of electrons via a d-orbital centre. Since chelates in this group are charged, they are highly solvated in DMF and similar solvents. Part of the coordination capacity of the metal can be consumed in the interaction with the solvent, particularly when the ligands have polar groups. The formation of a solvation shell hinders electron transfer to the depolariser, i.e. gives rise to an overvoltage. Thus, on passing to solvents with high donor numbers and high dielectric constants, the reversibility of the reduction diminishes[3] and $E_{1/2}$ undergoes a cathodic shift[91].

This review describes the results of some of the studies on the coordination compounds of metals and similar systems by modern electrochemical methods, which are being prosecuted at the present time[92–94]. Presumably the conclusions and generalisations concerning electrochemical properties of metal chelates with organic ligands having comparatively simple structures will in future prove useful in the study of complexes with more complex ligands, whose oxidation-reduction reactions simulate the biological functions of natural products (vitamins, enzymes, etc.) belonging to the class of coordination compounds. The electrochemical processes involving many organic physiologically active compounds are known to occur at fairly high potentials, which are not attainable in biological systems. It is logical to suppose that the physiological activity of many of these compounds may be due to complexes of the compound with microelements in living tissues and not to the initial compound itself. The redox properties of such complexes can differ significantly from those of the organic compound and their oxidation-reduction potentials are usually much lower and are within the scale of potentials characteristic of the living cell[95]. Finally, the study of the properties of chelates makes it possible to select conditions for the electrosynthesis of compounds with valuable properties, including catalytic activity in homogeneous processes[96,97]. This should be encouraged by the development of research into the reactions of chelates at electrodes made of materials of different types[98,100] and a deeper investigation into the essential features of the processes involving coordination compounds, which is impossible without further comprehensive study of their structures by various methods, including electrochemical methods.

Dissociative Ionisation of Nitro-derivatives of Arenes and Heterocyclic Compounds

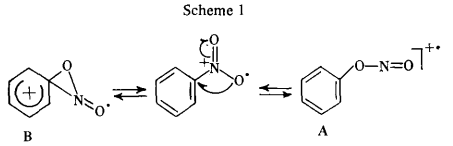
R.A.Khmel'nitskii and P.B.Terent'ev

The mass-spectrometric behaviour of nitro-derivatives of aromatic and heterocyclic compounds is examined. Attention is concentrated on the influence of the relative positions of nitro- and other functional groups on the mode of decomposition in the mass-spectrometry of positive and negative ions.
The bibliography includes 92 references.

CONTENTS

I. Introduction 463
II. Nitroarenes 463
III. Nitro-derivatives of heterocyclic compounds 468

I. INTRODUCTION



Numerous mass-spectrometric studies have been devoted to analysing the behaviour of various classes of organic compounds on electron impact. However, it has now become necessary to examine various classes of compounds containing functional groups which have a decisive influence on the mode of fragmentation. The types of decomposition associated with different positions of the functional groups in the aromatic or heterocyclic ring are particularly important. One of the most important and frequently encountered functional groups in organic compounds is the nitro-group, whose presence frequently leads to specific modes of decomposition of molecular ions. There are no reviews in the literature of studies on these problems; the aim of the present review is to fill this gap. It includes studies published up to the end of 1975.

II. NITROARENES

The first studies on the mass-spectrometric behaviour of mono- and polynitrobenzenes [1-7] established the occurrence in their dissociative ionisation processes of three main characteristic pathways: the formation of the ions $(M - O)^+$, $(M - NO)^+$, and $(M - NO_2)^+$. However, under these conditions the probability of the first process was very low and the intensity of the corresponding peak in the mass spectrum did not usually exceed 1-2% (of the maximum peak).

It has been suggested [1] that the molecular ion derived from nitro-compounds partly rearranges with formation of aryl nitrite ions A before dissociation:

Scheme 1

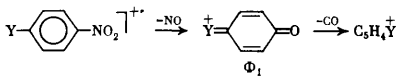
B A

However, according to other workers [2], the rearranged ion has the *spiro*-structure B.

The occurrence of the isomerisation of the nitro-group was subsequently confirmed and accepted all by investigators of the mass spectra of nitro-derivatives of aromatic and heterocyclic compounds.

Having compared the mass spectra of all the isomeric dinitrobenzenes (see Table), Beynon et al. [1] and Fields and Meyerson [3] concluded that the modes of decomposition of these compounds and other nitroarenes are similar. It was noted that the mass-spectra of *meta*- and *para*-isomers are very similar, but differ markedly from that of the *ortho*-isomer [1,4]. Thus the intensity of the M^+ peak is appreciably lower in the mass spectrum of the *ortho*-isomer, which reflects its lower stability. In this connection one should note that the mass spectrum of *ortho*-dinitrobenzene exhibits [8] the peak of the $(M - O_3)^+$ ion (mass 120), to which the authors attributed the structure of benzo[3,4]-1,2,5-oxadiazole and showed that this compound is indeed formed also in the pyrolysis of *o*-dinitrobenzene at 650°C.

The peak intensities of the characteristic ions in the mass spectra of isomeric dinitrobenzenes (as percentages of the total ionic current). [1,4]

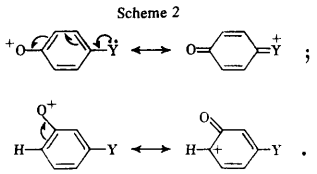


Ion	Position of nitro-group		
	ortho-	*para*-	*meta*-
M^+	6.98	11.00	10.30
$(M—O)^+$	0.24	0.63	0.57
$(M—NO)^+$	0.07	0.21	0.34
$(M—NO_2)^+$	0.41	4.76	4.12
$(M—NO—NO)^+$	0.03	0.04	0.09
$(M—NO—NO_2)^+$	1.66	5.82	3.64
$(M—NO_2—NO_2)^+$	3.84	11.20	9.18
$(M—NO_2—HNO_2)^+$	2.03	10.80	11.30
NO^+	26.70	17.20	21.30

The nature of the decomposition of the negative molecular ions of mono- and poly-nitrobenzenes [9,10] does not differ fundamentally from that of the processes described above, although the fragmentation of such ions is more selective.

Meyerson et al. [5] used the defocussing method and high-resolution mass spectrometry for a detailed study of 1,3,5-trinitrobenzene. For 23 ions, they observed 96 corresponding metastable peaks, which enabled them to devise a very complex scheme relating the precursor ions to daughter ions; the authors reduced the main "chains" of molecular ion decomposition processes to six pathways, resembling the pathways in the fragmentation

of dinitrobenzene (see Table). It is very remarkable that in the first stage the elimination of NO_2 plays the main role. In contrast to mono- and di-nitrobenzenes[1,6,7], the abstraction of O from M^+ is not observed for trinitrobenzene. It is also of interest to note that the mass spectrum of nitrosobenzene contains the peak of the $(M - N)^+$ ion with a mass of 93, but the authors did not express a view concerning the process involving its formation[11].

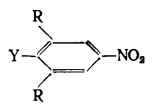


The studies of Bursey and McLafferty[2] showed that the abstraction of NO from M^+ for certain substituted aromatic nitro-compounds is associated with the appearance of peaks with a flat top due to metastable ions, which indicates the liberation of kinetic energy. The generation of a metastable peak associated with the elimination of NO is characteristic of all 27 compounds investigated, but the formation of the peaks with a flat top was noted for only five of them, the amount of energy liberated being in the range 0.38–0.84 eV. The liberation of kinetic energy is associated with the following type of decomposition of the system:

Φ_1

in which the ion Φ_1 formed undergoes resonance stabilisation by the electron donor substituent in the *ortho*- or *para*- (but not *meta*-) position[2]:

Scheme 2



Indeed the liberation of kinetic energy was observed only for *para*-substituted nitrobenzenes and only for substituents with $\sigma_Y > 0.40$.

A study of the dissociative ionisation of mono- and di-nitro-phenyl sulphones[12,13] also showed that the probability of the nitro–nitrite isomerisation of M^+ is determined by the position of the nitro-group in the molecule. It occurs most readily when one or both nitro-groups are in the *para*-positions relative to the sulphone group. We need only note that a competing S–O migration of the aryl group, leading to the formation of aryl esters of arene sulphinic acids, is observed in the decomposition of the above sulphones.[14]

In full agreement with the above considerations, the liberation of the greatest amount of kinetic energy was noted in the mass spectra of the negative ions[9] of isomeric dinitrobenzenes on formation of the ion $(M - NO)^+$ (0.89 eV) from the *para*-isomer, the value for the *meta*-isomer being significantly smaller (0.36 eV). As was also to be expected, the intensity of the $(M - NO)^+$ ions in the mass spectra of negative ions (in full contrast to the mass-spectra of positive ions) was directly proportional to the electron-accepting properties of the substituent in the *para*-position[10].

Many other studies on the mass spectra of both negative[15,16] and positive[17-20] ions support the maintenance of the non-identity of the positions in the series of nitroarenes in both the first and subsequent decomposition stages. In particular, having analysed the mass spectra of three series of sterically hindered *para*-substituted nitroarenes having the general formula

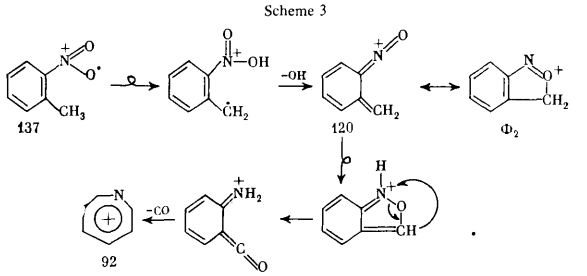
Y=HO, CH_3O, H_2N, or $(CH_3)_2N$; R = H, Cl, or Br.

Bursey[21] showed that the displacement of the substituent Y from the plane of the benzene ring, which promotes a decrease of the p–π conjugation between them, reduces the intensity of the peak of the $(M - NO)^+$ ion. These data also support the view that substituents influence the decomposition of nitroarenes.

The results of an earlier study[22], dealing with the ionisation potentials (IP) and appearance potentials (AP) of ions arising, apparently, in the competing reactions involving the decomposition of $M^{+\cdot}$ with formation of the $(M - NO_2)^+$ ion and the rearrangement of the molecular ion with formation of the (M – NO) fragments in the series of *meta*- and *para*-substituted nitrobenzenes (with the substituents Y = NH_2, OH, OCH_3, CH_3, H, Cl, Br, CN, or NO_2), lead to the same conclusion. The differences between the IP and AP, which represent the approximate activation energies (ϵ_0) for the decomposition of the molecular ion leading to the formation of the $(M - NO_2)^+$ fragment are the same for the *meta*- and *para*-positions, whereas in the formation of the $(M - NO)^+$ ion they are different. Finally, having compared the shapes of the peaks due to metastable ions in the mass spectra of *para*-substituted anisoles and nitrobenzenes, Davies and Williams[23] concluded that the structures of the $(M - CH_3)^+$ ions of anisoles and the $(M - NO)^+$ ions (Φ_1) of nitrobenzenes are identical, which suggests that there is no randomisation in these processes.

Nevertheless there have been a number of studies in which the possibility of the randomisation of hydrogen in the fragmentation of benzene[24] and its derivatives[11,25] was demonstrated fairly convincingly. It has also been established[26] that, in the mass spectrum of 4-nitroaniline containing ^{13}C in the 1-position, the $(M - NO)^+$ ion loses one-sixth of the labelled carbon in the form of CO, which indicates a randomisation process involving at least this ion. However, later these data were disproved[27].

Thus, there is as yet no unanimous view concerning the retention or non-retention of the identity of the position of the substituent in the molecular ions of nitroarenes.



Comparison of the mass spectra of the isomeric nitrotoluenes leads to the conclusion that the decomposition reactions of their *meta*- and *para*-isomers are very similar to the decomposition of nitrobenzene[1]. Thus both isomers are characterised by intense peaks due to the molecular ion (>70% of the maximum), the intensity being comparable to the intensity of the peak of the $M^{+\cdot}$ radical-ion derived from nitrobenzene (49%). For all three compounds, the maximum peak in the mass spectrum corresponds to the $(M - NO_2)^+$ ions, the intensity of the peaks due to the $(M - NO)^+$ ions is 10%, while the peak of the $(M - O)^+$ ions amounts to 1–2% of the maximum peak.

At the same time the mass spectrum of *o*-nitrotoluene exhibits significant differences. The peak of the M^+ ion amounts to only 25%, there is no peak due to $(M - O)^+$ ions, and the maximum peak corresponds to ions with a mass of 120, which are absent from the mass spectra of the *meta*- and *para*-isomers.

The use of high-resolution mass spectrometry and of data for metastable processes, enabled Beynon et al.[1] to establish unambiguously that these ions can have the elemental composition C_7H_6NO, i.e. correspond to the $(M - OH)^+$ ions with the probable structure Φ_2. Subsequently ions having this mass lose 28 atomic mass units (a.m.u.) (CO) and are converted into ions with a mass of 92, which probably have the structure of the azatropylium ion, because the last stage in its decomposition involves the elimination of hydrocyanic acid.

Thus the characteristic pathways leading to the fragmentation of *o*-nitrotoluene reduce to three consecutive processes†:

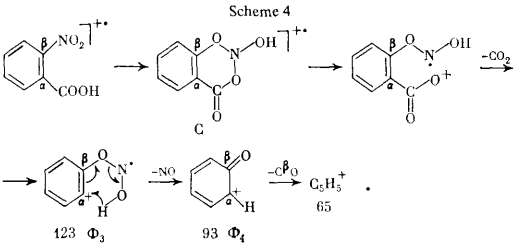
Scheme 3

Only the $(M - NO)^+$ and $(M - NO_2)^+$ ions were observed in the mass spectra of *m*- and *p*-nitrotoluenes. The $(M - OH)^+$ ions were characteristic of both nitro-*p*-xylene and of polynitrotoluenes[1]. Similar processes are characteristic also of the mass spectra of the negative ions of nitrotoluene or analogous compounds[10,28], whereas the ions $[(M + H) - OH_2]^+$ were observed in the mass spectrum of trinitrotoluene obtained by chemical ionisation[29].

When one of the hydrogen atoms of the methyl group in *o*-nitrotoluene is replaced by an amino-group, the $(M - OH)^+$ ion subsequently loses NO and not CO, which indicates its non-cyclic structure[30].

The formation of the $(M - OH)^+$ ions is observed also in the series of isomeric nitroanilines[1,31]. Thus, whereas the mass-spectrum of *o*-nitroaniline contains the peak of the $(M - OH)^+$ ion (although it is less intense than in the mass spectrum of *o*-nitrotoluene), such a peak is not characteristic of the *meta*- and *para*-isomers. The same process, involving the loss of an OH group, is also typical for the mass spectra of negative ions derived from *o*-nitrotrifluoroacetanilides and it has also been shown that the hydrogen ion is eliminated from the NH group[32].

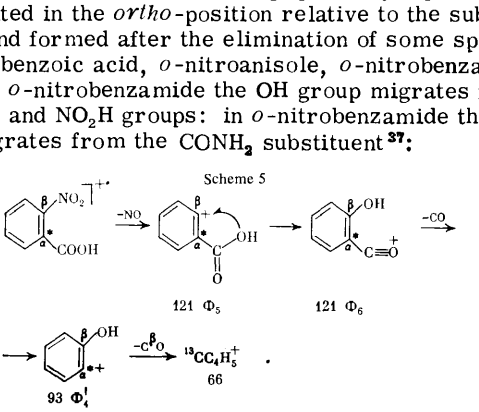
On the basis of the foregoing considerations, one can conclude that the early studies on the mass spectra of nitroarenes already gave rise to the necessity for a detailed investigation of the influence of the *ortho*-effect[33,34] on dissociative ionisation. This influence applies particularly when the substituent in the *ortho*-position relative to the nitro-group contains a hydrogen atom, which makes possible the abstraction of the hydroxy-group from M^+.[35] Such elimination of OH does not occur for the *meta*- and *para*-isomers.



†Here and henceforth the number under the formula of the ion represents the corresponding value of *m/e*, the number in round brackets represents the intensity of the peak of the given ion as a percentage of the maximum peak in the spectrum, and the number in square brackets represents the intensity of the peak of the given ion as a percentage of the total ionic current.

It has been suggested[1] that this process proceeds via a six-membered transition state with migration of a hydrogen atom to an oxygen atom of the nitro-group and the OH group is eliminated from the non-rearranged M^+ ion and not from the ion in the nitrite form.

Williams and coworkers[36] investigated the *ortho*-effect in the mass spectra of certain nitroarenes, where the substituent in the *ortho*-position contained oxygen. All the decomposition mechanisms involved interaction between the *ortho*-groups; however, this was accompanied by unexpected effects, which may be associated with the presence of impurities or with thermolysis of the nitro-compounds.



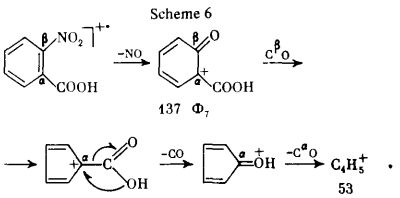
Benoit and Holmes[37] examined this problem in relation to the dissociative ionisation of *o*-nitrobenzoic acid, *o*-nitroanisole, *o*-nitrobenzamide, *o*-nitrobenzyl alcohol, and *o*-nitrobenzaldehyde. Some of the compounds investigated were labelled with deuterium, while in other cases the ^{18}O label was used. It was concluded that there are two types of *ortho*-effects. The first was already noted above in connection with the migration of a hydrogen atom from one substituent to another. In the compounds under consideration such migration to an oxygen atom of the nitro-group is usually accompanied by a complex rearrangement and leads to the elimination of a neutral species (a molecule). Such a process proceeds as a rule with the intermediate formation of a five- or six-membered cyclic structure. In the case of *o*-nitrobenzoic acid, *o*-nitroanisole, and *o*-nitrobenzaldehyde the formation of a cyclic intermediate structure is accompanied by the nitro–nitrite isomerisation (Scheme 4). The same processes characterise also the mass spectra of negative ions[10,38].

Scheme 4

The second type of *ortho*-effect is associated with the migration of an atom or group of atoms from the substituent to a vacant site in the ring (probably a positive hole) located in the *ortho*-position relative to the substituent and formed after the elimination of some species. In *o*-nitrobenzoic acid, *o*-nitroanisole, *o*-nitrobenzaldehyde, and *o*-nitrobenzamide the OH group migrates from the COOH and NO_2H groups: in *o*-nitrobenzamide the NH_2 group migrates from the $CONH_2$ substituent[37]:

Scheme 5

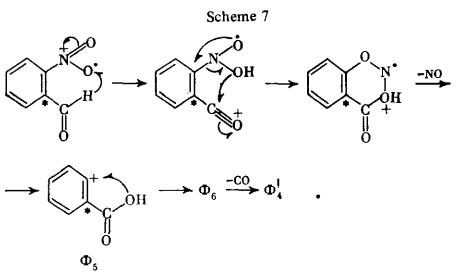
Here the asterisk denotes a ^{13}C atom.



Many efforts have been made to elucidate the mechanism and the pathways leading to the formation and decomposition of the ion with a mass of 93 in the mass

spectrum of *o*-nitrobenzoic acid. Benoit and Holmes [37] proposed two alternative mechanisms, the first of which (Scheme 4) presupposes the migration of acid hydrogen to the isomerised nitro-group with formation of a cyclic structure C, which, having eliminated CO_2, gives rise to the ion Φ_3. The latter next ejects an NO molecule and forms an ion with a mass of 93 (Φ_4). The loss of CO by the latter leads to the formation of the hydrocarbon ion $C_5H_5^+$ (with a mass of 65). The second probable pathway leading to the formation of an ion with a mass of 93 presupposes the ejection of the nitro-group (the Φ_5 ion), the migration of the hydroxy-group (Φ_6), and the loss of CO (the Φ_4 ion) (see Scheme 5).

Having investigated the mass spectra of *o*-nitrobenzoic acid containing ^{13}C in the 1-position using ionising electron energies of 17 and 15 eV, Djerassi and coworkers [39] found that the label is not lost up to the ion with a mass of 65. However, analysis of the mass spectrum of the compound containing ^{18}O in the hydroxy-group showed that the label is not lost on formation of the ion Φ_5, but the ion Φ_4 contains only part of the label. Thus both mechanisms (Schemes 4 and 5) operate.

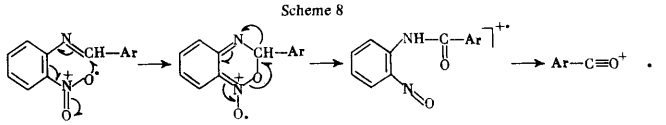


Benoit and Holmes [37] proposed also a third mechanism for the dissociative ionisation of the molecular ion of *o*-nitrobenzoic acid (Scheme 6), which is also consistent with Djerassi's data [39]. However, the ions $\Phi_7 - \Phi_{10}$ formed via this pathway give rise to much less intense peaks than the ions $\Phi_2 - \Phi_6$, so that one can assume that the above pathway does not play a significant role in the overall decomposition mechanism:

Scheme 6

The migration of hydrogen to the oxygen of the nitro-group is observed also in the mass spectrum of *o*-nitrobenzaldehyde in which the $(M - NO)^+$ ion next loses CO and the process proceeds via Scheme 7, proved by Djerassi and coworkers [39] by analysing the mass spectrum of the compound containing ^{13}C in the formal group:

Scheme 7



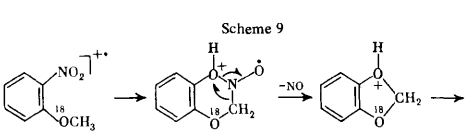
Here the asterisk denotes a ^{13}C atom. There is a possibility of the migration not only of a hydrogen atom but also of an amino-group to an oxygen atom of a neighbouring nitro-group [40], while in the mass spectra of negative ions even the phenyl group can migrate [41], as has been shown for the isomeric phenyl nitrosalicylates and *o*-nitrophenyl ether [42].

The replacement of oxygen by nitrogen in *o*-nitrobenzaldehyde does not change significantly the primary decomposition in both positive [43] and negative [44] mass spectra.

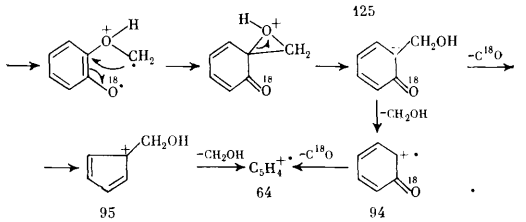
However, there is no $(M - OH)^+$ ion in the mass spectra of the benzylidene derivatives of *o*-nitroaniline, [42] but the transfer of the oxygen of the nitro-group to the methylidyne carbon atom with the simultaneous migration of hydrogen and the formation of the $(Ar - CO)^+$ ion are observed:

Scheme 8

A similar transfer of the oxygen of the nitro-group to the C=C double bond has been observed for esters of α-benzylidene-*o*-nitrobenzoylamino acids [45]. The same type of migration of an oxygen atom of the nitro-group to a neighbouring double bond [(C=C) or C=N] was noted by investigators [46] who studied the dissociative ionisation of 40 compounds comprising nitrophenylhydrazones, aromatic aldehydes and ketones, nitrostilbenes, and nitrobenzylideneacetophenones.

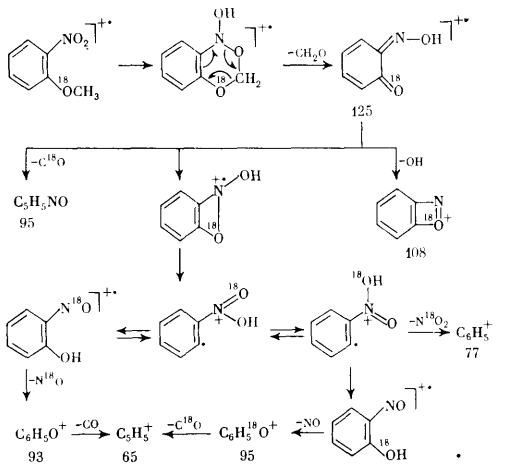


An analogous transfer of an oxygen atom from the nitro-group has been observed in the mass spectrum of *o*-nitrostyrene [there are intense peaks due to the $(M - CO)$, $(M - CHO)$, and $(M - CH_2O)$ ions]. [47] Finally, the migration of an oxygen atom of the nitro-group to a sulphur atom with subsequent elimination of the *p*-tolyl sulphoxide residue has been observed in the molecular ion derived from *p*-tolyl *o*-nitrothiobenzoate. [48]



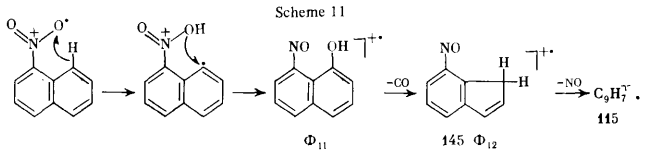
The study of the behaviour of *o*-nitroanisole under electron impact showed [37] that the main primary process in the decomposition of its molecular ion is the loss of 30 a.m.u. with formation of an ion having a mass of 123. Using high-resolution mass spectra it was established that the loss of CH_2O proceeds to an extent that 80% and that of NO only to an extent of 20%.

Analysis of the mass spectrum of *o*-nitroanisole containing ^{18}O in the methoxy-group established unexpectedly [39] that the elimination of CH_2O does not entail the loss of labelled oxygen. Schemes 9 and 10 explain all the experimental facts and include, as in the previous instance, the migration of the OH group to a vacant site at a ring carbon atom. It must be emphasised that the thermal decomposition processes involving *o*-nitroanisole proceed with loss of HNO and HNO_2. [49]



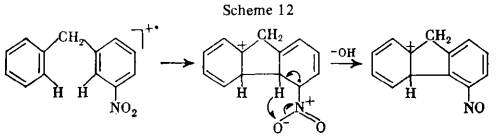
Hydrogen can also migrate to the nitro-group from the *peri*-position. Thus the mass spectra of nitro-compounds exhibiting *peri*- and *ortho*-effects have been examined [36] and the authors observed a number of analogies in the behaviour of nitro-compounds in photochemical reactions and under electron impact. The study of the decomposition of 1-nitronaphthalene showed [36] that the mass spectrum contains the ion Φ_{12} [$(M - 28)^+$] with a mass of 145, which was identified as the $(M - CO)^+$ ion on the basis of high-resolution mass spectrometric data. The appearance of such ions was not noted in the mass spectra of nitrobenzenes.

Scheme 9



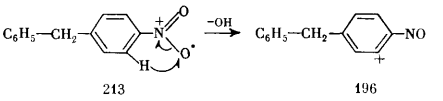
Scheme 10

Its formation is most probably caused by the formation of a new bond between the $C_{(8)}$ *peri*-carbon atom and an oxygen atom of the nitro-group, which enabled the authors to propose a mechanism for the elimination of CO:



Scheme 11

According to this scheme, there is initially the migration of a hydrogen atom in the $M^{+\cdot}$ species derived from nitronaphthalene and then the migration of the hydroxy-group. The ion Φ_{11} with a nitrosophenol structure formed in this process can eliminate CO, similarly to the process observed for phenols[50]. The subsequent decomposition of the ion Φ_{12} is confirmed by the proposed mechanism. It is important to emphasise that 1,5-dinitronaphthalene does not eliminate CO under electron impact. An analogous reaction has been observed[51] in the photolysis of 6-nitrocholesteryl acetate.



Similar processes involving the migration of an aromatic hydrogen atom in a neighbouring aryl group have also been discovered[52] in the mass spectra of the isomeric *o*-, *m*-, and *p*-benzylnitrobenzenes. It was established that the $(M - OH)^+$ ion, the formation of which can be readily accounted for in the case of the *ortho*-isomer, is observed also in the mass spectra of other isomers. The study of the dissociative ionisation of the deuterium-labelled compounds made it possible to show that the process involving *m*-benzylnitrobenzenes proceeds via the scheme

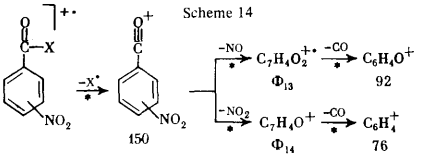
Scheme 12

In the *para*-isomer, where the $(M - OH)^+$ ion is formed with a low probability, hydrogen also migrates, but from the CH_3 group and not the *ortho*-position:

Scheme 13

It was later established that the formation of the $(M - OH)$ and even $(M - 2\ OH)$ (in the case of *ortho*-isomers) ions is characteristic of the mass spectrometric behaviour of nitrodiphenylamines.[53] Beynon and coworkers observed the peaks of the $(M - NO)$ ions also in the mass spectra of esters, amides, thioamides, hydrazides, and iminoesters of *p*- and *m*-nitrobenzoic acids. They explained their formation by a multistage migration of a hydrogen atom from the substituent to an oxygen atom of the nitro-group[54].

The migration of a hydrogen atom from a neighbouring ring was also observed for nitrodiphenyl ethers[53,55] and in the mass spectra of the negative ions of cyclic thioacetyls and of *o*-nitrobenzaldehyde[56].



A careful study of the mass-spectrometric behaviour of nitrodiphenyl ethers made it possible[57] to examine the problem of the possible migration of the charge in the excited ion, which has been frequently the subject of a critical discussion in the literature[58,59]. It has been concluded[57] that the nature of the substituent (X) in the B ring plays an important role in the intensity of the fragment ions produced as a result of the nitro–nitrite isomerisation in the ether:

Furthermore, a linear relation has been observed between the intensity of the peaks of the $(M - NO)^+$ ions and the IP, on the one hand, and between the intensity of the peaks of the $(M - NO)^-$ ions and the Hammett constant, on the other. According to the authors[57], the results show that the substituent X in the B rings of the nitroether derivatives investigated has a considerable influence on the electronic state of the A ring and that the electron density in the ion with an odd number of electrons migrates from the electron-depleted A ring to the B ring.

Shapiro and Serum[60] investigated the mass spectra of derivatives of *m*- or *p*-nitrobenzoic acids $O_2NC_6H_4COX$, where X = OCH_3, NH_2, or $NHCH_3$, in order to study the behaviour of the ion with a mass of 150 and an even number of electrons (the nitrobenzoyl cation), formed on elimination of the substituent X and subsequently decomposing via two alternative pathways leading to the formation of the ions Φ_{13} and Φ_{14}, having odd numbers of electrons‡:

Scheme 14

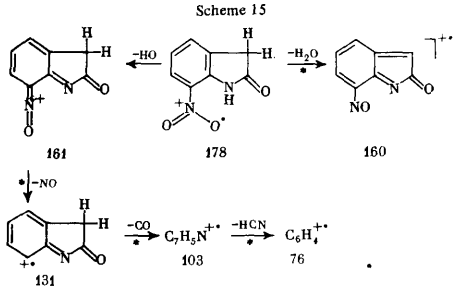
It was shown that the removal of NO from the ion with a mass of 150 for *p*-nitro-compounds proceeds with a much greater probability than for the *m*-isomers.

---

‡Here and henceforth an asterisk in the Schemes denotes a process confirmed by the presence of a metastable ion.

Analogous data were obtained in the study of the behaviour of $(M - X)^+$ ions with an even number of electrons and a mass of 136, formed in the dissociative ionisation of the nitrobenzyls *m*- or *p*-$O_2NC_6H_4CH_2X$, where X = Br or OC_6H_5, which decompose subsequently with the elimination of NO and NO_2.[60] It was concluded that, regardless of the pathway leading to the formation of the initial ion and its structure, the ion with a mass of 136 does not have the nitrotropylium structure and its structure is more likely to be of the nitrobenzyl type.

A correlation between the electronic properties of the substituents and the intensity of the peaks of fragment ions as well as their AP in the series of nitroarenes has also been observed in the mass spectra of negative ions, and has been demonstrated convincingly in a series of studies by Bowie and coworkers [15,16,41,42,44]. They established that in carbonyl-containing nitroarenes (nitrobenzophenones, nitrobenzoates, etc.) the negative charge is localised preferentially at the oxygen atom of the carbonyl group. Thus in the series of isomeric nitrobenzophenones the IP and the AP of the $(M - C_6H_5CO)^+$ ions and the heats of their formation are similar to those of the *meta*- and *para*-isomers, but differ from the corresponding values for the *ortho*-isomers.[61]



The same workers[61] showed that the mass spectra of negative ions of nitroarenes do not indicate their valence isomerisation or randomisation processes. Similar conclusions were reached also in the analysis of the mass spectra of the negative ions of nitrophthalic anhydride.[62] A considerable similarity between the main dissociative ionisation pathways of this compound in the mass spectra of negative and positive ions[63] and even the mass spectra obtained under the conditions of ion–molecule reactions[64] was noted.

III. NITRODERIVATIVES OF HETEROCYCLIC COMPOUNDS

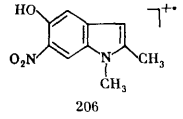
In contrast to nitroarenes, nitro-derivatives of heterocyclic compounds have been studied to a much lesser extent. The results are difficult to survey owing to the fragmentary nature of the available information about the decomposition reactions of many types of heterocyclic compounds, in the study of which high-resolution mass spectrometry and labelled compounds have been rarely used.

Analysis of the mass spectra of 5-nitro-,[65] 7-nitro-, and 5,7-dinitrooxindoles [66] showed that 7-nitro-oxindole decomposes via the elimination of OH and H_2O from $M^{\ddagger}$ species (Scheme 15), whereas in the fragmentation of 5-nitro-oxindole such ions are not observed and only the $(M - NO)^+$, $(M - HCO)^+$, and $(M - CO)^+$ ions with masses of 148, 149, and 150 are formed:

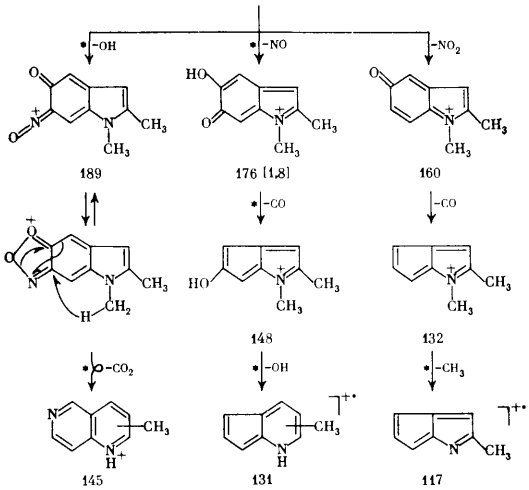
Scheme 15

The mass spectrum of 5,7-dinitro-oxindole is characterised by decomposition pathways similar to those of 7-nitro-oxindole. Together with the molecular ion, it contains peaks due to the $(M - OH)^+$, $(M - H_2O)^+$, and $(M - OH - NO)^+$ ions with masses of 206, 205, and 176 respectively.

As was to be expected, the introduction of the nitro-group into the molecules of alkylindoles destabilises the molecular ion[67,68]. The primary dissociative ionisation processes are characterised in the first place by the formation of the $(M - NO)^+$ and $(M - NO_2)^+$ ions. Since the nitro–nitrite rearrangement always takes place in the first stage of the decomposition process, the ratio of the peak intensities of these ions reflects qualitatively the statistical weight of the isomerised structure of the molecular ion.



It has been shown[65] that, for an energy of 50 eV, the non-isomerised $M^{\ddagger}$ structures predominate and the fraction of nitrite ions is high only for 1-methyl-3-nitro-indole. The isomerisation proceeds more readily when the nitro-group is in the 6-position and not in the 5-position. The isomerisation of $M^{\ddagger}$ involving the 4- and 7-positions is probably hindered by the stabilisation of the nitro-group as a result of the *peri*-interaction. A decrease of the energy of ionising electrons, which increases the relative probability of rearrangements, increases the probability of the formation of "nitrite" ions approximately by an order of magnitude.

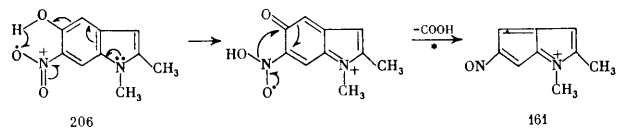


The β-decomposition processes (loss of hydrogen or of an alkyl group), which are typical of methyl indoles[69,70], proceed only in the second decomposition stage in the series of isomeric methylindoles. The presence of a methyl group in the *peri*-position relative to the nitro-group [68] or in the *ortho*-position [71] leads to the appearance of intense $(M - OH)^+$ ions, which permits a reliable identification of the isomers formed in the nitration of methylindoles. Although it is known that the presence of $(M - OH)^+$ ions is also characteristic of the mass spectra of *o*-nitroaniline and its derivatives [1,31], such ions are not observed in the mass spectrum of 7-nitroindole,[68] which is probably associated with the change in the nature of the amino-group in these compounds and the stabilising influence of the fused pyrrole ring.

The introduction of the hydroxy-group into the methyl-nitroindole molecule stabilises somewhat the molecular ion[68,72]. In contrast to oxindoles,[73] significant differences are observed between the mass spectra of the isomeric compounds. Although the stabilities of the $M^{\ddagger}$ species derived from 5-hydroxy-1,2-dimethyl-4-nitroindole and 5-hydroxy-1,2-dimethyl-6-nitroindole are similar, the intensities of certain characteristic ions [for example, $(M - OH - CO_2)^+$, $(M - NO_2 - CO)^+$, and a number of others], typical of *o*-nitrophenol,[1,29] differ by a factor of 2 and more. This indicates the absence of randomisation at the molecular ion stage, probably owing to the presence of the nitro-group. Analogous conclusions were reached in Bowie's study, already mentioned[32].

However, the characteristic pathways leading to the fragmentation of two isomeric nitro-oxindoles, illustrated in Scheme 16 in relation to the 6-nitro-isomer and confirmed by the determination of the elemental compositions of the fragment ions, are fundamentally similar.

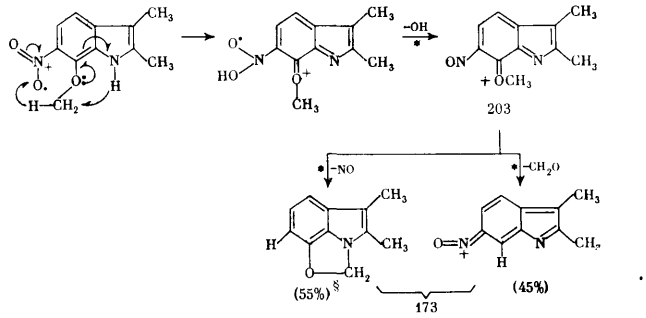
Scheme 16



It must be emphasised that, as for methylnitroindoles, the intensity of the $(M - H)^+$ ionic peak in the mass spectra of hydroxymethylnitroindoles does not exceed 0.3–0.4% of the total ion current. This finding suggests a virtually complete suppression of processes typical for the decomposition of alkylindoles, whereas in the mass spectra of hydroxyscatoles peaks of the $(M - H)^+$ and $(M - alkyl)^+$ ions are fairly intense[68].

The presence of a pyrrole ring fused to a benzene ring promotes the stabilisation of intermediate transition states arising in complex rearrangements. Thus, although the principal pathways leading to the dissociative ionisation of nitro-oxindoles,[68,72] containing these functional groups in the 4- and 5-positions or in the 6- and 5-positions, are similar to the fragmentation of *o*-nitrophenol (the successive loss of OH and CO_2 by the moleculer ion or nitro–nitrite rearrangement with elimination of NO), the loss of NO from indole derivatives is three times more intense than in the case of *o*-nitrophenol. Furthermore, the possibility of the elimination of CO_2H from a series of nitro-oxindoles must also be explained by the stabilising influence of the pyrrole ring:

Scheme 17



The decomposition pathways of isomeric methoxynitroindoles [68,72] are even more characteristic and differ in many respects from the dissociative ionisation of *o*-nitroanisole. Analysis of the intensities of the characteristic ions in the mass spectra of six isomeric methoxymethylnitroindoles, containing nitro- and methoxy-groups in the *ortho*-positions relative to one another, makes it possible to isolate fragments characteristic solely of the given compound. This permits the identification of each isomer from its mass spectrum. Thus the intense peaks of the $(M - CH_3)^+$ ion (whose intensity in the spectrum of *o*-anisole is low) are characteristic solely of methoxynitroindoles containing the methoxy-group in the 6-position. The rapid loss of the hydroxy-group by the molecular ion is characteristic only of compounds containing the nitro- and methoxy-group in the 6- and 7-positions respectively. However, if there is a methyl group in the 1-position of indole under these conditions, an intense peak of the $(M - NO_2)^+$ ion, which is virtually absent from the mass spectrum of the analogous unsubstituted indole, is observed.

The $(M - OH)^+$ ion mentioned above is completely uncharacteristic of the mass spectra of *o*-nitroanisole and its formation has been attributed[68,72] to the presence in the above structures of the N–H or CH_2–H group in the *peri*-position relative to the methoxy-group, which favours the push–pull transfer of hydrogen to an oxygen atom of the nitro-group (Scheme 18).

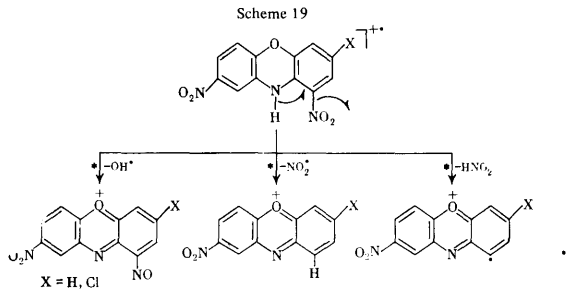
When the indole molecule contains simultaneously nitro- and carboxy-groups[71,74], the primary decomposition processes are characterised in the first place by the elimination of an ethoxy-group or an ethanol molecule, which is typical for ethoxycarbonylindoles.[75,76] The elimination or isomerisation and decomposition of the nitro-group take place only in the second stage, i.e. the formation of the primary ions is controlled only by one of the functional groups.

Thus, in contrast to *ortho*-substituted nitroarenes, the *ortho*-substituted nitroindoles decompose via specific channels, which depend on the position of the nitro-group and another functional group relative to the pyrrole nitrogen atom.

Scheme 18

In the series of nitrocarbazoles [77] there are no characteristic pathways which would permit the identification of the isomeric compounds and the most intense fragment ions are $(M - NO)^+$ and $(M - NO_2)^+$. The probability of the nitro–nitrite rearrangement increases by an order of magnitude when the ionisation energy is reduced from 50 to 15 eV. Nevertheless one should note that the ratio of the intensities of the ions $Z = I_{M-MO}/I_{M-NO_2}$ for 3,6-dinitrocarbazole is 1.1, whereas in the case of 3,8-dinitrocarbazole the probability of the elimination of the nitro-group is greater ($Z = 0.72$).

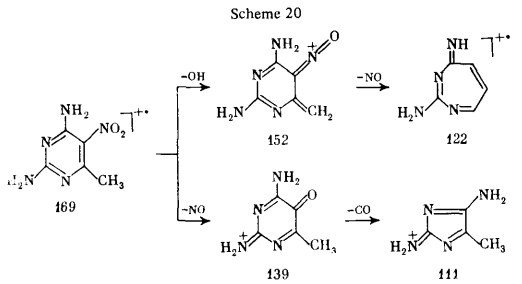
Analogous differences between the values of Z were observed in the series of nitrodibenzofurans,[78] where the 3-nitro-isomer, in which the nitro-group is conjugated with the oxygen atom of the heterocycle, shows the greatest capacity for rearrangement. The same conclusions also follow from the analysis of the mass spectra of a series of isomeric nitroxy-4-oxo-2-chromenes [79] and nitro-substituted N-aryliminopyridyl- and isoquinolinyl-betaines [80] and from the analysis of the mass spectra of negative ions of nitrophenyltriazoles.[81]



In the dissociative ionisation of nitrophenoxazines and azaphenoxazines [82] the fraction of rearranged ions is very low and the main primary decomposition processes are associated with the elimination of the nitro-group from the molecular ion and, in the case of the 4,6-dinitro-derivative, of a nitrous acid molecule, In the latter case

§The fraction of the ion having the given composition in the ion with $m/e = 173$.

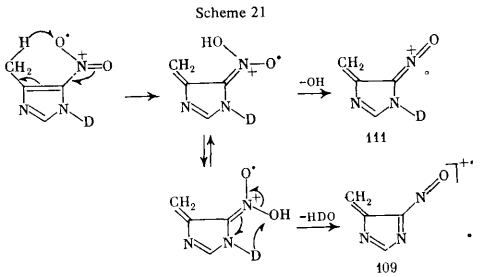
the $(M - OH)^+$ ion, formed with participation of the hydrogen atom of the NH group, is also observed (Scheme 19).



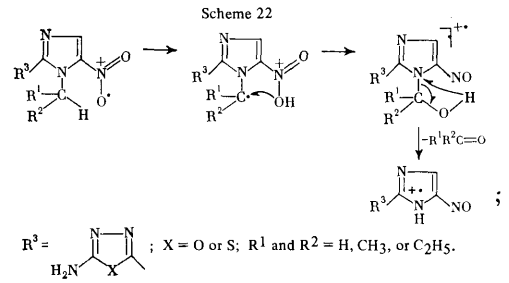
In many instances the occurrence or non-occurrence of the nitro–nitrite rearrangement is associated with the conditions under which the mass spectrum is recorded. Thus the mass spectra of *N*-nitroaminopyridines [83] can be obtained only when they are cautiously introduced into the mass spectrometer by direct injection into the ion source. In this case dissociative ionisation leads to intense peaks of the $(M - NO_2)^+$ ions. On the other hand, the introduction of *N*-nitroaminopyridines via the filling cylinder or using a glass system entails intense pyrolysis, as a result of which the mass spectrum consists of NO_2^+ and NO^+ ions and the products of the dissociative ionisation of aminopyridine, probably formed as a result of an ion–molecule reaction. The mass spectrum of 2-(*N*-methyl-*N*-nitro)aminopyridine, obtained on apparatus with direct injection [into the ion source] shows that the only important decomposition pathway of the molecular ion involves the abstraction of NO_2.

Scheme 19

At the same time the $(M - NO_2)^+$ ions are completely absent from the mass spectra of 4-substituted 2-amino-6-methyl-5-nitropyrimidines [84] and the primary decomposition pathways of these compounds involve the elimination of NO (the main process) or the ejection of OH (as a result of the *ortho*-effect):



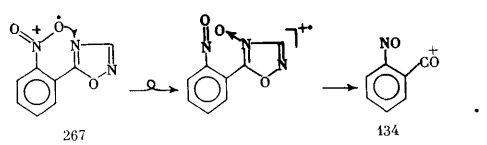
Scheme 20



It is of interest that the mass spectrum of this compound also contains the $(M - OH - H_2O)^+$ ion, whose formation is apparently to be accounted for by a double rearrangement of the type found by Lord and Millard [85]. In a study of the mass spectrum of 4(5)-methyl-5(4)-nitroimidazole they observed the so-called "double *ortho*-effect", as a result of which water is eliminated from the molecular ion (Scheme 21), which has been demonstrated by the analysis of the mass spectra of deutero-derivatives.

Van Lear [86] reported an unusual rearrangement associated with the migration of the oxygen of the nitro-group from the nitrogen atom to a carbon atom, which he observed in the dissociative ionisation of a series of 1-alkyl-2-substituted 5-nitroimidazoles. In contrast to the instances described above, the $(M - 30)^+$ ion in the mass spectra of compounds of this type corresponded to the abstraction of CH_2O and not the elimination of NO. In order to account for the findings, a complex mechanism of the rearrangement was proposed, involving double hydrogen transfer and migration of the hydroxy-group (Scheme 22).

Scheme 21



Scheme 22

It must be emphasised that, when the substituents R^3 are alkyl groups, the $(M - 30)^+$ ion is the usual $(M - NO)^+$ ion.

The unusual migration of an oxygen atom of the nitro-group to the nitrogen atom of the heterocyclic ring has also been noted for 5-(*o*-nitrophenyl)-1,2,4-oxadiazole [87]:

Kato and Hirao [88] showed in relation to the mass-spectrometric decomposition of a series of nitrofuryltriazoles that in the case of bisheterocycles the ring containing the nitro-group is mainly cleaved. The kinetic energy liberated as a result of the elimination of the nitroso-group (~0.77–0.81 eV) actually exceeds the value for the analogous processes in the mass spectra of 5-nitro-2-furonitrile and *o*-nitrophenol. [19,20]

Unfortunately, the partial mass spectra of triazoles presented in the literature [88–91] do not permit a sufficiently accurate assessment of the probability of the nitro–nitrite rearrangement when the nitro-group is located in this type of heterocyclic ring. In the case of 10-alkyl-3-nitrophenothiazines and their oxides [92] the $(M - NO)^+$ and $(M - NO_2)^+$ ions were observed solely in the mass spectrum of the 10-methyl derivative without the oxide group.

In the dissociative ionisation of isomeric nitrophenylisoxazoles [93–95] the intensity of the $(M - NO)^+$ ionic peaks is as a rule higher than that of the peaks due to the $(M - NO_2)^+$ ions and a definite correlation has been established between their intensity and the stability of the conjugate cyclic structures where the charge is localised at the oxygen atom.

In the spectra of saturated heterocycles such as isoxazolidines, containing a nitro-group in the 8-position,[96,97] M^+ species are not observed at all and the ions with the maximum mass are $(M - NO_2)^+$.

Thus examination of processes involving the dissociative ionisation of nitro-derivatives of arenes and heterocyclic compounds shows that the occurrence of rearrangements in the molecular ion itself and in the first stages of its decomposition is characteristic of these compounds. The nitro–nitrite rearrangement takes place with a high probability in compounds without any substituents in the *ortho*-position. In this case the probability of the nitro–nitrite rearrangement is related to the electronic influence of the substituents in other positions in the aromatic ring. When an *ortho*-substituent is present, the principal rearrangements are determined by the interaction of the nitro-group with the substituent, which leads to the suppression of the nitro–nitrite rearrangement and the appearance of new decomposition channels characteristic of the given substituent.

Phosgene in the Chemistry of Organosilicon Compounds

V.F.Mironov, V.D.Sheludyakov, and V.P.Kozyukov

A systematic account of data concerning the problems of the synthesis of a wide variety of organic and organosilicon derivatives of carbonic acid (chlorocarbonates, carbonates, isocyanates, carbodiimides, acylcarbomoyl chlorides, etc.) by the reaction of phosgene with *N*- and *O*-silyl-substituted amines, amides, diazoles, iminoesters, and ethers derived from alcohols, glycols, etc. is given for the first time.
The bibliography includes 113 references.

I. Introduction 473
II. Reactions of phosgene with organosilicon compounds having carbon-containing functional groups 473
III. Reactions with compounds having silicon-containing functional groups 475

I. INTRODUCTION

Phosgene is known[1-8] to be very important for preparative and particularly applied organic chemistry. However, there have been only a few scattered studies on the use of phosgene in the chemistry of organosilicon compounds up to 1965. Systematic investigation of the interaction of phosgene with various classes of organosilicon compounds was begun in 1965;[9] more than a hundred publications have now appeared in this field. These studies showed that, as in organic chemistry, $COCl_2$ has led in the chemistry of organosilicon compounds to simple methods for the synthesis of previously unobtainable substances and even whole classes of compounds.

The most novel results have been obtained in the reactions with phosgene of compounds having silicon-containing functional groups, particularly *N*-silylsubstituted derivatives. For example, the use of amines, amides, etc. silylated at the nitrogen atom instead of the corresponding initial organic compounds leads not only to better quantitative results but frequently also better qualitative results. In particular, new preparative pathways leading to the synthesis of lower organic isocyanates, which are difficult to obtain, previously unknown acylcarbamoyl chlorides, and other compounds have been developed.

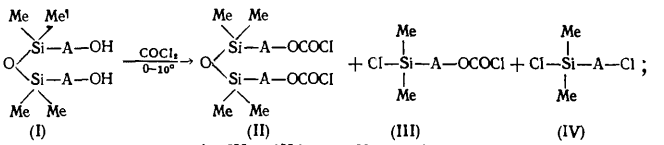
It must be emphasised that silylation of organic compounds with functional groups, i.e. the replacement by a silyl group (usually Me_3Si) of the mobile hydrogen atom in hydroxy-, amino-, mercapto-, and other groups, can be achieved very simply using readily available reagents[10,11].

II. REACTIONS OF PHOSGENE WITH ORGANOSILICON COMPOUNDS HAVING CARBON-CONTAINING FUNCTIONAL GROUPS

C-Silyl-substituted alcohols, phenols, amines, and mercaptans react, as expected, with carbonic acid chlorides (phosgene, chlorocarbonates) without any fundamental differences from the analogous organic compounds.

1. *C*-SILYL-SUBSTITUTED ALCOHOLS, PHENOLS, AND MERCAPTANS

When $COCl_2$ interacts with organosilicon alcohols, the corresponding chloroformates (chlorocarbonates) are formed in a high yield[9,12-15]:



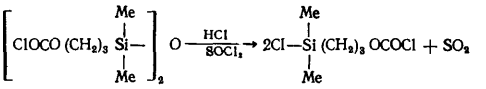
$$R_3Si(CH_2)_nOH \xrightarrow[-HCl]{COCl_2} R_3Si(CH_2)_nOCOCl\ ;\quad R=Alk,\ n=1,2,3.$$

In order to avoid the formation of the diesters of carbonic acids—the organosilicon carbonates $[R_3Si(CH_2)_nO]_2C{=}O$—in a side process, the reaction is carried out at temperatures not exceeding 0–5°C. The position of the hydroxy-group relative to the silicon atom does not influence significantly the yield and mode of reaction.

In contrast to alcohols, silylated mercaptans are more inert in the reaction with phosgene and require the presence of the HCl acceptor for the reaction to be completed[9,12,13,15]:

$$Me_3Si(CH_2)_3SH + COCl_2 \xrightarrow[-Et_3N\cdot HCl]{Et_3N} Me_3Si(CH_2)_3SCOCl\ .$$

The study of the interaction of organosilicon diols of the disiloxane series (I) with phosgene showed that the formation of the desired bischloroformates (II) is accompanied by the cleavage of the siloxane and ether linkages[9,14-20]:



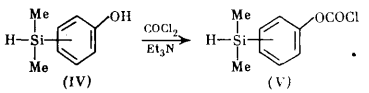
(I) (II) (III) (IV)

A=CH_2, $(CH_2)_3$, or $CH_2OCH_2CH_2$.

It was found that the fraction of side products depends on the type of diol employed[16,21], i.e. on the nature of A.

Special experiments showed[9,14,16] that neither $COCl_2$ nor the bischloroformate (II) are involved directly in the cleavage of the siloxane linkage, while the monochloroformate (III) is formed as a result of the action of HCl, liberated during the reaction, on the disiloxane linkage. For example, the reaction

(IIa) (IIIa)

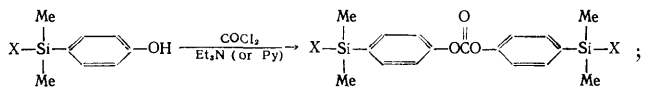


does not occur in the absence of HCl.[9] Like $SOCl_2$, phosgene is an insufficiently powerful reagent for the cleavage of the disoloxane group. For example, when $COCl_2$ is passed for a long time through boiling hexamethyldisiloxane, the rupture of disiloxane linkages does not occur[9,14]. It is also appropriate to mention here that the Si–H bond in hydrosilanes is likewise resistant to the action of $COCl_2$: $SiCl_4$ is formed on contact between $HSiCl_3$ and $COCl_2$ only under very severe conditions (~500°C).[9]

Organosilicon diols containing ether linkages react with $COCl_2$ via a still more complex mechanism[16,21]:

$$[HOCH_2CH_2OCH_2SiMe_2-]_2O \xrightarrow{COCl_2} \underset{65\%}{[ClOCOCH_2CH_2OCH_2SiMe_2-]_2O} + \underset{(17.0\%)}{ClOCOCH_2CH_2OCH_2SiMe_2Cl} + \underset{(2.0\%)}{[ClOCOCH_2SiMe_2-]_2O} + \underset{(1.8\%)}{[ClCH_2SiMe_2-]_2O} + \underset{(3.7\%)}{ClCH_2SiMe_2Cl} + \underset{(3.3\%)}{(ClOCOCH_2-)_2} + \underset{(1.6\%)}{ClCH_2CH_2Cl} .$$

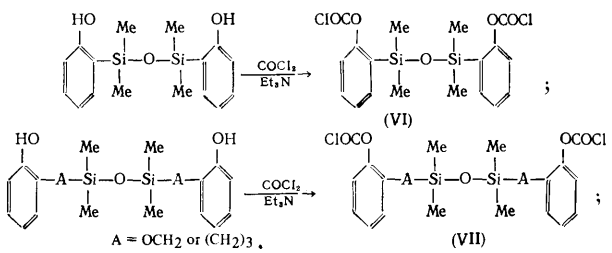
In order to suppress side reactions, it is necessary to remove more completely the hydrogen chloride liberated: diols are treated with phosgene in the absence of solvents capable of retaining HCl, which is displaced by bubbling with dry nitrogen or bound by organic bases[14-16,18,19,22].



In contrast to aliphatic compounds, organosilicon phenols (IV) are inert in relation to $COCl_2$ at moderate temperatures. In order to avoid the thermal rearrangement of silylphenols to phenoxysilanes[23,24] as well as other side reactions, organosilylphenyl chloroformates (V) were therefore synthesised in the presence of organic bases as HCl acceptors[15-18,21,23,25,26], for example[16,23]:

(IV) (V)

o- and *p*-isomers



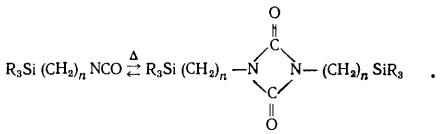
In the presence of an excess of phenol, the corresponding carbonates are formed in a single stage[16,23,26]:

X=H, Cl, or OAlk.

Analogous carbonates were obtained also by the esterification of chlorocarbonates of type (V) by the corresponding silylphenols[16,17,23].

The bischloroformates (VI) and (VII) have been synthesised from bisphenols of the disiloxane series[15-18,21,23,25,26]:

A = OCH_2 or $(CH_2)_3$.

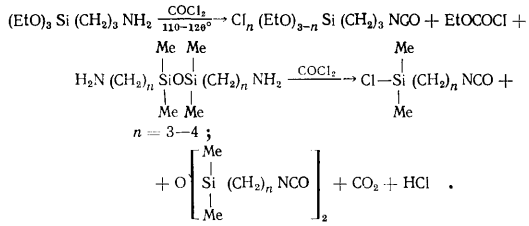


The above bischloroformates are thick transparent compounds soluble in the usual organic solvents. They always distil in an atomosphere of nitrogen without decomposition on heating to 300°C. This finding demonstrates yet again the stability of the Si–O–Si linkages in relation to the action of the chloroformate group even at elevated temperatures. The disiloxane fragment in the above compounds is resistant in the absence of HCl also to the action of $COCl_2$, COF_2, and $SOCl_2$.[16,21,27]

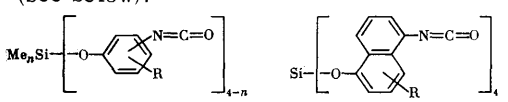
2. *C*-SILYLALKYL(ARYL) AMINES

The reaction of aminoalkylsilanes with phosgene, like the reactions of the *C*-silyl-substituted alcohols, phenols, and mercaptans discussed above, do not show fundamental differences from the reactions of the corresponding purely organic compounds[9,12-15,28]:

$$2R_3Si(CH_2)_nNH_2 + 2COCl_2 \rightarrow 2R_3Si(CH_2)_nNCO + 4HCl ;$$
R = Alk or Ar; $n = 1, 3$.



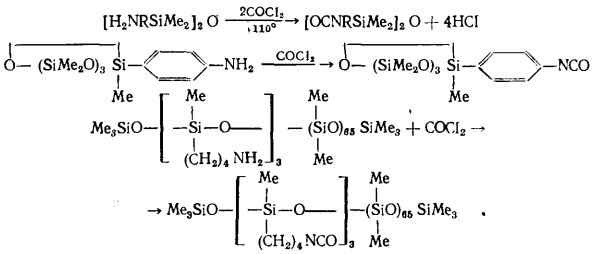
The dimeric compounds (VIII) [9,12] (analogous to the dimers of organosilicon ketens[29]) are formed as side products, which tentatively have the uretidinedione structure and which are in equilibrium with the monomeric form when heated†:



(VIII)

Nevertheless the monomeric isocyanatoalkylsilanes isolated in a pure form are entirely stable. For example, $Me_3Si(CH_2)_3NCO$ does not dimerise on storage or during distillation[9].

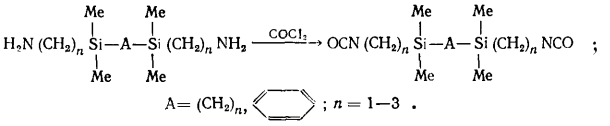
When $COCl_2$ interacts with amines containing alkoxy-groups at the silicon atom or siloxane units, the reaction can involve Si–O bonds[9,13,14,31-33]:



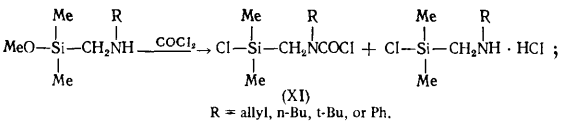
Silyl ethers of aminoalcohols of the type $R_2Si(OCH_2CH_2.NH_2)_2$ are fully cleaved by phosgene at Si–O bonds[32], but the final products have not been identified. At the same time the analogous aminophenol and aminonaphthol derivatives, both in the form of free bases and as the hydrochlorides, form the corresponding isocyanates (IX) and (X) [32,34] (see below):

(IX) (X)

$n = 1-3$; R = H, or Me.

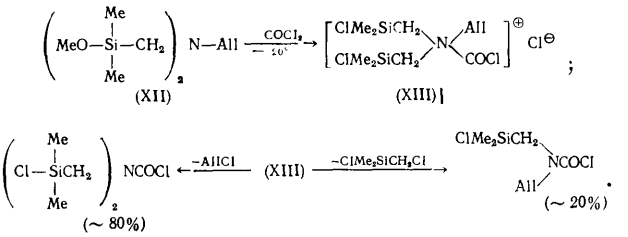


Examples of the synthesis of organosilicon mono- and di-isocyanates by treating with aminoalkylphosgene and aminophenyl derivatives of di-, tetra-, and oligo-siloxanes are known[33,35-37]:

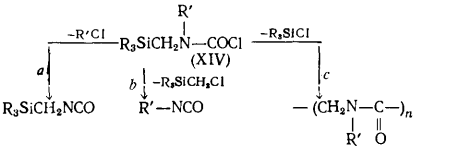


† The formation of the dimers (VIII) was also noted in the reaction of halogenoalkylsilanes with KOCN in dimethylformamide[30].

The retention of siloxane linkages on treatment with phosgene and HCl under severe conditions is doubtful, because it conflicts with the above findings, showing the undoubted cleavage of these bonds[9,14,15].



Organosilicon bifunctional monomers of another type were obtained when diamines with alkylene or phenylene bridges between silicon atoms were treated with phosgene[9,28]:



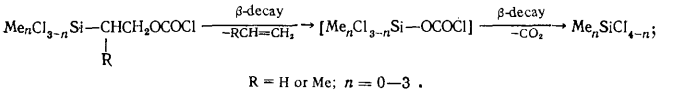
Secondary aminoalkylsilanes react with phosgene to form the corresponding organosilicon carbamoyl chlorides (XI). As for primary amines, when -Si-OAlk groups are present, they are converted into Si-Cl groups[38]:

At 20°C the tertiary organosilicon amine (XII) forms with phosgene an intermediate complex (XIII), which on heating splits off one of the substituents in the form of RCl:

It has been established that the pyrolysis of asymmetrically substituted organosilicon carbamoyl chlorides (XIV) leads to organic and organosilicon isocyanates‡. The mode of decomposition under these conditions depends on the nature of the substituents at the nitrogen and silicon atoms (see Table)[38,39]:

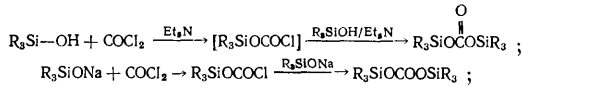
Silyl group	Group R′	Mode of decomposition
$ClMe_2Si$	$ClMe_2Si$	$a > c$
$ClMe_2Si$	All	$b > a + c$
Me_3Si	All	$c > a$

‡ It is known[40] that disubstituted organic carbamoyl chlorides of the type $Me_3CN(R)COCl$ (R = $PhCH_2$, allyl, or t-Bu) decompose to RNCO and Me_3CCl at 200°C.



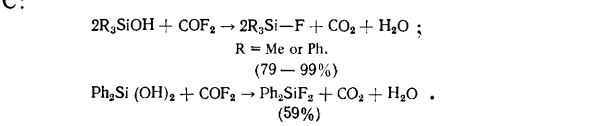
III. REACTIONS WITH COMPOUNDS HAVING SILICON-CONTAINING FUNCTIONAL GROUPS

1. COMPOUNDS CONTAINING THE SILOXANE LINKAGE



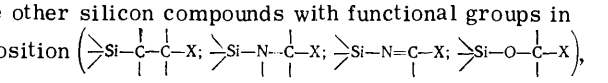
When phosgene interacts with organosilicon compounds containing the siloxane linkage (Si-O), the latter is frequently cleaved, not so much directly by phosgene as by reaction products such as HCl, carbamoyl chlorides, etc. The particular mode of the reaction involving the cleavage of the siloxane linkage is determined mainly by the nature of the atom or group X at the siloxane linkage Si-O-X.

(a) Silanols



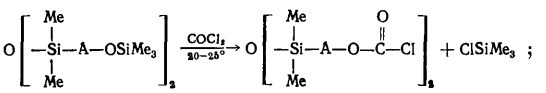
The silyl esters of chlorocarbonic acid—organosilyl chlorocarbonates (organosilyl chloroformates)—of the type $R_3SiOCOCl$, which should be formed from silanols and phosgene, are at present unknown. Such compounds are only mentioned as possible unstable intermediates[9,41,42]:

They are probably formed also in the synthesis of disilyl carbonates[16,17]:



In the absence of an HF acceptor, difluorophosgene acts on silanols and silanediols as a fluorinating agent at 0°-20°C:[27]

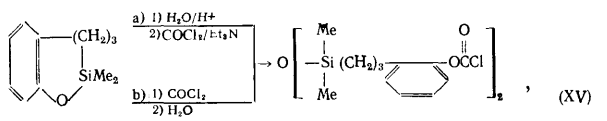
The instability of the silyl esters of chlorocarbonic acids can be explained by their extremely high tendency towards β-elimination:



i.e. like other silicon compounds with functional groups in the β-position (), compounds of this class exhibit a distinct 1 - 4 interaction between the silicon and halogen atom (σ,σ-conjugation[43-47]). The rate of β-decomposition increases with increasing electronegativity of the group X: Cl ≫ OR > $OSiR_3$ > NR_2.[48-52]

(b) The Silyl Ethers Derived from Alcohols, Glycols, and Phenols and Silylcarboxylate Esters

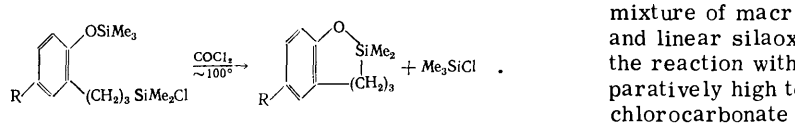
Treatment of silyl ethers derived from alcohols and phenols with phosgene is in many cases preparatively preferable to the direct reaction of $COCl_2$ with the corresponding alcohols, diols, phenols, and dihydric phenols.



Firstly, at the end of the reaction, the reaction mixture does not contain the corrosive HCl; instead the product is chlorotriphenylsilane, which is readily

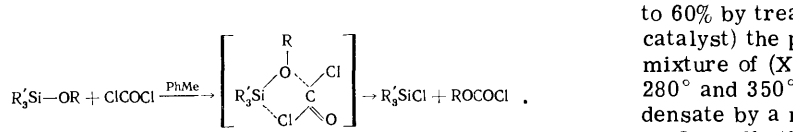
removed and which does not cleave the Si–Ar, C–O–C, Si–O–Si, and Si–O–C linkages[15–17,22,23,25,53–56], for example:

$A = CH_2$, $CH_2OCH_2CH_2$, or $CH_2CH_2CH_2$.



Secondly, the formation of both carbonates and chloroalkylsilanes under the influence of tertiary amines, usually employed as HCl acceptors, is fully ruled out. For example, of the following two mechanisms of the synthesis of compound (XV) (pathways *a* and *b*)

(XV)



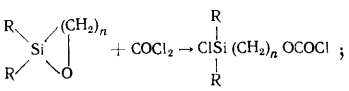
the latter is preferable, since it rules out contact between the chlorocarbonate formed and Et_3N.

Sometimes an attempt to treat substituted silylated phenols with phosgene does not lead to the required chloroformate, because the *trans*-silylation reaction is faster than the insertion of the $COCl_2$ in the Si–O bond, and the resulting heterocycles react with phosgene at much higher temperatures[16]:

As was to be expected, the reactivities of alkoxysilanes and acyloxysilanes in the reaction with $COCl_2$ proved to be different and were found to be determined by the nature of the groups incorporated in the organic and organosilicon parts of the molecule[16,55].

Reactions involving the nucleophilic substitution of the group RO in the silanes R'_3SiOR in a non-polar solvent evidently proceed via a mechanism with formation of a four-membered transition complex[40]:

Difluorophosgene reacts with alkoxysilanes like phosgene[27]. In the presence of a deficiency of COF_2 the yield of EtOCOF in the reaction with $Me_2Si(OEt)_2$ falls to 56%, since part of it is consumed in the formation of diethyl carbonate:

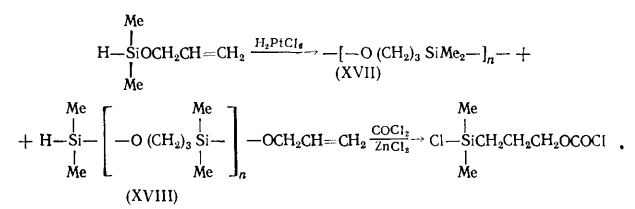


$$Me_2Si(OEt)_2 + 2EtOCOF \rightarrow Me_2SiF_2 + (EtO)_2CO .$$

Difluorophosgene does not cleave the siloxane linkage in $PhOSiMe_3$ and hexamethyldisiloxane at 20°C.

Compared with $COCl_2$ and ROCOF, aliphatic and aromatic chlorocarbonates are less reactive in relation to silyl ethers derived from alcohols and phenols. The reaction proceeds at an appreciable rate only at 120–220°C even with alkoxytrimethylsilanes which are most readily cleaved by phosgene[16,17,55,56]. As in the case of $COCl_2$, the Si–OCAr bond proved to be less reactive than Si–OCAlk.

(c) Silaoxacycloalkanes and Their Polymerisation Products

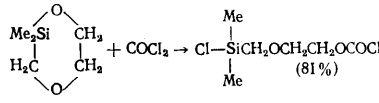


Silaoxacycloalkanes, which are cyclic silyl ethers derived from alcohols, react with phosgene, undergoing ring cleavage at the Si–O bond and giving rise to chloroformates[9,16,17,22,25,53–58]:

(XVI) R = Alk or AlkO; $n \geqslant 3$.

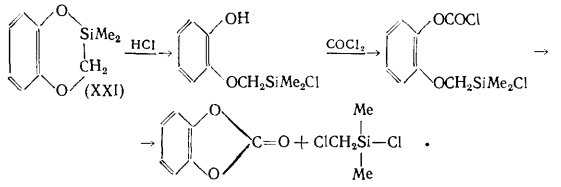
The reactivity falls in the series of silaoxacycloalkanes with increasing ring size[9,16,54,55]. For example, whereas silaoxacyclopentanes (XVI, $n = 3$) interact vigorously with $COCl_2$ even in the cold, the reaction of silaoxacyclohexanes (XVI, $n = 4$) with phosgene is slow even at a higher temperature (20–50°C). The reaction is sharply accelerated with increase of temperature to 100–150°C and is catalysed by Lewis acids ($ZnCl_2$, $AlCl_3$, etc.). In view of the relatively ready availability of silaoxacycloalkanes, the above reaction constitutes one of the most convenient methods for the synthesis of organosilicon monochlorocarbonates, whose yield reaches 80%.

The products of the polymerisation of silaoxacycloalkanes as well as macrocyclic silaoxacycloalkanes proved to be more passive in relation to $COCl_2$.[9,16,22,25] In particular, the study of the oligomeric product having the general formula $-[-O(CH_2)_3SiMe_2-]_n-$ and consisting of a mixture of macrocyclic silaoxa-alkanes (XVII, $n = 7–9$) and linear silaoxa-alkanes (XVIII, $n = 7–9$), showed that the reaction with phosgene does not occur even at comparatively high temperatures and the corresponding chlorocarbonate can be obtained in a yield of ~17% only in the presence of catalytic amounts of $ZnCl_2$:[9,22,54]



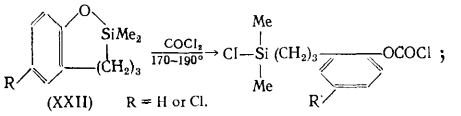
(XVII) (XVIII)

Incidentally, the yield of chlorocarbonate can be raised to 60% by treating with phosgene (in the absence of a catalyst) the products of the thermal depolymerisation of a mixture of (XVII) and (XVIII), obtain by distillation at 280° and 350°C with subsequent rapid cooling of the condensate by a mixture of dry ice and acetone[9,22,54].



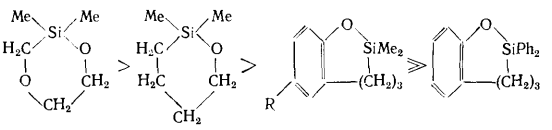
Overall, the reactivity of silaoxacycloalkanes and their condensation (dimerisation, trimerisation, etc.) products with respect to $COCl_2$ is found to be inversely related to their resistance to polymerisation.

Apart from ring strain in silacycloalkanes, the rate at which their rings are opened by phosgene is influenced also by other factors. For example, the siladioxan (XIX) reacts vigorously with $COCl_2$ and gives high yields of the chlorocarbonate (XX):[16]



(XIX) (XX) (81%)

120–140°C and the ring is open and undergoes a rearrangement only when $COCl_2$ and gaseous HCl are passed jointly through heated (XXI):[16,24]



The cleavage of the Si–OC_{Ar} bond in other benzosilaoxacycloalkanes by phosgene also takes place under severe conditions at 170–190°C,[16,54] for example:

(XXII) R = H or Cl.

The replacement of methyl groups in the heterocycle (XXII) by phenyl groups makes the molecule completely inert to the action of HCl/$COCl_2$ mixture even when it remains in contact with the reagents at 200°C.

The decrease of the reactivity of silaoxacycloalkanes in the series of compounds

like that in the series of linear silyl ethers, is caused by the weakening of the nucleophilic properties of the O atom in the siloxane bond.

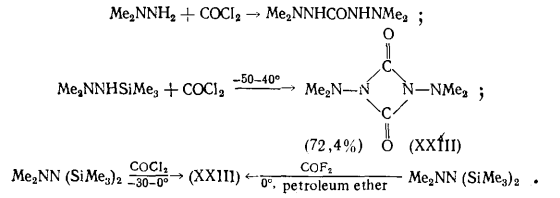
A number of procedures have been proposed for the activation of the reaction of phosgene with compounds containing the Si–O–C_{Ar} linkage. One can use Lewis acids as reaction catalysts[9,16,54], which, however, have also a side effect—the initiated decomposition of the required chlorocarbonates to alkyl(aryl) halides. Another group of initiators was therefore put forward[9,16–53]—inorganic acids or hydroxylated organic compounds. The possibility of initiating the reaction by tertiary amines (pyridine, dimethylaniline, etc.), which are capable of ionising the $COCl_2$ molecule, merits attention.

Thus the reaction of $COCl_2$ with silyl ethers—intermediates in the synthesis of glycols and dihydric phenols of the siloxane series—is of preparative value in relation to alcohol derivatives, but is of limited importance in the case of compounds with an Si–O–C_{Ar} linkage.

2. COMPOUNDS CONTAINING THE Si–N BOND

When the N–H bond in a wide variety of nitrogen-containing compounds is replaced by the N–Si bond their reaction with phosgene frequently follows another pathway. This can sometimes be accounted for by the absence of side and reversible reactions ($ClSiMe_3$ is formed instead of HCl), but the main explanation involves the formation of extremely unstable intermediates containing the σ,σ-conjugated bond system and responsible for the occurence of the irreversible β-elimination reaction

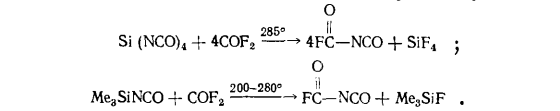
(a) Silazanes, Silylhydrazines, Cyanosilanes, and Isocyanatosilanes



When $COCl_2$ interacts with hexamethyldisilazane, a complex mixture of products is formed[59–61]:

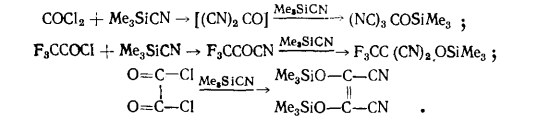
$$4\,(Me_3Si)_2NH + 3COCl_2 \rightarrow 5Me_3SiCl + 3Me_3SiNCO + NH_4Cl\ .$$

Sodium bis(trimethylsilyl) amide reacts with $COCl_2$ to give a 60% of *N,N'*-bis(trimethylsilyl)carbodi-imide[60,61]:



$$2\,(Me_3Si)_2NNa + COCl_2 \rightarrow Me_3SiN{=}C{=}NSiMe_3 + (Me_3Si)_2O + 2NaCl\ .$$

By protecting Me_2NNH_2 with a silyl group before its reaction with COF_2 and $COCl_2$, it was possible to obtain the dimethylaminoisocyanate dimer[62,63] instead of the corresponding urea[64], formed from dimethylhydrazine itself§:

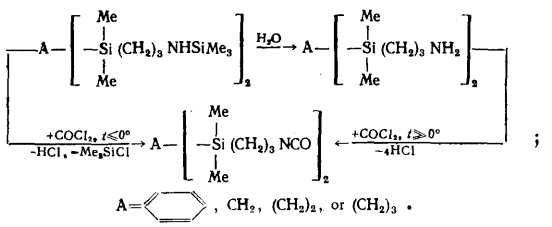


The yield of uretidinedione (XXIII) from $Me_2NN(SiMe_3)_2$ and $COCl_2$ is nearly quantitative (96.5%)[63], whereas in the reaction with COF_2 it is smaller approximately by a factor of two (46.0%)[62].

When isocyanatosilanes—$Si(NCO)_4$ or Me_3SiNCO—interact with COF_2 in an autoclave, the NCO group is substituted with formation of fluorocarbonyl isocyanates[65]:

Like trifluoroacetyl chloride and oxalyl chloride, phosgene interacts with Me_3SiCN to form the corresponding cyano-derivatives of carbonyl compounds[66]. However, dicyanocarbonyl is extremely reactive, combining with a Me_3SiCN molecule via the carbonyl group under the reaction conditions:

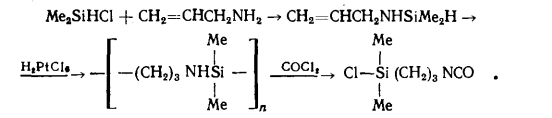
On treatment with Me_3SiCN, chloroformates give rise to cyanoformates[67]:



$$ROCOCl + Me_3SiCN \rightarrow ROCOCN + Me_3SiCl\ .$$

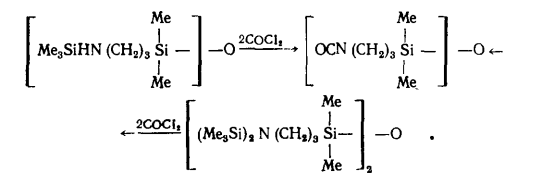
(b) *N*-Silyl-Substituted Amines

It was observed in 1969 that organosilicon di-isocyanates[9,28] are formed in high yields and under milder conditions when $COCl_2$ is allowed to react with *N*-silyl



§The uretidinedione structure has been tentatively attributed[42] to the dimethylaminoisocyanate dimer (on the basis of the analysis of the infrared and ^1H NMR spectra).

derivatives of the initial amines rather than the initial amines themselves[9,68]:

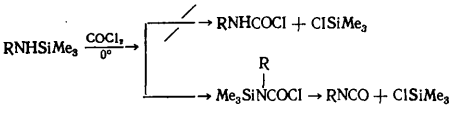


Monoisocyanates were obtained similarly[9,68-77]:

These observations made possible an exceptionally convenient procedure for the synthesis of one of the promising organosilicon monomers—γ-(chlorodimethylsilyl)propyl isocyanate—via the following mechanism[9,69,78]:

This compound had been obtained earlier as a side product in the reaction of $O-[-SiMe_2(CH_2)_3NH_2]_2$ with $COCl_2$.[9,13,14]

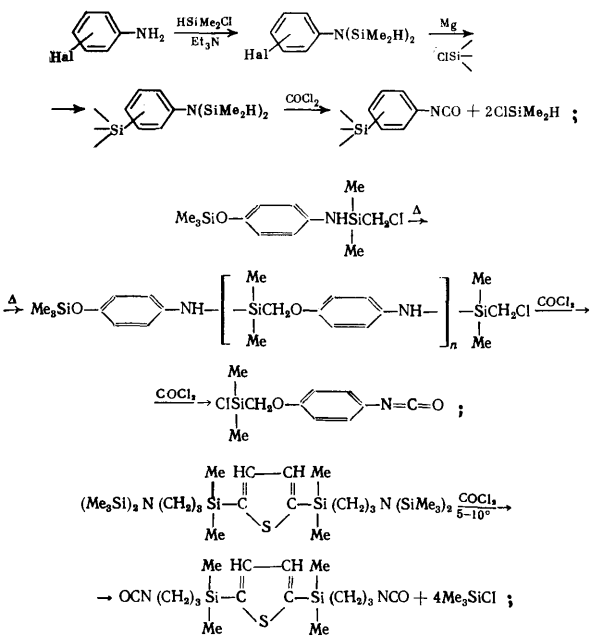
Subsequently it was established[9,68,69,78-83] that the reaction of phosgene with *N*-silyl-substituted primary amines is of a general type and can be used to synthesise not only organosilicon but also any other isocyanates containing groups sensitive to heat and the action of HCl, $COCl_2$, and $-NHC(O)Cl$. In particular, this made it possible to simplify the synthesis of di-isocyanates of the disiloxane series which has been difficult to obtain previously[9,69]:



A detailed study of this new reaction in relation to many examples[9,68-84] showed that, on treatment with phosgene, any primary *N*-silyl-substituted amines give rise to high yields of the corresponding isocyanates at appreciably lower temperatures (between −60° and 0°C) than the initial free amines. The latter factor revealed particularly clearly the advantages of the above method for the synthesis of lower isocyanates[69-77]. For example, it is known that treatment of methylamine with phosgene results in the formation of methylcarbamoyl chloride, which begins to decompose at temperatures of 100°C to methyl isocyanate and hydrogen chloride:

However, the latter reaction is reversible and the separation of gaseous methyl isocyanate and hydrogen chloride is extremely difficult. The dehydrochlorination of methylcarbamoyl chloride is therefore usually carried out with the aid of organic or inorganic bases. This applies equally to the synthesis by a similar procedure of ethyl, allyl, and other low-boiling isocyanates.

On the other hand, the reaction of *N*-silyl-substituted amines with phosgene, which leads to the formation of the extremely unstable *N*-silylcarbamoyl chloride[9,68,69,79,80], decomposing irreversibly to an alkyl isocyanate and chlorotrimethylsilanes, can serve as a new and convenient preparative method for the synthesis of lower alkyl isocyanates[9,68-83]:



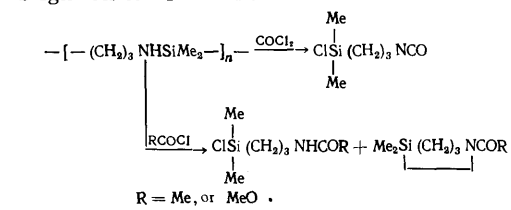
The occurrence of the reaction via the upper pathway is ruled out, since it is known that alkylcarbamoyl chlorides are stable up to ~100°C, while the above reaction takes place almost quantitatively at temperatures below zero.

On the other hand, the probability of ready dehydrochlorination of alkylcarbamoyl chlorides under the reaction conditions (under the influence of aminosilanes or the chlorosilanes formed) is low, and special experiments showed that, for example, methylcarbamoyl chloride does not change even after prolonged refluxing with chlorosilanes[9,69].

Nevertheless, the Si–N bond is also very readily cleaved by phosgene. For example, the reaction with *N*,*N*-disilyl-substituted amines takes place at low temperatures and the yield of the corresponding isocyanates is sometimes actually better, owing to the complete absence of hydrogen chloride, than in the reaction employing *N*-monosilyl-substituted amines[9,12,69-86]:

It must be emphasised that, when silyl-substituted amines are treated with phosgene, the corresponding silyl chloride, used to introduce a protective silyl group into the initial amines, is almost quantitatively regenerated. The above findings give rise to the hope that certain isocyanates (for example, methyl isocyanate) will be synthesised not only in the laboratory but also under industrial conditions[15]. Simple methods for the synthesis of certain organosilicon, organotin, and organogermanium isocyanates, which are of preparative value but are difficult to obtain, are presented below[9,15,78,81,82,85-89]:

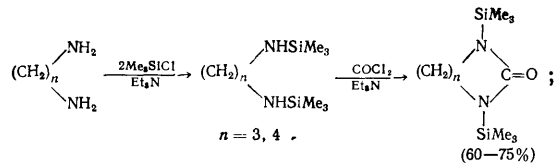
$$Bu_3Sn(CH_2)_3NHSiMe_3 \xrightarrow{COCl_2} Bu_3Sn(CH_2)_3NCO\ ;$$



$$Bu_3Sn(CH_2)_3N(SiMe_3)_2 \xrightarrow{COCl_2} Bu_3Sn(CH_2)_3NCO\ ;$$

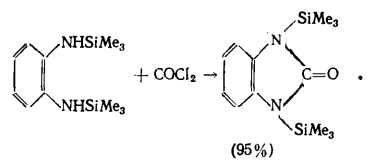
$$Et_3Ge(CH_2)_3NHSiMe_3 \xrightarrow{COCl_2} Et_3Ge(CH_2)_3NCO\ .$$

N-Silyl-substituted secondary amines undergo an exothermic reaction with phosgene, giving an almost quantitative yield of a trialkylchlorosilane and the corresponding dialkylcarbamoyl chloride[9]:



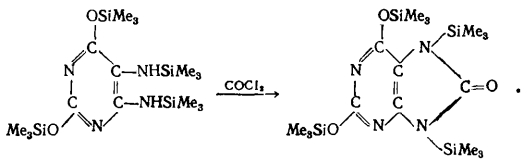
$$R_2N{-}SiMe_3 + COCl_2 \xrightarrow[-15-0^\circ]{} \underset{(88\%)}{R_2NCOCl} + \underset{(97\%)}{Me_3SiCl}\ .$$

It is appropriate to mention here that the Si–N bond in aminosilanes is cleaved by acyl halides and chlorocarbonates at a much lower rate than in the case of $COCl_2$.[38, 59, 90–92] This follows, for example, from the fact that in the absence of a catalyst (concentrated H_2SO_4), the compounds ROCOCl do not interact with $R'N(SiMe_3)_2$ even on heating[38, 91]. Slow acylation of the oligomer $-[-(CH_2)_3NH.SiMe_2-]_n$ with methyl chlorocarbonate or acetyl chloride is accompanied by the competing dehydrochlorination reaction, which on treatment with phosgene takes place to only a slight extent if at all:



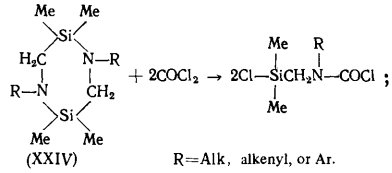
R = Me, or MeO .

A departure from the general rule governing the interaction of phosgene is shown by certain silylated diamines[93]:



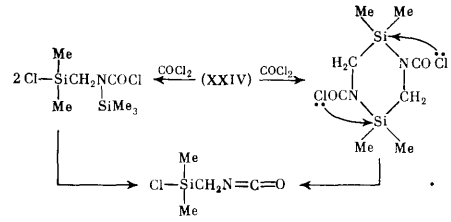
$n = 3, 4$.

Under the same conditions, *N*,*N*′-bis(trimethylsilyl)-*O*-phenylenediamine reacts with $COCl_2$ to form *N*,*N*′-bis-(trimethylsilyl)-2-benzimidazolone in a high yield[93]:

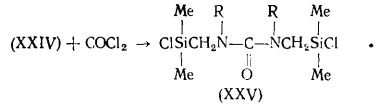


(95%)

2,4-Bis-(*O*-trimethylsilyl)-5,6-bis(trimethylsilylamino)-uracil, formed on silylation of 5,6-diaminouracil, reacts with $COCl_2$ in toluene to form tetrakistrimethylsilyluric acid[93]. Without the protection of the *N*-functional group by silylation, this reaction does not occur. The above synthesis is remarkable also because, by virtue of silylation, the reaction with 5,6-diaminouracil can be carried out in a hydrocarbon solvent[93]:

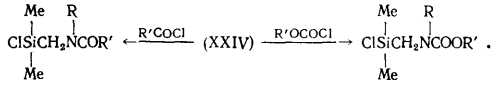


The ease of the cleavage of the 2,5-disilapiperazine ring in compound (XXIV) by phosgene combined with the complete absence of any side products makes this reaction extremely promising for preparative purposes[38]:



(XXIV) R=Alk, alkenyl, or Ar.

When R = $SiMe_3$, the reaction does not stop at the stage involving the formation of carbamoyl chloride, since its β-decomposition causes its dechlorosilylation to the isocyanate:

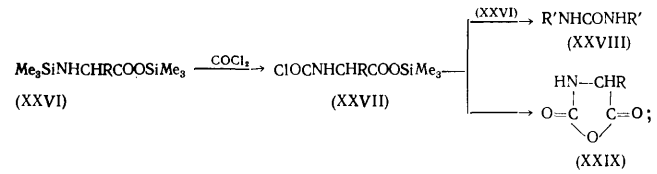


It has been shown[38] that, whereas the isocyanate is formed regardless of the order in which the reactants are mixed when R = $SiMe_3$, in the remaining cases a constant excess of $COCl_2$ must be ensured in the course of the reaction in order to obtain carbamoyl chlorides. Otherwise the ureas (XXV) are produced:

(XXV)

The disilapiperazine ring is readily cleaved by chlorocarbonates and carboxylic acid chlorides with formation of urethanes and amides respectively[38]:

(d) Silyl Derivatives of Aminoacids



The reaction of phosgene (thiophosgene) with silyl derivatives of aminoacids is used particularly frequently in the synthesis of esters of isocyanatocarboxylic acids and *N*-carboxyanhydrides.

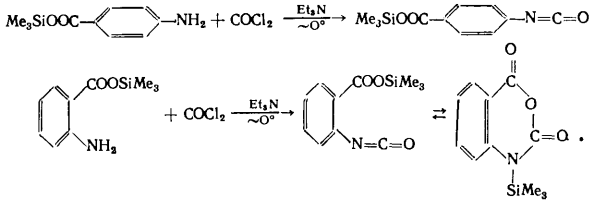
The interest in the esters of isocyanatocarboxylic acids is due primarily to the fact that, in combination with *N*-protected aminoacids, they can be regarded as convenient intermediates in the stepwise synthesis of di- and poly-peptides.

The silyl esters of isocyanatocarboxylic acids are much more readily hydrolysed than alkyl esters and some workers[94] have for this reason regarded them also as a potential source of free isocyanatocarboxylic acids O=C=NCH(R)COOH which had been little studied hitherto and which have been frequently mentioned in the literature as possible highly reactive monomers for the synthesis of polypeptides and polyamides (the intermediate formation of these compounds was postulated, particularly, in a study of the polymerisation of *N*-carboxyanhydrides).

N-Carboxyanhydrides of aminoacids (also referred to as oxazolidine-2,5-diones or leuchs anhydrides) are in their turn convenient and frequently employed starting compounds for the synthesis of polyaminoacids.

Thus Kricheldorf[95] showed that the trimethylsilyl esters of *N*-trimethylsilylaminoacids (XXVI) react with phosgene, eliminating Me_3SiCl and forming initially the silyl esters of *N*-chloroformylaminoacids (XXVII), which then either react with the initial substance to give urea derivatives (XXVIII) or cyclise to oxazolidine-2,5-diones (XXIX):

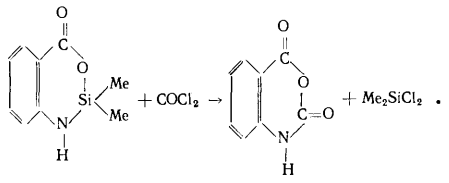
(XXVI) (XXVII) (XXVIII) (XXIX)



R′=CHRCOOSiMe$_3$.

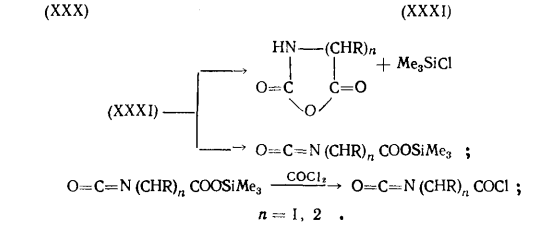
The formation of the urea derivative in this reaction can be avoided by using an excess of phosgene and by adding slowly the silylated aminoacids to the latter[95]. Intramolecular cyclisation is favoured by an increased temperature and a branched structure of the hydrocarbon residue of the aminoacid.

The advantage of this method of synthesising *N*-carboxyanhydrides of aminoacids over known methods is that it does not entail the evolution of hydrogen chloride, which permits a retention of the ester groups and of the multiple bonds in the molecule. In particular, the *N*-carboxyanhydride of *O*-trimethylsilyl-L-tyrosine was obtained by this procedure in a satisfactory yield[95]. For comparison, one may note that the formation of this product by silylating the *N*-carboxyanhydride of L-tyrosine with the Me_3SiCl/Et_3N mixture cannot be achieved, because the product of this reaction polymerises after a short time.



The use of silyl esters (in contrast to the *N*-benzyloxycarbonylaminoacids normally employed) also has the advantage that most of them can be vacuum distilled without decomposition[96]. Thus silylation (and subsequent distillation) can serve as a convenient method for purifying the initial aminoacids or their derivatives, which frequently show only a small capacity for crystallisation. Furthermore, in contrast to aminoacids with a free carboxy-group, silyl esters dissolve even in non-polar solvents (for example, in petroleum ether), which makes it possible to eliminate the initial substance as an impurity in the *N*-carboxyanhydride, which is precipitated[96].

Mono- and *N*, *O*-bis-silyl derivatives of aromatic aminoacids react with phosgene to form different products, depending on the conditions. Whereas in the absence of Et_3N monosilyl derivatives form mainly polymeric compounds (or the anhydride of isatinic acid in the case of the *O*-trimethylsilyl ester of anthranilic acid), the reaction in the presence of Et_3N makes it possible to obtain high yields of trimethylsilyl esters of isocyanatocarboxylic acids whose *ortho*-derivatives show a tendency towards tautomeric transformations[87]:



N,*O*-Bis-silyl derivatives can react with $COCl_2$ under mild conditions (0–20°C) to form trimethylsilyl esters of isocyanatocarboxylic acids also in the absence of Et_3N, whereas under more severe conditions polymeric products having tentatively the uretidine dione structure are formed[87].

The action of phosgene on 4,4-dimethyl-1,6-benzo-3-oxa-4-sila-5-aza-2-cyclohexanone leads to the virtually quantitative formation of the anhydrides of isatinic acid:

N,*O*-Bis-silylated *N*-acylaminoacids react with phosgene with difficulty at 80°C; *N*-carboxyanhydrides are formed in this case with a low yield[95]. The reactions described proceed without the inversion of configuration[95].

Above 0°C, the trimethylsilyl esters of *N*-siloxycarbonylaminoacids (XXX) react readily with phosgene, eliminating two Me_3SiCl molecules and forming *N*-carboxyanhydrides[97]. The *N*-siloxycarbonyl group then exhibits a higher reactivity than the *C*-siloxycarbonyl group, as a result of which trimethylsilyl esters of *N*-halogenocarbonylaminoacids (XXXI) are formed as intermediates, which then cyclise to form *N*-carboxyanhydrides[97,98]. The esters of halides of isocyanatocarboxylic acids are formed as side products, which predominate in the case of β-aminoacids[97]:

(XXX) (XXXI)

n = 1, 2 .

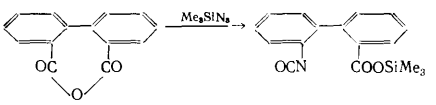
Since alkoxy- and aryloxy-trimethylsilyl groups are still less reactive than trimethylsiloxycarbonyl groups (the reactivity of various siloxy-groups in relation to acid chlorides diminishes in the sequence $R_2NCOOSiMe_3 > RCOOSiMe_3 > AlkOSiMe_3 > ArOSiMe_3$), [96] the reaction with phosgene by this procedure can yield *N*-carboxyanhydrides containing silyl substituted alcoholic or phenolic groups[97,98]. The above method for the synthesis of *N*-carboxyanhydrides have also the advantage that, compared with the established procedure, it makes it possible to obtain them in higher yields (>90%) and with a very high degree of purity. It is also superior to the synthesis of *N*-carboxyanhydrides from trimethylsilylesters of *N*-trimethylsilylaminoacids discussed above, since in this case the risk of the formation of urea by a side reaction is eliminated.

The interaction of thiophosgene with the hydrochlorides of the trimethylsilyl esters of aminoacids is one of the most convenient preparative methods for the synthesis of trimethylsilyl esters of isothiocyanatocarboxylic acids according to Kricheldorf's data[99]:

(75–85%)

These acids can be used[100] as convenient intermediates in the synthesis of free isothiocyanatocarboxylic acids¶ (S=C=NCHRCOOH) and thiazolidine-2,5-diones.

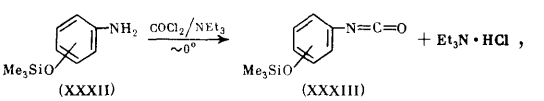
On passing from trimethylsilyl esters to ordinary esters of aminoacids silylated at the nitrogen atom, the interaction with $COCl_2$ terminates with the formation of the corresponding derivatives of isocyanatocarboxylic acids[101]:



$$Me_3SiNHCHRCOOEt \xrightarrow[0^\circ]{COCl_2} OCNCHRCOOEt\ ;$$

R=Me, or iso-Pr.

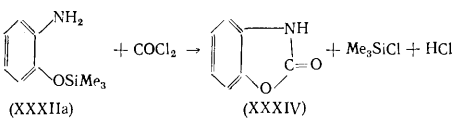
The possibility of using PhOCOCl instead of $COCl_2$ for the synthesis of these compounds has been demonstrated:



$$NH_2(CH_2)_4COOH \xrightarrow[3)\ Et_3N]{1)\ Me_3SiCl;\ 2)\ PhOCOCl} OCN(CH_2)_4COOSiMe_3 + PhOSiMe_3$$

or one can use a phosgene-free method[102]:

(e) Silyl Derivatives of Aminophenols



Silyl derivatives of aminophenols react vigorously with phosgene to form a wide variety of products. Thus, whereas siloxyanilines (XXXII) are converted into the corresponding isocyanates (XXXIII, a and b) on treatment with phosgene under mild conditions (~0°C) and in the presence of Et_3N, [88]

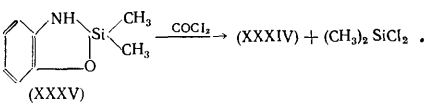
(XXXII) (XXXIII)

[*a*) *ortho*-isomer; *b*) *para*-isomer]

when the temperature is raised in steps (initially 20–40° and then 100–110°C), isocyanates are not formed, since the Si–OC bonds are ruptured. The main product in the reaction of (XXXIIa) is the benzoxazolinone (XXXIV)[88]:

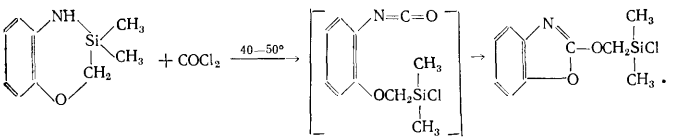
(XXXIIa) (XXXIV)

while the reaction of (XXXIIb) gives rise to an oligomer:



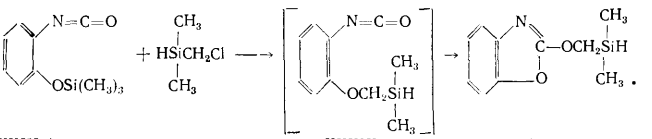
The substitution of one of the hydrogen atoms in the NH_2 group by the trimethylsilyl residue makes it possible to obtain the isocyanate (XXXIIIb) from the para-isomer[88]:

However, the yield of the product is low, since even under the mild conditions employed the reaction is accompanied by the formation of a polymer having the above structure via a side process.



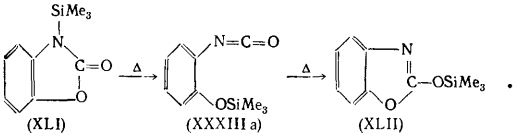
The Si–OC bond is even more readily cleaved in the cyclic compound (XXXV), whose reaction with $COCl_2$ results in its complete conversion into benzoxazolinone even at a temperature of –40°C and below:

(XXXV)



This increase of reactivity can be accounted for by the increased polarisation of the Si–O bond owing to the reduced amount of double bond character of the linkage between the O and Si atom due to the inclusion in the silicon *d* orbital of the free electron pair not only at the oxygen atom but also at the nitrogen atom.

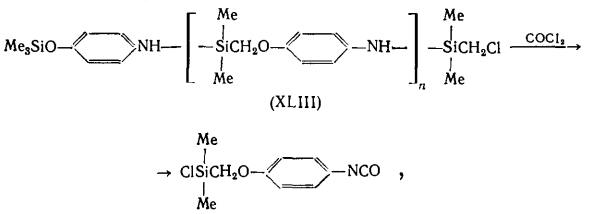
The reaction of $COCl_2$ with the cyclic compound (XXXVI) had an unexpected course: instead of the expected isocyanate, a high yield was obtained of the isomeric product (XXXVIII). Evidently, the isocyanate (XXXVII) formed in the first stage is unstable and isomerises rapidly to (XXXVIII):



(XXXVI) (XXXVII) (XXXVIII)

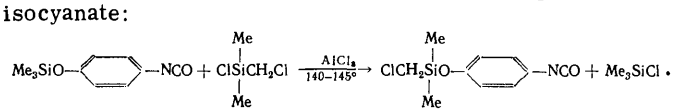
The instability of isocyanates containing silylmethoxy-groups as well as Me_3SiO groups in the *ortho*-position relative to NCO was confirmed also by studies on a number of other reactions[88]. Thus the transalkylation of *o*-trimethylsiloxyphenyl isocyanate (XXXIIIa) by reaction with chloromethyldimethylsilane results in the evolution of up to 85% of the theoretical amount of Me_3SiCl, but instead of the isocyanate (XXXIX) the product is the isomeric compound (XL):

(XXXIII a) (XXXIX) (XL)



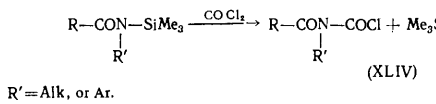
The initial product of this reaction—*o*-trimethylsiloxyphenyl isocyanate (XXXIIIa)—is the most stable of the *o*-substituted phenyl isocyanates examined. It can be isolated in an analytically pure form by vacuum distillation and is stable on storage. Nevertheless, under comparatively severe conditions this compound is capable of cyclising. For example, it has been observed that *N*-trimethylsilylbenzoxalinone (XLI), formed when benzoxalinone is treated with chlorotrimethylsilane in the presence of Et_3N, undergoes intramolecular β-elimination even under the conditions of its formation (80°C) and is converted into *o*-trimethylsiloxyphenyl isocyanate (XXXIIIa). On heating (3 h, 160–200°C), the latter isomerises to the benzoxazolinone derivative (XLII)[43,88]:

(XLI) (XXXIII a) (XLII)



¶ β-, γ-, and ε-isothiocyanatocarboxylic acids and their silyl esters are exceptionally active physiologically, giving rise to a very severe rash. Even in very low doses, they can cause painful blisters and wounds[100].

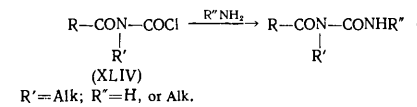
In contrast to *o*-derivatives, *p*-siloxyphenyl isocyanates are quite stable can be obtained not only via the reactions discussed above but also on treatment of the polymer (XLIII) with phosgene[88]:



(XLIII)

and by the transalkylation of *p*-trimethylsiloxyphenyl isocyanate:

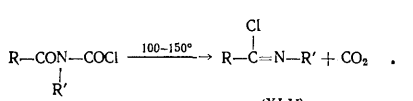
(f) *N*-Silyl-Substituted Carboxylic Acid Amides



N-Acylcarbamoyl chlorides. The reaction of *N*-alkyl(aryl)-*N*-(trimethylsilyl)-amides with phosgene was found to give high yields of the first examples of a hitherto unknown class of organic compounds—*N*-alkyl-(aryl)acylcarbamoyl chlorides (XLIV)[9,43,80,84,103,104]:

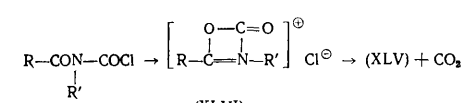
(XLIV)

R′=Alk, or Ar.



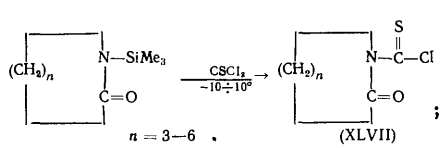
It has been shown[9,43,104] that *N*-acyl-*N*-alkylcarbamoyl chlorides (XLIV) are converted into *N*-acyl-*N*-alkylureas on treatment with aqueous ammonia:

(XLIV)



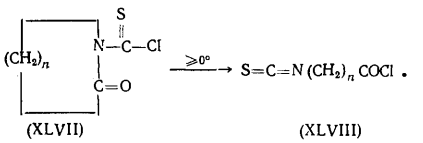
R′=Alk; R″=H, or Alk.

When acylcarbamoyl chlorides (XLIV) are heated to 100–150°C, they undergo quantitative decarboxylation to the corresponding imidochlorides (XLV)[9,43,80,84,103,104]:



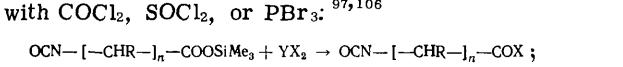
(XLV)

Presumably the decomposition of these compounds proceeds via the intermediate formation of the salt (XLVI)[43,104]:



(XLVI)

Lactams silylated at the nitrogen atom, which are cyclic amides, interact with thiophosgene via a similar mechanism[105]:

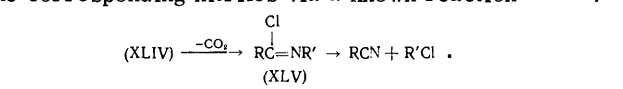


$n = 3-6$. (XLVII)

However, *N*-chlorothioformyl derivatives (XLVII) isomerise even at 0°C to the chlorides of ω-isothiocyanatocarboxylic acids (XLVIII), which can be isolated in a pure form:

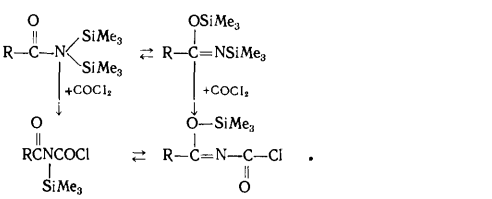
(XLVII) (XLVIII)

The oxygen analogues of the acid chlorides (XLVIII), i.e. the chlorides of isocyanatocarboxylic acids, have been obtained by treating the silyl esters of isocyanatocarboxylic acids with $COCl_2$, $SOCl_2$, or PBr_3:[97,106]

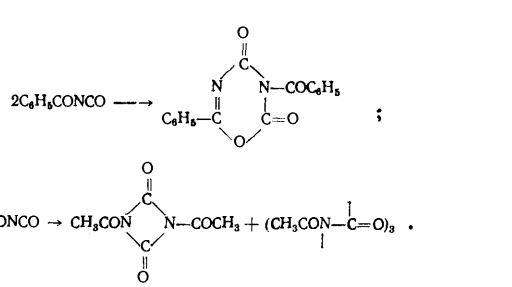


R = H or Alk; n = 1,2; X=Cl, or Br; Y=SO, CO, or PBr .

In contrast to *N*-alkyl(aryl)-*N*-silyl-substituted amides, *N*-silyl-substituted amides give rise to the corresponding nitriles on reaction with phosgene (at temperatures not exceeding room temperature)[9,43,84,103,104]:

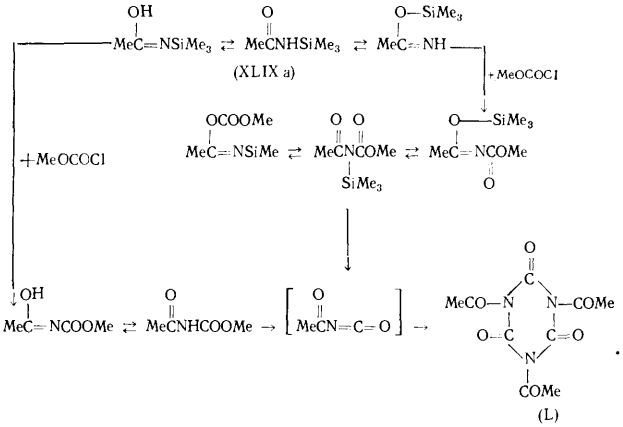


Presumably here too the reaction proceeds, as in previous instances, via the formation of acylcarbamoyl chlorides (XLIV, R′ = H), which subsequently decompose to the imidochlorides (XLV), and the latter are converted into the corresponding nitriles via a known reaction[9,103,104]:

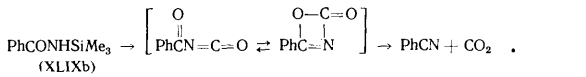


(XLV)

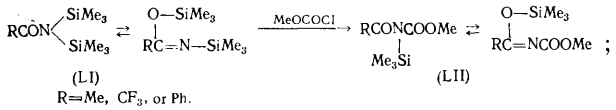
In contrast to compounds with R′ = alkyl or aryl, acylcarbamoyl chlorides with R′ = H apparently have extremely low thermal stabilities. Similar relations are known to be characteristic also of the imidochlorides RC(Cl)=NR′, which are also extremely unstable when R′ = H.



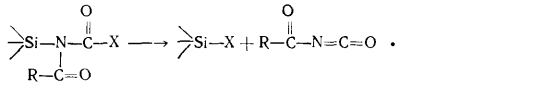
Disilyl substituted carboxylic acid amides react very vigorously with phosgene and form a mixture of di- and tri-meric forms of the acyl isocyanate[38,43,107]. The reactions probably proceed via mechanisms involving the formation of *N*-silyl substituted acylcarbamoyl chlorides with the Si–N–C–Cl system of conjugated bonds[43]:



β-Decomposition of these compounds leads to acyl isocyanates, which undergo further reactions:

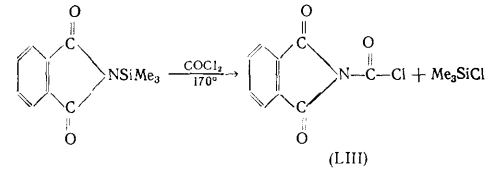


Monosilyl-substituted acetamides and benzamides react in different ways with methyl chloroformate, depending on their possible tautomeric forms: the reaction of silylated acetamide (XLIXa) led to the isolation of triacetyl isocyanurate (L) as a result of the following probably reactions:

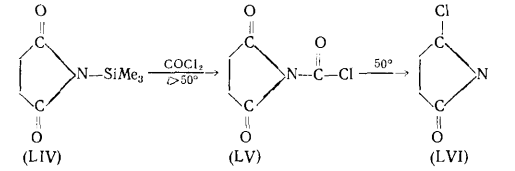


However, the monosilylbenzamide (XLIXb) is converted into benzonitrile under these conditions. The difference between the final reaction products is caused by the tendency of benzoyl isocyanate, which is stable under other conditions, to eliminate CO_2:

In the course of the study of the reaction of disilyl-substituted amides (LI) with chloroformates a new class of organo silicon compounds was obtained, namely the esters of silyl-substituted acylcarbamic acids (LII):[43]

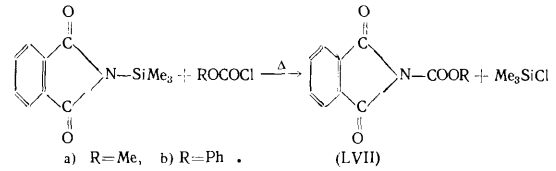


The possibility of isolating these compounds in a pure state, in contrast to the related *N*-silyl-substituted *N*-acylcarbamoyl chlorides, is due to the significantly lower electronegativity of the alkoxy- groups in the β-position relative to the silicon atom in the system of conjugated bonds $\equiv Si-\overset{|}{N}-\overset{|}{C}-X$ (X = OAlk or Cl) and the consequent lower tendency towards β-decomposition:



The reactivity of the amides (LI) is greatly influenced by the electronegativity of the substituent R, which is ultimately responsible, on passing from the methyl to the phenyl and trifluoromethyl groups, for the weakening of the nucleophilic properties of the molecule as a whole. Indeed, whereas bis(trimethylsilyl)acetamide (LI, R = Me) reacts readily with methyl chloroformate, the phenyl analogue (LI, R = Ph) requires the presence of catalytic amounts of H_2SO_4, as in the reaction of disilyl-substituted amines. The disilyl derivative of trifluoroacetamide does not undergo this reaction at all.

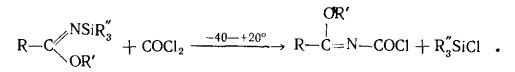
Carboxylic acid amides are known to be weaker bases than amines. Since silylation at the nitrogen atom lowers the basicity of compounds, the disilyl-substituted amides should be still weaker bases and hence should be less reactive in relation to chloroformates than the corresponding amines. The observed enhanced reactivity of disilyl derivatives of acetamide and benzamide can be accounted for by their interaction with chloroformates in the imidol form.



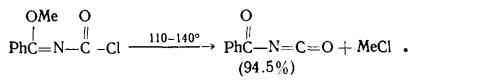
N,N-Diacylcarbamoyl chlorides[107,108]. In contrast to *N*-acyl-*N*-alkyl(aryl)carbamoyl chlorides, *N*-chlorocarbonylphthalimide (LIII), i.e. the first representative of *N,N*-diacylcarbamoyl chlorides, is formed only under very severe conditions, for example, in boiling pseudocumene on treatment of *N*-trimethylsilylphthalimide with phosgene:

On the other hand, *N*-trimethylsilylsuccinimide (LIV) reacts vigorously with $COCl_2$ and *N*-chlorocarbonylsuccinimide (LV) is decarboxylated under the reaction conditions to 2-chloro-Δ^1-5-pyrrolinone (LVI):

N-Trimethylsilylphthalimide reacts with methyl and phenyl chloroformates as well as $COCl_2$, undergoing cleavage at the Si–N bond and giving rise to the corresponding *N*-methoxycarbonyl- and *N*-phenoxycarbonylphthalimides (LVII, a and b):

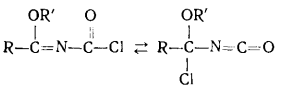


The thermal stability of the *N*-phenoxycarbonyl derivative of phthalimide is higher than that of *N*-chlorocarbonylphthalimide; it is decarboxylated only in boiling hexamethylphosphoramide (230–240°C).



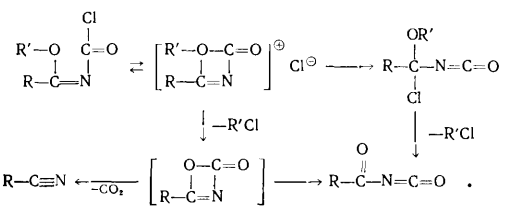
(g) *N*-Silyl-Substituted Iminoesters and Amidines

N-Silyl-substituted iminoesters proved to be much more stable than the initial iminoesters, which makes it possible to use them in reactions which had been previously difficult to control.

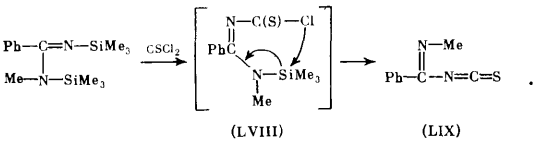


For example, it has been observed[109] that, when iminoesters are acted upon by phosgene, *N*-chlorocarbonyliminoesters are formed. The reaction of phosgene with *N*-silyliminoesters proceeds under incomparably milder conditions and leads to the formation of *N*-chlorocarbonyliminoesters in much higher yields[43,80,110]:

The *N*-chlorocarbonyliminoesters obtained are thermally unstable and tend to form acyl isocyanates on heating[43,80,110]:

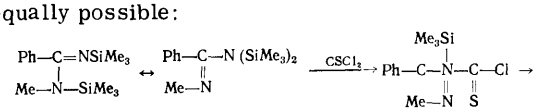


Apart from the intense absorption bands due to the C=N (1640 cm^{-1}) and C=O (1760 cm^{-1}) groups, the infrared spectra of *N*-chlorocarbonyliminoesters contain a weak absorption band due to the N=C=O group at 2252 cm^{-1}. The simultaneous presence of these bands in the spectra of compounds of this kind is explained[109] by the tautomeric equilibrium



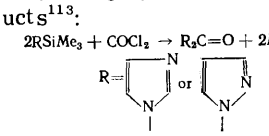
which is analogous to the familiar equilibrium of α-halogeno-substituted isocyanates[111]:

However, we believe that one cannot rule out the possibility also that *N*-chlorocarbonyliminoesters exist in the form of transitional "onium" complexes, which undergo the following reactions[43]:

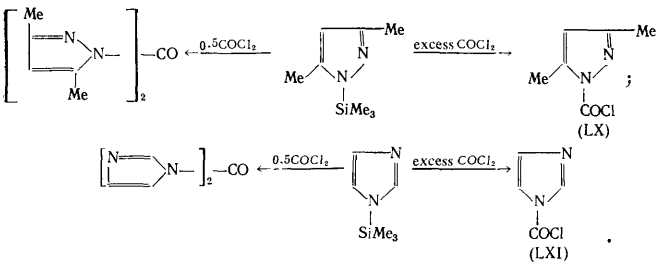


Having studied the reaction of *N*-methyl-*N*,*N*'-bis-(trimethylsilyl)benzamidine with thiophosgene, Barnikow and Ebeling[112] put forward the following mechanism for the formation of *N*-methylbenzimidoisothiocyanate (LIX):

(LVIII) (LIX)

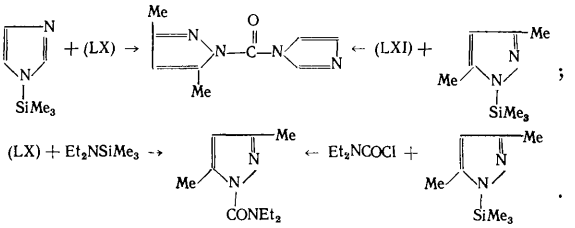


However, one should note that at least two other versions are equally possible:

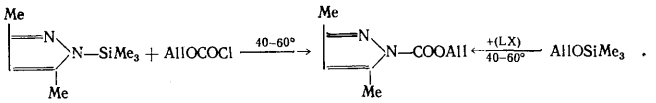


(LVIII) ↔ (LIX) .

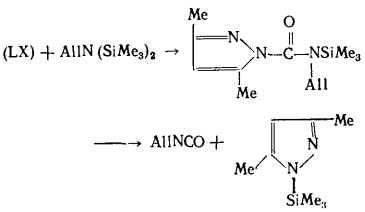
(h) *N*-Silyl-Substituted Azoles



As early as 1960, Birkofer et al. showed that *N*-trimethyl-substituted diazoles react almost quantitatively with phosgene at 0–20°C to form the corresponding acylation products[113]:



However, it was found that the nature of the final products is determined by the ratio of the initial reactants and the order in which they are introduced into the reaction:



Carbamoyl chlorides (LX) and (LXI) as well as Et_2NCOCl react with *N*-silyl-substituted azoles to form symmetrically and asymetrically constructed carbonyl compounds[90]:

In contrast to $COCl_2$ and carbamoyl chlorides, allyl chlorocarbonate is less reactive in relation to *N*-trimethylsilyldiazoles and react with the latter on heating:

The carbamoyl chlorides (LX) and (LXI) react with $AllN(SiMe_3)_2$ to form the corresponding urea, whose pyrolysis under the conditions of the synthesis leads to AllNCO:

The Etherates of Organoaluminium Compounds

V.P.Mardykin, P.N.Gaponik, and A.F.Popov

The literature data on the synthesis and chemical and physicochemical properties as well as the applications of the etherates of organoaluminium compounds are considered systematically and critically. The similarity and differences between the properties of the etherates and ether-free aluminium alkyls are demonstrated and the applications of the etherates of aluminium alkyls are discussed.
The bibliography includes 321 references.

I. INTRODUCTION

The application of organoaluminium compounds (OAC) have been greatly extended recently[1-6], but many difficulties arise in studies involving OAC due to their highly corrosive nature. A number of workers have found that many chemical reactions of OAC are characteristic of their etherates, which have been more readily available and are more convenient to handle and therefore can be used successfully instead of the ether-free OAC. Furthermore, examples are known where the use of etherates involves the manifestation by the latter of completely specific properties.

No attempts have been made to survey the literature data on OAC etherates, probably because the principal results concerning the specific features of these compounds have been obtained during the last ten years and their importance is still not adequately recognised[5,6]. The available reviews of OAC coordination complexes, including individual data on etherates, are based on results published up to the beginning of the 1960s [1,7-10] or are devoted to special problems (polymerisation[11,12], ligand exchange[13,14]). A monograph[15] deals with the literature up to 1966, mainly concerning various aspects of physicochemical studies on aluminium complexes; another publication[16] is descriptive.

The aim of the present review is to draw the attention of investigators to certain aspects of the chemistry of OAC etherates and to the possibility of their employment. The review deals systematically and critically with the literature data of the synthesis, physicochemical and chemical properties, and applications of the etherates of OAC complexes published mainly during the last decade. The properties of the etherates are compared with those for the ether-free aluminium alkyls. The influence of complex formation on OAC reactions is discussed. The tables present the constants of the most typical etherates among those which have not been included in the reviews mentioned above.

The conclusions reached can be used in considering many general problems of the chemistry of organometallic compounds, including the chemistry of complexes of aluminium alkyls with S-, N-, and P-organic donors.

II. THE ETHERATES OF ALUMINIUM TRIALKYLS

1. Composition and Structure

It has been established by various methods that the composition of the etherates usually corresponds to monomeric 1:1 complexes having the general formula $R_3Al.OR_2$. This composition is most likely for monofunctional ethers and aluminium alkyls with not unduly cumbersome side groups[7,8,17-23], but in the case of t-butyl compounds stoichiometry breaks down[23-25].

Bi- and poly-functional ethers can combine with several aluminium alkyl molecules. Dioxan[20-23,26], monoglyme[27,28], diglyme[28,29] and *p*-dimethoxybenzene[30] form stable 1:2 adducts; the 1:1 compounds are labile and exist in the presence of an excess of the donor. Acetals give rise to both 1:1 and 2:1 complexes[23,31]. The formation of complexes of triethylaluminium with dimethyl[29] and diethyl[31] ethers of ethylene glycol, the dimethyl ether of tetraethylene glycol[31], and polyethers with higher molecular weights[6,32,33] involves the attainment of an Al:O ratio of 1:1. However, the products formed are unstable and on heatin *in vacuo* split off part of their aluminium trialkyl and are converted into compounds of the type

$$-O-CH_2CH_2-O-CH_2CH_2-$$
$$\downarrow$$
$$AlEt_3$$

Complex formation with a single oxygen atom in such systems (ΔH = 10–10.5 kcal mole) reduces the electron donating properties of the neighbouring oxygen atom to such an extent that the next AlR_3 molecule is coordinated via at least one heteroatom, reducing still more the basicity of the oxygen which has not reacted[31,34]; this atom is the last to be coordinated (ΔH = −1.5–4 kcal mole^{-1} [31]).

Owing to steric hindrance, substituted poly(vinyl ethers) react with iso-Bu_3Al via only some of the ether groups[23]. Even in the presence of a triple excess of the acceptor, the degree of complex formation never reaches

50%. Furthermore, steric hindrance depends on the regularity of the polymer structure. It is noteworthy that, depending on the conditions (the state of aggregation, the concentration of the solution, temperature, etc.), polymeric ligands assume different conformations and possibilities are created for the occurrence of a wide variety of modes of coordination [23,32]. Systematic study of the formation of complexes by AlR_3 with polydentate ligands will assist in providing an answer to a number of questions concerning the specific features of the behaviour of such complexes in certain reactions (see, for example, Ivanov et al. [35]).

On the basis of spectroscopic data [17,18,36], the structure with C_S symmetry (as for $BF_3.OMe_2$) was postulated for the simplest etherate ($Me_2Al.OMe_2$). A number of infrared and Raman spectroscopic data [6,15] as well as X-ray diffraction [37] indicate an appreciable distortion of the tetrahedron in compounds of this kind. The molecule of triethylaluminium dioxanate has C_{2h} symmetry and the dioxan molecule exists in the chair form [38]. The coordination of the aluminium atom is closer to trigonal than tetrahedral, which can be accounted for by the electrostatic reduction of the electron pairs involved in the Al–C bond.

The coordination compounds of aluminium alkyls with electron-donating molecules, including ethers, readily conduct electricity [3,8,15,39] ($\kappa = 10^{-9}-10^{-7}$ m^{-1} cm^{-1} in solution in hydrocarbons and 10^{-6} in a pure state), which indicates the presence of the ionic complexes $[R_2Al.2OR_2]^+AlR_4^-$ as well as the neutral complex.

2. Methods of Synthesis

Etherates are obtained in high yields by the reactions

$$n\,RMgX + R_{3-n}AlX_n \xrightarrow{Et_2O} R_3Al \cdot OEt_2 + n\,MgX_2 \quad (n = 1-3)\ ^{1,6,7,40-42},$$

$$3LiR_3 + AlCl_3 \xrightarrow{Et_2O} R_3Al \cdot OEt_2 + 3LiCl\ ^{25,43,44}.$$

In principle, various ethers can be used as the solvent and the corresponding etherates can thus be obtained, but only the use of diethyl ether has been described. The etherates R_3Al (R = Me, Et, n-Pr, or n-Bu), [1,7,43,44] iso-Pr_3Al, [41] t-Bu_3Al, [24,25,41] $Al(CH_2SiMe_3)_3$, [42] and optically active tri-2-methylbutylaluminium etherate [5] have been obtained in this way.

The etherates are usually obtained by mixing trialkylaluminium with ether (exothermic reaction)—this was the method used to synthesise the adducts of Me_3Al, [17,18,29,36,45] Et_3Al, [18,20,21,46-48], and iso-Bu_3Al [22,46,48] with a series of dialkyl, alkylaryl, and cyclic ethers as well as $Et_2AlCH_2X.OEt_2$ (X = Cl, Br, or I) [49] and $(n\text{-}C_{10}H_{21})_3Al.iso\text{-}OPr_2$. [7]

When the etherate is acted upon by another ether which is a more powerful electron donor, a new complex is formed. The 2:1 adducts of trimethylaluminium with dioxan [26] and monoglyme [27] as well as compounds of triethyl-, [20,21] tripropyl-, and tributyl-aluminium [50] of various ethers have been obtained in this way.

According to patent data [5], the etherates of trimethyl- and triethyl-aluminium have been synthesised via the scheme

$$3NaAlR_4 + Al + 3Hg \xrightarrow{THF} 4R_3Al \cdot THF + 3NaHg.$$

A number of etherates have been obtained by adding the etherates of aluminium hydride to olefins on heating under pressure [1,6,7]:

$$AlH_3 \cdot Et_2O + 3CH_2{=}CHR \rightarrow (RCH_2{-}CH_2)_3Al \cdot OEt_2;$$
$$R = H,\ Me,\ Et,\ Pr,\ C_{10}H_{21}\ etc.$$

The above methods are simple in principle, but their application requires the availability of the organometallic compounds. A more convenient procedure involves treatment of alkyl halides in ether with metallic aluminium and magnesium:

$$2Al + 3Mg + 6RX \xrightarrow{ether} 2AlR_3 \cdot ether + 3MgX_2.$$

According to the latest data [51-56], the use of methods described previously [1,7] leads to the cleavage of the ether and the yield of the pure etherate is appreciably reduced [51,52]. Conditions preventing the ether cleavage have been found and triethylaluminium phenetolate has been obtained in 80% yields under these conditions [53,54]. However, a large excess of the ether is used to obtain a liquid reaction mixture and the final solution frequently contains organomagnesium compounds in addition to the OAC. It is more convenient to carry out this reaction in a hydrocarbon medium in the presence of 1.0 mole of ether per gram-atom of aluminium [21,50,55-57]. As a result, there is no need for vacuum distillation. The solution contains only the OAC and can be used directly, for example, in alkylation or polymerisation reactions, which greatly simplifies the experimental technique.

3. Physical and Chemical Properties

(a) Stability. With rare exceptions the etherates are colourless liquids which distil *in vacuo*. Compounds of the type $R_3Al.OR'_2$, where R, R' = Me or Et, can be distilled at atmospheric pressure. The adducts of trimethylaluminium and ethers containing more than one oxygen atom are solid crystalline substances soluble in hydrocarbons.

The heats of formation of the etherates can serve as an indication of their stability. Table 1 shows that, when complexes are formed by aluminium trialkyls with aliphatic ethers, the length of the groups linked to aluminium or oxygen has a small influence on the heat of formation. The stability of the complexes is greatly reduced on passing from aliphatic to aromatic ethers. In benzene [62] and toluene [63] Me_3Al does not form compounds with diphenyl ether. Experiments on the displacement of ethers from etherates [20] showed that the relative stability of the complexes with aluminium trialkyls increases in the sequence $Ph_2O < PhOR < R_2O <$ dioxan $<$ THF $< (PhCH_2)_2O$; if the position of dibenzyl ether is disregarded, this series is consistent with existing ideas concerning the electron-donating properties of ethers [64,65]. The displacement of tetrahydrofuran and dioxan by dibenzyl ether is associated with the high boiling point of the latter. According to ^1H NMR data for Et_3Al etherates at 20°C, the electron-donating capacity of dibenzyl ether is low (as for aromatic alkyl ethers [21]: $Ph_2O < (PhCH_2)_2O \leq PhOR < Bu_2O$. Ethers are readily displaced by nitrogen- and phosphorus-containing electron-donating molecules [26,43,66-69]. Exceptions are known, concerning mainly phenyl-containing donors [6,44,70] and sterically hindered aluminium alkyls [24].

The formation of the etherate stabilises the Al–C bond in straight-chain and branched aluminium trialkyls, which is reflected by a decrease of their tendency towards isomerisation [24] and racemisation [6] and also by an increase of their thermal stability (depending on the nature of the ether and the strength of the Al ← O bond, the decomposition temperature increases by 35–100°C). [22,48]

Apart from certain adducts with aromatic ethers [20,21,48,57,62] and polyethers [6,15,29,33], etherates do not usually dissociate into components. Dissociation is observed only

when the complexes are diluted by hydrocarbons [71]. On heating or irradiation, the etherates are cleaved, but the OAC undergoes further transformations under these conditions. The photochemical cleavage of etherates derived from aromatic ethers, aromatic alkyl ethers, and dioctyl ether [72] as well as thermal cleavage of etherates derived from dimethyl [53], diethyl [6,24], allyl propyl [17], and allyl phenyl [58] ethers, anisole [21,53-56,73] and its substituted derivatives [53], phenetole [21,53,54], diglyme [29], chlorex [58,74], tetrahydrofuran [24], and other cyclic ethers [4,75-77] have been described. The following reactions are therefore used to convert the etherates into free aluminium trialkyls [5,6,41]:

$$R_3Al \cdot OR_2 \xrightarrow[-R_2O]{BF_3 \cdot R_2O} R_2AlF \xrightarrow{RLi} R_3Al$$

$$R_3Al \cdot OR_2 \xrightarrow[-R_2O]{KF} (R_3Al)_2 \cdot KF \rightarrow AlR_3 \cdot KF + R_3Al \quad (R_3Al \cdot OR_2)$$

$$R_3Al \cdot OR_2 \xrightarrow{AlCl_3} R_2AlCl \cdot R_2O \xrightarrow[-R_2O]{LiH} R_2AlH \xrightarrow{olefin} R_3Al$$

$$R_3Al \cdot OR_2 \xrightarrow[-R_2O]{Na} NaAlR_4 \xrightarrow{AlCl_3} R_3Al \ .$$

The free R_3Al can be isolated from the etherate also with the aid of transolvation with ethers of polyethylene glycols and subsequent thermal dissociation of the complexes formed [6,15].

(b) Physicochemical constants. More or less complete sets of physical properties (boiling and melting points, heats of evaporation and formation, etc.) are available only for isolated examples of aluminium trialkyl etherates [15,45,78]. The simplest constants, such as specific gravity and refractive index, are rarely encountered in the literature [22]. A large number of etherates have been described in the studies quoted (Tables 2 and 3); only the most typical examples are presented here.

In addition, there is some information about the infrared [6,15,18,26,27,36,79,80], NMR, [13,19,39,63,71,81-87] and NQR [88] spectra, luminescence spectra [32], electrical conductivity [22,28,39,59,82], magneto-optical properties [46,89,90], optical rotation [23,91,92], inversion [93,94], dipole moments [3,65], and thermodynamic characteristics [51,78,95-99].

(c) Reactions with inorganic compounds. Me_3Al does not usually react with alkali metals, but in the presence of ether or tetrahydrofuran (THF) the reaction proceeds smoothly with formation of $MAlMe_4$. [5] Other R_3Al readily react both in ether and in a hydrocarbon. The etherates react in a very unusual manner with alkali metals or magnesium in the presence of unsaturated hydrocarbons. In this case interesting cyclic OAC are formed together with $MAlR_4$, [100-104] for example:

Free aluminium trialkyls react very vigorously with water (explosively); on the other hand, the corresponding etherates interact quietly [105], particularly in the presence of a solvent, an alkane and aluminium hydroxide being produced. For the molar ratio R_3Al : water = 2 : 1, hydrolysis at room temperature leads to the etherates of alkyl aluminoxanes [106]:

$$2R_3Al \cdot Et_2O + H_2O \rightarrow (R_2Al)_2O \cdot Et_2O + 2RH + Et_2O \ .$$

The yield of tetra-alkylaluminoxanes formed from the etherates is much higher (90%) than in the hydrolysis of free R_3Al (25–30%).

Aluminium trialkyl diethyl etherates begin to react with carbon dioxide at 100–120 °C. The final product is the dialkylaluminium salt, which readily hydrolyses to a

carboxylic acid[24,107-109]. When etherates are treated with CO_2 under pressure, a second Al–C bond is involved in the reaction[6,7]. R_3Al diethyl etherates react with sulphur dioxide to form the corresponding sulphinic acids. The reaction proceeds readily at −50°C via the three Al–C bonds; the yield of highly pure aluminium trisulphinate is quantitative[109,110]. The yields of carboxylic and sulphinic acids in reactions involving etherates are much higher than for ether-free aluminium trialkyls, since the etherates do not undergo side reactions.

Alkali metal hydrides and fluorides (except LiF) react with R_3Al and their etherates to form complexes of the type $M[AlR_3X]$, where X = H or F;[5,6] they do not react with chlorides and bromides. Ethers accelerate the reaction of lithium hydroxide with Me_3Al, which leads, depending on the reactant ratio to $[Me_2AlOLi].AlMe_3$ or $Me_2AlOLi.R_2O$. The ability to accelerate this reaction decreases with enhancement of the electron-donating properties: PhOMe > Et_2O > THF.[111] Triethylaluminium and its tetrahydrofuranate do not react with CaH_2; treatment with BaH_2 leads to $Ba[AlEt_3H]_2$.[112]

On interaction with the acid derivatives of many metals and metalloids, the OAC exchange the organic group for the acid residue with formation of organoelemental compounds:

$$R_3Al \cdot OR'_2 + EX_n \rightarrow ER_n + X_3Al \cdot OR'_2 \ .$$

In these reactions the etherates are as a rule more effective than ether-free aluminium alkyls. The synthesis of trialkylboranes (yield 87–98%),[1,7] alkylmercury compounds (80%),[7,113] dialkylthallium chlorides (57–63%),[7] mixtures of ethylsilanes (85%),[5,6,14] and trialkyl derivatives or gallium[114], antimony, and bismuth[1] has been described. The etherates are particularly effective in the synthesis of alkyl derivatives of phosphorus[6,7], lead[6], and tin[115,116].

Transition metal salts, which do not form stable alkyl compounds, are reduced by etherates to lower-valence compounds or to the free metal[51,117-119]. The reaction proceeds in general at a high rate and to a higher extent than in the case of ether-free trialkylaluminium[21,120-122]. In the presence of stabilising ligands (phosphines, 2,2-bipyridyl, olefins, etc.) it is possible to isolate the intermediates[5,123]. A multiplicity of transition metal compounds have been synthesised in this way, for example: $(Ph_3P)_3Co(N_2)H$;[5] $MeCu(PPh_3)_3.0.5Et_2O$;[124,125] $(Ph_3P)_2Ni.(C{\equiv}CPh)H$;[126] $R_2M(bipy)_2$[125] (M = Fe, Co, or Ni); $(Ph_3P)_4RuH_2$;[5] $MnAl_2Et_4L_4.4THF$;[127] $RCrCl_2.3THF$.[128,129]

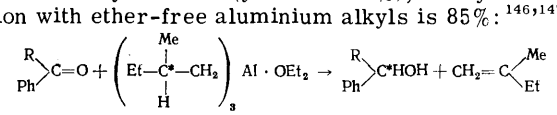
The reduction of chromium, molybdenum, tungsten, and manganese salts by aluminium alkyls in an ethereal medium in the presence of carbon monoxide has been proposed for the synthesis of the corresponding metal carbonyls (yield 85–86%),[3] which are otherwise difficult to obtain.

(d) Reactions with organic compounds. In contrast to the free tri-n-alkyl derivatives of aluminium, their diethyl etherates do not add to olefins. However, the etherates of aluminium trialkyls containing branched groups react with ethylene (under certain conditions, the yield of the product is quantitative)[24]:

$$(Me_3C)_3Al \cdot OEt_2 + 3C_2H_4 \rightarrow (Me_3C{-}CH_2{-}CH_2)_3Al \cdot OEt_2 \ .$$

Like aluminium trialkyls, the etherates catalyse the migration of the double bond in olefins when it is present in the centre of the chain[130]. Under the influence of $Et_3Al.OEt_2$, dodec-6-ene is converted into dodec-5-ene and dodec-4-ene. Hex-2-ene isomerises to hex-1-ene with a much higher yield than in the presence of ether-free aluminium alkyls[131]. The etherates inhibit the *cis–trans* isomerisation of straight-chain octenes, which proceeds under the influence of γ-rays in the presence of aluminium alkyls[132]. When ethylene and triethylaluminium are heated together, a mixture of olefins is formed; in this reaction the etherate gives rise predominantly to α-olefins[6].

Etherates react with molecules containing an active hydrogen atom similarly to free R_3Al (with liberation of RH) but more smoothly[5,133-135]. The reactions of etherates with imines[5] and carboxylic[109], thiocarboxylic[136], dithiocarboxylic[137], dimethylarsinic, and dimethylphosphinic[109,138] acids are therefore used to synthesise the corresponding dialkylaluminium derivatives. The reaction of trimethylaluminium with an excess of MeSH in pentane gives rise to $(MeS)_2AlMe$, while in ether the product is $(MeS)_3Al$ in a yield of approximately 100%.[139]



Strong electron donors displace the ethers from etherates, forming complexes with aluminium trialkyls:

$$R_3Al \cdot OR'_2 + D \rightarrow R_3Al \cdot D + R'_2O.$$

A number of such reactions have been achieved, where the donors (D) were NMe_3, PMe_3, and C_5H_5N,[1,7] *N*,*N*,*N*′,*N*′-tetra-alkylethylenediamines[27,66], 2,2′-bipyridyl[26,66,140], 1,10-phenanthroline[26,66], *N*-methylmorpholine and *N*,*N*′-dimethylpiperazine[26], *N*,*N*-dimethylaminomethoxyethane[27], iminotriphenylphosphine[67], R_nEO (E = S, N, or P),[43] and R_3EnPR_3 (E = Si, Sn, or Ge).[44,68,69] The electron-donating capacity of compounds and the rate of displacement decrease in the following sequence[43,68]: $Me_3NO > Me_3PO > Me_2SO > Et_2O$; $Me_3GeNPEt_3 > Me_3GeNPMe_3 > Et_2O \simeq Me_3SiNPMe_3 > Me_2SiPPh_3$.

Aluminium trialkyls in ether do not react with alkyl halides and the reaction with $ClCH_2OMe$ gives a low yield of ethers[141]. In the presence of ether (ether : $R_3Al < 1$) the above reactions proceed readily[74]. Etherates react with CCl_4 to form free radicals and vinyl chloride introduced into this mixture is converted quantitatively into a polymer[142].

The diethyl etherates of R_3Al behave in many instances as effective reducing agents for aldehydes and ketones. Chloral is reduced to trichloroethanol in 89% yield, cinnamaldehyde is converted into ethylstyrylmethanol (95%)[7] and benzophenone is converted into diphenylmethanol (94%).[143] Various alkyl methyl ketones react with $Et_3Al.OEt_2$, forming mainly tertiary alcohols, while free Et_3Al gives a mixture of secondary and tertiary alcohols[144]. The dialkyl etherates of triethylaluminium interact with benzylideneacetophenone via a 1,2-addition mechanism, the yield of the addition product being higher (82%) in the reaction of the di-isopropyl etherate than in the reaction of Et_3Al (69%).[145] The etherates of chiral aluminium trialkyls reduce alkyl phenyl ketones, forming optically active secondary alcohols (yield 91–97%); the yield in the reaction with ether-free aluminium alkyls is 85%:[146,147]

It has been established that, when optically active ethers are used, the aluminium alkyl does not lose the coordinated ligand in this reaction and gives rise to a six-membered transition complex with a pentacoordinate aluminium atom[147]. The nature of the solvent, aluminium alkyl, ether, carbonyl compound, etc. plays a major role in reactions of this type[148-156]. As a rule, on passing to THF and stronger electron donors (amines), the

yields diminish or the reaction does not take place at all [147,153,157-159]. Aluminium trialkyls behave differently in the reactions with anhydrides. The yield of ketene formed from $(CH_3CO)_2O$ increases when the diethyl etherate and particularly the tributylaminate is used instead of free R_3Al. [160]

In a mixture with HCN the etheral aluminium alkyls behave as stereoselective agents for the hydrocyanation of α,β-unsaturated ketones [161-163], for example, cholestenones. The same mixture cleaves the epoxy-groups of steroids, giving high yields of diaxial products. Etherates readily convert epoxyalkanes into the corresponding alcohols [76,150,151]; under certain conditions, triethylaluminium in ether condenses epoxyalkanes to 1,4-dioxan derivatives [164,165]. In contrast to aluminium trialkyls, the etherates interact only insignificantly with the oxygen–oxygen bonds of peroxides [166,167]. The reaction with hydroperoxides [40] proceeds even at 0–20°C, involving the active hydrogen atom and giving rise to organoaluminium peroxides, which are stable in solution for several hours. The diethyl etherate of tri-isobutylaluminium reduces benzonitrile exclusively to benzaldehyde, while free iso-Bu_3Al gives a mixture of the aldehyde and a ketone [168].

III. THE ETHERATES OF ALKYLALUMINIUM HALIDES

With the exception of fluorine-containing OAC, which do not form complexes with ethers [5,10,41], alkylaluminium halides form etherates with a stronger donor–acceptor bond than do aluminium trialkyls. The tendency towards complex formation increases with increasing electronegativity of aluminium: $Et_3Al < Et_2AlCl < Et_2AlBr < EtAlCl_2$. Using the ^1H NMR, [83] cryoscopic [62], conductimetric, and calorimetric [87] methods, a somewhat different OAC acidity series was found: $Et_2AlCl < Et_3Al < EtAlCl_2$; this is associated with the fact that Ph_2O is too weak a base to cleave the diethylaluminium chloride dimer. Diethylaluminium bromide and iodide, which exhibit a greater tendency towards dissociation, add to diphenyl ether [21,87].

Synthesis. These complexes can be obtained by the reaction involving a redistribution of ligands between the alkyl derivatives of sodium [3,169], magnesium [1], or aluminium [1,24] and aluminium halides in ether, for example:

$$n\,RNa + AlCl_3 \xrightarrow{Et_2O} R_nAlCl_{3-n}\cdot OEt_2 + n\,NaCl\ ;$$

$$n\,R_3Al + AlCl_3 \xrightarrow{Et_2O} R_nAlCl_{3-n}\cdot OEt_2\ ;$$

R=Et, Bu, or t-Bu

If the reaction of aluminium with alkyl halides is carried out in ether, a mixture of etherates is formed [21,57]:

$$2Al + 3RX \xrightarrow{R'_2O} R_2AlX\cdot OR'_2 + RAlX_2\cdot OR'_2\ .$$

Higher alkyl halides are cleaved during the synthesis [6,8]. Since ethers retard the cleavage reaction, it is possible to synthesise propyl- and butyl-aluminium sesquichlorides [5], propyl- and isopentyl-aluminium sesqui-iodides, and octyl-aluminium sesquibromides [1] in diethyl ether. Hydrocarbon solutions of diethylaluminium bromide and diethylaluminium iodide etherates have been obtained in 65–90% yield and by the reaction [21,55-57]:

$$2Al + Mg + 4EtX + 2D \rightarrow 2Et_2AlX\cdot D + MgX_2\ ;$$

D = Ph_2O, MeOPh, or EtOPh.

A number of etherates of alkyl aluminium halides have been synthesised by mixing the components and subsequent distillation [15,16,18,48,170] or crystallisation [29,171,172]. In the synthesis of their components account must be taken of the tendency of alkylaluminium dihalides towards disproportionation [173-175]; this tendency increases in the sequence $RAlI_2 < RAlBr_2 < RAlCl_2$: [172,174]

$$2RAlX_2 + \text{ether} \rightarrow R_2AlX + AlCl_3.\text{ether}.$$

The optimum Al : ether ratio can be various and is determined by the nature of the ether [6,172,176]. In this connection it was impossible to obtain the diphenyl etherate [176] and dioxanate [172] of ethylaluminium dichloride in paraffinic hydrocarbons. The dioxanates of ethylaluminium dihalides can be readily obtained from ethylaluminium sesquihalides [172]:

$$2Et_3Al_2X_3 + C_4H_8O_2 \rightarrow [EtAlX_2]_2\cdot C_4H_8O_2 + 2Et_2AlX\ .$$

The formation of Et_2AlX disproves the possibility of disproportionation. The method is of interest, because it makes it possible to obtain the individual compounds from the readily available mixture of alkylaluminium halides.

**With decomposition.

Properties. The majority of the compounds obtained are colourless liquids which can be distilled *in vacuo* and which do not ignite in air; the 2 : 1 complexes with dioxan and monoglyme are crystalline substances (Table 4). According to cryoscopic measurements [18], the etherates of alkylaluminium halides are monomeric. The 1 : 1 compounds of methyl- and ethyl-aluminium halides with di- and poly-functional ethers (dioxan [172], diglyme [29]) are more stable than the R_3Al compounds, and on heating *in vacuo* they split half the ether and are converted into 2 : 1 complexes. Diethylaluminium chloride adds to polyethylene glycol up to the ratio Al : O = 1 : 1, the organic molecule passing from the skew to the transoid conformation in the process [177-179]. 2 : 1 complexes are also

formed under certain conditions [178]. Owing to the presence of the CH_3 side group, polypropylene glycol is incapable of being fully "saturated" by the acceptor. The methylenealuminium compounds $C_2Al-CH_2-AlCl_2$ and $Cl_2Al-CH_2-Al(Cl)-CH_2-AlCl_2$ form complexes with two and three diethyl ether molecules respectively [171,180-182]; on heating above 120°C *in vacuo*, these complexes split off part of the ether with simultaneous disproportionation and polymerisation [171]. The physical properties of the etherates of alkylaluminium halides have been investigated to an even lesser extent than for the etherates of R_3Al. Apart from the data presented in Table 4, there is isolated information about the heats of formation [3,87,177,178], infrared spectra [15,18,178,179], NMR spectra [13,83,171,181-183], and magneto-optical properties [170].

The etherates of alkylaluminium halides show a tendency towards rupturing the C–O ether bond with liberation of the alkyl halide and the formation of alkoxy-compounds of aluminium. Allyl [184] and alkyl phenyl [53-56,73,118] ethers are particularly readily cleaved, while dialkyl ethers [53] and diglyme [29,185] are cleaved with more difficulty. The "stabilising effect" of dialkyl ethers is therefore less pronounced than in the case of R_3Al (the Et_2AlCl decomposition temperature increases from 160° to 170–180°C on formation of the complex with Bu_2O and Et_2O; on the other hand, alkyl phenyl ethers reduce this temperature to 130–135°C [48]). The tendency towards cleavage in the series of aluminium alkyls increases with increase of their acidity: $R_3Al < R_2AlX < RAlX_2$, [73,184] while for different X the tendency increases in the sequence $Cl < Br < I$. [21]

In contrast to free R_2AlCl and $RAlCl_2$, the diethyl etherates of alkylaluminium chlorides do not react with ethyl chloride and vinyl chloride [186], while their reaction with NaF and LiH (in the case of $R_2AlCl.Et_2O$) results in the formation of dialkylaluminium fluorides and hydrides respectively [1]. Alkali metals dehalogenate the etherates of R_2AlCl, sometimes with the cleavage of the ether and liberation of aluminium. The presence of aromatic hydrocarbons rules out side processes, which leads to the formation of the etherates of aromatic alkyl compounds of aluminium [6,187,188]. The etherates of alkylaluminium halides react with tin dichloride and tetrachloride to give a high yield of dialkylstannanes [189] and tetra-alkylstannanes [115] as well as dialkyltin dichlorides [6]. These etherates are used to synthesise various aluminoxanes [106, 190,191], including aluminosiloxanes [192]:

$$2R_2AlCl \cdot Et_2O + H_2O \rightarrow (RAlCl)_2O \cdot Et_2O + 2RH + Et_2O \ ;$$
$$R_2AlCl \cdot THF + R_2AlOLi \rightarrow (R_2Al)_2O \cdot THF + LiCl \ ;$$
$$RAlCl_2 \cdot Et_2O + 2R_3SiONa \rightarrow (R_3SiO)_2AlR + 2NaCl \ .$$

The interaction of methylenedialuminium compounds with aldehydes in tetrahydrofuran has been suggested as a method of synthesising olefins [193]:

$$RCHO + Br_2Al-CH_2-AlBr_2 \xrightarrow{THF} RCH=CH_2 \ .$$

Styrene, nitrostyrene, and vinylnaphthalene have been obtained in yields of 65, 60, and 80% respectively.

In contrast to hydrocarbon solutions of OAC and pure R_3Al, which give rise to a maximum in electrical conductivity on mixing with electron-donating molecules in proportions of 1 : 1, pure Et_2AlCl and $EtAlCl_2$ mixed with diethyl ether and tetrahydrofuran exhibit a maximum corresponding to the ratio Al-alkyl : ether 2 : 1. [39] On subsequent dilution with a hydrocarbon, the position of the maximum shifts, tending towards the 1 : 1 ratio. These results have not been explained satisfactorily.

IV. THE ETHERATES OF ORGANOALUMINIUM COMPOUNDS OF THE TYPE R_2AlY (Y = H, OR, NR_2, ETC.)

The etherates of these compounds are less stable than those described above; this is due to the competing interaction of R_2AlY molecules with one another, forming extremely stable associated species. Dialkylaluminium hydrides do not form stable adducts with ethers for this reason [62], but the existence of such compounds has been demonstrated by infrared spectroscopy [6,15] and calorimetric measurements [59].

Like the R_2AlH, their etherates readily add to multiple bonds, but in many instances this entails the formation of other products [194-199]. Thus the etheradduct Et_2AlH reacts with hexa-1,5-diene to form the etherate of diethylhex-5-enylaluminium [196]:

$$(H_2C=CH-CH_2)_2 + Et_2AlH \cdot Et_2O \rightarrow Et_2Al(CH_2)_4CH=CH_2 \cdot Et_2O \ .$$

In the absence of ether, a cyclic OAC is formed, giving rise to methylcyclopentane after hydrolysis [197,198]. In the presence of ether 1,1-dimethylindene interacts stereospecifically with di-isobutylaluminium hydride, forming a product with the *cis*-configuration, while in the absence of ether a molar mixture of the *cis*- and *trans*-isomers is obtained [200]. The reaction of the etherates of dialkylaluminium hydrides with alkenylacetylenes proceeds via two pathways: addition (as for the free R_2AlH) and metallation (as for the aminates of R_2AlH). [201] Two moles of OAC add to alkynes of the type HC≡CR in ethers [202,203]:

$$R'_2AlH + HC \equiv CR \rightarrow R'_2Al-CH=CHR \xrightarrow{R'_2AlH} (R'_2Al)_2CH-CH_2R \ .$$

With increasing basicity of ethers, the yield of product rises [203]. In octane and toluene only the first stage of this reaction occurs, while in triethylamine metallation takes place.

The introduction of a donor alters the reactivity of dialkylaluminium hydrides, probably as a result of the loosening of the Al–H bond, which increases with increasing strength of the donor [6,204]. In the absence of an ether, diazomethane reacts more effectively with the less associated R_3Al than with R_2AlH. In the presence of an ether, the Al–H bond is preferentially involved in the reaction [205]. Apparently this is why R_2AlH are frequently used as reductants in the form of etheral solutions. The alkyl and alkyl halide derivatives of certain elements (Be, Si, Sn, etc.) are reduced by dialkylaluminium hydrides in ether to the hydrides of these elements [6,206,207]. The reduction of optically active R_3SiX by the etherate of iso-Bu_2AlH takes place without change of configuration (X = OMe or OPh) or with its inversion (X = F, Cl, or SMe), depending on the nature of X. [208,209]

The diethyl etherate of di-isobutylaluminium hydride reduces epoxides quantitatively to primary and secondary alcohols [210]. The presence of stronger electron donors leads to an increase of the yield of the secondary alcohol, while pure iso-Bu_2AlH gives preferentially the primary alcohol. Di-isobutylaluminium hydride in ether reduces nitriles, carboxylic acids, esters, and *N*,*N*-disubstituted amides [6,211] to the corresponding aldehydes. In the presence of an excess of iso-Bu_2AlH amides are readily reduced to the amines. Ethereal solutions of R_2AlH can be used to hydrogenate nitrogen-containing heterocycles, for example, quinoline [211]. The reduction proceeds much more readily and in a higher yield than in the case of $LiAlH_4$.

On heating, dialkylaluminium hydrides cleave dialkyl ethers[53], tetrahydrofuran[75,212] and other cyclic ethers[75], diglyme[29], anisole[53], phenetole, and benzyl ethyl and allyl phenyl ethers[5,7] with formation of compounds of the type R_2AlOR'. Diphenyl ether[53] is cleaved above 200°C, while α,β-unsaturated ethers[213] are cleaved at temperatures as low as 25–35°C. Iso-Bu_2AlH reacts with alkyl allyl ethers as a rule at the double bond, giving rise to inner complexes[5].

The presence of a bond between aluminium and O, N, P, and S atoms greatly reduces the electron-accepting properties of aluminium alkyls, but does not eliminate the possibility of the formation of complexes by these compounds with ethers in many instances. Compounds having the composition $Et_2AlPPh_2.Et_2O$,[5,6] $Et_2AlN_2.THF$,[214] and several adducts of the type $R_2AlNR'_2$.ether[59,215] have been described. A number of etherates of alkylaluminoxanes (Table 5), which undergo polycondensation with formation of polyalkylaluminoxanes on heating, have been synthesised and characterised (Table 5).

V. THE ETHERATES OF UNSATURATED ORGANOALUMINIUM COMPOUNDS

Unsaturated OAC were discovered comparatively recently. Their synthesis in the form of etherates or aminates constitutes frequently the only possibility of isolating them in a pure form; many studies dealing with compounds of the vinyl, acetylene, allyl, and other series have been published.

The direct proximity of a C=C or C≡C bond to aluminium greatly reduces the electron accepting properties of aluminium alkyls owing to the interaction of the π electrons of the multiple bond with the vacant p orbitals of the aluminium atoms in a second molecule, which leads to the formation of a complex with a relatively high dissociation energy[224,225]. On the other hand, aluminium trialkynyls form very stable etherates, sometimes with two ether molecules[224,226]. This is due to a uniform distribution of electron density in the molecule, as a result of which each individual bond has a low polarity; for this reason, the associated species are unstable and are readily cleaved by ether. The foregoing considerations have been confirmed by infrared[227,228] and ^1H NMR[227–231] spectroscopy.

The principal methods for the synthesis of the etherates of unsaturated OAC involve the interaction of alkyl halides and aluminium trihalides with alkenylmagnesium halides[224,229,230,232], alkenyl-lithium[229,230], or sodium acetylides[224,227,228,233,234] in ether. In addition, the reactions of aluminium with vinyl[224] and acetylenic[3] organomercury compounds as well as complex acetylides of the type $MAl(C\equiv CR)_4$ (M = Li or Na) and $NaAlR_n(C\equiv CR)_{4-n}$ are used[224,226]. The etherates of aluminium acetylides are sometimes synthesised by displacing one ether by another in the sequence $Et_2O \rightarrow THF \rightarrow$ dioxan[227] and also by the exchange reaction of $Al(C\equiv CR)_3$ with triethylaluminium or aluminium trichloride in ether[233]. The synthesis of the etherates of allyl-, crotyl, and propargyl-aluminium sesquibromides from aluminium and the corresponding organic bromides has been described[5,232]. The dibutyl etherate and anisolate of but-3-enylaluminium have been synthesised from the Al/Mg alloy and 1-bromobutene[3] in butyl ether or anisole[232]. A method has been patented for the synthesis of the dioxanates, tetrahydrofuranates, and diethyl etherates of a wide variety of cycloalkenylaluminium compounds by the reaction of aluminium, dialkylaluminium hydrides (or $NaAlR_4$), and a conjugated diene in an ethereal medium[235–241].

With the exception of allyl derivatives[6,229,230,232], the etherates of unsaturated OAC are relatively unstable (Table 6). As a rule, compounds with a double bond are mobile liquids, while acetylides are solid crystalline substances. The triacetylides are monomeric in dioxan, while in benzene the molecular weight of $Al(C\equiv CBu)_3.C_4H_8O_2$ varies with concentration (the association factor of 0.7–1% solutions is 1.3–1.5).[224] The molecular weight of the diethyl etherate of trivinylaluminium corresponds to the monomeric form.

*With decomposition.
**C_6H_9 = cyclohexenyl.

The chemical properties of the etherates of unsaturated OAC are somewhat unusual, but in general they resemble those of the etherates of aluminium alkyls. They are unstable in air and are explosively decomposed by water[228,242]. The dioxanate of the triacetylide[224] is inert with respect to CO_2 up to 100°C, condenses with acetone and mesityl oxide, does not react with dimethyl sulphate and ethylene, but initiates the polymerisation of

olefins in combination with $TiCl_4$.[233] The etherates of unsaturated OAC react with various aldehydes and ketones to give the corresponding alcohols[6,227,228,243-245]. In contrast to the etherates of aluminium trialkyls, the etherates of allylaluminium compounds add readily (at 25 to 100°C) to olefins, forming 1 : 1 adducts[229,230].

By virtue of the electron-accepting effect of the vinyl and ethynyl groups, the polarity of the Al–R bond in compounds of the type $R_2AlC\equiv CR'$ and $R_2AlCR'=CHR''$ diminishes, which entails a diminution of its nucleophilic properties. The vinyl and ethynyl groups are therefore more reactive in the reactions of vinyl- and ethynyl-alkyl mixed compounds with carbonyl compounds[169,226,228,244,246], CO_2, alcohols[226,246], and halogens[246,247], which makes it possible to carry out the reactions selectively with the unsaturated group without affecting the alkyl group. Furthermore, the vinyl group in the compounds $R_2AlCR'=CHR''$ is more reactive than the alkyl group in R_3Al.[246] The reactivity of the ethynyl group depends on the nature of the reactants: the ethynyl group reacts more readily with bromine and isopropyl alcohol, while the alkyl group reacts more readily with iodine and CO_2. The reactivity of the groups usually increases in the sequence alkyl < alkynyl < alkenyl. Compounds of the type $R_2AlC\equiv CR'$ are partly associated even in the presence of an ether, while the ethynyl group is in the bridging position, which lowers its reactivity compared with the vinyl group.

VI. THE ETHERATES OF OTHER ORGANOALUMINIUM COMPOUNDS

In the first place mention should be made of the etherates of aromatic organoaluminium compounds for which there are about twenty publications. However, since in many chemical reactions (with I_2, alkyl halides, carboxylic acids, metal salts, ketones, aldehydes, nitriles, and esters) these compounds resemble alkyl analogues with rare exceptions (the reactions with α,β-unsaturated ketones[4] and diphenylacetylene[248]) and the data can merely supplement those described above, there is no point in presenting them here.

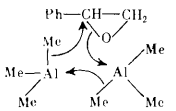
An extensive class of compounds $M[AlR_4]$.ether, where M is an alkali or alkaline earth metal and R = alkyl, alkenyl, alkynyl, H, OR, etc., is also known. The ether in these compounds is coordinated to the other metal cation and not to aluminium[112,249], but the coordination is significantly influenced also by the group linked to aluminium[224,250]. A series of such compounds, many of which are valuable alkylating and reducing agents, have been obtained and investigated[5-7,15,16,35,224,233,250-253].

VII. THE REACTIVITY OF ETHERATES

When OAC etherates are used instead of ether-free aluminium alkyls in various reactions, the characteristic features of the etherates are manifested: (a) the yield of the desired product is in many instances increased; (b) the reaction frequently proceeds via another pathway and many reactions are characteristic solely of etherates; (c) the reactivity of etherates depends on the strength of the donor–acceptor bond.

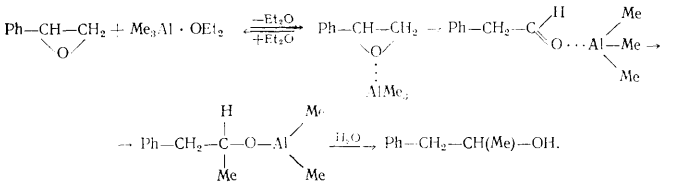
It has been shown frequently that coordination of the type of *at*-complexes leads to a weakening of the metal–carbon bonds[254], which is usually attributed to an increase of the amount of their ionic character (the carbanionic mobility of the alkyl groups[15,255-266]), which leads in its turn to an increase of the reactivity of the metal alkyl. An extensive generalisation of this postulate is apparently not feasible, since, together with an increase of the polarity of the Li–C,[256-258] Mg–C,[259,260] Hg–C,[261-263] and certain other bonds[263,264], coordination has been found to entail an acceleration of the homolytic rupture of the Ti–C[267-270] and V–C[271] bonds. Furthermore, it is known that the presence of electron-donating molecules stabilises transition metal–carbon bonds[272,273], but in many instances the opposite effect has been observed[268,274]. The results of ^1H NMR studies on OAC (enhancement of the electropositive nature of the aluminium atom)[63,82,83,275] and of conductimetric studies (a sharp increase of conductivity)[21,22,39] suggest the "ionic loosening" of the Al–C bond:

On the other hand, infrared spectra[30,36,228] and X-ray diffraction[38] indicate only a slight change in the nature of this bond.



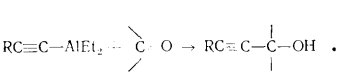
In order to explain processes involving organometallic compounds, it is insufficient to take into account only the polarity of the metal–ligand bond[256,276]. In most cases metal alkyls are associated, the associated species ranging from dimers to hexamers. Coordination to molecules of other compounds, accompanied by changes in the geometry of the organometallic compound, leads to the dissociation of the associated metal alkyls, the nature of which depends on the nature of the alkyls[256,259,277]. Furthermore, many metal alkyls have several comparatively readily accessible vacant orbitals, so that their complexes are capable of being coordinated to the reacting molecule, which results in a decrease of the activation energy in the transition state. Consequently the decisive factor in a particular reaction may not be the amount of ionic character, but the state of the coordination sphere of the metal. Having combined with the electron-donating molecule, the OAC lose or undergo a sharp reduction in their capacity for further coordination (the *d* orbital of aluminium is not readily accessible), so that certain reactions of the etherates of aluminium alkyls are slower or are altogether ruled out. These include primarily the reactions with CO_2, halogens, alkyl halides, H_2S, O_2, olefins, certain carbonyl compounds, nitriles, and all possible ligand exchange processes. However, the decrease of reactivity frequently entails an increase of the yield of the desired product[6,106,107-110,131,144,278]. For example, the presence of an ether or another electron donor has a favourable influence on the alkylation of the salts of various elements by organometallic compounds, which is usually attributed to the enhanced nucleophilic properties of the latter[255]. We believe that a more significant factor in the case of OAC is that the ether neutralises the strong Lewis acid (usually $AlCl_3$) arising during synthesis, reducing its dealkylating and electron accepting capacities, for example[115]:

$$4R_3Al.ether + 3SnCl_4 \rightarrow 3R_4Sn + 4AlCl_3.ether.$$



Without the involvement of an ether in this reaction, a mixture of organotin compounds alkylated to different extents is formed, since $AlCl_3$ forms stable complexes of the type $AlCl_3.R_nSnCl_{4-n}$, which prevent further alkylation of tin. This is confirmed by the finding that diphenyl ether, which has only a weak influence on the Al–C bond but forms stable complexes with $AlCl_3$, is effective in this reaction, and this is also true of tetrahydrofuran.

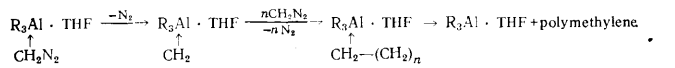
The different types of behaviour of etherates and ether-free OAC are frequently due to the different structures of these compounds[161,167,194,197,198,202,246]. In a pure state and



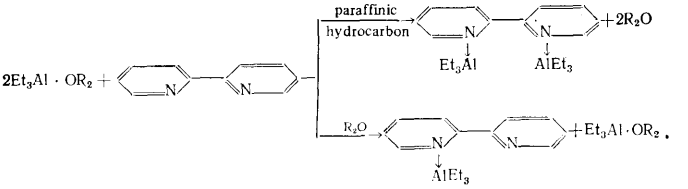
in solution in hydrocarbons aluminium alkyls as a rule exist in a dimeric form [3]. In this form they attack various molecules (aldehydes, ketones, α-olefins, etc.), forming many-centre intermediate complexes [143,148,167,279], for example, the complex of phenyloxiran (styrene oxide) and trimethylaluminium [150,151]:

A further transformation of this complex leads to the primary alcohol $PhCH(Me)CH_2OH$. Etherates, which are saturated monomeric molecules, are effective in such reactions when the ether is displaced by the reacting molecule. The resulting coordination complex reacts further in a manner which depends on the structure of the components. Thus phenyloxiran isomerises to phenylacetaldehyde and, reacting via the carbonyl group, gives rise to a secondary alcohol:

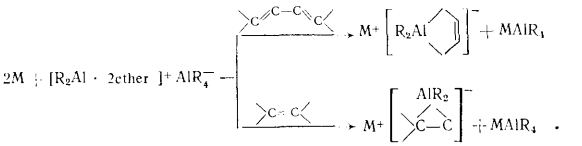
In mixed alkenyl- and alkynyl-alkyl compounds of aluminium the most reactive group (the unsaturated group) is in the bridging position in the absence of an ether [225,246] which lowers its reactivity. In complex formation the reactivity of the unsaturated group increases, so that, for example, the reactions with carbonyl compounds proceed more effectively in ether than in hexane and benzene [169]:



Thus acetone gives the corresponding alcohol in ether with a yield twice as great as in a hydrocarbon, while 2-methylcyclohexanone gives 96% of 2-methyl-1-propynylcyclohexanol in THF and 87% in benzene.



The properties of the whole class of various OAC etherates cannot be judged on the basis of individual instances (for example, $Et_3Al.OEt_2$). Apart from all other factors, the properties of etherates depend on the strength of the Al ← O bond [12,21,151]. For example, on reacting with the anisolate of R_3Al, diazomethane displaces anisole and the resulting adduct rearranges as in the case of the ether-free aluminium alkyl [205]:



The reaction with $R_3Al.THF$ takes place differently, because tetrahydrofuran is a stronger donor than diazomethane. As a result, diazomethane coordinates via the free *d* orbital (the fifth coordination site of aluminium) with its subsequent polymerisation via the mechanism

Apart from the strength of the donor–acceptor bond, the reactivity of etherates is influenced by the presence of an excess of the ether [7,140]. One must therefore treat with much caution conclusions concerning the reactivity of etherates if the study has been carried out in an ethereal solution. Thus the claim that the etherates cannot be used to synthesise the 2:1 complex of triethylaluminium with 2,2′-bipyridyl has been disproved [140]:

Finally, in connection with the tendency of the etherates of R_3Al to dissociate into the ions $[R_2Al.2ether]^+$ and AlR_4^-, a large group of reactions characteristic of such ions, with participation of alkali metals or magnesium and unsaturated compounds (aromatic hydrocarbons, olefins, and conjugated diolefins), has been observed [100–103]:

Ether-free R_3Al react quite differently, for example, in the case of butadiene we have

In the presence of stronger solvating agents (diglyme, hexamethylphosphoramide) the formation of butadienes polymerisation products was observed.

Thus the difference between the reactivities of etherates and ether-free OAC is due to the following factors: (a) the decrease of the degree of association of the aluminium alkyl; (b) the change in its geometry; (c) the increase in the degree of electrolytic dissociation; (d) the change in the polarity of the Al–C bond; (d) the ability of the ether to bind side products. The results of the reaction may depend on energy of the Al ← O bond in the etherate. Although some of these factors are interrelated and their effects overlap, in many cases individual factors are decisive. The problem of the dominant influence of one or several of the above factors must be solved in each specific instance, taking into account the specific features of the mechanism of the given reaction and the structure of the intermediate complex.

VIII. THE APPLICATIONS OF ETHERATES

The application of OAC etherates as components of polymerisation catalysts have been reported in reviews [11, 12]. Publications [48,280–285] recommending that etherates be used for a particular purpose in the polymerisation process have now appeared. The use of Et_2AlCl etherates [286,287] or of an ethereal solution of Et_3Al [288] to polymerise ϵ-caprolactam has been described. The ether adducts of aluminium trialkyls are promising in the polymerisation of epoxy-compounds [289–291], as catalysts [292,293], and as reagents [102] for selective hydrogenation and hydroalumination [200,294].

Etherates are fairly mild alkylating agents and this feature permits their employment in the synthesis of incompletely alkylated compounds of various elements: R_2Sn [189] and $RECl_2$ [295] (E = As, B, or P), the yield being appreciably higher than in the case of ether-free aluminium alkyls. Apart from the examples presented in the preceding sections, the use of the ether adducts of OAC

for the synthesis of organic derivatives of beryllium [14], cadmium [295], boron [14,296], aluminium [297-299], niobium and tantalum [42], and titanium [300] and also for the synthesis of alkylcylcopropanes [301], cyclopentanes [299], a wide variety of olefins [235-239,295], alcohols [4-7,224,239-241,302,303], ketones [4,158,304], and carboxylic, sulphinic, and sulphonic acids and their aluminium salts [5,305,306] is of interest.

Etherates are frequently used as the starting materials in the synthesis of other complexes. Many such examples are known among alkyl [24,26,27,43,44,66-69,140,190,307], alkenyl [232], alkynyl [224,227], and phenyl [308,309] OAC. The free aluminium alkyls can also be obtained from the etherates. It has been shown that iso-Pr_3Al and t-Bu_3Al can be most-simply synthesised from their etherates [41].

The heat treatment of various etherates is used to obtain high-purity aluminium (>99.99%), [310] diethylaluminium arylalkoxides [311], and organoaluminium polymers used as components of rocket fuels [312,313]. The employment of etherates makes it possible to increase the yield and purity of polyalkylaluminoxanes [314]. Finally, the formation of stable complexes by aluminium alkyls with ethers is used for their separation [172,315], analysis [3,105,316], and isolation from various hydrocarbon mixtures [317-321].

Extraction of Heteropolycompounds and Its Application in Inorganic Analysis

E.N.Dorokhova and I.P.Alimarin

Data on the extraction of heteropolycompounds published in the period 1965 - 1977 have been reviewed. The principal directions of study and recent achievements in establishing the regular features of extraction and investigating the mechanism of extraction have been examined. Data on the use of extraction to separate and determine elements in inorganic analysis have been given. The bibliography contains 211 references.

I. INTRODUCTION

The extraction of heteropolycompounds is recognised as a reliable method for separating a number of elements and for determining trace quantities in various materials. Up to 1965, a comparatively large amount of experimental material had been published on the optimum conditions for the extraction of molybdenum and, to a smaller extent, tungsten heteropolycompounds (this work has been reviewed[1]). In the last ten years, workers engaged in the extraction of heteropolycompounds have carried out theoretical studies devoted to the establishment of the regular features of the process and the mechanism of extraction, and also applied studies, which have lead to success in the development of methods for separating and determining a number of elements. The development of ideas in the extraction of heteropolycompounds is related to the latest achievements in the chemistry of heteropolycompounds[2-4]. A partial bibliography on problems of extraction can be found in Refs. 5–8. An important contribution to the development of the theory and practice of the extraction of heteropolycompounds has been made by combined schools of research workers[8-126]. The behaviour of heteropolycompounds in non-aqueous and mixed media has been described[28,88,98,127,128,129,130-132]. Methods have been developed for determining traces of elements in highly pure materials[14,25,35,101,117,122,123,133-156].

Until the nineteen-sixties, most studies of the extraction of heteropolycompounds were of an applied nature, and included the results of the empirical selection of the optimum conditions for the extraction of a given heteropolycomplex. In recent years there has been an increase in the number of papers devoted to the systematic study of the influence of various factors on extraction equilibrium, the determination of quantitative relationships, and the calculation of extraction constants. Attention is being paid to the composition of the compounds extracted, the nature of the chemical bonding in these compounds, the stoichiometry of extraction, and processes in the organic phase. Amines of high molecular weight, and other extracting agents, are being introduced in place of the traditional oxygen-containing solvents. A number of papers have been devoted to the extraction of ionic associates of heteropolyacids with dyes of various classes.

In analytical chemistry it is possible to distinguish a trend associated with the development of indirect methods for determining elements. These are based on the extraction of a heteropolycompound and the determination of the element from the concentration of the ligand after re-extraction and decomposition of the complex. A characteristic feature of studies in recent years is the introduction of physicochemical and physical methods in the study of extraction (infrared and NMR spectroscopy, radiometry, and polarography). Many analytical procedures recommend a combination of different methods. Extraction has been combined with chromatographic, luminescent, polarographic, atomic-absorption, and neutron-activation methods to determine and separate elements as heteropolycompounds.

II. FACTORS INFLUENCING THE EXTRACTION OF HETEROPOLYCOMPOUNDS

The extraction equilibrium in a system formed by a heteropolycompound and an organic solvent is determined by many factors operating simultaneously. The principal factors are the nature of the extracting agent, the nature and concentration of the heteropolycomplex being extracted, the nature and concentration of mineral acid in the aqueous phase, the presence of neutral salts, and temperature. The extraction equilibrium is reversible, so that the regular features of the extraction and re-extraction are the same. A universal characteristic of extraction is the equilibrium constant. Unfortunately, there are few experimental data on the determination of extraction constants and distribution coefficients. A number of papers give distribution coefficients (or extraction factors) for a definite acidity of the aqueous phase, and this makes it difficult to compare the data of different authors.

1. Nature of the Extracting Agent

Comparison of the properties and extracting power of more than forty solvents of different classes shows that extraction is influenced to a considerable extent by their

basic strength and dielectric constant, and also by their structure and miscibility with water. Attempts to obtain the dependence of the extraction properties of a solvent on any single factor lead to lack of agreement between the theoretical and experimental extraction series. If only the basic strength of the solvent is taken into account, the theoretical order is: nitrobenzene > methyl isobutyl ketone = methyl ethyl ketone > ethyl acetate > pentyl acetate, whereas the experimental order is: pentyl acetate < nitrobenzene < ethyl acetate < methyl isobutyl ketone < methyl ethyl ketone < isopentyl alcohol < octanol < butanol[77].

The extracting power of a solvent shows a correlation with the solubility of heteropolycompounds in it and the dielectric constant of the solvent. Murata and Kiba[107] divided solvents into three groups: those in which heteropolyacids are sparingly soluble (ϵ = 2–4), soluble (ϵ = 3–8), and highly soluble (ϵ = 5–18).

The relationship between the extracting power and solubility of heteropolycompounds has also been studied by other workers[76] (Table 1). Among oxygen-containing solvents, alcohols have the highest extracting power. They extract all known heteropolyacids, in both oxidised and reduced forms. Alcohols are also the best reagents for the extraction of ionic associates of heteropolyacids with dyes of different classes[17,30]. Cyclic alcohols are better extracting agents than aliphatic alcohols[8]. The action of esters and ketones is more selective. Increase in the length and degree of branching of the carbon chain leads to a decrease in extraction[8,10,90,104,157] (Table 2). The distribution coefficients of reduced molybdophosphoric acid in 1.5 M sulphuric acid solutions for extraction by isomeric alcohols and esters are given below[104]:

butanol	pentanol	butyl acetate	isobutyl alcohol	isopentyl alcohol	isobutyl acetate
279.0	259.3	0.42	70.1	85.1	0.28

Table 1. Distribution coefficients of tungstophosphoric acid between aqueous and organic phases (28 ± 1°C, initial concentration 6.1×10^{-3} M).[76]

Solvent	D	Basic strength*	Solubility, M	ε
o-Dichlorobenzene	$4.1 \cdot 10^{-5}$	—	—	—
Chloroform	$2.0 \cdot 10^{-5}$	—	—	4.8
Carbon tetrachloride	$2.0 \cdot 10^{-5}$	—	—	2.2
Benzene	$2.2 \cdot 10^{-5}$	—	—	2.3
Pentyl acetate	$1.1 \cdot 10^{-2}$	90	0.023	4.8
Nitrobenzene	$3.1 \cdot 10^{-2}$	28	0.0146	34.8
Ethyl acetate	$3.2 \cdot 10^{-2}$	84	0.031	6.0
Methyl ethyl ketone	1.5	77	0.171	—
Methyl isobutyl ketone	0.11	77	0.043	13.1
Octanol	2.2	—	0.073	—
Butanol	2.4	—	0.88	17.1

* The basic strength was measured from the displacement of the CH_3OD band in the infrared spectra.

The addition of an inert solvent to the extraction system decreases the extraction[1,90,94]. The use of solvent mixtures is convenient in practice, since in this case the separation of the phases is more rapid (because of the decrease in the miscibility with water), and the organic phase becomes heavier. In the selection of solvent in analysis, account is taken of the miscibility with water, the absorption of light in a given range of the spectrum, the selectivity, and the possible extraction of the ligand. Sometimes, in addition to the principal extracting agent, a solvent having a high solubility in water is added (acetone, propanediol carbonate[45]) to eliminate emulsified water from the extract. Amines, tributyl phosphate, and dimethyl sulphoxide are used only in mixtures with a diluent, polar or non-polar.

Table 2. Influence of the length of the carbon chain on the extraction ($\lg K_{ex}$) of heteropolyacids by alcohols (pH 1, $HClO_4$).[10]

Alcohol	Mo-P	Mo-Si
Propanol	3.29	—
Butanol	1.85	6.29
Pentanol	1.95	6.29
Hexanol	1.66	6.04
Octanol	0.63	5.64

2. Nature of the Compound Being Extracted

The extraction of heteropolycompounds depends on the nature of the central atom and, to a lesser extent, on the nature of the ligand. The decisive factors are the valency of the central atom (which is related to the charge of the anion) and its size. Extraction decreases with decrease in the valency of the complex-forming atom, that is with increase in the charge of the heteropolyanion (Table 3)[8,10,68,77]. In a series of heteropolycompounds of elements of identical valency, the extraction decreases with increase in the ionic radius of the element. The distribution coefficients of molybdophosphoric and molybdoarsenic acids under identical conditions[67] are given below:

	HCl, M	for Mo-As	for Mo-P
Butyl acetate	1.2	$10^{-2} \times 4.4$	100
Butanol + chloroform	0.35	$10^{-3} \times 1.4$	30

The distribution coefficients and extraction constants for molybdenum and tungsten heteropolyacids having the same central atom are of the same order of magnitude in all solvents studied[67,68,77,78] (Table 3).

Table 3. Distribution coefficients of molybdenum and tungsten heteropolyacids of silicon and phosphorus[77].

Solvent	Mo—P	W—P	Mo-Si	W—Si
Pentyl acetate	$1.9 \cdot 10^{-2}$	$1.1 \cdot 10^{-2}$	$2.26 \cdot 10^{-4}$	$1.7 \cdot 10^{-4}$
Nitrobenzene	0.21	$3.1 \cdot 10^{-2}$	$4.2 \cdot 10^{-3}$	$3.08 \cdot 10^{-3}$
Ethyl acetate	0.23	$3.2 \cdot 10^{-2}$	$8.5 \cdot 10^{-4}$	$3.9 \cdot 10^{-4}$
Methyl isobutyl ketone	1.08	0.11	$1.1 \cdot 10^{-2}$	$7.0 \cdot 10^{-3}$
Methyl ethyl ketone	1.58	1.5	0.42	0.18
Isopentyl alcohol	3.7	1.8	$1.1 \cdot 10^{-2}$	$1.06 \cdot 10^{-2}$
Octanol	9.6	2.2	$2.5 \cdot 10^{-3}$	$1.04 \cdot 10^{-3}$
Butanol	9.2	2.4	4.28	1.32

Comparison of the distribution coefficients calculated by different workers for specific conditions casts doubt on the above relationships. Under real conditions, however,

the distribution coefficient is influenced by many factors (the stability of the given heteropolycomplex, the nature of the mineral acid, the concentration of the ligand, and temperature), so that the breakdown of the relationships is only apparent (Table 4).

Table 4. Optimum concentration of hydrochloric acid for the extraction of molybdenum heteropolyacids, and their distribution coefficients[6].

Extracting agent	v/v_0	HCl, M	D	v/v_0	HCl, M	D
	Molybdophosphoric acid			Molybdosilicic acid		
Diethyl ether	1.7	1.0—1.3	1.65	1.0	0.1—4.0	0.01
Diethyl ether–pentanol (5:1)	4.2	0.1—1.5	410	4.2	1.5—4.0	410
Butyl acetate	0.3	0.1—1.0	620	1.0	3.0	0.6
Methyl isobutyl ketone	0.3	0.1—1.5	620	7.1	0.1—4.0	710
Chloroform–butanol (4:1)	1.0	0.5—1.5	1.2	1.0	0.1—2.0	0.01
	Molybdoarsenic acid			Molybdogermanic acid		
Diethyl ether	1.0	0.5	1.1	1.0	2.0	0.06
Diethyl ether–pentanol (5:1)	4.2	0.1—1.5	1.1	4.2	1.0—1.4	100
Butyl acetate	1.0	2.0	0.07	1.0	2.0	0.08
Methyl isobutyl ketone	0.3	0.1—1.5	620	1.0	0.1—2.0	620
Chloroform–butanol (4:1)	1.0	0.1—2.0	0.01	1.0	0.1—2.0	0.01

The composition of the heteropolyanion remains unchanged on transfer to the organic phase. This is indicated by the fact that the absorption spectra of aqueous solutions and re-extracts of the heteropolycompounds are identical[76], and is confirmed by chemical analysis of the organic phases[7,76,77], by the isomolar-series method[11], by radiometric measurements[158], and by other methods. The fact that the composition of the heteropolycomplex remains unchanged on extraction has made it possible to detect unsaturated complexes of molybdophosphoric acid, formed under certain conditions. At pH 1, complexes having a ratio Mo : P < 12 (even at a ratio Mo : P = 42 in the aqueous phase), extracted quantitatively by butyl acetate and heptanol, are formed[105]. Solutions of phosphate and molybdenum contain highly coordinated forms (Mo : P ≥ 18), extracted by a mixture of butanol and chloroform[13]. The preferential extraction of unsaturated complexes of phosphorus, silicon, and germanium by butanol, and of complexes having a higher molybdenum content by a mixture of butanol and chloroform, has been confirmed[83,85,87]. In some cases, decomposition of the mixed complexes on extraction and the transfer of the binary compounds to the organic phase have been observed[103,159].

Special comparative studies of the extraction of the α- and β-isomers of heteropolycompounds have not been carried out. It has been reported that there are no significant differences in the extraction of the isomers of molybdosilicic acid by dioctylamine[74] and isobutyl alcohol[129].

3. Nature and Concentration of Mineral Acid

In spite of lack of agreement in published data on the pH at which extraction starts, it can readily be seen that the greater the extracting power of a solvent and the ability of the heteropolycompound to be extracted, the lower the acidity of the aqueous phase at which extraction of the complex begins. It is for this reason that in most studies, the comparative extracting power is estimated from the pH corresponding to the start or completion of the extraction of the heteropolycompound. The dependence of the extraction on the acidity of the aqueous phase is represented in the form of distribution curves obtained by plotting the distribution coefficient D (or the percentage extraction, optical density of the organic phase, etc.) against pH, and also in the form of distribution diagrams obtained by plotting lg D against pH (Figs. 1 and 2). The distribution curve has three sections: in the first section, the extraction increases with increase in the acidity, the second section is the range of optimum extraction (D = const), and in the third section the extraction decreases with increase in the acidity. Published papers do not always give all sections of the distribution curve; most frequently, only the first two are given.

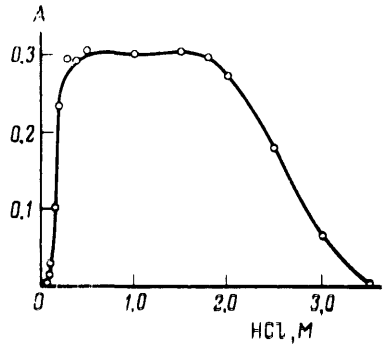

Figure 1. Dependence of the extraction of molybdoarsenic acid by butanol on the concentration of hydrochloric acid in the aqueous phase[67].

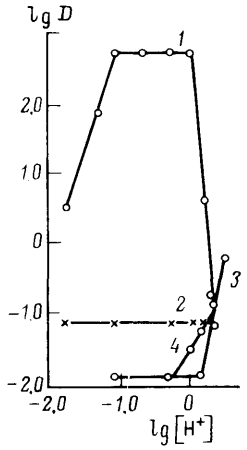

Figure 2. Distribution of molybdenum heteropolyacids between the aqueous phase and butyl acetate[6]: *1*) Mo–P, *2*) Mo–As, *3*) Mo–Si, *4*) Mo–Ge.

The functional pH dependence of the distribution constant on the first section of the curve has the form[1]:

$$\lg D = n \lg [H^+] + \text{const} \ .$$

Using this relationship, some authors attempt to determine the degree of participation of hydrogen ions in the reaction involved in extraction (Table 5). The results are contradictory, and this casts doubt on the justification of determining the number of hydrogen ions by this method. In fact, a priori assumption that the distribution constant remains constant is not completely correct in such a complex system as the heteropolycompound–acid–ligand–solvent system. Simon and Boltz[6] suggest that a correlation cannot be drawn between the slope of the $\lg D$–pH curves and the number of hydrogen ions. This method, which gives good results in the study of the extraction of hydrogen halogenometallates, cannot be used in systems in which, in the opinion of the authors cited[6], the solvent plays a definite role in the formation of the compound being extracted.

Table 5. Experimentally determined numbers of hydrogen ions n taking part in the extraction of heteropolyacids.

Extracting agent	Mineral acid	pH	n	References
Molybdophosphoric acid				
Butanol–kerosene	HCl	1.2—1.5	3	107
Propyl acetate	HNO_3	0.6—1.4	2	9
Propyl acetate	HNO_3	0—0.6	0	9
Butanol, alkyl acetates	$HClO_4$	1—2.5	1	10
Butyl acetate	HCl	1—2	3.3	6
Diethyl ether	HCl	0—1	2.6	6
Chloroform–butanol	HCl	0—1	2	6
Molybdosilicic acid				
Methyl ethyl ketone	HCl	0—2	2	77
Alcohols	$HClO_4$	0—1.5	2	9
Diethyl ether–pentanol	HCl	0—1	3.3	6
Molybdogermanic acid				
Diethyl ether–pentanol	HCl	0—1	3.3	6
Tungstophosphoric acid				
Methyl ethyl ketone	HCl	0—3	1	76
Ethyl acetate, methyl isobutyl ketone, isopentyl alcohol	HCl	0—3	2	76
Nitrobenzene	HCl	0—3	0.5	76

The nature of the anion of the mineral acid has little influence on the first section of the distribution curve, but has a considerable influence on the third section, that is in the range of acidity in which decomposition of the complex takes place. The decrease in the extraction takes place at a lower acidity in sulphuric acid than in nitric acid and other media. This phenomenon is not observed for the extraction of tungsten acids. The difference can be attributed to possible complex formation by molybdenyl ions with sulphate ions[67].

4. Presence of Neutral Salts and Ligand Ions

The influence of added electrolytes on the extraction equilibrium has not been studied systematically. The mechanism of the influence of electrolytes on extraction is not clear. In the opinion of some authors[6,68], the published quantitative characteristics of extraction are greatly distorted, since most measurements have been made at a high concentration of electrolytes, that is in the range in which the discrepancy between the concentration of the components and their activity is considerable. The impossibility of comparing the experimental data obtained by different workers is often due to the difference in the ionic strengths at which the experiments were carried out.

Data have been published on the influence of various ions on the degree of extraction of heteropolyacids in the analysis of specific materials for silicon, phosphorus, and arsenic[106,107,113–116,141,143,144,160]. The mechanism of the influence of neutral salts on the extraction equilibrium is apparently different in each case. Previously, the increase in the distribution coefficients of heteropolyacids at high salt concentrations was attributed to the salting-out effect[1], but recent data show that the influence of sodium, lithium, and caesium salts cannot be regarded as merely due to the change in the ionic strength[76,161–166]. Extracts of heteropolyacids of molybdenum and tungsten with silicon and phosphorus have been found to contain compounds in which the ratio of lithium to the heteropolyanion is 1 : 1.[76] The extraction of molybdophosphoric acid at pH 1–2 is more complete in the presence of sodium, potassium, and lithium chlorides than in their absence, because of the formation and extraction of sodium molybdophosphate having a ratio Na : P = 2.5.[166] Caesium can be extracted quantitatively from solutions of heteropolyacids as a consequence of exchange between caesium ions from the aqueous solution and hydrogen ions of the heteropolyacid from the organic phase[163].

The extraction of salts of molybdenum and tungsten is of particular interest, since all heteropolycompounds are formed and are stable in aqueous solutions only in a definite excess of the ligand ions. It is particularly important to take account of the possible extraction of the ligand in the development of indirect methods for determining an element via the ligand. Isopolymolybdates and isopolytungstates are extracted less effectively than the corresponding heteropolycompounds. Their extraction obeys the same regular features as the extraction of heteropolycompounds[8,105,110,167–169]. Isopolymolybdates are extracted most effectively by alcohols, and least effectively by esters and ketones[7,67,68]. Metatungstate is extracted only by butanol and methyl isobutyl ketone at a concentration of mineral acid $\geq$ 5 M.[68] The distribution of isopolymolybdate between the aqueous and organic phases depends on the nature of the mineral acid, because of complex formation by molybdenum(VI) ions with the anions of mineral acids.

Babko and coworkers[8] introduced the separation factor of molybdenum heteropolyacids and isopolymolybdates, equal to the ratio of their distribution coefficients, and calculated its values in the molybdophosphoric acid–sodium molybdate–solvent system. The greatest separation effect[8] is observed for extraction by esters ($\gamma > 1000$ for propyl acetate at pH 0.2), and the least effective differentiation is observed for alcohols ($\gamma < 50$ in butanol and pentanol). Isopolymolybdates are extracted effectively by solutions of amines of high molecular weight in various diluents[110,167].

5. Time and Temperature

It is considered that shaking a mixture of an aqueous solution of a heteropolycompound with an extracting agent for 1–2 min is sufficient for maximum extraction of the complex into the organic phase under given conditions[7,8,29,66]. It has been reported that equilibrium is established after shaking for 30 s [101] or even 20 s [105,170]. Other studies[66,67] have shown, however, that the percentage extraction of

molybdoarsenic and molybdophosphoric acids increases with increase in the duration of extraction to 30 min. When the extraction mixture is shaken for such long periods, separation of the phases into layers becomes unsatisfactory[170]. It is considered[104] that the time required for extraction equilibrium to be established depends on the initial concentration of the complex in solution. A study of the kinetics of the extraction of α-molybdosilicic acid by trioctylamine in toluene showed that the process is heterogeneous and involves several stages[42].

The influence of temperature on the extraction equilibrium has not been described. The choice of temperature has been determined only by the conditions of formation of the given heteropolycomplex[105].

III. EXTRACTION OF MIXED HETEROPOLYCOMPOUNDS

Considerable attention is being paid to the study of the extraction of mixed complexes, chiefly because of the possible extension of the range of elements whose determination is based on the formation of heteropolycompounds (particularly in the development of indirect methods of analysis), and also because extraction has proved to be an effective method for studying mixed complexes in solution. Mixed complexes are extracted less effectively than the corresponding binary compounds, although the regular features of extraction, noted above, are preserved. The best extracting agents are alcohols and methyl isobutyl ketone[90,104,106,159,171,172]; ethers and esters either do not extract mixed complexes at all or require a high acidity for extraction[31,159,173]. The process is sometimes accompanied by decomposition of the compound[103,159]. Mixtures of alcohols with esters or hydrocarbons extract a complex more effectively, the higher the concentration of alcohol. This is used in analysis to separate mixed complexes from binary complexes[15,47,56,58,60,82]. Trioctylamine extracts mixed molybdenum heteropolyacids quantitatively over a wide range of acidity[35,37].

Extraction depends on the nature and number of atoms replacing the ligand atoms in the coordination sphere. The greatest ability to be extracted is shown by mixed complexes of phosphorus with the maximum number of molybdenum atoms. When molybdenum(VI) is replaced by V(V), W(VI), Nb(V), Th(IV), Ti(IV), and Zr(IV), the ability to be extracted decreases. The extraction of molybdenum complexes of phosphorus decreases in the order Th(IV) > Ti(IV) > Zr(IV), and the form of the curves giving the dependence of the distribution coefficient on the ratio of chloroform and butanol in the extraction mixture is specific for each compound[15]. The greater the metal : molybdenum ratio, the less effective the extraction of the complex[90,159]. In the extraction of the compounds formed in the systems Ge(IV)–Mo(VI)–Cr(III) and P(V)–Mo(VI)–Cr(III), only compounds having a low chromium content are extracted into the organic phase[80,82].

The extraction of a number of mixed complexes of molybdenum and phosphorus has been studied, and the results have been used for the indirect determination of metals[56–58,60,61]. It is considered that the complexes have the compositions P : Nb : Mo = 1 : 1 : 11 for niobium, Ti : Mo = 2 : 11 for titanium, Ce : P = 2 : 1 for cerium, and Th : P = 2 : 1 for thorium. On extraction by alcohols and esters, the thorium and cerium complexes decompose[103], and molybdophosphoric acid passes into the organic phase. The extraction of vanadomolybdophosphoric acid having a ratio P : V : Mo = 1 : 1 : 11 has been most fully studied. The complex is extracted quantitatively by pentanol at pH 0,[48,50] by butanol at pH 1,[60] by methyl isobutyl ketone at pH 0.3,[106] by a mixture of pentanol and diethyl ether[49], and by trioctylamine in various diluents[35,37]. Methyl isobutyl ketone is used particularly frequently. The composition of the complex is preserved on extraction.

Phosphorus compounds are extracted much more effectively than compounds containing other central atoms[100,173].

IV. EXTRACTION OF REDUCED HETEROPOLYCOMPOUNDS

The structures of the yellow (oxidised) and blue (reduced) forms of heteropolycompounds are identical[2], so that it is to be expected that the principal regular features of extraction should be preserved after reduction of the complex.

Unfortunately, it is very difficult to compare published quantitative data, since the distribution data (distribution coefficients, percentage extraction) have been obtained under the optimum conditions for the extraction of the given complex, that is at definite concentrations of the ligand ions, mineral acid, and added electrolytes. This has led firstly to lack of agreement in the results obtained by different workers, and secondly to conclusions which are not fully justified, since the variations in the distribution data are small (under optimum conditions, extraction is practically quantitative) and can be attributed to experimental errors.

Alcohols are recognised as the most effective extracting agents for molybdosilicic acid blues. Isopentyl alcohol is usually employed. Although alcohols having a similar number of carbon atoms in the molecule have a greater extracting power, isopentyl alcohol is sparingly soluble in water, and this is a practical advantage. For molybdophosphoric acid, methyl isobutyl ketone is more frequently used[160,174], in spite of the fact that alcohols have a higher extracting power[7,175,176]. It has been reported that there is a decrease in the molar absorptivity with preservation of a high percentage extraction of acid blues by various oxygen-containing solvents, and that the stability of the complexes in the organic phase depends on the nature of the extracting agent[29,175]. Unfortunately, the works cited do not give the purity of the solvents used, or data on the extent of the oxidation of the heteropolyanion in the organic phase, so that there is some doubt as to whether the decrease in the value of $\bar{\epsilon}$ is due to the partial oxidation of the heteropolyanion blue by impurities in the solvents, particularly since data on the stability of reduced complexes in the organic phase do not always agree[7,176]. Thus the conclusion[175] that the properties of the compound formed in the organic phase depend on the nature of the extracting agent is not completely correct.

The transfer of reduced heteropolycompounds from an aqueous solution to an organic solvent is accompanied by a displacement of the absorption bands in the visible range of the spectrum. The displacement of the absorption maximum is generally hypsochromic (Table 6). In the extracts of heteropolycompound blues reduced by tin(II) salts, a second absorption maximum appears. The reduction products have been divided into two groups, according to their extraction behaviour[7,29]: a) those obtained by the action of "mild" reducing agents (ascorbic acid, 1-amino-2-naphthol-4-sulphonic acid, hydrazine sulphate, p-methylaminophenol sulphate), for which the spectrum of the extract gives one absorption maximum; and b) those obtained by the action of tin(II) salts, for which the spectra

of the extracts contain two absorption maxima. The position of the absorption band is independent of the extracting agent. It has been reported, however, that the absorption spectra of molybdophosphoric acid blues depend on the extracting agent[176]. The α- and β-isomers show different behaviour on extraction[29].

Table 6. Positions of the absorption maxima (nm) for reduced heteropolyacids in aqueous solutions and extracts after extraction by butanol.

Hetero-polyacid	Tin(II) salts		Ascorbic acid		1-Amino-2-naphthol-4-sulphonic acid		Hydrazine sulphate		Refs.
	water	butanol	water	butanol	water	butanol	water	butanol	
α-Mo—Si	740	630 and 720	720	720	—	—	790	720	32
β-Mo—Si	800	630 and 720	800	780	805	800	825	805	32
Mo—P	740	625 and 725	825	780	825	780	825	780	7
Mo—Nb—P	700	730	—	—	—	—	—	—	104

Amines of high molecular weight extract reduced heteropolyacids more effectively than oxygen-containing solvents[24,33]. Thus molybdosilicic acid blue is extracted quantitatively by trioctylamine at pH 1–1.6. The extraction is accompanied by a displacement of the absorption maximum; the magnitude of the displacement depends on the diluent and the nature of the heteropolyacid, but is independent of the nature of the amine[24,26]. Reduced mixed heteropolycompounds are extracted less effectively than the binary compounds.

In analysis, use is made of the extraction of heteropolyacids reduced in aqueous solution, and also of a heteropolycompound in the organic phase after its extraction in the non-reduced form[69,91-93,95,113,115,122-124,133,134,138,141,143,146,147,149,152-156,177-179]. Although the last procedure is more widely used, the process of reduction in organic solvents has been very little studied. The reduction of heteropolycompounds is more difficult in the organic phase than in aqueous solution. The use of tin(II) chloride, mixtures of iron(II) chloride[180] with ascorbic acid[137], and ferrocene[154] have been recommended.

In the reduction of the isomers of molybdosilicic acid, the formation of two-electron blues of β-molybdosilicic acid, and two- and four-electron blues of the α-isomer, has been observed in extracts obtained using dioctylamine in chloroform[73]. In the opinion of the authors cited[72], the four-electron β-isomer can exist only in aqueous solution, and not in the organic phase. Similar results were obtained in a study of the reduction of the isomers of molybdosilicic acid in oxygen-containing solvents[72]. The formation of intermediate products of the reduction of the α-isomer, containing tin(IV) as hetero-atom, is assumed[72].

The polarographic behaviour of heteropolycompounds in organic solvents has been studied in most detail. It is difficult to compare the results of polarographic studies by different workers, since the experiments have been carried out under different conditions (supporting electrolyte, nature of the electrodes, and solvent). The magnitude of of the reduction potential and the intensity of the signal are influenced by many factors, but the mechanism of their action is not clear[53,69-73,91-96,99,111,112,122,123,179,181].

V. EXTRACTION OF HETEROPOLYCOMPOUNDS BY AMINES OF HIGH MOLECULAR WEIGHT

The extraction of heteropolycompounds by amines has been comparatively little studied[24,33-42,72-75,109-172,182-185]. The use of amines is extremely promising in analysis, since the presence, in the molecule of the extracting agent, of the nitrogen atom, which is more basic than the oxygen atom, ensures the quantitative extraction of the elements as the heteropolycompounds. It is true that this is accompanied by a decrease in the selectivity of extraction. The theoretical study of the extraction of heteropolyacids as ionic associates is of interest. Amines in which the hydrocarbon chain contains less than seven carbon atoms are not used, because of their ready miscibility with water. Primary amines extract heteropolyacids with the formation of precipitates, which float at the interface between the phases, particularly in non-polar diluents. The formation of precipitates is also observed in extraction by secondary and even tertiary amines at low concentrations. In the opinion of some authors[24], secondary amines are better extracting agents than tertiary amines.

Extraction by amines is carried out over a wide range of acidity, restricted only by the protonation of the amine and the stability of the heteropolyanion. The extraction of reduced forms begins at a higher acidity[24,33]. The extraction without acidification, reduction of the heteropolycomplex by trioctylamine is observed[39]. The reduction of molybdophosphoric acid by other amines in sulphuric, perchloric, and hydrochloric (but not nitric) acids has been observed by Ivanov[182]. In the extraction of heteropolyacids by insufficient quantities of an amine in diluents having a low polarity, extraction of the complex in quantities greater than that corresponding to the stoichiometry of the ionic associate formed is observed[34]. This effect, which is characteristic of all strong acids, is probably due to the extraction of additional molecules of the heteropolyacids by the compound extracted.

No significant differences are observed in the extraction of the isomers of molybdosilicic acid[35,74]. The composition of the coordination sphere of the heteropolycomplexes remains unchanged on extraction. In the extraction of molybdoarsenic acid from hydrochloric acid solution, however, the ratio of the number of central atoms to the number of ligand atoms is 1 : 11.[74] It was suggested[74] that two forms of complex are extracted: a saturated form having a ratio As : Mo = 1 : 12, and an unsaturated form having a ratio As : Mo = 1 : 9. At the interface between the phases, the colourless unsaturated complex is partly converted into the yellow saturated complex.

The compounds formed on extraction are ionic associates[34,109]. The compositions of the products extracted correspond to the complete replacement of the protons in the non-reduced forms[34,37,109,182]. Fractional amine : heteropolyacid ratios have been found[74], however (from saturation curves). This is attributed to the possible existence of different protonated forms of the complexes in the strongly acidic media in which the experiment was carried out.

The nature of the absorption spectra of the organic phase is independent of the nature of the amine. In the opinion of some authors[24], the position of the maximum in the spectra of extracts of reduced molybdophosphoric acid depends on the reducing agent and the solvent used to dilute the amine.

The mechanism of the extraction of heteropolycompounds as their associates with dyes and quinolinol is probably similar to that for extraction by amines. Heteropolyacids

react with basic organic compounds (generally containing a nitrogen atom in the molecule) to give products sparingly soluble in water. From the nature of the bonding, they can be regarded as ionic associates. In some cases, these compounds dissolve in organic solvents which are immiscible with water, that is it is possible to extract the heteropolycomplex as ionic associates with organic bases (various types of dye, 8-quinolinol). The use of dyes as extracting agents in analysis is promising, since most dyes have high molar absorptivities. The compounds of molybdophosphoric acid with a number of dyes (Crystal Violet, Methyl Violet, Malachite Green, Iodine Green, Safranine, Rhodamine, etc.) are extracted by hydrocarbons, alcohols, and ketones[17,18,22,23,25,59]. The compounds of molybdosilicic acid with dyes of the triphenylmethane, xanthone, and antipyrine series are also soluble in alcohols and ketones, but are not extracted by hydrocarbons and nitrobenzene[30]. Molybdoarsenic acid reacts with dyes to form compounds which can be extracted by alcohols and ketones[16].

Alcohols and ketones, particularly the aromatic and cyclic compounds[17,30], and propyl acetate, are regarded as the best extracting agents for the ionic associates formed by heteropolyacids with dyes. Extraction is sometimes accompanied by flotation at the interface between the phases[30,18]. The extraction of ionic associates takes place in a definite range of acidity, which is broader than that for the extraction of heteropolycomplexes by oxygen-containing solvents. According to some authors[17], the ionic associates of molybdophosphoric acid are extracted at pH 1.3–1.5; according to others[59], the ionic associate of the same acid with Rhodamine B, $[RhB]_3^+[Mo\text{–}P]$, is extracted at the pH of formation of the complex without additional acidification. The same is observed in the extraction of the reduced molybdophosphoric acid by Safranine T.[25] As in the case of extraction by amines, the acidity range is apparently restricted by the stability of the heteropolycomplexes.

The compositions of the compounds formed by molybdosilicic acid with dyes depend on the nature of the dye: the molecule of the molybdosilicic heteropolyacid adds on four molecules of Rhodamine 6G and three molecules of Methyl Violet[30]. 8-Quinolinol also reacts with molybdophosphoric acid to form a compound which is sparingly soluble in water but soluble in oxygen-containing organic solvents[19]. The ability of the compound formed by 8-quinolinol with molybdophosphoric acid to pass into the organic phase decreases in the solvent order[79]: nitrobenzene > carbon tetrachloride > chloroform, that is the order coincides with the order of extraction of the heteropolycomplex in the absence of quinolinol[79]. It is suggested that the compound $[PMo_{12}O_{40}](HOx)_3$, where Ox = 8-quinolinol, is formed.

VI. MECHANISM OF THE EXTRACTION OF HETEROPOLYCOMPOUNDS

Various suggestions have been made regarding the mechanism of the extraction of heteropolycompounds, but the experimental material available up to the nineteen-sixties did not make it possible to give preference to any of these[1]. It is now possible to exclude from the number of hypotheses the suggestion that there is physical distribution of the heteropolycompound between the aqueous and organic phases. The solubilities of heteropolycompounds in water and organic solvents are commensurate, so that the distribution coefficient for a physical distribution mechanism should be ~1, which is not confirmed by experimental data. Experimental observations also do not confirm the hypothesis of an oxonium mechanism of extraction by oxygen-containing solvents, according to which heteropolycompounds are extracted as alkylsubstituted oxonium salts, the so-called etherates. In this case the extraction should take place in a strongly acidic medium, whereas the extraction of heteropolycompounds has been reported even at pH 3–1.

At the present time, two mechanism of extraction, based on the assumption that the heteropolycompound reacts with the extracting agent, are being discussed. According to the donor–acceptor mechanism, extraction is accompanied by the formation of a coordination compound between the molecule of the organic solvent (electron donor) and the heteropolyanion (electron acceptor). The formation of the coordination compound involves the oxygen, nitrogen, or phosphorus atoms of the organic solvent and an atom of the ligand of the heteropolycomplex, in particular molybdenum, which in this case has a coordination number equal to eight. According to the hydrate–solvate mechanism, the reaction of the solvent with the heteropolycompound involves its cationic part. For the extraction of heteropolycompounds by amines of high molecular weight and in the form of compounds with dyes, the ion associate mechanism and anion exchange are also being discussed.

The reaction between heteropolycompounds and the solvent is indicated by changes in the absorption spectra in the visible, ultraviolet, and infrared ranges, and in the PMR and NMR spectra. The spectra of extracts of molybdophosphoric acid show a maximum in the range 308–320 nm;[5,9,109] the same maximum is observed when molybdophosphate is formed in aqueous organic media[28,130]. In the spectra of extracts of tungsten heteropolyacids, the absorption maximum is displaced by 10–15 nm.[68,76,108] In the extraction of the reduced forms, a hypsochromic shift of the absorption maxima in the visible range is observed. The PMR spectra show the chemical shifts and the change in the width of the lines due to water, and also the chemical shifts of the signals of the proton-containing groups of the solvent[83,86,186].

The changes in the absorption spectra are not always interpreted correctly, however. In the opinion of some authors[24,25], the hypsochromic shift of the absorption maximum in the spectra of the extracts of reduced heteropolyacids is due to the donor–acceptor interaction of the molybdenum(VI) atom of the heteropolyanion with the oxygen atom of the solvent. The changes in the spectra might have been due to other factors, however. Thus a change in the oxidation state of the heteropolyanion leads to a change in the absorption spectrum. The products of the attachment of from one to six electrons to molybdosilicic acid differ in the positions and intensities of the absorption band maxima[187]. Differences are also observed in the absorption spectra of the products of the reduction of α-molybdosilicic acid by two and four equivalents of tin(II) chloride or oxalate[29,75].

Changes in the spectra may also be due to a change in the degree of protonation of the heteropolyanion, as shown by a number of workers[188]. The protonation of the sextuply-charged α-molybdosilicate blue leads to a bathochromic shift of the absorption maximum by 60–70 nm, whereas for β-molybdosilicate, a hypsochromic shift of 80–100 nm is observed. Moreover, tin(IV) evidently takes part in the formation of intermediate compounds in the reduction of heteropolycompounds by tin(II) salts. The stabilisation of intermediate mixed compounds may also lead to changes in the absorption spectra of extracts, compared with those of the aqueous solutions. The suggestion

that there is donor–acceptor interaction between the heteropolyanion and the oxygen atom of the solvent, based on the displacement of the bands in the infrared spectra in heteropolyacid–ketone systems[86], was found to be unjustified. It was later shown that the displacement of the bands is due to the formation of new compounds in the system, including alkyl derivatives of benzene[186].

In the opinion of Lebedeva and Vanchikova[83,84,87], evidence in support of the donor–acceptor mechanism of extraction of heteropolycompounds is provided by data obtained in the study of the solvation of molybdenum and tungsten heteropolycompounds of phosphorus, silicon, and germanium by NMR and PMR spectroscopy. According to their observations, the extraction of the heteropolyacids of silicon and phosphorus takes place by different mechanisms. In the presence of an organic solvent, the anionic part of the heteropolycomplex is solvated, whereas in an excess of the solvent, the cationic part is also solvated. The donor–acceptor mechanism has been used[83,84,87] to explain various regular features of the extraction of saturated and unsaturated molybdenum heteropolycomplexes, and also the differences in the extracting power of oxygen-containing solvents. Thus the greater extracting power of alcohols can be attributed to their greater solvating power, since they can act as both electron donor and proton donor; esters and ketones, however, exhibit only electron-donor properties.

Most of the regular features of the extraction of heteropolyacids can be described satisfactorily on the basis of the hydrate–solvate mechanism of extraction of strong acids. The participation of the functional groups of the organic solvents in hydrogen bond formation is indicated by the displacement of the bands due to the stretching vibrations of the OH bonds in butanol and the C = O bonds in propyl acetate towards lower wavenumbers (by 170 cm^{-1} and 40 cm^{-1} respectively) in the infrared spectra of the extracts[9]. In Ivashkovich's opinion[9], the increase in the extraction of molybdophosphoric acid with increase in the acidity of the aqueous phase, that is with suppression of the acidic dissociation of the complex acid, indicates the possible existence of a hydrogen bond between the hydrogen ions of the heteropolyacid and the oxygen atom of the solvent. This gives an associate which is extracted into the organic solvent by a hydrate–solvate mechanism. The formation of an ion pair between the triply-charged anion of molybdophosphoric acid and a solvated hydroxonium ion is assumed by a number of authors[76,77,107,159]. Simon and Boltz draw an analogy between extraction systems of the type iron(III)–hydrochloric acid–organic solvent and the heteropolyacid–organic solvent system; for molybdophosphoric acid, the equation for the reaction involved in extraction should be written in the form[6]:

$$3H(H_2O)\,(S)_x^+ \cdot Cl + [PMo_{12}O_4]^{3-} \rightleftarrows 3H(H_2O)\,(S)_x^+ \cdot [PMo_{12}O_{40}]^{3-},$$

where S represent the solvent.

For the description of the same process, with the assumption that a hydrated heteropolyanion is present in the aqueous solution, Ivashkovich[9] proposed the equation

$$[PMo_{12}O_{40}]^{n-} \cdot m\,H_2O\ (aq) + n\,H^+ \rightleftarrows H_n[PMo_{12}O_{40}]\,m\,H_2O\ (aq) + q\,S \rightleftarrows \rightleftarrows H_n[PMo_{12}O_{40}] \cdot m\,H_2O\,q\,S.$$

A similar equation for extraction has been put forward by other workers[10].

Using the equations for extraction and generally accepted techniques, various authors have tried to determine the solvation number, that is the number of molecules of the solvent taking part in the formation of the ion pair (Table 7). The results are contradictory, and this casts doubt on the justifiability of determining solvation numbers in this case by the usual methods. In fact, in extraction by mixtures of an extracting agent and inert diluents of different composition, the changes in the dielectric constant of the extracting agent are usually not taken into account. It has been shown[78] that the increase in ϵ with increase in the proportion of tributyl phosphate in its mixtures with chloroform leads to an increase in the dissociation of the ion pair in the organic phase, and in the final analysis to a value of the solvation number which is too high. This possibly explains the value of the solvation number, equal to six, found in a study of the tungstophosphoric acid–tributyl phosphate system[189].

Table 7. Experimentally determined solvation numbers m.

Solvent	Medium	m	References
	Molybdophosphoric acid		
Any solvent	HCl	6	91
Propyl acetate	pH 0.3; HNO_3	8	9
	pH 2.0; HNO_3	6	9
Alcohols	$HClO_4$	5	10
Tributyl phosphate		8—9	87
Esters, ketones		0.26—5.3	186
Tributyl phosphate		3	78
	Molybdosilicic acid		
Alcohols	$HClO_4$	8	10
Tributyl phosphate		3	78
		12	87
Dibutyl sulphoxide		6	190

Tributyl phosphate	HNO_3	6	189
»		3	78
	Tungstosilicic acid		
Tributyl phosphate		3	78

The values obtained for the solvation numbers, and also the numbers of hydrogen ions involved in the reaction (Table 5), have been used to calculate the extraction constants[10,77–79,97]. The values of the constants found by different authors naturally do not coincide. However, the extraction constants and distribution coefficients found under the same conditions can be used to estimate the comparative extracting power of solvents or the extraction of different heteropolycompounds, so that their determination is undoubtedly necessary.

Various reactions may take place in the organic phase containing extracted compounds, Lakshmanan[77] showed that ion pairs dissociate in nitrobenzene with the removal of the solvated proton. This provides evidence in support of a hydrate–solvate mechanism of extraction.

The differences in the extraction of heteropolyacids having different central atoms are readily explained by the hydrate–solvate theory: the greater the charge of the heteropolyanion, the less effectively it should be extracted. This is confirmed by experimental data (Table 3). The decrease in the extraction of mixed heteropolycompounds compared with the binary compounds can also be understood, in view of the increase in the charge of the heteropolyanion when the molybdenum(VI) atom is replaced by an atom of lower valency (vanadium(V), niobium(V), titanium(IV), etc.). The suggestion that the decrease in

extraction is due to steric hindrance[31] is apparently not fully justified, since the replacement of one atom by another in the coordination sphere has no significant influence on the size of the anion, and the structure of the complex remains unchanged.

Contradictory views have been put forward on the comparative extraction of reduced and non-reduced forms. From the hydrate–solvate mechanism of extraction, a decrease in extraction on reduction should be expected, since the charge of the heteropolyanion increases. According to some authors[19], molybdophosphoric acid blue is extracted more effectively than the yellow form, and this was attributed to a decrease in the acidic dissociation of the compound and a decrease in the hydration of the anion in the aqueous phase. As noted above, however, the conditions under which the extraction of the two forms was studied were not identical, so that in this case, conclusions cannot be reached regarding the comparative extraction of the complexes. The hydrate–solvate mechanism of extraction of heteropolycompounds is confirmed indirectly by the fact that the α- and β-isomers are extracted to practically the same extent (the charges of the two forms are identical).

The same ideas can be used to explain the low value of the extraction factor for isopolymolybdate ions, which carry a high charge (hepta- and octamolybdates). The complex dependence of the distribution coefficient of molybdenum(VI) on the concentration of hydrogen ions and molybdate in the aqueous phase agrees with the suggestion that molybdate solutions contain polymeric species, the composition and charge of which are determined by the concentration conditions and pH.

Extraction by amines can most probably be represented by the following scheme: protonation of the amine, formation of an ionic associate of the heteropolyacid and the mineral acid with the amine (neutralisation), extraction of ionic associates into the organic phase, ion exchange between the mineral acid and the heteropolyacid, and dissociation of the ionic associate in the organic phase. The first attempt to obtain the quantitative characteristics of the extraction equilibrium in a heteropolyacid–amine system was made by workers[109] who determined the composition of the compound extracted in the extraction of α-molybdosilicic acid by tri-iso-octylammonium nitrate in dichloroethane and suggested that the compound is dissociated in the organic phase. From a study of the distribution of the heteropolycomplex between the aqueous and organic phases, they proposed the following equation for the extraction:

$$H_4[SiMo_{12}O_{40}]\ (aq) + 4R_3NHNO_3\ (org) \rightleftarrows \{[SiMo_{12}O_{40}]\ (R_3NH)_{4-n}^{n-}\}\ (org) + n\,R_3NH^+\ (org) + 4NO_3^-\ (aq) + 4H^+\ (aq).$$

From the relationship between the equilibrium concentrations of the components and the stoichiometry of the compound extracted, other workers[109] obtained an equation which made it possible to determine the stoichiometry of the dissociation of the complex in the organic phase, and they calculated the conditional extraction equilibrium constant. According to their calculations, the ionic associate dissociates with the removal of one protonated amine particle; the equilibrium constant depends on the concentration of acid in the aqueous phase, because of the protonation of the heteropolyanion.

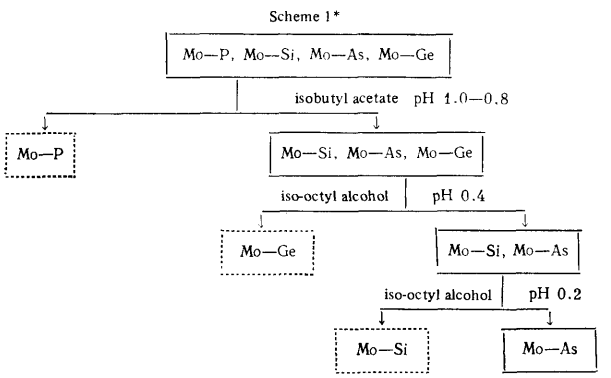
Suggestions[109] regarding the nature of the bonding, composition, and behaviour of the ionic associate in the organic phase were confirmed by studies of the extraction of molybdosilicic and vanadomolybdophosphoric acids by trioctylamine in various diluents[34,36,37,41]; infrared spectroscopy and isolation in solid form established that the compounds extracted are ionic. The dissociation of the associates was confirmed conductometrically[36,41].

The nature of the diluent plays an important part in extraction by amines. The extraction is influenced by the dielectric constant and solvating power of the solvent[37,38]. Solvation may involve the cationic part of the heteropolycomplex in the case of a diluent having nucleophilic properties (benzene, toluene), or the anionic part in the case of a diluent having electrophilic properties (dichloroethane). The extraction constant and the distribution coefficient should reflect the overall result of the electrostatic and solvating effects of the diluent and be determined by the contributions made by each. A specific feature of heteropolycompounds is that the charge density on the anion is very low (because of the large size of the anion), so that solvation of the anionic part of the complex has a low probability.

A method has been proposed[182] for calculating the overall constant for the extraction and formation of heteropolyacids by amines, based on published data on the polymerisation of molybdenum(VI) in solution:

$$H_3PO_4 + \frac{3}{2}\,H_4Mo_8O_{26} + 3BHNO_3 \rightleftarrows (BH)_3PMo_{12}O_{40} + 3HNO_3 + 3H_2O,$$

where B represents the amine. No allowance was made, however, for processes in the organic phase.

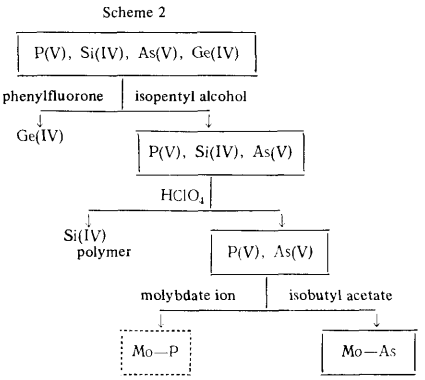


Thus the study of the mechanism of the extraction of heteropolycompounds raises many unresolved problems, and final conclusions regarding the mechanism of the transfer of heteropolycompounds to the organic phase can only be reached using a large amount of experimental material, including the results of kinetic studies of the process.

VII. ANALYTICAL APPLICATION OF THE EXTRACTION OF HETEROPOLYCOMPOUNDS

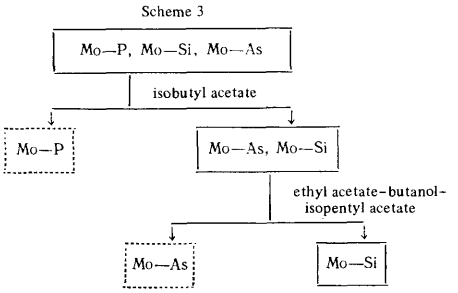
1. Separation of Elements by Extraction

The greatest number of schemes has been proposed for the separation of phosphorus, silicon, arsenic, and germanium. Methods have been developed for the successive separation of all four elements, the extraction of one of the heteropolyacids in the presence of the others, and the separation of combinations of two or three elements. The distribution diagrams for molybdenum heteropolyacids in oxygen-containing solvents and their mixtures[6] can be used to select conditions for the quantitative separation of many elements (Table 4). Paul[63] put forward a scheme for separating the same elements, based on selective extraction in perchloric acid (scheme 1).



Scheme 1*

† The continuous lines denote aqueous phases, and the broken lines organic phases.



The separation schemes sometimes include reactions not associated with the formation of heteropolycompounds (polymerisation, complex formation by one or several elements, precipitation). Thus a scheme for separating germanium, phosphorus, silicon, and arsenic[64] proposes the separation of germanium as its complex with phenylfluorone, and the conversion of silicon into polymeric forms which do not give a complex with molybdate ions (scheme 2).

Scheme 2

The following scheme has been proposed for separating phosphorus, arsenic, and silicon by varying the extracting agents[191]:

Scheme 3

Amines of high molecular weight are less selective, but it is possible to separate the molybdosilicate complex from 2 M sulphuric acid solution and the molybdophosphate complex from 2 M perchloric acid solution using tri- and dioctylamine in chloroform, in the presence of arsenic and germanium[74].

Methods have been proposed for separating silicon from its mixtures with phosphorus and arsenic by the extraction of the molybdenum complex into methyl isobutyl ketone in the presence of citrate ions, which decompose the phosphorus and arsenic complexes[191], and for separating silicon from arsenic by extracting the molybdosilicate into iso-octyl alcohol[192]. A method has been proposed for separating phosphorus from the same mixture by extracting the compound of molybdophosphate with Crystal Violet into alkyl acetates at pH 0.2–0.5. The extraction is not affected by the presence of unlimited quantities of silicon, or by a tenfold excess of arsenic[8].

A method has been proposed for separating phosphorus from silicon and germanium by extracting the tungsten heteropolycomplex into butyl acetate or its mixtures with diethyl ether from 0.5–1 M sulphuric acid solution[68].

A method has been proposed[124] for separating the corresponding molybdenum heteropolyacids from a mixture of silicon, phosphorus, and arsenic by extracting into isobutyl alcohol at different acidities. Methods for separating pairs of elements (phosphorus and silicon, phosphorus and arsenic, phosphorus and germanium) are based on the ease of extraction of the heteropolycompounds of phosphorus[62,63,105,142,193]. Various methods for separating elements are based on a combination of extraction and the selective decomposition of the heteropolycomplexes in mineral acids[35].

2. Extraction Methods for Determining Elements

Extraction–photometric methods for determining elements are most widespread. This is natural, in view of the high molar absorptivity of heteropolycompounds, particularly the reduced forms (in the visible range) and the mixed complexes. Extraction extends considerably the possibilities provided by the photometric method for a number of reasons: firstly, the element is concentrated; secondly, the unstable isomers of heteropolycomplexes are stabilised; thirdly, the separation from the excess of molybdate or tungstate ions makes it possible to carry out measurements in the near ultraviolet range, where the absorption by the complexes is a maximum; and finally, extraction has provided extensive possibilities for developing indirect methods for the photometric determination of elements via the ligand.

The extraction of molybdosilicic acid by pentanol is used to determine down to 0.02% silicon in copper and brass[150], and by ethyl acetate to determine silicon in sea water[157]. In the extraction of reduced forms, butanol is used to determine down to 5×10^{-4}% silicon in titanium[101], isopentyl alcohol is used to determine silicon in a number of salts, alloys, and steels[113,120], and traces of silicon in antimony, thallium, gallium, and indium[133,134], and a mixture of chloroform and propane-1,2-diol carbonate is used to determine down to 0.2 $\mu g\ ml^{-1}$ silicon in solutions[45]. A number of methods for determining silicon are based on the extraction of the yellow forms of heteropolyacids with subsequent reduction in the organic phase. Extraction of molybdosilicic acid by pentanol with reduction by tin(II) chloride has been proposed for determining silicon in highly pure aluminium[149], extraction by butanol with reduction by a mixture of iron(II) sulphate and ascorbic acid for the determination of down to 2×10^{-3}% silicon in niobium and tantalum[137,138], extraction by methyl isobutyl ketone with reduction by tin(II) chloride for the determination of down to 2×10^{-3}% silicon in vanadium[140] and in solutions of hydrogen fluoride in the presence of tantalum[155], and extraction by isopentyl alcohol with reduction by tin(II) chloride for the determination of traces of silicon in copper and copper alloys[114].

Amines of high molecular weight are being widely used as extracting agents. Conditions have been recommended for the extraction of yellow molybdosilicic acid by a solution of tri-iso-octylammonium nitrate in dichloroethane for the determination of down to 10^{-4}% silicon in solutions[109], by a solution of trioctylamine in toluene for the determination of down to 10^{-3}% silicon in vanadium pentoxide[35], by solutions of di- and trioctylamine in chloroform for the determination of silicon in steels[74], and by a solution of diethylhexylamine in dichloroethane for the determination of down to 1 $\mu g\ ml^{-1}$ silicon in solutions[183]. The extraction of the reduced forms of molybdosilicic acid by amines has also been proposed: by a solution of dioctylamine in pentanol for the determination of down to 0.01 $\mu g\ ml^{-1}$ silicon in solutions[26]; by a solution of trioctylamine in toluene for the determination of silicon in plants and fertilisers[33]; and by a polyethoxylated amine in butanol for the determination of down to 10^{-7}% silicon in pure water[194].

Extraction by isopentyl alcohol of molybdoarsenic acid reduced by hydrazine sulphate is used for the extraction–photometric determination of down to 5×10^{-5}% arsenic in tin, antimony, aluminium, thallium, and indium[133,134,136]. A method involving reduction of the complex by tin(II) chloride after its extraction by a mixture of diethyl ether and butanol, having a detection limit of 10^{-4}% arsenic[148], and also a method for extracting the non-reduced complex by di- and trioctylamine (detection limit 10^{-4}%) and by a number of other amines for the determination of down to 0.04 μg ml^{-1}, [152,184] have been proposed. Arsenic and phosphorus can be determined in tungsten–rhenium alloys[156].

The extraction of molybdophosphoric acid by butyl acetate has been recommended for determining down to 4×10^{-6}% phosphorus in iron[177] and 0.35 μg ml^{-1} in solutions[195], extraction by isobutyl alcohol in mixtures with benzene and ethanol for the determination of phosphorus in solutions containing the products of the deprotonation of adenosine triphosphate[196], and extraction by di- and trioctylamine for determining phosphorus in steels[74]. Most extraction–photometric methods for determining phosphorus, however, used extraction of the mixed vanadomolybdophosphoric acid, and also reduction of the complex in the aqueous phase before extraction or in the organic phase after extraction. Extraction of the mixed heteropolycomplex by methyl isobutyl ketone is proposed for determining phosphorus in steels and alloys[105,144], in ferroniobium, ferrotitanium, and niobium ores[121], in ferrovanadium and ferrous alloys[120], extraction by butanol for the analysis of silicon tetrachloride (detection limit 5×10^{-7}% phosphorus)[133], by pentanol for the analysis of solutions containing down to 1.5 μg ml^{-1} phosphorus[50], and by trioctylamine in toluene for determining down to 10^{-3}% phosphorus in vanadium pentoxide[35].

Reduced forms of molybdophosphoric acid are extracted by mixtures of dioctylamine with pentanol and chloroform in the analysis of solutions with a detection limit of 0.01 μg ml^{-1} phosphorus[26], by isopentyl alcohol for determining down to 10^{-6}% phosphorus in tin[133] and down to 5×10^{-7}% phosphorus in methyltrichlorosilane[139], by methyl isobutyl ketone for the analysis of pure iron, and by butanol and isobutyl alcohol for the analysis of solutions containing down to 0.05 μg ml^{-1} phosphorus[175,176]. Many procedures recommend the extraction of the yellow molybdophosphate complex with subsequent reduction in the organic phase, most frequently using tin(II) chloride. The extraction is usually carried out by alkyl acetates; butyl acetate for determining traces of phosphorus in salts, metals, and alloys[115], and isobutyl acetate[63], ethyl acetate[62,180], and isopentyl acetate[178] for the analysis of iron and steels[147]. Various authors recommended diethyl ether[133], alcohols, and their mixtures with chloroform[141,143,146,177]. A method involving the reduction of the molybdophosphate complex by ascorbic acid in the re-extract after extraction by butanol has also been proposed for the analysis of alloy steels[151].

A number of methods for determining phosphorus in solution are based on the extraction of the ionic associates of molybdophosphate with dyes of different types[12,17,18,25,59].

In addition to traditional extraction–photometric methods, methods based on the reactions of heteropolycompounds in organic phases are now being developed. Titrimetric methods for determining phosphorus and silicon, based on the neutralisation of the heteropolyacids by strong bases in the organic phase with visual[20,21,197] and conductometric indication of the end-point of the titration[198], have been proposed. Phosphorus in natural waters has been determined by flame photometry in sodium molybdophosphate extracts[166] (detection limit 10^{-3} μg ml^{-1} phosphorus). A neutron-activation method has been proposed for determining phosphorus in steels, involving the extraction of molybdophosphoric acid by butanol and measurement of the quantity of ^{32}P ($T_{1/2}$ = 14.3 d) in the re-extracts[145].

A number of methods have been proposed for determining silicon, phosphorus, and germanium in steels, bronzes, and solutions, based on the polarographic reduction of heteropolycomplexes in the organic phase[53,69-71,73,91,92,95,96,122-124,179]. A method has been proposed for determining small quantities of elements from the chemiluminescence of the compounds formed by heteropolyacids with luminol after extraction by solvent mixtures[199,200].

Extraction is also used to determine elements which are not typical complex-forming elements in heteropolycompounds. Thus an extraction–photometric method has been proposed for determining down to 0.04 μg ml^{-1} niobium[104] and antimony[173]. Methods have been developed for extracting caesium by nitrobenzene in the presence of molybdophosphoric acid[162-165]. Extraction can also be used to determine elements which act as ligands in heteropolycomplexes. Methods have been described for the photometric determination of down to 25 μg ml^{-1} vanadium, involving the extraction of vanadotungstophosphoric acid by methyl isobutyl ketone[172] and isobutyl alcohol[201]; for the polarographic determination of molybdenum, involving the extraction of vanadomolybdophosphoric acid by isopentyl alcohol[93]; for the extraction–photometric determination of vanadium in aluminium with a detection limit of 4×10^{-4}%;[171] and for the determination of tungsten, involving the extraction of tungstophosphate[202].

In the last ten years, indirect methods have been developed for determining elements by the formation and extraction of heteropolyacids. These are based on the extraction of the heteropolycomplex under the conditions of minimum extraction of molybdate ions, decomposition of the heteropolycomplex, and determination of molybdenum(VI). The favourable stoichiometric ratio of the central atom and the ligand makes this method extremely promising for decreasing the detection limit (the multiplication factor in most cases is twelve) and extends the range of reagents and methods.

A large number of indirect methods use the photometric version, based on the formation of coloured complexes of molybdenum(VI). The use of the familiar formation of the complex of molybdenum(V) with thiocyanate ion has made it possible to develop methods for determining phosphorus in solutions (effective molar absorptivity 1.56×10^5),[65] and for determining down to 10^{-6}% phosphorus in iodine and highly pure tin[133]. A number of methods, including the determination of down to 10^{-7}% phosphorus in hydrochloric and nitric acids, are based on the kinetic determination of molybdenum(VI).[117-119] The use of organic reagents for determining molybdenum(VI) is particularly effective. Indirect photometric methods involving the use of phenylfluorone[129], azo-compounds[27], 2-amino-4-chlorobenzenethiol[54], benzidine, and gallic acid in the presence of hydrogen peroxide[203] have been proposed. Conditions have been recommended for determining microquantities of phosphorus and arsenic in rhenium using zinc dithiol (effective molar absorptivity 1.7×10^5 for phosphorus and 2×10^5 for arsenic) and Sulphonitrophenol M ($\bar{\epsilon}_{eff} = 4.6 \times 10^5$ for phosphorus and 4.5×10^5 for arsenic)[142].

An indirect titrimetric method with complexometric titration of molybdenum(VI) after the extraction of molybdosilicic acid by isopentyl alcohol with subsequent decomposition has been proposed for determining silicon in silicides[204], and titration of Mo^{III} by permanganate after the reduction of Mo^{VI} in a reductor has been recommended for the analysis of silicates containing up to 68% SiO_2.[205] The intense absorption by molybdenum(VI) in the ultraviolet range of the spectrum is used in a number of methods for determining 0.1 μg ml^{-1} silicon and phosphorus[51], 0.3 μg ml^{-1} germanium[48], and 0.48 μg ml^{-1} vanadium[47].

Methods using atomic-absorption spectroscopy are of particular interest. Atomic-absorption spectroscopy is usually employed for the direct determination of metals. The method is inconvenient for determining non-metals, since the resonance lines of non-metals lie in the far ultraviolet range of the spectrum. In this case it is appropriate to use indirect methods combined with extraction separation from the excess of the element via which the measurement is being made. For example, molybdenum has a resonance line at 313.3 nm; the concentrations of phosphorus, vanadium, and other elements can be determined from the intensity of this line. The indirect method is also used to determine a number of metals which form mixed heteropolycomplexes, extracted under definite conditions.

The method was first used to determine down to 0.015 μg ml^{-1} phosphorus in solutions[125,126]. A number of methods, including descriptions of the conditions of formation, extraction by a suitable extracting agent, decomposition of the heteropolycomplex, and elimination of the co-extraction of molybdenum(VI), were later proposed for determining metals and non-metals. Methods have been proposed for determining silicon, phosphorus, arsenic, and germanium[6], down to 0.01 μg ml^{-1} phosphorus and silicon, and 0.025 μg ml^{-1} arsenic[191]; down to 0.08 μg ml^{-1} silicon and phosphorus[55]; silicon in organic compounds[206,207]; down to 0.005 μg ml^{-1} silicon (including the precipitation of lead molybdate)[46]; down to 0.07 μg ml^{-1} arsenic[52]; down to 0.01 μg ml^{-1} arsenic[191]; small quantities of phosphorus[208], arsenic[209], and germanium[210] in water; down to 0.05 μg ml^{-1} germanium[48] and arsenic in sulphides[211]; and down to 0.5 μg ml^{-1} vanadium in solutions[49] and aluminium alloys[60]. Kirkbright and coworkers proposed a number of methods for determining metals, involving the determination of molybdenum by atomic absorption: niobium[56], cerium[61], thorium[57], and titanium[58]. In some procedures, the direct introduction of the extracts into the flame is recommended, avoiding the operations of re-extraction and decomposition of the complexes[196].

Almost all papers giving specific recommendations for the extraction of heteropolycompounds give data on the influence, on the degree of extraction, of various ions present in the solution at the moment of formation of the complex and its extraction into the organic phase; iron(II), iron(III), aluminium(III), chromium(III), tin(IV), tungsten, and others (a total of ~40 ions). In the present review, however, it is not possible to deal with the results of these studies in detail, and readers are referred to the papers dealing with each specific determination.

* * *

The above review shows that in recent years, considerable success has been achieved in the theory and practice of the extraction of heteropolycompounds: experimental material has been accumulated, making it possible to discuss the mechanism of extraction; the limits of detection of elements by extraction methods have been lowered considerably; and the range of materials and elements extracted as heteropolycompounds has been extended. The mechanism of the transfer of a heteropolycompound from the aqueous to the organic phase has not yet been determined (that is the kinetics of the process have not been studied), however, and there is lack of agreement on the mechanism of formation of the compound extracted. The mechanism of the reduction of complexes in the organic phase is not clear, and the mechanism of the influence of added salts on extraction has not been studied. There are no sufficiently clear-cut practical recommendations on the separation of elements having similar properties at low absolute concentrations, or on the determination of a small quantity of a given element in the presence of large quantities of other elements having similar properties.

The Use of High-pressure Liquid Chromatography in the Analysis of the Structural Components of Nucleic Acids

V.K.Kagramanova, S.N.Bubenshchikova, and L.A.Baratova

The advances in the analysis of the structural components of nucleic acids by high-pressure liquid chromatography are described and surveyed. The general ideas concerning the requirements imposed on sorbents at the present time in order to increase the efficiency of the chromatographic process are summarised. The methods and the results of the employment of effective ion-exchange sorbents in the separation and ultramicroanalysis of mixtures of the heterocyclic bases, nucleosides, nucleotides, and their derivatives are briefly considered.
The bibliography includes 82 references.

III. The separation of the structural components of nucleic acids by high pressure liquid chromatography 519

I. INTRODUCTION

The development of effective analytical methods plays a decisive role in the study of the structure of nucleic acids. The improvement of the technique of paper and thin-layer chromatography and the use of these methods in conjunction with electrophoretic and radiometric techniques made it possible to increase considerably their sensitivity and resolving capacity[1-4]. However, in view of the complexity and long time required for the application of these analytical methods, the problem of the structural analysis of nucleic acids cannot be regarded as solved.

The introduction into the ultramicroanalytical practice of a special spectrophotometric technique, the use of pumps permitting a low and controlled flow rate, and the preliminary formation of gradients in the capillary[5,6] permitted a successful solution of certain specific problems of the separation and analysis of oligonucleotides with the aid of column liquid chromatography[7]. However, the need to increase the rate of separation and the employment for this purpose of much higher pressures required a modification of the chromatographic technique. The construction in recent years of high-pressure chromatographs equipped with a reliable automatic control system and highly sensitive detecting devices as well as the appearance of new and effective sorbents greatly extended the prospects for the development of the analytical chemistry of nucleic acids[8-10], permitting the use of high-pressure liquid chromatography in the rapid ultramicroquantitative analysis of a wide variety of structural components.

Unfortunately the large-scale practical application of high-pressure liquid chromatography in structural studies on nucleic acids is to a large extent held back by the inadequate, in our view, information about the possibilities of modern ion-exchange sorbents and hence the difficulty of selecting the optimum conditions for a particular analysis. It therefore appears timely and useful to survey and give a systematic account of studies published hitherto concerning the employment of this method in the analysis of the structural components of nucleic acids and also to outline the trends in its development and further prospects for its application.

This review does not deal with the general problems of the theory of chromatography, which have been described in detail in a number of articles and monographs[8,9,11-17].

II. ION-EXCHANGE SORBENTS USED IN EFFECTIVE HIGH-PRESSURE LIQUID CHROMATOGRAPHY

The theory of chromatography developed by Martin and Synge[11], Lapidus and Amundsen[12], Giddings[13,18], and a number of other investigators[19] permits the formulation of the requirements which must be met by the sorbents used in column liquid chromatography and whose fulfilment is necessary for the optimisation of the separation of the components of the mixtures analysed. We shall consider here only some of the principles underlying the theory of high-pressure liquid–liquid chromatography.

According to the Beer–Lambert law, in the region of linear working characteristics of the spectrophotometric detector (used most frequently in column liquid chromatography in the analysis of components of nucleic acids), i.e. under conditions where the detector signal is proportional to the concentration of the absorbing substance in the cell, the optical density A of the substance is specified by the equation

$$A = \lg \frac{I_0}{I} = \varepsilon c l, \qquad (1)$$

where I_0 and I are the intensities of the incident and transmitted radiation respectively, ϵ is the molar extinction coefficient of the substance, and l is the optical path length. For the Gaussian distribution, the maximum concentration of the test substance (c_{max}) in the absence of the "spreading" of the peaks in the detector cell is defined by the expression[19]

$$c_{max} = 4M/w_V\sqrt{2\pi}, \qquad (2)$$

where M is the amount of the substance in moles and W_V the width of the peak expressed in units of volume. Thus the optical density of the substance at the maximum on the distribution curve (A_{max}) is described by the equation

$$A_{max} = \varepsilon l \frac{4M}{w_V\sqrt{2\pi}}. \qquad (3)$$

The highly sensitive spectrophotometric detectors with a small cell volume (down to 8–10 μl) constructed at the present time make it possible to record extremely small (picomolar) amounts of the nucleotide[17]. Detectors of this class ensure a minimal contribution to the peak variance (up to 8%). Consequently the lower limit of the sensitivity, determined by the value of A_{max}, depends on

the "spreading" of the band of the test substance in all the remaining parts of the chromatographic system, in the first place in the chromatographic column.

The efficiency of the chromatographic column, expressed in terms of the number of theoretical plates N or the height equivalent to the theoretical plate H, is related to the peak width as follows[11]:

$$N = \frac{16t^2}{w_t^2} \quad (4)$$

or

$$H = \frac{L}{N} = \frac{Lw_t^2}{16t^2}, \quad (5)$$

where t is the retention time of the test substance on the column, w_t the peak width expressed in units of time, and L the column length (in cm).

The generalised non-equilibrium Giddings theory[12,13] makes it possible to estimate the contributions of the main components of the overall variance, which are due to the turbulent and longitudinal molecular diffusion as well as the resistance to mass transfer. The overall height equivalent to the theoretical plate, equal to the sum of the heights corresponding to the contributions of the above peak "spreading" factors, is

$$H = H_1 + H_2 + H_3, \quad (6)$$

where H_1, H_2, and H_3 are components caused respectively by the turbulent and longitudinal diffusion and the resistance to mass transfer. According to the Giddings theory[13], H_1, H_2 and H_3 can be calculated from the equations

$$H_1 = 2\lambda d_p, \quad (7)$$

$$H_2 = \frac{2\tau D_m}{v}, \quad (8)$$

$$H_3 = \frac{qrd_p^2 v}{D_s} + \frac{\omega d_p v}{D_m}, \quad (9)$$

where λ, τ, q, and ω are constants which depend on the structure of the filler as well as the form and size of the column, d_p the diameter of the filler particles v the linear rate of migration of the mobile phase, D_m the diffusion coefficient of the test substance in the mobile phase, D_s the diffusion coefficient of the test substance in the stationary phase, and r a quantity which depends on the relative rate of migration of the substance analysed and the mobile phase. As a rule, the spreading of the band of the test substance associated with longitudinal molecular diffusion is small under the conditions of the migration of the mobile phase usually employed in liquid chromatography. On the other hand, the variance of the peak due to turbulent diffusion and the resistance to mass transfer are evidently smaller, the smaller the diameter of the sorbent particles (d_p).

Thus, the direct approach to an increase of the detection limit consists in shortening the diffusion pathway of the molecules of the test substance into the sorbent particles, which can be achieved in two ways: (a) by decreasing the intrinsic size of the sorbent particles and (b) by limiting the thickness of the sorbent layer as a result of its deposition on the surface of other (inert and impermeable) particles. Both procedures are used in the modern techniques for the preparation of effective sorbents.

The development of the technology for the synthesis of polymerisation (based on styrene and divinylbenzene) fine-grain ion-exchange sorbents led to the formation of effective cation- and anion-exchange spherical microbead resins, which have been used successfully for the rapid analysis of nano- and pico-gram amounts of nucleosides and nucleotides[20,21]. For example, Fig. 1 illustrates the separation of a mixture of ribonucleosides obtained by Burtis[21] using a column with the VC-10 (×10) cation exchanger (Sondell Scientific Instruments, USA). Certain characteristics of the spherical microbead polymerisation ion-exchange sorbents used in high-pressure liquid chromatography are listed in Table 1. It is noteworthy that the use of sorbents with a very small particle diameter necessitates an appreciable increase of pressure in order to ensure the required rate of elution. This imposes in its turn a limitation on the employment of sorbents whose polymer matrix consists of a styrene–divinyl–benzene copolymer with a low (up to 7–8%) degree of cross linking. It has been shown[22] that the gel properties of such sorbents, manifested by their swelling, contraction, and compaction, as well as the decrease of their permeability, etc., give rise to virtually insurmountable technical difficulties under conditions of high-pressure chromatography.

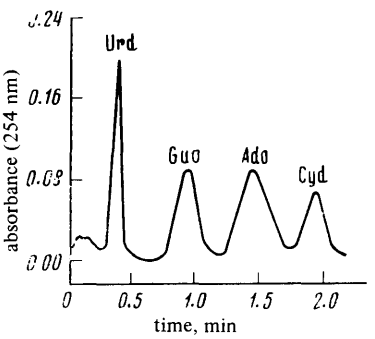

Figure 1. Separation of a mixture of ribonucleosides (300 nmoles) on a 2.4 mm × 25 cm column with a VC-10 (×10) cation exchanger in a 0.4 M $HCOONH_4$ solution (pH 4.75) at 55°C.[21]

Table 1. Certain characteristics of spherical microbead polymerisation sorbents.

Commercial name	d_p, μm	Functional groups	Capacity, mequiv. g^{-1}	Company

Aminex A-28	7—11	NR_4^+	4	Ditto

The possibility of decreasing the thickness of the sorbent bed, in which the molecules of the test substance diffuse, by converting into an ion exchanger only the surfaces of the carrier particles was first discussed in the

literature at an early stage by Pepper[23] and Weiss[24]. The successful practical utilisation of this idea in the separation of proteins on zeolite particles coated by a cation-exchange resin[25,26] stimulated the development of other surface ion-exchange sorbents and the study of their chromatographic properties[27,28]. Further development of methodological procedures involving the deposition of thin ion-exchange coatings onto glass, Teflon, and silica particles led to the creation of the so-called pellicular sorbents[29,30] and sorbents with a "controllable surface porosity".[31]

Certain characteristics of these sorbents, known under the commercial name of "Pellionex", are presented in Table 2. Sorbents of the "Pellionex" type are obtained by the copolymerisation of styrene and divinylbenzene on the surface of spherical glass particles with subsequent introduction of the appropriate functional groups[30]. In sorbents of the "Zipax" type the polymer containing functional groups is introduced into the pores of the particles[31]. Anion-exchange sorbents with a controllable surface porosity contain quaternary alkylammonium groups attached to a polyacrylic matrix and cation-exchange sorbents contain a sulphonated fluoro-polymer.

Table 2. Certain characteristics of pellicular ion-exchange sorbents and sorbents with a controllable surface porosity.

Commercial name	d_p, μm	Functional groups	Capacity, mequiv. g^{-1}	Company
Cation-exchange sorbents				
Pellionex SCX	40	SO_3^-	10	M.Reeve Angel and Co., USA
Zipax-SCX™	25—37	SO_3^-	3.2	Du Pont, Wilmington, Del., USA
Anion-exchange sorbent				
Pellionex SCX	40	NR_4^+	10	H.Reeve Angel and Co., USA
Zipax-SAX™	25—37	NR_4^+	12	Du Pont, Wilmington, Del., USA
Zipax-WAX™	25—37	NH_2	12	Ditto

The use of pellicular ion-exchangers and sorbents with a controllable surface porosity permits the rapid separation of complex mixtures of nucleotides as well as other structural components of the nucleic acid[9,32,33]. As an example, Fig. 2 presents the separation of a mixture of nucleoside mono-, di-, and tri-phosphates[29].

An undoubted advantage of surface ion-exchange sorbents is the possibility of using particles of greater size (up to 40–50 μm) in order to achieve the same efficiency of mixture separation as for fine (3–7 μm) polymerisation sorbents[9]. This permits their separation under the conditions of a high rate of elution and a considerably lower pressure. The low capacity of these sorbents[34] as well as the low mechanical strength of ion-exchange coatings, which sometimes leads to the breakdown of the surface layer during ordinary stirring of a suspension of the sorbent[9], must be regarded as their disadvantages. Furthermore, one should note the difficulty of preparing such sorbents and their high cost.

Systems with an inverted phase, known in the literature by the designations RPC-1–RPC-5,[35-38] can also be classified as surface ion-exchange sorbents. Some of them are used successfully at the present time for the separation of transport RNA[38] and the fractionation of oligo- and polynucleotides[39,40]. Silica gel or fluoro-polymer grains coated by a thin layer of liquid quaternary ammonium salts, such as trimethyloctyl- or trimethyldecyl-ammonium chlorides, are used as the stationary phase in these systems. The attainment of equilibrium between the liquid stationary and mobile phases during elution leads to a gradual "washing away" of the stationary phase. In order to increase the useful life of these sorbents, it is recommended that elution gradients and high flow rates are not used[41].

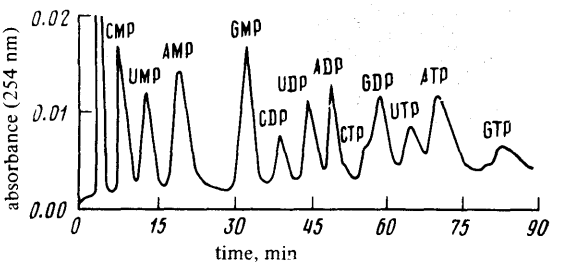

Figure 2. Separation of a mixture of nucleoside mono-, di-, and tri-phosphates (1.5–3.5 nmoles of each) on a 1 mm × 193 cm column with a Pellionex anion exchanger in a solution with a linear $HCOONH_4$ concentration gradient (0.04–1.5 M, pH 4.35) at 25°C. Rate of elution 12 ml h^{-1}; pressure 50 atm.[29]

Thus a general tendency in the development of modern high-pressure liquid chromatography is a change-over to sorbents ensuring a high rate of mass transfer and a high efficiency of the chromatographic process. A comparatively large number of effective ion-exchange sorbents, with a wide variety of structures and chromatographic properties, can be used in the analysis of the structural components of nucleic acids. The nature of the ion-exchange sorbent employed in many respects determines the conditions of the analysis. In the next section we shall consider in detail the methodological characteristics of the separation of mixtures of the most important structural components of nucleic acids under the conditions of high-pressure chromatography.

III. THE SEPARATION OF THE STRUCTURAL COMPONENTS OF NUCLEIC ACIDS BY HIGH-PRESSURE LIQUID CHROMATOGRAPHY

1. Analysis of the Heterocyclic Bases

The presence in the molecules of purine and pyrimidine bases of at least one and in most cases of several functional groups capable of acid or basic dissociation permits their conversion, depending on the acidity of the medium, into anions or cations and their separation by ion-exchange chromatography. Under the conditions of high-pressure column liquid chromatography, cation-exchange sorbents are most often used for the separation of the heterocyclic bases[30,42,43], although these compounds can also be separated with the aid of anion exchangers[44].

Table 3. Conditions for the separation of the heterocyclic bases by cation-exchange chromatography on pellicular sorbents and sorbents with a controllable surface porosity.

Compn. of mixture to be separated*	Type of sorbent	Column dimensions	Eluent composition	Rate of elution, ml h^{-1}	Pressure, atm	Elution temp., °C	Separation time, min	Refs.
Ura, Gua, Ade, Cyt	Pellionex SCX	1 mm × 300.7 cm	0.02 M $NH_4H_2PO_4$ (pH 5,50)	33,4	180	68	6	30
Ura (Thy), Gua, Cyt, Ade	Pellionex SCX	1 mm × 300 cm	0.05 M $NH_4H_2PO_4$ (pH 2,55)	40	115—143	70	10	42
Ura, Gua, Cyt, Ade	Pellionex SCX	1 mm × 250 cm	0.025 M $NH_4H_2PO_4$ (pH 4,40)	36	200	70	5	42
Ura, Hyp, Gua, Cyt, Ade, 6-MePu	Zipax-SCX™	2.1 mm × 100 cm	0.1 *N* HNO_3	120	53	63	15	43

*The compounds are quoted in order of increasing retention time on the column. The following abbreviations are used: Ura = uranil; Gua = guanine; Ade = adenine; Cyt = cytosine; Thy = thymine; Hyp = hypoxanthine; 6-MePu = 6-methylpurine.

It has been shown[30,42,43] that the effective separation of standard mixtures of heterocyclic bases can be achieved after 5–10 min using sorbents of the Pellionex or Zipax-SCX™ type. The detailed conditions for the separation of mixtures of heterocyclic bases are presented in Table 3.

In view of the comparatively small differences between the positive charges of the heterocyclic bases, they are usually separated under isocratic† elution conditions. The most satisfactory separation of the four nucleic acid bases on columns with a cation exchanger of the Pellionex type is achieved on elution with a 0.02 M $NH_4H_2PO_4$ solution (pH 5,2–5,5) at 68°C[30] (Fig. 3).

The behaviour of compounds in the course of chromatographic analysis is known to be determined both by the charge of their molecules and by their non-ionic affinity for the sorbent. Analysis of the elution sequence of the heterocyclic bases when the latter are separated on columns with sorbents of the Pellionex and "Zipax-SCX™" type (Table 3) permits the conclusion that ionic interactions are in this instance expressed more strongly than in the case where the usual polymerisation cation-exchange sorbents of the type Dowex-50, Amberlite IRC-50, etc. are used[45]. Indeed, when the eluent is a buffer at pH 5.5, the elution sequence of Uracil, guanine, (pK'_a = 3,3), adenine (pK'_a = 4,2), and cytosine (pK'_a = 4,6) corresponds to an increase of the pK_a values for the bases (i.e. to an increase of the positive charge of the molecules[46]). On the other hand, at lower pH values the order in which adenine and cytosine are eluted is reversed[42,43]. The data obtained by Horvath and Lipsky[30] also indicate an anomalous behaviour of guanine on columns with a Pellionex cation exchanger at pH 5.2 ("twinning" of the peak corresponding to guanine was observed).

It is apparently impossible to explain these phenomena from the standpoint of the non-polar interactions of the molecules of the test substance with the sorbent particles, because the non-polar affinity is almost independent of the pH of the medium[45]. The authors' suggestion that the anomalous behaviour of the test compounds on pellicular sorbents may be associated with kinetic effects in the course of the attainment of the sorption–desorption equilibrium involving the molecules of the test substance in the stationary and mobile phases also appears unconvincing[30].

†Isocratic elution is elution with a solution at a constant ionic strength.

It is noteworthy that the use of the Zipax-SCV™ cation-exchange sorbent with a controllable surface porosity permits the elution of bases with a solution having a lower ionic strength (even at a lower pH of the eluent), because of its lower capacity (Table 2).[43]

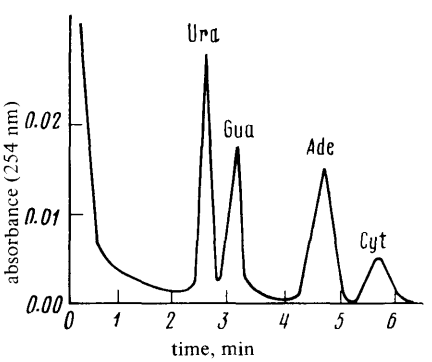

Figure 3. Separation of a mixture of heterocyclic bases (0.8 nmole of each) on a 1 mm × 300.7 cm column with a Pellionex cation exchanger in a 0.02 M $NH_3H_2PO_4$ solution (pH 5.5) at 68°C. Rate of elution 33.4 ml h^{-1}; pressure 177 atm.[30]

The possibility of employing spherical microbead polarisation cation-exchange resins under the conditions of high-pressure chromatography for the analysis of the heterocyclic bases was first demonstrated[47] in the determination of the amount of DNA in various tissues on the basis of their thymine context. The separation of the mixture of the heterocyclic bases formed as a result of the active hydrolysis of DNA has been achieved[48] on a column with the Aminex A-7 sorbent in 1 M NaH_2PO_4 (pH 3,4). Under these conditions, the non-ionic interactions of the mixture components with the organic matrix of the sorbent were suppressed by the increased elution temperature and the addition of alcohol to the solution. The necessity for the separation of mixtures of the heterocyclic bases arises fairly frequently in the course of a whole series of biochemical studies, particularly in the determination of the composition of RNA and DNA, in the elucidation of the

possible reaction pathways of free nucleotides *in vivo*, in the study of the mechanism of the action of certain enzymes etc., and in all cases high-pressure ion-exchange chromatography is as a rule one of the most effective analytical methods[8,9,49,50].

2. Analysis of Nucleosides

Numerous studies have been devoted to the separation and analysis of mixtures of nucleosides and their derivatives under the conditions of high-pressure ion-exchange chromatography[9,21,30,42]. This is associated primarily with the increased availability of highly purified enzymes in recent years, which permits the hydrolysis under mild conditions of ribo- and deoxyribo-nucleotide chains to nucleosides, as a result of which many problems involved in the study of the structures of nucleic acids can be solved at the level of the analysis of the nucleosides.

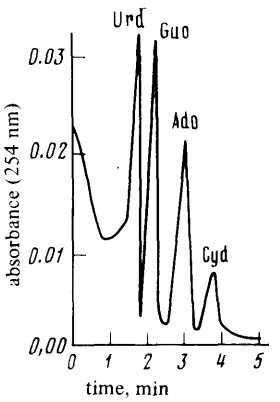

Figure 4. Separation of a mixture of nucleosides (approximately 0.3 of a nmole of each) on a 1 mm × 151.7 cm column with a Pellionex cation exchanger in a 0.02 M $NH_4H_2PO_4$ solution (pH 5.5) at 24°C. Rate of elution 32.5 ml h^{-1}; pressure 38 atm.[22]

Table 4 summarises the literature data for different types of sorbents and separation conditions most frequently used in the analysis of nucleosides. Evidently both spherical microbead polymerisation cation-exchange resins[21] and pellicular cation exchangers of the Pellionex[22,41] type as well as Zipax-SCX™ sorbents with a controlled surface porosity[9] can be used for the separation of nucleosides and many of their derivatives under the conditions of high-pressure liquid chromatography. However, a more detailed analysis of the results of the separation obtained using the above sorbents suggests that preference should be given to spherical microbead polymerisation resins, because the sorption of uridine and thymidine on columns with sorbents of the Pellionex and Zipax-SCX™ types under the conditions of optimum separation of the nucleoside peaks is extremely low, as noted by Horvath[9]. Because of this, the above nucleosides are eluted in a very narrow band and their peaks are as a rule superimposed on the "injection peak", which normally accompanies the introduction of the analysed solution into the column (Fig. 4). This hinders and sometimes altogether precludes a correct interpretation of the results of the separation process. On the other hand, the use of spherical microbead cation-exchange resins, whose polymeric matrix in all probability ensures a fairly intense sorption, makes it possible to overcome these difficulties. The best results in the separation of nucleosides and many of their derivatives were obtained by Burtis[21] on columns with the finest DC-x8 (Fig. 1) and VC-10 cation-exchange resins. Burtis also confirmed the theoretical conclusion that the maximum efficiency of the separation can be achieved when the column is filled with finer particles (Table 5).

Table 5. The efficiency of columns with spherical microbead cation-exchange polymerisation sorbents in the separation of nucleosides in 0.4 M ammonium formate solution (pH 4.55).[42]

Sorbent	d_p, μm	Column dimensions	Temp., °C	Rate of elution		Pressure, atm	N	H, mm
				ml h^{-1}	cm s^{-1}

Urd, Guo, Ado, Cyd	VC-10 (×10) (7-10 μm)	2.4 mm × 25 cm	0.4 M $HCOONH_4$ (pH 4.50)	50	330	75	4	21

*The compounds are quoted in order of increasing retention time on the column. The following abbreviations are used: Urd = uridine; dAdo = deoxyadenosine; dGuo = deoxyguanosine; dThd = deoxythymidine; dCyd = deoxycytidine; Ino = inosine.

Spherical microbead polymerisation cation-exchange sorbents have been used successfully in the analysis of the enzymatic hydrolysates of many RNA specimens in order to elucidate their nucleoside composition[9,21,42] and also for the investigation of the content of various minor nucleosides in DNA[51] and individual transport RNA[34,50] preparations.

Mixtures containing simultaneously ribo- and deoxyribo-nucleosides can be separated comparatively rapidly on columns with the Aminex A-7 sorbent proposed by Duch and Laskowski[52]. The difference between the retention times of ribose and deoxyribose derivatives can be most probably accounted for by the secondary interactions of the nucleosides with the sorbents (by hydrogen bonding, etc.) rather than ionic interactions. The method has been used successfully to determine the impurity amounts (down to 0.2–0.4%) of RNA in DNA preparations after the enzymatic degradation of the polymeric molecules to nucleosides[52].

The traditional procedure for the preparation of carbohydrate-borate complexes, proposed as early as 1951[53] and developed in detail subsequently[45,54], has also been used successfully to separate ribo- and deoxyribo-nucleosides under the conditions of effective liquid chromatography. By combining ion-exclusion and partition chromatography in columns with the Aminex-A-6 sorbent using a 0.1 M ammonium borate solution as the eluent (pH 7.4), it is possible to separate ribo- and deoxyribo-nucleosides in view of the capacity of the former for complex formation with the borate ions of the eluent. The ribose derivatives converted into anions under these conditions are "expelled" from the negatively charged stationary phase.

Ion-exclusion chromatography has been used recently on an increasing scale for the separation of mixtures of nucleosides. The principle of this method has been frequently discussed in the literature[55,56]. The difference between the negative charges of the molecules as well as the different degrees of their non-specific sorption permit a comparatively rapid separation in an alkaline medium (pH 9.5) of complex mixtures of nucleosides on columns with Aminex A-6 cation-exchange resins[57,58].

The use of finer polymerisation resins and higher flow rates in ion-exclusion chromatography apparently makes it possible to increase greatly the efficiency of the method, which thus leads to considerable prospects for the employment of the high-pressure chromatographic technique.

3. Analysis of Mononucleotides and Their Derivatives

Anion-exchange sorbents are usually employed for the separation of mixtures of mononucleotides, because these compounds and the majority of their derivatives exist in the anionic form as a result of the acid dissociation of the phosphate groups ($pK_a^1 = 1$; $pK_a^2 = 6-7$[59]) over the entire range of the pH of the eluents normally used in ion-exchange chromatography. The data presented in Table 6 show that the Pellionex anion exchangers and the Zipax-SAX^{TM} sorbents are used most extensively for the analysis of these compounds under the conditions of high-pressure chromatography. The employment for these purposes of columns with spherical microbead polymerisation anion-exchange resins is limited[60,61], which in our view is due to the breakdown of the column packing in consequence of

Table 6. Conditions for the separation of nucleotides and their derivatives by high-pressure anion-exchange chromatography.

**Gradient elution.

***Isocratic elution.

the change in the swelling of the sorbent. In addition, a change in the composition of the eluting buffer normally leads to the compaction of the polymerisation sorbents, which is extremely undesirable under the conditions of high-pressure chromatography.

Attention should be drawn to the difference between the conditions for the separation of mixtures of nucleotides on various sorbents (Table 6), which may be caused by the different chemical structures of the sorbents themselves. Thus the separation of certain mixtures (for example of ribonucleotides, deoxyribonucleotides, etc.) under the conditions of isocratic elution[43,62] can be achieved on columns with the Zipax-SAX^{TM} ion exchanger. In particular, an effective and rapid separation of nucleoside 5′-phosphates has been achieved on columns with this sorbent using a 0.002 M KH_2PO_4 solution at pH 3.75 (Fig. 5). The use of a Pellionex carrier for this purpose requires the application of gradient elution[9,42]. Changes in the pH of the eluent are also frequently used together with changes in concentration in order to improve the resolution and shape of the peaks[9,42,43].

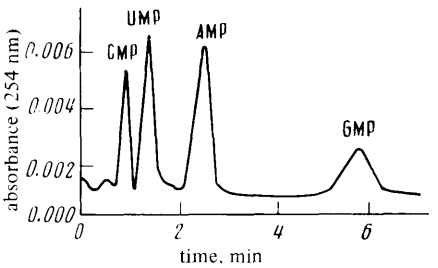

Figure 5. Separation of a mixture of nucleoside 5′-phosphates on a 2.1 mm × 100 cm column with the Zipax SAX^{TM} sorbent in a 0.002 M KH_2PO_4 solution (pH 3.75) at 60°C. Rate of elution 114.6 ml h^{-1}; pressure 64 atm.[43]

The position of the phosphate group in the nucleotide molecule influences the degree of protonation of the heterocyclic base[59] and hence the overall charge of the molecule and permits thereby the separation of isomeric nucleoside phosphates[9]. The conditions indicated in Fig. 6 for the separation of a mixture of nucleoside 2′,3′-phosphates have been used to analyse alkaline hydrolysates of RNA.[53]

The technique of high-pressure anion-exchange chromatography and the use of effective sorbents permit comparatively rapid separation of mono-, di-, and triphosphates of ribo- and deoxyribo-nucleosides[9,29,54] (see also Fig. 7), which require elution for many hours under the conditions of the usual chromatography[65]. Table 7 presents the retention times of nucleoside mono-, di-, and triphosphates as well as a number of their derivatives obtained by Brown[66] in chromatography on a Pellionex anion exchanger, which are extremely useful for the interpretation of chromatograms obtained in the separation of mixtures of free nucleotides and their derivatives from various extracts.

The possibility of rapid analysis of picomolar amounts of adenosine 5′-phosphate, adenosine 3,5′-cyclic phosphate, and adenosine 5′-triphosphate on columns with a Pellionex anion exchanger has been studied by a number of investigators in order to determine the activities of adenylate cyclase and adenosine 3′,5′-cyclic phosphate diesterase, which catalyse the reactions of the corresponding adenylic acid derivatives in tissue cells[67-69].

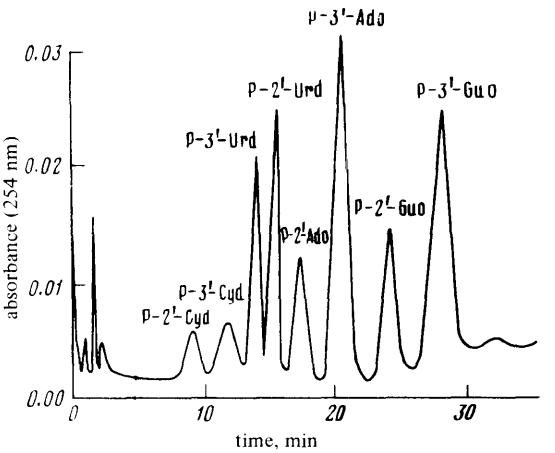

Figure 6. Separation of a mixture of nucleoside 2′,3′-phosphates (approximately 1 nmole of each) on a 1 mm × 300 cm column with a Pellionex anion exchanger in a solution with a linear KH_2PO_4 concentration gradient (0.01 M, pH 3.35–1.0 M, pH 4.20) at 75°C. Rate of elution 48 ml h^{-1}; pressure 207 atm.[64]

* Chromatographic conditions[66]: elution in a linear phosphate buffer gradient [0.015 M KH_2PO_4 (pH 3.25)–0.25 mm KH_2PO_4 (pH 4.20), 2.2 M KCl] at 75°C. Rate of elution 12 ml h^{-1}.

** The following abbreviations are used: 6Me–sPuoMP = 6-methylthioribosylpurine 5′-phosphate; sGMP = mercaptoguanosine 5′-phosphate; NAD^+, NADH = nicotinamide-adenine dinucleotide (oxidised and reduced); UDP-Glc = uridine diphosphate-glucose; UDP-GlcCOOH = uridine phosphate-glucuronic acid.

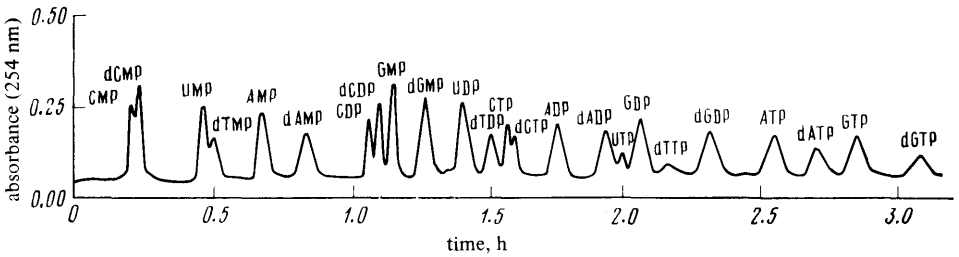

Figure 7. Separation of a mixture of ribo- and deoxyribo-nucleoside phosphates on a 0.62 mm × 20 cm column with the Aminex A-28 sorbent in a solution with a sodium nitrate concentration gradient (pH 8.6) at 70°C. Rate of elution 36 ml h^{-1}; pressure 15 atm.[64]

The successful separation of a mixture of nucleosides and nucleotides on columns with the Aminex A 28 polymerisation anion exchanger[48] (Fig. 8) permits rapid analysis of the oligonucleotide end groups, which is one of the essential stages in the study of the primary structure of the fragments of native nucleic acids.

Numerous studies on the content of the mononucleotides and their derivatives in various extracts in connection with biochemical and medicobiological research[70-73] also indicate the unique possibilities of high-pressure liquid chromatography, with which none of the available analytical methods can compete nowadays in this field.

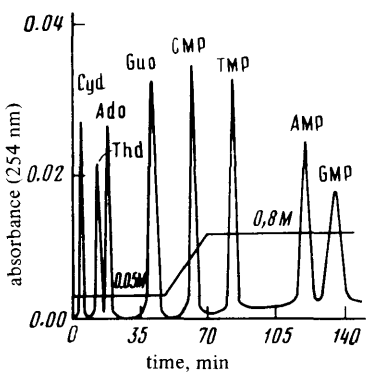

Figure 8. Separation of a mixture of deoxyribonucleosides and deoxyribonucleoside 5′-phosphates on a 1.8 mm × 50 cm column with the Aminex A-28 sorbent in a solution with a concentration gradient of a phosphate–borate buffer (0.05–0.8 M, pH 7.8) at 60°C. Rate of elution 25 ml h^{-1}; pressure 220 atm.[48]

4. Chromatography of Oligo- and Poly-nucleotides

Highly efficient separation of oligo- and poly-nucleotides with respect to both chain length and nucleotide composition is one of the urgent problems in the analytical chemistry of nucleic acids. The possibilities of high-pressure liquid chromatography as regards the solution of this problem have so far been inadequately investigated. The choice of sorbents for the separation of oligo- and poly-nucleotides whose behaviour in chromatography is determined not only by the structure of heterocyclic bases, the nature of the sugar residues, and the overall charge of the molecule but also by the molecular weight and characteristics of the steric interaction with the surface of the ion exchanger[77,78], constitutes a fairly complex problem. In this connection the permeability of sorbent particles to large molecules assumes particular importance. Thus the spherical microbead polymerisation anion exchangers with a high content of cross-links (up to 8–10%), used in high-pressure liquid chromatography are either altogether impermeable to polyanions with a high molecular weight or their permeability is extremely low owing to the low rate of diffusion of these compounds into the sorbent particles. On the other hand, as mentioned above, sorbents with a smaller content of cross-links are not used in high-pressure liquid chromatography in view of their more pronounced gel properties. They can be employed only as an ion-exchange film coating in the so-called pellicular sorbents[9]. However, the possibility of using such sorbents in the practical chromatography of oligonucleotides has been scarcely elucidated. Pellicular anion exchangers have so far been used only for the separation of dinucleotides[9,42,64].

The RPC-3 and RPC-5 anion-exchange systems with an inverted phase are used most frequently for the analysis of oligo- and poly-nucleotides[35-38]. These sorbents, first introduced into liquid chromatography by Kelmers and coworkers[35] for the fractionation of transfer RNA, are nowadays used successfully also for the separation of oligo- and poly-nucleotides[39,40]. Their chromatographic characteristics depend on the chemical nature of the liquid stationary phase, which usually consists of liquid tetraalkylammonium salts, as well as the structure of the particles which serve as the solid support.

The solid supports in the RPC-3 and RPC-4 systems consist of silica or silica gel particles. To ensure the firm binding of the liquid quaternised amine to the surface of such particles, the latter are silylated, i.e. treated with trialkyl- or triarylchlorosilanes[37,39]. The data obtained by Holton et al.[39] suggest that the use of chlorotriphenylsilane for this purpose is preferable, because it improves considerably the chromatographic properties of the sorbent. Holton et al.[39] were able to achieve with the aid of the sorbents the separation of thymidylic acid oligonucleotides under the conditions of isocratic elution with a 0.5 M solution of an ammonia–formate buffer (pH 5.25). The RPC-5 system, where fluoro-polymer particles are used as the solid support, also proved to be effective for the

fractionation of oligo- and poly-nucleotides with respect to their chain length[40]. Use of the system enabled the authors[40] to achieve the separation of a 60-component mixture of homologous nucleotides having the general formula $(Ap)_xU$ ($x = 1, 2, 3, \ldots$).

The lack of information concerning the separation on these sorbents of mixtures of oligo- and poly-nucleotides with a more complex structure precludes so far an assessment of the prospects and limits of their employment. There is no doubt that the capacity of certain oligonucleotides for self aggregation in aqueous salt solutions[79] and the associated enhancement of the role of secondary non-ionic interaction create certain difficulties in their chromatography on sorbents of this kind. On the other kind, the impossibility of employing under the conditions of high-pressure liquid–liquid chromatography of organic compounds such as urea, dioxan, etc. (normally used to suppress secondary interactions of this kind[80,81]), owing to the considerable increase of the viscosity of the mobile phase and the increase of the solubility in the latter of the liquid stationary phase, aggravate these difficulties still further.

In this connection the study of the possibility of using for the separation of mixtures of oligo- and poly-nucleotides of coarsely porous sorbents with a bound ion-exchange phase[41] in which the hydrocarbon groups of amines are attached to silica gel particles via strong covalent bonds, which have become available in recent years, appears to be very promising. These sorbents include Partisil-10 SAX (Whatman, England) and Lichrosorb NH_3 (E.Merk, German Federal Republic). While possessing all the advantages of systems with an inverted phase, they permit an extensive variation of the composition of the eluates, extending thereby appreciably the scope of their applications.

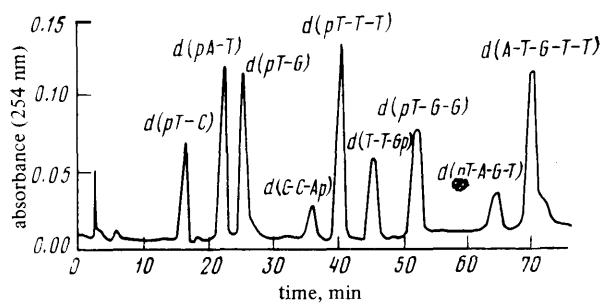

Figure 9. Chromatography of oligodeoxyribonucleotides on a 2 mm × 25 cm column filled with silica gel (particle size approximately 10 μm) with covalently attached hydrocarbon groups of primary amines in a solution with a linear phosphate buffer concentration gradient (0.10 M KH_2PO_4, pH 3.30–0.75 M KH_2PO_4, pH 4.25) at room temperature. Rate of elution 60 ml h^{-1}; pressure 180 atm.[81]

Data obtained by Aukati et al.[81] have shown that columns containing silica gel with grafted aminoalkyl groups can be used successfully for the fractionation of olinucleotides with respect to both their length and composition (Fig. 9). The stability of the stationary phase in such columns with respect to organic solvents and their stability over a wide pH range (1–8.5) ensure a satisfactory reproducibility of the analytical results and a long lifetime of the columns[82].

---o0o---

Summarising the data discussed in this review, one must conclude that the application of modern high-pressure ion-exchange chromatography permits the successful separation of ultramicroanalytical amounts of a very great variety (as regards complexity) of mixtures of the structural components of nucleic acids. The commercial availability of the necessary chromatographic apparatus and ion-exchange sorbents ensuring a high rate of mass transfer and the associated efficiency of the chromatographic process permit the employment of the high-pressure liquid chromatographic technique in the solution of a very large number of problems in research on the composition, structure, and functional role of nucleic acids. One may hope that further investigation of the possibilities of the sorbents already available and the appearance of new ion-exchange materials will eventually permit a further extension of the limits of applicability of the high-pressure liquid–liquid chromatographic technique, whose efficiency is in many instances comparable to that of gas chromatography.

The Oxygen Radical-anion O_2^- in Chemical and Biochemical Processes

I.B.Afanas'ev

The review considers studies of the chemical and biochemical processes with participation of the oxygen radical-anion O_2^- and its principal physicochemical characteristics. Methods for the preparation of O_2^- in aqueous and aprotic media, are examined as are protonation, nucleophilic substitution and oxidation-reduction reactions involving this species, the formation of O_2^- in enzymatic processes and in photosynthesis, the role of O_2^- in the oxygenation of haems, phagocytosis, pathological processes, the toxic effect of oxygen etc.
The bibliography includes 675 references.

I. INTRODUCTION

In 1957-1960 Emanuel' and coworkers[1-3] demonstrated for the first time the importance of the involvement of free radicals in normal and pathological vital processes of organisms. One of the most convincing confirmations of the free-radical hypothesis in biology proved to be the identification in biological systems of the oxygen radical-anion O_2^-. The hypothesis of the involvement of O_2^- in enzymatic processes was put forward by Fridovich and Handler in 1958-1962[4-6]. However, as early as 1934 the possible involvement of O_2^- in chemical reactions was pointed out by Haber and Weiss[7,8] in a study of the decomposition of hydrogen peroxide and the oxidation of metal ions by oxygen in aqueous solutions:

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + HO^{\cdot} + HO^- , \quad (1)$$

$$HO^{\cdot} + H_2O_2 \rightarrow H_2O + HOO^{\cdot} , \quad (2)$$

$$HOO^{\cdot} \rightleftarrows H^+ + O_2^{\cdot-} , \quad (3)$$

$$Fe^{2+} + O_2 \rightleftarrows Fe^{3+} + O_2^{\cdot-} . \quad (4)$$

At the present time the formation of O_2^- has been demonstrated in many chemical reactions. Studies on biochemical processes involving O_2^- (enzymatic reactions

catalysed by oxidoreductases, the interaction of haems with oxygen, the mechanism of the protection of the organism from the toxic effect of oxygen, problems of phagocytosis, etc.) have begun to develop, particularly vigorously. A number of reviews devoted to various problems of the chemistry and biochemistry of O_2^- have been published recently[9-19]. In the present review we thought it useful to survey all the principal investigations of the chemical and biochemical properties of O_2^-.

II. PHYSICAL PROPERTIES OF O_2^-

In the "free" oxygen radical-anion the unpaired electron is delocalised over both oxygen atoms. However, in liquid and solid phases there is a possibility of the formation of ion pairs of O_2^- and counterions—metal or organic cations. The compounds NaO_2 and KO_2 are crystalline substances which are sparingly soluble in organic solvents. In contrast to them, NR_4O_2 (R = alkyl) readily dissolves in dimethylformamide (DMF), dimethyl sulphoxide (DMSO), acetonitrile, etc. The structure of MO_2 (M = metal) was investigated by infrared and Raman spectroscopy[20-24] and EPR[25-34]. The EPR spectrum of O_2^- has been observed only at a low temperature (77 K). It was found[25] that the EPR spectrum of O_2^-, obtained by the electrochemical reduction of oxygen in DMF, is characterised by an anisotropic g-factor ($g_1 = 2.006$, $g_2 = 2.009$, and $g_3 = 2.041$). Analogous EPR spectra were obtained when O_2 was reduced in pyridine[26], for MO_2 complexes (M = Ti^{4+}, Hf^{4+}, Tl^{4+}, Sn^{4+}, etc.) in solution[30,31], and for crystalline NaO_2.[29] In addition, using a rapid freezing technique, the EPR spectra of O_2^- and $^{17}O_2^-$ have been obtained[27,28] in the course of the oxidation of xanthene by xanthene oxidase. The observed values of the g-factor can be accounted for by the interaction of O_2^- with the solvent or cations[34]. Apart from the complexes of O_2^- with metal cations, its compounds with cobalt(III)[35-37] and rhodium(III)[38] complexes, which can exist both as monomers and dimers, have been described.

It has been found by the technique of pulse radiolysis that the ultraviolet spectrum of O_2^- in aqueous solutions has a maximum at 250 nm (ϵ = 1800–2000 litre mole^{-1} cm^{-1}).[39-44] λ_{max} = 462 nm for O_2^- in solution in pyridine[45]. The spectrum of O_2^- in acetonitrile, with a maximum at 250 or 255 nm, has been described[46,47]. However, the observation of this maximum may be a consequence of instrumental errors[47], particularly since it is known[48,49] that the absorption maxima of radical-anions in aprotic solvents should be displaced towards longer wavelengths compared with aqueous solutions in consequence of the hydration of the radical-anions in the latter.

The reduction of oxygen in aprotic solvents involves a one-electron mechanism. It has been shown[25] that O_2 is reduced in DMSO and DMF at $E_{1/2}$ = −0.73 and −0.80 V respectively and O_2^- is reduced at −2.40 and −2.8 V. Analogous data were obtained for the reduction of O_2 in DMSO on platinum, gold, and mercury[26,50,51] and in pyridine, dimethylacetamide (DMA), acetonitrile, acetone, methylene chloride, etc. on mercury[26,52-54]. The one-electron reduction of oxygen is quasi-reversible[26], the deviation from reversibility being apparently due to the protonation and dismutation of O_2^-.[55] Owing to the rapid reaction of O_2^{2-} with the solvent, the reduction of O_2^- is fully irreversible[56]. When oxygen is reduced in DMF and DMSO in the presence of metal cations, there is an anodic shift of the one-electron wave (owing to the formation of MO_2 ion pairs) and a mixture of the corresponding metal peroxides and superoxides is formed[51,57].

In contrast to aprotic solvents, in aqueous solutions oxygen is reduced electrochemically via a formally two-electron mechanism consisting of two one-electron stages[58]

$$O_2 \xrightarrow{e} O_2^{\cdot-} \xrightarrow{H^+} HOO^{\cdot} \xrightarrow{e} HOO^- . \qquad (5)$$

However, it has been observed recently[59,60] that, in the presence of surface-active substances (quinoline or triphenylphosphine oxide) the protonation of O_2^- on the surface of the cathode is difficult. Under these conditions and at high pH (when the rate of disproportionation of O_2^- is low), O_2^- can be obtained also in aqueous solutions. It has also been suggested that O_2^- be generated by the continuous radiolysis of a formate solution saturated with oxygen[50,51].

Recently much attention has been devoted to a more accurate determination of the O_2 reduction potential in aqueous solution—a parameter which is of great biochemical importance. The initial value $E_0(O_2/O_2^-) = -0.56$ V (relative to the hydrogen electrode)[63] is undoubtedly too low. Thermodynamic calculation yielded $E_0(O_2/O_2^-) = -0.18$ V.[44] Wood examined critically the published values of E_0[60,63,65,66] and concluded that $E_0 = -0.33 \pm 0.01$ V.[64] Then, in a later study[67], a higher value $E_0(O_2/O_2^-) = 0.07 \pm 0.02$ V was again obtained. However, this problem can now apparently be regarded as solved: in a number of independent studies on the reduction of O_2 in the presence of surface-active substances[68] and of the equilibria in the reactions of O_2^- with quinones[69-71] and with cytochrome c[72] values in the range $E_0(O_2/O_2^-) = -0.28$ to −0.32 V were obtained. One should bear in mind that these values were calculated for $p_{O_2} = 1$ atm; adjustment to $[O_2] = 1$ M leads to $E_0(O_2/O_2^-) = -0.11$ to −0.15 V respectively. The higher O_2 reduction potential in aqueous solutions compared with aprotic solvents can probably be accounted for by the difference between the O_2^- solvation energies[73]. Indeed the energy of solvation of O_2^- by water molecules in the gas phase is higher by 2–3 kcal mole^{-1} then the energy of solvation by acetonitrile molecules[74].

III. CHEMICAL PROPERTIES OF O_2^-

1. The Lifetime of O_2^- in Solution

Earlier it was postulated that the lifetime of O_2^- in aqueous solution is very short and that the disproportionation rate constant is high: $k_6 = 2 \times 10^7$ litre mole^{-1} s^{-1}:[75-77]

$$O_2^{\cdot-} + O_2^{\cdot-} \xrightarrow{2H_2O} H_2O_2 + O_2 + 2HO^- . \qquad (6)$$

However, it was later shown that $k_6 < 10$ litre mole^{-1} s^{-1},[42,68,78] so that at pH > 7 O_2^- exists for a relatively long time (the half-life is approximately 1 min at pH 13)[68]. According to the latest data, reaction (6) can be altogether neglected ($k_6 < 0.3$ litre mole^{-1} s^{-1}) and in real aqueous solutions O_2^- disappears as a result of reaction with HOO$^{\cdot}$ or impurities[79].

In aprotic solvents O_2^- exists much longer. Depending on the oxygen reduction conditions and primarily on the possibility of contact between O_2^- and aqueous solutions and the anolyte as well as the O_2^- concentration, the half-life of O_2^- in basic solvents (DMF, DMSO) is 1–20 h[50,73,80-84]. In acetonitrile the stability of O_2^- is much lower[84,85] and one cannot therefore agree with recommendations concerning the use of acetonitrile solutions of O_2^- in biochemical experiments[46,47]. Data[46] showing the instability of O_2^- in DMF can probably be accounted for by the presence of moisture and other impurities in the solvent employed[83].

2. The Reactions of $O_2^{\cdot-}$ in Aqueous Solutions

The oxygen radical-anion can be formed in aqueous solutions in various oxidation-reduction processes, for example in the Haber–Weiss cycle mentioned previously[7,8], and also in the oxidation of hydroquinones[86] and anthranols[87] in an alkaline medium. However, photolysis and radiolysis of oxygen-saturated aqueous solutions, which can contain hydrogen peroxide or formic acid, are nowadays widely used for the generation of $O_2^{\cdot-}$†:

$$H_2O \rightarrow H^{\cdot} + HO^{\cdot} + e(aq) \quad , \tag{7}$$

$$e(aq) + O_2 \rightarrow O_2^{\cdot-} \quad , \tag{8}$$

$$HO^{\cdot} + HCOO^- \rightarrow H_2O + COO^{\cdot-} \quad , \tag{9}$$

$$COO^{\cdot-} + O_2 \rightarrow CO_2 + O_2^{\cdot-} \quad , \tag{10}$$

$$H^{\cdot} + O_2 \rightarrow HOO^{\cdot} \tag{11}$$

$$HO^{\cdot} + H_2O_2 \rightarrow H_2O + HOO^{\cdot} \tag{12}$$

$$HOO^{\cdot} \rightleftarrows H^+ + O_2^{\cdot-} \quad . \tag{13}$$

*Method of competition kinetics.
**The stopped flow method.
***Flash photolysis; in the remaining cases pulse radiolysis was used to determine the constants.
****Neutral protonated radical.

In addition $O_2^{\cdot-}$ can also be formed in electron transfer processes:

$$A^{\cdot-} + O_2 \rightarrow A + O_2^{\cdot-} \quad . \tag{14}$$

†It has recently been suggested that KO_2 be used to investigate the reactions of $O_2^{\cdot-}$ in aqueous solutions[78,88]. However, the accuracy of quantitative calculations in this case is doubtful.

The rate constants for these reactions are listed in Table 1. The formation of $O_2^{\cdot-}$ in the oxidation by oxygen of macrocyclic nickel(I) complexes, on the one hand, and of univalent Ag^+, Cd^+, Co^+, $HgCl^+$, Pb^+, and Zn^+ ions, on the other, has been described by Tait et al.[104] and Sellers and Simic[105] respectively.

Neutral organic radicals as a rule react with oxygen to form peroxy-radicals. However, the final product of the oxidation of α-hydroxyalkyl radicals in an alkaline medium can be $O_2^{\cdot-}$:[106,107]

$$HOCR_2OO^{\cdot} \overset{pH\ 9.8}{\rightleftarrows} H^+ + {}^-OCR_2OO^{\cdot} \rightarrow O_2^{\cdot-} + CR_2O \quad . \tag{15}$$

A bimolecular process is also possible:

$$HO^- + HOCR_2OO^{\cdot} \rightarrow H_2O + {}^-OCR_2OO^{\cdot} \rightarrow O_2^{\cdot-} + CR_2O \quad . \tag{16}$$

The rate constants have been found for the following radicals:

Radical	k_{15}, s^{-1}	k_{16}, litre mole^{-1} s^{-1}
$HOCH_2OO^{\cdot}$	$< 10^{5}$[108]	$1.5 \cdot 10^{10}$[108]
$HOCH(CH_3)OO^{\cdot}$	52[108]	$8 \cdot 10^{9}$[108]
$(CH_3)_2C(OH)OO^{\cdot}$	550[107], 665[108]	$5 \cdot 10^{9}$[108]
$(HO)_2C_6H_5OO^{\cdot}$	$8 \cdot 10^{3}$[109]	—
$^-OOCCH(NH_2)OO^{\cdot}$	$1.5 \cdot 10^{5}$[110]	—

The most important chemical processes involving $O_2^{\cdot-}$ are protonation and electron transfer reactions. The protonation reaction (13) is reversible. Its equilibrium constant is usually characterised by the pK for the radical $HOO^{\cdot}$. It has been shown[42,44] that the previously published values of pK($HOO^{\cdot}$) are too low and pulse radiolysis gave pK($HOO^{\cdot}$) = 4.9 ± 0.1. The heat of ionisation and hence the heat of reaction (13) are zero[44]. It has been found recently that $k_{-13} = 4.7 \times 10^{10}$ litre mole^{-1} s^{-1} [68] and $(5 \pm 1) \times 10^{10}$ litre mole^{-1} s^{-1};[94] $k_{13} = (7 \pm 2) \times 10^5$ s^{-1}.[94]

The one-electron $O_2^{\cdot-}$ oxidation reactions

$$O_2^{\cdot-} + A \rightarrow O_2 + A^{\cdot-} \tag{17}$$

in aqueous solutions have been studied mainly by pulse radiolysis. The rate constants for reactions (17) are listed in Table 2. The reactions involving the reduction of $O_2^{\cdot-}$ to the dianion of hydrogen peroxide O_2^{2-} in aqueous solutions are unknown. A combination of two processes is energetically more favourable: the protonation of $O_2^{\cdot-}$ and the reduction of the resulting peroxy-radical. Thus it has been found[67] that the rate constants for the reaction

$$QH_2 + O_2^{\cdot-} \rightarrow HOO^- + QH^{\cdot} \tag{18}$$

are $(1.3–1.7) \times 10^7$ litre mole^{-1} s^{-1} (QH_2 is hydroquinone, methylhydroquinone, or 2,5-dichlorohydroquinone).

It has been shown recently that $O_2^{\cdot-}$ can add to cobalt(II)[125] and iron(II)[120,129] complexes as well as Mn^{2+} ions[127,130] in aqueous solutions without a change in the valence of the metals. The reaction products have the structures of superperoxy- or peroxy-complexes. Analogous oxygenated complexes are formed in the reactions of $O_2^{\cdot-}$ with natural cobalt and iron complexes and their analogous (see Section VI).

3. The Reactions of $O_2^{\cdot-}$ in an Aprotic Medium

Solutions of $O_2^{\cdot-}$ in aprotic solvents can be prepared in two ways: using NaO_2, KO_2, and $R_4N^+O_2^{\cdot-}$ formed beforehand or by the electrochemical reduction of oxygen in the presence of tetra-alkylammonium salts ($R_4N^+O_2^{\cdot-}$ can be obtained by mixing K_2O and R_4NOH powders[131,132]). Furthermore $O_2^{\cdot-}$ is formed when various organic compounds (diketones,

hydroquinones, azo- and nitro-compounds, enolates, etc.) are oxidised by oxygen [133-138], for example [136]:

$$PhNO_2^-K^+ + O_2 \rightarrow PhNO_2 + KO_2 \ . \qquad (19)$$

i bipy = 2,2-bipyridyl.
j Radiolysis in a flow system.
k Rotating sector method; in the remaining cases pulse radiolysis was used to determine the rate constants.

Similarly $Ru(bipy)_3^+$ reduces O_2 to O_2^- in acetonitrile with $k = 8.5\times10^8$ litre mole^{-1} s^{-1}.[139] It has been observed recently that O_2^- is formed in the decomposition of hydrogen peroxide induced by bases in pyridine[140].

It was shown in an early study[20] that KO_2 and NaO_2 in tetrahydrofuran (THF) and benzene react with acid anhydrides and chlorides via the S_N2 mechanism, forming acyl peroxides. These results have been recently confirmed[141]. It was observed[142] that the solubility of KO_2 in aprotic solvents increases sharply in the presence of crown-ethers. Subsequently it was shown that, under these conditions, KO_2 readily reacts with alkyl halides[143-145], tosylates[143,145], sulphonates[144], and esters[146]. Depending on the solvent, peroxides[144] or alcohols[143,145,147] can be formed. The latter are apparently the products of the transformations of hydroperoxides[145,148]. Using the method of "spin traps", the formation of RO$^\cdot$ radicals in the reaction of KO_2 with RHal was demonstrated; they probably arise as a result of side reactions of ROO$^\cdot$.[149] The rate constants for the reactions of KO_2 with alkyl bromides have been determined by the stopped flow method in DMSO at 25°C: 670 ± 20 litre mole^{-1} s^{-1} for MeBr, 350 ± 20 litre mole^{-1} s^{-1} for EtBr, 150 ± 10 litre mole^{-1} s^{-1} for BuBr, and 65 ± 1 litre mole^{-1} s^{-1} for iso-PrBr.[150] The authors concluded that O_2^- is apparently the most powerful nucleophile in aprotic solvents.

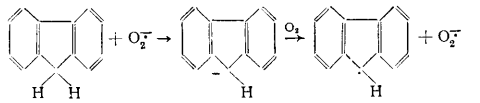
Like alkyl halides, aryl halides react with KO_2 to give a high yield of phenols[151,152]. However, in this case the reaction probably proceeds with electron transfer, because atmospheric oxygen is introduced into the reaction product:

(20)

Similarly, bromo- and chloro-quinolines react with KO_2 to form hydroxyquinolines[153], while bishalogenomethylarenes are converted into cyclic peroxides[154].

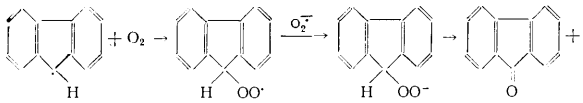
Somewhat earlier the nucleophilic reactions of the oxygen radical-anion were investigated using O_2^- prepared electrochemically. It was shown[155,156] that O_2^- reacts with primary alkyl halides in DMF and DMSO, forming alkyl peroxides quantitatively, and the nucleophilic substitution mechanism was proved for the first time:

$$O_2^- + AlkX \rightarrow AlkOO^\cdot + X^- \ , \qquad (21)$$



$$AlkOO^\cdot + O_2^- \rightarrow AlkOO^- + O_2 \ , \qquad (22)$$

$$AlkOO^- + AlkX \rightarrow AlkOOAlk + X^- \ . \qquad (23)$$



It has been shown recently[157] that reactions of the electrochemically generated O_2^- with phenyl benzoate and *p*-chlorophenyl benzoate result in the formation of aryl peroxides with rate constants of 3 ± 0.3 and 25 ± 5 litre mole^{-1} s^{-1}. $k_{21} = 1.1\times10^4$ litre mole^{-1} s^{-1} for benzyl bromide[158].

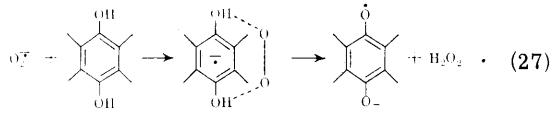
The protonation of O_2^- by phenols, carboxylic acids, and alcohols in DMF has been investigated polarographically[159]. The reaction rate constants are in the range 10^2–10^3 litre mole^{-1} and are not correlated with the pK of the proton donors. It has been pointed out[160] that the acid-catalysed disproportionation (6) is responsible for the ability of O_2^- to react with weak acids such as water. It has been suggested in a number of studies that O_2^- can abstract a hydrogen atom from compounds with an active C–H bond.

Thus the following reaction mechanism has been proposed for the chain oxidation of fluorene by the superoxide ion[73]:

(24)

(25)

The current yield of fluorenone is 5000%. Diphenylmethane is oxidised to benzophenone via an analogous mechanism (yield 400%) and 9,10-dihydroanthracene is oxidised to a mixture of anthracene and anthraquinone (yield 2000%). Apart from DMF, pyridine[45] and DMSO[161] can be used as solvents. The nucleophilic addition of O_2^- to activated double bonds has also been described; for example, benzylidenefluorene reacts with O_2^- to form fluorenenone[155] and hexa-1,3-diene and hexa-1,4-diene are converted into benzene[161]. Cyclohex-2-en-1-one forms an epoxide under analogous conditions[155]. According to the latest data, in an aprotic medium O_2^- oxidises hydrazines[162], hydrazones[162], amines[163], benzopyridine derivatives[164], and nitroalkylbenzenes[165], and reduces styrene[166].



As in aqueous solutions, in aprotic solvents O_2^- readily reduces quinones (whose redox potentials are greater than that of O_2) to semiquinones. The reaction of O_2^- with benzoquinone, trimethylbenzoquinone, menadione, ubiquinones Q_0 and Q_9, tocopherylquinone, and vitamin K_1 in DMF have been investigated[80-82,167,168]. Apart from benzoquinone, the reaction is reversible in all cases. The equilibrium constants have been determined spectrophotometrically for the reactions of O_2^- with the following quinones: trimethylbenzoquinone (7.9 ± 0.6), menadione (1.5 ± 0.1), ubiquinone Q_0 (2.0 ± 0.4), ubiquinone Q_9 (2.9 ± 0.2), tocopherylquinone (1.9 ± 0.2), and vitamin K_1 (5.6 ± 0.4).[168] The closeness of the equilibrium constants to unity suggests that natural quinones can function in biological systems as traps for O_2^- (see below). One-electron reduction of quinones[169] and α-methylacridinone[170] has also been observed in reactions with KO_2; the latter readily reduces copper(II) to copper(I) in phenanthrene complexes[142] and organic copper salts[171]. The reduction of phenoxy-radicals to phenols by the superoxide ion[172] and the reaction of O_2^- with the thianthrene radical-cation[173] have also been described.

It has recently been observed[174,175] that O_2^- is capable of quenching singlet oxygen via an electron transfer reaction:

$$O_2^- + O_2(^1S) \rightarrow O_2 + O_2^- \quad . \qquad (26)$$

According to Guirand and Foote[174], $k_{26} = 1.6 \times 10^9$ litre mole^{-1} s^{-1} in DMSO. An appreciably lower value of k_{26} was found in another study[46], apparently owing to the use of an incorrect extinction coefficient[46] in the calculation of the O_2^- concentration. It is suggested that electron transfer is the first stage in the interaction of KO_2 with the chalcones $RC_6H_4COCH{=}CHC_6H_4R$[176] and tetracyclanes[177].

The possibility of the oxidation of *p*- and *o*-hydroquinones by the superoxide ion in an aprotic medium was first demonstrated in 1976.[178-180] It was observed that the reduction proceeds with the intermediate formation of semiquinone radical-anions; in particular, the semiquinones derived from catechol[178-181], trimethylhydroquinone, dopamine[167,181], adrenaline, and noradrenaline[167] were identified with the aid of electronic and EPR spectroscopy. The absence of oxygen from the reaction mixture indicates a single-stage mechanism of the formation of semiquinones[181]:

(27)

The reduction of O_2^- to O_2^{2-} by aromatic dianions with rate constants of 10^{-3} litre mole^{-1} s^{-1} at 0°C has been described[182].

The reactions of O_2^- accompanied by chemiluminescence are of special interest, primarily for biochemical research. In the initial studies by Stauff and coworkers[183,184] it was pointed out that chemiluminescence due to the formation of singlet oxygen is observed in the reaction of O_2^- with HOO· and on disproportionation of O_2^-:

$$O_2^- + HOO\cdot \rightarrow O_2(^1S) + HOO^- \quad , \qquad (28)$$

$$(O_2 \cdot O_2(^1S)) \rightarrow 2O_2 + h\nu \quad . \qquad (29)$$

According to Khan's data[185], chemiluminescence with the same origin is observed in reactions of KO_2 with anthracene, fluorescein, etc., while Arneson[186] showed that it occurs in reactions catalysed by xanthine oxidase.

Although subsequently doubt was thrown on these results[169,187,188], the formation of $O_2(^1S)$ on protonation of O_2^- was confirmed by experiments involving a specific reagent for singlet oxygen—1,3-diphenylisobenzofuran[189]. Since the formation of $O_2(^1S)$ is possible only when the heat of reaction is greater than the energy of the excitation of O_2 from the ground triplet state to the excited singlet state, the chemiluminescence due to the formation of $O_2(^1S)$ should be observed in the fastest reactions of O_2^-. Indeed, the formation of $O_2(^1S)$ in recombination reactions of O_2^- with radical-cations has been noted[190]. It is noteworthy that, as early as 1970, Dietz et al.[73] suggested that $O_2(^1S)$ is formed in the reaction of O_2^- with diphenylanthracene radical-cations. Khan[191] examined the possibility of the formation of $O_2(^1S)$ as a result of the direct disproportionation of O_2^-, but, Bielski and Allen[79] believe that this process is impossible in real systems. The formation of singlet oxygen has been recently observed in the reaction of O_2^- with diacyl peroxides[192].

Apart from $O_2(^1S)$, the chemiluminescence in the reactions of O_2^- can be due to other compounds. Thus the emission of light has been observed in the reactions of O_2^- with lucigenin[193], *N*-methylacridinone[170], luminol, and luciferin[194]. Some of these reactions were used in biochemical research for the identification of O_2^-.

IV. THE FORMATION OF O_2^- AND ITS INTERACTION WITH BIOLOGICALLY ACTIVE SUBSTRATES

Since O_2^- is present in virtually all components of the living cell, the elucidation of the sources of its formation and the probable mode of its subsequent reactions constitute an urgent problem. This section deals with reactions involving biologically active substrates; enzymatic reactions of O_2^- and interaction with haems are discussed below.

In 1969 Massey et al.[195] noted that O_2^- is formed when reduced flavins are irradiated with visible light under aerobic conditions. The reactions were inhibited by

superoxide dismutase (SOD)—an enzyme which causes the rapid dismutation of $O_2^{\cdot-}$ to O_2 and H_2O_2 (see Section V). Analogous results were obtained in another study[196] where fluorescein, eosin, Methylene Blue, and acridine were used in addition to flavins as one-electron reductants for oxygen. Photolysis resulted in the reduction of nitro blue tetrazolium, which indicated the formation of $O_2^{\cdot-}$.[197-199] The one-electron reduction of oxygen by flavin radicals and reduced flavins was studied by pulse radiolysis and photolysis in water[200-202] and by the stopped flow method in DMF[203]. Fluorescein, tryptophan, and $NADPH_2$ are capable of initiating the formation of compound III of lactoperoxidase (Fe^{3+}-complex of $O_2^{\cdot-}$) on irradiation under aerobic conditions[204]; this reaction is inhibited by SOD. It has been shown[205] that $O_2^{\cdot-}$ is formed in the aerobic oxidation of $NADH_2$ by phenazine methosulphate. The methods described are widely used nowadays for the generation of $O_2^{\cdot-}$ in biochemical experiments.

Other procedures for the generation of $O_2^{\cdot-}$ are also known. It has been shown that $O_2^{\cdot-}$ is formed in the photolysis of water and by its treatment with ultrasound[206,207], in the decomposition of K_3CrO_8 in aqueous solutions[208], and in the photolysis of aqueous CdS suspensions[209]. It has been observed with the aid of SOD that $O_2^{\cdot-}$ is formed in the oxidation of pyrogallol[210], thiols (dithiothreitol, mercaptoethanol, and glutathione)[211], 2-amino-4-hydroxy-6,7-dimethyl-5,6,7,8-tetrahydropteridine and a natural cofactor (tetrahydrobiopterin)[212-214], phenylhydrazine[215], a number of cytotoxic agents (6-hydroxydopamine, 6-aminodopamine, dialuric acid, etc.)[216-218], hydroxylamine[219,220], and dihydroxyfumaric acid[221] and in the photolysis of solutions of tryptophan[222,223], dianisidine[224], and phenoxazine derivatives[225]. The formation of $O_2^{\cdot-}$ in the oxidation of the radical-cation of the herbicide paraquat (1,1-dimethyl-4,4-bispyridinium ion) is biologically important (see Section VII)[226]. Evans et al.[227] questioned the possibility of this reaction but subsequent studies[228,229] confirmed the initial conclusions[226].

The study of reactions of $O_2^{\cdot-}$ with biologically active substrates is of particular importance, because the mechanism of the toxic effects of $O_2^{\cdot-}$ in living organisms and the possibility of combatting them can be discovered in this way. In this connection there has been much interest shown in the reactions of $O_2^{\cdot-}$ with natural hydroquinones, whose mechanism in an aprotic medium was examined previously (see Section III). As early as 1970 Miller observed[198] that *o*-dihydroxybenzenes (catechol, Tiron, and 3,4-dihydroxybenzoic acid) inhibit the reduction of cytochrome *c* by the superoxide ion. It has been shown[230] that $O_2^{\cdot-}$ generated by xanthine oxidase oxidises adrenaline to adrenochrome. This reaction has become an important method for the identification of $O_2^{\cdot-}$ in biological systems. However, one must bear in mind that the oxidation of adrenaline and other catecholamines entails the formation of $O_2^{\cdot-}$.[231,232] Subsequently the reactions of $O_2^{\cdot-}$ with *o*-dihydroxybenzene were investigated by pulse radiolysis[233,234].

α-Tocopherol is not oxidised by the oxygen radical-anion in an aqueous solution[235,236]. However, this is probably due to the low solubility of tocopherol, because $O_2^{\cdot-}$ reacts with its water-soluble analogue in water[235] and with 6-hydroxy-2,2,5,7,8-pentamethylchroman in THF.[237] It has been shown recently[167] that both tocopherol and tocopheryl acetate are capable of reacting with $O_2^{\cdot-}$ in DMF. Ascorbic acid reacts with $O_2^{\cdot-}$ can be formed in the oxidation of ascorbic acid[238]. However, the identification[239] of $O_2^{\cdot-}$ in this process was erroneous[240] and ascorbic acid is therefore an effective "trap" for the superoxide ion. Thiols can also function as traps for $O_2^{\cdot-}$.[236,241] The generally accepted mechanism of these reactions involves two stages with the intermediate formation of a neutral semiquinone:

$$AH_2 + O_2^{\cdot-} + H^+ \rightarrow AH^{\cdot} + H_2O \quad , \qquad (30)$$

$$AH^{\cdot} + O_2^{\cdot-} + H^+ \rightarrow A + H_2O_2 \quad . \qquad (31)$$

However, one must bear in mind the possibility of reactions with the formation of radical-anions, as was shown for analogous processes in an aprotic medium (see Section III).

Yang[242] showed in 1970 that the oxidation of methionine by sodium bisulphite under aerobic conditions is inhibited by SOD, which led him to suggest the involvement of $O_2^{\cdot-}$ in this reaction. (However, according to the latest data[243], $O_2^{\cdot-}$ is capable of reacting with methional to only a slight extent.) The involvement of $O_2^{\cdot-}$ in the sulphoxidation of ethionamide (2-ethyl-4-thioisonicotinamide—an active second-order tuberculostatic agent) by the $NADH_2$–phenazine methosulphate system and in the corresponding enzymatic process has also been suggested[244]. The possibility of the specific interaction of $O_2^{\cdot-}$ with model lipid membranes, due to the attraction of $O_2^{\cdot-}$ to the positively charged side of the membrane, has been demonstrated[245].

Table 3. Rate constants for the reactions of biologically active substrates and enzymes with $O_2^{\cdot-}$ and O_2.

a,b,cMethods of flash photolysis, stopped flow, and competition kinetics were used to determine k respectively; in the remaining cases pulse radiolysis was used.
d $PQ^{\cdot} + O_2 \rightarrow PQ^{2+} + O_2^{\cdot-}$.
e pH ~ 7.
f pH ~ 8.4.
g pH 9.

The possibility of the interaction of $O_2^{\cdot-}$ with H_2O_2 (the "Haber–Weiss reaction")—a process ensuring the formation of the hydroxy-radical in living cells, i.e.

$$O_2^{\cdot-} + H_2O_2 \rightarrow O_2 + HO^- + HO^{\cdot} \qquad (32)$$

has been studied in a number of investigations. In contrast to the initial hypothesis, the rate of reaction (32) is extremely low according to the latest data[246-248] (although

the reaction between O_2^- and t-BuOOH is possible[249]). However, HO· is apparently formed in the presence of iron or copper complexes[248,250,251]:

$$O_2^- + M^{n+1} \rightarrow O_2 + M^n \quad , \tag{33}$$

$$M^n + H_2O_2 \rightarrow M^{n+1} + HO^- + HO\cdot \quad . \tag{34}$$

The rate constants for reactions of biologically active substrates and enzymes with O_2^- and O_2 are listed in Table 3.

V. THE PARTICIPATION OF O_2^- IN ENZYMATIC OXIDATION-REDUCTION PROCESSES

1. The Participation of O_2^- in Reactions Catalysed by Dehydrogenases, Oxygenases, Hydroxylases, and Peroxidases

In the early studies by Fridovich and Handler[4-6] the hypothesis of the formation of O_2^- in reactions catalysed by milk xanthine oxidase (EC 1.2.3.2)‡—an enzyme under the action of which xanthine is oxidised to uric acid—was based on the ability of the system to initiate the oxidation of sulphite. It was suggested that the O_2^- involved in the reaction is bound to an enzyme. Subsequently a specific enzyme—superoxide dismutase (SOD, EC 1.15.1.1), capable of inducing rapid dismutation of O_2^-—was discovered[271,272]. O_2^- was identified by EPR directly in the reaction of xanthine with xanthine oxidase (XO)[27,28] and also in the oxidation of reduced tetra-acetylriboflavin[263] and ferredoxin[273]. Gray et al.[28] used isotopically substituted oxygen for the final identification of O_2^- in reactions.

The problem of which XO active centres are responsible for the formation of O_2^- was discussed in the literature for a number of years. Massey et al.[195] showed that under aerobic conditions reduced flavins readily reduce cytochrome *c*, the reaction being inhibited by SOD. It has also been shown[273,274] that, after the removal of flavin, XO is incapable of producing O_2^-. On this basis, it was concluded that O_2^- is generated in XO by flavin-adenine dinucleotide (FAD). However, it has been found[275,276] that the rate of generation of O_2^- by ferredoxin is higher by a factor of approximately 12 than the rate of generation by flavins.

A recent careful analysis of the inter-relations between various electron transferring agents in XO showed[277,278] that the oxidation of the reduced enzyme by oxygen consists of two stages; the first, rapid stage, during which five electrons are transferred to oxygen, is due to the interaction of oxygen with a flavin, while the second, slow stage, in which one electron is transferred, is due to the interaction of oxygen with ferredoxin. The authors proposed the following process mechanisms:

$$FADH_2 + O_2 \rightleftarrows FADH_2 \cdot O_2 \, , \tag{35}$$

$$FADH_2 \cdot O_2 \rightarrow FADH \ldots O_2^- + H^+ \, , \tag{36}$$

$$FADH_2 \ldots O_2^- + H^+ + e \xrightarrow{\text{very fast}} FAD\text{-}H_2 \ldots O_2^- \, , \tag{37}$$

$$FADH_2 \ldots O_2^- \xrightarrow{\text{very fast}} FAD\text{-}H\cdot + H_2O_2 \, , \tag{38}$$

$$FADH \ldots O_2^- \rightarrow FADH\cdot + O_2^- \, , \tag{39}$$

$$FADH \ldots O_2^- + H^+ \rightarrow FAD + H_2O_2 \quad . \tag{40}$$

As already stated, the reactions catalysed by XO are accompanied by chemiluminescence[186], which indicates the accumulation of O_2^- in the course of the first three minutes of the reaction[279]. However, the source of the luminescence has not been established[280].

It is natural to suppose that xanthine oxidase cannot be the only enzyme generating O_2^-; the latter should undoubtedly be formed also in other enzyme systems. As early as 1969 it was suggested[281] that O_2 can be reduced to O_2^- in any biological system with strong reducing properties.

Massey et al.[282] postulated that three groups of flavoproteins—dehydrogenases (participating in dehydrogenation processes), oxygenases (under the action of which two oxygen atoms are introduced into the substrate), and hydroxylases (which introduce the hydroxy-group into the substrate)—are capable of reacting with O_2 in their reduced form, forming peroxy-compounds FlOOH, but the latter decompose into a flavosemiquinone and O_2^- only in the case of dehydrogenases. This view concerning the structure of the intermediate compounds of dihydroflavins with oxygen has been generally accepted[283], but later it was suggested that a charge-transfer complex and not a hydroperoxide decomposes into a semiquinone and O_2^-.[284]

The ability of dehydrogenases to generate the superoxide ion has been demonstrated in a number of studies. Massey et al.[195] observed that SOD inhibits the aerobic reduction of cytochrome *c* by the $NADPH_2$ + lipoxidase (EC 1.13.11.12), $NADPH_2$ + glutathione reductase (EC 1.6.4.2), $NADPH_2$ + ferredoxin-NADP reductase (EC 1.6.99.4), and $NADPH_2$ + reduced NADP dehydrogenase (EC 1.6.99.1) systems, i.e., as in the case of XO, electron transfer from these systems to cytochrome *c* is achieved with the aid of the oxygen radical-anion. These data have been confirmed for the $NADPH_2$ + ferredoxin-NADP reductase system[285]. It was shown subsequently that the above enzyme system can produce O_2^- in the oxidation of ferredoxin[276], FMN, or menadione[286]. The ferredoxin–ferredoxin–NADP reductase complex can also generate O_2^-, and, according to the authors[287,288], O_2^- is formed in this case on oxidation of ferredoxin and not the flavin.

It was observed in 1969[289] that, when lactoperoxidase (EC 1.11.1.7) is added to the $NADPH_2$ + reduced NADP-cytochrome *c* reductase (EC 1.6.2.4) system, compound III of peroxidase, which is a complex of O_2^- with the enzyme, is formed. On this basis, it was concluded that reduced NADP-cytochrome *c* reductase can generate O_2^- and this was subsequently confirmed[290-292]. It has been shown[293] that at low temperatures cytochrome oxidase forms the oxygenated complex $Cu(II)Fe(II)O_2^-$.

In contrast to earlier data[195], Nakano et al.[291] showed that at pH > 9, L-aminoacid oxidase (EC 1.4.3.2) is probably capable of generating O_2^-. The involvement of O_2^- (in the form of the active complex $Cu^{2+}O_2^-$) in reactions catalysed by galactose oxidase (EC 1.1.3.9) has been demonstrated[294,295]. Earlier data[296], showing the absence of inhibition of the reaction by SOD, can be accounted for by the presence of peroxidase[295]. The O_2^- ion is formed in the oxidation of 2-nitropropane to acetone, catalysed by 2-nitropropane dioxygenase, which is indicated by the inhibition of the reaction following the addition of SOD and by its acceleration when KO_2 is added[297]. According to some data[298-300], O_2^- is formed in reactions catalysed by mitochondrial enzymes: dihydroorotate dehydrogenase (EC 1.3.3.1) (DOD) and possibly succinate dehydrogenase (EC 1.3.99.1) (SD). DOD contains flavin and non haem iron and its properties should therefore resemble those of xanthine oxidase. Indeed it has been observed[298-300] that

‡The classification of enzymes is based on the recommendations of the Commission on Biochemical Nomenclature[270].

the reduction of dichlorophenolindophenol in reactions catalysed by DOD is 30% inhibited by the addition of SOD. Although the analogous reaction involving SOD is fully inhibited by SOD, its initial rate is only 3% of the rate of oxidation of succinate to fumarate and in the presence of phenazine methosulphate SOD does not inhibit the reduction of dichlorophenolindophenol by succinate dehydrogenase. It is believed that phenazine methosulphate and oxygen compete in the interaction with the active centre of SD.

The role of lactate dehydrogenase (EC 1.1.2.3) (LDH) in the oxidation of $NADH_2$ by the superoxide ion is very interesting. It is known[301] that in the presence of protons $O_2^{\cdot-}$ can slowly oxidise $NADH_2$:

$$NADH + H^+ + O_2^{\cdot-} \rightarrow NAD + H_2O_2 \quad . \qquad (41)$$

It has been observed[302,303] that the rate of oxidation of $NADH_2$ increases sharply when $NADH_2$ is bound to LDH. The reaction proceeds via a chain mechanism (the chain length at pH 7.35 is 6.2) and is inhibited by SOD. The formation of $NADH_2$ complexes with a non-specifically binding protein (albumin) did not accelerate the oxidation. The following reaction mechanism was proposed[256,260]:

$$LDH + NADH \rightleftarrows LDH.NADH \quad (K = 10^{-6} \text{ litre mole}^{-1}), \qquad (42)$$

$$LDH.NADH + H^+ + O_2^{\cdot-} \rightarrow LDH.NAD^{\cdot} + H_2O_2 \quad [k_{43} = (1.0 \pm 0.2) \cdot 10^4 \text{ litre mole}^{-1}\,s^{-1}], \qquad (43)$$

$$LDH.NAD^{\cdot} + O_2 \rightleftarrows LDH.NAD^+ + O_2^{\cdot-} \quad (k_{44} = 10^9 - 10^{10} \text{ litre mole}^{-1}\,s^{-1}), \qquad (44)$$

$$LDH.NAD^+ \rightleftarrows LDH + NAD^+ \quad (K = 10^{-4} \text{ mole litre}^{-1}). \qquad (45)$$

As already pointed out, according to Massey et al.[282] oxygenases and hydroxylases should generate $O_2^{\cdot-}$ much less effectively than dehydrogenases. However, one must bear in mind that here one is dealing with a comparison of the activities of flavins forming part of the composition of the enzyme; naturally, there exist also other active centres generating $O_2^{\cdot-}$ (for example haems and non-haem iron).

Brady et al.[304] pointed out the possibility of activating tryptophan oxygenase (EC 1.13.11.11) by the oxygen radical-anion, but they thought that such activation was insignificant. However, it has been shown in a number of studies[305-311] that $O_2^{\cdot-}$ is a substrate in reactions catalysed by this enzyme, forming with haemin an oxygenated complex, whose decomposition in the presence of tryptophan leads to the formation of the reaction product—formylkynurenine. It has been observed[312] that luciferin is oxidised by electrolytically produced $O_2^{\cdot-}$ to hydroxyluciferin. It is believed[312] that $O_2^{\cdot-}$ is also involved in the oxidation of luciferin by luciferase from *Pholas dactylus*. However, this reaction is not inhibited by SOD because, according to the authors, $O_2^{\cdot-}$ is bound to the Fe^{3+}-form of the enzyme. The participation of $O_2^{\cdot-}$ in the oxidation of cystamine catalysed by cystamine oxygenase has been demonstrated[313].

There is evidence for the possibility of the involvement of $O_2^{\cdot-}$ or the products of its subsequent reactions, $HOO^{\cdot}$ and $O_2(^1S)$, in the hydroxylation of aromatic compounds[314-317]. As for model systems, SOD inhibits hydroxylation in the presence of a number of enzymes. Thus it has been shown that SOD inhibits the hydroxylation of *n*-hydroxybenzoate and anthranilate by 3-hydroxybenzoate 4-monooxygenase (EC 1.14.93.13) and anthranilate 3-monooxygenase (EC 1.14.16.3),[318] the oxygenation of dopamine to noradrenaline by dopamine β-monooxygenase (EC 1.14.17.1) from the adrenal gland[319], and the hydroxylation of benzphetamine by a set of three microsomal components: cytochrome "P-450", reduced NADP cytochrome "P-450" reductase, and phosphatidylcholine[320,321], i.e. in all these enzyme systems the formation of $O_2^{\cdot-}$ may be expected.

The mechanism of hydroxylation with participation of cytochrome "P-450" was studied in greater detail. Strobel and Coon[320] suggested that, among the three microsomal components mentioned above, hydroxylation is carried out by cytochrome "P-450", while reduced NADP cytochrome "P-450" reductase transfers electrons from $NADPH_2$ to cytochrome *c* and phosphatidylcholine transfers electron from $NADPH_2$ to cytochrome "P-450". However, in 1973 Coon and coworkers[322] observed that $O_2^{\cdot-}$ is formed both in the presence and absence of cytochrome "P-450", i.e. is produced by the reductase; $NADPH_2$ and the reductase can be replaced by other systems generating $O_2^{\cdot-}$, for example the XO + xanthine system. It has been shown[323,324] that, when camphor is hydroxylated by the $NADH_2$ – putidaredoxin oxidoreductase + putidaredoxin (a protein containing two iron atoms and two sulphur atoms) + cytochrome "P-450cam" from *Pseudomonas putidas*, chemiluminescence inhibited by SOD is observed. It is assumed that $O_2^{\cdot-}$ is formed in this system as a result of the oxidation of the oxygenated cytochrome "P-450cam" complex via a side reaction[325].

Earlier it had been suggested[326,327] that $O_2^{\cdot-}$ is not formed in the terminal hydroxylation of alkanes and aliphatic acids by the enzyme system consisting of rubredoxin, reduced NAD rubredoxin oxidoreductase (EC 1.6.99) and ω-hydroxylase (EC 1.14.99) from *Pseudomonas oleovorans*, because the reaction is not accelerated by XO and is not inhibited by SOD. However, May et al.[328] showed that in the presence of $NADH_2$ the above system initiates the oxidation of adrenaline inhibited by SOD, i.e. $O_2^{\cdot-}$ is generated. The hydroxylation of aromatic compounds by hydroxylases, for example, the rat liver benzopyrene 3-monooxygenase (EC 1.14.14.2) containing cytochrome "P-450", is also induced by $O_2^{\cdot-}$.[329,330]

As early as 1963 it was suggested[331] that $O_2^{\cdot-}$ is involved in reactions catalysed by peroxidases (EC 1.11.1.7). Indeed it has been shown[332-335] that the oxygenated form of myeloperoxidase and horse radish peroxidase (compound III) is the product of a reaction of the Fe^{3+}-forms of the enzymes with $O_2^{\cdot-}$. For example, compound III of myeloperoxidase is formed when the enzyme is treated with a solution of $O_2^{\cdot-}$ in DMF.[335] It has also been shown[336] that peroxidase induces the hydroxylation of coumaric acid inhibited by SOD. Compound III of peroxidase can dissociate into the Fe^{3+}-form of the enzyme and $O_2^{\cdot-}$, because it oxidises $NADH_2$ and adrenaline[334,337], both reactions being inhibited by SOD. Bielski and coworkers investigated the reaction of $O_2^{\cdot-}$ with horse radish peroxidase by pulse radiolysis[261,338] (see Table 3).

It has been suggested that $O_2^{\cdot-}$ is involved in the oxidation of $NADH_2$[339-342] and dihydroxyfumaric acid[221] catalysed by peroxidases. $NADH_2$ is apparently oxidised via an analogous mechanism by catalase in the presence of hydrogen peroxide[343]. There is a possibility of the involvement of $O_2^{\cdot-}$ in the biosynthesis of prostaglandins[344] and reactions catalysed by ceruloplasmin[345].

It has been shown that $O_2^{\cdot-}$ is formed in the mitochondria of the liver[346] and heart muscle[347-350] and in liver microsomes[351,352]. It has been stated[347] that $O_2^{\cdot-}$ is generated by a component of the mitochondrial respiratory chain localised between the sites of inhibition by antimycin and rotenone and is then converted under the influence of SOD, which protects enzymes and membranes from its toxic activity, into H_2O_2. However, approximately 20% of the total amount of $O_2^{\cdot-}$ apparently fails to react with SOD and

migrates via membranes causing the peroxidation of lipids[353].

The question of the production of $O_2^{\cdot-}$ in microsomes by flavins[354], cytochrome b_{566},[353] mitochondrial ubiquinones[355,356] and microsomal cytochrome "P-450"[357-359] and reduced NADP cytochrome *c* reductase[360,361] needs to be considered. According to the results of Bartoli et al.,[361] $O_2^{\cdot-}$ is generated in the liver microsomes of new born rats only by reduced NADP cytochrome *c* reductase, while in adult animals both the reductase and cytochrome "P-450" act with equal efficiency. However, the evidence for the formation of $O_2^{\cdot-}$ under the influence of reduced NADP cytochrome *c* reductase was recently questioned[362]. Rich and Bonner[363] believe that the formation of $O_2^{\cdot-}$ in mitochondria has no special physiological significance, constituting a "short circuit" in the electron transfer chain.

When studying the ability of mitochondria and microsomes to generate $O_2^{\cdot-}$ account must be taken of possible artefacts induced by a change in the concentration of oxygen in the experiments *in vitro*. In particular, it is unlikely that $O_2^{\cdot-}$ can be produced by ubiquinones[355,356], because both hydroubiquinones and ubiquinones are effective "traps" for the oxygen radical-anion[167,168].

2. Reactions of Superoxide Dismutase

As already stated, SOD is an enzyme which causes the dismutation of $O_2^{\cdot-}$ to H_2O_2 and O_2. Cu-containing SOD has been isolated from bovine blood erythrocytes[272]. Subsequently Mn- and Fe-containing SOD were isolated from the bacteria *E. coli*.[364] The mechanism of the interaction of SOD with $O_2^{\cdot-}$ is based on the ability of a variable-valence atom (for example a copper atom) to oxidise and reduce $O_2^{\cdot-}$ alternately in the presence of protons:

$$E\text{-}Cu^{2+} + O_2^{\cdot-} \rightarrow E\text{-}Cu^{+} + O_2 \quad , \qquad (46)$$

$$E\text{-}Cu^{+} + O_2^{\cdot-} + 2H^{+} \rightarrow E\text{-}Cu^{2+} + H_2O_2 \quad . \qquad (47)$$

It is believed[365] that one of the coordination sites of the copper atom is free and that it is the site where $O_2^{\cdot-}$ is bound. However, calculation of the redox potential of oxygen based on the thermodynamics of the interaction of SOD with $O_2^{\cdot-}$ favours an outer-sphere mechanism[71]. It has been shown that water protons are not involved in reaction (47).[366] According to the latest data[367], the most likely proton donor is the imidazole residue, which binds zinc and copper ions:

$$Zn^{II}\text{—}N\!\!\left\langle\!\!\begin{array}{l}\diagup\\ \diagdown\end{array}\!\!N\text{—}Cu^{II}\text{—}OH_2 \underset{O_2^{\cdot-}}{\overset{O_2^{\cdot-}}{\rightleftarrows}} Zn^{II}\text{—}N\!\!\left\langle\!\!\begin{array}{l}\diagup\\ \diagdown\end{array}\!\!NH\cdot Cu^{I}\text{—}OH_2 \quad . \qquad (48)$$

In a study of the optical spectra of the reduced and oxidised forms of Cu-containing SOD, Fielden et al.[368] showed that, after the addition of the $O_2^{\cdot-}$ solution, an equilibrium mixture of both forms is formed in both cases. Hodgson and Fridovich[369] demonstrated the reversibility of reactions (46) and (47) using tetranitromethane, a strong electron acceptor, to achieve a leftward shift of the equilibrium. It is believed[370] that at pH > 12 SOD binds hydroxide ions and promotes their oxidation by oxygen with formation of $O_2^{\cdot-}$. It has been shown that univalent anions (Cl^-, HO^-, etc.), capable of combining with a copper atom, are competitive inhibitors of SOD[371,372].

The rate constants for reactions catalysed by SOD have been found by pulse radiolysis, polarographically, and by the method of competitive kinetics (Table 4). Table 4 shows that $k_{46} \simeq k_{47} = (1-3) \times 10^9$ litre mole^{-1} s^{-1} and that the values of k_{46} for Cu-containing SOD are almost independent of pH. For Mn- and Fe-containing SOD, the values of k_{46} decrease with increasing pH. The activation energy for reaction (46) has been found to be 4600 cal mole^{-1}.[376]

Table 4. The rate constants (litre mole^{-1} s^{-1}) for the oxidation-reduction reactions of SOD at 25°C and pH 6–7.

***The values of k_{46} have been divided by 2, since the enzyme consists of four subunits instead of two.

Two $O_2^{\cdot-}$ destruction processes were observed in the reaction of Mn-containing SOD: a rapid process in which the valence of manganese changes from 3 to 2 and a slow process in which Mn^+ is formed[380]. However, it may be that Mn^{2+}- and Mn^{3+}-SOD (and not Mn^+-SOD) are also involved in the slow catalytic process but at a different hydrolytic state.[383] Only rapid reactions apparently occur *in vivo*. A linear relation has been observed[384] between lg k_{46} and $I^{1/2}$ (I is the ionic strength of the solution), whose slope is −1.5 for the ClO_4^-, SO_4^{2-}, and HPO_4^{2-} anions and −2.23 for Cl^-. It is suggested[384] that a slope of −1.50 is consistent with the Brønsted theory. However, this claim is incorrect, because in fact the species reduced in reaction (7) is not $O_2^{\cdot-}$ (as assumed in the calculations), but $HOO^{\cdot}$. The influence of electrolytes on the catalytic activity of SOD has also been studied in another investigation[385].

When SOD is used to identify $O_2^{\cdot-}$, account must be taken of the fact that Cu-containing SOD is inactivated by hydrogen peroxide[366,386,387], the inactivation being accompanied by luminescence and the reduction of cytochrome *c*. In doubtful cases one must therefore use Mn-containing SOD. The use of Fe-SOD can also lead to errors owing to the presence in it of traces of iron capable of reacting with $O_2^{\cdot-}$.[388]

The ability of SOD to induce the rapid dismutation of $O_2^{\cdot-}$ was regarded previously as a unique characteristic of this enzyme. However, as early as 1973 Sawada and Yamazaki observed[262] that peroxidase exhibits a dismutase activity. Similarly a non-specific SOD activity has been observed for galactose oxidase[389], catalase, haemoglobin, and methaemoglobin[390]. Weser and coworkers[123,379,391,392] showed that simple copper(II) chelates exhibit dismutase activities. A similar activity is apparently shown by quinoline complexes of manganese[388,393] and iron[394].

The problem of whether or not O_2^- is the sole substrate of SOD or whether the enzyme is capable of suppressing the formation of singlet oxygen has been discussed recently in the literature[395,396]. According to some data[397,398], SOD does not inhibit the reaction of singlet oxygen obtained by traditional methods. However, contrary results have been obtained by Weser and coworkers[397-402], so that the question remains obscure.

3. The Involvement of O_2^- in Photosynthesis

The problem of a possible role of O_2^- in photosynthetic processes has been discussed in a number of studies. It has been observed[403-405] that the aerobic oxidation of sulphite and the reduction of cytochrome *c* by spinach chloroplasts is inhibited by SOD. It has been suggested[403-405] that O_2^- is generated by photosystem I, because the blocking of electron transport by photosystem I led to the inhibition of the photochemical oxidation of adrenaline. Epel and Neumann[406] postulated that O_2^- is formed in the oxidation of electron acceptors with a low redox potential such as Methyl Viologen, which was confirmed by experiments using free radical traps[407]. The primary electron acceptor photosystem I apparently generates O_2^-,[403-405,408] although the involvement of ferredoxin is not ruled out[409,410]. It has been shown[411] that O_2^- is also formed on irradiation of hydrolysed chlorophyll.

The manganese(II) compounds present in chloroplasts exhibit a dismutase activity[128,412]. It has been shown[128] that manganese(II) pyrophosphate undergoes non-catalytic oxidation by the superoxide ion. It has been suggested[413] that O_2^- formed in chloroplasts can be involved in the hydroxylation of *p*-coumaric acid. According to some data[414,415], the reduction of oxygen to O_2^- by chloroplasts is stimulated by ascorbate, which oxidises O_2^- via the mechanism examined previously (see Section IV). It has been suggested[416] that O_2^- is involved in the oxidative cleavage of α,β-dihydroxyethyl(2)thiamine pyrophosphate catalysed by transketolase during photosynthesis.

VI. THE PARTICIPATION OF O_2^- IN THE OXIDATION-REDUCTION REACTIONS OF NATURAL MACROCYCLIC METAL COMPLEXES AND THEIR MODELS

The interaction of natural metal complexes, for example, porphyrin complexes of iron (haems), with oxygen can be represented in a general form by the equation

$$PFe^{II} + O_2 \rightleftarrows \underset{(I)}{PFe^{II}O_2} \rightleftarrows \underset{(II)}{PFe^{III}O_2^-} \rightleftarrows PFe^{III} + O_2^- \quad . \qquad (49)$$

Haemoglobin (Hb) and myoglobin (Mb) are known to form stable oxygenated complexes (HbO_2 and MbO_2), whereas oxygenated forms have not been observed for cytochromes (with the exception of cytochrome "o"[417]). In contrast to Co-analogues of haems, for which it has been established firmly that their oxygenated complexes have the structure of the ion pairs $Co^{III}O_2^-$,[418-432] the structure of the oxygenated complexes of haems continues to be discussed in the literature. There are data supporting both structure (I)[433-437] and structure (II)[306,332,438-443]. In a recent study[444] based on the analysis of the fluorescence spectra of MbO_2 it was concluded that there is an equilibrium between forms (I) and (II), which is displaced towards the former under the usual conditions. It has been shown in recent years that simple iron(II) complexes of porphyrins can form oxygenated structures at a reduced temperature and in the case of sterically hindered complexes at the normal temperature[437,444-450].

Eqn. (49) shows that O_2^- can be formed on decomposition of oxygenated complexes of haems. Indeed the superoxide ion has been observed in the autoxidation of oxyhaemoglobin and oxymyoglobin[451-454]. It has been shown that the oxidation of HbO_2, accompanied by the formation of O_2^-, is accelerated under the influence of phenoxides[455,456], hydroquinone, catechol[457], phenylhydrazine[455,458], menadione[458], etc. Presumably the reaction with electron donors (hydroquinones, phenoxides) involves the reduction of coordinated O_2^- to HOO^- with subsequent dissociation of the complex to methaemoglobin and HOO^-.[456] A similar reaction has been described for oxygenated cobalt complexes[460]. In the presence of electron acceptors (for example, quinones) direct one-electron oxidation of oxyhaemoglobin is possible[459]. In addition, O_2^- is formed in the flash photolysis of HbO_2[461] and in ligand substitution reactions[462,463]:

$$Hb^{II}O_2 + X^- \rightarrow Hb^{III}X^- + O_2^- \quad ; \qquad X^- = CN^-,\ N_3^-\ \text{etc.} \qquad (50)$$

The kinetics of the reaction of O_2^- with cytochrome *c* have been investigated in detail[263-268] (see Table 3):

$$O_2^- + \text{cytochrome } (Fe^{III}) \rightleftarrows O_2 + \text{cytochrome } c\,(Fe^{II}) \quad . \qquad (51)$$

The distinctive features of reaction (51) are a comparatively low rate and the dependence of the rate constant on pH. It is believed[267] that the low rate of this reaction can be accounted for by the involvement of water molecules in the transition state; according to Koppenol et al.,[268] O_2^- attacks the edge of the porphyrin ring. The reaction proceeds without the formation of an intermediate complex[266,267]. The dependence of the rate constant on pH is apparently due to the change in the conformation of cytochrome[266,267], but the result may be distorted by the influence of the ionic strength[268]. Apart from cytochrome *c*, O_2^- is capable of reducing its derivatives, for example, acetylated cytochrome *c*.[464]

The autoxidation of ferrocytochrome *c* is a slow reaction ($k_{-51} = 3 \times 10^{-2}$ litre mole^{-1} s^{-1} [72]). As was to be expected, SOD accelerates autoxidation, causing a rapid dismutation of O_2^-.[465,466] Cytochrome b_5, whose reduction potential is lower by 200 mV than that of cytochrome *c*, is oxidised with formation of O_2^- but at a much lower rate (the rate constant is 23 litre mole^{-1} s^{-1}).[257] In conformity with Eqn. (49), the reaction of O_2^- with metHb results in the formation of HbO_2,[269,467-469] but there is no reaction with $metHb_4$.[469] At the same time O_2^- can oxidise HbO_2 to metHb, evidently via the mechanism examined above[269,467,470,471]. In contrast to normal haemoglobin, the reaction of O_2^- with unstable haemoglobins results in the oxidation of thiol groups and the formation of dimers[467].

The study of the mechanism of the interaction of O_2^- with natural metal complexes and their models in an aprotic medium has begun recently. It is of particular importance, because real biochemical processes involving haems take place in a hydrophobic environment. As early as 1973 Ellis and Pratt[472] showed that O_2^- forms at −50°C an oxygenated complex with hydroxocobalamin (vitamin B_{12a}) in DMF. Analogous observations were made also for the reaction of O_2^- with the dimethyl ether of Fe(III)-protoporphyrin IX.[473] It has been shown recently[474] that at room temperature O_2^- reduces Co(II)-phthalocyanine ($Co^{II}Pc$) to $Co^{I}Pc$, while the reaction of O_2^- with Co(II)-tetraphenylporphyrin ($Co^{II}TPP$) leads to the formation of the dinuclear complex $TPPCo^{II}OOCo^{II}TPP$,[475] although $Co^{I}TPP$ is also formed as an intermediate. In aqueous solutions O_2^- is

apparently incapable of reducing cyanocobalamin[258], but it reacts in DMF at room temperature with both hydroxy- and cyano-cobalamin, the former being reduced to the Co(II)-form (vitamin B_{12r}).[476] The final reaction products are probably dinuclear peroxy-complexes in both cases[475].

Like cyanocobalamin, haemin chloride is not reduced by the oxygen radical-anion in aqueous solutions[477], but the reaction does proceed in DMF, a new oxygenated haem complex, having the structure $PFe^{II}O_2^-$ or $PFe^{II}(O_2^-)_2$ being formed in the presence of a large excess of O_2^-.[478] The reliability of the identification of the oxygenated complex in the reaction of O_2^- with the dimethyl ether of protoporphyrin IX[473] is questioned in the same investigation[478]. The reduction of Mn(III)-tetraphenylporphyrin by the oxygen radical-anion in DMSO at room temperature[479] and the formation of the oxygenated complex $ZnTPPO_2^-$ in the reaction of KO_2 with ZnTPP[480] have also been described.

VII. THE TOXIC EFFECT OF O_2^- AND ITS INVOLVEMENT IN PATHOLOGICAL PROCESSES AND PHAGOCYTOSIS

Presumably the O_2^- formed in enzymatic reactions is capable of involvement in side reactions with its immediate environment and exerts thereby a toxic effect on the cell structure. As early as 1969, it was suggested[272] that SOD plays a protective role against the toxic effect of O_2^- in the organism. It was shown subsequently[481] that, when the microorganisms *Str. faecalis* and *E. coli* are grown under oxygen pressure up to 20 atm, the content of SOD increases sharply. The suppression of the synthesis of SOD by puromycin led to a decrease of the number of viable cells. The addition of SOD increased the lifetime in an oxygen medium of *E. coli* cells grown anaerobically and also suppressed the toxic effect of streptonigrin on the latter[482,483], which demonstrates, according to the author, the ability of streptonigrin to generate O_2^- under aerobic conditions. Analogous effects were observed in air and in an oxygen medium for the eukaryote *Saccharomyces cerevisiae*, grown under anaerobic conditions[484].

It has been shown that an increase of the activity of SOD in erythrocytes assists the survival of new born babies[485]. The liver of rat embryos does not contain SOD and its formation is induced by respiration[486]. The radioprotective action of SOD has been discovered recently. It was found that oxygen increases the lethal effects of radiation of cells (apparently in consequence of the formation of O_2^-), while SOD increases their resistance[487-493].

As already stated, *E. coli* cells contain Mn- and Fe-SOD. It has been found[364] that Mn-SOD is localised in the cell matrix and protects the organism from the action of endogenic O_2^-, while Fe-SOD, present in the periplasm, offers protection against exogenic O_2^-. It has been shown[494,495] that the pulmonary toxicity of oxygen is due to the formation of O_2^-. The damage to lungs due to this cause can occur during the oxidation of the herbicide paraquat[496,497], the ability of which to generate O_2^- has also been demonstrated in other biological objects[498,499] (see also Section IV). In order to reduce the effect on the lungs of the O_2^- generated during smoking, it has been suggested that SOD be used as a medicinal preparation[500]. Furthermore, O_2^- can cause the oxidative degradation of ribonuclease and the autoxidation of lysyl-tRNA synthetase (EC 6.1.1.6)[501], can reduce the level of glutathione in cells with a deficiency of glucose-6-phosphate dehydrogenase[502], and can inactivate DNA[503].

Various mechanisms of the toxic effect of O_2^- have been considered in the literature. In a number of studies it has been suggested that O_2^- or the singlet oxygen formed as a result of its dismutation are involved in the peroxidation of lipids[400,504-512]. However, it may be that O_2^- participates in the peroxidation of lipids only indirectly by reducing the complex Fe^{3+}-ADP to Fe^{2+}-ADP, which then reacts with lipids[513,514]. It has been shown[515] that O_2^- cannot react directly with cholesterol—an important component of lipid membranes. It has been postulated that O_2^-, formed in the autoxidation of menadione[459,502], 1,4-naphthoquinone-2-sulphonate[516], phenylhydrazine[455,458,502,517], dialuric acid[217], and dihydroxyfumaric acid[518,519], induces the haemolysis of erythrocytes. However, it is more likely that the true haemolytic agents are HO$^\cdot$, $O_2(^1S)$, and H_2O_2,[520-522] formed as a result of secondary reactions of O_2^-.

It has been observed that the reactions of O_2^- with catecholamines[167], cobalamins, and their models[125,475] lead to the formation of stable compounds, which are apparently no longer capable of participating in the normal metabolic processes. This has been confirmed in a study[523] where it was observed that the interaction of O_2^- with catecholamines in rat liver microsomes induces the covalent binding of catecholamines to proteins, which may be the cause of hepatitis. The ability to generate O_2^- is probably the cause of the toxic effect of 6-hydroxy- and 6-amino-dopamines[217] and of β-lapachone[524].

It has been shown recently[525] that O_2^- causes a decrease in the viscosity of the synovial fluid as a result of the depolymerisation of hyaluronic acid, which, according to the author, leads to the development of inflammatory arthritis; SOD inhibits this process and can therefore be used in the treatment of such diseases. There is also other evidence for the involvement of O_2^- in inflammatory processes[526-528] and certain anti-inflammatory drugs and their derivatives (copper complexes of salicylic acid[171,529], and penicillamine[530], corticosteroids[527,528], and others) are capable of interacting effectively with O_2^-. However, according to some data[351], corticosteroids do not inhibit and actually promote the formation of O_2^-. Na_2PtCl_6 exhibits a similar activity[531]. The formation of O_2^- in inflammatory processes can be the cause of the aggregation of thrombocytes and the liberation of serotonin[532].

Tyler observed[533] that O_2^- can inhibit the activity of reduced NAD dehydrogenase. In order to protect the enzymes of the respiratory chain from O_2^- generated in the course of respiration, mitochondria therefore contain SOD located in the immediate vicinity of reduced NAD dehydrogenase[349]. It has been shown[534] that O_2^- generated by xanthine oxidase can induce the mobilisation of iron from ferritin.

The problem of the role of the superoxide ion in cancer is of very great interest. It has been shown[535] that O_2^- can increase the carcinogenic effect of aromatic hydrocarbons. The generation of O_2^- could be the cause of the carcinogenic effect of 4-nitroquinoline *N*-oxide[536]. There are contradictory data concerning the presence and role of SOD in tumour tissues[346,537-543]. The view has been expressed[537] that cancer tissues are more sensitive to the action of O_2^- than normal tissues. It is believed[544] that O_2^- contributes to the inhibiting effect of bleomycin on cancer tissues. The role of O_2^- in the activity of another group of anticancer antibiotics, namely adriamycin, daunomycin, etc., has been discussed in a number of studies. It was observed that these antibiotics promote the formation of free radicals[545] and accelerate the oxidation of $NADPH_2$ in microcomes[546,547] and submitochondrial

particles[548]. The formation of O_2^- has been noted in all cases, which may be the cause of the high cardiotoxicity of the above antibiotics (as a result of the peroxidation of lipids[549]).

However, the hypothesis that adriamycin and daunomycin semiquinones can reduce oxygen to the superoxide ion[546-549] was not confirmed in the study of the interaction of O_2^- with adriamycin in an aprotic medium[550]. On the contrary, it was observed that, when solutions of O_2^- and adriamycin in DMF are mixed, the adriamycin semiquinone is formed quantitatively, i.e. adriamycin behaves as an effective trap for O_2^-. Consequently, adriamycin has a relatively high redox potential, which accounts for its ability to inhibit respiration in mitochondria[551,552]. The formation of O_2^- in the presence of adriamycin is apparently a consequence of unknown side reactions.

The high reactivity of O_2^- can be responsible not only for pathological phenomena but also for the protective response of the organism against external influences. The problem of the possible involvement of O_2^- in phagocytosis is therefore widely discussed in the literature. Thus Babior et al.[553] showed that polymorphonuclear leukocytes reduce cytochrome *c*, the process being inhibited by SOD. According to the data of Johnson et al.,[554] the introduction of SOD on latex particles into phagocytic vacuoles together with the bacteria *E. coli* and *Str. aureus* leads to the complete inhibition of phagocytosis. Subsequently, the formation of O_2^- in phagocytosis was confirmed for both polymorphonuclear and mononuclear leukocytes[555-567], macrophages[568,569], and blood plasma[570]. The generation of O_2^- by human blood thromobocytes has also been observed[571]. O_2^- can be regarded as one of the agents on which the bactericidal activity of leukocytes depends[572,573] although $HO^\cdot$ and H_2O_2 are apparently much more active[573,574].

Phagocytosis is accompanied by a sharply increased absorption of oxygen by granulocytes[555,576]. It is believed that an enzyme system, which employs $NADPH_2$ as the electron donor and generates O_2^-, is responsible for the respiratory burst[576]. It is interesting that increased absorption of oxygen and an increased rate of production of O_2^- in phagocytosis are not observed in patients suffering from chronic granulomatosis (CGM).[577] However, the subcellular fractions of normal and CGM leukocytes generate O_2^- at the same rates[559,578]. It is therefore possible that the cause of CGM is outside the oxygen metabolic system[578].

The mechanism of the involvement of O_2^- in phagocytosis is insufficiently clear. It has been suggested that O_2^- is formed in the phagosome as a result of the enzymatic[579] or Mn^{2+}-catalysed[580] oxidation of $NADPH_2$. The system generating O_2^- is probably associated with the surface of the leukocyte[581]. However, it is not clear how the activity of the enzyme increases sharply during phagocytosis, whether its action is suppressed by virulent bacteria, or whether the latter are specially protected against O_2^-. The generation of O_2^- in phagocytosis is enhanced in the presence of sulphydryl groups, fluoride ions, cytochalasins[582,583], immunoglobulin G[563,584], aliphatic acids[585], and anionic detergents (digitonin, deoxycholate, and zymosan)[584,586-590]. The membrane sialic acid apparently plays an important role in stimulating the formation of O_2^- in phagocytosis[591], while myeloperoxidase[592] and certain local anaesthetics[593] inhibit its formation. Doubts have been expressed also concerning the reliability of certain experiments demonstrating the involvement of O_2^- in phagocytosis[594,595]. Thus the problem of the role of O_2^- in phagocytosis still awaits its final elucidation.

During the preparation of the review for the press, new studies on the chemical and biochemical properties of O_2^- were published. New methods of generating O_2^- were described: by the oxidation of Cu_2O[596] and metal ions[597], by the decomposition of H_2O_2 on metal oxides[598], by the photolysis of aqueous solutions[599], by the photolysis of CdS in non-aqueous media[600], of $Ru(bipy)_3^{2+}$,[601] and of a melamine suspension[602], and also in electrocatalysis in the presence of cobalt chelates[603]. In contrast to earlier data, it was found that O_2^- is not formed in the reaction of $NADH_2$ with phenazine methosulphate[604]. The study of the chemical properties of O_2^- is being continued, namely: nucleophilic substitution reactions with alkyl halides, peroxides[605], and esters[606], electron transfer reactions with copper(II) salicylates[607] and cytochrome *c*[608], and the interaction of O_2^- with ascorbic acid and tocopherol[609-611], hydrogen peroxide (in the presence of iron ions)[612,613], olefins[614] and ketones (in the presence of catalysts of interphase transfer)[615]. The formation of nitroxy-radicals in the reaction of O_2^- with the *N*-oxides of heterocyclic compounds[616,617] and chemiluminescent reactions of O_2^- in the presence of carbonate[618], as well as new compounds of O_2^- with Ba^{2+} and Ca^{2+}[619] and with rhodium(III)[620] and cobalt(III)[621] complexes have been described.

The generation of O_2^- by mitochondria[622,623] and microsomes[624-627] and by reduced FMN[628] and microbial nutrient solutions[629] has been investigated in a number of studies. The study of the properties of SOD and its models has been continued[630-635] and it has been shown that data concerning the involvement in catalysis of only one of the two copper atoms are apparently incorrect[636]. The involvement of O_2^- in reactions catalysed by azoreductase[637], dopamine β-hydroxylase[638], kidney diaminooxidase[639], and 2-nitropropane dioxygenase[640] has been demonstrated. A study has been made also of the participation of O_2^- in reactions of peroxidase[641,642] and *m*-hydroxybenzoate 4-hydroxylase[643], in the vitamin K-dependent carboxylation of the glutamic acid residues of prothrombin[644], in the oxidation of cytochrome oxidase by oxygen at 173 K[645], and in the inactivation of papain[646]. The role of O_2^- in photosynthetic processes was also studied[647,648].

The investigation of the reactions of O_2^- with haems[649,650], the role of O_2^- in cancer[651,652], and the involvement of O_2^- in inflammatory processes[653-657] and in phagocytosis[658-666] have been continued. The involvement of O_2^- in processes associated with the radiation-induced damage of bacteriophages[667], the haemolysis and autoxidation of oxyhaemoglobin[668,669], the damage of the membranes of erythrocytes by copper salts[670], the autoxidation of linoleic acid[671], and the degradation of hyaluronic acid[672] has been demonstrated. It has also been shown that O_2^- is able to pass through erythrocyte membranes via anionic channels[673] and that SOD plays a protective role in the tissues of the crystalline lens of the eye[674,675].

Group-theoretical Methods in Quantum-chemical Calculations

I.G.Kaplan

Group-theoretical methods used in quantum chemistry have been reviewed. The method for constructing the basis functions of the irreducible representations of finite groups by means of projection operators has been examined in detail. Particular attention has been paid to the use of the theory of permutation groups for constructing the eigenfunctions of the operator of the square of the total spin S^2 and obtaining closed equations for the matrix elements of the Hamiltonian in a state having a definite value of S. A method has been described for finding the allowed molecular states and the orders of the secular equations obtained in variation quantum-chemical calculations. The use of the mathematical apparatus of continuous groups in quantum-chemical calculations has been discussed.
The bibliography contains 60 references.

I. INTRODUCTION

The methods of group theory are at present being widely used in chemistry. The application of the abstract apparatus of group theory to specific problems of the structure of molecules is based on the symmetry properties of the systems studied. Two types of symmetry can be distinguished: a) symmetry with respect to spatial transformations, and b) symmetry with respect to the permutation of identical particles. Both types of symmetry emerge from the properties of the Schrödinger equation for many-electron systems.

In addition to the symmetry with respect to the transformation of the coordinates of real three-dimensional space, for a number of problems the Schrödinger equation may exhibit symmetry with respect to the transformation of variables in a fictitious n-dimensional space. In these cases, the term latent or dynamic symmetry is used. A widely studied example is the symmetry, discovered by Fock, of the Schrödinger equation for the hydrogen atom, written in the momentum representation, in a four-dimensional space of dynamic variables.

Many familiar concepts used in quantum chemistry are based on the group-theoretical properties of many-electron systems. Thus Pauli's principle for many-electron systems is related to the forbidden character of all irreducible representations of the permutation group of the electrons except the antisymmetric. The conservation with time of various quantities characterising the state of a molecule, such as the spin, momentum, and orbital angular momentum of an isolated molecule, is related to the fact that these quantities are characterised by the irreducible representations of groups whose operations leave the Hamiltonian of the system invariant.

The introduction of the apparatus of group theory makes it possible to explain qualitatively a number of properties of the systems being considered without resorting to numerical calculations, for example to determine the degree of degeneracy and symmetry of the allowed states and the probability of quantum transitions (selection rules). At the same time, group theory simplifies the quantitative calculation considerably, since it makes it possible to obtain effective equations for calculating the matrix elements of the physical quantities being sought.

In the present review, attention is paid to both aspects of the application of the apparatus of group theory. The construction of the basis functions of irreducible representations by means of projection operators is examined in detail. This method makes it possible to standardise this procedure completely, and does not require the solution of systems of equations or the introduction of intuitive considerations for the selection of independent functions, as is often suggested in many quantum-chemical handbooks.

Particular attention is paid in the present review to the construction of the eigenfunctions of the operator of the square of the total spin S^2. In the case where spin is preserved, the antisymmetric total wavefunction, which is an eigenfunction of the operator S^2, can be represented as a linear combination of the products of coordinate and spin functions, transforming as the conjugate irreducible representations of the permutation group. This makes it possible to develop effective methods for classifying the molecular states obtained in a specific quantum-chemical calculation, that is to find the allowed types of point symmetry and the corresponding values of the electron spin (see Section V). The secular equation of the variational problem breaks down into secular equations for each molecular multiplet.

For calculating the properties of a molecule which are independent of spin interactions, it is sufficient to know only the coordinate wavefunction, the permutation symmetry of which is related unambiguously to the value of the total electron spin. This approach was proposed by the author of the present review[1-3] (the method of coordinate wavefunctions) and independently by Matsen[4,5] (spin-free quantum chemistry). The use of coordinate wavefunctions instead of Slater determinants makes it possible to obtain closed equations for the matrix elements of the Hamiltonian in states with a definite value of the spin S.

Section VI of the present review gives these expressions for the case of the configuration of non-orthogonal orbitals. The equations for the configurations of orthogonal orbitals are obtained as particular cases of the general equations. These equations are subsequently used (Section VII) to derive self-consistent field spin-projected equations for the case of an arbitrary molecular configuration containing both closed and open shells.

In addition to the traditional point groups, and also permutation groups, in recent years use has been made of unitary groups[6-9]. The final section of the present review describes an approach to the calculation for many-electron systems based on the use of the apparatus of unitary groups, and discusses its possibilities.

II. SYMMETRY GROUP OF THE SCHRÖDINGER EQUATION. CONSTRUCTION OF THE BASIS FUNCTIONS OF IRREDUCIBLE REPRESENTATIONS

All applications of group theory in quantum mechanics are based on the result obtained by Wigner[10] in 1927, often called Wigner's theorem: the wavefunctions belonging to a given energy level transform as a representation of the symmetry group of the Schrödinger equation, that is as a representation of the group whose operations leave the Schrödinger equation invariant.

The Schrödinger equation of an isolated quantum-mechanical system is invariant with respect to the operations of the following groups:

a) the group of displacements in space of the system as a whole; the irreducible representations of this group are characterised by the value of the momentum of the system,

b) the group of orthogonal transformations in three-dimensional space, consisting of rotations about any axis passing through the centre of gravity of the system, taken as the origin of coordinates, and inversion with respect to the origin of coordinates; the irreducible representations of this group are characterised by the values of the angular momentum of the system and the parity of the basis functions,

c) the group of permutations of identical particles; the characteristics of the irreducible representations of a permutation group will be discussed below.

If the system is placed in an external potential field, the symmetry groups of the Schrödinger equation are as follows:

a) the symmetry group of the external field,

b) the group of the permutations of identical particles.

In the adiabatic approximation, the motion of the electrons in a molecule can be regarded as taking place in the external field of stationary nuclei situated in equilibrium positions†. The potential field in this case exhibits the symmetry of the point group of the molecule. Thus according to Wigner's theorem, the electronic wave-functions of the molecule belonging to a given energy level should transform as the irreducible representations of the symmetry point group of the molecule and the permutation group of the electrons. There are no restrictions on possible irreducible representations of the point group, but of the irreducible representations of the permutation group of the electons, only the antisymmetric is realised. This last restriction is usually called the Pauli principle.

To find the basis function of the representation $\Gamma^{(\alpha)}$ of a given point group G of order g it is sufficient to apply the operator

$$\varepsilon_{ik}^{(\alpha)} = \frac{f_\alpha}{g} \sum_R \Gamma_{ik}^{(\alpha)}(R)^* R \tag{1}$$

to an arbitrary function ψ_0,

$$\psi_{ik}^{(\alpha)} = \varepsilon_{ik}^{(\alpha)} \psi_0 = \frac{f_\alpha}{g} \sum_R \Gamma_{ik}^{(\alpha)}(R)^* R\psi_0. \tag{2}$$

In Eqn. (2), $\Gamma_{ik}^{(\alpha)}(R)$ denotes the matrix element of the representation $\Gamma^{(\alpha)}(R)$ corresponding to the operation $R \in G$; the summation is carried out over all elements k of the group; f_α gives the dimension of the representation.

It can readily be shown[14] that for an arbitrary operation $Q \in G$

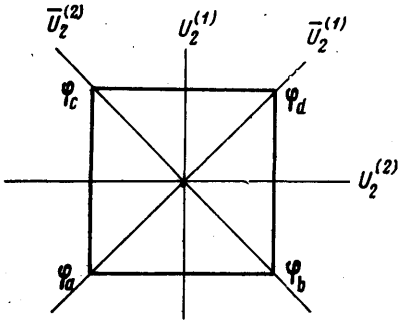
$$Q\psi_{ik}^{(\alpha)} = \sum_l \Gamma_{li}^{(\alpha)}(Q^{-1})^* \psi_{lk}^{(\alpha)}. \tag{3}$$

For unitary representations

$$Q\psi_{ik}^{(\alpha)} = \sum_l \Gamma_{li}^{(\alpha)}(Q)\, \psi_{lk}^{(\alpha)}, \tag{4}$$

that is the functions $\psi_{ik}^{(\alpha)}$ are transformed by the operations of the group according to the ith column of the irreducible representation $\Gamma^{(\alpha)}$, and the set of f_α functions $\psi_{ik}^{(\alpha)}$ with fixed index k forms the basis of the irreducible representation $\Gamma^{(\alpha)}$. Thus by changing the values of the index k it is possible to form f_α independent bases. This is realised if ψ_0 does not exhibit symmetry properties with respect to the operations of the group G. Otherwise, the result of the application of the operator $\epsilon_{ik}^{(\alpha)}$ to it may give zero. The operator $\epsilon_{ii}^{(\alpha)}$ converts the function $\psi_{ik}^{(\alpha)}$ into itself. The operators exhibiting this property are called projection operators. For these, the following operator equation is applicable:

$$\varepsilon_{ii}^{(\alpha)} \varepsilon_{ii}^{(\alpha)} = \varepsilon_{ii}^{(\alpha)}. \tag{5}$$



The procedure for constructing the bases of irreducible representations by means of characters[15,16], usually employed in quantum chemistry, does not make it possible to distinguish the basis functions in the case of multiple irreducible representations. Eyring, Walter, and Kimball[15] put forward a method for separating independent basis functions by solving a system of equations. Streitwieser[16] states that it is necessary to use intuition to solve this problem. The method using the projection operators (1), however, makes it possible to standardise completely the procedure for finding the bases of irreducible representations, and intuition is not required.

The effect of the operation R on the original non-symmetrised bases is found from simple geometric considerations. The original basis is broken down into separate sets in such a way that the functions belonging to a given set are transformed only into one another by the operations of the group G. These representations obviously cannot

† In a degenerate electronic state, the adiabatic approximation becomes inapplicable. Symmetrical arrangements of the nuclei now do not correspond to an energy minimum (Jahn–Teller theorem). As a consequence of electronic-vibrational interaction, instead of one minimum for a symmetrical configuration of the nuclei, there appear several minima for unsymmetrical configurations of the nuclei. The potential surface becomes multi-sheeted, and the nuclei undergo a complex motion over this surface (see Refs. 11–13 for more details).

be broader than the regular one, so that the number of times it contains an irreducible representation $\Gamma^{(\alpha)}$ is not greater than its dimension f_α. This feature makes the procedure for constructing the basis using the operators $\epsilon_{ik}^{(\alpha)}$ unambiguous, since there are f_α independent sets of operators $\epsilon_{ik}^{(\alpha)}$ differing in the value of the index k. The matrices of the irreducible representations of all the point groups and permutation groups π_3–π_6 required in order to use Eqn. (2) in specific calculations are given in a book by the author of the present review[14], which also gives examples of the construction of basis functions.

The procedure for constructing basis functions, based on the method of projection operators, can be examined for the simple example of a system of four equivalent atoms situated at the corners of a square *a*, *b*, *c*, *d*. It is assumed that an orbital of the same type is given on each atom:

This atomic configuration is invariant with respect to the operations of the point group $\mathbf{D}_4$. The four orbitals φa, φb, φc, φd form the basis of a four-dimensional reducible representation Γ of the group D_4. The characters $\chi^{\Gamma}(R)$ of this representation are equal to the number of orbitals remaining invariant on application of the corresponding operation R of the group $\mathbf{D}_4$:

R	E	C_2	$2C_4$	$2U_2$	$2\bar{U}_2$
$\chi^{\Gamma}(R)$	4	0	0	0	2

The representation Γ is readily broken down into the irreducible representations of the group $\mathbf{D}_4$ using the character tables of the irreducible representations $\Gamma^{(\alpha)}$ of the group $\mathbf{D}_4$. According to the theory of representations, the number of times the representation $\Gamma^{(\alpha)}$ appears in the breakdown of the representation Γ is given by the equation

$$a^{(\alpha)} = \frac{1}{g}\sum_R \chi^{\Gamma}(R)\,\chi^{(\alpha)}(R)^*. \qquad (6)$$

This gives‡

$$\Gamma \doteq A_1 + B_2 + E. \qquad (7)$$

The basis functions of the irreducible representations appearing in the breakdown (7) are constructed by applying the appropriate operators $\epsilon_{ik}^{(\alpha)}$ to any of the orbitals. To be specific, the orbital φa can be taken. The following are the orbitals into which the orbital φa is transformed by the eight operations of the group $\mathbf{D}_4$:

R	E	C_4	C_2	C_4^3	$U_2^{(1)}$	$U_2^{(2)}$	$\bar{U}_2^{(2)}$	$\bar{U}_2^{(1)}$
$R\varphi_a$	φ_a	φ_b	φ_d	φ_c	φ_b	φ_c	φ_a	φ_d

Character tables are sufficient for constructing the basis functions of the one-dimensional representations A_1 and B_2. To construct the basis of the two-dimensional irreducible representation E it is necessary to know its matrix elements. The matrix elements for the irreducible representations of the group D_4 are given below:

	E	C_4	C_2	C_4^3	$U_2^{(1)}$	$U_2^{(2)}$	$\bar{U}_2^{(1)}$	$\bar{U}_2^{(2)}$
A_1	1	1	1	1	1	1	1	1
B_2	1	−1	1	−1	1	1	−1	−1
E	$\begin{pmatrix}1&\\&1\end{pmatrix}$	$\begin{pmatrix}&1\\-1&\end{pmatrix}$	$\begin{pmatrix}-1&\\&-1\end{pmatrix}$	$\begin{pmatrix}&-1\\1&\end{pmatrix}$	$\begin{pmatrix}&-1\\-1&\end{pmatrix}$	$\begin{pmatrix}1&\\&1\end{pmatrix}$	$\begin{pmatrix}1&\\&-1\end{pmatrix}$	$\begin{pmatrix}-1&\\&1\end{pmatrix}$

Since each representation $\Gamma^{(\alpha)}$ appears once in the breakdown (7), in this example multiple representations do not appear. To construct the basis of the representation E, it is sufficient to use either of the two sets of projection operators: $(\epsilon_{11}^{E}, \epsilon_{21}^{E})$ or $(\epsilon_{12}^{E}, \epsilon_{22}^{E})$. This gives the following normalised functions:

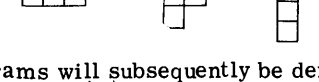
$$\sigma^{A_1} = \frac{1}{2}(\varphi_a + \varphi_b + \varphi_c + \varphi_d),$$

$$\sigma^{B_2} = \frac{1}{2}(\varphi_a - \varphi_b - \varphi_c + \varphi_d),$$

$$\begin{cases}\sigma_1^{E} = \frac{1}{\sqrt{2}}(\varphi_a - \varphi_d),\\ \sigma_2^{E} = \frac{1}{\sqrt{2}}(-\varphi_b + \varphi_c).\end{cases}$$

Because of the importance of permutational symmetry in the quantum theory of many-electron systems, it will be considered separately.

III. PERMUTATIONAL SYMMETRY



In the theory of the permutation group[14,17,18], it is shown that each irreducible representation of the permutation group of N objects, denoted π_N, can be associated with one of the partitions of the number N into integral positive terms (partition numbers). These terms are arranged in descending order:

$$\lambda^{(1)} + \lambda^{(2)} + \ldots + \lambda^{(m)} = N,\ \lambda^{(1)} \geqslant \lambda^{(2)} \geqslant \ldots \geqslant \lambda^{(m)}. \qquad (8)$$

The number of non-equivalent irreducible representations of the group π_N is equal to the number of such partitions. For example, for $N = 3$ there are three partitions:

$$3,\ 2+1,\ 1+1+1. \qquad (9)$$

The partitions (8) and (9) are represented effectively by so-called Young diagrams, in which each number $\lambda^{(i)}$ is associated with a row consisting of a number of squares equal to $\lambda^{(i)}$. Thus for $N = 3$, in accordance with Eqn.(9), three Young diagrams are possible:

The Young diagrams will subsequently be denoted by the symbol $[\lambda] \equiv [\lambda^{(1)}\lambda^{(2)}\ldots\lambda^{(m)}]$; the existence of several rows $\lambda^{(i)}$ of identical magnitude, for brevity, will be denoted by the power of $\lambda^{(i)}$. Thus the Young diagrams

‡ The point above the equality symbol indicates that this is not a literal algebraic equation; the representations in the right hand side of Eqn. (7) are contained in the representation Γ.

represented above are denoted by the following symbols: [3], [21], [1^3].

The Young diagrams characterise the symmetry of the basis functions with respect to permutation of the arguments. A Young diagram consisting of one row corresponds to a function symmetrical with respect to all its arguments; a Young diagram consisting of one column corresponds to a function antisymmetric with respect to all arguments. All other Young diagrams characterise intermediate symmetry types. There are rules which make it possible to find the matrices of the irreducible representations of the group π_N using only Young diagrams. These rules are particularly simple in the case of the so-called standard orthogonal representation§ (the Young–Yamanouchi representation[14,17]). The matrices of the standard representation for $N = 3$ are given below. In this case there are three irreducible representations, two of which are one-dimensional; $\Gamma^{[3]}(P) = 1$, and $\Gamma^{[1^3]}(P) = (-1)^p$, where p is the parity of the permutation. The representation $\Gamma^{[21]}$ is two-dimensional, and is given by the following matrices:

$$1 \quad P_{12} \quad P_{23} \quad P_{13} \quad P_{123} \quad P_{132}$$
$$\begin{pmatrix}1\\&1\end{pmatrix}\begin{pmatrix}1\\&-1\end{pmatrix}\begin{pmatrix}-\frac{1}{2}&\frac{\sqrt{3}}{2}\\\frac{\sqrt{3}}{2}&\frac{1}{2}\end{pmatrix}\begin{pmatrix}-\frac{1}{2}&-\frac{\sqrt{3}}{2}\\-\frac{\sqrt{3}}{2}&\frac{1}{2}\end{pmatrix}\begin{pmatrix}-\frac{1}{2}&\frac{\sqrt{3}}{2}\\-\frac{\sqrt{3}}{2}&-\frac{1}{2}\end{pmatrix}\begin{pmatrix}-\frac{1}{2}&-\frac{\sqrt{3}}{2}\\\frac{\sqrt{3}}{2}&-\frac{1}{2}\end{pmatrix}.$$

The basis functions of the irreducible representations $\Gamma^{[\lambda]}$ are found by applying the projection operators (1) to the non-symmetrised function Φ_0, which can be taken in the form of a product of orbitals or geminals, or in any other cluster form. In the case of a permutation group, it is more convenient to use, instead of the operator (1), the so-called Young operator¶

$$\omega_{rt}^{[\lambda]} = \sqrt{\frac{f_\lambda}{N!}} \sum_P \Gamma_{rt}^{[\lambda]}(P)\, P, \tag{11}$$

where f_λ is the dimension of the representation $\Gamma^{[\lambda]}$. The right hand side of Eqn. (11) differs from the right hand side of Eqn. (1) by a factor which is chosen in such a way that the action of $\omega_{rt}^{[\lambda]}$ on the orthonormalised product Φ_0 of one-particle functions gives a normalised function.

For representations characterised by single-row $[N]$ or single-column $[1^N]$ Young diagrams, the operator (11) is the ordinary symmetrisation or antisymmetrisation operator:

$$\omega^{[N]} = \frac{1}{\sqrt{N!}} \sum_P P, \tag{12}$$

$$\omega^{[1^N]} = \frac{1}{\sqrt{N!}} \sum_P (-1)^p P. \tag{13}$$

It is possible to find basis functions

$$\Phi_{rt}^{[\lambda]} = \omega_{rt}^{[\lambda]}\Phi_0 = \sqrt{\frac{f_\lambda}{N!}} \sum_P \Gamma_{rt}^{[\lambda]}(P)\, P\Phi_0 \tag{14}$$

for the irreducible representations of the group π_3 in the case where Φ_0 is a product of orbitals. For the representation $\Gamma^{[21]}$ it is possible to construct two independent basis sets. This is due to the fact that the 3! functions $P\Phi_0$ in this case form the basis of a regular representation of the group π_3, and in the breakdown of the regular representation, the number of times each irreducible representation appears is equal to its dimension. Use of the explicit form of the matrix elements $\Gamma_{rt}^{[21]}$ gives:

$$\Phi^{[3]} = \frac{1}{\sqrt{6}}\{\varphi_a(1)\varphi_b(2)\varphi_c(3) + \varphi_a(2)\varphi_b(1)\varphi_c(3) +$$
$$+ \varphi_a(3)\varphi_b(2)\varphi_c(1) + \varphi_a(1)\varphi_b(3)\varphi_c(2) + \varphi_a(2)\varphi_b(3)\varphi_c(1) + \varphi_a(3)\varphi_b(1)\varphi_c(2)\}$$

$$\Phi^{[1^3]} = \frac{1}{\sqrt{6}}\{\varphi_a(1)\varphi_b(2)\varphi_c(3) - \varphi_a(2)\varphi_b(1)\varphi_c(3) -$$
$$- \varphi_a(3)\varphi_b(2)\varphi_c(1) - \varphi_a(1)\varphi_b(3)\varphi_c(2) + \varphi_a(2)\varphi_b(3)\varphi_c(1) + \varphi_a(3)\varphi_b(1)\varphi_c(2)\},$$

$$\begin{cases} \Phi_{11}^{[21]} = \frac{1}{\sqrt{12}}\{2\varphi_a(1)\varphi_b(2)\varphi_c(3) + 2\varphi_a(2)\varphi_b(1)\varphi_c(3) - \\ \quad - \varphi_a(3)\varphi_b(2)\varphi_c(1) - \varphi_a(1)\varphi_b(3)\varphi_c(2) - \\ \quad - \varphi_a(2)\varphi_b(3)\varphi_c(1) - \varphi_a(3)\varphi_b(1)\varphi_c(2)\} \\ \Phi_{21}^{[21]} = \frac{1}{2}\{-\varphi_a(3)\varphi_b(2)\varphi_c(1) + \varphi_a(1)\varphi_b(3)\varphi_c(2) - \\ \quad - \varphi_a(2)\varphi_b(3)\varphi_c(1) + \varphi_a(3)\varphi_b(1)\varphi_c(2)\}, \end{cases}$$

$$\begin{cases} \Phi_{12}^{[21]} = \frac{1}{2}\{-\varphi_a(3)\varphi_b(2)\varphi_c(1) + \varphi_a(1)\varphi_b(3)\varphi_c(2) + \\ \quad + \varphi_a(2)\varphi_b(3)\varphi_c(1) - \varphi_a(3)\varphi_b(1)\varphi_c(2)\} \\ \Phi_{22}^{[21]} = \frac{1}{\sqrt{12}}\{2\varphi_a(1)\varphi_b(2)\varphi_c(3) - 2\varphi_a(2)\varphi_b(1)\varphi_c(3) + \\ \quad + \varphi_a(3)\varphi_b(2)\varphi_c(1) + \varphi_a(1)\varphi_b(3)\varphi_c(2) - \\ \quad - \varphi_a(2)\varphi_b(3)\varphi_c(1) - \varphi_a(3)\varphi_b(1)\varphi_c(2)\}. \end{cases}$$

IV. CONSTRUCTION OF ANTISYMMETRIC WAVE-FUNCTIONS WHICH ARE EIGENFUNCTIONS OF S^2. "SPIN-FREE QUANTUM CHEMISTRY"

Although the introduction of the concept of spin has made it possible to explain the chemical bond, electron spins do not take direct part in chemical bond formation; the interactions responsible for chemical bonding are purely electrostatic in character. The coordinate and spin variables in the electronic wavefunction are separated, and the function can be represented as the product of coordinate and spin wavefunctions. The fact that the energy of a system of electrons depends on the value of their total spin S is due to the existence of a unique correspondence between the permutational symmetry of the coordinate wavefunction and the value of the spin $\mathbf{S}$.

The electronic wavefunction of a molecule should satisfy three symmetry conditions:

1) the exclusion principle, that is it should be antisymmetric with respect to permutation of the electrons;

2) it should belong to one of the irreducible representations of the group of rotations in spin space, that is it should be an eigenfunction of the operator $\hat{S}^2$;

3) it should belong to one of the irreducible representations Γ^α of the symmetry point group of the molecule.

States of a molecule characterised by definite S and Γ^α are usually called electronic molecular multiplets, and denoted $^{2S+1}\Gamma^{(\alpha)}$.

To find a function satisfying the third condition, it is sufficient to use the operator $\epsilon_{ik}^{(\alpha)}$ defined by Eqn. (1). For the first two conditions to be fulfilled, instead of using the cumbersome procedure involving the construction of appropriate linear combinations of Slater determinants, it is convenient to use the apparatus of the permutation group. The representation of the complete wavefunction in the form of the product of coordinate and spin wavefunctions,

---

§ The matrices of the orthogonal representation satisfy the condition:

$$\Gamma_{rt}(P^{-1}) = \Gamma_{tr}(P). \tag{10}$$

¶ The operator (11) should not be confused with the operator of symmetrisation with respect to the rows and antisymmetrisation with respect to the columns of the Young diagram, which is also often called the Young operator[17,18].

symmetrised with respect to the irreducible representations $\Gamma^{[\lambda]}$ of the permutation group, makes it possible to satisfy the first two conditions automatically. For this purpose, the coordinate and spin Young diagrams should be dual with respect to one another, that is one should be obtained from the other by interchanging rows and columns. The representation $\Gamma^{[\tilde{\lambda}]}$ ($[\lambda]$ is the Young diagram dual with respect to the diagram $[\lambda]$) is conjugate with respect to the representation $\Gamma^{[\lambda]}$, and this means that their matrix elements are related by the expression

$$\Gamma^{[\tilde{\lambda}]}_{rt}(P) = (-1)^p \Gamma^{[\lambda]}_{rt}(P), \tag{15}$$

where p is the parity of the permutation P.

It will be shown that the function

$$\Psi^{[1^N]} = \frac{1}{\sqrt{f_\lambda}} \sum_r \Phi^{[\lambda]}_r \Omega^{[\tilde{\lambda}]}_{\tilde{r}}, \tag{16}$$

where $\Phi^{[\lambda]}_r$ is a many-electron coordinate function, and $\Omega^{[\tilde{\lambda}]}_{\tilde{r}}$ is a spin function, is antisymmetric with respect to the simultaneous permutation of the space and spin variables. An arbitrary permutation $P \in \pi_N$ is applied to Eqn. (16). From Eqn. (4) it follows that

$$P\Psi^{[1^N]} = \frac{1}{\sqrt{f_\lambda}} \sum_{u,v} \sum_r \Gamma^{[\lambda]}_{ur}(P)\, \Gamma^{[\tilde{\lambda}]}_{\tilde{v}\tilde{r}}(P)\, \Phi^{[\lambda]}_u \Omega^{[\tilde{\lambda}]}_{\tilde{v}}. \tag{17}$$

From the definition of the conjugate representation (15) and the properties of orthogonality of the matrices of the representation $\Gamma^{[\lambda]}$, it follows that

$$P\Psi^{[1^N]} = \frac{1}{\sqrt{f_\lambda}} \sum_{u,v} \left[\sum_r \Gamma^{[\lambda]}_{ur}(P)\, \Gamma^{[\tilde{\lambda}]}_{vr}(P) \right] (-1)^p \Phi^{[\lambda]}_u \Omega^{[\tilde{\lambda}]}_{\tilde{v}} =$$

$$= \frac{1}{\sqrt{f_\lambda}} \sum_u (-1)^p \Phi^{[\lambda]}_u \Omega^{[\tilde{\lambda}]}_{\tilde{u}} = (-1)^p \Psi^{[1^N]},$$

which it was required to prove.

The symmetrised coordinate function $\Phi^{[\lambda]}_r$ is constructed, as described in the previous section, using Young operators. For a non-symmetrised function Φ_0 consisting of the product of N different orbitals, it is possible to obtain f^2_λ independent functions $\Phi^{[\lambda]}_{rt}$ which break down into f_λ basis sets, corresponding to different values of the index t.

The spin function $\Omega^{[\tilde{\lambda}]}_{\tilde{r}}$ is obtained analogously by applying the Young operator $\omega^{[\tilde{\lambda}]}_{\tilde{r}\tilde{t}}$ to the product of the one-electron two-component spin functions χ_σ, which are spinors[19]:

$$\Omega_{\sigma_1,\ldots,\sigma_N} = \chi_{\sigma_1}(1)\, \chi_{\sigma_2}(2) \ldots \chi_{\sigma_N}(N). \tag{18}$$

The set of 2^N quantities $\Omega_{\sigma_1 \ldots \sigma_N}$ form a tensor of rank N in two-dimensional spinor space. On rotation of the system of coordinates, a 2^N-dimensional representation of the group of the rotations is induced in the components of Eqn. (18). This is broken down into irreducible parts by the application of the Young operators to the function (18) (see section 4-2 in Ref. 14). The spin functions obtained

$$\Omega^{[\tilde{\lambda}]}_{r,\sigma_1 \ldots \sigma_N} = \omega^{[\tilde{\lambda}]}_{\tilde{r}\tilde{t}} \Omega_{\sigma_1 \ldots \sigma_N} \tag{19}$$

for a fixed set $\sigma_1 \ldots \sigma_N$, transform as an irreducible representation of the permutation group $\Gamma^{[\tilde{\lambda}]}$, and for a fixed $\tilde{r}$ they transform as an irreducible representation $D^{(S)}$ of the group of three-dimensional rotations, that is the number of independent functions (19) with a fixed $\tilde{r}$ is equal to $2S + 1$ (this explains the absence of the index $\tilde{t}$ from the left hand side of Eqn. (19); to find one of the f_λ basis sets corresponding to the representation D^S, it is sufficient to select any fixed $\tilde{t}$ for which the application of $\omega^{[\tilde{\lambda}]}$ to $\Omega\sigma_1 \ldots \sigma_N$ does not give zero).

The spin variables for an electron take only two values. Since an antisymmetric function becomes zero when the variables coincide, the spin Young diagrams for electrons cannot contain more than two squares in a column, that is the spin diagram $[\tilde{\lambda}]$ contains not more than two rows. If the projection of the spin of the electron in one square of a column of the spin Young diagram is 1/2, the projection of the spin of the electron in the other square should be equal to −1/2, that is the spins of these electrons are paired. It is obvious that a contribution to the total spin of the system will be made only by unpaired spins, the number of which is determined as the difference in the rows of the Young diagram ($\tilde{\lambda}^{(1)} - \tilde{\lambda}^{(2)}$). Thus the value of the total spin corresponding to the function (19) is defined unambiguously by the spin Young diagram $[\tilde{\lambda}]$ and is equal to†:

$$S = \frac{1}{2}(\tilde{\lambda}^{(1)} - \tilde{\lambda}^{(2)}), \tag{20}$$

where $\tilde{\lambda}(i)$ is the length of the ith row, and the value of the projection of the spin is determined from the equation

$$M_S = \sum_{i=1}^{N} \sigma_i. \tag{21}$$

Thus for example for three electrons, two independent spin functions, transforming as the representation $\Gamma^{[21]}$ of the group π_3 and describing the state with $S = 1/2$ and $M_S = 1/2$, are found by applying the Young operator $\omega^{[21]}_{\tilde{r}\tilde{t}}$ to $\Omega_{\frac{1}{2},\frac{1}{2},-\frac{1}{2}} \equiv \alpha(1)\alpha(2)\beta(3)$. Since the matrices of the representation $\Gamma^{[21]}$ are related to the matrices of the representation $\Gamma^{[21]}$ (Russian page 1033) by Eqn. (15), it follows that

$$\Omega^{[21]}_{1,\alpha\alpha\beta} = \frac{1}{\sqrt{2}} [-\alpha(1)\beta(2)\alpha(3) + \beta(1)\alpha(2)\alpha(3)],$$

$$\Omega^{[21]}_{2,\alpha\alpha\beta} = \frac{1}{\sqrt{6}} [2\alpha(1)\alpha(2)\beta(3) - \alpha(1)\beta(2)\alpha(3) - \beta(1)\alpha(2)\alpha(3)].$$

In quantum chemistry, the term covalent structure is used to describe a configuration of atoms with one valency electron on each atom, characterised by a definite way of combining the spins of the valency electrons to give the total spin S. The number of such ways determines the number of independent covalent structures with spin S. In classical textbooks of quantum chemistry, it is determined by the so-called Rumer rule[15]. Since a configuration of valency electrons is in fact a configuration of singly-filled orbitals, the wavefunction describing it can be written in the form

$$\Psi^{[1^N]}_t = \frac{1}{\sqrt{f_\lambda}} \sum_r \Phi^{[\lambda]}_{rt} \Omega^{[\tilde{\lambda}]}_{\tilde{r}}, \tag{22}$$

† This unique correspondence between the Young diagram and the total spin applies only to particles having a spin of 1/2. For particles having $s > 1/2$, several values of S may correspond to the permutational symmetry of the given Young diagram. Thus if the spin of the particle $s = 1$, the diagram[31] corresponds to values of the total spin $S = 1, 2, 3$.[14]

where the subscript t numbers the independent states, the number of which is equal to the dimension f_λ of the irreducible representation $\Gamma^{[\lambda]}$. The expression for f_λ is written in terms of N and S [14]:

$$n(N, S) \equiv f_\lambda = \frac{N!\,(2S+1)}{\left(\frac{N}{2}+S+1\right)!\left(\frac{N}{2}-S\right)!}. \qquad (23)$$

This is also the equation for the number of covalent structures. For example, in the case of the singlet state for the six π-electrons of the benzene molecule, there are five covalent structures (corresponding to the three Kekule structures and the two Dewar structures); for the triplet state, $n(6,1) = 9$.

In problems not involving spin interactions, it is sufficient, for a complete description of the system, to give only the coordinate wavefunction. The "memory" of spin is preserved, since it is contained in the permutational symmetry of the coordinate wavefunction. Thus for a description of covalent structures it is sufficient to give the coordinate functions $\Phi_{rt}^{[\lambda]}$ found from Eqn. (14). The use of coordinate wavefunctions is also convenient in more complex cases (see subsequent sections). This "spin-free quantum chemistry", as already noted in the Introduction, was first proposed in papers by the author of the present review[1-3] and Matsen[4,5]. This approach has been widely used in recent years[20-28].

It should be noted that calculations using the complete wavefunction in the form (16) are equally convenient in those cases where characteristics of the molecule associated with spin are being dealt with. This applies particularly to the calculation of spin density[29,30]. In the case of the calculation of spin-orbital interactions, since in non-relativistic theory these calculations are carried out using perturbation theory, it is again convenient to take the wavefunctions of the zeroth approximation in the form (16).

V. QUASI-DIAGONALISATION OF THE SECULAR EQUATION. DETERMINATION OF ALLOWED MOLECULAR MULTIPLETS

Most procedures in present-day quantum-chemical calculations are based on the one-electron approximation. In calculations taking account of the possible realisation of different orbital configurations in the system, the problem of solving secular equations of very high order arises (the order of the equations is determined by the number of many-electron states considered). The total number of states in an N-electron system with allowance for all configurations in a basis of k orbitals is equal to[14]

$$n(k, N) = \binom{2k}{N} = \frac{(2k)!}{(2k-N)!\,N!}. \qquad (24)$$

Thus the order of the secular equation obtained is very large, even for small systems. Thus for six electrons and six orbitals, $n(6,6) = 924$.

If however the states of the system are described by wavefunctions belonging to bases of irreducible representations of the symmetry group of the Hamiltonian, the secular equation is quasi-diagonalised. It follows from the Wigner–Eckart theorem[14] that if the function $\psi_{ik}^{(\alpha)}$ belongs to the kth basis of the representation $\Gamma^{(\alpha)}$ of the symmetry group of the Hamiltonian $\mathcal{H}$, then

$$\langle \psi_{ik}^{(\alpha)} | \mathcal{H} | \psi_{i'k'}^{(\alpha')} \rangle = \delta_{\alpha\alpha'}\delta_{ii'} \langle k \| \mathcal{H} \| k' \rangle^{(\alpha)}, \qquad (25)$$

where δ_{ik} is the Kronecker symbol ($\delta_{ii} = 1$, $\delta_{ik} = 0$ for $i \neq k$). The diagonal terms relating to the same irreducible representation are equal. All the non-diagonal terms become zero, except the matrix elements with functions from different bases, transforming according to the same column i; the double bar in the matrix element indicates that it is independent of the number i of the basis function.

Thus the original secular equation breaks down into equations relating to separate irreducible representations. The order of the secular equation corresponding to the representation $\Gamma^{(\alpha)}$ is equal to the total number of times $\Gamma^{(\alpha)}$ appears in the breakdown of the reducible representation induced by the original set of variation functions.

Since the Hamiltonian of a molecule is invariant with respect to permutation of the electrons, in the construction of the wavefunction from Eqn. (16) the secular equation breaks down into blocks, each of which corresponds to a definite irreducible representation $\Gamma^{[\lambda]}$ of the permutation group. As shown in the previous section, the representation $\Gamma^{[\lambda]}$ is related unambiguously to the value of the total electron spin of the system S.

Further diagonalisation of the secular equation takes place in the construction, from functions corresponding to a definite value of S, of linear combinations transforming as the irreducible representations $\Gamma^{(\alpha)}$ of the symmetry group of the Hamiltonian, that is in the construction of the eigenfunctions of the molecular multiplets ${}^{2S+1}\Gamma^{(\alpha)}$. This is achieved by applying the operators $\epsilon_{ik}^{(\alpha)}$ to the functions $\Phi_{rt}^{[\lambda]}$. The variation problem reduces to the solution of the secular equation for each multiplet.

Thus before carrying out the variation calculation it is appropriate to find all possible molecular multiplets for the given problem and the orders of the corresponding secular equations. This problem can be examined for the case of a system of N equivalent atoms, on each of which one degenerate orbital $\varphi_{m,a}^{(l)}$ is given, where a is the number of the atom, and l and m the orbital angular moment and its projection on the z axis respectively. It is assumed that the number of electrons is equal to N. The total number of non-symmetrised coordinate states, described by functions of the type

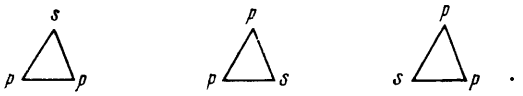
$$\Phi_{m_1 \ldots m_N}^{(l)} = \varphi_{m_1 a}^{(l)}(1)\,\varphi_{m_2 b}^{(l)}(2) \ldots \varphi_{m_N q}^{(l)}(N). \qquad (26)$$

is obviously equal to $(2l+1)^N$. The construction, from the functions (26), of the basis of the representation unambiguously related to the spin S is carried out by applying the Young operators $\omega_{rt}^{[\lambda]}$ to $\Phi_{m_1 \ldots m_N}^{(l)}$. The order of the reducible representation induced in these functions is $f_\lambda (2l+1)^N$. To find the characters of this representation, the operation of the symmetry point group (this operation, given at the origin of coordinates, is denoted $\mathfrak{R}$) is applied to the function $\omega_{rt}^{[\lambda]} \Phi_{m_i \ldots m_N}^{(l)}$. The application of $\mathfrak{R}$ to the configuration of localised orbitals reduces to the permutation P of the centres of the orbitals and the operations of the point symmetry R in the atomic system of coordinates. For the operation $\mathfrak{R}$, this corresponds to the permutation P with the cyclic structure $\{1^{\nu_1} 2^{\nu_2} \ldots k^{\nu_k}\}$, where ν_i is the number of cycles of length i, the equation for the character being sought can be written in the form[31]:

$$X^{[\lambda]}(\mathfrak{R}) = \chi^{[\lambda]}(P)\,[\chi^{(l)}(R)]^{\nu_1}\,[\chi^{(l)}(R^2)]^{\nu_2} \ldots [\chi^{(l)}(R^k)]^{\nu_k}, \qquad (27)$$

where $\chi^{(l)}(R)$ is the character of the irreducible representation $D^{(l)}(R)$ of the group of orthogonal transformations of three-dimensional space corresponding to the operation of the point symmetry R.

When orbitals of different types are given on the atoms, it is possible to have several covalent configurations, differing in the permutations of orbitals between identical atoms. A contribution to the character is made only by those configurations which are transformed into themselves by the operation $\mathfrak{R}$. The number of such configurations will be noted $\tau(\mathfrak{R})$. The equation for the character has the following form:



$$X^{[\lambda]}(\mathfrak{R}) = \chi^{[\lambda]}(P)\,[\chi^{(l_1)}(R)]^{\nu_1}\,[\chi^{(l_2)}(R^2)]^{\nu_2} \ldots [\chi^{(l_k)}(R^k)]^{\nu_k}\tau(\mathfrak{R}). \quad (28)$$

The orbital momenta l_i for the atoms appearing in a given cycle should coincide, otherwise the character becomes zero. If all the atoms are equivalent, and l_i are identical, it follows that $\tau(\mathfrak{R}) = 1$, and Eqn. (28) becomes Eqn. (27).

The breakdown of the representation with the characters (28) into irreducible representations $\Gamma^{(\alpha)}$ gives the allowed types of point symmetry. The corresponding values of the electron spin S, according to Eqn. (20), are determined unambiguously by the form of the spin Young diagram $[\widetilde{\lambda}]$, dual with respect to the coordinate Young diagram $[\lambda]$. This is a consequence of the fact that a unique correspondence exists between the irreducible representations $U_2^{[\widetilde{\lambda}]}$ of the unitary group $\mathbf{U}_2$, induced in the spin functions $\Omega^{[\widetilde{\lambda}]}$, and the irreducible representations $D^{(S)}$ of the group of rotations $\mathbf{R}_3$.[14] The method for finding the allowed molecular multiplets can be represented schematically as follows:

$$\begin{array}{ccc} U^{[\lambda]}_{l_1 l_2 \ldots l_k} & \leftrightarrow & U_2^{[\widetilde{\lambda}]} \\ \downarrow & & \downarrow \\ \Gamma^{(\alpha)} & \longleftrightarrow & D^{(S)} \end{array} \quad . \quad (29)$$

An example is provided by a system of three equivalent atoms, with point symmetry $\mathbf{C}_{3v}$, where p orbitals are given on two of the atoms, and an s orbital is given on the other:

Three covalent configurations are possible. The state of the system with $S = 3/2$ can be considered. This corresponds to the spin Young diagram $[\widetilde{\lambda}] = [3]$. The permutational symmetry of the coordinate wavefunction in this state is characterised by the Young diagram $[1^3]$. The group $\mathbf{C}_{3v}$ contains three classes of operation. For the identity class E, all three configurations make a contribution to the character, that is $\tau(E) = 3$. Each of the operations of the class σ_v leaves one of the configurations invariant, so that $\tau(\sigma_v) = 1$. On application of the operation C_3, the configurations are converted into one another, that is $\tau(C_3) = 0$. The permutations corresponding to the operations of the point group have the following cyclic structure:

$$\begin{array}{ccc} E & C_3 & \sigma_v \\ \{1^3\} & \{3\} & \{12\} \end{array} \quad .$$

From Eqn. (28) and the equality $\tau(C_3) = 0$, it follows that

$$X^{[1^3]}(E) = \chi^{[1^3]}(\{1^3\})\,\chi^{0}(E)\,[\chi^{(1)}(E)]^3\,\tau(E),$$

$$X^{[1^3]}(C_3) = 0,$$

$$X^{[1^3]}(\sigma_v) = \chi^{[1^3]}(\{12\})\,\chi^{(0)}(\sigma_v)\,\chi^{(1)}(\sigma_v^2 \equiv E)\,\tau(\sigma_v).$$

Since moreover $\chi^{(0)}(E) = \chi^{(0)}(\sigma_v) = 1$, $\chi^{(1)}(E) = 3$, and $\chi^{[1^3]}(\{12\}) = -1$, the characters of the reducible representation are:

$$\begin{array}{ccc} E & 2C_3 & 3\sigma_v \\ 27 & 0 & -3 \end{array} \quad .$$

Breakdown of this representation into the irreducible representations of the group $\mathbf{C}_{3v}$ gives the allowed quartets and their multiplicity 3^4A_1, 6^4A_2, 9^4E. The maximum order of the secular equation corresponds to the term ^4E and is equal to nine.

The use of the methods of group theory also makes it possible to solve a more general problem, namely to find the allowed molecular states which can be formed from given atomic states. The solution of this problem was first given by Kotani[32] and was subsequently generalised for the case of complexes of impurity ions in a crystal[33,34]. Kotani's method, however, requires the tedious calculation of the spin factor. The present author[35,36] showed that the determination of the allowed states of a system is simplified considerably by breaking down the complete wavefunction into coordinate and spin functions (16). This approach was used as a basis for the development of general methods for classifying the states of many-electron systems for given states of the sub-systems[31,37]. In these methods, the permutations of the sub-systems reduce to the permutations of particles between the sub-systems. For systems in which the number of particles $N \geqslant 10$, this is no longer effective. Since in the given problem the internal structure of the sub-system is not important, it is more natural to regard each sub-system as a single whole. This approach was developed in Refs. 38–41. The essential features of the method proposed in Ref. 39 will be described briefly.

A many-particle system consisting of n many-particle sub-systems, which may be atoms, ions, combinations of ions (ligands), etc., can be considered. From the viewpoint of the transformational properties of the wavefunction of the system of interest, each of the sub-systems can be regarded as a single particle having spin S_a. Depending on whether S_a is integral or half-integral, the sub-systems obey Bose–Einstein or Fermi–Dirac statistics, and the total wavefunction of the system is symmetric or antisymmetric with respect to permutations of the sub-systems. The wavefunction of the system, which exhibits regular permutational symmetry, can be represented in the form

$$\Psi = \frac{1}{\sqrt{f_\lambda}} \sum_r \Phi_r^{[\lambda]} \Omega_r^{[\bar{\lambda}]}, \quad (30)$$

where

$$[\bar{\lambda}] = \begin{cases} [\lambda] & \text{for boson sub-systems,} \\ [\widetilde{\lambda}] & \text{for fermion sub-systems,} \end{cases}$$

$[\widetilde{\lambda}]$, as in Eqn. (16), is the Young diagram dual with respect to the diagram $[\lambda]$.

The coordinate function with symmetry corresponding to the Young diagram $[\lambda]$ is constructed by means of the Young operators from the coordinate functions of the sub-systems, each of which belongs to a given irreducible representation $\Gamma^{(\alpha_a)}$ of the local symmetry group of the sub-system $\mathbf{G}_a$. The group $\mathbf{G}_a$ may be either the group of orthogonal transformations in three-dimensional space $\mathbf{O}_3 = \mathbf{R}_3 \times C_i$ (the sub-systems are assumed to be free) or a symmetry point group (the sub-systems are considered in an external field, usually a crystal field). The expression for the character of the reducible representation

$U^{[\lambda]}_{\alpha_1 \ldots \alpha_k}$ induced in the coordinate functions of the entire system, is analogous to Eqn. (28):

$$X^{[\lambda]}(\Re) = \chi^{[\lambda]}(P)\,[\chi^{(\alpha_1)}(R)]^{\nu_1}\,[\chi^{(\alpha_2)}(R^2)]^{\nu_2} \ldots [\chi^{(\alpha_k)}(R^k)]^{\nu_k}\tau(\Re). \quad (31)$$

The breakdown of the representation (31) into irreducible representations gives the allowed types of point symmetry. To determine the corresponding values of the total electron spin of the system S, it is necessary to break down the representation $U^{[\tilde{\lambda}]}_{^2S_a+1}$ of the unitary group $U_{^2S_a+1}$, induced in $(2S_a + 1)$-dimensional spin space in the functions $\Omega^{[\tilde{\lambda}]}_{\tilde{r}}$, into the irreducible representations of the group R_3. In contrast to the case where $S_a = 1/2$, when there is a unique correspondence of the representations $U^{[\tilde{\lambda}]}_2$ and $D^{(S)}$, in the case where $S_a > 1$ a single Young diagram can correspond to several different values of the total spin S. Tables of these quantities are given in Appendix 3 of Ref. 14.

Thus the procedure for finding the allowed multiplets can be represented schematically in the form

$$\begin{array}{ccc} U^{[\lambda]}_{\alpha_1 \ldots \alpha_k} & \leftrightarrow & U^{[\tilde{\lambda}]}_{^2S_a+1} \\ \downarrow & & \downarrow \\ \Gamma^{(\alpha)} & \longleftrightarrow & D^{(S)} \end{array} . \quad (32)$$

Since with the exception of the case where $S_a = 1/2$ the Young diagram $[\tilde{\lambda}]$ can correspond to several values of S, the procedure (32) is carried out systematically for all allowed Young diagrams of n squares, after which the sums of identical terms are taken.

An expression can readily be obtained for the characters of the reducible representation containing all terms of a given multiplicity. As shown in Refs. 38–41, the equations for the characters can be derived in terms of the coefficients of the plethysm of the unitary groups introduced by Littlewood[42]. On the other hand, the same equations are expressed in terms of the $3nj$ symbols of the group of three-dimensional rotations. As a result, it is possible to obtain a relationship between the coefficients of the plethysm and the $3nj$ symbols[39–41].

This method has been generalised for the case of spin-orbit coupling, and examples have been given for various specific systems[39–41].

VI. CALCULATION OF THE MATRIX ELEMENTS OF THE HAMILTONIAN IN A STATE HAVING A DEFINITE TOTAL SPIN

The representation of the eigenfunctions of the operator $\hat{S}^2$ in the closed form (16), instead of the linear combinations of Salter determinants, makes it possible to obtain equations for the matrix elements of a Hamiltonian not depending on spin[43] for the case of an arbitrary configuration of non-orthogonal orbitals. The coefficients in these equations include explicitly the dependence on spin, since they contain the matrix elements of the irreducible representation $\Gamma^{[\lambda]}$, unambiguously related to S. The expressions for the configurations of orthogonal orbitals usually employed are obtained as particular cases.

It is possible to give the corresponding equations for the configuration of singly-filled non-orthogonal orbitals‡:

$$K: \varphi_1\varphi_2 \ldots \varphi_N,\ \langle\varphi_a|\varphi_b\rangle = s_{ab} \neq 0, \quad (33)$$

used in the spin-projected method of "different orbitals for different spins". The non-symmetrised coordinate function of this configuration can be denoted Φ_0:

$$\Phi_0(K) = \varphi_1(1)\varphi_2(2) \ldots \varphi_N(N).$$

As a consequence of the non-orthogonality of the orbitals, the symmetrised coordinate function $\Phi^{[\lambda]}_{rt}$, obtained by applying $\omega^{[\lambda]}_{rt}$ to Φ_0, must be normalised:

$$\Phi^{[\lambda]}_{rt} = N^{[\lambda]}_t(K)\,\omega^{[\lambda]}_{rt}\Phi_0(K). \quad (34)$$

It can readily be shown[44] that the normalisation factor $N^{[\lambda]}_t(K)$ is given by the following equation:

$$[N^{[\lambda]}_t(K)]^{-2} = \sum_P \Gamma^{[\lambda]}_{tt}(P)\,\langle\Phi_0(K)|P\Phi_0(K)\rangle = \\ = 1 + \sum_{P_{ab}} \Gamma^{[\lambda]}_{tt}(P_{ab})\,s^2_{ab} + \sum_{P_{abc}} \Gamma^{[\lambda]}_{tt}(P_{abc})\,s_{ac}s_{ba}s_{cb} + \ldots \quad (35)$$

The index t numbers the different states, differing in the way in which the spins of the individual electrons are combined to give the total spin S. The number of such states is equal to f_λ. The average value of the Hamiltonian for the configuration (33) and a particular choice of ways of combining the electron spins was obtained by Goddard[20] using the apparatus of the permutation group. The equations in Goddard's paper are very complex, however. Gerratt[23] (see also Ref. 44) obtained much more compact expressions for an arbitrary way of combining the spins. Since the Hamiltonian of a molecule is the sum of one-electron and two-electron operators

$$\mathcal{H} = F + G = \sum_{i=1}^{N} f_i + \sum_{i<j}^{N} g_{ij}, \quad (36)$$

expressions can be given for the matrix elements of the operators F and G. These matrix elements can be represented as follows:

$$\langle Kt|F|K\tilde{t}\rangle^{[\lambda]} = N^{[\lambda]}_t(K)\,N^{[\lambda]}_{\tilde{t}}(K)\sum_{a,b} N^{[\lambda]}_{t\tilde{t}}(K_a, K_b)\,f_{ab}, \quad (37)$$

$$N^{[\lambda]}_{t\tilde{t}}(K_a, K_b) = \sum_{P'} \Gamma^{[\lambda]}_{t\tilde{t}}(P'P^{ia}_b)\,\langle\Phi_0(K_a)|P'\Phi_0(K_b)\rangle, \quad (38)$$

where K_a is the configuration obtained from the configuration K by removing the orbital φ_a; the permutation P^{ia}_b moves the electron of the orbital φ_a into the orbital φ_b in the function $\Phi_0(K)$; the permutations P' belong to the group π_{N-1}, obtained from π_N by removing the electron i_a; and $f_{ab} = \langle\varphi_a|f|\varphi_b\rangle$ is the one-electron matrix element.

$$\langle Kt|G|K\tilde{t}\rangle^{[\lambda]} = \frac{1}{2}N^{[\lambda]}_t(K)\,N^{[\lambda]}_{\tilde{t}}(K) \times \\ \times \sum_{a,b}\sum_{c,d} \gamma_{ac}\gamma_{bd}N^{[\lambda]}_{t\tilde{t}}(K_{ac}, K_{bd})\,g_{ac,bd}, \quad (39)$$

$$N^{[\lambda]}_{tt}(K_{ac}, K_{bd}) = \sum_P \Gamma^{[\lambda]}_{tt}(P''P^{ia'c}_{bd})\,\langle\Phi_0(K_{ac})|P''\Phi_0(K_{bd})\rangle. \quad (40)$$

‡ To avoid confusion, it should be emphasised that the subscripts a and b number the orbitals, and are not related to the numbering of the atoms, that is the orbital φ_a may denote either an atomic (if the valency scheme method is used) or a molecular orbital, including contributions from all the atoms.

In Eqn. (39), $\gamma_{ac} = 1 - \delta_{ac}$, which corresponds to the single filling of the orbitals of the configuration K. The permutation $P^{i_a i_c}_{bd}$ moves the electrons from the orbital φ_a to φ_b and from φ_c to φ_d; the permutations P'' belong to the group π_{N-2}, obtained from π_N by removing the electrons i_a and i_c. The two-electron matrix element is $g_{ac,bd} = \langle \varphi_a(i)\varphi_c(j)|g_{ij}|\varphi_b(i)\varphi_d(j)\rangle$.

For antisymmetric coordinate states with $[\lambda] = [1^N]$, corresponding to the maximum value of the spin, it can readily be shown that Eqns. (37) and (39) become Löwdin's familiar equations[45] for the one-determinant wavefunction constructed on non-orthogonal spin-orbitals:

$$\langle K|F|K\rangle^{[1^N]} = \frac{1}{\det|s_{mn}|}\sum_{a,b}(-1)^{i_a-i_b}\det|s_{mn}|_{ab}f_{ab}, \quad (41)$$

$$\langle K|G|K\rangle^{[1^N]} = \frac{1}{\det|s_{mn}|}\sum_{a<c}\sum_{b<d}(-1)^{i_a+i_b+i_c+i_d}\det|s_{mn}|_{ac,bd}(g_{ac,bd}-g_{ac,db}), \quad (42)$$

where $\det|s_{mn}|_{ab}$ is the minor of the determinant $\det|s_{mn}|$ obtained by deleting the ath row and the bth column.

Equations as simple as Eqns. (41) and (42) are obtained only for the case of maximum spin or for a one-determinant wavefunction, not corresponding in general to a definite value of S. For an arbitrary spin, it is necessary to use Eqns. (37)–(40). The calculation of the non-orthogonality coefficients $N^{[\lambda]}_{tt}(K_a, K_b)$ and $N^{[\lambda]}_{tt}(K_{ac}, K_{bd})$ is most complex. These coefficients are related to one another by the simple expression

$$N^{[\lambda]}_{\bar{t}\bar{t}}(K_a, K_b) = \sum_d \gamma_{ac}\gamma_{bd}N^{[\lambda]}_{\bar{t}\bar{t}}(K_{ac}, K_{bd})\,s_{cd}, \quad (43)$$

which is fulfilled for any $c \neq a$. The following equation, analogous to Eqn. (43),

$$N^{[\lambda]}_{\bar{t}\bar{t}}(K_{ac}, K_{bd}) = \sum_f \gamma_{ace}\gamma_{bdf}N^{[\lambda]}_{\bar{t}\bar{t}}(K_{ace}, K_{bdf})\,s_{ef}, \quad (44)$$

is fulfilled for any $e \neq a, c$. The symbol $\gamma_{abc} = (1-\delta_{ab})(1-\delta_{ac})(1-\delta_{bc})$. The quantities $N^{[\lambda]}_{tt}(K_{ace}, K_{bfd})$ are determined from equations analogous to Eqns. (38) and (40):

$$N^{[\lambda]}_{\bar{t}\bar{t}}(K_{ace}, K_{bdf}) = \sum_{P''}\Gamma^{[\lambda]}_{\bar{t}\bar{t}}(P''P^{i_a i_c i_e}_{bdf})\langle\Phi_0(K_{ace})|P''\Phi_0(K_{bdf})\rangle. \quad (45)$$

Analogous quantities can be determined for the configuration with four "separated" orbitals, etc., including the limiting case corresponding to the "separation" of all N orbitals of the configuration:

$$N^{[\lambda]}_{\bar{t}\bar{t}}(K_{ace\ldots q}, K_{bdf\ldots r}) = \Gamma^{[\lambda]}_{\bar{t}\bar{t}}(P^{i_a i_c i_e \ldots i_q}_{bdf\ldots r}). \quad (46)$$

It is convenient to use the chain of recurrence equations (43)–(46) for the computer calculation of $N^{[\lambda]}_{tt}$. For this it is sufficient to give the matrix of the overlap integrals and the matrices of the transpositions $\Gamma^{[\lambda]}(P_{i,i+1})$, since all other permutations are expressed in terms of the products of transpositions of this type. Here it is necessary to take account of the fact that the form of the coefficients $N^{[\lambda]}_{tt}$ remains unchanged for identical permutations of the indices in the two configurations appearing in the argument.

In the case of a configuration of orthogonal orbitals, the expressions for the matrix elements are simplified considerably. An arbitrary configuration of orthogonal orbitals

$$K: \varphi_a^{n_a}\varphi_b^{n_b}\ldots\varphi_q^{n_q},\ \sum_a n_a = N,\ \langle\varphi_a|\varphi_b\rangle = \delta_{ab}. \quad (47)$$

can be considered. Expressions can be obtained for the matrix elements, diagonal with respect to configuration, of the operators F and G. The matrix element of the operator F is independent of the symmetry of the state

$$\langle Kt|F|K\bar{t}\rangle^{[\lambda]} = \delta_{\bar{t}\bar{t}}\sum_a n_a f_{aa}. \quad (48)$$

For the operator G, an elegant result is obtained: the entire dependence on spin is included in the coefficient of the exchange integral:

$$\langle Kt|G|K\bar{t}\rangle^{[\lambda]} = \delta^{t}_{\bar{t}\bar{t}}\sum_a{}' g_{aa,aa} + \sum_{a<b} n_a n_b\,[\delta_{\bar{t}\bar{t}}g_{ab,ab} + \Gamma^{[\lambda]}_{\bar{t}\bar{t}}(P_{ab})\,g_{ab,ba}]. \quad (49)$$

The prime of the sum over a denotes that the sum is taken only over doubly-filled orbitals. The coefficients of the exchange integrals are equal to the matrix elements of the transposition P_{ab} between the orbitals. If the orbitals φ_a and φ_b are doubly filled, it is possible to take as P_{ab} any permutation of the electrons between the orbitals φ_a and φ_b, since for these permutations, $\Gamma^{[\lambda]}_{tt}(P_{ab})$ are identical.

For brevity, the following symbols are introduced:

$$g_{ab,ab} = \alpha_{ab},\ g_{ab,ba} = \beta_{ab}.$$

Eqns. (48) and (49) make it possible to represent the matrix elements of the Hamiltonian $\mathcal{H} = F + G$ as a sum of two terms. The first contains the one-electron and Coulomb integrals, and the second is the sum of only exchange integrals:

$$\langle Kt|\mathcal{H}|Kt\rangle^{[\lambda]} = \delta_{\bar{t}\bar{t}}Q + J^{[\lambda]}_{\bar{t}\bar{t}}, \quad (50)$$

where

$$Q = \sum_a n_a f_{aa} + \sum_a{}'\alpha_{aa} + \sum_{a<b} n_a n_b \alpha_{ab}, \quad (51)$$

$$J^{[\lambda]}_{\bar{t}\bar{t}} = \sum_{a<b} n_a n_b \Gamma^{[\lambda]}_{\bar{t}\bar{t}}(P_{ab})\,\beta_{ab}. \quad (52)$$

The non-diagonal elements of the energy matrix contain only the exchange integrals with coefficients which depend on the spin of the state. Since a contribution to the spin is made only by unpaired electrons, the coefficients of the exchange integrals can be determined in the group of the permutations of not all but only the unpaired electrons. For this purpose, the configuration K must be represented in the form K_0K_1, putting the doubly filled orbitals first (configuration K_0), and then the singly filled orbitals (configuration K_1). The Young diagram characterising the symmetry of the configuration K_1 is obtained from the Young diagram $[\lambda]$ by removing the m upper rows (m is the number of doubly filled orbitals), and is denoted $[\lambda^{(m)}]$. In the equation given below, the letters a and b are used to denote the orbitals of the configuration K_0 and the letters c and d the orbitals of the configuration K_1. Thus by making use of the properties of the standard representation of the group of permutations[14] for the spin-dependent non-diagonal elements of the Hamiltonian (52), it is possible to obtain the following expression:

$$J^{[\lambda]}_{\bar{t}\bar{t}} = -\sum_{a<b} 2\beta_{ab} - \sum_{a,c}\beta_{ac} + \sum_{c<d}\Gamma^{[\lambda^m]}_{t_i t_i}(P_{cd})\,\beta_{cd}. \quad (53)$$

In molecular calculations, the number of singly filled molecular orbitals is usually small. The matrices $\Gamma^{[\lambda]}(P_{ab})$ for all transpositions of the groups π_3–π_4 and the transpositions of the type $P_{i,i+1}$ of the groups π_5–π_6 are given in the Appendix to Ref. 14, and the matrices of all the transpositions of the groups π_3–π_6 are given in the expanded edition of the book by the present author[46].

VII. SPIN-PROJECTED SELF-CONSISTENT FIELD EQUATIONS

In the valence bond method and in the simple molecular orbital method, the one-electron functions are assumed to be known. It is possible, however, in the one-particle approximation, to formulate the many-electron problem without imposing previous restrictions on the one-electron functions. This approach, first proposed and developed for the atom by Hartree[47] and Fock[48] (see also Slater's paper[49]), is usually called the Hartree–Fock or self-consistent field (SCF) method.

The derivation of the equations which must be satisfied by the one-electron functions being sought is based on the variation principle

$$\bar{E} = \int \Psi^* \mathcal{H} \Psi \, \mathrm{d}V = \min \tag{54}$$

with the additional condition

$$\int \Psi^* \Psi \, \mathrm{d}V = 1, \tag{55}$$

but only the determinants of the one-electron functions are allowed as competing functions. Since for arbitrary Ψ the variation principle (54) and (55) leads to the Schrödinger equation (see for example Ref. 19), the best function of this type is found by solving the variation problem with a determinantal wavefunction.

In molecular calculations, the term Hartree–Fock equation is usually employed to describe the SCF equations obtained in the description of the system by a single determinant with doubly filled orbitals. This determinant corresponds to the spin $S = 0$, and describes the ground state of most molecules. The derivation of the Hartree–Fock equations can also be carried out without relating it to the determinantal representation of the wavefunction. As noted above, all the properties of a molecule which are independent of spin interactions are described by giving only the coordinate wavefunction. In fact, the derivation of the SCF equations requires only an expression for the average value of the energy in the state being considered. By partitioning the total wavefunction into coordinate and spin functions, expressions of this kind were obtained in the previous section for an arbitrary configuration in a state with a definite value of the spin S. This makes it possible to derive the SCF equations in the general case and to obtain all particular cases from them, without deriving these equations separately for each state being considered, as has to be done when operating with wavefunctions in the form of linear combinations of determinants.

With allowance for Eqns. (48) and (49), an expression can be written for the average energy in a form symmetrical with respect to the indices a and b:

$$\bar{E} = \mathcal{H}_{tt}^{[\lambda]}(K) = \sum_a n_a f_{aa} + \frac{1}{2}\sum_{a,b} \beta(n_a, n_b)\,[\alpha_{ab} + \Gamma_{tt}^{[\lambda]}(P_{ab})\,\beta_{ab}],$$
$$\beta(n_a, n_b) = \begin{cases} n_a n_b & a \neq b, \\ 1 & a = b. \end{cases} \tag{56}$$

For $a = b$, $\Gamma_{tt}^{[\lambda]}(P_{ab}) = 1$. Following Roothaan[50], it is possible to introduce Coulomb $\hat{\alpha}_b$ and exchange $\hat{\beta}_b$ operators, defined by the relationships

$$\hat{\alpha}_b(i)\,\varphi_a(i) = \left[\int \varphi_b^*(j)\,\varphi_b(j)\,g_{ij}\,\mathrm{d}V_j\right]\varphi_a(i),$$
$$\hat{\beta}_b(i)\,\varphi_a(i) = \left[\int \varphi_b^*(j)\,\varphi_a(j)\,g_{ij}\,\mathrm{d}V_j\right]\varphi_b(i). \tag{57}$$

It can readily be verified that the operators $\hat{\alpha}_b$ and $\hat{\beta}_b$ are Hermitian, that is they satisfy the relationships§

$$\langle\psi|\hat{\alpha}_b|\varphi\rangle = \langle\varphi^*|\hat{\alpha}_b^*|\psi^*\rangle,$$
$$\langle\psi|\hat{\beta}_b|\varphi\rangle = \langle\varphi^*|\hat{\beta}_b^*|\psi^*\rangle. \tag{58}$$

The operators (57) make it possible to write the Coulomb and exchange integrals as one-electron integrals:

$$\alpha_{ab} = \langle\varphi_a|\hat{\alpha}_b|\varphi_a\rangle = \langle\varphi_b|\hat{\alpha}_a|\varphi_b\rangle,$$
$$\beta_{ab} = \langle\varphi_a|\hat{\beta}_b|\varphi_a\rangle = \langle\varphi_b|\hat{\beta}_a|\varphi_b\rangle. \tag{59}$$

The following expression is obtained for the average energy E (56) with allowance for Eqns. (59):

$$\bar{E} = \sum n_a\langle\varphi_a|\hat{f}|\varphi_a\rangle + \frac{1}{2}\sum_{a,b}\beta(n_a, n_b)\langle\varphi_a|\hat{\alpha}_b + \Gamma_{tt}^{[\lambda]}(P_{ab})\,\hat{\beta}_b|\varphi_a\rangle. \tag{60}$$

Thus the solution of the variation problem (54) and (55) involves the determination of the set of orbitals φ_a minimising the energy (60), with fulfilment of the conditions for orthonormalisation of the orbitals

$$\langle\varphi_a|\varphi_b\rangle = \delta_{ab}. \tag{61}$$

This problem can be solved by the Lagrange method, and reduces to the determination of the unconditional extremal value of the function

$$J = \sum_a \left\langle \varphi_a \left| n_a\hat{f} + \frac{1}{2}\sum_b \beta(n_a, n_b)\,[\hat{\alpha}_b + \Gamma_{tt}^{[\lambda]}(P_{ab})\,\hat{\beta}_b \right| \varphi_a \right\rangle - \sum_{ab}\varepsilon_{ba}\langle\varphi_a|\varphi_b\rangle, \tag{62}$$

where ϵ_{ab} represents the Lagrange factors. For this it is necessary to find the first variation of the functional J. When taking the variation with respect to φ_b^* and φ_b, it is convenient to use the equivalence of the two forms in which the Coulomb and exchange integrals (59) can be written. Allowance for the Hermitian character of the operators $\hat{f}$, $\hat{\alpha}_b$, and $\hat{\beta}_b$ makes it possible to represent the variation in the form

$$\delta J = \sum_a \left\langle \delta\varphi_a \left| n_a\hat{f} + \sum_b \beta(n_a, n_b)\,[\hat{\alpha}_b + \Gamma_{tt}^{[\lambda]}(P_{ab})\,\hat{\beta}_b] \right| \varphi_a \right\rangle - \sum_{a,b}\langle\delta\varphi_a|\varepsilon_{ba}\varphi_b\rangle +$$
$$+ \sum_a \left\langle \delta\varphi_a^* \left| n_a\hat{f} + \sum_b \beta(n_a, n_b)\,[\hat{\alpha}_b^* + \Gamma_{tt}^{[\lambda]}(P_{ab})\,\hat{\beta}_b^*] \right| \varphi_a^* \right\rangle - \sum_{a,b}\langle\delta\varphi_a^*|\varepsilon_{ab}\varphi_b^*\rangle. \tag{63}$$

By equating δJ to zero and making allowance for the independence of the variations $\delta\varphi_a$ and $\delta\varphi_a^*$, it is possible to obtain two complex-conjugate systems of equations, which are equivalent if the matrix of the Lagrange coefficients is Hermitian:

$$\varepsilon_{ba} = \varepsilon_{ab}^*. \tag{64}$$

The required set of minimising orbitals should be a solution of the integro-differential equations

$$\hat{\mathcal{H}}_a\varphi_a = \sum_b \varepsilon_{ba}\varphi_b, \quad a = 1, 2, \ldots N - m \tag{65}$$

with the one-electron Hamiltonian

$$\hat{\mathcal{H}}_a = n_a\hat{f} + \sum_b \beta(n_a, n_b)\,[\hat{\alpha}_b + \Gamma_{tt}^{[\lambda]}(P_{ab})\,\hat{\beta}_b]. \tag{66}$$

The system of $(N - m)$ equations (65) and (66) contains $(N - m)$ unknown functions φ_a (for the configuration of singly filled orbitals there are N functions, and for the configuration K_0 with all doubly filled orbitals there are $N/2$ functions) and $(N - m)^2$ unknown Lagrange factors ϵ_{ba}.

---

§ It may be remembered that $\langle\psi|\hat{\alpha}_b|\varphi\rangle \equiv \int\psi^*\hat{\alpha}_b\varphi\,\mathrm{d}V$.

It must therefore be supplemented by an additional $(N-m)^2$ equations. Multiplication of Eqn. (65) by φ_b^* and integration with respect to the whole of space give

$$\varepsilon_{ba} = \langle \varphi_b | \hat{\mathcal{H}}_a | \varphi_a \rangle. \quad (67)$$

In practice, it is more convenient to use the more symmetrical form of writing the Lagrange factors:

$$\varepsilon_{ba} = \frac{1}{2}\langle \varphi_b | \hat{\mathcal{H}}_a + \hat{\mathcal{H}}_b | \varphi_a \rangle. \quad (68)$$

Eqns. (65) describe the state of an arbitrary molecular configuration with value of the total spin S. In this general case, each orbital φ_a has its own Hamiltonian $\hat{\mathcal{H}}_a$; the coefficients ϵ_{ba} do not have a definite physical significance.

For a closed electron level, when all the orbitals are doubly filled, Eqns. (65) are simplified. This state corresponds to the spin $S = 0$, and the orbital Young diagram $[\lambda] = [2^m]$. Since $\Gamma^{[2n]}(P_{ab}) = -1/2$ (see Ref. 14), $n_a = n_b = 2$, and $\hat{\alpha}_b$ and $\hat{\beta}_b$ are equivalent for $a = b$, it is found that all orbitals of the configuration K_0 satisfy the single equation

$$\hat{\mathcal{H}}_0 \varphi_a = \sum_b \varepsilon_{ba} \varphi_b, \quad (69)$$

$$\hat{\mathcal{H}}_0 = 2\hat{f} + 2\sum_b (2\hat{\alpha}_b - \hat{\beta}_b). \quad (70)$$

It can readily be shown (see Ref. 50) that the operator (70) is invariant with respect to an arbitrary unitary transformation of the orbitals. If the transformation which diagonalises the Hermitian matrix of the Lagrange factors (68) is used as unitary transformation, Eqns. (69) can be transformed to a problem in the eigenvalues of the operator $\hat{\mathcal{H}}_0$.

$$\hat{\mathcal{H}}_0 \varphi_a = 2\varepsilon_a \varphi_a. \quad (71)$$

The factor 2 in front of ϵ_a is introduced so that ϵ_a has the significance of the energy of the electron in the orbital φ_a¶. By separating the analogous factor from the operator $\hat{\ }_0$ (70), it is possible to obtain the familiar Hartree–Fock equation for a closed level

$$\hat{\mathcal{H}}_0 \varphi_a = \varepsilon_a \varphi_a, \quad (72)$$

$$\hat{\mathcal{H}}_0 = \hat{f} + \sum_b (2\hat{\alpha}_b - \hat{\beta}_b). \quad (73)$$

The orbitals satisfying the Hartree–Fock equations (72) are eigenfunctions of the same Hamiltonian. From this it follows immediately that: a) the self-consistent orbitals corresponding to different eigenvalues of Eqn. (72) are orthogonal to one another; and b) the orbitals corresponding to a given eigenvalue transform as the irreducible representations of the symmetry group of the Hamiltonian (if there is no accidental degeneracy). The operator $\hat{\mathcal{H}}_0$ consists of the one-electron operator $\hat{f}$, the symmetry of which is determined by the equilibrium configuration of the nuclei, that is it coincides with the symmetry group of the molecule, and the sum of the Coulomb and exchange operators, which depends on the orbitals. The last sum, as noted above, is scalar with respect to the operations of the unitary group, and hence to the operations of its point sub-group. Thus the symmetry of the Hamiltonian coincides with the symmetry of the operator $\hat{f}$, and the solutions of the Hartree–Fock equation should transform as the irreducible representations of the symmetry point group of the molecule.

It is obvious that

$$\varepsilon_a = \langle \varphi_a | \mathcal{H}_0 | \varphi_a \rangle = f_{aa} + \sum_b (2\alpha_{ab} - \beta_{ab}). \quad (74)$$

If the sum of the energies ϵ_a over all electrons, is now taken, it is found that

$$2\sum_a \varepsilon_a = 2\sum_a f_{aa} + 2\sum_{a,b} (2\alpha_{ab} - \beta_{ab}). \quad (75)$$

On the other hand, the total energy of the electrons for the configuration K_0 being considered, according to Eqn. (50), is

$$E_0 = 2\sum_a f_{aa} + \sum_{a,b} (2\alpha_{ab} - \beta_{ab}), \quad (76)$$

that is the sum of the one-electron energies is greater than the total energy of this system by an amount corresponding to the energy of interaction of the electrons. This is related to the fact that in the summation with respect to all the electrons, the interaction of each pair of electrons was included twice. It may be noted that it is because the total energy is not equal to the sum of the one-electron energies that the filling of the orbital states does not always take place in order of increasing ϵ_a, since the term containing the interaction

$$\sum_{a,b} (2\alpha_{ab} - \beta_{ab})$$

may compensate the loss in energy, obtained by the "irregular" filling of the orbitals.

The expression for the total energy (76) can also be written in the additive form:

$$E_0 = \sum_a \left(2f_{aa} + \sum_b (2\alpha_{ab} - \beta_{ab})\right) = \sum_a \varepsilon'_a, \quad (77)$$

$$\varepsilon'_a = 2\varepsilon_a - \sum_b (2\alpha_{ab} - \beta_{ab}), \quad (78)$$

that is the electronic energy can be represented as the sum of appropriately renormalised one-electron energies. This explains why, with an appropriate selection of parameters in some semi-empirical calculations, it is possible not to take explicit account of electron interactions (for example in the Hückel method).

VIII. THE USE OF THE APPARATUS OF CONTINUOUS GROUPS IN QUANTUM-CHEMICAL CALCULATIONS

The mathematical apparatus of unitary groups can be used not only for the classification of states[38–41,51] but also directly in the calculation of the matrix of the Hamiltonian[6–9,59,60]. Its application is based on the following features.

A many-electron wavefunction can always be expanded in a series with respect to products of orthonormalised one-electron functions (spin-orbitals). This expansion is accurate when account is taken of all configurations in the complete (infinite) set of one-electron functions. Practical

¶ The need to introduce the factor 2 for the interpretation of φ_a as the one-electron energy is related to the fact that when taking account of the bonding conditions by means of the Lagrange factor in Eqn. (62), the summation was carried out only with respect to the orbitals, without allowance for the multiplicity of the filling. Thus in the SCF equations, represented in the form of the eigenvalue problem of the one-electron operator $\mathcal{H}_a(i)$, ϵ_a characterises the total energy of all the electrons in the orbital φ_a, that is, for doubly filled orbitals, the energy of two electrons.

calculations are naturally based on a finite set; its order is denoted $2q$. These $2q$ orthonormalised spin-orbitals can be regarded as the basis unit vectors of a $2q$-dimensional vector space. The complete many-electron wavefunction is constructed from the products of N vectors of this space, and is an antisymmetric tensor of rank N in the space of $2q$ measurements. In the original one-electron basis it is possible to construct a model Hamiltonian for which a given many-electron function is not an approximate but an exact eigenfunction. In the representation of secondary quantisation, the model Hamiltonian has the following form:

$$\mathcal{H} = \sum_{k,l}^{2q} f_{kl} a_k^+ a_l + \frac{1}{2} \sum_{kl,m,n} g_{km,ln} a_k^+ a_m^+ a_n a_l, \qquad (79)$$

where the operators for the generation a_k^+ and annihilation a_k of an electron in the state $k = \varphi_a \chi \sigma_k$ satisfy the fermion commutation relationships:

$$[a_k, a_l^+]_+ = \delta_{kl}, \quad [a_k^+, a_l^+]_+ = [a_k, a_l]_+ = 0. \qquad (80)$$

For the operators f_i and g_{ij}, which do not depend on spin, the matrix elements are

$$f_{kl} = \delta_{\sigma_k \sigma_l} f_{ab}, \quad g_{km,ln} = \delta_{\sigma_k \sigma_l} \delta_{\sigma_m \sigma_n} g_{ab,cd}, \qquad (81)$$

when the one-electron and two-electron matrix elements f_{ab} and $g_{ab,cd}$ are defined in the orbitals φ_a, and not in the spin-orbitals k.

If the matrix elements (81) are not calculated, but are found from the comparison with experimental data, Eqn. (79) is a semi-empirical model Hamiltonian. Thus in the Pariser–Parr–Pople Hamiltonian

$$g_{ab,cd} = \delta_{ac} \delta_{bd} I_{ab}, \qquad (82)$$

and in the Hubbard Hamiltonian

$$g_{ab,cd} = \delta_{ac} \delta_{bd} \delta_{ab} I. \qquad (83)$$

Using the anticommutation relationships (80), it can readily be shown that the commutator

$$[a_k^+ a_l, a_m^+ a_n]_- = \delta_{lm} a_k^+ a_n - \delta_{kn} a_m^+ a_l. \qquad (84)$$

Eqns. (84) coincide with the commutation relationships for the infinitesimal generators of the unitary group, defining the structural constants of the corresponding Lie algebra[6,17]:

$$[E_{kl}, E_{mn}]_- = \delta_{lm} E_{kn} - \delta_{kn} E_{ml}. \qquad (85)$$

Thus the operators a_k^+ and a_l are algebraically equivalent to the infinitesimal generators E_{kl} of the unitary group, and can be identified with them.

Since

$$a_k^+ a_m^+ a_n a_l = a_k^+ a_l a_m^+ a_n - \delta_{lm} a_k^+ a_n, \qquad (86)$$

the Hamiltonian (79) can be expressed in terms of the generators E_{kl}. Thus

$$\mathcal{H} = \sum_{k,l}^{2q} f_{kl} E_{kl} + \frac{1}{2} \sum_{k,l,m,n} g_{km,ln} [E_{kl} E_{mn} - \delta_{lm} E_{kn}]. \qquad (87)$$

As noted above, a many-electron wavefunction is an antisymmetric tensor of rank N in the space of $2q$ measurements. Since the Hamiltonian is assumed to be independent of the spin variables, the total wavefunction can be broken down into coordinate and spin functions, and the coordinate wavefunction is defined in the space of q measurements. For unitary transformations of space, the coordinate wavefunction transforms as the tensor representation of the group U_q. The representation breaks down into the irreducible representations $U_q^{[\lambda]}$ on symmetrisation of the tensor in accordance with a Young diagram of N squares[14,52]. As early as 1950, Gel'fand and Tseitlin[53,54] determined the canonical basis for the irreducible representations of the unitary group, in which there are simple equations for the matrix elements of the infinitesimal generators of the unitary group, Since the Hamiltonian (87) is a polynomial of second degree in the generators E_{kl}, the problem of calculating the matrix elements using the Gel'fand–Tseitlin basis becomes very simple.

A similar approach was proposed by Matsen[6], and realised by Paldus[8] for computer calculation in the approximation of the configuration interaction method. The program compiled is very efficient. Thus for a six-electron problem and the Pariser–Parr–Pople Hamiltonian, the time required on an IBM 360/75 computer for calculating the complete matrix of the configuration interaction for singlet states (order of the matrix 175×175) or triplet states (order of the matrix 198×198) is less than 1 s.[8]

The use of an anlogous approach for calculating atomic states was proposed by Patera[55] and Harter[9,56]. In a central field for an orbital momentum of the electron $l \geq 2$, the problem of the additional quantum numbers identifying the state arises, since the same value of the total orbital momentum L may be encountered several times in a configuration[14,57]. For the one-level configuration l^N, the space of the orthogonal orbitals has the dimension $2l + 1$. In unitary transformations of this space, the many-electron coordinate function transforms as the tensor representation of the group of unitary transformations U_{2l+1}. The Gel'fand–Tseitlin basis separates the irreducible representations $U_{2l+1}^{[\lambda]}$ and corresponds to the reduction in the chain of groups $U_{2l+1} \subset U_{2l} \supset U_{2l-1} \supset \ldots \supset U_1$. This reduction ensures that a complete set of quantum numbers is obtained for all many-electron states.

However, although the wavefunctions in the Gel'fand–Tseitlin basis are eigenfunctions of the operators $\hat{S}^2$, $\hat{S}_Z$, and L_Z, they do not correspond to a definite value of the orbital momentum L. This leads to large orders of the secular equations. This is not a problem for modern fast computers, but for carrying out analytical calculations, the generally accepted procedure for calculations using the Racah technique appears much more convenient. There therefore does not seem to be sufficient basis for the opinion, put forward by Harter and Patterson[9], that the method of calculation using the apparatus of unitary groups should completely replace the Racah method. A more detailed comparison of the two methods is given in a review[58] of the book by Harter and Patterson[9].

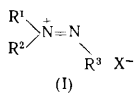
Diazenium Salts

M.A.Kuznetsov



The literature on compounds of the type $[R^1R^2N=NR^3]^+X^-$ (diazenium salts) is surveyed. Their structures and properties are considered and methods for their synthesis as well as a wide variety of the chemical reactions of these reactive hydrazine derivatives are discussed.
The bibliography includes 122 references.

I. INTRODUCTION

Diazenium salts constitute a new class of nitrogen compounds having the general formula (I) containing the functional group $\rangle N^+=N$, which is not part of an aromatic system:

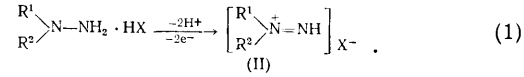
(I)

R^1=H, Alk, or Ar;
R^2=H, Alk, or Ar;
R^3=H, Alk, Ar, OAlk, or OAc;
X^-=Hal^-, ClO_4^-, BF_4^-, $SbCl_6^-$, etc.

The cations of diazenium salts are referred to as diazenium cations. The name of the salts is based on the nomenclature proposed for compounds containing two adjacent nitrogen atoms[1]. The complete name indicates the anion and all the substituents and their positions in the cation. For example, $[Me_2N^+=NH]Br^-$ is 1,1-dimethyldiazenium bromide, $[(PhCH_2)_2N^+=NOEt]BF_4^-$ is 1,1-dibenzyl-2-ethoxydiazenium tetrafluoroborate, and $[Ph_2N^+=NPh]ClO_4^-$ is triphenyldiazenium perchlorate.

The closest analogues of diazenium salts are, on the one hand, the well known diazonium salts and, on the other hand, the immonium salts $[R_2N^+=CR'_2]X^-$; one may therefore expect some similarity between the structures and properties of these compounds, which, as will be shown below, is indeed the case. The behaviour of diazenium salts is fully determined by the structure of the cation; the nature of the anion is not very important. Diazenium salts can be divided into several groups on the basis of the number and nature of substituents in the cation, differing appreciably in stability, properties, and the extent to which they have been investigated.

1,1-Disubstituted salts (I, R^3 = H), which have attracted the attention of investigators for a number of reasons, have been studied in greatest detail. Firstly, they are of interest in connection with the study of the mechanism of the oxidation of 1,1-disubstituted hydrazines, which is of practical importance; in acidic media this process proceeds via a stage involving the formation of the corresponding diazenium cations and the properties of the latter in many respects determine further reactions. Secondly, 1,1-disubstituted diazenium cations can be regarded as the conjugate acids of 1,1-diazenes or aminonitrenes $[R_2N^+=\bar{N} \rightleftharpoons R_2N-\ddot{N}:]$, which are unstable sextet species playing an important role in the chemistry of hydrazine derivatives[2-4]. The relation between aminonitrenes and 1,1-disubstituted diazenium cations, their interconversions in the reactions of hydrazine derivatives, and the possibility of regenerating aminonitrenes from 1,1-disubstituted diazenium salts are therefore of interest. Finally, many reactions of these salts are of independent synthetic value.



On the other hand, the properties of the isomeric 1,2-disubstituted diazenium salts have been scarcely investigated. There is also little information about the trisubstituted salts, with the exception of the so-called alkoxydiazenium salts (I, R^3 = OAlk). Fully unsubstituted and monosubstituted diazenium salts are so far unknown. The corresponding cations are apparently extremely unstable and, even if they can be generated in some reactions, so far no one has been able to detect their formation.

The literature dealing with diazenium salts is extensive, but hitherto has not been treated systematically to any great extent. Previously the syntheses and properties of diazenium salts were partly dealt with in reviews of aminonitrenes[2,3] and also in a review of reactive nitrogen-containing intermediates[5], but, in our opinion, their treatment has been inadequate. Furthermore, in recent years many new important studies have been published in this field. It therefore appears necessary to describe the present state of the chemistry of diazenium salts.

II. METHODS OF PREPARATION

1. Oxidation of Hydrazine Derivatives

In 1957 McBride[6] established that, whereas the oxidation of the simplest 1,1-dialkylhydrazines in an alkaline or neutral medium (a reaction known since the time of E. Fischer) leads to 2-tetrazenes, in an acidic medium in the cold the products obtained after the consumption of two equivalents of the oxidants are previously unknown compounds whose spectroscopic and chemical properties correspond to the structure of "diazo-like substances" (II):

(1)

(II)

McBride regarded the cations in (II) as protonated aminonitrenes (1,1-diazenes)[2-5] and therefore subsequently proposed[7] that they be called 1,1-disubstituted diazenium cations and that the salts (II) be referred to as diazenium salts.

Since then the oxidation of asymmetric disubstituted hydrazines in an acid medium [Eqn.(1)] became the usual and virtually the only method of synthesising 1,1-disubstituted diazenium salts. The oxidants used for 1,1-dialkylhydrazines have usually been halogens and alkali metal halogenates.[6-25] In addition, use was made of transition metal salts [Ce(IV) [25], Hg(II),[26] Cu(II) [27]] and peracids.[28] Hünig postulated the formation of diazenium cations in the oxidation of a number of 1,1-diarylhydrazines by $FeCl_3$ and $K_3[Fe(CN)_6]$.[29,30] However, in the latter case the oxidation was carried out in a weakly acidic (CH_3COOH) and even alkaline (pyridine, ammonia) media; under these conditions, 1,1-disubstituted diazenium salts cannot exist for any long period (see below); Hünig's claim therefore appears doubtful. It has been reported[14] that the oxidation of arylhydrazines with bromine yielded only decomposition products. However, it is more likely that this process involves the usual bromination of the aromatic ring, analogous to the bromination of analines, rather than oxidation, and that diazenium salts are not formed at all. Chemical oxidation has usually been carried out in aqueous solutions and only once in acetonitrile.[14]

Diazenium salts have been obtained by the electrochemical oxidation of 1,1-diaryl- and 1-alkyl-1-arylhydrazines at platinum electrodes in acetonitrile[14,31-37] and also of 1,1-dimethylhydrazine in aqueous H_2SO_4.[25,38] However, the attempt at an anodic oxidation of 1,1-dimethylhydrazine to a diazenium salt in acetonitrile under conditions completely identical with those in the oxidation of arylhydrazines was unsuccessful: oxidation does not occur in the presence of acid and in neutral and alkaline media other products are formed[39]. Nor was it possible to oxidise 1,1-dibenzylhydrazine under these conditions[14].

It follows from coulometric data[31-34,36-38,40,41] and from the results of potentiometric titration of 1,1-disubstituted hydrazines with KIO_3 in acid solutions[42] that two-electron oxidation takes place in conformity with Eqn.(1), the products being comparatively stable species which are not oxidised further. The EPR spectrum recorded in the oxidation of 1,1-dimethylhydrazine by Ge(IV) in H_2SO_4 showed the presence of the signal of the 1,1-dimethylhydrazinium radical-cation $[(CH_3)_2NNH_2]^{\cdot+}$, which led to the conclusion that the oxidation of 1,1-disubstituted hydrazines in acid solutions (at least by one-electron oxidants) proceeds in two stages and that the diazenium cation is preceded by the hydrazinium radical-cation[25]. On the other hand, in the electrochemical oxidation of the same hydrazine there are no EPR signals. In this case hydrazine apparently loses both electrons almost simultaneously at the anode surface[25].

The 1,1-disubstituted diazenium salts formed in the oxidation process in almost quantitative yields are most stable in strongly acidic solutions below 5°C, but even under these conditions they decompose slowly, the rate of decomposition increasing with temperature[6]. Salts with aryl substituents are stable only in non-aqueous solutions.

A salt of type (II) has been synthesised in a dry form in only one instance—McBride obtained crystalline 1,1-dimethyldiazenium perchlorate[6]:

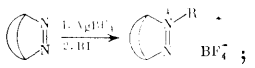
$$Me_2NNH_2 + I_2 + 2AgClO_4 \rightarrow [Me_2\overset{+}{N}{=}NH]\,ClO_4^- + HClO_4 + 2AgI\ .$$

It is noteworthy that the fully stable hydrazides of sulphonic acids (III) can be regarded formally as diazenium salts. It is claimed that in both acid[17] and neutral and alkaline polar solutions[43] they can dissociate reversibly into diazenium cations and sulphinate anions:

$$\underset{\text{(III)}}{R^1R^2N{-}NHSO_2R^3} \rightleftharpoons \left[R^1R^2\overset{+}{N}{=}NH\right] + R^3SO_2^- \quad (2)$$

The occurrence of this equilibrium has been confirmed by a number of experiments on the exchange of sulphonic acid residues in hydrazides[43] (see Section V in this review), from which it follows, in particular, that 1,1-dialkylhydrazides dissociate most readily. However, even for these substances the position of equilibrium (2) is apparently strongly displaced to the left, since signals corresponding to diazenium cations could not be detected in the ^1H NMR spectra of their solutions[43]. The dissociation itself can be regarded as an intramolecular oxidation-reduction process: here the hydrazinium residue is oxidised to the diazenium cation and the sulphonyl group is reduced to the sulphinate ion.

Trisubstituted salts (I, R^3 = Ar or t-Bu) can be obtained by the chemical (Ag^+)[44] and electrochemical[34,37,44-46] oxidation of the corresponding trisubstituted hydrazines, which is in many ways analogous to the formation of 1,1-disubstituted diazenium salts:



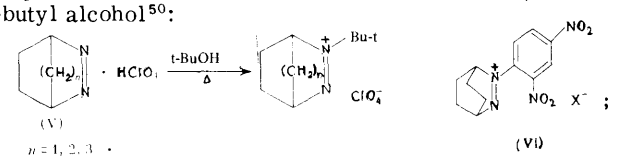
$$R^1R^2N{-}NHR^3 \xrightarrow[-H^+,-2e^-]{X^-} R^1R^2\overset{+}{N}{=}NR^3\ X^-\ . \quad (3)$$

However, the anodic oxidation of trimethylhydrazine in acetonitrile does not occur in the presence of acid, while in neutral and alkaline media formaldehyde dimethylhydrazone is formed[39]. At the same time, it is believed that the chemical oxidation of trimethylhydrazine in aqueous acid solutions and the dissociation of 1,1,2-trimethyl-2-tosylhydrazine,[17] analogous to the reaction (2), proceed via the formation of the trimethyldiazenium cation. Other trisubstituted hydrazines, which have no dissociable protons at the α-carbon atoms of the substituents, can be oxidised electrochemically in neutral and alkaline media to the corresponding diazenium cation; however, on being protonated, they are not oxidised even in aqueous solutions[44].

2. The Alkylation of Azo-Compounds and *N*-Nitrosamines

Apart from the anodic oxidation of trisubstituted hydrazines, treatment of azo-compounds with strong alkylating agents constitutes an effective method for the synthesis of trisubstituted diazenium salts. Dry crystalline salts, which are fairly stable in air, are obtained in 60–90% yield.

Thus 2,3-diazabicyclo[2,2,1]heptane and a number of azo-compounds with a symmetrical environment around the azo-group have been alkylated[44,47,48]:



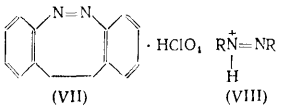
R = Me, Et, or t-Bu;

a series of 1,2-diaryl-1-methyldiazenium salts have been obtained[49]:

$$\underset{\substack{\text{(IV)}\\ R = F \text{ or } CF_3.}}{ArN{=}NAr'} \xrightarrow{MeOSO_2R} \underset{RSO_3^-}{\overset{Ar}{\underset{Me}{\overset{+}{N}}}{=}NAr'} + \underset{RSO_3^-}{ArN{=}\overset{+}{N}\overset{Ar'}{\underset{Me}{<}}}\ ;$$

If Ar = Ar′ in (IV), then alkylation proceeds preferentially and sometimes exclusively at the nitrogen atom linked to the more electron-donating substituent. When the ring contains an electron-accepting substituent, the nitrogen atom linked to it is not alkylated[49].

Trisubstituted diazenium salts are obtained unexpectedly readily and smoothly (85–90% yield) by refluxing the perchlorates of bicyclic azo-compounds (IV), in t-butyl alcohol[50]:



(V)

$n = 1, 2, 3$.

(VI)

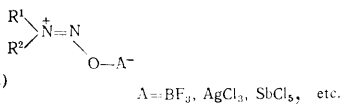
It is remarkable that in all the instances described the introduction of the t-butyl group into the molecule does not entail the liberation of isobutene.[44] Under still milder conditions (25°C, ether), the salt (VI, X = Br) can be obtained in 83% yield from 2,3-diazabicyclo[2,2,2]octene and 1-bromo-2,4-dinitrobenzene.[50]

The alkylation of protonated azo-compounds proceeds similarly[50–52]. It follows from the ^{1}H NMR spectra of certain azo-compounds in strongly acid media at a low temperature[51,52] and also from electronic spectroscopy for chemical analysis (ESCA) that the protonation of both the *cis*- and *trans*-forms of azobenzene, pyridazine, and *o*,*o'*-azobibenzyl (VII) [52] gives rise to asymmetric classical ions (VIII):

(VII) (VIII)

i.e. 1,2-disubstituted diazenium cations are produced and not a bridge ion with the proton located symmetrically relative to both nitrogen atoms. Many facts, previously treated as evidence for the formation of non-classical ions and which have aroused a prolonged discussion concerning the structure of protonated azo-compounds (see Refs. 51 and 52 and the literature quoted therein), can apparently be accounted for by very rapid proton transfer between two nitrogen atoms under the usual conditions, for example, in solutions. The classical structure of protonated azo-compounds is supported by the fact that, according to calculations in terms of CNDO/2 and MINDO/2 approximations for protonated azomethane and azobenzene, the ion (VIII) is more stable than any of the possible bridge ions[52]. Thus the salts of azo-compounds can be regarded as 1,2-disubstituted diazenium salts.

In 1962 Hünig and coworkers obtained alkoxydiazenium salts for the first time by the reaction of aliphatic *N*-nitrosamines with triethyloxonium tetrafluoroborate [53]:

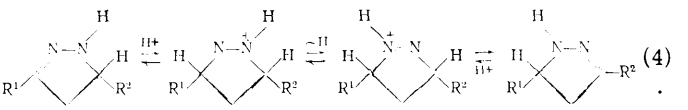


Since then alkoxydiazenium salts have been obtained by the alkylation of purely aliphatic and alkylaryl-substituted *N*-nitrosamines with trialkyloxonium tetrafluoroborates,[53–57] trialkyloxonium hexachloroantimonates,[58] and alkyl halides in the presence of $SbCl_5$,[55,57] $AgClO_4$,[54,55] dimethyl sulphate,[58–60] and benzoyl chloride[61] (strictly speaking the product in the last case is not an alkoxy-salt but an acyloxydiazenium salt). The alkylation proceeds very readily and smoothly: it is sufficient to mix the reactants in a suitable solvent (CH_2Cl_2, $C_2H_4Cl_2$, etc.) with (sometimes) slight heating. Since the yields of alkoxydiazenium salts are nearly quantitative, no attempts were therefore evidently made to obtain them by other means.

In a dry form alkoxydiazenium salts are crystalline substances; only some of the lowest homologues are oily liquids at room temperature. In the absence of moisture, they can be stored for months without decomposition; they dissolve without decomposition in many solvents, including water, but decompose when the solutions are made alkaline [55]. Their toxicity is lower than that of the initial nitrosamines and is directly proportional to the electrophilicity of the cation. When administered subcutaneously to rats, many alkoxydiazenium salts induce extensive sarcomas[62].

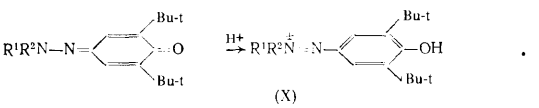
3. Other Sources of Diazenium Salts

N-Nitrosamines form complexes with Lewis acids to which structure (IX), analogous to that of alkoxydiazenium salts, was attributed on the basis of infrared and ^{1}H NMR spectra[63,64]:



(IX)

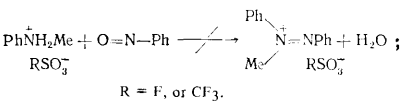
A = BF_3, $AgCl_3$, $SbCl_5$, etc.



On the basis of the ultraviolet spectra of solutions of dialkylnitrosamines in a trichloroacetic acid-cyclohexane mixture, it has been concluded that nitrosamines are at least partly protonated at the oxygen atom, i.e. that hydroxydiazenium salts are formed[65].

C-Analogues of nitrosamines (hydrazones) are usually protonated and alkylated at nitrogen atoms. Nevertheless, in order to explain the isomeric transformations of 2-pyrazolines in an acid medium, their *C*-protonation with formation of a diazenium fragment has been postulated[66]:

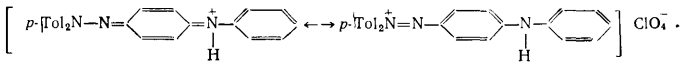
(4)



It has also been reported[67] that, when 2,6-di-t-butylbenzoquinone monohydrazones are dissolved in a 1 : 1 CF_3COOH–C_3F_7COOH mixture, trisubstituted diazenium cations (X) are formed:

(X)

However, in this case the closest analogous process is *O*-protonation of *N*-nitrosamines and the cation (X) is a phenylogue of the hydroxydiazenium cation.



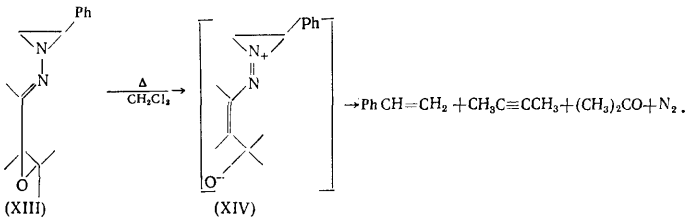
The only attempt hitherto to obtain a diazenium salt by condensing a nitroso-compound with a secondary ammonium salt was unsuccessful[49]:

R = F, or CF_3.

The fragment $\rangle N^+{=}N\langle$ is sometimes present in only one of several limiting structures possible for the given compound. However, if the contribution to the structure is large, the properties of such compounds can be similar to those of the usual diazenium salts. Thus, the dyes of type (XI) isolated by Hünig[5,29,30,68] following the oxidation of 1,1-diarylhydrazines in the presence of aromatic

amines can be assigned to the class of trisubstituted diazenium salts:

(XI)

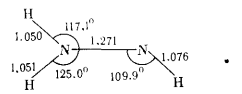


Compounds which can be regarded as a kind of intramolecular diazenium salt are also of interest. An example is the cyclopentadienone dimethylhydrazone (**XII**) [59,60]:

(XIIa) (XIIb)

The appreciable contribution of structure (**XIIb**) is confirmed by the large dipole moment of this compound (3.3 D), which greatly exceeds the dipole moments of the usual hydrazones [69] and can probably be accounted for by the ease of formation of the aromatic cyclopentadienyl anion.

The formation of another intramolecular trisubstituted diazenium salt (**XIV**) is postulated as an intermediate stage in the decomposition of the hydrazone (**XIII**) [70]:



(XIII) (XIV)

Finally, up to 70% of the ions corresponding to the most intense $(M-H)^+$ line in the mass spectrum of the surface ionisation of 1,1-dimethyl-2,2-dideuterohydrazine were formed as a result of the abstraction of a deuterium atom, i.e. had a mass $M-2$, which led to the claim that this ion has the structure of a 1,1-disubstituted diazenium cation [71].

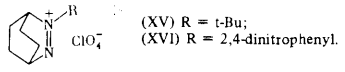
By analogy with the involvement of di- and tri-substituted diazenium cations in a number of reactions of di- and tri-substituted hydrazines, it is suggested that monosubstituted diazenium cations can be formed at intermediate stages of the corresponding reactions of monosubstituted hydrazines. For example, the formation of the methyldiazenium cation has been postulated in the oxidation of methylhydrazine and the decomposition of its tosylate in an acid medium [17]. However, in contrast to di- and tri-substituted diazenium cations, the monosubstituted cations are extremely unstable (if they are formed at all) and there are so far no reliable data concerning their existence.

III. STRUCTURE AND SPECTROSCOPIC CHARACTERISTICS

Almost all the available literature information about the structure of diazenium salts has been obtained by quantum-chemical calculations on their cations. For the simplest diazenium cation $N_2H_3^+$, it has been found by the *ab initio* method on the STO-3G basis as a result of the complete optimisation of the geometry [72] that such species can exist (an energy minimum corresponds to it), is planar, and has the following structure (the bond lengths are quoted in angstroms):

The nitrogen–nitrogen bond length in $N_2H_3^+$ has been determined by the semiempirical CNDO/2 method as 1.23 Å, [73] i.e. somewhat smaller than in the previous case [72]. Apart from the difference between the methods of calculation, the discrepancy may be caused by the fact that Bespalov and Kuznetsov [73] did not carry out a complete optimisation of the geometry and the trigonal hybridisation of both nitrogen atoms adopted in calculations on $N_2H_3^+$ and equal lengths of all the N–H bonds (1.01 Å) constitute a fairly rough simulation of the optimum geometry. The same semiempirical method yielded a structure for the hydroxydiazenium cation with an N=N bond length of 1.24 Å and the preferential transoid conformation with respect to the N–O bond [73]. Despite certain differences, it is seen from the data presented that the N=N bond length in diazenium cations is close to the usual value for the N=N bond in uncharged species (1.238 Å in *trans*-diazene HN=NH). [74]

The electronic structures of a number of simplest substituted diazenium cations have also been calculated by the CNDO/2 method [73]. It has been found that the order of the N=Nπ bond in alkyl- and aryl-substituted cations is very high (0.95–0.96), i.e., in conformity with the canonical structure (I), this is virtually a double bond. In alkoxydiazenium ions the order of the bond is somewhat lower (0.86–0.89) and the multiplicity of the N–O bond is increased, which indicates $p-\pi$ conjugation in these species [73].



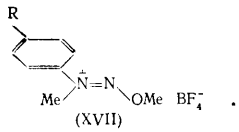
According to the canonical structure (I), the double bond between the nitrogen atoms arises as a result of the "delocalisation" of the lone electron pair of the $N_{(1)}$ atom. However, despite the high order of the π bond, the populations of the p_Z orbitals of the two nitrogen atoms are by no means equal: the population of the p_Z orbital of the $N_{(1)}$ atom remains significantly greater (1.15–1.20 for alkyldiazenium cations and 1.30–1.37 for alkoxydiazenium cations†), while the p_Z orbitals of the $N_{(2)}$ atom are less than unity [73]. The usual formula (I) reflects even less satisfactorily the distribution of the charges on the atoms: it follows from the calculations for a number of cations that the positive charge, formally wholly located at $N_{(1)}$, is to a large extent distributed over the nearest atoms. Such "smearing" of the charge is extremely typical of charged species (see, for example, Haselbach et al. [52]), the charge being distributed mainly in conformity with the electronegativities of the atoms, and ultimately an appreciable proportion of the positive charge is located at hydrogen atoms. For example, according to calculations for azobenzene and the 1,2-diphenyldiazenium cation by the CNDO/2 and MINDO/2 methods, the changes in the charges on two nitrogen atoms on protonation of azobenzene are very similar in magnitude and amount to only 0.13–0.17. [52] These conclusions have been confirmed experimentally: it has been shown by the ESCA method that, when azobenzene is converted into its perchlorate (actually into 1,2-diphenyldiazenium perchlorate), the binding energy of the 1s electrons of the nitrogen atom E_b(N 1 s) increases slightly. E_b(N 1 s) = 404.5 eV for

†Calculations by the Hückel method on 1-aryl-2-methoxy-1-methyldiazenium cations gave a still greater population of the p_Z orbital of $N_{(1)}$—about 1.49. [55]

azobenzene, and the X-ray electronic spectrum of the perchlorate has a broadened band with its centre at 406.7 eV, which is formed as a result of the superposition of two bands separated by approximately 2 eV. The splitting of the band indicates the non-equivalence of the two nitrogen atoms in the perchlorate and the experimental splitting agrees satisfactorily with the value obtained from the calculated charge distribution in the *trans*-1,2-diphenyldiazenium cation[52]. A similar picture is observed in the X-ray electronic spectra of the perchlorates of pyridazine and *o*,*o*′-azobibenzyl (VII).[52]

As a result of the delocalisation of the positive charge in diazenium cations, only a small proportion of it (0.1 to 0.2) remains at the $N_{(1)}$ atom. On the other hand, there is a fairly significant charge on the neighbouring $N_{(2)}$ atom, which is comparable (0.2–0.25) in alkoxydiazenium salts to the charge on the terminal nitrogen atom in the phenyldiazonium cation (0.20) and the carbon atom in immonium ions (approximately 0.2).[73] This apparently determines the ability of alkoxydiazenium salts, like that of diazonium and immonium salts,[75] to undergo coupling reactions (see Section V). At the same time, the comparatively small charge on the $N_{(2)}$ atom in alkyl-substituted diazenium cations (0.03–0.10) suggests a lower reactivity of the corresponding salt in reactions of this type.

The ultraviolet spectrum of 1,1-dimethyldiazenium perchlorate exhibits an absorption at 280 nm ($\epsilon = 150$),[7] while the spectrum of the perchlorate (XV) has λ_{max} 311 nm ($\epsilon \simeq 100$)[50]:



(XV) R = t-Bu;
(XVI) R = 2,4-dinitrophenyl.

The spectrum of 1-methyl-1-phenyldiazenium perchlorate has λ_{max} = 313 nm (ϵ = 6700)[37] and that of 1,1-diphenyldiazenium perchlorate has λ_{max} = 330 nm (ϵ = 9600).[31,37] The bathochromic shift and the hyperchromic effect are exhibited to an even greater extent on passing to salts with three aromatic substituents: the spectra of triphenyldiazenium perchlorate, 1,1-di-*p*-tolyl-2-(*p*-dimethylaminophenyl)diazenium perchlorate, and 1,1-di-*p*-tolyl-2-(*p*-anilinophenyl)diazenium perchlorate (XI) have λ_{max} = 430 nm (ϵ = 15 400),[37,45] 535 nm (ϵ = 55 000), and 556 nm.[29,68] λ_{max} = 232 nm (ϵ = 22 400) has been observed for 1,1-dimethyl-2-(2′,4′-dinitrophenyl)diazenium perchlorate[46] and λ_{max} = 286 nm (ϵ = 7400) has been found for the salt (XVI) in acetonitrile.[50]

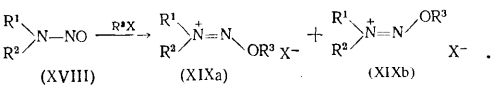
The nature of the long-wavelength band in the ultraviolet spectra of alkyldiazenium salts (more precisely their cations) is analogous to that of the long-wavelength absorption of aliphatic azomethines, but not to that of the seemingly similar $n-\pi^*$ transition in saturated azo-compounds[76,77]. In both $\overset{+}{N}{=}N$ and $C{=}N$ groups only one lone electron pair adjoins the π bond and the ultraviolet spectra of compounds of both classes therefore contain bands associated with the $n-\pi^*$-transition having similar energies and extinction coefficients. The appearance in azocompounds of a second lone electron pair at the neighbouring nitrogen atom leads to a qualitatively different picture, since the interaction of the non-bonding orbitals results in the formation of hybrid ψ_+ and ψ_- orbitals. The energy of one of these orbitals is smaller and that of the other approximately just as much greater than the energy of the "pure" *n*-orbital; under these conditions, for example, in *trans*-azomethane, photoelectron spectroscopic data[78] show that the splitting of the non-bonding levels reaches 3 eV. The longest-wavelength transition $\psi_+-\pi^*$ in *trans*-azo-compounds (or the $\psi_--\pi^*$ transition in *cis*-azo-compounds)[78] therefore requires a lower energy than the usual $n-\pi^*$ transition in diazenium cations, while the difference between the symmetries of the ψ_+ or ψ_- orbital, on the one hand, and the virtually localised orbital of the lone electron pair, on the other, leads to a difference in the selection rules and hence in the intensities of the corresponding absorption bands in the ultraviolet spectra of diazenium salts and azo-compounds.

An absorption maximum in the region of 217–226 nm with $\epsilon \simeq (7–9) \times 10^3$ [55] is characteristic of alkoxydiazenium salts with alkyl substituents; it corresponds to the $\psi_2-\psi_3$ transition in the fragment $\overset{+}{N}{=}N{-}O$, whose π-electron system is isoelectronic with that of the allyl anion by virtue of $p-\pi$ conjugation [73]. The ultraviolet spectra of aliphatic alkoxydiazenium salts therefore differ appreciably from those of other diazenium salts, but are similar to the spectra of alkylhydrazones [76,79] and enamines,[80] for which the existence of $p-\pi$ conjugation has been demonstrated[81]. The latter compounds are also isoelectronic with the allyl anion.

If R^1 = Ar in alkoxydiazenium salts, then a bathochromic shift is observed, but the extinction hardly changes. The shift of λ_{max} in the ultraviolet spectra of 1-aryl-2-methoxy-1-methyldiazenium salts (XVII) relative to the absorption band of the compound adopted as the standard is consistent with the results of calculations by the Hückel method[82] and is described satisfactorily by the Hammett equation[55]:

(XVII)

According to ultraviolet spectroscopic data, only diazenium salts with anions exhibiting weak electron-donating properties (I, $X^- = BF_4^-$, ClO_4^-, etc.) are purely ionic. Diazenium cations form ion pairs with more electron-donating anions[7] and a long-wavelength charge-transfer band appears in the ultraviolet spectra of the salts (I, $X^- = Br^-$ or I^-).[50,82] With decrease of the polarity of the solvent, the intensity of this band increases[82]. The absorption maximum shifts towards lower energies as the electron-donating properties of the anion and the electron-accepting properties of the cation are enhanced[50,82].

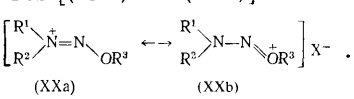


Infrared spectra have been obtained only for alkoxydiazenium salts. Purely aliphatic salts have an intense band at 1540–1575 cm^{-1} in the infrared spectrum[53–55], due to the stretching vibrations of the $\overset{+}{N}{=}N$ bond. For the compound (XVII), this band is weakened and shifts to 1510 cm^{-1}, so that its presence is masked in certain cases by the strong absorption of the aromatic ring at approximately 1500 cm^{-1}. Furthermore, if the anion is BPh_4^- or $SbCl_6^-$, then an intense band, which has been attributed to the stretching vibrations of the N–O bond, is seen in the range 1000–1200 cm^{-1}, usually obscured by the absorption due to the BF_4^- or ClO_4^- anions[55]. On average, the frequency of the stretching vibrations of the $\overset{+}{N}{-}N$ bond in alkoxydiazenium salts proved to be somewhat lower than the stretching vibration frequency of the N=N

bond in aliphatic azo-compounds (1574 cm^{-1} for azomethane[83]), which confirms the conclusion that there is $p-\pi$ conjugation in the $\rangle\overset{+}{N}{=}N{-}O\langle$ system.

The ^1H NMR spectra of diazenium salts have characteristic signals due to protons at the α-carbon atoms of the substituents, but the chemical shifts of the signals to the groups at the neighbouring nitrogen atoms in 1,2-di- and tri-substituted diazenium salts differ very little (0.1 to 0.3 p.p.m.). When $R^3 \neq$ OAlk, the typical range of δ values for α-methyl groups is 4.3–5.1 p.p.m.,[11,15,19,44,49,67] while the signals due to α-methylene (δ = 4.7 to 5.4 p.p.m. for ethyl groups[19,44], and δ = 5.5–6.0 p.p.m. for allyl[44] and benzyl[14] protons) and α-methylidyne protons (δ = 5.6–6.2 p.p.m.[19,44,47]) are located in a weaker field. The same dependence of the chemical shift on the type of α-protons is observed for alkoxydiazenium salts, but the corresponding signals are displaced upfield by approximately 0.5–0.8 p.p.m.[55] On the other hand, the signals of the α-protons of the alkoxy-group in these salts are in the range δ = 4.5–5.2 p.p.m., i.e. in weaker fields than the signals of α-protons in alcohols and ethers (δ = 3.2–4.1 p.p.m.)[84].

The t-butyl substituents at the nitrogen atoms in all the diazenium salts absorb in the region δ = 1.47–1.75 p.p.m.[44,47,51,55] The proton of the N–H group in disubstituted diazenium salts usually gives rise to a common signal with the solvent protons owing to rapid (on the ^1H NMR time scale) exchange. On the other hand, if the exchange can be retarded, then the absorption of the N–H proton is observed in a very weak field (δ = 12.9–16.6 p.p.m.[24,51,52]).



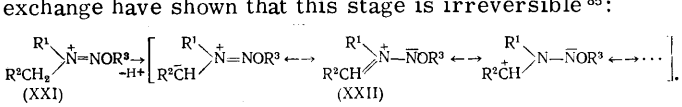
Owing to the high nitrogen–nitrogen bond order, *syn–anti* isomerism is possible for diazenium salts. The ^1H NMR spectra of salts (XIX) therefore contain two signals even for $R^1 = R^2$, corresponding to the protons at the α-carbon atoms of the groups in the *syn*- and *anti*-positions relative to the alkoxy-group[55,58]. The alkylation of nitrosamines (XVIII, $R^1 \neq R^2$), which are themselves usually a mixture of *syn*- and *anti*-isomers, yields, both isomeric alkoxydiazenium salts [(XIXa) and (XIXb)]. An exception is provided by nitrosamines with R^1 = t-Bu where only the *anti*-isomer (XIXa) is formed even for R^3 = Me[55,57]:

(XVIII) (XIXa) (XIXb)

In 1,1-disubstituted diazenium salts, *syn-anti* isomerism has not so far been observed. Under the usual conditions of the recording of the ^1H NMR spectra (HBr/H_2O, 25–30°C), there is a rapid exchange of N–H protons with the solvent and the two substituents R^1 and R^2 give rise to a common signal in the ^1H NMR spectrum. When HBr/H_2O is replaced by DBr/D_2O, the form of the spectrum changes: the lines are broadened and the fine structure of the multiplets is smeared, which can be regarded as a consequence of the slow exchange of protons at the α-carbon atoms of the substituents for deuterium.[19] However, the integral intensity of the signal due to α-protons hardly decreases and in addition it is found that the ^1H NMR spectra in HBr/H_2O assume the same form when the temperature is reduced to 0°C; here too a diffuse signal due to the N–H proton is observed in weak fields ($\delta \simeq$ 16.6 p.p.m.)[24]. Thus the changes in the spectra most probably are not due to the deuterium exchange involving α-protons, but are caused by the retardation of the exchange of the N–H proton with decrease of temperature, or following its replacement by deuterium, which leads to the non-equivalence of the *syn*- and *anti*-substituents. In DBr/D_2O at 0°C the exchange becomes so slow that the signals of the *syn*- and *anti*-substituents in the ^1H NMR spectra of 1,1-diethyl- and 1,1-di-isopropyldiazenium bromides are clearly different. However, for 1,1-dimethyldiazenium bromide, an appreciable signal separation has not been observed even under these conditions[24].

Summarising the calculated and experimental data concerning the diazenium salt structure described above, one may say that, in conformity with the canonical structure (I), the N=N bond in these compounds is virtually a double bond. Owing to the appreciable $p-\pi$ conjugation in the $\overset{+}{N}{=}N{-}O$ fragment, in alkoxydiazenium salts the order of this bond is somewhat lower, so that the structure of such salts should be described, in the language of valence bond schemes, not by one but by a superposition of at least two structures [(XXa) and (XXb)]:

(XXa) (XXb)



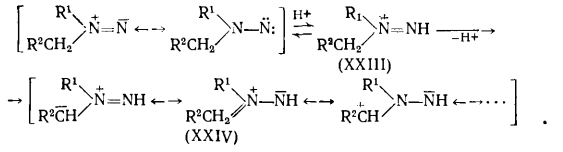
Finally the distribution of charges in diazenium cations is described quite unsatisfactorily by the canonical formula—instead of being located at the $N_{(1)}$ atom, part of the positive charge is "smeared" over neighbouring atoms, which conflicts with the formula.

IV. THE ACID PROPERTIES OF DIAZENIUM CATIONS

The presence of a positive charge in diazenium cations determines in many respects their acid properties. On the one hand, diazenium cations can be regarded as Lewis acids, which accounts for their electrophilic properties and tendency towards the formation of charge-transfer complexes. On the other hand, they can behave as H-acids (Brønsted acids) and the ability to split off a proton also plays an important role in the chemistry of diazenium salts.

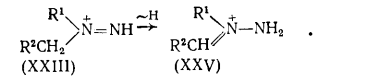
The α-protons of the substituents in the $\rangle\overset{+}{N}{=}N\langle$ fragment are extremely acidic. The proton is split off particularly readily from a substituent at the second nitrogen atom. For example, in all reactions which could lead to the trimethyldiazenium cation, only formaldehyde dimethylhydrazone was obtained[17,38]; furthermore, the formation of a 1,2-disubstituted diazenium cation, which readily tautomerises, and the rapid loss of a proton by the latter from the α-carbon atom at $N_{(2)}$ were suggested by Elguero et al.[66] to account for the isomerisation of 2-pyrazolines in an acid medium [reaction (4)]. This is why, among diazenium salts having a proton at the α-carbon atom in the substituent at $N_{(2)}$, only those in which the carbon atom is of a bridge type have been obtained hitherto. The removal of a proton from it is then forbidden by the Bredt rule[47,48,50].

The abstraction of a proton by a nucleophile from an α-carbon atom at $N_{(1)}$ via scheme (5) has been proposed as the first stage in the majority of reactions of alkoxydiazenium salts (XXI),[5] and experiments on deuterium exchange have shown that this stage is irreversible[85]:



(XXI) (XXII)

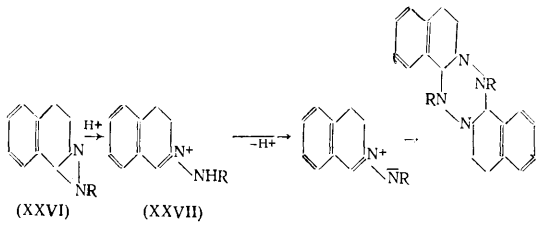
(5)



The methyl group in 1,1-dimethyl-2-(2′,4′-dinitrophenyl)-diazenium cations, which have a strong electron-accepting substituent at the second nitrogen atom, is lost very readily [46].

An analogous abstraction of a proton from the α-carbon atom with formation of dipolar azomethineimines (**XXIV**) is believed to be possible for 1,1-disubstituted diazenium cations (**XXIII**) and it is postulated [43,86] as an intermediate stage in the isomerisation of aminonitrenes to azomethine-imines:

(XXIII) (XXIV)

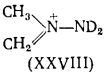


Apart from this, another similar process has also been considered, namely the transfer of an α-proton to the terminal nitrogen atom [15,17-19,24,26,27,46,87]:

(XXIII) (XXV) (6)

The virtually complete absence of the deuterium exchange of α-protons in 1,1-dialkyldiazenium cations in DBr/D_2O [24] is consistent with the results obtained for alkoxydiazenium salts [85] and permits the conclusion that the abstraction of an α-proton from the cation (**XXIII**) is irreversible and the previously postulated [15,18,19,26,27] tautomeric equilibrium (**XXIII**) ⇄ (**XXV**) does not occur in solutions of diazenium salts. The changes in the ^1H NMR spectra of 1,1-dialkyldiazenium salts on passing from HBr/H_2O to DBr/D_2O, which had been treated as a possible consequence of deuterium exchange [19], are induced by the retardation of the exchange of the N–H proton, as stated above‡.

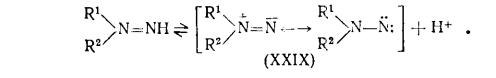
Structures of type (**XXV**), isomeric in relation to the diazenium cations, had already been considered earlier by Schmitz [88-90], who suggested the formation of (**XXVII**) as a result of the opening of the diaziridine ring in (**XXVI**) and also on treatment of *o*-(β-chloroethyl)-benzaldehyde with hydrazine hydrate:



(XXVI) (XXVII)

Under the influence of bases, the cation (**XVII**) splits off a proton to give the corresponding azomethineimine and then dimerisation products, but the salts (**XXVII**) are stable and Schmitz was able to isolate the chloride (**XXVII**, R = Me) [89] and the picrate (**XXVII**, R = H). [90]

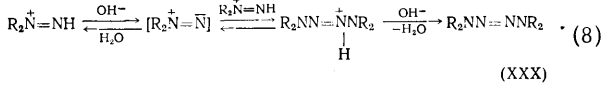
‡However, it is claimed [15] that evidence has been obtained for deuterium exchange involving 1,1-dimethyldiazenium bromide in DBr/D_2O and CF_3COOD, although experimental facts are not quoted. It is quite possible that this claim is due to a similar error in the interpretation of the results.



When 1,1-dimethyl-2,2-dideuterohydrazine is ionised by electron impact, more than 95% of the peaks of the $(M-H)^+$ ions are obtained as a result of the abstraction of hydrogen from the methyl group; these ions can be represented as:

(XXVIII)

Their proportion in the surface ionisation spectra is 30%, and the remaining ions of this type arise by the abstraction of deuterium from a nitrogen atom [71].



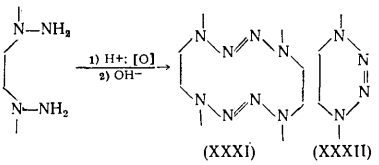
In disubstituted diazenium cations, the loss of the N–H proton is an alternative to the abstraction of protons from the α-carbon atom and the former process is probably reversible and fairly rapid. In the first study on diazenium salts [6] it was already noted that 1,1-disubstituted diazenium cations are N–H acids conjugated with respect to the corresponding aminonitrenes (**XXIX**) and the occurrence of the following acid–base equilibrium in solutions was postulated:

(XXIX) (7)

The position of equilibrium (7) is determined to a first approximation by two factors—the acidity of the medium and the basicity of the aminonitrene (**XXIX**), which depends in its turn on the substituents R^1 and R^2.

The influence of the acidity of the medium can be readily followed. Whereas acid solutions of diazenium salts (I, R^3 = H) are fairly stable in the cold, when they are made alkaline equilibrium (7) shifts to the right with formation of products typical for reactions involving aminonitrenes. Thus, when acid solutions of these salts are neutralised by the addition of a solution of alkali, the corresponding 2-tetrazenes (**XXX**) are formed in high yields [6-10,13,15,20,23,27,28,91], their formation being regarded as a result of the reaction of intermediate aminonitrenes with the surrounding diazenium cations [2,7]:

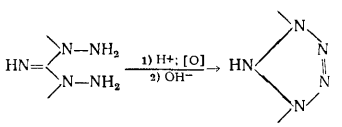
(XXX) (8)



Reaction (8) has been patented as a method for the synthesis of 2-tetrazenes [9], which had been believed hitherto to be its sole products.

However, when the opposite method of neutralisation is used, involving the addition of a solution of the salt (I, R^3 = H) to a solution of alkali, and at a low salt concentration, the yield of the tetrazene is low [7,20], since in this version the aminonitrenes formed virtually lack an environment made up of electrophilic diazenium cations. At the same time, these conditions favour intramolecular transformations of aminonitrenes, as a result of which it is possible to detect virtually the entire set of products typical for reactions involving aminonitrenes: mono- and disubstituted hydrazones, tetrazenes, and geminal azohydrazines [20]. This result constitutes important evidence confirming the formation of aminonitrenes when 1,1-disubstituted diazenium salts are treated with bases and suggests that the neutralisation reactions of acid solutions of these salts can serve as a convenient source of aminonitrenes under extremely mild conditions [20].

The neutralisation of solutions of two different diazenium salts (I, R^3 = H), prepared separately and then mixed, leads to a mixture of all three tetrazenes (symmetrical and asymmetrical) in the statistically expected proportions [6-8,27]. The joint neutralisation of a large number of



salts leads to a corresponding increase of the number of tetrazenes, and their number is also similar to that expected on statistical grounds [7].

When an attempt was made to synthesise tetrahydrotetrazine (**XXXII**) by the intramolecular closure of the tetrazene chain, only the twelve-membered bistetrazene (**XXXI**) was isolated [91]:

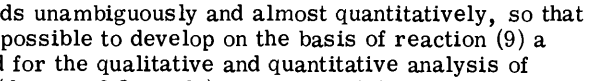
(XXXI) (XXXII)

although, according to McBride's report, the tetrazene fragment was incorporated in the five-membered ring under completely analogous conditions [6]:

The formation of tetrazenes in concentrated solutions of 1,1-dialkyldiazenium salts begins already at pH 0.5–1,[7] so that tetrazenes or the products of other reactions of aminonitrenes, but not diazenium salts, are formed immediately in the oxidation of the corresponding hydrazines in a weakly acid medium.

On passing from 1,1-dialkyl to 1,1-diaryl-diazenium salts, the basicity of the corresponding aminonitrenes should decrease and equilibrium (7) should shift to the right. It may be that, precisely because of this, 1,1-diphenyldiazenium perchlorate is significantly less stable than 1-methyl-1-phenyldiazenium perchlorate [37], since the former should be converted more rapidly into a tetrazene, which readily decomposes further in an acid medium.

The N–H proton of 1,1-disubstituted diazenium cations is also very mobile. Under the influence of nucleophiles, it is readily split off with the regeneration of the initial azo-compound and in the cation it is involved in a rapid exchange between neighbouring nitrogen atoms [51,52].



By comparing the tendencies towards the elimination of N–H and α-C–H protons from disubstituted diazenium cations, one may reach the purely qualitative conclusion that in the majority of cases the N–H proton is more acid and mobile. However, virtually no one has made a quantitative comparison of the acidities of these hydrogen atoms and, as shown above, in certain cases one must assume that, even in the presence of the N–H group, a proton may be abstracted preferentially from α-carbon atoms.

V. REACTIONS OF DIAZENIUM SALTS

1. Decomposition Reactions

Information about the decomposition pathways of diazenium salts is fairly contradictory and confused§, probably owing to the large number of secondary reactions in which the primary decomposition products can be involved. It is therefore not surprising that sometimes it is merely concluded that the decomposition of the salts takes place and no attempt is made to establish the structure of the products, let alone the decomposition mechanism [6,13,46].

On the basis of literature data, one can conclude that the first stage in the decomposition of diazenium salts is usually the abstraction of a proton by a nucleophile from the α-carbon atom in the substituent at $N_{(1)}$, already considered, or the transfer of this proton to $N_{(2)}$. The subsequent attack by the nucleophile leads to the dissociation of the highly polarised carbon–nitrogen bond and the decomposition of the diazenium cation. The hydrolysis of 1,1-disubstituted diazenium cations [reaction (9)] apparently proceeds in this way [17,18,26,27], its last stage being analogous to the ready hydrolysis of immonium cations [75,92]:

(XXIII) (XXV) (9)

In the cold reaction (9) is virtually negligible but, with increase of temperature, its rate increases rapidly and on boiling hydrolysis terminates in several minutes. 1,1-Diisopropyldiazenium bromide hydrolyses with greater difficulty than salts having primary substituents; if R^1 in (**XXIII**) is a primary group and $R^1 \neq R^2CH_2$, then hydrolysis takes place via both possible pathways, but if R^1 is a secondary group, then R^2CHO and R^1NHNH_2 are formed exclusively [18,26]. In dilute solutions the decomposition proceeds unambiguously and almost quantitatively, so that it was possible to develop on the basis of reaction (9) a method for the qualitative and quantitative analysis of small (down to 0.2 μmole) amounts of 1,1-dialkylhydrazines by determining the carbonyl compounds formed [26].

The hydrolysis products—monoalkylhydrazines and (usually) an aldehyde—can react subsequently with one another, which may be the cause of the appearance of the corresponding monoalkylhydrazones in certain reactions involving 1,1-dialkyldiazenium cations [27,38]. Incidentally, there are no grounds for ruling out other possible pathways leading to the formation of hydrazones, for example, the conversion of the cation (**XXIII**) into the azomethineimine (**XXIV**) with the rearrangement of the latter into a hydrazone, i.e. the reaction can be regarded tentatively as the concluding stage of the so-called "diazene–hydrazone" rearrangement of aminonitrenes [2,86], or the true diazene–hydrazone rearrangement of aminonitrenes, which are involved in equilibrium (7) with 1,1-disubstituted diazenium cations. Then the formation of a monoalkylhydrazone must be regarded as the primary reaction and the monoalkylhydrazine and the aldehyde must be regarded as secondary products of the hydrolysis of the monoalkylhydrazone. If in addition account is taken of the fact that the protonation of the aminonitrene to give a diazenium cation is postulated as one of the intermediate stages in the diazene–hydrazone rearrangement [2] and that there is as yet no satisfactory mechanism for the rearrangement itself [2,5,93], then evidently it would be premature to reach final conclusions about the mechanism of the hydrolysis of 1,1-dialkyldiazenium cations.

When 2,4-dinitrophenylhydrazine (2,4-DNPH) is added to solutions of 1,1-dialkyldiazenium salts, a precipitate of the 2,4-dinitrophenylhydrazone is formed even in the cold, albeit fairly slowly [18,24]:

(10)

§ For example, according to one set of data [6], the decomposition of 1,1-dialkyldiazenium salts in acid solutions is a first-order reaction with respect to the diazenium salt, while in a later study [15] it is mentioned casually that the decomposition of 1,1-dimethyldiazenium bromide in HBr obeys the equation for a second-order reaction with respect to the diazenium salt.

When $R^1 \neq R^2CH_2$, reaction (10) resembles the hydrolytic reaction (9), but the interaction of 1,1-di-isopropyldiazenium bromide with 2,4-DNPH in the cold does not give a precipitate at all[18,24]. One can also postulate at least two mechanisms for the interaction with 2,4-DNPH: preliminary hydrolysis or the direct reaction of 2,4-DNPH with the species (XXV) isomeric with the diazenium cation; a more definite choice cannot as yet be made[24].

The decomposition reactions of alkoxydiazenium[55] and in certain cases trisubstituted diazenium salts[46] in the presence of water are apparently similar to the hydrolysis of 1,1-dialkyldiazenium salts. The preliminary elimination of an α-proton is indicated, for example, by the fact that, with increase of its acidity, the stability of alkoxydiazenium salts diminishes[55]. A mechanism in many respects analogous to reaction (9) has been proposed by Norman et al.[87] for the formation of benzylhydrazine and benzaldehyde in the oxidation of 1,1-dibenzylhydrazine with lead tetra-acetate, which involves the isomerisation of the diazenium cation to a species of type (XXV) and its acetolysis.

Another decomposition pathway, which is usual for 1,1-disubstituted diazenium salts, is the formation of tetrazenes and their subsequent decomposition. This yields primary and secondary amines, aldehydes, and nitrogen[94]. This process plays a notable role in weakly acid or highly concentrated solutions and also for very acidic diazenium cations[6,7,37]. It has also been observed that, after stirring a solution of 1,1-di-isopropyldiazenium bromide at 0°C for 4 h, neutralisation leads to the formation of 60% of di-isopropylamine and only 23% of 1,1,4,4-tetrapropyl-2-tetrazene.[13] The cause and mechanism of such extensive decomposition are obscure.

The decomposition of diazenium cations can result from attack on them by halide ions. Thus it is claimed[17] that 1,1-dialkyldiazenium cations react with Cl^- or Br^- anions in concentrated HCl or HBr with formation of alkyl halides and ultimately of a di-imide which rapidly decomposes under these conditions, reducing some of the reactants:

$$Me_2\overset{+}{N}{=}NH\ \overset{HX}{\longrightarrow}\ MeX + Me\overset{+}{N}H \rightarrow MeX + HN{=}NH \quad . \qquad (11)$$

The reaction is rapid on boiling but, if a solution of 1,1-dimethyldiazenium bromide in HCl is allowed to stand at room temperature, CH_3Cl, CH_3Br, and N_2 are liberated. However, one should note that the total volume of the evolved gases does not exceed 10% of the amount calculated by Eqn.(11) and that the role of such processes is apparently small.

Whereas attack on alkoxydiazenium salts by strong nucleophiles usually begins with the abstraction of a proton from the α-carbon atom of the substituent at $N_{(1)}$, weak nucleophiles remove the substituent at the oxygen atom. Thus the salts (XIX) are readily dealkylated by sulphides to give the initial nitrosamines[58]:

$$\underset{R^2}{\overset{R^1}{>}}\overset{+}{N}{=}NOR^3\ X^- \xrightarrow{R^4_2S} \underset{R^2}{\overset{R^1}{>}}N{-}NO + R^3\overset{+}{S}R^4_2\ X^-$$

(XIX)

while dealkylation by iodide ions proceeds as follows[55,82]:

$$(XIX) \xrightarrow{I^-} \underset{R^2}{\overset{R^1}{>}}N{-}NO + R^3{-}I - X^- \quad . \qquad (12)$$

Reaction (12) is almost instantaneous at room temperature.

Other diazenium salts are also unstable in the presence of iodide ions, because the latter can reduce diazenium cations[15,50]. Furthermore, diazenium cations can be reduced by the primary products of their decomposition or other reactions (examples will be examined below), which also leads to their disappearance.

2. The Reduction of Diazenium Salts

1,1-Disubstituted diazenium salts can be reduced to the initial hydrazinium salts both chemically (with $SnCl_2$[6,28] or HI[15]) and electrochemically[31-33,37,38] with nearly quantitative yields:

$$\underset{R^2}{\overset{R^1}{>}}\overset{+}{N}{=}NH\ X^- \xrightarrow[+2H^+]{+2e^-} \underset{R^2}{\overset{R^1}{>}}N{-}NH_2{\cdot}HX \quad . \qquad (13)$$

The electrochemical reduction of trisubstituted diazenium salts takes place similarly, yielding trisubstituted hydrazines[37,45,46], but the hydrogenation of alkoxydiazenium salts gives rise to disubstituted hydrazines[53,54]. For example:

$$\overset{+}{N}{=}NOEt\ BF_4^- \xrightarrow[MeOH]{H_2/Pt} N{-}NH_2{\cdot}HBF_4 + EtOH \quad .$$

97%

In an aprotic medium the electrochemical reduction of trisubstituted diazenium salts is a one-electron process[44,45,48,82,85] and stops at the stage involving the formation of hydrazyl radicals (XXXIII):

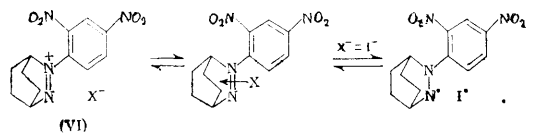
$$\underset{R^2}{\overset{R^1}{>}}\overset{+}{N}{=}N{-}R^3 \xrightarrow{+e^-} \underset{R^2}{\overset{R^1}{>}}N{-}\dot{N}{-}R^3$$

(XXXIII) .

Furthermore, reversible one-electron reduction can be observed also in highly alkaline aqueous solutions but, with decrease of pH, the protonation of the radical (XXXIII) is accelerated and the resulting radical-action is readily reduced to hydrazine—the overall process requires a two-electron mechanism[44].

According to polarographic data, typical half-wave potentials $E_{1/2}$ for the one-electron reduction of alkyldiazenium salts are in the range between −0.5 and −0.8 V,[44,48] the values for salts with phenyl substituents are in the vicinity of 0 V,[31,37,45] and the introduction of the 2,4-dinitrophenyl group into the diazenium cation shifts the half-wave potential to 0.2 V.[46,50] $E_{1/2}$ for 1-aryl-2-methoxy-1-methyldiazenium salts (XVII) varies from −0.35 to −0.04 V, and it has been shown that the dependence of $E_{1/2}$ on the substituent in the aromatic ring is described satisfactorily by the Hammett equation[82]. In one-electron reduction $E_{1/2}$ can be regarded as a quantity characterising the energy of the lowest unoccupied orbital (LUMO) of the diazenium cation to which an electron is in fact transferred. When electron-accepting substituents as well as substituents capable of conjugation, for example, aryl groups, are introduced into the ion, the above energy level is lowered and reduction is correspondingly facilitated; electron-donating substituents have the opposite effect. It is therefore not surprising that the changes in $E_{1/2}$ for the salts (XVII) are also satisfactorily correlated with the LUMO energy differences calculated by the Hückel method[82].

Reduction is a side reaction in many reactions of diazenium salts, other components of the reaction mixture behaving as reductants. For example, it has been found that 1,1-dimethyldiazenium bromide is reduced to the initial hydrazine by acetaldehyde[11]. The primary products of the reaction of 1,1-diphenyl-[33,34] and 1-methyl-1-phenyldiazenium perchlorates[34] with *trans*-stilbene are tetra



hydrocinnolines; the triazolidines obtained in the reaction with alkoxydiazenium salts with Schiff bases[53,96-98] reduce diazenium salts under the reaction conditions, i.e. diazenium salts can behave as oxidants.

Finally, diazenium cations can be reduced by the counterions, possibly via the formation of donor–acceptor complexes, which we shall now consider.

3. Donor–Acceptor Interactions in Solutions of Diazenium Salts

Depending on the structure of the substituents and the nature of the counter-ion, the group $\overset{+}{N}{=}N$ can behave partially or even completely as an electron acceptor. It has already been stated that, according to ultraviolet spectroscopic data, diazenium cations exist only in solutions of diazenium salts in combination with anions which are poor electron donors in polar solvents. On the other hand, in other cases the diazenium cations form ion pairs and donor–acceptor complexes with the counterions[7,50]. The stability of the complexes and the degree of charge transfer increase with enhancement of the electron-donating properties of the anion, for example, in the sequence $Cl^- < Br^- < I^-$, after the introduction of electron-accepting substituents into the cation, i.e. when the difference between energies of the LUMO of the acceptor (diazenium cation) and the highest occupied orbital (HOMO) of the donor (the counterion) is reduced, and after a decrease of the polarity of the solvent. In the limiting case the electron is fully transferred—one-electron reduction of the diazenium cation takes place and a radical pair is formed.

It has been established[50] that the ultraviolet spectrum of the perchlorate (VI, $X^- = ClO_4^-$) changes little in solvents of different polarities; an intense long-wavelength charge-transfer band appears in the spectrum of the bromide on passing from an aqueous solution to one in acetonitrile and methylene chloride, while the iodide, which is still a salt in water, gives rise to green paramagnetic solutions in non-polar solvents—the ion pair is converted into a radical pair:

(VI)

On the other hand the replacement of the 2,4-dinitrophenol group in (VI, $X^- = I^-$) by the t-butyl group weakens the electron-accepting properties of the cation and complete electron transfer does not take place even in solvents of low polarity[50].

Another example is the interaction of a number of alkoxydiazenium salts (XVII) with NaI.[82] At room temperature rapid dealkylation takes place in accordance with reaction (12), but at −46°C in acetonitrile it is possible to detect the formation of donor–acceptor complexes of alkoxydiazenium cations with I^- ions. Since the HOMO energy of the donor (the iodide ion) is constant in the entire series of complexes, the energy of the charge-transfer band in the ultraviolet spectra changes in parallel with the calculated LUMO energy of the corresponding diazenium cations, and their $E_{1/2}$, as expected[82].

Apparently the same rules hold for exchange processes involving the 1,1-di-alkylhydrazides of sulphonic acids, which have been investigated in detail by Lemal[2,43], who observed that the sulphonic acid residue in hydrazides can be exchanged [reaction (14)] in polar solvents in the presence of sulphinate salts. It has been shown by ^1H NMR that, when solutions of the hydrazide and a sulphinate salt are mixed, the initial rate of exchange is independent of the concentration of the metal sulphinate, which led to the conclusion that the rate-determining stage is the dissociation of the hydrazide into a diazenium cation and a sulphinate anion, i.e. that an S_N1 mechanism operates[43]:

$$\begin{aligned} &\begin{matrix} R^1 \\ R^2 \end{matrix}\!\!>\!N{-}NHSO_2R^3 + R^4SO_2^- \underset{\text{fast}}{\overset{\text{slow}}{\rightleftharpoons}} R^3SO_2^- + \begin{matrix} R^1 \\ R^2 \end{matrix}\!\!>\!\overset{+}{N}{=}NH + R^4SO_2^- \underset{\text{slow}}{\overset{\text{fast}}{\rightleftharpoons}} \\ &\rightleftarrows \begin{matrix} R^1 \\ R^2 \end{matrix}\!\!>\!N{-}NHSO_2R^4 + R^3SO_2^- \end{aligned} \qquad (14)$$

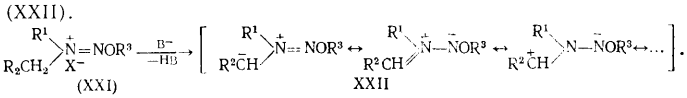
As a result of exchange with bisulphites, sulphonic acid, 1,1-dialkylhydrazides form little-dissociated sulphuric acid hydrazides, but there is no sign of interaction with effective nucleophiles such as the N_3^-, OCN^-, SCN^-, and $S_2O_3^{2-}$ ions[2,43]. The hypothesis was put forward that the selectivity of the diazenium cations and the stability of the hydrazides obtained are due to the ease of the interaction of the lone electron pair of the $N_{(2)}$ atom with the vacant *d* orbital of sulphur, as a result of which the multiplicity of the N–S bond in hydrazides should be increased. The fact that phosphines, where the phosphorus atom also has vacant *d* orbitals with a suitable energy and could therefore form a partial double bond with a nitrogen atom, give rise to adducts with 1,1-disubstituted[2,43] and trisubstituted[46] diazenium cations was explained from the same standpoints. For example:

$$(RCH_2)_2\overset{+}{N}{-}NC_6H_3(NO_2)_2 \xrightarrow{Ph_3P} (RCH_2)_2N{-}\overset{+}{N}\!\!<\!\!\begin{matrix} PPh_3 \\ C_6H_3(NO_2)_2 \end{matrix}$$

R = H or Ph.

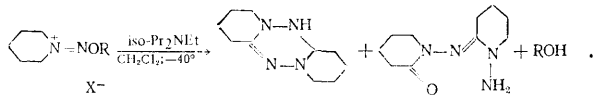
However, in the light of what was said at the beginning of this section, it appears more correct to treat all the instances discussed here as the usual donor–acceptor interaction. Evidently diazenium cations form stable complexes with reducing ions which have a high HOMO and readily give up an electron, reducing the diazenium ion to a hydrazyl residue; on the other hand, the nucleophilic properties of the anion do not in fact play an appreciable role in this instance. Adducts with phosphines are also formed as a result of electron transfer from phosphorus to nitrogen and not conversely; according to the results of Lemal himself, the hydrolysis of these adducts yields the corresponding hydrazines and phosphine oxide[2,43]. The decrease of the tendency of sulphonic acid hydrazides towards dissociation on passing from 1,1-dialkylhydrazides to aryl-substituted compounds and its increase when more electronegative groups are introduced into the sulphonic acid residue[43] is also consistent with the general characteristics of donor–acceptor interactions.

Finally, one may note that, according to some data[34,45] the triphenyldiazenium cation forms a stable complex with pyridine—a compound in which there are no low-lying vacant orbitals capable of interacting effectively with the lone electron pair of $N_{(2)}$ in the diazenium cation. We believe that the existence of the complex, which is fully analogous to the adducts of diazenium cations with phosphines, is ensured by the interaction of the LUMO of the triphenyldiazenium cation with the lone electron pair of the nitrogen atom in pyridine. This is also supported by



the absence of complex formation with 2,6-lutidine, where the nitrogen atom is sterically shielded[34,45].

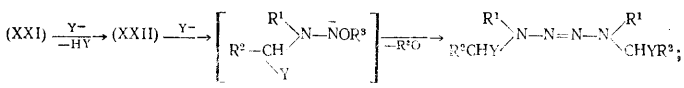
It may be that the reduction of 1,1-dimethyldiazenium cations in the KI/HCl system proceeds via a stage involving the formation of donor–acceptor complexes with iodide ions[15] and that in an acid medium two-electron reduction to a hydrazinium salt takes place.



4. Reactions of Diazenium Salts Via 1,3-Dipolar Species

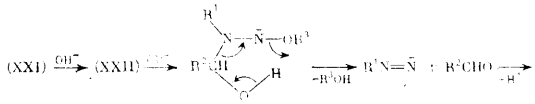
It was already noted above (Section IV) that treatment of diazenium salts with bases can lead to the irreversible abstraction of an α-proton from the substituents at the first nitrogen atom and the formation of 1,3-dipolar species (azomethineimines). Reactions beginning at this stage have been observed for various types of diazenium salts; they are most characteristic of alkoxydiazenium salts (XXI) whose properties are in many respects determined by the subsequent reactions of the corresponding 1,3-dipoles (XXII):

(XXII).

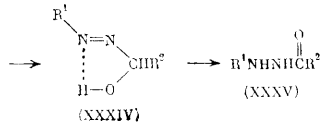


When azomethineimines are generated by weakly nucleophilic bases, dimeric products are obtained, in particular derivatives of 1,2,4,5-tetrazine[5].

For reactions in which the involvement of azomethineimines is postulated, the formation of a fully or partly saturated (most probably as a result of oxidation) tetrazine ring is extremely typical[2,5,99,100]. It was believed previously that perhydrotetrazines are produced by the concerted "head to tail" dimerisation of the azomethineimines themselves, but, firstly, the interaction of two such unstable intermediate species is unlikely for statistical reasons, and, secondly, it has been noted recently[100] that the concerted process is in this instance forbidden. It is therefore most probable that the dimers are the products of the interaction of azomethineimines with the initial compounds.



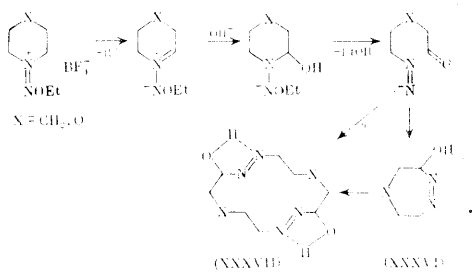
The more nucleophilic bases themselves react with the zwitterions formed initially. Thus treatment of alkoxydiazenium salts in alcoholic solution with alkoxide or azide ions leads to α-substituted tetrazenes[5,101]:



Y = OAlk or N_3.

The mechanism of the last stage is still obscure, but it may be that the reaction proceeds via the corresponding aminonitrene or the 1,1-disubstituted diazenium cation[101].

The products of the interaction of alkoxydiazenium salts and OH^- ions are extremely unexpected[53,57,85,102-104]. Only salts with aliphatic groups undergo this reaction and in the case of acyclic compounds[57,85,103] it leads to *trans*-azoalcohols (XXXIV), for the formation of which the following mechanism has been proposed:



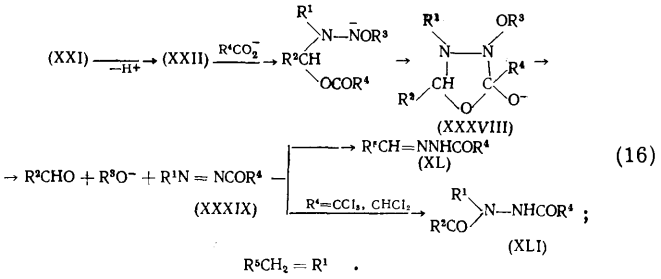
(XXXIV)

(15)

The intermolecular mechanism of reaction (15) has been demonstrated by kinetic data, by the formation of cross-products following the addition to the reaction mixture of both an extraneous monosubstituted diazene and an aldehyde, and also by the independent synthesis of a number of azoalcohols from aldehydes and monosubstituted diazenes[84,103]. It is remarkable that the decomposition into a diazene and an aldehyde strongly resembles the hydrolysis of 1,1-dialkyldiazenium cations examined above, and it can be treated (at least formally) as the hydrolysis of an alkoxydiazenium cation to an aldehyde and an alkoxyhydrazine $R^1NHNHOR^3$ accompanied by the elimination of R^3OH. It is noteworthy that, although 1,1-di-isopropyl-substituted alkoxydiazenium salts are decomposed by aqueous alkali, azoalcohols are not formed in this process[57¶].

Azoalcohols (XXXIV) readily isomerise and only the hydrazide (XXXV) can sometimes be isolated as a result of reaction (15).[84]

All the azoalcohols obtained in this way had the *trans*-configuration, which was additionally stabilised by an intramolecular hydrogen bond. Treatment of the alkoxydiazenium salts obtained from *N*-nitrosopyrrolidines and *N*-nitroso-4,4-dimethylpiperidine with bases should lead (and apparently does so) to cyclic *cis*-azoalcohols, but the latter decompose when an attempt is made to isolate them[103,104]. On the other hand, when derivatives of piperidine itself and morpholine were introduced into reaction (15), the products were not the seven-membered *cis*-azoalcohols (XXXVI), as had been suggested earlier[53], but their dimers—14-membered rings (XXXVII) containing only the N=N *trans*-bonds[102,104]:

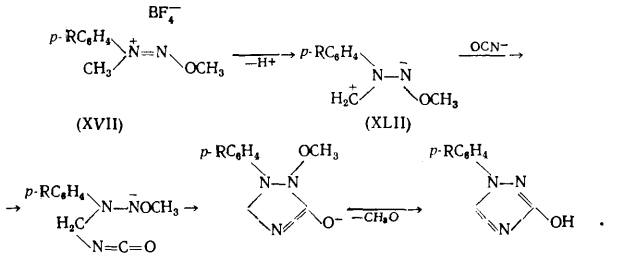


The ultraviolet spectra recorded in the course of the reaction show that the first stage involves the formation of the *cis*-azoalcohol (XXXVI), which is then rapidly converted into compound (XXXVII).[102-104]

The interaction of alkoxydiazenium salts with carboxylate ions gives high yields of acyldiazenes (XXXIX).[106-108] The proposed reaction mechanism involves the formation

¶ The attempts by Hünig to obtain an azoalcohol with a quaternary alcoholic carbon atom from acetone and t-BuN=NH were also unsuccessful[35]. However, it has been recently reported that this reaction has been successfully carried out in the synthesis of MeEtC(OH)N=NPh.[105]

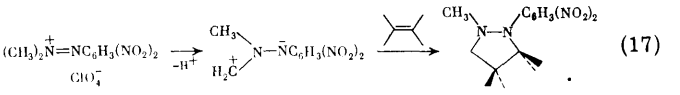
of a five-membered cyclic intermediate complex (XXXVIII) and its decomposition[5,108]:



(16)

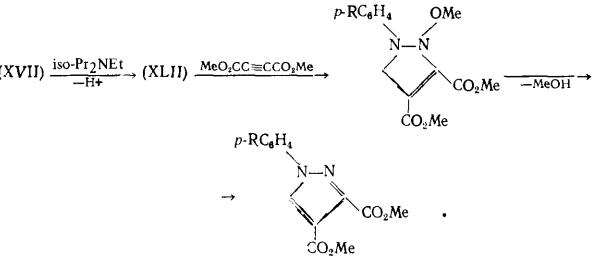
Reaction (16) depends little on the solvent and on the nature of the substituents R^1, but acyldiazenes can be isolated only when there are no hydrogen atoms at the α-carbon atom in R^1. Otherwise, (XXXIX) immediately isomerises to the acylhydrazone (XL).[107,108] If the primary group R^2CH_2 in (XXI) is replaced by the isopropyl group, the yield of the corresponding acyldiazene falls almost by a factor of two. The anions of both aromatic and aliphatic carboxylic acids readily undergo reaction (16), but for the acetate ion the yield is somewhat lower. According to Hünig the reaction of di- and tri-chloroacetate ions yields initially acyldiazenes, which are apparently capable of recombining with the aldehyde to form the hydrazides (XLI).[108] The interaction of (XXI) with formate ions proceeds quite differently and will be discussed below.

Aryl- and alkyl-acyldiazenes (XXXIX) obtained in this way can serve as a source of monosubstituted diazenes[108,109] and as effective acylating agents. It is therefore significant that reaction (16) takes place to an extent of 80–90% with the anions of *N*-protected aminoacids and can therefore be used to activate them in the synthesis of peptides[108].



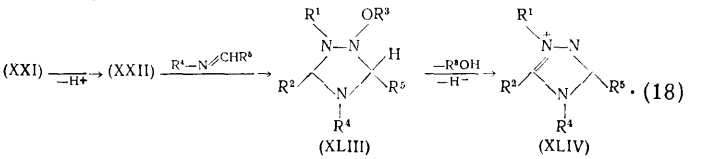
The reaction of 1-aryl-2-methoxy-1-methyldiazenium salts (XVII) with cyanate ions proceeds very similarly to reaction (16).[108] It results in a 40–70% yield of 1-aryl-3-hydroxy-1,2,4-triazoles:

The anomalous behaviour of alkoxydiazenium salts with isopropyl groups in the above reactions is noteworthy. Similar phenomena are observed in the hydrolysis and hydrazinolysis of 1,1-dialkyldiazenium salts—it is also found that salts with secondary groups react much less effectively. The common stage in both cases is usually the initial abstraction of an α-proton, so that one can postulate that the process involving secondary groups is hindered compared with the process involving primary groups. It is still not clear what causes this.



A common property of the azomethineimines obtained from diazenium salts, like that of other 1,3-dipoles, is their ability to undergo 1,3-dipolar addition to multiple bonds, with formation of five-membered heterocycles[99].

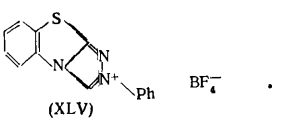
The interaction of 1,1-dimethyl-2-(2′,4′-dinitro)phenyldiazenium perchlorate with olefins is of this type[46]:



(17)

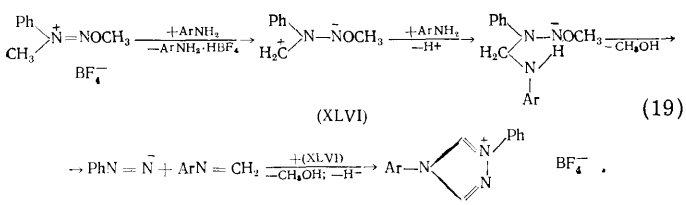
This is also true of the reactions of alkoxydiazenium salts (XVII) with dimethyl acetylenedicarboxylate[108]:

Reaction (17), involving *cis*- and *trans*-but-2-enes, proceeds with retention of configuration, which supports the operation of a concerted mechanism.



The 1,3-dipolar addition in the interaction of alkoxydiazenium salts with a C=N bond[56,96-98], the final products of which are *s*-triazolium salts (XLIV), has been studied on the greatest scale:

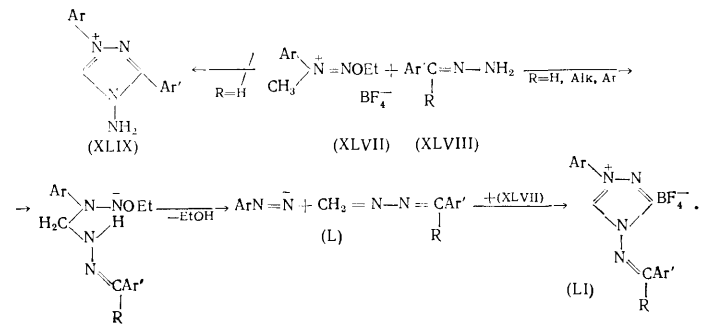
(18)



It is believed that a hydride ion is abstracted by the second cation of the diazenium salt in the transition (XLIII) → (XLIV),[56,98] but the yields relative to the initial diazenium salt frequently exceed 50%, so that it is assumed that the cation of the salt (XXI) can combine with more than one hydride ion.

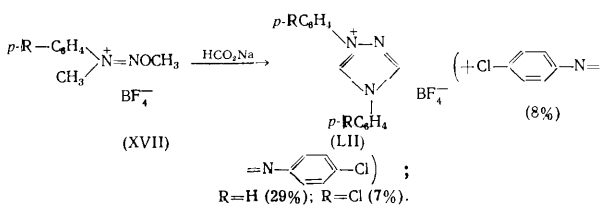
Reaction (18) proceeds best in CH_2Cl_2 at 0–20°C; a proton is abstracted from (XXI) by the imine component itself, for which various nitrogen-containing heterocycles[56,96,97], Schiff bases[96-98], azines and hydrazones[98] have been used. It has been established that any alkoxydiazenium salts (XXI, R^1 = Alk, or Ar, R^2 = Alk) can react with Schiff bases and heterocycles, but only the more reactive 1-aryl-substituted salts (XXI, R^1 = Ar) react with azines and hydrazones[56,98]. Among six-membered heterocycles, pyridine, quinoline, isoquinoline, and phenanthridine have been used; isoquinoline is the most reactive. Five-membered heterocycles (benzoxazole, indole, imidazole, etc.) could not be made to undergo this reaction with one exception: the adduct (XLV) has been obtained in 27% yield from benzothiazole[56]:

Schiff bases can be obtained directly in the reaction mixture from the amine and the aldehyde and the yield does not diminish under these conditions. It has been found possible to obtain *s*-triazolium salt (XLIV) when only the amine was introduced into the reaction. The second component (the aldehyde) is obtained from the



alkoxydiazenium salt by a reaction analogous to reaction (16). For example[56]:

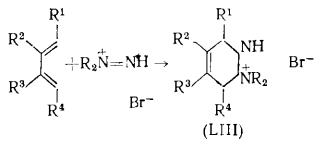
(19)



Only one C=N bond of the azines of aromatic aldehydes is involves in reaction (18).[98] The positive charge on the resulting triazolium ring (XLIV) apparently deactivates the remaining imino-group under these conditions. The presence of electron-donating substituents in the azine facilitates the interaction; on the other hand, the azines of nitrobenzaldehydes are inert in relation to alkoxydiazenium salts. Purely aliphatic azines and the azines of aromatic ketones also could not be made to undergo this reaction[98].

It was thought possible to synthesise *N*-aminotriazolium salts (XLIX) from unsubstituted hydrazones (XLVIII). However, contrary to expectation, the mixed azine (L) is formed initially by a process fully analogous to reaction (19) and only then the triazolium salt (LI) can be obtained only from the azine[98]:

The hydrazones of aliphatic carbonyl compounds do not undergo this reaction. Nor was it possible to isolate the products of the interaction of alkoxydiazenium salts with oximes and amidines[98], CS_2, and Ph–N=C=S.[108] It may be that the absence of cycloaddition products in the reactions of certain types of compounds can be accounted for by their low basicity and inability to abstract a proton from the salt (XXI) and to generate the dipole (XXII), rather than their inertness to dipolarophiles. One cannot therefore rule out the possibility that, when a non-nucleophilic base (for example iso-Pr_2NEt) is introduced into the reaction mixture, it is still possible to isolate the corresponding adducts.



Finally, yet another example of a reaction apparently proceeding via a 1,3-dipolar cycloaddition stage is the interaction of alkoxydiazenium salts (XVII) with formate ions in which it was possible to isolate only small amounts of triazolium salts (LII) containing two aryl residues, instead of the expected formyldiazenes (XXXIX, R^4=H)[56]:

If R = Cl in the salt (XVII), 4,4′-dichloroazobenzene is obtained in addition. The mechanism of this reaction is obscure; it has only been established that, when sodium formate labelled with ^{14}C is used, the triazolium ring does not contain the label[56].

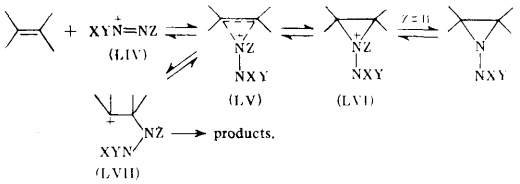
5. Diazenium Cations as Dienophiles

1,1-Dialkyldiazenium cations proved to be very active dienophiles, capable of undergoing the Diels–Alder reaction with many dienes in the cold. This gave satisfactory yields of Δ_4-tetrahydropyridazinium salts (LIII):

(20)

Reaction (20) was discovered by Urry and coworkers[10,11], and was then investigated in detail by other workers[12–14,110] for various dienes and diazenium salts. The yield of (LIII) exceeds 70% in almost all cases and even cyclohexa-1,3-diene, whose reactivity is reduced owing to the incomplete coplanarity of the double bonds in the six-membered ring and which therefore reacts only with very active azodienophiles, gives an adduct with 1,1-dimethyldiazenium bromide in 80% yield. However, reaction (20) does not take place at all with the still less reactive *trans*, *trans*-1,4-diphenylbuta-1,3-diene.[13] The structural specificity of the reaction is usual for diene synthesis: the *ortho*-isomers of the adducts (LIII) are obtained from 1-substituted dienes (piperylene), while the *para*-isomers are obtained from the 2-substituted dienes (isoprene, chloroprene).[10,12–14]

The branching of the alkyl groups in the diazenium cation is apparently important, because 1,1-di-isopropyldiazenium bromide could not be introduced into the synthesis, evidently owing to steric hindrance[13]. The 1,1-dibenzyldiazenium cation reacts in the usual way, but the reaction pathway for aryldiazenium cations changes: instead of diene synthesis, addition to one of the double bonds of the diene, which will be discussed below, takes place instead of diene synthesis[14]. The change in the nature of the interaction is evidently due to the conjugation of the N=N bond with the aryl substituents[14], but it is at present not clear which specific consequences of conjugation are of decisive importance under these conditions.

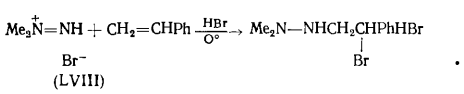


It is known that the diene usually behaves as the donor in the Fiels–Alder reaction, while the dienophile behaves as the electron acceptor. The high reactivity of diazenium cations as well as their analogues—immonium [111] and even diazonium [112] cations—in the Diels–Alder reaction is therefore not surprising.

On another occasion a small amount (12%) of tiglaldehyde dimethylhydrazone was isolated when 1,1-dimethyldiazenium bromide was allowed to react with isoprene [10], but since then nobody has observed the formation of such hydrazones simultaneously with reaction (20).

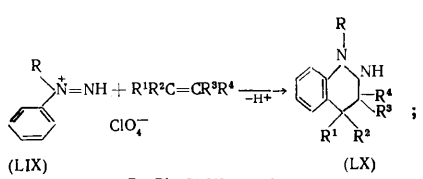
6. Reactions with Olefins

Formally, the interaction of diazenium salts with olefins can be regarded as the usual reaction of an electrophile (diazenium cation) with a multiple bond. It is therefore not surprising that mechanism (21), proposed to



account for such interaction [33,34], is merely a special case of the general mechanism of the addition of electrophiles to unsaturated systems [113] (see also Dolbier [114]):

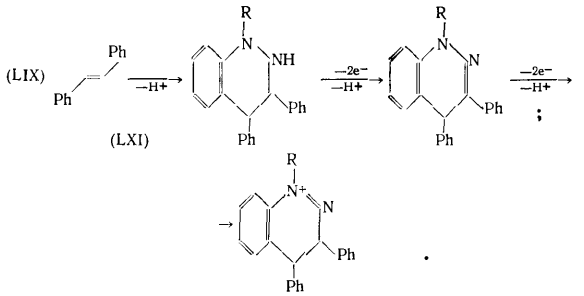
(21)



According to mechanism (21), the reaction begins with the attack by the diazenium cation (LIV) on the olefin and the formation of the π-complex (LV), which is in equilibrium with the azidirinium cation (LVI) (in actual fact a σ-complex) and with the carbonium ion (LVII). The positions of all these equilibria and hence the products of reaction (21) are in many respects determined by the structures of the diazenium salts and the olefin [33,34].

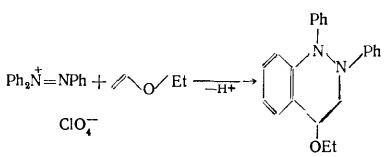
In conjugated olefins the substituents are capable of effectively stabilising the positive charge and the equilibrium position shifts in the direction of the ion (LVII). Urry et al. showed [11] that 1,1-dimethyldiazenium bromide (LVIII) reacts with styrene, indene, and 2-phenylpropene to form products, which can be regarded, on the basis of Eqn. (21), as a result of the addition of a bromide ion or water to an intermediate cation of type (LVII). For example:

It has been shown that this reaction is reversible and that the degree of conversion of the olefin and the equilibrium position depend strongly on the solubility of the product and the structure of the olefin. Thus 1-phenylpropene and *trans*-stilbene do not react with compound (LVIII) at all [11].



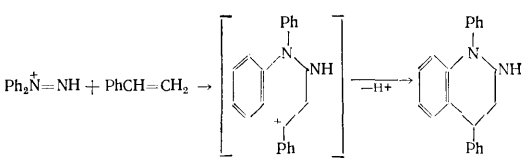
1,1-Diphenyl-, 1-methyl-1-phenyl-, and 1-benzyl-1-phenyl-diazenium perchlorates react quite differently with these olefins in acetonitrile [14,32-36], forming tetrahydrocinnolines (LX):

(22)

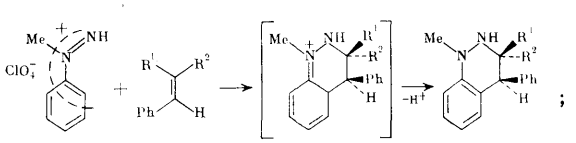


The yields are nearly quantitative when R = Ph and are somewhat lower than R = $PhCH_2$ or Me. Furthermore, the reaction is much slower in the latter case, probably owing to the weaker electrophilic properties of such diazenium cations.

Styrene, indene, 1,1-diphenylethylene, acenaphthalyne, 2-phenylnorbor-2-ene, and tetracyclone (tetraphenylcyclopentadienone) have been introduced into reaction (22). *cis*-Stilbene is inert under these conditions, which is believed [33,34] to be due to steric hindrance, and, although *trans*-stilbene does react, the resulting tetrahydrocinnolines (LXI) are oxidised by diazenium cations to cinnolinium salts:

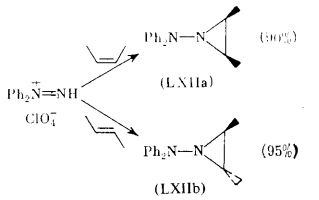


Tetrahydrocinnoline (LXI) was isolated only for R = Me (33%). [34]

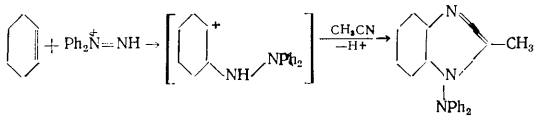


Triphenyldiazenium perchlorate is less reactive than compound (LIX) and does not react with the above olefins; however, its reaction with the more reactive vinyl ether gives the corresponding tetrahydrocinnoline in 95% yield [34,45]:

The formation of tetrahydrocinnolines has been considered, on the basis of mechanism (20), as a result of intramolecular coupling in the intermediate carbonium ion (LVII). [33,34] For example:



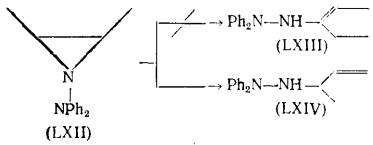
However, according to Zelenin [35], reaction (22) takes place differently and is a concerted [4 + 2] cycloaddition process with the reactants having inverse electronic properties (the so-called "reversed" diene synthesis [115]). Strong evidence in support of this treatment is provided by the complete retention of the configuration of the initial olefin in the tetrahydrocinnoline, which has been demonstrated by the reaction of 1-methyl-1-phenyldiazenium perchlorate with *cis*- and *trans*-β-deuterostyrenes [35]:



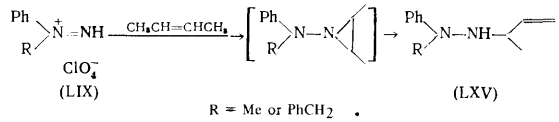
(a) $R^1 = D$, $R^2 = H$; (b) $R^1 = H$, $R^2 = D$.

Only the most electrophilic diazenium cations react with non-conjugated olefins. Thus the reaction of compounds (LIX, R = Ph) with *cis*- and *trans*-but-2-enes in acetonitrile led to the isolation of the aziridines (LXII):

(23)



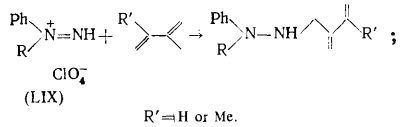
but the reaction with cyclohexane unexpectedly gives an 80% yield of 2-methyl-1-diphenylaminohexahydrobenzimidazole [33,34]:



(24)

The difference between the products of reactions (23) and (24) is attributed to steric strain, which reduces in the latter case the stability of the bicyclic aziridinium ion (LVI) [reaction (21)], and to the steric hindrance of the formation of aziridine from cyclohexene. [33,34]

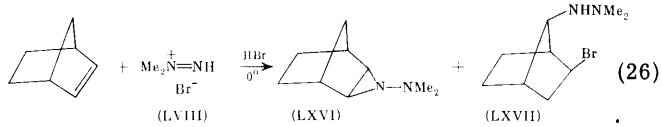
In an acid medium both *cis*- and *trans*-aziridines (LXII) decompose in an extremely non-trivial manner, giving, instead of compound (LXIII), the isomeric hydrazine (LXIV); *trans*-aziridine is much less stable than its *cis*-isomer [33,34]:



1-Methyl-1-phenyldiazenium perchlorate (LIX, R = Me) does not react with cyclohexene at all and its reaction with *cis*- and *trans*-but-2-enes is much slower than that of (LIX, R = Ph). The corresponding aziridines (LXII) are apparently unstable under these conditions and only the product of their decomposition—a hydrazine (LXV)—can be isolated in approximately 35% yield [34]. 1-Benzyl-1-phenyldiazenium perchlorate reacts similarly with but-2-enes, but the yield of the hydrazine is somewhat higher [14]:

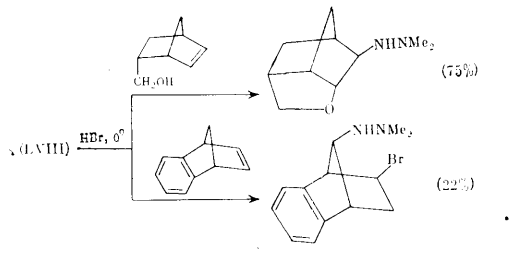
; (25)

R = Me or $PhCH_2$.



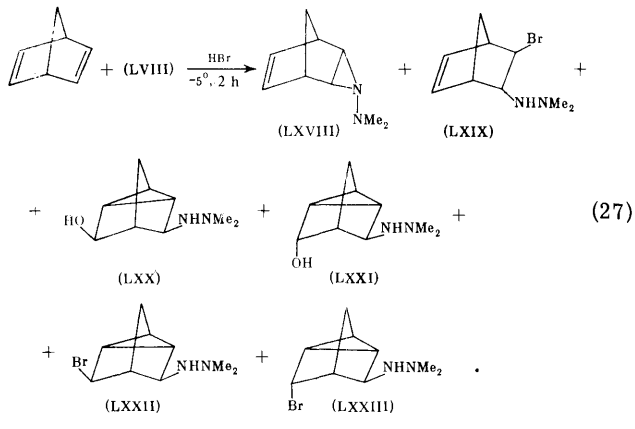
The interaction of aryldiazenium salts (LIX) with 1,3-dienes is apparently analogous to reaction (25). This reaction also leads to the formation of unsaturated hydrazines [14]:

;



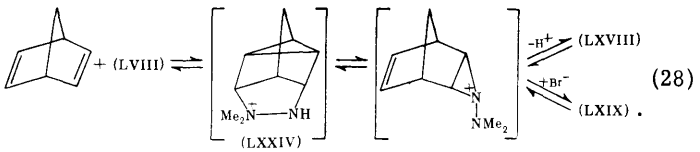
R' = H or Me.

1,1-Dialkyldiazenium salts are evidently less electrophilic than aryldiazenium salts and do not react with the usual olefins. However, the reaction does nevertheless occur with the more reactive double bonds of compounds of the norbornene series. Thus, 1,1-dimethyldiazenium bromide (LVIII) reacts with norbornene to form *exo*-*N*-dimethylaminoaziridine (LXVI) (in 59% yield), and also the bromohydrazine (LXVII) or the corresponding hydrazinoalcohol [15]:



(26)

If account is taken of the possible rearrangements of the norbornyl cations, reaction (26) can be readily accounted for in terms of mechanism (21). The interaction of (LVIII) with *endo*-2-hydroxymethylnorborn-5-ene and benzonorbornadiene also fits satisfactorily within the framework of this mechanism [15]:

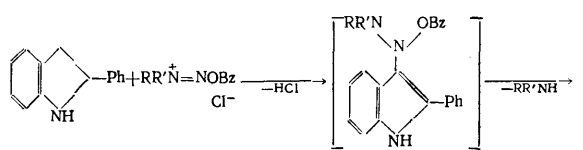


It is noteworthy that in the above examples the first reaction stage is *exo*-attack by the diazenium cation on the norbornene double bond, which is typical for electrophilic addition to such systems. However, the reaction of (LVIII) with norbornadiene yielded the *endo*-aziridine (LXVIII) as well as a series of products of both *endo*-addition [compound (LXIX)] and *exo*-addition [compounds (LXX)–(LXXIII)] with an overall yield in excess of 95% [15]:

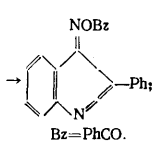
(27)

The authors [15] explained the formation of the *endo*-products by the fact that the 1,1-dimethyldiazenium cation can react with norbornadiene not only as an electrophile but also as a dienophile, and that certain reactions of conjugated dienes are characteristic of norbornadiene. It is suggested that the initial [2 + 2 + 2]-cycloaddition product

(**LXXIV**) is subsequently converted into an *endo*-aziridinium ion, which is then transferred into compounds (**LXVIII**) and (**LXIX**):



(28)

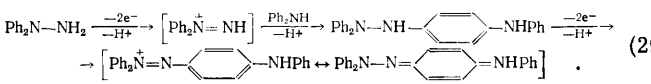


With increase of the HBr concentration, the yield of the *endo*-aziridine (**LXVIII**) falls sharply (from 52% to 0) and, although the amount of (**LXIX**) increases, the *endo* : *exo* ratio in the reaction products diminishes. To explain this, it has been suggested[15] that the dication $Me_2\overset{+}{N}=\overset{+}{N}H_2$ is involved in the reaction; its addition to norbornadiene takes place with formation of an *exo*-adduct, from which all the *exo*-products (**LXX**)–(**LXXIII**) are subsequently obtained.

However, the existence of this dication is extremely unlikely even in a very strongly acid medium and the *exo*-products are most probably formed via a less exotic route. It appears that, when compound (**LVIII**) interacts with norbornadiene cycloaddition [reaction (28)] leading to *endo*-products is accompanied by the usual electrophilic attack at a comparable rate via reaction (26) with formation of an *exo*-π-complex and possibly the corresponding *exo*-aziridine. *exo*-Derivatives of norbornene are known to react with nucleophiles at a rate higher by several orders of magnitude than their *endo*-isomers[116,117], so that *exo*-aziridine should be converted into the decomposition products (**LXX**)–(**LXXIII**) much faster than the *endo*-isomer (**LXVIII**) and its absence from the reaction mixture is quite understandable. It is also possible that the attack by the nucleophile takes place at the stage of the *exo*-π-complex. With increase of HBr concentration, the main role in the alteration of the composition of the products of reaction (27) is apparently played by the increase of the concentration in solution of the extremely nucleophilic bromide ions rather than a change in the pH of the medium.

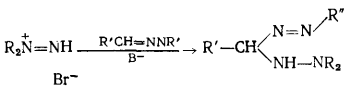
7. Diazenium Cations in Coupling Reactions

Although coupling reactions are typical for the closest analogues of diazenium salts (diazonium and also immonium salts[75]), there are comparatively few examples of such processes involving diazenium cations. Only the most electrophilic diazenium cations undergo coupling reactions with aromatic compounds. Thus the coupling of benzoyloxydiazenium chlorides (**LXXV**) with 2-phenylindole leads to 3-benzoyloxyimino-2-phenylindolenine[61]:



Cyclopentadienone dimethylhydrazone has been obtained from 2-methoxy-1,1-dimethyldiazenium methyl sulphate and cyclopentadienylsodium[59,60]:

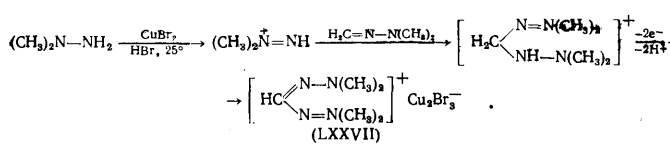
Hünig postulated the involvement of 1,1-diaryl-substituted diazenium cations in the oxidative coupling of 1,1-diarylhydrazines wtth aromatic amines, phenols, etc.[5,29,30,68,118]. For example:



(29)

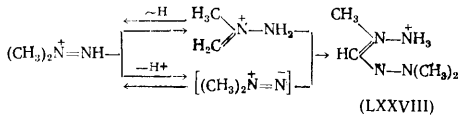
However, it was already noted above (Section II) that the involvement of diazenium cations in these coupling reactions is fairly controversial, since the oxidation was carried out only in a weakly acid and even in an alkaline medium. The formation of tetrazenes, the typical products of the oxidation of asymmetric hydrazines, competes with the coupling reaction[2-5] and in certain cases only the tetrazene is obtained. The yield of coupling products has amounted to between 10 and 50%.[29,30,68]

When 1,1-dialkyl- and 1-alkyl-1-arylhydrazines, except 1-methyl-1-*p*-nitrophenylhydrazine, are used instead of 1,1-diarylhydrazines, the coupling reaction does not occur at all[29,30]. The attempt to couple 1,1-dimethyldiazenium bromide (**LVIII**) with aniline and phenol in an acid medium was also unsuccessful[11].



Despite the relatively low reactivity of diazenium salts in relation to aromatic compounds, their interaction with hydrazines takes place smoothly. The coupling of diazonium salts with hydrazones leads to formazans and the corresponding reaction involving diazenium salts was found to lead to the formation of various compounds with the dihydroformazan group. Thus the addition of acid solutions of 1,1-dialkyldiazenium bromides to aldehyde monoalkylhydrazones in the presence of bases led to the synthesis of a series of 3,4-dihydroformazans (**LXXVI**)[20-22,24]:

(30)

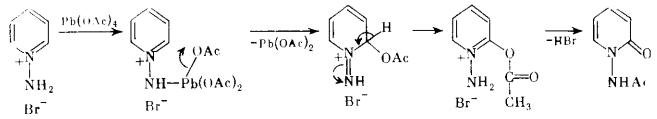


The formation of compound (**LXXVI**) can be treated as a result of the coupling of the hydrazone either directly with the diazenium cation or with the aminonitrene formed from the latter under the influence of the base. It is so far difficult to reach a final conclusion, although the second mechanism is apparently more probable, since compounds (**LXXVI**) have been isolated also following the reaction of hydrazones with aminonitrenes generated in other ways[22].

On the other hand, coupling of the diazenium cation with the hydrazone has been postulated as one of the intermediate stages in the formation of the copper complex of 1,1,5,5-tetramethylformazanium cation (**LXXVII**), which is very similar to reaction (30)[27]:

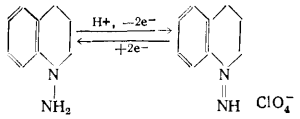
The structure proposed for (LXXVII) is consistent with the infrared and ^1H NMR spectra as well as X-ray diffraction data. Furthermore, when the complex is decomposed in an alkaline medium, the product is 1,5,5-trimethylformazan—the simplest formazan obtained hitherto[27].

Finally, yet another version of this type of coupling has been put forward by Urry[15]. He believes that the following reactions are possible in a solution of 1,1-dimethyldiazenium bromide [cf. Eqns. (6) and (7)]:



(LXXVIII)

There is no evidence for the structure of the dihydroformazanium ion (LXXVIII) in his paper[15]. It is merely stated that the ion can be hydrolysed to 1,1-dimethylhydrazine, methylhydrazine, and formic acid or can react further to give 1-methyl-1,2,4-triazole and dimethylamine.[15]

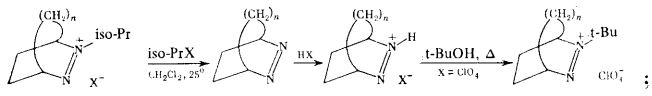


o0o

Several studies on the methods of synthesis and properties of diazenium salts were published in 1977.

The formation of diazenium cations was suggested to account for the oxidation of *N*-aminopyridinium bromide by lead tetra-acetate [119]:

The perchlorate (LXXIX) (λ_{max} = 319 nm, ϵ = 9900),[120] whose properties are in many respects similar to those of 1-alkyl-1-aryldiazenium salts investigated previously, was obtained by the electrochemical oxidation of *N*-amino-1,2,3,4-tetrahydroquinoline in acetonitrile ($E_{1/2}$ = 0.87 V):



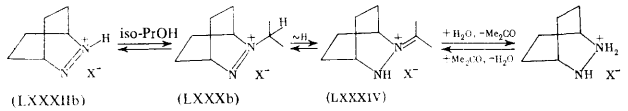
(LXXIX)

Its reduction ($E_{1/2}$ = −0.18 V) regenerates the initial hydrazine in 80% yield and its reaction of type (22) with acenaphthylene, 1,1-diphenylethylene, and indene leads to the corresponding tetrahydrocinnolines (LX) in 54 to 67% yield.

In their study of the mass spectra, generated by electron impact, of various hydrazines, tetrahydrocinnolines (LX), and pyrazolidines, prepared by the condensation of diazenium salts with olefins [reactions (25), (22), and (17) respectively], Cauquis et al.[121] concluded that the main pathway in the fragmentation of the molecular radical-anion is in all cases the retroreaction—the decomposition to the olefin of the diazenium cation or the protonated azomethineimine.

A number of bicyclic trisubstituted diazenium salts (LXXX) were obtained in 90–100% yield by the alkylation of the corresponding azoalkanes with isopropyl bromide in an atmosphere of nitrogen in the presence of $AgClO_4$.

Isopropyl iodide alkylates (LXXXIb) even on simple mixing of the reactants without the addition of a silver salt (yield 86%) [122]:



(LXXX, a and b) (LXXXI, a–d) (LXXXII, a–d) (LXXXIII, a–c)

(a) n = 1, (b) 2, (c) 3, (d) 4; X = Cl, Br, I or ClO_4.

When a gaseous hydrogen halide was passed through an ethereal solution of (LXXXI) or the latter was treated with 70% $HClO_4$, the corresponding 1,2-disubstituted diazenium salts (LXXXII) were obtained in 70–100% yield. The trisubstituted salts (LXXXIII) were then synthesised from the perchlorates (LXXXII) in 80–85% yield on refluxing in t-butyl alcohol[122].

The attempt to use the last reaction for the introduction of groups other than t-butyl were unsuccessful: when methyl, ethyl, and isopropyl alcohols were used, (LXXXII) was reduced to hydrazine instead of being alkylated. It has been shown for (LXXXIIb) that the reduction is a reversible process proceeding via stages involving alkylation, isomerisation, to (LXXXIV), and hydrolysis, the rate of equilibration depending on the nature of the anion[122]:

(LXXXIIb) (LXXXb) (LXXXIV)

It is important to note that Snyder et al.[122] were able to isolate a number of salts of the type (LXXXIV) (cf. Section IV).

The Stereochemistry of Organoarsenic Compounds

F.D.Yambushev and V.I.Savin

The structure of organic compounds of arsenic is considered. Data are presented on the configurational stability and the energy of the inversion barrier in asymmetric arsines. The methods of synthesis of tertiary asymmetric arsenic compounds are surveyed. The results of the separation of asymmetric arsines into optically active isomers and the mechanisms of their transformation as well as the influence of substituents in the benzene ring on the optical activity are described. An analogy is drawn between the stereochemistries of organophosphorus and organoarsenic compounds.
The bibliography includes 220 references.

IV. Stereochemistry of organoarsenic compounds 587

I. INTRODUCTION

The stereochemistry of organoelemental compounds, which has been developing vigorously recently, is being gradually transformed into an independent section of organic chemistry. This field of stereochemistry is important for the understanding of the general characteristics of optical isomerism and stereochemical transformations, and also in the study of reactivity and reaction mechanisms. Stereochemical problems, particularly those which are associated with the reactions of optically active compounds, have been occupying an increasingly important place in research on the mechanisms of organic reactions. The study of the structure and the chemical and optical properties of asymmetric arsines is one of the urgent problems in this connection.

The number of publications dealing with problems of the stereochemistry of organoarsenic compounds has increased appreciably recently. However, so far there has been no complete compilation of the literature reflecting the state of research in this field during the latest period. The present paper surveys and considers in detail data concerning the structure, methods of synthesis, and the stereochemistry of organoarsenic compounds. Our aim was not an all-embracing discussion of the problem and we endeavoured to concentrate attention on asymmetric arsenic compounds which have been studied systematically recently. In certain cases a comparison is made with the analogous phosphorus compounds.

II. THE STRUCTURE OF ARSENIC COMPOUNDS

As representatives of Group V in the Periodic System, phosphorus and arsenic exhibit certain analogies in the structure of their electron shells. In contrast to its closest analogue—phosphorus in the Third Period, arsenic, which is an element in the Fourth Period, has a completed M shell and an incomplete N electron shell. The following electronic configurations correspond to neutral phosphorus and arsenic atoms:

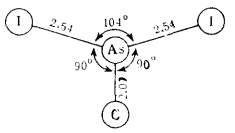
$$\text{P}—1s^2 2s^2 p^6 3s^2 p^3;\quad \text{As}—1s^2 2s^2 p^6 3s^2 p^6 d^{10} 4s^2 p^3.$$

In neutral phosphorus and arsenic atoms the outer energy levels are not fully occupied by electrons: they contain two electrons with antiparallel spins in the s orbital and only one electron in each of the three p orbitals. The $3d$ orbital in phosphorus atoms and the $4d$ and $4f$ orbitals in arsenic atoms are unoccupied. It is assumed[1] that these orbitals are used in the formation of bonds in the maximum-valence phosphorus and arsenic compounds. Their $4s$, $4p$, and $3d$ orbitals are most available as regards energy for the formation of chemical bonds[2]. Phosphorus and arsenic atoms in their various compounds can be surrounded by between three and six substituents[3].

Within the framework of the present review, organic derivatives of tervalent arsenic as well as individual representatives of quinquevalent arsenic having the structures

$$R_3As,\ R_3As{=}O,\ R_3As{=}S,\text{ and }[R_4As]^{\oplus}X^{\ominus}$$

are considered in greatest detail.



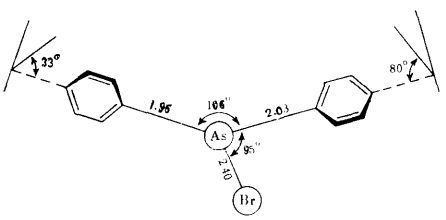
In compounds phosphorus and arsenic atoms have the following electronic configurations: p^3, sp^3, sp^3d, and sp^3d^2. Certain tervalent phosphorus and arsenic compounds, for which the p^3 structure has been postulated, are stable under the usual conditions[4,5]. Examples are provided by phosphine PH_3 and arsine AsH_3. Spectroscopic studies have shown that the hydrogen atoms in the PH_3 and AsH_3 molecules are equivalent and that the H–P–H and H–As–H valence angles are 94° and 92° respectively[6,7]. These angles are greater by 4° in phosphine and 2° in arsine than the angle formed by the overlap of pure p orbitals (90°). Hence it follows that the H–P and H–As bonds are formed with an appreciable involvement of p orbitals and that the lone electron pair is localised predominantly in the s orbitals of phosphorus and arsenic atoms.

Spectroscopic data[7-10] have shown that the replacement of hydrogen by a halogen, alkyl, or aryl in tervalent phosphorus and arsenic compounds leads to an increase of valence angles. The relative content of lone electron pairs of the p type in these compounds increases. The valence angles in trimethyl and trifluoro-derivatives of phosphorus and arsenic increase to 99° and 96° and to 104° and 102° respectively.

The valence angles in certain tervalent phosphorus and arsenic compounds show that there is no significant difference between the types of hybridisation of the lone electron pair orbitals in phosphorus and arsenic. The content of lone electron pairs of the p type in tertiary phosphines and arsines varies near 50%, while in secondary and primary phosphines and arsines it is much less[11]. With

increase of the p character of the lone electron pairs, there is also an increase of the capacity of the hybrid lone pair for p,π conjugation [11].

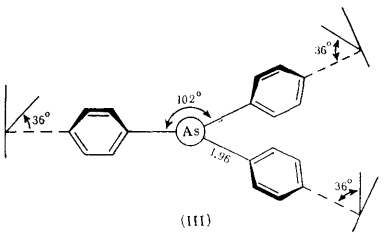
Comparison of the lengths and energies of arsenic–halogen bonds [10,12–21] shows that shortest and strongest bonds are observed for the F substituent. On passing to Cl, Br, and I, the lengths of the bonds with arsenic increase and there is a corresponding decrease of the dissociation energy. The structure of primary halogenoarsines has been studied in relation to difluoromethyl- and di-iodomethyl-arsines (I). The valence angles and intraatomic distances have been determined by a microwave spectroscopy [22,23].



(I)

Among unsaturated compounds, the structure of β-chlorovinyldichloroarsine has been studied by electron diffraction [24]. Appreciable differences in the C–As–Cl valence angles and As–Cl distances relative to saturated compounds were not observed, except that the As–C bond length is reduced (to 1.90 Å). Secondary halogenoarsines were also studied by electron diffraction. In these compounds the C–As–X bond lengths and the valence angle are influenced by the nature of the substituent.

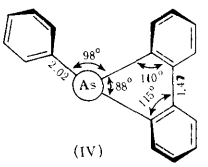
It has been shown [15] that the As–C bond lengths in halogenodimethylarsines $(CH_3)_2As–X$ (where X = Cl, Br, or I) are approximately the same (1.98 Å). The C–As–Cl and C–As–I valence angles are similar, while the C–As–Br valence angle (96°) is smaller than in chloro- and iodo-arsines. The C–As–C valence angle is 96°. [25–27]



The C–As bonds linking the two aromatic groups in diarylhalogenoarsine molecules are not the same [19,21]. The C–As bond lengths in $(C_6H_5)_2As–Br$ (II) are 1.96 and 2.03 Å. The C–As–C and C–As–Br valence angles are 106° and 95° respectively. The As–Br interatomic distance (2.40 Å) is shorter than in alkylhalogenoarsines. The benzene rings in bromodiphenylarsine are inclined at different angles to the base of the pyramid. Their planes make angles of 33° and 80° with the plane of the base.

(II)

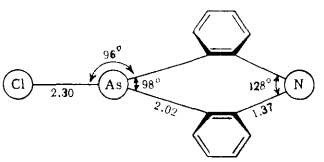
In the series of tertiary aliphatic arsenic derivatives the structure of trimethylarsine $As(CH_3)_3$ has been thoroughly investigated. It has been established by electron diffraction, X-ray diffraction, and microwave spectroscopy [15,27,28] that all the As–C bonds in trimethylarsine are equivalent. The As–C interatomic distances are equal (1.98 Å) and the C–As–C valence angles are the same and amount to 96°.



Among aromatic derivatives of tervalent arsenic, the structures of tritolyl arsine (III) and trixylylarsine have been most thoroughly investigated [10,26,29]. The molecules have identical symmetries, similar As–C bond lengths (1.96 and 1.99 Å), and equal (102°) C–As–C valence angles.

(III)

The benzene rings in crystalline tritolyl- and trixylylarsines are located in the plane of the base of the molecule at approximately the same angles, which are 36° and 37° respectively.

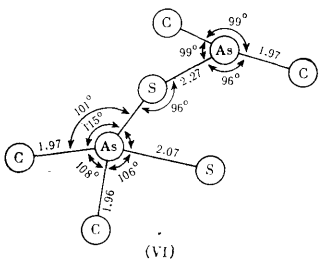


Among cyclic tervalent arsenic compounds, the molecule of 9-phenyl-9-arsafluorene (IV) has been thoroughly investigated.

(IV)

The C–As–C valence angle in the ring is 88°. The length of the C–C bond between the aromatic rings is 1.47 Å. These rings are located in one plane, while the isolated phenyl group is almost perpendicular to it. Its C–As–C valence angle is greater by 10° than the endocyclic angle and the As–C interatomic distances are 2.02 Å.

Among tervalent arsenic compounds with a six-membered ring, the molecule of 10-chloro-5,10-dihydrophenarsazine (V) has been investigated [31].



(V)

The three condensed rings do not lie in one plane. The angle of the bend along the As–N axis is 169°. The As–Cl interatomic distance (2.30 Å) is somewhat greater than in $(C_6H_5)_2As–Cl$. The C–N–C angle (128°) is greater than the analogous C–As–C angle (98°). According to Camerman and Trotter [31], the characteristic feature of the molecular structure of this compound can be explained by the interaction of the π electrons of the phenyl groups with the free electron pair of nitrogen and the d orbital of arsenic.

Tetracoordinate arsenic derivatives—sulphides (As=S), oxides (As=O), and arsonium compounds $(=As=)^+X^-$—have a tetrahedral configuration. It has been suggested that $p_\pi–d_\pi$ conjugation is characteristic of the corresponding As=O and As= bonds [32,33].

The two arsenic atoms in the cacodyl disulphide (VI) molecule [34] are in different valence states (As^{III} and As^{V}). Apart from the three substituents surrounding the central

atom, the tetracoordinate arsenic atom has a fourth substituent—sulphur. The C–As=S valence angle is 106° and the As=S bond length (2.07 Å) approaches the As–C bond length (1.96 Å). The C–As–C valence angles are 108°, being similar to the analogous C–As–S angle (106°). The average lengths of all the bonds and all the valence angles in this compound approach the parameters characteristic of a tetrahedral structure.

(VI)

In compounds of quinquevalent phosphorus and arsenic, where the central atom is surrounded by four substituents one of which is linked to it by a double bond, a tendency appears towards the formation of new types of asymmetric molecules. It has been suggested[35] that in compounds of this kind one encounters a new geometrical model, which consists of a distorted tetrahedron with a single double bond directed to one of the vertices. If the three remaining substituents are different, then the molecule has no symmetry plane. Hence it follows that the molecules corresponding to this model are asymmetric and exist in the form of two sterically incompatible optically active isomers. The problem of the optical activity of these compounds is discussed below.

III. METHODS OF SYNTHESIS OF CHIRAL ORGANOARSENIC COMPOUNDS

1. The use of Organometallic Compounds

Of the existing methods of synthesis of tertiary arsines, in the present review we shall consider only those which are used most frequently to synthesise chiral organoarsenic compounds. The commonest method involves the interaction of secondary organoarsenic halides with organic derivatives of Group I, II, and IV metals. In this method sodium can be successfully replaced by other metals: Li, K, Mg, Zn, and Hg.[36-57] Organozinc and organomercury compounds have been recently displaced to an increasing extent by the more readily available and effective for comparative purposes lithium compounds and Grignard reagents[58,59].

When organomagnesium compounds are used, the reaction is usually carried out in ether. Benzene, iso-octane, and tetrahydrofuran are sometimes used successfully. The yield of the required products increases when arsenic iodide compounds are employed[60]. Preliminary dilution of halogenoarsines with dry petroleum ether[61] or benzene[62] also increases the yield of tertiary arsines. Various chiral alkylarylarsines have been synthesised by this method[63-66]:

$$\begin{matrix}\mathrm{Alk}\\ \mathrm{Ar}\end{matrix}\!\!>\!\mathrm{AsCl} + \mathrm{RMgHal} \rightarrow \begin{matrix}\mathrm{Alk}\\ \mathrm{Ar}\end{matrix}\!\!>\!\mathrm{AsR} + \mathrm{MgHalCl} \quad .$$

Under the conditions of the Grignard reaction, chiral arsines can be obtained in high yields by treating a mixture of two Grignard reagents with alkyl- and aryldichloroarsines[67]. Isopropylmethylphenylarsine, for example, was obtained in this way:

$$\mathrm{C_6H_5{-}As}\!\!<\!\!\begin{matrix}\mathrm{Cl}\\ \mathrm{Cl}\end{matrix} + \mathrm{CH_3MgI} + \text{iso-}\mathrm{C_3H_7MgBr} \xrightarrow{\text{ether/THF}} \text{iso-}\mathrm{C_3H_7{-}As}\!\!<\!\!\begin{matrix}\mathrm{CH_3}\\ \mathrm{C_6H_5}\end{matrix} \quad .$$

The reaction involves the formation of a certain amount of symmetrical arsines. In many instances the method can be more effective than the existing multistage syntheses. The reaction of halogenoarsines with Grignard reagents is used as the principle method for the synthesis of tertiary aliphatic and aromatic arsenic derivatives[68]. Apart from halogenoarsines, the corresponding arsine oxides[69], aminoarsines[70], and arsinic acid esters[71] react similarly with Grignard reagents:

$$\begin{matrix}\mathrm{RO}\\ \mathrm{R'O}\end{matrix}\!\!>\!\mathrm{As{-}OR} + \mathrm{R''MgCl} \rightarrow \begin{matrix}\mathrm{RO}\\ \mathrm{R'O}\end{matrix}\!\!>\!\mathrm{As{-}R''} + \mathrm{ROMgCl} \quad .$$

Grignard reagents are most convenient not only for the synthesis of aliphatic or aromatic arsenic compounds but also for the synthesis of certain other tertiary arsines[72-77], including unsaturated arsines[78-87].

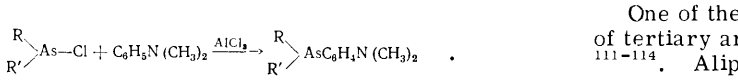
There exist a series of special methods for the synthesis of chiral arsines and their analogues, examples of the use of which are not numerous. They include in the first place the Wurtz–Fittig reaction, which consists in the interaction of halogeno-substituted organoarsenic derivatives with alkyl halides or aryl halides in the presence of metallic sodium. In the field of organoarsenic compounds it is known as the Michaelis condensation[88], Michaelis having used it to synthesise triarylarsines and mixed arsenic compounds without functional groups in the chain. It has been suggested[89] that an intermediate is formed with an As–Na bond, which leads to a tertiary arsine on interaction with an alkyl or aryl halide:

$$\mathrm{RR'As{-}Hal} + 2\mathrm{Na} \leftrightarrow \mathrm{RR'As{-}Na} + \mathrm{NaHal} \quad ,$$
$$\mathrm{RR'As{-}Na} + \mathrm{Hal{-}R''} \rightarrow \mathrm{RR'AsR''} + \mathrm{NaHal} \quad .$$

The yield of the final product is independent of the nature of the halogen, the form of sodium employed playing a more important role[90]; the highest yield is obtained with dispersed sodium[91]. The reaction is carried out in dry benzene, toluene, or ether and is catalysed by ethyl acetate. It is normally used to synthesis triaryl- or alkylaryl-arsines[92-99].

The allyl esters of asymmetric arsinous acid have been synthesised by the reaction of ethylphenylarsine oxide with allyl alcohol[87]:

$$\left(\begin{matrix}\mathrm{C_2H_5}\\ \mathrm{C_6H_5}\end{matrix}\!\!>\!\mathrm{As}\right)_2\mathrm{O} + 2\mathrm{HOCH_2{-}CH{=}CH_2} \rightarrow 2\begin{matrix}\mathrm{C_2H_5}\\ \mathrm{C_6H_5}\end{matrix}\!\!>\!\mathrm{As{-}OCH_2CH{=}CH_2} + \mathrm{H_2O} \quad .$$



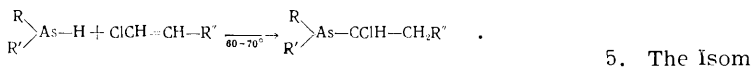
A new method of synthesis of chiral arsines[67] is based on the ability of arsonium salts to alkylate triphenylphosphine:

$$\mathrm{C_6H_5AsCl_2} \xrightarrow[-\mathrm{MgHalCl}]{+2\mathrm{C_6H_5CH_2MgHal}} \mathrm{C_6H_5As(CH_2C_6H_5)_2} \xrightarrow{+\mathrm{RHal}}$$
$$\rightarrow \left[\begin{matrix}\mathrm{C_6H_5CH_2}\\ \mathrm{C_6H_5CH_2}\end{matrix}\!\!>\!\mathrm{As}\!\!<\!\!\begin{matrix}\mathrm{C_6H_5}\\ \mathrm{R}\end{matrix}\right]^{\oplus}\mathrm{Hal}^{\ominus} \xrightarrow[[(\mathrm{C_6H_5})_3\mathrm{PCH_2C_6H_5}]^{\oplus}\mathrm{Hal}^{\ominus}]{(\mathrm{C_6H_5})_3\mathrm{P}} \mathrm{R{-}As}\!\!<\!\!\begin{matrix}\mathrm{C_6H_5}\\ \mathrm{CH_2C_6H_5}\end{matrix};$$
$$\mathrm{R}=\mathrm{CH_3},\ \mathrm{C_2H_5},\ \mathrm{C_3H_7},\ \text{or n-}\mathrm{C_4H_9};\ \mathrm{Hal}=\mathrm{Br}\ \text{or}\ \mathrm{I}.$$

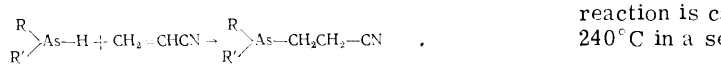
The reaction proceeds under mild conditions in dimethylformamide. The yields of tertiary arsines are nearly quantitative.

Tertiary arsines have been obtained in fairly high yields by the condensation of secondary chloroarsines with aromatic hydrocarbons in the presence of aluminium

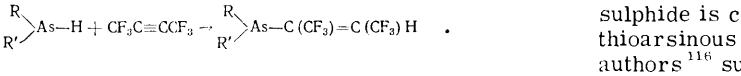
chloride[100,101]. The presence of electron-donating groups in the aromatic ring facilitates the condensation:



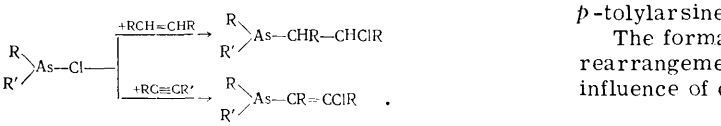
2. Syntheses with Participation of Mobile Atoms



Tertiary arsines with triple carbon–carbon bonds have been synthesised[102] by the direct interaction of acetylene derivatives with halogenoarsines under ultra violet irradiation:

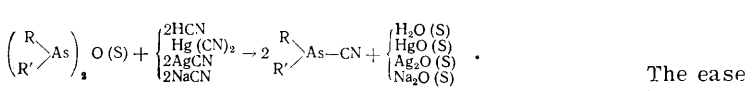


Secondary arsines readily add to chlorine- and fluorine-containing unsaturated hydrocarbons[103–107]. This reaction leads to the formation of tertiary asymmetric arsines in a high yield:



It has been shown[105] that, owing to the mobility of hydrogen, secondary arsines add smoothly to acrylonitrile in the presence of bases with formation of the corresponding chiral arsinonitriles:

The addition of secondary arsines to acetylenic hydrocarbons has been studied in relation to a limited number of examples. It has only been shown that the reaction proceeds readily with formation of tertiary ethylene derivatives of arsenic[102]:



Asymmetric arsines have been obtained[103] by the analogous reaction of secondary halogenoarsines with ethylenic and acetylenic hydrocarbons after prolonged heating at 180°C:

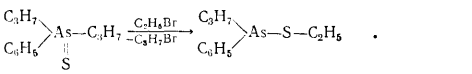
3. Syntheses Based on Hydrocyanic Acid Derivatives

The asymmetric derivatives of tervalent arsenic containing the cyano-group are of interest for the investigation of stereochemical properties. Hydrolysis of arsinonitriles leads to the corresponding carboxy-derivatives of arsenic. The synthesis of tertiary arsines containing a cyano-group linked directly to the arsenic atom is achieved by the interaction of secondary arsine oxides or sulphides with hydrocyanic acid and mercury, silver, and alkali metal cyanides[108–110]:

The same compounds can be obtained in high yields also from secondary halogenoarsines[108–110].

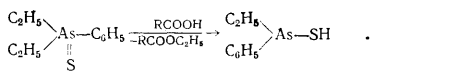
4. The Reduction of Arsine Oxides

One of the most convenient methods for the preparation of tertiary arsines involves the reduction of their oxides[111–114]. Aliphatic, aromatic and mixed arsines are obtained by this procedure.



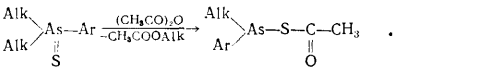
When tervalent arsenic oxides containing three different hydrocarbon groups are reduced, chiral arsines are formed. The reaction is carried out in an acid medium. The reducing agents most frequently employed are sulphur dioxide and tin and the acids are hydrochloric and phosphoric:

The yields of desired products are almost quantitative. When arsine oxides are reduced by sulphur dioxide in hydrochloric acid, an alcoholic solution of iodine or a potassium iodide solution are used as catalysts.

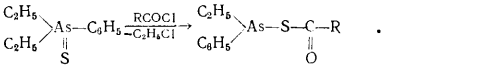


5. The Isomerisation Reaction

Asymmetric compounds containing the =As–S–R linkage are obtained by a rearrangement of alkylarylarsine sulphides on interaction with alkyl halides[115]. The reaction is carried out by heating the reactants at 100 to 240°C in a sealed tube without a solvent for 7–25 h:

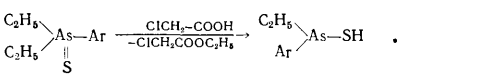


The study of the rearrangement of ethylphenyl-α-naphthylarsine sulphide under the influence of methyl iodide and ethyl bromide established[116] that the arsine sulphide is converted into the ester of the corresponding thioarsinous acid with elimination of the alkyl group. The authors[116] suggest that the reaction pathway can change depending on the reaction conditions. If the reaction is carried out in dry benzene, then the above pathway predominates; however, in the absence of a solvent it proceeds in the opposite direction. Analogous results were obtained[117] in a study of the rearrangement of ethylphenyl-*p*-tolylarsine sulphide.



The formation of thioarsinous acids was noted in the rearrangement of diethylphenylarsine sulphide under the influence of carboxylic acids[118]

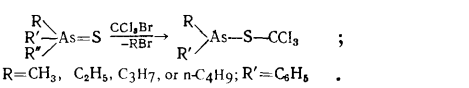
The rearrangement of dialkylarylarsine sulphides under the influence of carboxylic acid anhydrides[118] leads to the corresponding mixed anhydrides:



The reaction with carboxylic acid halides takes place similarly[118]:

The ease of reaction depends on the nature of the reactants. Compared with acid anhydrides, the corresponding acid chlorides are more reactive. The reactivity falls with increase in the length of the hydrocarbon chain. For

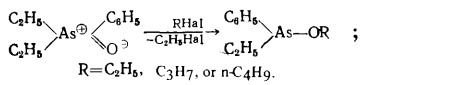
example, it has not been possible to obtain the products of the isomerisation of diethylphenylarsine sulphide under the influence of palmitoyl chloride.



The reaction of diethylphenylarsine sulphide with chloroacetic acids yields the corresponding ethylphenylthioarsinous acids [119,120]:

The rate of reaction increases with increasing number of chlorine atoms in the acid molecule.

It has been shown by differential thermal analysis [121] that the rearrangement [122-124] begins with electrophilic attack by the alkyl group on the sulphur atom. The positive charge, which has arisen on the arsenic atom via an inductive mechanism, polarises the As–C bond, which breaks when attacked by the anion. This results in the formation of the corresponding thioarsinite ester and alkyl halide. The course of the process depends on the nature of the halogen and of the hydrocarbon group.

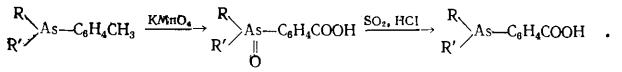


The analogous reactions of dialkylaryl- and trialkylarsine sulphides with bromotrichloromethane have been described [125]. They lead to the formation of the corresponding trichloromethyl esters of asymmetric thioarsinous acids:

It is suggested that, under mild conditions (heating of the reactants in benzene or nitromethane), the reaction proceeds via the mechanism described above, involving the electrophilic attack. The interaction of the above sulphides with bromotrichloromethane at 180°C in a sealed tube can evidently proceed also via a radical mechanism [126-128].

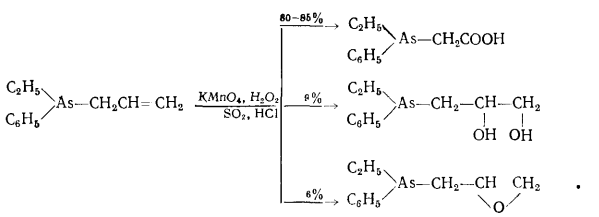
An analogous rearrangement is undergone by arsonic acid esters, for which it was first discovered [129] in 1947, and by arsine oxides [130] although it has been stated in a number of studies [131-133] that the rearrangement of oxides is more complex than that of arsine sulphides. However, in both cases the final reaction products are the corresponding esters.

It has been shown [133] that, when diethylphenylarsine oxide reacts with alkyl bromides, the corresponding esters of ethylphenylarsinous acid are formed in 70% yield:



According to the authors [133], the reaction mechanism involves the conversion of diethylphenylarsine oxide into a quasi-arsonium salt, which is then converted further into an ester of ethylphenylarsinous acid with liberation of ethyl halide. The intermediates could not be obtained in a pure form for a long time. The isolation of some of them has been reported only in the latest studies [132,133]. However, the products obtained are extremely unstable under the usual conditions. On exposure to atmospheric moisture, they are converted into oxyarsonium salts with rupture of the O–R bond.

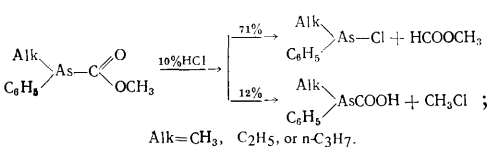
Thus it was shown in the above investigations that the reactions of tertiary arsine sulphides and oxides under the influence of electrophiles take place in the direction opposite to that of the Arbuzov rearrangement [134].



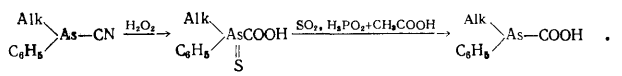
6. Arsines with Functional Groups

Organoarsenic compounds with functional groups, for example arsenic-containing acids or amines, are used in the resolution of racemic arsines with the aid of optically active components.

Asymmetric arsines of the type $RR'AsC_6H_4COOH$ have been synthesised [135-137] by oxidising the corresponding tolylarsines with aqueous $KMnO_4$ and subsequent treatment with gaseous sulphur dioxide in hydrochloric acid:

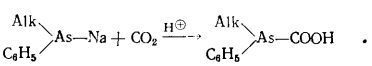


Ethylphenylarsinoacetic acid has been obtained by oxidising allylethylphenylarsine [138] with a solution of $KMnO_4$ and 26% H_2O_2 followed by reduction. This results in the formation of several side products, but ethylphenylarsinoacetic acid is obtained in a high yield:

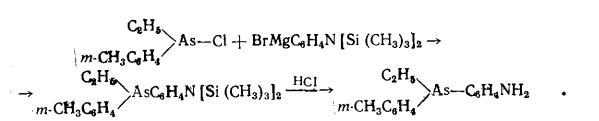


Racemic ethylphenylarsinoacetic acid was isolated from the mixture of products by repeated vacuum distillation.

Alkylarylarsinoformic acids have been obtained [139] by hydrolysing the corresponding esters and nitriles and by carbonating sodium arsenides:



Hydrolysis of methyl ethylphenylarsinoformate with 10% HCl leads to a mixture of products—a halogenoarsine and arsinoformic acid.



Hydrolysis [110] of arsinonitriles proceeds with formation of arsinoformic acid oxides, which are then reduced by sulphur dioxide to a mixture of hypophosphorus and acetic acids:

When sodium arsenides were carbonated [110], the corresponding arsinoformic acids were obtained in 75% yield:

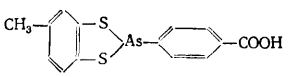
Asymmetric aminoarsines of the type $RR'AsC_6H_4NH_2$ have been synthesised with the aid of organosodium [140,141] and organomagnesium compounds [142]:

IV. STEREOCHEMISTRY OF ORGANOARSENIC COMPOUNDS

1. Configurational Stability

It was impossible for a long time to obtain stable optically active forms of phosphines and arsines. The difficulty of synthesising optically active phosphorus and arsenic compounds was explained by their low barrier to inversion[143], which apparently occurred via a planar transition state[144].

The inversion frequencies of phosphorus and arsenic hydrides were determined from spectroscopic data[145] (5×10^6 s^{-1} for PH_3, 16×10^4 s^{-1} for AsH_3, 6×10^2 s^{-1} for PD_3, and 30 s^{-1} for AsD_3). Evidently they decrease significantly with increasing mass of the substituents. This shows that the configurational stability should increase on passing to compounds with organic groups. Weston[146] calculated the temperatures at which the racemisation half-life of a number of compounds of Group V elements is 2 h. The temperatures for trimethylphosphine and trimethylarsine are 280° and 380°C respectively and the corresponding energies of the inversion barrier are 22.0 and 29.2 kcal $mole^{-1}$. These values were confirmed also by other workers. It has been shown experimentally[147,148] that, in the racemisation of methyl-n-propylphenylarsine, the inversion barrier reaches 28–30 kcal $mole^{-1}$, which indicates a fairly high configurational stability of tertiary racemisation of methyl-n-propylphenylarsine, the inversion barrier reaches 28–30 kcal $mole^{-1}$, which indicates a fairly high configurational stability of tertiary arsines in non-catalysed thermal racemisation.



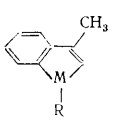
The racemisation of optically active isomers of ethylmethylphenylarsine has been investigated[149] in decalin at 217.6° ± 0.3°C. The activation energy for the inversion of these optical isomers is 42.4 ± 0.5 kcal $mole^{-1}$ at 217.6°C.

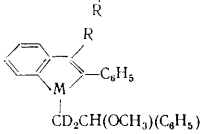
It has been shown[150–153] that, on heating at 200°C for 10 h, ethylmethylphenyl- and methylphenyl-n-propylarsines do not lose their optical activity. It has been suggested[150–153] that the calculated racemisation half-life of ethylmethylphenylarsine at 200°C is approximately 740 h. The energy required for the thermal racemisation of the above tertiary arsines should be 59.3–61.0 kcal $mole^{-1}$.

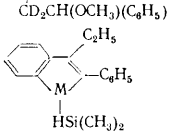
The configurational stability of optically active compounds of Group V elements depends not only on the nature of the central atom but also on the nature of the substituents and the strength of their bonds with the asymmetric atom. For example, it has been shown[154] that, on replacement of one of the three substituents in analogous trisubstitued compounds of nitrogen, phosphorus, and arsenic by groups containing arsenic, phosphorus, silicon, germanium, and tin, the inversion barrier decreases[155].

The configurational stability of arsines and analogous phosphines varies similarly as a function of structure[156] (Table 1). Consequently the electronegativity of the neighbouring heteroatom has a dominant influence on the configurational stability of the above compounds. This is confirmed by the data in Table 1, which show that an increase of the electronegativity of the heteroatom entails an increase of the energy of the barrier. The configurational stability depends also on the $p_\pi - d_\pi$ and $p_\pi - p_\pi$ conjugation of the substituents with the heteroatom[157].

Cyclic compounds of tervalent phosphorus and arsenic exhibit a high configurational stability. The optical activity of these compounds also persists on prolonged heating in non-polar solvents. For example, on heating in chloroform or ethanol, the optical activity of 2-carboxyphenyl-5-methyl-1,3-dithia-2-arsindan (VII) persists, but in an alkaline solution, the compound racemises very rapidly[158].







(VII)

According to the authors, the racemisation takes place as a result of the rupture of an As–S bond.

Table 1. Inversion barriers in tertiary arsines and phosphines[156,157].

Compound	Energy of inversion barrier, kcal $mole^{-1}$ (T, °C)	
	E = As	E = P
$(C_6H_5)(CH_3)ER$	43.1 (218)	33.3 (130)
$(C_6H_5)(CH(CH_3)_2)ESi(CH_3)_3$	25.1 (181)	18.9 (62)
$(C_6H_5)(CH(CH_3)_2)EGe(CH_3)_3$	27 (200)	21.4 (109)
$(C_6H_5)(CH(CH_3)_2)ESn(CH_3)_3$	25.9 (191)	19.3 (72)
$(C_6H_5)E(SiH)(CH_3)_2$	17.7 (49)	12.2 (42)

Table 2. Inversion barriers in cyclic arsines and phosphines[159].

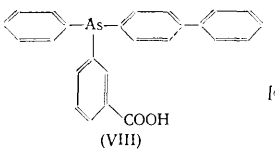
Compound	Energy of inversion barrier, kcal $mole^{-1}$ (T, °C)	
	E = As	E = P
	46.48	35.3 (130)
	35.2 (151)	23.7 (165)
	24.3 (161)	16.6 (180)

The barrier to inversion in certain phospha- and arsaindoles is also lower (Table 2) than for acyclic arsines and phosphines (Table 1).[159] The decrease of the barrier in cyclic compounds probably occurs as a result of the involvement of the free electron pair of phosphorus or arsenic in $(3p_\pi - 2p_\pi)$- or $(4p_\pi - 2p_\pi)$-cyclic delocalisation in the planar transition state.

The configurational stability of optically active phosphines and arsines depends also on the solvent. The probability of the loss of optical properties increases in polar solvents. The process can take place both with complete racemisation and with inversion of configuration.

2. Tertiary Arsines

The positive results obtained in the study of the optical isomerism of cyclic phosphorus and arsenic compounds [160-175] aroused interest in the study of the optical properties or acyclic tertiary phosphines and arsines. Stable enantiomers of the type RR'R'' E were not obtained until 1961.[176-179] They were synthesised by the electrochemical reduction of optically active phosphonium and arsonium salts at a mercury cathode.



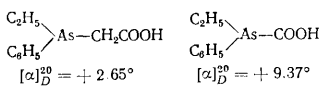
(+) or (−) (+) or (−)

E = P or As

R	R'	R''	$[\alpha]_D^{20}$
CH_3	C_2H_5	C_6H_5	+15.0°
CH_3	C_3H_7	C_6H_5	+16 8°
CH_3	C_2H_5	C_6H_5	+1.9°
CH_3	C_4H_9	C_6H_5	+12.4°

The dextro- and laevo-rotatory isomers of benzyl-n-butylmethylphosphine with the specific rotations $[\alpha]_D^{27} = 24.0°$ and $[\alpha]_D^{27} = -28.2°$ were obtained later [180]. They were synthesised by cleaving with sodium methoxide the optically active (−)- and (+)-isomers of acid benzyl-n-butyl-β-cyanoethylmethylphosphonium dibenzoyltartrates.

The next stage in the development of the stereochemistry of tertiary arsines involved the search for easier methods for the resolution of non-heterocyclic arsines. Asymmetric arsenic derivatives could not be resolved for a long time via their diastereoisomeric salts. The failure was associated with the difficulty of selecting optically active reagents and solvents as well as the appropriate conditions for the fractional crystallisation of diastereoisomeric pairs. An acyclic tervalent arsenic compound (VIII) was resolved only recently using this classical method [181]:



(VIII)

$[\alpha]_D^{20} = +8°$, $[\alpha]_D^{20} = -7°$.

The resolution of triaryl- and alkyldiaryl-arsines containing a functional group (COOH, NH_2) in the aromatic ring has been reported in a number of studies [135-137,182]. (+)-Quinine, (−)-α-phenylethylamine, morphine, and (+)-tartaric acid were used respectively as the asymmetric reagents for the separation of these compounds into optically active isomers. The diastereoisomeric salts were decomposed by treatment with an excess of H_2SO_4 and NH_4OH solutions. The specific rotations of the enantiomers were determined in benzene.

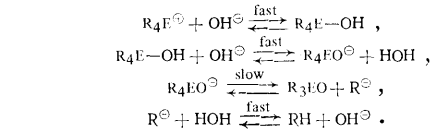
R	R'	R''	$[\alpha]_D^{20}$ (+)	$[\alpha]_D^{20}$ (−)
C_2H_5	$C_{10}H_7$-β	C_6H_4COOH-*o*	6.04°	4.94°
C_2H_5	C_6H_5	C_6H_4COOH-*n*	11.64°	5.35°
C_2H_5	C_3H_7-*n*	C_6H_4COOH-*n*	3.01°	2.12°
C_2H_5	$C_6H_4CH_3$-*o*	$C_6H_4NH_2$-*o*	2.69°	2.34°

Ethylphenylarsinoacetic [138] and arsinoformic [183] acids were resolved similarly with the aid of (−)-α-phenylethylamine and quinine.

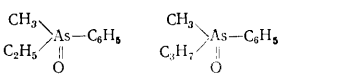
$[\alpha]_D^{20} = +2.65°$ $[\alpha]_D^{20} = +9.37°$

3. Tetracoordinate Compounds

The study of the optical properties of phosphonium [184-187] and arsonium [188-190] salts showed that most of them lose their optical rotation in polar solvents (acetone, alcohol), possibly owing to dissociation to the initial phosphines or arsines and the corresponding alkyl halides:



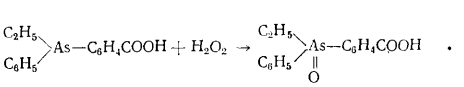
R=CH_3; R'=C_2H_5, R''=C_6H_5; R'''=$C_6H_5CH_2$; Hal=Cl, Br, or I; E = P or As.



Depending on the nature of the halogen, the rate of racemisation [191] increases in the sequence Cl < Br < I.

The results of the study of the relative configurations of phosphonium and arsonium salts are also of much interest. When optically active tertiary arsines react with alkyl halides, optically active arsonium salts with the same sign of rotation as in the initial arsines are obtained. However, the absolute value of the specific rotation of the salts is greater than that of the initial arsines. This confirms that the hydrocarbon group adds to the arsenic atom via the free electron pair with retention of its relative configuration.

In an alkaline medium optically active phosphonium and arsonium salts are converted into the corresponding oxides [192]. The stereospecific resolution of these salts consists of several stages whose stereochemical mechanism has been examined in detail [193-195]:



New ways of synthesising optically active tertiary phosphine oxides by the direct oxidation of the corresponding enantiomers have now become available [176]. However, it was for a long time impossible to obtain optically active arsenic oxides with the aid of this method. Horner and Winkler [196] reported the synthesis and a study of the enantiomers of ethylmethyl- and methyl-n-propylphenyl-arsine oxides:

$[\alpha]_D^{20} = +2.4°$ $[\alpha]_D^{20} = +6.4°$; $-18.0°$

It was found that these oxides are optically unstable and racemise rapidly. Evidently the conversion of the oxides into the racemic modification is achieved by their conversion into the hydroxide under the influence of moisture.

An attempt to obtain optically active tertiary arsine oxides by oxidising the enantiomers of aliphatic-aromatic arsines by H_2O_2 under mild conditions has been reported [197]:

However, the products obtained in this reaction did not exhibit an optical activity.

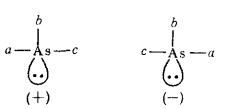
Owing to the extremely high hygroscopicity of the above oxides, they were synthesised [198] by oxidising optically active tertiary arsines with nitrogen dioxide in dry

nitromethane.

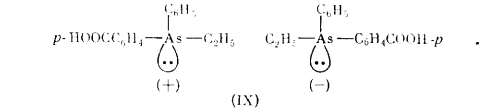
R	R′	R″	$[\alpha]_D^{20}$ (+)	$[\alpha]_D^{20}$ (−)
C_2H_5	C_3H_7-*n*	C_6H_4COOH-*p*	8.63°	7.54°
CH_3	C_6H_5	C_6H_4COOH-*p*	11.84°	9.26°
C_2H_5	C_6H_5	C_6H_4COOH-*p*	13.52°	10.92°
C_2H_5	C_6H_5	C_6H_4COOH-*o*	21.28°	23.59°

The racemisation of the oxides was studied by differential thermal analysis [193,199]. The formation of hydroxides was confirmed on the basis of the differential thermographic curves obtained in the course of the oxidation of (+)-*p*-carboxyphenylethylphenylarsine and the decrease of the specific rotation.

In contrast to their phosphorus analogues, the enantiomers of arsine oxides are optically unstable and show a tendency towards racemisation regardless of the methods and conditions of their synthesis. The rate of racemisation also depends on solvents, increasing in the sequence benzene < chloroform < nitromethane.

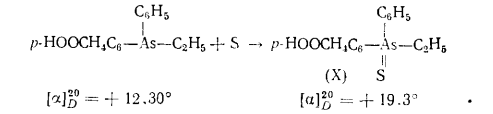


Compared with the oxides, arsenic sulphides are stable. They have been investigated by a number of workers [177,200,201], who were able to resolve them into opically active isomers via diastereoisomeric salts. A convenient method for the synthesis of sulphides, consisting in the interaction of the corresponding arsine with elemental sulphur, has been proposed by Horner and Fuchs [177]. Using this procedure, they obtained from (+)-ethylmethylphenylarsine the enantiomer of its sulphide with the same sign of rotation. Both racemic forms [202] of asymmetric arsenic sulphides [the attempt to separate them chromatographically [203] with the aid of (+)-lactose, (+)-glucose, (+)-starch, and (+)-quartz was unsuccessful] and optically active sulphides [204,205] have been obtained by this procedure.

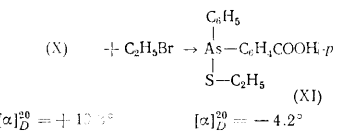


R	R′	R″	$[\alpha]_D^{20}$ (+)	$[\alpha]_D^{20}$ (−)
C_2H_5	C_3H_7-*n*	C_6H_4COOH-*p*	3.84°	4.02°
C_2H_5	C_4H_9-*n*	C_6H_4COOH-*p*	7.32°	7.73°
CH_3	C_6H_5	C_6H_4COOH-*p*	12.50°	9.31°
C_2H_5	C_6H_5	C_6H_4COOH-*p*	19.23°	16.93°

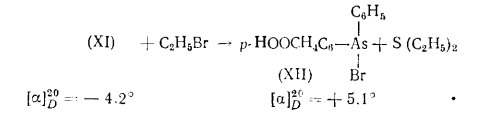
It has been shown that the addition of sulphur to arsenic takes place with retention of the sign of the rotation of the initial enantiomer. It has been established that, when the compounds obtained are heated in benzene at up to 100°C, racemisation does not occur. However, at higher temperatures slow racemisation is observed. It is probably caused by the fact that at high temperatures the enantiomers of the sulphides isomerise to the corresponding thioesters [206].



It has been suggested [207] that the (+)-enantiomer has a configuration in which the substituents are arranged in order of their decreasing polarisability in the sequence $a > b > c$. The arrangement of substituents in the opposite sequence corresponds to the (−)-enantiomer.

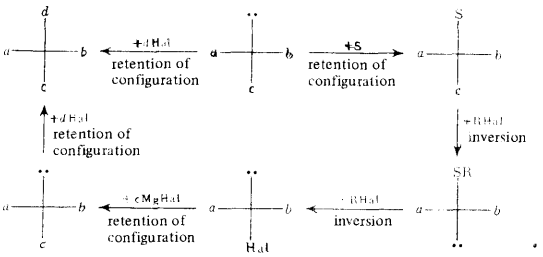


According to this scheme, the molecules of (+)- and (−)-enantiomers of *p*-carboxyphenylethylphenylarsine (IX) have the following form:



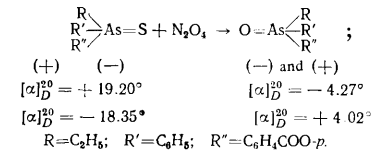
The relative configuration of (IX) has been studied [207] with the aid of the reaction of the (+)-enantiomer with sulphur:

The formation of the (+)-enantiomer of the sulphide (X) with a high specific rotation is due to the increase of the asymmetry of the entire molecule, since the reaction takes place with retention of the relative configuration of the initial product. The interaction of (+)-(X) with ethyl bromide leads to the formation of a product with the opposite sign of rotation [204]. The explanation is that the reaction proceeds via a bimolecular mechanism, involving the bonds between the asymmetric arsenic atom and two substituents. The substituents are arranged during the reaction in a sequence which is different from that obtaining before the reaction. This is accompanied by the inversion of the configuration and a change in the sign of rotation.

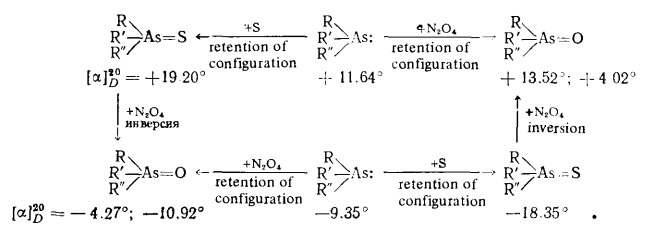


On treatment with ethyl bromide, (−)-(XI) undergoes a further transformation, which leads to the formation of dextrorotatory phenyl-*p*-carboxyphenylbromoarsine (XII) [207]:

(XII) reacts with ethylmagnesium bromide to form compound (IX) with the same sign of rotation:

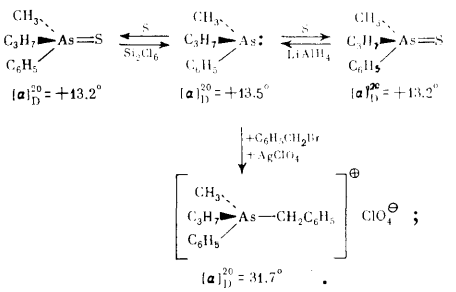


The above cycle of transformations takes place in accordance with the following scheme:

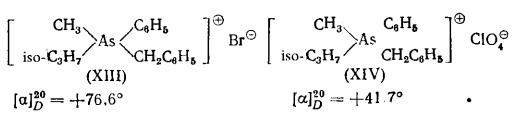


The reaction of optically active sulphides with N_2O_4 [198] in nitromethane at −15°C leads to the formation of the

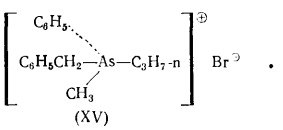
corresponding oxides with the opposite sign of rotation:



This reaction is accompanied by an inversion of configuration, which follows from the data below:



The optically active oxides of acyclic phosphines are reduced stereospecifically by hexachlorodisilane to the corresponding phosphines with inversion of configuration [208]. The reduction of methylphenyl-n-propylarsine sulphide, which has the *R* configuration, with hexachlorodisilane and lithium tetrahydroaluminate proceeds with almost complete retention of configuration at the arsenic atom [209]. The above transformations have been achieved under mild conditions in tetrahydrofuran and di-n-butyl ether.



The stereospecific transformations of the arsenic compounds under consideration are illustrated schematically below:

The absolute configuration of chiral isopropylmethylphenylarsonium salts has been determined by the method of quasi-racemates [210]. These salts have been obtained by the reaction of the corresponding diastereoisomers of acid D-(−)- and L-(+)-arsonium dibenzoyltartrates with ammonium bromide and perchlorate in methanol. This led to the isolation of dextro- and laevo-rotatory benzylisopropylmethylphenylarsonium bromide (XIII) and the dextro-rotatory perchlorate (XIV):

The dextro-rotatory benzylmethylphenyl-n-propylarsonium bromide (XV) has the *S*-configuration [211]:

However, when the n-propyl group is replaced by the isopropyl group, the molecular configuration may be inverted [210]. The fusion diagram (Fig. 1) for mixtures of enantiomers of benzylmethylphenyl-n-propylarsonium bromide (XV) with $[\alpha]_D^{20} = +33.4°$ and $[\alpha]_D^{20} = -33.0°$ shows that the enantiomers have a melting point of 188°C, while the racemate melts at 170°C; the eutectic composition is 31% of the (+)-isomer and 69% of the (−)-isomer of compound (XV).

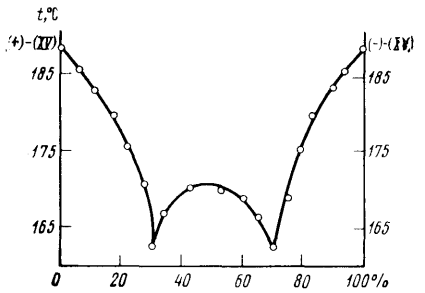


Figure 1. Fusion diagram for a mixture of enantiomers of benzylmethylphenyl-n-propylarsonium bromide (XV).

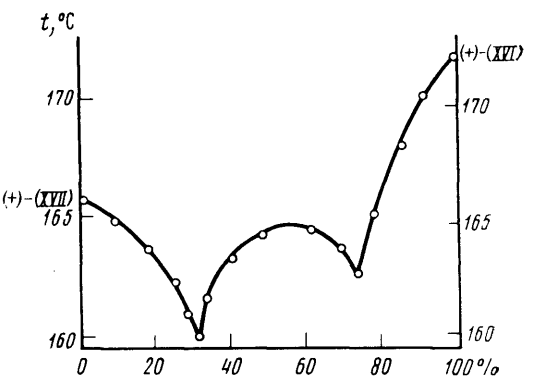

Figure 2. Fusion diagram for a mixture of (+)-(XVI) and (+)-(XVII) tetraphenylborates.

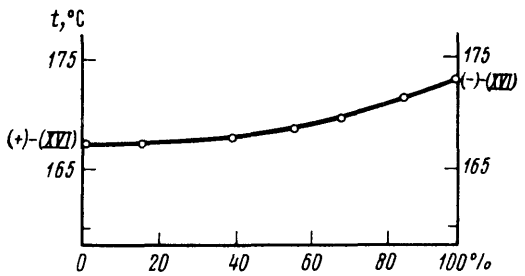
Dextro- and laevo-rotatory benzylmethylphenyl-n-propylarsonium tetraphenylborates (XVI) melt at 172°C, while (+)-benzylisopropylmethylphenylarsonium tetraphenylborate (XVII) has a melting point of 166°C. The fusion diagram (Fig. 2), obtained by combining (XVI) and (XVII) in various proportions, is characteristic of a quasi-racemate with two eutectics melting at 160° and

163°C. This phenomenon shows that the mixture components have the opposite configurations. The same conclusions can be arrived at by comparison with the fusion diagram (Fig. 3) of mixtures of the (+)- and (−)-tetraphenylborates (XVI) in various proportions.



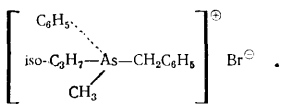


Figure 3. Fusion diagram for a mixture of (+)- and (−)-(XVI) tetraphenylborates.

The above arguments lead to the conclusion that benzylisopropylmethylphenylarsonium (XIII) has the *R*-configuration:

4. The Influence of Substituents in the Benzene Ring on the Optical Activity

It is of definite interest to establish a relation between the structure and the optical rotation of the molecule, which can be followed by introducing various substituents into the aromatic ring joined to the asymmetric atom.

The data in Table 3 show that the absolute specific rotations of *o*-, *m*-, and *p*-carboxy-, methoxycarbonyl-, bromo-, and amino-substituted arylarsines and their sulphides decrease steadily [212-217], although the change is sometimes very slight. When the optical rotations of carboxy-derivatives of arsines and their methyl esters are compared, the specific rotation of the latter is found to be higher than that of the initial arsines. This is probably associated with the increase of the asymmetry of the molecule due to the bulky ester group. The optical rotation of the sulphide is higher than that of the initial arsine enantiomers. This can also be attributed to the increase of the asymmetry of the molecule.

Presumably the change in the optical activities of the above compounds occurs in consequence of the steric influence [218,219] of the substituents on the internal rotation of the groups linked to the asymmetric arsenic atom. The process is evidently accompanied by a change in the "normal" angle of rotation of the aromatic rings. This hypothesis arose when Stuart–Briegleb models were examined. The close proximity of the carboxy-group to the arsenic atom in *ortho*-isomers retards the internal rotation of the groups about the As–C bond axis, which reduces the possibility of the rotation of the phenyl groups and can increase the optical activity of the molecule. In the *meta*-substituted compound the carboxy-group is quite remote from the asymmetric As atom, so that its influence on the attainment of a hindered conformation and the optical activity is diminished. On the other hand, the steric effects due to the presence of two phenyl groups remain, although free rotation remains possible for the ethyl group. In the molecule of the *para*-substituted compound the influence of the carboxy-group on the optical activity is reduced to a minimum, which has been confirmed by the specific rotation.

			−134	82	—	—

The possibility of the rotation of the phenyl group about the As–C bond has been studied [220] by NMR. The specimens used were compounds of tervalent arsenic of the type RR'AsCl and RR'R''As (Table 4), where R = C_6H_5, *p*- and *m*-$CH_3C_6H_4$, or *p*- and *o*-$CH_3OC_6H_4$, R' = C_2H_5, and R'' = $N(CH_3)_2$, for which the spin–lattice relaxation times T_1 and $T_{1\rho}$ were measured. The second moments of the NMR line were calculated by analysing the solid-echo signals. The measurements were made on an NMR pulse spectrometer at a frequency of 27.5 MHz in the temperature range from −190°C to +20°C.

Several relaxation regions, associated with individual forms of intramolecular motion, were observed for all the test specimens. All the arsines containing the ethyl group give rise to a minimum at $10^3 T^{-1} = 6$ on the curve relating the relaxation time to temperature, while for specimens without this group there is no such minimum. This makes it possible to assign the given relaxation region to reorientations of the ethyl group about the As–C bond. Substances containing the methoxy-group exhibit a minimum at $10^3 T^{-1} = 5.5$, which is associated with the mobility of the methoxy-group. The compound containing the dimethylamino-group has a relaxation region at $10^3 T^{-1} = 5.5$ associated with its rotation. At higher temperatures all the specimens exhibit a relaxation period T_1 associated with the mobility of the molecule as a whole. At the temperatures investigated the relaxation regions associated with the mobility of the benzene ring were not observed. The absence of a minimum on the curves for the temperature variation of T_1 and $T_{1\rho}$, corresponding to compounds with a phenyl group, may indicate a greater degree of retardation of the rotation of the aromatic rings. Consequently one can postulate that steric factors hinder the reorientation of the aromatic groups and determine their angle of rotation. This can be in turn one of the causes which determine the angle of rotation of optically active compounds.

Electrophotographic Phenomena in Linear Polymers with Saturated and Conjugated Bonds

Yu.A.Cherkasov and M.I.Cherkashin

The possibilities of varying the most important characteristics of organic polymers-electronic absorption spectra and the spectra of the quantum yield of the internal photoeffect, which to a large extent determine the limiting light sensitivity of silver-free and in the first place electrophotographic processes, are examined. The ways of increasing the quantum yield (electrophotographic sensitivity) by sensitising the internal photoeffect (spectral, structural, and injection) are analysed for linear polymers with saturated and conjugate bonds and polymeric charge-transfer complexes.
The nature of the phenomena underlying the photogeneration of free charge carriers in the class of substances under consideration is discussed. It is shown that the maximum electric fields under electrophotographic conditions ensure the attainment of the maximum quantum yield and correspondingly the maximum light sensitivity compared with other applications of organic semiconductors in photographic processes. The bibliography includes 97 references.

I. INTRODUCTION

The development of methods for the optical recording of information and of means for its storage and processing as well as coherent optics requires the development of photographic processes with new characteristics, which are frequently in principle unobtainable in classical photochemical processes (treatment in a realistic time interval, the possibility of repeated recording of information, etc. as well as economic characteristics).

One of the new photophysical processes with the required characteristics is electrophotography (EP) based on the phenomenon of the photoeffect in electrically charged high-resistance films. Organic polymeric photoconductors are a promising class of materials for the formation of EP media. The combination of thermal stability and effective mechanical and other specific properties of polymers with those of photoconductors suggests that they will be widely used in the future as a basis for the creation of new photographic processes. Polymeric photoconductors possess technically important properties such as optical transparency, capacity for forming films, flexibility, and thermoplasticity and ensure that the appropriate layers can be readily manufactured on a technological scale at a low cost. The attractive possibility of synthesising photoconductors and particularly polymers with specified properties by methods of organic chemistry also initiated a vigorous development of research on these substances.

Studies on the possibility of manufacturing EP and other silver-free layers on the basis of polymeric photoconductors are being prosecuted at the present time in the USSR, the USA, Poland, Japan, German Federal Republic, and other countries and definite successes have been achieved in this field. Information about the applications and properties of organic photoconductors which are in principle suitable for EP processes can be found in a number of publications [1-6]. We shall only note that molecular organic compounds of a wide variety of classes, particularly anthracene and its substituted derivatives, pyrene, aryl-, diaryl-, and triaryl-amines, triaylmethane dyes and their leuco-bases, tetraarylmethanes, derivatives of furan and thiophen, pyrazolines, phthalocyanines, vinyl derivatives of heterocyclic compounds, organometallic compounds, polymeric compounds, polyacetylenes, polyvinylanthracene, polyacrylamide, modified poly(vinyl chloride), polyselenomethylene, and many others are used as light sensitive media. Numerous studies have been devoted to the use in electrophotography of poly-*N*-vinylcarbazole and other polymers containing in their structure the carbazole ring system, for example, polyallylcarbazole, polypropenylcarbazole, and poly-*N*-acryloylcarbazole and their derivatives, polymers and copolymers based on 1,4-divinylcarbazole, as well as polymers based on polyvinylcarbazole with amino-, nitro-, and halogeno-substituents introduced into the aromatic ring.

However, the problem of the relation between the magnitude and spectrum of the photosensitivity, on the one hand, and the structure of polymers, on the other, and of the limiting possibilities, particularly the limiting light sensitivity of photographic processes in organic polymers, still remains obscure. Nevertheless, interest in the study of these problems is associated not only with the possibility of improving considerably the parameters of the existing silver-free photographic processes but also with the possibility of discovering new promising principles for achieving such processes. The solution of these problems involves considerable difficulties, related not only to the usually low light sensitivity of polymeric structures but also to the extremely limited number of film-forming substances which can be used to create thin homogeneous photosensitive films.

In the present review an attempt is made to examine the relation between the quantum yield of the internal photoeffect and the structure of linear polymers and to investigate the possibility of increasing the quantum yield (EP-sensitivity) by sensitising the internal photoeffect (photoconductivity). Polymers with saturated and conjugated bonds and polymeric charge-transfer complexes

are examined from this standpoint and the possibility of their structural, injection, and spectral sensitisation is analysed. The aim of the present review is not to cover fully all the existing studies; furthermore, only those publications have been selected which contain data on the molecular and supermolecular structures.

II. STRUCTURAL CHARACTERISTICS AND ELECTRONIC SPECTRA OF LINEAR POLYMERS

In contrast to the π and σ electrons localised between two nuclei in saturated systems, the π electrons in compounds with a polyconjugation system belong to the entire conjugated section of the molecule as a whole, which leads to a different distribution of molecular energy levels. A relation between the position of the absorption band and the length of the polyene system has been established[7]. Theoretical examination of the spectra of infinite polymers with a conjugated system has shown that, when the length of the conjugated section $n_c \to \infty$, the distance between the ground and excited electronic levels $\Delta E \neq 0$.[8-10] In polyenes states with alternating single and double bonds are energetically more favourable. The absence of a bathochromic shift of the spectrum with increase of the degree of polymerisation n_p can therefore indicate both that $n_c \ll n_p$ and that initially the conjugated chain length n_c is the same as n_p when the degree of polymerisation increases, after which the bathochromic shift ceases[11]. According to estimates by different workers, ΔE is in the range 0.5–2.0 eV.

1. POLYMERS WITH SATURATED CARBON–CARBON BONDS IN THE MAIN CHAIN

The electronic absorption and reflection spectra in the vacuum ultraviolet region have been studied for a wide range of light-sensitive organic polymers with different molecular structures: vinyl polymers with functional groups; copolymers based on them; vinyl polymers containing aromatic substituents in a side chain; polymers with conjugated bonds in the main chain and with aromatic substituents; polymers containing aromatic rings as elements of the main chain[12-22].

The reflection spectra of vinyl polymers with different functional groups and copolymers based on them consist of a series of overlapping bands with individual maxima for each polymer (Fig. 1*a*). The spectrum of polyacrylonitrile (curve *1*) shows distinctly a band with a broad diffuse maximum at 115–140 nm and a maximum in the region of 100 nm. The reflection spectra of copolymers based on vinyl chloride consist of two bands with maxima near 90–100 nm and 145–155 nm. The reflection spectra of polymers containing benzene rings (Fig. 1*b*) consist of two bands: a short-wavelength band in the range 50–150 nm and a long-wavelength band in the range 150–250 nm. The band structure is specific to each polymer, but all the spectra show maxima near 195 and 90–100 nm. A decrease of temperature to 170 K (Fig. 1*a*) leads to the splitting of the maxima and a narrowing of the bands[13]. Thus maxima at 110, 137, 150, 184, and 210 nm are clearly seen for polyacrylonitrile; when the temperature is reduced, each of the two maxima of poly(vinyl chloride) is apparently split in two: the first has peaks at 97 and 110 nm and the second at 125 and 143 nm and a new maximum appears at 210 nm.

It has been shown[15] in relation to polystyrene that the reflection and absorption spectra in the vacuum ultraviolet region coincide. In relation to the absorption spectra of polymers with saturated bonds, the molecular exciton theory, based on the hypothesis that the bonds in the ground state do not interact and that there is a dipole–dipole interaction between them on excitation, predict a quasi-continuum[23]. The presence of absorption bands with distinct maxima in the spectra, the high photoconductivity quantum yield, reaching unity[24], and the correspondence between the positions of the absorption maxima in the spectral region associated with the ionisation of the monomeric unit [115 nm for poly(vinyl chloride) and 104 and 127 nm for polyacrylonitrile][25] makes it possible to relate the nature of the absorption by these polymers to the ionisation of the corresponding monomeric unit.

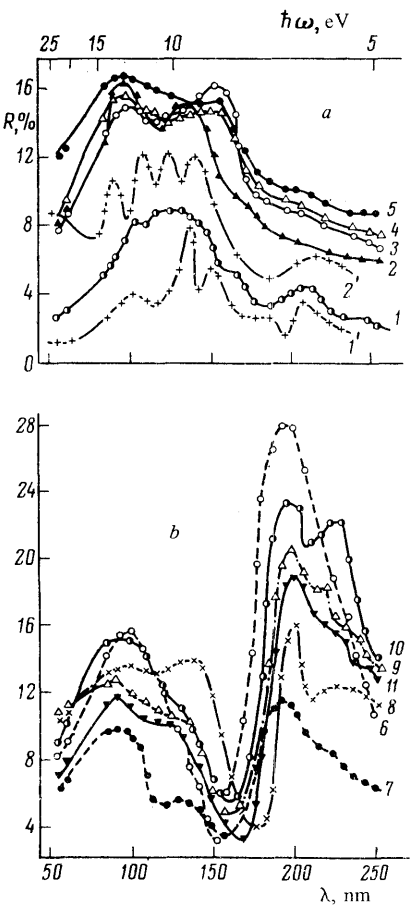

Figure 1. The reflection spectra of organic polymers with functional groups (*a*) and benzene rings (*b*)[13,14]: 1) polyacrylonitrile; 2) poly(vinyl chloride) [1^1) and 2^1) at 170 K]; vinyl chloride–vinylidene chloride copolymer; 4) vinyl chloride–vinyl acetate copolymer; 5) vinyl chloride–methacrylate copolymer; 6) polystyrene; 7) styrene–acrylonitrile copolymer; 8) styrene–2-ethylhexyl acrylate copolymer; 9) polytolane; 10) styrene–polytolane copolymer; 11) polycarbonate.

The presence in the reflection spectra of polymers containing benzene rings of maxima at 195 and 90–100 nm, characteristic of the excitation (195 nm) and ionisation (95 nm) [25] of benzene, suggest that the mechanism of light absorption by these polymers is determined by the properties of the benzene ring. Indeed the electron density of the monomer unit may shift towards the benzene ring in polymers containing benzene rings as elements of the main chain or side groups [26]. The nature of the absorption spectra of such polymers is then apparently determined by the properties of the benzene ring perturbed by the remaining atoms of the monomeric unit. In the 180–250 nm region of the spectrum (long-wavelength band), the π electrons of the benzene ring are responsible for the absorption [27], while in the short-wavelength region two excitation mechanisms probably operate: based on the π electrons and σ electrons of the bonds in the benzene ring. The latter process may be accompanied by the abstraction of a proton, since the energy of the C_6H_5–H δ bond is 12.6 eV (98 nm). [25]

The the absorption spectrum of vinyl polymers with different functional groups in the region 5–23.1 eV is determined by the properties of the monomeric unit and not the isolated bonds. The absorption spectra of polymers containing benzene rings either in the main chain or as side groups are determined by the properties of the benzene ring perturbed by the remaining atoms in the monomeric unit.

The low-temperature effect involving an "enhancement of the structure" of the absorption spectra [13] is associated with the vibrational excitation processes involving the molecules of a solid having a molecular structure. This effect can probably serve as direct proof of the significant role of vibrational excitation in making the structure of the energy spectra of photoelectrons less definite at 293 K for a number of aromatic crystals in the range 6–14.5 eV, which was observed by Zagrubskii and Vilesov [28]. The diffuse nature of the photoelectron spectra (this is also pointed out by Zagrubskii and Vilesov [28]) cannot serve as adequate evidence for the presence in the organic semiconductors of broad filled bands. Although Geacintov and Pope [29] showed by an analysis of literature data that the theory developed for indirect transitions in inorganic substances [30,31] is applicable to organic solids with a molecular structure (anthracene, tetracene), the idea of a continuous distribution of electrons with respect to energies in a molecular crystal is physically unjustified. The low mobility of charge carriers and the agreement between the absorption spectra of the crystal and the free molecule shows that the energy bands in these substances are very narrow [30–33].

On excitation with ultraviolet radiation, polymers of the vinyl series exhibit a universal luminescence in the range 70–400 nm, which depends strongly on the chemical structure, the degree of polymerisation, the degree of cross-linking of the polymer chains, the state of aggregation, and temperature, while on excitation with vacuum ultraviolet radiation the luminescence quantum yield depends on the wavelength of the exciting radiation [19,34–40].

2. POLYMERS WITH CONJUGATED CARBON–CARBON BONDS IN THE MAIN CHAIN

Since the chain in the polymer is non-planar and the degree of overlap of the π-electron orbitals depends on the angle of rotation about a single bond, it follows that, in all cases where the size of the conjugation block or the degree of conjugation in the block n_c are considered and compared with planar polyene reference systems, one is dealing with an effective conjugation where the size of the conjugation region n_c is not equal to the number of units in the block n_p. The effective conjugation is usually determined by comparing the positions of the maxima in the optical spectra of the polymer investigated and reference systems having a planar polyene chain [11].

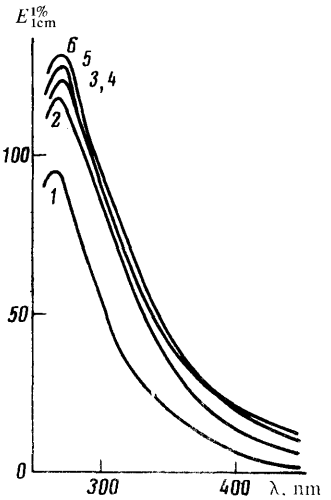

Figure 2. Absorption spectra of polychlorocyclopentene (solution in benzene) [11] for different molecular weights: 1) 450; 2) 1075; 3) 2450; 4) 3000; 5) 3660; 6) 4220 ($E^{1\%}_{1\,cm}$ optical density of 1% solutions for a cuvette 1 cm thick).

(a) Polymers with Double Bonds (Polyene Chain)

Poly-3-chlorocyclopent-1-ene (PCCP). An increase of the molecular weight (M) of the low-molecular-weight fraction entails an increase in the absorption intensity in the long-wavelength part of the spectrum [11] (Fig.2). The spectra of molecular fractions are very similar and the position of the maximum (270–274 nm) does not change from fraction to fraction and shows that small conjugated regions, embracing three units of the micromolecule (there are sections containing up to seven double bonds) predominate.

(b) Polymers with Aromatic Substituents [11]

Polyphenylacetylene, whose structure contains polymeric aromatic PPAT-150 conjugation blocks (phenylacetylene polymer obtained at 150°C) together with polyene units, has conjugation regions with an average length n_c, which is not the same as the length of the molecule and is smaller than the length of the lowest-molecular-weight fraction, i.e. $n_c \leq n_p = 8$. Treatment of PPAT-150 at 300°C (PPAT-150-300) results in an increase of absorption, although the molecular weight of the polymer

decreases (Fig. 3*a*). Comparison of the spectra of the PPAT-150 and PPAT-150-300 fractions leads to the conclusion that the average lengths of the conjugation regions in these polymers is smaller than the length of the units of the lowest-molecular-weight fraction, i.e. $n_C \leq 5$. Since the extinction coefficient ϵ is related to the optical density by the expression $\epsilon = E^{1\%}_{1\,cm} \times M/10$, where M is the molecular weight and $E^{1\%}_{1\,cm}$ the optical density of 1% solutions for an optical path length in the cuvette of 1 cm, it is found to be proportional to M of the fraction at the same wavelengths and the number of absorbing centres increases with increase of M of the polymer. The dimensions of the absorbing centre incorporate a region smaller than the length of the polymer chain.

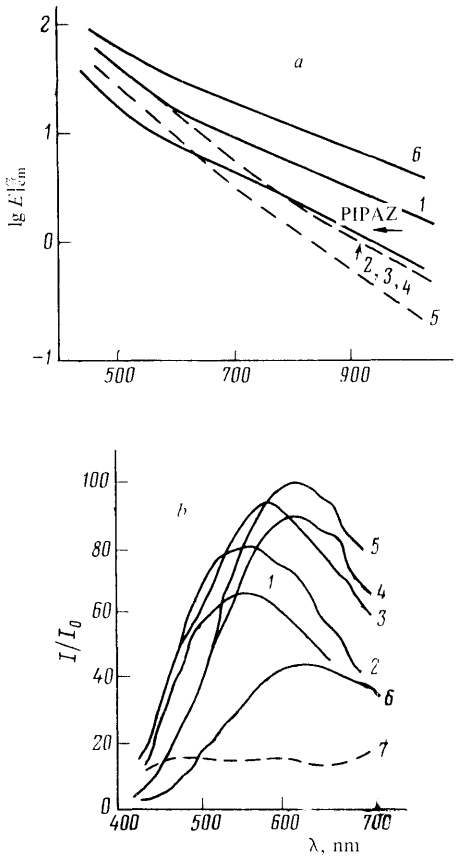

Figure 3. Absorption (*a*) and luminescence (*b*) spectra of polyphenylacetylene [11]: *a*) [1) PPAT-150 (790); 1′) PPAT-150 (1370); 2) PPAT-150-300 (500), PPAZ (2900); 3′) PPAZ-760; 4) PPAT-300 (760); 5) PPAT-400 (300); 6) PPAT-150-400 (650)]; *b*) [1) PPAT-150 (1060); 2) PPAT-150 (1590); 3) PPAT-150 (800); 4) PPAT-150 (1310); 5) PPAT-150 (1340); 6) PPAT-150 (1510); 7) PPAT-150 (2160); 8) PPAT-150 (1200); 9) PPAZ (1020); 10) PPAZ (2900); 11) PPAZ (5300); 12) PPAZ (7600)]. Here and henceforth the numbers in round brackets are the molecular weights M and the numbers in front of the brackets represent the polymerisation or heat treatment temperature (°C). The luminescence spectra are given in relative equienergetic units (I/I_0).

The average length of the PPAZ conjugation region [phenylacetylene polymer obtained in the presence of the $(C_2H_5)_3AlTiCl_3$ catalyst] proves to be greater than for PPAT-150 and PPAT-150-300, but smaller than for PPAT-300. Despite the fact that the average number of polymer units in PPAZ is 70–80, the average length of the conjugation region does not exceed the length of the conjugation region in PPAT-300, i.e. $n_C < 8$. Since the absorption of PPAZ is weaker than that of PPAT-300, it is difficult to suppose that the absence of a bathochromic shift of the PPAZ absorption spectrum is associated with the attainment of the equality $n_C - n_p$. PPAC apparently consists of individual short conjugation regions [11]. The spectra of the PPAT-150-400 fractions have a different form. Here there is a distinct increase of absorption intensity in the long-wavelength region with increase of M of the polymer. The increase of absorption intensity in the region of long wavelengths with increase of the temperature of the synthesis or heat treatment corresponds to the formation of longer conjugation regions. At the same time the average length of the polymer chain decreases. The average length of the conjugation region in PPAT-150-400 now includes the entire macromolecule. The value of M shows that PPAT-150-400 cannot have a value of n_C greater than 3–7. Comparison with the spectra of polyenes shows that the average length of the conjugation region does not exceed 5–6 for PPAT and 7–8 for PPAZ.

The luminescence spectra of PPAT [11] consist of a family of similar curves whose maxima are located at similar wavelengths (580–660 nm) with certain differences in the structure and intensity of the lines (Fig. 3*b*). It had been established earlier that similar changes in the spectra, characterised by a redistribution of the intensities in their fine structure, are observed when M (chain length) and polymer structure are altered, being particularly pronounced for chain molecules with a conjugation system [41]. Hence it follows that identical, within certain limits, positions of the maxima in the luminescence spectra are characterised by the same effective conjugation n_C. Assuming that the positions of the maxima in the luminescence spectra of PPAT and polyene chains are the same, one can conclude that the PPAT-150 fractions contain conjugation blocks with $n_C = 5–6$. This follows from a comparison of the PPAT spectra with the spectra of diphenylpolyenes both in solution and in the solid state. The average position of the maximum in the luminescence spectra of the PPAT-150 fractions is at ~620 nm, i.e. in the region between the maxima of diphenylhexatriene (530 nm) and diphenyloctatetraene (670 nm). One can therefore suppose that the conjugated chains of the PPAT-150 fraction have luminescence characteristics identical with those of a compound having intermediate properties.

The fact that the spectra of different fractions have different structures with some variation in the position of the maximum (which should not happen if the continuous conjugation sections contain identical numbers of units) confirms that the fractions contain in their chains different combinations consisting mainly of blocks with $n_C = 5$ and 6. The luminescence spectra of such polymer chains, in which regions with the larger value of n_C predominate in the solid state, should exhibit a lower intensity and the band maxima should be displaced towards longer wavelengths as a result of a redistribution of intensities in the individual bands of the fine structure of the spectrum. When regions with the lower value of n_C predominate, the opposite rearrangement of the structure of the absorption spectrum should occur. The statistical contribution of

regions with $n_C < 6$ and $n_C < 5$ is very insignificant: they are not observed in the spectra. Conjugation regions with $n_C > 6$ cannot actually be manifested in the spectrum owing to the low intensity of their luminescence in the solid polymer and the small number of such regions. On the other hand, regions with $n_C = 4$, the luminescence intensity of which in the solid state exceeds that observed for the conjugated regions with $n_C = 5$ by a factor of ~10, should appreciably increase the luminescence intensity of the spectrum in the region of 440 nm even when their content in the chain is low. However, the luminescence of the polymer in this region is insignificant, so that one may conclude that the number of conjugate regions with $n_C = 4$ in the overall balance is extremely small. The spectra of the PPAT fractions 6 and 8 (Fig. 3) characterise chains made up of individual conjugated regions with $n_C = 5$ and 6. In terms of the relative luminescence yields of these regions, their ratio in the above fractions can be estimated as 1 : 7.

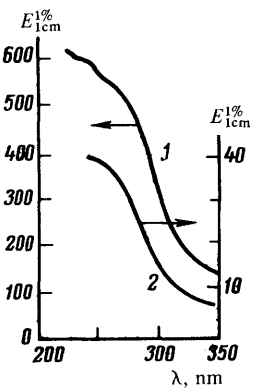

Figure 4. Absorption spectra of polymethylethynylpyridine (curve *1*) and polyphenylacetylene (curve *2*).[11]

With increase of M, the maximum in the luminescence spectra of PPAZ is steadily displaced towards longer wavelengths and the intensity falls sharply[11,41,42]. This change in the spectrum shows that M and the conjugation increase in parallel. PPAZ differs markedly from PPAT by a higher molecular weight M and a more extensive continuous conjugation. Analysis of the spectra shows that the chains in all the fractions of this polymer consist of different combinations of regions with $n_C = 6$–9. The markedly diffuse nature of the maxima in the spectra of all the fractions indicates a broad statistical distribution in terms of the extent of conjugation. All the fractions should therefore contain the regions with all the continuous conjugations enumerated above in the appropriate proportions. The PPAZ fraction 5 contains predominantly regions with $n_C = 6$ and 7, conjugation regions with $n_C = 7$ predominate in the PPAZ fraction 6, while regions with $n_C = 8$ predominate in the PPAZ fraction 8.

Polymethylethynylpyridine (PMEP) [11] does not differ from PPAT as regards the principle underlying the structure of the macrochain and the earlier conclusions are valid also for it. The electronic spectra of PMEP and PPAT (Fig. 4) do not show significant differences, particularly in the region of 300 nm, and consist of curves without appreciable maxima, which decrease in the direction of longer wavelengths; the absorption in the visible region is insignificant. It appears that the continuous conjugation extends to regions with $n_C = 3$–5.

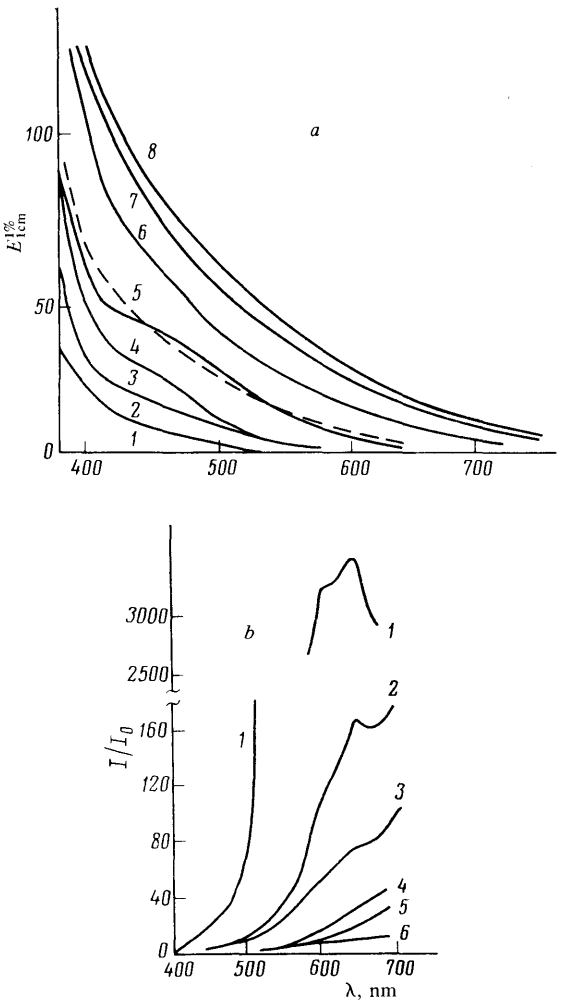

Figure 5. Absorptions (*a*) and luminescence (*b*) spectra of polydiphenylacetylene [11]: *a*) [1) 400 (406); 2) 300 (675); 3) 300 (830); 4) 300 (920); 5) 350 (1060); 6) 400 (860); 7) 400 (950); 8) 400 (660)]; *b*) [1) 300 (850); 2) 300 (850); 3) 350 (1060); 4) 400 (660); 5) 400 (930); 6) 400 (1200)].

(c) Polymers with Two Aromatic Substituents

Polydiphenylacetylene (PDPA) consists of a linear polymer whose structure contains a system of conjugated bonds and aromatic side groups which stabilise the main polyene chain of the macromolecule[43]; the end groups consist of hydrogen atoms. An increase of M induces a bathochromic shift of the absorption band (Fig. 5*a*), i.e. the length of the conjugation region is comparable to the

length of the macromolecular chain. However, an increase of polymerisation temperature causes an even greater shift for the same value of M (curves 6 and 9), which is apparently due to the inclusion of benzene rings in the conjugation chain.

The luminescence spectra of PDPA [11,44] (Fig. 5*b*) are analogous to those of PPAT and PPAZ. The position of the PDPA-300 (polymer obtained at 300°C) luminescence maximum shows that these polymers are characterised by $n_C = 6$ with some proportion of regions with $n_C = 7$ and an insignificant content of regions with $n_C = 5$. Since PDPA-300-6 and PDPA-300-10 (polymerisation times 6 and 10 h respectively) have molecular weights of 850 and 930 respectively, while $M = 180$ for the monomeric unit, the PDPA-300-6 chains are continuously conjugated over the entire length of the system; the benzene rings are then included in the conjugation chain. The high intensity of the luminescence of PDPA-300-6 is comparable to the intensity of the luminescence of special technical phosphors.

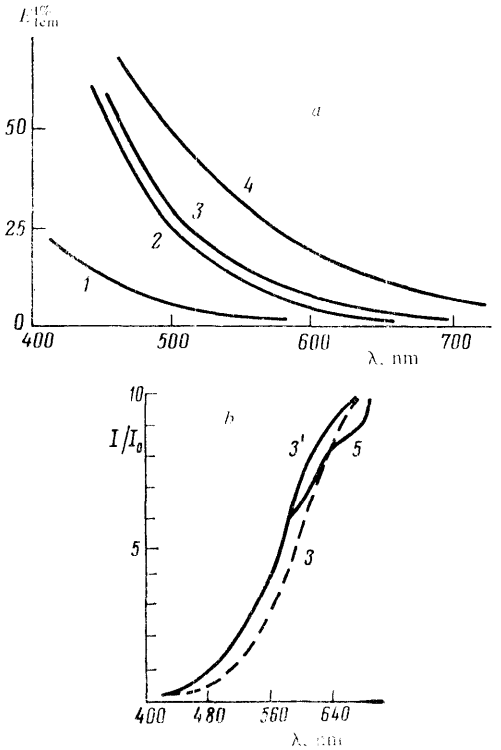

Figure 6. Absorption (*a*) and luminescence (*b*) spectra of polydiphenylbutadiyne [11]: *a*) [1) (1080); 2) (1450); 3) (3500); 4) product of the heat treatment of the non-fractionated polymer at 400°C ($M = 2100$)]; *b*) [3) (940); 3′) (2000); 5) (2120)].

(d) Polymers with a Binary Conjugation System (Acene Structures) [11,44]

Polydiphenylbutadiyne (PDPB). A change in M by a factor greater than 2 (from 1450 to 3500) does not entail a significant change in the spectrum (Fig. 6*a*). On this basis, it is suggested that the degree of continuous conjugation n_C in PDPB is constant and does not agree with the length of the macromolecule. Heat treatment of the polymer at 400°C is accompanied by an appreciable increase of absorption intensity in the long-wavelength region of the spectrum. The increase of the conjugation block on heat treatment can be associated primarily with the additional cyclisation of the polyene fragments. Furthermore, heat treatment promotes a coplanar arrangement of sections of the macromolecule which had been rotated in different ways prior to this and also a decrease of strain within the cyclic regions of the chain and the inclusion in the conjugation chain of some of the benzene rings in the side groups. However, within certain limits the positions of the bands in the luminescence spectra characterise the same values $n_C = 6$ and 7 (Fig. 6*b*).

Optically homogeneous films can be obtained from PDPB by vacuum vaporisation [44]. In a vacuum of 10^{-5}–10^{-6} mmHg at a melt temperature of 500°C, a rate of deposition of the layer not exceeding 0.05 μm min^{-1}, and a temperature of the surface (support) in which the vapour is condensed up to 450°C, optically homogeneous layers are obtained, greatly exceeding in terms of this parameter layers prepared by casting from solution [44]. Vacuum sputtering increases appreciably the optical density of the layer compared with the layers obtained from solution (Fig. 7). A determination of the average molecular weight of the PPAZ decomposition products [45] suggests that the PDPB molecule is broken up during vacuum sputtering at the weakest sites in the chain into blocks consisting of several units.

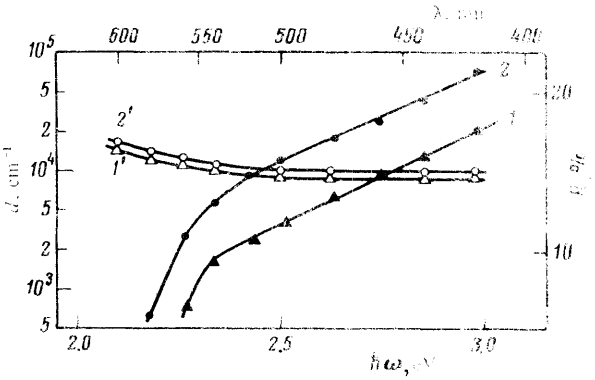

Figure 7. Absorption (curves 1 and 2) and reflection (curves 1′ and 2′) spectra of polydiphenylbutadiyne films obtained from solution (curves 1 and 1′) and by evaporation in a high vacuum (curves 2 and 2′). [44]

Poly-β-iodophenylacetylene. β-Iodophenylacetylene polymers obtained by thermal polymerisation (PIPAT) and polymerisation in the presence of Ziegler–Natta catalysts (PIPAZ) exhibit an appreciable absorption in the visible and ultraviolet regions characteristic of conjugated systems [11] (Fig. 8*a*). In the red and near infrared regions the absorption of PIPAT is stronger than that of PIPAZ. In the blue-violet region their absorptions are approximately the same. There is no structure whatever in the spectrum and the latter is markedly diffuse.

The continuous conjugation extends over regions which are small compared with the length of the molecule. The low value of $E^{1\%}_{1\,cm}$ shows that the fraction of molecules with long conjugation regions is small.

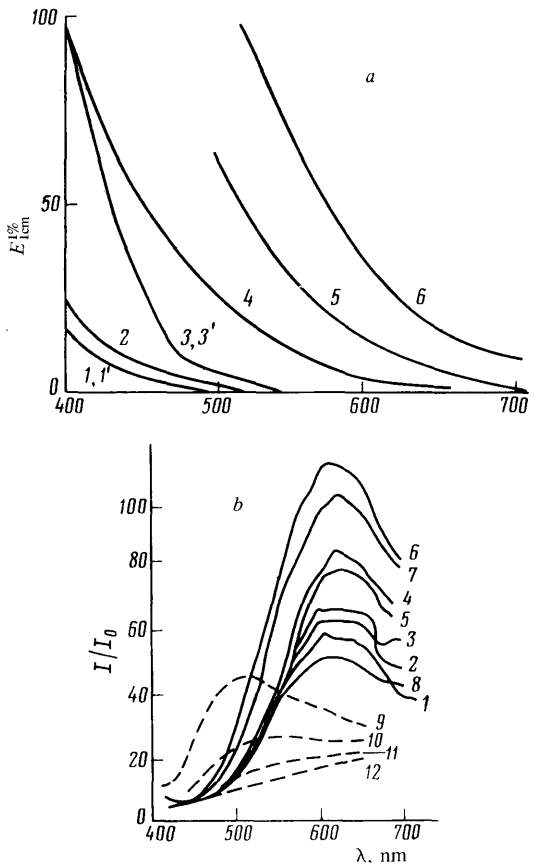

Figure 8. Absorption (*a*) and luminescence (*b*) spectra of polyiodophenylacetylene[11]: 1) (1300); 2) (1000); 3) (1770); 4) (2200); 5) (870); 6) (2400); 7) iodophenylacetylene (IPA) dimer with M = 456, PIPAZ (1680).

Bearing in mind that the different substitutions of side groups by other groups in simple carbon–carbon chains leads to an alteration of the structure of the spectra the extent of which is much smaller than the change in the position of the maximum caused by the difference in the degree of continuous conjugation in the chain[41], and despite the possible influence of iodine, one can estimate approximately the structure of the chains. Thus fractions *1* and *2* contain blocks with n_C = 6 and n_C = 6 and 7 respectively; fraction *3* contains regions with n_C = 7 and to a small extent n_C = 6; fractions *4* and *6* consist predominantly of regions with n_C = 7 and 8. Comparison of the molecular weights and the sizes of the conjugation region shows that in this instance continuous conjugation does not apparently embrace the entire macromolecule and individual conjugation blocks exist.

3. POLYMERS WITH CONJUGATED CARBON–NITROGEN BONDS IN THE MAIN CHAIN

Polymers with conjugated carbon–nitrogen multiple bonds, the so-called poly-Schiff bases[45,47], are organic polymers which contain in the main chains systems of conjugated >C=C< and >C=N– bonds as well as nitrogen atoms containing in the outer energy level electrons which are not involved in chemical binding. Poly-Schiff bases are synthesised[48,49] by the polycondensation of diamines (*p*-phenylenediamine, *m*-phenylenediamine, and benzidine) with dicarbonyl compounds (benzil) using an excess of one of the bifunctional compounds.

The influence of the molecular and supermolecular structures on the optical and photoelectric properties was studied for three types of compounds: (I) initial poly-Schiff bases; (II) hydrogenated polymers; (III) block-copolymers[50].

The initial polymers, obtained from *p*-phenylenediamine and benzil using an excess of the diamine or benzil, from *m*-phenylenediamine and benzil, and from benzidine and benzil, consist of coloured powders. The hydrogenated polymers are amorphous powders with a lighter colour than the corresponding initial polymers. The absence of degradation in the course of hydrogenation was confirmed by measurements of the molecular weights of the polymers and by infrared spectroscopy. The softening temperature of the hydrogenated polymers is reduced and their solubility is improved somewhat. The block-copolymers can be divided into two groups[48,49]. The first group includes products of the combination of dicarbonyl polyconjugated blocks with diamines. These copolymers have a lighter colour and are more soluble in dimethylformamide than the initial polymers. The comparatively low viscosities, high softening temperatures, and low solubilities of the products of the coupling of the blocks to one another are apparently due to the strong interaction between the polyconjugated blocks of different chains and the limited mobility of the blocks when they are incorporated in a polymer chain[51]. The second group of block copolymers are products of the coupling of polyconjugated blocks containing terminal amino-groups to flexible poly(ethylene glycol) blocks. With increase of the length of the flexible block, the interaction between flexible blocks and between polyconjugated blocks diminishes in this group. It is noteworthy that, by virtue of the above factors, those copolymers lose their capacity for crystallisation (they are amorphous).

In molecules with conjugated bonds containing heteroatoms, the lone electron pair of nitrogen is conjugated with the π electrons of the conjugated bond[46] and this so-called n,π conjugation, which influences the molecular geometry, obtains in addition to the π,π conjugation. The polyconjugated systems considered do not therefore constitute a single conjugation system and are made up of a collection of sections with delocalisation of electron density. The weakening of the delocalisation of electrons along the conjugation chain can occur as a result of the displacement of the system from coplanarity, the introduction of a benzidine group and *meta*-substituted benzene rings, and hydrogenation. This result is confirmed by the nature of the electronic absorption spectra. Thus the spectra (Fig. 9, curves *4–6*) clearly reveal the disappearance on hydrogenation of the long-wavelength maxima corresponding to the conjugation system (the signal characteristic of polymers with a conjugation system disappears from the EPR spectra of the hydrogenated polymers). An increase of molecular weight also weakens the

delocalisation of electrons. In the series of polymers with M = 600, 1000, and 1330 (Fig. 9) the maximum is displaced towards shorter wavelengths, from 372 to 350 nm, which indicates the occurrence of this effect.

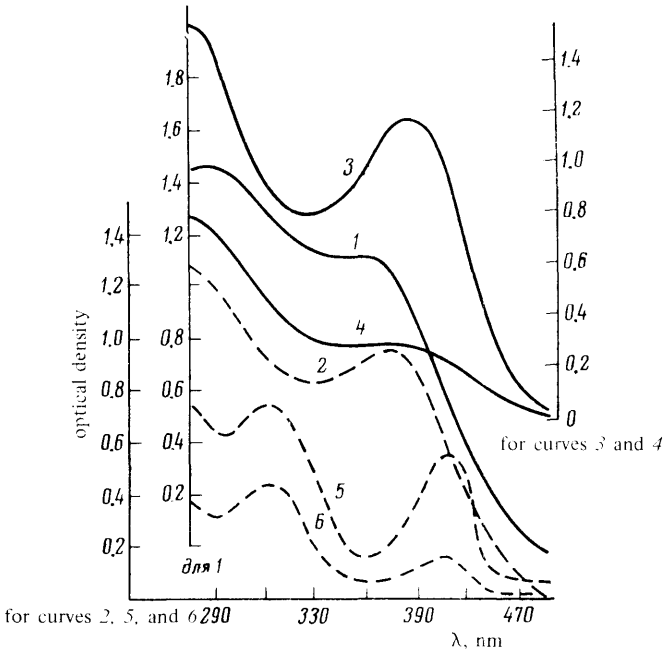

Figure 9. Absorption spectra of poly-Schiff bases with different molecular weights [1) 1330; 2) 1000; 3) 600] and hydrogenated specimens (curves 4–6).[50]

4. POLYMERIC CHARGE-TRANSFER COMPLEXES

Polymeric charge-transfer complexes (CTC) have been recently examined in a review[2]. In CTC the generation of photocarriers is associated with charge transfer from the donor to the acceptor in the molecules of the complex, accompanied by the liberation of the charge-transfer energy $E_{ct} = I - E_A - E_c$, where I is the ionisation potential of the donor, E_A the electron affinity of the acceptor, and E_c the energy of the Coulombic interaction between the ions A and D.[52] The generation of the charge carrier can be described by the following equation:

$$(D \ldots A \leftrightarrow D^+ \ldots A^-) \overset{h\omega, ct}{\rightleftarrows} (D^+ \ldots A^- \leftrightarrow D \ldots A),$$

so that in the excited state the equilibrium is displaced towards the ionic form.

To a first approximation photoexcitation (or the charge-transfer energy) depends on the two quantities I and E_A and, when I = const., E_{ct} can be reduced as a result of an increase of E_A, which is equivalent to a bathochromic shift of the absorption band[53,54]. It is noteworthy that in the general case there is no correlation between the electron affinity of the acceptor in polyvinylcarbazole (PVC) complexes and the photoconductivity of the CTC for acceptors of different classes. Such correlation occurs only for acceptors with similar π-electron clouds and the relative dimensions of the donor and the acceptor can apparently play an appreciable role in this process[55–57].

(a) The Similarity of the Electronic Natures of Organic High- and Low-Molecular-Weight Photoconductors

In polymers with a conjugation system, for example in PPA, PDPA, PDPB, etc., continuous conjugation does not embrace the entire macromolecule and consists of individual conjugation sections (blocks), so that the size of the macromolecule greatly exceeds the size of the average conjugation block. The conjugation between blocks is to a large extent weakened owing to their non-coplanarity. The mechanism of the formation of conjugation blocks in the polymerisation of compounds of the acetylene series is associated with the dependence of the electronic transition energy ΔE_π on the number of π electrons.[11] Fig. 10 illustrates the dependence of ΔE_π on the number of π electrons (N_π) for α,ω-diphenylpolyenes and polyacenes.[58] Whereas in α,ω-diphenylpolyenes containing conjugated double bonds there is a tendency towards a limit and, when $n > 5$, the quantity $\Delta E \to 2.5$ eV [$\Delta E = 2.5$ for the system R(–HC=CH–)$_n$R, where R = CH_3 and $n = 15$ [58]], in acene systems with a slight alternation of bonds ΔE_π decreases fairly rapidly with increase of N_π and there is only a slight tendency towards a limit. The results obtained from electronic absorption spectra are confirmed by theoretical calculations by the Hückel method. For α,ω-dimethylpolyenes containing conjugated double bonds, the calculated limiting value is $\Delta E = 2.25$ eV.[59]

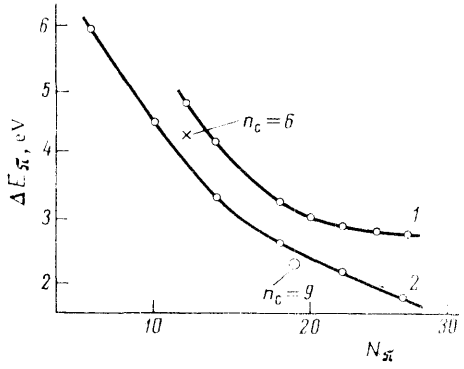

Figure 10. Dependence of the electronic transition energy ΔE_π on the number of π electrons for α,ω-diphenylpolyenes (curve 1) and acenes (curve 2). The crosses represent the activation energies for conduction in polymers with different conjugation blocks: $n_c = 6$ for PPAT, $n_c = 9$ for PPAZ and PDPB.[11]

Thus experimental data and quantum-chemical calculations show that the energy gain in diphenylpolyenes in the optical transition changes insignificantly on successive increase of the conjugation blocks and gradually tends to zero when ΔE_π approaches 2.5 eV. For definite value of

n, a non-coplanar addition of the $(n + 1)$th unit is thermodynamically favourable, which leads to the formation of a new conjugation block non-coplanar with the preceding block. Analogous conclusions are valid for acene structures.

The data examined above suggest that the extent of π conjugation necessary for specific properties of polyconjugated polymers, including photoconductivity, does not exceed the extent of conjugation in low-molecular-weight organic compounds and the electronic structures of organic high- and low-molecular-weight substances are therefore the same.

III. STRUCTURAL SENSITISATION OF THE ELECTROPHOTOGRAPHIC RESPONSE

Electrophotography (EP) is based on the possibility of the formation in the material, when the latter is charged, of an electrical double layer made up of the surface charge and the shielding charge arising in the bulk phase or the conducting base, with subsequent local modulation of its power (the product of the charge density and the thickness of the double layer) as a result of photoconductivity. The drift of the charge carriers generated by light in the electric field of the double layer leads to the neutralisation of the surface charge or to a decrease of the thickness of the double layer.

The study of the problem of the non-photoactive absorption in molecular (polymeric) photoconductors under EP conditions led to the observation of the phenomenon of the so-called structural sensitisation of the photoeffect[60]. The phenomenon consists in the dependence of the spectrum and the quantum yield of the internal photoeffect on the molecular and supermolecular structures of the photoconductor. The nature of the molecular and supermolecular structures determines the probability of the generation of free charge carriers from the first bound state on absorption of a light quantum.

We shall consider this phenomenon in greater detail for polymeric photoconductors of different classes.

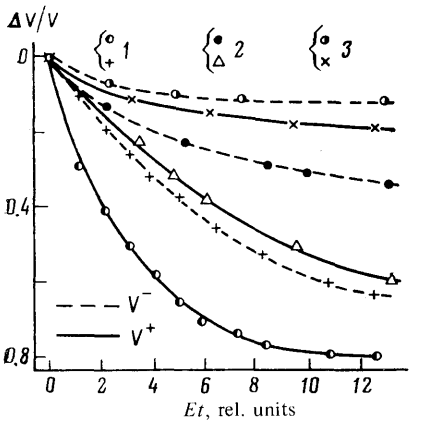

Figure 11. Monochromatic curves for the photodischarge of polystyrene EP layers (0.3 μm) [61]; λ (nm): 1) 115; 2) 147; 3) 180; Et = degree of illumination (relative units).

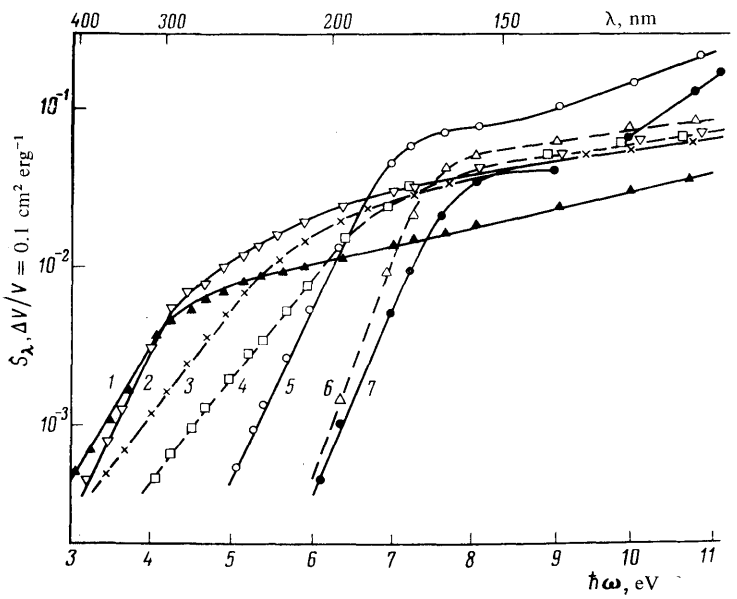

Figure 12. EP sensitivity spectra of polymer layers with saturated and conjugated bonds in the main chain constituting the basis of a catalogue of EP layers with a variable long-wavelength light sensitivity limit[61-64]: 1) polydiphenylbutadiyne; 2) polyvinylcarbazole; 3) polyphenylacetylene; 4) polyethylene; 5) polyacrylonitrile; poly(vinyl chloride); 7) polystyrene.

1. POLYMERS WITH SATURATED CARBON–CARBON BONDS

Among studies on the photoconductivity of polymers of the vinyl series with various functional groups[60-78], those devoted to the intrinsic photoconductivity occupy a special place. The phenomenon of the intrinsic photoconductivity of vinyl polymers in the vacuum ultraviolet region of the spectrum was observed in 1968 independently by two groups of investigators and was examined in two corresponding series of studies by Cherkasov and coworkers[60-65] and Ofran and coworkers[72-74].

Quantitative studies on the EP sensitivity spectra were carried out in the range 3–11 eV for polyethylene, poly(vinyl chloride), and polyacrylonitrile layers and in the range 3–21 eV for polystyrene layers[61-64]. The kinetics of the photodischarge of the EP layers based on the above polymers are characterised by curves which are asymmetric relative to the sign of the surface charge (Fig. 11). The shape of the curves depends on the wavelength: with increase of the latter, the rate of photodischarge decreases faster and the residual potential (the threshold value of the electric field for the non-photoactive absorption of light) increases. The nature of the EP sensitivity spectra of saturated polymers (as well as polymers with a polyconjugation system) in the vacuum ultraviolet region is approximately the same: the EP sensitivity depends on the sign of the surface charge and, for example, for polystyrene with a positive charge, it is greater by a factor of four than for the polymer with a negative charge. The dependence on the wavelength is more pronounced: for the same polystyrene, the EP sensitivity increases by a factor of 100–150 with decrease of wavelength by a factor of three (from 180 to 60 nm). The position of the long-wavelength limit of the EP sensitivity (Fig. 12) depends on the structure of the polymer and, for polymers of the vinyl series, is displaced towards longer wavelengths to an increasing extent in the presence of the following groups: benzene ring, chlorine, cyano-group, hydrogen, and the carbazole ring.

We may note that the above polymers (except polyethylene) are amorphous (vitreous). Polyethylene is crystalline, while polystyrene is atactic and isotactic and is capable of crystallising with a glass point at 95.5°C; poly(vinyl chloride) is atactic and has not been obtained in a crystalline form, its glass point being 80°C; polyacrylonitrile is atactic and has a flow temperature above the decomposition temperature; polyvinylcarbazole has a glass point of 117°C. In the above series the shift of the EP sensitivity limit is largely due to the shift of the absorption limit.

The study of the influence of the structure of the polymers with saturated bonds on the quantum efficiency showed (in relation to polystyrene)[61] that the latter is independent of the molecular weight in the range from 10^3 to 10^6. On the other hand, the number of double bonds in the main chain, which has been varied in a controlled manner by dehydrogenation, has a selective spectroscopic effect[61] (Fig. 13). Thus the quantum efficiency is constant in the range 120–135 nm, where valence electrons of the molecule are responsible for absorption, decreases in the range 135–180 nm with increase of the number of double bonds, and increases in the range 180–220 nm owing to the photoactive absorption by the C=C bonds of the main chain with their subsequent photodegradation accompanied by a decrease of the absorption in this part of the spectrum.

The above data on the energetic EP sensitivity of saturated polymers in the vacuum ultraviolet region made it possible for the first time to characterise quantitatively the photoconductivity phenomena and to determine in the first place the absolute quantum yield of the internal photoeffect.

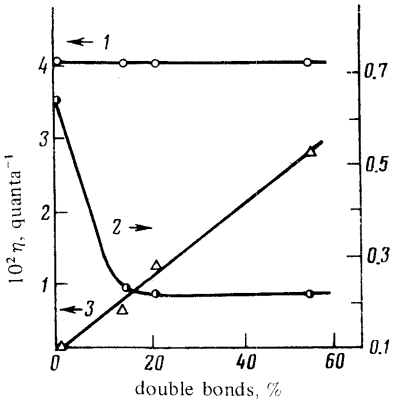

Figure 13. The selective spectroscopic effect of the change in the number of double bonds in the main chain of polystyrene on the EP sensitivity (quantum yield) of the layers[61]; $\Delta\lambda$ (nm): 1) 120–135; 2) 135–180; 3) 180–220.

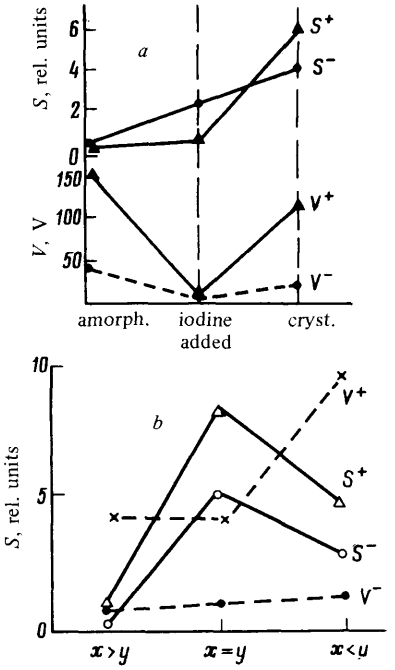
Comparison of the sensitivity spectra of EP layers of polystyrene, EP layers of selenium, and photographic layers based on silver thiocyanate, developed specially for the vacuum ultraviolet region, showed[62,65] that the EP sensitivity of polystyrene layers exceeds that observed for silver thiocyanate layers and in the region of 60 nm approaches the sensitivity of selenium layers. The amount of light necessary to record the image (based on the criterion of the relative change in the potential of the EP layer $\Delta V/V = 0.1$) is 28 erg cm^{-2} at λ = 115 nm and 2.8 erg cm^{-2} at λ = 58.4 nm. The fairly high EP sensitivity of polymers of the given class in the vacuum ultraviolet region combined with a low sensitivity in the longer-wavelength part of the spectrum made it possible to reduce the background due to the scattered long-wavelength light in the recordings of images and led to the creation of a catalogue of EP layers for the vacuum ultraviolet region with a variable light sensitivity limit[66,68].

2. POLYMERS WITH CONJUGATED CARBON–CARBON BONDS

Polymers with a polyene chain (PCCP) do not exhibit EP sensitivity in the part of the spectrum under consideration, although they are charged to appreciable potentials.

For polymers with aromatic substituents (PPAT, PIPAT), the EP sensitivity and the limiting potential of the layers were found to depend on the supermolecular structure and on the presence of iodine atoms in the structure[64] (Fig. 14). Amorphous PPAT layers have a high limiting potential (both positive and negative), but their sensitivity is extremely low. The presence of iodine

atoms in PIPAT greatly reduces the limiting potential (to 5–10 V) but at the same time increases the EP sensitivity. The change of the supermolecular PPAZ structure from amorphous to crystalline (with a degree of crystallinity up to 80%) on slight decrease of the limiting potential leads to an appreciable increase of the EP sensitivity. The layers exhibit EP sensitivity in the <600 nm region of the spectrum with a maximum in the region of < 300 nm (Fig.15).



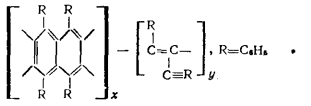


Figure 14. The influence of the structure of polymers on the EP properties of layers[64]; S—spectral sensitivity; V—limiting charging potential; *a*) polyphenylacetylene with a variable supermolecular structure and with the introduction of iodine atoms: PPAT (amorph.), PIPAT, PPAZ (cryst.); *b*) PDPB with a variable ratio of the initial components during synthesis:

The solvent has a marked influence on the EP parameters[60,64]. Aromatic solvents (toluene) are removed with much more difficulty from polymer films than solvents such as carbon tetrachloride. Thus CCl_4 is fully removed from the polymer film in the course of 4 h in a vacuum of 10^{-2} mmHg, while the complete removal of toluene requires a vacuum of 1×10^{-5} mmHg. Concentration and type of solvent do not affect the limiting potential of the EP polymer layers, but the presence of a solvent in the layer accelerates the dark relaxation of the positive potential in the polymer layers and to a greater extent at higher solvent concentrations (Fig. 16); on the other hand, the dark relaxation of the negative potential under these conditions remains almost unchanged. Rather thick (up to 10 μm) EP layers based on PPAZ, completely freed from the solvent, do not exhibit EP sensitivity in the ultraviolet and visible regions of the spectrum. The presence of a certain amount of solvent in polymer films leads to the appearance of EP sensitivity but only in positively charged PPAZ layers (Fig. 16). Thin (3 μm) PPAZ layers exhibit an appreciable EP sensitivity after the removal of the solvent (Fig. 16).

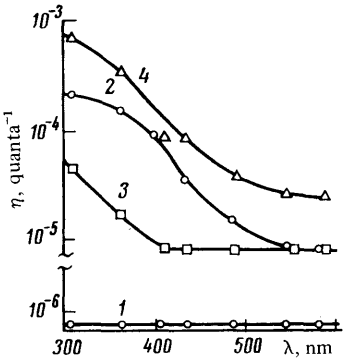

Figure 15. The spectrum of the quantum yield in layers of polyconjugated polymers[60]: 1) polychlorocyclopentene; 2) polyphenylacetylene; 3) polydiphenylacetylene; 4) polydiphenylbutadiyne.

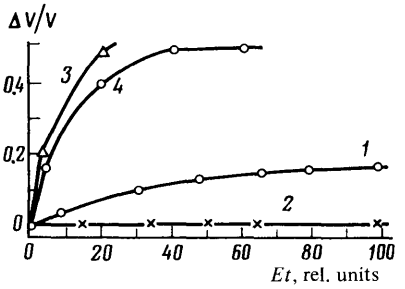

Figure 16. The retardation of the rate of photodischarge of EP layers following the removal of solvent (carbon tetrachloride) from polyphenylacetylene [64] (*Et* is the degree of illumination expressed in relative units): 1) and 3) initial layers [1) 11 μm; 3) 3 μm]; 2)–4) after the removal of the solvent.

EP layers based on polymethylethynylpyridine (PMEP) [11,64] are characterised by an asymmetry of the limiting potential and the kinetics of dark relaxation as well as the kinetics of photodischarge. The layers also exhibit a sensitivity only for a negative surface charge, which indicates the predominance of n-type charge carriers in the layers. The EP sensitivity is independent of the molecular weight and of the different types of treatment (polymers both soluble and insoluble in benzene have been isolated for a polymerisation temperature of 300°C).

The layers exhibit EP sensitivity in the ultraviolet part of the spectrum (< 400 nm); the sensitivity is then lower by an order of magnitude than for PPA layers (Fig. 15). The low EP sensitivity can be naturally accounted for by the high efficiency of the competing process—luminescence.

Polymers with a Double Conjugation System

The EP sensitivity of PDPB layers, obtained by casting from solution, depends on the ratio of x and y units in the structure (Fig. 14*b*). A common feature over the entire range of contents of the initial components is the asymmetry of the potential: the positive potential greatly exceeds the negative potential. The EP sensitivity varies in a complex manner: it is low for $x > y$, passes through a maximum at $x = y$, and decreases for $x < y$. The positive limiting potential then increases. The layers exhibit EP sensitivity over a wide spectral range (<600 nm) (Fig. 15) and have a broad maximum at 400–440 nm and a second maximum at shorter wavelengths.

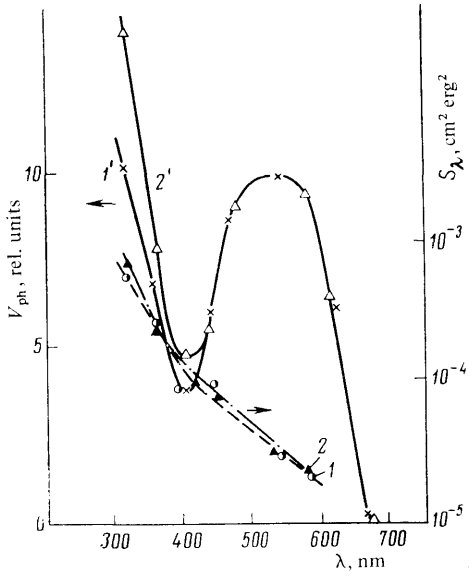

Figure 17. *EP*-sensitivity (curves *1* and *2*) and photo-e.m.f. (curves *1'* and *2'*) spectra of polydiphenylbutadiyne layers obtained from solution (curves *1* and *1'*) and by evaporation in a high vacuum (curves *2* and *2'*).[44]

A characteristic feature of polyphenylacetylene layers obtained by vacuum sputtering[44] is an increase of the mobility of charge carriers from 7×10^{-5} cm^2 V^{-1} s^{-1}, a value characteristic of layers obtained by casting from solution, to 0.07–0.01 cm^2 V^{-1} s^{-1}.[45,78] The energy required to generate a single electron–hole pair has been shown[45] to depend on the nature of the polymer, its structure, and the evaporation conditions; it can reach high values (300–500 eV), which indicates a complex mechanism of the generation of charge carriers.

A comparative study of the photo-e.m.f. and EP-sensitivity spectra for two types of layers (obtained from solution and by vacuum evaporation) (Fig. 17) showed that they are virtually the same and that there are therefore no differences between the quantum efficiencies of the generation in such layers. An important advantage of the layers obtained by vacuum sputtering is high optical quality, comparable to the quality of inorganic vitreous photoconductor films such as those of selenium.

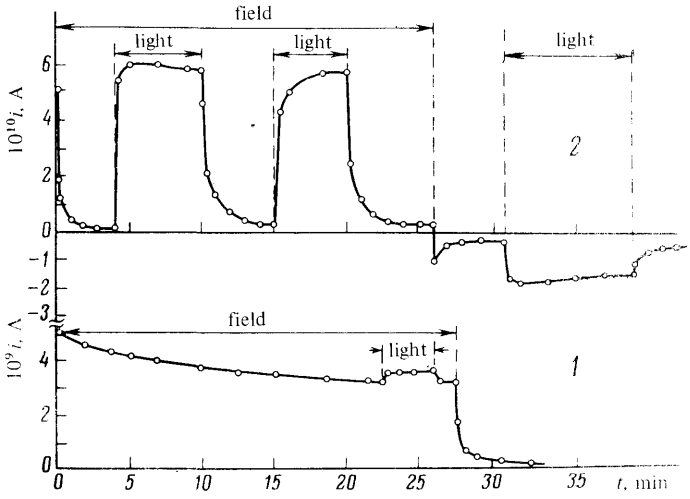

Figure 18. Kinetics of the photoconduction in PDPB layers obtained from solution (1) and by evaporation in a high vacuum (2).[44]

In conclusion we shall note yet another difference between the properties of the layers—the difference between the kinetic characteristics of the photoconductivity and polarisation phenomena (Fig. 18). The non-monotonic establishment of a stationary photocurrent (transverse photoconductivity conditions) in the course of the first illumination and the presence of depolarisation currents are characteristic of high-resistance compounds, both inorganic[79] and organic[80,81], although they have not been observed for a whole series of substances, particularly for many organic dyes[82]. In the PDPB layers of the two types under consideration these phenomena are manifested fairly clearly, which can be seen from the kinetic curves in Fig. 18.[44] When an electric field is applied, the dark polarisation-type current decreases more slowly for the layers obtained from solution. The dark current in these layers is higher by an order of magnitude than in the layers obtained by vacuum sputtering, which is correlated with the reduced "memory" under the EP conditions. Next, when the first light II-pulse is applied to a layer in an electric field, the photocurrent reaches a stationary value after passing through a maximum, although in subsequent exposures a stationary current is established monotonically (curve *2*). A monotonic form of the curve is also observed for PDPB layers of the other type (curve *1*). When the field is removed from the specimen (curve *2*), a depolarisation current is observed and in the subsequent

exposure there is a depolarisation photocurrent. For the other type of layers, depolarisation effects were not observed.

We may note that both types of layers exhibit hole conductivity, which has been established on the basis of the sign of the photo-e.m.f. and the nature of the photodischarge curves under EP conditions. The relaxation characteristics described[44] were obtained for the transverse conductivity of the layers in a field of 10^4 V cm^{-1}. Under EP conditions (longitudinal photoconductivity) in fields of 2×10^5 V cm^{-1}, such slow kinetic effects are not manifested, although a tendency towards polarisation effects can be responsible for the decrease of the EP sensitivity with decrease of field strength.

3. POLYMERS WITH CONJUGATED CARBON–NITROGEN BONDS

Polymers of this class exhibit an electrical conductivity of $10^{-10} - 10^{-13}\ \Omega^{-1}$ cm^{-1}. Their EP properties vary within wide limits depending on the molecular and supermolecular structures[50]. Under these conditions, the light relaxation curves for layers based both on the monomers and on the polymers have two sections—with rapid and slow rates of relaxation and a fairly high residual potential.

Layers based on monomers (benzylideneaniline, 2,3-diphenylquinoxaline, and dibenzylidene-*p*-phenylenediamine) have low limiting electric field strengths and do not exhibit an appreciable photoeffect. The introduction of the benzidine group into benzylideneaniline or *meta*-substituted benzene rings leads to an appreciable increase of the limiting field strength (up to 20 V m^{-1}). At the same time EP sensitivity appears in the ultraviolet. The maximum quantum efficiency is 1.5×10^{-5} quantum^{-1}.

Layers based on poly-Schiff bases have a limiting field strength which varies within wide limits (10–200 V μm^{-1}). Almost all the polymers sensitised exhibit EP sensitivity in the ultraviolet. Its magnitude increases, as for the monomers, when a benzidine group or *meta*-substituted benzene rings are introduced into benzylideneaniline. Polymers obtained from *p*-phenylenediamine and benzil with an excess of the diamine exhibits the highest limit sensitivity (quantum efficiency 1×10^{-4} quantum^{-1}), whereas the quantum efficiency of polymers obtained with an excess of benzil is lower (4×10^{-5} quantum^{-1}). The EP sensitivity is almost independent of the length of the molecular chain but depends strongly on the regularity of the supermolecular structure: for many polymers in the crystalline state, it is higher by an order of magnitude than in the amorphous state. It is noteworthy that hydrogenation also leads to the appearance of light sensitivity in amorphous polymers and block copolymerisation both increases and decreases the light sensitivity of the initial polymers.

We may note a characteristic feature of the above monomeric and polymeric layers, which consists of the "memory" of the previous history of the layer. In contrast to the familiar instances of "memory" in organic photoconductors, characterised by a monotonic variation of the light sensitivity, for polymeric photoconductors of the above class the memory involves relations with an extremum, for example, in the limiting potential and in the EP sensitivity of the "memory" layers and in the number of charging-exposure cycles. The light sensitivity of such layers passes through a maximum[50].

The observed characteristics of the influence of the molecular and supermolecular structures on the photoconductivity can be interpretated within the framework of the following general ideas. The photocurrent depends on the conditions governing the generation, transport, and recombination of charge carriers and all three stages can depend on the molecular and supermolecular structures. In particular, an enhancement of the delocalisation of electrons along the conjugation chain of the molecule and an increase of the regularity of the supermolecular structure should, by improving the transport conditions, lead to an increase of light sensitivity. As shown above, light sensitivity does indeed increase with increasing regularity of the structure (on transition from the amorphous to the crystalline state).

The nature of the possible influence of the molecular structure is more complex. The experimentally observed increase of the quantum efficiency of polymers when the delocalisation of electrons along the conjugation chain is weakened (primarily by the introduction of the benzidine group and *meta*-substituted benzene rings) is apparently associated with the increase of the efficiency of the generation of electron–hole pairs, which proceeds via an exciton stage. The impairment of the conditions for the transport of free carriers in this instance is probably not of decisive importance for the EP sensitivity in consequence of the presence of a strong electric field, which is responsible for the appreciable migration of the carriers even when their mobility is low. However, the regularity of the structure in the case of exciton generation can alter significantly the diffusion distance of the excitons, reducing the probability of their decomposition (accompanied by the generation of free carriers) and thereby influencing actively not only the transport stage but also the stage in which charge carriers are photogenerated.

IV. SPECTRAL SENSITISATION OF THE ELECTROPHOTOGRAPHIC RESPONSE

The spectral sensitisation of polymers is of considerable interest not only from practical but also from theoretical points of view[55,83-87]. The current hypotheses concerning the mechanism of spectral sensitisation are based on two alternative process mechanisms[88-90]: involving the transfer of excitation energy from the dye molecule to the photoconductor, under the influence of which a free charge carrier subsequently appears, or the transfer of a photoelectron to the excited dye molecule. There is at present no unambiguous experimental evidence in support of one or other mechanism, but, presumably, if the excitation energy transfer mechanism operates in a substance with exciton generation of photocarriers, then the spectral sensitisation can be regarded as the "pumping" of the energy absorbed by the dye into the sensitised photoconductor; the quantum yield η in the sensitisation region is then determined by the value of η of the sensitised photoconductor. Organic polymeric photoconductors with exciton generation of photocarriers then exist under very unfavourable conditions, since their quantum yield of the internal photoeffect in the visible region is low, which is due to fundamental causes arising from the exciton generation mechanism[60]. The conditions governing the dissociation of excitons can be made easier and the quantum yield increased by the formation of charge-transfer complexes from the initial polymers.

In the study of sensitisation, two extreme cases, differing in the concentration of dye molecules in relation to the sensitised polymer or the CTC based on it, are of interest. The first case involves high concentrations of carriers. The greatest number of studies have been devoted to it and extensive data have now been obtained for the quantum yields in the generation of photoholes from complexes based on polyvinylcarbazole (PVCA) on sensitisation with triarylmethane and pyrylium dyes, monomethinecyanines, and trimethinecyanines.[1,91] The quantum yield in the region of sensitisation reaches 50%. However, the use of high concentrations of dyes and CTC makes the system heterophase; an opalescence usually appears and the resolution diminishes. Such a system does not exhibit thermomechanical properties important for applications in a photothermoplastic EP process.

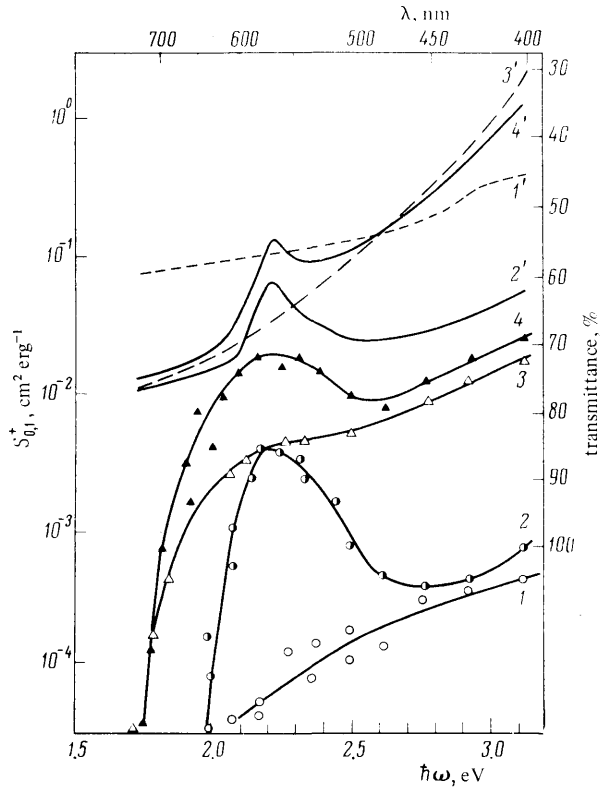

Figure 19. EP-sensitivity spectra of PVCA (curve *1*) and PVCA–TNF charge-transfer complex (curve *3*) layers; 2) and 4) corresponding layers sensitised by rhodamine B; 1′)–4′) transmission spectra of layers *1–4* respectively[92] ($S_{0,1}$—spectral sensitivity in absolute energy units).

The above disadvantages can be eliminated by reducing the concentrations of CTC and dyes (second case), but the nature of the phenomenon can then be significantly altered. As in the first case the formation of complexes and the sensitisation of PVCA by dyes causes a significant increase of the EP sensitivity of PVCA [92] (Fig.19). In order to examine the nature of the effect, we turn to Fig.20, which illustrates the absorption spectra and the spectral sensitivity of optically homogeneous layers of PVCA and its complexes as well as layers sensitised by rhodamine B.[93] Fig. 20 shows that the charge-transfer complex exhibits a broader absorption region than the initial polymer and a much higher light sensitivity (curve *3*). One need only note that the efficiency in relation to the absorbed energy at the maximum does not exceed 20% (taking into account the reflection). The sensitisation by rhodamine B increases by a factor of ~15 the light sensitivity of the polymer and by a factor of 5 that of its charge-transfer complex. The absolute quantum yields of the internal photoeffect at the 567 nm absorption maximum (in the presence of a superimposed electric field of 7×10^{-5} V cm^{-1}) are as follows:

Layer	PVCA	CTC	PVCA sensitisation by rhodamine B	CTC sensitisation by rhodamine B
η, %	~1	3.3	1.1	3.6

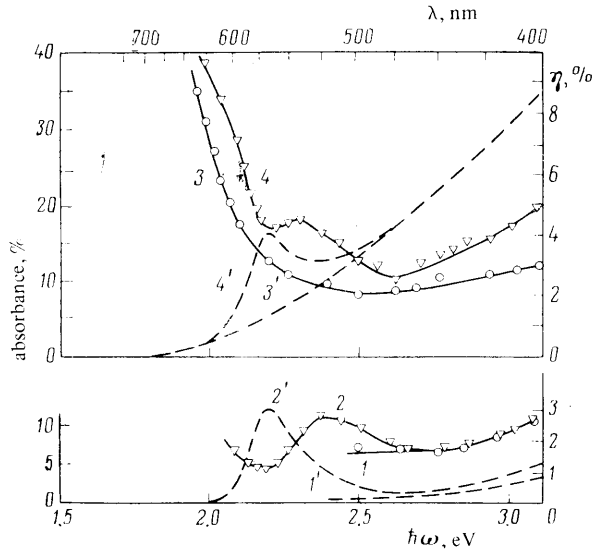

Figure 20. Quantum yield spectra (η is the absolute quantum yield of charge carriers per quantum, %) of the internal photoeffect (curves *1–4*) and the absorption spectra (curves *1′–4′*) of PVCA (curves *1* and *1′*), PVCA sensitised by rhodamine (curves *2* and *2′*), PVCA–TNF charge-transfer complex (curves *3* and *3′*), and PVCA–TNF charge-transfer complex sensitised by rhodamine B (curves *4* and *4′*) [93]; dye concentration 0.28 mole %; trinitrofluorenone concentration 3.2 mole %.

Thus the efficiency of the sensitisation, defined as the ratio of η at the sensitisation maximum to η for the initial polymer, remains constant and close to 100% despite the different initial values of η. The relation obtained shows that the mechanism of the spectral sensitisation in the case of exciton generation under consideration is due to the "pumping" of energy into the polymer by the dye. In both instances of sensitisation examined, its efficiency must therefore be regarded as a maximum and the light sensitivity is limited solely by the fraction of energy absorbed in the layer.

We may note that, as can be clearly seen from the experimental data (Fig. 20, curves *3* and *4*), the introduction of a dye leads to an increase of the quantum yield not only in the region of the sensitisation of the CTC but also in the region of shorter wavelengths, which may be evidence for the formation of complexes in the PVCA–dye systems. In this sense, the sensitisation of PVCA by dyes leads to the possibility of increasing the quantum yield over a much wider region of the spectrum in the short-wavelength range compared with the absorption spectrum of the sensitiser dye.

V. INJECTION SENSITISATION OF THE ELECTROPHOTOGRAPHIC RESPONSE

The increase of light sensitivity and the extension of the region in which it occurs for polymeric photoconductors can be achieved by injection sensitisation based on the phenomenon of photoinjection in film heterostructures. The principle of the construction of heterostructures with EP sensitivity makes it possible to control the properties of the layers, in the sense of extending the width of the region of spectral sensitivity and improving the memory, and ensures the thermoplastic visualisation of the latent image in the presence of the appropriate thermomechanical properties of the component which does not carry the photogeneration function[94]. Among all the possibilities enumerated above, the case of high light sensitivity achieved by the photoinjection of carriers, which ensures their transfer through the heterostructure, is of greatest interest.

A heterostructure with EP sensitivity is nowadays achieved on the basis of inorganic systems, because an organic component as a rule gives rise to a potential carrier, which prevents injection[95]. A system containing selenium and PVCA is exceptional in this respect[96,97], but here injection has been observed only from heterophase *p*-selenium, which did not ensure a high resolution.

High-resolution heterostructures based on amorphous forms of selenium and thermoplastic compositions based on PVCA have been investigated recently[94]. The heterostructures were made in glass frames with a conducting layer of lead dioxide on which layers of *n*- and *p*-type selenium and PVCA 0.1–0.3 μm thick were deposited in succession. The study of dark EP properties of the above heterostructures showed that, for the negative surface charge corresponding to the injection of holes into PVCA, the associated limiting field strength (3×10^5 V cm^{-1}) corresponds to that observed for selenium layers and the dark relaxation time corresponds to that for PVCA layers. The retention of properties indicated above (in contrast to, for example, selenium–polystyrene heterostructures[95]) indicates the absence of an energy barrier at the inner boundary of the heterostructures when a field (of definite polarity) is imposed. The absence of a barrier is important for ensuring the possibility of the transfer of carriers, generated in selenium, through the heterostructure and, according to preliminary EPR data, can be associated with the formation of a charge-transfer complex at the selenium–PVCA boundary. In fact, on the one hand, the ability of polycyclic aromatic systems, including PVCA, to form charge-transfer complexes with electron acceptors is known and, on the other hand, the ability to add an additional electron to the electron shell is characteristic of atoms with an unfilled outer electron shell (the *p*-shell in selenium is unfilled).

The shape of the photodischarge curves confirms the photoinjection of holes and the absence of the injection of electrons. Injection is observed from both *p*- and *n*-type selenium, which is due to the mixed nature of the photoconductivity of the two forms of selenium. At any rate, an electron-hole pair is initially photogenerated in selenium after which carriers predominating in PVCA (holes) are injected through the boundary and transported through PVCA.

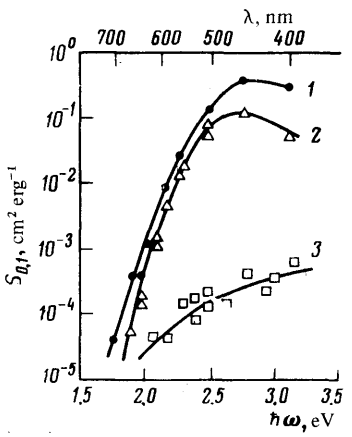

Figure 21. EP-sensitivity spectra of PVCA layers (2 μm thick) in injection sensitisation by selenium [94]: 1) *p*-Se (0.2 μm); 2) *n*-Se (0.3 μm); 3) no selenium.

The light sensitivity of the heterostructure significantly exceeds that of PVCA and in the region of strong absorption virtually corresponds to the light sensitivity of selenium layers, decreasing with increase of the wavelength owing to the decrease of the absorption of energy (Fig. 21), while the quantum yield η corresponds to η for amorphous forms of selenium over the entire spectral range investigated. The data in Fig. 21 were obtained for a field strength of 3×10^5 V cm^{-1}. The light sensitivity depends markedly on the field over the entire range of the spectrum and, in contrast to PVCA, there is a critical field of $\sim 6 \times 10^4$ V cm^{-1} for the heterostructure, below which there is no light sensitivity. If it is assumed that the traps in PVCA are small and that a space charge does not therefore arise on photodischarge, the threshold field can be interpreted as the field necessary to ensure the photoinjection of charge carriers from selenium into PVCA. The dependence of the light sensitivity of *n*-type selenium on the field can be naturally accounted for by the dependence of η on the field[60], or, in the case of *p*-type selenium, it is probably associated with the dependence of the conditions for the transport of carriers on the field.

Thus photoinjection in the heterostructures examined makes it possible to combine the high light sensitivity of selenium with the effective thermomechanical properties of compositions based on PVCA, which ensures the resolution of an element whose size does not exceed the wavelength of visible light when the light sensitivity is high.

VI. THE QUANTUM YIELD AND THE STRUCTURE OF POLYMERS

Systematic studies have demonstrated a fundamental difference between the spectra of the quantum yield of the internal photoeffect in polymeric photoconductors and classical semiconductor crystals such as those of germanium and silicon. Whereas the quantum yield in the above semiconductor crystals (which represents the number of free charge carriers generated by a single absorbed quantum) is constant over a considerable range of energies of the quantum and close to 100% up to the absorption limit, in polymeric photoconductors it is close to zero in the region of the absorption limit, increasing in the interior of the absorption band[60]. The photogeneration of charge carriers over a wide range of energies of the quanta via the state involving a Coulombically bound electron–hole pair (exciton) plays a decisive role in the establishment of the structure of the quantum yield spectrum. The probability of the separation of the pair depends on the kinetic energy of the electron which has absorbed the quantum and on the rate of loss of this energy. The reverse recombination of the electron with its "own" hole or its "own" ion, which leads to a non-photoactive absorption, takes place as a result of the decrease of the kinetic energy of the electron to the thermal energy level before the electron moves outside the limits of the sphere of the Coulombic field of its partner in which the electron attraction energy exceeds the $\frac{3}{2}kT$ level. The external electric field facilitates the photogeneration process by reducing the Coulombic barrier and increasing thereby the probability of the escape of the carrier (the Frenkel–Poole effect).

We shall now consider the spectra of the quantum yield of the internal photoeffect in anthracene single crystals, polyconjugated polymers of the same electronic type as anthracene (polymers of the acetylene series), and saturated polymers having the same composition as anthracene (polystyrene and other polymers of the vinyl series).

Unique possibilities for the investigation of the absolute quantum yield of the internal photoeffect arise under EP conditions. To achieve such conditions, an ionic contact is made with the surface of the layer located on a conducting support. The density of the ionic charge, generated by the ionisation of air molecules, reaches 10^{12} cm^{-2} for an average interionic distance of 100 Å. Such contact ensures optical transparency over the entire experimental part of the spectrum and the maximum possible electric field strength which is not limited by the "weak sites" in the layer in view of the absence of longitudinal conductivity and which makes it possible to obtain saturation currents for substances with a low mobility of charge carriers such as the photoconductors investigated. Furthermore, the ionic contact ensures a virtually complete exclusion of an external photoeffect in the ultraviolet, which is limited to the strong fields of the electrical double layer formed, reaching 10^6 V cm^{-1}.

The number of charge carriers n generated by light is related to the change in the potential of the layer ΔV when the carriers have been completely collected, by the expression

$$n = \varepsilon \cdot \Delta V/4\pi de|_{\Delta V \to 0},$$

where ϵ is the dielectric constant and D the effective thickness of the layer. The condition $\Delta V \to 0$ ensures a quasi-stationary potential. One of the fundamental difficulties when the EP method is used involves demonstrating the complete collection of carriers; several pieces of evidence in support of this claim can be adduced:

(1) the presence of a linear section on the photodischarge curve.

(2) Direct calculation of the shift of charge carriers. Thus a 100% collection coefficient for electrons and holes was ensured in single-crystal anthracene layers 15 to 20 μm thick[51]. The mobility of holes $\mu_g = 5 \times 10^{-1}$ cm^2 m^{-1} s^{-1}, $E = (2-20) \times 10^4$ V cm^{-1}, and $d = 20$ μm; the time of flight of holes $t_{fl} = d/\mu E = (2-20) \times 10^{-8}$ s is much shorter than $\tau_g = 3 \times 10^{-5}$ s (τ_g is the lifetime of holes); the electron mobility $\mu_e = 3 \times 10^{-1}$ cm^2 V^{-1} s^{-1} and the time of flight of electrons $t_{fl} = (3-30) \times 10^{-8}$ s^{-1} $\tau_e = 2 \times 10^{-6}$ s.

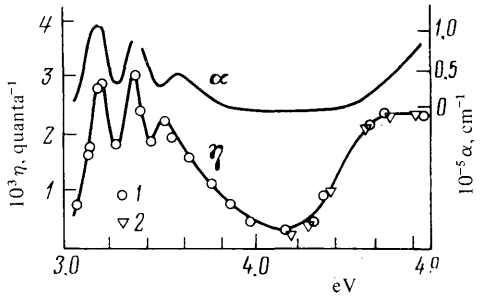

Figure 22. Absorption (α) and quantum yield (η) spectra of a single-crystal layer of anthracene[51,61]: 1) holes; 2) electrons; $E = 2 \times 10^5$ V cm^{-1}.

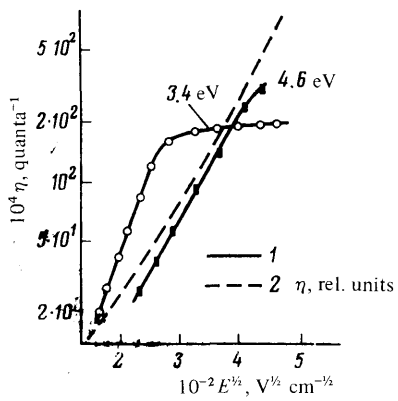

Figure 23. Dependence of the quantum yield for anthracene layers on the electric field[60]: 1) experimental data; 2) calculated data.

For polystyrene (PS) layers, we have $\mu_g = 10^{-4}$ cm^2 V^{-1} s^{-1}, $E = (4-15) \times 10^5$ V cm^{-1}, $d = 0.3$ μm, and $t_{fl} = (2-8) \times 10^{-7}$ s $< \tau_g = 1 \times 10^{-6}$ s (estimate under EP conditions from $\mu\tau$ for $\eta = 100\%$). For polyacetylene layers, particularly for polydiphenylacetylene, $\mu = 5 \times 10^{-4}$–6.5×10^{-5} cm^2 V^{-1} s^{-1}, which also ensures a complete collection of carriers.

(3) Whereas it is known that in the region of strong absorption 100% collection of carriers is ensured, in the region of weak absorption, which softens the collection conditions, the collection can also be complete. A decrease of light sensitivity with decrease of absorption coefficient is in this case caused solely by a change in generation conditions.

An exceptional value of η close to 100% can also serve as evidence for complete collection.

In order to eliminate the influence of space charge in the measurement of $\eta(E)$, a family of photodischarge curves at different initial potentials was obtained. It is noteworthy that, when η depends on E, a linear photodischarge plot is not observed even in the region of complete collection ($\mu\tau E = d$) (the current is not saturated).

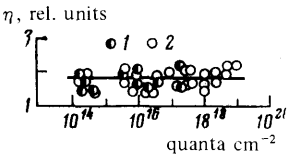

Figure 24. Dependence of the quantum yield for an anthracene layer on the ionisation density[95] ($E = 2 \times 10^5$ V cm^{-1}): 1) 3.4 eV; 2) 4.1 eV.

For anthracene, the spectrum of η values in the region of energies of the quanta $\hbar\omega$ less than the width of the forbidden gap $E_g = 3.9$ eV is associated with the diffusion of molecular excitons (with a small radius) to the surface and corresponds to the optical absorption spectrum (Fig.22). In the region where $\hbar\omega > E_g$, η increases with increase in $\hbar\omega$. In both regions the photogeneration is controlled by the electric field (Fig. 23). The influence of the field cannot be associated with the change in the conditions for the recombination of free carriers, since there is no dependence of the quantum yield on the ionisation density within the limits of five orders of magnitude (Fig. 24) and the change in the saturation of generation centres as the field strength is varied in the region of $\hbar\omega < E_d$ would lead to a decrease of η with increase of the field.

The effect of the field in the region of molecular excitons indicates the existence of an intermediate state in the formation of free carriers as a result of the interaction of the exciton with a centre (in anthracene this can be oxygen) having a high electron affinity and weakening the electron–hole interaction of the Coulombically bound electron-hole pair. The probability of the escape of one of the carriers of the pair from the stationary (in the interaction with the centre) or mobile partner is determined by the electric field (Fig. 23). There is a threshold quantum energy $\hbar\omega \simeq E_g$, above which there is a finite probability that the primary pair gives rise to free carriers as a result of an excess energy equal to $\hbar\omega - E_g$. In this region η is therefore independent of the absorption coefficient α and increases with increase of $\hbar\omega$. In the region where $\hbar\omega < E_g$ it is necessary to supply an additional energy to the pair in order to cover the energy deficiency; in the given instance this energy is drawn from the crystal lattice (the generation centres). For the operation of this mechanism, the bound pair (exciton) must be mobile if the generation centres are mainly in the surface region. The difference between the dependences of η on the field in the two regions, namely the occurrence of saturation and a different slope of the $\eta(E)$ relation when the Frenkel–Poole law $\lg\eta \propto E^{1/2}$ holds over a wide range of E values in the given model, can be explained by the limited number of generation centres, so that all the excitons interacting with the centres in fields of 2×10^5 V cm^{-1} give rise to free carriers. The change in the slope of the $\eta(E)$ line is due to the change of the constant in the Frenkel–Poole equation: in the region where $\hbar\omega < E_g$ charge carriers escape from the stationary centre (in this region only holes are mobile), while in the region where $\hbar\omega > E_g$ the carriers move away from one another ($\eta_e \simeq \eta_h$).

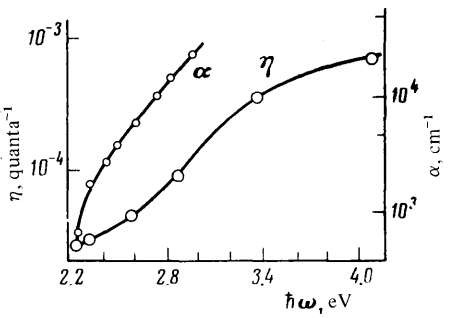

Figure 25. Absorption (α) and quantum yield (η) spectra for PDPB layers[95].

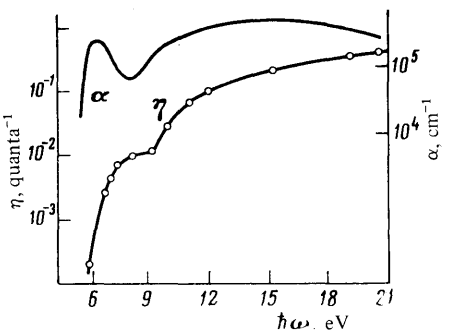

Figure 26. Absorption (α) and quantum yield (η) spectra for a polystyrene layer[15].

Polyacetylenes (Fig. 25—polydiphenylbutadiyne) and polymers of the vinyl series (Fig. 26—polystyrene) in the amorphous state are also characterised by a value of η which increases with increase of $\hbar\omega$ and E. The maximum value of η for PDPB is of the same order of magnitude as the value for molecular crystals (this question is discussed in greater detail elsewhere by one of the authors of the review[60]).

The relations obtained indicate the occurrence of exciton effects in molecular, crystalline, and amorphous photoconductors, which lead to a broad region of non-photoactive absorption at the edge of the spectrum. The probability of the decomposition of the primary bound states arising following the absorption of a light quantum depends on the structure of the photoconductor, which leads to the possibility of the structural sensitisation of the photoeffect.

Excess Electrons in Non-polar Molecular Liquids

B.S.Yakovlev

The results of recent experimental and theoretical studies of the properties of an excess electron in non-polar liquids have been summarised. Various models of electron transfer, and the role of localised and quasi-free states of the excess electron in chemical reactions have been discussed. The bibliography contains 142 references.

CONTENTS

I. Introduction 615
II. The mobility and energy of an excess electron 616
III. Chemical reactions 621

I. INTRODUCTION

The discovery of the solvated electron in water about fifteen years ago laid the foundation for intensive studies of the properties of a "chemically non-combined" or excess electron in molecular liquids. Until recently, these studies were related chiefly to polar media. It was found that an excess electron is one of the most chemically active species and plays an important role in many electrical, photochemical, and radiation-chemical processes[1-4].

Until 1968, experimental studies of the excess electron in non-polar liquids were restricted to the study of the mobility of the electron in liquefied noble gases and diatomic liquids (this work has been reviewed[5-7]). In the last few years, the study of the properties and elementary chemical reactions of the excess electron has been extended to liquids consisting of complex non-polar molecules—liquid hydrocarbons and various organosilicon compounds. This has been made possible by the development of the technique of recording fast reactions, particularly the use of nanosecond techniques, and the improvement of methods of purifying liquids from electron acceptors.

Intensive studies in this field began after the possibility of recording an excess electron in liquid hydrocarbons had been demonstrated in the period 1968–1970[8-11].

A large amount of factual material relating to the study of the physical properties and reactivity of an excess electron in non-polar liquids has now accumulated. It has been found that the excess electron is a much more active species in these media than in the polar liquids. The direct experimental data obtained on the mobility and rate constants of the reaction of the electron differed so sharply from the values previously assumed that they led to a change in ideas regarding the time scale of processes involving an excess electron in photochemical and radiation-chemical changes in non-polar liquids. New data are extending the possibility of studying reactions with electron transfer in condensed media. These data can be used in the physics of dielectrics to study the initial stages of electric breakdown, and in experimental nuclear physics to create liquid ionisation chambers. This explains the increasing interest shown by specialists in different fields in the study of the properties of the excess electron in non-polar liquids.

The problems of the behaviour of an electron in molecular liquids, including non-polar liquids, have been reviewed[12-14]. The present review summarises the results of work published up to 1977. Particular attention has been paid to the mobility and reactivity of an excess electron in liquid hydrocarbons. In the last part of the review, new data on the properties of the excess electron are used to discuss the kinetics of the primary electronic processes of the radiolysis of non-polar molecular liquids.

II. THE MOBILITY AND ENERGY OF AN EXCESS ELECTRON

The experimental data at present available on the mobility and reactivity of the excess electron in non-polar liquids relate chiefly to an electron in thermal equilibrium with the medium. In polar liquids, the state of an equilibrium excess electron is localised. The electron in this state is in a potential well, formed as a result of the polarisation interaction of the electron with the dipolar molecules of the medium. For an excess electron in non-polar liquids, generally speaking, it is not clear whether the equilibrium state is localised, since the orientational polarisability of molecules in these media does not play a significant role in the localisation of an electron. According to existing views of the states of an electron in disordered systems[15,16], at thermal equilibrium in a non-polar liquid an excess electron can in principle also exist in a delocalised state. In this state the electron occupies the volume of many molecules, and its interaction with the medium is determined only by their electronic polarisability. It is assumed that the delocalised or quasi-free electron has a much higher mobility than an ion.

As shown below, data on the mobility of the excess electron indicate that in many non-polar liquids an equilibrium electron is neither completely localised nor quasi-free, but is most probably in neither state. It is still possible, however, to regard an excess electron as a species in an "equilibrium" state in processes for which the characteristic time is greater than the relaxation time of various states of the electron. Processes of this kind are usually dealt with in experimental studies of the mobility and rates of chemical reactions of an excess electron in non-polar liquids.

1. Measurements of Drift Mobility

The drift mobility μ or the ratio of the average velocity of the electron v in an electric field to the field strength E

$$\mu = v/E \qquad (1)$$

is one of the most definite characteristics of the motion of an electron in a liquid. Einstein's relationship makes it possible to relate μ to the coefficient of diffusion of the electron $D = k_B T/e\mu$, where k_B is the Boltzmann constant, T the absolute temperature, and e the charge of the electron.

The first reliable measurements of the value of μ for an excess electron in liquid hydrocarbons were made comparatively recently, in 1968–1969[9-11]. It has now become clear that the failure of the many earlier attempts to carry out these measurements were due to the use of liquids not sufficiently purified from electron acceptors. In most cases, rapid disappearance of the excess electrons and the formation of the negative ions of the acceptor molecules took place. A direct indication of the existence in liquid hydrocarbons of current carriers more mobile than ions was obtained by Tewari and Freeman[8], who detected the formation of short-lived charged species in liquid neopentane under the influence of ionising radiation. The use of thoroughly purified liquids in later work made it possible to determine the average velocity of these species in an electric field from the time of flight over the distance between two electrodes.

The values of μ obtained from these measurements were 10^2–10^5 times greater than the mobility of ions, so that the current carriers recorded were identified as excess electrons. This conclusion was confirmed by studies[10] of the current of electrons photo-injected from a metal into "pure" liquid hydrocarbons. These studies gave the same values of μ.

The purity of the liquids required for the measurement of the time of flight of excess electrons over the distance between electrodes (t_f) can be judged from the lifetime of electrons before their capture by the molecules of acceptors, which in these measurements must be greater than t_f. The acceptable concentration of electron acceptors, estimated from this condition and the known rate constants of reactions involving the capture of an excess electron, often did not exceed 10^{13} cm^{-3}.

The mobilities of excess electrons have now been measured for more than fifty different non-polar molecular liquids, including saturated[9-11,18-38], unsaturated[18,34,39], normal, cyclic[34], and aromatic[40] hydrocarbons, and various organosilicon compounds, such as tetramethylsilane[11,21]. Table 1 gives some published values of μ for liquids at room temperature. More complete data have been published[12-14,38]. The results lead to the following general conclusions.

Table 1. Drift mobility of an excess electron μ, activation energy of the mobility E and the energy of the ground level of a quasi-free electron V_0 in non-polar molecular liquids.

Liquid	T, K	μ, ($cm^2 V^{-1} s^{-1}$)	E, eV	V_0, eV
Tetramethylsilane	296	90[11]	0.018[11]	−0.61[42], −0.62[41] −0.55[43], −0.51[47]
Neopentane	296	70[26,40]	—	−0.43[41,42], −0.35[43]
2,2,4,4-Tetramethylpentane	295	24[21]	0.064[21]	−0.33[50]
2,2,5,5-Tetramethylhexane	293	12[21]	0.05[21]	—
2,2-Dimethylbutane	296	10.9[11]	0.052[11]	−0.24[42], −0.15[46]
2,2,4-Trimethylpentane	296	7[11]	0.06[17], 0.51[33], 0.046[36]	−0.15[42], −0.18[41] −0.14[43], −0.19[52]
Cyclopentane	296	1.1[11]	—	0.17[43], 0.28[42]
Cyclohexane	294	0.35[11], 0.45[21]	0.17[21]	0.01[50]
Butane	296	0.4[11]	—	—
n-Pentane	293	0.15[74]	—	0.01[47]
Benzene	293	0.114[40]	0.32[40]	−0.14[44]
n-Hexane	296	0.09[11], 0.082[29]	0.19[18,28,33] 0.16[36]	−0.09[42], 0.04[41] 0.16[49], 0.2[47]
Toluene	292	0.063[40]	0.15[40]	−0.22[44]
n-Decane	296	0.038[36]	0.21[36]	0.18[49]
n-Pentadecane	296	0.03[35]	0.16[35]	—
Methane	111	400[22,25]	—	0.0[48]
	140	430[20]	−0.007[30]	—
Ethane	130	0.014[30]	0.08[30]	0.22[46]
Propane	175	0.05[30]	—	0.11[50]

1. The mobility of an electron in different liquids, even at a given temperature, cover a wide range of values: from 3×10^{-2} cm^{2}V^{-1}s^{-1} in n-decane to 10^2 cm^{2}V^{-1}s^{-1} in neopentane and tetramethylsilane. The mobility of the

electron is unusually "sensitive" to the structure of the molecules of the liquid. For example, for n-pentane and neopentane the values of μ differ by a factor of more than 400. The mobilities of the electron in *cis*- and *trans*-butenes differ by a factor of approximately 100. For normal hydrocarbons, the mobility at first decreases rapidly with increase in the number of carbon atoms from two to six. Further increase in the number of carbon atoms leads to only a slight change in μ. The position of the double bond in a molecule determines whether μ increases or decreases. It is difficult to relate the influence of the structure of molecules on the mobility of an excess electron to any single property of the molecules of the liquid. The nature of the movement of an electron in liquid saturated hydrocarbons apparently depends to a considerable extent on the shape of the molecule: more spherically symmetrical molecules correspond to a greater mobility. The greatest mobilities are shown by electrons in methane, neopentane, and tetramethylsilane, which have highly symmetrical molecules.

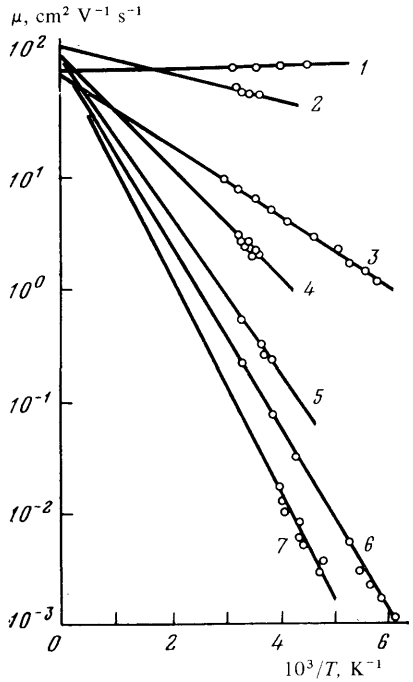

Figure 1. Temperature dependence of the drift potential of an excess electron in various molecular liquids: 1) tetramethylsilane[33], 2) neopentane[20], 3) iso-octane[17], 4) 2-methylbut-2-ene[20], 5) 66% n-hexane in neopentane[20], 6) 3-methylpentane[66], 7) n-hexane[20].

2. For all hydrocarbons studied, except liquid methane[35], the mobility of the electron decreases with decrease in temperature (Fig. 1). The temperature dependence of μ for most saturated hydrocarbons is described by the Arrhenius equation

$$\mu = \mu_0' \exp(-E/k_B T) \qquad (2)$$

with pre-exponential factors μ_0' from 10^2 $cm^2V^{-1}s^{-1}$ to 10^3 $cm^2V^{-1}s^{-1}$. The $\mu(T)$ relationship for liquid ethane and n-pentane is more complex. The activation energy increases with decrease in T in the first case, and decreases in the second. $\mu(T)$ relationships of this kind are also typical of unsaturated hydrocarbons.

3. The mobility of the excess electron is independent of the electric field strength, that is $v \sim E$ up to values of $E \simeq 10^4$ V cm^{-1}. In liquids with a relatively high mobility (liquefied methanol, neopentane, iso-octane), further increase in E leads to a decrease in μ.[23,26,32] In this range of values of E, the velocity of the electron $v \sim E^{0.5}$. This $v(E)$ relationship is characteristic of the movement of an electron in semiconductors, and is usually related to an increase in the average kinetic energy of the electron in the electric field. Another type of relationship was established for liquids with a low mobility: in the range of strong fields, μ increases with increase in E (liquefied ethane, propane, pentane[25-27,38]). A similar relationship was previously found for substances in which the movement of the electron takes place in hops from one localised state to another. It is assumed that in this so-called "hopping" mechanism of electron transfer, the electric field increases the probability of a hop.

4. The mobility of an electron shows a correlation with the energy V_0 of the ground state of the quasi-free electron in the liquid, that is with the energy which must be expended to transfer a stationary electron from a vacuum to a lower delocalised state in the liquid. As a rule, the lower V_0, the higher the mobility of the excess electron. This dependence of μ on V_0 is one of the characteristic features of the movement of an electron in non-polar liquids (for polar liquids, a correlation between μ and V_0 has not been established). It is assumed that the position of the level of a quasi-free electron in some cases also determines the reactivity of the excess electron (see Part III). It is therefore not surprising that the discussion of data on V_0 at present occupies an important place in the examination of the properties of an excess electron in non-polar liquids.

2. Energy of a Quasi-Free Electron

Data on the magnitude of V_0 for non-polar liquids have been obtained chiefly by two methods: from the difference in the work functions for an electron from a metal in a vacuum φ_V and in a liquid φ_l,[41-49] or from the difference in the ionisation potentials of the molecules in the gas I_g and in the liquid I_l.[50,51] The energy of the quasi-free electron is determined in the first method as the difference $V_0 = I_l - \varphi_V$, and in the second case as $V_0 = I_l - I_g - P_+$, where P_+ is the energy of the polarisation of the positive ion in the liquid. The results obtained by the two methods show good agreement.

The values obtained for V_0 for non-polar liquids (see Table 1) lie in a range from −0.6 eV to +0.2 eV, that is they are much higher than the corresponding values for polar liquids (for example, for water $V_0 = -1.3$ eV[4]). Positive values of V_0 mean that it is energetically more favourable for the electron to move into a vacuum from the quasi-free state in the liquid. Experimental confirmation of the existence of this transition is provided by the observation of the effective emission of excess electrons from liquid n-hexane and iso-octane into the gaseous phase[52,53].

A number of attempts have been made to interpret the properties of a quasi-free electron in non-polar molecular liquids using the same approach as in the case of liquefied

gases, since high values of V_0 were previously obtained for the latter. For liquefied gases, from data on the scattering of an electron by atoms in the gaseous phase, it is assumed that an electron cannot approach an atom to a distance less than the so-called radius of a "hard sphere" a. According to the theory[6], in this approach,

$$V_0 = T_k(a, n) + U(\alpha, n), \quad (3)$$

where T_k is the energy, often called "kinetic", although it is the energy of an electron at the foot of the conductivity zone. Physically, this energy is related to the same quantum effect as the increase in the energy of the ground state of an electron in a potential well when the walls of the well approach one another. The role of the walls in the model of the electron being considered is played by the surface of the "hard spheres". As expected from this interpretation, the value of T_k increases with increase in a or the number of molecules in unit volume n. The average polarisation energy U can be calculated[6] from the known polarisability of the atom α and the density of the liquid.

There are at present few data on the reaction of low-energy electrons with complex molecules in a liquid, so that there is much less justification for using this method of calculation for liquid hydrocarbons than in the case of atomic liquids. Nevertheless, the values calculated using Eqn. (3) show good agreement with experimental data in this case also (Fig. 2). The values of a used in this calculation show a qualitative correspondence to data on the scattering of electrons by hydrocarbon molecules in the gaseous phase[54]. Moreover, the calculation of V_0 for a mixture of hydrocarbons from the values of α and a for the components gives good agreement with experiment [14,55].

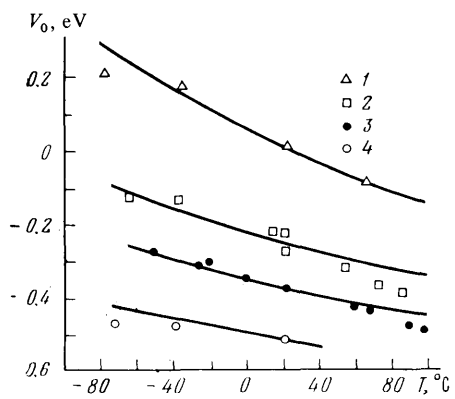

Figure 2. Temperature dependence of the energy of the ground state of a quasi-free electron in liquids. The points give the experimental data[47], and the continuous lines the results of a calculation[47] by the Wigner–Seitz method: 1) n-hexane, 2) iso-octane, 3) 2,2,4,4-tetramethylpentane, 4) tetramethylsilane.

3. Optical Absorption

Because of the high reactivity of an excess electron in non-polar liquids, the measurement of its optical absorption in these media, particularly at room temperature, is more complicated than that for polar liquids. At present, the optical absorption of an excess electron is known for only a few hydrocarbons: for propane at 88 K and 108 K,[56] 3-methylhexane at 193 K,[57] and methylcyclohexane at 160 K and 293 K.[58] In all cases the form of the absorption spectrum was found to be close to the spectrum of a trapped electron in solid amorphous hydrocarbons. Fig. 3 gives as an example the optical absorption spectra of an excess electron in liquid propane and solid 3-methylpentane.

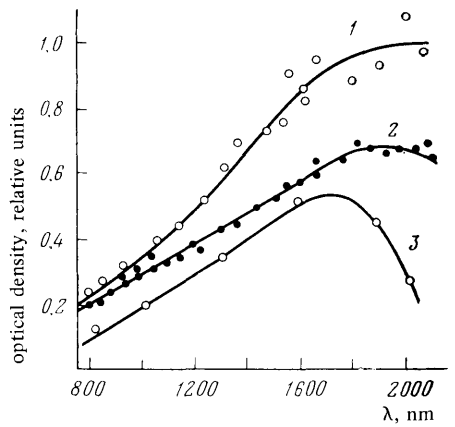

Figure 3. Spectral dependence of the optical absorption: 1) excess electron in liquid propane at 88 K[56] 2×10^{-6} s from the start of a generating pulse of duration 1×10^{-6} s; 2, 3) captured electron in solid amorphous 3-methylpentane at 77 K, 10^{-5} s (2) and 380 s (3) from the start of a generating pulse of duration 10^{-6} s.[59]

The observation of the optical absorption of an excess electron indicates that at least some of the electrons are in a localised state for times greater than the absorption recording time ($> 10^{-8}$ s). At present there is no generally accepted viewpoint on the nature of the localised state of an electron in liquid hydrocarbons. According to a general approach[60], localised states in a liquid may be formed as a result of the capture of an electron by several fluctuations, for example fluctuations in the density or the orientation of the molecules. Studies of the mobility of an electron in a mixture of hydrocarbons[23,29,31] also lead to the conclusion that several molecules take part in the formation of a localised electron.

Of the proposed mechanisms of the localisation of an excess electron in liquid hydrocarbons, the capture of the electron by a cavity between molecules has been examined in most detail[44,61,62]. A similar mechanism was established for liquid helium and neon[6,7], and is assumed for liquid hydrogen and nitrogen[63,64]. Studies of positron annihilation in a number of liquid hydrocarbons[65] confirmed the existence in these liquids of cavities having a radius of ~ 4 Å, suitable for electron capture. Cavities of this size are also postulated in the interpretation of the form of the optical absorption spectrum of a captured electron in solid amorphous hydrocarbons[66]. Numerical calculation[62] of a simple model of a cavity with rectangular walls (see Fig. 4) shows that an electron in a ~ 4 Å cavity may in fact be a stable system in liquid hydrocarbons. For this it must be assumed that the value of the dielectric constant close to the walls of the cavity, determining the energy of

the polarisation of the medium by a localised electron U_{loc}, is greater than the macroscopic value of the dielectric constant. This assumption is justified by the fact that the electron in a cavity "feels" the uncompensated C–H dipole moments of the surrounding molecules. The orientation of these dipoles is apparently responsible for the "blue" shift with time in the absorption spectrum of a captured electron in solid hydrocarbons (see Fig. 3).

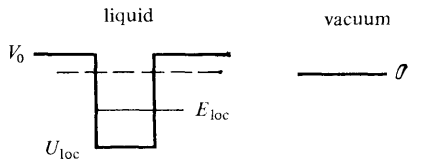

Figure 4. Energy diagram for an electron localised in a cavity. The broken line gives the energy level of the stationary electron in a vacuum, V_0 is the energy of the ground state of the quasi-free electron, and E_{loc} the energy of the localised state.

These proofs of the localisation of the electron in a cavity can only be regarded as indirect, however. It is not excluded that, because of the high dipole moment of individual C–H bonds (~ 0.4 D [67]), the electron is localised, for example, by a "fortuitous coincidence of rotational phases of neighbouring molecules" [11].

4. Some Models of Transfer

The observation of high values of the drift mobilities of an electron in liquid hydrocarbons led immediately to the suggestion that the unusual mobility of the electron in these media is due to the participation, in transfer processes, of an electron in a quasi-free state. Ideas on the high mobility of the quasi-free electron in a liquid had previously been introduced to explain the mobility of the electron in liquefied noble gases. For these media, a theory of the mobility of the quasi-free electron in a liquid was also developed in detail.

The quasi-free electron in monatomic liquids is regarded as a plane wave coherently scattered on atoms. This approach, used by Cohen and Lekner [68,69], was found to be fruitful for the estimation of the mobility of an electron in a weak electric field μ_0, and also in the interpretation of the temperature dependence $\mu_0(T)$ [70] and the dependence of the mobility on the electric field strength in liquid argon. The structure of the liquid was taken into account by means of a radial function of the interatomic distances, and the model potential of the interaction of the electron with an atom was the potential used in the calculation of the energy of the quasi-free electron. According to the theory [68,69]

$$\mu_0 = \frac{2}{3} e (2/\pi m k_B T)^{1/2} / n\sigma S(0), \qquad (4)$$

where $\sigma = 4\pi a^2$ is the cross-section of the elastic scattering of an electron on a sphere having a radius a, $S(0) = nk_BTx$, and x is the coefficient of isothermal compressibility of the liquid.

Fueki and coworkers [54] assumed that Eqn. (4) is also applicable for the mobility of a quasi-free electron in a molecular liquid, if the values obtained from the experimentally determined energies of the quasi-free electron according to Eqn. (3) are used for a. According to their estimates, $\mu_0 = 150 \pm 70$ cm^{2}V^{-1}s^{-1} for various liquids at $T \simeq 300$K. The value $\mu_0 \simeq 150$ cm^{2}V^{-1}s^{-1} for n-hexane, neopentane, and their mixtures is also given by a more rigorous calculation [71] based on a modified Cohen–Lekner theory for monatomic liquids [72].

The data in Table 1 show that the experimental values of the drift mobility of the excess electron in many molecular liquids is much smaller than the assumed values of μ_0 for the quasi-free electron. Moreover, in contrast to the calculated temperature dependence of the mobility of the quasi-free electron, $\mu_0 \sim T^{-3/2}$, for most liquid hydrocarbons the mobility of the excess electron has activational character, which usually indicates that a significant part is played by localised states. Thus the nature of the transfer of an excess electron is different for non-polar molecular liquids, polar liquids, and liquefied noble gases.

The mechanism of electron transfer in non-polar molecular liquids is not clear at present. A common feature of proposed models is the use of ideas on the distribution of the excess electrons between localised and quasi-free states. The following models of the transfer of an excess electron are examined in the literature, depending on the energy distribution of the traps and the mechanism of the liberation of the electron from the trap.

a) "Trap" model

In this model it is assumed that a quasi-free electron in a liquid is captured for a time interval τ_{loc} by structural traps, from which it can be liberated again by thermal excitation. In this case the measured mobility is the sum of the mobilities of the electron in the quasi-free state μ_0 and in the localised state μ_{loc} with allowance for the proportion of the time spent by the electron in these states, that is

$$\mu = \mu_0(1 - P) + \mu_{loc}P, \qquad (5)$$

where P is the probability that the electron is in the localised state.

For the simplest case where all the traps are identical, $P = \tau_{loc}/(\tau_0 + \tau_{loc})$, where τ_0 is the lifetime of the quasi-free electron before capture by the trap. If the mobility of the localised electron is neglected, and it is assumed that $\tau_{loc} = \nu^{-1}\exp(E/k_BT)$, where E is the activation energy of the liberation of the electron from the trap, ν is a frequency factor, and $\tau_0 \ll \tau_{loc}$, then Eqn. (5) gives an Arrhenius type of temperature dependence for the mobility: $\mu = \mu_0\tau_0\nu \exp(-E/k_BT)$. Comparison of the pre-exponential factor of this relationship and the experimental value for $\tau_0 \simeq \nu^{-1}$ leads to the conclusion that μ_0 is approximately the same, ~ 10^2 cm^{2}V^{-1}s^{-1}, for different liquids, in agreement with theoretical estimates.

The pre-exponential factor in the relationship $\mu = \mu_0' \exp(-E/k_BT)$ acquires a different physical significance if a distribution of the traps with respect to energy is assumed. Thus for a linear distribution from 0 to E, we have [29]:

$$\mu = \mu_0(1 + E_1/k_BT)\exp(-E_1/k_BT).$$

Comparison of this form of $\mu(T)$ relationship with the experimental relationship gives values of μ_0 which are smaller, the smaller μ. This change in μ_0 is more realistic, since liquids having a lower value of μ, as a rule,

have less "spherical" molecules, for which stronger scattering of the quasi-free electrons should be expected.

A more complex form of distribution of traps with respect to depth was used by Freeman and coworkers[73,74]. With the assumption that the distribution is Gaussian, and that the position of its maximum is linearly dependent on V_0, they obtained satisfactory agreement with the experimental $\mu(V_0)$ relationship for various hydrocarbons and tetramethylsilane (see Fig. 5).

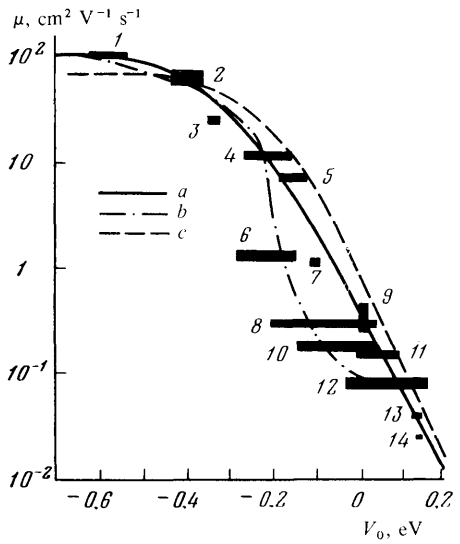

Figure 5. Dependence of the mobility of an excess electron on the energy of the quasi-free electron in a liquid at $T = 294 \pm 2$ K.[74] The lines give the calculated relationships: a) "trap" model with Gaussian distribution, b) "partial localisation" model, c) Kestner–Jortner model. Experimental data: 1) tetramethylsilane, 2) 2,2-dimethylpropane, 3) 2,2,4,4-tetramethylpentane, 4) 2,2-dimethylbutane, 5) iso-octane, 6) cyclopentane, 7) 2,3-dimethylbutane, 8) 2-methylpentane, 9) cyclohexane, 10) 3-methylpentane, 11) n-pentane, 12) n-hexane, 13) n-octane, 14) n-decane.

b) Fluctuation models

Schiller and coworkers[44,61] and Kestner and Jortner[75] tried to describe electron transfer with allowance for fluctuation processes in a liquid. A common feature of these approaches is the assumption that the mobility of the quasi-free electron $\mu_0 \simeq 10^2$ cm^{2}V^{-1}s^{-1} is approximately the same for all liquids.

In the "partial localisation" model[44,61], the probability that an electron is in a localised state P is related to a fluctuation in energy. Here, a central assumption is that there is "unrestrictedly fast exchange of energy between the electron and the molecules of the medium". In accordance with this assumption, the electron is in a quasi-free state if $E_{loc} + E > V_0 + \bar{E}$ (where E and $\bar{E}$ are the energy of the molecules forming the localised state of the electron, and its average value), and becomes localised when $E_{loc} + E < V_0 + \bar{E}$. In this case

$$P = \frac{1}{\sqrt{2\pi\sigma^2}} \int_{-\infty}^{V_0} \exp[-(E - E_{loc})^2/2\sigma^2]\, dE,$$

where σ^2 is the dispersion of the distribution with respect to E.

Satisfactory agreement with experimental data for V_0 and μ for $T \simeq 300$ K was obtained for $\sigma = 0.12$ eV (see Fig. 5). The order of magnitude of this value is consistent[44] with the known specific heat capacity of aliphatic hydrocarbons, $C_V = 50$ kcal mole^{-1}K^{-1}.

Kestner and Jortner[75] examined the mobility of a classical electron in a macroscopically non-uniform medium consisting of regions with different potentials of the interaction of the electron with the molecules (V). They assumed that these regions can be divided into two types, depending on the ratio of the values of E and V: "effectively conducting", with electron mobility μ_0, if $E > V$, and "poorly conducting", with electron mobility μ_1 of the order of ionic conductivity, if $E < V$. In this case[75], from the theory of electron transfer in disordered systems[75-78],

$$\mu = \mu_0\left(\frac{3}{2}C - \frac{1}{2}\right), \text{ for } C > 0.4,$$

where C is the volume fraction of the "effectively conducting" regions. Decrease in C from 0.4 to 0 is accompanied by a sharp decrease in μ to the value μ_1 at $C = 0$. To calculated C in various hydrocarbons it was assumed that the difference $\bar{V} - V_0$ (where $\bar{V}$ is the average value of V), and also the average value of E, are constant for all liquids.

Fig. 5 shows that this model is also consistent with experimental data for various liquids. As in other treatments, an exception is provided by the data on μ and V_0 for liquid methane.

c) "Hopping" model

For liquids having a relatively low electron mobility $\mu < 1$ cm^{2}V^{-1}s^{-1}, a transfer mechanism without conversion of the electron to a quasi-free state has also been proposed[79-81]: the electron remains in a localised state until a fluctuation produces in its proximity the same kind of trap, into which the electron "hops". In this case the activation energy of the mobility will be related to the processes of new trap formation and the "hopping" of the electron between traps. This so-called "hopping" mechanism of transfer is used to interpret the mobility of an electron in a large number of solids in which the electron has a low mobility[82], and also in polar[3] and weakly polar molecular liquids.

For liquid normal hydrocarbons at $T \simeq 300$ K, an indication of the hopping mechanism may be provided by data[36], according to which, with increase in the number of carbon atoms in the molecule $n_C > 7$, the mobility of the electron remains approximately constant (~ 0.04 cm^{2}V^{-1}s^{-1}), whereas V_0 continues to increase. In the transfer models examined above, this means that for $n_C > 7$, the quasi-free state does not make a contribution to the mobility, although its value still remains much greater than the mobility of ions.

---o0o---

Thus the comparison of various models of the transfer of an excess electron in non-polar liquids with experiment involves the introduction of many simplifying assumptions. There are insufficient experimental data on $\mu(T)$ and $V_0(T)$ relationships to establish the transfer mechanism, since different models on the whole give satisfactory agreement with experiment. It is therefore necessary to introduce other experimental data. Information on the mobility of a quasi-free electron μ_0 and the density of the energy levels of an excess electron in a liquid $n(E)$ are particularly important. The use of one of the direct methods for determining μ_0—measurement of the Hall effect—is difficult for non-polar liquids, because of the low concentration of excess electrons, and has not yet given any results. The experimental determination of the $n(E)$ relationship can in principle be based on a study of the spectrum of the photo-detachment of an electron from a negative ion in a liquid, by analogy with the method of impurity photoconductivity for semiconductors. The possibility of recording photoconductivity due to the photo-detachment of an electron from negative ions in a non-polar liquid was recently demonstrated[83-85].

A fundamental difference between the mechanisms examined for the transfer of an excess electron in non-polar and polar liquids is the postulate that there is an appreciable probability that the electron is in a delocalised quasi-free state. This characteristic feature of non-polar liquids makes it possible to use direct experimental methods to study the reactivity of a delocalised electron—a short-lived species in condensed matter which is comparatively new in chemical kinetics.

III. CHEMICAL REACTIONS

The view that an excess electron has high reactivity arose in a study of the radiolysis of solutions of electron acceptors[86] long before the drift mobilities of the electron in "pure" liquids were measured. The estimation of the rate constants of the elementary reactions of an electron from the results of these studies was difficult, however, because of the complex kinetics of radiolysis processes. The use of thoroughly purified liquids in experiments made it possible to employ more direct methods to study the reactivity of an excess electron. One of the first direct methods was based on the determination of the lifetime of an excess electron in solution by recording the kinetics of the decrease in its optical absorption[56-58].

The method most widely used at present is pulse electrical conductivity, first used to determine the rate constants of the reactions of an electron by Fuochi and Freeman[19] and Yakovlev and coworkers[87].

Pulse Electrical Conductivity Method

In this method, the electrical conductivity of solutions is measured in a direct current circuit with the pulse generation of excess electrons in it (Fig. 6). The electrons are generated by the ionisation of solvent molecules by hard radiation (high-energy electrons, bremsstrahlung) or by two-quantum photo-ionisation of impurity molecules[24,88]. The ionisation of molecules in an amorphous substance leads to the formation of two types of electron-ion pair: pairs in which the electrons recombine with "their own" positive ion or an ion of "their own" tracks (so-called "primary" recombination), and pairs which avoid primary recombination or "free charges". The electrical conductivity method is convenient in that it is "sensitive" only to "free" electrons and ions, since the pairs taking part in the "primary" recombination do not make an overall contribution to the transfer of charge in a constant electric field. Processes involving "free" species can be described by the equations of ordinary homogeneous kinetics, and this simplifies considerably the analysis of the data obtained.

Since the mobility of an excess electron is much greater than the mobility of ions, excess electrons make the greatest contribution to the electrical conductivity with the condition that their concentration is comparable with the concentration of ions. These conditions are produced, for example, after the action of a short pulse of ionising radiation for times comparable with the lifetime of the excess electrons in solution. The rate of disappearance of the electrons in a solution is determined by several processes: recombination with positive ions in solution or at an electrode, and reactions with impurity molecules. Since electrical conductivity can be measured at very low concentrations of electrons ($\sim 10^8$ electron cm^{-3}) and large distances (~ 1 cm) between the electrodes, the experimental conditions can be selected so that one of these processes is the chief process.

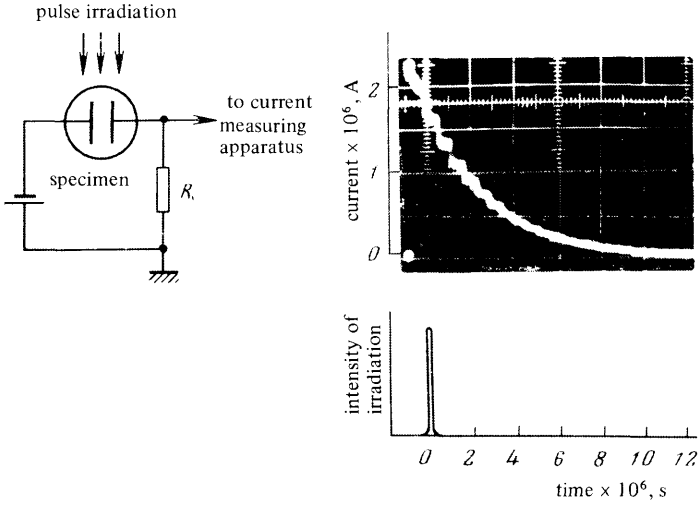

Figure 6. Measurement of the current of excess electrons in the pulse electrical conductivity method. The oscillogram of the current for a solution of pyrene in n-hexane at a concentration 1×10^{14} cm^{-3}.[28]

If the disappearance of the electrons takes place chiefly at the electrodes, it follows that for generation which is uniform throughout the volume, at $t = 0$, the decrease in the current will be described by a linear time dependence:

$$I \sim (1 - t/t_{\lim}) \text{ for } t < t_{\lim}.$$

Most of the data on the mobility of an excess electron have been obtained by recording relationships of this kind.

Under conditions in which the electrons disappear chiefly as a result of their capture by a molecule of an acceptor A

$$e^- + A \rightarrow A^-, \qquad (6)$$

when $[A] \gg [e^-]$, the decrease in the current will be described by an exponential relationship

$$I(t) \sim [e^-] \sim \exp(-t/\tau_3) \qquad (7)$$

where $\tau_3^{-1} = \Sigma k_i[A_i]$, $[e^-]$ is the concentration of excess electrons, k_i the rate constant of reaction (6), and $[A_i]$ the concentration of the acceptor i.

To illustrate this form of time dependence of the current, Fig. 6 gives the oscillogram of the current induced by a pulse of ionising radiation in a solution of pyrene in liquid hexane at a concentration of 1×10^{14} cm^{-3}. As follows from Eqn. (7), an increase in the concentration of the acceptor is accompanied by a decrease in the lifetime of the excess electron in solution (see for example Fig. 7). The rate constant of the capture reaction can be determined from the time of the exponential decrease in current if the duration of the generating pulse is sufficiently short, or from an analysis [29,87] of the more complex character of the change in current if $\tau_{pulse}^{-1} < k[A]$.

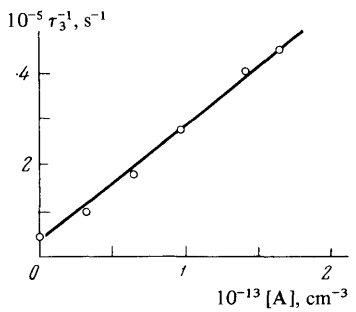

Figure 7. Plot of the reciprocal of the lifetime of an excess electron in liquid iso-octane solutions at 296 K against the pyrene concentration [17].

The electrical conductivity method has now been used to measure a large number of rate constants for the reactions of an excess electron in various liquid hydrocarbons. These reactions involve chiefly the capture of the excess electron by a neutral molecule of an acceptor (5) and the recombination of the electron with a positive ion

$$e^- + M^+ \rightarrow \text{(disappearance of } e^-\text{)}. \qquad (8)$$

2. Recombination Reaction

In the experimental study of reaction (8) in liquid hydrocarbons, it is usual to select conditions in which recombination is the chief process responsible for the disappearance of the excess electrons in the volume between the electrodes. In this case, data on the kinetics of the electrical conductivity, induced in the liquid by the pulse of ionising radiation, during [29,87,89] or after [89-91] the pulse make it possible to determine the ratio k_r/μ, where k_r is the recombination rate constant, and, when μ is known, to obtain k_r.

Fig. 8 gives the dependence of k_r on the mobility of the excess electron in various hydrocarbons and tetramethylsilane. For liquid hydrocarbons with an electron mobility $\mu < 10$ cm^{2}V^{-1}s^{-1}, the values of k_r, within the limits of accuracy of the measurements (~ 10%), satisfy the Langevin relationship

$$k_r = 4\pi e\mu/\varepsilon \qquad (9)$$

where ϵ is the dielectric constant. Eqn. (9) is based on the assumption that the reaction rate is limited by the diffusion of the recombining species, and that their path length before the loss of momentum l is shorter than the distance r_c at which the energy of the Coulombic interaction between the positive current and the electron is equal to k_BT (for non-polar liquids at $T \simeq 300$K, $r_c \simeq 300$ Å). For the excess electron, the last condition agrees with the assumed relatively low value of the mobility of the quasi-free electron ($\mu_0 \simeq 10^2$ cm^{2}V^{-1}s^{-1}), which corresponds to $l \simeq 60$ Å.

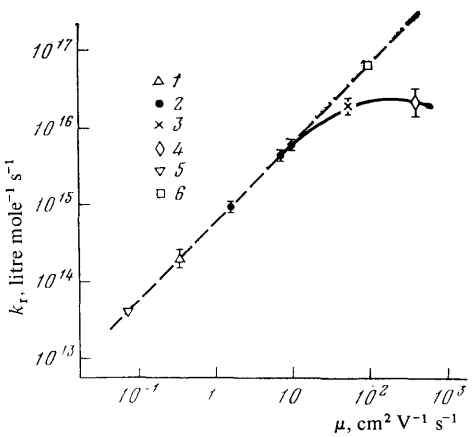

Figure 8. Dependence of the rate constant for electron-ion recombination on the mobility of an excess electron in non-polar liquids: 1) cyclohexane, 296 K [87]; 2) iso-octane, 200, 296, and 340 K [90]; 3) neopentane, 296 K [89]; 4) methane, 110 K [87]; 5,6) n-hexane, tetramethylsilane, 296 K. [29]

For liquids with a high excess electron mobility (neopentane, tetramethylsilane), the recombination rate constant has the highest values for bimolecular reactions in a liquid, ~ 10^{15} litre mole^{-1}s^{-1}. It is at present not clear whether the value of k_r for these liquids obeys the Langevin relationship: some data [19,29] give a ratio k_r/μ equal to the theoretical value, whereas other data [89] give values for this ratio which are smaller by factors of 1.5 for neopentane and 15 for liquid methane.

3. Capture Reactions

The reaction rate constants k for the capture of an electron in many non-polar liquids are now known for various acceptors. The following list of acceptors for which constants have been determined gives some idea of the range of studies carried out: O_2, [24,25,29,57,91-97] I_2, [92] CO_2, [91,93,95,98] N_2O, [33,84] SF_6, [33,99] CCl_4, [24,33,62,91-93,95,96] CH_3I, [29] C_2H_5Cl, [33] C_2H_5Br, [29,33] C_2HCl_3, [33] C_2H_3Cl, [33] biphenyl [24,96,91-93], pyrene [28,62,87,96,99], perylene [96], naphthalene [91], diphenylanthracene [93], and alcohols [91,100]. For "good"

electron acceptors, such as CCl_4, SF_6, N_2O, etc, in liquid hydrocarbons at $T \simeq 300$ K, the rate constants lie in the range 10^{12}–10^{14} litre mole^{-1}s^{-1}, that is they are 10–10^3 times greater than the rate constants of the analogous reactions of the hydrated electron.

Since in polar liquids the rate of the fast reactions of an electron are limited by the diffusion of the electron to the molecule of the acceptor, it is natural to relate the unusually high value of k primarily to the high mobility of the excess electron in non-polar liquids. The increase in k on going to liquids exhibiting a high mobility is also observed for non-polar liquids with a relatively low electron mobility (< 10 cm^{2}V^{-1}s^{-1}). For these liquids, the increase in reaction rate with increase in temperature characteristic of chemical reactions is also observed (Fig. 9). The dependence of k on T and μ for the capture of an electron by various acceptors in liquids with a high electron mobility is more unusual: k increases with decrease in T and decreases on going to liquids exhibiting a higher mobility.

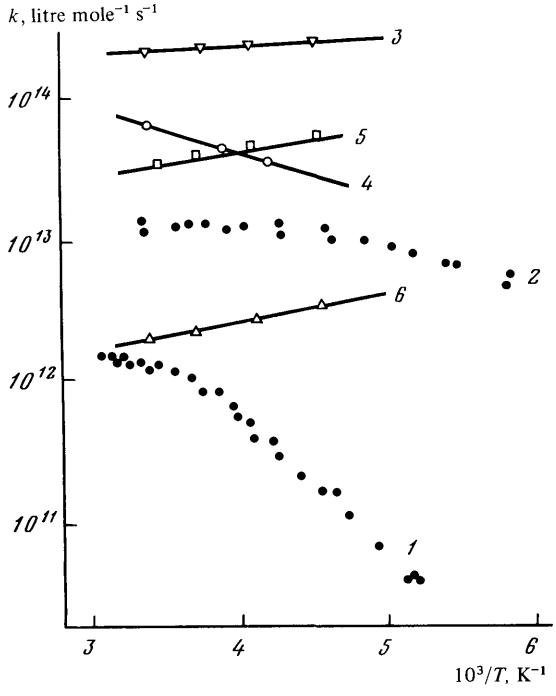

Figure 9. Temperature dependence of the rate constants for the capture of an excess electron by acceptor molecules: 1) and 2) pyrene in n-hexane[28] and iso-octane[17]; 3,4,5), and 6) SF_6, CCl_4, C_2HCl_3 and N_2O in tetramethylsilane[33].

The study of the mechanism of the capture of an electron in non-polar liquids has only begun. One of the tasks in this field is to determine the state, localised or quasi-free, in which the electron is captured by the acceptor molecule.

4. Role of the Localised and Quasi-Free Electron

With allowance for the two states of an excess electron in non-polar liquids—localised e^-_{loc} and quasi-free e^-_0—the kinetic scheme for the capture reaction can be represented in the form

$$\begin{array}{ccc} e^-_0 + A & \xrightarrow{k_0} & \\ \downarrow\uparrow & & A^-. \\ e^-_{loc} + A & \xrightarrow{k_{loc}} & \end{array}$$

From various estimates[101,102], the time required to establish the equilibrium $e^-_0 \rightleftharpoons e^-_{loc}$ is much shorter ($< 10^{-11}$ s) than the characteristic reaction times in the experimental determination of rate constants ($> 10^{-8}$ s), so that the values of the constants can be broken down into two components

$$k = k_{loc} P + k_0 (1 - P) \qquad (10)$$

where P is the probability of localisation, and k_{loc} and k_0 the reaction rate constants for the capture of an electron in localised and quasi-free states.

Which of these states makes the main contribution to the reaction rate? In the examination of this question for a qualitative estimate of the magnitude of P it is convenient to use the relationship

$$P = 1 - \mu/\mu_0, \qquad (11)$$

applicable for the trap model of the mobility of an excess electron, with the assumption that the mobility of the quasi-free electron is approximately the same for different liquids.

a) Reactions of a localised electron

It may be expected that for liquids for which the degree of localisation of an excess electron is high, so that its mobility is low, the localised state plays an important role in the chemical reactions of the excess electron.

For the capture of an electron by an O_2 molecule, which is a "poor" electron acceptor in non-polar liquids, this assumption is confirmed by the determination of the reaction rate constant $k(O_2)$ in various liquid hydrocarbons. The experimental data[94,97,103] show that the values of $k(O_2)$ are approximately constant for all liquids with low electron mobility studied (n-hexane, methylcyclohexane, cyclohexane, iso-octane), although for these liquids, the coefficient of diffusion of the electron and hence μ change by a factor of more than 70 (see Fig. 10). Eqns. (10) and (11) and the dependence of $k(O_2)$ on μ indicate that the main contribution to the reaction rate is made by the localised electron.

It may be assumed that the molecules of "good" acceptors in hydrocarbons having a low electron mobility also capture chiefly excess electrons in a localised state. In fact, the rate constants for the reactions of an electron with these acceptors are extremely high. For example, in n-hexane at $T \simeq 300$ K for SF_6, CO_2, pyrene, C_2H_5Br, etc., $k > 10^{12}$ litre mole^{-1}s^{-1}. If the contribution of localised electrons to the reaction rate were not the main contribution, then from Eqns. (10) and (11) it would be necessary, for these values of k, to assume values of $k_0 \simeq k/(1-P)$ which are too high. Thus in the "trap" model of transfer for $k = 10^{12}$ litre mole^{-1}s^{-1}, $\mu = 0.1$ cm^{2}V^{-1}s^{-1}, and $\mu_0 = 10^2$ cm^{2}V^{-1}s^{-1}, it would be necessary to assume that $k_0 = 1.2 \times 10^{15}$ litre mole^{-1}s^{-1}, which is greater than the limiting value for the reaction of a thermal electron in the gaseous phase $k_{lim} = \pi\lambda^2 v$, where $2\pi\lambda$ is the de Broglie wavelength, and v the velocity of the electron.

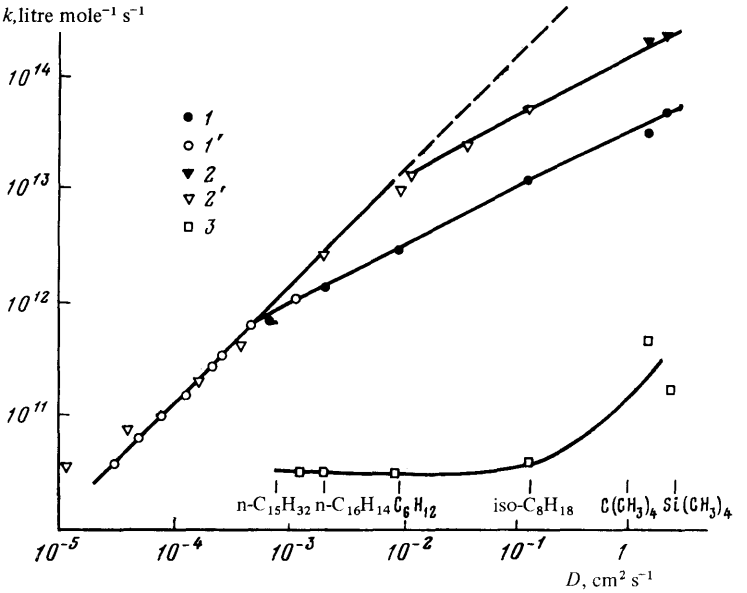

Figure 10. Relationship between the coefficient of diffusion of an excess electron and the reaction rate constants for the capture of the electron by the molecules of: 1,1′) pyrene in n-hexane, cyclohexane[28], iso-octane[17], pentadecane, and neopentane[135]; 2,2′) SF_6 in propane, ethane, n-hexane[99], and iso-octane[43]; 3) O_2 in methylcyclohexane, n-hexane, cyclohexane, iso-octane, neopentane, and tetramethylsilane[94,103]. The points *1*, *2*, and *3* relate to room temperature. The broken line corresponds to the relationship $k = 4\pi DR$ for $R = 16$ Å.

b) Reactions limited by diffusion

Fig. 10 gives data on the dependence of the rate constants for the capture of an electron by "good" acceptors on the diffusion coefficient of the excess electron D. The values of D were determined from the mobility of the electron using Einstein's relationship $D = kT\mu/e$. It can be seen that at values of $D < 10^{-3}$ cm^2s^{-1} (or $\mu < 0.1$ $cm^2V^{-1}s^{-1}$), the values of k are approximately proportional to D. This $k(D)$ relationship indicates that the reaction rate is limited by the diffusion of the excess electron to the acceptor molecule. For reactions of this type in non-polar liquids, the values of the radius of the reaction, characterising the distance between the species at the moment of electron transfer, are unusually high. Table 2 shows that the Debye–Smoluchowski equation for the radius of the reaction $R = k/4\pi\ (D + D_A)$, where $D_A \ll D$ is the diffusion coefficient of the molecule of the acceptor, gives values of 10–30 Å for the reactions of electron capture in liquid hydrocarbons, whereas for the diffusion-limited reactions of the solvated electron in water, R amounts to 2–3 Å.

The reason for the high values of the radii of reactions in liquid hydrocarbons is not clear. Estimates[28,104] show that it is difficult to attribute these values to the polarisation interaction of the excess electron and the acceptor molecule. If it is assumed that the electron is captured by the acceptor chiefly from the localised state, the high values of R can in principle be attributed to the large radius of the localised electron[28]. Radii of 20–30 Å for the localised electron are also postulated in the discussion of data on the mobility of an excess electron in liquid propane and pentane in strong electric fields[37].

It is possible, however, that the values obtained for R are effective values and are associated with a tunnel reaction mechanism.

Table 2. Radii of the reaction for the capture of an excess electron, calculated from the equation $R = ek/4\pi k_B T\mu$.

Acceptor	Liquid	T, K	μ, $cm^2\ V^{-1}\ s^{-1}$	k, litre $mole^{-1}\ s^{-1}$	R, Å
Pyrene	pentadecane	296	$3\cdot10^{-2}$ [135]	$6.6\cdot10^{10}$ [135]	11.6
SF_6	n-hexane	246	$1.8\cdot10^{-2}$ [99]	$3.8\cdot10^{11}$ [99]	13.5
C_2H_5Br	n-hexane	250	$2.3\cdot10^{-2}$ [28]	$5.0\cdot10^{11}$ [28]	13.8
Pyrene	n-hexane	250	$2.3\cdot10^{-2}$ [28]	$5.9\cdot10^{11}$ [28]	16.3
C_2HCl_3	n-hexane	253	$2.24\cdot10^{-2}$ [33]	$6.4\cdot10^{11}$ [33]	18
SF_6	propane	139	$3\cdot10^{-3}$ [99]	$7.2\cdot10^{10}$ [99]	26.5
SF_6	ethane	142	$4\cdot10^{-2}$ [99]	$1.0\cdot10^{12}$ [99]	27.5
SF_6	ethane	110	$1.3\cdot10^{-3}$ [99]	$5.0\cdot10^{11}$ [99]	55

c) Tunnel mechanism of capture

This mechanism has recently been frequently introduced in the discussion of the capture of an excess electron in polar liquids and solids[105–108]. With allowance for the diffusion of the electron and the acceptor molecule[108], the reaction rate constant for capture by a tunnel mechanism can be represented in the form $k = 4\pi DR_{eff}$, where the effective radius of the reaction is given by

$$R_{eff} = R_a + [1.15 + \ln(\alpha'/\beta^2 D)]/\beta, \qquad (12)$$

R_a is the sum of the radii of the acceptor molecule and the localised electron, α' a frequency factor, and $\beta = 2\hbar^{-1}[2m(V_0 - E_{loc})]^{1/2}$ is the attenuation factor of the wave function of the localised electron.

Eqn. (12) makes it possible to explain the high values of the radius of the reaction for the capture of an electron in liquid hydrocarbons. In fact, for these media the magnitude of the electron tunneling barrier $V_0 - E_{loc}$, equal in the simple trap transfer model to the activation energy of the mobility of the electron, is apparently less than 0.2 eV. If it is assumed that $\alpha' \simeq 10^{13}\ s^{-1}$, as is usually done for tunnel reactions in solid solutions [108], then for $V_0 - E_{loc} = 0.2$ eV and $D \simeq 10^{-4}\ cm^2 s^{-1}$, Eqn. (12) gives $R_{eff} \simeq 3R_a$. This estimate, for $R_a \simeq 5$ Å, shows qualitative agreement with the experimental data for the capture of an electron by "good" acceptors in liquid hydrocarbons characterised by low excess electron diffusion coefficients. It should be noted that the tunnel reactions of an electron in non-polar liquids differ from those in polar liquids in that the barrier to tunneling is appreciably smaller (for water, $V_0 - E_{loc} \simeq 1.5$ eV [108]). This means that, other conditions being equal, the rate of tunnel transfer from a distance of ~ 20 Å is $\geq 10^8$ times higher in liquid hydrocarbons than in water.

The assumption that the magnitude of the electron tunneling barrier in liquid hydrocarbons is approximately equal to the activation energy of the mobility of the electron also makes it possible to understand the order of magnitude of k for liquids with a high electron diffusion coefficient $D > 10^{-3}\ cm^2 s^{-1}$. In this range of values of D, the ratio k/D for many "good" acceptors decreases with increase in D (see for example Fig. 10), indicating that diffusion restrictions on the rate of reaction are removed. A qualitative estimate of the rate constant k' for the reaction not restricted by diffusion can be obtained by assuming that the concentration of localised electrons is independent of the distance r to the acceptor molecule. In this case

$$k' = \int_{R_a}^{\infty} 4\pi r^2 \omega(r)\, dr, \qquad (13)$$

where $\omega(r) \simeq 10\alpha' R^2 e^{-\beta(r-Ra)}/4r^2$ [108] is the probability of tunnel transfer, if the distance between the localised electron and the acceptor molecule is equal to r.

Eqn. (13) for $\alpha' \simeq 10^{13}\ s^{-1}$, $B_a = 5$ Å, and $V_0 - E_{loc} \simeq 0.1$ eV gives $k' \simeq 10^{13}$ litre $mole^{-1} s^{-1}$, which is of the same order of magnitude as the experimental values of k for acceptors such as N_2O, CCl_4, pyrene, biphenyl, and CO_2 in liquids with a high excess electron mobility (iso-octane, neopentane). At present, however, the tunnel mechanism of capture is not unambiguous for non-polar liquids with a high excess electron mobility. It is possible that as a consequence of the low degree of localisation of the electron in these liquids, the acceptor captures the electron in a quasi-free state.

d) Reactions of the quasi-free electron

The chemical reactions of a delocalised electron in condensed media have recently been introduced to interpret fast reactions involving electrons formed in the tracks of charged particles. It is assumed that in polar liquids, the delocalised state of the track electron, often called "dry", precedes the formation of the solvated electron. Attempts to determine the reactivity of "dry" electrons have been based on the study of the influence of an acceptor on the yield of solvated electrons [109-114] or the probability of positronium formation in a positron track [115-117]. Because of the short lifetime of the "dry" electron in polar liquids and the complex nature of the kinetics of track processes, the use of these methods to study the elementary reactions of a delocalised electron presents considerable difficulties. In the case of non-polar liquids, it is possible to use for this purpose a more direct method based on the study of the reactions of excess electrons which have avoided track recombination. The use of this method for electrons in liquefied noble gases, for which the quasi-free state of an electron is stable, has shown [118,119] that the reaction rate constants for the capture of a quasi-free electron may reach extremely high values (for example, 3×10^{14} litre × $mole^{-1} s^{-1}$ for SF_6 in liquid xenon).

In non-polar molecular liquids, the study of the reactions of the quasi-free electron is complicated by the fact that the reactions of the excess electron in the localised state are also possible. In the case of the reactions of an excess electron not restricted by diffusion, the reaction rate constant for the capture of a quasi-free electron k_0 can be estimated from Eqns. (10) and (11) and the experimental $k(\mu)$ relationship for different liquids. This approach has been used [94,103] to study the reaction

$$e_0^- + O_2 \rightarrow O_2^-. \qquad (14)$$

As already noted, the reaction rate constant for the capture of an excess electron by an O_2 molecule is approximately the same for different liquid hydrocarbons having an electron mobility $\mu < 10\ cm^2 V^{-1} s^{-1}$. On going to liquids with high values of μ (neopentane, tetramethylsilane), the value of the constant increases considerably (see Fig. 10). This increase can be attributed to an increase in the contribution of the quasi-free electron e_0^- to the reaction rate. The values obtained with this assumption for the rate constant of reaction (14), $k \simeq 3 \times 10^{11}$ litre × $mole^{-1} s^{-1}$ at 300 K, and the activation energy, < 0.01 eV [94,103], agree with the results of the study of the capture of a quasi-free electron in liquid krypton and argon [119].

The assumption that the capture of an electron in a quasi-free state predominates in liquids characterised by a high electron mobility makes it possible to explain the negative activation energy for various reactions, and also the existence of a maximum on the curve giving the dependence of k on the energy of the quasi-free electron (see Fig. 11). For the interpretation of these results, existing views on the reaction of low-energy electrons with molecules in the gaseous phase have proved useful.

e) Comparison with gas-phase data

At present, only the first attempts [33,103,120,121] have been made to examine theoretically the capture of a quasi-free electron by an acceptor molecule in a liquid. These attempts are based on the assumption that the mechanism of these reactions is analogous to that of the reactions of ar electron with molecules in the gaseous phase. In the last case it is usually assumed [123,124] that for an electron with a low energy (< 3 eV) the reaction takes place in two stages:

$$\text{I.}\quad e_0^- + A \underset{\tau_1^{-1}}{\overset{k'}{\rightleftarrows}} (A^-)^*$$

$$\text{II.}\quad (A^-)^* \longrightarrow \begin{cases} \rightarrow A^- \\ \rightarrow B^- + D \end{cases}.$$

Stage I is the formation of an intermediate vibrationally excited ion $(A^-)^*$ (τ_1 is the lifetime of the ion with respect to self-ionisation), and stage II is the stabilisation of the

ion as a result of collision with a third particle or dissociation. For the first stage of the reaction, the difference from the gaseous phase is that in the liquid, the term of the initial state (acceptor molecule + delocalised electron) is displaced along the energy scale by an amount V_0, and the term of the final state (the negative ion of the acceptor) is displaced by an amount equal to the energy P_- of the electronic polarisation of the molecules of the medium by the negative ion, situated in the same environment as the acceptor molecule before electron capture. Thus in the gaseous phase the formation of various states of the negative ion takes place at an electron energy ϵ_m, whereas in the liquid this requires the kinetic energy of the quasi-free electron

$$\tilde{\epsilon}_m = -V_0 + P_- + \epsilon_m \ . \qquad (15)$$

For many negative ions in non-polar liquids, $-P_- = 1.5 \pm 0.8$ eV.[85,121] Thus a thermalised quasi-free electron in a liquid with $-0.6 < V_0 < +0.2$ eV may lead to the formation of the same states of the negative ion as an electron in the gas with an energy 0.3–2.5 eV.

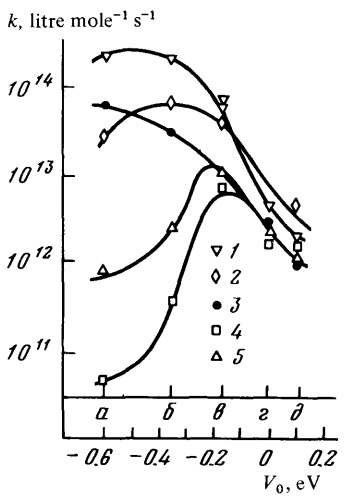

Figure 11. Relationship between the energy of a quasi-free electron V_0 and the reaction rate constants for the capture of an excess electron by molecules of SF_6 (1), C_2HCl_3 (2), CCl_4 (3), C_2H_5Br (4), N_2O (5).[33] The values of k and V_0 were measured for the following liquids at room temperature: tetramethylsilane (a), neopentane (b), isooctane (c), cyclohexane (d), and n-hexane (e).

In this approach it is possible to attribute the maxima on the curve giving the dependence of k on V_0 (see Fig. 11) to the fact that the thermal energy of the quasi-free electron corresponds to a maximum cross-section for the formation of the intermediate ion, that is $3/2k_BT = \epsilon_m - V_0 + P_-$. For the C_2HCl_3 molecule, for example, $\epsilon_m = 0.4$ eV,[125] so that for $P_- \simeq -0.7$ eV,[33] a maximum capture cross-section should be expected at $V_0 \simeq -0.3$ eV, in agreement with the data in Fig. 11. Since for $3/2k_BT > \epsilon_m - V_0 + P_-$ a decrease in V_0 leads to deterioration in the resonance conditions, it is also possible to understand the decrease, unusual for classical diffusion theory, in the reaction rate constant on going to liquids with a higher electron mobility and hence a lower value of V_0. A decrease in k with decrease in V_0 is characteristic of not only C_2HCl_3 but also other acceptors: N_2O, CO_2, and C_2H_5Br, the molecules of which have a negative electron affinity in the gaseous phase[33,120].

The assumption that the mechanism of the capture of a quasi-free electron is analogous to that of the reaction in the gas also makes it possible to explain the negative activation energies for various reactions involving the capture of an excess electron in a non-polar liquid (see Fig. 9). In fact, for $3/2k_BT > \epsilon_m - V_0 + P_-$, decrease in temperature leads to an improvement in the conditions for resonance, since V_0 increases (see Fig. 2). Moreover, an estimate[103] of the absolute magnitude of the rate constant of the reaction $e_0^- + O_2 \rightarrow O_2^-$, based on gas-phase data on the cross-section for the formation of the intermediate ion O_2^-, gives satisfactory agreement between experiment and the activation energy and the order of magnitude of k.

5. Excess Electrons in the Primary Processes of Photolysis and Radiolysis

Recent quantitative data on the mobility and reactivity of an excess electron are extending considerably the possibilities provided by the analysis of the kinetics of various electronic processes in molecular liquids. Of greatest interest among these, judging from the number of published papers, are the primary photochemical and radiation-chemical processes in liquid solutions.

As already noted, the ionisation of molecules in a liquid leads to the formation of two types of electron–ion pair: pairs involved in "primary recombination", and pairs which avoid this recombination, or "free" charges. In the formation of electron–ion pairs under the influence of ionising radiation[126,127] or as a result of two-quantum ionisation[128], only a small fraction of the electrons become "free" (from 2% in liquid n-hexane to 20% in neopentane). For many-component systems, the direction of the chemical processes taking place after ionisation is determined to a great extent by the proportion of electrons captured by acceptor molecules before recombination.

The theoretical approaches used to describe the kinetics of "primary" recombination in the presence of electron acceptors are based on the theories of diffusion and drift in the Coulombic field of the electrons, which are regarded as classical charged particles, in thermal equilibrium with the medium[129–132]. The most widely accepted theory at present is that proposed by Hummel[130] and subsequently developed for radiation problems[132–134].

This theory examines the distribution with respect to lifetimes $n(t)$ of the number of electrons undergoing "primary" recombination in the pure solvent. It is assumed that among these electrons, the proportion of electrons recombining with a positive ion in the presence of an acceptor is given by

$$N = \int_0^\infty n(t)\, e^{-k[A]t}\, dt, \qquad (16)$$

where k is the rate constant of the capture reaction. In this approach, the moment of time corresponding to the recombination of the negative ion A^- formed by the capture of an electron by the acceptor can be expressed simply in terms of the lifetime of the electron in the pure solvent $t(e^-)$ and the ratio of the drift mobilities of the electron and the ion r_d. In fact, for classical particles, the rate of

recombination is inversely proportional to the sum of their mobilities, so that $t(A^-) = t_c + [t(e^-) - t_c]\gamma_d$, where t_c is the time of electron capture, and $t(A^-)$ the time of ion recombination. A knowledge of the distribution of the mobilities and the rate constants of the charged species makes it possible to obtain a complete description of the kinetics of "primary" recombination.

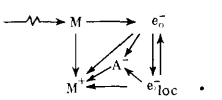
Eqn. (16), which is the Laplace transform for the function $n(t)$, makes it possible to establish the distribution of electrons with respect to lifetime up to the moment of recombination from the experimental dependence of N on [A]. In the case of the radiolysis of non-polar solutions, for the determination of $N([A])$ in the Hummel–Schuler theory, the empirical dependence of the yield of the ions A^- on the concentration of the acceptor[86] is used:

$$G(A^-) = G_{fi} + G_{prim}\frac{(\alpha[A])^{1/2}}{1+(\alpha[A])^{1/2}}, \qquad (17)$$

where G_{fi} is the yield of "free" ions, $G_{prim} \simeq 4$ is a parameter interpreted as the yield of electrons taking part in "primary" recombination, and α a coefficient which depends on the properties of the acceptor and the solvent. From Eqn. (17) it follows that

$$1 - N = \frac{(\alpha[A])^{1/2}}{1+(\alpha[A])^{1/2}}. \qquad (18)$$

According to a calculation[132] based on Eqns. (16) and (18), $\alpha = k/\lambda$, where λ is a coefficient characterising the rate of the "primary" recombination, and the distribution function has the form:



$$n(t) = -\frac{d}{dt}\left[e^{\lambda t}\left(1 - \frac{2}{\sqrt{\pi}}\int_0^{\sqrt{\lambda t}} e^{-x^2}dx\right)\right]. \qquad (19)$$

The value of λ can be estimated from experimental data for k and α. For example, for liquid cyclohexane at $T \simeq 300$ K, this estimate gives $\lambda \simeq 2 \times 10^{11}$ s^{-1},[33] which for $n(t)$ of form (19) corresponds to a time of recombination of 50% of the electrons $t_{1/2} = 0.6\,\lambda^{-1} = 3 \times 10^{-12}$ s.

Values recently obtained for k and the mobility of an excess electron show satisfactory agreement[135-139] within the framework of the diffusion models with data for the yield of negative ions in liquids with a relatively low electron mobility ($\mu < 10$ cm^{2}V^{-1}s^{-1}). Moreover, the results of the study of the $n(t)$ relationship, obtained by measuring the optical density of electrons[56,58], lead to $\int_t n(t)dt \sim t^{-1/2}$, which corresponds to Eqn. (19) for $t \gg \lambda^{-1}$. It has also been established that diffusion theory effectively described the kinetics of the decrease in the quantity of biphenyl ions formed in the nanosecond radiolysis of a solution of biphenyl in cyclohexane[140].

In the interpretation of the results in all these cases, the electron was regarded as a classical particle with a mobility equal to the drift mobility of the excess electron. In relation to recently discussed models of the movement of an electron in a non-polar liquid, which assume the participation of quasi-free and localised states of the electron, these ideas can be justified if two conditions are satisfied. Firstly, the free path l of the quasi-free electron must be less than the characteristic dimension of the problem being considered[141]. In the study of the kinetics of "primary" recombination, this dimension is the distance from the positive ion on which the electron is thermalised. For most excess electrons generated by ionising radiation in a non-polar liquid, this distance is 60–100 Å.[40] In photo-ionisation it may be even smaller (~ 30 Å[50]). Since the assumed value of the mobility of a quasi-free electron, $\sim 10^2$ cm^{2}V^{-1}s^{-1}, corresponds to $l \simeq 60$ Å, this condition is apparently fulfilled only for a small proportion of the excess electrons, thermalised at distances greater than the average thermalisation length. Secondly, the processes being considered must be sufficiently slow, compared with the time taken for equilibrium to be established between the quasi-free and localised states, since otherwise it is not possible to use the drift mobility to determine the rate of recombination of the electron, and the constant k to calculate the probability of the capture of an electron by an acceptor molecule.

In the more general case it is necessary to consider a scheme of "primary" recombination including processes involving the capture and recombination of a quasi-free electron before localisation:

In contrast to diffusion models, the description of the kinetics of the processes in this scheme requires data on the spatial and time distribution separately for both the quasi-free e_0 and localised e^-_{loc} electrons and the probabilities of their reactions with an acceptor molecule.

The satisfactory agreement, described above, between diffusion theories and experiment is apparently related to the fact that in all cases the processes considered were comparatively slow, with characteristic times greater than the lifetime of the localised electron. For cyclohexane, for example, the lifetime of an electron in a localised state is $\tau_{loc} \simeq 10^{-10}$ s at $T = 300$ K, if it is assumed that the energy of liberation of an electron from a structural trap in the liquid is equal to the activation energy of the mobility of the electron (0.17 eV[21]), and the frequency factor is $\nu \simeq 10^{13}$ s^{-1}. Thus by using nanosecond technique for kinetic studies of "primary" recombination in this liquid, it is possible to "feel" only those electrons which are captured many times by the traps. This conclusion also applies to the method of studying kinetics based on an analysis of the concentration dependence of the yield of the negative ions of the electron acceptors, at concentrations of the acceptor $[A] \leq 10^{-2}$ M, for which $k[A] < \tau^{-1}_{loc}$.

At acceptor concentrations $[A] \simeq \tau^{-1}_{loc} k^{-1}$, the acceptor will efficiently capture electrons which have undergone a small number of transitions between localised states. The value of the drift mobility of the electron cannot be used to describe the motion of these electrons and hence the kinetics of the recombination of the negative ions for which they are the precursors.

At even higher acceptor concentrations, the quasi-free electron may be captured by an acceptor immediately after ionisation, before it is thermalised or localised in a structural trap. This possibility at $[A] > 10^{-1}$ M is assumed, for example, in the discussion of the influence of electron acceptors on the yield of "free" ions[142] or on the probability of positronium formation in a positron track[116,117]. In this case the equilibrium distribution of the excess electron with respect to states is broken down, so that Eqn. (16) becomes inapplicable.

Thus the determination of the distribution function of the electrons $n(t)$ from the experimental dependence of $G(A^-)$ on [A] at $t < \tau_{loc}$ can hardly be reliable. This possibly explains why the time of the "primary" recombination of 50% of the electrons in liquid cyclohexane, estimated by this method (3×10^{-12} s), was found to be shorter than the

lifetime of the electron in a localised state (10^{-10} s), assumed from data on the mobility of the excess electron.

Thus the use of the diffusion approach in the analysis of electron processes following ionisation is justified only for processes with a characteristic time $\gg \tau_{loc}$. In the examination of processes involving an excess electron for times $< \tau_{loc}$, the data at present available on the reactivity and mobility of the excess electron are inadequate. It is necessary to have data on the dynamics of the thermalisation and localisation of the electron, on the proportion of electrons recombining with a "free" ion without the stage involving localisation in the liquid, and on the distribution of these electrons with respect to their lifetime before recombination. Direct quantitative data of this kind will apparently be obtained in the near future by the use of nanosecond techniques.

Mass Spectrometry with Chemical Ionisation

A.A.Solov'ev, V.I.Kadentsev, and O.S.Chizhov

The fundamental processes occurring in the interaction of organic molecules with Brønsted and/or Lewis acids in the gas phase are discussed and the fragmentation of the principal classes of organic compounds initiated by chemical ionisation is examined. It is shown that the unique advantages of mass-spectrometry with chemical ionisation are manifested most strikingly in structural studies of complex natural and synthetic products with labile bonds.
The bibliography includes 107 references.

I. INTRODUCTION

The origins of the development of chemical ionisation (CI) must be sought in experiments with molecular beams and the study of ion–molecule reactions in the gas phase†. The bibliography of the research on ion–molecule reactions during 1900–1966 includes more than 430 references and half of these cover the period since 1962.[4] In 1952 Tal'roze and Lyubimova detected for the first time the CH_5^+ ion (the methonium ion) in the ionisation chamber of a mass-spectrometer[5]. The first mass spectra with chemical ionisation[6,7] (CIM-spectra) were obtained in 1965 by Munson and Field on the Esso chemical physics mass-spectrometer[6,7]. These were the spectra of C_2H_6, n-C_3H_8, H_2O, and NH_3.[6,7] However, the application of CI in analytical chemistry began in 1966.[8] The extensive incorporation of CI in practical research is associated with the modification in 1969 of the two most common high-resolution mass-spectrometers—AEI MS-902 [9] and Du Pont/CEC 21-110C.[10] The development of a combined analytical method based on a gas–liquid chromatograph and a mass-spectrometer with chemical ionisation (GLC/MS-CI [11]) led to the intensive employment of CI in studies on complex biochemical mixtures. The application of CI in physicochemical research is associated with the development by Field of a method for the estimation of the kinetic parameters of reactions involving the molecular decomposition of protonated molecular ions and a method for the investigation of the kinetic parameters of reversible reactions[12] and also to some extent with the development of a procedure for the estimation of the proton affinities of the test compounds[13]. Finally the development of the CI-mass-spectrometry of negative ions made it possible to investigate S_N2 reactions in the gas phase[14-17].

The Essential Features of Chemical Ionisation‡. Problems of Nomenclature

At low pressures (10^{-5} mmHg and below) the ionisation of molecules and unimolecular decomposition of the ions formed take place in the ionisation chamber of the mass-spectrometer under electron impact. For example, the following reactions take place in methane:

$$CH_4 + e \rightarrow CH_4^{+\cdot}, CH_3^+, CH_2^{+\cdot}, CH^+, \ldots + 2e \quad . \tag{1}$$

The ions formed under these conditions are primary and the spectrum recorded is the primary spectrum of the reactant gas.

With increase of pressure, ion–molecule reactions between the primary ions and neutral molecules begin to occur together with reactions of type (1). For example, the following reactions take place in methane[5,21]:

$$CH_4^{+\cdot} + CH_4 \rightarrow CH_5^+ + CH_3^{\cdot}, \tag{2}$$

$$CH_3^+ + CH_4 \rightarrow C_2H_5^+ + H_2, \tag{3}$$

$$CH_2^{+\cdot} + CH_4 \rightarrow C_2H_4^{+\cdot} + H_2, \tag{4}$$

$$CH_2^{+\cdot} + CH_4 \rightarrow C_2H_3^+ + H_2 + H^{\cdot}, \tag{5}$$

$$C_2H_3^+ + CH_4 \rightarrow C_3H_5^+ + H_2 \cdot \tag{6}$$

The ions formed under these conditions can be secondary or reagent ions and the spectrum recorded is the secondary spectrum of the reagent gas. Reactions (2)–(6) assume a significant importance at pressures above 0.01 mmHg and are characterised by extremely high rate constants (virtually each collision of a primary ion with a neutral molecule terminates in reaction). At 1 mmHg the CH_5^+, $C_2H_5^+$, and $C_3H_5^+$ ions constitute 95% of the overall ionic current (48, 51, and 6% respectively)[4]. It is significant that the secondary ions as a rule do not interact

† The term chemoionisation (chemiionisation) appeared in the literature in 1949 [1] and is used (in contrast to CI) to denote a wide variety of reactions between neutral atoms and molecules, leading to the formation of electrons and ions[2,3].

‡ In principle, chemical ionisation can be achieved in at least three ways[18]: (1) on double mass-spectrometers (tandems); (2) by ionic cyclotron resonance; (3) using the high-pressure mass-spectrometric technique. In the present review this problem is discussed only in relation to the use of the high-pressure mass-spectrometric technique. The experimental aspect of CI is examined in other reviews[19,20].

(or interact very slowly) with the neutral molecules of the reagent gas, i.e. the ratios of the intensities of the signals of the secondary ions in a specified range of reactant gas pressures do not vary to a first approximation (in the case of methane the $C_2H_3^+$ ion is an exception).

If approximately 0.1% of the test substance (the *substrate*) is added to the recent gas, then secondary ions interact with the substrate molecules, a proton or a hydride ion being transferred, i.e. they act like Brønsted and/or Lewis acids [reactions (7) and (8)]. The BH_2^+ ion will henceforth be referred to as the *protonated molecular ion* or the quasi-molecular ion $[M + H]^+$ and the ion B^+ will be called a *quasi-molecular ion* $[M - H]^+$. The BH_2^+ and B^+ ions can decompose under certain conditions [reactions (9)–(11)]. Reactions (12)–(14) illustrate the formation of cluster-ions§. The ions on the right-hand side of Eqn.(7)–(14) form the CH_4 spectrum of BH. The interaction with electrons and with the primary ions of the substrate molecules can be neglected in view of the low concentrations of the latter:

$$BH + CH_5^+ (C_2H_5^+) \rightarrow BH_2^+ + CH_4 (C_2H_4) \quad , \tag{7}$$

$$BH + C_2H_5^+ (CH_5^+) \rightarrow B^+ + C_2H_6 (CH_4 + H_2) \quad , \tag{8}$$

$$BH_2^+ \rightarrow B^+ + H_2 \quad , \tag{9}$$

$$BH_2^+ \rightarrow A_i^+ + B_i \quad , \tag{10}$$

$$B^+ \rightarrow A_{i'}^+ + B_{i'} \quad , \tag{11}$$

$$BH + C_2H_5^+ \rightarrow BH \cdot C_2H_5^+ \quad , \tag{12}$$

$$BH + C_3H_5^+ \rightarrow BH \cdot C_3H_5^+ \quad , \tag{13}$$

$$BH + BH_2^+ \rightarrow (BH)_2 H^+ \quad . \tag{14}$$

II. MAIN DEFINITIONS, PRINCIPLES, AND RELATIONS

One must distinguish two most common types of interactions occurring during CI: (1) acid–base interactions and (2) interactions of the oxidation-reduction type. The ions formed in the former and latter cases have even and odd numbers of electrons respectively. Examples of interactions of the first type are provided by reactions (7)–(14). Reactions of the second type are charge-transfer processes:

$$M + X^{+\cdot} \rightarrow M^{+\cdot} + X, \tag{15}$$

where M is a substrate molecule and X = He, Ne, Ar, Xe, NO, N_2, etc. The internal energy of the molecules ion formed (E_{in}) is equal in the given case to the difference between the recombination energy $RE(X^{\cdot})$ of the reagent ion in the gas phase and the ionisation potential IP(M) of the substrate molecule[23]: $E_{in} = RE(X^{\cdot}) - IP(M)$. Exact knowledge of this quantity can prove extremely useful in theoretical studies. Charge transfer between the substrate molecule and reagent ion can be observed (and is indeed observed) for reagent gases of the first type (see Table) against the background of acid–base interactions if the recombination energy of reactant ions is fairly large. In the CH_4 spectra a phenomenon of similar kind has been observed for the reagent ions $C_2H_4^+$, $C_2H_5^+$ [29] and CH_5^+.[30]

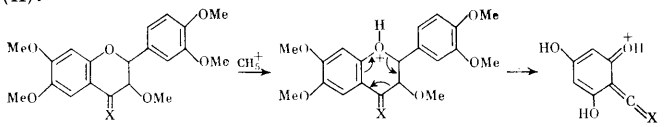
§ The presence of cluster ion peaks in the CIM-spectrum greatly simplifies the solution of the problem of the identification of the peak due to the quasi-molecular ion $[M + H]^+$.[22]

Only processes leading to the formation of ions with an even number of electrons will be examined in detail in the present review. The following generalisations are applicable to them.

1. In contrast to photoionisation and ionisation by electrons, CI processes occur with an equilibrium of atomic nuclei and electrons (in the ground state).
2. The internal energy of the ions formed is much lower than in ionisation by electrons and approaches the energy of ions formed in ion–molecule reactions in the condensed phase.
3. The ions formed in CI interact with gas molecules, transferring the excess energy until the occurrence of thermal equilibrium; it is therefore assumed that the range of ionic energies is fairly narrow and corresponds approximately to the range of energies in the usual chemical reactions in solution[29,31]¶.

The reagent gases used for chemical ionisation [PA(X) is the proton affinity and $RE(X^+)$ (eV) the recombination energy].

Acid–base reactions (type 1) (Refs.22–27)			Charge transfer (type 2) (Ref.28)		
gas (X)	reagent ions	PA(X), kcal mole^{-1}	gas	principal ion	$RE(X^+)$, eV
H_2	H_3^+	100	He	$He^{+\cdot}$	24.6
CH_4	CH_5^+	127	Ne	$Ne^{+\cdot}$	21.6; 21.7
CH_4	$C_2H_5^+$	159	Ar	$Ar^{+\cdot}$	15.8; 15.9
CH_4	$C_3H_5^+$	—	Ar	Ar^{2+}	~24
C_2H_4	$C_2H_5^+$	160	N_2	$N_2^{+\cdot}$	15.3
iso-C_4H_{10}	t-$C_4H_9^+$	195	N_2	N^+ or $(N_2)^{2+}$	
iso-C_5H_{12}	t-$C_5H_{11}^+$	—	N_2	$N_4^{+\cdot}$	
C_6H_{14}	$C_6H_{13}^+$	—	Kr	$Kr^{+\cdot}$	14.0; 14.7
C_8H_{18}	$C_8H_{17}^+$	—	Kr	Kr^{2+}	~21
C_8H_{18}	$C_6H_{13}^+$	—	CO	$CO^{+\cdot}$	14.0
C_8H_{18}	$C_5H_{11}^+$	—	CO	$(CO)_2^{+\cdot}$	11–12
H_2O	H_3O^+	165	CO_2	$CO_2^{+\cdot}$	13.8
H_2S	H_3S^+	170	CO_2	$(CO)_2^{2+}$	—
CH_3OH	$CH_3OH_2^+$	182	CO_2	$O_2^{+\cdot}$	9.7–17.0
NH_3	NH_4^+	207	Xe	$Xe^{+\cdot}$	12.1–13.4
CH_3NH_2	$CH_3NH_3^+$	216	Xe	Xe^{2+}	18–20
$(CH_3)_2NH$	$(CH_3)_2NH_2^+$	222	O_2	$O_2^{+\cdot}$	9.7–17.0
$(CH_3)_3N$	$(CH_3)_3NH^+$	227	CF_4	CF_3^+	IP=9.17
$(CH_3)_4Si$	$(CH_3)_3Si^+$	—	NO	NO^+	9.25 (8.3)



All three factors determine the specific nature of even-electron CIM-spectra, namely (a) the degree of fragmentation is smaller than in ionisation by electrons, (b) the peaks of quasi-molecular ions $[M + H]^+$ and /or $[M - H]^+$ are usually very intense, and (c) fragment ions giving rise to fairly intense peaks and having masses close to that of the quasi-molecular ions are as a rule identified in the CIM-spectrum.

¶ However, one must bear in mind that, although comparison with behaviour in solution is attractive and fruitful, it suffers from certain limitations due to the following three factors: (1) the reaction time in CI is much shorter (approximately 10^{-6} s); (2) the energies of the ions are somewhat higher; (3) there is no solvation.

It is noteworthy that complex molecules, when the latter can be transferred to the gas phase without decomposition, can suffer less fragmentation than relatively simple ions, in view of the greater possibility of a rapid redistribution of the vibrational energy of the ions among the internal degrees of freedom under conditions where the local excess energy is still insufficient for bond dissociation[32].

It is assumed that in a non-polar or weakly polar molecule fragmentation occurs as a result of random attack by the reagent ion on a particular section of the molecule, but fragmentation is as a rule localised at the site of attack (see, however, Foltz and Fentiman[33]). It has been shown that the presence of a static dipole in the molecule appreciably increases the cross-section of ion–molecule reactions[34], so that it is reasonable to suppose that the greatest number of effective collisions of the reactant ions with substrate molecules involve functional groups[29]. When the molecule contains several functional groups, the attack occurs to some extent via all the functional groups and the CIM-spectrum can be usually regarded as a combination of ions formed as a result of attack via each functional group separately. Such behaviour can be accounted for by the fact that the ions formed in CI have a relatively low energy and the migration of the charge in an even-electron ion usually requires the simultaneous migration of atoms or a group of atoms in the ion.

It follows from the foregoing considerations that the fragmentation of a polyfunctional compound with an increased lability of the molecule can nevertheless lead to the appearance of an intense peak of the $[M + H]^+$ ion when the molecule contains at least one group which "leaves with difficulty". For example the presence of the carbonyl group, which is readily protonated with formation of a stable ion, in the molecule of the flavanoid 2,3-*trans*-3,5,7,3′,4′-pentamethoxyflavanone (I) leads to an appreciable increase of the stability of the ion $[M + H]^+$ compared with 2,3-*cis*-3,5,7,3′,4′-pentamethoxyflavan (II):[35,36]

(I): X=O, $[M + H]^+$ (52%)*, *m/e* 181 (16%); (II): X=H_2, $[M + H]^+$ (18%), *m/e* 167 (44%)*. (16)

An analogous example with fragmentation of 5α-androstan-17β-ol (III) and 17β-hydroxy-5α-androstan-3-one (IV), for which the $[M + H]^+$ peak intensities are 3.9 and 50.2% respectively, has been published[20]†. The low intensity of the peak due to the ion $[M + H]^+$ derived from compound (III) is due to the great ease of the elimination of the OH group as H_2O following its protonation. The sharp increase of the stability of the ion $[M + H]^+$ derived from compound (IV) is associated, as in the previous example, with the presence of the carbonyl group.

The tendency of various functional groups to be eliminated has not been subjected to a systematic comparative study, but it is known, for example, that NH_2 is eliminated in the form of NH_3 with difficulty, halogens are eliminated as HHal, and the acetoxy-group is eliminated as CH_3COOH (the last two processes take place relatively readily), etc. It has been suggested[29] that the ease of elimination of the functional group Y from the molecule RY for the same R is inversely related to the proton affinity of the HY molecules and the following sequence, in terms of increasing ease of elimination of the most common functional groups, has been proposed (based on the proton affinities taken from Haney and Franklin[37]):

$$NH_2 < CH_3S \simeq C_6H_5 \simeq CH_3O \simeq OC(:O)H < CN \simeq SH < OH < I \simeq Cl \simeq Br\ .$$

The influence of the nature of R on the ease of elimination of the functional group can be estimated from general considerations. Thus, if R is an alkyl group, then the ease of elimination of Y increases in the sequence[38]: $k_{prim} < k_{sec} < k_{tert}$.

The substrate molecule is protonated only if the proton transfer from the reagent ion is an exothermic reaction. The heat of proton transfer is determined by the proton affinity of the substrate molecule M and that of the conjugate base X of the reagent ion, which is a measure of the acid properties of the reagent ion as a Brønsted acid: $\Delta H = PA(X) - PA(M)$. Consequently, by varying the acid strength of the reagent ion, it is possible to vary the exothermic property of the proton transfer reaction and hence the degree of fragmentation[23].

It can now be regarded as established that thermally activated fragmentation can occur under CI conditions. Thus the extremely significant influence of the temperature of the ion source on the degree of fragmentation of t-pentyl acetate and benzyl acetate in the presence of iso-C_4H_{20} has been noted[12]. It was found that CH_3COOH is eliminated with absorption of heat. Furthermore, when account was taken of the insignificant exothermic effect of protonation in the presence of iso-C_4H_{10} (between −8 and −13 kcal mole^{-1}) and the large number of collisions (approximately 200) of the protonated ion with the surrounding gas molecules, it could be claimed with sufficient confidence that the weakly excited ions formed initially rapidly reach thermal equilibrium with the surrounding medium, i.e. their distribution with respect to energies becomes of the Boltzmann type or approaches the latter. Kinetic analysis of experimental data obtained from iso-C_4H_{10} spectra recorded over a fairly wide temperature range showed that the rate constants for the unimolecular decomposition of ions obey the Arrhenius equation[12]. The use of reagent ions with fairly high acid strengths leads to fragmentation in a vibrationally excited state before the attainment of thermal equilibrium with the surrounding medium. For example, the protonated molecular ion of N-valeryl-leucine, formed in a methane plasma, decomposes in the energy state equivalent to the energy state of the same ion in the isobutane plasma at a temperature higher by 167 ± 10 K than the temperature of the methane plasma[39]. Thus, when the CIM-spectra obtained with different reagent gases are compared, the temperature of the ion source must be taken into account.

III. MASS SPECTRA OF THE CHEMICAL IONISATION OF DIFFERENT CLASSES OF ORGANIC COMPOUNDS

The most important factor in the study of the CI-fragmentation of organic compounds is that the reactions occurring in the ion source of the mass spectrometer obey the majority of the rules developed for ion–molecule reactions in the condensed phase. As one of the "mildest" ionisation methods, the CI procedure is most suitable in the study of the structures of labile molecules; it ensures

† As in the previous example, here the peak intensity is expressed as a percentage relative to the overall ionic current.

as a rule the presence of an intense peak due to the quasi-molecular ion for a fairly high degree of fragmentation. The nature of fragmentation in CI gives rise to the hope that this method will be most useful in the study of the content of functional groups in the substrate molecule and in the study of the nature and sequence of large blocks joined by labile bonds in the molecule. In ionisation by electrons [the electron impact (EI) method] the molecule is subjected to a more severe influence, as a result of which one can obtain data for the structure of its rigid skeleton. Thus the two methods (CI and EI) yield mutually supplementary information about the molecular structure.

1. Alkanes

The CH_4 spectra of n-alkanes consist of the peak due to the ion $[M - 1]^+$, which has the maximum intensity, and the peaks of the fragment alkyl ions, whose intensities are approximately equal but much lower than that of $[M - 1]^+$, located at intervals of 14 a.m.u.[8] The relative intensity of the ion $[M - 1]^+$ is independent of chain length, and the form of the CH_4 spectra, for example, for $n\text{-}C_{44}H_{90}$ and $n\text{-}C_8H_{18}$, is completely analogous. On the other hand, in the electron impact (EI) ultraviolet spectra of n-alkanes the maximum intensity corresponds to the $C_3H_7^+$, $C_4H_9^+$, and $C_5H_{11}^+$ ions, while the intensity of the peaks due to ions with large masses rapidly decreases with increase of m/e.[40] In the CH_4 spectra of branched alkanes the intensity of the ion $[M - 1]^+$ is somewhat lower than for n-alkanes, but the decrease is much smaller than in the case of electron impact, where the M^+ intensity becomes negligibly small[40]. The rate of dissociation of the C–C bond at the branching site increases appreciably, which can be attributed to exothermic β-cleavage (on the other hand, for unbranched alkanes the β-cleavage reaction is endothermic[8]):

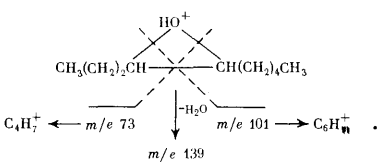
$$CH_3CH_2CH_2\text{—}\overset{\curvearrowright}{CH_2}\text{—}\overset{+}{C}H\text{—}C_{13}H_{27} \longrightarrow CH_3CH_2CH_2^+ + C_{15}H_{30}\ ; \qquad (17)$$

(V) (endothermic process)

$$C_6H_{13}\text{—}\underset{C_3H_7}{\underset{|}{CH}}\text{—}\overset{\curvearrowright}{CH_2}\text{—}\overset{+}{C}HC_4H_9 \longrightarrow C_6H_{13}\text{—}\overset{+}{C}H\text{—}C_3H_7 + C_6H_{12}\ . \qquad (18)$$

(VI) (exothermic process)

In the CH_4 spectrum of compound (VI) the peaks of the fragment alkyl ions $C_{13}H_{27}^+$ and $C_{10}H_{21}^+$ are appreciably more intense compared with those of other alkyl ions. In addition, the olefin ions $C_{13}H_{26}^+$ and $C_{10}H_{20}^+$, which have a considerable diagnostic importance, are formed in small but detectable amounts; the mechanism of the formation of these ions has not been elucidated. Until recently, it has been suggested that the fragment alkyl ions are formed in n-alkanes exclusively as a result of the electrophilic attack by the reagent ion on the C–C bond[8]. It has now been demonstrated experimentally that their formation via an alternative mechanism with abstraction of an olefin from the ion $[M - 1]^+$ also takes place[41].

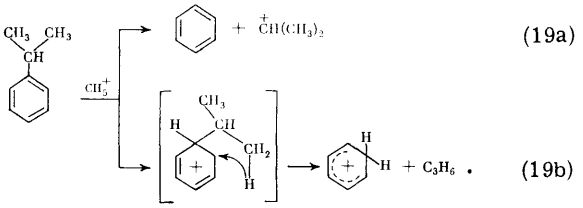


2. Cycloalkanes

Two series of ions have been detected in the CH_4 spectra of cycloalkanes: (1) $[M + 1]^+$ and $C_nH_{2n+1}^+$—the series of alkyl ions; (2) $[M - 1]^+$ and $C_nH_{2n-1}^+$—the series of alkenyl ions. The ion $[M + 1]^+$ is formed as a result of exothermic proton transfer from the reagent ion on ring opening. The ion $[M - 1]^+$ is formed when a hydride ion is split off from the cycloalkane molecule; it has the maximum intensity in the spectra. The study of the CH_4 spectra of cyclo-C_6D_{12} led to the conclusion that there is no hydrogen exchange between the substrate molecule and the reagent ions and that the $C_6D_{11}^+$ ion has the cyclohexyl and not the alkenyl structure. The presence of the $C_3D_7^+$ and $C_3D_6H^+$ ions indicates the occurrence of rearrangements with migration of hydrogen, because these ions originate from the hexyl ion $C_6D_{12}H^+$ and their peaks have approximately equal intensities[42].

3. Alkenes and Alkynes

The CH_4 spectra of monoalkenes resemble those of cycloalkanes, but the degree of fragmentation and the relative peak intensities corresponding to low m/e are greater for monoalkenes. Hydrogen is split off most readily from allyl positions. For polyenes, cycloalkenes, and alkynes, two series of ions are also observed, one of which originates from the quasi-molecular ion $[M + H]^+$ and the other from the quasi-molecular ion $[M - H]^+$.[43] A technique has been developed for the determination of the position of the double bond in the molecule of the initial olefin via its epoxy-derivative, using CH_4 or iso-C_4H_{10} as reagent gases (this method requires not more than 1 μg of the test substances):



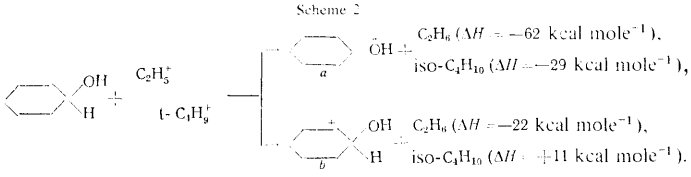
Scheme 1

The position of the epoxide ring and hence of the double bond can be readily established from the fragment peaks (see Scheme 1). Unfortunately no differences have been observed between the *cis*- and *trans*-isomers in any of the CIM-spectra of the epoxy-derivatives investigated[44].

4. Aromatic Hydrocarbons[45]

Aromatic rings are resistant to the action of reagent ions of the first type (see Table). For example, ions with a mass smaller than that of M^+ are not observed in the CH_4 spectrum of benzene. Together with the ions $[M + H]^+$, cluster ions having the composition $[C_6H_6 + C_2H_5]^+$, $[C_6H_6 + C_3H_5]^+$, etc. are formed. Alkyl groups are readily split off in the form of carbonium ions [reaction (19a)]. Furthermore, the alkyl side groups in aromatic hydrocarbons can undergo a fragmentation analogous to that of alkanes (see above). A hydride ion is split off from methyl groups with formation of a benzyl cation. In the presence of a side chain with three and more carbon atoms reactions involving hydrogen transfer and the elimination of an olefin [reaction (19b)] take place:

(19a)

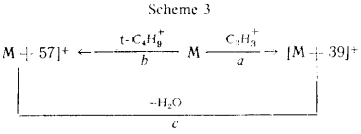


(19b)

5. Alcohols

The form of the iso-C_4H_{10} spectra of alkanols depends on the length and degree of branching of the hydrocarbon chain. For the first three members of the homologous series, the peak of the ion $[M + 1]^+$ has the maximum intensity in the spectrum. With increase of the length of the hydrocarbon chain, the intensity of the $[M + 1]^+$ peak falls sharply and the latter is altogether absent from the spectra of members of this series starting with C_8. The peak of the ion $[M - 1]^+$ is present with a fairly high intensity in the iso-C_4H_{10} spectra of all alcohols, with the exception of tertiary alcohols. The mechanisms of the formation of the ion $[M - 1]^+$ have been discussed in a number of studies[38,46,47]. One should note in the first place that initially the formation of this ion was considered exclusively in terms of hydride transfer from the alcohol molecule to the reagent ion[38]. However, the metastable transition $[M + 57]^+ \xrightarrow{*} [M - 1]^+$ has been observed[47]. Consequently at least some of the ions $[M - 1]^+$ should be formed when C_4H_{10} is split off from $[M + t\text{-}C_4H_9]^+$.

The initial hypothesis that α-hydrogen is split off preferentially in the spectra with CH_4 also proved to be invalid, because it was soon found[46] that in the CH_4 spectrum of 1-decan-1,1-d_2-ol the observed degree of elimination of α-deuterium would be expected on statistical grounds (10%). A more detailed study of this problem was undertaken[47] and it was found that specific elimination of α-deuterium is not observed in the CH_4 spectrum of cyclohexan-1-d-ol, but the extent of this process is inconsistent with that expected on statistical grounds. On the other hand, in the presence of iso-C_4H_{10} α-deuterium is split off preferentially (93%). It has been suggested that the abstraction of hydrogen is determined by the thermochemistry of competing reactions (Scheme 2):



Scheme 2

If one takes into account the fact that endothermic reactions in CI are slow, it is not surprising that in the presence of iso-C_4H_{10} a specific exothermic reaction, involving the formation of the ion a with elimination of α-hydrogen, takes place, while in the presence of CH_4 the specific elimination of α-hydrogen is not observed (see Scheme 2).

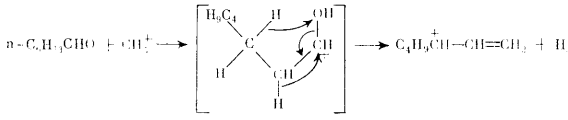
The intensity of the peaks of the cluster ions observed in the iso-C_4H_{10} spectra of alcohols, namely $[M + 39]^+$, $[M + 57]^+$, and $[2M + 1]^+$, depends greatly on the conditions under which the spectrum is recorded[38]. Earlier studies of the CI-fragmentation of alcohols[38] led to the idea that the ions $[M + 39]^+$ and $[M + 57]^+$ are formed via pathways a and b:

Scheme 3

However, in spectra with a high resolution only the peaks of ions having the composition $[M + C_4H_9 - H_2O]^+$ were found and not $[M + C_3H_3]^+$.[47] Consequently the ion $[M + 39]^+$ is formed when H_2O is split off from $[M + 57]^+$ (pathway c). It has been observed recently that the initial reaction between t-$C_5H_{11}OH$ and iso-C_4H_{10} involves the formation of the cluster ion $[C_9H_{20}OH]^+$, which rapidly dissociates with formation of $[C_9H_{19}]^+ + H_2O$ and $[C_5H_{11}]^+ +$ neutral products[48]. It is noteworthy that in the iso-C_4H_{10} spectra of alkanols, starting with C_5, the C_nH_{2n+1} peak has the maximum intensity in the spectrum. When CH_4 is used, the ion decomposes further with formation of a series of alkyl and alkenyl ions[38].

As regards the analytical applications of CI, it is of interest to examine the method whereby primary, secondary, and tertiary alcohols can be distinguished, and which is based on the significant differences between the ease of elimination of the hydride ion from the molecules of these compounds. When $(CH_3)_2CO$ or CH_3CHO is added to CH_4 in proportions of 20 : 1, methane reagent ions react almost completely with the carbonyl compound [reaction (20)]:

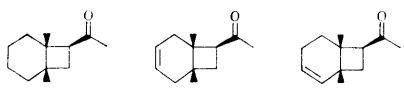
$$CH_5^+ (C_2H_5^+) + (CH_3)_2CO \rightarrow CH_4 (C_2H_4) + [(CH_3)_2COH]^+, \quad (20)$$



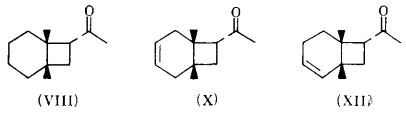
(21)

The oxonium ions formed in reaction (20) interact with secondary alcohols. This involves the elimination of hydrogen (in all probability from the α-position) and the formation of the ion $[M - 1]^+$ [reaction (21)]. An analogous reaction with primary alcohols takes place only in the presence of acetaldehyde. The ion $[M - 1]^+$ is not formed from tertiary alcohols[49].

6. Aldehydes and Ketones



The CH_4 spectra of aliphatic aldehydes contain the peak due to the ion $[M + H - H_2O]^+$ in addition to that of the ion $[M + 1]^+$:

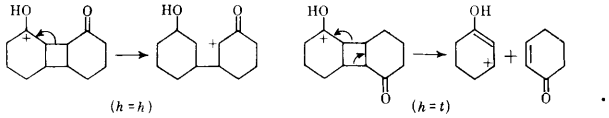


(22)

The driving force of reaction (22) is apparently the formation of a substituted allyl ion[50]. However, it must be emphasised that there is at present no independent evidence for the elimination of β-hydrogen from aldehyde molecules.

The CH_4 spectra of aliphatic ketones recorded under analogous conditions do not contain the $[M + H - H_2O]^+$ peak. Thus the spectrum of 2-octanone $C_{16}H_{13}COCH_3$ consists virtually of three peaks: $[M + 1]^+$, $[M + 29]^+$, and $[M + 41]^+$.[50] However, one should note that the formation of the ion $[M + H - H_2O]^+$ has been observed in the bicyclic ketones (VII)–(XII) and it has been found that the $[M + H - H_2O]^+$ peak for the *endo*-isomers (X) and (XII) is twelve times more intense than for the *exo*-isomers (IX) and (XI).[51] A test based on Dreiding models showed that the carbonyl oxygen in the *endo*-isomers (VIII), (X), and (XII) can approach closely to the hydrogen atoms of the six-membered ring, whereas in the *exo*-isomers it cannot. However, an increase of peak intensity is observed only for (X) and (XII) but not for (VIII), because in compounds (X) and (XII) hydrogen is transferred from the allyl position to the carbonyl group[51]:

(VIII) (IX) (XI)



(VIII) (X) (XII)

7. Photodimers of Cyclic α,β-Unsaturated Ketones

The photodimerisation of α,β-unsaturated ketones results in the formation of isomeric compounds: $(h-h)$ and $(h-t)$. Comparison of the intensities of the peaks of the ions $[M+H]^+$ and $[M/2+H]^+$ in the CH_4 spectra of these compounds[52] showed that the intensity of the $[M/2+H]^+$ fragment peak for the $(h-h)$ isomers is appreciably lower than for the $(h-t)$ isomers. This fairly general phenomenon was explained by the fact that, in the β-cleavage of the C–C bond in the $(h-h)$ isomer, the positive charge must be localised in the vicinity of the carbonyl group, which inhibits the fragmentation[52]:

Scheme 4

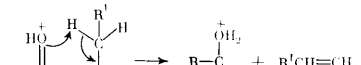
$(h=h)$ $(h=t)$

8. Substituted Benzophenones[53]

The peaks of the ions $[M+H]^+$ and substituted and unsubstituted benzoyl ions were observed in the CIM-spectra of substituted benzophenones. It is believed that an increase of electron density at the substituted benzene ring leads to its preferential protonation. Since the fragmentation of the ion $[M+H]^+$ formed in this case leads to the formation of an unsubstituted benzoyl ion, its intensity in the CIM-spectrum increases:

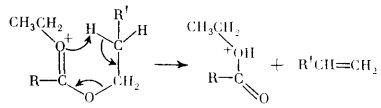
(23)

Protonation of the carbonyl oxygen apparently leads to the stable ion $Ar-\overset{+}{C}OH-Ar$, which exhibits no tendency towards fragmentation. Under electron impact, electron-donating substituents promote the formation of substituted benzoyl ions, probably in consequence of the stabilisation of the positive charge produced.



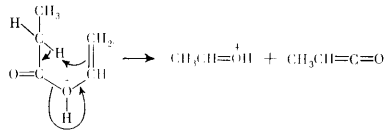
9. Esters

The peak of the ion $[M+H]^+$ in the CIM-spectra of esters is fairly intense (5% of the overall ionic current in the CH_4 spectrum of n-heptyl propionate) and exhibits no tendency towards a decrease with increase in the length of the hydrocarbon chain of the alcohol for a specified acid group. The ions R'^+ and $R-C\equiv O^+$, formed in heterolytic α-cleavage, give rise to moderately intense peaks:



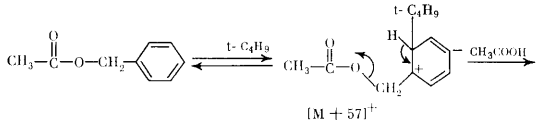
(24)

Alkenyl ions, formed when H_2 is split off from alkyl ions, are observed. As in the McLafferty rearrangement, processes responsible for β-cleavage lead either to the formation of the ion of a protonated carboxylic acid, which usually exhibits the maximum intensity in the spectrum [reaction (25)], or to transesterification if addition of the reagent ion takes place instead of protonation [reaction (26)]:



(25)

(26)



In the latter case ions with a moderate peak intensity are formed[54,55].

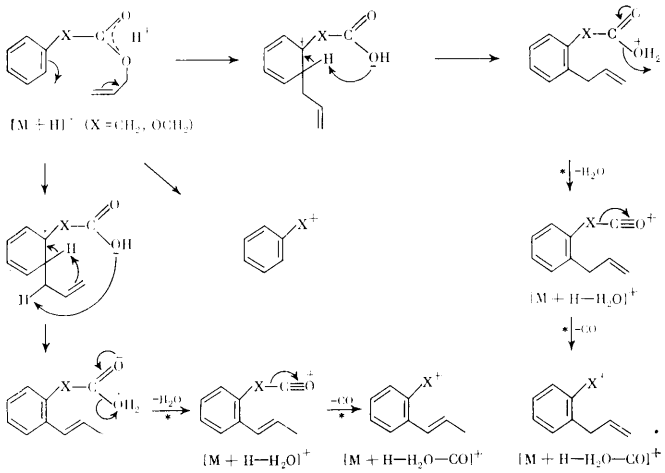
If the alcoholic component of the ester molecule possesses basic properties, for example, contains a double bond, it can itself serve as a proton acceptor. In this case reactions of type (25) and (26) are suppressed and are replaced by a proton transfer reaction with formation of a protonated aldehyde and the elimination of a keten-like molecule[54]:

(27)

The additional nucleophilic centre can also become an acceptor of the reagent ion[56]. This concept made it possible to identify the ions $[M-3]^+$ in the iso-C_4H_{10} spectra of acetates, which had not been previously assigned[56,57]:

(28)

For formates, these ions are manifested as $[M+11]^+$ species, for propionates as $[M-17]^+$ species, etc.



10. Fragmentation of Allyl Phenylacetates as an Example of Skeletal Rearrangements in Chemical Ionisation[58]

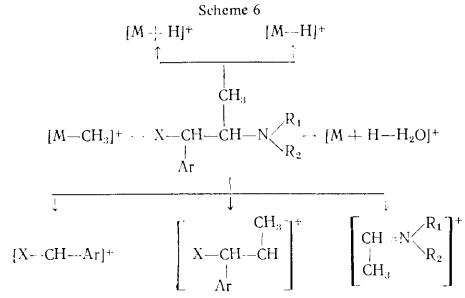
Under electron impact, the decomposition of the molecular ion is frequently accompanied by rearrangements[50,60]. In CI the rearrangements, particularly skeletal rearrangements, are encountered much more rarely. Field and Munson noted the occurrence of skeletal rearrangements in the bicyclo[2,2,2]octane[42], bicyclo[2,2,2]octene[43], and norbornadiene[61] systems using CH_4 as the reagent gas. The ions formed as a result of the rearrangements constitute approximately 18% of the overall ionic current. The formation of the rearranged ion $[CH_2OH]^+$ has been studied[62] in the protonation of $(CH_3)_2CO$ using H_2 as the reagent gas.

In the CH_4 spectra of allyl phenylacetate and allyl phenoxyacetate the ions formed in skeletal rearrangements constituted more than 40% of the overall ionic current[58]. The principal pathway to the fragmentation of the above compounds involves skeletal rearrangements and includes the successive elimination of elements of H_2O and CO from $[M+H]^+$ (Scheme 5). The *o*-allylation stage is analogous to the reaction in the condensed phase (the Claisen rearrangement)[63,64]. Allyl *ortho*-substitution is accompanied by the migration of H to the carbonyl group either from the *ortho*-position in the ring or from the allyl group. In

both cases the driving force of the reaction is the rearomatisation of the ring before the elimination of H_2O. If both *ortho*-positions in the ring are blocked, as, for example, in allyl 2′,6′-dichlorophenylacetate, then a simple ester fragmentation is observed, i.e. the splitting off of allyl alcohol with subsequent elimination of CO. Electron-accepting groups in the *para*-position also suppress *o*-allylation. Electron donors in the *para*-position promote a sharp intensification of competing fragmentation reactions with formation of benzyl (tropylium) ions. There is no rearrangement on ionisation by electrons and only the formation of tropylium ions is observed. Thus the EI-sprectra of allyl phenylacetates are simpler than the CIM-spectra.

Scheme 5

11. Amines



It has already been noted that the NH_2 group belongs to those which "leave with greatest difficulty" the protonated substrate molecule (Section II). Similarly the peak of the ion $[M + H]^+$ has the maximum intensity in the CIM-spectra of amines. The main fragmentation process on protonation of the amine molecule is due to the α-cleavage of the C–C bond relative to N. Thus the intensity of the peak with *m/e* 142 in the CH_4 spectrum of tributylamine is 19.9% of the overall ionic current, which is apparently due to the stabilising influence of the nitrogen atom[8,20]:

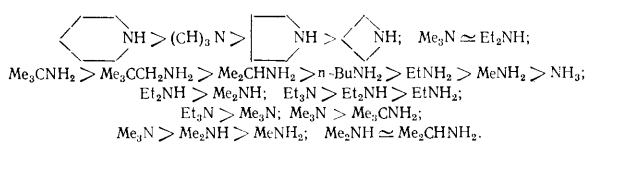
$$(n\text{-}C_4H_9)_3N + CH_5^+ \rightarrow \underset{m/e\ 142}{(n\text{-}C_4H_9)_2\overset{+}{N}{=}CH_2} + C_3H_8 + CH_4 \quad . \qquad (29)$$

The peak of the ion $[M - H]^+$ has a high intensity, probably for the same reason. Ions due to β- and γ-cleavage give rise to peaks with low and approximately equal intensities. The very intense peak due to the ion $[M - C_4H_9]^+$ was observed in the H_2 spectrum of tributylamine[65]. The postulate that the degree of fragmentation is independent of chain length, which is general for CI with transfer of even-electron species, has been confirmed in relation to polymeric tertiary amines[66].

The CH_4 spectra of four types of phenethylamine [α-amphetamine (XIII), *dl*-metamphetamine (XIV), *dl*-ephedrine (XV), and *dl*-methylephedrine (XVI)] have been investigated. There is no peak of the molecular ion in the EI-spectra of these compounds. The maximum peak of the ion $[CH_3{-}CH{=}N^{R_1}_{R_2}]^+$ is due to the α-cleavage of the C–C bond in relation to N and, with the exception of low-intensity ionic peaks with *m/e* 91 ($C_7H_7^+$) for (XIII) and *m/e* 77 ($C_6H_5^+$) for (XV), other characteristic peaks are absent from the EI-spectra of (XIII)–(XVI).

Scheme 6

(XIII): X = H, $R_1 = R_2 = H$;
(XIV): X = H, R_1 = H, $R_2 = CH_3$;
(XV): X = OH, R_1 = H, $R_2 = CH_3$;
(XVI): X = OH, $R_1 = R_2 = CH_3$.



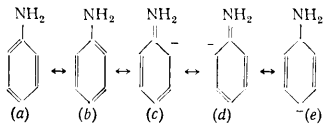
On the other hand, Scheme 6 shows that the CH_4 spectra of these compounds would alone be sufficient for the complete determination of their structure[65].

12. The Relative Basicity of Amines in the Gas Phase

The knowledge of relative basicities in the gas phase is of considerable interest for theoretical chemistry, since it makes it possible to infer the internal electronic effects in the molecule in the absence of a solvent. The determination of the relative basicities by the CI method is based on the fact that proton transfer is observed only in exothermic reactions with a negligible activation energy, i.e. the reaction

$$XH^+ + M \rightleftarrows X + MH^+ \qquad (30)$$

can proceed to the right only when $PA(M) > PA(X)$ (Section II). The relative basicities of amines determined in this way can be arranged in the following sequences[67]:



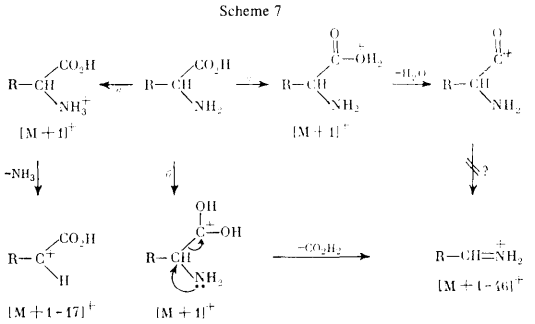
In conformity with the $+I$ effect, when the hydrogen in NH_3 is replaced by alkyl groups, the basicity of the amine should increase, which we observed in the gas phase. However, in solution there is a different order of basicities owing to the influence of solvation. For example, in aqueous solutions the basicity of methylamines falls in the following sequence:

$$Me_2NH > Me_3N > MeNH_2 > NH_3.$$

The explanation of this phenomenon is that the stabilisation of the system as a result of the formation of hydrogen bonds with H_2O diminishes with decrease of the number of H atoms linked to N and in the case of Me_3N the given effect predominates over the increase of the stability of the cation due to the $+I$ effect of the methyl groups[67,68].

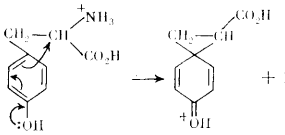
In aqueous solutions the basicity of anilines is much lower than that of ammonia and methylamines [$pK_b(C_6H_5NH_2) = 9.42$; $pK_b(NH_3) = 4.77$]. An attempt was made to account for this finding by the contribution of resonance structures (*c*)–(*e*) to the additional stabilisation of anilines, which

would vanish on protonation, and also by the electron-withdrawing influence of the phenyl group[69]:



However, the difference between the resonance energies of benzene and aniline is not more than 2–4 kcal mole^{-1} and the contribution of structures (*c*)–(*e*) to the resonance stabilisation should be minimal, since they include charge separation. In the gas phase aniline is more basic than NH_3, which can apparently be accounted for by the high polarisability of the phenyl group, stabilising the positive charge. This hypothesis is confirmed by the fact that the basicity of *N*,*N*,*N*-triphenylamine is higher than that of aniline[70].

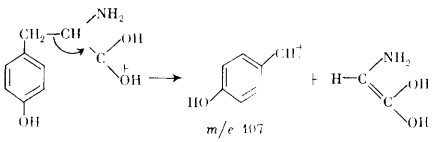
The low basicity of pyridine (lower than that of NH_3) has nowadays come to be explained by the sp^2 hybridisation of the N-atom, but, it has been shown[70] that in reality the basicity of pyridine in the gas phase exceeds that of dimethylamine and that the reason for the low basicity of pyridine in aqueous solution should therefore be sought in the first place in the effect of solvation and not hybridisation.



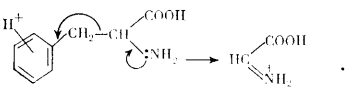
13. Aminoacids and Peptides

The presence of the ions $[M + 1]^+$, $[M + 1 - 18]^+$, $[M + 1 - 17]^+$, and $[M + 1 - 46]^+$ is characteristic of the CIM-spectra of the majority of aminoacids[71,72]:

Scheme 7



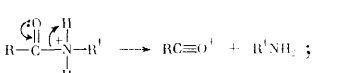
The fragmentation of glutamic acid, arginine, citrulline, and ornithine does not fit within the framework of this scheme[73]. The ion $[M + 1]^+$ has high-intensity peaks in all cases; the above aminoacids, where the peak due to the ion $[M + 1 - 18]^+$ has a high intensity and which are formed on pyrolytic elimination of H_2O, are an exception. The fragmentation of glycine, alanine, valine, leucine, isoleucine, and proline is confined to pathways *a* and *b*. A second H_2O molecule is abstracted from hydroxyaminoacids—serine, threonine, and 3-hydroxyproline. The peak due to the metastable ion, confirming the abstraction of CO, has not been observed in any of the CIM-spectra of aminoacids[72]. Fragmentation with elimination of elements of CO, which is extremely common under electron impact, is apparently encountered very rarely under CI conditions. The abstraction of NH_3 from $[M + 1]^+$ is of greatest theoretical interest. The fact that the peak of the ion $[M + 1 - 17]^+$ is not observed in the spectra of unsubstituted aliphatic aminoacids is evidence against a simple interpretation of the elimination, represented in Scheme 7 (pathway *b*). The elimination of elements of NH_3 is observed only for aminoacids containing a second nucleophilic group, which apparently indicates the involvement of this group in substitution and is accompanied by the formation of new bonds, for example:



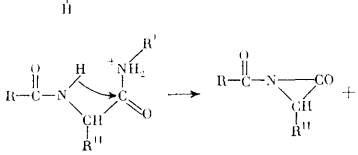
(31)

Such "co-operative" reactions are apparently of general importance in CI-fragmentation processes involving molecules of compounds with two and more nucleophilic centres (see, for example, Chizhov et al.[95]). The fairly intense peak of the ion with *m*/*e* 107, formed on cleavage of the α,β-bond, merits attention in the CIM-spectrum of tyrosine:

(32)



An analogous cleavage has been observed also for other aromatic aminoacids: phenylalanine, tryptophan, and histidine. In the absence of electron-donating substituents, the charge can be localised also on the amino-fragment:



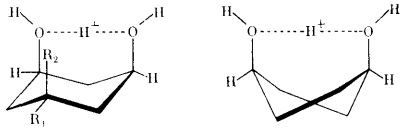
(33)

One of the most important methodological problems in bio-organic chemistry at the present time is the determination of the aminoacid sequence in peptides. The solution of this problem by mass spectrometry is based on the preferential cleavage of amide bonds in the ionisation of the peptide molecule[74]. To ensure their adequate volatility, peptides are modified by acylating the terminal amino-group and esterifying the terminal acid group. The EI-spectra usually contain only a complete set of amino-fragments (acylium ions). In addition, the interpretation of the EI-spectra of peptides is complicated as a result of the fragmentation of the molecules with elimination of side chains and requires the use of high-resolution mass spectrometers. The low peak intensities in the region of high masses lower the sensitivity of the method.

In CI there is usually a complete set of fragments of both the amino-type [reaction (34)] and the acyl type [reaction (35)]:

(34)

(35)



The presence of two series of ionic peaks in the CIM-spectra of peptides reduces the uncertainty in the determination of the aminoacid sequence and one can use for this purpose mass spectra with single focussing[75]. Owing to the lower degree of fragmentation and the relatively small difference between the densities of peaks due to ions with large and small masses, a much smaller amount of the specimen is required than in the recording of the EI spectrum (by a factor of approximately 100).[76] The CI method makes it

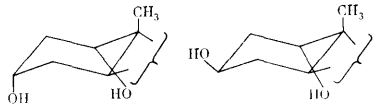
possible to record the spectra of peptides with a higher molecular weight than in the EI method.

The determination of satisfactory mass spectra of involatile substances and particularly peptides is one of the fundamental and most difficult problems in modern mass spectrometry. The most promising approaches in this field are those which do not require the modification of the initial substance in order to increase its volatility. Thus the application of the desorption method in an electric field apparently makes it possible to investigate unmodified peptides with a lower volatility and a greater variety of aminoacids than in the CI method[77]. However, the number of fragment ion peaks in the mass spectrum is frequently insufficient for the determination of the aminoacid sequence in the initial peptide. Considerable advances have been made recently also in the determination of the CIM-spectra of involatile substances by means of special methods[78-80]. Satisfactory spectra have been obtained for nonapeptides containing unprotected arginine and histidine, which made it possible to determine unambiguously the aminoacid sequences[78].

14. The Dependence of the Fragmentation in CI on the Stereochemistry and Conformation of Molecules in Relation to Cyclic Polyols and Steroid Aminoalcohols

As early as 1971, it was established[46] in relation to α,ω-diols, α,ω-dithiols, and α,ω-diamines with a long hydrocarbon chain that the formation of intramolecular hydrogen bonds stabilises the quasi-molecular ion $[M+H]^+$.[46] This phenomenon was used to investigate the stereochemistry of cyclic polyols[81]. The formation of proton bridges in the chair-conformation of *cis*-cyclohexane-1,3-diol (XVII) or the twist-form of *cis*-cyclohexane-1,4-diol (XVIII) lead to a marked suppression of the elimination of H_2O molecules from $[M + H]^+$. The addition of a third hydroxy-group to the molecule to give (XIX, R_2 = OH) results in a further stabilisation of the ion $[M + H]^+$ in consequence of the formation of two additional hydrogen bonds.

(XVII)

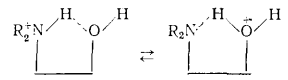


(XVIII)

(XVII): $R_1 = R_2 = H$;
(XIX): $R_1 = H$, $R_2 = OH$;
(XX): $R_1 = H$, $R_2 = CH_3$.

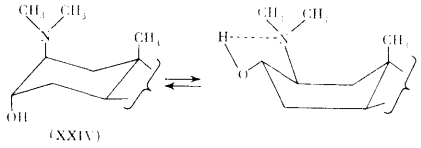
The presence of a bulky substituent in the 5-position in (XX, $R_2 = CH_3$) destabilises the structure with a proton bridge and increases the degree of fragmentation. It is noteworthy that this increase is more pronounced for a high ionisation energy (CH_4 or iso-C_4H_{10} at high temperatures).

In contrast to their *cis*-isomers, the CIM-spectra of *trans*-cyclohexane-1,3-diol and *trans*-cyclohexane-1,4-diol contain intense peaks due to the ions $[M + H - H_2O]^+$ and $[M + H - 2H_2O]^+$, because stabilising proton bridges are not formed in the ions $[M + H]^+$ derived from these compounds. As in the spectra of monohydric alcohols, the spectra of the *trans*-isomers also contain an extremely intense peak due to the quasi-molecular ion $[M + H]^+$. It is believed[82] that a linear structure of the O...H⁺...O fragment, which cannot occur in *cis*- and *trans*-cyclohexane-1,2-diols, is necessary for the formation of a strong hydrogen bond; the flexibility of the cyclohexane ring leads to the final disappearance of the stereochemical advantage of the formation of the proton bridge in the *cis*-isomer, so that the CIM-spectra of *cis*- and *trans*-cyclohexane-1,2-diols are completely similar. However, the ion $[M + H]^+$ derived from cyclopentane-1,2-diols is appreciably more stable for the *cis*-isomer, which is probably associated with rigidity of the cyclopentane ring.



The results described above can be extended with reasonable confidence to more complex systems, although a significant difference between the stabilities of the ions $[M + H]^+$ derived from 5α-androstane-1α,3α-diol (XXI) and 5α-androstane-1α,3β-diol (XXII) was not observed[83].

(XXI) (XXII)



However, the use of milder ionisation conditions (95°C, direct injection of the specimen into the isobutane plasma[79]) made it possible to discover the differences between the spectra of (XXI) and (XXII) corresponding to the CIM-spectroscopic data for cyclohexane-1,3-diols[31].

When one of the hydroxy-groups is replaced by an amino-group, the main factor stabilising the quasi-molecular ion $[M + H]^+$ becomes proton transfer from oxygen to nitrogen in the bridge structure[83]:

(36)

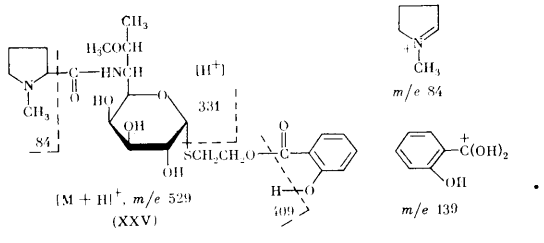
This is why the *cis*-1,2- and *cis*-1,3-isomers are more stable than their *trans*-analogues, in which there is no proton transfer. It has been suggested[83] that the molecular conformation can play a very significant role in CI-fragmentation. The iso-C_4H_{10} spectra of 3α-dimethylamino-2β-hydroxypregnane (XXIII) and 2β-dimethylamino-3α-hydroxypregnane (XXIV) were interpreted from this standpoint. It has been shown by infrared spectroscopy[84] that an intramolecular hydrogen bond is formed in the corresponding *trans*-isomers of the cholestane series (evidently when the A ring of the steroid skeleton assumes the boat conformation):

(XXIV)

(37)

i.r.	30%	70%
CI	26.5%	73.5%

Using model compounds for which a transition to the boat conformation is known not to occur, the authors[83] estimated the conformational equilibrium for (XXIII) and (XXIV) on the basis of their iso-C_4H_{10} spectra. The results proved to be in excellent agreement with infrared spectroscopic data, which is extremely surprising bearing in mind the differences between the experimental conditions. Evidently further studies on these lines are extremely promising.

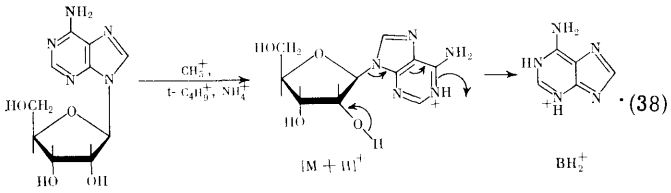


15. Carbohydrates, Nucleosides, and Macrolide Antibiotics

Mass spectrometry with electron impact is used nowadays to investigate carbohydrates and their derivatives[85]. When very small amounts of the specimen are available (sometimes $<10^{-6}$ g), valuable information about the molecular weight of the carbohydrate molecule, the nature and sequence of monosaccharide units, and in certain cases the position of the glycosidic linkages between the individual units can be obtained. The most suitable volatile derivatives for the study of the structures of oligosaccharides by the EI method are their acetates and methyl and trimethylsilyl ethers. However, the extremely low intensity and in certain cases the absence of the peak due to the molecular ion and the low intensities of the peaks due to fragment ions with high molecular weights impose very significant limitations on the analysis.

The most promising approach used to overcome these limitations involves the application of "mild" ionisation methods, for example, ionisation in a field[86], desorption in a field[86], and CI. It has been found that the degree of fragmentation under the conditions of ionisation in a field and desorption in a field is insufficient for the investigation of the structure. In studies involving the CI- fragmentation of carbohydrates and related compounds, the spectra of pentoses, hexoses, and their simple derivatives[32,87-92], oligosaccharide acetate[93,94], the methyl ethers of glycosyl- and biosyl-polyols[95], the antibiotics celesticetin and clindamycin, aminoacylthioglycosides[96,97], nucleosides[28,98,99], and macrolide antibiotics[24,100,101] were examined.

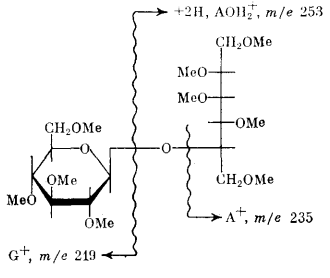
The results obtained fit within the framework of the generalisations developed in the study of the CIM-spectra of other classes of organic compounds. Thus the peak of the adduct ion $[M + NH_4]^+$ has been observed in the NH_3 spectra of oligosaccharide acetates (up to tetrasaccharides inclusive). The formation of this ion in the case of higher oligosaccharide acetates is apparently prevented by the thermal instability of these compounds when they are vaporised[93,94]. However, when the molecule contains a highly basic nitrogen atom, the peak of the ion $[M + NH_4]^+$ is absent from the NH_3 spectrum, since, instead of simple association, there is proton transfer from NH_4^+ to the nitrogen in the substrate molecule with formation of the ion $[M + H]^+$.[32] Thus the iso-C_4H_{10} and NH_3 spectra of the antibiotic celesticetin (XXV) differ markedly, because protonation in the presence of NH_3 can occur exclusively at nitrogen atoms remote from the aromatic part of the molecule and the formation of the ion with m/e 139 is strongly suppressed. On the other hand, in the iso-C_4H_{10} spectrum the ion has the maximum intensity, because protonation proceeds readily at the oxygen atom at the ester group of the salicylate. The peak of the methylpyrrolidinium cation with m/e 84 in the iso-C_4H_{10} spectrum has an extremely low intensity, while in the NH_3 spectrum its intensity is high[96]:



Scheme 8

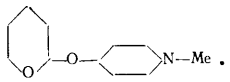
The fragmentation of derivatives of pentoses and hexoses is extremely simple and in essence consists in successive and/or simultaneous elimination of functional groups, the degree of fragmentation being determined, as usual, by the acid strength of the reagent ions. For example, a detailed study of the fragmentation pathways of β-methyl-2,3,4,6-tetra-O-methyl-D-galactopyranoside using its deuterated analogues showed that the dominant process in the formation of ions with m/e 187 and 155 is the abstraction of methoxy-groups (in the form of methanol molecules) from the 3- and 4-positions and in the formation of ions with m/e 187 the most preferred process is abstraction from the 3-position. The first stage in the decomposition of the quasi-molecular ion $[M + H]^+$ with abstraction of methanol from the glycosidic centre was regarded as analogous to the rate-limiting stage in the acid hydrolysis of methylglycosides[90]. It has been shown[91] that the anomeric effect has a significant influence on the rate of decomposition of quasi-molecular ions and on the ratio of the intensities of the peaks due to the ions $[M+H]^+$ and $[M + H - CH_3OH]^+$ (m/e 251 and 219 respectively) and in the spectra of α- and β-methyl-2,3,4,6-tetra-O-methyl-D-galactopyranosides.

Examination of the iso-C_4H_{10} spectra of the methyl ethers of methyl deoxyhexosides led to the conclusion that the position of the deoxy-unit in 2,3-, 4-, and 6-deoxysaccharides can be determined from the ratio of the intensities of the peaks with m/e 125, 157, and 189 in spectra recorded at the same temperature[92].



A complex aglycone, particularly when it contains powerful nucleophilic centres, tends to be split off in the form of a protonated species[27,88]. This decomposition pathway predominates in the CI-fragmentation of nucleosides:

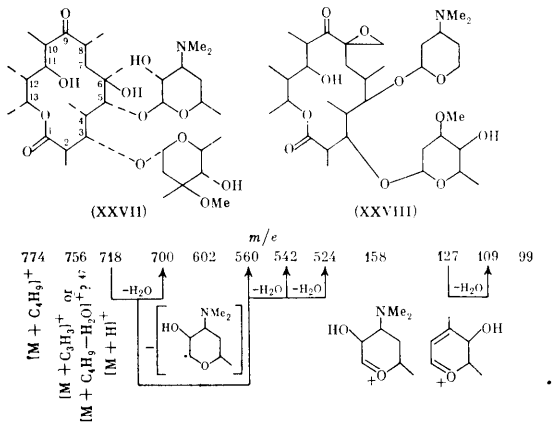
(38)



The formation of glycosyl ions in the given instance constitutes a much less probable fragmentation pathway[27,98]. The decomposition of the methyl ethers of glycosyl- and biosyl-polyols also proceeds with the preferential formation of the protonated aglycone (in this case the initial protonation apparently involves one of the five oxygen atoms in the methoxy-groups of the aglycone); however, also formed are the ions A^+ (probably on dissociation of the C–O bond on the side of the aglycone) and the glycosyl ion G^+ (with a much lower intensity) and it has been shown that the ratio of the intensities of the A^+ and AOH_2^+ peaks depends greatly on the position of the glycosidic linkage (1 → 2, 1 → 3, 1 → 4, and 1 → 6) in glycosylsorbitols[95]:

Scheme 9

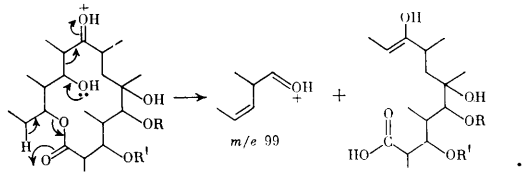
The fragment ion peaks make it possible to determine directly the nature and sequence of the monomeric units of both glycosyl- and biosyl-polyols[95]. This is also true of the CIM-spectra of oligosaccharide acetates[93,94].



The ideas about the mechanism with the excitation centre remote from the site of bond dissociation were first formulated in the discussion of the fragmentation of macrolide antibiotics[100]. The possibility of fragmentation via this mechanism has been demonstrated rigorously and experimentally for compound (XXVI), which serves as a model of a glycoside with a complex aglycone[33]:

(XXVI)

The study of the CIM-spectra of macrolide antibiotics was stimulated by the fact that the EI peak of the molecular ion M^+ has an extremely low intensity and cannot always be detected. All the high-intensity peaks are located in the region of low mass numbers and the majority of them correspond to aminosugar fragments. The fragment ions corresponding to portions of the macrolide ring and neutral sugars are suppressed, so that it is extremely difficult to obtain structural information about these components of the molecule. On the other hand, in the iso-C_4H_{10} spectra of these compounds the peak of the ion $[M + H]^+$ has a very high intensity. The fragment ions in the middle part of the spectrum correspond to the successive elimination of sugar residues from $[M + H]^+$. Ions with low masses arise from sugar fragments when glyosidic linkages are broken with subsequent loss of one and more oxygen substituents—see Scheme 10 for the decomposition of the ion $[M + H]^+$ derived from erythromycin B (XXVII):



Scheme 10

(XXVII) (XXVIII)

Only the formation of fragment ions with *m/e* 99 and 602, giving rise to intense peaks, requires the dissociation of the C–C bond in the macrolide ring. The formation of an ion with *m/e* 99 can be regarded as the result of the protonation at the 9-oxo-group with subsequent opening of the ring at the lactone linkage as a result of the McLafferty rearrangement and the cleavage of the $C_{(10)}$–$C_{(11)}$ bond via a retroaldol type of fragmentation process (Scheme 11). The ion with *m/e* 602 corresponds to the protonated fragment (XXIX) after the elimination of one water molecule.

Scheme 11

(XXIX)

The structure of oleandomycin (XXVIII) resembles that of erythromycin B, but there are distinctive differences, the majority of which are clearly seen from the inspection of the iso-C_4H_{10} spectrum. Thus the peak of the ion arising in the retroaldol cleavage is very intense, but is displaced towards *m/e* 85, since the 13-substituent in (XXVIII) is a methyl group and not an ethyl group as in (XXVII). There is no peak due to the ion $[M + H - H_2O]^+$ in the spectrum of (XXVIII). This ion arises in acid-catalysed reactions involving macrolides which have a hydroxy-group in the 6-position, which is conformationally suitable for attack by the carbonyl group in the 9-position[102].

Information about the nature of the sugar units can be obtained by examining the ions arising in the cleavage of glycosidic linkages[24,100,101]. The iso-C_4H_{10} spectra of macrolide antibiotics with 16-membered rings have been examined[101]. They contain an extremely intense peak due to the $[M + H]^+$ ion and the peaks of fragment ions corresponding to the successive elimination of sugars and other smaller molecules—water, acetic acid, and methanol. The cleavage of C–C bonds is not a characteristic feature of the 16-membered macrolide ring.

The combination of CI, infrared, ultraviolet, and NMR spectroscopic methods and the mass-spectrometric method with electron impact together with a few rationally selected degradation reactions ensures a rapid and reliable determination of the structures of new compounds in this and related series.

IV. MASS SPECTROMETRY OF NEGATIVE IONS WITH CHEMICAL IONISATION. THE S_N2 REACTION IN THE GAS PHASE

Chemical ionisation by anions is significantly "milder" than ionisation by cations, which is understandable when one compares the proton (150–250 kcal $mole^{-1}$) and anion (5–25 kcal $mole^{-1}$)[17] affinities of molecules. Yet another cause of the "mildness" of CI by negative ions is associated with the fact that in the gas phase an odd-electron anion has sufficient energy for autoneutralisation, i.e. for the ejection of an electron, and the activation energy for the reaction must be very much smaller than the electron affinity of the neutral molecule. In the association of the molecule with an even-electron anion in the presence of an excess of internal energy there is a possibility of the reverse decomposition into a neutral species and an anion[17]. The CI-mass-spectrometry of negative ions has become readily available after the development of an ion source with a Townsend discharge, which makes it possible to obtain beams of positive and negative ions of comparable intensity[103,104]. The range of its analytical applications is limited apparently by the need to determine traces of substances, especially halogen-containing compounds (in particular, chlorine-containing pesticides[105] and insecticides[106]). Its application in general structural analysis is probably limited by inadequate fragmentation (however, see Hunt et al.[104]).

An interesting application of gas-phase reactions of anions as a guide to carrying out the corresponding reactions in solutions has been outlined[107].

The most fruitful application of the CI-mass-spectrometry of negative ions was found in physicochemical research. Having examined the changes in the heats and entropies of association of Cl^- in the series CH_3Cl, CH_2Cl_2, $CHCl_3$, and CCl_4 and having taken into account the fact that 1-bromoadamantane and 1-bromo[2,2,2]bicyclooctane do not combine with Cl^-, Br^-, and I^-, Dougherty and coworkers concluded that the ionic clusters RXY^- (where X and Y are halogens) are identical with the S_N2 transition state in Finkelstein's reactions[14]. Thus the data obtained for these ions can be used to estimate the influence of the solvent on the reactivity in S_N2 reactions. Both the influence of the nucleophilic properties of the attacking base[15] and the structural influence of the alkyl groups[16] have been examined. It has been found that the nucleophilic properties of Cl^-, Br^-, and I^- in the gas phase are approximately the same and that the differences between the nucleophilic properties of the same bases in Finkelstein's substitution reactions are caused mainly by the changes in the relative degrees of solvation of the reactants and the transition states in exchange processes[15].

It is believed that a branched hydrocarbon group interferes with S_N2 reactions. Thus the exchange of the halogen in neopentyl bromide via an S_N2 mechanism is to a large extent suppressed[108]. However, this classical model is apparently applicable solely to S_N2 reactions in the condensed phase, because it has been found[16] that the heats of association of Br^- increase in the sequence MeBr < EtBr < iso-PrBr < t-BuBr (α-branching) and EtBr < iso-BuBr < neopentyl bromide (β-branching). The entropies of association of these compounds in the gas phase vary approximately in parallel with the corresponding changes in solution. The conclusion that the structural influences of the alkyl groups on the reactivity in S_N2 reactions in solution are controlled exclusively by solvation is therefore valid.

---o0o---

The foregoing review shows that the CI method has been finding increasingly wide applications in the identification and determination of the structures of organic compounds. Its advantages when used for these purposes compared with the electron impact method consist in the presence of stable MH^+ ions even in those cases where the M^+ ion is unstable. This makes it possible to find the molecular weight directly from the CIM-spectra. The differences between the CIM-spectra of structural isomers and stereoisomers are frequently greater than in the EI method, which makes the CI method particularly valuable for the solution of structural and stereochemical problems, which cannot be solved by EI-mass-spectrometry. Furthermore, the CI method has proved extremely promising for the investigation of the mechanisms of various gas-phase reactions and the determination of the intrinsic values of fundamental characteristics of molecules and other species, such as basicity and nucleophilicity. All these factors give rise to the hope that new valuable results will be obtained in the immediate future with the aid of the CI method.

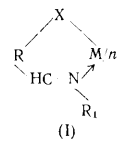
Dinuclear and Polynuclear Complexes with Azomethine Ligands and Their Magnetic Properties

V.A.Kogan, V.V.Zelentsov, O.A.Osipov, and A.S.Burlov



The review deals with di- and poly-nuclear metal complexes of Schiff bases whose magnetic properties are interpreted, within the framework of the exchange mechanism, as due to an exchange interaction between paramagnetic centres. The principal types of di- and poly-nuclear complexes with azomethine ligands and the factors influencing the strength and nature of the exchange interaction (the nature of the bridge groups and the stereochemistry of the coordination units) are examined. The problems of the specific selection of ligands for the synthesis of the above complexes are discussed.
The bibliography includes 112 references.

CONTENTS

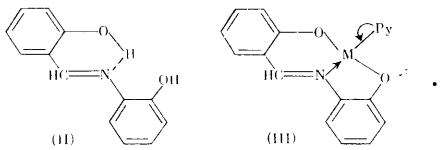
IV. Dinuclear complexes with polydentate dimerising ligands 652

I. INTRODUCTION

Metal complexes of type (I) with azomethine ligands (Schiff bases) have been vigorously investigated since the 1930s.[1]

(I)

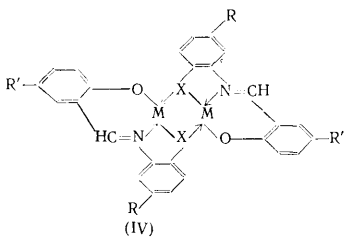
The experimental data accumulated hitherto[2-4] make it possible to deduce definite correlations between the electronic and molecular structures of these compounds, on the one hand, and their physicochemical properties, on the other. A detailed study of the structure–property relation is possible if one can vary (a) the ligand fragments R and R_1 in (I) while keeping constant the immediate environment of the metal atom, (b) the electron-donating atoms X (O, N, S, or Se) for the same R and R_1, and (c) the central atom M while keeping constant R, R_1, and X. Comparison of systematic series of complexes with a regular variation of particular physicochemical properties makes it possible to discover which structural factors are responsible for these changes[5,6].



The wide variety of types of monomeric chelates becomes appreciably greater when di- and poly-nuclear compounds are formed from tri- and poly-dentate azomethine ligands or inner complexes of type (I). Compounds in which exchange interactions between paramagnetic centres are manifested are of greatest interest.

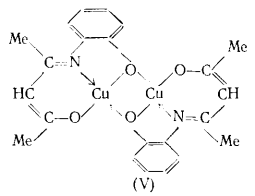
The use of azomethine compounds as ligands in order to obtain the so-called exchange-bound clusters makes it possible to follow the influence of stereochemical and electronic factors on the extent and nature of exchange interactions when substituents in the ligands and the ligands themselves are varied. The exchange properties of the complexes are determined by the structure of the ligand and the nature of the bridge groups.

This review deals with studies which illustrate most fully these characteristic features of di- and poly-nuclear complexes with azomethine ligands. The principal types of di- and polynuclear complexes with exchange interactions and factors which determine the specific selection of ligands in order to obtain these compounds are considered.



II. COMPLEXES WITH TRIDENTATE AND SIMILAR LIGANDS

The ability to form dimeric and polymeric complexes is always manifested when organic compounds with an appropriate structure, giving rise on interaction with the metal to coordination-unsaturated complexes in the monomeric state, are used. One of the most common types of compounds of this kind are complexes of 3*d* metals obtained on the basis of salicylidene-*o*-aminophenol (II):



(II) (III)

If monomeric complexes (III) are formed, in which the fourth coordination site is occupied by a solvent molecule [in the present case pyridine (Py)], then they have effective magnetic moments μ_{eff} corresponding to a single unpaired electron (for example, with $M=Cu^{II}$).[7-9] If the monomers are coordination saturated by interaction with one another, dimeric complexes of types IV and V are formed:

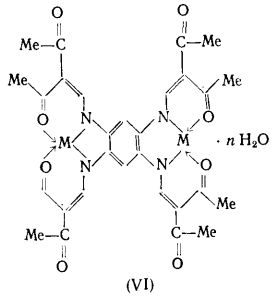
(IV)

(V)

Here two paramagnetic centres are fairly close to one another and exchange interaction takes place between them. This was established for the first time for complexes of type (IV) (with M = Cu and X = O, [7-9] with M = VO and X = O, [10,11] and with M = Ni [12]) on the basis of the decrease of μeff relative to the "spin only" value. An analogous phenomenon was observed for complexes of type (V). [7,11-14] An X-ray diffraction study confirmed the dimeric structure of (V) in which the Cu–Cu distance is 2.99 Å, the temperature dependence of the magnetic measurement indicating the antiferromagnetic nature of this exchange interaction[13,14]. Cu^{II} and VO^{II} complexes of types (V) [11,17] and (IV) [15-22] with various substituents have been investigated particularly thoroughly[23]. Careful analysis of the temperature dependence of the magnetic susceptibilities of complexes of type (V) (μeff = 1.39–1.00 μB at 203–88 K) showed that it does not obey the Bleany–Bowers equation[24]†

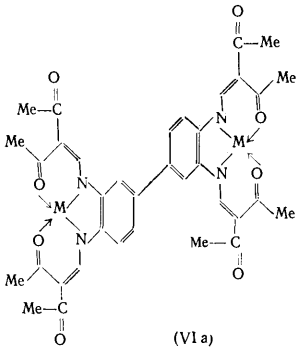
$$\chi = \frac{Ng^2\beta^2}{3kT}[1 + 1/3\exp(2J/kT)]^{-1} + N\alpha, \qquad (1)$$

which takes into account only the exchange interaction between the paramagnetic ions in the dimeric molecule[17]. An additional interaction of the dimeric fragments with one another has been established for this compound as well as a number of other Cu^{II} and VO^{II} complexes of type (IV). [22,25]



The study of complexes of types (IV) and (V) showed that the model taking into account only the direct metal–metal interaction, as a result of the partial overlap of the *d* orbitals of the metal atoms, cannot adequately account for the paramagnetism; ideas postulating an indirect exchange interaction via bridge groups X have been developed[10,11,14-17]. This was convincingly confirmed also by studies of the influence of the substituents R and R′ in (IV, N = Cu, X = O) on the strength of the exchange interaction in the dimeric molecules (Table 1)[15].

Table 1. The effective magnetic moments, *g*-factors, and exchange integrals for complexes of type (IV, M = Cu, X = O).



R	R′	*T*, K	μ_{eff}, μ_B	*g*	$-2J$, cm^{-1}
H	H	45—292	0.10—1.31	1.97±0.1	289±10
H	Me	47—296	0.11—1.47	2.10±0.1	245±10
H	Cl	43.2—296	0.15—1.25	2.16±0.1	371±25
H	Br	40—300	0.11—1.28	2.13±0.1	341±20
H	NO_2	20.7—294	0.17—1.25	—	—
Cl	H	4.95—295	0.10—1.60	1.86±0.1	46±20
NO_2	H	35—294	0.30—1.55	1.97±0.1	125±5
Cl	Cl	6.3—299	0.22—1.60	1.88±0.1	39±20
NO_2	NO_2	47—295	0.10—1.30	2.05±0.1	307±10

It has been shown that electron-accepting groups in the R′ position tend to increase the extent of the antiferromagnetic interaction, while the same groups in the R position tend to decrease it. From the standpoint of the mechanism[26] postulating that the indirect exchange is determined by the antibonding *d* orbitals of the metal and the hybrid *sp* orbitals of the ligand atoms, the different effects of the substituents R and R′ can be explained by the fact that electron-accepting substituents in the R′ position influence the non-bridging oxygen and nitrogen atoms, while those in the R position influence the bridging oxygen atom.

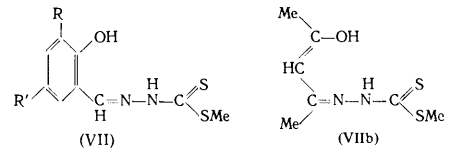
The use of complexes with azomethine ligands as models made it possible subsequently to obtain unambiguous evidence showing that the exchange interaction can be only indirect. Thus the magnetic properties of complexes (VI) and (VIa) were compared[27]:

(VI)

(VIa)

M=Cu^{II}, Ni^{II}, or VO^{II}.

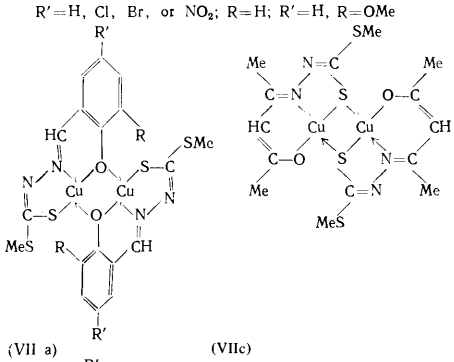
A direct copper–copper exchange is ruled out in complex (VI), but, despite this, an antiferromagnetic interaction is observed between the copper ions with $2J = 12.2$ cm^{-1} (μeff = 1.8–0.42 μB at 216–4.2 K). It was assumed that the interaction is due to the polarisation of the spins of the unpaired electron of the copper atom and the electrons of the nitrogen atom, which is then distributed via the π-electron system of the benzene ring to the second copper atom. The presence of the C–C single bond in complex (VIa) prevents such delocalisation and an antiferromagnetic interaction is not observed (μeff = 1.83–1.69 μB at 241–4.2 K). [27]



Sulphur-containing ligands also form di- and polynuclear complexes with exchange interaction[17,28,29]. As for complex (III), the addition of a pyridine molecule in these compounds promotes the formation of a complex with a normal magnetic moment[29]. When the bridging O atom is replaced by S, the magnetic properties of the complexes change.

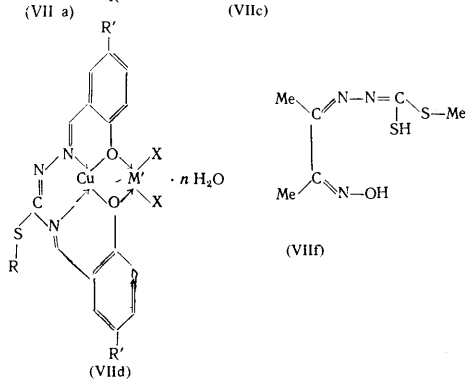
The effective magnetic moments of complexes of type (IV, X = S, M = Cu) are almost independent of temperature (μeff = 1.73–1.85 μB at 291–80 K), [17] which was explained by the increase of the copper–copper distance and the change of the angles in the bridge fragment.

The copper complexes (VIIa) and (VIIb), obtained by the interaction of *S*-methyldithiocarbazide with salicylaldehyde (VII) and acetylacetone (VIIb), [28-32] as well as complexes with the thiosemicarbazones of *o*-hydroxyaldehydes (VIId) [30,31] and with tridentate ligands (VIIe), obtained by the condensation of diacetyl monoxime and its *O*-methyl



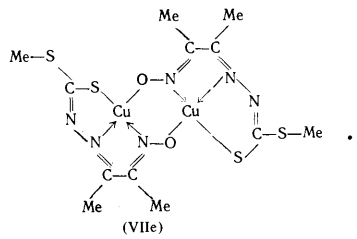
† Here *N* is the Avogadro number, $2J$ the exchange integral, μ_B the Bohr magneton, *k* the Boltzmann constant, *T* the absolute temperature, and $N\alpha$ the temperature-independent paramagnetism.

ether with methyl hydrazinethiocarboxylate (VIIf) have been investigated:



(VII) (VIIb)

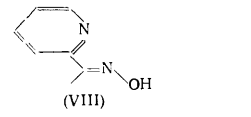
R′=H, Cl, Br, or NO_2; R=H; R′=H, R=OMe



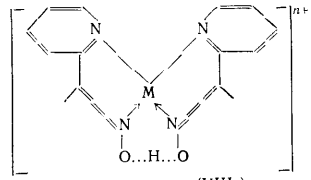
(VII a) (VIIc)

(VIIf)

(VIId)



M′=Cu^{II}, Fe^{II}, or Zn^{II}; R=Me, or Et; R′=H, or Me; X=Cl, or Br

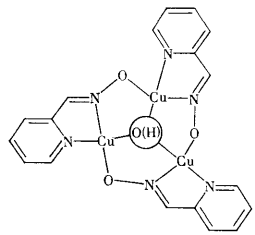


(VIIe)

Complexes (VIIe) are characterised by anomalous magnetic properties characteristic of exchange-bound clusters[32]; the compounds retain a similar structure when the sulphur atom is replaced by oxygen.

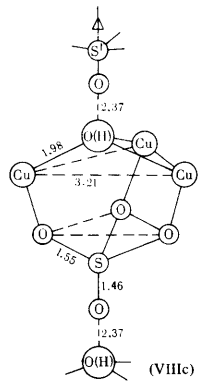
It has been found that complexes (VIIa) can manifest exchange interactions of both antiferromagnetic and ferromagnetic types depending on the nature of the substituents R and R′ (Table 2). An exchange interaction of the ferromagnetic type has also been observed for complex (VIIc) (μ_{eff} = 1.59–1.81 μ_B at 333–83 K). It has been suggested[29] that the indirect electronic influence of the substituents R and R′ and ultimately the change in the nature of the packing in the unit cell of the crystal have an effect here. Whereas complexes with an antiferromagnetic exchange interaction have a dimeric planar structure, complexes with a ferromagnetic exchange interaction consists of tetranuclear clusters in which copper atoms occupy the vertices of a distorted tetrahedron. The antiferromagnetic exchange interaction in complexes (VIId) depends on the nature of the substituents at the sulphur atom and in the benzene ring[30,31].

(VIII)



(VIIIa)

Table 2. Magnetic properties of copper complexes of types (VIIa) and (VIId).



Type of complex	R′	R	X	T, K	μ_{eff}, μ_B
(VIIa)*	NO_2	H	—	333—83	2.02—2.43
(VIIa)	H	H	—	313—93	1.09—0.60

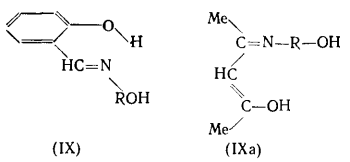
(VIId)	H	n-Bu	Cl	297.6—78.8	1.65—0.80
(VIId)	H	iso-Bu	Cl	297.6—78.2	1.62—0.99

* Ferromagnetic interaction; in the remaining cases the interaction is antiferromagnetic.

Depending on the method of synthesis of the complex, pyridinealdoxime (VIII) (HLig) can behave either as a bidentate ligand forming monomeric paramagnetic complexes[33] (VIIIa) or as a tridentate ligand forming coordination-unsaturated monomeric complexes, which are combined in the course of the reaction into trimeric molecules (VIIIb).

(VIIIb)

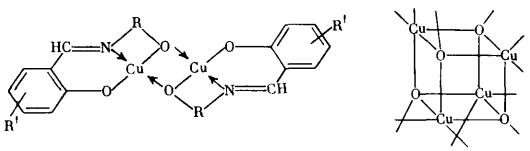
(VIIIc)



Several trinuclear copper complexes of this kind have been obtained: $[Cu_3Lig_3OH]X_2.H_2O$, where X = $\frac{1}{2}SO_4^{2-}$, I^-, NO_3^-, ClO_4^-, or OH^-; they all have anomalously low magnetic moments[34-37]. The study of the temperature dependence

of the magnetic susceptibility[37] as well as structural studies[36,37] confirmed the hypothesis that compounds of type (VIIIb) are trinuclear clusters in which copper ions are bound by an antiferromagnetic exchange interaction.

A cluster structure of the cation has been established for the complex $[Cu_3(C_6H_5N_3O_3)OH]SO_4.16H_2O$. The copper atoms are located at the corners of an equilateral triangle and the oxygen atom of the hydroxy-group is suspended over its centre at a distance of 0.71 Å. Each of the symmetrically linked aldoxime groups is a bridge group linking adjacent copper atoms. An interesting structural feature of this trimer is the fact that the three oxygen atoms of the sulphate ion augment the coordination polyhedron of each of the three copper atoms in the cluster to form a square pyramid. The trinuclear clusters are linked to one another via hydrogen bonds between the proton of the hydroxyl of one trimer and a non-coordinated oxygen atom in the sulpho-group of a neighbouring cluster.



Similar trinuclear clusters with an antiferromagnetic exchange interaction have been obtained and investigated also with other analogous tridentate azomethine ligands[38-43].

The use of tridentate ligands of another type for the synthesis of complexes via the condensation of amino-alcohols with salicylaldehyde (IX) and acetylacetone (IXa),

(IX) (IXa)

made it possible to follow clearly the influence on the nature of the exchange interaction in complexes (IXb) of the structural factor determined by the length and branching of the hydrocarbon group R.[43-47] It was found that only one compound among those investigated [R = $(CH_2)_3$] exhibits an exchange interaction of the antiferromagnetic type.

(IXb) (IXc)

The other compounds exhibit an exchange interaction of the ferromagnetic type (Table 3)[46].

A study of a complex of type (IXb) with R = $(CH_2)_3$ established tentatively its dimeric structure[45] and, in view of the influence of the transmission of the electronic effects of the substituents on the strength of the exchange interaction, it was postulated that the oxygen atoms of the alcohol and not the phenol are involved as bridge groups in the dimeric fragment  .[43] An X-ray diffraction study of the analogous copper complex (IXa), obtained from acetylacetone and having a very low magnetic moment (0.41 μ_B at room temperature) showed that this complex has a dimeric structure where the oxygen atoms of the alcohols function as the bridge groups[47]. In structures (IXa) and (IXb) the planes formed by the tetracoordinate environment of the copper ion and the tricoordinate environment of the oxygen bridge atoms are coplanar. It is suggested that this structural feature in fact accounts for the strong antiferromagnetic interaction [$-2J$ = 884 cm^{-1} and g = 2.20 were obtained for (IXb)][46] via an indirect exchange interaction π-mechanism [$Cu(3d_{xz})$ – $O(2p_\pi)$ – $Cu(3d_{yz})$], involving the d_{xz} and d_{yz} orbitals of the copper ion[47], rather than via the expected exchange via a σ-mechanism

$$\{Cu\,(3d_{x^2-y^2}) - O\,(2p_\sigma) - Cu\,(3d_{x^2-y^2})\}\ .$$

A decrease of the length of the hydrocarbon group to R = $(CH_2)_2$ leads to the formation of tetrameric exchange-bound clusters (IXc).[47] This structure explains the ferromagnetic nature of the exchange in complexes (IXb) (Table 3).

III. DI- AND POLY-NUCLEAR COMPLEXES BASED ON CHELATES WITH SCHIFF BASES AS LIGANDS

One of the commonest types of di- and poly-nuclear complexes with exchange interaction comprises compounds obtained by the insertion of a paramagnetic centre in the coordination unit of a chelate with a paramagnetic metal ion. These compounds are usually obtained either by the interaction of metal salts with chelates of tetradentate Schiff bases (X), whereupon di- and tri-nuclear complexes with a *cis*-structure (XI, a and b) are formed[48-66], or by the interaction of metal salts with the chelate (XII) formed by bidentate ligands, whereupon di- or poly-nuclear complexes with a *trans*-structure (XIII) are formed[44,49-51,53,54,57,59-67,70-77].

(X) (XIa) (XIb)

R = $(CH_2)_n$, n = 2, 3; R' = H, or Me; A = Cl, Br, or NO_3; X = H, 5-Cl, 5-Br, or 5,6-C_4H_4; M = Cu^{II}, Ni^{II}, Co^{II}, $Fe^{II,III}$, or Mn^{II}

(XII) (XIII)

R = Alk or Ar

X = H, 5-Cl, 5-Br, 5,6-C_4H_4, or 3-OMe; A = Cl or Br

Chelates with tridentate Schiff bases behave as neutral bidentate ligands coordinated to the metal atom of the MX_2 molecule via the two phenolic oxygen atoms, which is confirmed by the change in the vibration frequency of the Ph–O bond in the infrared spectra[53,54,67,77,83,85]. Dinuclear complexes of type (XIa, $n = 2$, M = Cu, A = Cl) are formed, the temperature dependence of the magnetic susceptibility of which obeys the Bleany–Bowers equation with $J < 0$. The exchange intergrals ($-2J$) and the g-factors are presented in Table 4.[52,61]

Table 4. The exchange integrals and g-factors for copper complexes of type (XIa).

* m is the number of water molecules.
** M = Fe^{III}.
*** M = Mn^{II}.

It has been noted in a number of studies[49,53,54,78,80] that the two metal atoms Cu(1) and M(2) in dinuclear complexes of type (XIa) are in different environments: Cu(1) in a square-planar environment and M(2) in a pseudotetrahedral environment (Fig. 1). The symmetry of the M(2) coordination unit depends significantly on the number of R = $(CH_2)_n$ bridge groups[75]. In complexes (XIa) with $n = 2$ the M(2) unit has the structure of a distorted tetragonal pyramid (as a result of the additional coordination of chlorine from a neighbouring molecule); for complexes with $n = 3$, M(2) has a pseudotetrahedral stereochemistry. The magnetic properties of complexes (XIb), forming trinuclear compounds, have been interpreted on the assumption that the metal atoms are located at the vertices of an equilateral triangle[50], the antiferromagnetic properties increasing in the sequence Co < Ni < Cu.[51] The relative stability of complexes (XIb) and the energy of d–d transitions were found to vary in parallel with the extent of the antiferromagnetic interaction, which can be accounted for by the successive increase of the tetragonal distortion of the M(2) coordination unit in many copper, nickel, and cobalt complexes (Fig. 1),[49,53,54]. However, one must bear in mind that this explanation is not always correct owing to the possibility of an increase of the coordination number of Cu(2) to five, and M(2) can partly displace copper from the "planar" complex.

It has been shown[60,62,66] that the interaction of complexes [X, R = $(CH_2)_2$, M = Cu^{II}, Ni^{II}, Co^{II}, or Fe^{III}] with the Lewis acids SnX_2, SnX_4, $TiCl_4$, SbX_5, $InCl_3$, $CaCl_2$, PCl_3, and $AsCl_3$ (where X = Cl or Bi) leads to the formation of dinuclear complexes in which the initial chelate with a tetradentate Schiff base can exchange the metal with the Lewis acid, forming various structures. Only when cyclic polymeric-tetrahedral adducts (XIa, M = Co or Cu) and polymeric-octahedral adducts (XIa, M = Ni^{II}) are formed with PCl_3 and $AsCl_3$, is the non-linearity of the temperature dependence of the reciprocal of the magnetic susceptibility attributed to the antiferromagnetic interaction. For the compound with PCl_3, a satisfactory agreement is observed between the experimental susceptibility and the value calculated using the linear chain model ($g = 2.11$, $2J = -55$ cm^{-1}).[65]

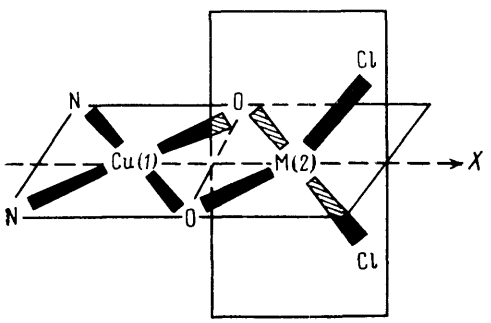

Figure 1. A fragment of the structure of a dinuclear complex of type (XIa).

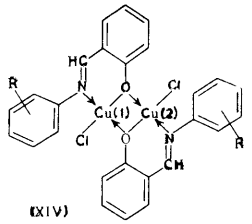

In dinuclear complexes (XIa, M = Ni), containing a water molecule, the exchange interaction can exhibit ferromagnetic features[72].

When Lewis acids interact with copper(II), cobalt(II), and nickel(II) complexes of type (XII), there is a possibility, judging from the changes in the infrared and electronic spectra, of the cleavage of the metal chelate ring in the initial chelate, which leads to the formation of complex dinuclear structures[83–86]. The effective magnetic moments of the above compounds, calculated per atom of the paramagnetic metal, have normal values. However, the coordination-unsaturated compounds formed as a result of the cleavage of the metal-chelate ring interact with one another and not with the Lewis acid and give rise to insignificant amounts of compounds with exchange-bound [electron] pairs as impurities in the main product, as shown by the appearance of a broad absorption band in the EPR spectra of the copper complexes in the region corresponding to weak fields.

Dinuclear copper complexes based on chelates with bidentate ligands (XIII) also manifest an appreciable exchange interaction of the antiferromagnetic type. The exchange integrals ($-2J$) and average g-factors of some of these are presented in Table 5.

In the dinuclear ecomplexes (XIa) and (XIII) the Cu–Cu distance is ~3 Å,[78–81] as in the copper complex of N-(2-hydroxyphenyl)acetylacetoneimine[13,14]. In the dimeric copper complex of the tetradentate N,N'-bis-(2-hydroxyethyl)acetylacetonediimine the Cu–Cu distance increases to 4.99 Å and the exchange integral is $2J = -94$ cm^{-1}.[82] In the trinuclear complexes $(NiL_2)_2.Ni(NO_3)_2$ there is a weak ferromagnetic interaction[71].

Systematic studies of dinuclear complexes of type (XIV)

(XIV)

showed[69,70,75-77] that, as in the analogous dinuclear complexes of copper halides with pyridine *N*-oxides[73,74], the substituents R have a weak influence on the energy of the *d–d* transitions and the effective magnetic moments. Nevertheless the bands corresponding to the *d–d* transitions in dimeric complexes with *ortho*-substituents are shown at shorter wavelengths than for the corresponding complexes with *meta*- and *para*-substituents (Fig. 2), which is believed to correspond to a decrease of μeff in dinuclear complexes with *ortho*-substituents compared with complexes having *meta*- and *para*-substituents[69,75,76].

There is a linear relation between the magnetic moment and the position of the band due to the *d–d* transition (Fig. 3)[75]. The same type of relation has been found also for dinuclear complexes of copper with tetradentate Schiff bases of type (XIa).[53,54] It has been suggested[77] that this type of linear relation indicates a transition from a distorted pseudotetrahedral configuration to a planar configuration when *ortho*-substituents are introduced. An increasing degree of planarity leads to a hypsochromic shift of the *d–d* band and to a decrease of the magnetic moment owing to the appreciable overlap of the metal atom orbitals with the orbitals of the bridging oxygen atoms. A similar effect involving the "flattening" of the coordination unit following the introduction of *ortho*-substituents has been observed for monomeric copper complexes of salicylidenearylamines[6] and can be accounted for by the steric conditions arising after the introduction of *ortho*-substituents, since the benzene rings both in copper complexes of salicylideneaniline derivatives and in the dinuclear complexes investigated are located at an angle of 60° relative to the plane of the coordination unit.

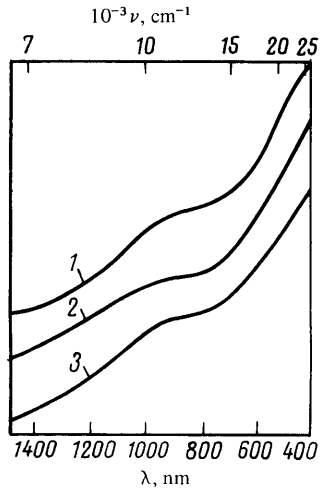

Figure 2. Diffuse reflection spectra of complexes (XIV); R: 1) 2-Me; 2) 3-Me; 3) 4-Me.

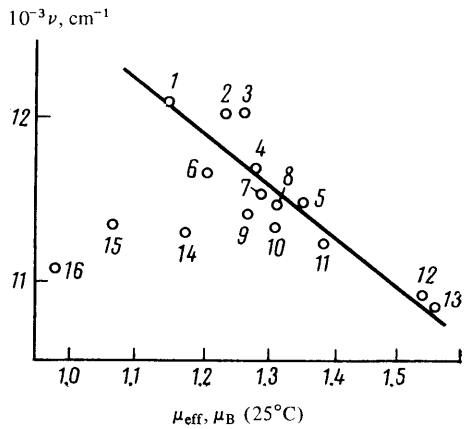

Figure 3. Dependence of the position of the *d–d* transition bands and μeff (at 25°C) on the substituent R for complexes of type (XIV); R: 1) 2-Cl; 2) 2-Me; 3) 3-Cl; 4) 2,4-Me_2; 5) 2,6-Me_2; 6) 2,6-Cl_2; 7) 3,4-Cl_2; 8) 4-Me; 9) 3,5-Cl_2; 10) 4-Cl; 11) H; 12) 3-NO_2; 13) 3-Me; 14) 2,5-Cl_2; 15) 2-NO_2; 16) 4-NO_2.

An analogous relation has been established for dinuclear complexes (XIII, R = alkyl) with alkyl substituents. As for mononuclear chelates, the replacement of a straight-chain alkyl group by a bulky branched group (for example, the replacement of n-C_3H_7 by iso-C_3H_7 or of n-C_4H_9 by t-C_4H_9) leads, with rare exceptions (R = Me),[81] to a tetrahedral distortion of the geometry and to a corresponding increase of μ_{eff} and a decrease of the frequency of the d–d transition[77].

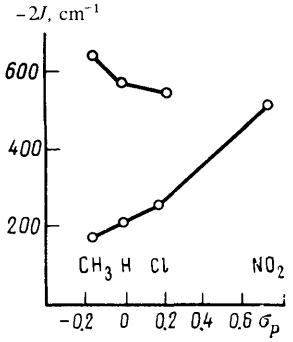

Figure 4. Dependence of the exchange integral on the Hammett constants σ_p for complexes of type (XIXa).

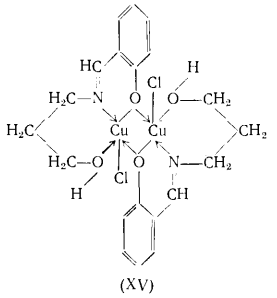
Thus there is a direct relation between the degree of tetrahedral distortion of the coordination unit in dinuclear complexes of type (XIII) and the decrease of the antiferromagnetic interaction between pairs of copper atoms[81]. The dihedral angles τ between the planes in which the copper atoms of the two halves of the dimeric molecules of (XIII) are located have been compared[81] with the integrals $-2J$. The values of τ are respectively 33.1°, 35.7°, 35.5°, and 39.3° for complexes with the following substituents: A = Cl, X = H, and R = Et; A = Br, X = H, and R = Et; A = Br, R = n-C_4H_9, and X = 5-Cl; A = Cl, X = H, and R = Me; the corresponding values of $-2J$ are 240, 205, 220, and 146 cm^{-1}.

If the structure of the complexes differs from the pseudotetrahedral structure, a linear relation is not observed between μ_{eff} and the d–d transition frequency. Depending on the conditions of synthesis and the nature of the alkyl substituent introduced into the aldehyde ring of the liquid, complexes (XIII) with different stereochemistries of the coordination units can be obtained[77]. The above compounds have been classified on the basis of the results: (1) type B—pseudotetrahedron; (2) type YG—square pyramid with a weak distortion in the direction of a trigonal-pyramidal configuration; (3) type Y—trigonal bipyramid with a weak distortion in the direction of a square-pyramidal configuration; (4) type Y'—trigonal bipyramid with a large distortion in the direction of a square-pyramidal configuration.

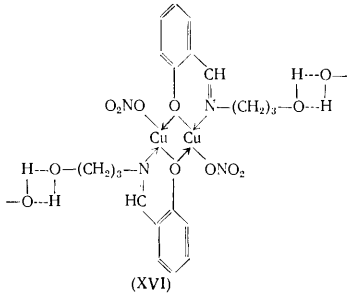
Naturally, for different stereochemical configurations, the dependence of μ_{eff} on the d–d transition frequency is different[77]. For regular square-pyramidal dinuclear structures, antiferromagnetic exchange via oxygen bridges should take place, as for planar complexes:

$$3d_{x^2-y^2}\,[\mathrm{Cu}\,(1)] - p_\sigma\,(\mathrm{O}) - 3d_{x^2-y^2}\,[\mathrm{Cu}\,(2)] \quad \sigma\text{-mechanism};$$
$$3d_{xz}\,[\mathrm{Cu}\,(1)] - p_\pi\,(\mathrm{O}) - 3d_{yz}\,[\mathrm{Cu}\,(2)] \quad \pi\text{-mechanism}.$$



For regular trigonal-bipyramidal structures, antiferromagnetic exchange takes place as follows:

$$3d_{x^2-y^2}\,[\mathrm{Cu}\,(1)] - p_\sigma\,(\mathrm{O}) - 3d_{z^2}\,[\mathrm{Cu}\,(2)] \quad \sigma\text{-mechanism},$$
$$3d_{xy}\,[\mathrm{Cu}\,(1)] - p_\pi\,(\mathrm{O}) - 3d_{yz}\,[\mathrm{Cu}\,(2)] \quad \pi\text{-mechanism}.$$



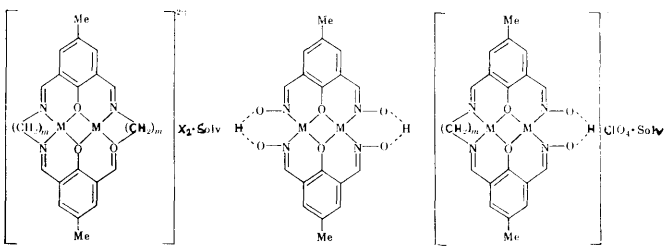
This approach makes it possible to infer the nature of the antiferromagnetic interaction and the symmetry of the coordination unit on the basis of the study of the dependence of the d–d transition energy on the effective magnetic moment in systematically selected series of complexes.

The complexes Cu(SalNROH)X (X = Cl, NO_3, or ClO_4), which are obtained by the interaction of copper salts and copper chelates with N-hydroxyalkylsalicylideneamines (IX), can have different compositions, structures, and magnetic properties depending on the method of synthesis, the nature of the anion, and the steric conditions (determined by the length and degree of branching of the hydroxyalkyl group)[46,87,88].

Whereas antiferromagnetic interactions of different strengths are observed for complexes with R = $(CH_2)_2$, $(CH_2)_3$, or CH_2–CH(Me) and X = Cl or ClO_4, when a nitro-group is introduced into the aldehyde ring of the ligand [for the complex with R = $(CH_2)_2$ and X = Cl] and with increase of the degree of branching of the group [R = Me–CH(Me), X = Cl or NO_2], these complexes behave as the usual paramagnetic materials[88]. It is suggested that the nature of the exchange interaction in the dimeric compounds (XV) is associated with the different degrees of distortion of the coordination unit as a function of R. For compounds with R = $-(CH_2)_3-$ and X = Cl, X-ray diffraction analysis revealed a distorted trigonal-pyramidal structure (XV):[89,90]

(XV)

(XVI)

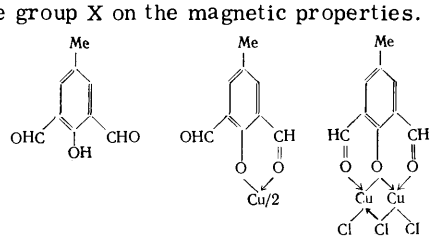


These are thus complexes of the second type, obtained on the basis of 3-hydroxy-N-propylsalicyclideneamines [the first type is a dimer (IXb) with a strong exchange interaction]. It has been shown[87] that these two types of complexes can undergo an interconversion under certain conditions. It has been suggested[87] that interaction with copper nitrate gives rise to compound (XVI), in which the alcoholic group is not deprotonated and is not coordinated to the metal, but forms a polymer chain via hydrogen bonding. An antiferromagnetic type of exchange is also

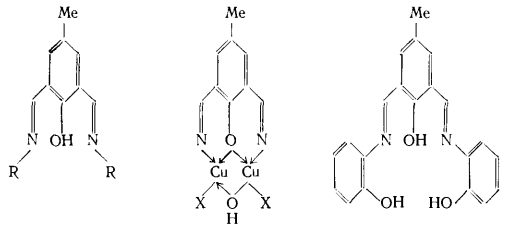
characteristic of complex (XVI), but its magnetic properties cannot be interpreted unambiguously[87,91].

The influence of the structural factor on the magnetic properties of copper compounds with *N*-hydroxyethyl-5-R-salicylaldimines of type (XV, R = H, Me, Cl, or NO_2) has been investigated[88]. A dinuclear structure with chloride bridges has been established for $[Cu(5\text{-}RSaL.NEtOH)Cl]_2$ with R = H or Me; a dinuclear structure with a phenolic oxygen as the bridge has been found for Cu-(5-MeSal. .NEtOH)Br.0.1 DMF (DMF = dimethylformamide); a linear trinuclear structure (also with the phenolic oxygen as the bridge) has been determined for $Cu_3(Sal.N.EtOH)_2Cl_4$. .2EtOH. The magnetic properties of these complexes are presented in Table 6. The form of the temperature dependence of the magnetic susceptibility permits a polymeric chain structure of $Cu_2(5\text{-}MeSalNEtOH)Cl_3.0.5H_2O$. For other complexes of this type, the structural data have also been correlated with their magnetic properties (Table 6).

IV. DINUCLEAR COMPLEXES WITH POLYDENTATE DIMERISING LIGANDS



The azomethine derivatives (XVIII) and (XIX), obtained on the basis of 3-formyl-5-methylsalicylaldehyde (XVII), are typical dimerising ligands[92,93].



(XXa) (XXb) (XXc)

M = Cu, Ni, or Co; X = Cl or ClO_4; Solv = H_2O; m = 2, 3 . M = Cu or Ni M = Cu or Ni; Solv = DMF or H_2O

The effective magnetic moments of the mononuclear complex (XVIIa) and the dinuclear complex (XVIIb) are respectively 1.81 and 1.58 μ_B, while the μ_{eff} for dinuclear azomethine complexes of type (XVIIIa) are 0.8–1.29 μ_B at room temperature, depending on the substituent R.[93] Hence one may conclude that azomethine ligands give rise to dinuclear complexes (XVIIIa) with a stronger exchange interaction than complexes (XVIIb). These compounds were described for the first time by Robson[92], who investigated complexes (XIXa) with the ligand (XIX). The structure of (XIXa) has been confirmed by X-ray diffraction[92]. Several types of complexes (XXIa) have been synthesised by condensing (XVII) with various amines and investigated[92,94–97]. Comparison of complexes of type (XIXa) with different bridge groups but with identical Z (nos. 1–7, Table 7) reveals the influence of the nature of the bridge group X on the magnetic properties.

* Compound having the general formula $Cu_n(5\text{-}R'.Sal.N.ROMe)_m.X.Solv$.

On the other hand, when complexes with the same group but different Z are compared (Nos. 2 and 8, Table 7), the enhancement of the exchange interaction following the replacement of oxygen by sulphur in the coordination unit is clearly manifested, and the ligand residue does not apparently have a significant influence in these complexes

on the nature of the exchange interaction, as shown by a comparison of the properties of complexes of different types [(XIXa) and (XXIa)] but with the same bridge groups X and identical Z (Nos. 8 and 9 and 10 and 11, Table 7).

(XXI)

(XXIa)

M=Cu^{II} or Ni^{II}; X=$C_3H_3N_2$, N_3 or Cl .

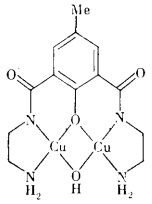
* At room temperature.
** In the range 351–89 K.
*** In the range 286–90 K.

According to a hypothesis[95], confirmed by X-ray diffraction analysis of analogous complexes[97], compounds (XIXa) have a tetrameric structure and the change in magnetic properties is to a large extent determined by the distortion of the coordination unit on formation of the tetramers.

It is of interest to compare the behaviour of dinuclear complexes of type (XIXa) having identical Z and X (Z = O, X = OMe) but variable R. [98] A certain correspondence between the electronic influence of the substituents R (Hammett σ_p constants) and the quantity $-2J$ (Fig. 4 and Nos. 13–20 in Table 7) has been explained[98] by the fact that the overlap of the d_{xy} orbitals in the vanadyl complexes increases in the sequence R = Me < H < Cl in parallel with the deviation of the vanadium atom from the plane of the coordination unit. On the other hand, $-2J$ for tetragonal copper complexes is influenced to the greatest extent by the change in the equatorial bonds involved in the exchange. This is why $-2J$ decreases with enhancement of the electron-accepting properties of the substituent R, leading to the combination of electron density at the phenolic oxygen bridge. Complexes (XIXa) with R = NO_2 for which a polymeric structure has been established, constitute a special case.

A strong antiferromagnetic interaction has been observed for complexes (XXa) (Nos. 13 and 14, Table 8). The square-pyramidal structure (XXII)

(XXII)



was assigned to them on the basis of X-ray diffraction studies of similar compounds[96].

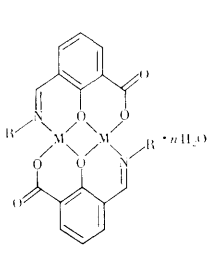
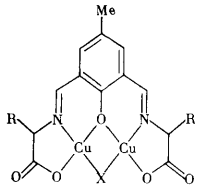
* The value of μeff was found on the assumption that one nickel atom is diamagnetic.



Dinuclear complexes (XXIIIa) with analogous ligands (XXIII) have been synthesised[100]:

(XXIII)

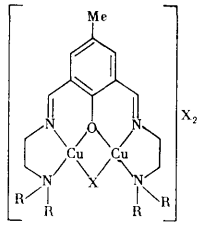
(XXIIIa)



(XXIIIb)

M = Cu^{II}, or Ni^{II}; R = Alk .

It has been shown that the exchange interaction is greatly intensified on passing from (XXIII) (μ_{eff} = 1.14 μ_B at T_{room}) to (XXIIIa) (μ_{eff} = 0.79 μ_B at T_{room}), because the system is more rigid and because of the introduction of the conjugated azomethine fragment. At the same time, dimeric complexes (XXIIIb) have been obtained on the basis of 3-formylsalicylic acid[99]; the parameters characterising the exchange interaction in (XXIIIb) were compared with the values for the analogous complexes (XIII). The authors[99] emphasise that the substituents R in compounds (XXIIIb) have a weaker steric influence than in (XIII).



Complexes (XXb) and (XXIV) have been synthesised and investigated[101-103]:

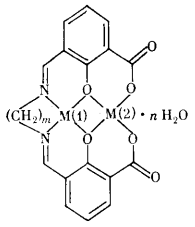
(XXIV)

R = Me, X = Cl;

R = H, X = Cl, Br, or OH

(XXV)

R = Me, Et, or H;



X = Cl, Br, OH, or NSC

A significant change in their magnetic properties was demonstrated on varying the bridge group X [101-103] (Table 8): for X = OH, a strong antiferromagnetic interaction is observed, while for X = Cl or Br, it is significantly less intense[101-103]. Since the Cu–Cu distance in a dimeric molecule is 3.4 Å, an indirect exchange interaction via the bridge groups is observed. It is suggested that this change in magnetic properties indicates a change in the extent of the indirect interaction of the bridge groups in the sequence OH $\gtrsim$ Cl $\simeq$ Br. At the same time the authors[103] assume that the high effective magnetic moments of compound Nos. 5, 6, and 7 in Table 8 can be due to the distortion of the plane of the coordination unit.

An analogous effect of bridge groups was investigated in greater detail in relation to complexes of type (XXV).[104] It was shown on the basis of the temperature variation of the magnetic susceptibility that the antiferromagnetic exchange interaction between two copper atoms diminishes in the sequence OH $\geqslant$ Br > Cl for the same contribution of the phenolic oxygen to the indirect exchange. However, one must bear in mind (Nos. 8–10, Table 8)[104] the role of the geometrical factor. It has been postulated[104] that the above complexes with a chloride anion have a tetragonal-pyramidal structure and, judging from the electronic spectra, complexes (XXV) with X = OH have a structure different to that of complexes with X = Cl or Br. Indeed the introduction of the group X = SCN leads[105] to the formation of tetrameric structures in which two dimers are linked to form a tetramer via intermolecular S...Cu bonds. The Cu–Cu interaction in the dimers remains antiferromagnetic.

A strong exchange interaction has been observed also for complexes of type (XX, b and c) (Nos. 11–15, Table 8)[106]. A tetragonal-pyramidal structure was also attributed to them. The enhancement of the exchange interaction between them is explained by a more rigid matrix due to the ligand.

Polydentate ligands based on 3-formylsalicylaldehyde[107,108] have been used to obtain di- and poly-nuclear complexes whose molecules contain two different metals (Cu and Ni).[107,111] Bimetallic complexes of type (XXa), each molecule of which contains Co^{II} and Co^{III},[110] as well as complexes of type (XXVI) based on 3-formylsalicylic acid[110-112] have been synthesised.

M(1) = Cu, m = 3, M(1) = Cu, n = 1;

m = 2, M(2) = Co, Fe, Mn, Ni, UO_2, or Th/2; n = 0–3.

(XXVI)

It is noteworthy that the possibilities of complexes of this series have been by no means exhausted and, on the basis of studies carried out hitherto[92-111], it is difficult to make general conclusions concerning the correlation between the structure, the nature of the bridge groups, and the exchange interaction. This is because the structures of these compounds have been inadequately elucidated and the conclusion that the complexes have the same structures, reached when a systematic comparison is made of series of such complexes, are mainly based on the analogy with the known structural data for other similar systems.

The Hydride Addition of Organohydrosiloxanes to Compounds with a Multiple Carbon-Carbon Bond

K.A.Andrianov (deceased), J Souček, and L.M.Khananashvili

Reactions leading to the formation of an Si-C bond—the hydrosilylation of unsaturated organic compounds by organohydrosiloxanes and the hydride addition of organohydrosiloxanes to organosilicon compounds containing multiple carbon-carbon bonds—are examined. Factors influencing the course of the reaction and the properties of the addition products are discussed. The bibliography includes 153 references.

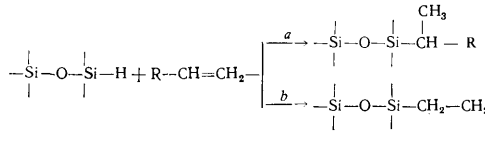
IV. The principal factors influencing the course of the hydride addition reaction 662

I. INTRODUCTION



Hydride addition reactions are common in organic and organoelemental chemistry. Using these reactions, a wide variety of numerous organosilicon compounds have been synthesised. The addition of hydrogen-containing organosilicon compounds to compounds with a multiple carbon–carbon bond, the so-called hydride addition or hydrosilylation reaction, constitutes one of the methods for the formation of an Si–C bond[1-3].

The hydride addition reaction has been widely used recently not only for the synthesis of organosilicon monomers and oligomers but also for the conversion of linear and branched organoelemental polymers into polymers with a network structure. The hydride addition reaction has also acquired great importance for the synthesis of polycarbo-organosiloxanes.

Since studies on the hydride addition of organohydrosiloxanes to various organic and organosilicon unsaturated compounds published up to 1964 have already been examined in a monograph[2], studies published from 1964 to 1976 are discussed in the present review.

II. THE HYDRIDE ADDITION OF ORGANOHYDROSILOXANES TO COMPOUNDS WITH A MULTIPLE CARBON–CARBON BOND

The addition of organohydrosiloxanes as well as other hydrogen-containing organosilicon compounds to unsaturated compounds can proceed with formation of α- and β-addition products. Consequently this reaction can proceed both in accordance with the Markovnikov rule (pathway *a*) and contrary to this rule, i.e. in accordance with Farmer's rule (pathway *b*):

The hydrosilylation of hex-1-ene, hex-2-ene, and hex-3-ene by 1,1,3,3-tetramethyldisiloxane has been investigated[4]. As a result of this reaction, hex-1-ene gives rise exclusively to the 1-hexyl adduct, while hex-2-ene and hex-3-ene lead to a mixture of isomers. At the same time the hexenes themselves isomerise. The hydrosilylation reaction was carried out at 100°C for several days and the addition products obtained were converted into $(CH_3)_3SiC_6H_{13}$. The proportions of the isomers in the final products are illustrated in the Table.

The content of $(CH_3)_3SiC_6H_{13}$ isomers as a function of the structure of the initial olefin.

Initial olefin	Content of $(CH_3)_3SiC_6H_{13}$ isomers, %		
	1-hexyl	2-hexyl	3-hexyl
Hex-3-ene	76	10	14
Hex-2-ene	88	7	5
Hex-1-ene	99	traces	0

The hydride addition of pentamethyldisiloxane to hex-1-ene in the presence of various catalysts (Group VIII transition metals) has been investigated[5]. It has been shown that this reaction is effectively accelerated by rhodium and platinum complexes; palladium and nickel complexes do not catalyse this reaction.

In the hydrosilylation of styrene by methylhydrosiloxanes having the general formula $(CH_3)_{3-n}HSi-[-OSi(CH_3)_3]_n$, where $n = 0-3$, in the presence of chloroplatinic acid in isopropyl alcohol (the Speier catalyst), both α- and β-addition products are formed[6]:

The fraction of β-addition products varies from 80 to 100% depending on the structure of the methylhydrosiloxanes. The tendency of methylhydrosiloxanes to form a β-adduct decreases in the following sequence as a function of the number of trimethylsiloxy-groups (n): $0 > 3 > 2 > 1$.

It has been found[7] that in the presence of the Speier catalyst, the main reaction involving the hydrosilylation of hex-2-ene by bis(trimethylsiloxy)methylsilane is accompanied by the disproportionation of the silane, i.e. the

exchange of methyl and trimethylsiloxy-groups in accordance with the mechanism

$$(CH_3)_2HSi-[-OSi(CH_3)_3]_2 \rightarrow (CH_3)_2HSiOSi(CH_3)_3 + [(CH_3)_3SiO-]_3-SiH.$$

As a result of the above hydrosilylation reaction at 138°C for 10 h with subsequent fractionation of the products, a mixture consisting of 56.6% $[(CH_3)_3SiO]_2Si(CH_3)(C_6H_{13})$, 14.5% $[(CH_3)_3SiO]_3SiH$, and 12.5% $(CH_3)_3SiOSi(CH_3)_2(C_6H_{13})$ was obtained. In addition 6.4% of $\{[(CH_3)_3SiO]_2SiCH_3\}_2O$ (the product of the oxidation of the initial silane) was also isolated.

The hydrosilylation of 3-oxapentadiene by 1,1,3,3-tetramethyldisiloxane leads to 1,1,3,3-tetramethyl-1-(3-vinyloxyethyl)disiloxane in yields up to 15%:[8]

$$CH_2=CHOCH=CH_2 + H(CH_3)_2SiOSi(CH_3)_2H \xrightarrow{H_2PtCl_6} \rightarrow H(CH_3)_2SiOSi(CH_3)_2CH_2CH_2OCH=CH_2.$$

The low yield of the adduct and the large amount of the non-distilling residue makes 1,1,3,3-tetramethyldisiloxane relatively unpromising, according to Voronkov et al.[8], as a hydrosilylating agent.

The hydrosilylation of phenylacetylene and *p*-diethynylbenzene by 1,1,3,3-tetramethyldisiloxane in the presence of chloroplatinic acid yielded phenyl-substituted 2,2,5,5-tetramethyl-1-oxa-2,5-disilacyclopentanes[9]:

$$[(CH_3)_2HSi]_2O + C_6H_5C\equiv CR \rightarrow (CH_3)_2Si\begin{array}{l}\diagup\\\diagdown\end{array}\!\!\begin{array}{c}C_6H_5\ R\\|\quad|\\CH-CH\\\diagdown\quad\diagup\\O\end{array}\!\!\begin{array}{l}\diagdown\\\diagup\end{array}Si(CH_3)_2\ ;$$

R = H or C_6H_5.

The hydrosilylation of phenyl-substituted acetylenes by 1,3-diethyl-1,3-dimethyl-disiloxane proceeds similarly.

It has been found[10] that certain organosiloxycycloalkanes are capable of polymerising spontaneously. The polyaddition of 1,1,3,3-tetramethyldisiloxane to phenylacetylene and *p*-diethynylbenzene in the presence of H_2PtCl_6 in THF has been reported recently[11,12]. It has been shown that this process consists of consecutive-parallel reactions and is accompanied by the appearance of branching centres:

$$C_6H_5C\equiv CR + H-Si\begin{array}{l}\diagup\\\diagdown\end{array} \rightarrow C_6H_5CH=CRSi\begin{array}{l}\diagup\\\diagdown\end{array} + C_6H_5C=CHR$$

cis-, *trans-*

$$C_6H_5CH_2-CR\left(Si\begin{array}{l}\diagup\\\diagdown\end{array}\right)_2 \quad C_6H_5-CH-CHR \quad C_6H_5C-CH_2R\ ;$$

R = H or C_6H_5.

It has been found[11] that the rate of this reaction is determined by the equation $v = K[\equiv Si-H][C_6H_5C\equiv CR][Cat]^{0.5}$ and the apparent activation energy is 11–18 kcal mole^{-1}. The addition of pyridine in amounts comparable to the amount of the catalyst inhibits this reaction, which is believed[11] to be due to the formation of inactive platinum–pyridine complexes.

The hydrosilylation of styrene, α-methylstyrene, methyl methacrylate, and allyl cyanide by dimethyl(methylhydro)cyclosiloxanes in the presence of chloroplatinic acid has been investigated[13]. It follows from ^{1}H NMR data that the product of the addition of tetramethylcyclotetrasiloxane to α-methylstyrene has the structure $[(CH_3)_2(C_6H_5\underset{\displaystyle CH_3}{\underset{|}{C}}HCH_2)SiO]_4$, i.e. the reaction proceeds in accordance with Farmer's rule.

The hydrosilylation of non-1-ene, α-methylstyrene, methyl methacrylate, and allylamine by heptamethylcyclotetrasiloxane as well as the hydrosilylation of methyl methacrylate by tetramethylcyclotetrasiloxane (in the presence of chloroplatinic acid as the catalyst) has been achieved[14]. Analysis of the reaction products by infrared and ^{1}H NMR spectroscopy established, that, regardless of the nature of the unsaturated compound, the addition takes place in accordance with Farmer's rule without the opening of the initial cyclotetrasiloxane fragment.

Data have been published[15] on the hydrosilylation of allyl cyanide, styrene, α-methylstyrene, and methyl acrylate by tetramethyl- and tetraethyl-cyclotetrasiloxanes in the presence of chloroplatinic acid. The addition products were studied by infared and ^{1}H NMR spectroscopy; in contrast to the data of Reikhsfel'd and Grigor'eva[13] and Borisov[14], it was observed that in all cases the addition products are mixtures of α- and β-adducts with similar boiling points.

Andrianov et al.[16] examined the hydrosilylation by pentamethyldisiloxane and bis(trimethylsiloxy)methylsilane of a number of unsaturated compounds in the presence of H_2PtCl_6: hept-1-ene, cyclohexene, styrene, indene, allyl bromide, acrylonitrile, dicyanoethylene, 2-vinylpyridine, hept-1-yne, isopropylacetylene, 2,5-dimethylhex-3-yne-2,5-diol, isoprene, 1,4-dichlorobut-2-yne, cyclopentadiene, and dichloromethylvinylsilane. It was noted that the above methyl hydrosiloxanes do not add to acrylonitrile in dicyanoethylene. Apart from H_2PtCl_6, amines and their derivatives and Pd/C were also tried as catalysts of the addition reaction. Here too the addition does not occur, which has been explained by steric hindrance. When methylhydrosiloxanes were allowed to add to cyclopentadiene, the dimerisation of the latter was observed. Allyl bromide does not add to pentamethyldisiloxane and the interaction of these compounds leads to the formation of pentamethylbromodisiloxane.

The occurrence of side reactions was observed[17] in the addition of methylhydrosiloxanes having the general formula $(CH_3)_{3-n}HSi[OSi(CH_3)_3]_n$ to β-methylallyl chloride in the presence of chloroplatinic acid:

$$\equiv Si-H + CH_2=\underset{\displaystyle CH_3}{\underset{|}{C}}-CH_2Cl \rightarrow \underset{\text{(I)}}{\equiv SiCH_2\underset{\displaystyle CH_3}{\underset{|}{C}}HCH_2Cl} + \underset{\text{(II)}}{\equiv SiCl} + \underset{\text{(III)}}{\equiv SiCH_2\underset{\displaystyle CH_3}{\underset{|}{C}}=CH_2}.$$

Depending on the structure of the initial methylhydrosiloxane, different amounts of reaction products are formed. Thus pentamethyldisiloxane forms only addition products (I) in 97% yield. Bis(trimethylsiloxy)methylsilane gives rise to 34% of (I), 18% of (II), and 9% of (III). Tris(trimethylsiloxy)silane forms the following products: 14% of (I), 42% of (II), and 23% of (III). According to the current ideas[18] about the mechanism of the hydrosilylation reaction in the presence of H_2PtCl_6, the stability of the intermediate complex with the catalyst should increase with increasing amount of the electronegative trimethylsiloxy-groups in the methylhydrosiloxane molecule; this should lead to an increase of the reactivity of the methylhydrosiloxanes, but the role of steric factors in this reaction is also important, so that the reactivity of methylhydrosiloxanes is determined by both factors. The authors suggest that chloromethylsilanes of type (II) are formed as a result of the destabilising effect of methylhydrosiloxanes on the π-allyl complex. Silylmethylallyl derivatives (III) are probably formed from the intermediate complex of the olefin, methylhydrosiloxane, and platinum.

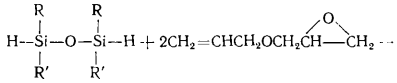
It has been established[19] that, when methylhydrosiloxanes react with unsaturated compounds, side reactions occur together with hydrosilylation:

$$(CH_3)_3SiOSi(CH_3)_2H + CH_2=CH-CH(OCH_3)_2 \xrightarrow{H_2PtCl_6} \rightarrow (CH_3)_3SiOSi(CH_3)_2CH_2CH_2(OCH_3)_2 + (CH_3)_3SiOSi(CH_3)_2(OCH_3) + + (CH_3)CH=CH(OCH_3) .$$

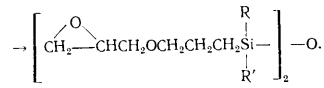
The addition of 1,1,3,3-tetramethyldisiloxane takes place similarly, the β-adducts being formed in both cases.

The addition of linear organohydrosiloxanes to allylamine has been investigated[20]. In the presence of H_2PtCl_6 or the complex of platinum with the vinylpyridine ligand $[(C_5H_5NCH=CH_2)Cl]_2Pt$ allylamine reacts with pentamethyldisiloxane and 1,3-dimethyl-1,3-diphenyldisiloxane to give at 150°C addition products containing the amino-group in the γ-position in the organic group relative to the silicon atom.

The hydrosilylation of allylamine by α,ω-bis(hydromethylsiloxy)methylphenylsiloxane leads to α,ω-bis(γ-aminopropyldimethylsiloxy)methylphenylsiloxanes[21]. On polycondensation with dicarboxylic acids of the dimethylsiloxane series, the latter give rise to elastic organosilicon polyamides, which are soluble in organic solvents.



Monoaddition products have been obtained by the reaction of alkyldiallylamines $RN(CH_2CH=CH_2)$, where $R = CH_3$, C_2H_5, or n-C_4H_9, with 1,1,3,3-tetramethyldisiloxane[22]. Kinetic studies[22] have shown that 1,1,3,3-tetramethyldisilazane is less reactive than 1,1,3,3-tetramethyldisiloxane in the hydrosilylation of diallylethylamine.



It is noteworthy that pentamethyldisiloxane and 1,1,3,3-tetramethyldisiloxane react with 2-vinylpyridine to form α-addition products only, while heptamethyl-, hexamethyl-, pentamethyl-, and tetramethyl-cyclotetrasiloxanes give rise to a mixture of α- and β-addition products under these conditions[23].

A convenient method for the synthesis of nitroaryl(alkyl)siloxanes involves the hydrosilylation of *m*-nitrostyrene by organohydrosiloxanes[24]. The reaction of 1,1,3,3-tetramethyldisiloxane and heptamethylcyclotetrasiloxane with *o*-, *m*-, and *p*-aminostyrenes in the presence of the Speier catalyst yielded the corresponding aminoaryl(alkyl)siloxanes[25]. ^1H NMR and gas–liquid chromatography (GLC) established that hydrogen and the silicon atom in methylhydrosiloxanes adds to both α- and β-carbon atoms of the C=C bond in aminostyrenes. The addition of 1,1,3,3-tetramethyldisiloxane to thienylmethylphenylvinylsilane has been achieved in the presence of the Speier catalyst[26]. Mono- and di-addition products, which are β-adducts, are formed as a result.

The corresponding organosilicon derivatives have been obtained by the addition of bis(trimethylsiloxy)methylsilane to *N*-propargylpiperidine, perhydroazepine, and morpholine in the presence of H_2PtCl_6.[27] Mono- and di-substituted acetyl- and γ-chloropropyl derivatives of disiloxane have been obtained by the hydrosilylation of vinyl acetate and allyl chloride respectively with 1,3-dimethyl-1,3-diphenyldisiloxane in the presence of H_2PtCl_6.[28]

The reaction of dihydromethylsiloxanearylenes with epoxy-compounds containing an unsaturated bond yielded organosilicon epoxy-derivatives in yields up to 80%. The reaction was carried out at 60–70°C in the presence of chloroplatinic acid[29]. Organosilicon epoxy-compounds with various substituents at the silicon atom have also been obtained by the addition of 1,1,3,3-tetraorganodisiloxanes to unsaturated epoxides in the presence of the Pt/C catalyst[30]:

It has been recommended[30] that the diaddition products be used as modifying additives to epoxy-resins and also to phenolic, alkyd, and polyester resins in order to increase their thermal stability. Following their addition to organosilicon resins, the diaddition products improve the adhesion of the former and their mechanical properties[30].

Compounds of the type

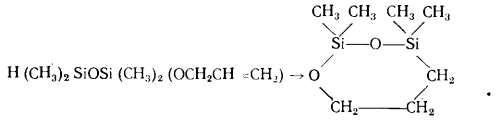
$$(CH_3)_3SiO-[-(CH_3)Si-[-(CH_2)_xO(C_2H_4O)_y-]-AO-]_n-Si(CH_3)_3,$$
$$A = H \text{ or } COOR,$$

have been obtained by the addition of methylhydrosiloxanes to polyethers containing an unsaturated group, in the presence of H_2PtCl_6. The products are recommended as additives to polyurethane foam plastics[31]. Products with an analogous structure, recommended as foam stabilisers in the manufacture of flexible polyetherpolyurethanes, have also been described in patents[32,33].

Hydrosilylation of acrylic[34,35], and methacrylic[36] acids by α,ω-dihydromethyl(methylphenyl)siloxanes in the presence of the Speier catalyst yielded the corresponding organosiloxane-α,ω-dicarboxylic acids. It has been established by infrared spectroscopy that these reactions give rise to β-addition products.

Carbaborane derivatives of silicon have been obtained by the addition of 1,3-dichlorotrimethyldisiloxane and heptamethylcyclotetrasiloxane to unsaturated carbaborane derivatives[37]:

Isopropenylcarbaborane also adds to linear polyalkylhydrosiloxanes with formation of linear polycarbaboranesiloxanes[38].



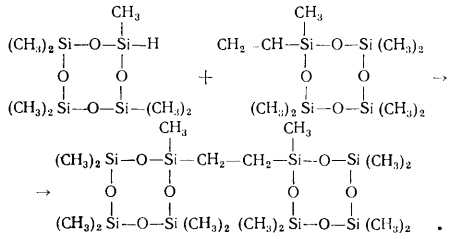
Polyorganosiloxanes containing the $\geq Si-H$ groups react with various organic compounds via the hydrosilylation mechanism[39]. It has been shown, for vinyl derivatives of styrene and divinylbenzene, that the addition of polyorganohydrosiloxanes proceeds in accordance with Farmer's rule.

The hydride addition of polyorganohydrosiloxanes to allyl acetate in the presence of platinum catalysts yielded liquids which are suitable for hydraulic shock absorbers in motor cars[40].

Reactions involving the hydride addition of organohydrosiloxanes to various organosilicon compounds containing unsaturated organic groups as well as the addition of hydrogen-containing organosilicon compounds to organosiloxanes with unsaturated organic substituents have been reported[2]. The addition of chloromethylhydro- and chloroethylhydro-silanes to methylvinylcyclosiloxanes has been described[41,42]. In the presence of the Speier catalyst these reactions yielded compounds capable of being converted further via their hydrolytic condensation. The addition reactions proceed with formation of β-addition products. The hydride addition of 1,1,3,3-tetramethyldisiloxane and tetramethylcyclotetrasiloxane to chloromethylvinyl- and methoxy-silanes in the presence of H_2PtCl_6 have been used to synthesise the initial compounds for the preparation of oxadisilacyclopentanes[43].

It has been shown[44] that, when allyloxyhydromethylsiloxanes are heated in the preeence of the Speier catalyst, intramolecular cyclisation takes place with formation of

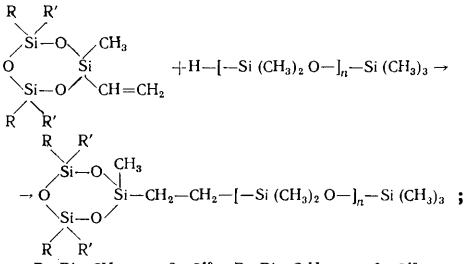
methyloxasilacycloalkanes, for example:



The addition of 1,1,3,3-tetramethyldisiloxane to trimethylsilyl vinylacetate has also been achieved[45]:

2-Silalactones have been obtained by the hydrolysis of the product.

A bicyclic organosiloxane has been obtained by the reaction of heptamethylvinylcyclotetrasiloxane and heptamethylcyclotetrasiloxane in the presence of chloroplatinic acid[46]:



A bicyclic product of the addition of hexamethylphenylcyclotetrasiloxane to heptamethylvinylcyclotetrasiloxane has been obtained similarly[46].

The addition of pentamethyldisiloxane to heptamethylvinylcyclotetrasiloxane in the presence of various complex catalysts based on Group VIII transition metals has been investigated in detail[5,47]. The addition products were isolated by preparative GLC; analysis of the infrared and ^{1}H NMR spectra showed that, in the presence of platinum and rhodium compounds, this reaction proceeds mainly with formation of β-adducts.

The addition of pentamethyldisiloxane and 1-hydroheptamethyltrisiloxane to bis(methylphenyl)bis(methylvinyl)-cyclotetrasiloxane yielded the corresponding organocyclotetrasiloxanes containing dimethylsiloxane chains with terminal trimethylsiloxy-groups as a framework surrounding the silicon atom[48]. Infrared and ^{1}H NMR data led to the conclusion that the addition products are β-adducts. They do not polymerise under the influence of anionic catalysts [KOH at 140°C; $(CH_3)_4NOH$ at 80°C]. The addition of sulphuric acid (1%) induces structure formation in these adducts at 50°C in the course of 3 h with formation of cross-linked polymers.

The addition of vinylorganocyclotrisiloxanes to compounds having the general formula $H-[-Si(CH_3)_2O-]_n-Si(CH_3)_3$, which results in the formation of organocyclotrisiloxanes with methylsiloxane-ethylene groups at the silicon atom, has also been investigated[49,50]:

Dimethylcyclotrisiloxanes with methylsiloxane-ethylene branches give rise to cross-linked polymers in the presence of tetramethylammonium polydimethylsiloxanolate at temperatures from 20° to 75°C. This has been attributed[50] to chain transfer to siloxane-ethylene groups under the conditions of block polymerisation. Diphenylcyclotrisiloxanes with methylsiloxane-ethylene branches form polymers with a molecular weight of 187 000 under these conditions, the size of the siloxane-ethylene group in the initial compounds having little influence on the rate of formation of polymers.

Organosiloxanes with a cyclolinear structure have been obtained by the addition of pentamethyldisiloxane to hexamethyldivinylcyclotetrasiloxane in the presence of tris(triphenylphosphine)rhodium chloride[51]. It has been established with the aid of infrared and ^{1}H NMR spectroscopy that they are products of β-addition with an admixture (up to 10%) of α-addition products. GLC showed that both monoaddition and diaddition products are a mixture of stereoisomers. Cyclolinear organosiloxanes have also been obtained by the addition of α,ω-dihydrodimethylsiloxanes having the general formula $HSi(CH_3)_2O-[-Si(CH_3)_2O-]_n-Si(CH_3)_2H$ ($n = 0-3$) to heptamethylvinylcyclotetrasiloxane in the presence of tris(triphenylphosphine)rhodium chloride[52]. Analysis of the addition products with the aid of infrared and ^{1}H NMR spectroscopy established that the reaction proceeds preferentially in accordance with Farmer's rule

Reactions involving the addition of pentamethyldisiloxane to methylvinylsiloxanes having the general formula $(CH_3)_{3-n}(CH_2{=}CH)Si-[-OSi(CH_3)_3]_n$, where $n = 0-3$,[53] as well as reactions involving the addition of heptamethylvinyldisiloxane to methylhydrosiloxanes having the general formuls $(CH_3)_{3-n}HSi-[-OSi(CH_3)_3]_n$, where $n = 0-3$, have been described[54]. It has been shown that in the presence of platinum and rhodium compounds these reactions proceed with the preferential formation of β-adducts.

Organosiloxanes with ferrocene groups[55] have been obtained by the reaction of organosilicon ferrocene derivatives containing the $\geq Si-H$ bond with allylorganosiloxanes.

III. THE HYDRIDE POLYADDITION OF ORGANODIHYDROSILOXANES TO DI- AND POLYFUNCTIONAL UNSATURATED COMPOUNDS

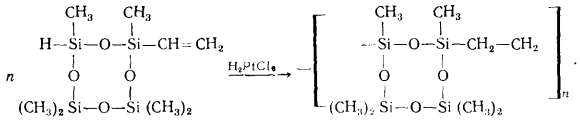
This section deals with methods for the preparation of polycarbaorganosiloxanes using the hydride polyaddition of organohydrosiloxanes to organoalkenylsiloxanes and to organoalkenylhydrosiloxanes. Various organosilicon oligomers and polymers have been synthesised by the hydride polyaddition reaction[2,3,38]. There are two main methods for the preparation of oligomers and polymers of this kind.

1. Polyaddition of organosilicon compounds containing both an $\geq Si-H$ linkage and an unsaturated group in the molecule:

where R are various organic groups and R′ is an organic group with $n \geq 0$.

2. Polyaddition of organosilicon compounds containing two or more $\geq$Si–H linkages to bifunctional or polyfunctional unsaturated compounds (a) or to acetylene and its derivatives (b):

$$\text{a)}\quad m\,\mathrm{H}-(-\mathrm{SiR_2O}-)_n-\mathrm{SiR_2H} + m\,(\mathrm{CH_2{=}CH})_2\,\mathrm{A} \xrightarrow{\text{cat.}} \rightarrow -[(-\mathrm{SiR_2O}-)_n-\mathrm{SiR_2}\,(\mathrm{CH_2})_2\,\mathrm{A}\,(\mathrm{CH_2})_2-]_m- \quad ,$$



where R are various organic groups, A is an organic or organoelemental group, and $n \geq 0$;

$$\text{(b)}\quad m\,\mathrm{H}-(-\mathrm{SiR_2O}-)_n-\mathrm{SiR_2H} + m\,\mathrm{CH}{\equiv}\mathrm{CH} \xrightarrow{\text{cat.}} \rightarrow -[(-\mathrm{SiR_2O}-)_n-\mathrm{SiR_2}-\mathrm{CH_2}-\mathrm{CH_2}-]_m- \quad ,$$

where R are various organic groups and $n \geq 0$.

The possibility of synthesising linear polymeric products by the polyaddition reaction of *p*-vinylphenylmethylhydrosiloxanes having the general formula $CH_2{=}CHC_6H_4.Si(CH_3)_2-[-OSi(CH_3)_2-]_n-H$, where $n = 1-4$, has been demonstrated[56]. Polycarbaorganocyclosiloxanes have been obtained by the polyaddition of organohydrocyclotetrasiloxanes, containing vinyl and allyl groups, in the presence of H_2PtCl_6.[57,58]

The polyaddition reaction of hexamethylvinylcyclotetrasiloxane, whose polymeric products contain methylcyclotetrasiloxane units in the main chain linked by ethylene bridges, has been studied in greater detail[59]:

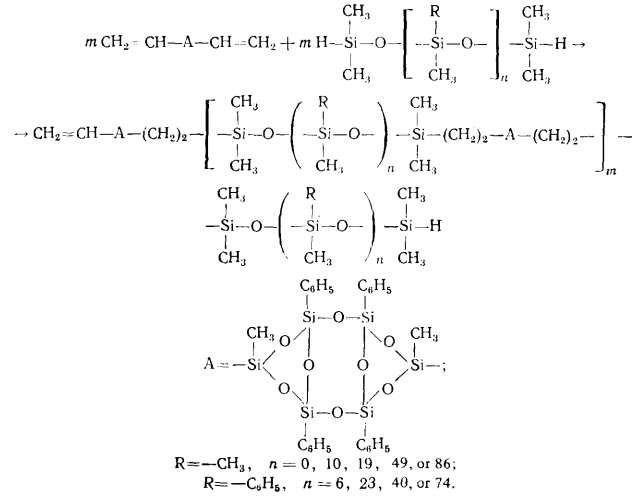
The reaction was carried out in carbon tetrachloride solution at 75°C in the presence of H_2PtCl_6. The products were viscous liquids with a molecular weight of 2200, which dissolved in benzene and other organic solvents. The infrared and ^{1}H NMR spectra of the addition products did not reveal the presence of the $\rangle$CH–CH$_3$ group, which led the authors[59] to the conclusion that the polyaddition reaction takes place with formation of β-adducts. Kinetic measurements at 50–80°C and a catalyst concentration of $(1.4-4.2)\times10^{-4}$ mole/mole showed that the reaction is described satisfactorily by a second order equation with respect to the monomer with first-order control with respect to the catalyst. It was shown that the reaction proceeds via a state involving the formation of an intermediate compound of the monomer and the catalyst.

Methods have been developed for the synthesis of polycarbaorganosiloxanes by the polyaddition of dihydroorganosiloxanes to dialkenylorganosiloxanes. This work was initiated by a study[60] of the addition of 1,3-diethyl-1,3-dimethyldisiloxane to 1,3-diethyl-1,3-dimethyl-1,3-divinyldisiloxane and to 1,3-diallyl-1,1,3,3-tetramethyldisiloxane in the presence of H_2PtCl_6. Next mention should be made of studies involving the polyaddition of α,ω-dihydrodimethylsiloxanes to α,ω-divinyl- and α,ω-diallyldimethylsiloxanes in the presence of Pt/C.[56,61] The products were linear polymers having the general formula

$$\mathrm{R(CH_3)_2Si}-\{[-\mathrm{OSi(CH_3)_2}-]_n-(\mathrm{CH_2})_m-\}_x-\mathrm{Si(CH_3)_2}-[-\mathrm{OSi(CH_3)_2}-]_n-\mathrm{R'};$$

R=R′=—CH=CH$_2$ or H, m=2, n=2, 4, 5, x=3–250;

R=R′=—CH$_2$—CH=CH$_2$ or H, m=3, n=1, 2, x=3–250.



Their molecular weights, determined cryoscopically and on the basis of the content of the end groups, were 1000 to 25 000. The polyaddition products consisted of viscous liquids or gel-like substances. Infrared spectra led to the conclusion[56,61] that these are β-polyaddition products without $\rangle$CH–CH$_3$ groups.

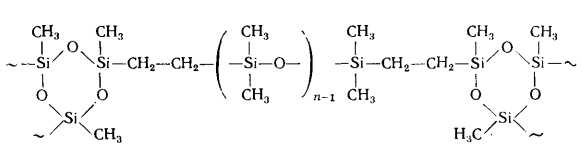
The polyaddition of linear dihydromethylsiloxanes to methyldivinylsiloxanes with terminal trimethylsiloxy-groups has been studied in the presence of the Speier catalyst[62]. Products with a molecular weight <2000, consisting of slightly viscous liquids, were obtained. Comparison of the rates of addition of $[(CH_3)_2SiH]_2O$ and $(CH_3)_3SiO-[-(CH_3)HSiO-]_2-Si(CH_3)_3$ to $(CH_3)_3SiO-[-(CH_3).(CH_2{=}CH)SiO-]_2-Si(CH_3)_3$ established that 1,1,3,3-tetramethyldisiloxane adds 100 times faster than methyldisiloxane with terminal trimethylsiloxy-groups. The difference between the rates of addition is attributed to steric hindrance. It has been shown by ^{1}H NMR that β-addition products are formed.

The polyaddition of α,ω-dihydro-organosiloxanes to α,ω-divinylorganosiloxanes with methyl, ethyl, and phenyl groups at the silicon atoms has also been studied[63]. It was established that, for both α,ω-divinylorganosiloxanes and α,ω-dihydro-organosiloxanes, the rate of reaction decreases when the methyl group is replaced by the more electronegative phenyl group. Together with electronic factors, the rate of reaction is influenced also by steric factors.

Linear polycarbadiorganosiloxanes with methylcyclotetrasiloxane fragments in the polymer chain have been obtained by the polyaddition of α,ω-dihydrodimethylsiloxanes to hexamethyldivinylcyclotetrasiloxane[64]. The polyaddition reaction was carried out in an atmosphere of argon with an equimolar ratio of the initial components at 100–110°C for 50–160 h. The catalyst was chloroplatinic acid in an amount of $(1-1.5)\times10^{-5}$ g per gramme of the initial mixture. Part of the catalyst was introduced before the start of the reaction and the rest after 25–140 h. The products were viscous colourless transparent liquids whose molecular weight increased from 75 000 to 471 000, depending on the molecular weight of the initial α,ω-dihydrodimethylsiloxane. When the addition products were heated in the presence of 0.0001–0.1% of an anionic polymerisation catalyst, the viscosity increased sharply and a gel was formed.

Polyorganosiloxanes with linear and cyclic fragments in the chain have been obtained[65] by the addition of 1,7-dimethyl-3,5,9,11-tetraphenyl-1,7-divinyltricyclohexasiloxane to α,ω-dihydrodimethyl(methylphenyl)-siloxanes in the presence of H_2PtCl_6 in THF:

Polymers with linear dimethylsiloxane and aromatic fragments in the chain have been synthesised by the addition of diallyl isophthalate to α,ω-dihydrodimethylsiloxanes[65]. It was established[65] that, with increase of



the fraction of siloxane tricyclic and aromatic fragments in the linear siloxane chain, the glass points of the polymers increase. Thermogravimetric analysis showed that the stability of the polymers in relation to thermo-oxidative degradation increases with increasing fraction of aromatic fragments in the linear dimethylsiloxane chain.

Three-dimensional polymers have been obtained by the polyaddition of tetramethylcyclotetrasiloxane to tetramethyltetravinylcyclotetrasiloxane in the presence of chloroplatinic acid[66], while polyaddition of α,ω-dihydrodimethylsiloxanes having the general formula $H(CH_3)_2SiO-[-Si(CH_3)_2O-]_n-Si(CH_3)_2H$, where $n = 0-200$, to tetramethyltetravinylcyclotetrasiloxane yielded cross-linked polycarbadiorganosiloxanes with a regular structure[67]. In the latter case the polyaddition reaction was carried out at 100–110°C in the presence of H_2PtCl_6. Depending on the ratio of the initial components, liquid or solid, infusible products, partly soluble in organic solvents, were obtained. The study of the properties of the products established that their thermo-oxidative stability decreases with increasing length of linear organosiloxane units. The authors explain[67] this phenomenon by the fact that, when the products are heated above 200°C, the rings in the polymer structure apparently open with a consequent increase in network density. This process results in an inhibition of degradation. The relatively low temperature of the onset of thermo-oxidative degradation of polymers, which is 310°C for $n = 0$ in the initial α,ω-dihydrodimethylsiloxane or 200°C for $n = 200$, is attributed to the presence of the platinum catalyst in the products.

The mechanical properties of cross-linked organosilicon polymers obtained by the polyaddition of 1,5-dihydrohexamethyltricyclosiloxane to trimethyltrivinylcyclotrisiloxane and to tetramethyltetravinylcyclotetrasiloxane have been investigated[68]. The existence of structural formations, which decompose as a result of slight deformations and under the influence of temperature, was noted.

Polymers have been synthesised by the addition of tetramethylcyclotetrasiloxane to trimethyltrivinylcyclotrisiloxane, to tetramethyltetravinylcyclotetrasiloxane, and to tetraphenyltetravinylcyclotetrasiloxane in the presence of H_2PtCl_6.[69] Thermogravimetric analysis of the products in oxidising (in air) and inert (in a stream of argon) atmospheres showed that the thermal and thermo-oxidative stabilities of the polymers, determined by the temperature of the onset of decomposition of the polymer in the course of dynamic heating, are independent of the nature of the groups surrounding the silicon atom. However, the temperature at which 10% of the weight of the polymer is lost depends on the nature of the organic groups at the silicon atom in both inert and oxidising atmospheres. For polymers with methyl groups, this temperature is higher than for polymers with phenyl groups.

The influence of the crystallisation of cross-linked polycarbadimethylsiloxanes with rings at the nodes of the network, of the type

$n = 36, 60, 150$,

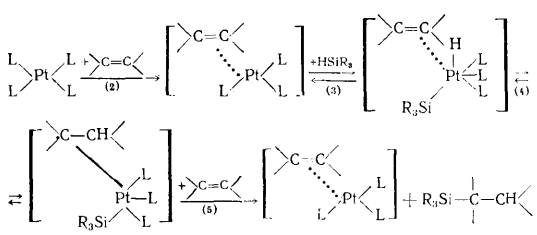
on longitudinal NMR relaxation has been investigated[70]; it was shown that, with increase of the extent of the linear dimethylsiloxane chains, i.e. in the sequence $n = 36$, 60, 150, the segmental mobility of the chains between the network nodes increases.

It follows from the foregoing that the hydride addition of organohydrosiloxanes to organoalkenylsiloxanes is widely used to synthesise a wide variety of monomers, oligomers, and polymers. The reaction is also used for the hardening of organosilicon resins, the vulcanisation of siloxane elastomers, and the synthesis of various compositions.

The preparation of cross-linked polymers by the addition of polyhydro-organosiloxanes to polyvinylorganosiloxanes has been studied[71,72] in the presence of H_2PtCl_6 and it has been established that the replacement of methyl groups by phenyl groups in the initial polyorganosiloxanes leads to a decrease of the degree of hardening of the products due to steric hindrance, which interferes with the polyaddition reaction. Compared with their polyorganosiloxane analogues, polymers with disilylethylene groups exhibit a smaller thermo-oxidative stability but a greater thermal stability under conditions which rule out the dissociation of the C–C bond as a result of oxidation, i.e. in the absence of atmospheric oxygen[71,72].

The vulcanisation of linear polyorganosiloxanes with vinylsiloxy-units in the chain has been achieved by the hydride addition reaction; various organohydrosiloxanes were then used as structure-forming agents[73]. The vulcanisation was as a rule carried out at 50–100°C, which led to the formation of disilylethylene groups, which then functioned as cross-linking units in the formation of linear diorganosiloxane macromolecules. The use of polyorganosiloxanes containing vinyl groups makes it possible to obtain polymeric coatings with an enhanced strength and flexibility[74]. Elastic compositions suitable as adhesives and current-conducting materials have been obtained on the basis of the above cross-linking agents[75] using various hydrosilylation catalysts, in the first place H_2PtCl_6 and platinum complexes[74,76].

Polyorganosiloxanes which are effective foam stabilisers for the preparation of fire resistant polyurethane foam plastics have been synthesised by hydride addition in the presence of the above catalysts[77].



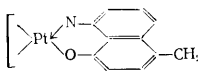
IV. THE PRINCIPAL FACTORS INFLUENCING THE COURSE OF THE HYDRIDE ADDITION REACTION

The addition of organohydrosiloxane to organovinylsiloxanes is a special case of the hydride addition reaction and obeys the general rules governing the latter. The hydride addition reaction is influenced, together with general factors (concentrations of the reactants, reaction temperature and time, the nature of the solvent, etc.), also by specific factors such as the type of catalyst used and the structure of the unsaturated and hydrogen-containing organosilicon compounds. This section deals with the effects of such specific factors.

The hydride addition reaction can be carried out in the absence of catalysts; for example, the addition of trichlorosilane to olefins at 300°C takes place without a catalyst[78,79]. Various initiators and hydride addition catalysts are used to reduce the temperature, to increase the rate of reaction, to increase the yield of addition products, and to suppress undesirable side reactions. The initiating effect of ultraviolet light, γ-radiation, various peroxy-compounds and other substances readily forming free radicals, as well as organic electron-donating compounds such as amines, amides, phosphines has been demonstrated[2,3].

Group VIII metals fixed on carriers or forming part of the composition of various compounds are effective catalysts of the hydride addition reaction. Compounds of other metals (copper, zinc, zirconium, chromium, molybdenum, etc.) are also known to exhibit a catalytic activity. The most active catalyst is chloroplatinic acid[80], which is used in the form of a solution in isopropyl alcohol (the so-called Speier catalyst). By virtue of the ease of its use and high catalytic effect, chloroplatinic acid is the most common catalyst of reactions of this type. However, its application also suffers from certain disadvantages, namely an induction period necessary for the manifestation of catalytic action, in some cases an acceleration of side reactions, and insolubility of the catalyst in many organic solvents.

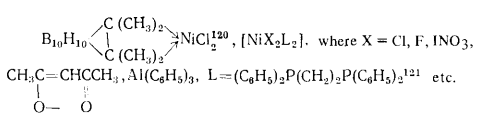
On the basis of detailed studies of hydride addition[18] and by analogy with other homogeneous-catalytic processes, a mechanism has been proposed for the hydride addition reaction catalysed by H_2PtCl_6,[81] the first stage of which involves the formation of a platinum complex $Pt(L)_4$ with replacement of chlorine atoms by hydrogen; R_3SiH is the source of hydrogen. Next the reaction proceeds in accordance with the following scheme:



where L = Cl, H, or a coordinated solvent molecule.

Thus the hydride addition reaction consists of the following stages: (1) reduction of H_2PtCl_6 by the organosilicon hydride; (2) π-coordination of the unsaturated component with simultaneous displacement of one of the ligands; (3) oxidative addition of the organosilicon hydride with formation of an unstable hexacoordinate platinum complex with inclusion in the inner sphere of hydrogen and the silyl group; (4) displacement of a hydrogen atom from platinum to the coordinated olefin and the formation of an alkyl–platinum σ bond; (5) reductive displacement of the alkylsilane via the coordination of another molecule of the unsaturated component.

The catalytic effect of Group VIII transition metal complexes has been recently examined in many studies of the hydride addition reactions. The use of complexes of various metals in different oxidation states and coordinated to a wide variety of ligands as catalysts has been described. On the basis of the mechanism proposed above, which has been extended[18] to Group VIII transition metal complexes, a distinct catalytic effect is to be expected for compounds which satisfy the following requirements: (a) unsaturated reagents can coordinate to them; (b) they activate the hydrogen-containing organosilicon reagent, i.e. they cleave the $\geq$Si–H bond and at the same time both fragments formed can be coordinated to them; (c) they are not reduced by hydrogen-containing organosilicon compounds with formation of the free metal.



The following platinum complexes can be used as catalysts of the hydrosilylation reaction: $\{[(C_6H_5)_3P]_2.Pt(C_2H_4)\}$[82] and $[(C_6H_5)_3P]_4Pt$[83–85]—i.e. compounds containing zerovalent platinum; $(alkene)_2PtCl_2$,[86–88] $[(C_6H_5)_3P]_2PtCl_2$,[89] $(CH_3CN)_2PtCl_2$ and $(C_6H_5CN)_2PtCl_2$,[90] *trans*-$[(C_2H_5)_2OSC_2]_2.PtCl_2$,[91] *cis*-$(CO)_2PtCl_2$,[92] $[(CH_3)_3Si(CH_2)_nP(C_4H_9)_2]_2PtCl_2$ with $n = 1-3$,[93] $(cyclo\text{-}C_6H_{11})_2PtCl_2$,[94] and di-iodohexamethyldipyridineplatinum[95]—i.e. compounds containing bivalent platinum; $[Pt(CH_3)_3]_2$ and $(CH_3)_3PtI$[96]—i.e. compounds containing quadrivalent platinum; the polymeric chelate complex[97]

complexes of platinum chlorides with olefins, compounds of the pyridine series, thioimides, alkylthioureas, phosphines, and nitriles[98], platinum complexes with olefins or cyclopropane[99], as well as platinum complexes stabilised by phosphines and nitriles[100].

Palladium complexes have also recently begun to be used as catalysts of the hydride addition reaction, although they are readily reduced by the hydrogen-containing compounds. The complexes $[(C_6H_5)_3P]_4Pd$,[101,102] metallic palladium, and bivalent palladium complexes with ligands such as trialkyl(aryl)phosphines[101], $Pd(PR_3)_mL_n$, where R is an aliphatic, aromatic or alicyclic group, L is another ligand or an acid residue, $m = 1-4$, and $n + m = 4$,[103] nitrile complexes of bivalent palladium halides[104,105], $(R_3P)_2PdCl_2$,[106] $[(CH_3)_3SiCH_2P.(C_4H_9)_2]_2PdCl_2$,[93] a polymeric chelate complex containing palladium[97], the complex $[PdCl(\pi\text{-}C_5H_5)_2]$,[107] and other palladium complexes also exhibit effective catalytic properties.

A catalytic activity in hydrosilylation reactions has been noted for certain nickel complexes. In particular, nickel carbonyl compounds $Ni(CO)_4$[108] and $[(\pi\text{-}C_5H_5)_2Ni(CO)]_2$,[109] phosphine complexes of nickel $(R_3P)_2NCl_2$ and $\{[C_6H_5)_3P]_2Ni(C_2H_4)\}$,[110–112] $(C_5H_5N)_2NiCl_2$, $Ni(Cp)_2$, and $\{[(C_6H_5)_3P]Ni(Cp)(C_2H_5)\}$, where Cp is the cyclopentadienyl ligand[113], $Ni(acac)_2 + Al(C_2H_5)_3$,[114–118] $Ni(COD)_2$ and the $NiCl_2$ (or $NiBr_2$) + PR_3 + sodium bis-(2-methoxyethoxy)-hydroaluminate[119], a polymeric chelate complex (whose structure is analogous to that of the chelate complex of platinum mentioned above)[97], the complexes $[(CH_3)_3Si.(CH_2)_nPR_2]_2NiX_2$, where $n = 1$ or 2, R = C_4H_9 or C_6H_5, and X = Cl or Br,[93] and

It is believed[122] that the mechanism of the addition of organohydrochlorosilanes to olefins in the presence of phosphine complexes of nickel is analogous to the mechanism of the hydrosilylation reaction in the presence of H_2PtCl_6. The hydrosilylation reaction in the presence of phosphine complexes of nickel takes place at a temperature $>90°C$ and most effectively at ~120°C.[122] It is accompanied by the exchange of hydrogen and chlorine atoms:

$$2RCH{=}CH_2 + 3R'_2SiHCl \xrightarrow{Ni^{II}} RCH_2CH_2SiR'_2Cl + RCH_2CH_2SiR'_2H + R'_2SiCl_2.$$

The exchange is faster and more extensive the more pronounced are the electro-accepting properties of the phosphorus-containing ligands. It has been found[122] that the addition takes place *cis*-stereospecifically. As in catalysis by H_2PtCl_6, the reactivities of chloromethylhydrosilanes decrease in the sequence

$$HSiCl_3 > (CH_3)\,HSiCl_2 > (CH_3)_2\,HSiCl \gg HSi\,(CH_3)_3.$$

It is of interest that the catalytic action of nickel(II) complexes is characterised by a longer induction period than the action of the zerovalent complexes. Among

cobalt complexes, the carbonyl compounds have been widely used as catalysts of the hydrosilylation reaction. These are primarily dicobalt octacarbonyl and π-cyclopentadienyldicobalt dicarbonyl[123], in the presence of which the hydrosilylation reaction sometimes takes place even at room temperature.

It has been established[124] that, in the presence of dicobalt octacarbonyl, the addition of $\geq$Si–H to olefins is directed to form β-adducts, this being accompanied by the isomerisation of the initial olefin. In view of the low thermal stability of dicobalt octacarbonyl, when the reaction is carried out at a temperature >60°C, the yield of addition product falls. It is believed[125] that the reaction includes the following stages:

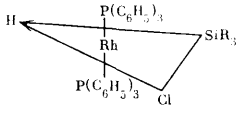
$$R_3SiH + Co_2(CO)_8 \rightarrow R_3SiCo(CO)_4 + HCo(CO)_4 ,$$

$$HCo(CO)_4 + R'CH=CH_2 \rightarrow R'CH_2CH_2Co(CO)_4 ,$$

$$R'CH_2CH_2Co(CO)_4 + R_3SiH \rightarrow R'CH_2CH_2SiR_3 + HCo(CO)_4 ,$$

$$R'CH_2CH_2Co(CO)_4 + R_3SiCo(CO)_4 \rightarrow R'CH_2CH_2SiR_3 + Co_2(CO)_8 .$$

There is also a possibility of the reactions



$$2HCo(CO)_4 \rightarrow Co_2(CO)_8 + H_2 ,$$
$$HCo(CO)_4 + R_3SiH \rightarrow R_3SiCo(CO)_4 + H_2 .$$

The latter are undesirable and so is the formation of the complex $R_3SiCo(CO)_4$, which is catalytically inactive. An excess of the unsaturated compound is necessary to suppress these undesirable reactions.

The hydrosilylation reaction has been achieved in the presence of the phosphine complexes of cobalt $[(C_6H_5)_3P]\cdot CoH_3$, $[(C_6H_5)_3P]CoH(N)$,[126] a two-component system of the Ziegler type $Co(acac)_2 + Al(C_2H_5)_3$,[115-118] etc.

Rhodium complexes are highly active as catalysts of the hydrosilylation reaction. These are primarily the phosphine complexes $[(C_6H_5)_3P]_3RhCl$ (the so-called Wilkinson catalyst),[127-129], $[(C_6H_5)_2PH]_3RhCl$,[130] $\{[(C_6H_5)_3P]_4RhH\}$,[131] $\{[Rh(1,5\text{-}C_6H_{12})Cl]_2\} + L$, where L = P(cyclo-$C_6H_{11})_3$, $P(CH_3)_2C_6H_5$, $PCH_3(C_6H_5)_2$, $P(C_6H_5)_3$, $P(OC_4H_9\text{-}n)_3$, $P(OC_6H_5)_3$, or $(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2$,[132] $\{L_2RhH[Si(OC_2H_5)_3]Cl\}$, where L = $(C_6H_5)_3P$, $(p\text{-}CH_3C_6H_4)\cdot(C_6H_5)_2P$, C_6H_5 (cyclo-$C_6H_{11})_2P$, or $(C_6H_5)_2$(cyclo-$C_6H_{11})P$,[133] the carbonyl complexes $[(CO)_4Rh_2Cl_2]$,[125] $\{[(C_6H_5)_3P]_2\cdot Rh(CO)Cl\}$, and $\{[(C_6H_5)_3P]_3RhH(CO)\}$,[85,125,132] the olefin complex $[(C_2H_4)_2Rh_2Cl_2]$, a polymeric chelate complex containing rhodium[97], and others.

The same mechanism, in principle, has been proposed for the hydrosilylation reaction in the presence of rhodium complexes as in the presence of H_2PtCl_6.[18] The pentacoordinate rhodium complex[127]

is believed to be catalytically active[127]. This complex is formed as a result of the reaction

$$[(C_6H_5)_3P]_3RhCl + R_3SiH \rightleftarrows [(C_6H_5)_3P]_2Rh(SiR_3)HCl + (C_6H_5)_3P.$$

Its stability under the conditions obtaining in the reactions of chloroethylhydrosilanes depends on the nature of the groups SiR_3 and decreases in the sequence

$$-Si(C_2H_5)_3 < -SiCl(C_2H_5)_2 < -SiCl_2(C_2H_5) < -SiCl_3.$$

Among other transition metal complexes proposed as catalysts of the hydrosilylation reaction, mention should be made of iron carbonyls[135], a two-component catalyst of the Ziegler–Natta type $Fe(acac)_2 + Al(C_2H_5)_3$,[115] manganese[136,137], ruthenium[138], and iridium[127] complexes, and $Co(CO)_6$ (the last complex is used in combination with ultraviolet irradiation)[139].

Together with the homogeneous catalysts indicated above, which are used in the form of solutions, catalysts based on transition metals bound to carriers have been developed recently. These forms of catalysts are interesting because they combine the advantages of homogeneous and heterogeneous catalysts, namely high catalytic activity, the possibility of the repeated use of the catalyst, and applicability to continuous processes. Thus the preparation of phosphine complexes of rhodium chemically bound to organic polymeric materials, for example, on a butadiene–styrene copolymer, and their application in hydrosilylation reactions have been described[140]. The catalyst $[Rh(CO)_2Cl]_2$ deposited on a modified styrene–divinylbenzene copolymer has also been proposed[141]. Alumina, glass, molecular sieves, silica, and other materials are also employed as catalyst carriers[140,142].

Platinised ion-exchange resins can be used as catalysts of the hydrosilylation reaction[143,144].

The catalytic activities of various platinum, rhodium, palladium, nickel, and cobalt compounds in reactions involving the addition of pentamethyldisiloxane to methylvinylsiloxanes with linear and cyclic structures have been investigated[5,145]. The palladium and nickel compounds hardly catalyse the above reactions, while the platinum and rhodium compounds exhibit a high catalytic activity. It was noted that the rhodium compounds ensure a greater β-selectivity of the addition process. Dicobalt octacarbonyl exhibits a high catalytic activity at higher concentrations.

The structure of unsaturated and hydrogen-containing organosilicon compounds exerts an appreciable influence on the rate and direction of the hydrosilylation reaction. The relative rate constants for the addition of trichlorosilane to various unsaturated compounds have been determined by the method of competition kinetics[146]. It was established that the reactivity of the unsaturated compounds depends mainly on the electron density at the double bond and sometimes on steric factors. The reactivities of the test compounds in the reaction under consideration decrease in the sequence hept-1-ene > *cis*-hept-2-ene > allylbenzene > t-butylethylene > dec-1-ene > styrene > allyl chloride > cyclohexene.

The reactivity of unsaturated compounds in relation to alkylhydrocyclosiloxanes decreases in the sequence[147] styrene > α-methylstyrene > methyl methacrylate > allyl cyanide. The decrease is correlated with the decrease of the electron density of the double bond. α-Methylstyrene, where the influence of steric factors is significant, constitutes an exception.

The rate of hydrosilylation of halogeno-olefins decreases in the following sequence in the presence of H_2PtCl_6:[148]

$$CH_2=CH_2 > CH_2=CF_2 > CF_2=CFCl > CF_2=CF_2.$$

Attack by the olefin on the $\geq$Si–H bond is easier the greater the electron density in the double bond[149]. Hydrogenation of the unsaturated component is facilitated simultaneously.

The reactivity of methylvinylsiloxanes having the general formula $(CH_2=CH)(CH_3)_{3-n}Si[OSi(CH_3)_3]_n$ decreases with increase of the number of trimethylsiloxy-groups (n was varied from 3 to 1) when sulphur compounds are added to them in the presence of H_2PtCl_6.[18]

The reactivity of methylvinylsiloxanes having the general formula $(CH_3)_{3-n}(CH_2{=}CH)Si[OSi(CH_3)_3]_n$, where $n = 0-3$, in relation to pentamethyldisiloxane in the presence of tris(triphenylphosphine)rhodium chloride has been investigated by the method of competition kinetics[53]. It was established that, with increase of the number of trimethylsiloxy-groups in methylvinylsiloxanes, the reactivity of the latter decreases in the sequence[53]

$$(CH_3)_3(CH_2{=}CH)Si > (CH_3)_2(CH_2{=}CH)SiOSi(CH_3)_3 > CH_3(CH_2{=}CH)Si[OSi(CH_3)_3]_2 > CH_2{=}CHSi[OSi(CH_3)_3]_3.$$

The influence of substituents at the silicon atom bound to the vinyl group on the reactivity of linear α,ω-divinyldiorganosiloxanes in the addition reactions of α,ω-dihydrodiorganosiloxanes has been investigated[63]. The observed rate constants for the addition reaction show that the replacement of the methyl group by the more electronegative phenyl group reduces the reactivity of vinylorganosiloxanes. The steric influence of the phenyl groups has also been noted in isolated instances.

Thus the reactivity of unsaturated compounds is higher the greater the electron density in the double bond. Naturally, in the presence of steric hindrance due to bulky substituents, the reactivity of unsaturated compounds can decrease.

The reactivity of hydrogen-containing organosilicon compounds in reactions involving addition to unsaturated compounds also depends on structural factors. Thus the reactivity of chloroethylhydrosilanes in reactions involving addition to hept-1-ene in the presence of H_2PtCl_6 increases in the following sequence[150]:

$$(C_2H_5)_3SiH < (C_2H_5)_2SiHCl < C_2H_5SiHCl_2 < HSiCl_3.$$

The observed increase of the reactivity of chloroethylhydrosilanes is due to the decrease of the electron density in the $\rangle Si-H$ bond when ethyl groups are replaced by the electronegative chlorine atoms. A similar behaviour has been observed in the study of the addition of chloroethylhydrosilanes to hept-1-ene in the presence of dicobalt octacarbonyl[151].

In the addition of hydrogen-containing organosilicon compounds to diethyl allylmalonate in the presence of H_2PtCl_6 the amount of adduct formed increases with increase of the number of electronegative substituents at the silicon atom[152]:

$$R_3SiH < R_2SiHCl < RSiHCl_2 < HSiCl_3;$$
$$R_3SiH < R_2SiH(OR') < RSiH(OR')_2 < HSi(OR')_3.$$

The reactivity of organochlorosilanes in relation to acrylonitrile decreases in the sequence[153]

$$HSiCl_3 > (C_6H_5)HSiCl_2 > (CH_3)HSiCl_2 > (C_6H_5)_2HSiCl > (C_6H_5)(CH_3)SiHCl \gg (CH_3)_2HSiCl.$$

Comparison of the relative rate constants for the addition of ethoxypropylhydrosilanes $(C_3H_7)_nHSi(OC_2H_5)_{3-n}$ to hex-1-ene in the presence of tris-(triphenylphosphine)-rhodium chloride and dicobalt octacarbonyl (determined by the method of competition kinetics) shows that the observed increase of the reactivity of ethoxypropylhydrosilanes with increasing content of ethoxy-groups takes place in the following sequence: tripropylsilane < ethoxydipropylsilane < diethoxypropylsilane < triethoxysilane[151].

There are relatively few data concerning the influence of the structure of organohydrosiloxanes on their reactivity in reactions involving addition to unsaturated compounds. The study of the kinetics of the addition of 1,1,3,3-tetramethyldisiloxane and octamethyl-3,5-dihydrotetrasiloxane to heptamethyl-3-vinyltrisiloxane showed that the introduction of the trimethylsiloxy-group into methylhydrosiloxanes hinders the reaction appreciably[62].

The reactivity of methylhydrosiloxanes having the general formula $(CH_3)_{3-n}HSi[OSi(CH_3)_3]_n$, where $n = 1-3$, in the reaction involving addition to hex-1-ene and heptamethylvinylcyclotetrasiloxane in the presence of H_2PtCl_6 is determined predominantly by steric factors[51,145]. The methylhydrosiloxanes investigated can be arranged in the following sequence in terms of the decrease of their reactivity in the above hydride addition reactions:

$$(CH_3)_2HSiOSi(CH_3)_3 > (CH_3)HSi[OSi(CH_3)_3]_2 > HSi[OSi(CH_3)_3]_3.$$

It has been established by the method of competition kinetics[52] that the reactivities of dimethyl-α,ω-dihydrosiloxanes having the general formula $H-Si(CH_3)_2O-.[-Si(CH_3)_2O-]_n-Si(CH_3)_2-H$, where $n = 0-3$, in reactions involving addition to hept-1-ene in the presence of tris-(triphenylphosphine)rhodium chloride decrease with increase of molecular weight. This can be accounted for by the decrease of molecular mobility and probably by differences in the stability of the intermediate compound involving the catalyst.

It has also been shown[52] that the replacement of the methyl group in dimethyl-α,ω-dihydrosiloxanes by the electronegative phenyl group does not increase the reactivity in reactions involving addition to methylvinylsiloxanes. The reactivity actually decreases owing to steric hindrance.

Thus the reactivity of hydrogen-containing organosilicon compounds in reactions involving addition to unsaturated compounds is determined by steric and electronic factors. In particular, the introduction of electronegative groups and the associated increase of the positive charge on the silicon atom promote the dissociation of the hydrogen atom as a proton. This is manifested by an increase of the reactivity of hydrogen-containing organosilicon compounds.

---o0o---

The data reviewed show that there have been many studies on the hydrosilylation of unsaturated organic compounds and on the hydride addition of organohydrosiloxanes to organosilicon compounds containing multiple carbon–carbon bonds. It has been established that the hydrosilylation reaction is important for the synthesis of a wide variety of organosilicon compounds. Hydride addition constitutes a convenient method for the synthesis of high-molecular-weight compounds and gives rise to extensive possibilities for their modification in order to convert them into systems with three-dimensional and cross-linked structures.

The Conformation of γ-Aminobutyric Acid and Its Analogues

I.A.Sytinskii and A.T.Soldatenkov

Theoretical and experimental data on the steric structure of γ-aminobutyric acid and its analogues are presented. The possible relation between the structural flexibility of the γ-aminobutyric acid molecule and its biological activity is examined. The bibliography includes 90 references.

I. INTRODUCTION

γ-Aminobutyric acid (GABA) was obtained for the first time in 1883.[1] In the middle of the present century it was detected in the nerve tissues of the central nervous system (CNS) of mammals. It has recently come to be realised that GABA is one of the most important natural products from the biological point of view. It is a specific chemical mediator (transferring agent) in the inhibition of nerve pulses in CNS.[2-6] Recently (since 1960) GABA and its derivatives have begun to be used as medicinal preparations in the treatment of nervous and psychiatric conditions[7]. The successful use of GABA and its derivatives in the treatment of various neurotic and psychopathic states led to the possibility of synthesising new synthetic drugs with selective action and with a low toxicity by virtue of their similarity to the metabolic products in the brain. In this connection the problem of the influence of the steric structure of GABA on its biological and pharmacological activity assumes considerable importance. Like many substances with pharmacological activity, GABA has a non-planar structure. Conformational changes in the GABA molecule can lead to its incomplete interaction with its receptor. Probably only a specific conformation of the GABA molecule ensures the optimum disposition of its structural elements relative to the receptor, necessary for the manifestation of the maximum physiological activity. Probably not only the conformation but also the electronic properties of the molecules play a significant role in the pharmacological properties of GABA and its derivatives. Numerous studies, published during the last five years, have been devoted to the relation and between these properties and their mutual influence and to the determination of the active conformations of GABA and its analogues. Both theoretical and experimental methods are widely used in the solution of these problems.

II. THE STERIC STRUCTURE OF γ-AMINOBUTYRIC ACID AND ITS ANALOGUES

1. Quantum-Chemical Modelling of the GABA Molecule

Quantum mechanics permits an approximate calculation of the energy of molecules in terms of the molecular orbital theory by solving the Schrödinger wave equation. Since all the valence electrons can be taken into account in such calculations, the total energy of the molecule becomes sensitive to changes in its conformation. Minimisation of the total energy as a function of specified angles between bonds in the molecule makes it possible to predict its preferred energetically most favourable conformation. Quantum-chemical calculations also permit the determination of the electronic structures of the conformers from the corresponding wave functions, to predict the chemical behaviour of the molecule, to derive parameters associated with the reactivity of a biologically active molecule, etc.

a *b*

Figure 1. The skeleton of the GABA molecule: *a*) extended structure; *b*) folded structure.

Several semiempirical molecular orbital methods have been used to determine the preferred conformation of GABA.[8-10] The latter was first determined theoretically in 1970;[11] the authors carried out a calculation on this molecule with the aid of the extended Hückel method (EHM).[12] The method takes into account the interactions not only between atoms linked to one another but also between remote atoms, so that the total energy of the molecule is evaluated as a function of the coordinates of all the atoms in the molecule. The calculation showed that in the preferred conformation of GABA the 'onium and α-methylene groups are in the transoid positions and the carboxy-group can rotate freely by 360° (Fig. 1*a*). The GABA molecule is represented as a zwitterion with a distance between the charge centres (N^+ and O^-) of 5.0–6.0 Å, which corresponds to an extended (unfolded) conformation of GABA. However, one should bear in mind that the mutual repulsion of electrons is not taken into account in

EHM, so that the results can sometimes conflict with data derived by other methods, particularly for polar molecules [13].

A more exact quantum-chemical theory—the method of complete neglect of differential overlap (CNDO)—was developed by Pople [14,15]. Calculation for the GABA molecule by this method [10] led to the opposite results—a folded conformation (Fig. 1*b*) is preferred for the isolated GABA molecule in both neutral and zwitterionic forms, which is consistent with data obtained by ^1H nuclear magnetic resonance [16,17]. It has been noted [10] that the influence of the solvent can induce conformational changes and calculations have indeed demonstrated that in the presence of a solvent the extended conformation becomes preferred. However, Pople's theory also suffers from definite limitations [13]. Thus a satisfactory description of the charge distribution is obtained in most cases only for mobile π electrons, the polarisation of single σ bonds being neglected, although the latter may be important for polar molecules, i.e. for the majority of pharmacologically active compounds.

*"+" or "–" implies that the given conformation is (or is not) preferred; the distance between N^+ and O^- in Å is indicated in brackets.
**Both conformations are equally probable.

The third quantum-chemical approach to the determination of the GABA conformation employs the method of localised molecular orbitals (LMO), which takes into account configurational and electronic interactions. This method is believed [9,18] to be the most accurate for calculations on highly polarised molecules. The theoretical search for the energetically favourable GABA conformation by the LMO method showed [9] that the folded conformation of the zwitterion is the most stable. The minimum total energy of the extended conformation of an isolated flexible GABA molecule exceeds by 54 kcal mole^{-1} the energy of the folded conformation, which is apparently favoured by the mutual approach of the ionic ends of the molecule in the folded form. The folded conformation is also preferable for the cationic form of GABA (as the hydrogen chloride), although in this case the energy of the extended conformation is higher by only 5 kcal mole^{-1}. Inspection of Dreiding steric models also made it possible to postulate the existence of a folded conformation of the GABA zwitterion with an angle of 40° between the C–N bond and the plane in which the three atoms of the carboxylate group are located, which indicated some interaction between the NH_3^+ and COO^- groups [19].

Conformational analysis of GABA with the aid of X-ray diffraction confirmed that its molecule is fairly flexible and can exist in different conformations [20–24]. In the solid phase GABA forms prismatic crystals with a melting point of 203°C and exists in the zwitterionic form [20–23]. X-Ray diffraction showed that the GABA molecule is to some extent folded with a distance between charge centres of 4.2–5.75 Å [22,23] and that a hydrogen bond with a length of 2.7–3.1 Å can be formed with a deviation from linearity in the N–H...O linkages not greater than by 25°. Nor can one rule out the possibility of the "forking" of the hydrogen bond between adjacent molecules, which is consistent with the melting point [19,22]. The COO^- group is located in the plane passing through the chain of carbon atoms [21,22]. The orientation of this group changes (it becomes almost perpendicular to the given plane) in copper di-γ-aminobutyrate [23]. In the crystalline hydrochloride GABA exists in the cationic form $HOOC(CH_2)_3NH_3^+$. [24] In these crystals the cationic group is always relative to the CH_2COO^- group, while the conformation relative to the $C_{(2)}-C_{(3)}$ bond is either skewed or transoid. Thus both fully extended and partly folded GABA conformations may be found to be preferred in the crystalline state. The zwitterion apparently tends to stabilise the extended conformation, since the oppositely charged atoms of the neighbouring molecules can be located closer to one another than the similar atoms of the same molecule [22].

2. The Conformation of GABA and Its Structural Analogues

Quantum-chemical modelling and X-ray diffraction analysis of GABA make it possible to investigate its static steric structure. However, static stereochemistry does not provide a final answer to the question concerning the conformation of the molecule at the instant when it exhibits its pharmacological activity. Methods for the direct determination of the steric structures of medicinal drugs when the latter act on biological objects have not so far been adequately developed. An indirect approach, which consists in the search for, synthesis, and biological tests of various conformationally constrained analogues of GABA, is therefore extremely fruitful in the solution of stereochemical problems.

Fig. 2 and the Table presents certain fundamental structural GABA analogues exhibiting a GABA-like biological activity. The first of the structural GABA analogues investigated was the natural product muscimol (Fig. 2*b*), which is 5-aminomethyl-3-hydroxyisoxazole, isolated from the fungus *Amanita muscaria* [25]. Johnston et al. [26] suggested that muscimol is an analogue of the fixed extended GABA conformation. Subsequently, in the course of biological tests of this compound, it was found

that, like GABA, it has an inhibiting effect on the central and peripheral neurons [27,28], i.e. it is an agonist of GABA and not its antagonist. The structural analogy between GABA and muscimol is also confirmed by the fact that the latter's bicyclic derivative 4,5,6,7-tetrahydroisoxazolo-[4,5-*c*]pyridine-3-ol proved to be a competitive inhibitor of the absorption of GABA by rat brain sections [29]. In conformity with Dreiding models, the distance between the nitrogen of the tetrahydropyridine ring and the oxygen of the hydroxy-group proved to be 4.4 Å. [30]

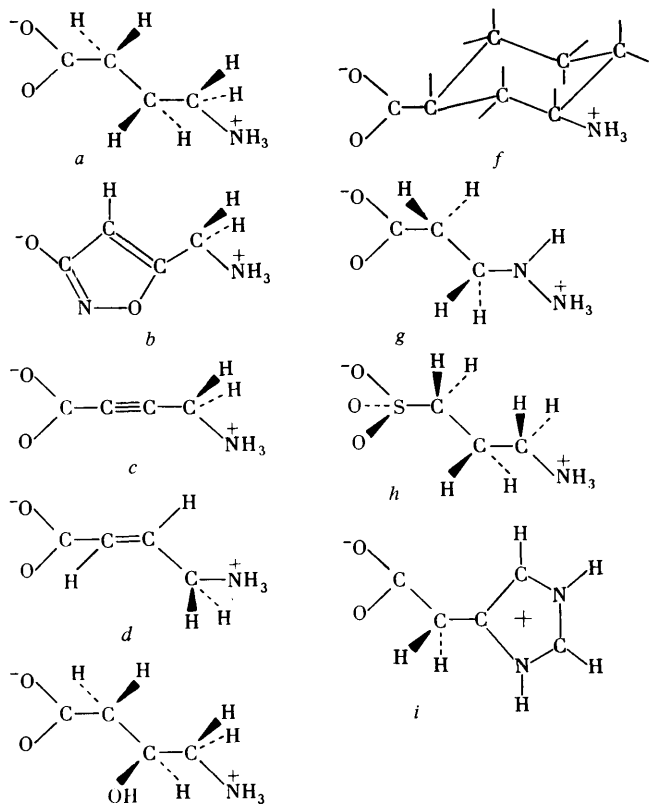

Figure 2. Structural formulae of GABA and some of its agonists: *a*) GABA; *b*) muscimol; *c*) 4-aminotetrolic acid; *d*) 4-amino-*trans*-crotonic acid; *e*) β-hydroxy-GABA; *f*) *cis*-3-aminocyclohexanecarboxylic acid; *g*) hydrazinopropionic acid; *h*) homotaurine; *i*) imidazolylacetic acid.

Theoretical calculations [11] showed that muscimol can assume a conformation analogous to that of GABA, the conformation in which the side chain is coplanar with the five-membered ring and is rotated in the direction of the endocyclic oxygen atom having the minimum total energy. The charged exocyclic oxygen atom is located at a distance of 5.8 Å from the positively charged nitrogen atom. These data suggest, on the one hand, a fully extended chain of carbon atoms in GABA, and, on the other hand, agree with the presence in muscimol of the postulated pharmacophoric GABA group [11]. Steric models showed that the nitrogen atom and the carboxy-group of GABA are isosteric with the exocyclic nitrogen atom and the O–C=N group in the muscimol ring [30]. Such correspondence between the molecular structures of these substances is observed for the extended GABA conformation. X-Ray diffraction studies also indicate the presence of elements of structural analogy between GABA [21] and muscimol [32]. In the crystal state of the latter the side chain is indeed bent in the direction of the oxygen ring atom and makes an angle of 60° with the plane of the ring [32]. The distance between the charged centres in muscimol is then 5.77 Å, which corresponds to the theoretical data [11] for the extended conformation of GABA.

Johnston et al. [30] investigated the relation between the structures of a number of miscimol derivatives and their GABA-like biological activity. An increase in the length of the muscimol side chain by one CH_2 group or substitution of an aliphatic hydrogen atom by the CH_3 group leads to an appreciable lowering of its depressant effect on nerve structures. The substitution of aromatic hydrogen atoms by alkyl groups in muscimol and some of its derivatives led to a sharp decrease of the depressant activity. The authors therefore suggest that the methylidyne group in the 4-position of muscimol is isosteric with the α-methylene group of GABA. The introduction of alkyl groups in the 4-position in the isoxazole ring leads to an increase of its structural rigidity which probably hinders the interaction of substituted muscimol derivatives with the postsynaptic GABA receptors. The study of the biological activities of many muscimol analogues enabled the authors [30] to suggest that different conformers are involved in the absorption of GABA by nerve structures and in its interaction with postsynaptic receptors.

The problem of the preferred GABA conformation was also studied with the aid of its conformationally constrained analogue 4-aminotetrolic acid (4-ATA). [33] In this compound the linearity of the triple bond fixes the positions of the four carbon atoms in such a way that the charged N^+ and O^- centres of the zwitterionic form are located at a distance of 5.2–5.8 Å from one another. The rigid 4-ATA molecule cannot assume a folded conformation and its structure corresponds to the extended GABA conformer. In the study of the action of 4-ATA on the spinal neurons of the cat [34] it was observed that it exhibits between one-half and one-fifth of the activity of GABA on these receptors. Other facts confirming the physiological activity of this compound were also obtained. The GABA-like activity of 4-ATA suggests that GABA exhibits its biological activity in the extended conformation and that the 4-ATA structure apparently includes a GABA-like pharmacophore [11]. This hypothesis received additional experimental confirmation after Johnston et al. [35] synthesised and tested on the same biological objects *cis*- and *trans*-aminocrotonic acids, which are relatively rigid structural analogues of GABA with folded and extended conformations respectively. The *cis*-isomer did not exhibit biological activity, while the *trans*-isomer, which simulates the extended GABA conformer, acted on the central nervous system of mammals just as effectively as GABA. X-Ray diffraction showed that the structure of *trans*-4-aminocrotonic hydrochloride exhibits a definite similarity to that of GABA hydrochloride [20].

The study of other sterically restricted analogues of GABA (see Table) showed [36] that only compounds which simulate the extended GABA conformation and in which the distance between N^+ and O^- differs insignificantly from the corresponding distance in GABA exhibit physiological

activity. Thus, in the series of aminocyclohexanecarboxylic acids, only *cis*-3-aminocyclohexanecarboxylic acid (but not the *trans*-isomer) exhibited a GABA-like activity [36]. The distance between the charges is identical with that in the extended GABA conformation only in the diequatorial conformer.

In the series of piperidinecarboxylic acids, nipecotinic acid (piperidine-3-carboxylic acid), which functions as a strong non-competitive inhibitor of the absorption of GABA by brain sections, is of interest [30]. It possesses conformational rigidity, which can be used in the study of "active" conformations of GABA. In aqueous solution and in the solid state nipecotinic acid exists in the "chair" conformation with the carboxy-group in the equatorial position [30]. The distance between N^+ and O^- in this form of the acid is 4.24–4.76 Å according to NMR and X-ray diffraction data [30].

The discovery of this new inhibitor of the absorption of GABA extended the range of GABA-like compounds. It was found that a series of betel nut (*Areca catechu* L.) alkaloids (arecoline, arecaidine, etc.) combined with nipecotinic acid enhanced the inhibiting effect of GABA on the bioelectrical activity of nerve cells [37].

Kier et al. [38] carried out theoretical calculations on hydrazineopropionic, imidazolylacetic, and 3-aminopropanesulphonic (homotaurine) acids and taurine (Fig. 2 and Table) in order to determine the preferred conformation and the structural elements of similarity with GABA. It has been shown recently [39-43] that these compounds can simulate the specific biological activity of GABA. The results of the calculations [36] demonstrated that the extended conformation is preferred for all the compounds in the zwitterionic form; with the exception of taurine, the extended conformation includes analogous groups, separated from the oxygen atom by an average distance of 5.8 ± 0.2 Å, which are believed [11] to be responsible for the pharmacological activity of GABA. In taurine, where the *gauche*-conformation is energetically more favourable, this distance is somewhat shorter (on average about 5.0 Å). X-Ray diffraction confirmed the existence of the extended conformation in crystalline homotaurine with an analogous N^+-O^- distance [44]. Experimental data for taurine [45] also agree with theoretical calculations [38].

Measurement of the dipole moments of α-, β-, γ-, and ω-aminoacids (up to C_{11}) showed [46,47] that in solution these acids assume mainly the fully extended conformation. Nevertheless, quantum-chemical calculations predict [9,10] that this is not the only possible conformation and there is an extremely high probability that the pharmacological activity is due to the existence of several conformations [48,49]. Indeed, it has been found that in aqueous solutions at pH 7.0 GABA consists of a mixture of both conformers [36,50]. However, it has been suggested [50] that the physiological activity of GABA is associated with the fully extended conformation of its molecule.

Interesting results were obtained [51] in the calculation of the preferred conformation of β-hydroxy-γ-aminobutyric acid (BHGABA), which is an agonist of GABA. [52] Two energetically equally favourable BHGABA conformations have been determined by the extended Hückel method. The first is characterised by an angle of 180° (along the $C_\alpha - C_\beta$ bond), free rotation of the carboxy-group, and a distance of 5.0–6.0 Å between the 'onium group and the oxygen atoms of the carboxy-group. This transoid conformation is consistent with the extended GABA structure predicted theoretically in an earlier investigated [11] and with experimental crystallographic studies [20,21]. An angle of 300° ($C_\alpha - C_\beta$ bond) with a close proximity between hydroxy- and carboxy-groups (apparently by virtue of hydrogen bonding) and with a fixed position of the carboxy-group (an $O=C=C_\alpha$ angle of 120°) is characteristic of the second conformation of BHGABA (the *gauche*-conformation), which corresponds to the folded form of the molecule in crystalline GABA. [19]

Steward and Clarke [53] attempted to establish the relation between the structures of twelve GABA agonists [26,33,53-56] and their activities. Using classical calculations of the potential energy, they determined the probability of the existence of a conformer with minimum energy. Their results are "qualitatively analogous" to data obtained in an NMR study [17] on γ-aminobutyric acid and a number of its agonists. The internuclear distances in various conformational states of the agonists were calculated with the aid of molecular models. The authors [53] took into account the fact that, according to quantum-chemical calculations [57], the charges on the zwitterions are apparently mainly concentrated on the hydrogen atom of the protonated basic group and on the oxygen atoms of the acid groups. On the basis of their calculations, Steward and Clarke [53] concluded that the greatest activity is shown by agonists [22,32,57,58] in which the distance between the zwitterionic charges is approximately 5.4 ± 0.4 Å (see Table). These data support the view that the biological activity of the GABA molecule is associated with its extended conformer.

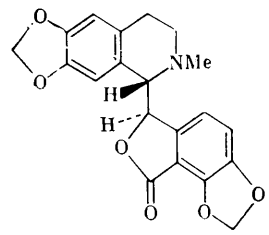

Figure 3. The structural formula of the alkaloid bicuculline.

3. The Conformation of the Alkaloid Bicuculline—a GABA Antagonist

A considerable amount of attention has been devoted recently to the study of the structural characteristics of GABA inhibitors in order to determine the similarity of the agonists and to identify the pharmacophoric group in GABA. The structure of bicuculline—a plant alkaloid of the phthalide–isoquinoline series isolated from *Coridalis species* (Fig. 3), is of greatest interest. Curtis et al. [31] were the first to show that, among the series of alkaloids with convulsant activity which they tested, containing the isoquinoline structure and potentially capable of combining with GABA receptors, bicuculline is the most specific antagonist of the depressant activity of GABA; the antagonism is probably due to the competition for the same receptors on the postsynaptic membrane. The discovery of a selective GABA antagonist stimulated theoretical and experimental studies designed to determine the structural analogy between GABA and its receptor. Attempts were made [19,35] to account for the antagonistic properties of bicuculline in relation to GABA by their stereochemical correspondence, i.e. by the fact that part of the alkaloid

molecule must be isosteric with the biologically active conformation of GABA and certain conformationally constrained GABA analogues [35,60]. This enables the bicuculline molecules to compete with GABA for a proportion of its receptors. Examination of the molecular models of the two compounds showed that the extended (i.e. fully transoid) GABA molecule, containing at its end the nitrogen atom and the carboxylate group O=C−O, can be exactly isosteric with the section of the bicuculline molecule with the nitrogen atom and the O=C−C group [31,35]. The structure of the partly folded GABA conformation is more isosteric with the section of the bicuculline molecule containing the nitrogen atom and the lactone group O=C−O.[19] Subsequent experimental and theoretical studies [61-63] confirmed the correspondence between the steric structures of these sections of the molecules of the two substances and demonstrated the similarity of the charge distribution among the atoms in these groups.

In all probability the early molecular models of bicuculline [19,34] were based on an incorrect configuration of the alkaloid [11] and merely represented its diastereoisomer with a pseudoaxial (and not pseudoequatorial) disposition of the CH_3 group at the nitrogen atom of the piperidine ring [62-64]. However, this should not be reflected in the determination of the isosteric groups of GABA and bicuculline [62]. The absolute configuration of crystalline bicuculline was determined by the analysis of the anomalous dispersion of X-rays [61,65]. Fig. 4*a* illustrates the absolute steric structure of the bicuculline molecule in the crystalline state [61]. The relative configurations of the asymmetric carbon atoms in the molecule are of greatest interest. Fig. 4*b* illustrates schematically the central part of the bicuculline molecule, which is usually compared with the GABA molecule. It has been established that in this conformation of crystalline bicuculline the $N_{(6)}$ and $O_{(3)}$ atoms are antiperiplanar (almost *trans*-) in relation to the $C_{(4)}-C_{(5)}$ bond. The fully extended form of GABA requires only a slight constraint in order to correspond to the bicuculline conformation in the crystalline state. The carboxy-group of GABA is isosteric with the group of $O_{(1)}$, $C_{(2)}$, and $C_{(26)}$ atoms of bicuculline. The conformation of bicuculline corresponding to the extended form of GABA is consistent with data obtained in a study [23] of the steric structure of one of the crystalline forms of the copper(II) complex of GABA.

However, bicuculline hydrochloride and methochloride, which are also biologically active [60], can have other conformations, different from the extended conformation of crystalline bicuculline. Fig. 4*a* shows that the introduction of a proton or a methyl group at the $N_{(6)}$ atom of the alkaloid causes an appreciable steric hindrance between $H_{(19)}$ and $N_{(6)}$, which are separated by a maximum distance of 2.86 Å in the free state. This can lead in its turn to the rotation of the aromatic groups about the $C_{(4)}-C_{(5)}$ bond and to a change in the conformation of the GABA-like fragment of the bicuculline molecule. EHM [51] and LMO [65] calculations as well as ^{1}H NMR data for the protonated form of the alkaloid and its methochloride in aqueous solutions [50,66] were used to determine the preferred conformation of bicuculline. Protonated bicuculline was found to have a preferred conformation with the proton in the *cis*-position relative to the lactone ring [50]. The lowest energy level was observed for the *cis*-position with a dihedral angle between the aromatic rings of approximately 90°. In this conformation the distance between the 'onium group and the carbonyl oxygen is 5.6 Å, which indicates the presence in bicuculline of the structural features and dimensions corresponding to the extended conformation of GABA. Andrews and Johnston's data [66] do not conflict with this hypothesis and show that rotation about the $C_{(4)}-C_{(5)}$ bond is possible (Fig. 4*a*) in the range from −70° to −110°† and that preferred rotational conformers should therefore exist. It was then noted that the free alkaloid in solution can have a conformation different to that of bicuculline salts. Within the limits of the angular rotation indicated, there is a possibility of the attainment of an isosteric correspondence between a fragment of the alkaloid, on the one hand, and the structure of GABA and a number of its agonists (in which there is some variation of the distances between N^+ and O^-), on the other. The N-containing ring of the protonated alkaloid has a preferred "half-chair" conformation with a pseudoaxial disposition of the phthalide ring.

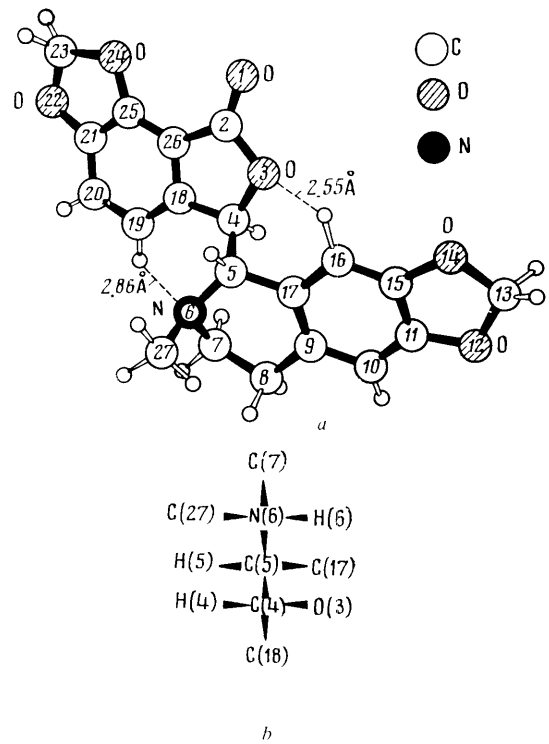

Figure 4. The configuration of bicuculline in the crystal: *a*) absolute configuration; *b*) relative configuration of the asymmetric atoms of the protonated molecule (the numbering of the atoms is in accordance with Gilardi's paper [61]).

The distribution of the charges on the atoms in three-dimensions has a definite importance for the determination of the preferred conformations of bicuculline, for distinguishing GABA agonists and antagonists, and for the elucidation of the mechanism of the interaction of GABA with its receptor. Fig. 5 illustrates the molecular skeletons of GABA (extended conformation) and protonated

† The torsional angle is positive if $N_{(6)}-C_{(5)}$ rotates clockwise about $C_{(4)}-C_{(5)}$.

bicuculline with calculated atomic charges[67]. Calculations have shown[67] that the $O_{(10)}-C_{(11)}=O_{(12)}$ group (Fig. 5*a*) exhibits a greater similarity to the carboxylate group of the GABA zwitterion than does the $C_{(2')}-C_{(11)}=O_{(12)}$ group, the negatively charged atoms of the lactone group of bicuculline (Fig. 5*a*) having smaller charges than the atoms of the GABA carboxylate group (in its partly coiled conformer the charges change insignificantly).

The part of the bicuculline molecule isosteric with GABA contains two asymmetric centres, which corresponds to the possibility of the existence of four optical isomers. Since earlier studies[31,34] were performed on (+)-bicuculline only (Fig. 3), Collins and Hill[68] synthesised by the method of Teitel et al.[69] the methochloride of its (−)-isomer (Fig. 6*a*), which is rarely encountered in nature[70], and tested its biological activity. The results of the tests showed that only the (+)-form of bicuculline methochloride‡ exhibits an antagonistic effect on both the depressant properties of GABA and on its presynaptic inhibition. Furthermore, the (+)-isomer is a stronger convulsant than the (−)-isomer (approximately by a factor of 400). Evidently the conformation of the (+)-isomer is more isosteric with the preferred biologically active conformation of GABA than that of the (−)-isomer.

(+)-Bicuculline has the 1*S*,9*R*-configuration [its (−)-form has the 1*R*,9*S*-configuration[64,73]] and one can probably expect that only analogues with a similar configuration at the asymmetric centres will exhibit a physiological GABA inhibiting activity. The study of the structural and functional analogues of bicuculline will therefore help in the elucidation of the problem of the optical selectivity of this alkaloid and the mechanism of its antagonism. One of such compounds, which has the same configuration as (+)-bicuculline (1*S*, 9*R*),[68] is corlumine[74] (Fig. 6*b*), which, like the methyl ester of bicucine (Fig. 6*c*) is an effective GABA antagonist[60]. However, their close analogues bicucine[75] and laudanosine (Figs. 6*d* and 6*e*) do not exhibit a GABA-inhibiting activity[31,60]. It is therefore of interest to investigate the biological activity of bicuculline epimers and related compounds in order to determine whether the 1*S*,9*R*-configuration can serve as a criterion of antagonism in relation to GABA in this series of alkaloids[60,68].

It has recently been suggested[76] and then confirmed experimentally[77,78] that 2,6-dithia-1,3,5,7-tetraza-adamantane 2,2,6,6-tetraoxide or tetramethylenedisulphotetramine[79] (Fig. 6*f*) can serve as a GABA antagonist. This substance is a powerful convulsant and, like

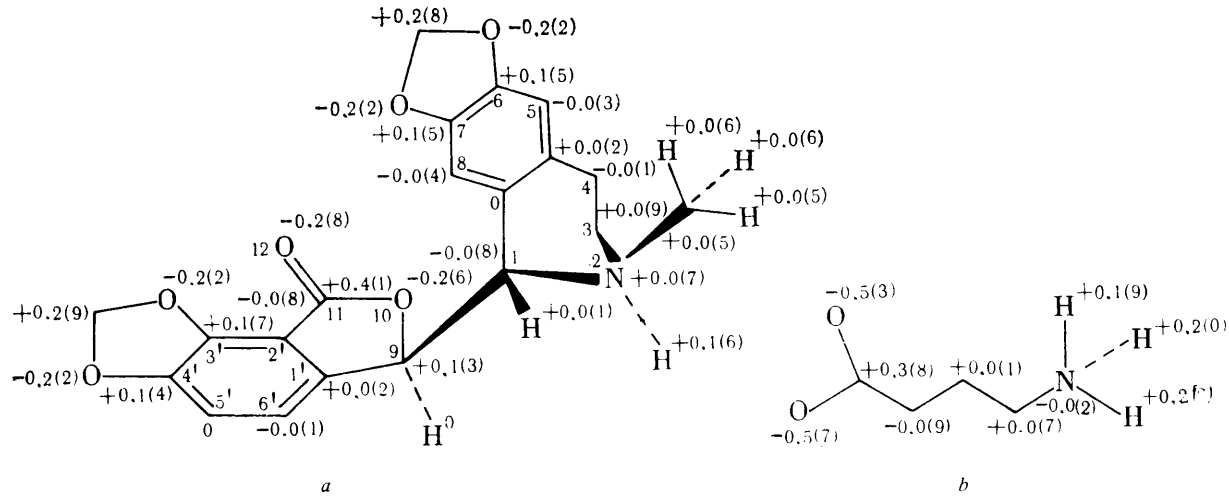

Figure 5. The distribution of charges in bicuculline and GABA: *a*) protonated bicuculline (in the conformation preferred for a solution of the alkaloid); *b*) GABA zwitterion (the numbering of the atoms is in accordance with the paper of Steward et al.[67]).

‡ One should note that the solubility of bicuculline hydrochloride at the "biological" pH is very low and this has led to certain contradictions in the determination of the efficiency of the action of the (+)-form of the alkaloid[17,72]; furthermore, it has been found recently[60] that the (+)-form of bicuculline methochloride is an effective GABA antagonist and is 100 times more soluble in water than the hydrochloride of the alkaloid.

bicuculline, inhibits the depolarising effect of GABA in the sympathetic ganglion of the rat. However, in contrast to bicuculline, the action of tetramethylenedisulphotetramine is non-competitive and probably non-specific. It may be that the nature of its antagonism is different to that of bicuculline[80]. It is noteworthy that pentamethylenemonosulphotetramine (Fig. 6*g*) a very close analogue of the new antagonist, does not exhibit a GABA-inhibiting activity[80]. The study of the nature of the antagonism of tetramethylenedisulphotetramine, which at first sight bears no structural analogy to GABA, is of special interest in connection with the possibility of a new approach to the explanation of the physiological activity of GABA and its analogues.

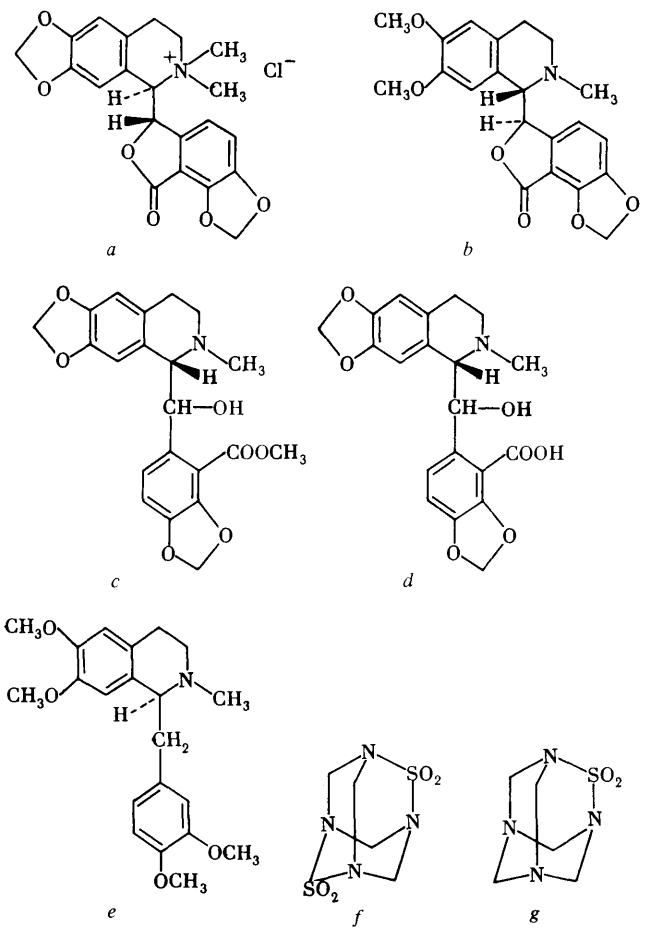

Figure 6. Structural formulae of certain GABA antagonists and their analogues: *a*) (−)-bicucullinemethochloride; *b*) corlumine; *c*) methyl ester of bicucine; *d*) bicucine; *e*) laudanosine; *f*) tetramethylenedisulphotetramine; *g*) pentamethylenemonosulphotetramine.

III. MODELLING OF THE INTERACTION OF γ-AMINOBUTYRIC ACID WITH ITS RECEPTOR

The depressant effect of GABA on nerve structures is achieved by the interaction with its receptor. Information about the chemical nature of GABA receptors is extremely fragmentary and to a large extent speculative. The study of the steric structures of many GABA agonists, which are structurally similar and have a qualitatively similar physiological activity, helps to elucidate in greater detail the structure of the receptors. According to modern ideas, these receptors consist of a protein material[81] in a lipid (hydrophobic) phase, which is located in presynaptic or postsynaptic membranes[82,83]. Receptors capable of capturing GABA can apparently differ from receptors associated with its physiological activity.

One of the probable mechanisms of the interaction of the receptor with the GABA molecule—an agent transmitting the nerve pulse—is based on the idea[49,84] that GABA can exist in the form of two conformers. The receptor initially "recognises" one of the GABA conformations in terms of molecular size, the presence of N^+ and O^- charges, their magnitude, and the distance between them, and attracts this conformation. This is followed by the stage of the interaction of the initial conformer with the receptor, which apparently proceeds with the fixation of a definite GABA conformation on the receptor. The ionised state of the GABA molecule, which varies as a function of the pH of the medium, is responsible for the specific sorption of its molecule on the outer side of the membrane, where sodium is the dominant cation. The sites where GABA is bound to sodium apparently constitute the receptor sections on the membrane where the adsorbed GABA exhibits its physiological effects. This bound form of GABA freely exchanges molecules with the GABA molecules present in solution.

The second conformer can participate in the formation of a GABA – receptor complex in the course of the change of membrane conductivity. The interaction of GABA in a definite "rigid" conformation with the receptor leads to a change in the orientation of the double layer of lipid and phospholipid molecules, an increase of the strength of the bond between GABA and the receptor, and the formation of pores in the membrane. The pore dimensions are determined by the distance between the two charged groups in the GABA molecule, whose position on the membrane is fixed by electrostatic forces and hydrogen bonds. Univalent potassium or chloride ions[85,86], which ensure the inhibition process in neurons, or hydrated sodium ions, responsible for the transmission of excitation[85], enter the cell or emerge from it via the membrane pores. The ability of GABA to exhibit both an inhibiting and an exciting influence on neurons has been observed earlier by Kerkut and Walker[87,88]. The selective change in the permeability of the membrane to various ions is apparently associated not only with conformational changes in the GABA molecule but also with changes in the geometry of the active sections of the receptor, which bears a definite analogy to stereospecific reactions.

The formation of hydrogen bonds ensures the rigidity of the GABA conformer structure within the membrane, which is particularly important in solution, where the GABA molecules can exist in several conformations. The distance between the two charged groups of the extended GABA conformer is between 5.4 and 6.3 Å and, when the conformer reacts with the receptor, it can open pores within the membrane whose size is about 5.4 Å (Fig. 7*a*),[84] which ensures the transport of hydrated sodium ions (whose size is 4.8–5.1 Å) and hence the excitation of the neuron and the transmission of the nerve pulse[89]. In the partly folded GABA conformation the pore size in the membrane diminishes to 4.4 Å (Fig. 7*b*),[84] which is sufficient for the passage of hydrated chloride ions only (their size is 3.32–3.86 Å),[90] the latter being responsible for the

inhibition of nerve signals. This model of the interaction of GABA with the receptor is consistent with all the theoretical and experimental facts obtained previously. Thus the difference between the distances separating the N^+ and O^- charges in a series of GABA agonists showed that the active section in the GABA receptors is somewhat elastic, which permits the variation of the distance between the charged reaction centres of the receptor within a certain range[53]. This idea is consistent with the flexible nature of membrane proteins.

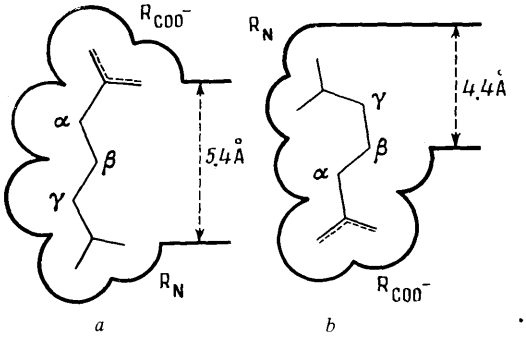

Figure 7. Schematic illustration of the interaction of the conformers of GABA with its receptor (R_{COO^-} and R_N are the active sections of the receptor interacting with a carboxylate and amino-groups of GABA and its analogues)[84]: *a*) extended conformer; *b*) folded conformer.

The inhibiting and exciting effect of GABA on two types of cells in the neurons of the snail *Helix aspersa*[87-89] can be accounted for by the flexibility and the ready change of the structural specificity of this molecule (the interconversion of the conformers) under the influence of external conditions and also by the possibility of structural changes of the receptors themselves in different types of cells[84]. A GABA molecule in the extended conformation interacts with one of the receptors (under these conditions, β-alanine in the two possible conformers of which the N^+-O^- distances are 3.4 and 4.7 Å,[53] does not exhibit a physiological activity, while muscimol is 10–100 times more active than GABA [84]), while the partly folded GABA conformer interacts with the other receptor (in this case β-alanine exhibits a GABA-like activity, while the effectiveness of muscimol does not differ from that of GABA [84]).

The antagonism of bicuculline and related compounds can be associated with the fact that, after the "recognition" by the receptor of the GABA-like element in the alkaloid structure, the latter cannot assume the second conformation[49,53]. This is apparently associated with the charge distribution in the remainder of the cumbersome three-dimensional bicuculline molecule[67]. Its competitive antagonism may depend on the smaller negative charges on the atoms of the lactone ring in bicuculline compared with the COO group in GABA, which leads to a weaker (hindered) binding of the bulky molecule of the alkaloid to the receptor; this weak binding cannot be induced by conformational changes corresponding to the terminal stages in the action of GABA. It has also been suggested[49] that the charges on the residue of the bicuculline molecule can interact with the environment of the active section of the receptor and can thus prevent a rapid liberation of the latter. Furthermore, there is a possibility of a large energy barrier in bicuculline to conversion into another conformer[49]. Bicuculline thus inhibits the activity of GABA, imitating its "initial" conformer and occupying the reaction centres of the receptor without manifesting at the same time a GABA-like physiological activity.

The absence of elements of structural similarity in another GABA antagonist (tetramethylenedisulphotetramine) suggests the possibility of the complete blocking of the receptor and the prevention of access to the latter by GABA molecules as a result of the electrostatic interaction of the charged groups of the receptor and the antagonist. This hypothesis is supported by the non-specificity of the action of the antagonist and the non-competitive antagonism.

Van Gelder[90] suggested a different mechanism for the interaction of GABA with the receptor. According to his model, the inhibition process is associated solely with the configuration at the γ-carbon atom in GABA, namely with the steric influence of the γ-hydrogen atom. When GABA interacts with the receptor, the γ-hydrogen atoms determine the pore dimensions in the membrane, which are 3.7–4.5 Å according to calculations[90], corresponding to the diameter of hydrated chloride ions. However, this theory cannot explain the activity of certain GABA antagonists and also the exciting activity of GABA.[88,89]

In conclusion, the following structural features of compounds with GABA-like activity should be noted.

(1) Free amino- and carboxy-(or sulphoxy-)groups are necessary for the manifestation of GABA activity, because derivatives with ester or amide groups have almost no activity[7]. The comparative ineffectiveness of branched or substituted GABA derivatives can apparently be accounted for by the fact that the substituents interfere with the orientation of GABA relative to the receptor groups.

(2) The optimum length of the atomic chain between the nitrogen of the basic group and the oxygen of the acid group corresponds to four atoms. Molecules with 2–3 or 5–6 atoms in this chain exhibit a low activity or are completely inactive.

(3) GABA receptors react with a molecule having at least two highly charged regions whose charges are of opposite sign to those of the centres of positive and negative charges on the amino- and carboxylate groups respectively.

(4) A GABA-like compound must exhibit a structural stereospecificity, i.e. must correspond to one of the GABA conformations. For activity to be shown, the charges on the cationic (N^+) and anionic (O^-) groups of the zwitterionic form must be at a distance of 5.0–6.0 Å (exciting activity) or 3.7–4.5 Å (inhibiting activity)[84,90].

(5) Not only the properties indicated above are important for the interaction with the receptor; in certain cases the "recognition" of the molecule by the receptor requires a specific optical configuration. In order to account for the chiral specificity of the receptor, further investigation of the physiological activity of alkaloids of the phthalide–isoquinoline series is required.

---oOo---

The interaction of a biologically active molecule with a macromolecular receptor is possible by virtue of the influence of intermolecular forces and presupposes a definite intermolecular orientation, which apparently does

not rule out a change in the conformation of the molecule when it approaches the receptor, The final solution of the problem of the preferred conformation of medicinal drugs depends on direct experimental observations on the complexes of the active molecules with the receptor. The most promising methods for the determination of the "topography" of the active centres of the receptors and for the elucidation of the mechanism of the action of GABA and other medicinal preparations may be X-ray diffraction and nuclear magnetic resonance of GABA–receptor complexes in the biophase itself. Computer quantum-chemical analysis is of great assistance to chemists, biochemists, and pharmacologists in the solution of these problems. In addition, when account is taken of the influence of the surrounding medium and the receptor on the energetically favourable GABA conformation and of the conformational and electronic changes in the structure of the macromolecular drug–receptor complex for various GABA-like medicinal preparations, such analysis may be used in future to predict and design new effective drugs with a desirable range of action on the central nervous system of man.

Advances in the Search for Medicinal Drugs Based on γ-Aminobutyric Acid

V.M.Kopelevich

Problems associated with the search for new psychotropic agents based on γ-aminobutyric acid—a mediator of central inhibition—are examined, the principles of the rational synthesis of new medicinal drugs in the series of γ-aminobutyric acid derivatives are discussed, and methods for their chemical synthesis are described. Data are presented on the conformation of γ-aminobutyric acid and the structure of its receptor; certain features of the relation between structure and biological activity in the above series of compounds are considered.
The bibliography includes 178 references.

I. INTRODUCTION

Since it was observed in 1950 that γ-aminobutyric acid (GABA) is present at high concentrations in the central nervous system (CNS), workers in various fields carried out extensive studies designed to establish the role of this compound in the functioning of the brain. New data have been obtained in recent years showing that GABA is a mediator of inhibition in vertebrates, including mammals [1-3]. The development of improved methods for the identification of GABA and its metabolites yielded additional information about the metabolism of GABA in the central and peripheral nervous systems, about the enzymes involved in its synthesis and decomposition [4], and about the mechanism of inhibition with participation of the GABA system [5]. It was noted that in certain mental illnesses the GABA metabolism is affected [6]. These findings have served in recent years as a basis for a number of hypotheses concerning the pathogenesis of mental illness [7,8], although the use of GABA and its derivatives as medicinal drugs began much earlier. Pharmacological and clinical tests on GABA, begun at the beginning of the 1950s, have been completed by the synthesis of an effective medicinal drug [9], although its application in the treatment of diseases of the nervous system is complicated by the low permeability of the haemato-encephalic barrier (HEB) to this compound. Studies have therefore been carried out for a number of years on the synthesis of substances close to GABA in structure and having an analogous activity as well as GABA derivatives capable of penetrating into the brain and acting on CNS, and a combined investigation of the properties of such substances has been carried out.

The importance of GABA is not apparently restricted to its mediating function. It is encountered not only in the brain but also in other organs, playing a definite role in the metabolism of carbohydrates, aminoacids, biogenic amines, hormones, and phospholipids [10] and serving as a precursor of many physiologically active substances [11]. Studies in recent years demonstrated the important role of GABA in the synthesis of proteins [12,13]. These data lead to the possibility of using GABA derivatives not only as neurotropic preparations but also in many other fields of medicine.

In view of the considerable interest in the study of the mediating function of GABA, the literature on this field is exceptionally extensive. In recent years alone a series of reviews have been published on the physiological role of GABA [1,2], its biochemical functions [4,14], and clinical applications [9,15]. However, the reviews virtually do not reflect problems associated with the chemical aspects of the search for new medicinal drugs based on GABA, although during the past 10–15 years chemists have synthesised a considerable number of derivatives of this aminoacid. In the course of this research extensive data have accumulated on the methods of synthesis, physiochemical properties, and biological activity of the compounds; a survey of these data can play a definite role in the specific search for medicinal drugs based on GABA. The present review is mainly devoted to methods of synthesis and properties of GABA derivatives used as medicinal drugs or studied experimentally on animals, and to the determination of the relation between structure and biological activity in this series; attention has been concentrated on studies carried out in the last 5–10 years.

II. THE CONFORMATION OF GABA AND THE STRUCTURE OF THE GABA-RECEPTOR

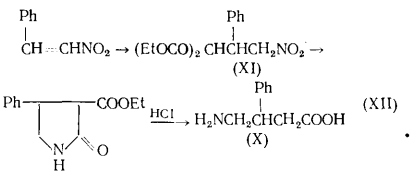
It is generally accepted that the physiological action of GABA is similar to that of the "inhibition factor" discovered by Florey in 1953. [16] Until recently it was believed that this factor is identical with GABA. However, in 1975 Florey showed experimentally that the inhibiting action of the inhibition factor is only 35% due to the presence of GABA in it [17]. Aspartic acid, glutamic acid, and taurine, forming part of the factor, exhibit a similar effect (30%); the remainder of the inhibiting effect is apparently due to the presence of β-guanidinopropionic, γ-guanidinobutyric, and γ-amino-β-hydroxybutyric acids [17,18]. A large group of natural and synthetic compounds, similar to GABA in structure and in inhibiting activity, is also known. These findings indicate the possibility of the interaction of GABA and its analogues with the same biochemical system present in the CNS; this system can be defined as the GABA-receptor. A number of studies in recent years have been

devoted to the determination of the characteristics of the structure of this receptor, the methods for its isolation, and the conditions for the interaction of GABA derivatives with it.

On the basis of ideas concerning the complementarity of the structures of the medicinal drug and the receptor, one of the ways of solving the problem of the structure of the GABA-receptor consisted in the investigation of the structural features of GABA and its agonists which ensure the optimum interaction with the receptor. Kier[19] suggested that the energetically preferred conformation of the substance is identical to that in which it interacts with the receptor. This hypothesis was found to be justified in the study of a large and varied group of preparations, including anti-inflammatory, adrenergic histamine derivatives, etc. The preferred GABA conformation was determined by the molecular orbital method (LCAO-MO) taking into account the principle of the minimisation of the total energy of the molecule. Calculations showed[20] that in this conformation the ammonium and α-methylene groups of GABA (I) are in the transoid positions, while the COO^- group can rotate freely. The distance between N^+ and O^- is in the range 5.0–6.1 Å. Calculation on the muscimol (II) molecule, which has an inhibiting effect similar to that of GABA[21] and acts on the same receptor[22], showed that in the preferred conformation the side chain is coplanar with the ring and is directed towards the ring oxygen. In this conformation the charged exocyclic oxygen atom is located at a distance of 5.8 Å from the 'onium nitrogen atom[20]. A similar calculation for a group of GABA-like substances showed that the distance between N^+ and O^- in γ-amino-β-hydroxybutyric acid (III),[23] β-hydrazinopropionic acid (IV), homotaurine (V), and imidazolylacetic acid (VI)[24] is 5–6 Å. It was also established that substances with a "rigid conformation"—γ-aminotetrolic acid (VII)[25] and *trans*-γ-aminocrotonic acid (VIII),[26] which are similar to GABA in its fully extended form and have an N^+–O^- distance in the range 5.2–5.8 Å—have an inhibiting effect similar to that of GABA. In the alkaloid bicuculline (IX),[27] which is a powerful competitive antagonist of GABA[28], the distance between the 'onium group and the oxygen atom of the carbonyl is 5.6 Å. Thus the distances between the charged groups in GABA and in compounds (II)–(IX) are approximately the same, demonstrating the importance of the extended conformation of GABA for its interaction with the central inhibition receptor, whose active section should have two charged regions of opposite sign located at a distance of 5–6 Å from one another. However, van Gelder proposed a folded conformation for GABA with a distance between nitrogen and oxygen atoms of 3.7–4.5 Å.[29] X-Ray diffraction study of the GABA zwitterion in the crystalline state also led to the conclusion that its molecule is to some extent folded[30,31], while crystalline GABA hydrochloride has an extended structure[32]. On the basis of molecular orbital calculations, Pullman suggested a folded conformation for the isolated GABA molecule, which is a consequence of the strong interaction of its two charged ends[33]. From the pharmacological point of view, the conformation in solution, where the inhibiting effect is manifested under physiological conditions, is of greatest importance. According to Pullman's data, a large number of stable conformations of the GABA molecule exist in solution, which apparently enables it to interact with different receptors[33].

During the last 3–4 years a number of publications concerning the direct investigation of GABA by methods used for the choline receptor have appeared[34–39]. Although these studies do not exhaust all the aspects of the problem associated with the structure of the GABA receptor, the information obtained can greatly facilitate the search for new synthetic GABA agonists and antagonists. On the other hand, systematic investigation of the relation between structure and pharmacological activity in this series of compounds makes it possible to obtain a more complete idea about the structure of the GABA receptor.

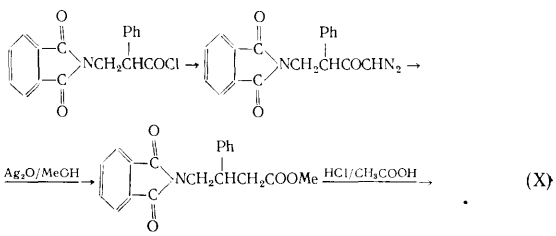
Among the numerous studies of natural and synthetic GABA analogues, derivatives with substituents in the hydrocarbon chain, compounds with modified COOH and NH_2 groups or with a trimethylene chain (structural analogues), as well as esters and *N*-acyl derivatives of GABA (bound forms) occupy an important place and these will be considered further.



III. γ-AMINOACIDS WITH SUBSTITUENTS IN THE HYDROCARBON CHAIN

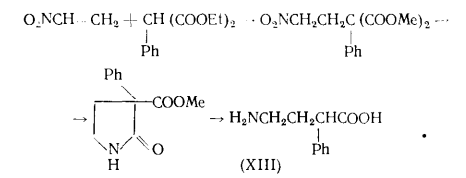
The main methods for the synthesis of GABA have been described[9] and they will not therefore be considered in the present review. We need only examine the single-step method for the preparation of GABA[40] by the selective oxidation of *p*-hydroxyphenylpropylamine with ruthenium tetroxide (in 69% yield). Labelled [^{14}C]GABA is synthesised by reducing the ethyl ester of labelled β-cyanopropionic acid under pressure[41]. Selective substitution of α-hydrogen atoms by deuterium yielded α-deutero-GABA in a high yield[42]. Enzymatic decarboxylation of glutamic acid and the microbiological synthesis of GABA from L-glutamic acid or ornithine may be of some interest for the preparation of GABA[43].

Up to the middle of the 1950s, the methods of synthesis of substituted γ-aminobutyric acids were little investigated and only after the mediating function of GABA in mammals had been discovered was the attention of synthetic chemists drawn to this problem. The aim of the investigations was the synthesis of compounds retaining the GABA carbon skeleton and both its functional groups but containing in the side chain lipophilic substituents capable of increasing the solubility of the entire molecule in fats and thus improving its permeation through HEB.



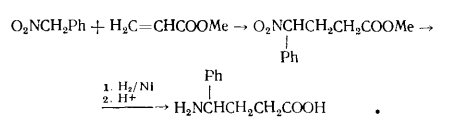
Systematic studies on the synthesis and chemical properties of unsaturated compounds have been carried out for many years in the Department of Organic Chemistry of the Leningrad State Pedagogic Institute, one series of which led to the preparation of GABA derivatives and α-pyrrolidinones. In 1954 Perekalin and Sopovoi[44] synthesised γ-amino-β-phenylbutyric acid (X), the pharmacological study of which demonstrated that it has the properties of a mild tranquiliser[45]. The subsequent cycle of investigations, carried out by members of this Department and the Bekhterev Leningrad Psychoneurological Institute, was completed by the synthesis of a new psychotropic preparation phenybut (β-phenyl derivative of GABA)[46]. A symposium devoted mainly to the chemistry, pharmacology, and clinical applications of Phenybut was held in 1974 in Olaine; the industrial manufacture of this preparation has now been organised. Phenybut was synthesised by the condensation of β-nitrostyrene with diethyl malonate, the subsequent reduction of the resulting ethyl ester of α-ethoxycarbonyl-γ-nitro-β-phenylbutyric acid (XI) in the presence of a nickel catalyst to 3-ethoxycarbonyl-4-phenylpyrrolidinone (XII), and treatment of the latter with 20% hydrochloric acid[44]. In recent years Perekalin and coworkers developed and patented a technological version of this synthetic scheme[47].

Scheme 1

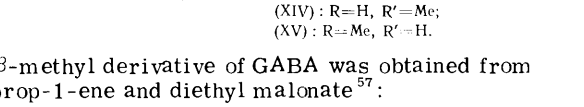


Kupryszewski and coworkers[48] obtained compound (X) by the reduction of β-cyano-β-phenylpropionic acid. A similar method of synthesis of the β-phenyl derivative of GABA by the reaction of phenylacetonitrile with ethyl bromoacetate and subsequent reduction and hydrolysis of the resulting ethyl β-cyano-β-phenylpropionate was described recently[49].

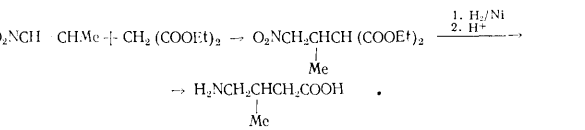
A new synthesis of compound (X) from α-phenyl-β-alanine using the Arndt-Eistert reaction was described in 1974[50]:



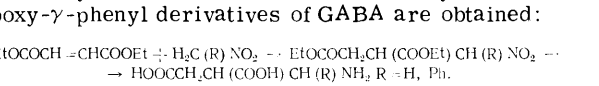
Studies by Perekalin and coworkers, devoted to the development of a general method of synthesis of substituted γ-aminobutyric acids, led to the preparation of various derivatives, which helped to elucidate the relation between the structure and pharmacological activity of compounds of this type. When other nitro-olefins were used instead of nitrostyrene, β-isopropyl, β-*p*-methoxyphenyl, β-*p*-hydroxy-*m*-methoxyphenyl, β-2-furyl and β-2-thienyl derivatives of GABA[51], β-(*o*-tolyl), β-(*n*-tolyl),[52,53] and β-(*p*-tolyl)[54] derivatives, as well as a number of derivatives of γ-amino-β-phenylbutyric acid containing various substituents in the benzene ring[55] were obtained via Scheme 1.



In order to synthesise the α-phenyl derivative of GABA (XIII),[56] nitroethylene was condensed with the phenylmalonic ester and the resulting ester of the γ-nitrocarboxylic acid was reduced to the corresponding ester of α-pyrrolidinone-β-carboxylic acid; hydrolysis of the latter led to compound (XIII):

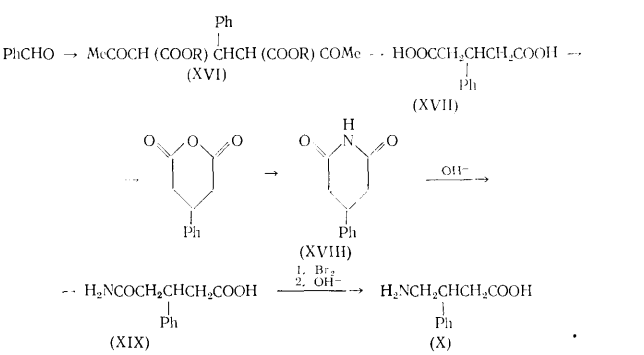


The interaction of phenylnitromethane with methacrylate[52] in the presence of potassium fluoride yielded methyl γ-nitro-γ-phenylbutyrate, which was then converted in the usual way into γ-amino-γ-phenylbutyric acid:

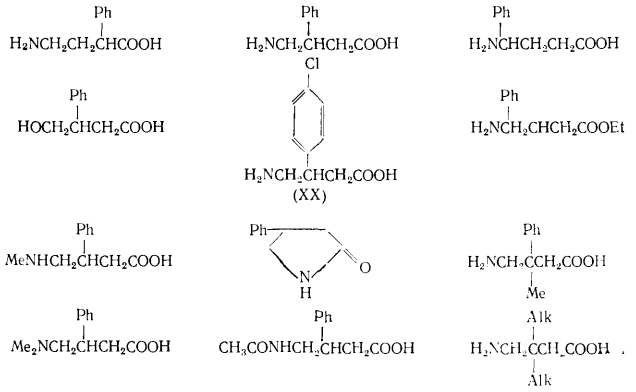


The methyl esters of α-methyl-γ-nitrobutyric acid (XIV) and γ-nitrovaleric acid (XV) were obtained similarly by the nucleophilic addition of nitromethane to methyl methacrylate and of nitroethane to methyl acrylate[57] and were then converted into α- and γ-methyl derivatives of GABA:

The β-methyl derivative of GABA was obtained from 1-nitroprop-1-ene and diethyl malonate[57]:

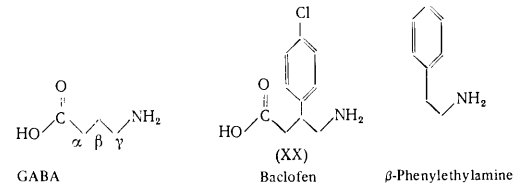


The nucleophilic addition of nitromethane and phenylnitromethane to diethyl fumarate[58] leads to the corresponding nitrodicarboxylic esters from which β-carboxy- and β-carboxy-γ-phenyl derivatives of GABA are obtained:



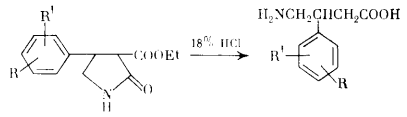
The pharmacological properties of Phenybut have been examined in detail in reviews [1,15] and in another publication[45]. Clinical and pharmacological studies of compounds of this series are still being continued. A report was published in 1975 concerning a comparative study of α-, β-, and γ-phenyl derivatives of GABA and the corresponding lactams. The β-phenyl derivative of GABA proved to be the most active in tests on the potentiation of the effects of barbiturates, ethanol, and morphine[59]. In contrast to the aminoacids, the corresponding lactams exhibited an anticonvulsant activity[60]. Individual compounds of this series were found to possess hypotensive and hypertensive activities[61].

A similar search for medicinal drugs among phenyl derivatives of GABA was carried out in the pharmaceutical chemistry division of the Ciba-Geigy Company[62,63]. γ-Amino-β-phenylbutyric acid (X) was initially synthesised via the mechanism



Condensation of 1 mole of benzaldehyde with 2 moles of acetoacetic ester leads to the ester of α,α'-diacetyl-β-phenylglutaric acid (XVI), which splits off both acetyl groups on treatment with alkali and is hydrolysed to β-phenylglutaric acid (XVII). Dehydration and cyclisation of the acid (XVII) in the presence of acetic anhydride and subsequent heating with ammonia lead to β-phenylglutarimide (XVIII), which is then converted into the amide (XIX). After the Hofmann rearrangement, the latter yields γ-amino-β-phenylbutyric acid. Intensive synthetic studies,

carried out by chemists of the Ciba-Geigy Company, led to the preparation of a whole series of GABA derivatives[62,63]:

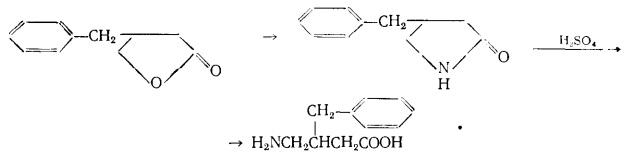


Among the derivatives obtained, capable of permeating through the HEB,[62] γ-amino-β-(*p*-chlorophenyl)butyric acid (XX) showed the greatest pharmacological activity. After extensive clinical tests, it was found that this compound is an effective muscle relaxant, and a preparation based on it began to be manufactured for medical applications under the commercial name Lioresal or Baclofen (the latter name is more common). In 1971 an international symposium devoted to the applications of this preparation in therapeutic practice was held in Vienna. Baclofen is mainly used in the treatment of spastic paralysis[64] including disseminated sclerosis[65]. Reports concerning the use of Baclofen in combination with phenothiazine preparations in the treatment of chronic schizophrenia are of considerable interest[66]. It has been suggested that the use of Baclofen (and a number of other GABA derivatives) in combination with neuroleptic agents ensures a more effective suppression of the dopaminergic mechanisms of the brain and hence a more successful treatment of schizophrenia with a reduced dose of neuroleptic agents[67].

The similarity of the chemical structures of γ-amino-β-(*p*-chlorophenyl)butyric acid and GABA suggested that the mechanism of the action of Baclofen is associated with the activation of the GABA receptor and that it can also influence the GABA formation and degradation processes. However, an experiment on an isolated frog brain established that Baclofen has only a weak inhibiting effect compared with GABA[68]. Furthermore, since the inhibiting effect of Baclofen was not reduced under the influence of bicuculine (a GABA antagonist)[69,70] and strychnine (a glycine antagonist)[69], its action on the CNS cannot be explained by the activation of the GABA and glycine receptors on spinal neurons. The administration of large doses of Baclofen to animals (30 mg kg^{-1}) had no appreciable influence on the GABA concentration in the brain[71]. All these findings give grounds for the hypothesis that GABA and Baclofen act via different mechanisms. It is believed[67] that the action of Baclofen is due to the activation of the adrenoreceptor and not the GABA receptor. Presumably the therapeutic activity of Baclofen as well as Phenybut is associated with the presence of the β-phenylethylamino-group in their molecules, particularly since a similarity has been noted between the inhibiting effects of catecholamines and derivatives of γ-amino-β-phenylbutyric acid[72].

The action of the β-(*m*-chlorophenyl), β-(*o*-chlorophenyl), β-(*p*-fluorophenyl), β-(*p*-isopropylphenyl), and β-(2-naphthyl) derivatives of GABA on the cortical activity in animals has also been studied[72]. All the derivatives investigated exhibited an inhibiting activity which was not weaker than that of Baclofen.

A number of derivatives of γ-amino-β-phenylbutyric acid, including Baclofen, have been suggested as sedatives. They have been synthesised by the acid hydrolysis of 3-alkoxycarbonyl-4-(R,R′-phenyl)-2-pyrrolidinones[73]:



R = H, R′ = *o*-, *m*-, or *p*-Cl; R = R′ = Cl.

An analogous method of synthesising a whole series of β-phenyl derivatives of GABA, consisting in the hydrolysis of the corresponding pyrrolidinones, has been patented[74].

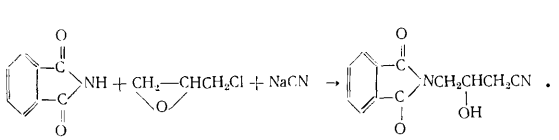
$H_2NCH_2CH(R)CH_2COOH$
R = *o*-ClC_6H_4, *p*-BrC_6H_4, *p*-tolyl, mesityl, *p*-dimethylaminophenyl, *p*-HOC_6H_4, 2-pyridyl, or 3-pyridyl.

In order to elucidate the relation between the structure of a substance and its physiological activity, it may be of interest to investigate the heterocyclic analogues of Phenybut; however, detailed data concerning biological activity are absent from the relevant patent[74] and it is merely stated that all the compounds obtained exhibit a sedative and soporific activity.

A sedative and anticonvulsant activity is also shown by γ-amino-β-benzylbutyric acid, which was obtained by aminating β-benzyl-γ-butyrolactone with liquid ammonia under pressure and subsequent treatment of the resulting 4-benzyl-2-pyrrolidinone with barium hydroxide and sulphuric acid[75]:

4-Phenyl-2-pyrrolidinone, formed on cyclisation of the β-phenyl derivative of GABA[76], as well as 4-(polyalkoxyphenyl)-2-pyrrolidinones also show a psychotropic activity[77].

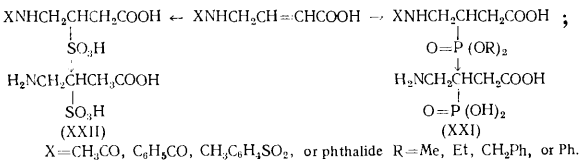
It is noteworthy that the racemates of the β-phenyl derivatives of GABA were used in pharmacological and clinical tests. In order to investigate the molecular mechanism of the action of these compounds, it is of great interest to study their stereospecificity. The first step in this direction was taken by Kupryszewski and coworkers[78], who were able to resolve the racemic γ-amino-β-phenylbutyric acid into its enantiomers $\{[\alpha]_D = +3.2°$ and $-3.7°\}$ by the fractional crystallisation of the diastereoisomeric salts of γ-amino-*N*-benzyloxycarbonyl-β-phenylbutyric acid with cinchonidine. In order to determine the absolute



configurations of the enantiomers, they were correlated with β-phenylbutyric acid, the configuration of which is known, by deamination with nitrosyl bromide and subsequent reduction of the resulting γ-bromo-β-phenylbutyric acids with sodium amalgam. It was established that the dextrorotary isomer has the L-configuration (or the *S*-configuration in the Prelog–Kahn system), while the laevorotatory isomer has the D(*R*)-configuration. Khaunina[79] showed that the L-β-phenyl derivative of GABA is twice as active as the DL-compound, while the D-isomer is completely inactive. The increase of activity on passing from the racemate to the L-isomer is not accompanied by an increase of toxicity, which according to the author[79] justifies the assumption that the L-isomer has a greater therapeutic effect and a greater range of the latter compared with the racemate used at the present time. Presumably one of the enantiomers of Baclofen is also more effective than the racemate.

Data concerning the presence of γ-amino-β-hydroxybutyric acid (III) in the brain were first published by Hayashi in 1956, and his subsequent investigations led to the hypothesis that this substance plays an important role in the activity of the brain. It was shown that compound (III) is an extremely interesting pharmacological agent and, under the commercial name Hamibetal, it has now found extensive applications in clinical practice[15]. The β-hydroxy-derivative of GABA was obtained for the first time by Tomita[80] in 1923. In the USSR the synthesis of this preparation, which was given the name Buksamin, was achieved by Mamaev and Shkuro at the Institute of Organic Chemistry of the Siberian Division of the USSR Academy of Sciences[81]. Japanese chemists[82] synthesised compound (III) from GABA, which is chlorinated in the β-position on irradiation with light from a mercury lamp. Treatment of the β-chloro-derivative of GABA with alkali leads to compound (III).

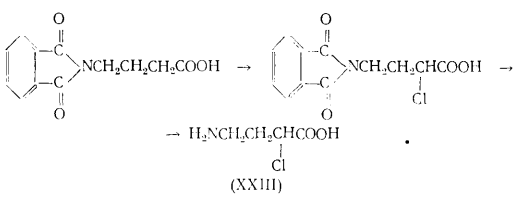
Another method of synthesis, consists in the treatment of γ-chloro-β-hydroxybutyronitrile with hydrogen peroxide and subsequent amination and hydrolysis of the resulting γ-chloro-β-hydroxybutyramide[83]:



$$ClCH_2\underset{\underset{OH}{|}}{CH}CH_2CN \rightarrow ClCH_2\underset{\underset{OH}{|}}{CH}CH_2CONH_2 \rightarrow \underset{\underset{OH}{|}}{H_2NCH_2CH}CH_2COOH \quad \text{(III)}$$

A convenient method of preparation of compound (III) involves the interaction of epichlorohydrin with phthalimide and sodium cyanide followed by the hydrolysis of the resulting β-hydroxy-γ-phthalimidobutyronitrile[84]:

The β-chloro-derivative of GABA, obtained by treating the methyl ether of the β-hydroxy-derivative of GABA with PCl_5 and the acid hydrolysis of the resulting ester, exhibits an anti-epileptic activity[49].



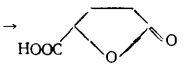
The β-phosphono-derivative of GABA (**XXI**), which exhibits a sedative activity and can be used in the treatment of epilepsy according to the authors, has been synthesised[85] by the reaction of *N*-substituted γ-aminocrotonic acid with trialkyl(allyl)phosphites and subsequent elimination of the protecting groups by refluxing with hydrobromic acid:

X=CH_3CO, C_6H_5CO, $CH_3C_6H_3SO_2$, or phthalide R=Me, Et, CH_2Ph, or Ph.

Treatment of γ-phthalimidocrotonic acid with sodium or potassium bisulphite leads to the β-sulpho-derivative of GABA (**XXII**), which has anti-epileptic and anticonvulsant activities[86].

Among the α-substituted GABA derivatives, the chloro-, amino-, hydroxy-, and mercapto-derivatives (the α-amino- and α-hydroxy-derivatives have been detected in the mammalian brains) have been subjected to extensive pharmacological tests[1]. γ-Amino-α-chlorobutyric acid (**XXIII**) is synthesised by hydrolysing with hydrochloric acid ethyl α-bromo-γ-phthalimidobutyrate, which leads to the replacement of the bromine atom by chlorine together with the removal of the phthaloyl group[87]. An improved method, consisting in the interaction of γ-phthalimidobutyric acid with gaseous chlorine and subsequent hydrolysis with hydrochloric acid, was described in 1971[88]:

(XXIII)

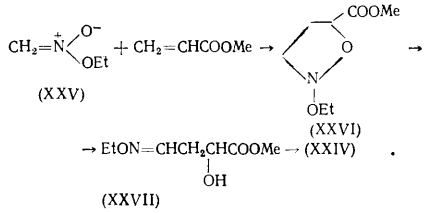


A pharmacological experiment showed that the α-chloro-derivative of GABA apparently permeates readily through the HEB and has a normalising activity in disturbances of the function of the brain[89]. In order to obtain optically active isomers, the phthaloyl derivative of the racemate (**XXIII**) was resolved using quinine[90], but the pharmacological properties of the resulting enantiomers $\{[\alpha]_D^{25} \pm 9.2°\}$ were not described.

α,γ-Diaminobutyric acid is highly neurotoxic[91]. The administration of this compound to animals leads to clonic spasms, which terminate in the death of the animals[92]. This acid is one of the principal structural elements of many peptide antibiotics and this is why its synthesis has been studied in detail[93]. An anticonvulsant activity, comparable to that of the β-hydroxy-derivative of GABA, is shown by the α-hydroxy-derivative of GABA (**XXIV**) when the latter is administered intraabdominally, and its toxicity is smaller than that of GABA; the α-mercapto-derivative of GABA does not exhibit an anticonvulsant activity[94].

A considerable interest has been shown in recent years in the α-hydroxy-derivative of GABA after it was established that new aminoglycosidic antibiotics, butyrosines A and B, which show a high antimicrobial activity, contain this aminoacid. In this connection a whole series of modified aminoglycosidic antibiotics, acylated by γ-amino-α-hydroxybutyric acid, have been synthesised[96–98] and new methods have been developed for the preparation of the aminoacid itself. A simple method for the synthesis of (**XXIV**) involves the replacement of the α-amino-group in α,γ-diaminobutyric acid by the hydroxy-group with the aid of diazotisation[99,100]. Japanese investigators obtained high yields of *R*- and *S*-enantiomers (**XXIV**) by the reaction

of *RS*-α-hydroxy-γ-butyrolactone with potassium phthalimide in dimethylformamide (DMF), the subsequent resolution of the phthalimide derivative into optical isomers via the L-amphetamine salts, and their hydrolysis with hydrochloric acid [101]. When sodium L-glutamate is treated with sodium nitrite and hydrochloric acid, γ-carboxy-γ-butyrolactone is formed and its interaction with ammonia results in its conversion into L-2-hydroxyglutaramic acid; the reaction of the latter with hypochlorite leads to the L-isomer of (**XXIV**) [102]:

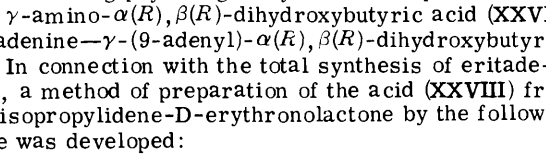


$$NaOOCCH_2CH_2CH(NH_2)COOH \rightarrow NaOOCCH_2CH_2CH(OH)COOH \rightarrow$$

$$\rightarrow HOOCCH(OH)CH_2CH_2CONH_2 \rightarrow H_2NCH_2CH_2CH(OH)COOH.$$

(XXIV)

The L-enantiomer of (**XXIV**) can also be obtained in 15.3% yield by the aerobic fermentation of certain *Acetobacter* strains in a nutrient medium containing the racemic mixture [103]. A fundamentally new method of synthesis of the α-hydroxy-derivative of GABA has been recently proposed by Japanese investigators [104]. The regiospecific dipolar cycloaddition of the nitronic ester (**XXV**) to methyl acrylate leads to the formation of 2-ethoxy-5-methoxycarbonylisoxazolidine (**XXVI**). Heating of compound (**XXVI**) at 100°C leads to the ethoxyimino-compound (**XXVII**), the hydrogenation of which and subsequent acid hydrolysis give rise to γ-amino-α-hydroxybutyric acid [104]:



(XXV) (XXVI)

$$\rightarrow EtON{=}CHCH_2CHCOOMe \rightarrow (XXIV).$$

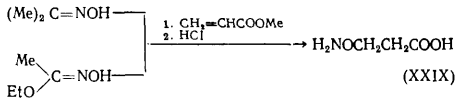
(XXVII)

Using methyl crotonate, α-amino-α-hydroxy-β-methylbutyric acid can be obtained by a similar scheme [104]. One may also note that the reaction of pantolactone (α-hydroxy-β,β-dimethyl-γ-butyrolactone) with potassium phthalimide and subsequent elimination of the phthaloyl group led to the synthesis of γ-amino-α-hydroxy-β,β-dimethylbutyric acid (γ-pantonine)—an analogue of pantoic acid, which is a precursor of panthothenic acid (vitamin B_3). [105]

An interesting physiologically active compound containing γ-amino-$\alpha(R),\beta(R)$-dihydroxybutyric acid (**XXVIII**) is eritadenine—γ-(9-adenyl)-$\alpha(R),\beta(R)$-dihydroxybutyric acid. In connection with the total synthesis of eritadenine [106], a method of preparation of the acid (**XXVIII**) from 2,3-*O*-isopropylidene-D-erythronolactone by the following scheme was developed:

(XXVIII)

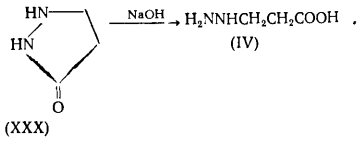
Together with a study of β-phenyl derivatives of GABA, the synthesis and pharmacology of the α-phenyl derivatives have been widely investigated [107]. However, the compounds obtained exhibited only a slight stimulating activity, so that further studies on these lines were not continued.



In analysing the available information about the pharmacological properties of GABA derivatives substituted in the carbon chain, one may reach certain conclusions concerning the relation between chemical structure and physiological activity in this series of compounds. The introduction of substituents (chlorophenyl, hydroxy-, sulpho-, and phosphono-groups) in the β-position leads to substances with a strong inhibiting activity. This suggests that such compounds permeate through the HEB, although direct evidence for their penetration into the brain has not been obtained in most cases. The migration of these groups to the α- or γ-position does not affect their permeation through the HEB, but leads to an appreciable decrease of the inhibiting effect, although in many instances the introduction of the substituents in the α-position (chloro-, hydroxy-, and amino-groups) imparts valuable pharmacological properties to the compounds. The presence of the phenyl and alkyl groups simultaneously in the β-position of the GABA molecule as well as one or two alkyl groups does not result in the appearance of neurotropic properties in these compounds. At the same time, γ-amino-α-hydroxy-β-phenylbutyric acid does not differ from γ-amino-β-phenylbutyric acid as regards the intensity of its action on the CNS [108]. An increase of activity was noted after the introduction of substituents into the benzone ring of γ-amino-β-phenylbutyric acid and an appreciable increase was noted for the *para*-derivatives [63].

As already mentioned, the inhibiting effect of HEBA is due to its interaction with the receptor. Presumably β-substitution is most favourable for the retention of the conformation of the molecule which corresponds to the postulated structure of the GABA receptor (this has been demonstrated by calculations for the β-hydroxy-derivative of GABA), and the presence of certain substituents can ensure an additional interaction with the active surface of the receptor. The important role of the steric structure of the molecule is convincingly demonstrated by the finding that pharmacological activity is shown only by one of the stereoisomers of γ-amino-β-phenylbutyric acid.

IV. STRUCTURAL ANALOGUES OF GABA



One of the procedures used to synthesise new medicinal drugs with specific activities consisted in the replacement of the CH_2, COOH, and NH_2 groups in the GABA molecule by structurally related groups. Such modifications led in many instances to the formation of substances which inhibit specifically the activity of enzymes involved in the metabolism of GABA and therefore influence its content in the brain. The most interesting substances of this type are isosteric analogues of GABA—β-aminohydroxypropionic acid (**XXIX**) and β-hydrazinopropionic acid (IV), in which the CH_2 group of GABA has been replaced by an oxygen atom and an NH group respectively. These compounds exhibit an exceptionally high inhibiting activity in relation to the GABA transaminase; this activity is determined by the presence of hydroxylamine [109] and hydrazine [110] residues, capable of reacting with the aldehyde group of pyridoxal 5′-phosphate, and also by the similarity of the structures of the compound and the substrate. Presumably compounds (**XXIX**) and (IV), which inhibit the transamination of GABA and thereby increase its content, possess psychotropic activity.

β-Aminohydroxypropionic acid has been synthesised by the Michael reaction of acetoxime [109] or hydroxyiminoacetic ester [111] with methyl acrylate and subsequent elimination of the protecting groups:

(XXIX)

Van Gelder [110] obtained β-hydrazinopropionic acid by hydrolysing 3-pyrazolidinone (**XXX**):

(IV)

(XXX)

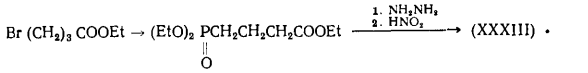
Another method of synthesising compound (**IV**) is based on the interaction of β-chloropropionic acid [112] or its t-butyl ester [113] with hydrazine. In the usual methods of administration β-hydrazinopropionic acid permeates through HEB and gives rise to a distinct sedative effect in mice, which is associated, according to the author [114], with the increased content of GABA in the brain.

The synthesis of γ-aminotetrolic acid by the amination of γ-chlorotetrolic acid has been reported [115]:

$$ClCH_2C \equiv CCOOH \rightarrow H_2NCH_2C \equiv CCOOH \rightarrow cis\text{-}H_2NCH_2CH{=}CHCOOH \quad .$$
(XXXI)

The acid (**VII**) is the simplest analogue of GABA with a fixed conformation owing to the presence of an acetylenic bond.

cis-4-Aminocrotonic acid (**XXXI**) has been synthesised by the reduction of compound (**VII**) over 10% palladium on barium sulphate; the *trans*-isomer (**VIII**) is formed on dehydration of γ-amino-β-hydroxybutyric acid with concentrated sulphuric acid. In view of the presence of the double bond, which restricts the mobility of the molecule, compounds (**VIII**) and (**XXXI**) can be regarded as rigid analogues of GABA in the open and folded conformations [26] respectively. In experiments on the upper neck ganglion in rats, analogues of compounds (**VII**) and (**VIII**) exhibit an inhibiting effect similar to that of GABA [116]. The acetylenic derivative (**VII**) is also a powerful competitive inhibitor of GABA transaminase [117]; it is extremely likely that the ethylenic analogue (**VIII**) also suppresses the activity of this enzyme.



3-Aminopropanesulphonic acid (homotaurine) (**XXXII**), the sulpho-analogue of GABA, has an inhibiting effect [118] and manifests hypotensive and cardiotonic activities [119]. It is stated in a patent [120] that homotaurine is used as a CNS depressant. The anti-epileptic activity of homotaurine has also been reported. The sulphonic acid (**XXXII**) is synthesised by converting 3-aminopropanol into 3-amino-1-chloropropane, which is then treated with sodium sulphite [120]:

$$H_2N(CH_2)_3OH \xrightarrow[\text{or } PCl_5]{SOCl_2} H_2N(CH_2)_3Cl \xrightarrow{Na_2SO_3} H_2N(CH_2)_3SO_3H \quad .$$
(XXXII)

γ-Aminopropylphosphonic acid (**XXXIII**), the phosphono-analogue of GABA, has been obtained by the addition of nitromethane to diethyl vinylphosphonate with subsequent reduction of the nitro-group and the hydrolysis of the phosphonate ester [122]:

$$CH_2{=}CHP(O)(OEt)_2 \rightarrow O_2NCH_2CH_2CH_2P(O)(OEt)_2 \rightarrow$$
$$\rightarrow H_2NCH_2CH_2CH_2P(O)(OEt)_2 \rightarrow H_2NCH_2CH_2CH_2P(O)(OH)_2 \quad .$$
(XXXIII)

The synthesis of compound (**XXXIII**) by the interaction of the γ-bromobutyric acid ester with triethyl phosphite and subsequent Curtius amination has also been described [123]:

(XXXIII) .

Unfortunately the available information about the pharmacological properties of compounds (**VII**), (**VIII**), (**XXIX**), (**XXXI**), and (**XXXIII**) is extremely limited or is altogether lacking.

The replacement of the NH_2 group in GABA by OH leads to γ-hydrobutyric acid. In the form of its sodium salt, this compound is widely used in medicine as a relatively non-toxic non-inhalation narcotic. A number of reviews have been devoted to studies on this preparation [124,125].

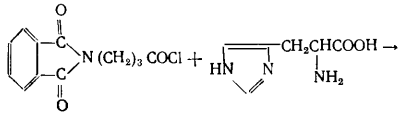
V. BOUND FORMS OF GABA

In the course of its metabolism in the brain tissue GABA is deaminated, which leads to the formation of γ-hydroxybutyric acid and the semialdehyde of succinic acid [1]. In the animal and human organisms there are other ways of utilising this compound which lead to physiologically active bound forms of GABA. The content of these substances in the brain varies from 0.0002 to 0.012%, but the specific metabolic pathways leading to the formation of the majority of them have not been investigated; very little is known about their physiological importance in the normal functioning of the brain. An experimental study of the bound forms of GABA showed that they possess valuable pharmacological properties and the possibility of their use in medical practice continues to be investigated. An extremely promising pathway in the search for new medicinal drugs based on GABA was found to involve the chemical combination of the GABA molecule with other physiologically active substances via the amino- or carboxy-groups, which tends to decrease the polarity and in many cases to enhance the lipophilic properties of the molecule and leads to substances which readily permeate through HEB and exhibit a predominantly central activity.

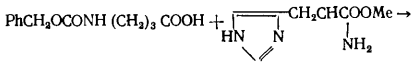
The esterification of GABA yielded its esters, which, when administered in the usual way, exhibited a distinct neurotropic activity similar to that of GABA itself [126]; the highest activity in doses much below the toxic level is shown by the cetyl ester, which has the longest chain among all the esters investigated [127], with the exception of the octadecyl ester [128]. γ-Aminobutyrylcholine, the choline ester of GABA, which has been detected in mammalian brains, has an inhibiting effect in various parts of the brain [129]. Howells [130] believes that γ-aminobutyrylcholine is a mediator of the inhibition in the nervous system, since it exhibits a greater degree of stereochemical similarity to bicuculline, a specific GABA antagonist, than γ-aminobutyric acid; however, this hypothesis did not receive additional experimental confirmation. Very few data are available on the pharmacological effect of γ-aminobutyrylcholine, which is apparently associated with its high toxicity (600 times greater than that of GABA [131]); it has an anticonvulsant activity [129].

γ-Guanidinobutyric acid (**XXXIV**), the guanidine derivative of GABA, has been detected in various animal organs, including the brain. It has been suggested that this compound is formed in the animal organism when GABA combines with the guanidino-group of arginine and that it is subsequently cleaved with formation of urea and GABA. In contrast to GABA, compound (**XXXIV**) has a stimulating

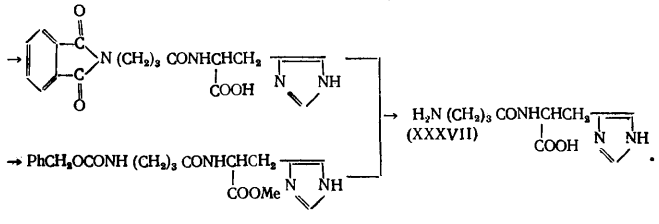
effect on the CNS.[132] γ-Guanidino-β-phenylbutyric acid exhibits a central activity, although it is weaker than that of γ-amino-β-phenylbutyric acid[63]. It has been shown recently that the amide (**XXXV**) lowers the content of urea and glucose in the blood of diabetics[133]. The acid (**XXXIV**) has been synthesised by the interaction of GABA with *O*-methylisothiourea[134]; the amide (**XXXV**) has been obtained in the usual way via the ester (**XXXVI**)[135]:



$$H_2N(CH_2)_3COOH \rightarrow \underset{\underset{NH}{\|}}{H_2NCNH}(CH_2)_3COOH \rightarrow$$



(XXXIV)

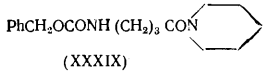


$$\rightarrow \underset{\underset{NH}{\|}}{H_2NCNH}(CH_2)_3COOMe \rightarrow \underset{\underset{NH}{\|}}{H_2NCNH}(CH_2)_3CONH_2 \quad .$$

(XXXVI) (XXXV)

During the last 15 years, a series of γ-aminobutyric acid dipeptides, including γ-aminobutyryl-L-histidine, homocarnosine (**XXXVII**), γ-aminobutyryl-*N*-methylhistidine, homoanserine, and α-(γ-aminobutyryl)-L-lysine (**XXXVIII**), have been detected in the brain tissues of various animals. Homocarmosine was isolated for the first time from ox brain in 1961 and was later detected in the brains of other animals (in appreciable amounts in the human brain). The pharmacological properties of homocarmosine, particularly its action on the CNS, have been described[136]; the anticonvulsant activity of homocarnosine had been noted earlier[137]. Together with carnosine and other histidine peptides, this compound has been proposed as one of the agents for increasing the resistance of the human and animal organism to various bacterial infections[138]. It is synthesised by the usual methods for the synthesis of peptides. The reaction of *N*-phthaloyl-γ-aminobutyric acid with L-histidine and the subsequent removal of the phthaloyl protective group lead to the dipeptide (**XXXVII**). In another procedure the *N*-benzyloxycarbonyl derivative of GABA is condensed with the methyl ester of L-histidine in the presence of ethyl chloroformate and homocarnosine (**XXXVII**) is obtained in high yields after the removal of the protective groups[139]:

The *p*-nitrophenyl ester of the *N*-benzyloxycarbonyl derivative of GABA can also be used as the starting compound for the synthesis of compound (**XXXVII**)[140].



Nakajima's group detected in the rabbit brain tissues[141] and isolated in a crystalline form[142] a dipeptide which was identified as α-(γ-aminobutyryl)lysine (**XXXVIII**). The concentration of this peptide in the brain is much lower than that of homocarnosine; it has been noted that its content in the brain and in the cerebrospinal fluid of the adult man is higher than in children, while the content of homocarnosine in the same tissues is higher in children[142]. It may be that the level of peptides (**XXXVII**) and (**XXXVIII**) in brain tissues is physiologically important, but their function has not so far been established. α-(γ-Aminobutyryl)-L-lysine has been synthesised by the mixed anhydride method involving the condensation of the *N*-benzyloxycarbonyl derivatives of GABA and L-lysine in the presence of ethyl chloroformate followed by the removal of the protective groups over palladium oxide[141]:

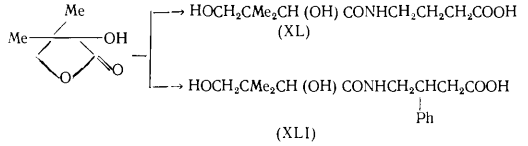
$$PhCH_2OCONH(CH_2)_3COOH + \underset{\underset{COOH}{|}}{H_2NCH}(CH_2)_4NHCOOCH_2Ph \xrightarrow[2.\ H_2/PdO_2]{1.\ ClCOOEt} \rightarrow$$

$$\rightarrow H_2N(CH_2)_3CONH\underset{\underset{COOH}{|}}{CH}(CH_2)_4NH_2 \quad .$$

(XXXVIII)

Fosker and Low[143] obtained various glutamyl derivatives of GABA in the hope that these would permeate through the HEB and would serve as an additional source of GABA; however, the compounds obtained were inactive in the biological systems tested. *N*-Benzyloxycarbonyl-γ-aminobutyric acid, which is an intermediate in the synthesis of GABA peptides, has a distinct anticonvulsant activity according to the corazole spasm and electric shock tests[94]; this is probably associated with the improvement of the transport of GABA to the brain. *N*-Benzyloxycarbonyl-γ-aminobutyrylpiperidine (**XXXIX**), which exhibits analgesic and antiacetylcholine activities, is obtained by the reaction of the *N*-benzyloxycarbonyl derivative of GABA with piperidine in the presence of condensing agents[144]:

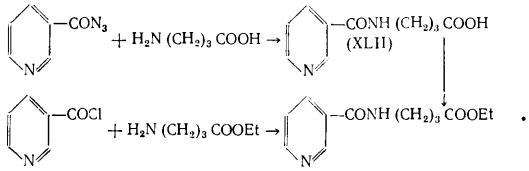
(XXXIX)



Perekalin and coworkers[145] achieved the synthesis of the dipeptides of γ-amino-β-phenylbutyric acid in order to prolong its action and to improve its permeation through the HEB. The condensation of the methyl ester of γ-amino-β-phenylbutyric acid with the *N*-benzyloxycarbonyl derivatives of α-, β-, and γ-aminoacids or of the methyl esters of α-, β-, and γ-aminoacids with *N*-benzyloxycarbonyl-γ-amino-β-phenylbutyric acid in the presence of phosphoryl chloride leads to the corresponding protected dipeptides, whose acid hydrolysis removes the protective groups and leads to the formation of the free dipeptides.

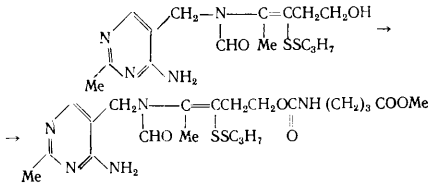
D-*N*-pantoyl-γ-aminobutyric acid (homopantothenic acid) (**XL**), which is a natural homologue of D-pantothenic acid (vitamin B_3), has been found in animal brain tissues, where it is present in amounts of 4–5 μg per gram of tissue[146].

It has been reported that the acetone powder of calf brain tissue contains an enzyme which can catalyse the condensation of pantoic acid and GABA, resulting in the formation of D-homopantothenic acid[147]; a similar enzyme has also been detected in rats[146]. However, the above synthetase has not been isolated in a pure form and its specificity has not been studied. A doubt has been expressed in a review[4] concerning the presence of homopantothenic acid in the brain.

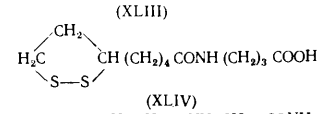


Homopanthothenic acid readily permeates into the brain[148], which indicates the importance of the pantoyl component of the molecule in passing through the HEB-lipid membrane. The distribution of [^{14}C] homopantothenic acid in various components of the mouse brain after parenteral administration[149] and its pharmacodynamics in the mouse brain have been recently investigated[150]. Extensive studies have been carried out on the biological properties[148] and therapeutic action[148,151] of compound (**XL**); the results suggest that the preparation is a new effective

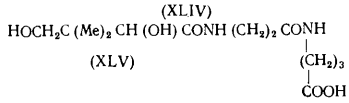
medicinal drug. The acid (XL) is synthesised by condensing D-pantolactone with GABA salts [152-154]. The introduction of the phenyl residue into the β-position of the aminoacid component of D-homopantothenic acid greatly increased its anticonvulsant activity, antagonistic in relation to thiosemicarbazide. The D-pantoyl derivative of γ-amino-β-phenylbutyric acid (XLI) has been synthesised by the action of D-pantolactone on γ-amino-β-phenylbutyric acid in the presence of diethylamine [155]:



(XLI)



One of the hypotheses concerning the causes responsible for mental illness, put forward by Pauling [156], attributes them to the disturbance of the optimum concentration of vitamins in the brain and it is suggested that high doses of vitamins be used in its treatment. In particular, it has been shown that the use of ultralarge doses of pantothenic acid [157] and particularly nicotinic acid [158] is helpful to schizophrenics. These ideas constitute the basis of the search for new neurotropic substances based on GABA and vitamins, taking into account also the transport functions of certain vitamins and their influence on the nervous system. In particular, it appeared useful to investigate the pharmacological properties of the nicotinoyl derivative of GABA (XLII), which was obtained by the reaction of nicotinoyl azide with GABA; its ethyl ester was synthesised by condensing nicotinoyl chloride with a GABA ester or by esterifying the acid (XLII). [159]



The nicotinoyl derivative of GABA and its ester exhibit a high physiological activity [160]. The GABA derivative of thiamine (XLIII) was synthesised for pharmacological study. When thiamine propyl disulphide is acted upon by phosgene, the product is *O*-chlorocarbonylthiamine propyl disulphide, the reaction of which with the methyl ester of GABA gives rise to the corresponding urethane derivative (XLIII) [161]:

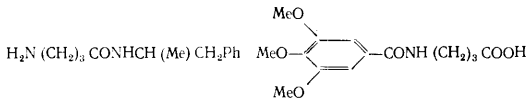
(XLIII)

(XLIV)

(XLV)

The detoxicating activity of the *N*-α-lipoyl derivative of GABA (XLIV) in poisoning with mercury and arsenic has been reported [162]. Compound (XLIV) has been obtained by condensing the mixed anhydride of α-lipoic acid [163] or its chloride [164] with GABA.

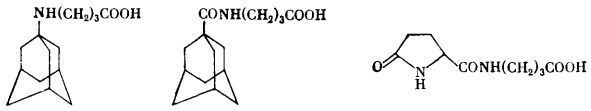
The *N*-D-pantothenoyl derivative of GABA (XLV) has been synthesised by the reaction of the mixed anhydride of D-pantothenic and ethylcarbonic acids with GABA [164]. There is no doubt that extensive investigation of the pharmacological properties of compounds (XLIII)–(XLV) as well as derivatives of GABA combines with other vitamins can be of great practical interest.



The addition of the GABA molecule to certain biologically active substances also resulted in many instances in the formation of compounds having different spectra of pharmacological activity. Bearing in mind the relatively high permeating capacity of γ-hydroxybutyric acid (GHBA) and its high neurotropic activity, γ-amino-γ-hydroxybutyrylbutyric acid (XLVI) was synthesised by condensing γ-butyrolactone with GABA [165,166]:

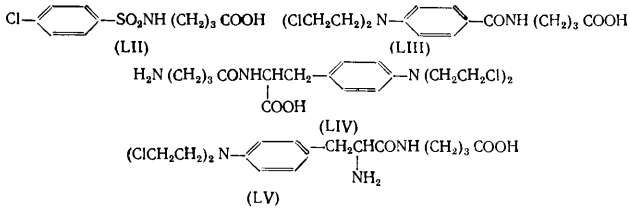
(XLVI)

The intra-abdominal administration of (XLVI) has a stronger sedative and hypothermic effect than the administration of GHBA or GABA. This is apparently due primarily to the specific influence of the entire molecule of the γ-hydroxybutyryl derivative of GABA on membranes and energetic processes in the brain tissue and not the activity of its decomposition products [167].



Gamophen (XLVII), the product of the condensation of GABA with phenamine, readily permeates through HEB and inhibits the orienting effects in white mice. The preparation has a hypothermic activity and potentiates the action of barbamyl and chloral hydrate, but, in contrast to the majority of depressants, it enhances the convulsant activity of corazole [168].

(XLVII) (XLVIII)



3,4,5-Trimethoxybenzoyl-γ-aminobutyric acid (XLVIII), which is a derivative of gallic acid, effectively prevents and suppresses in a pharmacological experiment (in doses of 100 μg kg^{-1}) the muscular tremor in white mice induced by tremorine or oxotremorine. Preliminary kinetic experiments demonstrated the possibility of using this compound in the treatment of Parkinson's disease [169] and the myocardial infarct [170]. The derivative (XLVIII) has been synthesised by the Schotten–Baumann acylation of GABA with 3,4,5-trimethoxybenzoyl chloride [171] or by the reaction of the mixed anhydride of 3,4,5-trimethoxybenzoic and ethylcarbonic acids with the ethyl ester of GABA followed by the hydrolysis of the resulting ester [170].

The introduction of the adamantyl group into the GABA molecule gives rise to γ-(1-adamantylamino)butyric acid (XLIX), which can be used in the treatment of Parkinson's desease [172]. However, it has been reported [128] that the ethyl ester of this acid does not exhibit signs of neurotropic activity. Together with antibiotic activity, the adamantoyl derivative (L) [173] exhibited a sedative effect [174]. The amide derivative of L-pyroglutamic acid and GABA (LI) shows a psychotropic activity [175].

(XLIX) (L) (LI)

In order to obtain new antidiabetic agents, the *N*-(*p*-chlorobenzenesulphonyl) derivative of GABA (**LII**) was synthesised among other compounds [176]. Attempts have been made to use GABA derivatives as antitumour agents by inserting GABA into the structure of a carcinolytic agent. GABA peptides containing the cytotoxic *N*-bis-(2-chloroethyl)amino-group, namely compounds (**LIII**) [177], (**LIV**), and (**LV**) [178], exhibited a high and selective antitumour activity.

(LII) (LIII)

(LIV)

(LV)

---o0o---

Thus the study of the pharmacological properties of a large number of GABA derivatives made it possible to discover and introduce into medical practice many effective preparations and to obtain much information about the relation between structure, physicochemical properties, and activity. In particular, it has been shown that the most active substances with depressant activity are those with substituents in the β-position and free amino- and carboxy-groups. Some data show that the manifestation of the pharmacological activity of GABA requires the presence of free amino- and carboxy-groups. At the same time, many natural and synthetic amides or esters of GABA have valuable pharmacological, including neurotropic, properties; on the one hand, this can be due to their high capacity for permeation through biological membranes with subsequent hydrolysis of the ester or amide group in the organism and, on the other hand, it may indicate the importance of the properties of the residue introduced into the GABA molecule. Analysis and survey of the results obtained empirically can play an important role in promoting a more rational synthesis of physiologically active GABA derivatives. However, the most important condition governing the specific search for new psychotropic preparations in this series is the elucidation of the molecular mechanisms of the action of GABA and its active derivatives.

The Reactivity of Aromatic Dialkenyl Compounds in Polymerisation Reactions

R.M.Nasirova, L.S.Murav'eva, E.A.Mushina, and B.A.Krentsel'

An attempt has been made for the first time to survey and describe systematically data on the characteristics of the polymerisation of aromatic dialkenyl compounds. The mechanisms of radical, cationic, and anionic polymerisations of these compounds as well as the structures of the resulting polymers, which are of theoretical and definite practical interest, are examined.
The bibliography includes 36 references.

CONTENTS

I. Introduction 692

IV. Anionic polymerisation 694
V. The dilithium catalyst based on *m*-diisopropenylbenzene 697

I. INTRODUCTION

Aromatic dialkenyl monomers (divinylbenzene and diisopropenylbenzene) are of interest for the synthesis of polymers of various structures by virtue of their ready availability and relative resistance to spontaneous polymerisation.

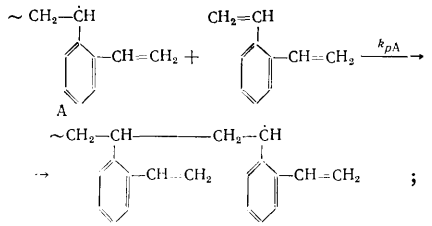
p-Diisopropenylbenzen (*p*-DIPB) polymerises in the presence of cationic catalysts to saturated and unsaturated polymers containing benzene rings in the main chain. In contrast to the *m*- and *p*-isomers, the radical polymerisation of *o*-divinylbenzene (*o*-DVB) yields a partly cyclised polymer. Anionic processes initiated by organolithium compounds give rise to considerable possibilities for the controlled synthesis of polymers with a definite set of properties, block copolymers, reactive oligomers, and polyfunctional polymerisation catalysts.

The relative reactivity of monomers in polymerisation depends on the polarity of the double bond, the stability of the active species formed when the monomer adds to the growing chain, and the steric hindrance in the transition state. In considering the radical, cationic, and anionic polymerisations of aromatic dialkenyl compounds, we therefore took these factors into account.

II. RADICAL POLYMERISATION

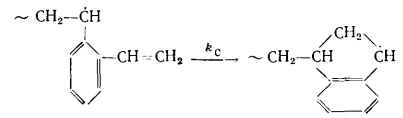
The reactivity of substituted styrenes in radical polymerisation has been widely studied[1]. Styrene is known to have a high electron density in the double bond (−0.80). The benzyl radical is greatly stabilised as a result of conjugation with the benzene ring. Depending on the type of group introduced and its position, in ring-substituted styrenes there is a possibility of both an increase and a decrease of the resonance stabilisation of the radical. The replacement of the hydrogen in the vinyl group of styrene can also influence the polarity of the monomer, the resonance stabilisation of the corresponding radical, and the steric hindrance in the transition state. Thus the presence of the methyl group in the α-position makes the vinyl group more electronegative but less reactive than the vinyl group in styrene, which can be due to steric hindrance.

A substituent in the *para*-position is known to influence the reactivity of styrene; *meta*-substitution has little or no influence on its reactivity. Hart[2] explains this difference by the fact that the *meta*-isomer is incapable of involvement in the resonance stabilisation of the charge, while the *para*-isomer is involved in this type of stabilisation.



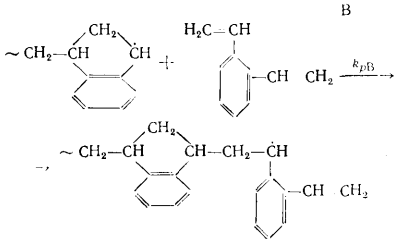
In radical polymerisation the propagation rate constants for the given polymer depends both on the reactivity of the monomer itself and on the reactivity of the radical formed from it. Thus an increase of conjugation energy, which tends to increase the stability of the radical, also increases the reactivity of the initial monomer[3].

It has been shown[4] that *m*- and *p*-divinylbenzenes are fairly actively involved in copolymerisation with styrene, forming three-dimensional copolymers. The copolymerisation of *m*- and *p*-divinylbenzenes with styrene, initiated by benzoyl peroxide, has been studied[5]. Analysis of the copolymer for a degree of conversion of 2−3% led to the following constants for the copolymerisation of styrene (r_1) with *m*-divinylbenzene (r_2) and of styrene (r_1') with *p*-divinylbenzene (r_3): $r_1 = 0.54$; $r_2 = 0.58$; $r_1' = 0.15$; $r_3 = 1.22$, i.e. the vinyl group in *p*-divinylbenzene is more reactive than in *m*-divinylbenzene.



There is a reversal of reactivities in the homopolymerisation of *m*- and *p*-divinylbenzenes using isobutyrodinitrile as the initiator: *m*-divinylbenzene is more reactive than *p*-divinylbenzene, i.e. the alkenyl group in the *para*-position has a stabilising influence on the *p*-divinylbenzene radical[6]. The homopolymerisation of *p*- and *m*-divinylbenzenes has also been studied in the presence of benzoyl peroxide up to the gel point[7]. It was shown that the *meta*-isomer is also more reactive.

In contrast to *m*- and *p*-divinylbenzenes, the polymerisation of *o*-divinylbenzene yields in most cases soluble polymers containing five-membered rings and double

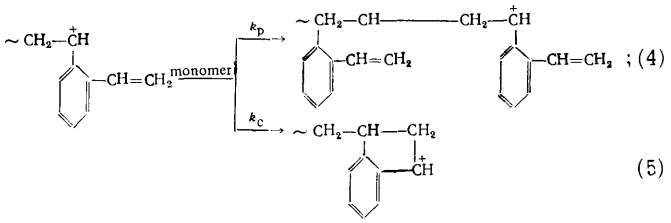


bonds in the side chain. *o*-Divinylbenzene has been polymerised at different temperatures in the presence of α,α'-azobisisobutyronitrile in benzene [8]. The residual unsaturation was determined spectroscopically and by bromination in CCl_4. The study led to three chain propagation mechanisms:

(1)

(2)

(3)



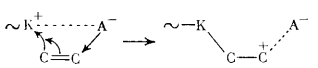
The content of monomeric units with vinyl groups diminishes with increase of the concentration of the monomer in the initial mixture and with increase of polymerisation temperature, since favourable conditions are then created for cyclisation. This finding can be explained by the difference between the activation energies for the propagation of the polymeric chain [reaction (1)] and for the intramolecular cyclisation reaction [reaction (2)]: the growing radical A has a somewhat greater resonance energy than the styrene radical and the cyclic radical B has a smaller resonance energy.

Like other allylic compounds, DIPB has a mobile hydrogen atom at the α-carbon atom. As a result of this, the copolymerisation of various monomers with DIPB leads to copolymers with a low molecular weight [9-11]. The rate constants for chain transfer to DIPB, found from the dependence of the degree of polymerisation of styrene on the concentration of the divinyl monomer in the initial mixture, have been published [12]. They are $8.59 \times 10^{-2} \pm 1.5 \times 10^{-5}$ for *m*-DIPB and $8.43 \times 10^{-2} \pm 3.6 \times 10^{-5}$ for *p*-DIPB (evaluated by the method of least squares), i.e. they are fairly large and almost equal, regardless of the position of the isopropenyl groups in the benzene ring.

III. CATIONIC POLYMERISATION

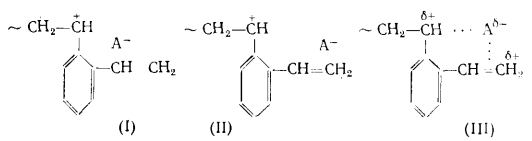
The cationic polymerisation of aromatic dialkenyl hydrocarbons was studied previously [13,15] in relation to *o*-divinylbenzene and *p*-di-isopropenylbenzene.

It is suggested that the *o*-divinylbenzene chain propagation reaction includes two competing stages: intermolecular propagation [reaction (4)] and intramolecular cyclisation [reaction (5)]:



(4)

(5)

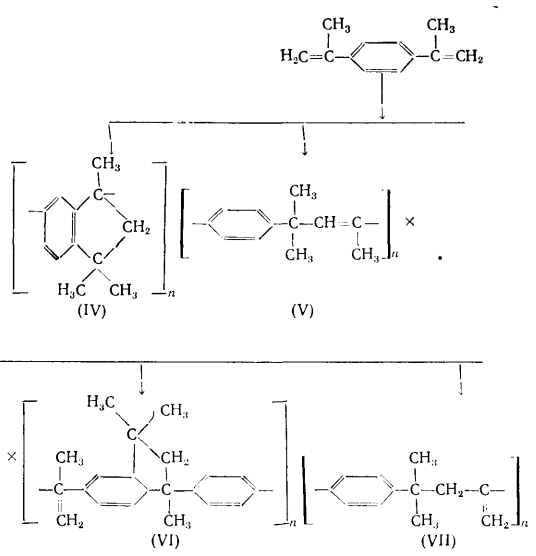


The cyclisation constant is defined as the ratio of two constants:

$$r_c = \frac{k_c}{k_p}$$

In cationic polymerisation, particularly in media with a low dielectric constant where the counterion is linked to the growing centre, the step involving the growth of the polymeric molecule can be represented as a result of the concerted donor–acceptor action by the carbonium ion–counterion pair on the double bond of the monomer:

The structure of the growing ion pair therefore depends on the nature of the anion. Thus the following cases are possible:



(I) (II) (III)

(Here A^- is the counterion).

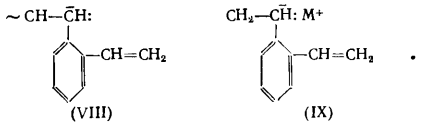
An interesting correlation has been found between r_c and the primary ionisation potential of the metal [13,14]. Thus the sequence of primary ionisation potentials Al > Ti > Sn > Fe > B > Zn agrees with the variation of r_c (excluding Ti and Sn). Strong Lewis acids lead to the ion pair (I) and a low value of r_c. [15] The weak interaction of the cation with the counterion permits the formation of the active cation (II) or the spreading of the positive charge to the vinyl group of (III) which failed to react. In polar highly solvating media the carbonium ion can form a free ion pair. The interaction with the vinyl group is therefore evidently replaced by the interaction with the molecules of the polar solvent, reducing the contribution of intramolecular cyclisation. The constant r_c increases with increasing temperature: 0.22 mole litre^{-1} at −20°C and 1.2 mole litre^{-1} at 20°C [15] (for divinylbenzene).

It has been shown [16,17] that *p*-DIPB polymerises under the influence of a cationic catalyst ($TiCl_4$, $SnCl_4$) to saturated and unsaturated polymers containing benzene rings

in the main chain:

(IV) (V)

(VI) (VII)



The polymers obtained exhibit a high heat resistance and thermal stability. It has been established on the basis of infrared spectroscopic data [17] that the saturated polymers have structure (IV) (an indan structure), while unsaturated polymers have structures (V)–(VII).

IV. ANIONIC POLYMERISATION

Evidently the possibility of the interaction of the π electrons of the double bond with the active centre in cationic polymerisation promotes cyclisation, whereas this type of interaction is less likely in anionic polymerisation. The polymerisation of *o*-divinylbenzene in the presence of anionic catalytic systems has been investigated [18] under different conditions. It was established that the cyclisation constant in anionic polymerisation is smaller than in the free-radical and cationic polymerisations. It is 2–4 mole litre^{-1} in free-radical polymerisation, 0.1–5 mole litre^{-1} in cationic polymerisation, and in most cases less than 1 mole litre^{-1} in anionic polymerisation.

The influence of solvent polarity, the nature of the alkali metal, and reaction temperature on the cyclisation constant has also been studied [18]. It follows from the experimental data that r_c increases with increasing solvent polarity in the sequence: tetrahydrofuran < ether < dioxan. The constant r_c in tetrahydrofuran varies with increasing temperature from 0.05 mole litre^{-1} at −78°C to 0.56 mole litre^{-1} at 20°C.

The nature of the solvent and the alkali metal (M) is known to influence the reactivity of the ion pair in anionic polymerisation. The uncyclised anion of *o*-divinylbenzene can exist as the free ion (VIII) and the ion pair (IX):

(VIII) (IX)

It was noted that the addition of $NaBPh_4$ to the polymerisation system lowers the reactivity of the ion pair and r_c. A free-anion propagation has therefore been suggested [18] for intramolecular cyclisation. As shown in Fig. 1, r_c diminishes also with increasing ionic radius of the counterion ($Li^+ > Na^+ > K^+$) in tetrahydrofuran; in dioxan the sequence based on the variation of r_c is reversed. It is suggested that the maximum degree of solvation of the Li^+ ion in tetrahydrofuran leads to the most reactive ion pair. In ether r_c diminishes in the sequence $K^+ > Li^+ > Na^+$. [18] The constant r_c in ether (dielectric constant $\epsilon = 4.3$ at 20°C) is intermediate between the value in tetrahydrofuran ($\epsilon = 7.4$ at 25°C) and in dioxan ($\epsilon = 2.2$ at 25°C).

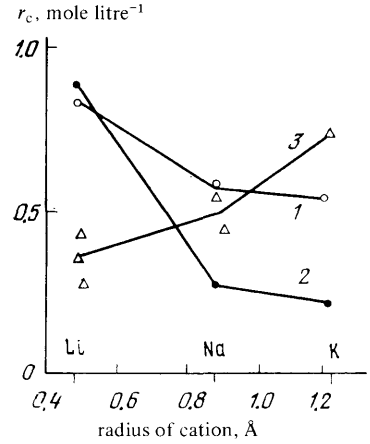


Figure 1. The effect of the counterion on the cyclisation constant of *o*-divinylbenzene in tetrahydrofuran: 1) at 20°C; 2) at 0°C; 3) the effect of the counterion on the cyclisation constant in dioxan at 20°C.

Thus one may conclude that the higher the reactivity of the growing ion pair, the greater the cyclisation constant.

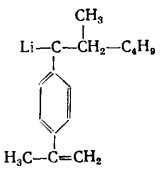
The available data for the influence of the monomer structure on the rate of chain propagation refer mainly to the addition of free ions. The kinetics of many anionic polymerisation processes involving vinyl compounds in tetrahydrofuran with Na^+ as the counterion have now been investigated. The copolymerisation data are most important. Thus the following bimolecular rate constants have been obtained for the addition of a series of dienes to living polystyrylsodium in tetrahydrofuran at 25°C: [19]

Diene	$k_{1,2}$, litre mole^{-1} s^{-1}
Butadiene	32.7
Isoprene	17.0
2,3-Dimethylbutadiene	0.4 - 0.5

Such decrease of the rate can be explained both by the inductive effect of the methyl groups and by steric factors.

In the study of the copolymerisation of α- and β-methylstyrenes with "living" polystyrylsodium it was shown that both isomers are 40–50 times less reactive than styrene.

Steric hindrance is responsible for the very low reactivity of vinylmesitylene. In this case the breakdown of the coplanarity of the vinyl and phenyl groups lowers the reactivity of the monomer[20].



A detailed study of the relation between the structure of the monomer and its reactivity was carried out by Shima et al.[21]; the results are presented in Table 1.

Table 1. The rate constants $k_{1,2}$ for the addition of styrene derivatives to polystyrylsodium in tetrahydrofuran at 25°C.

Monomer	$k_{1,2}$, litre mole^{-1} s^{-1}
Vinylmesitylene	0.9
β-Methylstyrene	18.0
α-Methylstyrene	27.0
p-Methoxystyrene	50.0
p-t-Butylstyrene	110.0
2,4-Dimethylstyrene	160.0
p-Methylstyrene	180.0
o-Methylstyrene	320.0
Styrene	950.0

All the data examined above show that the addition of styrene derivatives to polystyrylsodium has a nucleophilic mechanism.

It might have been expected that the presence of the isopropenyl group in the *para*-position in *p*-DIPB would facilitate the addition of n-butyl-lithium to one of the two isopropenyl groups as a result of the increase in the length of the conjugated chain. However, the compound obtained is not capable of reacting further with n-butyl-lithium under the same conditions owing to the presence of an electron-donating substituent in the *para*-position relative to the isopropenyl group.

The reactivity of hydrocarbon monomers in anionic polymerisation processes has been studied mainly in relation to styrene, its derivatives and dienes. The determination of the characteristics of the anionic polymerisation of aromatic dialkenyl monomers is important for the determination of the relation between the reactivity of the active centres and their structure. The principal features of the anionic-coordination polymerisation of *p*-DIPB have been investigated[22]. The kinetic curves for the polymerisation of *p*-DIPB in benzene at 50°C at different *p*-DIPB and n-butyl-lithium (n-BuLi) concentrations are illustrated in Figs. 2 and 3. The study of the dependence of the rate of polymerisation of *p*-DIPB on the concentrations of the monomer and the initiator showed[22] that the rate of polymerisation is directly proportional to the monomer and initiator concentrations: $w = k[M][n\text{-BuLi}]$. The overall activation energy for this process in the temperature range 30–50°C is 15.3 ± 1.5 kcal mole^{-1}.

The chain propagation reaction under the influence of organolithium compounds is known to involve the interaction of the monomer molecules with an unassociated active centre[23,24].

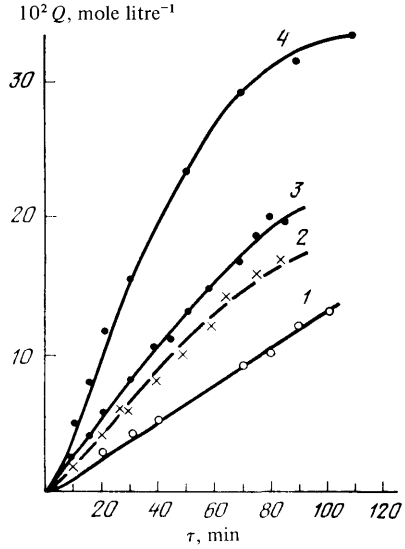


Figure 2. Kinetic curves for the polymerisation of *p*-DIPB under the influence of n-butyl-lithium in benzene at 50°C at different molar n-butyl-lithium concentrations: 1) 1.6×10^{-2}; 2) 3.5×10^{-2}, 3) 5.3×10^{-2}; 4) 8.4×10^{-2}; Q—the conversion of the monomer.

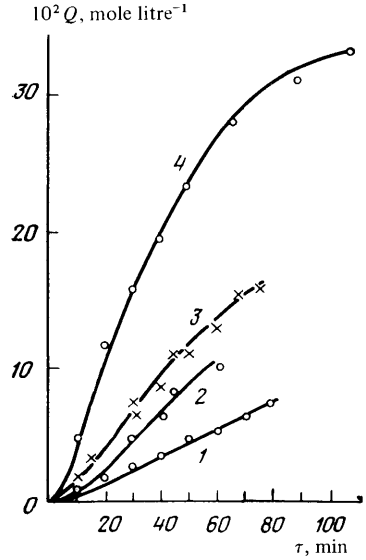

Figure 3. Kinetic curves for the polymerisation of *p*-DIPB under the influence of n-butyl-lithium in benzene at 50°C and different molar monomer concentrations: 1) 0.2; 2) 0.4; 3) 0.6; 4) 0.88.

It has been shown that the number of molecules in the associated species (n) and the stability of the latter increase in the sequence α-methylstyrene < isoprene < butadiene, i.e. the increase of the number and size of substituents in the carbanionic component of the active centre hinders association. Thus estimates by the kinetic method gave $n = 6$ for lithiopolybutadiene, 4 for polyisoprene, and 2 for polystyrene and poly-α-methylstyrene. The steric factors for p-DIPB fully inhibit association, as shown by the identical flow times of solutions of living and deactivated polymers at 50°C.[25]

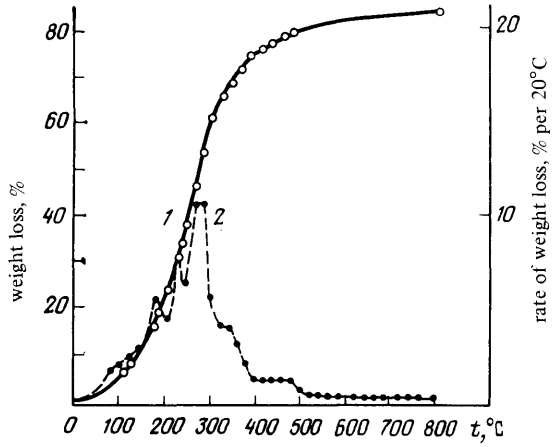

Figure 4. A gravimetric study of poly-p-DIPB in an atmosphere of argon: 1) weight loss (%); 2) rate of weight loss (% per 20°C).

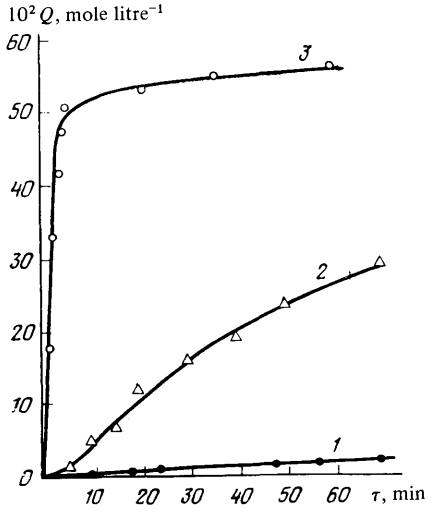

Figure 5. Kinetic curves for the polymerisation of α-methylstyrene (curve *1*), p-DIPB (curve *2*), and m-DIPB (curve *3*) in benzene.

The structure of poly-p-DIPB has been studied by infrared[26,27] and NMR spectroscopy[28]. It has been established on the basis of the changes in the intensity of the overtone C=CH_2 bond vibration band (1785 cm^{-1}), relative to the stretching vibration band (1620 cm^{-1}) characterising the vibration of the p-substituted benzene ring, that only one isopropenyl group is involved in the polymerisation of p-DIPB. The presence of the following structural elements has been established on the basis of the NMR spectra of the polymer: $CH_3-C\lesssim$ (chemical shift $\delta \simeq 0.4$ p.p.m.), $\gtrsim C-CH_2C\lesssim$ ($\delta = 1.4$ p.p.m.), $CH_3C=$ (two partly resolved peaks with $\delta = 2.05$ and 2.13 p.p.m.), CH_2 (several signals in the range $\delta = 5-5.4$ p.p.m.), and p-C_6H_4 (three peaks with $\delta = 6.6$, 6.9, and 7.2 p.p.m.).[28]

According to the results of thermomechanical analysis of poly-p-DIPB and the p-BIPB–butadiene copolymer, the glass point of poly-p-DIPB is 115°C and the yield point is 165°C; the glass point of the p-DIPB–butadiene copolymer is 41°C. A gravimetric study in an atmosphere of argon showed that the maximum extent of the main decomposition reaction of poly-p-DIPB is observed (on the basis of the overall weight loss of 88%) at 260–280°C (Fig. 4).[25]

In order to elucidate the influence of the second isopropenyl group on the polymerisation reaction under the influence of n-butyl-lithium, the authors[22] compared the reactivities of p-DIPB, m-DIPB, and α-methylstyrene. The kinetic curves for polymerisation in benzene (at 50°C) and in tetrahydrofuran (at 28°C), at monomer and initiator concentrations of 0.88 and 0.08 M respectively, established that the reactivities of the monomers decrease in the sequence m-DIPB > p-DIPB > α-methylstyrene[22,29] (Fig. 5).

Table 2. The electrical conductivities of solutions of "living" α-methylstyrene, p-DIPB, and m-DIPB polymers in tetrahydrofuran (cell constant 2.8×10^{-2} cm^{-1})*.

Solution	Resistance, Ω	κ, Ω^{-1} cm^{-1}	$10^{-3}\Lambda$, Ω^{-1} mole^{-1} cm^2
Poly-α-methylstyryl-lithium	$4.6 \cdot 10^5$	$6.0 \cdot 10^{-7}$	$7.1 \cdot 10^{-6}$
Poly-p-DIPB-lithium	$6.0 \cdot 10^4$	$4.7 \cdot 10^{-6}$	$5.6 \cdot 10^{-5}$
Poly-m-DIPB-lithium	$15.0 \cdot 10^3$	$1.9 \cdot 10^{-5}$	$1.2 \cdot 10^{-3}$

*Notation: κ is the specific conductance and Λ the molar conductance.

The high relative reactivities of m- and p-DIPB in the chain propagation steps in polymerisation in the presence of n-butyl-lithium can probably be explained by the decrease of the energy of interaction of the components of the ion pair due to steric factors (the branching of the carbanion). The experimental electrical conductivities of solutions of "living" polymers (Table 2) indicate an increase of the polarity of the lithium–carbon bond on passing from α-methylstyrene to p- and m-DIPB and show that the energy of the interaction of the components of the ion pair of the active centre decreases with increasing role of steric factors[25].

The electronic absorption spectra of "living" p- and m-DIPB polymers[25] (Table 3) showed that, when a more electron-donating solvent is used, the absorption maximum

undergoes a bathochromic shift and λ_{max} for poly-*p*-DIPB-Li, which is close to λ_{max} for 1,1-diphenylalkyllithium (428 μm), is evidently determined by the branching of the carbanion. With decrease of the stability of the associated species owing to steric hindrance, the relative content of the monomeric form increases and therefore at fairly high n-BuLi concentrations (10^{-3} M) there is a bathochromic shift of the absorption maximum on passing from benzene to tetrahydrofuran.

Table 3. The absorption spectra of "living" *p*- and *m*-DIPB polymers (25°C, n-BuLi concentration 10^{-3} M).

Monomer	Solvent	λ_{max}, nm
m-DIPB	benzene	335
m-DIPB	tetrahydrofuran	405
p-DIPB	benzene	424-425
p-DIPB	tetrahydrofuran	448-450

Table 4. The half-wave potentials (relative to the saturated calomel electrode).

Substance	$-E_{1/2}$, V	$I_c = i^*_{lim}/c$, A mole^{-1}
α-Methylstyrene	2.619	$2.3 \cdot 10^3$
p-DIPB	2.448; 2.691	$2.15 \cdot 10^3$, $2.9 \cdot 10^3$
m-DIPB	2.617	$4.6 \cdot 10^3$

*Notation: I_c is the specific current, i_{lim} the limiting current, and c the concentration of the given substance in solution.

Thus the characteristics of the propagation reaction and the nature of the structure of the active centres in the anionic polymerisation of aromatic dialkenyl monomers under the influence of n-butyl-lithium have been elucidated by kinetic, spectrophotometric, and conductimetric methods [27].

V. THE DILITHIUM CATALYST BASED ON *m*-DIISOPROPENYLBENZENE

In the polarographic determination of the electron affinities of α-methylstyrene, *p*-DIPB, and *m*-DIPB, (Table 4) it was found [29] that the addition of electrons to the isopropenyl groups in *m*-DIPB takes place independently; in *p*-DIPB the influence of the isopropenyl groups is manifested by the formation of two separate waves and a considerable displacement of the value of $E_{1/2}$ for the first wave relative to that for α-methylstyrene. Consequently n-butyl-lithium can add to the two isopropenyl groups in *m*-DIPB. This phenomenon, which was previously unknown for the given class of compounds, has been used to obtain dilithium catalysts based on *m*-DIPB. [29] The 890–900 cm^{-1} band was found to be missing from the infrared spectrum of the product of the carboxylation of dilithio-*m*-diisohexenylbenzene, which indicates the simultaneous addition of n-butyl-lithium to the two isopropenyl groups. The 1,3-disubstitution of the ring is responsible for the appearance of bands at 720 and 805 cm^{-1}; the 860 cm^{-1} band refers to the vibrations of the C=O group of the carboxyl. The results of the elemental analysis of this compound are in good agreement with the calculated values [29].

The molecular weight of polystyrene (W), determined from the intrinsic viscosities, was consistent with the relation [30]

$$W = 2M/N,$$

where M is the amount (in grams) of the polymerised monomer and N is the number of moles of catalyst which have been consumed. Consequently the active centres are dianions. The activity of the dilithium catalyst based on *m*-DIPB in the polymerisation of styrene is close to that of s-butyl-lithium (Fig. 6).

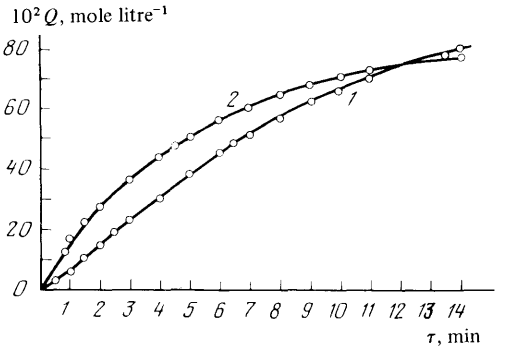

Figure 6. Kinetic curves for the polymerisation of styrene in the presence of dilithio-*m*-diisohexenylbenzene (curve *1*) and *s*-butyl-lithium (curve *2*) at 40°C; lithium concentration 3×10^{-3} M; styrene concentration 1 M; solvent—benzene.

The use of organodilithium compounds leads to extensive possibilities for the synthesis of ternary block copolymers of the type ABA and oligomers with terminal functional groups [31–36]. The previously known dilithium polymerisation initiators are largely insoluble in hydrocarbons or require the use of a homogenising comonomer, are frequently unstable, and require prolonged preparation.

Disodio, dilithio-, and dirubidio-α-methylstyrene tetramers, formed in the reaction between the alkali metal and a solution of α-methylstyrene in electron-donating media, have been described in the literature [34,35].

---o0o---

Thus the literature data examined in the present paper review and their analysis reveal the considerable possibilities for the employment of aromatic dialkenyl compounds in macromolecular chemistry.

The Sedimentation of Polydisperse Polymers

I.K.Nekrasov

The most important problems in the sedimentation of one component of two-component mixtures and polydisperse polymers have been discussed. Particular attention has been paid to the application of theory in the treatment of sedimentation data. It has been shown that to calculate the molecular mass distribution (MMD) from sedimentation diagrams of polydisperse polymers, the best theory is that based on the Trautman relationships describing the Johnston-Ogston effect for the case of a binary mixture, the concept of local concentration, and the principle of additivity of the paired interactions of the components of the mixture. Allowance for the diffusion broadening of the curves is made using Fujita's theory by means of model functions. The distribution with respect to the sedimentation coefficients (or the MMD) is calculated by means of a computer from one recording. The bibliography contains 99 references.

I. INTRODUCTION

One of the chief methods for determining the molecular mass distribution (MMD) of synthetic polymers is by the velocity sedimentation of polymer solutions in the ultracentrifuge[1-4].

The theoretical principles of the method of velocity sedimentation were formulated at an early date[5], various aspects of the application of the method to specific systems have been dealt with in many reviews and monographs[2-15], and the construction of ultracentrifuges is being improved[15-17]. Nevertheless, velocity sedimentation has not found extensive application in research by synthetic chemists. Both theoretical problems in the analysis of polymerisation mechanisms[18] and technical problems in modelling synthesis processes and the selection of reactor design[19,20] require rapid determination of the MMD. The generally adopted extrapolation method[2-6] for finding the MMD is too cumbersome and tedious, however, and the single-concentration and single-recording approximations[3,21-26] have insufficient theoretical foundation. The method of equilibrium sedimentation in an ideal solvent, which has good theoretical basis[2-7,11-15], is not used in practice to determine the MMD of polydisperse polymers. This method is inconvenient chiefly because it is necessary to carry out the ultracentrifuging of the polymer solutions for a long period (several days).

The form of the boundary in the sedimentation of a polydisperse polymer depends not only on the non-uniformity of the specimen but also on a number of other factors: the hydrostatic pressure, diffusion, the concentration dependence of the sedimentation coefficients S, the sector form of the cell, and the cross-term hydrodynamic interactions of the components—the Johnston-Ogston effect (JOE).[3,13,14,27-29] In spite of some progress in the understanding of the nature of these effects, there is no simple and reliable method which makes it possible to take account of all the factors influencing the form of the sedimentation boundary. It is obviously appropriate to raise the question of the influence of a given factor on the form of the sedimentation distributions, their dependence on the properties of the polymer-solvent system, the average molecular masses, the polydispersity, and the type of MMD curve. In particular, neither the hydrodynamic[30-32] nor the thermodynamic[33-35] aspects of the influence of the hydrostatic compression of the solvent on the sedimentation and flotation (negative sedimentation)[36-42] of solutions of polydisperse polymers have been fully studied.

The present review examines the sedimentation of one- and two-component† systems and polydisperse synthetic polymers, except for the special problems of the sedimentation of biological materials[7]. In the examination of the first two problems, only some fundamental questions will be dealt with.

II. SEDIMENTATION OF ONE COMPONENT

Velocity sedimentation gives directly the distribution $g(S_0)$ (S_0 is the sedimentation constant) of a polydisperse polymer. The molecular mass distribution $g(M)$ (M is the molecular mass) is then found from the equations

$$S_0 = K_S M^\gamma, \quad M = (S_0/K_S)^{1/\gamma}; \tag{1}$$

$$g(M) = \gamma S_0 g(S_0)/M, \tag{2}$$

where K_S and γ are constants for a series of polymer homologues in a given solvent. It can be seen that to determine the MMD from Eqns. (1) and (2) it is necessary to find both the sedimentation constants and the absolute molecular masses of the polymer fractions (preferably narrow).

The study of the sedimentation of the fractions is of not only practical but also theoretical interest (for the comparison of the results with conclusions reached from theory)[13,14]. To anticipate slightly, it may be noted that it is only for the sedimentation of one component that a rigorous theoretical approach has been developed[13,14] and

† Here and subsequently, reference is made to hydrodynamic and not thermodynamic components, that is the solvent is regarded not as a component but as the medium.

the molecular parameters of the solute and the solvent used to calculate the time dependence of the radial distribution of the concentration in the cell[13,14,43-49].

Polymers in all solvents, including thermodynamically ideal, are characterised by the following concentration dependence of the sedimentation coefficients:

$$S=S_0/(1+kc), \tag{3}$$

where S is the sedimentation coefficient of the component (fraction), c the concentration, and the coefficient k characterises the hydrodynamic interactions of identical macromolecules (which also depend on the thermodynamic properties of the system). A theoretical interpretation of the parameter k has been given[50,51], and in the study of fractions, extensive experimental material has been accumulated on the relationship between k and the characteristics of the polymer chains[3,36,52-62].

The influence of pressure P on the sedimentation coefficients is taken into account by means of the parameter μ:[2-15,43-49,53,63,64]

$$S^P=S^1/(1+\mu P), \tag{4}$$

or

$$S^P\approx S^1(1-\mu P), \tag{4a}$$

where S^P and S^1 are the sedimentation coefficients at pressures P and 1 atm respectively. It can be seen that Eqn. (4a) is a particular case of the more general equation (4), but before the work of Jones and coworkers[44-48], the theoretical analysis of sedimentation processes was based on Eqn. (4a). Eqns. (4) and (4a) lead to the following equations:

$$S^P=S^1/[1+m(r-1)],\ r=(x/x_0)^2; \tag{5}$$

$$S^P=S^1[1-m(r-1)]; \tag{5a}$$

$$m=\frac{1}{2}\mu\rho_0 x_0^2\omega^2, \tag{6}$$

where x and x_0 are the running coordinate and the coordinate of the meniscus respectively, ρ_0 the density of the solvent, and ω the angular rate of rotation of the rotor of the ultracentrifuge.

With allowance for the concentration dependence of the sedimentation coefficient, the influence of pressure and diffusion, and also the sector form of the cell, the equation for the ultracentrifuge was solved[48] by a numerical method, that is the time dependence of the radial distribution of the concentration and the concentration gradient was calculated. These calculated characteristics show good agreement with the experimentally observed relationships. It is usually necessary, however, to solve the inverse problem—to find the molecular parameters from experimental data. It was found that any analytical expressions describing sedimentation in terms of the coordinate of the boundary and time are approximate. The relative error between the exact (numerical) and approximate (analytical) solutions is 3% for S_0 and 12% for m. The theory[48] does not take account of the reflection of macromolecules from the meniscus[13,14] or the pressure dependence of the diffusion coefficient[49]. Moreover, in the analysis of experimental data, the correction for dispersal should not be forgotten[21,65,66]. In view of the approximate nature of the simple analytical expressions, it has been suggested[48] that the variable coordinate of the meniscus be used in calculations in the treatment of experimental data.

In spite of these unsatisfactory features, the theory[48] marks an important stage in the development of velocity sedimentation and makes it possible to interpret reliably the experimental data on the sedimentation of fractions of synthetic polymers. The most important conclusions from this work are examined below.

1. In agreement with experimental data[30,67], in the sedimentation of one component, there is produced a plateau region in which there is no concentration gradient.

2. The concentration in the range of the plateau (c_a) is given by the expression

$$c_a=c_0[1+m(r-1)]/r, \tag{7}$$

where c_0 is the initial concentration. Thus the simple dilution law $c_a = c_0/r$ is realised only in the limit as $m \to 0$. For $m = 1$, there is not change in concentration with time in the range of the plateau: $c_a(t) = c_0$; a value $m < 1$ corresponds to dilution, and $m > 1$ corresponds to concentration in the sedimentation process.

3. The determination of the position of the boundary from the second moment of the distribution of the displacements[3,13,21,43,53,65,68] is justified only for the limiting case[69] ($m = 0$, $c_a = c_0/r$) of the sedimentation of one component.

4. The following equation is proposed[48] for the determination of S_0 and m

$$\ln r/(2\omega^2 t)=B/2\omega^2 t+E+H\cdot 2\omega^2 t,$$

where t is the time, and B, E, and H are constants which are found by the least squares method. The constant B corresponds to the displacement of the meniscus (by not more than 1.2 mm), and can apparently partly compensate the effects of reflection from the meniscus and the displacement of the actual start of sedimentation. If the constants E and H are calculated, S_0 and m can be determined from the equations:

$$S_0=(1+\alpha)E,\ \alpha=kc_0;$$

$$m=[1/(2\alpha+1)]\cdot\left[\alpha-\frac{(1+\alpha)H}{E^2}\right].$$

5. Fujita's equation[13,14,43] has been widely used in the treatment of experimental data

$$S=\ln r[1-R(r-1)]/2\omega^2 t\ \ R=-\frac{m}{2}+\left(\frac{1-m}{2}\right)\frac{kc_0}{1+kc_0} \tag{8}$$

and is applicable for small values of m.

6. The fact that $\ln x$ or $\ln r$ are linearly dependent on t does not indicate that the effects of compression and dilution are compensated, just as extrapolation to the meniscus does not guarantee that complete allowance has been made for the influence of pressure. As already noted, this is due to the inadequacy of the simple analytical expressions for the actual sedimentation of a polymer fraction, characterised by a definite polydispersity.

7. In a number of cases[21,59,60,70], an increase in the coefficient k with increase in the angular rate of rotation of the centrifuge rotor ω has been detected. This effect is usually related to an increase, with increase in ω, in the average concentration in the region of the plateau, corresponding to the experimental range of change in the coordinate x; this leads to a decrease in S and hence to an increase in k. It is not accidental that with decrease in the molecular mass, the magnitude of this effect decreases.

8. The scatter in the values of m or μ determined by different methods[26] or even by the same method[21] is due both to the approximate nature of the original analytical

expressions and to the fact that these parameters are determined from small changes in the sedimentation coefficients.

III. SEDIMENTATION OF TWO COMPONENTS

The sedimentation of two macromolecular components is accompanied by cross-term hydrodynamic interactions, leading to an increase in c and a decrease in S for the slow component, and to a decrease in c and an increase in S for the fast component. Some experimental data[71] on the Johnston–Ogston effect will be examined.

Table 1. Characteristics of PαMS specimens[71].

Specimen	10^{-6} M	S_0, Svedberg units	k, dl g^{-1}	Solvent
A–S	0.73	13.89	0.489	cyclohexane
A–F	1.52	19.47	0.648	cyclohexane
B	0.46	11.37	1.98	toluene
C	1.38	17.78	4.01	toluene

Figure 1. Sedimentation diagram for a mixture of specimens A–S and A–F PαMS in cyclohexane: $c_0 = 0.316$ g dl^{-1}, 35°, $\omega = 59\,780$ r.p.m.

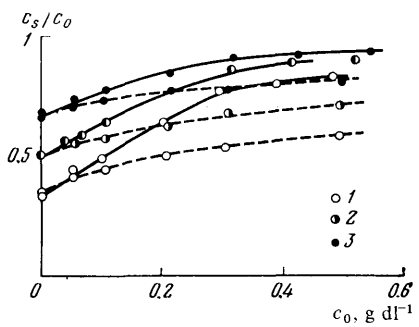

Figure 2. Dependence of the apparent relative concentration of the slow component of PαMS on the total initial concentration. The broken lines correspond to a mixture of specimens A–S and A–F in cyclohexane: *1*) $c_F^0/c_S^0 = 1.848$; *2*) 1.00; *3*) 0.478. The continuous lines give the data for a mixture of specimens B and C in toluene: *1*) $c_F^0/c_S^0 = 1.957$; *2*) 1.00; *3*) 0.498.

Fig. 1 gives the sedimentation diagram of a specimen A of poly-α-methylstyrene (PαMS) in cyclohexane (CH) at 35° (close to the θ-point). This specimen was obtained by anionic polymerisation[72] with the simultaneous use of mono- and bifunctional initiators, and is practically a mixture (1 : 1) of two specimens A–S and A–F (see Table 1). It can be seen that there is a marked difference in the areas under the peaks, although the original concentrations of the components are identical. Similar sedimentation diagrams were obtained for mixtures of specimens B and C. Fig. 2 gives the dependence of the apparent relative concentrations of the slow component of PαMS on the total initial concentration. The Johnston–Ogston effect (the increase in the concentration of the slow component) is clearly observed in both toluene and cyclohexane, but the effect is much greater in the thermodynamically good solvent (toluene) than in the ideal solvent (cyclohexane).

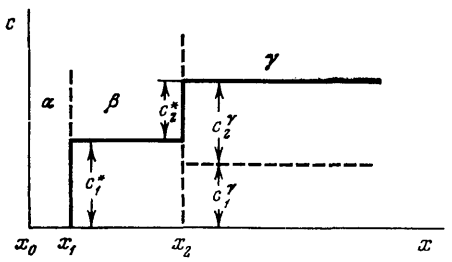

Figure 3. Schematic representation of the dependence of the concentration c on the coordinate x in the cell of the ultracentrifuge in the sedimentation of a two-component mixture.

A theory of the effect has been given[29] on the basis of the ideas of Johnston and Ogston[27]. The sedimentation of a two-component mixture can be considered; the slow component is denoted by the index 1, and the fast component by the index 2; the sedimentation constants of the components are S_{01} and S_{02} respectively, and $S_{02} > S_{01}$. At some moment of time in the cell of the ultracentrifuge, the dependence of the total concentration c on the coordinate x has the form shown in Fig. 3 (if the influence of diffusion is neglected). Here and subsequently it is assumed that the increments in the refractive indices of the components are identical, and that any optical system of the centrifuge can be used to determine this relationship. The α-region corresponds to the pure solvent, the β-region corresponds to the sedimentation of component 1, and in the region of the γ-plateau, movement of both components takes place (Fig. 3). The concentrations c_1^* and c_2^* are recorded directly. The expressions

$$p_i = c_i^* r_i / c_i^0, \quad i = 1, 2, \tag{9}$$
