r_{AMM}	0.2	1.0	1.0	3.5

The addition of water has virtually no influence on the copolymerisation constant for methyl methacrylate in both cases. Unfortunately no data are presented in the above communication[94] concerning the phase state of the reaction system and also the yields of the copolymers, so that it is difficult to account for the observed inconsistency with data obtained elsewhere[22,89,90].

The influence of hydrogen bonds between monomers and solvents on the reactivity of the former has been demonstrated particularly clearly in a series of studies[95–99]. The

copolymerisation constants for acrylamide, methacrylamide, *N*-methylacrylamide, and *N*-(1,1-dimethyl-3-oxobutyl)acrylamide (diacetoneacrylamide) with methyl methacrylate or styrene depend on the nature of the solvent (dioxan, ethanol, and their mixtures), the effect being most pronounced for acrylamide and methacrylamide (Table 12). In the copolymerisation of *N*,*N*-dimethylacrylamide with styrene or methyl methacrylate the quantities r_1 and r_2 are virtually the same in different solvents (dioxan, toluene, ethanol, dimethylformamide, and ethyl acetate). The difference between the behaviour of these monomers is apparently associated with the fact that, whereas acrylamide, methacrylamide, *N*-methylacrylamide, and diacetoneacrylamide can exist in the form of dimers (which are partly or fully decomposed as a result of the formation of hydrogen bonds with solvent molecules, which alters their reactivity and hence influences the copolymerisation constants), *N*,*N*-dimethylacrylamide molecules do not dimerise. The data presented also show that the hydrogen bonds between the solvent and the carbonyl group of amides have almost no influence on the reactivity of the amides.

The influence of the solvent on the intermolecular association of monomer molecules evidently explains the results obtained in the copolymerisation of methacrylamide with styrene in different solvents. The addition of ethanol, dimethylformamide, and pyridine to the mixture of monomers lowers the proportion of methacrylamide units in the copolymer [100]. The copolymerisation constant for methacrylamide changes little in the copolymerisation in acetic acid, ethanol, dimethylformamide, and pyridine (0.30–0.50), while the copolymerisation constant for styrene increases on passing from acetic acid (0.65) to other solvents (1.4–1.8). It has been assumed [100] that, in copolymerisation in acetic acid, methacrylamide reacts in the form of dimers, since the stereochemistry and size of the amide group of the monomer and those of the carboxy-group of the acid differ appreciably.

Indeed, the compositions of the methacrylamide–styrene copolymers obtained in acetic acid (in the region of homogeneous copolymerisation) and in benzene, which does not form hydrogen bonds with methacrylamide and does not therefore decompose its dimers, are the same. As for acrylamide and acrylic and methacrylic acids, the formation of hydrogen bonds between methacrylamide and solvent molecules in other solvents causes the dimeric methacrylamide aggregates to dissociate; this alters the electron density at the double bond of the monomer and decreases the reactivity of the latter.

The influence of the solvent on the copolymerisation of monomers of low polarity is much less marked, as in their separate polymerisation. Thus, in the copolymerisation of styrene (M_1) with methyl methacrylate at 60°C in benzene solution [48], the values of r_i are as follows: $r_1 = 0.57$ and $r_2 = 0.46$, whereas in phenol $r_1 = r_2 = 1.35$. A slight change in the reactivity of polymer radicals, which alters r_1 and r_2, has also been observed in the copolymerisation of cyclododecyl or cyclohexyl acrylate with acrylonitrile in solution in benzene, dioxan, and tetrahydrofuran. When styrene instead of acrylonitrile is used as the second comonomer, the solvent has no influence [101].

V. CONCLUSION

The above discussion shows that a definite influence of the nature of the solvent on the rates of polymer chain propagation and termination reactions under the conditions of radical polymerisation has now been established. Whereas in the case of weakly polar monomers the role of the solvent is largely manifested to only a slight extent, for polar monomers (acrylamide, acrylic acids, and *N*-vinylpyrrolidinone) an appreciable variation in the constant k_p is observed in solvents of different types.

The observed variation of k_p due to the different reactivities of the polymer radicals in different solvents is associated with different kinds of specific interactions between the reacting species and solvent molecules (donor–acceptor interaction, the formation of π-complexes, and hydrogen bonding). In the few studies dealing with the temperature dependence of the rates of the elementary chain propagation reactions it was shown that the variation of k_p is caused by the change in the activation energy for this reaction.

In the polymerisation of weakly polar monomers (particularly styrene) the relatively weak donor–acceptor interaction between the components of the reaction system apparently plays the main role. The solvent effect is therefore comparatively slight in this instance. The particularly marked differences observed in the polymerisation of water-soluble monomers in water, on the one hand, and in organic solvents, on the other, are probably associated both with the presence of hydrogen bonds between the reacting species and solvent molecules and with the formation of π-complexes between the solvent and the growing radicals.

Unfortunately, there are not yet any direct experimental literature data permitting the determination in each specific case of the type of interaction between the reacting species and solvent molecules, which determines the observed influence of the solvent. The claim that different kinds of complexes are formed between the components of the reaction mixture is merely tentative. The formation of such complexes has been demonstrated in only a few instances. Evidently further study should be directed towards the experimental determination of the constants k_p and k_t and the corresponding activation energies for other monomers in different solvents and their mixtures as well as towards the elucidation of the detailed mechanism of the influence of solvents.

Furthermore, it is quite likely that the influence of the solvent on k_p and k_t in radical polymerisation is also caused by a change in the conformation of the polymer radicals as a function of the nature of the medium. A clear relation has been established between the rates of polymerisation of monomeric electrolytes (acrylic acids, β-betaine) and the conformational state of the macromolecules. The rates of polymerisation and viscosities of polymer solutions vary in parallel as a function of the pH of the medium and the salt concentration in solution [8].

The polymerisation of acrylamide in the DMSO–water binary solvent has been investigated recently and an increase of the overall rate of reaction and of the molecular weight of the polymers with increasing water content in the solvent has been demonstrated. It has also been shown (on the basis of viscosity data) that the effective size of the macromolecular coils increases with increasing water content in the solvent. It is suggested that the influence of solvent composition on the rate of reaction is caused by a change in the local concentration of monomer molecules in the coils containing polymer radicals [102].

The recently published studies [103,104], where the constants k_p and k_t have been determined for the first time for the polymerisation of acrylamide in binary solvents, are significant. In DMSO–water mixtures the overall rate of reaction ($k_p/k_t^{1/2}$) and the constant k_p change sharply following the addition of even small amounts of DMSO and

then decrease more smoothly (Fig. 7). The constant k_t passes through a minimum as a function of solvent composition, corresponding to the maximum solvent viscosity (Fig. 7). In mixtures of water with dioxan and tetrahydrofuran having the same composition the quantities $k_p/k_t^{1/2}$ and k_p give rise to the sequence DMSO < dioxan < tetrahydrofuran, i.e. the same as in the polymerisation of acrylamide in one-component solvents [22,54,58].

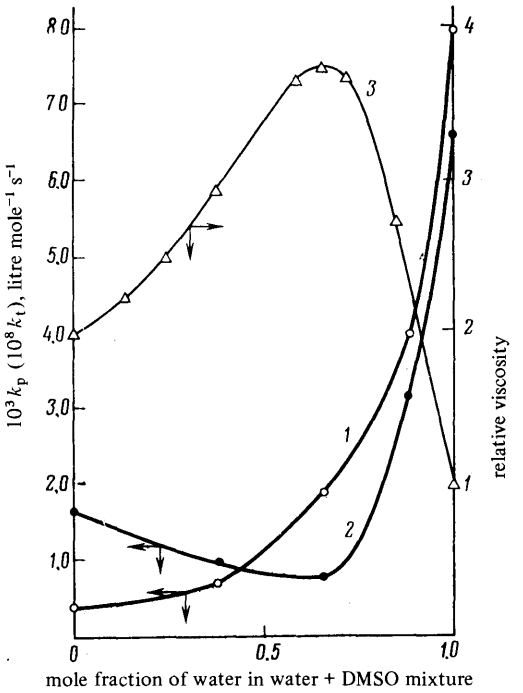

Figure 7. Dependence of k_p (curve *1*) and k_t (curve *2*) for the polymerisation of acrylamide in a water–DMSO mixture at 30°C and of solvent viscosity (curve *3*) on solvent composition.

The results [103,104] have been examined on the basis of the idea of complex formation between the growing radicals and solvent molecules. Furthermore, a correspondence has been demonstrated between the constants k_p and the intrinsic viscosities of the polymers in the solvents investigated; it is suggested that the influence of the solvent may be due to the different dimensions of the growing macroradical coils [104].

Thus, when the causes responsible for the influence of the solvent on k_p and k_t in radical polymerisation are examined, account must be taken of at least two factors:

1. The formation of complexes of different kinds by the reacting species with one another and with solvent molecules.

2. The state of the polymer coils (their dimensions) containing macroradicals and the dependence of this state on the nature of the reaction medium (solvent). Here the results of more detailed studies, for example, of the determination of the concentration of the monomer in the coil near the growing end of the polymer chain, are significant.

The contribution of each of these factors to the overall effect is at present obscure. It is probably different for different monomers and solvents.

Inorganic Radical-ions and Their Organic Reactions

A.F.Morkovnik and O.Yu.Okhlobystin

A systematic account is given of the available information about the simplest inorganic radical-ions O_2^-, O^-, O_3^-, CO_2^-, SO_4^-, etc., their reactions with organic substrates are considered, and their possible role in organic reactions is discussed. The bibliography includes 381 references.

I. INTRODUCTION

The salt-like derivatives of the radical-anion of molecular oxygen became known long before their true nature could be understood. Thus potassium superoxide $K^+O_2^-$ was described by Thenard and Gay-Lussac[1] as early as 1811. It would seem that the idea of the ability of the oxygen molecule to capture a single electron should have arisen for the first time in the study of the mechanism of the oxidation by oxygen, but in reality it was formulated by Bodenstein[2], who discovered the chain mechanism of the interaction of hydrogen with chlorine. Assuming initially that free electrons participate in chain initiation, Bodenstein explained the inhibiting activity of oxygen by the ability of its molecule to capture a single electron, i.e.

$$O_2 + e \rightarrow O_2^- .$$

Heavy alkali metals react with oxygen to form a large number of compounds, among which the "superoxides" MO_2 have been most thoroughly studied in the course of many years[3,4].

There is a striking contrast between the universal distribution of the radical-anion O_2^- in living nature and the small amount of information available about its reactions with organic compounds. However, in recent years a number of unusual reactions of this type were discovered. It was established that the adsorption of oxygen on various metal oxides is accompanied by the formation of the radical-anions O_2^-, O^- and O_3^-.[5] The available data suggest that the adsorbed oxygen radical-anions are responsible for the heterogeneous-catalytic oxidation of various substances by oxygen[5,6]. The formation of the radical-anion CO_2^- may be the first stage in the fixation of carbon dioxide in photosynthesis[7]. Data obtained in a study of the EPR spectra of inorganic radical-anions have been surveyed[8].

The available information about inorganic radical-anions is scattered throughout journals devoted to inorganic, analytical, organic, and physical chemistry, electrochemistry, and biochemistry. Without claiming to cover this field exhaustively, we attempted to compile the most important results obtained in these hitherto divergent disciplines and to deduce possible generalisations.

II. THE RADICAL-ANION OF MOLECULAR OXYGEN

1. Methods of Preparation and Physicochemical Properties

Molecular oxygen has a significant positive electron affinity (0.87 ± 0.13 eV);[9] for this reason, the principal methods for the preparation of superoxide compounds involve the reduction of oxygen. Potassium, rubidium, and caesium superoxides are formed on combustion of these metals in air or in oxygen[10-13]. On combustion, sodium forms a peroxide, since sodium superoxide is thermally unstable and decomposes even at 80–90°C into sodium peroxide and oxygen[14]. The converse reaction takes place at a higher pressure and is used as an industrial method for the preparation of NaO_2.[15]

Among superoxides with ionic structures, the lowest stability is shown by lithium and alkaline earth metal superoxides, which are obtained by ozonising the peroxides of these metals at low temperatures[16,17]. Barium peroxide is stable only below −50°C.[17]

The superoxide radical-anion (SORA), which is short-lived in aqueous solutions, is generated when molecular oxygen captures a hydrated electron[18]:

$$H_2O \xrightarrow{\nu} H^\cdot + {}^\cdot OH + e_{aq}^- + H^+ ,$$

$$H^\cdot + O_2 \rightarrow O_2^- + H^+ ,$$

$$e_{aq}^- + O_2 \rightarrow O_2^- \ (k = 1.9 \cdot 10^{10} \text{ (litre mole}^{-1}\text{ s}^{-1}\text{)}).$$

The most convenient method for the synthesis of sodium and potassium superoxides on a preparative scale involves the reduction of oxygen by solutions of the metals (in liquid ammonia)[19,20] or by ketyls, for example, sodiobenzophenone in tetrahydrofuran[21,22]:

$$Ph_2CO^-Na^+ + O_2 \rightarrow Ph_2CO + NaO_2 .$$

Tetramethyl- and tetraethyl-ammonium superoxides can be obtained by the double decomposition reaction between KO_2 and the corresponding tetraalkylammonium hydroxide[23-25]. In order to obtain Me_4NO_2, tetramethylammonium fluoride can be used instead of tetramethylammonium hydroxide[23]; tetraalkylammonium superoxides can be extracted with liquid ammonia:

$$R_4NX + KO_2 \rightarrow R_4NO_2 + KX ;$$
R=Me or Et; X=OH or F .

Tetramethyl- and tetraethyl-ammonium superoxides are yellow substances melting at 97°[23] and 50°C[25] respectively. In contrast to the thermally stable potassium, rubidium, and caesium superoxides, tetraalkylammonium superoxides decompose vigorously already at 100°C.[23,24]

Convenient methods for the preparative electrochemical reduction of molecular oxygen in aprotic media, leading to the formation of solutions of tetraalkylammonium superoxides, have been developed in recent years[26-31]. A solution of a supporting electrolyte R_4NX in an aprotic solvent (dimethylformamide, dimethyl sulphoxide, pyridine, and acetonitrile) is usually electrolysed at a controlled potential (−1.0 V) in a stream of gaseous oxygen; mercury, platinum, and gold cathodes are used. The resulting coloured solutions give rise to an EPR signal at a low temperature corresponding to the SORA.[26,27,30] It has been shown[32] that the SORA is generated also in the one-electron oxidation of hydrogen peroxide by an alkaline solution of sodium periodate.

Alkali metal superoxides are sparingly soluble in organic solvents. Incidentally, the solubility of KO_2 in dimethyl sulphoxide is sufficient for the measurement of EPR spectra[33]. The low solubility of alkali metal superoxides for a long time inhibited the investigation of their organic reactions. The situation changed significantly after the development of methods for the synthesis of tetraalkyl-ammonium superoxides, which are soluble in aprotic solvents, and also after the discovery in 1975 of the ability of potassium superoxide to dissolve in dimethyl sulphoxide[34] and even in benzene[35] in the presence of crown-ethers.

The crystal lattice of KO_2 is made up of regularly alternating K^+ and O_2^- ions, as in potassium chloride[15]. NaO_2 has a cubic face-centred lattice of the pyrite type[36]. The bond length in the O_2^- radical-anion is 1.29 Å.[37]

The conjugate acid of the SORA as a base is the free hydroperoxy-radical:

$$HO_2^{\cdot} \rightleftarrows H^+ + O_2^- \quad .$$

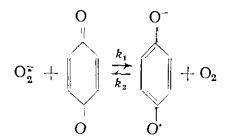
This radical is a fairly strong acid (pK_a = 4.45,[38] 4.5,[39] 4.88[40]); thus the hydroperoxy-radical exists preferentially in the form of the SORA even in weakly acid media.

2. Chemical Properties

In aqueous solutions alkali metal and tetraalkylammonium superoxides are unstable and rapidly disproportionate to hydrogen peroxide and oxygen[41]:

$$2MO_2 + 2H_2O \rightarrow H_2O_2 + O_2 + 2MOH \ .$$

On passing to strongly alkaline solutions, the rate of disproportionation is greatly reduced[42]. A KO_2 solution in 8 M KOH obtained at −50°C gives rise to the EPR signal of the O_2^- radical-ion[43]. (It is of interest that KO_2 does not react with a solution of hydrogen chloride in dry ether even at room temperature[44].)



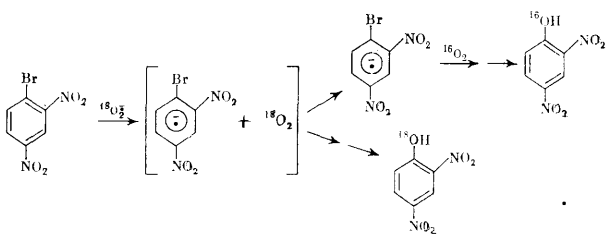
Despite the apparent simplicity of its electronic structure, the radical-anion O_2^- exhibits a varied and in many respects contradictory reactivity. At any rate the widely held view that superoxides with ionic structures can allegedly behave only as strong oxidants has since proved to be clearly untenable.

As a result of its intermediate position in the redox triad

$$O_2 \underset{-e}{\overset{+e}{\rightleftarrows}} O_2^- \underset{-e}{\overset{+e}{\rightleftarrows}} O_2^{2-}$$

the SORA exhibits a dual reactivity: depending on the nature of the substrate, it can behave both as an electron donor and an electron acceptor.

Studies in recent years have shown that the SORA can give up one electron to tetracyanoquinodimethane (TCQ),[33] quinones[45-49], and mono- and di-nitrobenzenes[33,50], converting them into radical-anions (detected by EPR):



($k_1 = 1.1 \cdot 10^9$ litre mole^{-1} s^{-1}, $k_2 = 10^7$ litre mole^{-1} s^{-1} (Ref.47))

$$TCQ + O_2^- \xrightarrow{-O_2} TCQ^- \ ;$$

$$O_2^- + ArNO_2 \xrightarrow{-O_2} ArNO_2^- \quad .$$

The radical-anions of aromatic nitro-derivatives formed in this process undergo further reactions under the influence of oxygen (and also the excess of SORA); in particular, in the case of dinitrobenzenes one of the nitro-groups is replaced by a hydroxy-group[50].

When halogenonitro- and halogenodinitro-benzenes are acted upon by KO_2 in the presence of a crown-ether, halogen atoms are replaced by hydroxy-groups[50]. It is believed[50] that the first stage in these reactions is not classical nucleophilic substitution, but electron transfer from the SORA to the halogenonitro-derivatives, accompanied by further reactions of the resulting halogenonitrobenzene radical-anions under the influence of oxygen. Owing to the rapid reaction of oxygen, the formation of radical-anions could be demonstrated with the aid of EPR only in the case of *m*-bromonitrobenzene. The one-electron mechanism of the first stage is supported, in particular, by the interaction of $K^{18}O_2$ with 2,4-dinitrobenzene in a solution saturated with $^{16}O_2$. Less than 10% of the resulting 2,4-dinitrophenol contained the ^{18}O isotope[50]:

The reactivity of halogeno-2,4-dinitrobenzenes with respect to KO_2 diminishes in the sequence F > Br ≃ I > Cl,[50] while the sequence F > Cl ≃ Br ≃ I is characteristic of nucleophilic substitution reactions[51].

The fact that the interaction of halogenonitrobenzene radical-anions with oxygen can lead to nitrophenols follows also from kinetic data for the reaction of *p*-chloronitrobenzene with sodium methoxide in the presence of oxygen[52].

An interesting reaction has been observed in a study[33] where it was shown by EPR that treatment of *p*-nitrotoluene with KO_2 leads to the formation of the radical-anion of *p*-nitrobenzaldehyde, which is apparently a product of further reactions of the *p*-nitrotoluene radical-anion in the presence of oxygen and an excess of KO_2.

Among other reactions of the SORA as a one-electron reductant, one may mention the reduction of ferricytochrome *c* to ferrocytochrome *c*,[29] of Nitrotetrazolium Blue

to the corresponding formazan[53], and of tetranitromethane to the nitroformate anion[29,39].

The conjugate acid of the SORA (the $HO_2^{\cdot}$ radical) is a weaker electron donor than the SORA itself[39]:

$$O_2^{\cdot-} + C(NO_2)_4 \rightarrow {}^{-}C(NO_2)_3 + NO_2 + O_2 ,$$
$$(k = 1.9 \cdot 10^9 \text{ (litre mole}^{-1}\text{)},$$
$$HO_2^{\cdot} + C(NO_2)_4 \rightarrow {}^{-}C(NO_2)_3 + NO_2 + H^+ + O_2 ,$$
$$(k < 1.9 \cdot 10^5 \text{ (litre mole}^{-1}\text{ s}^{-1}\text{)}).$$

The interaction of the SORA with alkyl halides (tosylates) leads mainly to alkyl peroxides[54-59]. A three-stage reaction mechanism, in which the first stage is bimolecular nucleophilic substitution involving the SORA as the nucleophile, has been proposed[51,52,55]:

$$RX + O_2^{\cdot-} \rightarrow ROO^{\cdot} + X^- ,$$
$$ROO^{\cdot} + O_2^{\cdot-} \rightarrow ROO^- + O_2 ,$$
$$ROO^- + RX \rightarrow ROOR + X^-$$
$$X = Hal, \text{ or } p\text{-}CH_3C_6H_4SO_3-.$$

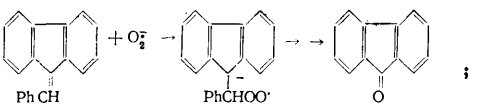
The above conclusion is based on the inversion of the configuration of the carbon atom linked to the halogen (the tosyl group) in the reaction of KO_2 with optically active halides or tosylates[55,60]. In addition, the sequence of the reactivities of the alkyl halides is the same as in the usual reactions of the S_N2 type (primary > secondary > tertiary; I > Br > Cl).[55,60,61]

The formal S_N2 mechanism does not rule out the possibility of one-electron transfer as one of the stages in the overall reaction[62,63]. In this connection the hypothesis[59] that the initial stage of the reaction under consideration is the reduction of the halide has attracted attention:

$$RHal + O_2^{\cdot-} \rightarrow [Hal^- \cdots R^{\cdot} \cdots O_2] \rightarrow RO_2^{\cdot} + Hal^- .$$

This mechanism is quite probable, since, as stated above, the SORA is a fairly effective electron donor and organic halides are capable of accepting an electron (see, for example, Refs. 64–68). The inversion of the configuration is in this case determined solely by the direction of attack on RHal from the side opposite to that of the halogen.

The formation of alcohols[60] as the main products of the reaction of alkyl halides (tosylates) with KO_2 in dimethyl sulphoxide takes place with participation of the solvent[59]. The ROO^- ion, formed "normally", reacts with dimethyl sulphoxide faster than with RX:



$$ROO^- + Me_2SO \rightarrow MeS(O^-)Me(OOR) \rightarrow Me_2SO_2 + RO^- .$$

An analogous reaction of the anion of triphenylmethyl hydroperoxide, leading to triphenylmethanol, has been observed[69].

The cleavage of tosylates and methanesulphonates to the corresponding alcohols on treatment with KO_2 in dimethyl sulphoxide, which takes place with complete inversion of the configuration at the carbon atom and which constitutes a synthetic chain procedure in the chemistry of prostaglandins[70,71], apparently also involves the interaction of the corresponding hydroperoxy-anions with dimethyl sulphoxide.

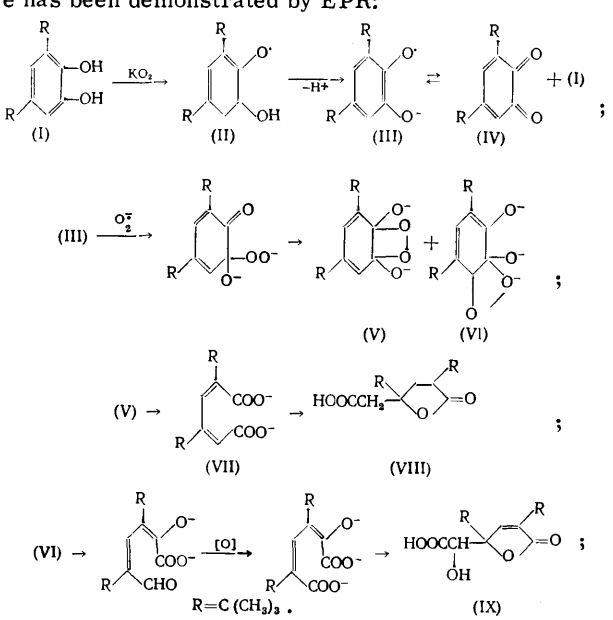
Acid anhydrides[54] and chlorides[44,55,72] are converted into acyl peroxides in high yields on treatment with KO_2, the reaction occuring in a non-aqueous medium. In contrast to the reactions of KO_2 with alkyl and acyl halides, only hexamethyldisiloxane is formed in a high yield by the reaction of chlorotrimethylsilane and KO_2.[44]

The initial nucleophilic addition of the SORA has been postulated in its reactions with benzylidenefluorenone[55] and esters[73,74]:

This mechanism is supported by the finding that, when the acetate derived from (-)(*R*)-2-octanol is cleaved, the configuration of the chiral carbon atom is almost completely preserved[73].

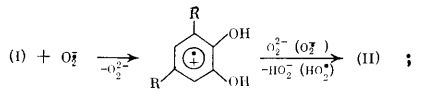
Despite the fact that the electrochemical reduction of the SORA to the O_2^{2-} anion is well known[28,75], there have been so far no studies in which the analogous reaction under the influence of chemical electron donors (DH), i.e. a reaction of the type

$$DH + O_2^{\cdot-} \rightarrow DH^{+\cdot} + O_2^{2-}$$



was clearly identified.

The study of reactions of this kind is significantly complicated by the fact that the electron transfer stage is masked by the subsequent rapid processes. For example, electron transfer should be accompanied in certain cases by the recombination or abstraction of a proton under the influence of O_2^{2-}:

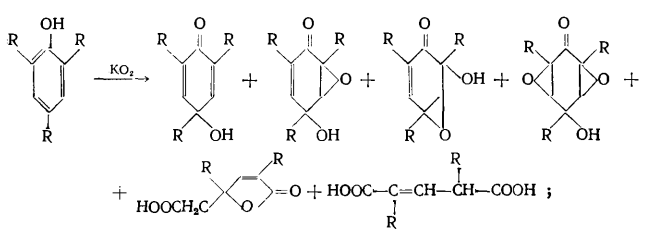


$$DH^+ + O_2^{2-} \rightarrow DHO_2^- ;$$
$$DH^+ + O_2^{2-}(O_2^{\cdot-}) \rightarrow D^{\cdot} + HO_2^-(HO_2^{\cdot}) .$$

Whereas in the first example the overall result of the reaction is the addition of the SORA to the substrate ($DH + O_2^{\cdot-} \rightarrow DHO_2^-$), the second example can be formally classified as a reaction of the S_H2 type ($DH + O_2^{\cdot-} \rightarrow D + HO_2^-$), i.e. one involving the abstraction of a hydrogen atom.

On treatment with KO_2, 3,5-di-t-butylcatechol (I) is converted largely into a mixture of 3,5-di-t-butyl-*o*-benzoquinone (IV) and compounds (VIII) and (IX).[76] The presence of the radical-anions (III) in the reaction mixture has been demonstrated by EPR:[77]

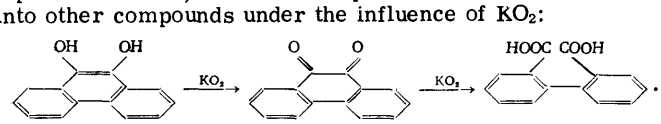
The intermediate relatively unstable diacid (VII) was isolated on a preparative scale in a low yield[77]. It is extremely likely that the first stage of the process actually consists of two such reactions:



R = C(CH$_3$)$_3$.

Indeed, the abstraction of a hydrogen atom from phenols under the influence of various oxidants is preceded by a stage involving electron transfer from the phenol molecule to the oxidant accompanied by rapid deprotonation of the phenol radical-cation formed[78]. A similar mechanism has been adopted for the abstraction of a hydrogen atom from aliphatic alcohols under the influence of the $SO_4^{\cdot-}$ radical-anion[79,80].

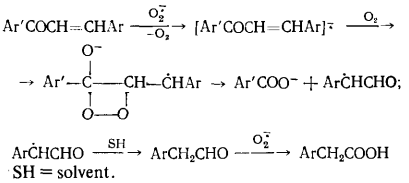
It is of interest to note that the oxidation of alkaline solutions of the catechol (I) by oxygen also leads to *o*-quinone (IV);[81] furthermore, under appropriate conditions the formation of compound (VIII) is also actually possible[82]. Apparently the similarity of the products of the reactions of polyhydric alcohols with oxygen and the SORA is associated with the fact that the SORA is involved in reactions where polyhydric phenols are oxidised by molecular oxygen. The above view is consistent with the data of a number of investigations[83-87], where the ability of polyhydric alcohols to reduce oxygen in the presence of bases was pointed out.



The oxidation of the catechol (I) by atmospheric oxygen in the presence of copper(I) chloride leads to *cis,cis*-di-t-butylmuconic acid[88], which, as stated previously, is also formed on oxidation of the above catechol derivative by KO_2.[73] In this case there is a preliminary activation of oxygen by the formation of its complex with Cu_2Cl_2, in which the reactivity of the dioxygen group in relation to the catechol (I) is probably similar to that of $O_2^{\cdot-}$ in KO_2.

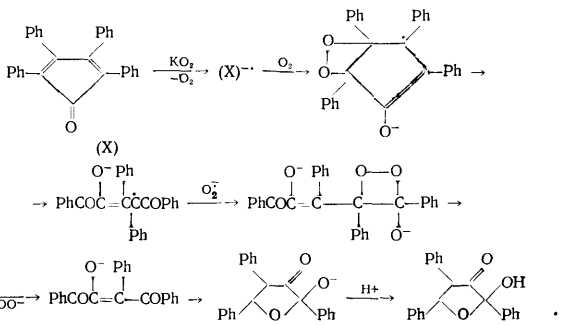
Treatment of 2,4,6-tri-t-butylphenol with potassium superoxide in the presence of 18-crown-6-ether leads to a very complex mixture of products[89]:

R=C(CH$_3$)$_3$.



The oxidation of 9,10-dihydroxyphenanthrene under the influence of KO_2 leads to 9,10-phenanthrenequinone and diphenic acid[54,76], which is incapable of further conversion into other compounds under the influence of KO_2:

The cleavage of the fragment –CO–CO– is a fairly general reaction of the SORA and usually leads to carboxylic acids in high yields[54,90,91]. Although San Filippo et al.[91], who investigated the reaction of KO_2 with benzil and its derivatives, speak of the oxidative cleavage of benzils by KO_2, this evidently applies only to the final result, since it is more likely that the reaction actually begins with electron transfer from the SORA to benzil:



A similar mechanism has been adopted for the cleavage of chalcones[92]:

It has been shown in separate experiments that, on reaction with KO_2, aldehydes can be indeed converted into the corresponding carboxylic acids[54,92].

On treatment with potassium superoxide, tetracyclone (X) is smoothly converted into 2-hydroxy-2,4,5-triphenyl-3-furanone[35,92]:

The cleavage of the C–C bond is also observed when various other carbonyl derivatives are acted upon by the SORA:[91]

It is seen from the examples presented that the SORA is capable of cleaving a very wide range of carbonyl compounds to form carboxylic acids.

Consideration of the reactions of the SORA with organic substrates accompanied by the cleavage of C–C bonds shows that the key factor in all such reactions is apparently the formation of labile dioxetans, which are known to decompose readily to carbonyl compounds[93].

Ascorbic acid is readily dehydrogenated by the SORA to dehydroascorbic acid[94,95] ($k = 2.7 \times 10^5$ litre mole^{-1} s^{-1})[95].

When 9,10-dihydroanthracene, fluorene, and diphenylmethane are treated with the SORA, the methylene groups are oxidised to carbonyl groups[31,56]. These reactions probably proceed via the abstraction of hydrogen atoms from methylene groups by the superoxide radicals and subsequent transformations of the resulting diarylmethyl radicals under the influence of oxygen and the excess SORA. If the molecule contains an activated methylidyne fragment, then the final product is a hydroperoxide:

The study of the reactions of KO_2 with secondary aliphatic and aromatic amines (by EPR) demonstrated the formation of nitroxy-radicals[33]. The reaction also takes place in the absence of molecular oxygen:

Secondary alcohols (isopropyl alcohol and diphenylmethanol) are oxidised by NaO_2 to ketones (the yields of acetone and benzophenone are 33 and 55% respectively)[96].

It has been found[97] that the SORA is capable of abstracting a hydrogen atom from cysteine; the hydroperoxy radical is not involved in this reaction:

$$RSH + O_2^- \xrightarrow[-HO_2^-]{} RS^\cdot$$

RSH = cysteine.

Under the usual conditions, the reaction of KO_2 with phenylhydrazine in the presence of dicyclohexyl-18-crown-6-ether can serve as a source of phenyl radicals[98]:

$$PhNHNH_2 \xrightarrow{O_2^-} PhN{=}NH \xrightarrow[-HO_2^-]{O_2^-} Ph^\cdot + N_2;$$

$$Ph^\cdot + PhN{=}NH \xrightarrow{-PhH} Ph^\cdot + N_2 \ ;$$

$$Ph^\cdot + PhH \rightarrow \rightarrow Ph{-}Ph \ .$$

On oxidation of other compounds with an N–N bond under the same conditions, the following products are formed[98] (the yields expressed as percentages are indicated in brackets): toluene (54), benzoic acid (15), benzyl alcohol (6), and benzaldehyde (6) from benzylhydrazine; n-octane (32) from n-octylhydrazine; *N*-nitrosodiphenylamine (50) from 1,1-diphenylhydrazine; *N*-methyl-*N*-nitroaniline (33) from 1-methyl-1-phenylhydrazine; azobenzene (98) from 1,2-diphenylhydrazine; benzophenone azine (83) from benzophenone hydrazone; fluorenone (86) from 9-diazofluorene. Many of these reactions apparently begin with the state involving the abstraction of a hydrogen atom from the substrate.

Summarising the foregoing findings, one should note that reactions where the SORA plays the role of a mild reductant, a moderately strong nucleophile, or a free radical exhibiting a moderate dehydrogenating activity are the most characteristic of this species. An interesting feature of the SORA is its ability to react with both π-electron deficient systems (aromatic nitro-compounds) and with compounds having an excess of π electrons (phenols) as well as nucleophiles of the amine type.

3. Reactions Involving the Intermediate Formation of the SORA

Having adopted the view that, after the preliminary binding of the reacting species in complexes, the displacements of the atomic nuclei relative to one another are usually preceded by electron transfer[63], the oxidation of various compounds by oxygen can be represented by the following scheme:

$$RH + O_2 \rightleftarrows RH \cdots O_2 \rightleftarrows [RH^{+\cdot} \cdots O_2^-] \quad (XI);$$

$$(\text{or } [R^\cdot \cdots H^+ \cdots O_2^-]) \rightarrow R^\cdot + HO_2^\cdot \ .$$

In particular, the results of studies on the kinetics of the oxidation of *o*-xylene by oxygen are treated in this way[99]. In this interpretation of the mechanism of the oxidation reaction the tendency towards an increase of the ease of oxidation of organic compounds by oxygen accompanied by an increase of their capacity for electron transfer, which is usually observed, can be naturally accounted for.

Electron transfer to the charge-transfer complex (CTC) (XI) can apparently be induced also by the irradiation of the RH–O_2 system by light whose wavelength corresponds to the absorption band of the charge-transfer process[100–102], for example[102]:

$$C_2H_5OH \cdots O_2 \xrightarrow{h\nu} [C_2H_5\dot{O}H \cdots O_2^{-\cdot}] \rightarrow \text{oxidation products.}$$

One of the types of reactions in which there is a possibility of the formation of the SORA is that of neutral free radicals with oxygen. Thus it has been noted[103] that the radical obtained in the one-electron reduction of the oxidised form of nicotinamide-adenine dinucleotide (NAD^+) in aqueous solutions is much less stable in the presence of oxygen than in its absence. This can be explained by the occurrence of the process

$$NAD^\cdot + O_2 \rightarrow NAD^+ + O_2^- \ (k = 1.9 \times 10^9 \text{ litre mole}^{-1}\,\text{s}^{-1}),$$

apparently accompanied by the decomposition of the resulting SORA under the influence of water.

It is extremely interesting that the rate of reaction with oxygen increases in parallel with the enhancement of the reducing properties of the radical in the sequence $^\cdot CH_2CMe_2OH \simeq {}^\cdot CH_2CH(Me)OH < {}^\cdot CH_2OH < (Me)_2{}^\cdot COH < {}^\cdot COOH$.[104] One of the possible explanations of this behaviour is electron transfer[104]:

$$R^\cdot + O_2 \rightarrow [R^+ \cdots O_2^-] \rightarrow RO_2^\cdot \ .$$

A fairly large number of examples characterising the ability of carbanions and cryptocarbanions to function as electron donors are available at the present time. Significant advances have been made in this field in recent years when it has been shown that this ability is exhibited in many fundamental reactions of organometallic chemistry[105]. The fundamental principle of the one-electron oxidation of carbanions by oxygen was formulated by Russell[69]:

$$R^- + O_2 \rightarrow R^\cdot \cdots O_2^- \begin{cases} \longrightarrow RO_2^- \\ \longrightarrow R^\cdot + O_2^- \end{cases};$$

$$R^\cdot + O_2 \rightarrow RO_2^\cdot \ ;$$

$$RO_2^\cdot + R^- \rightarrow RO_2^- + R^\cdot, \text{ etc.}$$

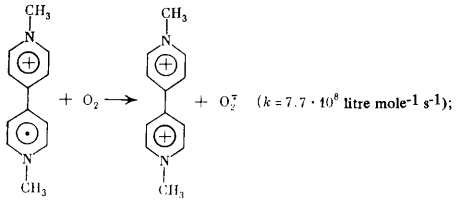
The formation of free radicals in reactions of organometallic compounds with oxygen has been reliably established[106–108]. Evidently electron transfer from the carbanion to oxygen must be preceded by the coordination of the oxygen atom to the metal atom[108]. A similar mechanism was adopted also for the oxidation with oxygen of various organometallic compounds having a covalent C–metal bond[108].

The oxidation of certain *O*-anions takes place similarly—with electron transfer to oxygen (see Section II, 6). The reaction of fused potassium, rubidium, and caesium hydroxides with oxygen at 410 °C leads to the formation of a mixture of the peroxide and superoxide of the corresponding metal[109]. According to McGrath's results[110], the Favorskii rearrangement includes a stage involving the one-electron reduction of oxygen by the alkali metal enolate.

The following mechanism, involving one-electron transfer from the anion R^-, has been proposed for the low-temperature oxidation of mercaptans by oxygen[111]:

$$RSH \rightleftarrows RS^- + H^+$$

$$RS^- + O_2 \rightarrow RS^\cdot + O_2^- \ ;$$



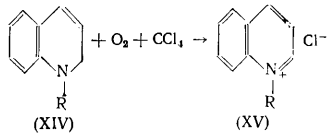
$$2RS^\cdot \rightarrow RSSR \ .$$

The participation of the SORA in the oxidation of mercaptans by oxygen has been demonstrated using a superoxide dismutase test[112] (see below).

It is of interest that, on passing from CH_3OH to tetrahydrofuran, dioxan, diglyme, and further to dimethylformamide, the rate of oxidation of butane-1-thiol increases by a factor of 334 in the presence of sodium methoxide. A possible explanation of this finding, postulating that the influence of the solvent is based on

the enhancement of the nucleophilic properties of CH_3O^- in the above sequence[111] is unconvincing because mercaptans are fairly strong acids and the change in the concentration of the thiolate anion on passing from methanol to dimethylformamide is hardly likely to cause such a large effect. The sharp acceleration of the reaction in highly solvating solvents is apparently associated with the significant decrease of the activation energy for electron transfer on passing from non-polar and weakly solvating media to polar and highly solvating media.

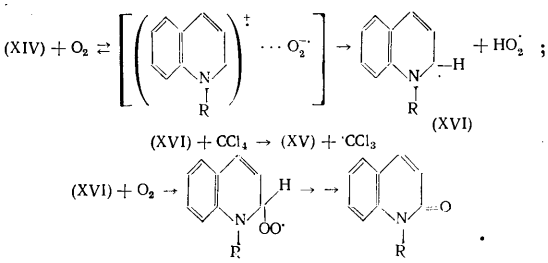
It has been shown by pulse radiolysis that the reaction of a radical-cation with oxygen in aqueous solution proceeds in two stages[113]:



(XII) (XIII)

$(k = 7.7 \cdot 10^8$ litre mole^{-1} s^{-1});

(XII) + $O_2^{\cdot-}$ → (XIII) + O_2^{2-} $(k = 6.8 \cdot 10^8$ litre mole^{-1} s^{-1}).



In methanol solution the reaction proceeds in a more complex manner [it is of second order with respect to (XII) and of first order with respect to oxygen][114].

In conformity with the results of kinetic studies, the involvement of the SORA in the oxidation by oxygen of certain aromatic amines in an aqueous medium has also been postulated[115]. An interesting reaction of 1,2-dihydroderivatives of quinoline with CCl_4, which proceeds only in the presence of oxygen and leads to quinolinium salts, has been described[116]:

(XIV) (XV)

The oxidation of dihydroquinolines in the absence of a solvent leads to the formation of the corresponding 2-quinolinones[116]. Analysis of literature data leads to the hypothesis that the above oxidation of 1,2-dihydroquinolines proceeds as follows:

(XVI)

(XVI) + CCl_4 → (XV) + $\cdot CCl_3$

Indeed, judging from polarographic reduction data, carbon tetrachloride is a fairly effective electron acceptor ($E_{1/2} = -0.25$ V relative to the saturated calomel electrode[117] in dimethylformamide as a solvent). It is to be expected that radicals of type (XVI) should be fairly strong reducing agents, since it is known, for example, that the radical $(CH_3)_2\dot{C}NH_2$, which contains the α-amino-group, is a strong reductant[118].

4. The Superoxide Radical-Anion and Singlet Oxygen (SO)

The hypothesis of the possible formation of oxygen in an excited state from the SORA has been put forward by Stauff et al.[119]

In a study of the hydrolysis of KO_2 in dimethyl sulphoxide in the presence of singlet oxygen acceptors Khan[120] concluded in 1970 that SO is formed in the disproportionation of the SORA:

$$2O_2^{\cdot-} + 2H^+ \rightarrow H_2O_2 + O_2(^1S).$$

Further investigations of a trapping of the SO formed in this reaction yielded contradictory results[33,121-124], which can be explained[125,126] by the rapid quenching of SO by the superoxide radical-anion, which competes with the capture of SO by the acceptors employed:

$$AO_2 \xleftarrow{A} O_2(^1S) \xrightarrow[-O_2^{\cdot-}]{O_2^{\cdot-}} O_2(^3S);$$

A = SO acceptor.

The mechanism of the formation of SO in the disproportionation of the SORA is still not clear, although one can assume that SO is formed in the one-electron oxidation of the SORA by its protonated form:

$$O_2^{\cdot-} + H\dot{O}_2 \rightarrow O_2(^1S) + HO_2^-,$$

since it has been shown that the oxidation of the SORA by strong one-electron oxidants leads to the formation of SO,[127] while in the reaction

$$2HOO^{\cdot} \rightarrow H_2O_2 + O_2$$

SO is not produced[128].

It is noteworthy that the reactions of dyes in an excited state (Dy^T) with molecular oxygen involving the conversion of the latter into SO, which formally reduce to energy transfer[129,130], can apparently proceed via an electron exchange mechanism with the intermediate formation of a radical-ion pair[131]:

$$Dy^T + O_2(^3S) \rightarrow [Dy^{\cdot+} \cdots O_2^{\cdot-}] \rightarrow Dy + O_2(^1S).$$

This is supported by the fact that the "annihilation" of oppositely charged radical-ions, responsible for the phenomenon of electrochemiluminescence[132], frequently results in the formation of electronically excited molecules:

$$Dy^{\cdot+} + A^{\cdot-} \rightarrow \begin{cases} \rightarrow Dy + A^* \\ \rightarrow Dy^* + A. \end{cases}$$

It has also been shown that the reaction of the SORA with certain radical-cations [the system of species belonging to the type forming the radical-ion pair $[Dy^{\cdot+} \ldots O_2^{\cdot-})$ leads to the formation of SO:[127]

$$Ferr^{\cdot+} + O_2^{\cdot-} \rightarrow Ferr + O_2(^1S);$$

Ferr = ferrocene.

The formation of radical-ion pairs $(Dy^{\cdot+} \ldots O_2^{\cdot-})$ in the reaction of dyes in triplet states has been postulated on the basis of kinetic data[133,134].

The transition of the dye molecules from the ground to the excited state can be accompanied by a sharp enhancement of the ability of the dye to function as an electron donor. It has been stated, for example, that the oxidation-reduction potential of the P_{700} pigment is +0.4 V in the ground state, while in the excited state it is −0.32 V (the sum $\Delta E_0 \simeq -0.7$ V!).[135]

5. "Covalent" Superoxides

The fact that many transition metal compounds which are effective reductants can be oxidised by oxygen naturally leads to the conclusion that the reaction

$$M^{n+} + O_2 \rightleftarrows M^{(n+1)+} + O_2^- .$$

is possible. This idea was apparently first formulated by Just[136], who investigated the oxidation of iron(II) salts by oxygen. Subsequently the idea of the involvement of the SORA in the oxidation of iron(II) via oxygen was developed by Weiss[137]:

$$Fe^{2+} + O_2 \rightleftarrows Fe^{3+} \cdot O_2^- \xrightarrow{H^+} Fe^{3+} + HO_2^\cdot \ ;$$
$$HO_2^\cdot + Fe^{2+} \rightarrow HO_2^- + Fe^{3+} \ ;$$
$$HO_2^- + H^+ \rightarrow H_2O_2 \ ;$$
$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + HO^\cdot + OH^- .$$

In subsequent years the problem of the structure of the intermediate oxygen adducts $[MO_2]^{n+}$, formed in the oxidation of transition metal compounds by oxygen and considered by Weiss as SORA derivatives, was at the centre of attention. Some of these adducts are sufficiently stable to be isolated in the pure state. A number of reviews are devoted to the consideration of their properties[138–140]. The interest in oxygen adducts has been aroused mainly by the search for effective synthetic molecular oxygen transferring agents[138] and also by the search for methods of activating oxygen in various oxidation processes[141,142].

The studies in recent years have been characterised by the application of a wide variety of physical methods to the solution of the problem of the structure of metal compounds containing an oxygen molecule as a ligand. The latest advances in this field are discussed below.

In 1964 Weiss suggested that oxygen adducts formed by natural oxygen transferring agents (haemoglobin Hb and myoglobin Mb) should be regarded as iron(III) compounds containing the superoxide ion, i.e. $HbFe^{3+}\cdot O_2^-$ and $MbFe^{3+}\cdot O_2^-$.[143] In support of this hypothesis, Weiss referred particularly to the similarity of the ultraviolet spectra of these adducts and those of methaemoglobin and metmyoglobin derivatives and the fact that oxygen is "activated" in oxyhaemoglobin. Within the framework of Weiss's hypothesis, the diamagnetism of oxyhaemoglobin is explained by the antiferromagnetic interaction in the ion pair $HbFe^{3+}\cdot O_2^-$. Pauling[144] opposed this treatment, stating that oxyhaemoglobin should be regarded as an iron(II) derivative having the formula $HbFe^{2+}=O^+_{O^-}$. Quantum-mechanical calculations[145] support the view that the iron in $HbFeO_2$ is tervalent.

The formation of the $Fe-O_2$ bond in adducts of iron(II) compounds with oxygen can be represented by a correlation diagram (Fig. 1) within the framework of the molecular orbital method[146]. However, one should note that the diagram presented says nothing about the amount of ionic character of the $Fe-O_2$ bond.

The use of physical methods in the solution of the problem of the nature of the bond in oxyhaemoproteins yielded results which are not susceptible to a simple interpretation. Thus studies by the Mössbauer method showed that the chemical shifts of iron in haemoglobin and oxyhaemoglobin are approximately the same[147], which corresponds to approximately identical states of the iron in these compounds. On the other hand, the similarity of the Raman spectra of oxyhaemoglobin and methaemoglobin derivatives was interpreted as a result of the presence of iron(III) in $HbFeO_2$.[148,149] Furthermore, the vibration frequency of the O–O bond is 1107 cm^{-1} in $HbFeO_2$ [150] and 1145 cm^{-1} in KO_2,[151] while in gaseous oxygen it is 1555 cm^{-1}.[152] The study of oxyhaemoglobin by X-ray fluorescence spectroscopy led to the conclusion that there is an unpaired electron at the iron atom in oxyhaemoglobin[153].

The problem of the nature of the $Fe-O_2$ bond, particularly of the amount of its ionic character in oxyhaemoproteins, probably cannot be regarded as finally solved. One can only note that the antiferromagnetic interaction in oxyhaemoproteins, postulated in Weiss's hypothesis, is equivalent to the formation of a new electron pair, giving rise to the $Fe-O_2$ bond owing to the comparatively short $Fe-O_2$ distance, i.e. in fact it corresponds to the absence of the O_2^- radical-anion from oxyhaemoprotein molecules. Naturally, this view in no way predetermines the solution of the problem of the amount of ionic character of the $Fe-O_2$ bond as well as the possibility or impossibility of the dissociation of the adducts $[FeO_2]^{2+}$ into Fe^{3+} and the SORA or the transition of the $Fe^{3+}O_2^-$ ion pair to the triplet state.

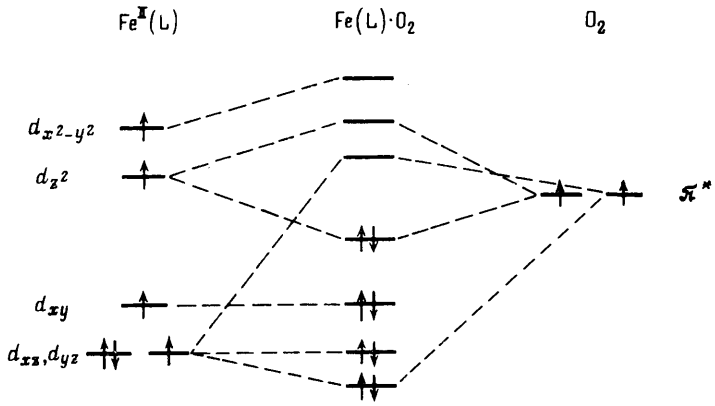


Figure 1. A molecular-orbital model of the coordination of oxygen to iron(II) complexes (L = ligand).

Recently the problem of the nature of the bond between oxygen and the metal atom in the oxygen complexes of transition metals has been vigorously discussed also in relation to octahedral oxygen complexes of bivalent cobalt. X-Ray diffraction data have shown that the oxygen atoms in the oxygen adducts of 1 : 1 cobalt(II) complexes are not equivalent and that the O–O bond length is in many instances close to that observed for the superoxide ion in KO_2.[154–156] The authors of these studies therefore regard these complexes as compounds containing tervalent cobalt and the SORA $\left[-\overset{\diagdown\ \diagup}{Co^{3+}}\cdot O_2^- \right]$.

The results of a study of the oxygen complexes of cobalt by X-ray electronic spectroscopy also agree much better with the formula $Co^{3+}\cdot O_2^-$ than with $Co^{2+}\cdot O_2$.[157,158]

The formula $Co^{3+}\cdot O_2^-$ for the oxygen complexes of cobalt was also adopted by investigators[159,160] who studied such complexes by EPR as well as investigators[161,162] who carried out quantum-mechanical *ab initio* calculations on the oxygen complexes of cobalt by the LCAO-MO-SCF method.

However, Tovrog et al.[146] published very recently a study where it is stated (these views are shared also by the authors of the present review) that the treatment of the oxygen complexes of cobalt(II) as $Co^{3+}\cdot O_2^-$ is only qualitatively correct, since the real degree of electron transfer is usually less than unity and varies in the range 0.1–0.8.

The formation of a complex between cobalt(II) compounds and oxygen has been regarded[146,162] as a result of the pairing of the spin of the electron in the d_z orbital of Co^{2+} with the spin of the electron in the π^* orbital of the oxygen atom. Depending on the strength of the ligand field around the cobalt atom, the complex approaches more or less closely the limiting case described by the formula $Co^{3+}\cdot O_2^-$.[146] The mixing of the Co^{2+} and O_2 orbitals can be represented by the diagram in Fig. 2: we have $Co^{3+}\cdot O_2^-$ for $\alpha = 0$ and $Co^{2+}\cdot O_2$ for $\alpha = \beta$.

Analogous problems concerning the nature of the metal–oxygen bond arise also for the oxygen complexes of Cu^+, Cr^{2+}, Ir^+, Ni^0, Pt^0, Pd^0, etc. For example, the ease of oxidation of copper(I) compounds has been explained by the formation of a π-complex, which is subsequently converted into a copper derivative of the SORA:[163]

$$Cu^+ + O_2 \rightleftarrows [Cu^+ \rightarrow O_2] \rightleftarrows Cu^{2+}\cdot O_2^- .$$

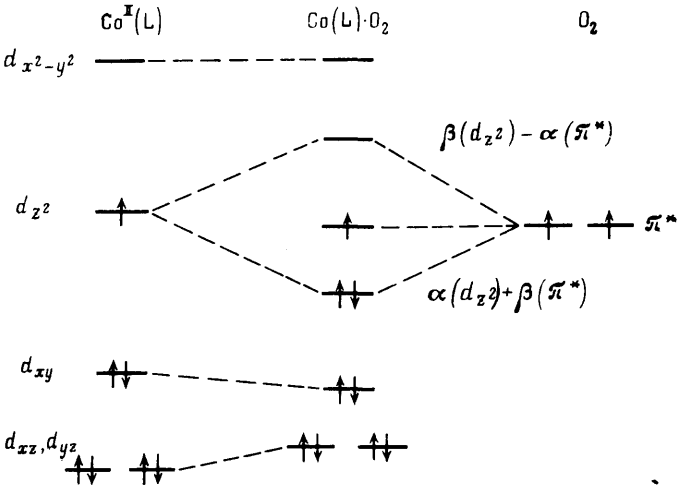

Figure 2. A molecular-orbital model of the coordination of oxygen to cobalt(II) complexes.

In the complexes $Ir(Hal)(CO)(PPh_3)_2.O_2$ the length of the O–O bond varies markedly depending on the nature of the halogen[164,165]: for Hal = Cl, it amounts to 1.30 ± 0.03 Å, while for Hal = I it is 1.47 ± 0.02 Å. Accordingly, La Placa and Ibers[164] regard these complexes as $Ir^{2+}(Cl)(CO)(PPh_3)_2\cdot O_2^-$ and $Ir^{3+}(I)(CO)(PPh_3)_2\cdot O_2^{2-}$. As a result of the difference between the structures of these complexes, reversible binding of oxygen is possible only for the complex $Ir(Cl)(CO)(PPh_3)_2$.[165]

In considering the problem of the way in which oxygen complexes of metals can serve as sources of the SORA, we shall point out the following pathways which are possible in principle:

(1) Direct dissociation (ionisation) of the complex:

$$M^{n+} + O_2 \rightleftarrows [MO_2]^{n+} \rightleftarrows M^{(n+1)+} + O_2^- .$$

On the basis of kinetic data, it is stated[166] that the oxygen complex of Cu^+ in an aqueous acetonitrile medium is capable of dissociating via the above mechanism, but the dissociation with formation of oxygen takes place at a rate which is higher by a factor of approximately 26 than the dissociation with formation of the O_2^- radical-ion.

(2) In protic media there is a possibility of indirect formation of the SORA:[34,166,167]

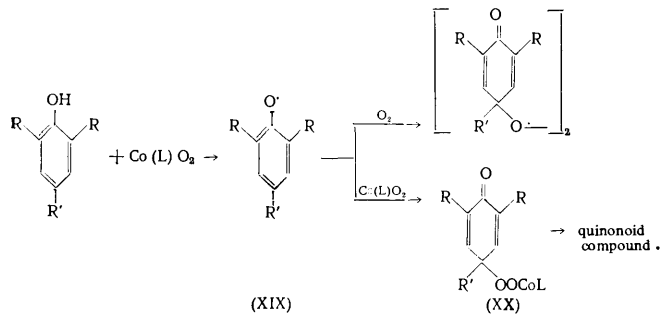
$$[MO_2]^{n+} + H^+ \rightarrow [MOOH]^{(n+1)+} \rightleftarrows M^{(n+1)+} + HO_2^\cdot ;$$
$$HO_2^\cdot \rightleftarrows H^+ + O_2^- .$$

In this case the formation of $HO_2^\cdot$ is significantly facilitated by the presence of anions capable of forming stable complexes with $M^{(n+1)+}$. Accordingly, the Fe^{2+}–pyrophosphate-anion–O_2 system is greatly superior, as regards the efficiency of the generation of the SORA in aqueous solution, to the analogous systems containing, instead of pyrophosphate, anions which are weaker complex-forming agents in relation to Fe^{3+}.[168]

Few data are as yet available concerning reactions of dioxygen transition metal complexes. Their study is complicated by different oxidation-reduction reactions of the substrate and its oxidation products, for example:

$$M^{(n+1)+} + RH \rightarrow M^{n+} + R^\cdot + H^+ ;$$
$$M^{(n+1)+} + ROOH \rightarrow M^{n+} + ROO^\cdot + H^+ ;$$
$$M^{n+} + ROOH \rightarrow M^{(n+1)+} + RO^\cdot + OH^- .$$

However, it has been established that the formation of complexes between oxygen and transition metal compounds alters significantly the reactivity of oxygen[140,142].

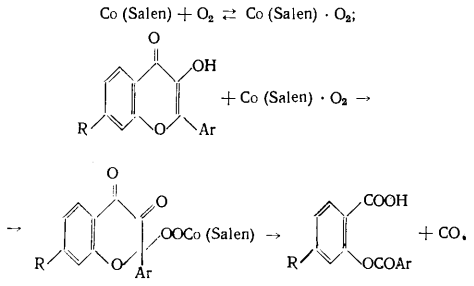


Presumably oxygen complexes of transition metal compounds containing the superoxide-like dioxygen ligand should be capable of abstracting hydrogen atoms from fairly reactive organic compounds. Indeed the available literature data confirm this view[169–173]. For example, in a study of the kinetics of the oxidation of cumene by oxygen, catalysed by the *o*-phenanthroline complex of copper, it was possible to show that the reaction of the oxygen complex of copper with cumene plays an important role in this process[171]:

$$\underset{\text{(XVII)}}{[Cu(phen)]^+} + O_2 \rightleftarrows \underset{\text{(XVIII)}}{[Cu(phen)]^{2+}\cdot O_2^-} ;$$
$$\text{(XVIII)} + RH \rightarrow \text{(XVII)} + HO_2^\cdot + R_2^\cdot ;$$
$$R^\cdot + O_2 \rightarrow RO_2^\cdot ;$$
$$RO_2^\cdot + RH \rightarrow ROOH + R^\cdot, \text{ etc.}$$

R = $PhCMe_2$; phen = *o*-phenanthroline.

It is appropriate to mention here that the abstraction of a hydrogen atom from cumene takes place also under the influence of alkali metal superoxides[31]. The oxidising properties of O_2 complexes with cobalt(II) compounds have been demonstrated convincingly also in relation to the complex $[Co(3\text{-MeO-Salen})\cdot O_2]^{2+}$.[174] This complex readily oxidises thiols, ascorbic acid, hydroquinone, and *N*,*N*,*N*′,*N*′-tetramethyl-*p*-phenylenediamine. In the last two instances it was shown by EPR that semiquinone radicals and the *N*,*N*,*N*′,*N*′-tetramethyl-*p*-phenylenediamine radical-cation are formed respectively.



It has been demonstrated that cobalt complexes capable of reversible binding of oxygen behave as homogeneous catalysts of the oxidation of substituted phenols by oxygen under mild conditions, which leads to a mixture of various quinonoid compounds[175-177].

(XIX) (XX)

Complex (XX), where R = R′ = t-C_4H_9 and L = bis-(3-salicylideneaminopropyl)amine dianion, was isolated in the reaction of 2,4,6-tri-t-butylphenol with a stoichiometric amount of CoL and oxygen[177]. Compound (XX) is also formed as a result of the recombination of two radicals—(XIX) and $Co(L)O_2$.

The *N,N′*-bis(salicylidene)ethyleneaminate complex of cobalt(II) [Co(Salen)], which is an effective oxygen transferring agent, catalyses at room temperature the oxidation of hydroxyflavones, simulating the enzymic oxidation of quercetin[178]:

It is of interest to note that the ability of various metal compounds having reducing properties to activate molecular oxygen by its partial reduction is apparently not unique. It appears almost self-evident that, in principle, there should exist activators of molecular oxygen which do not contain reducing metals at all. Thus, in the oxidation of cumene with oxygen, magnesium-phthalocyanine exhibits a catalytic activity[179]:

$$Pc + O_2 \rightleftarrows Pc \cdots O_2 \rightleftarrows Pc^{+} \cdots O_2^{-} \quad (XXI)$$

$$RH + (XXI) \rightarrow Pc + R^{\cdot} + HO_2^{\cdot};$$

R = $PhCMe_2$; Pc = magnesium-phthalocyanine.

The ability of the substrate to form complexes with oxygen clearly depends not only on the nature of the metal but also on the nature of its ligand environment and is thus a general property of the enzyme-like molecule. The study of metal complexes with ligands capable of undergoing ready and reversible one-electron transitions, which only partly involve the valence shell of the metal, is therefore particularly promising. Complexes with paramagnetic ligands are of special interest at the present time.

6. The Role of the SORA in Biochemical Processes

The study of the role of the SORA in living systems was stimulated by the studies of McCord and Fridovich[29,180-182] carried out in 1968–1970. Subsequent investigations initiated a new field in biochemistry—the biochemistry of the SORA. It became clear that the SORA plays an important role in all aerobic cells.

Molecular oxygen plays the role of a readily available electron acceptor in various biochemical oxidation reactions. As a result of such processes, the electrons of the oxidised substrates are passed to the electron transferring enzymes and then further to oxygen molecules, which are converted into the SORA.

The high reactivity of the SORA and of the hydroperoxy-radical, which always accompanies it in aqueous solutions, as well as the possibility of the formation of hydroxy-radicals in systems of this kind are responsible for the toxic effect of the SORA on living tissues[29,183-188]. In 1969 McCord and Fridovich discovered the first example of enzymes which protect living systems from the toxic activity of the SORA by its catalytic disproportionation[29]:

$$O_2^{\cdot-} + 2H^{+} \xrightarrow{\text{enzyme}} H_2O_2 + O_2;$$

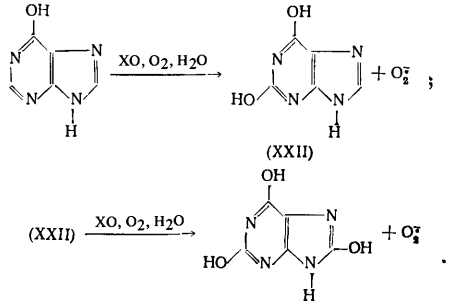
$$H_2O_2 \xrightarrow{\text{catalase}} H_2O + O_2.$$

This enzyme proved to be the copper-containing protein erythrocuprein, which had been known already for more than thirty years[189]. Other proteins, fulfilling an analogous function and given the general name of superoxide dismutases (SOD), were discovered subsequently. The active centres of the SOD are usually copper atoms: certain simple copper compounds also possess superoxide dismutase properties[190,191]. However, SOD containing metals other than copper are also known[192,193]. Vigorous research in recent years established the presence of SOD in living objects such as human cells[189,194,195], animal livers[196], plant leaves[179,198], wheat grains[199], and rod cells in animal eyes[200], yeasts[193,201], guinea pig leucocytes[202], etc.

The following sequence of reactions has now been adopted as the mechanism of the enzymic disproportionation of the SORA:[203,204]

$$E + O_2^{-} \rightarrow E^{-} + O_2 \quad (k = 1.2 \pm 0.2 \cdot 10^9 \text{ litre mole}^{-1} \text{ s}^{-1});$$

$$E^{-} + O_2^{-} \xrightarrow{2H^{+}} E + H_2O_2 \quad (k = 1 - 3 \cdot 10^9 \text{ litre mole}^{-1} \text{ s}^{-1});$$



$$E^{2-} + O_2^{-} \xrightarrow{2H^{+}} E^{-} + H_2O_2 \quad (k = 1.2 \pm 0.2 \cdot 10^9 \text{ litre mole}^{-1} \text{ s}^{-1});$$

E = erythrocuprein.

It is extremely significant that, in contrast to spontaneous dissociation, enzymic dissociation does not lead to the formation of toxic singlet oxygen[188].

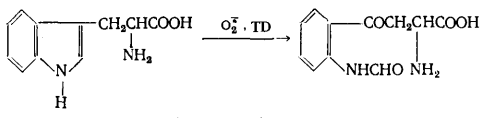
Following the discovery of the superoxide dismutase properties of erythrocuprein and other proteins, biochemists and organic chemists acquired a valuable test, which makes it possible to confirm or disprove the involvement of the SORA in a particular process. The system believed to generate the SORA is usually treated with compounds capable of reacting with the SORA; these are normally ferricytochrome *c* [29] and Nitrotetrazolium Blue,[53,183] which are reduced by the SORA to ferrocytochrome *c* ($k = 1.4 \times 10^6$ litre $mole^{-1}$ s^{-1};[205] $HO_2^{\cdot}$ does not reduce ferricytochrome *c* [205]) and formazan respectively, as well as adrenalin, which is oxidised by the SORA to adrenochrome[85]. If the system does indeed induce any of these reactions and catalytic amounts of SOD inhibit it fully (or significantly), it is concluded that the SORA is formed in the given system.

The formation of the SORA has been established in many enzymic and non-enzymic systems. The enzymic system which has been most thoroughly investigated and most frequently used for the generation of the SORA consists of a mixture of xanthine with a catalytic amount of xanthine oxidase (XO), which converts xanthine into uric acid in the presence of oxygen[32,180,181,206]. Hypoxanthine can be used instead of xanthine[185]:

(XXII)

It is believed that oxygen is reduced to the SORA by the reduced form of the isoalloxazine ring of the flavin-adenine dinucleotide associated with xanthine oxidase[207,208].

Oxygen is also reduced to the SORA when it is treated by the reduced form of a simpler flavin compound—flavin mononucleotide[182,208,209]. The formation of the SORA in the reaction of reduced flavins with oxygen was demonstrated directly by EPR.[210]



Misra and Fridovich[211], who discussed the problem of the possible generation of the SORA from the oxygen complexes of haemoproteins, noted that even their simple dissociation might lead to the SORA:

The properties of the SORA suggest the possibility of its formation from oxyhaemoglobin. Thus, in contrast to haemoglobin and methaemoglobin, the denaturation of oxyhaemoglobin by heat is accompanied by oxidation of its sulphydryl groups[212]. Catechol, hydroquinone[213], and aniline[214] exhibit a catalytic effect on the $HbFe.O_2 \rightarrow$ MetHbFe transition (as already mentioned, polyhydric phenols are capable of binding the SORA).

It has been possible to show that the autoxidation of haemoglobin in the presence of adrenalin leads to the oxidation of the latter to adrenochrome, which is inhibited by the addition of SOD.[211] These data indicate the formation of the SORA from oxyhaemoglobin. Other haemoproteins are also capable of generating the SORA from oxygen. Thus it has been concluded that the SORA is formed by the autoxidation of certain cytochromes[215,216].

The involvement of the SORA in the cleavage of tryptophan to formylkynurenine, catalysed by tryptophan 2,3-dioxygenase (TD), has also been demonstrated[217]:

The reaction is inhibited by SOD and the addition of electrochemically generated Bu_4NO_2 to a mixture of tryptophan and the enzyme leads to the rapid formation of formylkynurenine in an amount proportional to that of the added Bu_4NO_2.[217]

Horseradish peroxidase is also capable of reducing oxygen to the SORA.[218] The generation of the SORA by proteins containing non-haem iron (ferredoxins) has been demonstrated both with the aid of SOD[219] and by the direct detection of SORA with the aid of EPR.[206,220] Copper proteins are apparently likewise capable of generating the SORA from oxygen in certain instances[221].

It is extremely significant that photosynthesis is also accompanied by the generation of the SORA.[222-226] It is believed that it is formed on reduction of oxygen with ferredoxins and is consumed in the dehydrogenation of ascorbic acid. The familiar Hill reaction[227], which involves methylviologen as an electron acceptor, similarly leads to the formation of the SORA as a result of the reduction of oxygen by the methylviologen radical-cation[94,228].

The involvement of the SORA in the autoxidation of phenylhydrazine[229], mercaptans[112], and polyhydric phenols[87,230] and in the reaction of oxygen with the reduced form of phenazinium methosulphate has also been demonstrated with the aid of SOD.[231]

Phenothiazine derivatives, whose metabolism in the organism reduces to their conversion into S-oxides, give rise to S-oxides also on treatment with the SORA, which may indicate the involvement of the latter in the metabolism of medicinal substances derived from phenothiazine[232].

The enzymic reduction of nitro-compounds, which proceeds via the formation of their radical-anions, is inhibited by oxygen apparently in consequence of the reaction[233]

$$RNO_2^{\cdot-} + O_2 \rightarrow RNO_2 + O_2^{\cdot-} .$$

The inhibiting effect of SOD has been observed in the study of its influence on hydroxylation by a number of model non-enzymic systems[234,235]. SOD acts similarly also on a number of enzymic hydroxylation processes[236-239]. One can therefore assume that hydroxylation is in such cases a SORA-dependent process. However, the fact that the inhibition of hydroxylation by SOD is not complete may indicate the simultaneous operation of other, SORA-independent hydroxylation mechanisms. In addition to all other species involved in this process, the hydroxylating agents can be the $HO_2^{\cdot}$ radical and the hydroxy radical generated, for example, via the mechanism[235,240]

$$O_2^{\cdot-} + H_2O_2 \rightarrow O_2 + {}^{\cdot}OH + OH^- .$$

Studies in recent years[241,242] indicated the important role of the SORA in the mechanism of the bactericidal action of human leucocytes. The phagocytosis of latex particles or *Propionibacterium Shermanii* leads to chemiluminescence[243]. The addition of SORA oxidants (Nitrotetrazolium Blue or cytochrome *c*) lowers its intensity; SOD inhibits both chemiluminescence[244] and the reduction of oxidants by SORA[243]. These findings show that the bactericidal action of leucocytes is a SORA-dependent process. However, the direct bactericidal agent is not SORA, but the singlet oxygen formed from it. This is confirmed by the greater resistance to phagocytosis of bacteria containing carotenoids [powerful $O_2(^1S)$ quenching agents] compared with the analogous bacteria which do not contain them[245]. In this case the NADPH–NADPH oxidase system (NADPH is reduced nicotinamide-adenine dinucleotide phosphate) is responsible for the generation of the SORA.

The involvement of the SORA has also been postulated in various lipid oxidation processes[123,246-248], because the latter can be inhibited by SOD. Like the bactericidal

action of leucocytes, the oxidation of lipids is apparently caused by the singlet oxygen formed in the disproportionation of the SORA.[123] This is indicated by the inhibition of the oxidation of lipids by 1,3-diphenylisobenzofuran, which is an effective acceptor of singlet oxygen[123].

III. OTHER OXYGEN RADICAL-ANIONS

1. The Radical-Anion of Atomic Oxygen (ORA)

The properties of the ORA ($O^{\cdot-}$) have been little studied hitherto, in contrast to its conjugate acid—the hydroxy-radical. However, the data already available indicate a significant difference between the properties of the ORA and the hydroxy-radical[249].

The EPR signal of $O^{\cdot-}.nH_2O$, which consists of a broad singlet line, has been observed following the ultraviolet irradiation of frozen alkaline solutions in hydrogen peroxide[250].

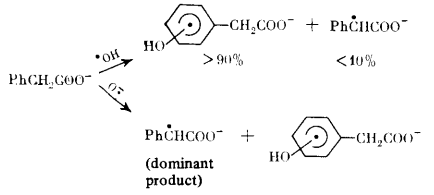
The usual method for the generation of the ORA involves the radiolysis of aqueous solutions of alkali saturated with nitrous oxide[251]. Nitrous oxide then behaves as an acceptor of hydrated electrons and decomposes with formation of the ORA:

$$H_2O \xrightarrow{\gamma} H^{\cdot} + {}^{\cdot}OH + e^-_{aq} + H^+ \ ;$$
$${}^{\cdot}OH + OH^- \rightarrow O^{\cdot-} + H_2O \ ;$$
$$N_2O + e^-_{aq} \rightarrow N_2O^{\cdot-} \rightarrow N_2 + O^{\cdot-} \ .$$

Nitrous oxide can be replaced by ammonium persulphate[252]:

$$S_2O_8^{2-} + e^-_{aq} \rightarrow SO_4^{3-} + SO_4^{\cdot-} \ ;$$
$$SO_4^{\cdot-} + 2OH^- \rightarrow SO_4^{2-} + O^{\cdot-} + H_2O \ .$$

The rate of reaction of the hydroxy-radical with potassium hexacyanoferrate(III) falls markedly with increase of the pH of the medium, which has been interpreted as a result of the dissociation of the hydroxy-radical, leading to the less active ORA:[253,254]



$${}^{\cdot}OH \rightleftarrows O^{\cdot-} + H^+ \ ;$$
$$Fe(CN)_6^{4-} \xrightarrow{{}^{\cdot}OH(O^{\cdot-})} Fe(CN)_6^{3-} \ ;$$
$$pK = 11{,}9 \ .$$

The main pathway in the destruction of the ORA in aqueous solution involves recombination to the peroxide ion[253]:

$$O^{\cdot-} + O^{\cdot-} \rightarrow O_2^{2-} \quad (2k = 2 \cdot 10^9 \text{ litre mole}^{-1}\,\text{s}^{-1}).$$

Kinetic parameters have now been obtained for a number of reactions in which the ORA behaves as an electron or hydrogen atom acceptor. The rate constants for the one-electron oxidation of the Br^-, I^-, SCN^-, Fe^{2+}, $Fe(CN)_6^{4-}$, and $C_6H_5O^-$ ions as well as aniline by the radical-anion $O^{\cdot-}$ are in the range $(0.03-3)\times 10^9$ litre mole^{-1} s^{-1}. Reactions involving the abstraction of hydrogen atoms from a number of organic substrates (CH_3OH, CH_3CN, polymethylbenzenes, pyrrolidine) are characterised by rate constants in the range $(0.22-21)\times 10^9$ litre mole^{-1} s^{-1}.[257-260]

Comparison of the reactivities of the ORA and the hydroxy-radical in reactions with organic compounds shows that the ORA is usually less reactive than the conjugate acid. At the same time, in reactions involving the abstraction of atomic hydrogen from organic compounds the reactivity of the ORA is only slightly inferior to that of the $^{\cdot}OH$ radical, but the rates of addition of the ORA to aromatic systems are smaller by 2–3 orders of magnitude than in the case of the hydroxy-radical. This leads to a significant change of the relative rates of the competing processes on passing from acidic and weakly alkaline media to strongly alkaline media. Thus, whereas at pH values corresponding to acidic and weakly alkaline media the dominant pathway in the reactions with many aromatic derivatives is addition of the hydroxy-radical to the aromatic ring, on passing to high pH values the abstraction by atomic oxygen radical-anions of hydrogen atoms which are not linked directly to the aromatic ring predominates[259,261,262].

Using an ionic cyclotron resonance mass-spectrometer, a study has been made of the reactions of the ORA with unsaturated hydrocarbons involving the abstraction of a proton:

$$CH{\equiv}CH + O^{\cdot-} \rightarrow C_2H^- + {}^{\cdot}OH \ ;$$
$$MeCH{=}CH_2 + O^{\cdot-} \rightarrow C_3H_5^- + {}^{\cdot}OH \ .$$

which can sometimes be accompanied by the subsequent abstraction of a hydrogen atom:

$$CH_2{=}CH_2 + O^{\cdot-} \rightarrow C_2H_3^- + H_2O \ ;$$
$$CH_2{=}CF_2 + O^{\cdot-} \rightarrow CF_2C^{\cdot-} + H_2O$$

which formally corresponds to the abstraction of the H_2^+ radical-cation from the substrate[263].

The oxidation of acetone by hydroxy-radicals and the ORA leads to different products[264]:

$$Me_2CO + {}^{\cdot}OH \rightarrow MeCOCH_2^{\cdot} \xrightarrow{O_2,\,H_2O} \rightarrow MeCOCOOH \ ;$$
$$Me_2CO + O^{\cdot-} \rightarrow Me{-}\underset{\displaystyle {}^{\cdot}O\quad O^-}{\overset{\displaystyle |\quad |}{C}}{-}Me \rightarrow MeCOO^- + Me^{\cdot} \ ;$$
$$Me^{\cdot} \dashrightarrow \rightarrow CH_2O \ .$$

2. The Ozone Radical-Anion (OzRA)

The ozone molecule exhibits a very high electron affinity (2.14 ± 0.15 eV,[265] 2.09 eV[266]), readily combines with an electron, and is converted into the OzRA ($O_3^{\cdot-}$). The OzRA salts of alkali metals (Na, K, Ru, Cs) and the $N(CH_3)_4^+$ cation[267-269] have been isolated in a pure state. They are usually obtained by treating solid alkalis[267,268] or alkali metal superoxides[270-272] with ozonised oxygen:

$$O_3 + MOH \rightarrow M^+O_3^{\cdot-} + {}^{\cdot}OH \ ;$$
$${}^{\cdot}OH + MOH \rightarrow M^+O^{\cdot-} + H_2O, \quad M = Na, K, Rb, Cs, \text{ or } NMe_4 \ ;$$
$$M^+O^{\cdot-} + O_3 \rightarrow M^+O_3^{\cdot-} + O_2 \ ;$$
$$M^+O_2^{\cdot-} + O_3 \rightarrow M^+O_3^{\cdot-} + O_2 \ .$$

Alkaline earth metal ozonides, which are stable only at low temperatures, can be obtained by the ozonisation of the peroxides of these metals[273,274].

Aqueous solutions of alkali containing nitrous oxide and oxygen are used to generate the OzRA in studies by pulse radiolysis[275-277]:

$$H_2O \xrightarrow{\gamma,\,N_2O,\,OH^-} O^{\cdot-} \ ;$$
$$O^{\cdot-} + O_2 \rightarrow O_3^{\cdot-} \quad (k = 2.5 \cdot 10^9 \text{ litre mole}^{-1}\,\text{s}^{-1}) \text{ (Ref.275).}$$

Alkali metal ozonides are orange or red crystalline compounds whose lattice is made up of regularly alternating alkali metal ions and O_3^- species. It has been found that[278] the O–O bond length in the O_3^- radical-anion is 1.19 Å and the O–O–O angle is 100°.†

Alkali metal ozonides dissolve in liquid ammonia, forming paramagnetic solutions. The maximum of the O_3^- absorption band is near 450 nm (liquid ammonia)[269,280] and in the region of 430–438 nm (water)[275–277].

The OzRA salts are rapidly decomposed by water via the mechanism[281]

$$MO_3 + H_2O \rightarrow {}^{\cdot}OH + O_2 + MOH\,.$$

It has been noted that this reaction can serve as a powerful source of hydroxy-radicals, which are formed in the absence of metal cations capable of forming complexes with them[282].

Low temperatures and a highly alkaline medium increase the stability of the OzRA in an aqueous medium (the half-life in 8 M KOH at −50 °C is 12 min)[43].

Virtually nothing is known about the organic reactions of alkali metal ozonides. It has been noted that solid KO_3 is capable of initiating the chain oxidation of acetaldehyde by oxygen, which is distinguished by an unusual chain length (more than 10^4 CH_3CHO molecules react per KO_3 molecule)[283]. The mechanism of the reactions of ozone with organic compounds has been comparatively little studied[284]. The initial stage in the oxidation of saturated hydrocarbons RH by ozone is a simple bimolecular reaction[285,286]. The most probable products under these conditions are the R˙ and ˙OH radicals and oxygen[287–291]. Like the oxidation of hydrocarbons by oxygen, their reaction with ozone apparently includes an electron transfer stage, which precedes the formation of weak CTC:[292–294]

$$RH + O_3 \rightleftarrows RH \ldots O_3 \rightleftarrows [RH^{+\cdot} \ldots O_3^-] \rightarrow [R^{\cdot} + O_2 + {}^{\cdot}OH] \begin{cases} \longrightarrow ROH + O_2 \\ \longrightarrow R^{\cdot} + O_2 + {}^{\cdot}OH. \end{cases}$$

Whereas in the reaction with oxygen the abstraction of a hydrogen atom by a triplet oxygen molecule can serve as an alternative mechanism, such an explanation is altogether impossible for the diamagnetic ozone.

At low temperatures, where the thermal oxidation reaction does not occur, the irradiation of ozone solutions in saturated hydrocarbons leads to their photochemical oxidation[294]. This apparently entails a photoinduced electron transfer to the CTC. Analysis of the composition and ratio of the oxidation products (alcohols, ketones) indicates the similarity of the mechanisms of the photochemical and thermal reactions of ozone with saturated hydrocarbons. In addition, both reactions of ozone with isomeric decalins proceed with approximately the same degree of retention of the configuration of the oxidation products[294].

The first stage in the oxidation with ozone of various organometallic compounds[108] as well as organic compounds containing heteroatoms[284] (amines, sulphides, nitroxy-radicals) also involves the formation of the OzRA as a result of electron transfer from the substrate to ozone.

The oxidation of trimesitylvinyl alcohol to the radical (XXIII) under the influence of ozone has been described[295]:

$$Mes_2C{=}C(OH)\,Mes + O_3 \rightleftarrows Mes_2C{=}C(OH)\,Mes \ldots O_3 \rightarrow \rightarrow \left[\left(\begin{array}{c} OH \\ | \\ Mes_2C{=}CMes \end{array}\right)^{\ddagger} \ldots O_3^-\right] \rightarrow Mes_2\dot{C}COMes\,.$$

(XXIII)

† In free ozone the O–O bond length is 1.26 Å and the O–O–O angle is 127°.[279]

The epoxidation of olefins and aromatic compounds by ozone begins in the same way:

$$\begin{array}{c} \diagup\!\!\diagdown C{=}C \diagup\!\!\diagdown + O_3 \rightleftarrows \diagup\!\!\diagdown C{=}C \diagup\!\!\diagdown \ldots O_3 \rightleftarrows \left[\left(\diagup\!\!\diagdown C{-}C \diagup\!\!\diagdown\right)^{\ddagger} \ldots O_3^-\right] \rightarrow \\ \rightarrow \left[\left(\diagup\!\!\diagdown C{=}C \diagup\!\!\diagdown\right)^{\ddagger} \ldots O^- \ldots O_2\right] \rightarrow -C\overset{O}{\diagup\!\!\diagdown}C- + O_2\,. \end{array}$$

In fact, as already mentioned, the OzRA is capable of dissociating into the ORA and O_2 ($k = 3.3 \pm 0.3 \times 10^3$ s^{-1}; 25 °C).[257]

In aqueous solutions of alkali, ozone decomposes via the mechanism[296]

$$\begin{gathered} O_3 + OH^- \rightarrow O_3^- + {}^{\cdot}OH\,; \\ {}^{\cdot}OH + OH^- \rightarrow O^{-\cdot} + H_2O\,; \\ 2O^{-\cdot} + H_2O \rightarrow O + 2OH^-\,; \\ O^{-\cdot} + O \rightarrow O_2^-\,; \\ 2O_3^- + H_2O \rightarrow HO_2^- + OH^- + O_2\,. \end{gathered}$$

The formation of the ˙OH radicals and the ORA is responsible for the extremely effective oxidising properties of ozone in an alkaline medium in relation to organic compounds (the final oxidation products are CO_2 and H_2O).[297] In the $O_3^- \rightleftharpoons O_2 + O^-$ system the most active species is the ORA, so that many reactions of the OzRA are in fact reactions of the ORA.

IV. THE CARBON DIOXIDE RADICAL-ANION

The existence of the carbon dioxide radical-anion (CRA) CO_2^- was demonstrated at the beginning of the 1960s in a study of the EPR spectra of alkali metal formate crystals subjected to γ- or X-irradiation[298–300].

In contrast to the carbon dioxide molecule, the CRA is non-linear[299,301]; the O–C–O angle is approximately 135°. The EPR spectrum of the CRA in aqueous solution (singlet line with $g = 2.0040$) has been observed in two investigations[104,302]. The available data concerning the magnitude of pK for the equilibrium $^{\cdot}COOH \rightleftharpoons CO_2^- + H^+$ are contradictory: 2.8 (Gutlbauer and Getoff[303]) and 1.4 (Buxton and Sellers[304]).

Since the CO_2 molecule apparently has a negative electron affinity (−0.36 eV according to the results of a quantum-mechanical calculation[301]) its direct chemical reduction proceeds with difficulty and is not at present used to generate the CRA. The simplest method of generating the CRA in an aqueous medium involves the interaction of hydroxy-radicals with formates. Hydrogen peroxide is usually reduced by Ti^{3+} salts in the presence of formate ions[104,305]:

$$\begin{gathered} Ti^{3+} + H_2O_2 \rightarrow Ti^{4+} + {}^{\cdot}OH + OH^-\,; \\ {}^{\cdot}OH + HCO_3^- \rightarrow CO_2^- + H_2O \\ (k = 2.7 \cdot 10^9 \text{ litre mole}^{-1}\,s^{-1}). \end{gathered}$$

The CRA is unstable and is rapidly converted into formate, bicarbonate, and oxalate anions and carbon monoxide[306–309]. The formation of the formate anion under these conditions undoubtedly begins with the protonation of the CRA. The subsequent stages may involve the reduction of the carboxy-radical and the protonation of the resulting formate anion. It has been suggested that the carbonate ion and carbon monoxide can be formed via a bimolecular reaction[306,309], but the possibility of the

unimolecular fragmentation of the CRA cannot be ruled out either:

$$CO_2^{\cdot-} + H_2O \rightleftarrows {}^{\cdot}COOH + OH^-;$$
$$^{\cdot}COOH + CO_2 \xrightarrow{-CO_2} {}^{-}COOH;$$
$$^{-}COOH \begin{cases} \longrightarrow HCOO^- \\ \xrightarrow{H^+} HCOOH \end{cases};$$
$$2CO_2^{\cdot-} \rightarrow CO_3^{2-} + CO;$$
$$CO_3^{2-} + H^+ \rightarrow HCO_3^-;$$
$$2CO_2^{\cdot-} \rightarrow (-COO^-)_2.$$

The electrochemical reduction of carbon dioxide in dimethyl sulphoxide, which takes place at high cathodic potentials (−1.9 to −2.0 V) according to coulometric measurements, may consist in the transfer of one electron (gold cathode) or between one and two electrons (mercury cathode) to the CO_2 molecule[306]. The main products are carbon monoxide and the bicarbonate anion.

The CRA is also formed when hydrated electrons, generated in the radiolysis of water, are accepted by carbon dioxide[310]:

$$CO_2 + e_{aq}^- \rightarrow CO_2^{\cdot-} \quad (k = 7.7 \cdot 10^9 \text{ litre mole}^{-1}\text{ s}^{-1}).$$

In this case the formation of the CRA is demonstrated, in particular, by the fact that in the presence of aliphatic alcohols they are carboxylated to α-hydroxyacids[311]:

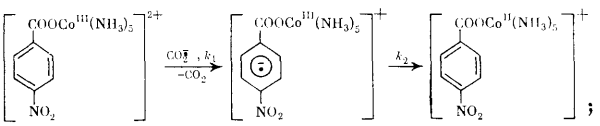
$$H_2O \xrightarrow{\gamma} H^{\cdot} + {}^{\cdot}OH + e_{aq}^- + H^+;$$
$$e_{aq}^- + CO_2 \rightarrow CO_2^{\cdot-};$$
$$RCH_2OH + {}^{\cdot}OH \xrightarrow{-H_2O} R\dot{C}HOH;$$
$$R\dot{C}HOH + CO_2^{\cdot-} \rightarrow RCH(OH)COO^-.$$

The CRA can also be generated by the one-electron oxidation of the oxalate anion. Examples of such reactions known at the present time are associated with the decomposition of tervalent manganese[312] and cobalt[313] oxalates and the chain oxidation of oxalate anions by persulphates[314]:

$$[M(C_2O_4)_n]^{(3n-3)-} \rightarrow M^{2+} + (n-1)C_2O_4^{2-} + CO_2^{\cdot-} + CO_2;$$
$$S_2O_8^{2-} \rightleftarrows 2SO_4^{\cdot-};$$
$$SO_4^{\cdot-} + C_2O_4^{2-} \rightarrow SO_4^{2-} + CO_2^{\cdot-} + CO_2;$$
$$CO_2^{\cdot-} + S_2O_8^{2-} \rightarrow CO_2 + SO_4^{\cdot-} + SO_4^{2-} \text{ etc.}$$

Reactions in which the CRA behaves as a one-electron reductant are most characteristic of this radical-anion. Thus, when a solution of manganese(III) oxalate is decomposed thermally in the presence of oxygen, an appreciable amount of H_2O_2 is formed[312], apparently from superoxide radical-anions:

$$CO_2^{\cdot-} + O_2 \rightarrow CO_2 + O_2^{\cdot-} \quad (k = 4.6 \cdot 10^9 \text{ litre mole}^{-1}\text{ s}^{-1}) \text{ (Ref.315)}.$$
$$2O_2^{\cdot-} + H_2O \rightarrow H_2O_2 + O_2.$$



The interaction of the CRA with alkyl halides[316,317] and also with compounds having an N–halogen bond[318] leads to the dissociative capture of an electron by halide molecules; the free radicals formed in this process have been identified by EPR:[317,318]

$$RX + CO_2^{\cdot-} \rightarrow R^{\cdot} + X^- + CO_2;$$
$$MeCONHBr + CO_2^{\cdot-} \rightarrow MeCONH^{\cdot} + Br^- + CO_2.$$

Apparently all iodo-derivatives as well as sufficiently reactive bromides and chlorides react with the CRA.[317]

The ability of the CRA to transfer an electron to the *p*-nitrophenyl diazonium cation[319], quinones[315,320], aliphatic nitro-compounds[319], nitrobenzene[321], acetaldehyde, acetone and certain other carbonyl compounds[322], maleimide[323], riboflavin[324], and a number of dyes[325] has been demonstrated.

Under the influence of the CRA, the complexes of tervalent cobalt and ruthenium are reduced to the corresponding derivatives of the bivalent metals[326–328]. The reduction of the CRA by *p*-nitrobenzoatopentammine-cobalt(III) ion is of particular interest[328]. In this case it was possible to detect by ultraviolet spectroscopy the primary reduction product [the radical-ion (XXIV)], which is converted by an intramolecular electron transfer into the final product—the *p*-nitrobenzoatopentammine-cobalt(II) complex:

(XXIV)

$k_1 = 4.9 \cdot 10^9$ litre mole^{-1} s^{-1}; $k_2 = 2.6 \cdot 10^3$ s^{-1}.

Certain reactions are known[319] which can be classified as free-radical additions of the CRA to multiple bonds (demonstrated with the aid of EPR):

$$RCH{=}\overset{+}{N}(O^-)O^{\cdot} + CO_2^{\cdot-} \rightarrow \underset{\displaystyle CO_2^-}{\overset{\displaystyle |}{RCH}}{-}N(O^-)O^{\cdot};$$
$$R^1R^2C{=}NOH + CO_2^{\cdot-} \rightarrow R^1R^2C(CO_2^-)NHO^{\cdot}.$$

In connection with the recent hypothesis of the possible involvement of the CRA in photosynthetic processes[7], the following considerations may be noted.

(1) The reduction to the CRA constitutes an extremely effective means of activating carbon dioxide.

(2) Since the fixation of carbon dioxide is a dark process, the problem arises of the nature of the reductant capable of reducing CO_2 molecules, which are fairly difficult to reduce. In this connection, one can postulate the possibility of the reduction of carbon dioxide to the CRA even by comparatively weak reductants when the molecules of the latter and CO_2 are located in different parts of the homogeneous systems at whose boundary the electrical double layer is capable of exerting a catalytic effect on electron transfer to CO_2. For example, it has been stated that pyrenesulphonic acid, which is incapable of being reduced by the CRA in a homogeneous medium, is readily reduced in the solubilised state (positively charged micelles) by the CRA present in the aqueous phase[329].

The electrical double layer apparently has an analogous influence in the photochemical oxidation of water by chlorophyll in the octane–water system (under homogeneous conditions, water is not oxidised)[330].

(3) The oxalic acid present in the leaves of certain plants can be a product of the dimerisation of the CRA.

V. THE $SO_4^{\cdot-}$ RADICAL-ANION

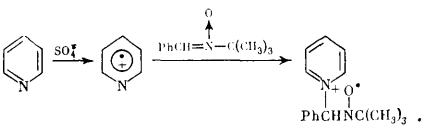
The formation of the sulphate radical-anion (SRA) $SO_4^{\cdot-}$ was first postulated as the initial stage in oxidation by alkali metal persulphates:

$$S_2O_8^{2-} \rightleftarrows 2SO_4^{\cdot-}.$$

Subsequently this view became generally accepted. The SRA is formed fairly rapidly only on heating aqueous solutions of persulphates to 80–100°C. At lower temperatures the CRA can be conveniently generated either

photochemically[331] or by treating persulphates with reductants (Fe^{2+}, Ti^{3+}, etc.)[332,333]:

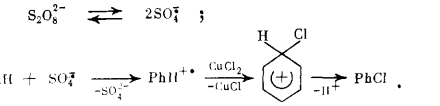
$$S_2O_8^{2-} \xrightarrow{h\nu} 2SO_4^{\cdot-} ;$$



$$S_2O_8^{2-} + M^{n+} \rightarrow SO_4^{\cdot-} + SO_4^{2-} + M^{(n+1)+} .$$

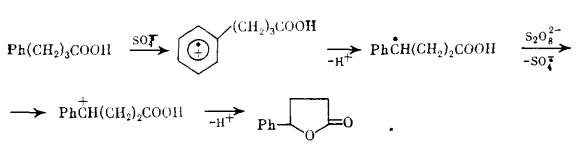
An anisotropic EPR signal ($g_1 = 2.004$; $g_2 = 2.012$; $g_3 = 2.030$), apparently due to the SRA, was detected in a study of crystalline barium sulphate labelled with the radioactive isotope ^{35}S.[334] The EPR signal of the SRA in solution has been detected[302].

The chemical properties of the SRA show that it is a powerful one-electron oxidant. Aromatic compounds are readily oxidised by this species to radical-cations[333,335,336]:



$$ArH + SO_4^{\cdot-} \rightarrow ArH^{+\cdot} + SO_4^{2-} .$$

Direct evidence for the formation of the radical-cations in the reaction of the SRA with aromatic compounds was obtained with the aid of EPR.[336] Even pyridine[337] and its derivatives[338] can be oxidised to radical-cations by treatment with the SRA. The formation of the pyridinium radical-cation was demonstrated with the aid of a spin-trapping agent (2-methyl-2-nitrosopropane)[337,338]:

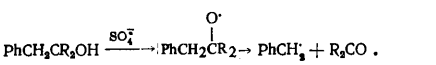


An interesting method for the chlorination of benzene and its homologues is based on the oxidation of these compounds to radical-cations; it consists in heating them with a mixture of sodium persulphate and copper(II) chloride in an aqueous acetonitrile medium[335]:

$$S_2O_8^{2-} \rightleftharpoons 2SO_4^{\cdot-} ;$$

A convenient method has been proposed for the synthesis of the lactone of γ-hydroxy-γ-phenylbutyric acid, based on the oxidation of γ-phenylbutyric acid[339]:

The interaction of the SRA with certain saturated compounds also begins with the abstraction of an electron from the latter[79,80,340]:

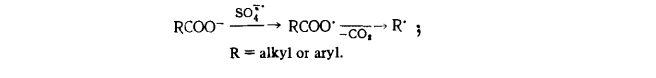


$$R^1R^2CHOH + SO_4^{\cdot-} \xrightarrow[-SO_4^{2-}]{} R^1R^2\dot{C}HOH \xrightarrow[-H^+]{} R^1R^2CHO \xrightarrow[-R^1R^2CHOH]{R^1R^2CHOH} R^1R^2\dot{C}OH$$

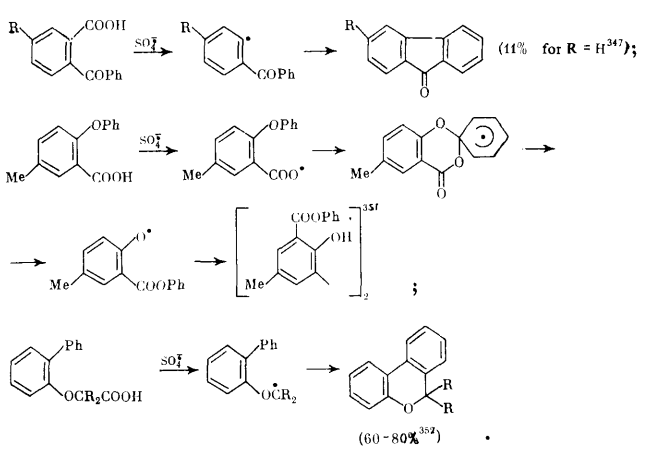
$$R_2S_2 + SO_4^{\cdot-} \xrightarrow[-SO_4^{2-}]{} R_2S_2^{\cdot+} .$$

Previously the reaction with alcohols was treated as abstraction of an α-hydrogen atom by the $SO_4^{\cdot-}$ radical-anion[341,342].

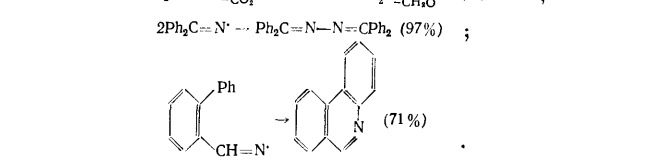
Alkoxy-radicals are also formed in the photochemical oxidation of alcohols by paraquat dichloride[343] and iron(III) compounds[344] as well as quinones[345].



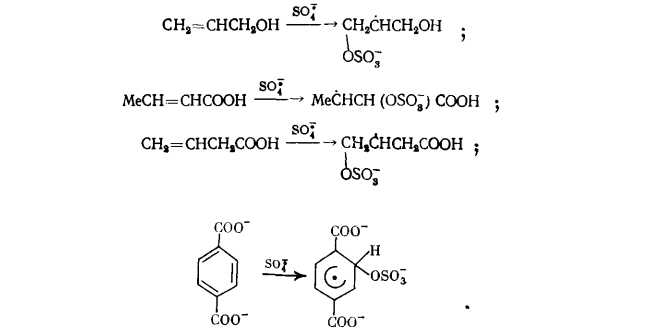
In the reaction with the SRA various alcohols, having the general formula $PhCH_2CR_2OH$, undergo oxidative fragmentation[80,333] (demonstrated by the spin-trapping method[80]):



The reaction of the SRA with the nitromethane anion leads to the nitromethyl radical[346]:



The SRA has found an important application in a simple and convenient method for the generation of alkyl and aryl radicals in aqueous solutions by the oxidative decarboxylation of carboxylic acids[333,347-350]:



In many instances the free radicals formed in the oxidation of carboxylic acids cyclise or fragment, which can be of definite synthetic interest:

Oxidative decarboxylation under the influence of the SRA can be used for the generation of iminyl radicals[353,354]:

Apart from the reactions in which the SRA behaves as an oxidant, reactions involving the addition of the SRA to unsaturated compounds are also known[333]:

It is interesting that the EPR spectra of the adducts of the SRA with a number of unsaturated acids (for example, maleic and fumaric) can be observed only at fairly high pH, which is associated with the greater reactivity of the

SRA in relation to carboxylate anions than in relation to neutral molecules of unsaturated acids. Hence it follows that the SRA is an electrophilic anion[333], which differentiates it sharply from organic radical-anions[355].

VI. OTHER INORGANIC RADICAL-IONS

A large number of other relatively unstable inorganic radical-anions have been described. Although very little is known about the organic reactions of these species, some of them are of considerable interest for organic chemistry. These include the relatively unstable molecular halogen ions $X_2^{\cdot-}$. Presumably the $X_2^{\cdot-}$ radical-anions should arise in organic reactions with participation of halogens acting as electron acceptors. For example, the reaction of tetramethylhydrazine with iodine is treated in this way[356]:

$$Me_2NNMe_2 + I_2 \rightleftarrows Me_2NNMe_2 \ldots I_2 \rightleftarrows [Me_2NNMe_2]^{\cdot+} + I_2^{\cdot-} .$$

Another pathway leading to halogen radical-anions involves the reaction of the halide ion with the atomic halogen:

$$X^{\cdot} + X^- \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} X_2^{\cdot-}$$

($k_1 = 2.1 \cdot 10^{10}$ litre mole^{-1} s^{-1}; $k_{-1} = 1.1 \cdot 10^5$ s^{-1}; $K = 1.9 \cdot 10^5$ litre mole^{-1} (Ref.357) (X = Cl)).

In practice the $X_2^{\cdot-}$ radical-anions are usually generated by the radiolysis of aqueous solutions of alkali metal halides[358-361].

Halogen radical-anions are apparently effective oxidants[103]. The oxidation of bicarbonate or carbonate ions by the hydroxy-radical[362] or the $SO_4^{\cdot-}$ radical-anion[363] as well as the flash photolysis of the salt (XXVI) [364,365] lead to the radical-anion $CO_3^{\cdot-}$:

$$HCO_3^- (CO_3^{2-}) + {}^{\cdot}OH \rightarrow CO_3^{\cdot-} + H_2O\,(OH^-) \ ;$$

$$CO_3^{2-} \xrightarrow[-SO_4^{2-}]{SO_4^{\cdot-}} CO_3^{\cdot-} \ ;$$

$$\text{(XXVI)} \quad [Co(NH_3)_4CO_3]ClO_4 \xrightarrow{h\nu} CO_3^{\cdot-} + Co + 4NH_3 + ClO_4^- .$$

The pK for the equilibrium $HCO_3^{\cdot} \rightleftarrows H^+ + CO_3^{\cdot-}$ is 9.5.[366,367]

The chemical properties of the $CO_3^{\cdot-}$ radical-anion are of considerable interest, since its formation is to be expected in living organisms exposed to ionising radiation (from the hydroxy-radical and the bicarbonate anion). In addition, another possible pathway leading to the formation of the carbonate radical-anion may involve the photochemical oxidation of the carbonate ion by quinones[368].

It has been found that this radical-anion reacts with alcohols, abstracting an α-hydrogen atom[365], and with aromatic compounds[369]; in the latter case it apparently adds to the aromatic ring.

---o0o---

Thus inorganic radical-anions and in the first place the oxygen and sulphate radical-anions, are extremely promising for synthetic and theoretical organic chemistry. The study of the properties of inorganic radical-ions constitutes an essential stage in the investigation of both photosynthetic and respiratory processes; without it, there can be no effective attempt at a functional modelling of these processes.

The chemistry of unstable inorganic radical-ions leads to new possibilities for the investigation of the mechanisms of reactions of organic substrates with inorganic reagents, including those of various heterogeneous-catalytic processes.

During the preparation of the review for the press, a number of interesting studies on the chemistry of the oxygen radical-anion were published[370-381].

Association of Dye Molecules and Its Spectroscopic Manifestation

V.I.Yuzhakov

Theoretical data for the influence of the association of the molecules of complex organic compounds (dyes) in solutions on their electronic spectra and other optical characteristics are examined and surveyed. The conditions for the formation of associated species and the influence of solvents, concentration, and temperature on this process are described. Methods for the determination of the association constants and the structure and compositions of the associated molecules are examined. The results of studies undertaken to investigate the luminescent associated dye species, their triplet states, and pathways leading to the deactivation of the electronic excitation are described. The nature of the forces which lead to the binding of the dye molecules in associated species is discussed and studies on the concentration-induced quenching of the luminescence of dye solutions are analysed.
The bibliography includes 197 references.

I. INTRODUCTION

Numerous studies have been carried out during recent decades on the association of the molecules of complex organic compounds in view of both scientific interest in the nature of excited electronic states and their role in chemical and biological processes and photochemical reactions, and the extensive use of organic dyes in laser technology, in cine-phototechniques, and in other fields. For example, in the course of photosynthesis chlorophyll functions in an associated state and haemoglobin consists of four subunits, the haem groups being involved in a close interaction. Nitrogen-containing bases, forming part of nucleic acids and interacting with one another, give rise to a molecular aggregate. The study of various properties of complex molecules which exist in the monomeric state in solution is complicated by different types of intermolecular interaction and this is the reason why studies on association permit a deeper understanding of their intramolecular energetics.

One of the most important classes of compounds with a complex molecular structure, which are widely used in technology, are organic dyes. Dyes are unique agents capable of transforming light energy. Their extensive technical applications are in fact due to their photophysical properties–their ability to absorb light and transform it into radiation at other frequencies. These properties depend on many factors, including intermolecular interaction. The association of dye molecules has a significant influence on their photophysical properties, resulting either in a loss of capacity for luminescence or in an appreciable redistribution of the emitted energy.

The association of molecules of complex organic compounds has been studied in numerous investigations. Nevertheless, there is not yet a unanimous view in the literature on many problems, such as, for example, the quantitative relation between the migration of the excitation energy in dye solutions and quenching of the luminescence, which are closely related to problems of association. All the aspects of the spectroscopic manifestation of association have not been ultimately elucidated either.

The aim of the present review is to give an account of the association of dye molecules from the standpoint of the influence of this process on their photonics and the spectroscopic changes occurring in their aggregation. Associated dye molecules, which are stable in the ground state and which are formed in weak and intermediate interactions, are examined; aggregates produced by covalent bonding (the so-called intramolecular associated species) and problems associated with formation of excimers and and charge-transfer complexes are not considered.

II. EXPERIMENTAL STUDY OF ASSOCIATION. CONDITIONS FOR THE FORMATION OF ASSOCIATED SPECIES AND THEIR STRUCTURE

The procedures used to investigate the aggregation of complex organic molecules are extremely varied: methods based on the study of diffusion[1], conductivity[2], light scattering[3], polarography[4,5], and electron paramagnetic resonance[6]. Spectroscopic methods (spectrophotometric and luminescence methods) are most widely used and yield the most fruitful results. This review presents the results of spectroscopic studies of association.

The association of dye molecules has been observed in various solvents and its nature (degree and order of association and the structure of aggregates) depend significantly on the nature of the solvent. Dye molecules are very effectively associated in water[7-11] and in mixtures of polar and non-polar solvents[12-15]. In polar solvents, where dye molecules are strongly solvated, their aggregation occurs at high concentrations[16,17]. In non-polar solvents chlorophyll molecules associated even at low concentrations[18,19], but dyes do not usually dissolve in such solvents. A decrease of the temperature of the solution intensifies association[20-27].

In the majority of studies of the association of the molecules of complex organic compounds the authors observed the occurrence of aggregation in different solvents, calculated the monomer–dimer equilibrium constants and the

heat of association (the binding energy of the molecules), isolated the spectrum of the associated species, and determined the degree (fraction of associated molecules) and order (number of molecules in the associated species) of association.

The most typical three kinds of changes in the absorption spectra of dyes occurring when their molecules are associated are as follows: (1) the formation of a narrow band (cyanine dyes); (2) decrease of absorbance (thiazine dyes); (3) the splitting of the absorption band into two and more components (xanthene dyes, acridine compounds, etc.).

Fig. 1 presents the absorption spectra of solutions of rhodamine 6G for different concentrations in an ethanol–carbon tetrachloride mixture. The changes in the spectra with increasing dye concentration indicate the formation of associated rhodamine species.

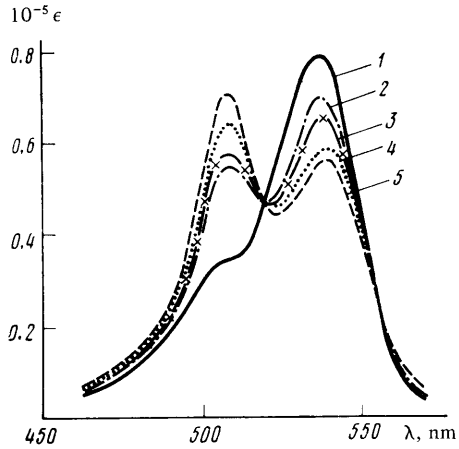

Figure 1. The absorption spectra of solutions of rhodamine 6G in a mixture of ethanol and carbon tetrachloride as a function of concentration (M): 1) 1.0×10^{-4}; 2) 6.4×10^{-4}; 3) 1.0×10^{-3}; 4) 2.5×10^{-3}; 5) 4.0×10^{-3}.

Association is most pronounced in aqueous solutions. Scheibe and coworkers[28,29] observed the formation in water of involved complexes of cyanine dyes, which have come to be called "Scheibe polymers". An increase of the concentration of these compounds leads to the appearance of a new very intense absorption band with $\lambda_{max} =$ 574 nm in the absorption spectra at $c = 4 \times 10^{-3}$ g ml^{-1}. The half-width of this band proved to be approximately six times smaller than that in the absorption spectrum of the dilute solution. The viscosities of such concentrated solutions are greatly increased; these phenomena are fully reversible on dilution or on heating of the solution. Förster[30] proposed a model for the Scheibe polymers, according to which the planar dye molecules are arranged in a row at equal distances from one another and have translational symmetry. If the oscillators of the individual molecules forming the polymer have the same amplitudes and vibration phases, the latter are added together, which gives rise to a resultant transition moment differing from the moment of each component oscillator; according to Förster, this should result in the appearance of a new absorption and luminescence band. The small width of this band is due to the fact that translational symmetry obtains only along the polymer axis. In this case the width is determined by the corresponding transitions allowed by selection rules. The formation of associated cyanine molecules has been observed not only in water but also in many organic solvents[31], for which narrow absorption bands appeared gradually with increased concentration of cyanine solutions and not abruptly; with increase of concentration, the association process is merely strongly accelerated. Aggregates of cyanine dyes, which are formed in aqueous ethanol solutions[32,33] also have an ordered layer structure with a definite distribution of anions between individual layers. This conclusion was based on a study of the concentration-induced changes in circular dichroism spectra and ultraviolet absorption spectra.

The concentration and temperature effects in aqueous solutions of rhodamines 3B and 6G have been investigated by Levshin and Baranova[7], who studied the influence of pH on the state of the dye and described a method for the determination of the degree of association in its solutions. The association of Congo Red, Methylene Blue, Crystal Violet, and other dyes in water and aqueous alcoholic solution has been studied[5,34,35] by both spectroscopic and polarographic methods. The authors of these investigations obtained conflicting results for the compositions of the associated species. Thus, according to their data, associated Crystal Violet species consist of 5–6 molecules. However, it has been noted[9] that this dye forms a mixture of associated species and the number of molecules in such association complexes increases with concentration. An estimate of this number based on diffusion measurements[1] yielded 18 molecules, while for substances analogous to those investigated by Hiroshi et al.[32] an association order of 2–3 was obtained.

With increase of dye concentration and with decrease of temperature, the equilibrium between monomeric dye molecules and associated molecules shifts towards the latter. A number of studies have been made on these problems for xanthene dyes in aqueous solutions[17,36-42]. On the assumption that the associated species of these dyes are dimers, methods have been developed for the isolation of their absorption spectra, the monomer–dimer equilibrium constants have been calculated, and chemical relaxations have been studied.

The influence of the solvent on aggregation processes is determined by the extent to which it promotes or hinders the combination of dye molecules by surrounding them with a solvation shell. The addition of organic solvents to aqueous solutions has a significant influence on the association of dye molecules[8,43-45], suppressing the latter. Absorption bands due to dimers and trimers have been observed in the absorption spectra of aqueous glycerol solutions and pyronine and fuchsine as a function of concentration ($5 \times 10^{-2} - 5 \times 10^{-6}$ M) at room temperature and at 80 K;[43] these spectroscopic changes can be satisfactorily accounted for within the framework of exciton theory.

The formation of associated species in aqueous solutions has been observed for thiazine dyes[46] (dimers), Acridine Orange, and Methylene Blue[47] (complex polymers), and for Bonadur Red[48] (dimerisation via hydrogen bonding with a heat of dimerisation of approximately 6 kcal mole^{-1}).

Associated species can also be formed from unlike molecules. However, the problem of association of unlike molecules of complex organic compounds has been inadequately investigated. There have been a few studies devoted to this subject[40,49-51]. It has been established[51]

that, with increase of the concentration of Acridine Orange and rhodamine 6G in aqueous solution of Methylene Blue, the absorbance falls both in the band of Methylene Blue (λ_{max} = 664 nm) and in the bands of Acridine Orange (λ_{max} = 492 nm) and rhodamine 6G (λ_{max} = 526 nm); in the first case new absorption bands do not arise. Such behaviour of the absorption spectra of the above systems indicates association of unlike species (their bond energy is 12 kcal mole^{-1} in the first case and 7 kcal mole^{-1} in the second). The study of such aggregates is the significant interest for the further development of the theory of the association of complex organic molecules.

The problem of whether or not dye molecules associate in solutions with a polar organic solvent remained unsolved for a long time. The difficulty was that the electronic absorption spectra of such solutions do not vary over a wide concentration range[52]. However, by measuring the concentration dependence of the average molecular weight of rhodamine dyes in alcoholic solutions, it was established[16] that in this case association takes place also. This was demonstrated indirectly in another study[53]. The degree of association in such highly concentrated solutions reaches 16%.[16] Associated species in alcoholic solutions of rhodamine dyes were detected also by EPR.[6] Nevertheless, studies where it is concluded that there is no aggregation of dye molecules in alcoholic solutions in view of the lack of any changes in the absorption spectra are still being continued[37,54]. The reason for this is that the degree of association of dye molecules in polar organic solvents is insignificant[16] and the absorption spectrum of the resulting associated species is similar to that of the monomer.

The study of the role of the anion in the association process[55,56] in various solvents showed that it does not have a significant influence on the aggregation of dye molecules. On the other hand, the structure of dye molecules has a strong influence on the development of association[57-59], which will be discussed below. The influence of temperature on the association of xanthene dye molecules has been studied[26,60-62]. Investigation of the ultraviolet absorption spectra of acridines in the range from 20° to −140°C [63] led to the conclusion that on cooling dimerisation takes place with participation of the hydrogen bonds in the NH groups.

The study of the association of dye molecules usually reduces to the determination of a number of constants, among which the number of molecules in the associated species n and the aggregation constant K_n are important. These constants are difficult to determine from spectroscopic data, since the number of unknowns is greater than the number of equations which can be set up. These difficulties have been overcome[20] with the aid of the equation

$$\lg [C_0(\varepsilon - \varepsilon_1)] = n \lg [C_0(\varepsilon - \varepsilon_n/n)] + \lg [K_n n (\varepsilon_1 - \varepsilon_n/n)^{1-n}], \quad (1)$$

where ϵ is the observed absorbance at a specified wavelength, ϵ_1 and ϵ_n are the absorbances of the monomer and the associated species, and C_0 is the overall concentration of the dye in solution. By plotting $\lg C_0(\epsilon - \epsilon_1)$ against $\lg C_0(\epsilon - \epsilon_n/n)$, it is possible to determine the order of the aggregation n from the slope of the resulting straight line and K_n can be found from the intercept on the ordinate axis. The difficulty of this method lies in the fact that one must know exactly the values of ϵ_1 and ϵ_n/n.

Other graphical methods have been proposed[64]. The authors call these procedures the "method of maximum slope" and the "method of optimum deviation". These methods make it possible to determine the molar extinction coefficient and the number of molecules in the dye aggregates provided that there is equilibrium between the monomers and associated species, and the absorption spectrum of the monomers is known. Comparison of the two methods[65] showed that they yield concordant results. A method for the determination of the order of association of dyes involving the study of the deviation from Beer's law has been described[66].

The knowledge of the geometrical structure of aggregates is of great interest for the theory of the association of complex molecules. In particular, it can help in the elucidation of the nature of the forces binding dye molecules into associated species. Although the geometry of such species can apparently be extremely varied in different instances, in theoretical calculations it is usually assumed that they have an ordered structure[67-70]. The spectra of solutions of dyes in which their molecules are associated also very often indicate the existence of such order. For a "sandwich" structure of the aggregates, the angle between the planes of the associated molecules φ is calculated from the formula[67,71-76]

$$\mu_s/\mu_d = (1 + \cos\varphi)/(1 - \cos\varphi), \quad (2)$$

where μ_S and μ_d are the electronic transition moments for the short- and long-wavelength absorption bands of the dimer, which are calculated with the aid of the relation $\mu^2 = 1.09 \times 10^{-19} \int \alpha(\nu) d\nu$ [$\alpha\nu$ is the absorption spectrum of the corresponding band]. The transition moments are related to the oscillator strength f by the expression

$$f = 8\pi^2 m_e c g \nu \mu^2 / 3he^2 \quad (3)$$

where ν is the frequency (cm^{-1}), m_e and e are the electronic mass and charge, g is the degeneracy of the excited state, and $\alpha(\nu)$ is the absorption spectrum of the corresponding band. The resolution of the spectrum of the dimer into the long-wavelength and short-wavelength bands presents a definite difficulty. Methods for such resolution in specific but practically important instances have been developed[77,78].

In order to solve the above problems, it is also necessary to know the concentration of the associated species in solution. This can be determined from absorption spectra[79] and by measuring the number-average molecular weight[16]. A method has been proposed[80] for the determination of the concentration of dimers and the equilibrium constants for their formation based on the measurement of the concentration dependence of the degree of polarisation and the luminescence quantum yield. A satisfactory agreement of the results obtained by this method and spectrophotometrically has been demonstrated for water–glycerol mixtures. The method is convenient when the dependence of the absorption spectra on concentration is insignificant.

The aggregates formed are very often treated as dimers in studies of association. However, when the order of the association is determined, experiments shows that this is by no means always the case. For example, in the study of concentrated solutions of 1,1-diethyl-2,2-cyanine bromide at low temperatures[81] it was possible to resolve the individual absorption bands referring to dimers (483 nm), trimers (465 nm), and tetramers (458 nm). On the basis of spectroscopic data, it was then concluded that several forms of aggregates exist: aggregates with a perpendicular disposition of the interacting molecules relative to the long axis of the aggregate and aggregates consisting of left- and right-hand helicoidal structures with eight monomers per turn of the helix. The study of the absorption and luminescence spectra of fluorescein, eosin, erythrosin, pyronine, and fuchsin at

different concentrations and temperatures[43,82] showed that, with increase of the concentration of dyes, characteristic changes occur in the spectra due to the formation of dimers and more complex aggregates. Electronic spectra for aggregates acquire partial exciton character.

The study of the association of rhodamines C, 3B, and 6G and of unsubstituted rhodamine in various solvents at 9° and 22°C [17,83,84] made it possible to obtain the aggregation constants and to reach a conclusion about the geometrical disposition of the molecules in the dimers ("in a stack" in water and "end to end" in ethanol). The study of azulenes in isopentane–methylcyclohexane glasses at 77 K and $c \simeq 10^{-3}$ M showed[85] that dimers are formed and their energy levels were calculated. The luminescence of such dimers was not detected. It has been established[16,26] that, in concentrated alcoholic solutions of rhodamine dyes at room temperatures, and on cooling, involved associated species comprising six dye molecules are formed on cooling. The molecules are arranged "end to end" and the angle between them decreases with decrease of the solution temperature. The geometrical structure of the aggregates of cyanine dyes has been studied[86] in various solvents by electron microscopy, optical microscopy, X-ray diffraction, and absorption spectroscopy. The results suggest that the planes of the molecules in the associated species are parallel, i.e. the aggregates have a "sandwich" structure. The authors separated the absorption bands for small aggregates up to pentamers.

On the basis of a study of the electronic spectra of a number of compounds in EPA (a mixture of ether, pentane, and ethanol), an interesting hypothesis has been put forward[87], namely that the spectroscopic changes on passing to dimers are due mainly to a change in the geometry of the monomer itself and that the splitting of the levels plays a secondary role. However, this hypothesis can be hardly regarded as sufficiently well founded.

The knowledge of the geometrical structure of the associated species may prove to be important for the elucidation of the nature of the forces responsible for the association of dye molecules. Quite inadequate attention has been devoted to this problem in the literature, evidently owing to the great complexity of the inter-molecular interactions in solutions of organic compounds. It has been concluded[88] that thionine and Methylene Blue dimers are formed as a result of van der Waals forces. The free energy of the dimerisation of Methylene Blue in water at 26.7°C was found to be 4.9 kcal mole^{-1}.

According to the theory of intermolecular interactions[89,90], the attraction energy of two identical molecules with a long-wavelength absorption band having a maximum at λ_0 is proportional to $f^2\lambda_0^3$, where f is the oscillator strength. Since f and λ_0 are large for dyes, the attraction forces between their molecules should also be greater when the latter approach one another sufficiently closely than for the corresponding colourless forms. These forces combine dye molecules into dimers or more complex associated species. Terms taking into account dipole–quadrupole and quadrupole-quadrupole interactions, evaluated by Margenau[90], may be added to those for the London dipole–dipole interaction[89] in the case of dyes.

Calculations by Davies and Coulson[91] showed that, for large molecules with extensive π-electron clouds, the dispersion forces, which make the greatest contribution to the van der Waals molecular interaction energy, may reach large values (tens of kcal mole^{-1}) for short intermolecular distances. These calculations were carried out for molecules which were simple compared with dyes.

The theory of van der Waals forces was constructed on the assumption that the distances between the interacting molecules are greater than their transverse dimensions[92,93].

For small intermolecular distances, characteristic of highly concentrated solutions, forces which decrease faster than as $1/R^6$, for example, forces associated with the quadrupole interaction, may become important also. It is usually believed that the energy of the van der Waals interaction does not exceed 2 kcal mole^{-1} for dye molecules[10,11]. However, this cannot apparently be regarded as a firmly established theoretical fact (for large molecules of the type of dyes, the bond energy has not been calculated rigorously) or as an accurate experimental result (the attempts at a quantitative test of the theory of universal molecular forces failed to yield sufficiently convincing results, since they were based on the measurement of integral effects which depend on the interaction of many molecules at different distances[94]). The view according to which dye molecules associate via van der Waals forces is shared also by many other workers[30,31,95–99], who investigated the association of the molecules of various compounds in different solvents.

Another view is that the association of dyes takes place via hydrogen bonding. It has been shown for a large number of dyes that the hypothesis of the major role of dispersion forces in the formation of associated species conflicts with many experimental facts. These are in the first place the strong dependence of the efficiency of the association process on the nature of the solvents employed and the structure of the dye molecules[13,93,100–102]. Concentration-induced changes in the absorption spectra, indicating the association of dye molecules in solutions, have been observed for compounds whose molecules have active N–H groups. The spectra of solutions of dyes whose molecules have no such groups do not change in the same solvents with increase of their concentration, which indicates the absence of association according to the authors of the above investigations.

Hydrogen bonds can be formed either directly between dye molecules or the latter may be combined with the aid of water molecules, which play the role of intervening bridges. The presence of intermolecular hydrogen bonds $\rangle$N–H...O=C$\langle$ and $\rangle$N–H...O$\langle$ has been established for rhodamine 6G also on the basis of infrared absorption spectra[103–105]. In chloroform–carbon tetrachloride mixtures the intensity of the absorption band due to free N–H vibrations (ν_{max} = 3445 cm^{-1}) decreases appreciably and the intensity of the broad band, which is appreciably displaced towards longer wavelengths (ν_{max} = 3200 cm^{-1}), increases in the spectrum of this dye with increased content of the non-polar component. This indicates the appearance of N–H vibrations perturbed by hydrogen bonding. Analogous changes occur in the infrared spectra of the solutions with increase of the dye concentration and with decrease of solution temperature[106].

Analysis of numerous experimental data obtained for solutions of xanthene and triphenylmethane dyes[105] showed that their associated species are formed on combination of two ion pairs via hydrogen bonds between the N–H group of the cation in one pair and the anion of another:

$$RN^+—H \ldots A^-RN^+—R.$$

The fundamental role of hydrogen bonds in the association of dye molecules in aqueous and aqueous alcoholic solutions as well as in binary mixtures of a polar and

non-polar solvent has also been indicated in other studies[60,107,108].

However, one should note that in the above studies it has been suggested that the polar organic solvents there is no association of dye molecules[109-111] because the active N–H groups of dyes are "occupied" by solvent molecules. Further study of this problem showed[16] that molecular associated species containing active N–H groups (rhodamine G, 6G, and others) and without active groups (rhodamine C, 3B, S, and others) are formed at high dye concentrations, the association in the former case beginning at lower concentrations. This apparently shows that association via hydrogen bonding takes place to a definite extent also in alcoholic solutions. In the second case associated species are evidently formed via van der Waals forces. This is indicated also by the finding that the associated species in such solutions are involved (approximately 6 molecules in a single aggregate). The energy of the bond between two molecules in such associated species is approximately 4 kcal mole^{-1} in all rhodamines[26], i.e. approaches the energy of the hydrogen bond.

In some studies it has been suggested that hydrophobic forces[107] and the interaction of dye molecules with the accompanying anions[56,112] are responsible for their association. The study of rhodamine dyes showed that the tendency towards association increases with increasing number and size of alkyl substituents[54].

The problem of the nature of the forces responsible for the association of dyes must apparently be solved in each specific instance in its own way. There is no point in extending the results for several examples to all cases. On the other hand, van der Waals forces, being universal, always act between dye molecules at a sufficiently short distance.

However, theories attempting to explain the spectroscopic changes occurring in the association of dye molecules do not take into account the nature of the intermolecular interactions.

III. THEORY OF THE SPECTRA OF ASSOCIATED MOLECULES

Förster's theory[30,113], describing the molecular properties of aggregates has been developed solely for dimers. It is assumed that the associated species consist of monomeric dye molecules whose planes are parallel to one another. Such dimeric molecules should possess an additional twofold symmetry axis apart from the symmetry elements of the monomer. The transition moments (oscillators) of these molecules are also parallel for the visible part of the spectrum. In consequence of thermal vibrations or structural assymmetry, the parallel arrangement may break down. For such a model, the oscillators of both molecules can be represented by two normal vibrations at different frequencies, each involving separate oscillators with the same amplitudes. However, the vibrations of one set of oscillators have the same phase, while those of the other set differ by 180°, i.e. the vibrations can be both symmetric and antisymmetric.

The vibrations of individual oscillators can be represented schematically as follows:

$$\rightleftarrows \quad \rightleftarrows \quad .$$

Symmetric vibrations give rise to a resultant non-zero dipole moment; for antisymmetric vibrations, the changes in the moments of individual oscillators cancel out. On absorption and emission of light, only symmetrical vibrations of the dipole are therefore excited, while the antisymmetrical vibrations are inactive. The two types of vibrations have different intrinsic frequencies due to the electric coupling of the two oscillators. Such coupling enhances in the case of the symmetric vibrations and weakens in the case of the antisymmetric vibration the force which restores the oscillators to the equilibrium position. As a result, compared with the vibration of the monomeric oscillator, the symmetric coupled vibration has a higher intrinsic frequency and the antisymmetric vibration has a lower frequency.

Thus, when two molecules approach one another, the electronic transition band is split. However, for the antisymmetric vibration the overall dipole moment of the dimer is unchanged and the absorption spectrum manifests only the transition associated with the symmetric vibrations of the oscillators, i.e. vibrations having a higher frequency. This leads to the experimentally observed hypsochromic shift of the absorption band on dimerisation of dye molecules. Since the transition corresponding to the antisymmetric vibrations, i.e. the transiton from the lowest excited level, is forbidden, the dimers do not luminesce.

This hypothesis cannot explain the finding that the spectra of the dye dimers frequently consist of two bands. According to Förster's theory the observation of such dimers would be impossible in view of the metastability of the excited state with the lower energy. Förster therefore suggests that in such cases the bond energy in the associated species is low and the oscillators of both molecules fail to attain a parallel arrangement in the ground state.

By applying the free electron model to a system consisting of two monomers, each of which has two electronic levels in the free state, Nikitin[114] obtained identical splittings of the energy levels of the ground and excited states, between which four electronic transitions are possible. Two of these have the same energy, equal to the transition energy in the monomer. The other two transitions are displaced–the frequency of one is smaller and that of the other greater than the frequency of the transitions in the monomer. The probabilities of the last two transitions proved to be much greater than the sum of the probabilities with identical frequencies. Thus Nikitin's calculation predicts qualitatively the splitting of the absorption band of the monomers into two components on formation of dimers. Förster's and Nikitin's theories explain only the displacement and splitting of the absorption spectrum on association of dye molecules. They do not yield quantitative relations for the calculation of the splittings.

Simpson and coworkers[115,116] carried out a quantum-mechanical calculation on dye dimers assuming that the molecular planes of their cations in the dimer are parallel ("sandwich" structure) and neglecting the interaction between the components corresponding to the monomers of the electronic wave functions for the ground state and the doubly degenerate first excited state. Thus it is suggested that the wave function of the ground state of the dimer has the form $\Psi_1\Psi_2$ and that of the excited state is $\Psi_1^*\Psi_2$ and $\Psi_1\Psi_2^*$, where Ψ_1 and Ψ_2 are the wave functions of individual molecules *1* and *2* forming the dimer and the asterisk denotes electronic excitation.

In their calculations Simpson and coworkers used the following expression for the molecular interaction potential:

$$V = (-2\Sigma z_1 \Sigma z_2 + \Sigma x_1 \Sigma x_2 + \Sigma y_1 \Sigma y_2)\, e^2/R^2, \qquad (4)$$

where e is the electronic charge, R the distance between the molecules, and x, y, and z are the coordinates of the electrons of the corresponding molecules. The exact wave function for the excited state is

$$\Psi_{\pm} = 2^{-1/2}(\psi_1^*\psi_2 \pm \psi_1\psi_2^*). \quad (5)$$

Simpson and coworkers[115,116] showed that, in the case of a strong interaction of the molecules of dyes *1* and *2*, the interaction energy in the dimer is given by the following expression in terms of the dipole approximation:

$$W_{\pm} = \pm \bar{m}_1\bar{m}_2/R^3, \quad (6)$$

where, for example, the x component of the dipole moment of the transition $\bar{m}_1$ can be written as follows:

$$(m_1)_x = e\int \psi_1 \Sigma x_1 \psi_1^* d\tau_1. \quad (7)$$

The transition moment for absorption by the dimer is given by the expression

$$\bar{m}_{\pm} = 2^{-1/2}(\bar{m}_1 \pm \bar{m}_2). \quad (8)$$

If the disposition of molecules in such that $\bar{m}_1 = -\bar{m}_2$, then the transition moment (on absorption of a light quantum) to the lower of the excited split levels with an energy W_+ is zero and the moment of the transition to the higher of the levels with an energy W_- is $2^{1/2}m_1$, which corresponds to an increase of the absorption intensity by a factor of two compared with a monomeric molecule.

Simpson and coworkers[115,116] explained the agreement between their model and experiment by the fact that the short-wavelength absorption band in the spectrum of the dimer is usually more intense than the long-wavelength band: on the other hand, the appearance of the latter can be accounted for by the fact that the molecular planes of dyes in the aggregate are not rigorously parallel. In their model the distance between identical molecules in the dimer is expressed in terms of the energy of the splitting of the levels by the formula

$$\Delta W = W_- - W_+ = 2|\bar{m}_1|2/R^3. \quad (9)$$

De Voe[117,118] developed a semiclassical theory of the electronic absorption spectra of associated species with weak bonding, where the Born–Oppenheimer approximation was used in the electronic and vibrational components as the zeroth approximation to the wave function for each monomer. Using the first-order perturbation theory, De Voe derived equations relating the extinction coefficient of the band due to the associated species to the parameters of the spectra of its constituent monomers.

De Voe's fundamental hypothesis is that the optical properties of each monomer can be described by one or several one-dimensional complex polarisabilities with different directions of polarisation and different frequency dependences. The associated species is characterised by M different polarisabilities $\alpha_i^0(\nu)$ of N monomers ($M \geqslant N$) and the directions of their polarisations are specified by unit vectors $\mathbf{e}_i$, where i varies from 1 to M. In quantum theory polarisability corresponds to the dipole moment of the transition from the ground to the excited electronic state. The vector $\mathbf{e}_i$ has the same direction as the electronic moment of the transition $\boldsymbol{\mu}_i^0$.

It is assumed that the associated species consists of N monomers and that it is small compared with the wavelength of the incident light. On can therefore neglect the lag effect and can assume that the electric field of the incident light is the same within the limits of the associated species. The polarisability of each monomer is determined by the strength of the local field in which the monomer is located (the field of the incident light plus the field due to other monomers). The real component of the polarisability describes the polarisation in phase with the electric field of the incident light and the imaginary component describes the out of phase polarisation causing the absorption of light.

If $\epsilon_i(\nu)$ is the molar extinction coefficient of an isolated monomer, then the real and imaginary components of $\alpha_i^0(\nu)$ are given by the following equations:

$$\mathrm{Re}\,\alpha_i^0(\nu) = \frac{6\cdot 2303c}{8\pi^3 N_0}\int \frac{\varepsilon_i(x)\,dx}{x^2-\nu^2} \equiv R_i(\nu), \quad (10)$$

$$\mathrm{Im}\,\alpha_i^0(\nu) = -\frac{3\cdot 2303c}{8\pi^2 N_0}\cdot\frac{\varepsilon_i(\nu)}{\nu} \equiv I_i(\nu), \quad (11)$$

where c is the velocity of light and N_0 the Avogadro number. The principal value of the integral is used.

If the aggregate is in the field $\mathbf{E}$ of plane-polarised light at a frequency ν, then each of the N monomers undergoes polarisation, which depends on the incident field and the field of the other monomers. The complex amplitude of the induced moment of the polarisability of an individual monomer can be formulated as follows:

$$m_i(\nu) = \alpha_i^0(\nu)\left[\mathbf{e}_i\mathbf{E} - \sum_{j=1}^{M} G_{ij}m_j(\nu)\right]. \quad (12)$$

The expression in brackets represents the amplitude of the local field along $\mathbf{e}_i$. The above equation expresses the induced moment of the polarisability of the ith monomer as a linear function of the induced moments of all other monomers in the aggregate. The interaction coefficient G_{ij} is interpreted as the energy of the Coulombic interaction between two point dipoles with dipole moments oriented along $\mathbf{e}_i$ and $\mathbf{e}_j$. In terms of the point dipole approximation, these coefficients are given by the expressions

$$G_{ij} = r_{ij}^{-3}[\mathbf{e}_i\mathbf{e}_j - 3(\mathbf{e}_i\mathbf{e}_{ij})\mathbf{e}_j\mathbf{e}_{ij})], \quad (13)$$

where $\mathbf{e}_{ij}$ is the unit vector along the line connecting the ith and jth monomers and r_{ij} is the distance between them.

For aggregates with an appreciable interaction between the monomers, De Voe[117,118] used the following expression for the density of the transition:

$$G_{ij} = V_{ij}/|\mu_i|\,|\mu_j|, \quad (14)$$

where V_{ij} is the energy of the Coulombic interaction between the charge densities of two molecules.

On solving M equations of type (12) written in matrix form, it is possible to calculate the optical properties of the aggregate. For a dimer with the same polarisability of each monomer ($N = M = 2$), the extinction coefficient is

$$\epsilon_d(\nu) = \sum_i\sum_{j\neq i}\varepsilon_i(\nu)\frac{1 - 2G_{12}R_i e_1 e_2 + G_{12}^2(I_1I_2 + R_j^2)}{[1 - G_{12}^2(R_1R_2 - I_1I_2)]^2 + [G_{12}^2(R_2I_1 + R_1I_2)]^2}. \quad (15)$$

De Voe[118] obtained a formula whereby G_{ij} can be expressed in terms of experimental quantities. For a dimer, G_{12} can be determined from the equation

$$\varepsilon(\nu) = \varepsilon^0(\nu)[1 - 2R(\nu)G_{12}(\mathbf{e}_1\mathbf{e}_2)],$$

where $\epsilon^0(\nu)$ and $\epsilon(\nu)$ are the extinction coefficients of the monomer and the dimer. Knowing the extinction coefficient of the monomer and the dimer for a specified value of ν and having calculated $R(\nu)$, it is possible to determine G_{12}.

The experimental study of the optical characteristics of the monomers, dimers, and more involved associated species of dyes[119-121] showed that there is only a qualitative agreement between De Voe's theory and experiment.

At the present time the main theory used to explain the spectroscopic features arising on aggregation of dye molecules is the exciton theory. The exciton model, developed by Davydov[122] for molecular crystals, has been used by a number of workers[67-70] to develop a theoretical method for the investigation of the spectra of associated species. For an aggregate comprising N molecules, the exciton band consists of N discrete levels. The dipole transitons in this system are allowed only for one or several (a small number equal to the number of molecules in the associated species) exciton states. The energy and wave function of the ground state of the aggregate are the same as for the monomers.

The wave function of the ground state of the dimer is

$$\Psi_0 = \psi_1 \cdot \psi_2, \tag{16}$$

where Ψ_1 and Ψ_2 are the wave functions of the ground state of the free monomer. The Hamiltonian of the dimer is

$$H = H_1 + H_2 + V_{12}, \tag{17}$$

where H_1 and H_2 are the Hamiltonians of the isolated molecules 1 and 2 and V_{12} is the intermolecular interaction potential (the Coulombic potential represented approximately by point dipole terms in the point-multipole expansion). The energy of the ground state of the dimer is obtained from the Schrödinger equation

$$E_0 = \int\int \psi_1\psi_2 H \psi_1\psi_2 \, d\tau_1 \, d\tau_2 \tag{18}$$

or

$$E_0 = E_1^0 + E_2^0 + \int\int \psi_1\psi_2 (V_{12}) \, \psi_1\psi_2 \, d\tau_1 \, d\tau_2. \tag{19}$$

The last term corresponds to the van der Waals interaction energy between the ground states of molecules *1* and *2* and E_1^0 and E_2^0 are the energies of the ground states of the isolated molecules.

The wave functions of the excited state of the dimer are written in the following form:

$$\Psi_E = r\psi_1^*\psi_2 + s\psi_1\psi_2^*, \tag{20}$$

where Ψ_1^* and Ψ_2^* are the wave functions of the excited state (with the energies E_1^* and E_2^*) and r and s are coefficients which must be determined. The Schrödinger equation for the excited state is

$$H(r\psi_1^*\psi_2 + s\psi_1\psi_2^*) = E_E(r\psi_1^*\psi_2 + s\psi_1\psi_2^*). \tag{21}$$

On multiplying the two sides of this equation by $\Psi_1^*\Psi_2$, integrating with respect to the coordinates of molecules *1* and *2*, and repeating this process for $\Psi_1\Psi_2^*$, we arrive at two equations containing terms which are symmetrical with respect to sub-scripts *1* and *2*:

$$\begin{aligned} H_{11}(=H_{22}) &= \int\int \psi_1^*\psi_2 H \psi_1^*\psi_2 \, d\tau_1 \, d\tau_2, \\ H_{12}(=H_{21}) &= \int\int \psi_1^*\psi_2 H \psi_1\psi_2^* \, d\tau_1 \, d\tau_2. \end{aligned} \tag{22}$$

The determinant of the coefficients r and s in these equations is zero for non-trivial solutions:

$$\begin{vmatrix} H_{11} - E_E & H_{12} \\ H_{21} & H_{22} - E_E \end{vmatrix} = 0. \tag{23}$$

The roots E_E are given by the following expressions in view of the equivalence of the terms of Eqns. (22):

$$\begin{aligned} E_E' &= H_{11} + H_{12} \text{ for } \Psi_E' = 2^{-1/2}(\psi_1^*\psi_2 + \psi_1\psi_2^*), \\ E_E'' &= H_{11} - H_{12} \text{ for } \Psi_E'' = 2^{-1/2}(\psi_1^*\psi_2 - \psi_1\psi_2^*). \end{aligned} \tag{24}$$

Having calculated E_E' and E_E'', we have, by virtue of the orthogonality condition for the wave functions of each molecule,

$$\begin{aligned} E_E' &= E_1^* + E_2 + \int\int \psi_1^*\psi_2 (V_{12}) \, \psi_1^*\psi_2 \, d\tau_1 \, d\tau_2 + \int\int \psi_1^*\psi_2 (V_{12}) \, \psi_1\psi_2^* \, d\tau_1 \, d\tau_2, \\ E_E'' &= E_1^* + E_2 + \int\int \psi_1^*\psi_2 (V_{12}) \, \psi_1^*\psi_2 \, d\tau_1 \, d\tau_2 - \int\int \psi_1^*\psi_2 (V_{12}) \, \psi_1\psi_2^* \, d\tau_1 \, d\tau_2. \end{aligned} \tag{25}$$

The last term in Eqns. (25) describes the exciton splitting:

$$\mathscr{E} = \int\int \psi_1^*\psi_2 (V_{12}) \, \psi_1\psi_2^* \, d\tau_1 \, d\tau_2, \tag{26}$$

It becomes, in terms of the point dipole approximation

$$\mathscr{E} = \mathbf{M}_1\mathbf{M}_2/r^3 - 3(\mathbf{M}_1 \cdot \mathbf{r})(\mathbf{M}_2 \cdot \mathbf{r})/r^5 \tag{27}$$

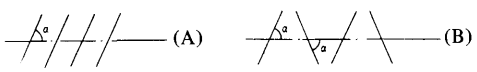
and represents the energy of the interaction due to the exchange of the excitation energy between molecules *1* and *2* at a distance r. The third term in Eqns(25) is analogous to the corresponding term in Eqn. (19) and corresponds to the van der Waals interaction between the excited molecule *1* and the ground state of molecule *2*. $\mathbf{M}_1$ and $\mathbf{M}_2$ are the transition moments in molecules *1* and *2* and r is the vector directed from molecule *1* to molecule *2*.

The exciton model describes the resonance splitting of the excited states of complex molecules. The ground state is displaced relative to the ground state of the initial molecules solely due to the van der Waals interaction.

Here one considers different limiting cases of the intermolecular bond. The ratio of the force of the intermolecular electronic interaction between excited states and the force of the intramolecular vibronic coupling serves in practice as a criterion for the assessment of the intermolecular bond[116]. For a strong bond, the following ratio is used as a criterion:

$$2U/\Delta\varepsilon \gg 1, \tag{28}$$

where $2U$ is the width of the exciton band and $\Delta\epsilon$ is the width of the Franck–Condon band of the corresponding molecular electronic transition in the monomer. The opposite inequality has been suggested as a criterion for a weak bond:



$$2U/\Delta\varepsilon \ll 1. \tag{29}$$

In the case of a strong bond, the electronic and vibrational wave functions are separated by the Born–Oppenheimer method. The absorption spectra of the dimer will be split if even one of the components of the electronic transitions is prohibited and is not shown in the spectrum. For a linear polymer of N molecules, the interaction of the latter leads to an exciton band consisting of N discrete exciton states. The selection rules for linear polymers have been developed by McRae and Kasha[67]. The bands of the resolved components then become very narrow, since excitation is in this case "smeared" over many molecules and each molecule has approximately the same electronic structure as the molecule in the ground state, i.e. the Franck-Condon principle allows in this case only the non-vibration 0–0 electronic transition.

A weak bond corresponds to the nonresolvability of the molecular wave functions by the Born–Oppenheimer method. In the limiting case of a weak bond no change in the spectral band is observed, but effects such as hypochromism or hyperchromism may be manifested.

The case of an intermediate bond constitutes an unsolved problem in exciton theory. Here one can observe a general distortion of the band contour.

McRae and Kasha[67] examined associated dye molecules having the following structures:

The theoretical calculation presented by the authors predicts the splitting of the energy levels of the excited states of associated species comprising N molecules into N levles. The splittings are

$$\mathscr{E} = 4\,[(N-1)/N\,](m^2/r^3)\,(1-3\cos^2\alpha), \tag{30}$$

for structure (A) and

$$\mathscr{E} = 4\,[(N-1)/N]\,(m^2/r^3)\,(1+\cos^2\alpha) \tag{31}$$

for structure (B), where m is the transition moment for the monomer. An increase of the probability of intercombination transitions in the association of dye molecules has been predicted[67].

In later studies the exciton theory was refined and tested experimentally. Thus, theoretical calculations of the spectroscopic characteristics of stable anthracene dimers were made and a satisfactory agreement with experiment was demonstrated[123,124]. An asymptotic expression for the shape of the dimer absorption bands has been obtained[125] by the method of exciton theory for the case of strong interaction of complex molecules. Allowance for intermolecular vibrations in dimers[126] made it possible to introduce certain refinements into the form of their absorption spectra. The vibrational states of the monomers constituting the molecular aggregates were also taken into account in the exciton theory[127]. The vibronic interactions in aggregates have been examined[128-131]. In this case the theory includes a parameter taking into account the intramolecular vibrations of the monomers and a parameter characterising the extent of the interaction between them. The theory taking into account such interactions has been tested in detail in experimental studies[132-134] whose results have been surveyed[135]. An experimental test showed that the predictions of the theory hold rigorously only for certain values of its parameters, which do not alway correspond to real systems.

Using the molecular exciton theroy, the vibronic interactions in helical aggregates were investigated theoretically[136] and a study was made of the influence of intramolecular vibrations of the monomers on their electronic absorption spectra.

More refined experiments[137], designed to investigate the absorption and polarisation spectra of luminescent dimeric forms of rhodamine C at room temperature and 77 K (in this case LiCl was added to improve the vitrification of the solutions), showed that the exciton theory cannot account for the measured polarisation characteristics of the dimers, whose interpretation requires allowance for the vibronic interactions in the molecules of the test compound. These ideas were subsequently developed[138] and confirmed experimentally for associated rhodamine and acridine dyes.

Thus the existing theories explain qualitatively many features arising in the electronic spectra of complex organic compounds when their molecules undergo association and also describe many quantitative effects. However, they apply only to dimers and more complex aggregates with a specific configuration. Complex associated species with an arbitrary structure, which can be formed in concentrated solutions, are not described by these theories.

One should note that the overall Hamiltonian (17) used in the exciton theory for the dimer does not take into account the perturbing effect of the field due to solvent molecules on the associated dye molecules.

Furthermore, it has been shown[139] that the stability of the associated species depends on the solvation shell consisting of solvent molecules, i.e. the theory must take into account also this form of intermolecular interaction.

IV. LUMINESCENT ASSOCIATED SPECIES

Association of dye molecules leads as a rule to the loss of their luminescent properties. However, under certain conditions the associated species fluoresce. The study of luminescent associated species is of both scientific and spectroscopic interest. Thus elucidation of the causes of the radiationless degradation of the electronic excitation energy of associated molecules can lead to the solution of a more complex problem, which Vavilov formulated as follows[140]: "The main problem of the photoluminescence of solutions, which has still not been solved even in broad outline, involves the question why some molecules luminescence while others do not". A study of the conditions governing the formation of luminescent associated species may help to elucidate the pathways whereby their electronic excitation energy is exchanged and the nature of their electronic spectra.

When non-luminescent associated species are formed, the absorption spectra of the dye solutions change, while their luminescence spectra do not undergo any alteration in form. Variable luminescence spectra and invariant absorption spectra would indicate the formation of excimers[141]. The formation of luminescent associated species in dye solutions is accompanied by the deformation of both their absorption spectra and their luminescence spectra.

In his study of the influence of concentration on electronic spectra, Levshin observed[142] that an increase of the concentration of fluorescein and Rhoduline Orange in rock candy leads to appreciable changes in their luminescence spectra. He also showed that Acridine Orange in rock candy forms luminescent associated species at 20° and −183°C.[143] At 20°C, starting from $c = 10^{-3}$ g g^{-1}, the luminescence spectra of rock candy activated with acridine show a gradual weakening of the green emission band (λ_{max} = 534 nm) due to the luminescence of monomers and the simultaneous increase in the intensity of the emission band of the associated species (λ_{max} = 575 nm). The influence of the concentration of this compound on the electronic spectra and the duration and yield of luminescence in frozen alcoholic solutions has been studied[144] and it has been shown that, with increase of the concentration of acridine from 1.6×10^{-6} to 1.3×10^{-2} M, the maximum in the overall luminescence spectrum shifts by 110 nm to the red region and the form of the spectrum change markedly. The fact that the association of Acridine Orange molecules leads to a marked weakening of the intensity of the long-wavelength absorption band and to the intensification of the short-wavelength band suggested that the transition to the upper electronic state is prohibited to some extent in associated molecules, i.e. that the associated molecules have a higher symmetry than the monomer.

In contrast to the spectra of aqueous solutions of Acridine Orange, the formation of a new band in the luminescence spectrum of rock candy is extremely slow, although the deformation of the absorption spectra begins to appear in both cases at approximately the same concentrations[143] and the positions of the maxima in the luminescence spectra are the same. However, it follows from the deformation of the absorption and luminescence spectra of Acridine Orange in rock candy that the amount of associated species in such solid solutions is smaller than in aqueous solutions at the same concentrations.

Measurement of the dependence of the pH of the solutions on the concentration of acridines showed that the changes in the spectra are not associated with the ionisation of their molecules in solution, as observed by Levshin[145]. The concentration-induced changes in the spectra of acridines occurred in the region corresponding to the existence of their molecules in the form of singly charged ions and must be attributed to their association. At the same time, it has been shown[20,143,144] that the associated Acridine Orange species exhibit an appreciable phosphorescence. This is caused by the higher probability of the transition of dimers to the triplet state as compared with the monomers.

With increase of the concentration of Acridine Orange above 10^{-3} M in ethanol, bands at 600 and 629 nm arise in the luminescence spectrum and their intensity increases[146]. They have been attributed to the luminescence of the associated Acridine Orange species. Eosin, whose monomeric form has a luminescence maximum at 568 nm, fluoresces with λ_{max} = 603 nm when associated species are formed in alcohols[147].

The study of the fluorescence of associated acriflavins and rhodamine 3B species in various solvents[148] showed that, when dimers, trimers, and more complex aggregates are formed, their luminescence maximum is displaced further towards the red region. Analysis of the spectroscopic data showed that the luminescence spectra of associated species are broader and the degree of polarisation of their luminescence is smaller than for the monomers[62,149].

As noted above, Scheibe polymers belong to the class of luminescent associated species. The luminescence of polymerised solutions of cyanine dyes proved to be very sensitive to the presence of various luminescence quenching agents. Thus the addition of approximately 10^{-5} M catechol to a solution containing 0.2% of pseudoisocyanine chloride[150,151] leads to a sharp decrease of the intensity of the luminescence of the dye. This implies that the emission of light by the entire complex is affected when even one of the dye molecules forming the chain comes into contact with a molecule of the quenching agent. It has been established[152] that, by virtue of the migration of excitation energy along the entire polymer chain, one molecule of the quenching agent per 10^3–10^6 dye molecules is sufficient for appreciable quenching. This suggested that the electrons of individual molecules in such polymers form a single electron cloud.

Another form of luminescent species made up of dye molecules has been observed[153,154] and investigated in detail by Morozov and coworkers[21,22]. When aqueous and aqueous alcoholic solutions are cooled to approximately −30°C, the luminescence of rhodamines virtually vanishes. Further cooling leads to the appearance of a new luminescence band displaced towards longer wavelengths. The intensity of this "red" luminescence band increases on successive cooling of the solutions. The addition of glucose, thiamine hydrochloride, etc. to the solution increase the intensity of the "red" band, but the "yellow" does not vanish completely. The addition of polar solvents to the solution (alcohol, pyridine, acetone, etc.) greatly weakens the above effects. In this case the intensity of the "yellow" band changes only slightly when the temperature of the solution is reduced and a weak "red" luminescence band appears only at approximately −100°C.

The above results have been explained[152] on the basis that freezing aqueous solutions removes the prohibition on singlet–triplet transitions and the "red" band is due to the phosphorescence of the associated dye molecules. The introduction of various additives into the solution alters, according to the author[152], the probabilities of the $S^* \rightarrow T_1$ and $T_1 \rightarrow S_0$ transitions. However, the marked dependence of the observed effects on the dye concentration in solution[22] indicates their relation with intermolecular processes. Furthermore, the durations of luminescence are the same order of magnitude for both rhodamine C bands: $\tau_L \simeq 10^{-8}$ s; $\tau_{Cr} \simeq 4.5 \times 10^{-9}$ s.

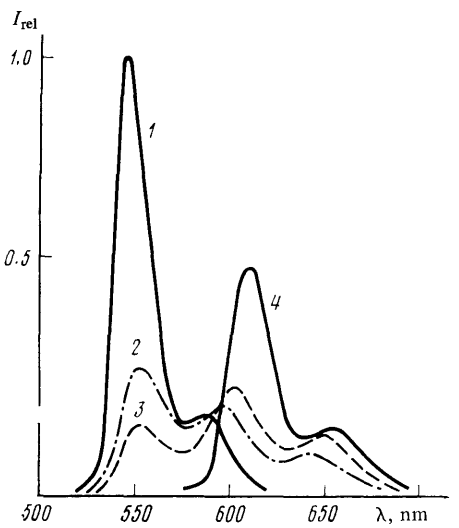


Figure 2. The luminescence spectra of solutions of rhodamine 6G in ethanol at −180°C as a function of concentration (M): 1) 1×10^{-5} (the I_{rel} scale has been reduced by a factor of 2); 2) 5×10^{-3}; 3) 1×10^{-2}; 4) 5×10^{-2}.

On the other hand, the difference between τ_L and τ_{Cr} for frozen solutions shows that different luminescence centres are responsible for the appearance of these bands.

The observed phenomenon has been explained[21,22] by the fact that the crystallisation of the solvent on freezing leads to the breakdown of the homogeneity of the solution, which decomposes into a solid phase consisting of the frozen solvent, not containing dye molecules, and a liquid phase to which virtually the entire dye is transferred together with the polar solvents added to the solution. The composition of the liquid phase differs from that of the initial solution by the markedly higher concentration of the dye. Cooling of such solutions leads to a gradual freezing out of water from the liquid phase and an

increase of the concentration of the dye in the latter, which creates favourable conditions for the formation of luminescent associated dye species. The authors[21,22] believe that the associated species formed under these conditions are dimers and that the "red" luminescence band is due to their fluorescence.

It was shown subsequently[6,24-26,62] that luminescent associated rhodamine dye species are formed also in purely polar solvents wihout breakdown of the homogeneity of the solutions on freezing. Not only dimers but also more complex associated species consisting of six molecules are formed in such solutions. Apparently in the instances described in the literature[21,22] the associated species are complex. The luminescence spectrum of such associated rhodamine 6G species in ethanol at −180°C is illustrated in Fig. 2. It consists of two luminescence maxima: the main maximum at $\lambda_{max} = 620$ nm and a lateral maximum at $\lambda_{max} = 670$ nm, which may constitute the manifestation of a vibrational structure. In the spectra of mixtures of polar and non-polar solvents at room temperature the luminescence maximum at $\lambda =$ 620 nm was attributed[155] to the phosphorescence of associated rhodamine dye molecules.

Luminescent associated rhodamine dye species have been detected at room temperature in mixtures of polar and non-polar solvents[156-161]. In this case the luminescence band of the associated molecules is displaced towards either shorter or longer wavelengths relative to the luminescence spectra of their monomeric molecules. The "red" luminescence of the associated species ($\lambda_{max} =$ 610 nm) has been observed for rhodamines in a mixture of chloroform (10%) and carbon tetrachloride (90%) at concentrations of approximately 5×10^{-4} M. The "blue" luminescence of the associated species of these dyes arises when the dyes are transferred to a non-polar medium by extraction from aqueous solutions with non-polar solvents (carbon tetrachloride). In the former case a long-wavelength maximum arises in the absorption spectra of the solutions, while in the latter case a short-wavelength maximum is generated. The formation of associated species comprising dye molecules in the above instances, which luminesce at room temperature, takes place as a rule in solutions whose homogeneity has been affected. Their structure and photoenergetics require further investigation.

V. TRIPLET STATES OF ASSOCIATED SPECIES

For many organic compounds, the triplet states of their molecules play the main role in radiationless electronic excitation energy exchange and in various photochemical reactions. The interest in the study of the triplet states of complex molecules is therefore understandable. However, the triplet states of associated molecules have been studied quite inadequately.

It is known from the theory of the electronic states of molecular aggregates[67,115,116,122] that, on molecular association, the singlet excited levels undergo appreciable changes, while the triplet levels change only slightly as a result of the spin-intercombination prohibitions.

The first experimental studies on the triplet state of associated dye molecules[162,163] confirmed these theoretical conclusions. A detailed study of the phosphorescence of associated Acridine Orange and rhodamine C species, dissolved in water and in a mixture of glucose and water, showed[162] that the maximum in the phosphorescence spectrum of acridine dimers is displaced towards longer wavelengths by approximately 100 Å relative to the phosphorescence line of its monomeric form. The values of τ for the phosphorescence of monomers and dimers then differ only slightly. For example, at room temperature $\tau_{phosph} = 10^{-2}$ s for the monomers and 6.3×10^{-2} s for the dimers of Acridine Orange, the ratio of these quantities remaining virtually unchanged on cooling the solutions. This shows that the probabilities of emission from the triplet levels and of the quenching of these levels are similar for the monomers and dimers. The phosphorescence yield for Acridine Orange dimers is much higher than for its monomeric form and depends on temperature to a greater extent. This can be explained by the mutual approach of the S_1^* and T_1 levels and the consequent increase of the probability of the $S_1^* \rightarrow T$ transition.

The phosphorescence spectrum of rhodamine C dimers in water with added glucose consists of two bands with maxima at approximately 620 and 690 nm. With decrease of temperature, the intensity of the short-wavelength band falls and that of the long-wavelength band increases. Since the maximum of the former band is close to that in the fluorescence spectrum of the dimers, the author[162] believes that it refers to α-phosphorescence, while the second band refers to the β-phosphorescence of the dimers.

Experimental evidence for the phosphorescence of the dimers of three organic compounds has been obtained[163]. The shape of the phosphorescence spectra of eosin, rhodamine C, and Acridine Orange in water at 77 K proved to be the same, but the phosphorescence spectrum of the dimers is displaced towards the red by 100–200 Å, relative to the phosphorescence spectrum of the monomers. The authors[163] concluded that both in the ground state of the associated species and in the triplet state the intermolecular distance is the same and that the decrease of energy by 300–500 cm^{-1} accompanying dimerisation is greater for the triplet state than for the ground state.

Spectroscopic methods make it possible to establish the probabilities of various transitions and the rate constants for many processes–emission and quenching of luminescence as well as intercombination transitions in organic molecules. Very few such measurements have so far been made for associated dye molecules and yet they are important not only for many practical tasks but also for the theory of association. The study of the redistribution of the probabilities of radiative and radiationless transitions, occurring when the dye molecules associate, is therefore of special interest. Such redistribution is caused particularly by a change in the relative disposition of the excited singlet and triplet levels when molecules associate.

Thus the influence of the association of eosin and erythrosin molecules at 80 K on processes involving the population and deactivation of the triplet state leads to an increase of the phosphorescence quantum yield relative to the fluorescence yield and a decrease of τ_{phosph} for solutions[164]. An increase of the concentration of solutions of these dyes in polar media results in a change of the probability of the intercombination transition and of the quenching of phosphorescence and has almost no influence on the probability of the radiative process.

New possibilities for the study of the triplet states of associated molecules of organic compounds arose following the discovery of the method of flash photolysis[165]. However, in contrast to the numerous studies of monomeric molecules by this procedure, the study of associated species is only beginning. Thus the triplet states and electronic excitation energy degradation processes in

associated rhodamine 6G–the dye most widely used in lasers†–have been investigated[166-168].

Associated rhodamine 6G species were obtained in two ways: (I)–concentrated solutions of the dye in a polar medium (aliphatic alcohols, acetonitrile, dimethyl sulphoxide, etc.) where diluted with a non-polar solvent (CCl_4, toluene, cyclohexane, etc.) so that the polar component did not exceed 0.2% of the volume of the solution; (II)–an aqueous solution of the dye was treated with polymethacrylic acid at the optimum concentration for the formation of associated species[169].

The results of the study of associated rhodamine 6G molecules reduce to the following findings. In binary mixtures dimers and complex associated dye species containing 15–20 molecules are formed. The associated species obtained by the second method consist of approximately 10 monomeric rhodamine molecules. The S_1^*-T splitting then depends on the order of the association. For example, the triplet level of rhodamine 6G dimers is higher ($14\,930\ cm^{-1} < E_T < 18\,400\ cm^{-1}$) than in more complex associated species ($14\,930\ cm^{-1} < E_T < 16\,800\ cm^{-1}$), while the positions of the triplet levels of the monomers and complex associated species are virtually the same[166]. The S_1^*-T splitting is directly related to the efficiency of the various pathways involved in electronic excitation exchange. For dimers, which are formed in solutions containing up to 80% of the non-polar component, there is a direct population of their triplet levels on pulse excitation. The luminescence quantum yield for the dimers is close to zero and the degradation of their singlet excitation energy takes place by a radiationless pathway as a result of an internal transition, which has a quantum yield $B_{it} \simeq 0.7$ and an intercombination transition whose quantum yield $B_T \simeq 0.3$.

In contrast to dimers, more complex associated rhodamine 6G species of both types luminesce with a fluorescence quantum yield of approximately 0.02.[167] The quantum yield of the intercombination transitions into the triplet state B_T is ≤ 0.2 for associated species of type (I) and 0.5 for those of type (II). Under pulsed illumination of deoxygenated solutions, complex associated species of type (I) are capable of a direct transition to the triplet state and in the spectra of such solutions the T–T absorption appears in the red region with $\lambda_{max} = 620$ nm. Fig. 3*a* illustrates the complete $T-T$ absorption spectrum of associated species of type (I). There is a great similarity between this spectrum and the $T-T$ absorption spectrum of rhodamine 6G monomers (fig. 3*b*). The study of the triplet states of associated rhodamine 6G species shows that they are characterised by a number of properties typical for the monomers of the dye: a long lifetime of the triplet state, the occurrence of bimolecular processes involving the deactivation of this state, and electron transfer reactions. The hypothesis of a high reactivity of the triplet states of monomeric molecules can therefore be applied to the triplet states of the associated species.

Measurements of the rate of deactivation of the triplet states of associated rhodamine 6G species showed, firstly, that their formation in solutions leads to an increase of the efficiency of the $T \rightarrow S_0$ intercombination degradation (this is consistent with the hypothesis of the intensification of the spin–orbital interaction in the associated dye), and, secondly, that the lifetime of the triplet states of the associated species is almost independent of the dye concentration, i.e. that the concentration-induced quenching of the triplet states, characteristic of rhodamine 6G monomers[168], hardly takes place with associated species. The latter finding conflicts with the conclusions reached in a study[164] where associated eosin and erythrosin species were investigated at a low temperature.

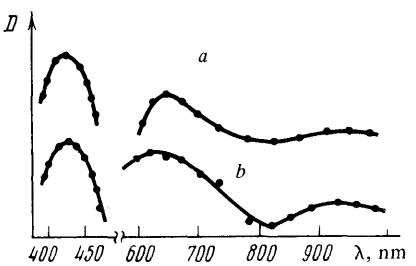

Figure 3. Triplet–triplet absorption spectra: *a*) of associated rhodamine 6G in carbon tetrachloride–butanol mixtures; *b*) of rhodamine 6G monomers in water (at pH 6).

In recent years the photonics of dye molecules have been studied in multicomponent solutions. Investigation of associated derivatives of biphenyl at different temperatures in three-component solutions showed[170] that the radiationless deactivation of their excited singlet state takes place without any appreciable involvement of the triplet level. The intramolecular radiationless deactivation of the fluorescent associated molecules takes place preferentially via the transition to the ground state.

The study of the triplet states and the pathways leading to the deactivation of the electronic excitation energy of associated dye molecules can lead to the elucidation of the causes of the loss of their capacity for luminescence.

VI. ASSOCIATION AND CONCENTRATION-INDUCED QUENCHING OF LUMINESCENCE

The phenomenon of the concentration-induced quenching of luminescence (CQL) consists in the fact that, starting from a threshold concentration of the dye solution, the luminescence yield falls. The concentration-induced quenching of luminescence is usually accompanied by a decrease of the lifetime of the excited state of the dye molecules and by depolarisation of the luminescence. The CQL for solutions of xanthene dyes has been studied quantitatively by Vavilov[171] and Levshin[172-174] and later by Dushinskii[175,176] and Pekerman[177,178]. A characteristic feature of the CQL is a distinct dependence of the nature of the luminescent substances–the CQL has not been observed for many organic compounds over a wide range of concentrations[177].

Physicochemical and physical hypotheses of second-order collisions[171], inductive quenching[179], etc. have been put forward to account for the CQL. Subsequently two approaches to the explanation of the nature of the CQL were outlined. The first is based on the possibility of

† See also A.K.Chibisov and T.D.Slavnova, J.Photochem., 8, 285 (1978).

the inductive resonance migration of the electronic excitation energy between monomeric dye molecules[180]. These ideas subsequently served as a basis of the migration theory of the CQL developed by a number or workers[181-183]. According to this theory, the quenching of the luminescence at high concentrations of the luminescent substances takes place as a result of the resonance transfer of electronic excitation from one dye molecule, in the monomeric form, to another similar molecule. Some of these transitions are accompanied by quenching. However, the cause of the development of radiationless transitions in the migration of excitation has not been specified more precisely. It has been suggested that quenching may occur also in the energy transfer between molecules separated by considerable distances, but the probability of the quenching of excitation in the course of migration increases faster with decrease of the distance than the probability of transfer without quenching. However, there are neither theoretical nor experimental data showing that the fluorescence lifetime and hence the luminescence yield should then decrease. This theory describes quantitatively the changes in the luminescence yield, in the lifetime of the excited state of dye molecules, and in the polarisation of their luminescence as a function of concentration.

Studies of alcoholic solutions of dyes whose electronic absorption spectra do not vary over a wide concentration range but where CQL develops served as an experimental justification of the migration theory of the CQL.[177,178] The absence of concentration-dependent changes in the absorption spectra indicated, according to the authors of the migration theory of the CQL, the absence of physicochemical interactions in solutions, i.e. of the association of dye molecules.

In order to account for the fact that the depolarisation of luminescence occurs appreciably before quenching, it was arbitrarily assumed that there exist two sorts of molecules in solutions: the transfer of excitation to molecules of one sort takes place without quenching, while that to the other involves quenching. The additional hypothesis of the sphere of instantaneous quenching around the excited molecule made it possible[52] to explain the experimental non-parallel concentration variation of the luminescence yield and τ.

Another approach to the explanation of the CQL emphasised the importance of the reversible association of the molecules of luminescent substances. In the first studies on the CQL this phenomenon was accounted for by the inactive absorption of the non-luminescent associated species. A theory of the quenching of luminescence as a result of the migration of excitation energy from monomers to associated species has been developed[184], but in this investigation no account was taken of the inactive absorption by associated species and a number of simplifications were made in the calculations; it was therefore not possible to obtain the correct concentration variation of the effects. The association theory of the CQL created by Levshin[185,186] provides for the intrinsic inactive absorption by the associated species and the migration of excitation from the monomers to these species. The postulates of this theory were subjected to a comprehensive experimental test. Thus, the study of the nature of the CQL in solutions of rhodamines 6G and 3B in various solvents[79,187] made it possible to separate various types of quenching of the luminescence. The associative nature of the CQL in aqueous and glycerol solutions of Na-fluorescein has been demonstrated[61]. In these and in a number of other studies[60,109] it was shown that, even if the migration of the electronic excitation between monomeric molecules does lead to radiationless processes in the latter, this plays a very insignificant role in the overall CQL.

The study of concentration effects in alcoholic solutions of rhodamine dyes[16], whose absorption spectra do not change appreciably even in the case of concentrated solutions, showed that the CQL observed in such spectra if related to the association of the dye molecules. This was established by measuring the number-average molecular weight. Fig. 4 presents the concentration variation of the luminescence yield (curve *1*) and of the relative number-average molecular weight of rhodamine 6G (curve *2*) in ethanol. The resolution of the CQL into migration quenching (curve *3*) and quenching due to the inactive absorption by associated species (curve *4*) showed that the variation of the migration quenching of luminescence and of τ with concentration is the same. This demonstrates that the discrepancy between the variation of the yield and τ with concentration is associated with the inactive absorption by the associated species and that the so-called sphere of instaneous quenching does not exist.

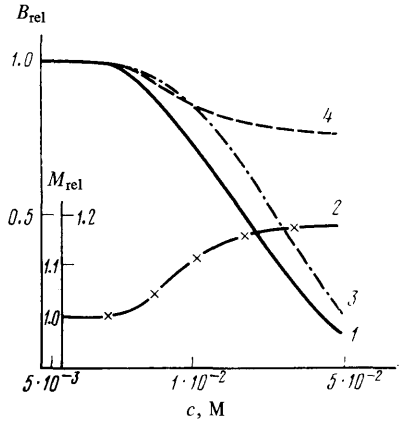

Figure 4. Dependence of the luminescence yield (curve *1*) and the number-average molecular weight (curve *2*) of rhodamine 6G in ethanol on concentration; 3) quenching due to the migration of energy; 4) quenching consequent upon the inactive absorption by the associated species.

Measurement of the differential spectra of alcoholic solutions of rhodamine dyes[188] also showed that associated species are formed at high concentrations.

In recent years both theoretical and experimental problems of the CQL in solutions of organic dyes have been considered by Bojarski and coworkers and other investigators[189-193], who based their treatment on association hypotheses. They take into account the possibility of multistage excitation energy transfer to associated species, involving several molecules, as a result of which the electronic excitation energy is converted into heat[194]. This more general theory of the CQL leads to the following dependence of the relative luminescence quantum yield B on concentration:

$$B/B_0 = [1 - f(\gamma)]/[1 - \alpha f(\gamma)], \quad (32)$$

where

$$f(\gamma) = \pi^{1/2}\gamma e^{\gamma^2}\left[1 - 2\pi^{-\frac{1}{2}}\int_0^{\gamma} e^{-t^2}dt\right],$$

$$\gamma = \gamma_м + \gamma_a = (c_м/c_{0м} + c_a/c_{0a})(\pi B_0)^{1/2}/2,$$

$$\alpha = \gamma_м/(\gamma_м + \gamma_a),$$

c_m and c_a are the concentrations of the monomers and associated species, c_{0m} and c_{0a} are the critical concentrations for the radiationless excitation energy transfer between monomers and between monomers and associated species, and B_0 is the luminescence quantum yield for the dye solution in the absence of quenching. For $\gamma_m \ll \gamma_a$, this expression becomes identical with that obtained by Förster[195]. An experimental test carried out on aqueous and aqueous glycerol solutions of xanthene dyes[191], including the anti-Stokes region[196], indicated a satisfactory agreement with theory. The parameter taking into account the quenching of the luminescence in the transfer of electronic excitation between monomers then has a value such that the above process hardly leads to CQL. It has been shown theoretically[197] that, in the dipole–dipole interaction between luminescent molecules, there is a change in the angular dependence of the probability of the absorption and emission of light with increase of their concentration. In the migration theory of the CQL [52] this change is taken into account with the aid of the hypothesis of an instantaneous transfer. An estimate[197] of the size of the "sphere of instantaneous transfer" showed that the angular effect can influence the anisotropy of the emission only in the presence of associated species in solution.

Thus theoretical and experimental studies fully confirm that the concentration-induced quenching of luminescence in solutions of organic dyes involves the formation of associated molecules in the latter.

Kinetics and Catalysis of the Oxidation of Titanium, Silicon, Germanium, and Gallium Arsenide

N.P.Peksheva and V.M.Strukov

A systematic account is given of the results of studies of the kinetics and catalysis of thermal gas-phase oxidation reactions of titanium, silicon, germanium, and GaAs. The influence of various factors (the nature of the reactant gas, the method of the preliminary treatment of the surface, and the nature of the substance oxidised) on the reaction kinetics has been estimated. The characteristics of the catalysis of heterogeneous oxidative processes are discussed and new ways of solving a number of practical problems are outlined.
The bibliography includes 133 references.

I. INTRODUCTION

The development of microelectronics, radio engineering, and laser and space technology has necessitated intense research into the characteristics of the chemical interaction of metals, alloys, and semiconductors with other elements and also a more detailed investigation of the structure of solids and of solid-state reactions.

Reactions involving the thermal oxidation of titanium, silicon, germanium, and gallium arsenide are technological processes in the radio engineering and semi-conductor industry. In order to obtain oxide films with specified properties, it is important to investigate the thermodynamics, kinetics, and mechanisms of these reactions. In the development of modern electronic engineering it is urgently necessary to accelerate the growing of oxide layers. Heterogeneous catalysis plays an important role in the solution of such problems.

However, despite the abundance of experimental data[1-14], many problems of the kinetics and catalysis of heterogeneous Ti, Si, Ge, and GaAs oxidation reactions have been by no means adequately investigated. The use of catalysis in the technology for the preparation of oxide films is hindered by the fact that the mechanism and nature of the catalytic acceleration of the reaction have not been ultimately elucidated and the selection and preparation of the catalyst presents certain difficulties[15-18].

The present review surveys the results of studies on the kinetics and catalysis of the high-temperature gas-phase oxidation of titanium, silicon, germanium, and gallium arsenide and describes practical ways of employing heterogeneous catalysis in technology.

II. THERMODYNAMICS OF THE OXIDATION OF TITANIUM, SILICON, GERMANIUM, AND GALLIUM ARSENIDE

In the thermal oxidation of metals and semiconductors there is a decrease of the free energy ΔG°_{T}. Analysis of the thermodynamics of titanium oxidation reactions in various gaseous media (in air, water vapour, and carbon dioxide) in the temperature range 400-1000°C and of the interactions of silicon, germanium, and gallium arsenide with oxygen showed that the most probable products of the interaction are crystalline or vitreous TiO_2, SiO_2, GeO_2, and Ga_2O_3 films[1,2,6,9-11,19-27]. Reactions (1)-(7), occurring under these conditions, are virtually irreversible[29,30]:

$$Ti(solid) + O_2(gas) = TiO_2(solid), \quad (1)$$

$$Ti(solid) + 2H_2O(gas) = TiO_2(solid) + 2H_2(gas), \quad (2)$$

$$Ti(solid) + 2CO_2(gas) = TiO_2(solid) + 2CO(gas), \quad (3)$$

$$Si(solid) + O_2(gas) = SiO_2(solid), \quad (4)$$

$$Ge(solid) + O_2(gas) = GeO_2(solid), \quad (5)$$

$$2GaAs(solid) + \tfrac{3}{2}O_2(gas) = Ga_2O_3(solid) + As_2(gas), \quad (6)$$

$$2GaAs(solid) + \tfrac{3}{2}O_2(gas) = Ga_2O_3(solid) + \tfrac{1}{2}As_4(gas). \quad (7)$$

The results of the calculations of the principal thermodynamic characteristics of reactions (1)-(7) using literature data[28] are presented in Tables 1 and 2. Table 1 shows that a high negative standard Gibbs free energy and highly exothermic heats are characteristic of reactions (1)-(3), which indicates their virtual irreversibility[30].

The thermodynamic probability of the oxidation of silicon, germanium, and gallium arsenide via the reactions[11,31,32]

$$Si(solid) + \tfrac{1}{2}O_2(gas) = SiO(gas),$$
$$Ge(solid) + GeO_2(solid) = 2GeO(gas),$$
$$2GaAs(solid) + \tfrac{1}{2}O_2(gas) = Ga_2O(gas) + As_2(gas).$$

increases with increase of temperature to 1000-1300°C. The equilibrium GeO vapour pressure is significant (approximately 10^{-5} atm) already above 600°C. The partial pressures of SiO and Ga_2O are negligible even at approximately 1300°C and oxygen pressures up to 10^{-9} atm.[11]

The oxidation of gallium arsenide involves the formation of gaseous arsenic in the form of As_2 and As_4.[11,33-37] Under these conditions, the presence of As_4 molecules in

the gas phase is thermodynamically more probable (see Table 2).

Table 1. Temperature variation of ΔH°_T, ΔS°_T, ΔG°_T, and $\lg K_p$ for the thermal oxidation of titanium [reactions (1) to (3)]. [130]

T, °C	ΔH°_T, kcal mole^{-1}	ΔS°_T, cal mole^{-1} K^{-1}	ΔG°_T, kcal mole^{-1}	$\lg K_p$

III. KINETICS AND MECHANISM OF THE OXIDATION OF METALS AND SEMICONDUCTORS

The rate of formation of thin films in the oxidation of metals and semiconductors are described by different equations depending on the temperature and the reaction time; it can obey the following laws[9,11,12,38–42]:

(1) A direct logarithmic relation:

$$y = k_1 \lg(B\tau + 1);$$

(2) An inverse logarithmic relation:

$$k_2/y = A + \lg \tau;$$

(3) A linear relation:

$$y = k_3\tau;$$

(4) A parabolic relation:

$$y^2 = k_4\tau;$$

(5) A cubic relation:

$$y^3 = k_5\tau,$$

where y is the thickness of the oxide film, τ the time, and A, B, and k_1–k_5 are constants. For thin films, logarithmic and cubic relations for their thickness as a function of time predominate, while for thick films the parabolic and linear relations predominate[43].

The study of the kinetics of the oxidation of titanium, silicon, germanium, and gallium arsenide led to the discovery of relations of three types[11,39]: linear, logarithmic, and parabolic (Fig. 1).

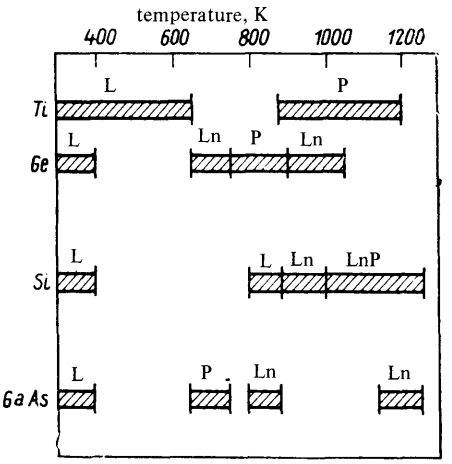

Figure 1. Dependence of the type of kinetic relation for the oxidation of titanium, silicon, germanium, and gallium arsenide on the process temperature: L = logarithmic relation; Ln = linear relation; P = parabolic relation; LnP = linear-parabolic relation.

Despite the satisfactory agreement between the experimental rates of oxidation, phase composition of the product, and other process parameters obtained by different workers, the treatment of the experimental results and of the oxidation mechanisms were different in different investigations[1,7,8,38,43–57]. Wagner[49,50] justifies a parabolic law governing the rate of growth. He postulates that, at comparatively high temperatures and for fairly high film thicknesses, the oxidation process takes place as a result of the diffusion of ions and electrons through the growing oxide; it is assumed that each volume element of the oxide is electrically neutral. The theory of Mott and Cabrera[51] explains the inverse logarithmic and parabolic variation of the rate of growth for comparatively thin films taking into account the influence of the electric field on the diffusion of ions in the oxide. However, Kubaschewski and Hopkins[43] believe that the films obtained in the oxidation of titanium at 300–500°C are somewhat thicker than should have been the case if their growth can be accounted for by the transport of material under the influence of the electric field. They begin with the hypothesis that microcavities are formed on the metal–oxide interface, i.e. they adopt the Evans theory[58], according to which the rate of formation of oxide films is determined by the transport of ions through a thin oxide film. The theory of Mott and Cabrera was subsequently developed by Hauffe and Ilschner[52], who explained the direct logarithmic relation for the rate of growth of the oxide film in the initial stages of the oxidation of metals and semiconductors.

A general model has been proposed for the mechanism of the growth of oxide films[53,54]. It is based on the treatment of processes involving the diffusion of ions and electrons through the oxide layer in which an electric field

created by these diffusing species operates. The difference between the proposed oxidation mechanism and those existing previously consists in the fact that, instead of one equation for the description of the diffusion of ions and electrons, two such equations are used in calculations of the rate of diffusion. This makes it possible (by combining the equations for total electric field) to simplify the description of the rate of growth of the oxide film thickness. However, the model suffers from the disadvantage that it does not take into account the transport process in the gas phase, the adsorption of oxidant on the surface of the oxide, and certain other factors[11].

The problem of the nature of diffusing species of oxidation remains controversial. Thus it has been shown[55] that an electric field at right angles to the outside film can accelerate or retard the oxidation of silicon, showing that the reaction takes place as a result of the transfer of ions through the oxide film. It has been established[56] that neutral oxygen atoms diffuse in addition to ions.

The rate of oxidation of gallium arsenide at comparatively low temperatures is controlled by diffusion through the oxide layer and at higher temperatures by the intrinsic chemical reaction between oxygen and gallium arsenide on the reaction interface[57]. This has been confirmed in studies[33,61] where the oxidation of GaAs was studied in oxygen at 600–900° C. It was established that the rate of oxidation below 600° C is insignificant, while on heating above 900° C the rate is so high that the oxidised specimen burns.

Thus the survey of literature data on the oxidation of titanium, silicon, germanium, and gallium arsenide shows that many problems of the kinetics and mechanisms for these chemical reactions are still unsolved. It is therefore of interest to investigate the influence of different factors on the oxidation kinetics: (a) the nature of the reactant gas; (b) the preliminary treatment of the metal surface; (c) the chemical composition of the alloy.

1. KINETICS AND MECHANISM OF THE OXIDATION OF TITANIUM IN AIR; IN WATER VAPOUR, AND IN CARBON DIOXIDE

The kinetics of the oxidation of titanium in various gaseous media have been little investigated at present as a function of temperature and the duration of heating of the metal. The oxidation of titanium is an extremely complex process, because, in contrast to other metals, the oxidation of titanium and its alloys leads to the formation of gas-saturated layers consisting of solid solutions of oxygen in α-titanium in addition to oxide films or scale.

Jenkins[62], who investigated the kinetics of the saturation of titanium with oxygen over a wide range of temperature, proposed a diagram illustrating the nature of the oxidation of titanium (Fig. 2). The diagram is divided into three main regions: *A*, *B*, and *C*. Region *A* characterises the oxidation at high temperatures in accordance with the parabolic law, which involves the simultaneous occurrence of two processes—the dissolution of oxygen and the formation of the oxide layer. The oxide grains are larger and better formed than at low temperature. Two-sided diffusion of oxygen and titanium through dense oxide layers takes place under these conditions. Region *B* corresponds to the oxidation of titanium at moderate temperatures where oxygen is absorbed via a parabolic law in the first stage and then, when the oxide thickness reaches a critical value, the latter is replaced by a linear law. The linear relation reflects mainly the growth of the oxide film, while the dissolution of oxygen continues at a rate determined by the oxygen concentration gradient and the diffusion coefficient of oxygen in the metal. The oxide lacks an appreciable protective capacity and has a porous structure, which facilitates the penetration of gaseous oxygen to the interface between the oxide and the metal. Region *C*, which characterises the oxidation of titanium at low temperatures, corresponds to a logarithmic law for the absorption of oxygen by titanium. Thus the difference between the types of kinetic curves is not associated solely with the temperature factor. The nature and mechanism of the oxidation and different stoichiometric compositions and crystal structures of the oxides formed on the metal surface play the main role.

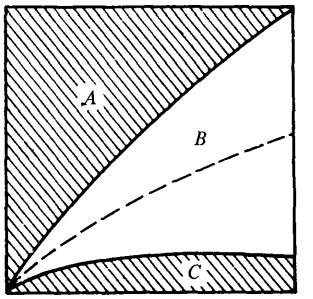

Figure 2. Titanium oxidation diagram: A) at high temperatures; B) at moderate temperatures; C) at low temperatures (V is the total amount of absorbed oxygen).

The interaction of metals with gases is due to diffusion and can be represented by three main stages[59]: (1) the adsorption of the gas on the metal surface; (2) the initiation of a crystal of the new compounds; (3) crystal growth. At a certain stage of the adsorption process, where the gas does not dissolve in the metal, a second type of crystal lattice arises on the surface of the metal instead of the single type of lattice of the main metal as a result of the solid-phase reaction. The interface then consists of two coherently bound crystalline layers—the metal and the oxide. The formation of the lattice of the new compound on the surface of the metal obeys the principles of orientation and dimensional correspondence[60].

(a) Interference Films on Titanium

The oxidation of metals by atmospheric oxygen or other oxidants results in the formation on their surface of oxide films whose thickness may vary within very wide limits. It is usual to distinguish three types of films: thin (from several angstroms to 200–400 Å), medium (from 400 to 5000–10 000 Å), and thick (above 5000–10 000 Å)[40,63–66]. For a thickness exceeding 200–400 Å, the films begin to acquire a colour due to the interference of light (interference colours)[38,42,43,64]. The phenomenon of the interference colours of films on metals has been studied fairly widely, particularly for elements such as iron, nickel, copper, silicon, and germanium[67–74]. However, despite

the abundance of the literature on the oxidation of titanium, the formation and properties of interference films on this metal have not been widely described in the scientific literature and are considered in only one monograph[1] devoted to the oxidation of titanium and its alloys.

This presents[1] the colours of four orders of spectra but the question of the number of spectra remained open. In order to study this problem in greater detail, the colour spectra of oxide films on iodide titanium (~99.90% Ti), technically pure VT-1 titanium (≥99.5% Ti), and OT4-0 (≥96.5% Ti) and OT4-1 (≥95% Ti) alloys were investigated[130] between 500° and 800°C.[17,21,22,25,73,130] At 500°C the oxidation is comparatively slow; a long time is required even for the completion of the formation of films giving the first-order spectrum. At 700° and 800°C there is a rapid growth of oxide films and at higher temperatures continuous observation of the change of the colour of the film is difficult owing to the high rate of oxidation and heating of the metal to a red glow, which masks the colour. At these temperatures the colour of the film can be more conveniently determined by quenching the specimens. For example, blue films (in a first-order spectrum) on specimens of the OT4-0 alloy are formed at 500°, 600°, 700° and 800°C respectively after 6000, 342, 70 and 30 s.

A temperature of 600°C, at which there is a smooth transition from one colour to another, made it possible to observe and record the alternation of five interference colour spectra on iodide and technically pure titanium and the OT4-0 titanium alloy and four such spectra on the OT4-1 alloy. Comparison of the times required to complete the first-order spectrum at 600°C showed that the oxidation proceeds at the highest rate on the VT-1 alloy (80 s) and at the lowest rate on the OT4-1 alloy (460 s). With increase of the thickness of the coloured film, the oxidation process slows down (Table 3).

Table 3. The formation of interference films with a first-order spectrum on titanium and its alloys in oxidation in air at 600°C.[130]

Colour of film	Oxidation time of specimens, s		
	VT-1	iodide titanium	OT4-0
Pale yellow	8	18	30
Yellow	13	27	39
Brown	22	37	60
Violet	26	55	85
Dark blue	35	123	169
Blue	49	330	342
Pale blue	80	367	390

The mechanism of the formation of thin oxide films on metals, proposed by Mott and Cabrera, presupposes the generation of an electric field in such films[38,42,51,52,69,76-78] whose potential gradient reaches approximately 10^7 V cm^{-1}. Under the influence of such films, the metal cations acquire a high mobility and migrate at a high rate through the film towards its boundary with the gas, which leads to a fairly rapid growth of the film on the metal surface. With increase of film thickness, the potential gradient diminishes significantly and the oxidation slows down.

We shall apply this oxidation mechanism to metals which give rise to semiconducting *p*-type films with an excess of cationic vacancies[43]. The applicability of this theory to the explanation of the oxidation of titanium is apparently somewhat limited for the following reasons: (1) titanium gives rise to the oxide TiO_2, which is an *n*-type semiconductor (with a deficiency of anions)[43]; (2) titanium is characterised by unusually high solubility of oxygen, which penetrates into the bulk of the metal[5,6,19,43]; (3) a film, whose thickness amounts to hundredths of angstroms within the limits of the operation of the logarithmic law, grows on titanium[1,79].

In our view extensive study of the properties of interference films on titanium and its alloys can yield valuable information about the kinetics, catalysis, thermodynamics, and physicochemical properties of the oxide layers formed and about the mechanism of the interaction of metals with the medium.

(b) Oxidation in Air

Studies on the kinetics of the oxidation of titanium in air are particularly important. Their results are presented in numerous publications[1,8,39,44-48], where it is shown that appreciable differences in the nature of the oxidation of titanium in oxygen and in air are not observed during the initial period[1,8]. In the oxidation by air, the shape of the kinetic curves and the form of the kinetic relation are analogous to those obtained in the oxidation of titanium in pure oxygen (700–1000°C), but the degree of oxidation is lower than in oxygen[1,8]. The rutile lattice constants in the oxides obtained by oxidising titanium in air and in oxygen are the same at temperatures below 1100°C.[8]

Subsequently (at higher temperatures) titanium absorbs a much greater amount of gases in oxidation in air than in oxidation in oxygen. Above 1150°C the oxidation of titanium in air is faster than in oxygen[80]. The process is complicated by the fact that, in the high-temperature oxidation of titanium in air, the metal reacts not only with oxygen but also with nitrogen. It has been established[59,80] that nitrogen enters the crystal lattice of rutile in the course of the high-temperature oxidation with air, which leads to the formation of a perforated structure and an increase of the volume of the unit cell. The formation of rutile with a defective lattice facilitates the diffusion of titanium ions to the outer surface of the oxide layer and the diffusion of oxygen into the bulk of this layer, which promotes a more rapid oxidation. At the same time, there is no unanimous view in the literature concerning the rate of oxidation of titanium in oxygen and in air. Apart from the data quoted above, it has also been claimed[81,82] that the oxidation of titanium at 1200°C in pure oxygen is much faster than in air and that the rate of oxidation is virtually the same in the two cases at 1000°C.

Studies of the initial stages of the oxidation of titanium are particularly difficult in view of the difficulty of measuring the thickness of the oxide layer and the amount of substances which have reacted in the course of the high-temperature chemical interaction. The method of interference indicators has been used in studies of the kinetics of the initial stages of the oxidation of titanium[17]. The rate of oxidation was found by observing the interference of the light waves in oxide films of specified thickness, formed as a result of the heterogeneous chemical interaction of the metal with the oxidising medium. The main advantage of this method is that one has only to determine the colour of the oxide and not its thickness. The method of interference indicators permits comparative kinetic studies and enables one to determine the influence of the chemical composition of titanium alloys on the initial stages of their oxidation[22,29,75,83-85], the difference between the

rates of reaction in air[17,29,84,85], water vapour[24,29,84–86], and carbon dioxide[24,29,84,85,87], the influence of catalysts on the process kinetics[88–92], and the dependence of the kinetics of the initial stages of the oxidation of titanium on the method of polishing of the metal surface[23,93,94] and other factors.

Table 4. Chemical composition of titanium alloys[22].

Alloy	Concentrations of components, wt.%						
	Ti	Al	Mn	Fe	Si	C	others
VT-1	99.5	—	—	—	—	—	—
OT4-0	⩾96	0.2–1.4	0.2–1.3	⩽0.3	⩽0.15	⩽0.1	⩽0.8
OT4-1	⩾95	1.2–2.5	0.7–2.0	⩽0.3	⩽0.15	⩽0.1	⩽0.8

A comparative study of the kinetics of the growth of interference oxide layers in the thermal oxidation in air of specimens of technically pure titanium of type VT-1 and of OT4-0 and OT4-1 titanium alloys has been carried out[17,29,84,85] (Table 4). Metal specimens with dimensions 20 × 10 × 1 mm were subjected to isothermal oxidation at 500–650°C in a furnace with transparent quartz inspection windows for the visual observation of the changes in the colour of the film during the reaction.

Table 5. The colours of titanium oxide films as a function of the thickness of the oxide layer[1].

Colour of film	y, Å
Pale yellow	344
Yellow	349
Brown	447
Violet	492
Dark blue	515
Blue	536
Pale blue	542

Table 6. The activation energies (E, kcal mole^{-1}) for the oxidation of titanium alloys by air with formation of interference films having a first-order spectrum[22,23].

Alloy	Change in film colour		
	from yellow to brown	from brown to violet	from violet to dark blue
VT-1	15.700	23.000	28.800
OT4-0	24.400	26.800	29.000
OT4-1	26.200	27.000	39.200

The relations between the colour of the first-order spectrum and the thickness of the oxide film on titanium are presented in Table 5 for interference films. Experiments at different temperatures led to the determination of the time corresponding to the change in the colour of the oxide film within the limits of two chosen colours–from yellow to brown (Δy = 98 Å), from brown to violet (Δy = 45 Å), from violet to dark blue (Δy = 23 Å), and from dark blue to blue (Δy = 21 Å). The experimental results were expressed by plots of $\tau = \varphi(t^0)$ and $\lg \tau = \varphi(1/T)$. Fig. 3 illustrates the kinetics of the oxidation of titanium alloys by air accompanied by a change in the colour of the film from yellow to brown[84]. Table 6 presents the activation energies for the oxidation of titanium alloys in air found from plots of $\lg \tau = \varphi(1/T)$.

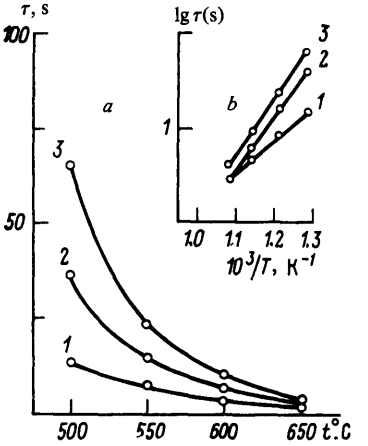

Figure 3. The film formation time τ in the yellow–brown colour range as a function of temperature t(°C) (*a*) and $1/T$ (*b*) in the oxidation of titanium alloys by air; alloy: *1*) VT-1; *2*) OT4-0; *3*) OT4-1.

(c) Oxidation in Water Vapour and Carbon Dioxide

In order to elucidate the influence of the nature of the oxidising medium on the rate of oxidation of titanium and its alloys, a study was made of the kinetics of the initial stages of the oxidation of the metal in water vapour and carbon dioxide under the conditions of the formation of an interference film with a first-order spectrum[24,29,84–87].

The kinetics of the oxidation of titanium in water vapour have been studied comparatively little. This problem has been described most completely in a monograph[1] and in a number of papers[95–97]. The studies showed that at a water vapour pressure of 1 atm and at 400–1200°C the oxide films grow faster than in air owing to the looser structure of the layer of scale. At 800–1000°C the thickness of the film increases in accordance with the same laws as in air[1].

The study[24,29,84–87] of the initial stages of the oxidation of titanium alloys in water vapour and carbon dioxide and comparison of the results with the oxidation kinetics in air showed that the nature of the oxidising medium has a significant influence on the rate of growth of the interference films. In the presence of water vapour the formation of a film having a standard colour is much faster on all three alloys in the range of experimental temperatures than in air and in carbon dioxide (Fig. 4).[24] For example, the change in the colour of the film from yellow to brown on specimens of the OT4-0 alloy at 550°C in water vapour,

air, and carbon dioxide takes place after 22, 230 and 287 s respectively. The apparent activation energies for the oxidation of titanium alloys in water vapour and carbon dioxide are presented in Table 7.

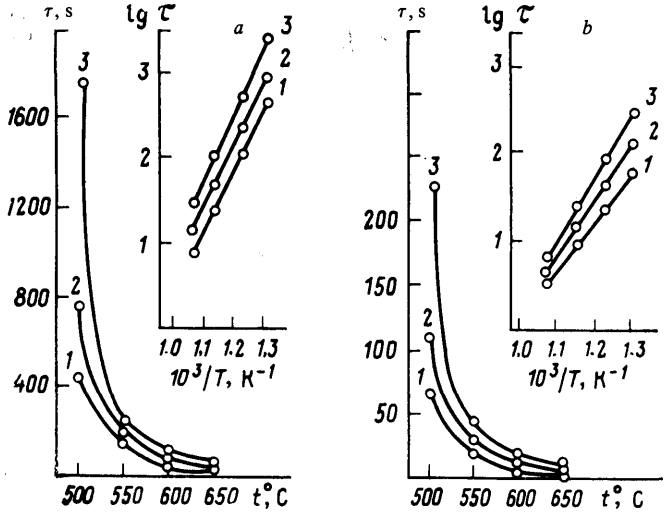

Figure 4. Dependence of the oxidation time τ of mechanically polished titanium alloy specimens on temperature in the formation of the film in the colour range from violet to dark blue: *a*) in carbon dioxide; *b*) in water vapour; alloy: *1*) VT-1; *2*) OT4-0; *3*) OT4-1.

Table 7. The activation energies (E, kcal mole^{-1}) for the oxidation of mechanically polished titanium alloy specimens in water vapour and carbon dioxide[24,29].

Alloy	Change in film colour			
	from yellow to brown	from brown to violet	from violet to dark blue	from dark blue to blue
	in water vapour			
VT-1	21.200	24.900	29.400	35.800
OT4-0	24.400	27.000	32.400	38.300
OT4-1	26.600	28.000	35.800	40.900
	in carbon dioxide			
VT-1	30.500	34.800	39.100	40.000
OT4-0	31.400	36.600	40.500	41.800
OT4-1	31.700	37.400	41.800	42.900

It follows from the analysis of the data presented in Tables 6 and 7 and in Figs. 3 and 4 that, in the formation of an oxide layer in air, water vapour, and carbon dioxide, technically pure VT-1 titanium is oxidised at the highest rate in all the intervals of the first-order colour spectrum investigated, while the lowest rate corresponds to the OT4-1 alloy with the highest aluminium content. According to some investigations[1,8,43], alloying with aluminium greatly increases the heat resistance of titanium alloys. The highest activation energies for the oxidation reaction correspond to specimens of the OT4-1 alloy under these conditions.

The retardation of the interaction of the metal with the medium as the thickness of the oxide layer (Figs. 5 and 6) increases and the increase of the activation energy for the process are characteristic of all three alloys. This can be explained by the fact that the oxide layer formed on the metal exhibits more effective protective properties and, by separating the reactants, strongly inhibits the chemical interaction and weakens the effect of the electric field arising on formation of interference oxide layers on metals[38,42,69].

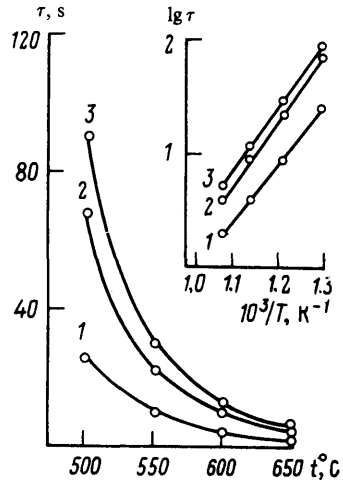

Figure 5. Dependence of the coloured film formation time in the oxidation of electrochemically polished titanium alloy specimens in water vapour on temperature in the colour range from yellow to brown; alloy: *1*) VT-1; *2*) OT4-0; *3*) OT4-1.

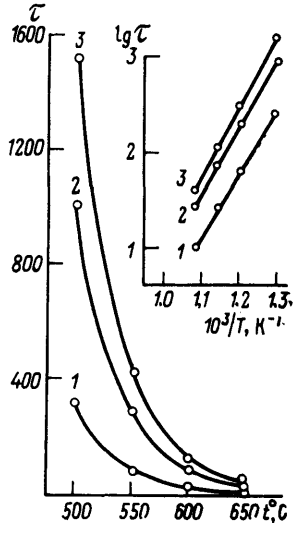

Figure 6. Dependence of the coloured film formation time in the oxidation of electrochemically polished titanium alloy specimens in carbon dioxide on temperature in the colour range from yellow to brown; alloy: *1*) VT-1; *2*) OT4-0; *3*) OT4-1.

An electron diffraction study of the phase composition of the interference films[98,99] formed in the thermal oxidation of titanium alloys in water vapour showed that the principal structural component of the films is rutile. The films obtained by oxidising the metal in CO_2 include three structural components: rutile, anatase, and titanium carbide[24,29].

The increase of the rate of oxidation of titanium in water vapour is due to the more porous structure of the oxide layer and the increase in the number of defects in the crystal lattice of rutile (an excess of titanium ions), which has been confirmed by electron microscope studies and is consistent with other data[95–97]. Under these conditions, there is a marked increase of the diffusional mobility of titanium ions. The diffusion coefficient of titanium ions in the oxide layer obtained in water vapour exceeds by 1–2 orders of magnitude that in the oxide obtained in air[1].

The decrease of the rates of the initial stages of the oxidation of the alloys during the formation of interference films with a first-order spectrum, in carbon dioxide is apparently associated with the formation of titanium carbide (a phase with a very great hardness and density in which the rate of diffusion of titanium ions is correspondingly reduced) in the surface layer of the metal. This is also indicated by the higher activation energy for the oxidation of titanium alloys in a stream of CO_2 compared with air and water vapour[24,29].

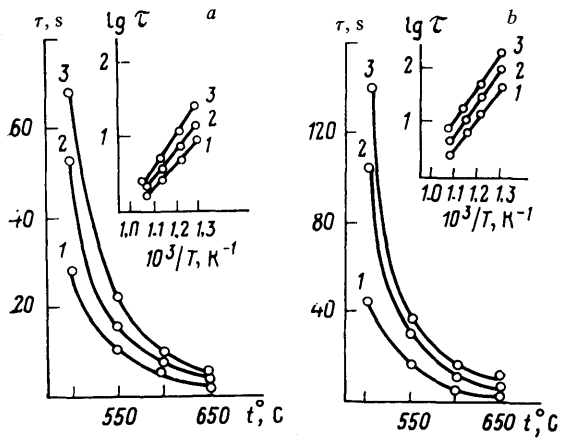

Figure 7. Dependence of the oxidation time for mechanically (*a*) and electrochemically (*b*) polished titanium alloy specimens on temperature (°C) in the formation of the film in water vapour in the colour range from brown to violet: *a*) water vapour; *b*) carbon dioxide; alloy: *1*) VT-1; *2*) OT4-0; *3*) OT4-1.

(d) The influence of the Method of Polishing the Surface on the Kinetics of the Oxidation of Titanium Alloys

The method of polishing the metal surface has an appreciable influence on its properties. For example, in electrochemical polishing the microgeometry and the physical and chemical properties of the surface are altered[100]. The method of preparation of the metal surface influences the kinetics of the initial stages of its oxidation[40]. However, the determination of the differences between the rates of oxidation of the surfaces of specimens of the metal having the same composition and structure but subjected to different types of treatment is experimentally difficult. The method of interference indication[17], which in the given instance is extremely sensitive and very promising, has been used to solve this problem.

In order to investigate the influence of the method of treatment of the surfaces of titanium alloys on the kinetics of their oxidation in different gaseous media, specimens of technically pure VT-1 titanium and OT4-0 and OT4-1 titanium alloys were subjected to two types of polishing: mechanical polishing to give a roughness of class 10–12 and electrochemical polishing in an electrolyte solution: the composition of the electrolyte and the process conditions have been described[101–103]. It has been shown that in the gaseous media investigated the initial stages of the oxidation of titanium specimens subjected to electrochemical polishing in the course of the formation of colour films with a first-order spectrum are much slower compared with specimens subjected to mechanical polishing (Fig. 7).[94] For example, the change in the colour of the film from violet to dark blue on mechanically polished specimens of the OT4-1 alloy at 550°C in water vapour, air, and carbon dioxide takes place after 45, 116, and 210 s, while on electrochemically polished specimens the corresponding times are 80, 660, and 756 s respectively.

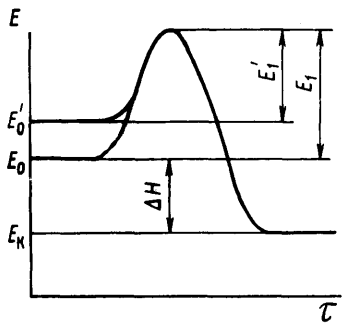

Figure 8. Variation of the energy levels of the surface atoms in the polishing process; E is the activation energy, τ is the time, E_0 and E_0' are the initial energy of the atoms in the surface layer for the electrochemically and mechanically polished specimens respectively, E_1 and E_1' are the activation energies for their oxidation, ΔH is the heat of the chemical reaction, and E_e is the energy of the reaction products.

The appreciable difference between the rates of the initial stages of the oxidation reaction can be explained by the fact that the energy levels of the atoms in the surface layer are higher for a mechanically polished (cold-worked) surface than for an electrochemically polished surface (Fig. 8).[94] The cold-worked layer, usually concentrated in the surface region, is removed by electrochemical polishing[104,105]. Furthermore, after electrochemical polishing one observes an increased resistance to gaseous corrosion due to the presence of a continuous thin and stable

oxide film on the surface of the metal[104,106–108]. On the other hand, in the case of mechanical polishing the scratches and foreign inclusions on the surface prevent the creation of such a continuous oxide layer and oxidation proceeds at a higher rate. With increase of the thickness of the coloured films, the rates of oxidation of both mechanically and electrochemically polished specimens of titanium alloys decrease in air, water vapour, and carbon dioxide.

Table 8 presents as an example the activation energies for oxidation in water vapour for specimens subjected to electrochemical polishing. Comparison of the data in Tables 6–8 shows that the activation energies for the oxidation of electrochemically polished titanium alloy specimens are appreciably higher than for mechanically polished specimens.

Table 8. The activation energies (E, kcal mole^{-1}) for the oxidation of electrochemically polished titanium alloy specimens by water vapour[84,94].

Alloy	Change in film colour			
	from yellow to brown	from brown to violet	from violet to dark blue	from dark blue to blue
VT-1	23.900	25.600	32.200	38.500
OT4-0	26.800	28.800	34.200	40.200
OT4-1	27.500	29.700	36.400	41.700

Regardless of the method of preliminary treatment of the surface, among the three alloys investigated technically pure VT-1 titanium and the OT4-1 alloys are oxidised at the highest and lowest rates respectively. Correspondingly, higher activation energies are characteristic of OT4-1 alloy specimens than of the VT-1 titanium.

Thus the method of interference indicators made it possible to observe the influence of the method of polishing the surface on the kinetics of the oxidation of titanium alloys of different composition in different gaseous media.

2. KINETICS OF THE OXIDATION OF GERMANIUM AND GALLIUM ARSENIDE

The kinetics of the thermal oxidation of germanium in air have been investigated[90,91,109,110] in the temperature 575–625°C in the region of the colour change at the GeO_2 film from colourless to green; with increase of the thickness of GeO_2 layers, an appreciable increase of the activation energy for the process is observed—from 47 to 128 kcal mole^{-1}.

Mathematical treatment of the results of the experiment on the oxidation of GaAs plates of AGET brand with atmospheric oxygen yielded[133] the following relations between the oxidation time τ and the temperature T in the range 600–675°C in different oxide colour ranges:

from colourless to brown:

$$\tau \simeq 52.48 \cdot 10^{-7} \exp(9950/T);$$

from brown to violet:

$$\tau \simeq 32.62 \cdot 10^{-17} \exp(33080/T);$$

from violet to dark blue:

$$\tau \simeq 12.59 \cdot 10^{-21} \exp(42300/T);$$

from dark blue to blue:

$$\tau \simeq 31.62 \cdot 10^{-24} \exp(47900/T).$$

It was shown that the activation energy for the formation of the β-Ga_2O_3 oxide film on the gallium arsenide specimens increases with increasing thickness of the oxide, within the limits of the first interference colour spectrum, from 19.81 to 95.32 kcal mole^{-1}.[133] This finding has been explained in a number of studies[11,42,77,78].

IV. CATALYSIS OF THE OXIDATION OF TITANIUM, SILICON, GERMANIUM, AND GALLIUM ARSENIDE

It is known that, in selecting catalysts for a given reaction, it is necessary to choose the latter from substances which are known as catalysts of analogous reactions and which form with initial reactants and the reduction products compounds which can be readily decomposed[111–115]. For titanium, silicon, germanium, and gallium arsenide heterogeneous oxidation processes, the optimum catalysts employed were therefore platinum, palladium, and silver, which are traditional catalysts of a large class of oxidation reactions[116].

1. METHODS OF PREPARATION OF THE CATALYSTS

The platinum, palladium, and silver catalysts have been obtained by electrolysing 3% aqueous solutions of chloroplatinic acid, palladium chloride, and potassium silver cyanide respectively. The carriers were platinum, silver, and nichrome. In addition, the platinum catalyst has been obtained by the thermal decomposition of $H_2[PtCl_6]$. For this purpose, a 50% aqueous solution of $H_2[PtCl_6]$ was deposited on the surface of a silicon plate and the latter was heated in air for 5 min at 700–1000°C. This resulted in the appearance of dispersed platinum on the silicon, which served as a carrier.

The use of electrolysis and of the thermal decomposition of chemical compounds for the preparation of disposed metals made it possible to obtain by a relatively simple technology catalysts with a comparatively high activity. Direct deposition of platinum and palladium blacks and of dispersed silver on a nichrome carrier or on the surface of the specimen being oxidised, for example, silicon, makes it possible to reduce the consumption of platinum, palladium, and silver under these conditions.

The degree of dispersion of the catalysts was determined by X-ray diffraction[98]. The average size of the crystals was 15, 230, and 2650 Å for palladium, platinum, and silver respectively, which corresponds approximately to the following specific surfaces ($m^2\ g^{-1}$): 370 for Pd, 12 for Pt, and 2.2 for Ag.[26,89,90].

2. THE ACCELERATING CATALYTIC EFFECT OF CATALYSTS ON THE OXIDATION OF TITANIUM, SILICON, GERMANIUM, AND GALLIUM ARSENIDE

(a) Catalysis of the Oxidation of Titanium

There is virtually no information in the literature about the kinetics of the growth of interference oxide layers on titanium in the presence of catalysts. We investigated

the catalytic oxidation of titanium by air in the presence of dispersed platinum, palladium, and silver in the temperature range 400–550°C.[88–92] The interference colours of the films were used as the indicator. Specimens of the OT4-0 titanium alloy (Ti ⩾ 96.5%), subjected to mechanical polishing to a roughness class of 10–12, were used in the experiments. A study was made of the kinetics of the film growth within the limits of the formation of the yellow–brown–violet–dark blue–blue first-order spectrum with the catalyst arranged parallel to the surface of the specimen being oxidised and in contact with it[99]. On formation of interference rutile films (TiO_2), the local catalytic action of platinum, palladium, and silver was observed for the first time. It was found that in the presence of these metals the rate of growth of the oxide layer in the region of direct contact between the catalyst and the specimen is much higher compared with the rest of the surface. Thus at 400°C the formation of a blue film in the absence of a catalyst takes place over a period of 130 h and 45 min, while in the presence of platinum the reaction takes 4 min and 12 s, i.e. the oxidation of titanium is accelerated by a factor of 1868. The degree of acceleration of the oxidation process depends on the nature of the catalyst employed, the temperature of the reaction zone, and the thickness of the film formed (Tables 9 and 10). Table 10 presents a quantitative estimate of the parameter of the local-catalytic acceleration (K) of the titanium oxidation reactions in the presence of the platinum and silver catalysts, K being defined as the ratio of the times required for the formation of the TiO_2 interference film with a standard colour in the absence and in the presence of a catalyst.

Table 9. Time required for the formation of interference rutile films in the catalyst–specimen contact zone[89,90].

Colour of film	Catalyst	Time, min			
		400° C	450° C	500° C	550° C
Brown	None	780	47	7.17	4.2
	Dispersed Ag	5.00	2.5	1.75	1.20
	Pt black	2.25	1.5	1.00	0.83
Violet	None	2970	270	26.42	10.75
	Dispersed Ag	6.5	3.00	2.17	1.33
	Pt black	3.15	1.85	1.30	1.00
Dark blue	None	5520	1140	85	19.66
	Dispersed Ag	8.1	4.6	3.17	1.83
	Pt Black	3.75	2.1	1.42	1.20
Blue	None	7845	2520	270	66
	Dispersed Ag	10.2	6.75	4.08	2.55
	Pt Black	4.2	2.4	1.6	1.35

The data presented in Tables 9 and 10 show that, with increase of the thickness of the TiO_2 oxide layer, the efficiency of the catalyst increases. Thus at 400°C platinum black accelerates the formation of the brown rutile film by a factor of 346, the violet film by a factor of 943, the dark blue film by a factor of 1470, and the blue film by a factor of 1868. With increase of temperature, the activity of the catalyst falls. For example, dispersed silver accelerates the formation of the violet rutile film by a factor of 457 at 400°C, 90 at 450°C, 12 at 500°C, and 8 at 550°C.

A difference between the catalytic activities of platinum, palladium, and silver was observed by the method of interference indication. The initial stages in the oxidation of the test alloys in the presence of platinum black take place at a higher rate than in the presence of dispersed silver. Thus the formation of a blue film on specimens of type OT4-0 at 400°C in the presence of platinum and silver catalysts takes place after 220 and 610 s respectively.

Table 10. The local catalytic acceleration (the values of K) for the oxidation of the OT4-0 titanium alloy in the presence of platinum and silver[89].

Colour of film	Pt				Ag			
	400° C	450° C	500° C	550° C	400° C	450° C	500° C	550° C
Brown	346.6	31.3	7.1	5.0	158	18.8	4.0	3,5
Violet	942.8	145.9	20.3	10.7	456.9	90.0	12.1	8.0
Dark blue	1472	542.8	59.8	16.3	681.5	247.9	26.8	10.7
Blue	1867.8	1050	168.7	48.8	771.2	373.0	66.0	25.8

(b) Catalysis of the Oxidation of Silicon

Polished plates of type KEF, oriented in the (111) plane, which catalysed oxidation by atmospheric oxygen in the range 450–1350°C, were used in the experiments on the catalytic oxidation of silicon[117,118,129]. The platinum, palladium, and silver catalysts, deposited on carriers in the form of a needle, were mounted with the aid of a special device over the silicon plate undergoing oxidation at right angles to its surface[117,118].

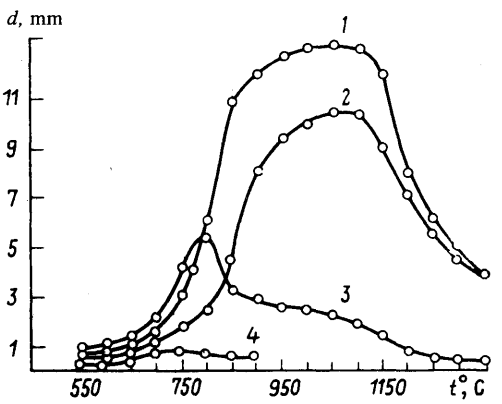

Figure 9. Dependence of the diameter d of the interference zone in the oxidation of silicon on temperature for platinum black (curves *1* and *2*), palladium black (curve *3*), and dispersed silver (curve *4*); wire carrier: *1*) and *3*) platinum; *2*) nickel–chromium; *4*) silver; oxidation time 5 min.

The observation of a sharp increase in the rate of oxidation of silicon in the presence of platinum, palladium, and silver must be regarded as the principal result of these experiments[92,109,117,118]. For example, at 700°C the rate of growth of the blue SiO_2 film with a thickness of 1500 Å increases by a factor of 10^4 in the presence of the platinum

catalyst. Comparison of the silicon oxidation times in the presence and absence of platinum black showed[92] that K increases with decrease of temperature and with increase of the thickness of the oxide layer obtained.

The diameter of the interference zone in the catalytic oxidation of silicon depends on the type of the catalyst, temperature, and oxidation time. Thus in the course of 5 min the diameter of the interference zone reaches its maximum value at 1000–1100°C for platinum black, at 800°C for palladium black, and at approximately 750°C for dispersed silver (Fig. 9).[117,133] Platinum and silver are characterised by the greatest and smallest zone diameters respectively.

A marked weakening of the catalytic activity of the metals takes place at the temperature of the most effective sintering and recrystallisation, which is usually two-thirds of the melting point. Indeed, Fig. 9 shows that a sharp decrease in the diameter of the interference zone begins at 1100–1150°C for platinum and palladium black. The diameter of the interference zone also depends on the type of carrier employed. Thus the use of platinum as the carrier for platinum black results in a zone with a larger diameter than in the case of nichrome (Fig. 9).

Comparison of the times required for the formation of a silicon dioxide layer 15400 Å thick at 700°C in the presence of platinum and palladium blacks and dispersed silver shows that the activities of these catalysts increase in the sequence Ag < Pd < Pt.

The influence of geometrical factors, particularly of the length and thickness of the layer of catalytically active substance deposited on the carrier as well as its distance from the surface of the specimen, has been studied[119]. The experiments were performed with two arrangements of the catalyst (Fig. 10): (a) platinum (or palladium) black was at a distance s from the end of the needle; (b) platinum (or palladium) black covered the wire carrier over a length l from the point of its contact with the specimen.

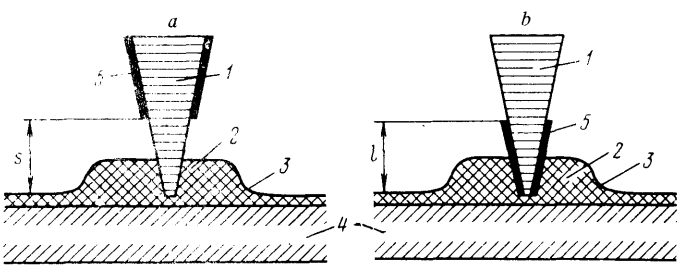

Figure 10. Schematic illustration (*a*) and (*b*) of the positioning of the catalyst relative to the silicon specimen: *1*) platinum or nichrome needle; *2*) SiO_2 film; *3*) interference colour rings; *4*) silicon plate; *5*) platinum or palladium black.

It was found that an increase of s reduces the catalytic effect. The catalytic effects of platinum black deposited on platinum and nichrome carriers differ significantly. The thickness of the SiO_2 film grown over a period of 5 min is independent of the extent l of the blackened section of the platinum wire.

Thus, with the aid of platinum, palladium, and silver catalysts, it is possible to achieve the local growth of oxide layers on silicon at temperatures of approximately 500–600°C at which the process virtually does not occur in the absence of the catalyst. The rate of the process depends significantly on temperature, the type of catalyst employed, and the distance of the active substance on the carrier from the silicon specimen.

The kinetics of the catalytic oxidation of silicon were determined by the mathematical treatment of the curves for the increase in the thickness in the SiO_2 film[129] obtained using platinum or silver foil, in contact with the surface of the specimen undergoing oxidation, as catalyst carriers. It was established that an increase of the film thickness with time is linear in the presence of platinum black and parabolic in the presence of palladium black and dispersed silver (Table 11). The activation energy for the oxidation process depends on the type of the catalyst. The oxidation of silicon in the presence of platinum black proceeds with a lower activation energy than in the presence of palladium black and dispersed silver; the activation energies at 500–700°C are 9.16, 9.75, and 12.76 kcal mole^{-1} respectively.

Table 11. Variation of the SiO_2 film thickness (y, Å) with time (τ, min) in the oxidation of silicon in air in the presence of catalysts[129].

Temperature, °C	Pt black	Dispersed silver	Pd black
500	$y = 1042\ \tau$	$y^2 = 33.16 \cdot 10^4\ \tau$	$y^2 = 80.66 \cdot 10^4\ \tau$
600	$y = 2329\ \tau + 3 \cdot 10^3$	$y^2 = 83.26 \cdot 10^4\ \tau$	$y^2 = 189.33 \cdot 10^4\ \tau$
700	$y = 3550\ \tau + 5.2 \cdot 10^3$	$y^2 = 121.93 \cdot 10^4\ \tau$	$y^2 = 444.66 \cdot 10^4\ \tau$

The equations for the rate constants for the catalytic oxidation of silicon, determined from the experimental data, are presented in Table 12, For the platinum catalyst, they are evidently different in the temperature ranges 500–700°C and 800–900°C.

Table 12. Dependence of the equations of the rate constants for the growth of the silicon oxide film on the type of catalyst employed and temperature[133].

Catalyst	500–700° C	800–900° C	Dimensions of rate constant
Pt black	$k = 4.08 \cdot 10^5 \exp(-4.62/T)$	$k = 1.86 \cdot 10^6 \exp(-5.01/T)$	A min^{-1}
Pd black	$k = 3.39 \cdot 10^9 \exp(-6.44/T)$	—	A^2 min^{-1}
Dispersed Ag	$k = 1.95 \cdot 10^8 \exp(-4.93/T)$	—	A^2 min^{-1}

The time (τ, s) corresponding to the appearance of SiO_2 films whose thickness corresponds to complete second-order (3500 Å) and eighth-order (15400 Å) colour spectra in the presence of platinum black varies with temperature in the following manner[129]:

For 3500 Å: $\tau \simeq 8.79 \times 10^{-2} \exp(5730/T)$, $E \simeq 11350$ cal mole^{-1};
For 15400 Å: $\tau \simeq 8.67 \times 10^{-4} \exp(11950/T)$, $E \simeq 27700$ cal mole^{-1}.

With increase of the oxide film thickness, the activation energy E for the oxidation of silicon increases.

Table 13 lists the times corresponding to the formation of SiO_2 films of different thickness in the isothermal oxidation of silicon in air in the presence (τ_2) and absence (τ_1) of $H_2[PtCl_6]$ at 700–1000°C and the increments in the rate of oxidation ($K = \tau_1/\tau_2$).[133] Evidently an increase of temperature lowers the efficiency of the catalyst.

Table 13.

Temperature, °C	SiO_2 film thickness, A	τ_1, min	τ_2, min	K
700	750	10 000	5	2000
800	1250	2 500	5	500
900	1500	700	5	140
1000	1750	300	5	60

(c) Catalysis of the Oxidation of Germanium

On direct contact with the specimen undergoing oxidation, platinum or palladium black leads to a local acceleration of the oxidation of germanium of type GES [32,90,91,109] at temperatures above 350°C (Table 14).

Table 14. Time required for the formation of the interference films in the catalyst–germanium specimen contact zone[90].

Colour of GeO_2 film (order of spectrum)	Catalyst	Time, min			
		350° C	400° C	450° C	500° C
Dark blue (I)	Pt black	5.0	3.25	1.0	0.75
" "	Pd black	10.1	5.4	1.5	1.1
Blue (I)	Pt black	6.0	4.0	1.25	1.0
" "	Pd black	15.3	7.1	1.8	1.25
Yellow (II)	Pt black	7.5	5.0	1.5	1.2
" "	Pd black	>30	8.7	2.2	1.4
Red(II)	Pt black	9.0	5.5	2.0	1.5
" "	Pd black	—	10.2	3.1	1.7
Green (II)	Pt black	10.0	6.25	2.5	1.8
" "	Pd black	—	13.5	4.25	2.1
Green (III)	Pt black	>30	7.5	3.0	2.1
" "	Pd black	—	17.1	5.1	2.8

It was found (Table 17) that, in the formation of interference oxide layers on germanium platinum is more active than palladium. The use of platinum and palladium catalysts makes it possible to oxidise germanium at an appreciable rate at approximately 400°C, i.e. 200° below the temperature in the absence of catalysts.

(d) Catalysis of the Oxidation of Gallium Arsenide

On heating in air, gallium arsenide begins to be oxidised at an appreciable rate above 600°C.[36,37] However, the use of the thermal oxidation method is significantly restricted by the fact that, on heating above 600°C, gallium arsenide crystals decompose appreciably to liquid gallium and gaseous arsenic in accordance with the equation

$$4GaAs(solid) = 4Ga(liq.) + As_4(gas).$$

A decrease of temperature and an increase of the rate of oxidation of GaAs are therefore of great practical interest.

In the presence of a platinum catalyst in contact with the specimen surface being oxidised the rate of oxidation of GaAs increases appreciably. Table 15 shows that the increase of the rate is greater the greater the thickness of the oxide layer.

Table 15. Dependence of the GaAs oxidation time in the absence (τ_1) and presence (τ_2) of platinum black and of the increment in the rate of oxidation $K = \tau_1/\tau_2$ on the thickness of the Ga_2O_3 oxide film[133].

Colour of β-Ga_2O_3 film (order of spectrum)	τ_1, min	τ_2, min	K
Brown (I)	1050	0.33	3150
Violet (I)	1350	0.41	3220
Dark blue (I)	1800	0.75	3600

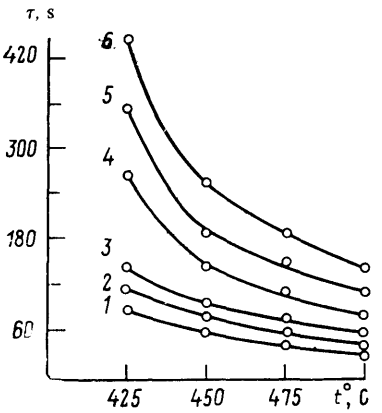

Figure 11. Temperature variation of the oxidation time τ of gallium arsenide in the presence of the platinum catalyst in contact with the specimen under-going oxidation before the appearance of brown (curve *1*), violet (curve *2*), dark blue (curve *3*), blue (curve *4*), yellow (curve *5*), and orange (curve *6*) oxide films.

The employment of platinum black reduces the GaAs oxidation temperature and makes it possible to obtain on the latter oxide films at a technologically acceptable rate at temperatures in the range 425–500°C (Fig. 11). The activation energy for the catalytic oxidation of GaAs varies in the range 9.4–21.1 kcal mole^{-1}.

3. THE INFLUENCE OF CATALYSTS ON THE OXIDATION OF TITANIUM, SILICON, AND GERMANIUM AT A DISTANCE

The catalytic oxidation of titanium, silicon, and germanium has been carried out[26,27,32,88–92,109,110,117–119] both with direct contact between them and dispersed metals and with the specimens undergoing oxidation placed at a certain distance from the catalyst. It was observed[27,89,90] that platinum and palladium coated with the corresponding blacks exert a catalytic influence on the rate of oxidation of titanium, silicon, and germanium placed at some distance from the catalyst (Tables 16–18). This effect begins to be observed at approximately 400°C. Table 17 shows that the growth of the SiO_2 film is observed in the course of approximately 4 min from the start of the oxidation; the subsequent reaction entails hardly any change in the thickness of the oxide film. An increase of the oxidation temperature (above 1000°C for platinum and above 800°C for palladium) lowers the catalytic influence of the dispersed metals (Fig. 12). The activity of the catalyst decreases with increasing distance between the dispersed metal and the specimen being oxidised. The catalytic activity of platinum black is higher than that of palladium black (Tables 16–18).

Table 16. Time required for the formation of rutile interference films with the catalyst acting at a distance (500°C).[89]

Distance from catalyst to specimen, mm	Catalyst	Time, min			
		brown film	violet film	dark blue film	blue film
0.1	Pt black	1.5	2.0	3.0	4.1
0.1	Pd black	1.5	2.3	3.7	4.8
0.5	Pt black	5.0	5.8	6.5	7.5
0.5	Pd black	5.0	6.9	8.0	10.0

Table 17. Dependence of the SiO_2 film thickness on the growth time at 650°C.[27]

Catalyst	Distance, mm	Film thickness, Å					
		1 min	2 min	3 min	4 min	5 min	6 min
Pt black	0.1	2000	2500	3900	5400	5400	5400
Pt black	0.4	1500	2000	3000	4260	4260	4260
Pt black	0.8	1000	1250	1500	2000	2000	2000
Pd black	0.1	1750	2000	2500	3500	3500	3500
Pd black	0.4	1250	1500	1750	2500	2500	2500

4. EXOELECTRON EMISSION FROM THE SURFACES OF DISPERSED PLATINUM, PALLADIUM, AND SILVER

The application of the method of exoelectron emission[120–123] makes it possible to obtain information about the energetic inhomogeneity, the density of defects, and the number of active centres on the surfaces of the catalysts investigated.

Exoelectron emission from the surfaces of compact platinum and platinum and palladium blacks was studied in a vacuum of approximately 10^{-5} mmHg on a specially designed apparatus[124] permitting the heating of the test catalyst to 400°C. An appreciable increase of the intensity of exoemission from the surfaces of the dispersed metals relative to the background level was observed on platinum black from 300°C, on palladium black from 350°, and on compact platinum from 370°C (Fig. 13). The most intense exoemission was observed for platinum black and the least intense for compact platinum. Evidently the energy of the liberation of the electron from the surface of platinum black is lower than from the surface of palladium black and compact platinum; in terms of increasing numbers of active centres, the catalysts can be arranged in the sequence compact platinum < Pd black < Pt black.

Table 18. Dependence of the time required for the formation of GeO_2 interference films and of the increment in the rate of oxidation of germanium (K) on the type of catalyst (450°C).[90,133]

Catalyst	Distance from catalyst to specimen, mm	Colour of GeO_2 film (order of spectrum)					
		dark blue (I)	blue (I)	yellow (II)	red (II)	green (II)	green (III)
		Time, min					
Pt black	0.1	1.0	1.5	2.0	2.5	3.0	4.0
Pt black	0.5	3.2	4.3	5.15	5.5	6.0	7.0
Pd black	0.1	3.0	4.5	5.0	6.0	7.0	9.0
Pd black	0.5	3.5	5.0	6.0	7.0	9.0	15
		K					
Pt black	0.1	1924	2198	2514	2841	3306	3620

Pd black	0.1	602	731	977	1184	1416	1600
Pd black	0.5	550	658	838	889	1100	—

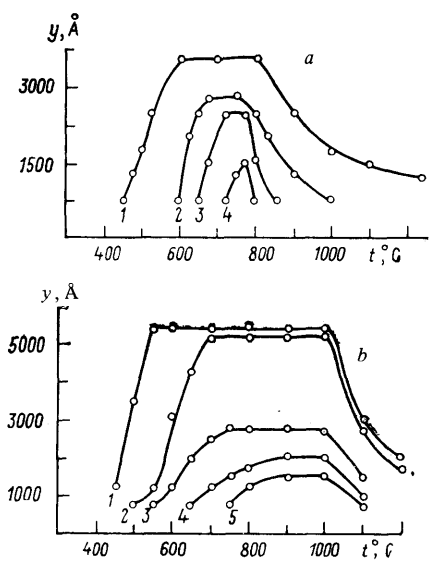

Figure 12. Temperature dependence of the SiO_2 film thickness in the oxidation of silicon in the course of 5 min in the presence of palladium (*a*) and platinum (*b*) catalysts: distance of the catalyst from the specimen surface (mm): *1*) 0.1; *2*) 0.4; *3*) 0.8; *4*) 1.0; *5*) 1.2.

5. GENERAL CHARACTERISTICS AND MECHANISMS OF THE REACTIONS INVOLVING THE CATALYTIC OXIDATION OF THE METALS AND SEMICONDUCTORS INVESTIGATED

Analysis of the experimental data for the catalytic acceleration of the oxidation of titanium, silicon, germanium, and GaAs by platinum, palladium, and silver[26,27,32,88-92,109,110,117-119,129] reveals the following features.

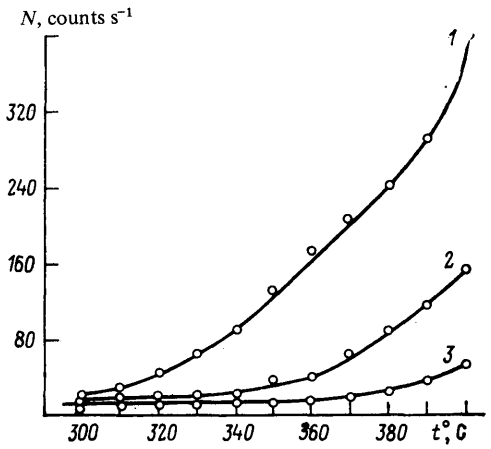

Figure 13. Temperature dependence of the intensity of exoelectron emission (N) from the surfaces of dispersed platinum (curve *1*) and palladium (curve *2*) and compact platinum (curve *3*).

Platinum, palladium, and silver catalysts accelerate the oxidation of the above metals and semiconductors above 350°C, the rate of reaction increasing by a factor of 100 to 1000. The catalyst accelerates the oxidation reactions both on contact and at a distance. The catalytic effect is more pronounced on direct contact between the catalysts and the specimens being oxidised. The catalysts accelerate the oxidation process in a zone directly adjoining them. The greatest catalytic activity among the dispersed metals employed is shown by platinum black and the smallest by dispersed silver.

In the presence of catalysts the Ti, Si, Ge, and GaAs oxidation temperature is reduced by hundreds of degrees and the rate of oxidation remains acceptable in practice. The efficiency of the catalysts increases with increasing thickness of the oxide layer formed (TiO_2, SiO_2, GeO_2 and Ga_2O_3).

Sintering of platinum and palladium blacks and of dispersed silver reduces the activity appreciably at temperatures amounting to two-thirds of the melting point of the catalyst. The difference between the laws governing the oxidation process in the presence of platinum, palladium, and silver catalysts (linear for platinum and parabolic for palladium and silver) is due to the unequal rates of their sintering, reducing the catalytic influence of the activated metals on the oxidation process.

The observed features can be accounted for in terms of modern ideas concerning the oxidation of metals and semiconductors[1,9,11,12,14,38-43,46,49-54,58,59,64,65,125] and heterogeneous catalysts[16,18,111-116,126-128].

The TiO_2, SiO_2, GeO_2, and Ga_2O_3 oxide films formed in the interaction of titanium, silicon, germanium, and gallium arsenide with oxygen cause a separation of the initial reactants in space. The subsequent reaction is limited by the migration of titanium, silicon, germanium, gallium, and oxygen ions through the growing oxide film. The diffusion process occurs in consequence of the generation of concentration gradients and of an electric field in the growing oxide layer[49-54]. The overall charge transfer current density j_i is then defined by the expression[14]

$$j_i = -c_i v_i (\Delta\mu_i + z_i e E) \ ,$$

where c_i is the concentration of species, v_i the mobility of the charges, $\Delta\mu_i$ the change in the chemical potential, z_i the valence of ions of type i, e the electronic charge, and E the electric potential gradient.

The large surface of the catalysts is capable of retaining considerable amounts of chemically adsorbed oxygen, the redistribution of which increases the oxygen concentration gradient in the oxide films and the electric field strength with increase of film thickness on metals and semiconductors. This increases the charge transfer current density and the rates of chemical interaction. In addition, the increase of the electric field strength lowers the activation energy for the oxidation process (for example, from 30-43 kcal mole^{-1} [9,11,12,14] to 9-13 kcal mole^{-1} [109,110,129,131] for silicon). As a result, the significant increase of the ionic diffusion flux density and the decrease of activation energy lead to an increase of the rate of oxidation in the presence of catalysts by factors of hundreds and thousands.

According to the existing electronic theories of heterogeneous catalysis[111,114,128], the gas, for example, oxygen, is activated by its chemisorption on the active centres of the catalyst surface and the activation is accompanied by the transfer of electrons from the catalyst to the adsorbed atoms. The amount of adsorbed oxygen is greater the greater the number of active centres from which electrons pass to oxygen comparatively readily. The results obtained by the method of exoelectron emission suggest that the number of these active centres is greater on platinum black than on palladium black. This apparently explains the higher catalytic activity of platinum black despite its smaller degree of dispersion.

The action of the catalysts at a distance can be accounted for in the following way. Evidently the activated species are dissolved from the catalyst surface into the surrounding gas phase[114,126-128]. With increase of temperature, this is accompanied by a displacement of the dynamic equilibrium towards desorption. The desorbed species retain their activity for some time at a short distance from the catalyst surface, after which they recombine[126,127]. Contact of the catalyst with the specimen undergoing oxidation facilitates the transfer of active oxygen species from the catalyst to the oxide film. This is why the catalytic activity of the activated metals is greater on contact than at a distance.

V. SOME PRACTICAL APPLICATIONS

The results presented in the present review permit practical recommendations for the use of the titanium, silicon, germanium, and gallium arsenide oxidation reaction.

Determination of the kinetic parameters of reactions. The kinetic parameters of heterogeneous reactions involving the oxidation of metals and semiconductors, for example, the activation energy, are determined by the mathematical treatment of data obtained as a result of the visual observation of the changes in the interference colours of oxide films in the course of the interaction. It is then possible to establish the dependence of the kinetic parameters of the reactions on temperature, the thickness of the interference film, the nature of the material being oxidised, and other factors.

It is possible to use TiO_2, SiO_2, GeO_2, and Ga_2O_3 interference films as decorative and protective coatings on the surfaces of metals, alloys, and semiconductors.

The accelerated formation of oxide films in the course of the oxidation reaction is achieved by employing platinum, palladium, and silver catalysts which are either in contact with the surface of the specimens being oxidised or are at some distance from them. The employment of catalysts permits the formation of films with the required thickness over a short time interval and at a lower temperature than in the thermal oxidation in the absence of catalysts.

The comparative activities of catalysts are determined by comparing the times required for the formation of oxide films of identical thickness in the presence (τ_1) and absence (τ_2) of the catalyst. The increase of the rate of oxidation $K = \tau_2/\tau_1$ can serve as a measure of the activity of the catalyst. Furthermore, the activity of the catalyst can be estimated approximately from the diameter of the interference zone (in this case it is necessary to employ a catalyst carrier in the form of a needle). In addition, the activity of the catalyst can be inferred from the intensity of the exoelectron emission, since the intensity increases with increasing number of active centres on the catalyst surface.

The marking of articles. The use of catalysts (acting on contact or at a distance) makes it possible to mark titanium, silicon, germanium, and gallium arsenide with appropriate symbols[132]. Such marking does not affect the surface oxide layer on the article and is distinguished by an improved thermal and corrosion resistance in corrosive media. Furthermore, in forming the symbol, the surface of the marked article is not strongly acted upon. All these factors lead to good prospects for the practical employment of heterogeneous catalysis in the oxidation of metals, alloys and semiconductors.

Reactions in a Protein-Polymeric Carrier System Used for the Immobilisation of Enzymes

M.I.Shtil'man

The review is devoted to methods for the formation of a covalent bond between a polymeric carrier and enzymes whereby the latter are immobilised.
The bibliography includes 474 references.

I. INTRODUCTION

Enzymes immobilised in various ways in order to make them water insoluble have been attracting increasing attention recently. The preparations thus obtained (immobilised or stabilised enzymes) are used in chemical engineering, medicine, and analytical chemistry.

Numerous reviews and a series of monographs devoted to the immobilisation techniques and the characteristics of the employment of such artificial catalysts have been published in recent years in both foreign and Soviet literature[1-14]. A special review deals with kinetic-thermodynamic aspects of catalysis by immobilised enzymes[15]. Problems of the immobilisation of enzymes have been considered in a fundamental publication by a team of workers from Moscow University[16]. There is no doubt that the greatest number of studies on immobilisation methods have been devoted to methods involving the formation of a covalent bond between the enzyme and the carrier, particularly a polymeric carrier. The number of publications in this field is continuously increasing. Nevertheless, we believe that the extensive information about this important field of reactions between proteins and synthetic or artificial polymers has been inadequately dealti with in the review literature.

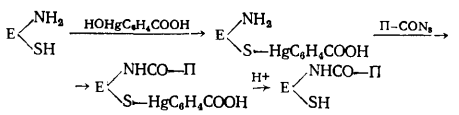
The immobilisation of enzymes by their attachment via a covalent bond to a polymeric carrier is based on the interaction of the reactive groups in the macromolecules of the polymeric carrier and the protein. In principle, the following functional groups forming part of protein aminoacids can react[4,16,17]: carboxy-groups (terminal groups and the groups in glutamic and aspartic acids), amino-groups (terminal groups and the groups of lysine and hydroxylysine), phenolic groups (in tyrosine), imidazole groups (in histidine), indole groups (into tryptophan), sulphydryl groups (in cysteine), disulphide groups (in cystine), hydroxy-groups (in serine, hydroxyproline, hydroxylysine, and hydroxyglutamic acid), guanidino-groups (in arginine), methylthio-groups (in methionine), phenyl groups (in tyrosine and phenylalanine), amido-groups (in asparagine and glutamine), and in certain cases peptide groups. In many cases it is difficult to determine with which protein group the carrier group reacts. For example, the acylating groups of the carrier can react both with amino- and with hydroxy- and mercapto-groups of the enzyme. The steric disposition of the reacting molecules plays an important role in such reactions.

A number of conditions must be observed in the immobilisation process. In particular, the reaction must proceed under conditions which rule out the denaturation of the protein. Furthermore, the functional groups of the carrier must not react with the groups of the protein responsible for enzyme activity[5].

Unfortunately the mechanisms of the reactions used to bind enzymes to polymeric carriers are obscure in many instances. This hinders significantly the classification of the known processes. However, among these one encounters both substitution and addition reactions involving aliphatic and aromatic carbon atoms as well as reactions at heteroatoms which proceed mainly via heterolytic mechanisms. Radical processes are used much more rarely.

II. ACYLATION REACTIONS

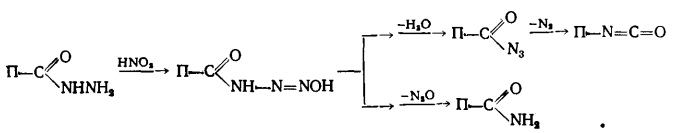
Amino-, hydroxy-, mercapto-, and guanidino-groups of enzymes can be involved in acylation reactions under the influence of the carrier. Although amino-groups are the most reactive, the mode of reaction depends significantly on many factors, particularly steric factors, the pH of the medium, etc.[4]



1. Acylation by Polymeric Azides

One of the first studies on the covalent binding of proteins to synthetic or artificial polymers was that of Micheel and Evers in 1949,[18] who used for this purpose carboxymethylcellulose activated by conversion into the azide[18]. In essence, this method is a modification of the familiar azide method for the synthesis of peptides proposed by Curtius in 1902.[19]

In this case the chemical reactions can be represented schematically as follows†:



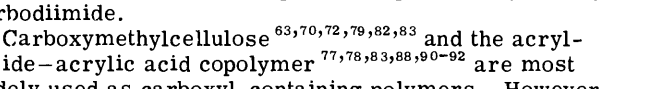
$$\text{П—OCH}_2\text{COOH} \rightarrow \text{П—OCH}_2\text{COOC}_2\text{H}_5 \rightarrow \text{П—OCH}_2\text{CONHNH}_2 \rightarrow$$
$$\rightarrow \text{П—OCH}_2\text{CON}_3 \xrightarrow{\text{H}_2\text{N—E}} \text{П—OCH}_2\text{CONH—E}$$

The stage involving the interaction of the azide with the functional groups of the protein takes place at 0–5 °C in the course of 1–2 h in a weakly alkaline medium. Under these conditions, azides react preferentially with amino-groups; however, they can also react with hydroxy- and mercapto-groups. Since the latter are frequently involved in the active centre of the enzyme, an attempt is made to avoid the formation of thioesters in such cases. For this purpose, mercapto-groups, for example, are temporarily protected by the introduction of an organomercury residue by reaction with *p*-hydroxymercuribenzoic acid. After the reaction with the carrier has been carried out, the protecting group can be removed in a weakly acid medium (10^{-6} M HCl):[4,20,21]

The azide method has been used fairly widely[20-32,34-69]; it has been examined more or less in detail in a number of reviews[1-8,16,69].

In the general case the immobilisation process is significantly complicated in view of the possible occurrence of a number of side reactions involving the azide group and its conversion products. In particular, when HNO_2 and hydrazides react, inactive amide and active isocyanato-groups can be formed together with azido-groups:

The isocyanato-groups can react in their turn with various groups of the protein (preferentially amino-groups), but after hydrolysis to amino-groups they can also give rise to urea groups in the carrier itself. All these factors require a rigorous observation of optimum reaction conditions (specified temperature, pH, etc.) (see Berezin et al.[16], p.159). The low stability of the azido-groups, which precludes the retention of activity by the carriers for a long time, also creates certain disadvantages. In recent years the azide method has been used fairly rarely.



Carboxymethyl derivatives of polysaccharides, for example, cellulose and dextran, are usually employed as the carboxyl-containing polymers[33,50,60,63,69,165]. Using the azide method, it is possible to employ also polymers without carboxy-groups as carriers. Thus hydrazido-groups have been introduced[42] by treating a cross-linked polyacrylamide with hydrazine:

$$\text{П—CONH}_2 \xrightarrow{\text{H}_2\text{NNH}_2} \text{П—CONHNH}_2 .$$

A number of enzymes were immobilised on the resulting polyhydrazide (under the commercial name "Enzacryl AH") after its conversion into the azide[42,53-59]. The use of polyacrylic acid azide, which is soluble in borate buffer, for the binding of enzymes has also been described[44]. Among other carriers employed, one may mention the hydrazide derivative of agarose[66], the azide of polyglutamic acid[67], the copolymer of maleic acid azide with acrylamide and methylenebisacrylamide[68], and a polymeric azide obtained from the graft copolymer of cellulose and methyl acrylate[80].

2. Acylation in the Presence of Carbodiimides

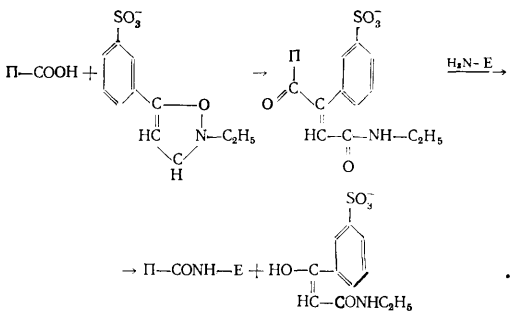
The carbodiimide method, which has come to be fairly widely used, was also borrowed from peptide synthesis. Low-molecular-weight carbodiimides can be used as cross-linking agents independently without a polymeric carried; at the same time, numerous studies have been devoted to the activation of the carboxy-groups of the polymeric carrier by carbodiimides with subsequent attachment of the protein molecule[70-79,81-96]:

Water-soluble carbodiimides[78,87-90], for example, 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride[88,95], 1-cyclohexyl-3-(*p*-diethylaminocyclohexyl)carbodiimide hydrochloride, and methyl toluene-*p*-sulphonate–1-cyclohexyl-3-(4-ethyl-2-morpholino)carbodiimide[90] (see also Berezin et al.[16], p.170) are sometimes used in this reaction instead of the most frequently employed dicyclohexylcarbodiimide.

Carboxymethylcellulose[63,70,72,79,82,83] and the acrylamide–acrylic acid copolymer[77,78,83,88,90-92] are most widely used as carboxyl-containing polymers. However, other polymers, for example, carboxy-methyl-Sephadex[82,83], Sepharose derivatives[87], polyamides[62], and the 2-hydroxyethyl acrylate–methacrylic acid copolymer[86] can also be used. α-Amylase has been attached to a carboxyl-containing carrier with the aid of carbodiimides[96]. A polypropylene fabric to which polyacrylic acid had been grafted and partially hydrolysed poly(ethylene terephthalate film) were used as carriers.

Other carriers were unsubstituted cellulose[4], copolymers of *N*-vinylpyrrolidinone and unsaturated acids[93], CH-Sepharose 4B, and AH-Sepharose 4B, containing the $-\text{OCONH(CH}_2)_6\text{COOH}$ and $-\text{OCONH(CH}_2)_6\text{NH}_2$ groups (Berezin et al.[16], p.172).

Valentova[89] used particles of hydroxyalkyl methacrylate gels (under the commercial name "Spheron") for the immobilisation of pepsin by this procedure. The gel particles were activated with bromide and then hexamethylenediamine or aminocaproic acid were grafted to it, which results in polymers containing carboxy- and amino-groups. The immobilisation was carried out in the presence of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide. Not only the carboxy-groups of the carriers but also, in principle, those of the enzyme can be activated by carbodiimide:

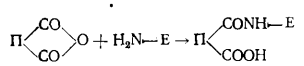


$$\text{E—COOH} + \text{H}_2\text{N—П} \xrightarrow{\text{R—N=C=N—R}} \text{E—CONH—П} + \text{R—NH—CO—NH—R} .$$

In this case the activated enzyme adds to the amino-polymer, for example, aminoethylcellulose[6]. Carboxyl-containing enzymes have been bound with the aid of dicyclohexylcarbodiimide to the product of the interaction of the ethylene–maleic anhydride copolymer with hexamethylenediamine[94].

† Here and henceforth π is the residue of the polymer chain of the carrier and E is the residue of the protein chain of the enzyme.

3. Acylation in the Presence of Woodward's Reagent



In 1961 Woodward et al.[97] described the use in peptide synthesis of activated esters obtained on the basis of *N*-ethyl-5-phenylisoxazolium 3′-sulphonate. Later this reaction was used[98,99] to obtained insoluble preparations with enzymatic activity; this method was also used in a number of other studies[41,100,101]:

Carboxy-containing polymers [carboxymethylcellulose[98] and the copolymer of L-alanine and L-glutamic acid (berezin et al.[16], p. 173)] have also been activated by Woodward's reagent. The advantage of this process is that it proceeds under fairly mild conditions[4]. Furthermore, in this case it is easy to regulate the number of active groups introduced into the carrier[5]. This method can supplement the carbodiimide method just discussed, since in the former the reaction proceeds in an alkaline medium and in the latter in an acid medium[4].

4. Acylation by Polymeric Anhydrides

The ability of polymeric anhydrides to interact in the cold with the protein molecules of enzymes (primarily with formation of amide groups) was first used probably in 1964[102,103] Subsequently this method gained wide currency[21,45,100,102-104,106-145]:

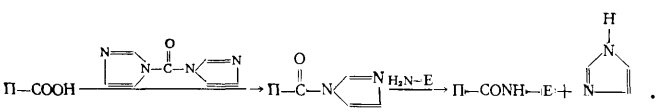
Mainly copolymers of maleic anhydride (see, for example, Refs. 46, 102, 103, 132, 134, and 139) were used. However, studies have been made on the use of copolymers of methacrylic acid anhydride[125,130] and also the anhydrides of itaconic and citraconic acids[133] and the homopolymer of the anhydride of methacrylic acid[208]. Ethylene[102,103,139], the divinyl ether of butanediol[45,131], ethyl vinyl ether and divinyl ether[133,134], methyl vinyl ether[136,144], and alkylene diacrylates[138] have also been used as comonomers with maleic anhydride.

Krömer and coworkers obtained and used for the immobilisation of enzymes a copolymer containing 32 mole % of methacrylic acid anhydride, 67 mole % of acrylamide, and 0.5–1.0 mole % of methylenebisacrylamide[125,130,143]. A homopolymer of maleic anhydride[142] and a number of other anhydride-containing polymers[145] have also been employed for immobilisation. In particular the anhydride groups intended for reaction with the protein molecule were obtained by heating to 180°C a copolymer of maleic acid, acrylamide, and methylenebisacrylamide[68].

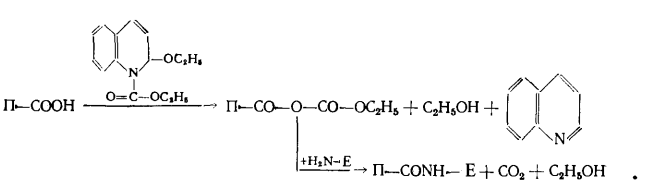
The immobilisation on amino-carriers of the soluble products of the interaction of enzymes with a copolymer of ethylene and maleic anhydride has been described[137,140]. The influence of the number of anhydride groups in the carrier molecules on the activity of the enzyme has been investigated[141]. The copolymers of the anhydrides of unsaturated carboxylic acids can be used both in the form of beads and as films or coatings[132,136].

5. Acylation with Cyclic Carbonates of Polymeric Alcohols

This method was proposed by Kennedy and coworkers[146-154] and consists in the interaction of enzymes with polymers (mainly polysaccharides) containing *trans*-3,4-cyclic carbonate groups, which are introduced into the polymer by the reaction of the polymeric alcohol with ethyl chloroformate. The reaction with the protein proceeds via the following mechanism[154] at ~4°C in a citrate buffer solution at pH 5.4:



Later studies were carried out in which other polymeric alcohols[155], particularly polyallyl alcohol[153], were used for reactions of this kind.

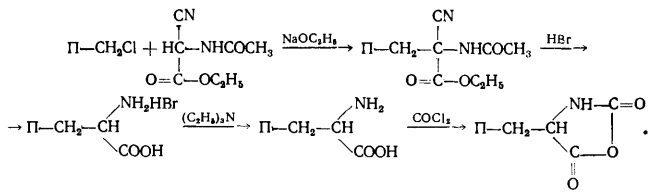


6. Other Acylation Methods

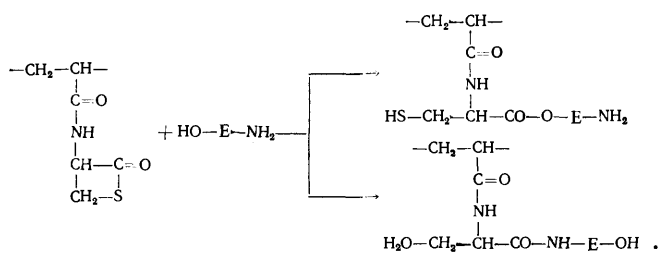
A number of other methods for immobilisation using acylation reactions, mainly reactions involving the formation of amide groups from the amino-groups of the protein molecule, have been developed in recent years.

Thus the copolymer of styrene and 4-vinylbenzoic acid has been used as a carrier[156-158], the reaction with the enzymes being carried out in the presence of carbonyldiimidazole in dimethylformamide:

The same workers suggested that the reaction of the carrier (the copolymer of 4-methacryloyloxybenzoic acid and divinylbenzene) with the amino-groups of enzymes be carried out in the presence of *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline introduced into the reaction as an activator[159,160]. The reaction evidently proceeds via a stage involving the formation of a mixed anhydride:

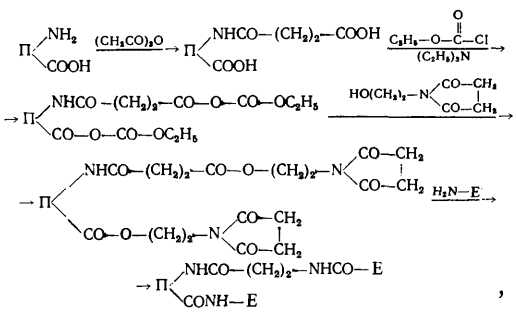


It has also been used by Sundaram[161], who used carboxymethyl-cellulose and carboxymethyldextran (Sephadex) as carriers.



Polymeric acylating carriers containing acyl chloride groups have been described[162,164-166].

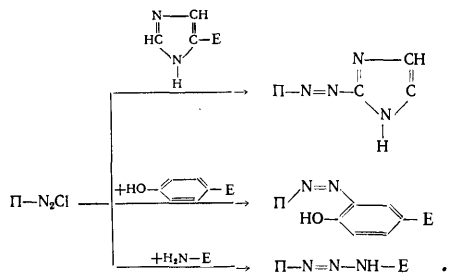
A polymeric cyclic *N*-carboxyanhydride, containing the 2,5-dioxa-4-oxaquinazolinedione group, has been used to bind a number of enzymes at 0°C in the course of 20 to 72 h.[167] This polymer was obtained from a chloromethylated polystyrene copolymer via the following



mechanism:

Derivatives of polyacrylamide or its copolymers containing thiolactone groups, manufactured under the commercial name "Enzacryl polythiolactone" can serve as acylating polymeric compounds [168,169]. This polymer can react with both amino- and hydroxy-groups of enzymes:

The use of polymeric carriers containing activated ester groups, for example, the copolymer of acrylamide and *p*-nitrophenyl acrylate [170], substituted cellulose [Cel–$OCH_2CH_2NHCO(CH_2)_2COOC_6H_4SO_2CH_3$] (see Berezin et al.[16], p. 167), polystyrene containing the $-CO(CH_2)_2-CO-O-C_6H_4NO_2$ group [171], and a partially hydrolysed polyamide in which the activated ester group with the alcoholic *N*-hydroxyethylsuccinimide residue was introduced by the procedure [172]

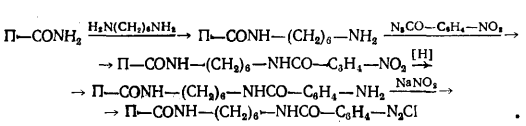


for the immobilisation of enzymes has been described.

III. THE AZO-COUPLING REACTION

The azo-coupling reaction has long attracted the attention of investigators in the field of the immobilisation of enzymes in view of its mild conditions and the ease with which the diazotisable aromatic amino-groups can be introduced into the carrier [173]. Later this reaction was employed in many investigations [26,34,38,42,70,102,104,109,112,163,169,174–202,204–207,209,211–243].

For example the following functional groups of the protein can be involved in the azo-coupling reaction:



In addition, guanidino- and mercapto-groups can react with diazo-compounds. Under these conditions, two-diazo-groups can react with a single protein group [4].

The most frequently employed carriers are *p*-aminobenzylcellulose (see, for example, Refs. 26, 173, 174, 187, 188, and 235), *p*-aminostyrene (for example, Refs. 174–176, 199, 214, and 218), and copolypeptides based on *p*-aminophenylalanine (for example, Refs. 107, 177, 178, 184, 201, and 223). It has also been suggested that the product of the interaction of dialdehyde-starch and 4,4′-diaminodiphenylmethane be used as a diazotisable carrier [139,192]. On reacting with the aldehyde groups of dialdehyde-starch, the diamine forms a three-dimensional network. Among other carriers, we may mention the copolymer of glutaraldehyde and *m*-phenylenediamine [233], the reduced graft copolymers of *p*-nitrophenyl acrylate with poly(vinyl chloride), polypropylene, and polyethylene, and the styrene–propene copolymer [236], *p*-aminobenzamidohexyl Sepharose [237–240], polysaccharide anthranilates [221,226,227], aromatic amino-derivatives of polyacrylamide [169,209,210,219,220,225], the products of the interaction of a partially hydrolysed polyamide, aromatic diamines, diisonitriles, and aldehydes [234], aromatic amino-derivatives of wool, silk, chitin, and phenolic resins [241], and polyvinyl-(3-amino)benzylidene [242].

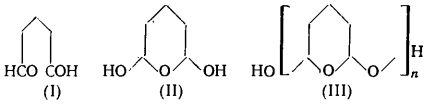
In order to obtain diazotisable carriers, the epoxy-resin based on di(hydroxyphenyl)propane and epichlorohydrin was treated with *p*-nitrophenylsulphonyl isocyanate with subsequent reduction of the nitro-group [243].

A multistage method has been proposed for the synthesis of diazo-derivatives of acrylamide [42]:

Diazotised aromatic diamines (benzidine-2,2′-sulphonic acid and *m*-phenylenediamine) have been used for the cross-linking of enzymes and polymeric carriers [107,197,205,211,224,228,232]. In order to increase the number of groups capable of undergoing the coupling reaction in the protein, the latter was treated with L-tyrosine *N*-carboxyanhydride [183]. The azo-coupling reaction has been used to bind not only enzymes but also other types of proteins, for example, antibodies, to the surface of the carrier [244].

IV. THE FORMATION OF AZOMETHINE DERIVATIVES

Aldehydes react with the amino-groups of proteins under mild conditions with formation of Schiff bases:



The characteristics of this reaction have been examined in detail in a review[105]. In recent years the reaction has served as the basis for one of the most vigorously developed procedures for the immobilisation of enzymes[21,88,94,171,245,247-253,255-298].

It is possible to isolate two trends in studies in this field—the use of polymers containing aldehyde groups (as shown in the above mechanism) and the use of low molecular weight aldehydes mainly glutaraldehyde) in order to bind enzymes to amino-carriers:

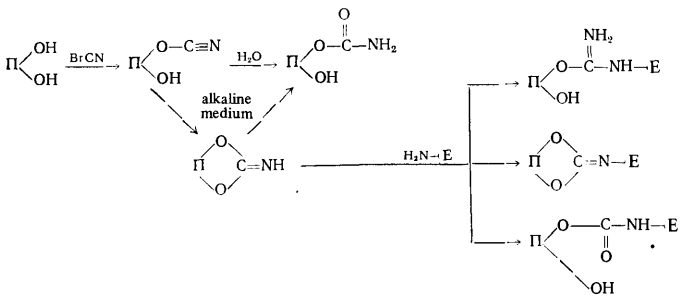
The glutaraldehyde used in the immobilisation reaction is in fact a fairly complex mixture of compounds. In particular, its aqueous solutions contain, apart from the aldehyde proper (I), also a low-molecular-weight cyclic acetal (II) and its oligomers (III). It has been stated (see Berezin[16], p. 208) that the mixture contains also derivatives of glutaraldehyde in which the α-position relative to the aldehyde group contains a double bond capable of involvement in an addition reaction with the amino-group[105]:

Among polymeric amino-carriers, aminoethylcellulose is most frequently used in combination with glutaraldehyde[21,245-247,250,257,277,287,290]. Among other amino-polymers, mention may be made of aminopolystyrene[21,171], partially hydrolysed polyamides[248,259-262,288,289], styrene–divinylbenzene copolymers modified by diamines[297], the maleic anhydride–ethylene copolymer treated with hexamethylenediamine[94], the products of the interaction of poly(methyl methacrylate) and 3-aminopropyltriethoxysilane[292], and polymers containing in the side chain lysine residues attached to the inner surface of a nylon tube activated with dimethyl sulphate[293]. Phenol-formaldehyde resins[241,265-267,275], gelatin[291], polyacrylamide[88,253], and certain other polymers[271,278] are also used for immobilisation in conjunction with glutaraldehyde.

A considerable number of studies have been devoted in recent years to the synthesis of polymers containing aldehyde groups in side chains and to their use as carriers for the immobilisation of enzymes. For these purposes, a number of acrolein derivatives were employed: the adduct of polyacrolein and sodium bisulphite[269,279,283], the acrolein–styrene copolymer[263], and the acrolein–acrylic acid copolymer[274]. The products of the partial oxidation of polysaccharides, accompanied by ring opening, particularly dialdehyde-cellulose[258,264,270,276], dialdehyde-Epidex[210,429], dialdehyde-dextran[280], ethoxycarbonyl-cellulose[249], the hydrolysis products of polymeric acetals[255,256,282,294], oxidised phenol-formaldehyde resins[256,241], polymeric derivatives of pyridoxal phosphate[239,240,295], polystyrene formylated by 1,1-dichloromethyl ether[171], copolymers of unsaturated aldehydes and vinylpyrrolidinone[93], and a polyacroleine reaction product[254] have also been made to react with enzymes.

The polymer of methacryloylvanillin {poly[4-formyl-2-methoxyphenyl methacrylate]} and its copolymers with allyl alcohols (p moles of allyl alcohol per mole of the aldehyde), known under the commercial names of Vanacryl and Covanacryl-p,[272,273,276,298] merit attention. Enzyme preparations immobilised on such carriers show a decrease of activity on storage in an aqueous medium, which is probably associated with the dissolution of part of the enzyme as a result of the hydrolysis of the ester group in the methacrylic acid residues[272,284].

Mention should also be made of a study[286] in which a method was proposed for the immobilisation of glucose oxidase on polyaminostyrene after preliminary oxidation (to give a 60% content of carbohydrate residues) of the enzyme with formation of aldehyde groups.



One should note that azomethine groups are insufficiently stable in acid media. In order to increase the stability of the polymer–protein system, it has been suggested that the azomethine groups be reduced with sodium tetrahydroborate[105,280,296]:

V. THE USE OF POLYIMIDOCARBONATES

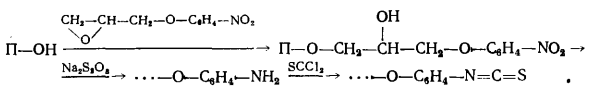
The reaction of the amino-groups of proteins with polyimidocarbonates is widely used for the immobilisation of enzymes. These compounds are usually obtained by the reaction of polymeric alcohols with cyanogen halides (mainly with cyanogen bromide)[41,63,77,80,219,247,299-370]. This method has been proposed in two studies[299,300] and is attractive because of the high rate of reaction, the relatively high stability of the activated carrier, and its high reactivity in relation to the amino-groups of the enzyme.

The reaction proceeds via the following mechanism[5,335]:

The polyimidocarbonate, formed as the main product in the activation of a polyhydric alcohol, can give rise to an inactive unsubstituted carbamide in an alkaline medium. The carbamate can also be formed from the intermediate cyanate under the influence of water.

The reaction of imidocarbonates with the amino-groups of proteins can proceed via several pathways, which give rise to isoureas and N-substituted carbamates (urethanes). The formation of an interchain imidocarbonate, which can also interact with the amino-groups of the enzyme, is likewise very probable (see Berezin et al.[16], p. 176).

In the vast majority of studies polysaccharides are employed as the polyhydric alcohols: agarose (Sepharose)[77,88,238-240,290,294,296,307,308,316,317,321-323,330,339-343,347-353,354-367], dextran (Sephadex)[302,315-318,320-323,328,331,338,341,345,347,367-369], and (more rarely) starch[317] and cellulose[41,306,344,346]. Among other natural polymers, alginic acid has been used[370]; in this case the polymer–enzyme system is



soluble at pH > 4, but is precipitated from solution at pH < 3. Synthetic polymers are used for these purposes much more rarely. In particular, the activation of the acrylamide–hydroxyethyl methacrylate copolymer with cyanogen bromide has been described [90]. Cyanogen chloride is much more rarely used for the activation of polymers in place of cyanogen bromide [371]. It has been stated that the imidocarbonate groups incorporated in the side chains of the polymer can be obtained by the interaction with polysaccharides with organic cyanates (see Berezin et al. [16], pp. 80 and 181).

Apart from enzymes, antibodies [372] and coenzymes [373] are also attached to carriers by the cyanogen bromide method.

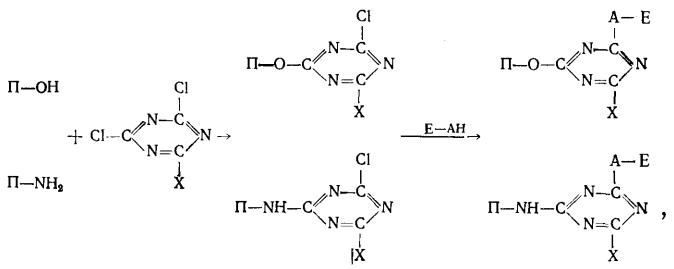
VI. THE USE OF POLYMERIC CARRIERS CONTAINING ISOCYANATO- AND ISOTHIOCYANATO-GROUPS

Polymers containing these highly reactive groups have been used successfully for the immobilisation of enzymes despite their relatively high reactivity in hydrolysis [56,166,204,209,242,374–387]. Although, in principle, the isocyanato-groups can interact with many groups in the protein molecule (carboxy-groups—with formation of amides, hydroxy- and phenolic groups—with formation of urethanes, amide groups—with formation of acylureas, etc.), at the moderate temperatures used in the interaction with the protein, the amino-group is most reactive, giving rise to urea and thiourea groups on interaction with isocyanates and isothiocyanates.

Both artificial and synthetic polymeric carriers have been used for immobilisation. In particular, the following scheme has been proposed for the preparation of polysaccharides containing isothiocyanato-groups [246,378]:

Among the synthetic polymers used for immobilisation, mentioned may be made of the copolymers of methacrylic acid, *p*-aminostyrene, and 3,5-diisocyanatostyrene [380], the copolymers of methacrylic and acrylic acids and 3-isocyanatostyrene [379], and graft copolymers of polypropylene and *p*-nitrostyrene, whose amino-groups, generated by reduction, were treated with thiophosgene [204,385].

Synthetic polymers containing terminal isocyanato-groups in the main or side chains, such as polyureas based on hexamethylene diisocyanate and tolylene diisocyanate or hexamethylenediamine and triethylenediamine [166], polyethers with terminal isocyanato-groups [381], polyurethanes based on poly(propylene glycol) and tolylene diisocyanate [386,387], and products obtained by treating poly(allyl alcohol) with 4-isothiocyanatophenyl isocyanate [242] have also been used for immobilisation.



It has been suggested that the enzyme (trypsin) be treated initially with tolylene diisocyanate and that the resulting polyisocyanate be then cross-linked with poly(propylene glycol) [387].

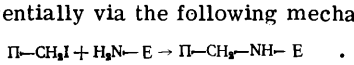
VII. THE USE OF POLYMERS WITH AN ACTIVE HALOGEN ATOM

1. Polymers Containing Chlorotriazine Groups

In connection with the widespread use of carriers containing aldehyde and imidocarbonate groups, there has been some decrease in interest in recent years in polymers containing an active chlorine atom incorporated in a triazine group. However, studies in which polymers containing these groups are used for the immobilisation of enzymes are still being continued [63,163,195,206,388–412].

In this method the activated carrier is formed by the reaction of a polymer containing a group containing an active hydrogen atom (a hydroxy- or amino-group) with cyanuric chloride or a monosubstituted dichlorotriazine. The remaining unsubstituted chlorine atoms (atom) form hydrogen chloride by reaction with the protein molecule:

where X = Cl or R, A is the residue of a hydroxy-, amino-, guanidino-, phenolic, or SH group of the enzyme molecule.



Among the polymers containing active atoms, polysaccharides (for example, Refs. 392, 398, and 410) or their aminoethyl derivatives (for example, Refs. 290, 308, and 399) have been most widely used. However, synthetic polymers, such as phenol-formaldehyde resins [409] and aminated polystyrene [171] have also been employed. Apart from cyanuric chloride, 2-amino-4,6-dichloro-*s*-triazine [63,290], 2-carboxymethylamino-4,6-dichloro-*s*-triazine [63], and Procion dyes [308] have been used to active these polymers.

Water-soluble derivatives of proteases have been obtained using a dextran modified with cyanuric chloride [93]. Arginase and urease have been attached with the aid of cyanuric chloride to different sides of a cellulose membrane [412]. The modification of enzymes by low-molecular-weight dichlorotriazine dyes followed by interaction with aminoethylcellulose has been described [407].

2. Polymers Containing An Active Halogen Atom Attached to Aliphatic and Aromatic Carbon Atoms

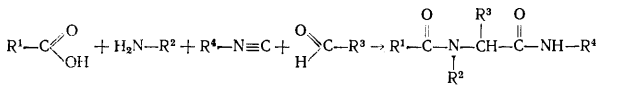
Publications about such carriers have appeared in the last 5–6 years. Thus it has been suggested that 4-iodo-n-butyl methacrylate polymers be employed; the exchange of a halogen in the reactions of monomeric and polymeric 4-chloro-n-butyl methacrylates with sodium iodide has been used to prepare such polymers [413–419].

The interaction of carriers of this kind with enzymes proceeds preferentially via the following mechanism:

Evidently other groups alkylated under these conditions can also react.

The copolymers of methacrylic acid and methacrylic acid 3-fluoro-4,6-dinitroanilide as well as the copolymers of these monomers with divinylbenzene [374-376,420-424] and the polymers and copolymers of fluorostyrenes and their derivatives [376,423] react similarly with enzymes.

Among other polymers containing an active halogen atom attached to aliphatic or aromatic carbon atoms used for the immobilisation of enzymes, we may mention bromo- and iodo-acetylcellulose [43,425,426], bromoacetamidohexyl-Sepharose [238-240,296], the products of the acylation of poly-(vinyl alcohol) with bromoacetyl bromide or bromoacetic anhydride [427], polyacrylamide derivatives containing iodoacetic acid residues [428], and 3-chloro-2-hydroxy-n-propyl-Epidex [429].

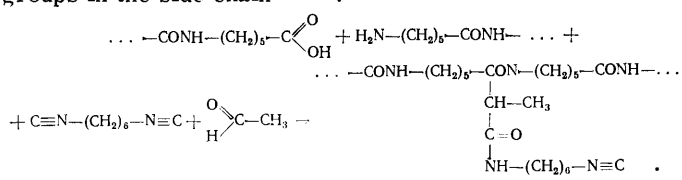


3. Polymers Containing Activated Halogen Atoms Forming Part of Inorganic Groups

Polymeric carriers containing activated halogen atoms in inorganic groups, mainly in inorganic acid residues, including acids derived from transition metals, are sometimes used. In particular, it has been suggested that synthetic polymers and polysaccharides be activated with thionyl chloride or sulphuryl chloride before interaction with enzymes [371,430,431]. A number of transition metal halides ($TiCl_4$, $SnCl_4$, VCl_3, $FeCl_2$, $FeCl_3$, and $ZrCl_4$), have also been used as activating agents. Both synthetic (polyamides) [432] and natural (cellulose [432-434] and chitin [435]) polymers have been treated with these compounds.

VIII. OTHER METHODS

1. The Use of Ugi's Method



Ugi [436] showed that aldehydes (ketones), isonitriles, and carboxy- and amino-groups can interact:

This reaction has been used to bind a number of enzymes to polymeric carriers [437-443]. For example, Sepharose has been oxidised with formation of a polymer containing aldehyde groups. In the presence of 3-dimethylamino-propylisonitrile this polymer binds chymotrypsin at pH 6.5 in the course of 6 h. [438,439]

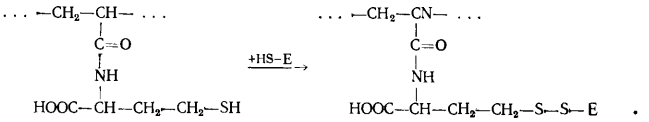
Carboxymethyl-Sephadex, aminoethylated polyacryl-amide [438], and a polyamine obtained by the interaction of diaminodiphenylmethane with Sepharose activated by cyanogen bromide [437] can be involved analogously in this reaction. The interaction of the last polymer with pepsin was carried out in the presence of phenylisonitrile and acetaldehyde.

Another pathway leading to immobilisation involves the initial preparation of a carrier containing a sufficient number of carboxy- and amino-groups. A partly hydrol-ysed polycarproamide has been used for this purpose. The reaction of this polymer with hexamethylenediisonitrile and acetaldehyde yields a polyamide containing isonitrile groups in the side chain [442,443]:

Finally, the reaction of this carrier with trypsin in the presence of acetaldehyde results in the fixation of the enzyme.

2. The Reaction of Enzymes with Polymers Containing Epoxy-groups

Publications describing the immobilisation of enzymes and polymeric carriers containing epoxy-groups have begun to appear recently [444-449]:



Thus the copolymers of epoxy-monomers (glycidyl meth-acrylate, glycidyl acrylate, and unsaturated glycidyl ethers) with other monomers, for example acrylonitrile and methacrylonitrile, have been used for this purpose [445,446]. The activity of the immobilised enzyme was higher when the carrier had been subjected to preliminary activation with an amine [444].

Urease was immobilised on a graft copolymer of carboxymethylcellulose and glycidyl methacrylate [447-449]. A method for the immobilisation of peroxidase, consisting in the copolymerisation with acrylamide of the enzyme subjected to a preliminary treatment with glycidyl meth-acrylate, is based on the ability of the amino-groups of proteins to react with epoxy-compounds [450].

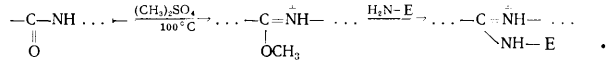
3. The Thiol–Disulphide Exchange Reaction

The "Enzacryl polythiolactone" mentioned above can be attached to the mercapto-groups of enzymes when it is introduced into the reaction in the form of a mercapto-acid [169]:

In order to increase the content of mercapto-groups in the initial enzyme, the latter can be subjected to a pre-liminary treatment with *N*-halogenoacetylcysteine thio-lactone [451] (see also Berezin et al. [16], p. 200).

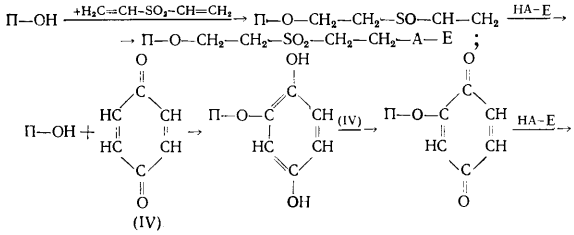
Carlsson et al. [452] proposed another method for the immobilisation of enzymes (amylase and chymotrypsin) with the aid of the thiol–disulphide exchange reaction. The method includes two stages. In the first stage the NH_2 groups of the enzymes were modified with the aid of methyl 3-mercaptopropioimidate, which resulted in the introduction of a mercapto-group into the protein. In the second stage the enzyme with the mercapto-group was bound to disulphide derivatives of agarose obtained by treating the mercaptopropyl ether of the latter with 2,2′-dipyridyl disulphide.

4. Reactions with Polymeric Imidoesters

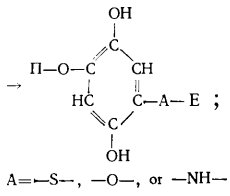


Polymers containing imidoester groups can interact with the amino-groups of proteins:

Thus Zaborsky introduced imidoester groups into a polyacrylonitrile powder by treating the latter with hydrogen chloride in methanol; this polymer was used as a carrier[453,454] and was also employed in a later study[456].



Imidoesters have been used also as cross-linking agents. In particular, a number of studies have been devoted to the interaction of enzymes and amino-polymers (aminoethylcellulose[455] and the products of the reaction of polyamides, activated by dimethyl sulphate, with lysine[293]) in the presence of diethyl adipimidate.



Yet another method for immobilisation (of glucose oxidase) using polymeric imidoesters has been proposed, namely on a polyamide treated with dimethyl sulphate[293]:

5. The Use of Carriers With an Activated Double Bond

Hydroxylated polymers can be activated by divinyl sulphone (Mosbach[460], p. 34) or quinone (Mosbach[460], p.35, and Tarasova et al.[461]). Such carriers can interact with the amino-, hydroxy-, or mercapto-groups of enzymes. The relevant processes can be represented schematically as follows:

(IV)

6. Radical Reactions

Radical procesees also play a definite role in the immobilisation of enzymes. This applies in the first place to the familiar processes involving the incorporation of an enzyme in a gel in the course of the polymerisation of unsaturated monomers (for example, acrylamide or its mixtures with methyl bisacrylamide, etc.), which is frequently accompanied by the formation of a covalent bond between the molecules of the enzyme and the gel-forming polymer as a result of a chain transfer reaction followed by grafting (see Berezin et al.[16], p.144). Cases of radical reactions in other systems are also known: for example, chymotrypsin is immobilised using the free radicals formed in aqueous solution as a result of ^{60}Co γ-irradiation[457]. Instances of the polymerisation of unsaturated derivatives of enzymes should also be classified as radical processes[458,459].

---o0o---

This review shows that many processes have now been developed whereby enzymes can be linked by covalent bonds to polymeric carriers and that the possibility of introducing various functional groups into the latter is widely used. Naturally, in the course of the development of this field of enzyme immobilisation many methods have lost or are gradually losing their importance, giving way to more effective procedures (this can be seen from the analysis of the literature quoted). Polymeric carriers have been used in different forms—as grains, coatings, fibres, tubes, membranes, and gels.

Data, permitting the prediction to some extent of the efficiency of a particular carrier have now accumulated. Thus Porath formulated a series of properties, which the "ideal carrier" should possess: total insolubility in water; high chemical and biological stability; high mechanical stability; high reactivity with respect to the enzyme and ease of imparting such reactivity to the carrier; a form suitable for practical application; finally, highly hydrophilic properties of the carrier permitting its employment in aqueous media (see Berezin et al.[16], p.68). Some attention has been given in certain investigations to other properties of carriers, particularly their polarity (ionic and electrical effects[15,462]).

However, systematic studies have not so far been made of the influence of the nature of the carrier, particularly its chemical structure, geometrical structure, and molecular-weight distribution (for soluble forms) both on the characteristics of its binding to the protein and on the efficiency of the resulting biocatalysts. In the vast majority of studies quoted in this review very moderate attention has been devoted to these problems. According to the data quoted in many of the investigations, it is impossible to reach conclusions about the number of functional groups in the carrier responsible for the reaction with the protein, about the degree of their reaction in the course of binding to the enzyme, and about the influence of the conditions used in the preparation of the polymer–enzyme system on its catalytic activity.

As an example of a publication of this kind, one may quote the work of Baum[171], who compared the activities of immobilised amyloglucosidase and papain, obtained using polystyrenes containing different functional groups, and established that the carriers containing different groups (aldehyde, chlorotriazine, and activated ester groups) yield preparations with different activities. However, the author[171] does not state, for example, how many groups were present in each initial carrier nor is it stated what kind of carrier was used, particularly whether it was a linear homopolymer or a three-dimensional carrier obtained using a cross-linking agent. In our view, all these factors play a significant role in the preparation of effective biocatalysts. In this connection, one may refer to the known relation, with an extremum, between the content of functional groups in the initial carrier (ethylene–maleic anhydride copolymer) and the activity of the enzyme immobilised on this carrier[141].

Aspects of the influence of the chemical structure of the carrier on the properties of immobilised enzymes, which are already well known, such as the fact that the disposition of the active groups at the ends of side branches rather than in the main polymer chain is preferable[293], the negative influence of the enrichment of such branches

in aromatic groups (see Berezin et al.[16], p.188), the negative influence of the presence of hydrolytically labile groups at the carrier–enzyme binding sites[454,455], as well as the presence of groups promoting such hydrolysis (see Berezin et al.[16], p.166) have not been investigated in detail either.

All these findings show that detailed and systematic study of the influence of the properties of the carrier on those of the systems obtained can reveal considerable further possibilities for both an increase of the activity of the resulting preparations and for an increase of their efficiency. Studies in this field should probably be developed in the following directions: (1) investigation of the influence of the chemical structure and the physical properties of the carrier on the characteristics of the polymer–enzyme reaction; (2) investigation of the influence of the chemical structure and physical properties of the carrier on those of the immobilised enzyme obtained.

We believe that particular attention should be devoted to the following features of the chemical structure of the polymeric carrier: the content of functional groups and the degree of their utilisation in the reaction with the protein, the structure of the surrounding groups and sections of the polymer chain adjoining the carrier-enzyme binding site, and the structure and content of the groups responsible for the hydrophilic properties and polarity of the carrier.

In this connection mention should be made of the studies of Berezin and coworkers, who proposed a method using a carrier which is "complementary" to the surface of the enzyme globule and consists in the copolymerisation of a hydrophilic monomer (sodium methacrylate) and a cross-linking agent (methylene bismethacrylate) with an enzyme (chymotrypsin) modified by an analogue of the monomer (methacryloyl chloride). An increase of the thermal stability threshold of the enzyme by 40°C was achieved in this way relative to the native specimen[458,459].

It is quite possible that definite information about the characteristic features of the reaction between the carrier and the enzyme can be obtained from kinetic studies on the formation of the immobilised enzyme.

The study of the conformational changes in the enzyme occurring during its reaction with the carrier merits the closest attention. The importance of this factor was demonstrated by Martinek and coworkers, who showed that the activity of the enzyme (chymotrypsin) can change significantly as the extention of the nylon or viscose thread or the human hair to which it has been attached by covalent bonds is varied[285,288].

During the preparation of the review for the press, numerous publications in the field under consideration appeared in the literature, among which mention should be made of Refs. 463–474.

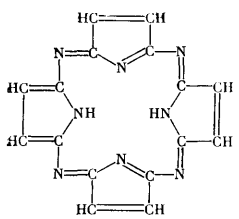
The Synthesis and Properties of Polymeric Azaporphin Compounds

A.A.Berlin (deceased) and A.I.Sherle



Data on the synthesis and principal properties of polymers with a conjugation system containing repeating azaporphin macrorings are surveyed and described systematically. An account is given of the change in properties on passing from metal-free polymers and their metal complexes, on the one hand, to the corresponding low-molecular-weight analogues, on the other. The bibliography includes 135 references.

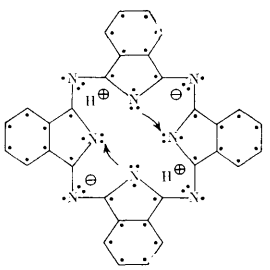
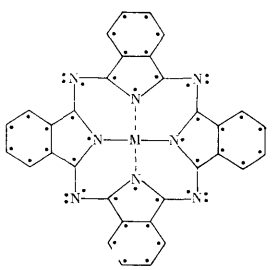
IV. Certain physicochemical, electrical, and catalytic properties 1130

I. INTRODUCTION

The cyclic systems (I), consisting of four pyrrole rings linked together in the α-positions by nitrogen atoms, are called azaporphins† or porphyrazines, in contrast to porphins (II), which have a similar structure but the rings are linked by methylidyne groups:



(I)



(II)

The pyrrole rings, which constitutes the basis of the azaporphin macroring, can be condensed with aromatic or heteroaromatic rings. Depending on the type of the latter, one can distinguish tetrabenzo-, tetranaphthalo-, tetrathiopheno-, and tetrafurano-azaporphins (tetrafuranoporphyrazines)[1,2]. Azaporphins whose pyrrole rings contain (usually in the 3- and 4-positions) various substituents—for example, octaphenyl-, dipropyl-, and octamethyl-porphyrazines, are known[2]. By analogy with porphins[3], such compounds could be usefully referred to also as azaporphyrins: octaphenyl-, dipropyl-, and octamethyl-azaporphyrins.

Despite the wide variety of porphyrazines, most investigations, among which those of Linstead, Vartanyan, and Berezin are the most important, were devoted to tetrabenzazaporphins, which are usually referred to as phthalocyanines. The structure and formulae of the metal-free phthalocyanine (III) and copper-phthalocyanine (IV) are given below‡:

(III)

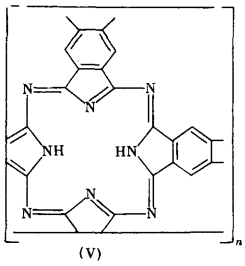
(IV)

As can be seen from formula (III), as a result of internal dissociation the two protons of the imino-group of the azaporphin are subjected to the symmetrical electric field set up by the lone electron pairs of the nitrogen atoms[4,5]. These electrons are not localised at the opposite exocyclic nitrogen atoms but are uniformly distributed throughout the macroring, since their pairing would lead to the breakdown of conjugation. Thus 18 electrons move in the plane of the macroring, giving rise to a ring current of delocalised π electrons. This imparts aromatic§ properties and high stability to the azaporphin ring and determines the specific physical and physicochemical properties of compounds containing such rings.

The introduction of a metal in the "window" of the macroring (IV) entails the filling of the dsp^2-hybrid or other orbitals of the metal ion, which is accompanied by a change in the electron density at the peripheral nitrogen atoms and a consequent difference between the properties of the metal complexes and the metal-free analogues. The

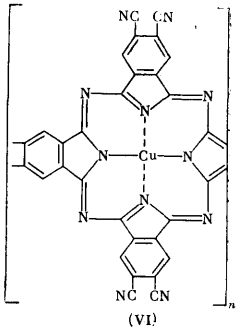
†The abbreviation of tetra-azaporphins.

‡Henceforth in this review the following abbreviations will be used: PC = metal-free phthalocyanine, PC_M = phthalocyanine complexes of different metals (where M = Cu, Fe, Ni, etc.), PPC = metal-free polyphthalocyanine, PPC_M = polyphthalocyanine complexes of metals, PTCE = metal-free polytetracyanoethylene, $PTCE_M$ = polymeric metal complexes of tetracyanoethylene, and AA_M = metal acetylacetonates.



§The extreme aromatic nature of these compounds is indicated particularly by the finding that the magnetic anisotropy of phthalocyanine is approximately 15 times greater than that of benzene[6].

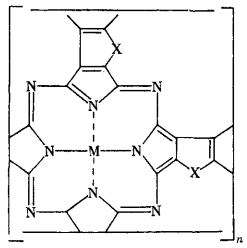
more covalent the >N–M–N< linkage, the greater the stability of the ring, and the greater the differences between the optical, magnetic, and electrical properties of the metal-free and metal-substituted porphyrazines[7-8].



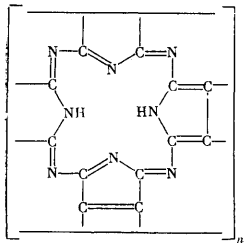
The unusual properties of phthalocyanines[9-12] stimulated the development of research on the synthesis of polymers containing azaporphin macrorings in their structure—polyazaporphins (PA) or polyporphyrazines. One might expect the possibility of the formation on the basis of these polymers of valuable materials combining the specific physicochemical and mechanical properties of high-molecular-weight compounds with the chemical and thermal stability, catalytic activity, and semiconductor properties characteristic of phthalocyanines.

The interest in systems of this kind is because the structure of PA resembles most closely (among the known synthetic polymers) that of natural compounds such as haemoglobin, chlorophyll, and the prosthetic groups of a number of enzymes (for example catalase). This fact is responsible for the exceptional importance of PA also as objects for the modelling of the biological activity of natural products.

All the PA known at the present time can be usefully divided into three groups differing in the nature of the functional groups joining the azaporphin rings in the macromolecule. The first group includes the PA in which the repeating units are joined via aromatic or heteroaromatic rings condensed to the pyrrole ring; these rings are shared by two adjoining units. In the naming of such polymers, it is reasonable to employ the name of the connecting ring¶—for example, polyphthalo-(V) and (VI), polynaphthalo-, polythiopheno-(VII), and polyfurano-cyanines (VIII)[14-16].

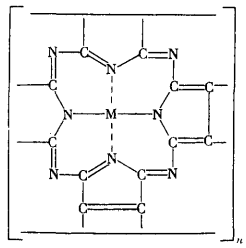


(V)



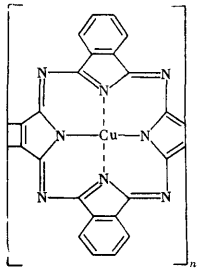
(VI)

The PA whose elementary units are linked directly by the pyrrole rings of the azaporphin in the 3- and 4-positions, for example, the polymers of tetracyano-ethylene[17,18], (IX) and (X), the copolymers of azaporphin with the nitrile of maleic acid, phthalonitrile (XI), etc.[19] should be included in the same group.

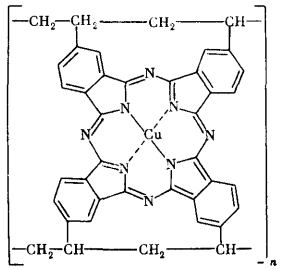


A distinctive feature of the PA of this group is the presence of a continuous conjugation chain throughout the macromolecule regardless of whether these polymers have ribbon [compounds (VI) and (XI)] or planar-network [compounds (V), (VII), and (X)] structures.

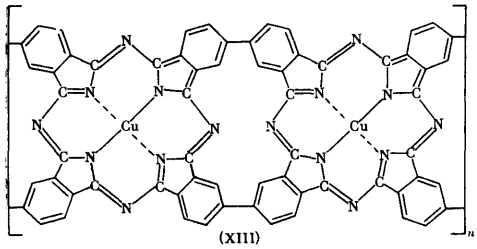
(VII) X = S;
(VIII) X = O



(IX)

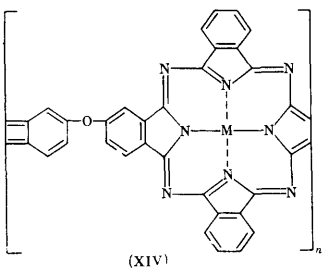


(X)



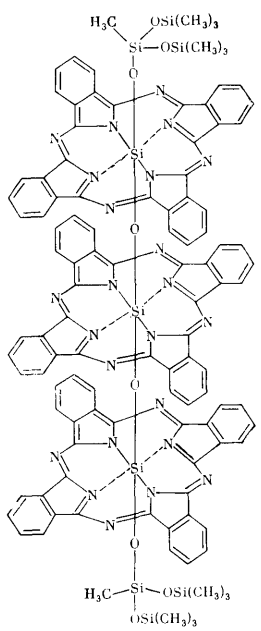
In the macromolecule of a PA belonging to the second group each aromatic (or heteroaromatic) ring linking up the azaporphin is associated with only one unit. In certain cases these rings can be linked in the macromolecule by various bridging groups, such as –O–, –S(O)–, –NH–C(O)–$(CH_2)_{n-2}$–, –C(O)–NH–, etc. The PA of the second group include polymers obtained by the interaction of *N*,*N*′-bis-(3,4-dicyanophenyl)alkylenediamines with metals or their salts[20], of bis-(3,4-dicarboxyphenyl) sulphone with copper[21], of 3,4-dichlorostyrene with copper cyanide [compound (XII)][2], of 3,3′,4,4′-tetracyanobiphenyl with copper [compound (XIII)][2], and of 2,3-dicyanohydroquinone with metal salts or oxides[22], as well as the copolymers of phthalic anhydride and bis(dicarboxyphenyl) ether [compound (XIV)][23], of phthalonitrile and bis(dicarboxyphenyl) sulphone[24], etc.

(XI)



(XII)

(XIII)



¶For a different nomenclature of the PA, see Smith[13].

(XIV)

The degree of delocalisation of π electrons and the type of conjugation of the PA of this group are various and are determined by the nature of the bridging groups. Together with the PA in which the conjugation between the units is almost unaffected or is only slightly affected, polymers are known with saturated bonds in the macromolecular chain where the azaporphin macrorings are present only at the ends of the chain[25] or exist in the form of individual fragments separated from one another by considerable distances[20,26-29]. However, even when azaporphin rings are only occasionally incorporated in the macromolecular chain, they alter the properties of the latter significantly. Polymers with such rings exhibit an enhanced electrical conductivity and thermal and chemical stabilities, which makes it possible to employ them as special binders, coatings, and adhesives[20,28,29].

Finally, the third group comprises PA whose individual units are joined by oxygen atoms linked directly to the metal atoms of two neighbouring rings[30-32]. These are PPC_{Ge}, PPC_{Si} (XV), etc., obtained by the interaction of the derivatives of the corresponding phthalocyanines. A distinctive feature of these polymers is the fact that the individual units are located in parallel planes and are joined to one another via -O-M-O- bridges, forming in space unusual stacks of rings.

(XV)

The above systematic arrangement is to a large extent arbitrary, requiring further improvement. Nevertheless, it can assist in a better understanding of the large class of PA and facilitates the comparison of the properties and the determination of the specific features of the polymers in each group.

Polymers have been obtained recently whose macrorings constitute a kind of modification of azaporphin: one or several pyrrole rings of the latter have been replaced by pyridine, pyrazine, or other heterocycles[33-35]. Owing to the insufficiency of experimental data, these polymers as well as other structural analogues of PA (polyporphyrins)[36] are not considered in this review; for the same reason, very little space has been devoted to the PA of the second and third groups.

This review presents a survey of the results of studies on the synthesis and certain properties of polymers with a continuous conjugation system whose macromolecules consist of repeating azaporphin macrocycles (PA belonging to the first group), carried out during the last 15–18 years.

II. PRINCIPAL METHODS OF SYNTHESIS

The majority of the PA known hitherto are oligomeric compounds in which the number of units varies from three to six–seven, i.e. having a molecular weight of 1500–5000[39,40]. For certain PA, the degree of polymerisation is 11 and even 14†.[39] According to Berezin and Shlyapova[39], the degree of polymerisation of metal-containing polyphthalocyanines depends on the nature of the metal. In the case of metals with a sterically strained coordination (Ru, Os, and Mo) it is lower than for metals whose coordination does not involve a distortion of the ligand field (for example, Cu, Ga, and Zn).

Metal-containing PA are obtained by the polycyclotetramerisation of tetrafunctional derivatives of aliphatic or aromatic acids having a suitable structure with metals or their oxides and salts. Pyromellitic acid tetranitrile[41] and dianhydride[42], diphthalyl ketone[43], tetracyanoethylene[19], 2,3,4,5-tetracyanothiophen, 2,3,4,5-tetracyanofuran, bis-(3,4-dicarboxyphenyl) ether[44], bis-(3,4-dicyanophenyl) ether[16], etc. are used as the initial compounds in this reaction. In the synthesis of PA having a ribbon structure, the above monomers are sometimes copolymerised with bifunctional compounds such as phthalonitrile, maleic acid dinitrile, etc.

The polycyclotetramerisation process accompanying the formation of the PA is frequently referred to as the "phthalocyanine synthesis" and is carried out similarly to the synthesis of low-molecular-weight porphyrazine complexes. The initial reactants are heated to a temperature from 100° to 300–350°C in solution (in nitrobenzene, ethylene glycol, cyclohexanone, biphenyl, etc.) or in the monomer melt for 10–20 h. The reaction catalysts are ammonia, urea, ammonium molybdate, etc., which in many instances not only accelerate the process but are also involved in the formation of the final products. Low-molecular-weight admixtures are extracted with acetone, alcohol, and benzene, depending on the nature of the starting materials and are also eliminated by vacuum heat

† Although various methods for the determination of the molecular weights of PA have been mentioned in the literature (spectroscopic[39], potentiometric titration of end groups[39,40] etc.), none of them yield exact information about the molecular weight of the polymers. The data obtained with the aid of these methods must be regarded as highly approximate.

treatment at 190–250°C and a residual pressure of 10^{-3}–10^{-5} mmHg. In order to remove traces of inorganic impurities (metals and their salts which failed to react, residues of inorganic catalysts, and their reaction products), the final products are subjected to an acid treatment. The choice of acid and of the conditions of this treatment depend on the type of complex-forming agent. Similarly, using mixtures of various metal salts, one can obtain di-, tri-, and poly-metallic complexes of PA with two and more different metals in the macromolecule[16,45].

The polycyclotetramerisation of the above compounds in the absence of metals leads to metal-free PA.[46,47] The latter are also obtained by the acid treatment of PA_{Na}, PA_{Ca}, etc.[42,48] (see Section IV).

When the "phthalocyanine synthesis" is used, the following factors should be taken into account.

1. The structure of the PA obtained in this way is as a rule inhomogeneous with respect to its chemical composition and contains an appreciable proportion of different defects. These include uncyclised sections of the macromolecule, intermediates attached to the chain, and residual amounts of the solvent and low-molecular-weight compounds firmly linked to the polymer. The higher the chemical reactivity of the monomer, i.e. the greater the tendency of the monomer to undergo various types of reactions in the course of polymerisation, the more defects are to be expected in the structure of its polymers under these conditions. Indeed, comparative study of the polymers obtained from tetracyanoethylene and tetracyanobenzene showed that the structure of the former is much more defective‡.

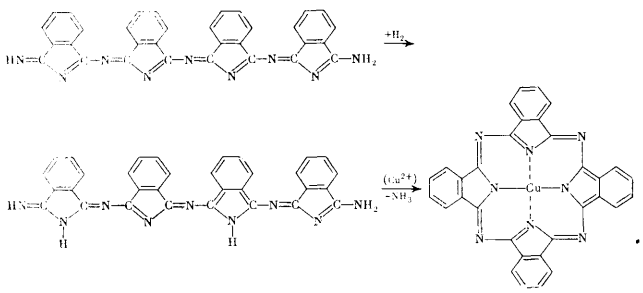
Copolymerisation of chemically reactive and relatively inactive monomers leads to the formation of copolymers with a more homogeneous chemical composition compared with the corresponding homopolymers (for example, the structures of the tetracyanoethylene–phthalonitrile of tetracyanoethylene–tetracyanobenzene copolymeric copper complexes are much more homogeneous with respect to chemical composition than that of $PTCE_{Cu}$[52]).

2. The use of ammonium molybdate as the reaction catalyst[53–55] leads to the formation of molybdenyl-phthalocyanine together with the main product[56]. Although PPC_{MoO_2} decomposes on prolonged treatment with concentrated H_2SO_4, the use of this catalyst complicates the isolation of the final products and contaminates them.

3. The acid purification of the PA synthesised is accompanied by the hydrolysis of the free groups of the polymer [terminal and surrounding ("framing") groups] and of various intermediates formed in the course of the synthesis, which increases the chemical inhomogeneity of the system to a still greater extent.

The inhomogeneity of the structure of the PA obtained by "phthalocyanine synthesis" is reflected significantly in their properties and hinders a comparative study of the properties of the PA complexes of different metals, particularly those synthesised by different workers. In this connection the series of critical comments by Boston and Bailar[14] concerning the work of Inoue et al.[45] apparently requires additional careful tests.

In order to reduce the defectiveness of the structure and to increase the degree of its homogeneity with respect to chemical composition, polymers are subjected to a prolonged vacuum heat treatment. This involves the splitting off of free functional groups and the removal of the residues of the solvent, monomer, and low-molecular-weight intermediates with simultaneous cross-linking and additional cyclisation, which leads to an increase of the regions of continuous conjugation and of the molecular weight of the specimen.[57–60] The latter is confirmed, in particular, by the change in the nature of the absorption spectrum of the heat-treated polymer relative to the initial specimen. The spectrum of the treated polymer is less steep, apparently owing to the increase of the absorption in the long-wavelength region due to the larger molecules formed on cross-linking[61]. The vacuum heat treatment can be accompanied by a change in the crystal lattice parameters of the PPC or the conversion of their structure into an amorphous form. As a rule, polymers lose their solubility and ability to be pressed after heat treatment.



The most effective way of increasing the chemical homogeneity of the structure involves polymerisation in the monomer vapour, developed in 1958–1960 in relation to the synthesis of polymeric tetracyanoethylene complexes[17,19]. Subsequently it was used to obtain also other PA. In order to obtain PA by this method, powders, films, or other types of solid metallic or non-metallic materials are heated in the vapour of the corresponding monomer in the presence of small amounts of moisture, ammonia, or other initiators. The reaction proceeds on the surface with formation of both metal-containing and metal-free PA in the form of films of any size and with any profile, depending on the form of the supports used. This method is free from many of the disadvantages of the usual "phthalocyanine synthesis". It does not require the application of acids, alkalies, or solvents, which promotes the formation of products with a more homogeneous chemical composition. When the reaction is carried out in the monomer vapour, the polymers are obtained in the form of film coatings, which eliminates the necessity for reprocessing, greatly facilitates the investigation, and leads to practical applications of the PA.

Despite the many years which have elapsed since the synthesis of the first porphyrazines§, the mechanism of their formation has been inadequately investigated. It is only known that transition from aromatic dinitriles, *o*-arylenedicarboxylic acids and their anhydrides and imides to phthalocyanines proceeds via 3-aminoiminoisoindolenine, a series of transformations of which leads to the azaporphin[62]. The final reaction stage has come to be

‡ The electron affinity of tetracyanoethylene is much greater than that of tetracyanobenzene [it amounts to 1.6–1.8 (Brieglebe[49]) or 2.8 (Batley and Lyene[50]) compared with 0.4 eV for tetracyanobenzene[51]] and the compound exhibits an exceptionally high chemical reactivity in substitution, Diels–Alder, oxidation-reduction, etc. reactions.

§ Phthalocyanines were discovered accidentally in 1928 and soon (1929–1930) systematic studies on these compounds were begun. The phthalocyanine dimer was obtained in 1949. The first publications on the synthesis of PA appeared in 1958–1959[15,17,18,23,40].

represented by the following scheme:

The replacement of bifunctional acids by tetrafunctional acids greatly complicates the reaction. Polycyclotetramerisation is determined to a greater extent than the formation of phthalocyanines by the nature of the initial reactants, particularly in its first stages. Thus it has been shown that the polycyclotetramerisation of tetracyanoethylene proceeds via the radical-anions of this monomer, the rate of formation of which parallels the rate of formation of the polymer[64,65]. Polyphthalocyanines are apparently synthesised via pyromellitic acid diimidine, which was detected in the interaction of tetracyanobenzene with ammonia and served as the starting material for the synthesis of PPC and PPC_{Cu}.[66] It is quite likely that pyromellitic acid diimidine plays the same role in the polycyclotetramerisation reactions as that of 3-aminoiminoisoindolenine in the synthesis of PC.

The study of the formation of PPC from tetracyanobenzene showed that oligomeric porphyrazines, soluble in organic solvents, are formed in the initial stages and are subsequently converted in the course of the reaction into insoluble planar cross-linked polymers. It is then unimportant whether the reaction takes place in the melt or in a monomer solution. In our view, the reported synthesis[47] of insoluble PPC did not involve polymerisation in solution at all, as stated erroneously by Radyushkina et al.,[67] but was associated with the nature of the solvent (formamide) employed in the reaction, which in this case behaves as a cross-linking agent. It has been shown that the polymerisation of tetracyanobenzene in the presence of specific amounts of the initiator leads to PPC which are believed to have a ribbon structure and are soluble in organic solvents.

The transition to insoluble PPC with a planar cross-linked structure takes place gradually and is faster the higher the reaction temperature and the greater amount of the initiator introduced into the system. An increase of pressure in the reaction mixture apparently has a similar influence on the rate of transition[68].

The formation of metal-substituted PA is accompanied in addition by oxidation-reduction reactions. This is indicated by the presence of the heterovalent Fe^{3+} and Fe^{2+} ions in the PPC_{Fe} molecules obtained by the interaction of tetracyanobenzene with $FeCl_3$.[69] The polycyclotetramerisation of tetracyanoethylene under analogous conditions leads to $PTCE_{Fe}$ with Fe^{3+} in the macroring and with Fe^{2+} in radical-ion salts, which are apparently located at the end of the macromolecule[69,70].

The method of "phthalocyanine synthesis" has been inadequately investigated. Nevertheless, this is the principal, widely used procedure for the synthesis of PA. Only a few types of PA among those investigated hitherto have been obtained by other methods. Germanium- and silicon-polyphthalocyanines having a "loop" structure have been synthesised by the interaction of derivatives of the corresponding phthalocyanines[30-32]. When PC_{Cu} was fused with sulphur, P_4S_{10}, or SCl_2 at 460°C, the products were PPC_{Cu} with sulphide bridges in the macromolecule[71]. New polyamides with azaporphin macrorings have been obtained by the condensation polymerisation of phthalocyanines, containing functional groups, with various diamines[26].

The synthesis of metal-substituted PA by treating the corresponding metal-free polymers with metal salts merits particular attention[19,70]. This method makes it possible to obtain the PA complexes of various metals under comparable conditions. With its aid, it has been possible to obtain for the first time and to separate the univalent complexes of PPC_{Fe} with bivalent and tervalent iron in the macroring[69,70]. The homogeneity of the structure is specified in this case by the initial metal-free polymer and does not undergo any appreciable changes on treatment with metal salts.

A more detailed development of methods specific to polymeric compounds, different from the method of "phthalocyanine synthesis", will lead in the future to new procedures for the formation of PA.

III. THE STUDY OF STRUCTURE

The structure of PA is studied mainly in order to detect azaporphin macrorings in the macromolecules synthesised. For this purpose, one uses as a rule elemental and spectroscopic analyses. However, this is difficult owing to the insolubility and infusibility of the majority of PA; the most reliable results have been obtained only for the soluble fractions of the polymers.

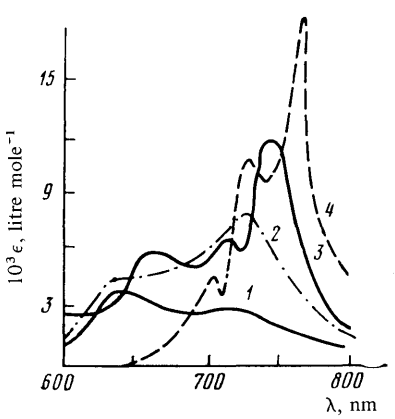


Figure 1. Electronic absorption spectra of PPC; solvents: 1) acetone; 2) dimethylacetamide; 3) concentrated H_2SO_4; 4) PC in concentrated H_2SO_4.

The azaporphin structure of the polymers synthesised has been confirmed by the presence in the spectra of these polymers of bands which are usually attributed to the azaporphin "skeleton". The infrared bands at 745–750, 810–885, 945–950, 1045–1060, 1080–1090, and 1118–1123 cm^{-1} correspond to the vibrations of the "skeleton"[72]; in the electronic absorption spectra there is a long-wavelength band in the range 600–800 nm.

Agreement between the spectra of the polymers and the corresponding low-molecular weight analogues is observed for all types of PA, both metal-free and metal-substituted, regardless of the nature of the metal and the molecular weight of the PA. The nature of the spectra depends significantly on that of the solvent employed (Fig. 1) for both PA and various derivatives of low-molecular-weight porphyrazines[73,74].

Recently published communications[69,75,76] concerning the studies of iron-phthalocyanines by Mössbauer spectroscopy report the development of a new extremely effective method for the investigation and identification of the structures of azaporphin complexes, including insoluble planar cross-linked complexes. The use of this method made it possible for the first time to carry out a comparative investigation of soluble and insoluble PA, to compare data for different types of PA, and to elucidate the influence of the conditions of synthesis and treatment on the structure of the polymers obtained. The study of the Mössbauer spectra of PC_{Fe}, soluble and insoluble PPC_{Fe}, obtained both by "phthalocyanine synthesis" (in solution, in the melt, and in the monomer vapour) and from PPC, as well as $PTCE_{Fe}$ revealed a fairly satisfactory agreement between their isomeric shifts (δI) and quadrupole splittings (ΔE). This indicates the presence in the structures of all the complexes of ligands having the same electronic structure[69,70]. Consequently all the polymers investigated have a structure analogous to that of PC_{Fe}, i.e. they contain azaporphin macrorings.

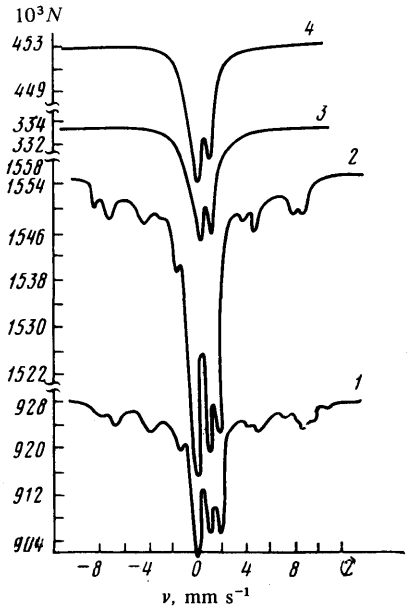

Figure 2. The Mössbauer spectra recorded at different temperatures for PPC_{Fe} obtained by the introduction of iron into PPC; temperature (K): 1) 2; 2) 4.2; 3) 90; 4) 300; v = speed of the source relative to the absorber; N = quantity proportional to the number of pulses.

It is noteworthy that hitherto there has been no unanimous view in the literature concerning the structures of polymeric tetracyanoethylene derivatives, because it is impossible to obtain reliable spectra of these polymers owing to their poor solubility. Their azaporphin structure was confirmed only by the results of elemental and chemical analyses[19,60,77]. However, there have been studies[78] in which a different structure was attributed to polymeric tetracyanoethylene derivatives. The agreement between the values of ΔE and δI for the Mössbauer spectra of $PTCE_{Fe}$, PC_{Fe}, and PPC_{Fe} constituted a convincing confirmation of the azaporphin structure of the given class of polymers.

The application of Mössbauer spectroscopy also made it possible to determine the valence of the metal in the polymeric iron-azaporphins and to elucidate the conditions for the formation of PPC_{Fe} with the metal having a particular valence[69,70].

As for PC_{Fe},[75,76] the values of $E\theta$ and δI for PA_{Fe} depend only slightly on temperature and the metal content or not at all. The study of PPC_{Fe} with different metal contents in the macromolecule[70] at 4.2 and 2 K revealed a hyperfine structure of the Mössbauer spectroscopic lines (Fig. 2), which indicates the operation of a powerful spin–spin mechanism of the relaxation of the electronic spin of Fe^{3+}. This suggests in its turn the occurrence in such systems of an exchange magnetic dipole interaction between the iron ions in the macromolecules.

A wider employment of Mössbauer spectroscopy will throw light in the future on many hitherto obscure problems concerning not only the structure but also the mechanism of the formation of PA.

IV. CERTAIN PHYSICOCHEMICAL, ELECTRICAL, AND CATALYTIC PROPERTIES

1. Physicochemical Properties

Polyazaporphins are infusible thermally stable dark-coloured compounds whose colour ranges from blue-green to black. Depending on the method of synthesis and the conditions in the subsequent treatment, they can be obtained in the amorphous and fully crystalline forms[16,68,79]. The thermal stability of the PA is determined by its chemical structure and the degree of its homogeneity, the nature and number of free functional groups, and the nature of the metal in the macroring. Unfortunately the available literature data do not allow a complete analysis and survey of the characteristics of the thermal stabilities of such systems. One can only reach a conclusion (and even that only very approximately) about the temperature to which PA may be heated without appreciable decomposition. Thus diphthalyl ketone polymers withstand heating to 450°C[43] and certain specimens of polymeric tetracyanoethylene derivatives are stable in air up to 300–350°C and in an inert atmosphere up to 500–550°C.[57]

On the other hand, polymeric tetracyanothiophen and tetracyanofuran derivatives decompose in air below 300°C.[16] The comparatively low stability of the latter is apparently associated with the presence of acetylacetonato-groups in their structure. The presence of such groups together with a variable-valence metal creates favourable conditions for the formation of peroxy-radicals capable of initiating the decomposition of the polymer, which has been demonstrated in the study of the thermal stabilities of $PTCE_{Cu}$, $PTCE_{Fe}$, etc.[57] In those cases where it was

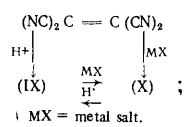
possible to eliminate these groups from the structure, the stability of the polymers increased appreciably. The increase of the chemical homogeneity of PA also promotes an increase of their thermal stability regardless of whether such homogeneity is obtained by the alteration of the conditions of synthesis or in the course of an additional treatment of the specimen[57].

Comparative study of the thermo-oxidative degradation of PC_{Co} and its polymeric analogue, on the one hand, and metal-free and metal-substituted PA, on the other, revealed a lower rate of thermolysis of PPC_{Co}, while the other reaction parameters remained unchanged[80], and a higher stability in air of metal-free polymers relative to PPC_{Cu} and PPC_{Fe}. The reduced stability of complexes of variable-valence metals on heating in air is associated with the fact that copper, iron, and other variable-valence metals are excellent initiators of the formation of peroxy-radicals (this is well known), which promote in their turn the degradation of the polymers. The stability series is based on their resistance to thermo-oxidative degradation, found for polymeric tetracyanoethylene complexes:[19] $PTCE > PTCE_{Mg} > PTCE_{Cu} > PTCE_{Fe}$; this series can apparently be repeated also for other PA.

The solubility of PA depends on the configuration of the chain and the "frame" surrounding the azaporphin macrorings. While planar cross-linked polyphthalocyanines, referred to as poly(tetramethineporphyrazines) by Akopov[13], do not dissolve in organic solvents, ribbon polyphthalocyanines [Akopov calls them poly(dimethinedibenzoporphyrazines)] partly dissolve in dimethylformamide, dimethylacetamide, and pyridine. Their solubility is higher the greater the number of end groups forming the "frame" in the macromolecule. A large number of functional groups in polymer macromolecules as well as bulky substituents in the molecules of low-molecular-weight porphyrazines[81,82] prevent the close packing of such systems, which increases their solubility.

Oligomeric PPC with a large number of surrounding ("framing") nitrile groups, which are soluble in acetone, have been obtained recently; poly(disulphonephthalocyanine), obtained from PA-bis(3,4-dicarboxyphenyl) sulphone, is soluble in water[24].

Despite the fact that the basicity of the azaporphin compounds is greatly reduced owing to the involvement of the free electron pairs of the peripheral nitrogen atoms in the construction of the metal-like molecule, a characteristic feature of these compounds is their solubility in concentrated H_2SO_4, the dissolution being accompanied by the protonation of the macromolecule[23]. The solubility of the PA in the acid is lower than the solubility of their low-molecular-weight analogues and depends on the structure of the polymer and on the nature of the central metal atom. Thus, in contrast to the ribbon PA, which are readily soluble in acid, the planar cross-linked PA dissolve in concentrated H_2SO_4 only after prolonged (up to 5–6 days) treatment. The solubility of metal-containing PA in concentrated H_2SO_4 is higher the more pronounced the electron-donating properties of the metal atom in the "window" of the macroring.



The resistance of PA to acid is determined by the configuration of the polymer chain and the nature of the central metal atom in the ring. As a rule, the PA of the first group (the section I) are less stable in acid than their low-molecular-weight analogues. Thus the stability of PC_{Zn} in acid is approximately 10 times greater than that of PPC_{Zn},[84] and the rate constant for the degradation of PC_{Co} in H_2SO_4 at 25°C is smaller by three orders of magnitude than for PPC_{Co}.[85] The resistance of silicon complexes to acid is also considerably inferior to that of their low-molecular-weight analogues, although the PPC_{Si} of the third group, having a "loop" structure, are much more stable in acid than PC_{Si}.[86,87]

Depending on the nature of the central metal atom, the PA as well as phthalocyanines[88] can apparently be divided into two groups in terms of their resistance to the action of concentrated H_2SO_4: stable PA which do not undergo an appreciable change when treated with the acid and labile complexes which lose the metal after the acid treatment and are converted into the metal-free polymers. In terms of the degree of elimination of the metal from the macroring, which is inversely proportional to the strength of the M–N interaction, metals can be arranged in the following sequence[26]:

$$Zn^{2+} > Fe^{3+} > Ni^{2+} > Co^{2+} \gg Cu^{2+} \quad .$$

The ability of the PA complexes of sodium, magnesium, calcium, etc. to lose the metal in the course of the acid treatment has found an application, as already stated, in the synthesis of metal-free PA. The ability of metal-free porphyrazines to interact with metals or their salts on heating is used to synthesise metal-substituted azaporphin complexes[89]. The reaction is carried out both in solutions[19,70] and in suspensions, the polymer powder being treated with a solution of the salt[90,91].

Thus PA as well as their low-molecular-weight analogues are a kind of molecular sieve which absorb and, under appropriate conditions, give up metal ions. In other words, they are capable of undergoing the polymer complex–metal-free polymer transition, illustrated schematically below for polymeric tetracyanoethylene derivatives[18]:

This property of polyazaporphins may lead in the future to their utilisation as complex-forming ion exchangers and organic molecular sieves operating at elevated temperatures.

2. Electrical Properties

The electrical properties of PA, whose study was begun in 1959–1960,[41,92] have been frequently discussed in connection with the consideration of the properties of organic semiconductors[93–95]. We shall therefore deal below only with questions which have not been adequately dealt with in the above monographs.

The specific conductances σ of polyazaporphins are higher by several orders of magnitude than for their low-molecular-weight analogues and the activation energies for electrical conduction E in the polymers are much lower (see Table). The dependence of E on the medium in which the measurements are made has been observed for a whole series of complexes (it is more pronounced in nitrogen and less so in ammonia than in air[16]) and E has been found to vary in parallel with the optical excitation energy (see Table).

The conductivity of $PTCE_{Cu}$ films obtained in monomer vapour has been found to be anisotropic: σ is greater by 3–7 orders of magnitude parallel to the film surface than in the perpendicular direction. The dielectric constants and σ of PA vary exponentially not only with temperature

but also with pressure. The linear decrease of the resistivities ρ with increase in pressure has been attributed to the increase of the intermolecular overlap, which facilitates charge transfer in the case of closer-packed polymer chains and layers [99].

One of the important problems in the study of the electrical properties of porphyrazines is that of the influence of the nature of the central metal atom and of the ligand on the electrophysical parameters. Many investigators have explained the slight decrease of E after the introduction of the metal into the PC by the fact that the conductivity of such systems is determined exclusively by the π electrons of the conjugated system of the macroring. Furthermore, the mobility of the current carriers μ depends on the degree of overlap of the metal and macroring orbitals. The greater the overlap, the higher the value of μ [thus $\mu(PC_{Ag}) > \mu(PC_{Cu})$], [100] so that the conductivity of the system should also be higher ($\sigma = en\mu$, where n is the concentration of current carriers). Indeed σ and E for polymeric tetracyanoethylene complexes of a number of metals are different and also differ from the analogous parameters of the metal-free polymer. For example E = 0.53, 0.32, and 0.18 eV have been obtained for PTCE, $PTCE_{Cu}$, and $PTCE_{Ag}$ respectively [101]¶.

The electrophysical parameters and the positions of the longest-wavelength absorption maximum for certain azaporphin compounds.

*All the specimens except Nos. 7, 11, and 12 were synthesised in melts of the initial reactants. Specimen No. 7 was obtained in solution in cyclohexanol and specimens Nos. 11 and 12 were synthesised in tetracyanoethylene vapour.

**The polymers were obtained by the interaction of the corresponding tetranitriles with metal acetylacetonates.

***The specimens were subjected to a preliminary heat treatment at 200–300°C.

¶For polymers obtained in the monomer vapour.

The dependence of the electrophysical parameters on the nature of the central metal atom is manifested also in the study of bimetallic PA [16,102] (see Table). An attempt has been made [16] to compare the experimental values of σ for the polymeric tetracyanothiophen complexes of various metals with the ionic radii and ionisation potentials (Fig. 3) of their cations.

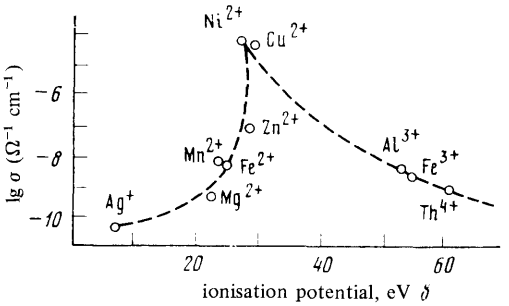

Figure 3. Dependence of the electrical conductivity of the polythiophenocyanine complexes of a number of metals on the ionisation potentials of the cations.

The fact that the maximum values of σ have been observed for PA containing metals whose cationic radius is approximately 0.75 Å is striking. If account is taken of the fact that the cations having such a radius can be accommodated most favourably in the "window" of the azaporphin macroring [103], the influence of the degree of overlap of the electronic orbitals of the metal and the ring on the conductivity of such systems becomes evident: the most complete overlap of the electronic orbitals of the metal and the ring leads to an increase of μ and hence also σ.

Analogous relations have been obtained also for polytetrathiafulvalenocyanines (PTTFC) [96]. The observed relations give rise to the following sequence of metal cations arranged in terms of decreasing electrical conductivities of their polyporphyrazine complexes:

$$Ni^{2+} > Co^{2+},\ Cu^{2+} > VO^{2+},\ Mn^{2+},\ Zn^{2+} > VO_2^{2+},\ Cr^{3+},\ Fe^{3+} > Mg^{2+}$$

Comparison of the electrophysical properties of various PA_{Cu} also revealed the influence of the nature of the ligand on σ and E. It was observed that E decreases in parallel with the decrease of the aromaticity of the rings connecting the azaporphin macrorings into a polymer chain—from benzene, via thiophen, to furan, i.e. in the sequence $PPC_{Cu} > PThiC_{Cu} > PFuC_{Cu}$, where $PFuC_{Cu}$ is the polymeric copper complex of tetracyanofuran and $PThiC_{Cu}$ is the polymeric copper complex of tetracyanothiophen [16].

We do not believe it is possible to arrive at more far-reaching conclusions about the influence of the nature of the ligand and the metal on the electrophysical properties of PA, because, despite the extensive experimental data available, there are no literature data on the purities and homogeneities of the structures of the given polymers. Frequently there is no description of the nature of the preliminary treatment of the specimens. At the same time, the Table shows that the change in the conditions of the synthesis (cf. specimens Nos. 6 and 7 and Nos. 10 and 11)

and additional heat treatment of (Nos. 11 and 12) have a significant influence on the electrophysical parameters of PA.

Numerous experiments have shown that an increase of the duration of the synthesis, additional vacuum heat treatment of the polymers, polymerisation in the monomer vapour, as well as copolymerisation with chemically inactive monomers promote the formation of more homogeneous and sometimes more ordered structures with an enhanced electrical conductivity (see Table). In this connection we may mention that the method of synthesis of metal-substituted PA with the aid of metal acetylacetonates, previously proposed by the present authors [79], does not appear to us to be altogether successful at the present time. Indeed, the polymers obtained by this method contain acetylacetonato-end groups (which frequently also make up the "frame") and these as a rule impair many of the properties of PA (see Section IV). Furthermore, and this is the most important factor, in the course of the above reaction appreciable numbers of insoluble side products are formed and are difficult to separate from the main bulk of the polymer, remaining in the specimen as impurities.

This makes the reaction of acid tetranitriles with metal acetylacetonates unsuitable for the synthesis of PA on a preparative scale, particularly when the aim is to discover the relation between the chemical structure and the properties of the polymers.

In order to investigate the mechanism of conduction in semiconductors, one usually determines the temperature variation of n, μ, thermo-e.m.f. (α), etc. Measurements of thermo-electromotive forces showed that the PA known at the present time exhibit different types of conductivity. Copper- and zinc-polytetrathiafulvalenocyanines exhibit p-type conductivity [96], while heat-treated films of the polymeric tetracyanoethylene complexes of various metals show n-type conductivity [104]. Electronic conductivity has been observed for scandium-, zirconium-, and cobalt-polyphthalocyanines. Over the entire experimental temperature range, the sign of the current carriers remains unchanged [98]. Sulphur-containing PPC_{Cu} specimens, synthesised from PC_{Cu}, exhibited p-type conductivity, whereas polymers obtained from tetracyanobenzene and subjected to a special treatment with sulphur showed n-type conductivity [71].

A change in the sign of the majority current carriers has been observed for the $PTCE_{Fe}$–metallic iron and $PTCE_{Ag}$–metallic silver compositions as a function of the conditions of the preparation of the system. The compositions obtained were converted in the course of 10–14 h into systems with hole conductivity, the sign of the current carriers changing with increase of the reaction time to 15–20 h [105]. The values of α for a number of PA are 50–70 $\mu V\ K^{-1}$. [96,104]

The mechanism of conduction has been studied in greatest detail for PPC_{Cu}. [106] In the study of the conductivity of this polymer, both positive and negative current carriers were detected, their concentration being almost independent of temperature, while α varied exponentially with temperature. This enabled the authors [106] to conclude that the migration of the current carriers in PPC_{Cu} is an activated process. Although the signs of the majority carriers in PPC_{Cu} and PC_{Cu} were the same, μ for the polymer proved to be smaller than for its low-molecular-weight analogue†. Extrapolation of the measured mobility to an "infinite" temperature, at which there is no hindrance to the migration of current carriers at the breaks in conjugation, leads to $\mu_\infty = 1.4\ cm^2\ V^{-1}\ s^{-1}$.

The results suggest that the comparatively high value of σ in such substances is associated with the high concentration of current carriers whose mobility is low and varies exponentially with temperature. On the basis of an estimate of the concentration of current carriers (10^{18}–10^{19} cm^{-3}), the authors of this investigation believe that the required concentrations of the impurities in polymers resembling those investigated must be reduced at least by 5–6 orders of magnitude compared with inorganic semiconductors.

The Hall effect was measured after frequent unsuccessful attempts only in one study [41]. The authors [41] observed two states for PPC_{Cu}: one state has $E = 0.26$ eV and $n = 10^{16}\ cm^{-3}$, n being independent of temperature, and the other (heat-treated polymer with p-type conductivity) has $n = 10^{18}\ cm^{-3}$, which remains constant within the limits of the measured temperatures. However, these results were not subsequently confirmed‡. Having estimated the sensitivity of the apparatus in which the Hall effect was measured for PPC_{Cu}, the authors [106] concluded that the mobility of the current carriers in the test specimens is not greater than 0.3 $cm^2\ V^{-1}\ s^{-1}$ at 18–250°C. This implies in its turn that the comparatively high electrical conductivity of the specimens (for example, $\sigma_{300} = 10^4\ \Omega^{-1}\ mm^{-1}$) must be due to a high concentration of current carriers, exceeding $2 \times 10^{17}\ cm^{-3}$. [106]

It is now well known that measurements carried out using a direct current cannot yield a unique picture of the conduction mechanism, which apparently involves two processes: the transport of carriers from one continuous conjugation region to another and the conduction within these regions themselves. In order to elucidate the conduction mechanism, measurements must be made of the frequency dependence of the electrical parameters; some of these parameters for polymeric tetracyanoethylene derivatives have been published [93].

The study of the frequency dependence of the dielectric constants and σ as a function of the electric field strength for PPC showed that these polymers are one-dimensional semiconductors in which the conductivity regions extend over 100–1000 Å. [99]

3. Catalytic Properties

The study of the catalytic properties of PA showed that, as in many other organic semiconductors, these compounds exhibit an enhanced activity in relation to oxidation-reduction reactions such as the oxidation of aromatic alkyl-substituted hydrocarbons [109,110] and certain aromatic and saturated aliphatic aldehydes [111], the decomposition of formic acid and hydrogen peroxide [112], etc.

In terms of their reactivity, the polymeric complexes are as a rule superior to their low-molecular-weight analogues. An exception is $PPC_{Os(SO_4)_2}$, whose catalase activity is five times smaller than that of $PC_{Os(SO_4)_2}$ and PPC_{RuHSO_4}, the latter having the same activity as

† According to Heilmeir et al., [107] μ for PC_{Cu} is 0.1–0.4 $cm^2\ V^{-1}\ s^{-1}$.

‡ It is quite likely that the Hall effect cannot be measured at all for PA as well as a whole series of semiconductors with a jump conductivity mechanism [108].

PC_{RuHSO_4}.[113] A characteristic feature of the polymeric complexes as oxidation-reduction catalysts is their appreciably greater selectivity than that of the corresponding low-molecular-weight analogues, reaching 100% in many instances, for example in the dehydrogenation of formic acid, the oxidation of cumene[110], etc.

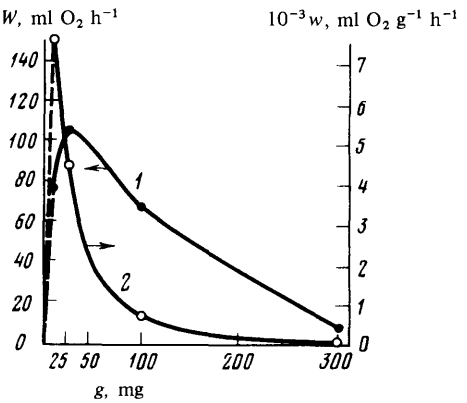

Figure 4. The influence of the amount of PPC_{Fe} on the rate of oxidation of cumene: 1) overall rate of reaction (W) relative to the catalyst sample (g); 2) specific rate of reaction (w) per gramme of catalyst.

Like certain other catalysts, PA exhibits a dual function in reactions. Depending on the amount of PA introduced into the reaction, the complexes behave as both process initiators and inhibitors. This property is illustrated in Fig. 4 in relation to the effect of PPC_{Fe} in the oxidation of cumene.

The problem of the centres which determine the catalytic activity of porphyrazines has not at first sight been solved unambiguously. On the one hand, there is evidence for the decisive influence of the nature of the metal on the catalytic activity of phthalocyanines and, on the other hand, there is evidence showing that the peripheral nitrogen atoms of the macroring play the main role without any participation of the metal. Indeed, while the activity of PPC and PTCE in the oxidation of cumene is insignificant, the complexes of these polymers with iron and copper show a fairly high activity, which depends on the amount of metal in the macromolecule and increases with the latter[110]. However, the introduction of a second metal does not cause an appreciable enhancement of the catalytic properties of PPC_{Cu} in this reaction[110], in contrast to the effect observed by Inoue et al.[102]

The dependence of the catalytic activity on the nature of the metal has been investigated much more extensively for phthalocyanines than for PA and has been demonstrated in relation to various reactions. Thus it has been shown[110] that in the oxidation of cumene the phthalocyanine complexes of variable-valence metals (copper, nickel, and cobalt) exhibit a much higher activity than the phthalocyanine complexes of zinc, mercury, and silver. In formic acid decomposition reactions the specific activity of PC_{Cu} is smaller by more than an order of magnitude than that of PC_{Fe}; in the decomposition of hydrazine the differences between the specific activities of these phthalocyanines exceeded two orders of magnitude, while the addition of PC had almost no influence on this process[114].

It is of interest that even the selectivity of phthalocyanines (but not PA) is related to the nature of the metal. For example, in the oxidation of cumene to its hydroperoxide the phthalocyanine complexes of manganese, iron, cobalt, and nickel are much inferior in their selectivity to the copper and zinc complexes[115].

The finding that PPC_{Fe} obtained without a catalyst is more active in the decomposition of hydrogen peroxide than "the same" complex synthesised in the presence of ammonium molybdate[54] can serve as additional confirmation of the dependence of the catalytic properties of PA on the nature of the metal. The presence in the specimen of admixtures of PPC_{MoO_2}, formed in the catalytic synthesis of PPC_{Fe}, reduced the activity of the latter in the above reaction. This finding shows yet again that catalytic properties as well as electrophysical characteristics must be studied only on carefully purified and chemically homogeneous compounds free from impurities which are not susceptible to analytical determination.

Theoretical calculations, confirmed by experimental data obtained in the study of the electrochemical reduction of oxygen[116,117], showed that the phthalocyanine complexes of metals can be arranged in the following sequence in terms of their decreasing catalytic activities: $PC_{Fe} > PC_{Co} > PC_{Ni} > PC_{Cu}$. Analogous relations have been observed for polymeric complexes. The influence of the nature of the metal on the catalytic activity of phthalocyanines has been observed also in the electrochemical reduction of oxygen on carbon electrodes saturated by the above complexes[67]. The activity series for the phthalocyanine complexes in relation to this reaction, based on the nature of the metal, did not agree with similar series for other reactions[118,119].

However, under certain conditions, there are no differences between the catalytic activities of the phthalocyanine complexes of a number of metals. It has been shown[121] that the catalytic activity of phthalocyanines is determined by the crystal form of the given substances to a greater extent than by the nature of the metal. The observed decrease of the activity of PC_{Cu} in the oxidation of cumene has been explained[122] by the conversion of the catalyst from the α-form into the β-form and the authors concluded that the π-conjugated phthalocyanine system is important.

It has been shown by spectroscopic methods[123,124] that the active centres for the adsorption of organic and inorganic acids can be the nitrogen atoms of the phthalocyanine ring and that the metal atom is not essential for the formation of the phthalocyanine–acid molecule complex. Investigators of polymeric compounds arrived at similar conclusions. Thus it has been shown[125] by kinetic and EPR methods that the active centres for deuterium exchange in PPC_{Cu}, which are active at temperatures above 100°C, arise as a result of the dissociation of double bonds and do not include copper atoms. The authors[125] carried out a thermodynamic estimate, which showed that the chemisorption of hydrogen and hence the catalytic processes involving it are possible on non-metallic centres on organic semiconductors for a width of the forbidden gap below a certain limiting value.

The study of the adsorption of formic acid on PPC_{Cu} by spectroscopic methods at temperatures close to that of the onset of the catalytic reaction demonstrated a decrease of the intensity of the stretching vibration bands of the C–N groups in the infrared spectrum (1090–1310 cm^{-1}) and of the bands in the PPC_{Cu} spectrum in the visible region

(630 and 725 nm) corresponding to the presence of a conjugated system in the polymer. Together with results obtained previously [126,127], these data show that the active centres for the adsorption and dehydrogenation of formic acid in polyphthalocyanines may be the peripheral nitrogen atoms of the azaporphin macrorings of the polymer. The same conclusion follows also from studies of the *para–ortho* transformation of H_2 and deuterium exchange on PPC_{Cu}.[128]

The phthalocyanine activity series in the oxidation of cumene $PC_{RuHSO_4} > PC_{Os(SO_4)_2} > PC_{Co} > PC_{Ni} > PC_{Cu}$ shows, according to Berezin and Shlyapova[129], that the initiation of the reaction is not associated with the interaction of oxygen or the hydroperoxide with the metal in the phthalocyanine complex, since this possibility is altogether lacking in the case of the very active $PC_{Os(SO_4)_2}$.

The above data concerning the nature of the active centres of azaporphin show that the π electrons of the macroring and the *dsp* electrons of the metal constitute a single conjugated system, whose properties depend significantly on the nature of both the ligand and the metal in the "window" of the macroring.

It is of interest that an enhanced activity in oxidation-reduction reactions is manifested only by semiconducting compounds and that polymers (for example, polyphenylene, polyphenylacetylene, etc.) exhibit no such activity whatever in the above reactions, behaving as insulators at the experimental temperatures. This is usually attributed to a correlation between the catalytic and semiconducting properties of compounds of this kind. Indeed, as for many organic semiconductors, it has been noted for PA that the higher the value of σ, the higher the activity of the compound in model reactions[109,110,129,130].

This is manifested particularly clearly when the catalytic activities of PA and their low-molecular-weight analogues are compared. As already mentioned, the electrophysical parameters of the latter are greatly inferior to those of the corresponding polymeric complexes (see Table). This was also observed when the catalytic properties were compared. For example, PPC_{Fe} and PPC_{Cu} exhibit a much higher specific activity in the oxidation of cumene than PC_{Fe} and PC_{Cu} respectively[110]. A similar behaviour has been observed also for the cobalt complexes in the electrochemical reduction of oxygen in the presence of PC_{Co} and its polymeric analogue[67]. In the hydrogen peroxide decomposition reaction the specific activity of PPC_{Cu} is only five times smaller than that of one of the best catalysts for this reaction—manganese dioxide, whereas PC_{Cu} is altogether inactive in this reaction[112]. The specific activities of the phthalocyanine complexes of copper and iron are inferior to those of their polymeric analogues also in the hydrazine decomposition reactions[131].

A correlation between the semiconducting and catalytic properties is also indicated by the parallel variation of the catalytic activity and the concentration of paramagnetic centres, which has been established for certain organic semiconductors[131]. A whole series of chemical reactions involving organic semiconductor catalysts can be accounted for solely in terms of the semiconducting properties of the latter. However, a clear-cut correlation between the electrical and catalytic properties of semiconductors, which might have been expected on the basis of the electronic theory of catalysis on semiconductors[132], is not observed in practice. This led some workers to the conclusion that such a correlation is altogether lacking[133]. For example, the catalytic properties of polychelates have been attributed[134,135] to the electronic state of the metal in the chelate unit and not to the semiconducting properties of these systems. The absence of a correlation between the catalytic and semiconducting properties has also been reported in other studies.

The available literature data do not permit at present any unambiguous conclusions concerning the relation between the semiconducting and catalytic properties. A more detailed investigation of the mechanism of the catalytic action of organic semiconductors together with the study of the mechanism of their conduction and comparison of these data will apparently provide in the future an answer to the question of the fundamental factors influencing the catalytic activity of semiconducting systems. Here one should take into account also other no less significant factors which determine the catalytic activity of semiconductors, namely the local chemical properties of their surfaces, their collective electronic properties, etc.

---o0o---

In conclusion, one should note that during the last 15–18 years extensive experimental data have been accumulated on the synthesis and properties of polymeric azaporphins, which undoubtedly constitute one of the most striking examples of polymers with a conjugation system. However, the lack of reliable methods for the synthesis and purification of PA has led to a very limited and extremely one-sided study of their properties and only a qualitative interpretation of the experimental data obtained.

Nevertheless, the unusual physical and physicochemical properties observed for these polymers make them valuable objects not only for a wide variety of scientific investigations but also for the creation on their basis of chemically and thermally stable specific catalytic systems as well as special semiconducting materials with a wide range of electrophysical parameters.

Some Problems of the Chemical Physics of the Ageing and Stabilisation of Polymers

N.M.Emanuel'

The ageing and stabilisation of polymers involves the chemical physics of coupled radical-chain, ionic, and molecular transformations in complex multicomponent systems which make up the polymeric material. In the present review the question of the ageing and stabilisation of polymers is formulated as a multifactor problem, where the study of the changes in the properties of the material under various conditions can be treated from a single standpoint, and the mechanism is represented by a set of interrelated elementary processes. Some new results and views are considered.
The bibliography includes 112 references.

I. INTRODUCTION

Ten years ago the field of the ageing and stabilisation of polymers was defined as the "chemistry and physics of coupled radical-chain, ionic, and molecular transformations in complex multicomponent systems"[1]. Since then numerous investigations of the detailed mechanism of the ageing processes of polymers and their kinetics as well as studies designed to develop rational stabilisation principles have been carried out[2-6].

Much scope has been found for the application in this field of the theoretical and experimental methods characteristic of chemical physics to the investigation of new phenomena and relations which are of enormous practical importance. A well-founded possibility of formulating the question of ageing and stabilisation of polymers as a multifactor problem, where the study of the changes in the properties of the polymeric material under various conditions can be treated from a single view point, became possible. This field acquired special significance as an important

branch of the chemistry of the solid state with allowance for the specific features of the chemical reactions of macromolecules.

In the course of the development of the first attempts at the identification of the active species responsible for ageing, numerous studies devoted to the elementary steps of the chemical reactions involves these species were carried out and their quantitative kinetic characteristics were determined. New experimental techniques made possible the determination of fine details of the structure of the active centres and at the same time raised the level and importance of the study of the elementary reactions in polymers.

The time is approaching when the ageing process will be treated quantitatively as a set of interrelated elementary reactions no longer in relation to individual model systems but in all cases on the basis of kinetic parameters of elementary processes compiled in tables and handbooks.

The principal task of chemistry, which is to establish relations between the structure of substances and their reactivity, acquires a new significance in the field of the ageing of stabilisation of polymers as the problem of the determination of relations between the changes in the properties of polymers during ageing and the kinetics of the chemical reactions in the polymer.

New principles of the stabilisation of polymers, based on the knowledge of the detailed mechanism of the ageing process, have arisen. New tasks in the field of the ageing and stabilisation of polymers arise in connection with their use in space apparatus and research, in medicine, in the building industry, and in many fields of modern engineering.

The present review deals with certain new results and views referring to the chemical-physical study of the ageing and stabilisation of polymeric materials.

II. THE AGEING OF POLYMERS AS A MULTIFACTOR PROBLEM

The polymeric material in the initial state possesses a definite set of properties y_i which vary with time during ageing, i.e. are functions of time.

The ageing of a polymer consists of a set of its chemical and physical transformations in the course of storage and use. The polymer is then subjected to the action of a wide variety of chemical and physical factors x_i: heat, light, penetrating radiation, oxygen, moisture, corrosive chemical compounds, and mechanical stresses. The operation of these factors creates conditions for the initiation and development of chemical reactions responsible for the ageing of the polymer. For a time the changes in the properties of the polymer may be insignificant from the standpoint of its suitability for practical use (the material is stable). The stability of the material can be characterised quantitatively by its useful life, i.e. the time during which the article or material loses its suitability for practical use under specified influences.

We shall assume that the properties of the material are characterised by a point Y in the space of properties (Fig. 1) at a given instance. The coordinates of this space y_i are quantitative characteristics of the properties, for example, the density, composition, physicomechanical characteristics, dielectric constant, absorption spectrum, etc. The conditions in the practical utilisation of the material can also be characterised by a point in the space of conditions whose coordinates x_i are quantitative characteristics of the conditions: temperature, intensity, and spectral composition of the radiation acting on the polymer, mechanical stress, moisture content, oxygen pressure, etc. The material is suitable for use as long as it possesses the required set of properties, i.e. as long as the point Y does not leave in the course of ageing a certain region of practical suitability ϵ_0 whose dimensions and form may be various depending on the requirements which must be met by the material.

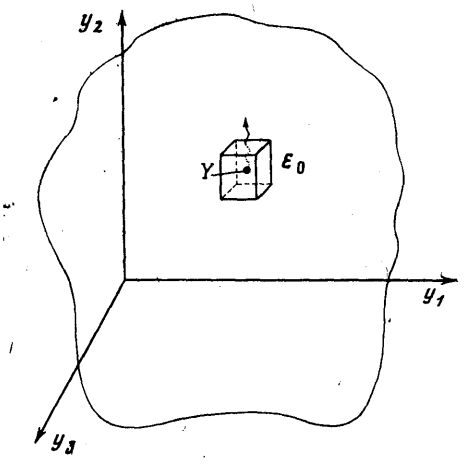

Figure 1. A qualitative picture of the time variation of the set of properties of a polymer y (special case—a point in three-dimensional space). ϵ_0 represents the region of the practical suitability of the polymer.

From the standpoint of chemical physics, the ageing of a polymeric material must be regarded as a process described by a single system of equations suitable for any conditions:

$$Y = f(X, t). \quad (1)$$

The introduction of the characteristics of the conditions into this system of equations makes it possible to determine how the properties of the polymer vary under these conditions. As a result, one can determine the instant when the point Y leaves the limits of any region ϵ_0, i.e. when the material ceases to satisfy the requirements imposed on it.

Thus the useful life of the polymeric materials is determined not only by its physicochemical properties, but also by the conditions under which it is used (X) and the requirements which it must meet whilst being used (ϵ_0).

1. Criteria of the Constancy of the Properties of Polymers

A quantitative treatment of the constancy of the properties of polymers in practice is exceptionally important. Indeed, if it were possible to devise rigorous criteria of the constancy of the properties of polymers, it would be easy to answer the question how far degradation can proceed without the polymer losing its initial properties in practice.

The study of the ageing and stabilisation processes of polymers involves slight chemical transformations in the material which may lead to considerable changes in the physical properties of the specimen.

It is frequently assumed that the properties of a substance virtually do not change if the number of elementary points of damage S (chain rupture, the appearance of new functional groups as a result of chemical reactions) is small compared with the total number of molecules n present in the specimen, i.e. if the condition

$$S/n \ll 1. \tag{2}$$

is fulfilled. If it is assumed that the degree of damage (degradation) δ is defined as the number of breaks per chemical bond in the main chain of the linear polymer molecule, then

$$\delta = \frac{S}{npz}, \tag{3}$$

where $p = M/m$ is the degree of polymerisation (the ratio of the molecular weight of the polymer to the molecular weight of the monomeric unit, which is equal to the number of monomeric units in the macromolecule) and z is the number of bonds in the main chain per monomeric unit. Hence

$$\frac{S}{n} = \delta pz = \delta \frac{M}{m} z, \tag{4}$$

and the condition for the constancy of the properties of the polymer becomes

$$\delta \frac{M}{m} z \ll 1, \text{ or } \delta M \ll \frac{m}{z}. \tag{5}$$

Evidently, for a given type of linear chain, the permissible degree of degradation is smaller the greater the molecular weight.

The use of this criterion leads to the conclusion that polymer materials should have much less constant properties than low-molecular-weight compounds. As an example, we shall compare the capacity for degradation of the polymethylene chains in low-pressure polyethylene ($M = 420\,000$) and in lubricating oil ($M = 420$). In both cases $z = 2$ and $m/z = 14$. We shall assume that 0.01% of all the carbon chains are ruptured in both specimens, i.e. $\delta = 10^{-4}$. We then find $\delta M = 10^{-4} \times 4.2 \times 10^2 = 4.2 \times 10^{-2} \ll 14$ for the lubricating oil, i.e. its properties remain virtually constant. On the other hand, for polyethylene we have

$$\delta M = 10^{-4} \cdot 4.2 \cdot 10^5 = 42 > 14. \tag{6}$$

Hence it follows that the condition for the constancy of the properties is not fulfilled in the latter case.

The significance of the results obtained is that only a small proportion of the molecules were damaged in the lubricating oil, while in the polymer there were several breaks in each macromolecular chain. Indeed $S/n = \delta Mz/m = 10^{-4} \times 420 \times 2/28 \simeq 3 \times 10^{-3}$ for the lubricating oil, while $S/n \simeq 3$ for the polymer.

The simplest criterion of the constancy of the properties of a polymer examined above is by no means universal; it can be used in characterising those properties of the polymer which are determined not only by its chemical structure, but also by the size of its macromolecules. These are, for example, the intrinsic viscosity of the polymer and the light scattering parameters of its dilute solutions. These properties are normally employed for analytical purposes in order to determine the changes in the molecular weight of the polymer during its degradation.

Properties of the polymer of practical importance usually vary with the molecular weight in a complex manner. For example, the stability of the majority of polymers with high degrees of polymerisation usually ceases to depend on the molecular weight, while the glass point, the brittle temperature, and the modulus of elasticity can assume extremum values (Fig. 2). For such a complex dependence of the properties of the polymeric material on its molecular weight, the simplest criterion of their constancy becomes inapplicable. The presence of a region where the properties of the polymer are independent of its molecular weight may result in the properties remaining unchanged for fairly high degrees of degradation. The properties of a polymeric material with a high molecular weight are therefore more stable.

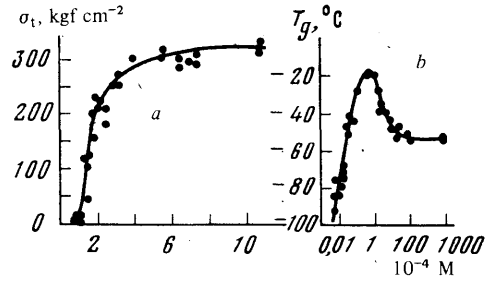

Figure 2. Dependence of the molecular weight M on the tensile strength σ_p of vulcanised natural rubber (a) and on the glass point T_g of poly(ethylene oxide) [7] (b).

It has been established that the reciprocals of many properties of polymeric materials are linearly related to the quantity which is the reciprocal of the molecular weight or the degree of polymerisation [7]:

$$\frac{1}{y} = A\left(1 + \frac{\mu}{M}\right), \tag{7}$$

where y is a characteristic of the properties of the material, for example, breaking strain, while A and μ are parameters. In this case the degree of the change in the property y can be adopted as a criterion of its constancy:

$$\frac{y_0 - y}{y} \ll 1. \tag{8}$$

The degree of damage of the polymer δ is related to its molecular weight by the expression

$$M = \frac{M_0}{1 + \delta M_0}, \tag{9}$$

where M_0 is the molecular weight of the initial polymer. We find from Eqns. (7)–(9)

$$\delta \mu M_0/(M_0 + \mu) \ll 1. \tag{10}$$

Hence the criterion of the constancy of the properties of the material is

$$\delta \ll (M_0 + \mu)/M_0\mu. \tag{11}$$

It follows from Eqn. (11) that for low-molecular-weight compounds ($M_0 \ll \mu$):

$$\delta \ll 1/M_0, \tag{12}$$

i.e. the properties of the substance are less stable the higher its molecular weight. For high molecular weights ($M_0 \gg \mu$), the stability of the material ceases to depend on the molecular weight:

$$\delta \ll 1/\mu. \qquad (13)$$

Unfortunately such criteria, relating the degree of degradation of the polymer to the change in its properties, are also not general. For example, they do not characterise the change in the molecular weight distribution or composition of the polymeric material and do not take into account the change in its molecular structure. In order to determine the extent of the change in the properties of polymeric specimens, one must therefore employ several methods. For example, one may point to methods for the determination of thermal stability from the change in the pressure in the system (manometric method) and from the weight loss (thermogravimetric method), methods based on the study of the change in physicomechanical properties, as well as procedures for the estimation of stability employing data obtained in the study of the polymer degradation products, etc.

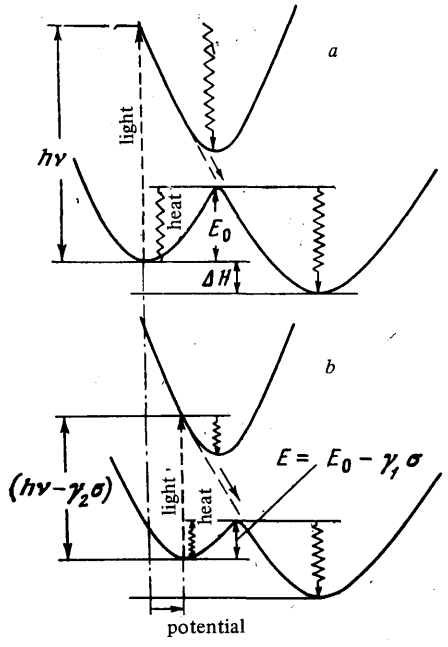

Figure 3. A qualitative picture of the cross-section through the potential surfaces along the elementary chemical reaction coordinate (*a*) and its variation under the influence of mechanical stresses (*b*).

2. The Elementary Step in the Chemical Reaction

In a quantum-mechanical treatment the elementary step of a chemical reaction in a polymeric material, as well as any other system, reduces to the movement of the initial species on the potential energy surface along the reaction coordinate.

Fig. 3 presents a qualitative picture of a section through the potential energy surface for the thermal, photochemical, and mechanical degradation of the polymer. The thermal transition is carried out adiabatically. The phototransition can include a non-adiabatic process stage associated with the absorption of a quantum with the energy $h\nu_0$. When the macromolecule is acted upon by mechanical stresses σ, the minima on the potential curves approach one another, which reduces the values of E and $h\nu$ for which the reaction can take place (in the zeroth approximation the decrease is linear). The rate constant for the elementary step then becomes

$$k = k_0 \exp\left(-\frac{E-\gamma\sigma}{RT}\right), \qquad (14)$$

where γ is a proportionality coefficient, which depends on the form of the potential curves. Since the lifetime of the material, i.e. the time which must elapse before degradation, is

$$\tau_p \propto 1/k,$$

we obtain from Eqn. (14)

$$\tau_p = \tau_0 \exp\left(\frac{E-\gamma\sigma}{RT}\right), \qquad (15)$$

i.e. the familiar Zhurkov equation.

This picture is characteristic of the influence of a field of mechanical forces on any elementary step of the chemical reaction regardless of its nature. When the influence of mechanical stresses on the stability of a polymeric material as a whole or its lifetime is estimated, account must be taken of this influence not on one but on all the elementary steps of the chemical reaction in the ageing process. The linear relationship between the logarithm of the lifetime and the stress

$$\ln\tau_p = \ln\tau_0 + (E-\gamma\sigma)/RT \qquad (16)$$

is therefore an effective characteristic of the process and usually holds over a narrow range of stresses, where the rate of the process is limited virtually by one elementary step. Over a wide range of variation of stresses, this relation is more complex, since the rate-limiting stage of the ageing process can vary with the stress.

3. The Nature of the Active Centres

Molecular reactions are not as a rule important in the mechanism of the ageing of polymers. In practice one must usually take into account reactions involving three types of active species: free radicals, excited species, and to a lesser extent ions.

Free radicals play the main role in the ageing of polymeric materials. This is because reactions involving either the homolytic dissociation of the main chain of the molecule or the homolytic abstraction of atoms or radicals from side groups are characteristic of the majority of polymers.

Ions are formed in polymers usually only in the stage involving the initiation of radiation-induced processes and in processes associated with the degradation of polymers in corrosive media. Data for the formation of ions in the mechanical degradation of polymers on friction and on breakdown of the polymeric material lead to the conclusion that ions play an insignificant role in these processes, their concentrations are low, and they are formed in

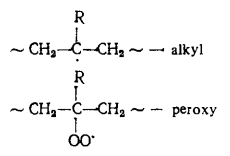
secondary reactions associated with the acquisition of electric charge by the polymeric material as the macroparticles move relative to one another. On the other hand, the chemical changes in the material, for example, its mechanical breakdown, are determined by radical and not ionic processes[8].

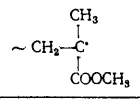
Electronically excited molecules in the lowest excited singlet (S_1) or lowest triplet (T_0) states play the greatest role in the photochemical ageing of polymers. Two-quantum photochemical processes occurring with participation of the highest triplet states can also be important[9]. The dependence of the quantum yield of a number of photochemical processes on the wavelength of the radiation acting on the polymer indicates the important role of the highest excited singlet states[10].

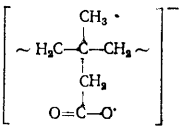
Together with electronically excited molecules, certain labile species in the excited state can participate in the photochemical ageing process. Thus thermal and photochemical decomposition of certain molecules can lead to the formation of excited ("hot") free radicals[11], which interact more effectively with the medium than the usual ("cold") free radicals. For high intensities of the light during photoageing, free radicals can absorb light quanta and pass to an electronically excited state[12]. The problem of the possible increase of the rate of the chain propagation reaction as a result of the absorption of a light quantum by the free radical is discussed in the literature[13].

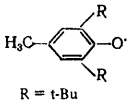
The structure and properties of radical active centres involved in the ageing of the polymeric material are various. Table 1 presents typical examples of active centres of this class and demonstrates their role in the ageing process.

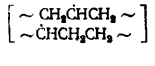
EPR has played a particularly important role in the study of radical active centres. It extended enormously the possibilities for the study of the structure of these centres and for the determination of their role in the ageing process.











Numerous EPR spectra of the "central" and "terminal" macroradicals of different types are now known (Figs. 4 and 5). The complex structure of the spectrum makes it possible to identify the structure of the macroradical. For example, the spectrum of the central macroradical of polypropylene (Fig. 4) consists of eight components with a splitting of 21 ± 1 G. Hence it follows that in all probability the spectrum refers to the radicals

because here the β-positions relative to the unpaired electron contain seven equivalent protons. Another example is the terminal macroradical of polyformaldehyde whose spectrum consists of a triplet with a splitting of 20 ± 1 G (Fig. 5). Since this type of spectrum corresponds to the interaction of the unpaired electron with two protons, it may be imagined that the given radical has one of two possible structures:

Table 1. Radical active centres and their role in the ageing process.

Type of radical active centre	Example	Formation pathways	Role in ageing process	Influence on direction and rate of ageing process
Central macroradical		chain propagation		
		oxidation of alkyl radicals	chain propagation, cross-linking, and polymer-analogue reactions	change in the structure of side chain, cross-linking, and change in MWD
Terminal macroradical		breaks in macromolecules and depolymerisation	cross-linking and depolymerisation	change in molecular weight and MWD
Low-molecular-weight radical	$\sim \dot{C}H_3$	decomposition of macro-radicals	migration of free valence; лентности	formation of volatile products
Radical-ion		exposure to penetrating radiation and two-quantum photoprocesses	chain initiation	increase of rate of ageing
Inhibitor radicals	 R = t-Bu	reactions involving stabilisers	chain termination and propagation	decrease of rate of ageing
Variable-valence metal ions	Fe^{3+}	catalyst residues, contaminations, and organometallic stabilisers	chain initiation and termination	change in rate of ageing
Radical pairs		decomposition of molecules	destruction in the cage and formation of free radicals	change in rate of ageing

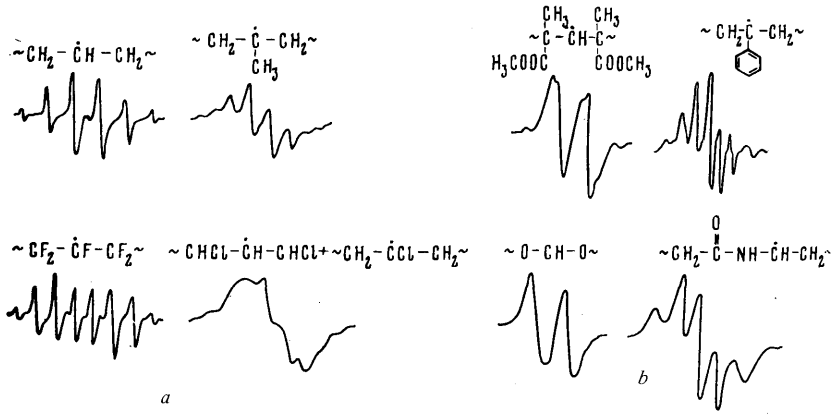


Figure 4. EPR spectra of central macroradicals: *a*) formed under the influence of γ-radiation of polyethylene, polypropylene, Teflon, and poly(vinyl chloride); *b*) formed from poly(methyl methacrylate), polystyrene, polyformaldehyde, and Kapron following the application of mechanical and radiation influences and light.

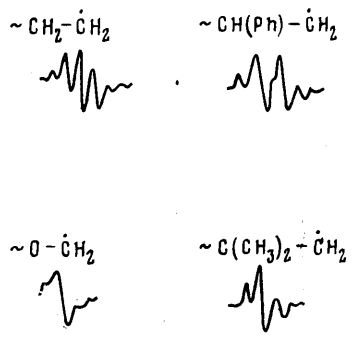

Figure 5. EPR spectra of the terminal macroradicals formed on mechanical degradation and under the influence of radiation for polyethylene, polystyrene, and polyformaldehyde, and polyisobutylene.

A number of workers have devoted particular attention to the interactions of macroradicals with inhibitors and other additives or admixtures present in real polymeric systems. The structures of an enormous number of inhibitor radicals (phenoxy-, nitrogen, and nitroxy-) and their behaviour in the oxidation of the corresponding polymers have been investigated. The scheme presented in Fig. 6 illustrates the conversion of the radicals $R\dot{O}_2$ into the radicals of phenolic inhibitors which occurs in a polypropylene melt at 200°C. Fig. 7 illustrates the EPR spectrum of the inhibitor radical in solid polypropylene [14].

Fig. 8 presents the kinetics of the variation of the concentration of α-naphthol radicals in the oxidation of a polypropylene melt. Evidently during the induction period (curve *2* describes the time variation of Δp_{O_2}) the change in the concentration of inhibitor radicals is autocatalytic. Next a sharp decrease of the amount of In$^{\cdot}$ in the system is observed. The kinetic curve shown agrees satisfactorily with the fact that the inhibitor is consumed as a result of the reaction and the concentration of $R\dot{O}_2$ increases.

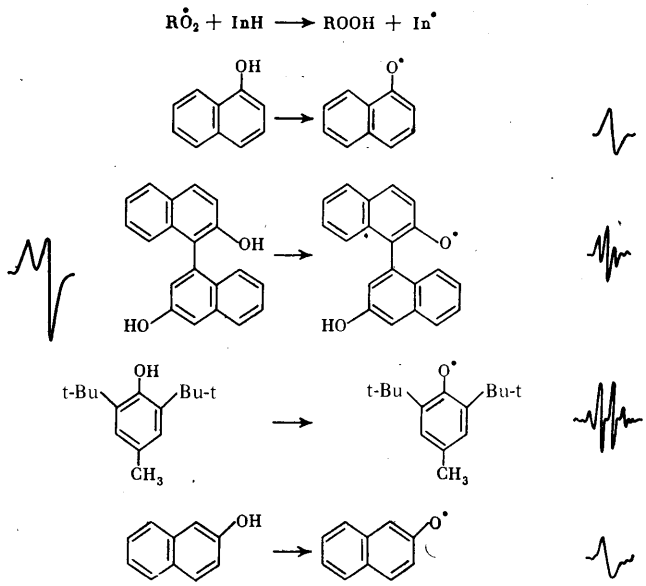

Figure 6. Schematic illustration of the replacement of the radicals $R\dot{O}_2$ by the inhibitor radical (polypropylene, melt); 200°C, p_{O_2} = 400 mmHg.

EPR makes it possible to record a special type of active radical centres—radical pairs. In low-molecular-weight substances EPR permitted the determination of the distance between the unpaired electrons for such stabilised pairs, which usually amounts to 4–7 Å.

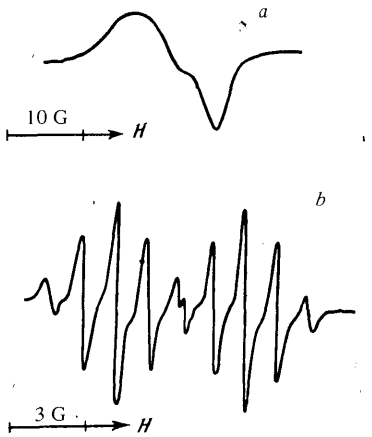
Since radical pairs represent in essence the triplet state arising in the interaction of two unpaired electrons, the EPR spectrum reveals the occurrence of two types of transitions between energy levels: with $\Delta M_S = 1$ (transitions in the usual magnetic fields, $g \simeq 2$) and forbidden transitions with $\Delta M_S = 2$ (in "half" fields, $g \simeq 4$) (Fig. 9).

Table 2 presents certain results of the study of the radical pairs in solid polymers at 77 K.

The study of radical pairs in polymers by EPR makes it possible to infer both the nature of the radical components and the mechanism of the elementary step in degradation and structure formation during ageing. For example, analysis of the EPR spectrum for $\Delta M_S = 2$ in γ-irradiated polyethylene led to the conclusion that a pair with the structure

$$\sim CH_2-\dot{C}H-CH_2\sim$$
$$\sim CH_2-\dot{C}H-CH_2\sim$$

is formed and not $\sim\dot{C}H_2\dot{C}H_2\sim$. Evidently such pairs are the kinetic precursors of the cross-links being produced.



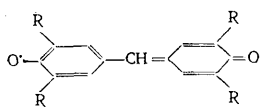


Figure 7. EPR spectrum of the inhibitor radical

(R = t-Bu) in solid polypropylene at 25 °C (*a*) and the spectrum of the same radical in benzene at 25 °C (*b*). In the solid polymer the spectrum is greatly broadened and the hyperfine structure disappears owing to the decrease of the rotation frequencies of the radical [14].

All the foregoing considerations referred to the identification of radical active centres arising in the degradation of polymers. Unfortunately, owing to the lack of special methods, similar to EPR, it is much more difficult to identify active centres in degradation via an ionic mechanism. In this field there have been virtually no systematic studies, with the exception of those which yielded data on the degradation of certain natural polymers in solution.

4. General Characteristics of the Ageing Process

Eqns. (1) are suitable for the description of the ageing process under any conditions. In principle, this problem is susceptible to solution in a general form by modern computer techniques. The thermal degradation, photodegradation, mechanical degradation, oxidation, hydrolytic degradation, etc. processes usually examined are limiting cases of a single ageing process in which the change of the properties of the material is determined by only one factor.

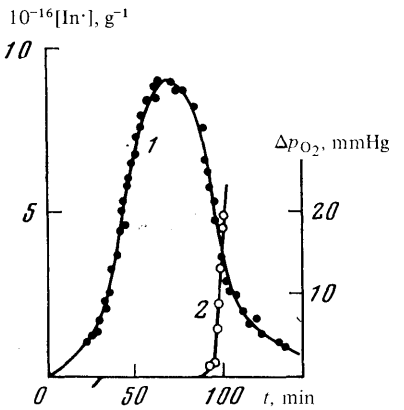

Figure 8. Kinetics of the variation of the concentrations of α-naphthol radicals in the oxidation of fused polypropylene: 1) variation of [In]; 2) kinetics of the absorption of oxygen [15].

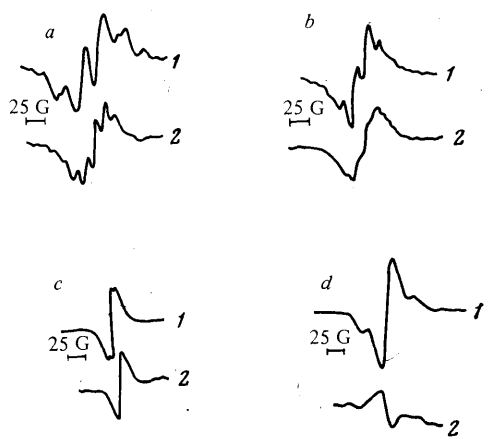

Figure 9. EPR spectra of transitions where $\Delta M_S = 1$ (curve *1*) and $\Delta M_S = 2$ (curve *2*) for polyethylene (*a*), polypropylene (*b*), polyoxymethylene (*c*), and polystyrene (*d*) irradiated with accelerated electrons at 77 K. [16]

In the general case the ageing process includes three main stages (Table 3):

(1) initiation—stage involving the formation of active centres;

(2) the development of ageing—the main stage determining the change in the properties of the polymeric material;

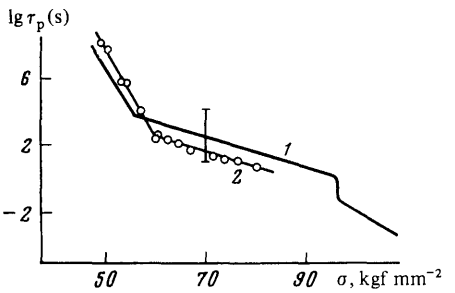
(3) the stage involving the destruction of active centres for ageing.

Table 2. EPR data for radical pairs in solid polymers at 77 K.[16]

Polymer	Ratio of integral intensities $\Delta M_S = 2$ and $\Delta M_S = 1$ in EPR spectra ($\Delta M_S = 2/\Delta M_S = 1 \times 10^5$)	HFS of spectra with $\Delta M_S = 2$
Polyethylene	6.1	16 G
Polypropylene	12.7	15 G
Polyoxymethylene	6.1	unresolved
Poly(ethylene oxide)	1.8	"
Poly(vinyl alcohol)	2.9	"
Cellulose	1.3	"

The physicochemical nature of the initiation stage can be various: in photoageing it is an elementary process with participation of light quanta and molecules in an excited state, while in the radiation-induced process it is a reaction involving ions. In mechanical degradation the initiation stage consists in the dissociation of molecules under the influence of mechanical forces with formation of free radicals.

The development of the ageing process takes place virtually independently of the nature of the initiation. For example, photoageing and radiation-induced ageing proceeds via the same elementary reactions as thermal ageing. External conditions determine in the first place the initiation stage (the formation of free radicals, ions, and excited species). Certain influences affect also the further development of ageing. For example, the presence of oxygen converts any process into an oxidation reaction (thermal degradation becomes thermal oxidation, photolysis becomes photochemical oxidation, and mechanical degradation becomes oxidation in the field of mechanical forces). Temperature influences all the elementary stages with the exception of processes whose activation energy is virtually zero.



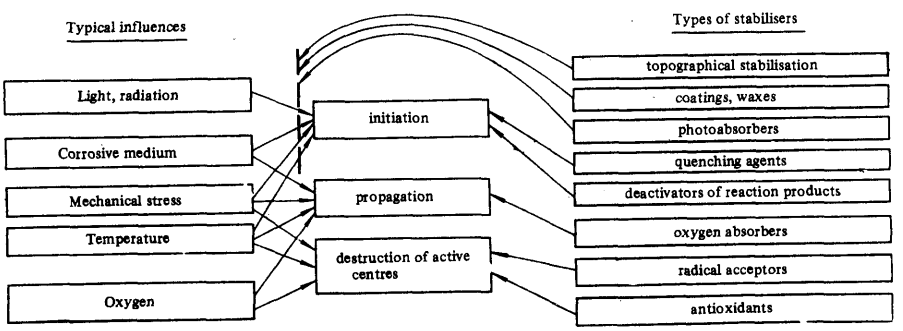


Figure 10. Comparison of the theoretical temperature dependence of the lifetime of polypropylene (calculation based on the radical-chain decomposition mechanism) (curve *1*) with experimental data (curve *2*). The vertical line indicates the error of the calculation.

The complex mechanism of the ageing of polymers makes the relatively simple relations governing a chemical process limited by a single elementary step unsuitable for the description of the ageing process over a wide range variation of conditions. For example, Fig. 10 shows that the semilogarithmic form of the relation between the lifetime of polypropylene and applied stress is not linear as required by Zhurkov's equation. This result has been explained[17] on the basis of a radical-chain mechanism of thermal mechanical degradation including chain initiation stages via the dissociation of the strained bonds of the macromolecules, depolymerisation, chain transfer with formation of a central radical, decomposition of the central radical under the influence of stresses, migration

Table 3. The principal stages in the ageing and stabilisation of a polymeric material.

of the free valence along the central radical, and chain termination:

$$\left.\begin{array}{l} PH \xrightarrow{k_1(\sigma)} 2R^{\cdot}_{term} \\ R^{\cdot}_{term} \xrightarrow{k_2} R^{\cdot}_{term} + M \\ R^{\cdot}_{term} + PH \xrightarrow{k_3} PH + R^{\cdot}_{cent} \\ R^{\cdot}_{cent} \xrightarrow{k_4(\sigma)} R^{\cdot}_{term} + PH \\ R^{\cdot}_{cent} \xrightarrow{k_5(\sigma)} R^{\cdot}_{term} \\ 2R^{\cdot}_{term} \xrightarrow{k_6} PH \end{array}\right\}. \qquad (17)$$

where M is the monomer and PH the polymer. Account was taken of the influence of the applied stress, in accordance with Zhurkov's equation, on the elementary steps in the decomposition of the polymer (k_1) and the macroradical (k_4 and k_5).

For small stresses, Eqn.(15) should hold; under these conditions, τ_0 and F are effective quantities and do not refer to any one elementary stage of the process:

$$\tau_p = a\sqrt{\frac{k_6}{k_1 k_3^2}}\exp\left(\frac{-\gamma\sigma}{RT}\right), \qquad (18)$$

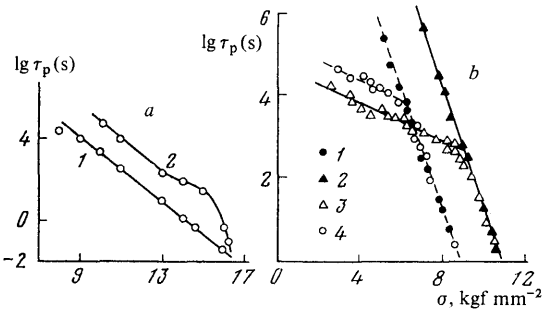
where a is a proportionality coefficient which depends on temperature. Accordingly, the pre-exponential factor for this process is not the average period of the thermal vibrations of the atoms, as in Eqn.(15), but is determined by the ratio of the pre-exponential factors associated with the rate constants for the elementary thermal degradation reactions.

Over a wide range of stresses, Eqn.(18) ceases to hold, because for large stresses the degradation process is so fast that there is insufficient time for the establishment of a quasi-stationary concentration of radicals. Calculation shows that, under these conditions, the plot of the logarithm of the lifetime against stress should be curved. This type of relation has been observed experimentally in the study of the thermal mechanical degradation of polypropylene[17].

Fig. 10 compares the experimental data with the results of a computer calculation using the known rate constants for the elementary reactions in the kinetic scheme (17). Not only a qualitative but also a quantitative agreement between calculation and experiment is evident; the break in both relations corresponds to approximately the same applied stresses.

The hypothesis of a radical-chain mechanism of thermal mechanical degradation suggests that inhibitors of free radical reactions, which increase the stability of the polymer on thermal degradation, should also increase its lifetime on application of a mechanical load. Indeed, when a stable nitroxy-radical, which functions as an acceptor of alkyl radicals, is introduced, the lifetime of nitrocellulose increases significantly (Fig. 11*a*).[18] On the other hand, an increase of the rate of initiation of the ageing process should decrease the lifetime of the polymers. An appreciable decrease of the lifetime of stressed polycarbonate, in which an additional amount of free radicals was produced as a result of the thermal decomposition of the benzoyl peroxide introduced into the polymer or via the photolysis of added iron(III) chloride, has been observed[79] (Fig. 11*b*).

For low stresses, the main source of radicals is the decomposition of initiators; the lifetime of the polymer in their presence decreases greatly and depends only slightly on the applied stress. For large stresses, free radicals are generated mainly as a result of the mechanical degradation of macromolecules, so that the lifetime of the polymer hardly changes after the introduction of additives.



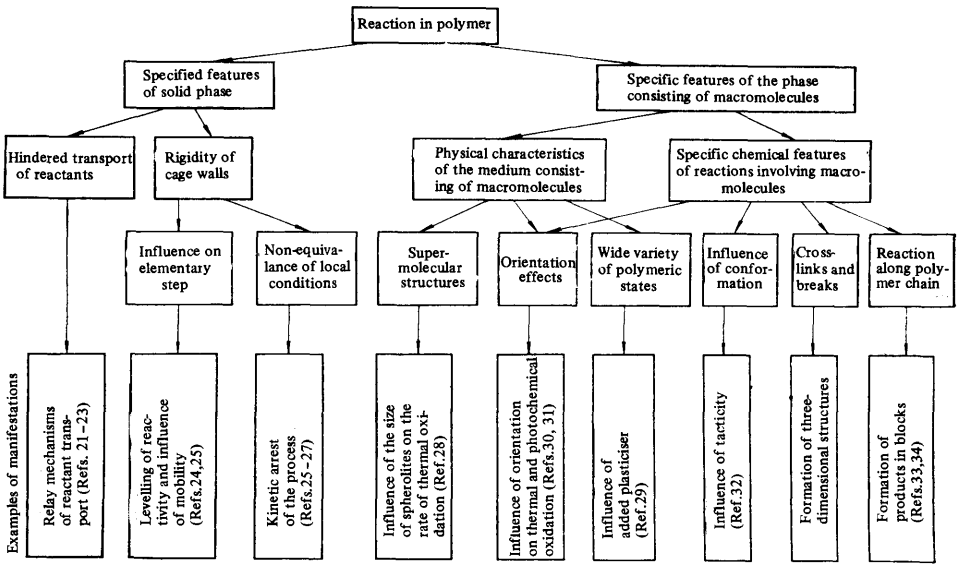


Figure 11. Variation of the lifetime of the polymer as a result of the introduction of inhibitors (*a*) and initiators (*b*) of radical reactions: *a*) nitrocellulose [1) pure; 2) with added 0.3% of 4-ethyl-4-hydroxy-2,2,6,6-tetramethylpiperidin-1-yloxy-radical]; *b*) polycarbonate [1) and 2) pure; 3) with added 0.34% $FeCl_3$ under the influence of the light from a mercury lamp; 4) with added 0.5% of phenyl peroxide; 2) and 3) 20°C; 1) and 4) 70°C].

The internal stresses arising the specimen, for example, during its hardening, can also alter the rate of ageing of the polymer. For example, cross-linked polyester-urethanes, obtained at 30°C, decomposes with an activation energy $E = 21-23$ kcal mole^{-1}, while the specimens synthesised at 60°C decompose much more slowly with $E = 46-50$ kcal mole^{-1}. It has been shown that this difference is associated with the competition between the urethane formation reaction and the relaxation of the internal stresses in the specimen as a result of conformational transitions[20]. At low temperatures there is insufficient time for the occurrence of the conformational transitions during synthesis, so that a polymer with strained bonds is formed, which facilitates its thermal degradation. At elevated temperatures there is sufficient time for relaxation processes during the synthesis of cross-linked polyurethanes, the number of strained bonds formed is very small, and the resulting polymer has a higher thermal stability.

III. CHARACTERISTICS OF THE CHEMICAL REACTIONS IN THE POLYMER MATRIX

As a subdivision of the chemistry of the solid state, the field of the ageing and stabilisation of polymers deals with the study of complex coupled radical-chain, ionic, and molecular reactions under the conditions of polymer matrices involving in the chemical process the very polymer molecules forming the matrix. Table 4 illustrates the principal features of the chemical reactions in the polymer matrix (PM). They have distinctive features as both solid-phase reactions and reactions of high-molecular-weight compounds.

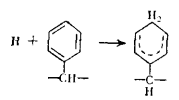
Table 4. Characteristics of the chemical reaction in the polymer matrix.

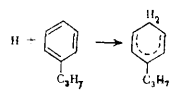
As in any solid-phase process, the kinetics of the reactions in the polymer matrix are influenced significantly by the transport of reactants and the stability of the cell walls surrounding the reactive centres. The first factor is particularly important in cases where the reactive centre is localised on a macromolecule. The diffusion of such centres is hindered and complex models, including many macromolecules or intermediate labile centres—the so-called models of the relay migration of the active centre—have been considered to explain processes with participation of such centres[21-23].

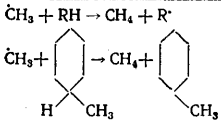
The stability of the cage environment of the active centre leads to two qualitatively different effects. On the one hand, the contact time between the reactants which have entered a single cage is much greater than in the liquid phase, which can reduce many types of steric hindrance and can lead to an appreciable degree of levelling of the reactivities of the species in the solid phase compared with the liquid phase[24,25]. On the other hand, the polymeric material usually contains defects, many of the formations in which can exist for a fairly long time. As a result of the wide variety of these defects, the occurrence of elementary chemical reactions under kinetically non-equivalent conditions is typical for a polymer matrix. This is manifested by the kinetic arrest of certain chemical reactions under conditions where the reactants have still not been exhausted[25,26] and also by the obligatory occurrence of certain photochemical processes which cannot be inhibited despite the virtually complete quenching of the luminescence of the excited species propagating the process[27].

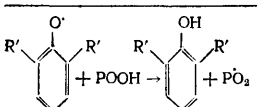
The polymer matrix cannot be regarded as a normal solid matrix. The polymeric material has as a rule a complex structure, because it is possible to distinguish in it a number of regions differing in the degree of order in the arrangement of the polymer chains and hence in the chemical reactivity. The most ordered regions, with a structure close to that of an ideal crystal, are characterised by the minimum free energy and close packing of the polymer chains and have a comparatively low reactivity. Crystalline regions with different structural defects, for example, dislocations, can exhibit a greater permeability with respect to small molecules and a somewhat higher reactivity. Finally, the least ordered amorphous regions are characterised by a low chain packing density, an increased concentration of impurities, and the maximum reactivity.

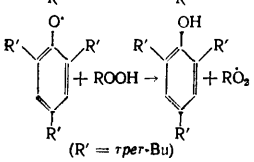
Because of this, the ageing of a polymeric material is influenced by its supermolecular structure[28]. Small amounts of added plasticiser alter the structure of the polymer matrix and change sharply the rate constant for the processes occurring in it[29]. Orientation effects, which result in a change of the physicomechanical properties of the polymeric material and of the rate and direction of the chemical reaction, are characteristic of the polymer matrix[30,31]. In the course of the ageing of the polymeric material, degradation processes and cross-linking reactions of the macromolecules, which are characteristic of high-molecular-weight compounds only and which lead to a change of the molecular weight distribution and sometimes to the formation of cross-linked three-dimensional structures, take place in the polymeric material in the course of its ageing.

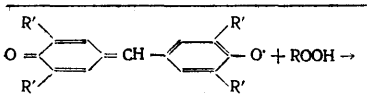


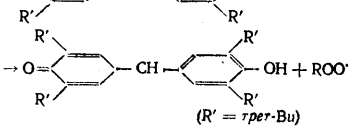


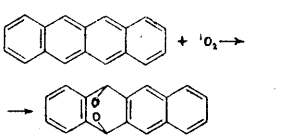


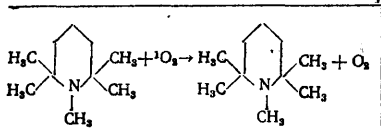












The kinetics of reactions in which high-molecular-weight compounds participate are influenced also by the conformations of the latter[32]. Furthermore, there are data indicating the development of the reaction along the polymer chain, which leads to the formation of reaction products in blocks, in the form of long sequences along the macromolecular chain[33,34].

1. The Influence of the Molecular Mobility of the Polymer Matrix on the Rate Constants for the Elementary Reactions Occurring in It

The dynamics of the molecular movements of the polymer exerts a significant influence on the kinetics of chemical reactions. This is caused by the change in the translational diffusion coefficients of the low-molecular-weight

reactants and the frequencies and amplitudes of segmental movements of the macromolecules and macroradicals, resulting in a change of the frequency of encounters of the reacting species. Furthermore, the molecular mobility of the medium influences directly the elementary step of the chemical reaction.

Table 5. The rate constants for chemical reactions in solid polymers and in the liquid phase.

Reaction	Polymer or solvent	t, °C	k, litre mole^{-1} s^{-1}	Refs.
	polystyrene	25	$1\cdot10^{4}$	35
	n-heptane	23	$3.3\cdot10^{8}$	36
$\dot{C}H_3 + RH \rightarrow CH_4 + R^{\cdot}$	polypropylene	100	0.2	37
	n-heptane	100	$3.8\cdot10^{3}$	36
	polypropylene	25	$4.5\cdot10^{-3}$	38
 (R′ = *tper*-Bu)	benzene	25	0.11	39
	polypropylene	25	$3.0\cdot10^{-5}$	14
 (R′ = *tper*-Bu)	benzene	25	$5.6\cdot10^{-4}$	
	polystyrene	20	$2.0\cdot10^{5}$	40
	methylene chloride	20	$1.8\cdot10^{7}$	
	polystyrene	20	$1.0\cdot10^{6}$	41
	methylene chloride	20	$5.4\cdot10^{7}$	

The rate constants for a number of bimolecular reactions in solid polymers are significantly lower than in the liquid phase. Certain examples of this kind are listed in Table 5. The decrease of the rate constants on passing to solid polymers is not associated solely with diffusion-dependent obstacles. The rate constants for the encounters between the reactants, estimated from the diffusion coefficients of the low-molecular-weight substances, exceed by several orders of magnitude the experimental rate constants for the reactions, i.e. these reactions are not diffusion-controlled.

The molecular mobility of the medium is known to influence the kinetics of the destruction of macroradicals in solid polymers which entails a decrease of the rate of destruction on passing from the amorphous to the crystalline phase [41-43], a decrease of the rate constant for destruction in oriented specimens compared with non-oriented specimens [44,45], an increase of the stability of the macroradicals on cross-linking of the polymer [46,47], an increase of the rate of destruction of macroradicals in three-dimensional polymers with the increase of the length of the oligomeric block [48], etc.

Molecular mobility can be varied in a controlled manner by changing the external pressure and by introducing chemically inert solvents into the polymer (plasticisation).

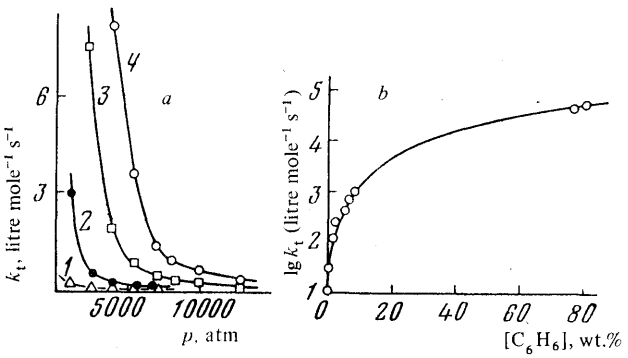


Figure 12. The influence of pressure (*a*) and plasticisation (*b*) on the rate constants for the destruction of free radicals in the polymer: *a*) poly(methyl metacrylate) [temperature (°C): 1) 80; 2) 100; 3) 120; 4) 130]; *b*) polystyrene with benzene as plasticising agent; $T = -10$°C.

In amorphous polymers at temperatures above T_g the radical recombination rate constants k_t decrease with increasing pressure p (Fig. 12*a*) [49-52]. At temperatures below T_g the influence of pressure on k_t is comparatively small. The strongest effect is observed for low values of p; at a pressure higher than a critical value p_{cr} the constant k_t depends only slightly on p. For $p < p_{cr}$, the dependence of k_t on p is described by the relation [53]:

$$k_t = k_t^0 \exp\left(-\frac{E + pV^*}{RT}\right), \qquad (19)$$

where V^* is the activation volume; here E sometimes changes to p. Pressure apparently influences the kinetics of the destruction of the macroradicals by altering the molecular mobility of the medium. With increase of

pressure, there is an increase of the density of the polymer and a decrease of the intensity of molecular movements, which is manifested, for example, by an increase of T_g, a decrease of the free volume and the melting point of the polymer, etc.

Eqn. (19) shows that an increase of p affects k_t in the same way as a decrease of temperature. The glass point is apparently attained at $p = p_{cr}$.

The plasticisation of the polymers has a significant influence on the kinetics of the destruction of macroradicals. The destruction of peroxy-radicals in polystyrene[23] (Fig. 12*b*) and polypropylene[54,55] is accelerated by small amounts of added chemically inert solvents. The accelerating effect can be explained only by the increase of molecular mobility in the polymer.

According to Roginskii and Miller[55], the variation of k_6 in solid polypropylene in the presence of *o*-dichlorobenzene is correlated with the frequency of the rotation of the paramagnetic probe characterising the mobility. Plasticisation of the polymer also leads to an increase of the liberation of radicals from the cage on decomposition of the initiator[14,55,56] and to an increase of the rate of chain oxidation of polypropylene[55].

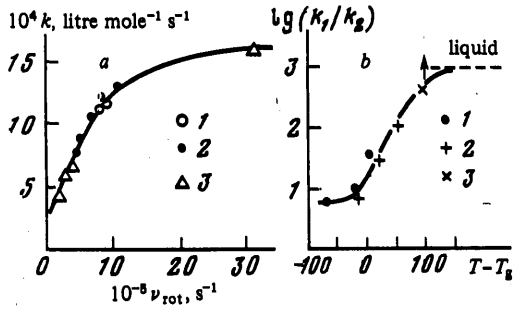

Figure 13. Relation between the rate constants for chemical reactions and the molecular mobility of the medium: *a*) rate constant for the reaction of 4-benzyloxy-2,2,6,6-tetramethylpiperidinyloxy-radical with 4,6-di-t-butyl phenol in various polymeric matrices plasticised with benzene (60°C) [1) polyethylene; 2) polypropylene; 3) polystyrene]; *b*) the ratio of the rate constants for the quenching of singlet oxygen by nickel dibutyldithiocarbamate and nickel ortho-ethoxy-(3,5-di-t-butyl-4-hydroxybenzyl)phosphonate [*O*-ethyl 3,5-di-t-butyl-4-hydroxybenzylphosphonate?] at different temperatures in different polymer matrices: 1) polystyrene; 2) BMK-5 copolymer; 3) polybutadiene.

The influence of molecular mobility on the reactions of phenoxy-radicals with the hydroperoxides of polyolefins[14,38] and of nitroxy-radicals with phenols in solid polyolefins has also been considered. The rates of these reactions are independent of the nature of the polymer and increase following the addition of aromatic solvents, whose role reduces to an increase of molecular mobility. Here the increase of the rate constant is correlated with the increase of the frequency of rotation of the paramagnetic probe[38,57] (Fig. 13*a*). Another phenomenon characteristic of the solid polymer matrix, the levelling of reactivity compared with the liquid phase for a series of compounds undergoing the same reaction, is also associated with the decrease of the molecular mobility of the medium in the polymer matrix.

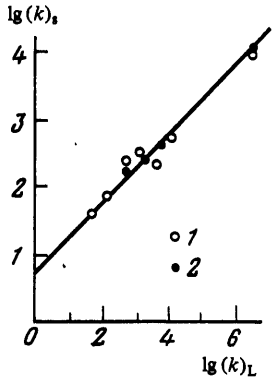

Figure 14. Logarithmic form of the dependence of the efficiency of the quenching of singlet oxygen by a number of quenching agents at different classes in polystyrene (1) and the butyl methacrylate–methacrylic acid copolymer (2) on the efficiency of the quenching by the same agents in liquid solution.

The levelling phenomenon was first observed for the reaction of a number of antioxidants with free radicals in solid polymers[24]. An analogous effect has been observed in processes with participation of singlet oxygen $^1O_2$.[40] Fig. 14 illustrates the logarithmic form of the relation between the efficiency of the quenching of $^1O_2$ by a number of quenching agents of different chemical types in a solid polymer on the efficiency of the same compounds in a liquid solution for two different polymer matrices (polystyrene and the butyl methacrylate–methacrylic acid copolymer). Evidently the range of differences between the efficiencies for the given series of quenching agents is over five orders of magnitude in the liquid phase and less than three orders of magnitude in the solid phase.

The relation between the observed phenomenon and the molecular mobility of the medium is demonstrated in Fig. 13*b*.[58] The degree of levelling presented in the figure is defined as the ratio of the quenching constants for two quenching agents with different efficiencies. The difference between the experimental temperature and the glass point of the matrix is a measure of the molecular mobility of the medium. Evidently the data obtained for different polymer matrices fit the same relation despite the fact that their absolute glass points differ by hundreds of degrees. The levelling of reactivity is apparently determined solely by the mobility of the medium and is independent of the chemical nature of the polymer.

The levelling phenomenon can be explained quantitatively by a change in the nature of the movement of a pair of reacting species in the solid matrix compared with the liquid phase[59]. It has been found that, for isotypical reactions, whose rate is limited by steric hindrance, the relative reactivities of the species in the solid polymer

(k_S) and in the liquid phase (k_L) are linked by the relation

$$\frac{(k_1)_S}{(k_2)_S} = \sqrt{\frac{(k_1)_L}{(k_2)_L}}. \quad (20)$$

Eqn. (20) is of considerable practical importance, since it is possible to select with its aid various stabilisers for polymeric materials (antioxidants and quenching agents) on the basis of much less laborious experiments, carried out in model liquid-phase systems.

2. The Influence of the Molecular Mobility of the Medium on the Kinetics of Reactions in Polymers

The equivalence of the local properties of the environment of the reactive centres and hence the sterically different activities of these centres is characteristic of polymers as structurally inhomogeneous systems. Chemical reactions occur in the first place in those regions where the conditions are most favourable. As a result, the concentration of active centres in these regions diminishes and there is a corresponding decrease of the effective rate constant for the reaction averaged with respect to the entire specimen. Different kinds of relaxation processes, which alter the local conditions around the reactive centres causing the migration of these centres to regions favouring chemical reaction, act in the opposite direction.

We shall introduce the concept of characteristic times of processes occurring in the polymer matrix. The chemical reaction time τ_{chem} can be characterised by a quantity which is the reciprocal of the rate of change of the relative concentration of the reactants (c/c_0):

$$\tau_{chem} = \left(\frac{d(c/c_0)}{dt}\right)^{-1}. \quad (21)$$

The duration of relaxation processes τ_c, which restore the equilibrium distribution of the local properties around the reaction centres disturbed by the chemical process, can be characterised by the correlation time of the reacting species with respect to all local properties of the medium which determine the reactivity of these species. If

$$\tau_{chem} \gg \tau_c, \quad (22)$$

the relaxation processes are so fast that the chemical reaction virtually does not alter the equilibrium distribution of the reactants and any reacting species has average properties throughout the entire process. Consequently the process as a whole will be described by a single average rate constant, as in classical liquid- or gas-phase kinetics. If condition (22) is not fulfilled, the reacting species will exist under non-equivalent conditions during the chemical process and the effective rate constant for the chemical reaction will gradually decrease.

The rate of change of the macroscopic concentration of the reacting substances is described by an integrodifferential equation which assumes the following form for the simplest unimolecular reaction:

$$\frac{d[A]}{dt} = -\int k(u) A(u) du, \quad (23)$$

where $k(u)$ is the rate constant for the chemical reaction and the local conditions characterised by the parameter u; the form of the function $k(u)$ is independent of time, since it determines the relation between the probability of the chemical reaction and the local properties of the medium; $A(u)$, the density of the distribution of the concentration of substance A with respect to the parameter u, varies in time owing to both the chemical reaction of substance A, described by Eqn. (23), and the relaxation and diffusion processes which alter the local properties of the medium around the reaction centre.

Eqn. (23) is converted into the classical expression when the local properties of the medium do not influence the probability of the chemical reaction:

$$k(u) = K^0 = \text{const} \quad (24)$$

or if the function $A(u)$ can be represented by the product of the concentration of substance A and the time-invariant characteristic form of the distribution of the local properties of the medium $\rho(u)$, i.e. if

$$A(u) = [A]\,\rho(u). \quad (25)$$

In such cases the rate of decrease of the macroscopic concentration of substance A is described, as in the liquid or gas phase, by the exponential relation

$$[A] = [A]_0 e^{-k_0 t} \quad (26)$$

or

$$[A] = [A]_0 e^{-\int k(u)\rho(u)du \cdot t}.$$

In all remaining cases the process inhibition is greater.

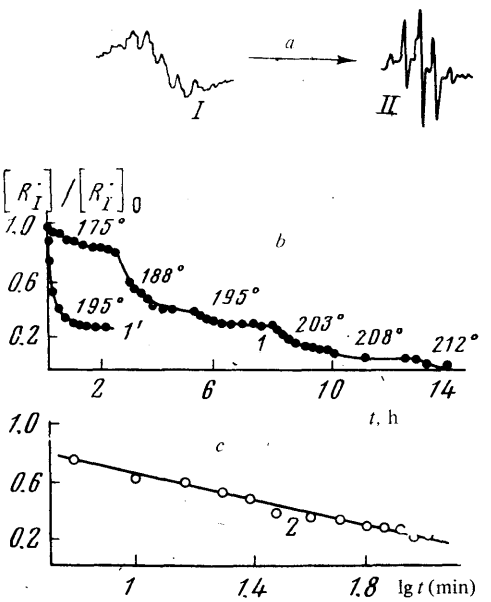

Figure 15. *a*) EPR spectrum of polymethacrylic acid (PMAA) macroradicals with the free valence localised at a tertiary carbon atom of the main chain (I) and of the terminal macroradicals (II) formed as a result of the thermal decomposition of the radicals (I); *b*) kinetic curves (curves *1* and *1'*) for the thermal decomposition of radicals (I) in PMAA in the temperature range 175–212 K; 2) a modification of the kinetic curve *1'* obtained by plotting $[\dot{R}_I]/[R_I]_0$ against lg*t* at 195 K.

Such inhibition is fairly common in chemical processes occurring in polymer matrices at temperatures below the glass point under conditions such that the molecular mobility of the medium is low. For a comparatively low degree of conversion, the reaction is inhibited but does not come to a complete stop. The inverse semilogarithmic $A/A_0 - \lg t$ form of the kinetic curve for the variation of the concentrations of the reactants is usually a straight line up to high degrees of conversion of the substance (Fig. 15)[66].

The phenomenon of such kinetic arrest of the reaction has now been observed in many processes in solid polymers: the destruction of the radicals involved in radical pairs[60], the oxidation of radicals[61], postpolymerisation[62], inhibited oxidation[63], oxidation by singlet oxygen[64], thermal isomerisation and photoisomerisation[65], decomposition of macroradicals with chain rupture[66], and dark cyclisation of spiropyrans[67]. These results can usually be described on the basis of the idea that, throughout the process, the reacting species are as it were frozen under different, but constant during the entire process, local conditions, i.e. $\tau_{chem} \ll \tau_C$. The equations of classical kinetics are then applicable only to species under identical conditions, i.e. for a distribution density $A(u)$. The inverse semilogarithmic plot is linear if it is assumed that the initial distribution $A(u)$ with respect to the free energy of activation for the process $\Delta G = E_a + IS$ is rectangular:

$$(A(u))_{t=0} = 1/S_0 \text{ when } 0 < u < S_0;$$
$$(A(u))_{t=0} = 0 \quad \text{when} \quad 0 > u > S_0. \qquad (27)$$

The solution of Eqn. (23) can then be written as follows:

$$[A] = -\frac{[A]_0}{S}\left[\ln(1.76k_0) - S_0 + \ln t - \frac{E_a}{RT}\right]. \qquad (28)$$

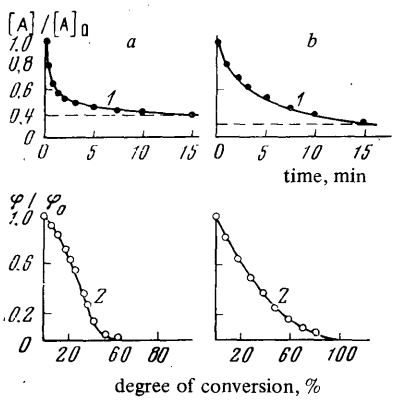

Figure 16. The photochemical reaction (λ = 365 nm) of anthracene in poly(methyl methacrylate): *a*) vacuum; *b*) air; 1) process kinetics; 2) dependence of the quantum yield on the degree of conversion of anthracene.

It has been shown that the semilogarithmic plot should remain linear for a rectangular distribution and for any law governing the consumption of A for reaction orders between first and third[68]. The change in the order of the reaction involving the consumption of A alters only the coefficient of the pre-exponential factor k_0 in Eqn. (28).

A characteristic feature of the kinetics of reactions in a solid polymer, the "stepwise" kinetics involving a kinetic arrest, can be used to regulate the corresponding processes. By changing the conditions, the temperature, and the viscosity, it is possible to accelerate greatly the inhibited process. On the other hand, without allowing the conditions to be altered, it is possible to avoid undesirable ageing reactions.

The decrease of the effective rate constant for the chemical reaction in the polymer matrix gives rise to the possibility of the "kinetic stabilisation" of substances fulfilling various functions in the polymeric material. For this purpose, one introduces into the polymer the substance at a concentration greater than necessary and the part of the substance under conditions favourable for chemical reaction is decomposed. The remaining additive is preserved by virtue of the kinetic arrest of reactions in polymers.

Anisimov[69] introduced anthracene into poly(methyl methacrylate) (PMMA) and illuminated the specimen with light at λ = 365 nm. Part of the anthracene was consumed as a result of the photochemical reaction; the remainder was as it were stabilised in the polymer (Fig. 16).

Hydrocarbons with condensed rings, of which anthracene is a representative, are widely used as luminescent labels for the recording of information, i.e. as photochromic materials. The kinetic stabilisation of these compounds in a polymer matrix is therefore of practical importance.

IV. QUANTITATIVE CHARACTERISTICS OF THE ELEMENTARY STAGES OF THE AGEING PROCESS

During recent years, apart from the study of the kinetics of the overall ageing process, numerous measurements have been made of the rate constants for the individual elementary stages of the complex process. The methods of their measurement in solid polymers do not differ in principle from those used in the liquid phase. The data obtained refer mainly to the thermal oxidation of polymers.

The rate of initiation w_i was measured with the aid of different versions of the method of inhibitors[63,70,71], based on the determination of the rate of consumption of a radical acceptor (X) taken at a concentration sufficient to cause the termination of all the oxidation chains. The independence of the rate of consumption of the acceptor of its concentration is an experimental criterion of the fulfilment of this condition:

$$w_i = n\frac{d[X]}{dt},$$

where n is the number of chains terminated by one acceptor molecule. Phenolic and amine inhibitors as well as stable radicals, mainly nitroxy-radicals, have been used as acceptors.

A method based on the determination of the induction period of the inhibited oxidation is also employed[72]. Some of the rate constants for the initiation of the reactions in solid polymeric media are listed in Table 6.

The parameters $k_p/\sqrt{k_t}$, which is the ratio of the rate constants for the chain propagation reaction (k_p) and the square root of the rate constant for the chain termination reaction (k_t) and characterises the oxidisability of the

polymer, is determined from the rate of the chain initiation of the oxidation process (w_i = const.); one can use as initiators not only specially added low-molecular-weight substances but also a "natural initiator"—a polymer hydroperoxide [10].

Table 6. The rate constants for initiation (k_i) in the decomposition of radical initiators in solid polymers.

Initiator*	Polymer	k_i, s^{-1}	References
AIBN	polypropylene	$5.1\cdot10^{17}$ exp (—37 000/*RT*)	70
AIBN	polystyrene	$8.4\cdot10^{13}$ exp (—30 800/*RT*)	63
CPC	polystyrene	$4.6\cdot10^{14}$ exp (—29 600/*RT*)	63
Benzoyl peroxide	polybut-1-ene	$1.5\cdot10^{-6}$ (80° C)	73
Cumenyl peroxide	polyethylene	$1.4\cdot10^{-6}$ (115° C)	74
Butyryl peroxide	polystyrene	$1.3\cdot10^{-7}$ (80° C)	75
Polymeric hydroperoxide	polypropylene	$1.0\cdot10^{13}$ exp (—30 500/*RT*)	70
Polymeric hydroperoxide	polyethylene	$1.6\cdot10^{14}$ exp (—35 000/*RT*)	76
2-t-Butylperoxy-2,4,6-tri-t-butylcyclohexa-3,5-dienone	polyprolyene	$4.5\cdot10^{16}$ exp (—35 500/*RT*)	77

*Notation: AIBN = azobisisobutyronitrile; CPC = cyclohexyl peroxydicarbonate.

Table 7. The chain propagation (k_p) and termination (k_t) rate constants in the oxidation of solid polymers.

Polymer	*t*, °C	$k_p/\sqrt{k_t}$, $kg^{1/2}\ mole^{-1/2}\ s^{-1/2}$	k_t, kg mole^{-1} s^{-1}	k_p, kg mole^{-1} s^{-1}
Polypropylene (atactic)	80	$1.8\cdot10^{-3}$ [79]	$1.2\cdot10^{3}$ [79]	0.055 [79]
Polypropylene (isotactic)	80	$8.1\cdot10^{-4}$ [70]	$3.5\cdot10^{3}$ [55]	0.1 [70]
Polyethylene	80	$4\cdot10^{-5}$ [60]	$4.8\cdot10^{4}$ [81]	$7.7\cdot10^{-3}$ *
Polybut-1-ene	80	$6.5\cdot10^{-4}$ [73]	—	—
Poly-4-methylpent-1-ene	80	$4\cdot10^{-4}$ [73]	—	—
Polystyrene	20	—	7.7 [61]	$0.7\div3\cdot10^{-4}$ ** [61]
Poly(methyl methacrylate)	20	—	0.5 [22]	$8\cdot10^{-4}\div8\cdot10^{-6}$ ** [69]

*Calculated from the data of Shilov and Denisov [80] and Davis et al. [81].
**Values obtained from data for the "stepwise" kinetics of the transformation $R\dot{O}_2 \rightarrow \dot{R}$ in an inert atmosphere.

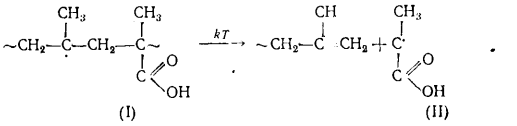
The rate of absorption of oxygen W is related as follows to w_i and $k_p/\sqrt{k_t}$:

$$W = (k_p/\sqrt{k_t})\,[RH]\,\sqrt{w_i} + mw_i,$$

where m is the number of oxygen molecules absorbed in the oxidation chain initiation and termination steps.

The absolute rate constant for chain termination is determined either from the absolute concentration of peroxy-radicals in the initiated process [78,79]

$$k_t = \frac{w_i}{[\dot{RO}_2]^2},$$



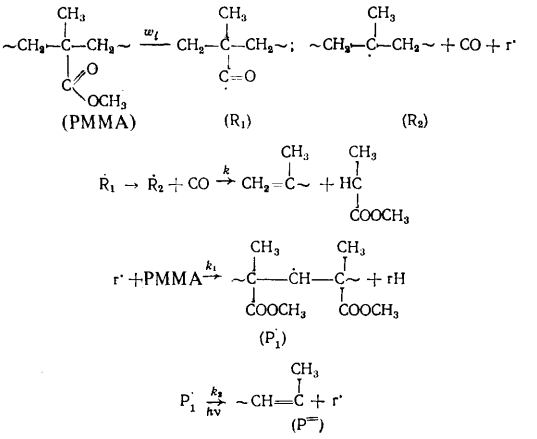
or by fitting an expression to the rate of destruction of radicals after brief exposure to light [54]:

$$\frac{[\dot{RO}_2]_0}{[\dot{RO}_2]} = 1 + k_t\,[\dot{RO}_2]_0\,t.$$

The latter method does not require a preliminary determination of w_i and the kinetic law governing the destruction of the radicals is established directly in the experiment. Table 7 lists the rate constants and the kinetic parameters $k_p/\sqrt{k_t}$ determined by these methods.

Together with the determination of the rate constants for the main stages of the chain thermal oxidation process, the detailed mechanism of the reactions of many macroradicals propagating the ageing process has now been investigated. It has been shown by EPR that the macroradicals of poly(methacrylic acid), generated at 77 K and having the free valence located at a tertiary carbon atom of the main chain as in (I) (Fig. 15*a*), are converted, on raising the temperature, into terminal radicals stable at room temperature, which are formed on thermal decomposition of (I).

The rate constants for the decomposition of the macroradicals of poly(methacrylic acid) with rupture of the main macromolecular chain were measured for the first time by Davydov et al. [66]:



(I) (II)

Above 212 K, this process is described by a first order equation with rate constants defined by expressions of the type

$$k = 10^{13\pm1}e^{-16500/RT}\ (s^{-1}).$$

On the other hand, at lower temperatures the molecular mobility in poly(methacrylic acid) decreases and, on converting radicals (I) into radicals (II), the reaction undergoes a kinetic arrest (Fig. 15), which can be interpreted qualitatively on the assumption of a rectangular distribution of the rate constants for the decomposition of radicals (I) with respect to activation energies, which has the parameters E_{min} = 13 kcal mole^{-1}, E_{max} = 16.1 kcal mole^{-1}, and $\lg k_0\,(s^{-1}) = 13.7$.

The free radical mechanism of the photolysis and thermally initiated and photoinitiated conversion of PMMA has been investigated at temperatures below 50 °C [82–85] where depolymerisation virtually does not occur. Six macroradicals were identified and the mechanism of their thermal reaction and photoreaction was investigated:

(PMMA) (R_1) (R_2)

(P_1)

($P^{=}$)

$$r^{\cdot} + P^{=} \rightarrow \sim\overset{\overset{H}{|}}{C}-\overset{\overset{r}{|}}{C}-CH_3 \quad (P_2^{\cdot})$$

$$P_2^{\cdot} + P^{=} \xrightarrow{k_4} P_{2(1)}^{\cdot}$$

. . . . . .

$$P_{2(i)}^{\cdot} + P^{=} \rightarrow P_2^{\cdot}(i+1)$$

$$P_{2(i+1)}^{\cdot} \xrightarrow[h\nu]{k_5} P^{=} + r$$

$$r^{\cdot} \xrightarrow{k_6} \text{destruction.}$$

Here $P^{=}$ is a polymer molecule containing a double bond, $P_{2(i)}$ is a polymer radical containing i double bonds, and $r^{\cdot}$ is a low-molecular-weight radical.

The calculation of the rate of accumulation of C=C bonds based on this scheme agrees with the empirical equation

$$[P^{=}] = [P^{=}]_{\infty}(1 - e^{-w_0 t/[P^{=}]_{\infty}}),$$

where $[P^{=}]_{\infty} = 1.6$ M and w_0 is the initial rate of formation of C=C bonds and of consumption of ester groups. All the free radicals were recorded by EPR and the regions of their thermal and photochemical stability were investigated.

V. CERTAIN NEW METHODS FOR THE INVESTIGATION OF FREE RADICALS

The wide-scale application of EPR in the chemical physics of polymers is in most cases limited by the difficulties associated with the elucidation of the complex EPR spectra of real polymer specimens. Although modern quantum chemistry and the use of computers make it possible to obtain information from the analysis of EPR signals, in the case of specially complex signals or spectra consisting of a superposition of signals due to different chemical centres, the methods of theoretical analysis are relatively ineffective [86].

The EPR signals of the vast majority of organic free radicals have virtually the same g-factor in the region $g_0 \simeq 2$, by differing $\Delta g \simeq 10^{-4}-10^{-5}$. The distance between the centres of such signals in units of the magnetic field $\delta H \simeq \Delta g H_0/g_0$ is approximately 1 G in the usual EPR spectrometers ($H_0 \simeq 3 \times 10^3$ G; 3 cm range). On the other hand, the intrinsic line width of organic radicals in polymers is not less than 3–10 G, so that the signals are usually superimposed.

Submillimetre EPR spectroscopy was used recently for the first time to investigate free radicals [87]. The magnetic field strength in such a spectrometer reaches 50 000 G (2 mm range). The distance between the signals of organic radicals is then found to be 10–20 G (on average 15 times greater than in the usual microwave spectrometer) and it is possible to record and analyse the spectra of individual radicals.

Fig. 17 presents the EPR spectra of macroradicals in polytetrafluoroethylene γ-irradiated in the presence of oxygen and then kept in the light [88]. It is evident that, in contrast to the EPR spectrum belonging to the usual 3 cm range, which contains relatively little information, the spectrum in the 2 mm range makes it possible to distinguish terminal alkyl, allyl, and terminal peroxy-radicals. Fig. 17*b* shows that the new method makes it possible to distinguish even terminal and central peroxy-radicals.

Thus there is a unique possibility of investigating the kinetics of complex free radical processes involving several kinds of free radicals.

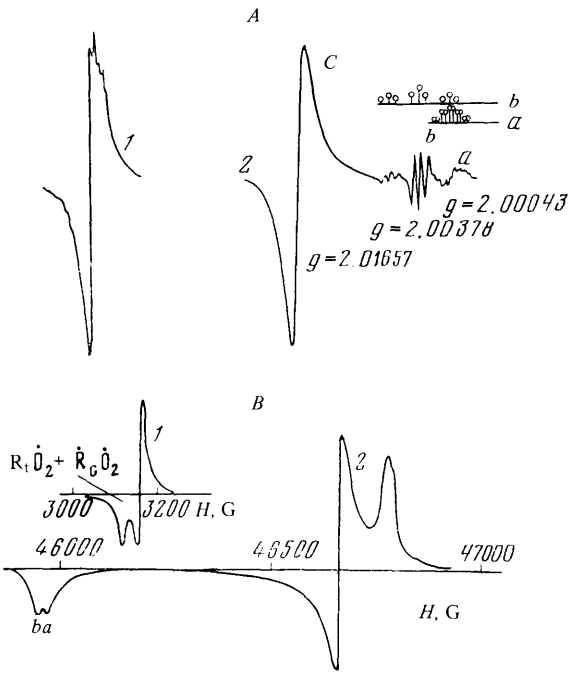


Figure 17. Comparison of the EPR spectra of polytetrafluoroethylene radicals obtained with the aid of 3 cm (curve *1*) and 2 mm (curve *2*) microwave spectrometers: *A*) allyl radicals (*a*), alkyl radicals (*b*), and peroxy-radicals (*c*); *B*) central R_cO_2 radical (a) and terminal R_tO_2 radical (b).

Under the real conditions in the ageing of polymers, the concentrations of the free radicals formed in the latter are too low to be detected by EPR. The application of the spin-trapping method is therefore apparently promising in this connection. The method has been used successfully in recent times for the investigation of radical processes in the liquid phase [89–91].

The principal idea of the spin trapping method consists in the conversion of an active short-lived radical $r^{\cdot}$ as a result of its addition to a specially selected acceptor T (spin-trapping agent) into a much more stable radical $rT^{\cdot}$ (the spin adduct):

$$r^{\cdot} + T \xrightarrow{k_1} rT^{\cdot}.$$

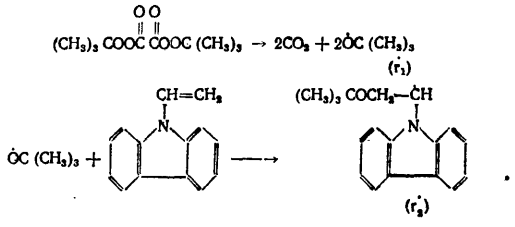
The latter can be accumulated in concentrations sufficient for its detection by EPR. In order to estimate the ratio of the steady-state concentrations of the active radical (in the absence of T) in the spin adduct, we shall consider the simplest kinetic scheme for the transformations of the

radicals in the presence of T:

$$\text{Initiation} \xrightarrow{w_i} r^{\cdot},$$
$$r^{\cdot} + r^{\cdot} \xrightarrow{k_t} \text{products},$$
$$r^{\cdot} + T \xrightarrow{k_1} rT^{\cdot},$$
$$r^{\cdot} + rT^{\cdot} \xrightarrow{k_t'} \text{products},$$
$$rT^{\cdot} + rT^{\cdot} \xrightarrow{k_t''} \text{products}.$$

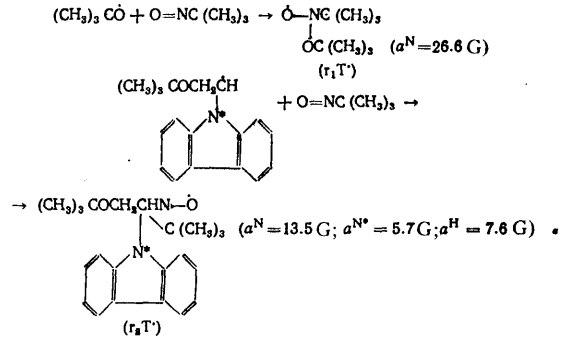
In the absence of the spin-trapping agent the stationary concentration of the active radicals is

$$[r^{\cdot}]_{st} = \sqrt{w_i/k_t}. \quad (29)$$



In the presence of a sufficient concentration of the spin-trapping agent $\{k_1[T] \gg k_t[r^{\cdot}]\}$, in the case where the spin adduct is sufficiently stable $\{k_t''[rT^{\cdot}] \ll k_t[r^{\cdot}]\}$, we have

$$[rT^{\cdot}]_{st} = \frac{k_1}{k_t'}[T]. \quad (30)$$



For low rate of initiation, we usually have $[rT^{\cdot}]_{st} \gg [r^{\cdot}]_{st}$.

The spin-trapping method not only makes it possible to detect free radicals, but, by analysing the EPR spectra of the spin adducts, one can determine the nature of the active radicals r$^{\cdot}$ combined. Various compounds with multiple bonds are used as spin-trapping agents—mainly nitroso-compounds and nitrones as well as thiocarbonyl compounds, nitro-compounds, quinones, acetylene derivatives, nitrile *N*-oxides, etc.

As an example we shall consider the results of the investigation by the spin-trapping method of the mechanism and kinetics of the polymerisation of *N*-vinylcarbazole initiated by di-t-butyl peroxyoxalate[89]:

In the presence of 2-methyl-2-nitrosopropane (T) the active radicals $r_1^{\cdot}$ and $r_2^{\cdot}$ add to the spin-trapping agent and give rise to two types of spin adducts $r_1T^{\cdot}$ and $r_2T^{\cdot}$ with markedly different EPR spectra (Fig. 18):

Analysis of the EPR spectrum of the spin adduct $r_2T^{\cdot}$ indicates the direction of the reaction involving the addition of the initiator radical to the monomer.

VI. RELATION BETWEEN THE CHANGES IN THE PROPERTIES OF POLYMERS OF PRACTICAL IMPORTANCE AND THE KINETICS OF AGEING

On the basis of individual elementary reactions, it is now possible to determine the complete process mechanism and to describe the kinetics of the variation of polymer properties of practical importance under any operating conditions.

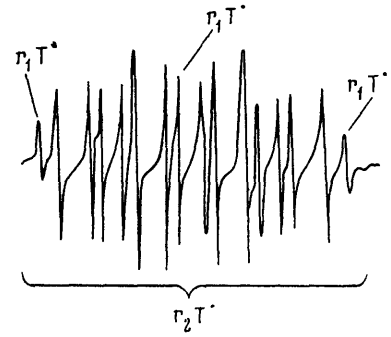


Figure 18. EPR spectrum recorded in the polymerisation of *N*-vinylcarbazole (0.52 M) initiated by di-t-butyl peroxyoxalate (4.3×10^{-2} M) in the presence of 2-methyl-2-nitrosopropane (2.3×10^{-2} M) as the spin-trapping agent; solvent—*p*-xylene; 25 °C.

The mechanism of the photochemical oxidation of polyolefins (ПН) has been investigated in greatest detail[92]. This process is a chain reaction with degenerate photobranching by the hydroperoxide and quadratic chain termination. The mechanism of the photochemical oxidation can be formulated as follows in a general form:

$$\text{ПН} \xrightarrow{h\nu} \rightarrow \text{ПО}_2^{\cdot}$$
$$\text{ПО}_2^{\cdot} + \text{ПН} \xrightarrow[k_p]{O_2} \text{ПООН} + \text{ПО}_2^{\cdot} \text{ — chain propagation},$$
$$\left.\begin{aligned} \text{ПООН} &\xrightarrow{h\nu} \text{ПО}^{\cdot} + {}^{\cdot}\text{ОН} \rightarrow 2\text{ПО}_2^{\cdot} \\ [\text{C=O}] &\xrightarrow{h\nu} f\text{ПО}_2^{\cdot} \end{aligned}\right\} \text{chain branching},$$
$$\text{ПО}_2^{\cdot} + \text{ПО}_2^{\cdot} \xrightarrow{k_t} [\text{C=O}] \text{ — chain termination}.$$

Here [C=O] represents carbonyl compounds, f is the probability of the formation of its free radical in the [C=O]-photochemical decomposition step.

The following system of differential kinetic equations corresponds to this scheme:

$$\left.\begin{aligned} \frac{d[\text{ПО}_2^{\cdot}]}{dt} &= 2\alpha[\text{ПООН}] - k_t[\text{ПО}_2^{\cdot}]^2 + \alpha' f[\text{C=O}]; \\ \frac{d[\text{ПООН}]}{dt} &= k_p[\text{ПН}][\text{ПО}_2^{\cdot}] - \alpha[\text{ПООН}]; \\ \frac{d[\text{C=O}]}{dt} &= \alpha[\text{ПООН}] - \alpha'[\text{C=O}] + \frac{k_t}{2}[\text{ПО}_2^{\cdot}]^2, \end{aligned}\right\} \quad (31)$$

where α and α' are the probabilities of the photochemical decomposition of the hydroperoxide and carbonyl compounds, which are defined by the following relation for thin

specimens:

$$\alpha = \int \varphi\varepsilon(\lambda) I(\lambda)\, d\lambda; \qquad (32)$$

where $\epsilon(\lambda)$ is the absorption spectrum of the decomposing compound, φ the decomposition quantum yield, and $I(\lambda)$ the spectrum of the radiation incident on the specimen.

In terms of dimensionless coordinates, the system of equations is

$$\left.\begin{aligned}
&\frac{d\rho}{d\tau} = (\pi - 4\rho^2 + k_2 fK)\, k_1;\\
&\frac{d\pi}{d\tau} = \rho - \pi/2;\\
&\frac{dK}{d\tau} = 2\rho^2 - k_2 K + \frac{\pi}{2};\\
&\rho = k_t [\Pi O_2^\cdot]/4k_p [\Pi H];\ \pi = [\Pi OOH]/[\Pi OOH]_\infty;\ K = [C{=}O]/[\Pi OOH]_\infty;\\
&k_1 = k_p [\Pi H]/2\alpha;\ k_2 = \alpha'/2\alpha;\ \tau = 2\alpha t;\\
&[\Pi OOH]_\infty = 2k_p^2 [\Pi H]^2/k_t\alpha.
\end{aligned}\right\} \qquad (33)$$

It follows from Eqns. (33) that, under quasi-stationary conditions with respect to $[\Pi O_2^\cdot]$, for different light intensities, and for the same spectral composition, the process kinetics should be described by a single relation in terms of the variables $[C{=}O]/[\Pi OOH]_\infty$ and αt. Fig. 19 illustrates the logarithmic form of this relation calculated using the rate constants for the elementary reactions determined independently. The experimental data fit satisfactorily on the calculated curve [93].

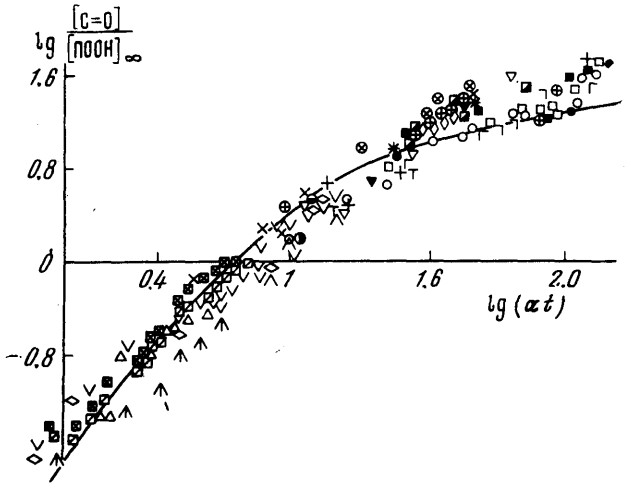

Figure 19. Logarithmic forms of the kinetic curves for the accumulation of carbonyl compounds in the photochemical oxidation of various polypropylene specimens; continuous line—calculation.

When polymeric materials are used in practice, an important factor is not the kinetics of the accumulation of the polymer oxidation products, but the change in characteristics of practical importance, for example, physicomechanical characteristics, the relative elongation on rupture, the tensile strength, etc. These characteristics are not unambiguously related to the composition of the polymer and depend to a large extent on its physical structure. It has been shown for the photochemical oxidation of polypropylene that the change in these characteristics is determined by the kinetics of the chemical reactions occurring in the polymer.

Fig. 20 illustrates the kinetic curves for the variation of the relative elongation on rupture (ϵ, %) in the course of the photochemical oxidation of various polypropylene specimens. Despite the fact that these curves are of different forms, they nevertheless have one feature in common: the change in the relative elongation on photochemical oxidation depends only on the amount of light incident on the polymer and not on its intensity; for high light intensities, the change in the properties takes place less effectively [93]. This is due to the fact that, in the case of quadratic chain termination for low light intensities, the effective oxidation chain length is greater than for high light intensities. Accordingly, at low light intensities there is a high yield of the branching product—the hydroperoxide, as a result of which all the degradation processes per quantum of the incident light take place more effectively.

The relations obtained for different light intensities can be combined into a single one if the number of radicals Ω formed in the polymer during oxidation, and not the amount of light incident on the polymer, is plotted along the abscissa axis (Fig. 2). In conformity with this mechanism, the number of radicals is determined as the sum of the steps involving the photochemical decomposition of the branching products—hydroperoxides and carbonyl compounds:

$$\Omega = \int_0^t (2\alpha [\Pi OOH] + f\alpha' [C{=}O])\, dt. \qquad (34)$$

Sometimes, for example, in the case of oriented polypropylene or polypropylene thermally stabilised by phenols, Ω can be calculated even if the overall kinetic mechanism of the photochemical process is unknown. This makes it possible to describe the kinetics of the change in the mechanical properties of polypropylene when the process mechanism is not completely known.

Thus the dynamics of the change in the physicomechanical properties of the polymer is related to the kinetics of the chemical ageing process and calculations on such dynamics can be performed on the basis of the measurement of its kinetic characteristics.

VII. PRINCIPLES OF THE STABILISATION OF POLYMERIC MATERIALS FROM THE STANDPOINT OF THE MECHANISM OF AGEING

The known methods for the stabilisation of polymeric materials can be divided in accordance with the stage of the ageing process on which they act (Table 3). The simplest procedure involves the mechanism of the action of stabilisers which prevent the initiation of ageing. These are, for example, waxes and coatings which prevent the penetration of chemical agents into the polymer and photoabsorbers—substances which absorb photochemically active light. Such stabilisers act in the surface layer of the polymeric material.

Substances which reduce the probability of the formation of an active centre in the initiation stage constitute a large group of stabilisers. These include agents which quench excited states ("quenchers")—substances which

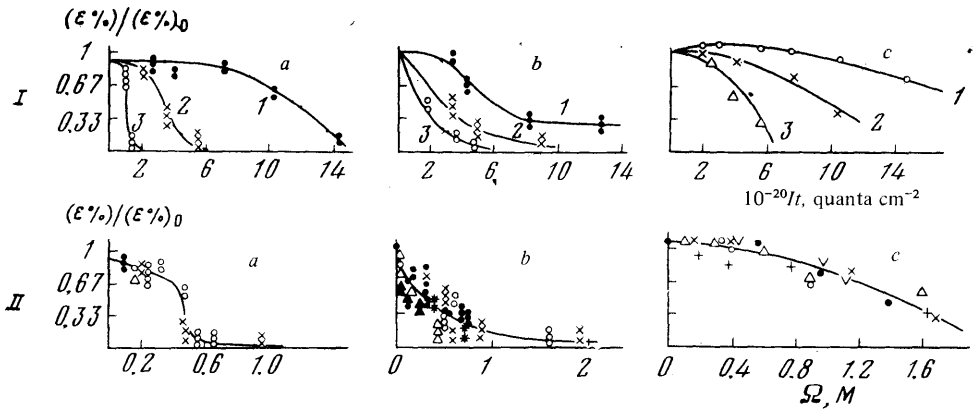

Figure 20. Variation of the relative elongation on rupture (ϵ, %) for polypropylene in the course of its photochemical oxidation: I) dependence on the light It incident on the specimen; II) dependence on the dose Ω of the radicals formed in the specimen in a given period; *a*) isotropic specimen; *b*) oriented annealed specimen; *c*) oriented specimen (950%). Light intensity $\eta = 254$ nm: 1) $\times 10^{15}$ quanta cm^{-2} s^{-1}; 2) 0.7×10^{15} quanta cm^{-2} s^{-1}; 3) 0.24×10^{15} quanta cm^{-2} s^{-1}.

react with various admixtures catalysing the decomposition of polymers. Stabilisers which deactivate chemically active reaction products, for example, substances which decompose hydroperoxides (the branching products of the chain thermal oxidation process) are of particular importance.

Stabilisers which influence the stage involving the development of the ageing process, for example, the oxidation chain propagation stage, include substances which prevent the penetration of oxygen into the polymeric material or reduce its concentration in the material. In the absence of oxygen the chemical composition of the product arising in the chain propagation stage changes, unstable branching products are not formed, and the ageing process is retarded. As an example of such stabilisers, one may quote finely dispersed metals and substances giving rise to them, which are used as stabilisers of thermostable materials [94].

The class of stabilisers which accelerate the stage involving the destruction of active centres, for example, free radical acceptors or inhibitors of free radical process InH are most widely used in practice and have been studied in greatest detail. By interacting with active radicals, they lead to the formation of relatively inactive inhibitor radicals In$^{\cdot}$.

The antiradical activity of such inhibitors (stabilisers) is usually characterised by the rate constant for their interaction with the active radical (k_7). [95] Their efficiency is determined also by the activity of the radical In$^{\cdot}$, which is characterised by the ratio k_{10}/k_p of the rate constants for the reactions

$$RO_2^{\cdot} + RH \xrightarrow{k_p} ROOH + R^{\cdot} \quad ,$$

$$In^{\cdot} + RH \xrightarrow{k_{10}} InH + R^{\cdot} \quad .$$

The lower this ratio the greater the inhibiting effect of the inhibitor.

In the thermal oxidation of polymers the practical efficiency of active radical acceptors is not only determined by the constants k_7 and k_{10} but depends also on the possibility of the additional initiation of the ageing process as a result of the interaction of the radical In$^{\cdot}$ with the hydroperoxide [96] and the decomposition of the quinolide peroxides formed in the reaction of the active radical with the stabiliser radical [97].

The set of these factors is taken into account in a special automated method for testing chemical compounds for their suitability as stabilisers of polymeric materials, which was developed recently in the Sector of the Kinetics of Chemical and Biological Processes of the Institute of Chemical Physics of the USSR Academy of Sciences. The measuring system includes a highly sensitive differential manometric apparatus with continuous recording of the rate of oxidation. At the same time the experimental data are automatically transmitted via a communication link to a BESM-6 computer, where they are interpreted. The mathematical solution of the problem consists of two dialogues incorporating approximately ten programs for the treatment of the data. The investigator controls the treatment directly from the laboratory via a "Videoton-340" display. Both the intermediate and final results of the calculations are displayed on the Videoton screen. The results are presented in the form of Tables and graphs executed with the aid of external devices of the computer. For control and storage, the initial information is coded by means of a Teleprinter on perforated tape. The system is designed for the simultaneous operation of four experimental sets of apparatus.

VIII. A NEW EFFECTIVE METHOD FOR THE STABILISATION OF POLYMERS—A "DEPOT" OF STABILISERS

Many stabilisers cannot be used at the required concentrations for different reasons. For example, certain stabilisers impart an undesirable colour to the polymeric material and thermal stabilisers can prove to be also effective photosensitisers. Free radicals formed from the stabilisers in some cases enter into reactions which promote the decomposition of the polymer. Furthermore, the stabiliser can be consumed in useless side reactions.

It is therefore desirable to create stabilising compositions in such a way that the effective inhibitor acts in accordance with the principle of *in statu nascendi*, i.e. that its main bulk should remain in the bound state, a kind of "depot", and that the active form of the stabiliser is released from the latter gradually or when necessary. A quantitative criterion of the effectiveness of the inhibitor *in statu nascendi* can be found by analysing a simplified kinetic scheme for the action of such inhibitors Z on an initiated chain process:

$\xrightarrow{w_i}$ r· — initiation of active radical;

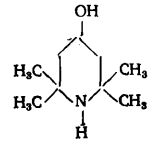
Z $\xrightarrow{k}$ R· — the formation of a "depot" of the active form of the inhibitor R which functions as the stabiliser (for simplicity, a stabiliser in a radical form is considered);

R· + r· $\xrightarrow{k_7}$ — inhibition reaction;

R· $\xrightarrow{k_{10}}$ r· — regeneration of the active radical via a reaction with participation of the inhibitor.

If the concentration of the stabiliser is fairly high and the active centres are destroyed only on interaction with it, then the efficiency of the stabilisation by such a stabiliser can be characterised by the ratio of the rates of initiation and consumption of the active form of the inhibitor:

$$\psi = \frac{w_i}{d[\dot{R}]/dt} \simeq \frac{w_i}{k[Z]} \quad (\text{when } k_{10} \gg k). \tag{35}$$



If an inhibitor is introduced initially at a concentration $[Z]_0$, then its efficiency ψ is defined by the expression

$$\psi_0 = \frac{w_i}{w_i + 2k_{10}[Z]_0}. \tag{36}$$

Since by hypothesis $k_{10} \gg k$, it follows that $\psi > \psi_0$. The ratio $\psi/\psi_0 = Q$ can serve as a criterion of the usefulness of the inhibitor *in statu nascendi*:

$$Q = \frac{\psi}{\psi_0} = \frac{w_i + 2k_{10}[Z]_0}{k[Z]_0} \simeq \frac{2k_{10}}{k}. \tag{37}$$

It has been shown recently that sterically hindered piperidines protect polymers from the action of light via the "depot" mechanism[98]. The mechanism of their light stabilising activity remained obscure for a long time. In the literature it was only noted that these compounds should not act via any one of the known mechanisms. In reality it was found that the stabilisers are not the piperidines themselves, being converted in the course of the ageing of the polymer into a mixture of nitroxy-radicals and other compounds which act as inhibitors. Fig. 21*a* presents kinetic curves for the photochemical oxidation of the butadiene–acrylonitrile copolymer. The initial section of the kinetic curve *2* for the oxidation in the presence of 2,2,6,6-tetramethyl-4-hydroxypiperidine

coincides with the curve for the unstabilised specimen (curve *1*) and the rate of oxidation falls only after some time has elapsed. During this period, stabile nitroxy-radicals accumulate in the specimen (curve *3*). The introduction into the polymer of a mixture of piperidine and radicals lowers the rate of the photochemical oxidation process from the very beginning. The addition to the polymer of nitroxy-radicals alone at the same concentration has little influence on the oxidation kinetics owing to the rapid consumption of the stable radicals.

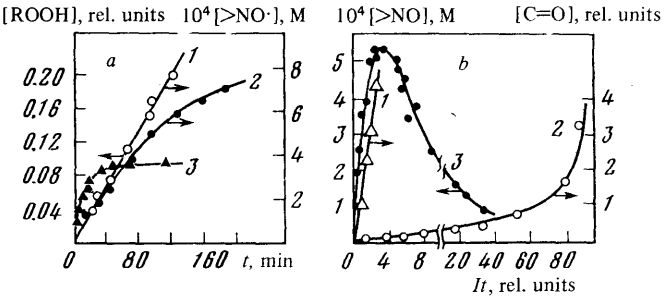


Figure 21. Kinetic curves for photochemical oxidation in the presence of 4-hydroxy-2,2,6,6-tetramethylpiperidine (NH); λ = 280 nm: *a*) butadiene–acrylonitrile copolymer (SKN-26). Accumulation of alcohols: 1) without stabiliser; 2) 2×10^{-1} M NH; 3) accumulation of NO in the specimen containing 2×10^{-1} M NH; *b*) polypropylene. Formation of carbonyl compounds: 1) without stabiliser; 2) 3.2×10^{-2} M NH; 3) variation of the concentration of NO.

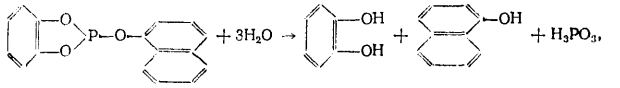
The mechanism of the stabilising action of sterically hindered piperidines is more complex than that considered above. It can be described qualitatively as follows:

$\xrightarrow{w_i}$ r· — photoinitiation;

>NH $\xrightarrow{+\dot{r}, +rO_2}$ >NO· + r· — generation of the stabiliser and the active radical;



>NO + r· → S
S + rO₂· → >NO₂ — inhibition and regeneration of stabiliser;

>NO· $\xrightarrow{h\nu}$ r· — generation of active radicals.

Here S is an intermediate product. The stage of the generation of the stabiliser involving the formation of nitroxy-radicals >NO·, which can proceed with participation of singlet oxygen or peroxy-radicals, and the reactions involving the regeneration of the active form as a result of the apparent conversion of the nitroxy-radical into hydroxylamine and an ether from which the nitroxy-radical can be reformed in its turn, are important. The possibility of the regeneration of the inhibitor of the system makes piperidines and nitroxy-radicals extremely effective polymer stabilisers.

Fig. 21*b* shows how the concentration of the nitroxy-radical formed from sterically hindered piperidine changes in the course of the photochemical oxidation of polypropylene. Evidently, throughout the reaction period, the concentration of nitroxy-radicals in the specimen is lower almost by two orders of magnitude than the initial concentration of piperidine. The introduction of nitroxy-radicals into the polymer at a high concentration at the beginning of the process is in the present instance undesirable owing to

the development of an intense colour in the specimen. The function of a "depot" can also be fulfilled by phosphite esters, whose hydrolysis leads to the formation of the corresponding phenols or catechols[99]:

as well as clathrate compounds from which the stabiliser is liberated on thermal or photochemical decomposition.

Not only compounds from which the stabiliser is synthesised during ageing but also the undamaged portion of the polymer from which the stabiliser diffuses to the degradation zone can be used as a "depot" of stabilisers. This phenomenon was recently observed in a study of the photochemical oxidation of polybutadiene films.

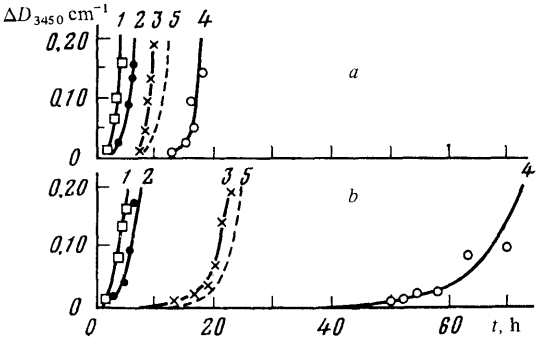


Figure 22. Kinetic curves for the photochemical oxidation of polybutadiene films 20 μm (*a*) and 60 μm (*b*) thick, without additives (curve *1*) and stabilised by additives; 2) 4-heptyloxy-2-hydroxybenzophenone UVA (3.6×10^{-2} M); 3) 2,6-di-t-butyl-4-methylphenol A (5×10^{-2} M); 4) their mixture with the same UVA and A concentrations (wavelength 254 nm); 5) calculated curves for films containing a mixture of UVA and an antioxidant corresponding to their additive activity.

In the presence of a u.v. absorber, light does not penetrate into the bulk of the polymeric specimen. Photochemical oxidation takes place only in the surface layer, which results in the consumption of the antioxidant (A). The concentration gradient of A rises and the antioxidant diffuses from the bulk of the polymer to the surface layer. Since deep layers serve as a source of the inhibitor, thick specimens are oxidised more slowly than thin specimens (Fig. 22). It has been shown recently that this phenomenon is the principal cause of the synergism observed in the stabilisation of polymers by mixtures of u.v. absorbers (UVA) and antioxidants, which interact with free radicals[100,101].

The problem of the influence of diffusion of A on the duration of the induction period in the oxidation reaction (T_{ind}) has been solved[101] for the unbranched chain photochemical oxidation reaction via the mechanism

$$S + h\nu \xrightarrow{PH,\ O_2} P\dot{O}_2 \quad ,$$

$$P\dot{O}_2 + PH \xrightarrow{k_2} POOH + P\dot{O}_2 \quad ,$$

$$P\dot{O}_2 + P\dot{O}_2 \xrightarrow{k_3} \text{chain termination},$$

$$P\dot{O}_2 + A \xrightarrow{k_4} \text{chain termination}.$$

Here S is the photosensitiser. The system of diffusion-kinetic equations describing the kinetics of the consumption of A and of the formation of $P\dot{O}_2$ in different sections of the polymer (x) during the induction period is as follows:

$$\left.\begin{aligned}
&\frac{\partial [PO_2(x,t)]}{\partial t} = -k_4 [A(x,t)]\,[PO_2(x,t)] + w_0 e^{-\alpha x} + D_{PO_2} \frac{\partial^2 [PO_2(x,t)]}{\partial x^2}\ ;\\
&\frac{\partial [A(x,t)]}{\partial t} = -k_4 [A(x,t)]\,[PO_2(x,t)] + D_A \frac{\partial^2 [A(x,t)]}{\partial x^2}\ ;\\
&0 < x < l;\ 0 < t < T_{ind};\\
&[PO_2(x,t)]_{t=0} = 0;\ [A(x,t)]_{t=0} = [A]_0;\\
&\frac{\partial [A(x,t)]}{\partial x}\Big|_{x=0} = \frac{\partial [PO_2(x,t)]}{\partial x}\Big|_{x=0} = 0;\\
&\frac{\partial [A(x,t)]}{\partial x}\Big|_{x=l} = \frac{\partial [PO_2(x,t)]}{\partial x}\Big|_{x=l},
\end{aligned}\right\} \quad (38)$$

where $\alpha = [A]_\epsilon$ is the UVA absorption index, D_i the diffusion coefficient, l the film thickness, and w_0 the rate of formation of free radicals on the surface of the film (for $x = 0$). The characteristic reaction conditions obtained by solving Eqns. (38) are illustrated in Figs. 23*a* to 23*c*.

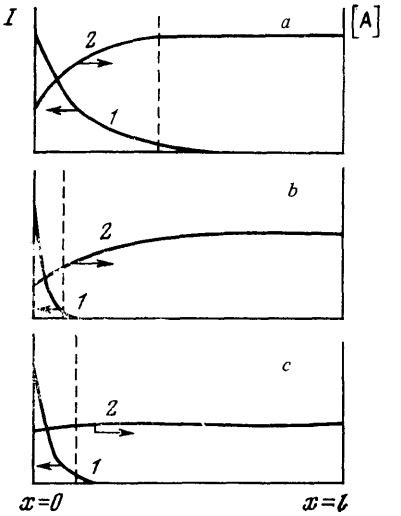

Figure 23. Distribution of light intensity (curve *1*) and antioxidant concentration (curve *2*) in the thickness of a polymer film for photochemical oxidation processes under different conditions: *a*) static; *b*) diffusion-controlled; *c*) rapid diffusion. The dashed line indicates the section in which the reaction is 20 times slower than on the surface. The photochemical reaction zone is located between this line and the surface ($x = 0$).

Under local conditions ($T_{ind} \ll l^2/\pi^2 D_a$, $T_{ind} \ll \alpha^2 l^4/\pi^2 T_A$), we have

$$T_{ind} = a[A_0]/I,$$

where I is the light intensity and a a constant. During the period T_{ind}, the diffusion of A is very slight and does not affect T_{ind}. Each layer reacts independently. The distribution of A in the film thickness at time t is therefore determined by the distribution of light intensity (Fig. 23*a*).

Under diffusion-controlled conditions ($1/\pi^2 D_A \alpha^2 \ll T_{ind} \ll l^2/\pi^2 D$, $\alpha l \gg 1$), we have

$$T_{ind} = bD_A \alpha^2 [A]_0^2/I^2. \quad (39)$$

In contrast to the local conditions, under these conditions there is an exchange of the antioxidant between neighbouring layers. As a result, $+d[A]/dt$ varies more smoothly than I along the thickness of the film (Fig. 23*b*).

Under rapid diffusion conditions ($T_{ind} \gg l^2/\pi^2 D_A$, $T_{ind} \gg 1/\pi^2 L_A \alpha^2$), we have

$$T_{ind} = a[A]_0 \alpha l/I, \quad (40)$$

i.e. [A] is virtually constant throughout the thickness of the film (Fig. 23*c*). Under these conditions, as under local conditions, the kinetics of the transformation of A are independent of D_A. T_{ind} is greater than under local conditions by a factor of αl. This is the maximum synergistic effect within the framework of the diffusion mechanism.

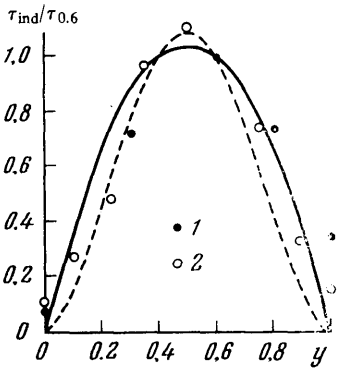

Figure 24. Dependence of the relative induction periods for the oxidation reaction $T_{ind}/\tau_{0.6}$ ($\tau_{0.6}$ is the induction period for $y = 0.6$) on the fraction of A: 1) in a mixture of 2,6-di-t-butyl-4-methylphenol and 4-heptyloxy-2-hydroxybenzophenone on irradiation of polybutadiene films 60 μm thick with light at 254 nm ($c\Sigma = 8.6 \times 10^{-2}$ M); 2) in a mixture of 2,2-methylenebis-(6-t-butyl-4-methylphenol) and 2-hydroxy-4-octyloxybenzophenone on irradiation of polychloroprene films[102]. Curves—calculation by Eqn.(41) (continuous curve) and by Eqn.(42) (dashed curve), normalised with respect to the experimental point corresponding to $y = 0.6$.

Analysis[100,101] showed that, for specified A and UVA concentrations, the synergistic effect can depend on I, D_A, and l, and the existence of such relations has been confirmed experimentally. The diffusion mechanism also made it possible to obtain the dependence of T_{ind} on the composition of the mixture of stabilisers. Under rapid diffusion conditions, we have

$$T_{ind} \sim c_\Sigma y(1-y) \quad (41)$$

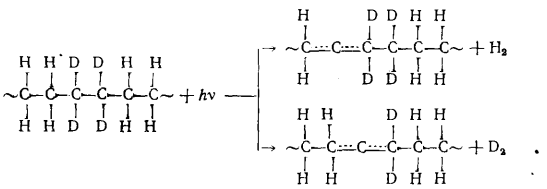
and under diffusion-controlled conditions

$$T_{ind} \sim [c_\Sigma y(1-y)]^2, \quad (42)$$

where $c\Sigma$ is the overall concentration of stabilisers and y the mole fraction of A in the mixture. Fig. 24 shows that Eqns. (41) and (42) reflect correctly, in qualitative terms, the form of the dependence of T_{ind} on the composition of the synergistic mixture.

Thus the diffusion mechanism explains the observed dependence of the synergistic effect on the composition of the mixture of stabilisers, I, D_A, and α. The principles of the selection of synergistic mixtures for different polymers and different operating conditions as well as the requirements which must be met by the thicknesses of the specimens and the conditions under which the tests of the resistance to light by polymers stabilised with synergistic mixtures have to be accelerated acquire theoretical justification. On the basis of this mechanism, the resistance to light will be presumably significantly influenced by the irradiation conditions. Under conditions of periodic irradiation, the synergistic effect will be greater than under conditions of continuous irradiation; in particular, an increased resistance to light should be promoted by the nightly interruption of irradiation. During the night, diffusion will increase [A] in the surface zone of the polymer where [A] was consumed during the day. It is also possible to account for the synergism between the effect of the UVA and substances causing a non-radical decomposition of hydroperoxides. On the basis of the diffusion mechanism, a quantitative mechanism of the synergistic effect is possible.

IX. THE AGEING OF POLYMERS UNDER SPECIAL OPERATING CONDITIONS



1. The Influence of Vacuum Ultraviolet Radiation on Polymers

In Space, a polymeric material is acted upon by vacuum ultraviolet (v.u.v.) radiation ($\lambda < 200$ nm). Such radiation constitutes a significant proportion of the spectrum of solar radiation, but does not reach the surface of the Earth, since it is absorbed by the ozone layer of the atmosphere.

The degradation of polymers under the influence of the v.u.v. differs from that under the influence of the softer u.v. with $\lambda > 200$ nm as well as the harder γ-radiation[103-106]. For example, polyolefins scarcely absorb light at a wavelength $\lambda > 200$ nm and their photodegradation under the influence of radiation in this spectral region therefore proceeds as a result of the absorption of light by impurities, which play the role of photosensitisers. The action of γ-rays on polyolefins is determined by the comparatively slow secondary electrons, which generate positively charged ions, free electrons, and excited molecules in the singlet and triplet states in the given substance. Secondary processes give rise to hydrogen atoms and free macroradicals, which initiate the radical degradation of the polymer.

The absorption maximum of polyolefins lies in the v.u.v. region. As a result of the absorption of a quantum of v.u.v. light with an energy insufficient for photoionisation, a polyolefin (polyethylene) molecule is transformed to an excited singlet state (in contrast to γ-radiolysis, the

probability of the formation of triplet molecules is extremely small). This state is unstable and the molecule decomposes mainly into molecular hydrogen and a polymer molecule containing a double bond of the *trans*-vinylene type. The hydrogen molecule is apparently abstracted from a single carbon atom, since the fraction of HD in the photolysis ($\lambda = 147$ nm) of the ethylene–deuteroethylene copolymer is small:

2. Degradation of Polymers in the Tissues of a Living Organism

In the last decade polymers have found extensive applications in medicine (cardiovascular surgery, surgery of the internal organs and tissues, traumatology, orthopaedic surgery, blood substitutes, agents prolonging the action of drugs, etc.). On contact with the tissues of the organism, polymeric materials undergo a change in properties to some extent and can influence the vital activity of the organism. The interaction of the polymer with the organism is a many-factor process, the understanding of which requires the investigation of processes involving the decomposition of implanted polymers, the metabolism of the decomposition products of the polymers and additives, and the genetic consequences of the action of polymers and their decomposition products on the organism.

In the general case implanted polymers are involved in three processes.

1. The sorption by the polymer of the components of the surrounding medium (water, salts, proteins, and lipids). For example, the sorption of lipids by cardiac valves made of polyorganosiloxanes leads to failure of the valves.

2. Desorption of low-molecular-weight compounds (catalysts, stabilisers, and fillers) from the polymers.

3. The decomposition of polymers as a result of degradation (thermal and mechanical energy, water, salts, enzymes) and dissolution. For example, the presence of low-molecular-weight oligomers, in equilibrium with the polymer, is characteristic of polycondensation polymers. The dissolution of these oligomers in the surrounding medium decreases the mass of the implanted material.

The macrokinetic features of the decomposition of polymers in the tissues of the living organism have been investigated[107,108]. Two main types of degradation of polymers in the organism are known—on the surface and in the bulk of the implanted material.

For the majority of hydrophobic polymers, the rate of decomposition of chemically unstable bonds under the influence of salts and enzymes greatly exceeds the rate of diffusion of these components in the polymer[107]. The degradation reaction proceeds in the surface of the implanted material at the rate

$$\frac{dn}{dt} = k^S C_m^S C_{cat}^S \cdot S, \qquad (43)$$

where n is the number of unstable bonds which have decomposed and C_m^S and C_{cat}^S are the surface concentrations of the chemically unstable bonds and the catalyst.

In the case of a simple fibre the change in the radius r, the mass m, and the breaking stress σ in the course of degradation, unaccompanied by the cracking of the surface, are described by the equations

$$\frac{r}{r_0} = 1 - k_{eff}^S \frac{t}{r_0 \rho}, \qquad (44)$$

$$\left(\frac{m}{m_0}\right)^{1/3} = \left(\frac{\sigma}{\sigma_0}\right)^{1/3} = 1 - k_{eff}^S \frac{t}{r_0 \rho}, \qquad (45)$$

where $k_{eff}^S = kC_m^S C_{cat}^S$ and ρ is the density of the polymer.

The degradation of poly(ethylene terephthalate) fibres in human subcutaneous cellular tissue has been investigated[108]. Fig. 25*a* shows that relation (45) holds satisfactorily. The experimental data make it possible to predict the time τ of the complete decomposition of the implanted material:

$$\tau = r_0 \rho / k_{eff}, \qquad (46)$$

which in the given instance is 30 ± 3 years.

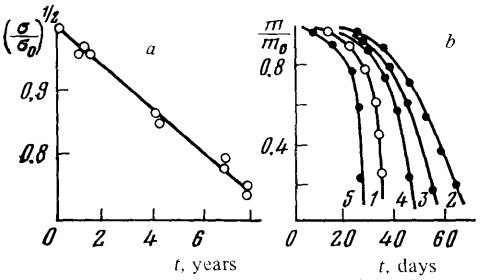


Figure 25. *a*) Variation of the relative breaking stress for a simple poly(ethylene terephthalate) fibre with $r_{init} = 11$ μm on the implantation time in the subcutaneous cellular tissue of man; *b*) kinetic curves for the variation of the mass m/m_0 of a polyglycolide fibre in the subcutaneous cellular tissue of rabbit (curve 1), in water (curve 2), and in phosphate buffer solutions at different concentrations: 1) 0.1 M; 4) 0.5 M; 5) 1.0 M; pH 7.4; 37°C.

In the degradation of the bulk phase of amorphous polymers, where the accessibility of all the chemically unstable bonds is as a rule the same, the degree of conversion with respect to the bonds and with respect to mass varies in accordance with the laws of homogeneous kinetics[107].

In amorphous-crystalline polymers the accessibilities of chemically unstable bonds in the amorphous regions and in the crystallites are different. The degradation of polyglycolide (degree of crystallinity approximately 80%) takes place under kinetic conditions in the amorphous regions and on the lateral surface of the crystallites.

Fig. 25*b* presents kinetic curves for the variation of the degree of conversion with respect to mass in the degradation of polyglycolide filaments in water, phosphate buffers of different concentrations, and in the subcutaneous cellular tissue of rabbits. Evidently phosphate ions greatly accelerate the degradation process and, for example in 1 M solution, the degradation of polyglycolide is faster than in the tissues of the living organism.

The variation of the mass of polyglycolide is described by the equation

$$\frac{m}{m_0} = \varphi_{cr} - \varphi_{am}[1 - \exp(-k_{eff}^{V} c_{cat}^{V} t)]^2 + \varphi_{cr}\left(1 - \frac{k_{eff}^{V-S} c_{cat}^{V-S} t}{N b_0 \rho}\right)^2, \quad (47)$$

where φ_{am} and φ_{cr} are the volume fractions of the amorphous and crystalline phases respectively, k_{eff}^{V} and k_{eff}^{V-S} are the effective rate constants for the degradation in the amorphous regions and on the surface of crystallites with a diameter b_0, and N is the number of crystallites per cross-section of the elementary filament.

The study of the characteristics of the degradation of polymer materials in the living organism makes it possible to predict the time required for the complete decomposition of the implanted materials.

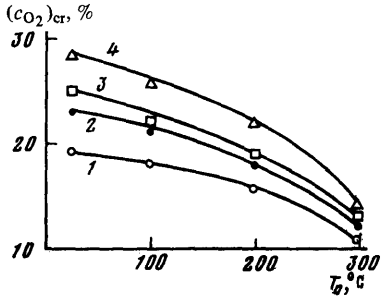

Figure 26. Decrease of the oxygen index $(c_{O_2})_{cr}$ with increase of the initial temperature T_0 of polystyrene specimens with added bromine-containing inhibitor (%): 1) 0; 2) 5; 3) 10; 4) 15.

3. Combustion of Polymers

The extensive use of polymeric materials in the building, textile, furniture, and other industries has greatly increased the importance of the problem of reducing the combustibility of polymers. Many of the commonest polymers—polystyrene, poly(methyl methacrylate), polyurethane, polyethylene, and natural and synthetic rubber—are highly combustible and readily ignite.

In order to estimate the degree of combustibility of the material, it is necessary to determine the conditions under which combustion is stable and the conditions under which it is quenched, i.e. it is necessary to find the critical conditions for combustion. These critical conditions are quoted in the literature: the minimum concentration of oxygen $(c_{O_2})_{cr}$, the minimum size of the specimen d_{cr}, the minimum pressure p_{cr}, the minimum temperature T_{cr}, etc. All these critical conditions are interrelated. For example, Fig. 26 [109] illustrates the decrease of $(c_{O_2})_{cr}$ with increase of the initial temperature of a polystyrene specimen—pure and with added bromine-containing inhibitor.

The oxygen index (OI)—the minimum concentration of oxygen $(c_{O_2})_{cr}$ at which combustion can still occur—is most often used to estimate the combustibility of the material. An advantage of the OI is its satisfactory reproducibility. However, the combustibility of the given material in air is of greatest interest, so that the characteristic based on the change in the composition of the atmosphere is not always suitable.

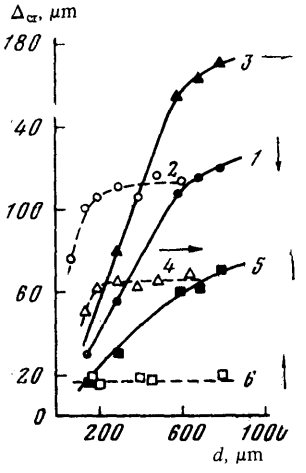

Figure 27. Dependence of the minimum thickness Δ_{cr} of PMMA films on the diameter d of copper wires (curves *1*, *3*, and *5*) and glass fibres (curves *2*, *4*, and *6*) in combustion from above downwards (curves *1* and *2*), horizontally (curves *3* and *4*), and from below upwards (curves *5* and *6*).

Table 8. Conditions for the quenching of the combustion of polymer films [poly(methyl methacrylate) on copper wire and glass fibres]. Test of the applicability of the Zel'dovich–Peclet number to polymer films.

Support	Direction of combustion	d, μm	Δ_{cr}, μm	w_{cr}, cm s^{-1}	L, cm	$10^5(dm/dt)_{cr}/\Delta_{cr}$, g cm s^{-1}
Copper	from above downwards	150	30	1.29	0.19	7.2
		300	55	0.70	0.30	8.3
		700	115	0.35	0.64	8.6
	horizontally	150	40	1.31	0.29	8.6
		300	80	0.70	0.53	10.0
		700	165	0.36	1.23	9.4
Glass	from above downwards	250	110	0.30	0.37	11.6
		350	110	0.21	0.29	10.3
		500	110	0.16	0.23	9.9
	horizontally	250	65	0.64	0.34	9.4
		350	65	0.46	0.32	7.2

Combustibility can be characterised by the minimum size of the specimen capable of combustion. This criterion is widely used for gaseous systems (particularly in the design of fire breaks), but is more rarely employed in the combustion of polymers. Fig. 27 and Table 8 illustrate the dependence of the minimum thickness Δ_{cr} of PMMA films on copper wires and glass fibres on the diameter d of the wire or fibre for different orientations of the specimen [110]. These results are of interest for the study of the combustion of insulating coatings on electric wires and also for the combustion of glass plastics. With increase of

the diameter of the wire, the quantity Δ_{cr} initially increases rapidly and then the relation $\Delta_{cr}(d)$ is weakened. For glass fibres, the $\Delta_{cr}(d)$ curves has a plateau. It might have been expected that thinner films would be capable of combustion on glass fibres than on copper wires. However, this is true only for a large diameter; for small values of d, thinner films can actually burn on copper than on glass. This is due to the fact that, for large diameters of the wire, the copper support removes heat from the burning polymeric films more effectively than the glass support and, for small values of d, the dominant factor is the supply of heat from the flame to the polymer via the wire.

By analogy with the Zel'dovich criterion for the quenching of homogeneous gaseous mixtures,

$$Pe = Pe_{cr} = ud_{cr}/a_T = \text{const} \quad (48)$$

(where Pe is the Peclet number, d_{cr} the critical diameter of the tube, a_T the thermal diffusivity of the fresh mixture, and u the linear rate of combustion), it was shown [110] that the product

$$\dot{m}_{cr} \cdot \Delta_{cr} = \rho w_{cr} \frac{\Delta_{cr}}{L}, \quad (49)$$

where m_{cr} and w_{cr} are the critical mass and linear rate of combustion, ρ the density of the polymer, and L the length of the pyrolysis zone (the distance from the flame barrier to the section where the film is fully gasified) can be used as a quantity characterising the stability of the combustion of polymer films. It follows from Table 8 that, when the thermal diffusivity of the support changes by more than two orders of magnitude (copper–glass) and the diameter of the wire (fibre) changes by a factor of 5, the quantity Δ_{cr} changes by a factor of 5.5, w_{cr} changes by a factor of 8, and the product $M_{cr}\Delta_{cr}$ changes only by a factor of 1.6.

The combustion of a polymer in a centrifuge has been studied [111]. Here the load factor a can serve as a critical parameter. It was observed that in the propagation of the flame along the acceleration vector, the ignition of paper takes place at an acceleration $a_{cr} = 5g$; on the other hand, if the flame is propagated in the opposite direction, ignition occurs at a much higher acceleration ($a_{cr} = 100g$), since in this case the hot combustion products flow in the direction of the propagation of the flame and heat ahead of the combustion front.

The knowledge of the critical combustion conditions makes it possible to arrange polymeric materials in a series based on decreasing combustibility with a particular degree of reliability. Only few polymeric materials have a low combustibility and do not require the addition of combustion inhibitors. Such materials include Teflon, rigid poly(vinyl chloride) (PVC) as well as synthetic fibres—Cordelan [based on PVC and poly(vinyl alcohol)] Nomex, and Kevlar (based on aromatic amine polymers).

However, for the majority of polymeric materials, the problem of the reduction of combustibility still remains extremely urgent. It is fairly difficult, since an increase of fire resistance usually has a number of undesirable consequences. For example, the majority of combustion inhibitors increase the toxicity of the combustion products. The amount of inhibitor which must be introduced to reduce significantly the combustibility of the polymer is usually extremely large. Thus self-extinguishing compositions based on polyethylene can be obtained only in the presence of at least 20–30 wt.% of the inhibitor.

Additives introduced in the form of mechanical admixtures are sometimes classified as chemically active and inert, although there is no sharp boundary between them. Mineral fillers such as SiO_2, chalk, kaolin, $Al_2O_3.3H_2O$, etc. may be referred to by convention as inert, while active fillers include Sb_2O_3 and alkali metal, barium, zinc, etc. borates and metaborates.

Chloralkanes (with a chlorine content up to 70%) alkyl and aryl phosphates and their halogeno-derivatives, etc. are used as plasticisers which reduce combustibility. In the chemical modification of a polymer carried out to reduce its combustibility halogens and phosphorus are introduced into its structure. A variant of this method involves the modification of the surface layers of the polymer only (halogenation, chlorosulphonation, etc.).

In the development of methods for suppressing the combustion of polymers one usually endeavours to achieve the following aims:

1. The reduction of the heat of combustion of polymeric materials following the introduction of thermodynamically inert additives. Particularly effective additives decompose with a fairly large endothermic heat change within the limits of the condensed phase of the polymer, which lowers the temperature of the surface of the latter and the rate of its combustion.

2. The formation on the polymer surface of a dense carbon residue under the influence of inhibitors, which prevents the supply of heat from the flame to the surface of the polymer and the diffusion of the polymer gasification products to the combustion zone. Readily fusible inhibitors, forming a layer of inert melt on the surface of the polymer, can act similarly.

3. The inhibition by additives (or their reaction products) of the chain oxidation reactions in the flame over the polymer surface.

X. CHEMICAL DEGRADATION AS A METHOD FOR THE MODIFICATION OF THE SURFACES OF POLYMERS

In many cases the operating properties of polymeric articles (for example, fibres and films) are determined by the properties of their surface. Chemical degradation permits a specific modification of the properties of the surfaces of polymers. It is important that the reaction should then involve only those macromolecules which are directly on the surface.

Under real conditions, the modification reaction takes place in a surface layer whose size depends on the ratio of the rate of diffusion of catalysts and reactants to the rate of decomposition of the chemically unstable bonds of the functional groups of the polymer.

The rate of decomposition of chemically unstable polymer bonds is

$$\frac{\partial c_n}{\partial t} = k(c_m^0 - c_n)\, c_{cat} c_{react}, \quad (50)$$

where c_m^0 is the initial concentration of the chemically unstable bonds, c_n the concentration of the bonds which have been ruptured, and c_{cat} and c_{react} are the concentrations in the catalyst and the reactant in the polymer respectively.

The changes in the concentrations of the catalyst and reactant in the polymer are described by the equations

$$\frac{\partial c_{cat}}{\partial t} = D_{cat}\nabla^2 c_{cat} - \sum_i k_i c_{cat} c_i, \quad (51)$$

$$\frac{\partial c_{\text{react}}}{\partial t} = D_{\text{react}}\nabla^2 c_{\text{react}} - k(c_m^0 - c_n)c_{\text{cat}}c_{\text{react}}, \quad (52)$$

where c_i is the concentration of the functional groups in the polymer capable of reacting with the catalyst with a rate constant k_i, D the diffusion coefficient, and ∇^2 the Laplace operator.

In the general case Eqns. (50)–(52) do not have an analytical solution but they can be solved on a computer. The equations are simplified if, for example, the reactant is water (hydrolytic reaction). In the diffusion of catalysts with a low vapour pressure into hydrophobic polymers we then have $D_{H_2O} \gg L_{cat}$ and the concentration of the reactant in the reaction layer is constant and equal to $c^0_{H_2O}$. In the case of catalysts with a high vapour pressure the diffusion of the catalyst and the solvent can be characterised by a single diffusion coefficient, since $D_{H_2O} \simeq D_{cat}$.

The case where the degradation proceeds under steady-state conditions in which the catalyst and reactant concentration gradients in the reaction layer are constant in time is frequently encountered. If the macromolecules decompose at random, the fragments formed on the polymer surface flake off and decompose in solution, i.e. $c^0_m - c_n \simeq c^0_m$. In this case the solution is

$$c_n = k_{\text{eff}}\, c^0_{\text{cat(surf)}} \cdot t \sqrt{\frac{D_{\text{cat}}}{k_{\text{eff}}}} \tanh\left(\frac{L}{2}\sqrt{\frac{k_{\text{eff}}}{D_{\text{cat}}}}\right), \quad (53)$$

where L is the thickness of the reaction layer on the surface of the polymeric article and $c^0_{\text{cat(surf)}}$ the concentration of the catalyst at the polymer–medium interface.

If the rate of decomposition of chemically unstable bonds is much greater than the rate of diffusion,

$$\frac{L}{2}\sqrt{\frac{k_{\text{eff}}}{D_{\text{cat}}}} \gg 1,$$

then

$$c_n = k_{\text{eff(surf)}} c^0_{\text{cat(surf)}} t, \quad (54)$$

where $k_{\text{eff(surf)}} = k_{\text{eff}}\sqrt{D_{\text{cat}}/k_{\text{eff}}}$ and the degradation reaction proceeds virtually on the surface of the polymeric article. This condition holds, for example, in the degradation of poly(ethylene terephthalate) (PETP) in concentrated KOH solutions [112].

The relative change in thickness (l) and mass (m) of the PETP film in concentrated solutions of alkalis is described by the equation

$$\frac{l}{l_0} = \frac{m}{m_0} = \left(1 - \frac{t}{\tau}\right), \quad (55)$$

where $\tau = l_0\rho / k_{\text{eff(surf)}} c^0_{\text{cat(surf)}}$ is the time required for the total decomposition of the polymer and ρ is the density of the polymer.

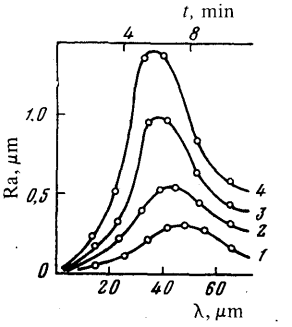
We shall now consider examples of the employment of the chemical degradation of polymer for the improvement of the properties of their surfaces.

1. The Preparation of Poly(ethylene terephthalate) Films with a Rough Surface

Films with a rough surface are used in modern computers, in radioelectronic, video-recording, and sound recording apparatus, in electrotechnical industry, and in cartography.

According to the generally accepted etching mechanism, a rough surface is formed when the amorphous phase is etched away and the bared crystallites form microrugosities [113]. Rudakova et al. [112] showed for the first time that, in degradative etching on the surface, a roughness arises as a result of the exposure of microdefects (for example, micropores) as the surface layer of the polymer is decomposed. As a result of the wedging pressure, the microdefects then initiate the growth of cracks. The number of micropores is non-uniform with respect to the thickness of the specimen, decreasing with increasing degree of crystallinity. It is to be expected that the surface with the greatest degree of roughness would be obtained in the etching of amorphous polymers.

Fig. 29 illustrates the dependence of the roughness factor Ra on the thickness of the layer λ removed from the surface of PETP films with different degrees of crystallinity. Evidently the maximum value of Ra is observed for amorphous PETP films following the decomposition of a 25–30 μm layer.



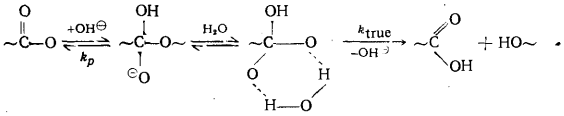


Figure 28. Dependence of the roughness factor Ra for poly(ethylene terephthalate) films treated with 49% KOH (108 °C) on the size of the decomposed layer λ and the degree of crystallinity (%): 1) 58; 2) 40; 3) 30; 4) 5.

Hydrolysis of the ester linkages in PETP proceeds via the mechanism [112]

The variation of k_{eff} with the thermodynamic parameters of the medium is described by the equation

$$K_{\text{eff}} = \frac{k_{\text{true}}\, a_{H_2O}}{1 + K_p/b_0}, \quad (56)$$

where K_p is the equilibrium constant for the addition of a hydroxide ion to the carbonyl carbon atom, b_0 the alkalinity, a parameter proportional to a_{OH^-}, a_{H_2O} the activity of water, and k_{true} the true rate constant.

The overall equation describing the variation of l with time, temperature, and the thermodynamic parameters of the medium is

$$l = l_0 - \frac{A\exp(-E/RT)\, a_{H_2O}\, t}{(1 + K_p/b_0)\rho}. \quad (57)$$

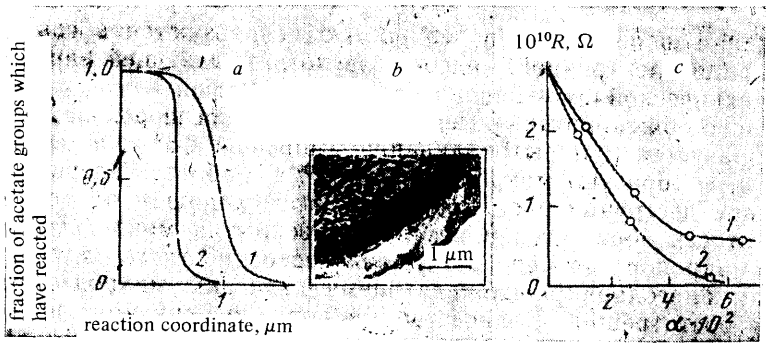

Figure 29. Preparation of diacetate filaments with reduced susceptibility to acquisition of an electrostatic charge: *a*) migration of the reaction front calculated by equations with $t/\tau = 0.1$ (τ is the time corresponding to the end of reaction) in solutions of different alkalis [1) NaOH; 2) $(C_4H_9)_4NOH$]; *b*) photomicrograph of a cross-section of the diacetate filament; *c*) dependence of the resistance of diacetate filaments R on the degree of conversion of the acetate groups in the filament α.

For this form of degradation, the degree of crystallinity of PETP has almost no influence on the kinetic parameters and Eqn. (57) makes it possible to find the optimum conditions for the etching of PETP films.

2. Preparation of Fibres with Reduced Susceptibility to the Acquisition of an Electrostatic Charge

A disadvantage of synthetic and artificial polyester fibres is their high susceptibility to the acquisition of an electrostatic charge. The employment of antistatic agents is frequently undesirable, since many of them can be readily eluted from the polymer and act as irritants to the skin and the mucous membrane of the eye.

Surface degradation is used successfully to reduce the susceptibility of artificial and synthetic fibres to the acquisition of an electrostatic charge. For example, such susceptibility of fabrics can be diminished if the hydrophobic ester groups in the surface layer of cellulose diacetate or triacetate filaments is replaced by the hydrophilic hydroxy-group of the regenerated cellulose. The conditions under which the rate of hydrolysis of the ester linkages is much higher than the rate of diffusion of the alkali into the filaments have been determined[114]. This is achieved (Fig. 29) by (1) using concentrated solutions of strong alkalis, i.e. by increasing k_{eff} for D_{cat} [Eqn. (53)] and (2) by employing alkali with a large bulky cation, for example $(C_4H_9)_4NOH$, i.e. by diminishing D_{cat} for a constant rate of hydrolysis, Both procedures lead to an appreciable reduction of the susceptibility of cellulose to the acquisition of an electrostatic charge.

---o0o---

Thus, over an extremely short period, the field of the ageing and stabilisation of polymers has become an important branch of the fundamental and applied chemical science, which is concerned with the study of the chemical changes in polymers and polymeric materials and with the development of rational methods for controlling these changes.

Thermochemical Studies Necessary for the Selection of Key Thermodynamic Quantities

V.A.Medvedev and I.L.Khodakovskii

The present state of experimental studies necessary for calculating key thermodynamic quantities has been reviewed. A list of substances for which experimental measurements of the enthalpies of formation, entropies, etc. are desirable has been proposed. Various problems in the calculation of the standard thermodynamic quantities for solutions have been examined. A list of international recommendations on key thermodynamic quantities has been given. The bibliography contains 50 references.

CONTENTS

I. Introduction 1168
II. Experimental studies of particular interest for the selection of key thermodynamic quantities 1169
III. Appendix 1172

I. INTRODUCTION

Thermodynamic quantities such as the enthalpy and free energy of formation and entropy represent a system of inter-related quantities. Thus the enthalpy of formation of methane depends on the values of the enthalpy of formation of H_2O and CO_2. The free energy, enthalpy of formation, and entropy of a substance are related by the equation $\Delta G = \Delta H - T\Delta S$. Thus with the exception of the standard entropy, the choice of the numerical value of a thermodynamic quantity from published data, or its calculation from experimental measurements, usually cannot be made without certain calculations using various other quantities. The quantities which are most frequently used in these calculations are usually called key thermodynamic quantities.

The quantities usually regarded as key quantities are the values of the enthalpy of formation and entropy at 298.15 K and the enthalpy $H^0_{298} - H^0(0)$ for such substances (basic(as H_2O (liquid, gas), CO_2(gas(, HF (gas), SiO_2 (α-quartz), NH_3 (gas), NH_3 (gas), O_2 (gas), H (gas), B (gas), Cl^- (aq), SO_4^{2-} (aq), Na^+ (aq), UO_2^{2+} (aq), etc.; that is the basic substances are usually elements in their standard states and in the state of free atoms, and also one or two compounds of each element and ions in the state of a standard aqueous solution. This is because these substances appear most frequently in thermochemical cycles and other calculations; the choice of values for these quantities influences the numerical values of the thermodynamic properties of a large number of other substances. Thus the values of the enthalpies of formation of H_2O and CO_2 appear in the calculation of the enthalpies of formation of a vast number of organic compounds, and the values of the thermodynamic properties of simple aqueous ions in the ground state appear in the calculation of the thermodynamic characteristics of solutions of acids, alkalis, salts, undissociated ionic complexes, and many salts in the crystalline state.

The choice of key quantities obviously acquires particular importance in the preparation of fundamental reference books on the thermodynamic properties of substances, summarising accumulated experimental material. The most important principle in the production of these reference works — the internal consistency of the values given — requires recalculation of the results of all experimental studies using the same key quantities. Here it is necessary to take account of the fact that, as shown by the experience of the US National Bureau of Standards[1,2] and the Academy of Sciences of the USSR[3,4], the complete production and publication of these fundamental reference works require about 15 years. Simply as a consequence of the fact that the work on the production of these reference books was begun at different times, the values of the thermodynamic properties given in them are based on different key quantities. When these reference works are used, particularly in the calculation of precise experimental measurements, it is necessary to take account of these differences and to avoid the use of values which are inconsistent with one another.

All the inconvenience and the possibility of misunderstanding and confusion introduced by differences in the values of key quantities are obvious. In order to at least partly eliminate these unsatisfactory features immediately and to remove them completely in the future, the Committee On Data For Science And Technology (CODATA) of the International Council Of Scientific Unions in recent years has been preparing single international recommendations of key thermodynamic quantities. Values have already been chosen for 125 substances, and the preparation of recommendations for several more tens of substances is being completed; some of these quantities have been published[5,6]. A complete summary Table is given in the Appendix at the end of the present review.

One of the aims of the present work is to draw the attention of experimentalists to these international recommendations and to discuss various characteristic features of their use in the calculations. It is necessary that in the future these recommendations become a general basis for calculating the results of experimental measurements and in the production of reference works. It should be borne in mind that the reference books widely used as a source of supplementary thermodynamic quantities[1-4] are based on key quantities which do not coincide with new international recommendations. Thus when the latter are used, it is necessary to introduce appropriate corrections to the data from reference works, which is not always easy.

In view of the situation which has now arisen, where in the literature there is lack of agreement on the choice of key quantities, and reference works on the thermodynamic properties of substances are based on different key quantities (which moreover do not coincide with prepared international recommendations), it is appropriate, in the opinion of the present authors, to make the

following recommendations as practical advice to authors of experimental papers. In those cases where the key quantities recommended by CODATA are sufficient (or almost sufficient) for the recalculation, these should be used. In those cases where the necessary recalculations are complex, and a large number of quantities other than those recommended by CODATA are required, it is preferable to use any one of the above mentioned reference works, since this guarantees that the values included in the calculations are consistent with one another. In any case, it is necessary to indicate in published work the source of the supplementary data used in the calculations (as required by an international resolution on the publication of calorimetric and thermodynamic data[7]). The observation of this and other requirements of the resolution[7] ensures the validity of the publication and makes it possible to estimate the reliability of the measurements made and to recalculate the results using other key quantities.

It is to be hoped that the confused situation discussed above, which has arisen as a result of differences in the values of key thermodynamic quantities used in reference works and in individual publications, will be eliminated in the comparatively near future, since it is planned, about 1980, to begin the preparation of an international reference work on the thermodynamic properties of substances.

II. EXPERIMENTAL STUDIES OF PARTICULAR INTEREST FOR THE SELECTION OF KEY THERMODYNAMIC QUANTITIES

The chief aim of the present work is to attempt to draw the attention of experimentalists to various studies of particular interest from the viewpoint of the values of key thermodynamic quantities (and hence from the viewpoint of the production of the future international reference work). In course of work already rried out on the preparation of reference books and on the choice of key quantities, the available published data for a wide range of substances have been critically analysed. It has been found that the results of measurements for a number of the most important substances are insufficiently accurate or non-existent. At the same time, each year there are published the results of studies of a large number of less important substances, the selection of which is apparently determined by accidental factors. For example, in recent years an extensive cycle of studies on the determination of the thermodynamic properties of many tens of selenates has been carried out. However, the standard enthalpy of formation and entropy of the selenate anion, which are key quantities, have not yet been reliably determined, and the choice of these quantities is based on old and unreliable data. Unfortunately, this is not an isolated example. It would thus be extremely valuable if experimentalists, when planning their work, took account of the need for and importance of studies aimed at determining key thermodynamic quantities. These measurements should naturally be particularly careful and precise, and their publication sufficiently detailed.

Some of the most important experimental measurements which are particularly urgently required are listed below; for each type of measurement, the substances are arranged in order of importance and urgency.

1. Entropies of Crystalline Substances

Measurements of the low-temperature heat capacity and their use to determine the standard entropies and enthalpies of substances in the condensed state are particularly important, since standard entropies are usually determined more accurately than the enthalpies and free energies of formation†, and their use in the calculation of key quantities is almost always preferred to other possible methods. A list of substances for which determination of the standard entropies S^0_{298} is necessary is given below; the temperature ranges (in K) in which the heat capacities of these substances were measured are given in brackets: β-$Be(OH)_2$(crystalline); $MgCl_2$(crystalline) (51–298);[8] $CaCl_2$(crystalline) (51–298);[8] $PbCl_2$(crystalline) (15–206)[9]; PbF_2(crystalline); α-PbO(crystalline, red) (51–298);[10] Hg_2Cl_2(crystalline) (22–99)[11] and (100–273);[12] $HgCl_2$ (crystalline); HgO(crystalline, yellow); SnO_2(crystalline); SnO(crystalline) (69.6–292.5);[13] PuO_2(crystalline) (11–100)[14] and (4–25);[15] SeO_2(crystalline) (53.5–305);[16] α-TeO_2(crystalline); TeO_3(crystalline); α-Sb_2O_3(crystalline, cubic) (65–298);[17] β-Sb_2O_3(crystalline, orthorhombic) (56.2–298)[18] and (65–298);[17] Tl_2O(crystalline); Tl_2O_3 (crystalline); MnO(crystalline) (52–298);[20] Mn_2O_3 (crystalline) (50–298);[20] ReO_2(crystalline); ReO_3(crystalline) (2–100)[21] and (1.4–4.2);[22] Tc_2O_7(crystalline); PdO(crystalline); RuO_4(crystalline); RuO_2(crystalline) (0.54–10);[23] IrO2(crystalline) (0.54–10);[23] OsO_2(crystalline); α-WCl_6(crystalline); $MoCl_6$(crystalline); $Cd(OH)_2$ (crystalline); Ta_2O_5(crystalline) (53.4–294);[24] Au_2O_3 (crystalline).

2. Enthalpies of Formation

The measurement of the standard enthalpies of formation is required particularly urgently for the following substances in the condensed and gaseous states: SrO (crystalline), BaO(crystalline), $SrCl_2$(crystalline), $BaCl_2$ (crystalline), NO(gas), H_2S(gas), NH_4NO_3(crystalline), NH_4NO_2(crystalline), BeO(crystalline), α-$BeCl_2$(crystalline), $MgCl_2$(crystalline), $MgSO_4.6H_2O$(crystalline), AlI_3 (crystalline), $MgSO_4.7H_2O$(crystalline), SnO_2(crystalline), ThF_4(crystalline), $AlCl_3$(crystalline), $FeCl_2.4H_2O$(crystalline), $FeCl_3.6H_2O$(crystalline), TeO_2(crystalline), $TiCl_3$ (crystalline), Tl_2O(crystalline), Na_2WO_4(crystalline), Tl_2O_3(crystalline), V_2O_5(crystalline), $CrCl_3$(crystalline), $CrCl_3.6H_2O$(crystalline), $InCl_3$(crystalline), $GaCl_3$(crystalline), $MoCl_5$(Crystalline), $ScCl_3.6H_2O$(crystalline), $DyCl_3$ (crystalline), $LuCl_3$(crystalline).

For most of these substances, measurements of the enthalpy of the reaction with the corresponding metals present particular difficulties.

The direct measurement of the enthalpy of formation of ions in the standard state (that is in infinitely dilute aqueous solution) is impossible. This quantity is deter-

---

† Here it should be borne in mind that the typical error of present-day measurements of the standard entropy (if there are no complicating features) is ~0.1 e.u. In the case of the calculation of the free energy or the equilibrium constant at 298 K, this error corresponds to an error in the enthalpy of the reaction of only 0.03 kcal $mole^{-1}$, which is not reached in all thermochemical measurements.

mined by extrapolating the results of measurements of the enthalpy of reaction, carried out at finite concentrations of the solution, to infinite dilution.

It should be noted that in most cases, including fundamental reference works[2,3], the standard heats of reactions in solutions at infinite dilution are determined by empirical extrapolation of the corresponding experimental data, obtained at definite ionic strengths of the solution I, to $I = 0$. These extrapolations have no rigorous theoretical basis; there are more rigorous methods of extrapolation, based on the electrostatic Debye–Hückel theory. As first shown in 1949,[25] in the determination of the form of the functional dependence of the enthalpies of dilution it is possible to use the equation for the mean-stoichiometric activity coefficients of the electrolytes $\gamma_\pm$ in the third approximation of the Debye–Hückel theory‡:

$$\lg \gamma_\pm = -\frac{|z_+ \cdot z_-| S_T \sqrt{I}}{1 + B\mathring{a}\sqrt{I}} + cI + bI^2 + \ldots, \quad (1)$$

where $S_T = 1.8246 \times 10^6 d^{0.5}/(DT)^{1.5}$; $B = 50.294 \times 10^8 d^{0.5}(DT)^{-0.5}$; d is the density of water; D the dielectric constant of water; T the temperature, K; z_i the charge of the ith ion; $I = \frac{1}{2}\Sigma m_i z_i^2$ is the ionic strength of the solution; $\mathring{a}$ the "ionic parameter"; and c and b empirical coefficients.

Using the familiar relationships

$$\bar{L}_2 = -\nu RT^2 \left(\frac{\partial \ln \gamma_\pm}{\partial T}\right)_{p,I}, \quad (2)$$

$$\bar{L}_2 = \varphi_H + m\frac{\partial \varphi_H}{\partial m} \quad (3)$$

and Eqn. (1), Owen and Brinkley[25] obtained in general form the dependence of the heat of dilution of electrolytes on the ionic strength of the solutions:

$$\varphi_H = \nu|z_+ \cdot z_-|\varphi_H\ (\text{D–H}) + c_H I + b_H I^2 + \ldots, \quad (4)$$

where $\nu|z_+ \cdot z_-|\varphi_H$(D–H) is the electrostatic contribution to the heat of dilution according to the Debye–Hückel theory, and c_H and b_H are empirical coefficients.

By solving Eqns. (1)–(3) simultaneously, Khodakovskii and Dorobeeva[26], independently of Owen and Brinkley, obtained an expression for φ_H(D–H):

$$\varphi_H\ (\text{D–H}) = \frac{S_H}{B\mathring{a}} J_1 + \frac{W_H}{(B\mathring{a})^2} J_2, \quad (5)$$

where

$$J_1 = 1 - \frac{2}{B\mathring{a}\sqrt{I}} + \frac{2\ln(1 + B\mathring{a}\sqrt{I})}{(B\mathring{a})^2 I}, \quad (6)$$

$$J_2 = 1 - \frac{4}{B\mathring{a}\sqrt{I}} + \frac{2}{(B\mathring{a})^2 I}\left[\frac{1}{1 + B\mathring{a}\sqrt{I}} + 3\ln(1 + B\mathring{a}\sqrt{I}) - 1\right], \quad (7)$$

and the coefficients S_H and W_H are functions of only temperature and pressure, and their numerical values are given in Ref. 26. The same equations (5)–(7) can be obtained by substituting in the expression for φ_H(D–H) obtained in Ref. 25 the symbols used in Ref. 26, and carrying out the appropriate mathematical transformations.

‡ Only the basic scheme of the calculation is given below. More detailed descriptions can be found in Refs. 25 and 26.

It may therefore be assumed that the analytical form of the relationship (5) has been fairly reliably established.

Since the form of the equation for the dependence of the activity coefficients of individual ions on the ionic strength of the solution is similar to that of Eqn. (1):

$$\lg \gamma_i = -\frac{z_i^2 S_T \sqrt{I}}{1 + B\mathring{a}\sqrt{I}} + cI + bI^2 + \ldots, \quad (8)$$

it is possible, using the approach proposed by Vasil'ev[29], to obtain refined equations for calculating the standard enthalpy change (ΔH°) for any reaction involving ions:

$$\Delta H_I - \Delta z^2 \varphi_H\ (\text{D–H}) = \Delta H^0 + \Delta c_{H,I} + \Delta b_{H,I}^2 + \ldots, \quad (9)$$

where ΔH_I is the enthalpy change of the reaction for an ionic strength of the solution equal to I; Δz^2 the algebraic sum of squares of the charges of the ions taking part in the reaction (for example, for the reaction $CuCl_2 = Cu^{2+} + 2Cl^-$ we have $\Delta z^2 = 4 + 1 + 1 = 6$).

The applicability of Eqn. (9) in the determination of the standard heats of reactions from data for solutions having a high ionic strength (as far as $I = 3$–5) has been demonstrated[26–28]. The use of Eqn. (9) is particularly important in those cases where, from the conditions of the experiment, the calorimetric study of the reaction can be carried out only at high ionic strengths of the solutions, for example for reactions involving multiply-charged cations which are readily hydrolysed in weakly acidic solutions.

Table 1. Comparison of the standard enthalpies of various reactions, calculated using Vasil'ev's equation[29] and Eqn. (9).

Reaction	Δz^2	ΔH^0_{298}, kcal mole^{-1}		Refs.
		from Vasil'ev's Eqn.(29)	from Eqn.(9)	
$Co(cryst.) + H_2O_2(soln.) + 2H^+(soln.) = Co^{2+}(soln.) + 2H_2O(liq.)$	2	−104.07±0.15	−104.13±0.15	36

$HfCl_4(cryst.) = Hf^{4+}(soln.) + 4Cl^-(soln.)$	20	−80.14±0.31	−79.30±0.35	35

It should be noted that in spite of the fact that in the works cited[26,27], attention was drawn to the inaccuracy of the determination of the form of the functional dependence of φ_H(D–H) on the ionic strength of the solutions in Ref. 29, the equation derived in Ref. 29 is still often used (see for example Refs. 33–35) to calculate the standard enthalpies of reactions. Table 1 clearly shows that if the value of Δz^2 is large, the difference in the values of the standard heats of reactions obtained by different extrapolation methods may be considerable, and may exceed the error of the experimental measurements.

The most complex problem in the determination of the standard enthalpies of formation of simple ions which are key quantities is the measurement of the standard enthalpies of formation of such readily hydrolysed cations as Al^{3+}, Ga^{3+}, In^{3+}, Tl^{3+}, Fe^{3+}, Cr^{3+}, Mn^{3+}, U^{4+}, Th^{4+}, Pu^{4+}, Sn^{4+}, Ge^{4+}, Zr^{4+}, Hf^{4+} and the anions SO_3^{2-}, $S_2O_3^{2-}$, SeO_3^{2-}, SeO_4^{2-}, TeO_3^{2-}, $Te(OH)_6^{2-}$, S^{2-}, Se^{2-}, Te^{2-}, etc. The standard enthalpies of formation of many of these ions can be determined by measuring the enthalpies of solution of the chlorides of the corresponding elements or their oxides in solutions of perchloric acid or alkali at concentrations of the latter which are sufficient for the practically complete suppression of hydrolysis. At the same time, quantitative allowance for the influence of hydrolysis processes also requires calorimetric measurements of the enthalpies of hydrolysis over a wide range of ionic strengths of the solutions.

3. Standard Entropies of Ions in Aqueous Solution

The most reliable values of the standard entropies for many simple cations and anions in aqueous solution in most cases are obtained from the value of ΔS°_{298} for the solution of the corresponding anhydrous salts or crystalline hydrates in water, in equilibrium with their saturated solutions:

$$K_m^{n+}A_n^{m-} \cdot xH_2O(\text{cryst.}) = mK^{n+}(\text{soln., standard state}) + nA^{m-}(\text{soln., standard state}) + xH_2O(\text{liq.}), \quad (10)$$

and also from the values of the standard entropy of the soluble salt, the entropy of the anion (or cation) and the entropy of H_2O(liquid) (in the case of crystalline hydrates). The values of ΔS°_{298} in turn is calculated from the values of ΔH°_{298} and ΔG°_{298} for reaction (10). For readily soluble salts, the reliable determination of the value of ΔG°_{298} is possible when there are experimental data on the mean-stoichiometric activity coefficients of the solutions $K_mA_n(\gamma\pm)$ and the activity of water in the case of crystal hydrates, up to the saturation concentration (m_{sat}). Since these calculations usually combine data obtained in different laboratories in methodologically different studies, generally not undertaken to solve the problem being considered in the calculations, the literature in many cases contains only some of the necessary data. Salts can be divided into three large groups, depending on the completeness of the available thermodynamic information.

The first group consists of salts for which it is sufficient to determine only one property in order to make possible the accurate calculation of the entropy of the cation (or anion). Thus for a number of salts there are reliable values of ΔS°_{298} for their solution (ΔG°_{298} and ΔH°_{298} for reaction (10) are known), but the calculation of the entropy of the ions cannot be carried out until sufficiently accurate values have been determined for the standard entropies of the corresponding crystalline substances. Accurate values of the latter can be obtained from measurements of the heat capacity in the temperature range 5–300 K. A list of these salts is given below; the temperature ranges (K) in which the heat capacities were measured are given in brackets.

β-$Be(OH)_2$, $MgSO_4\cdot7H_2O$, $Mg(ClO_4)_2\cdot6H_2O$, $Mg(NO_3)_2\cdot6H_2O$ (295—305) [37], $CaCl_2\cdot6H_2O$, $CaSO_4\cdot2H_2O$ (50—298) [39], $Ca(ClO_4)_2\cdot6H_2O$, α-$Ca(NO_3)_2\cdot4H_2O$ (40—300) [38] and (295—305) [37], $SrCl_2\cdot6H_2O$, $Sr(NO_3)_2\cdot4H_2O$, $SrSO_4$ $SrCO_3$(50—298) [39], $Ba(OH)_2\cdot8H_2O$, $Ba(ClO_4)_2\cdot3H_2O$, $Ni(ClO_4)_2\cdot6H_2O$, $Co(ClO_4)_2\cdot6H_2O$, $Mn(ClO_4)_2\cdot6H_2O$, $Mn(NO_3)_2\cdot6H_2O$, $Cu(ClO_4)_2\cdot6H_2O$, ZnI_2, $Zn(ClO_4)_2\cdot6H_2O$, $Zn(NO_3)_2\cdot6H_2O$, $CdCl_2\cdot2{,}5H_2O$, $CdBr_2\cdot4H_2O$, $Cd(NO_3)_2\cdot4H_2O$(160—320) [38], $Cd(ClO_4)_2\cdot6H_2O$, $NaClO_3$, $NaClO_4\cdot H_2O$, $NaBO_3$, $NaSCN\cdot2H_2O$, $Na_2CrO_4\cdot4H_2O$, $NaB(OH)_4\cdot2H_2O$, $NaBF_4$, $Na_3PO_4\cdot12H_2O$, K_2CrO_4 (60—300) [41], $K_2Cr_2O_7$ (80—300) [41, 42], KIO_4, $CsNO_3$, $CsBrO_3$, $RbBrO_3$, $RbNO_3$, $AgBrO_3$, Ag_2SeO_3, Ag_2SeO_4, Ag_2MoO_4, Ag_2WO_4, $ScCl_3\cdot6H_2O$, $UO_2SO_4\cdot2.5H_2O$, $UF_4\cdot2{,}5H_2O$, $ThF_4\cdot2.5H_2O$.

Salts for which only measurement of the enthalpy of reaction (10) is required: $AlCl_3.6H_2O$, $NH_4Al(SO_4)_2.12H_2O$, $NH_4Cr(SO_4)_2.12H_2O$, $(NH_4)_2SnCl_6$, K_2SnCl_6.

Salts for which only measurements of $\gamma\pm$ and a_{H_2O} for m_{sat} are required: $FeSO_4.7H_2O$, Cs_2CrO_4, $SnCl_2.2H_2O$, $(NH_4)_2SiF_6$, Na_2SiF_6, $NaHCOO.2H_2O$.

In the determination of the entropies of crystalline hydrates it is necessary to take account of the fact that some of them have a residual entropy at 0 K. To determine this it is necessary to know the entropy of the anhydrous salt (or crystalline hydrates containing a smaller number of water molecules) and the enthalpy changes in the dehydration. The latter can be calculated if the dissociation pressures of the crystalline hydrates and the enthalpies of solution of the anhydrous salts and the crystalline hydrates in water to give solutions of the salt having the same concentration are known. Examples of these calculations can be found in papers dealing with the determination of the standard entropies of $Na_2SO_4.10H_2O$,[43] $Na_2CO_3.10H_2O$,[44] $Na_2HPO_4.12H_2O$,[45] $ZnF_2.4H_2O$,[46] $ZnSO_4.7H_2O$,[47] etc.

The second group consists of salts for which two types of experimental study are required, namely:

a) ΔH°_{298} for reaction (10); $\gamma\pm$ and a_{H_2O} for m_{sat}—for Cs_2MoO_4, SnI_2, $SnSO_4$, NaN_3.

b) ΔS°_{298}; $\gamma\pm$ and a_{H_2O} for m_{sat}—for K_2SeO_3, K_2SeO_4, $Na_2SeO_3.5H_2O$, $Na_2TeO_3.5H_2O$, Li_2TeO_3, $CaSeO_4.2H_2O$, $NaVO_3.2H_2O$, $NpO_2(NO_3)_2.6H_2O$, $PuCl_3.6H_2O$, K_2PdCl_4, K_2PtCl_4.

c) ΔH°_{298} for reaction (10); S°_{298}—for $Cr(NO_3)_3.9H_2O$, $Cr_2(SO_4)_3.18H_2O$, $K_3PO_4.7H_2O$, $K_2HPO_4.3H_2O$, $K_4P_2O_7.3.5H_2O$, $Na_2SO_4.7H_2O$, α-$NaH_2AsO_4.H_2O$, $K_3AsO_4.7H_2O$, $K_2HAsO_4.3H_2O$, $Na_3AsO_4.8H_2O$, $NaCN.2H_2O$, $Na_2SiO_3.9H_2O$, $Na_2GeO_3.7H_2O$.

Finally, for salts of the third group there are no thermodynamic data making it possible to characterise reaction (10), except the concentration of the saturated solution, and for these, the measurement of all three properties is required: $NaIO_4.3H_2O$, $H_2TeO_4.2H_2O$, $U(SO_4)_2.8H_2O$, $Th(SO_4)_2.9H_2O$, $Zr(SO_4)_2.4H_2O$, $CrSO_4.7H_2O$, $Sc(NO_3)_3.4H_2O$, $Na_2H_2PO_3.2{,}5H_2O$, KVO_3, α-$Na_3VO_4.12H_2O$, $UO_2CrO_4.5.5H_2O$, $Bi(NO_3)_3.5H_2O$, $Hg(ClO_4)_2.6H_2O$, $Na_2.MoO_4.2H_2O$, $Na_2WO_4.2H_2O$.

In the field of high-temperature studies, it is desirable to obtain more accurate values for the enthalpies of sublimation of a number of elements (for example, Ge, B, Zr, U, Re, Tc, Si, Be, Al, and the actinides), to study the energies of dissociation and enthalpies of formation of gaseous As_4, As_2, Sb_4, Sb_2, Tc_2, Se_2, N_2, and O_2, and to study the spectra of atoms with incomplete electron levels (transition metals, lanthanides, actinides) to determine the types of ground electronic states and the energies of the low electronic states.

The thermodynamic studies proposed above, which should lead to a significant increase in the accuracy of key quantities, is of course to some extent subjective and incomplete, and may be extended considerably. The present authors hope that experimentalists in the field of thermodynamics will consider precise studies of the above substances.

III. APPENDIX

Key Thermodynamic Quantities Recommended by the Committee on Data for Science and Technology (CODATA) of the International Council of Scientific Unions§

§ The recommended values were prepared by the International Task Group of CODATA for Key Thermodynamic Quantities: J. B. Cox (Present President of the Group), J. Drowart, L. V. Gurvich, V. A. Medvedev, J. B. Pedley, S. Sunner, D. D. Wagman, L. G. Hepler, and W. H. Evans. From the Soviet Union, the following also took part in this work: G. A. Bergman, V. P. Vasil'ev, A. F. Vorob'ev, G. L. Gal'chenko, V. P. Kolesov, I. L. Khodakovskii, and V. S. Yungman. The Table includes material published in CODATA Bullentins (see Ref. 48), including Bulletins[49,50] published after the Seventh All Union Conference. In addition to the above CODATA Bulletins and other publications[5,6], more detailed and complete information on key thermodynamic quantities, including commentaries, bibliographies, atomic weights, energy units, etc. will be published in a special information bulletin being prepared by the State Standard Reference Data Service of Gosstandardt SSSR (USSR State Standards).

Advances in the Thermodynamics of Organic Compounds in the USSR

I.B.Rabinovich

The results of the determination of the thermochemical parameters of organic and organometallic compounds as well as studies on the thermodynamic criteria of the occurrence of polymerisation and polycondensation processes and reactions involving products of petrochemical synthesis, carried out in the USSR during 1971-1975, are described.
The bibliography includes 114 references.

I. INTRODUCTION

In order to lay the scientific foundations of the technology for the synthesis of new substances with the aim of obtaining materials having specified properties, it is necessary to determine optimum conditions, in the thermodynamic sense, for the new processes, i.e. conditions ensuring the optimum yield of products. It is therefore necessary to determine the enthalpies of formation and the entropies of many new substances and to calculate the Gibbs free energies of new processes as a function of temperature, pressure, and the reactant concentrations. Experimentally, this is mainly associated with the development of calorimetric research into the enthalpies of reaction and the temperature dependence of the heat capacities of substances. It is also extremely important to investigate phase equilibria involving new pure compounds and multicomponent systems of technological importance.

Since it is impossible to reflect the specific advances in all the fields indicated above in a single review, mainly studies on several fundamental subjects will be considered: studies on the enthalpies of combustion and formation of organic and organometallic compounds; measurements of their low-temperature heat capacities and thermodynamic functions; studies on the thermodynamics of a number of processes.

These investigations were carried out in the laboratories of thermodynamics and thermochemistry of Moscow, Gorky, and Belorussian State Universities, the Institute of Chemical Physics of the USSR Academy of Sciences, the State Institute of Applied Chemistry, the Mendeleev Moscow Institute of Chemical Engineering, the Kuibyshev Polytechnic Institute, and a number of laboratories of higher educational establishments and academic and industrial research institutes.

During the period indicated above, our laboratories have successfully applied new precision USSR produced apparatus—a bomb calorimeter rotating simultaneously about two mutually perpendicular axes, constructed by Kolesov[1], and a calorimeter with a microfurnace within the bomb, constructed by Gal'chenko[2] (Moscow State University); apparatus for the measurement of heat capacities from 4 K based on a special cryostat at the Physicotechnical Low-Temperature Institute of the Academy of Sciences of Ukrainian SSR[3] and a universal thermophysical apparatus of the VNIIFTRI (All-Union Institute of Physicotechnical and Radiotechnical Measurements)[4]; a differential automatic calorimeter (DAK-1) for the determination of the enthalpies of mixing of the SKB [synthetic rubber bureau (?)] of the USSR Academy of Sciences[5], and other apparatus. In particular automation designed to maintain precise adiabatic conditions in the measurements of the heat capacities in the above apparatus and the treatment of the results on a computer made it possible to increase significantly the productivity of the experiments.

There have been significant methodological advances. These involve the improvement of the technique of the combustion of gaseous and condensed of organic and fluoro- and chlorofluoro-compounds (Kolesov, Moscow State University[6]), the development of methods for the determination of the enthalpies of combustion of carbaboranes based on an explosive process (Gal'chenko, Moscow State University[7]), and the development of a novel technique for the determination of enthalpies of sublimation in a Calvet microcalorimeter[8] in relation to organoboron compounds (Moscow State University and the Institute of Chemical Physics of the USSR Academy of Sciences), and others.

In most of the studies adequate attention has been devoted to the purification and monitoring of the purity of substances and the estimation of errors of measurements. The purity in the relevant instances was not less than 99.9%; the error in the measurement of the enthalpies of combustion was 0.01-0.05%, depending on the nature of the substances, and that in the heat capacities was 0.2 to 0.5%, depending on the temperature range.

II. ENTHALPIES OF COMBUSTION AND FORMATION†

Mainly traditional studies on organohalogen and organoboron compounds have been continued at the Luginin Thermochemical Laboratory (Moscow State University). Table 1 presents the results of the determination of the enthalpies of combustion ($\Delta H°_c$) and formation ($\Delta H°_f$) of 19 organic chlorofluoro-compounds studied by Kolesov

† Throughout the text below, 1 cal = 4.1840 J, (g) or g denotes a gas, (liq) or liq denotes a liquid, (c) or c denotes a crystal, soln denotes a solution, v-e denotes the viscoelastic state, and v denotes the vitreous state. The superscript 0 to the thermodynamic functions indicates a standard state of 101.325 kPa.

and coworkers[6,9-14] (chlorofluoroalkanes and oxygen-containing organofluorine compounds — derivatives of alcohols, acids, ethers, and esters). The experimental data were used to determine the enthalpies of formation of fluoroethylenes, to select reference quantities for the calculation of the $\Delta H°_f$ of fluoro- and chlorofluoroalkanes by the method of group contributions, and to establish for oxygen compounds in what cases and to what extent the mutual influence of the electrophilic atoms and groups is manifested in the energy of formation of molecules. In 1976 Kolesov wrote a critical review on the thermochemistry of halogenomethanes[14]. Using his own and literature experimental data, he selected 17 reference values of $\Delta H°_f$ and calculated by the method of group contributions the enthalpies of formation of all the 70 halogenomethanes. Many of the halogenoalkanes are used in industry and their enthalpies of formation are necessary for technological calculations.

Table 1. The enthalpies of combustion and formation of organic chlorofluoro-compounds at 298.15 K.

* The final state for $\Delta H°_c$ was as follows: CO_2(g), H_2O.(liq), HCl(soln), HF(soln), and N_2(g).

Table 2 lists the enthalpies of combustion and formation of a number of representatives of 15 organoboron compounds of different classes studied by Gal'chenko and coworkers[2,7,8,15-17] [the carbaboranes $B_{10}C_2H_{12}$ and their derivatives, whose molecules contain a closed skeleton (nucleus) of boron and carbon atoms; acyclic aminoboranes; dialkyl-(γ-aminopropyl)boranes — boron–nitrogen inner complexes in which ring closure takes place via the N–B bond; azaborolidines and oxaborolanes — compounds with a five-membered ring incorporating B and N or B and O atoms respectively]. Apart from their independent importance, the results of these studies, continuing the many years of research by Gal'chenko into the thermochemistry of boron compounds, made it possible to discover and explain many regularities in the properties of these substances. In particular, it is of interest that the enthalpies of isomerisation of unsubstituted carbaboranes proved to be comparatively large. For the ortho → meta and meta → para transitions involving gaseous carbaboranes, they are almost identical and amount to ~ -17 kcal mole^{-1}. According to the authors, this suggests that the *para*-isomer is much more stable than the meta-isomer and the latter is more stable than the *ortho*-isomer. The enthalpies of cyclisation of dialkyl-(γ-aminopropyl)-boranes also proved to be large. The enthalpy in the liquid state is -18 kcal mole^{-1}, which accounts for the existence of cyclic compounds, while the corresponding acyclic compounds cannot be isolated. The strain in a five-membered ring with two heteroatoms, namely B and N and B and O, has been estimated as 6 ± 2 kcal mole^{-1}, which agrees with the strain energy in cyclopentane (according to the authors, due to the similarity of the atomic radii of C, O, N, and B).

The enthalpies of combustion and formation of 38 organic compounds of transition metals [tricyclopentadienyl-lanthanides (Table 3); dicyclopentadienyl compounds of metals of the 3*d* series; dicyclopentadienyl complexes of molybdenum, tungsten, zirconium, and hafnium hydrides, chlorides, and iodides (Table 4); alkylcyclopentadienyl and cyclopentadienyl phenyl compounds of titanium, zirconium, and platinum; arene derivatives of chromium; niobium and tantalum alkoxides (Table 5)] were determined by Rabinovich, Tel'noy, and coworkers at the Termochemical Laboratory of Gorky

State University[18–25]. The purity of these compounds was 99.97–99.99%. Special measures were taken to prevent their oxidation before combustion. The solid combustion products were determined chemically and by X-ray diffraction. The error of the determination of the enthalpy of combustion was 0.02–0.05%.

The enthalpies of formation of the above substances in the condensed state and the data in Refs. 18–25 or those of other workers for the enthalpies of sublimation or vaporisation were used to calculate the enthalpies of formation in the gaseous state and from the latter the average dissociation energies of many bonds formed by transition metals in their organic derivatives were calculated. Together with the results of calculations from thermochemical data in the literature for metal carbonyls and several alkoxides, these results are presented in Figs. 1–3.[23] In all cases the average dissociation energy of the M–L bond in the compounds ML_n with the same ligand and identical values of n increases down the Groups of the Periodic System as the atomic number of the metal increases. This is particularly interesting in view of the fact that the opposite variation has been observed for organic derivatives of non-transition elements (E) — the average dissociation energy of E–R bonds decreases in the compounds ER_n with the same R and n down the Groups of the Periodic System as the atomic number of the element increases (Fig. 4).[26] Clearly this behaviour of transition metal compounds is due to the specific features of the variation of their effective nuclear charge and of the configuration of the electron shell in the subgroups of the Periodic System. We established that similar opposed variations are observed also for inorganic compounds of transition and non-transition elements[26].

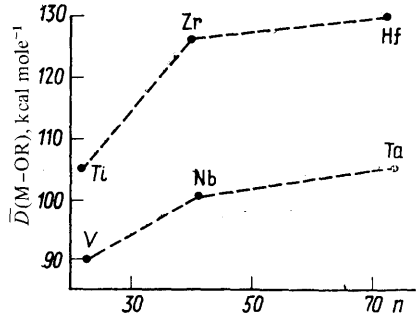

Figure 1. Dependence of the dissociation energy of M–OR bonds in transition metal alkoxides on the atomic number of the metal n.[26]

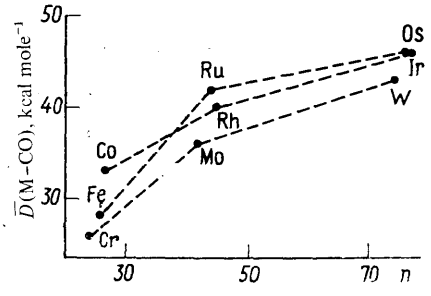

Figure 2. Dependence of the average dissociation energy of the M–CO bonds in metal carbonyls on the atomic number of the metals n.[26]

The enthalpies of combustion and formation of a further 54 organic compounds of metals, including 24 different silicon compounds, some of which are listed in Table 6, 14 germanium compounds (Table 7), and certain tin, aluminium, mercury, and magnesium compounds have been measured in the USSR. Most of these studies were carried out in Kostryukov's[27–30], Gadzhiev's[31–33], Shaulov's[34–42],

and the author's[43–47] laboratories. Tel'noy and Rabinovich wrote a review of the Soviet and foreign studies on the thermochemistry of organic compounds of transition metals[23].

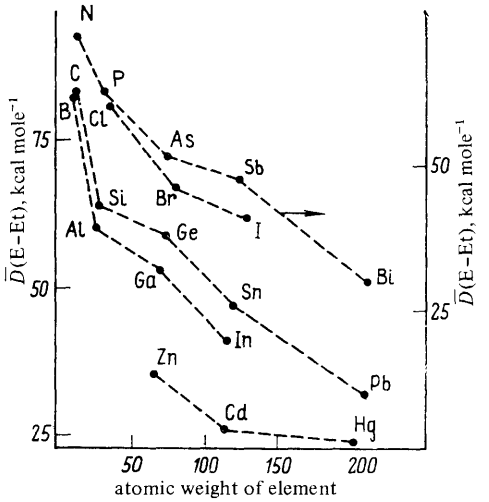

Figure 4. Dependence of the average dissociation energy of the element (E)–ethyl group (Et) bonds in the compounds EEt_n of non-transition elements on the atomic number of the element n.[26]

The enthalpies of combustion and formation of ~100 organic nitrogen compounds of different classes have been determined in Lebedev's[48–52] and Lebedeva's[53–57] laboratories. These are nitrohydrocarbons, alkylamines, amides, and nitriles, nitro- and amino-acids, as well as other compounds which are of considerable theoretical and applied interest. Finally, in this section we may mention studies on non-aromatic bicyclic and polycyclic compounds, which are being carried out systematically by Kozina and Gal'chenko at Moscow State University[58–60]. Together with their coworkers, they determined the enthalpies of combustion and formation of ~15 substances belonging mainly to the bicyclo[2,2,1]heptane (norbornane) and bicyclo[4,1,0]heptane (norcarane) series (Table 8). The energetics of these compounds are of considerable theoretical interest and some of them are used in industry.

In all, the enthalpies of formation of ~95 organic derivatives of metals were determined in the Soviet Union during 1971–1975, while in other countries similar determinations were made for altogether ~120 compounds.

III. THE LOW-TEMPERATURE HEAT CAPACITY AND THERMODYNAMIC FUNCTIONS

The temperature dependence of the heat capacities of 12 organoelemental compounds, including seven cyclopentadienyl derivatives of transition metals of the 3*d* series, in the range 5–300 K,[60–62], and 17 alkyl, carbonyl, and bisarene derivatives of metals in the range 60 to 300 K[60–62] were determined by Nistratov, Shaiman, and Maslova at the Thermochemical Laboratory of Gorky University. The thermodynamic functions of the above substances were calculated and the parameters of fusion

and transitions in the solid state were determined. Table 9 lists the entropies of the organoelemental compounds calculated from the temperature variation of the heat capacity.

Table 9. Thermodynamic functions of organoelemental compounds at 298.15 K[60–62] (calculations based on the heat capacities measured in the range 5–300 K)

Compound	$H^\circ(298.15) - H^\circ(0)$, kcal mole^{-1}	S°, kcal mole^{-1}	Compound	$H^\circ(298.15) - H^\circ(0)$, cal mole^{-1} K^{-1}	S°, cal mole^{-1} K^{-1}
$Hg(C_5H_5)_2$	10.28	67.44	$Mn(C_5H_5)_2$	8.34	60.08
$In(C_5H_5)_3$	14.55	88.67	$Co(C_5H_5)_2$	7.81	56.42
$Si(C_5H_5)_4$	15.52	98.44	$Ni(C_5H_5)_2$	8.25	60.47
$As(C_5H_5)_3$	12.90	84.48	$(C_5H_5)_2Ti(OCOC_6H_5)_2$	18.59	129.9
$V(C_5H_5)_2$	7.92	57.40	$(C_5H_5)_2HfCl_2$	10.27	73.27
$Cr(C_5H_5)_2$	7.71	56.40	$(C_5H_5)_2CrI$	10.18	74.54

Fairly distinct λ-transitions in the solid state were observed in the dicyclopentadienyl derivatives of vanadium, chromium, cobalt, and nickel; like the transitions known previously for ferrocene[63], these are transitions of the order–disorder type and are due to the manifestation of the hindered rotation of the ligands ‡. (Fig. 5 illustrates the λ-transitions in chromocene and cobaltocene).

‡ The rotation of the cyclopentadienyl rings, which alters their mutual intramolecular orientation, causes a significant change in the energy of the interaction of the rings of neighbouring molecules in the crystal lattice.

It is striking that the above compounds can be arranged in a series in terms of the enthalpies of the transitions (Table 10), which differs little from the series based on the absolute negative charges on the metal atoms, calculated by Armstrong et al.[64] The ratios of the hindered and eclipsed conformations of the molecules in each of the above four compounds were determined from the enthalpies of the transitions (Table 10). Here $\Delta S_t = R \ln X < R \ln 2$, where $X = 1.39$, 1.36, 1.17, and 1.16 for the cobalt, chromium, nickel, and vanadium compounds respectively ($X = 1.89$ for ferrocene).

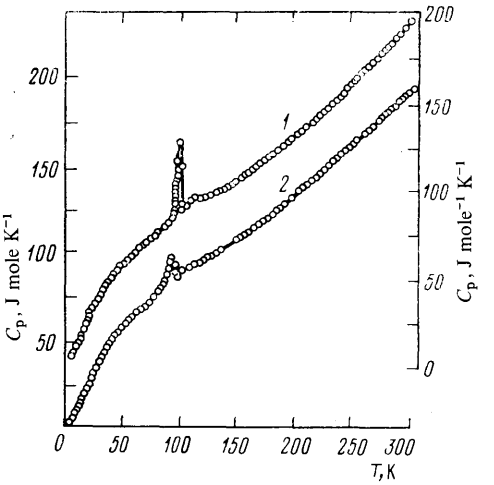

Figure 5. Occurrence of the λ-transitions in solid chromocene (curve *1*) and cobaltocene (curve *2*) on the curves representing the temperature variation of their heat capacities[65].

Table 10. Parameters of the λ-transitions of dicyclopentadienyl derivatives of transition metals of the 3*d* series[62].

Compound	T, K	ΔH_t^0, cal mole^{-1}	ΔS_t^0, cal mole^{-1} K^{-1}
$Fe(C_5H_5)_2$*	125—200	204	1.27
$Cr(C_5H_5)_2$	75—140	63.3±0.8	0.61±0.01
$Co(C_5H_5)_2$	70—120	56.8±0.5	0.65±0.01
$V(C_5H_5)_2$	120—200	46.8±0.5	0.29±0.01
$Ni(C_5H_5)_2$	100—190	43.4±0.5	0.32±0.01

* Data of Edwards et al.[63] (quoted for comparison with the parameters of the λ-transitions of other 3*d* metals).

It is of interest that the entropy of the λ-transition in dicyclopentadienyltitanium dibenzoate[65] proved to be $\sim R \ln 4$ ($\Delta S_t = 2.75$ cal mole^{-1} K^{-1}), which corresponds to the presence of four molecular conformations above the transition temperature, while there is only one conformation below this temperature. Presumably, two of the four conformations arise owing to the hindered rotation of the cyclopentadienyl rings and two are due to the rotation of the benzoate groups ($\Delta H_t = 392.5$ cal mole^{-1}).

The Gibbs free energies of the direct synthesis of the dicyclopentadienyl derivatives of metals of the 3*d* series as well as their thermal decomposition reactions, which are of interest for the preparation of the pure metals, were calculated from the enthalpies and entropies of formation of the compounds. Fig. 6 shows that the points of intersection of curves *1–6* with curves *7* and *8* determine the lower limits of the temperature ranges in which the above reactions are allowed for different metals at the standard pressure. It is therefore of interest that the coworkers of Academician G. A. Razuvaev (Institute of Chemistry of the USSR Academy of Sciences, Gorky) carried out direct syntheses of a number of cyclopentadienyl and arene derivatives from gaseous metals and solid hydrocarbons *in vacuo* at the temperature of liquid nitrogen[66] on the basis of analogous calculations using the data in Refs. 61–63.

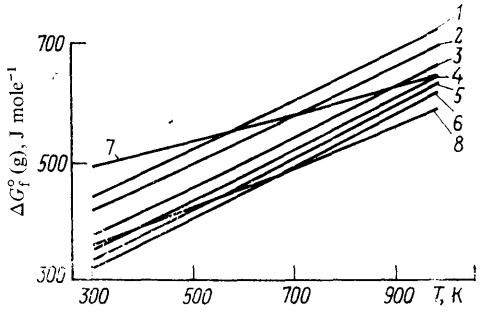

Figure 6. Graphical determination of the temperature ranges in which the reactions $M(g) + 2C_5H_6(g) \rightarrow (C_5H_5)_2.M(g) + H_2(g)$ and $(C_5H_5)_2M(g) \rightarrow M(g) + 2C_5H_5(g)$ at a pressure of 101.325 kPa are thermodynamically allowed (according to the Gibbs free energies of formation of the reactants)[65]: *1)–6)* $M(C_5H_5)_2$; M: *1)* Ni; *2)* Co; *3)* Mn; *4)* Cr; *5)* Fe; *6)* V; *7)* $2C_5H_5$; *8)* C_5H_6.

Kostryukov, Karasharli, and coworkers[67–69] investigated the temperature dependence of the heat capacities and calculated the thermodynamic functions in the range 12–370 K for 13 organosilicon compounds (siloxanes, silacyclanes, and silanes), some of which are listed in Table 11. Anomalies in the solid state, associated either with the deformation of the ring made up of silicon–oxygen bonds or with the hindered rotation of the methyl groups, have been found for a number of the above compounds.

Among other studies, mention should be made of investigations of the heat capacities of a number of benzene derivatives in the gaseous state [300–670 K, 10^5 (5–250) Pa] carried out by Akhundov[70] with the aid of an adiabatic flow calorimeter (error of the measurements ~0.45–0.65%), Kolesov's measurements of the low-temperature heat capacities of chlorofluoropropanes[71], and Paukov's studies on the heat capacities of substituted hexafluorobenzenes[72]. Altogether, in the period under consideration studies were made on the low-temperature heat capacities of ~70 organic compounds; among these ~50 compounds were investigated in the temperature range from 5–12 K to 300 K.

Approximately 30 studies were devoted to the calculation of the thermodynamic functions of organic compounds in the ideal gas state from molecular constants. Among them, special mention should be made of the research by Shaulov[73,74] and Pashinkin and coworkers[75] on the calculation of the thermodynamic functions of alkyl derivatives of Group III–V elements and certain carbonyls used to prepare pure metals and semiconducting compounds.

Clearly the determination of the entropies of ~100 important compounds will be useful for the corresponding technological calculations.

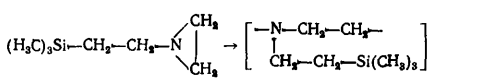
IV. THERMODYNAMICS OF POLYMERISATION AND POLYCONDENSATION PROCESSES

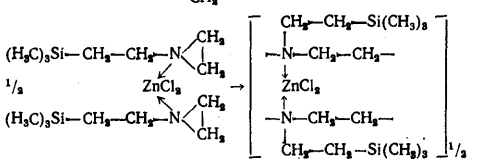
In connection with the needs of the rapidly developing polymer industry, a comparatively large amount of research has been done into the thermodynamics of the processes involving the synthesis of polymers. The enthalpies, entropies, and Gibbs free energies of the polymerisation of 20 carbocyclic and heterocyclic substances as well as organometallic compounds have been determined. Most of these studies were carried out by Lebedev and coworkers[76–80] at the Gorky University and in the laboratory of the present author.

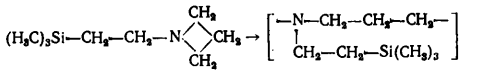
It was shown that the polymerisation of certain heterocyclic compounds, which could not be polymerised hitherto, is thermodynamically allowed. This applies particularly to *N*-(β-trimethylsilylethyl)ethyleneimine and the analogous derivative of trimethyleneimine, which are nowadays polymerised indirectly — via complexes with zinc chloride. Table 12 shows that the Gibbs free energies are fairly large and negative for the polymerisation of both the corresponding complexes and the individual imines. Evidently the role of complex formation reduces in these instances to decreasing the process activation energy.

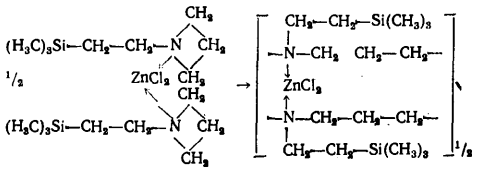
Another heterocycle — 1,1,3,3-tetramethyl-1,3-disilacyclobutane — has been polymerised catalytically near the standard temperature. Cyclopentene and cyclo-octa-1,5-diene also polymerise, giving rise to new varieties of synthetic rubber, glycolide forms a polymer which is used for medical purposes, and tetrahydrofuran polymerises

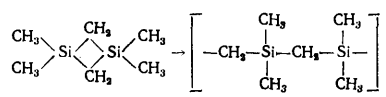
Table 12. Thermodynamic parameters of the polymerisation of *N*-(β-trimethylsilylethyl)-ethyleneimine and *N*-(β-trimethylsilylethyl)trimethyleneimine directly and via complexes with zinc chloride at 298.15 K.[78]

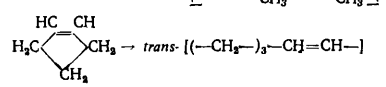


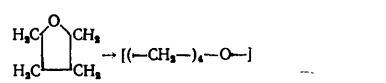


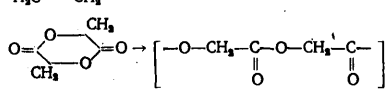


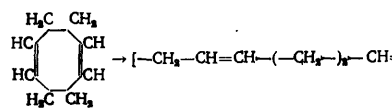












Process	State of reactants	$-\Delta H^\circ$, kcal mole^{-1}	$-\Delta S^\circ$, cal mole^{-1} K^{-1}	$-\Delta G^\circ$, kcal mole^{-1}
	liq → v-e	28.4	24.0	21.2
	c → v	31,5	3.56	30.4
	liq → v-e	27,5	19.9	21.6
	c → v	30.8	4.42	29.5

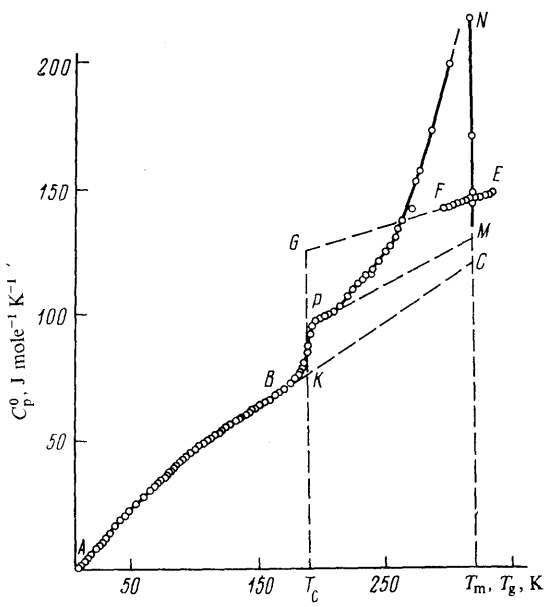
Table 13. Thermodynamic parameters of the polymerisation of certain cyclic compounds[80] at 298.15 K.

Process	*T*, K	State of reactants	$-\Delta H^\circ$, kcal mole^{-1}	$-\Delta S^\circ$, cal mole^{-1} K^{-1}	$-\Delta G^\circ$, kcal mole^{-1}
	298.15	liq → v-e	17,7	0.90	18.0
	298.15	liq → v-e	4,45	11.0	1.17
	298.15	liq → v-e	4,45	11.4	1.05
	550	liq → v-e	7,51	4.18	5.21
	298.15	liq → v-e	9.56	10.8	6.34

(Table 13). In all cases the polymerisation reaction takes place with ring opening and, in the absence of transitions involving different states of aggregation, the enthalpy of the process is close to the ring strain energy.

In the studies described the enthalpy of polymerisation was determined directly in a calorimeter or calculated from the experimental enthalpies of combustion of the polymers and monomers. The entropy of polymerisation was calculated from the temperature dependence of the heat capacities of the polymers and monomers measured from 4 or 8 K. Specimens of several of these polymers had a comparatively high degree of crystallinity: 40% for the polypentenamer, 65% for polytetrahydrofuran, and 67% for polyglycolide. The difference between the zero-point entropies of the polymers in the amorphous and crystalline states was calculated in these cases from plots of the temperature variation of the heat capacities of the fully crystalline and fully amorphous polymers obtained by extrapolating the corresponding experimental plots for the partly crystalline specimens[81]. For the polymers indicated above, the difference proved to be 3.5–4 cal mole^{-1} K^{-1}, which corresponds to approximately half the entropy of fusion of the above compounds under the conditions of 100% crystallinity. As an example, Fig. 7 presents the temperature dependence of the heat capacity of polytetrahydrofuran used to calculate the entropy.

Together with polymerisation reactions, the thermodynamics of the two-stage polycondensation synthesis of a number of polyheteroarylenes, distinguished by a comparatively high thermal stability, was investigated by Karyakin and coworkers[82–88] at the Thermochemical Laboratory of Gorky State University in collaboration with the laboratory of Academician V. V. Korshak (Institute of Organoelemental Compounds of the USSR Academy of Sciences) and the "Plastics Union". The first stage of the synthesis of these heterocyclic polymers consists in the interaction of aromatic diamines or their derivatives with acid dianhydrides in *N,N*-dimethylformamide with formation of an incompletely cyclised prepolymer. The enthalpies of these reactions were determined directly in an adiabatic calorimeter and their entropies were calculated from measurements of the heat capacities of solutions of each reactant in dimethylformamide as a function of temperature at concentrations corresponding to the polycondensation reactions. In all cases, differing in the composition of the initial amines and anhydrides, the standard Gibbs free energies of the processes at ~298 K show that their equilibria are almost completely displaced towards the formation of the prepolymers.



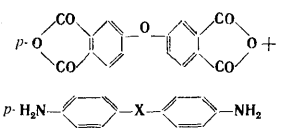


Figure 7. Temperature variation of the heat capacity of polytetrahydrofuran[80]: circles — experimental data for the polymer with a 65% degree of crystallinity; *ABKC*— experimental data for the polymer with 100% degree of crystallinity (extrapolation neglecting the difference between the heat capacities of the amorphous and crystalline polymers before devitrification); *ABPM*— experimental data for the specimen with a 65% degree of crystallinity (extrapolation); *ABGFE*— experimental data for the specimen with 0% degree of crystallinity (extrapolation); T_g and T_m are the glass and melting points respectively.

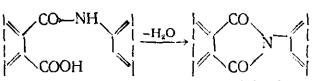
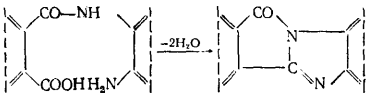
The second stage of the synthesis involves additional cyclisation of the prepolymer at elevated temperatures with evolution of water. The equilibrium constants of the cyclodehydration reaction were determined from the equilibrium vapour pressure and their temperature variation was used to find the enthalpies of the reactions. The results show that the thermodynamic criteria allow the cyclodehydration of the prepolymers to go virtually to completion over a wide temperature range. However, the reaction does not go to completion because of kinetic factors and the copolymers formed have both the final cyclic structures and the structures of the initial prepolymers. A method has been proposed for the determination of the compositions of such copolymers from their enthalpies of combustion. As an example, Tables 14 and 15 present the thermodynamic parameters of the reactions involving the formation of certain prepolymers and final polymers.





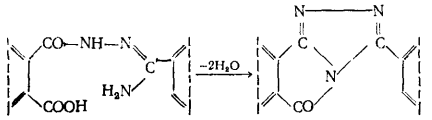


Table 14. Thermodynamic parameters of polycondensation reactions[83]:

V. THERMODYNAMICS OF REACTIONS OF PRODUCTS OF PETROCHEMICAL SYNTHESIS AND OTHER PROCESSES

In a number of higher educational establishments of the USSR studies have been made on the thermodynamics of ~150 isomerisation reactions of alkanes, alkenes, and their halogeno-derivatives (the results of some of these are listed in Table 16), the dehydrohalogenation reactions of halogeno-derivatives of alkanes and alkenes, and disproportionation reactions of alkenes. Rozhnov[89–92] (Kuibyshev Polytechnic Institute), Andreevskii and Kabo[93–96] (Belorussian State University), Vasil'eva and coworkers[97] (All-Union Petrochemical Synthesis Institute), and others studied experimentally the equilibria in the processes in the range from the standard temperature to 600 K and calculated the thermodynamic parameters of the reactions from their equilibrium constants and the temperature variation of the latter. Some of the processes investigated are already used in industry and others can be so employed. Particular mention should be made of the determinations, which are of practical importance, of the thermodynamic parameters of a number of reactions involving the pyrolysis of benzene[98], the synthesis of 4,4-dimethyl-1,3-dioxan from isobutene and formaldehyde and its conversion into isoprene[99], and the synthesis of alkylene carbonates[97] and Freon-11 and Freon-12,[100] as well as the investigation of the equilibria in the individual stages of the formation of isoprene and piperylene from isopentene[101], etc.

Table 16. The enthalpies and entropies of isomerisation of alkanes, alkenes, and their halogeno-derivatives[92–96].

Reaction	Conditions	$\overline{\Delta H^\circ}$, kcal mole^{-1}	$\overline{\Delta S^\circ}$, cal mole^{-1} K^{-1}
$CH_2Br-CH_2-CH_3 \rightleftarrows CH_3-CHBr-CH_3$	273–583 K; (liq)	−2.86±0.13	−3.66±0.38
$CH_2Br-CH(CH_3)-CH_3 \rightleftarrows CH_3-CBr(CH_3)-CH_3$	273–526 K; (liq)	−3.800±0.160	−5.8±0.5
$CH_3Cl-CH_2-CHCl-(CH_2)_2-CH_3 \rightleftarrows CH_3Cl-(CH_2)_2-CHCl-CH_2-CH_3$	273–363 K; (liq)	−0.530±0.030	0.90±0.09
erythro-$CH_3-CHCl-CHCl-CH_3 - CH_3 \rightleftarrows$ *meso*-$CH_3-CHCl-CH_2-CHCl-CH_3$	273–373 K; (liq)	1.890±0.100	2.43±0.32
$CH_2=C(CH_3)-(CH_2)_2-CH_3 \rightleftarrows CH_3-C(CH_3)=CH-CH_2-CH_3$	273–516 K; (gas) 101 кПа	−1.13±0.15	−0.30±0.35
$CH_3-CCl(CH_3)-CH_2-CH_3 \rightleftarrows CH_3-CH(CH_3)-CHCl-CH_3$	273–373 K; (liq)	1.89±0.05	1.75±0.2

Research into the thermochemistry of the complex formation reactions of organic compounds is being rigorously prosecuted in our country. Gur'yanova and Gol'dshtein and coworkers (Karpov Physicochemical Institute) investigated the formation of complexes by ethers, sulphides, selenides, amines, phenols, and organophosphorus compounds with alkyl derivatives of boron and aluminium, the halides of various elements, and other substances (for further details, see the monograph of Gur'yanova et al.[102]).

In the Thermochemical Laboratory of Gorky State University, Tsvetkov and coworkers carried out a series of studies on the thermochemistry of the interaction of alkyl derivatives of Group III–V elements with one another[103,104]. The corresponding complexes are of interest, because semiconducting compounds can be obtained from them. A large number of studies on the thermochemistry of hydrogen-bonded complexes have been described in detail in a recent review[105].

VI. LIQUID–VAPOUR EQUILIBRIA INVOLVING PURE SUBSTANCES

Data on the vapour pressures and enthalpies of vaporisation and sublimation of ~500 substances (the studies by Karapet'yants and coworkers on the precision measurements and approximate calculation of the vapour pressures of many organosilicon, organotin, and organogermanium compounds[106–108], a number of studies on the vapour pressures of linear and cyclic oligo-organosiloxanes and other organosilicon compounds with different substituents at the silicon atom[109,110], studies by Gal'chenko and Lebedev and coworkers on the direct determination of the enthalpies of sublimation of organoboron compounds[111], studies by Devyatykh and coworkers on the vapour pressures of cyclopentadienyl derivatives of the lanthanides[112], studies by Rabinovich, Kir'yanov, and coworkers on the vapour pressure of cyclopentadienyl derivatives of transition metals of the 3*d* series[20,21], studies by Baev at the Belorussian Technological Institute on the vapour pressures of alkyl derivatives of non-transition elements[113] and metal carbonyls[114], as well as those of many other investigators) were published in 1971–1975.

It is clear from the list of compounds whose vapour pressures have been investigated that they are of both theoretical and applied interest. In particular, the enthalpies of vaporisation and sublimation obtained have been used in a number of investigations to calculate the enthalpies of formation of compounds in the gaseous state from their experimental enthalpies of formation in the condensed state §.

§ This is why we have considered briefly studies on the vapour pressures of organic compounds, while those on phase equilibria in multicomponent systems have not been examined.

Exciting Developments in the Thermophysics of the Pnictides and Chalcogenides of the Transition Elements

E.F.Westrum Jr.

A terse reexamination of the thermophysical aspects of the chemical thermodynamics of the transition element chalcogenides is presented with a view to updating the Grønvold and Westrum approach of 1962. A somewhat more detailed progress report and insight into the situation pertaining to the transition element pnictides is also pursued in order to attain an impression of the similarities and differences between these two important classes of transition element compounds.
The increasing availability of high-temperature adiabatic calorimetric data to supplement that obtained by cryogenic calorimetry, a better appreciation of the dilatometric contribution (especially important as higher temperatures are considered), the effect of band structure and related problems are reviewed, and interesting examples of these and other phenomena are presented for a few selected substances including marcasite, cobalt ditelluride, iron diantimonide, chromium diantimonide, chromium monoarsenide, triuranium tetraarsenide and tetraantimonide, uranium diantimonide, diarsenide, and low-digenite ($Cu_{1.80}S$).
The bibliography includes 90 references.

At the very outset I would like to express my appeciation to the Organizing Committee of the All-Union Conference on Calorimetry (Moscow, 1977) and to the Academy of Sciences of the U.S.S.R. for providing this opportunity for us to meet together and to discuss progress on thermodynamic projects of mutual concern. I can remember well my first participation in the third of these impressive meetings and in the intervening conferences as well and hope that there will be many more as it is clearly to the mutual advantage of the advancement of our projects to learn of new developments—but more important—it results in an accelerated achievement of progress towards our ultimate goals. The excellence of the papers presented and the enthusiasm of the participants attests to the careful planning by the Organizing Committee.

I. PERSPECTIVE AND INTRODUCTION

Approximately a decade and a half ago, Grønvold and Westrum, in the first issue of the then new Journal, "Inorganic Chemistry", presented an extensive paper concerned with the correlation and estimation of the entropies of the transition element chalcogenides[1]. By way of reminder, the most striking outcome of this analysis involved the fact that the cationic entropy contribution according to Latimer[2], instead of increasing gradually and continuously in a monotonic logarithmic aspect, leveled off essentially in "shelves" for each of the successive n-levels of the principal "d" quantum numbers as shown in Fig. 1. Although this approach was not adopted by Mills in his mammoth compilation of the thermodynamics of the sulphides, selenides, and tellurides[3], we are undaunted as to its essential correctness and believe that he did not detect it primarily because he was using equilibrium as well as the direct adiabatic calorimetric determination of entropies and simply did not, therefore, enjoy the same high precision of resolution that was possible to us. As a matter of fact, a recent application of this scheme to the lanthanide halides has done much to verify its essential correctness insofar as the lanthanides are concerned[4,5].

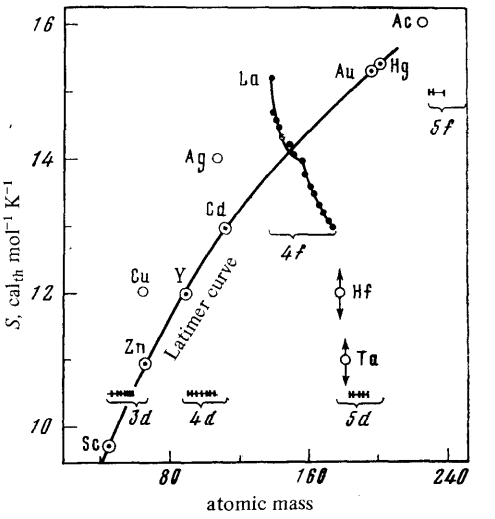

Figure 1. Modification of the Latimer cation scheme for transition[1], lanthanide[6], and actinide[1] elements.

In surveying the progress that has been made in this area subsequent to 1962, we note particularly that more than anything else the era is characterized by a relatively slow accumulation of data on the transition-element chalcogenides. Only within the last two years have F. Grønvold and the author been involved once again in this study and most of this work remains as yet unpublished. Some idea of the recent progress is summarized in Table 1; the most important new development has been the determination of the higher-temperature heat capacities by adiabatic calorimetry done primarily by Grønvold at Oslo.

Table 1. Chalcogenides and pnictides for which Third-Law entropy data have recently been obtained in the author's laboratory.

Chalcogenides				Pnictides		
		3d			*3d*	
FeS_2 (marcasite)	$CoTe_2$	NiS	$Cu_{1.00}S$ (covellite)	CrAs	FeAs	NiAs
	$CoSe_2$		$Cu_{1.75}S$ (anilite)	CrSb		
			$Cu_{1.80}S$ (low-digenite)	$CrSb_2$		
			$Cu_{1.96}S$ (djurleite)		*5f*	
			$Cu_{2.00}S$ (chalcocite)	$ThAs_2$		UAs_2
		4d		$ThSb_2$		USb_2
$RuSe_2$		Ag_2S				U_3As_4
		5f				U_3Sb_4
$ThSe_2$						

In considering a similar (preliminary) survey of the transition element pnictides we find that the availability of high-temperature data is an important aspect. In some ways many of these compounds are more metallic than the corresponding chalcogenides, and band structures replace the convenient discrete electronic levels characteristic of many of the chalcogenides. This involved new problems of interpretation and correlation. At the present time, thermophysical data on a baker's dozen of these have been generated—primarily through our own endeavours—and we continue to pursue enthusiastically these very interesting substances. It is too soon yet to attempt a true overview, but this paper will present some of the interesting developments which have thus far been encountered in both classes of compounds. In the presentation which follows an arbitrary selection of the results has been made to emphasize particularly the interesting phenomena encountered over high- and low-temperature ranges in both chalcogenides and pnictides. Hopefully, the time will soon be ripe for a more detailed analysis and correlation of the pnictides. I want to emphasize that without the great skill in synthesis that has been developed at the Kjemisk Institute at Oslo, initially under Professor Haakon Haraldsen and more recently by Dosent Grønvold, neither temperature range could have been covered with assurance that the materials were "well characterized". The work has been materially accelerated by other collaborators as noted in the acknowledgement.

II. CONTRIBUTIONS TO THE HEAT CAPACITIES

A perpetual endeavour in our studies is first of all to understand the resolution of the heat capacity into the several most important contributions involved. This resolution, based in part upon knowledge of the compound from other auxiliary techniques, is important, not merely as an exercise in itself, but also as a means of enhancing our ability to estimate the thermodynamic properties of transition elements, chalcogenides, and pnictides. We may consider the observed heat capacity to be a sum of the following contributions:

$$C_p = C_v(l) + C(e) + C(m) + C(s) + C(d).$$

Here $C_V(l)$ is the lattice-vibrational heat capacity at constant volume, $C(e)$ the conduction electron contribution, $C(m)$ the cooperative magnetic contribution from population of excited electronic states, $C(s)$ the Schottky contribution, and $C(d)$ the dilation contribution. In transition regions the various contributions may be coupled, but the feasibility of their separation is assumed.

Lattice heat capacity at constant volume. This prime contribution to the heat capacity may usually—in the absence of more detailed information—be expressed by a single Debye function with constant characteristic temperature, Θ_D, for a simple monatomic substance, or by a sum of Debye and Einstein functions for a compound. As a first approximation, the higher-temperature heat capacity is often calculated after evaluating an effective Debye temperature from the heat capacity over the 50 to 100 K region.

Conduction electron contribution. The molar electronic contribution to heat capacity is in the first approximation proportional to the thermodynamic temperature T and equal to

$$C_v(e) = \frac{4\pi^2 k^2 m T N_A}{h^2 (3\pi^2 N/V)^{2/3}} = \gamma T,$$

where k is the Boltzmann constant, m the electron rest mass, L the Avogadro number, h the Planck constant, and N/V the number of electrical carriers per unit volume. The γ's calculated from electrical measurements are, however, often smaller than those derived from low-temperature, heat-capacity measurements.

Magnetic and Schottky contributions [$C(m)$ and $C(s)$]. These contributions often occur either as a cooperative transition from a magnetically ordered state (ferro-, ferri, antiferro-, or heli-magnetic state) or from a gradually changing electron distribution with temperature, i.e. a Schottky transition. For the former case, the magnetic entropy change is related to the changes in the observed magnetic moment or to susceptibility below and above the transition, but the interpretation is still uncertain in most cases. The molar heat capacity from a non-cooperative, Schottky-type transition can be expressed as

$$C(s) = RT\partial^2\{T \ln \Sigma g_i \exp(-E_i/kT)\}/\partial T^2,$$

where g_i is the degeneracy of the ith level, separated from the ground level by an electronic energy E_i. Differentiation yields an expression suitable for computer calculations[6]:

$$C(s) = (1/RT^2)\left[\frac{\Sigma E_i^2 g_i \exp(-E_i/kT)}{\Sigma g_i \exp(-E_i/kT)} - \left\{\frac{\Sigma E_i g_i \exp(-E_i/kT)}{\Sigma g_i \exp(-E_i/kT)}\right\}^2\right].$$

This contribution should by no means be regarded as important only at very low temperatures. Sommers and Westrum have shown it to be important above 300 K also [4,5]. Furthermore, the paper by Rakhmenkulov et al. [7] presented at this meeting has provided much interesting information on lanthanide phosphides.

The dilation contribution. In general, this contribution is

$$C(d) = C_p - C_v = \alpha^2 VT/\beta,$$

where α is the thermal expansivity, V the molar volume, T the thermodynamic temperature, and β the isothermal compressibility. When the thermal expansivity is known, but not the compressibility, the dilation contribution can be estimated by use of the Grüneisen relation:

$$C(d) = \alpha\Gamma C_v T,$$

where the Grüneisen parameter Γ is chosen on the basis of values for related substances. A better estimate is obtained when both α and β have been determined at one and the same temperature but Γ is in general slightly temperature dependent. When neither α nor β is known—the dilation contribution may be estimated according to Nernst and Lindemann as

$$C(d) = AC_p^2 T/T_f,$$

where the "universal" constant $A = 0.005$ J^{-1} K for one gram-atom and T_f is the melting temperature of the substance.

III. CALORIMETRIC TECHNIQUE

Heat capacity measurements were made in a Mark II adiabatic cryostat over the 50 to 300 K region at the University of Michigan. This cryostat was described previously [8]. The samples were contained in gold-plated copper calorimeters which incorporated a gold-gasketed seal and gold-plated copper vanes to enhance conductivity. Temperatures were measured with a platinum, capsule-type, 25-ohm (nominal) resistance thermometer inserted into a re-entrant well in the calorimeter.

The calorimetric apparatus and measuring technique for the region 300 to 1030 K at the University of Oslo have been described [9]. The calorimeter was intermittently heated, and surrounded by electrically heated and electronically controlled adiabatic shields. The substance was enclosed in an evacuated and sealed silica glass tube of about 50 cm^3 volume, tightly fitted into the silver calorimeter. A central well in the tube served for the heater and platinum, resistance thermometer.

The cryogenic thermometer had been calibrated by the U. S. National Bureau of Standards, and that for the high-temperature calorimeter locally, at the ice, steam, tin, zinc, and antimony points. Temperatures are judged to correspond to IPTS-68 within 0.03 K from 5 to 300 K and within 0.05 K between this temperature and 900 K. The uncertainty rises to 0.2 K at 1030 K. Resistance, energy, and mass were measured with reference to calibrated instruments by the U. S. National Bureau of Standards.

The heat capacities of both types of empty calorimeters were determined in separate series of experiments. It is emphasized that both sets of measurements were made by adiabatic calorimetry and that equilibrium was typically achieved in all determinations.

IV. MARCASITE/PYRITE METASTABLE TRANSFORMATION

One of our most satisfying publications of 1976 has been the resolution of the stability of marcasite vis-ã-vis pyrite [10]. As is well known, iron disulphide occurs in nature (and can be prepared in the laboratory also) in two polymorphic forms, marcasite and pyrite. While a considerable amount of thermodynamic data exists for pyrite [3,11], such data are virtually unknown for marcasite, except for some measurements of its enthalpy of combustion [12-14]. In order to remedy this situation and to evaluate the stability conditions for the polymorphs, the heat capacity of marcasite has been determined from 5 K to the temperature region where it transforms into pyrite. Measurements on the previously studied pyrite sample [1] have been extended to 770 K.

The heat capacity of the pyrite sample increased gradually over the temperature range 5 to 770 K without any sign of transformation [10]. The values were usually 0.1 to 1.0 per cent lower than for marcasite at the corresponding temperature. The higher-temperature, heat-capacity measurements on marcasite were quite normal until an energy input produced a somewhat higher temperature increment and brought the temperature up to 706.43 K. Here the drift-rate gradually changed from a slightly negative value of about -0.0009 K min^{-1} to large positive values after a period of 2 h. The subsequent gradual temperature increase was followed for a further 96 h, at which time the temperature was estimated to be not more than (0.15 ± 0.25) K from the limiting value T_∞. [15] The enthalpy of transformation of marcasite to pyrite at 700 K is $\Delta H^\circ_{tr} = (-1050 \pm 50)$ cal$_{th}$ mol^{-1}†. When the heat-capacity measurements were continued after 96 h, the heat capacity corresponded closely to that of pyrite, and X-ray powder photographs taken of the sample after completion of the measurements showed the presence only of pyrite.

In the absence of a zero-point entropy in this system, marcasite even in the vicinity of the transformation temperature is thermodynamically metastable with respect to pyrite. Since the transformation is monotropic and irreversible, we cannot ascribe an entropy increment to the transformation and instead utilize an enthalpy cycle for the marcasite-pyrite system through $T = 0$. Taking into account the enthalpy increment for the marcasite to pyrite transformation to 700 K, $H(T = 0,$ marcasite$) - H(T = 0,$ pyrite) is found to be (0.99 ± 0.05) kcal$_{th}$ mol^{-1}. This value should, therefore, be incorporated into $[G^\circ(T) - H^\circ(0)]/T$ for marcasite for chemical thermodynamic calculations. Moreover, marcasite is seen to be clearly metastable with respect to pyrite above $T = 0$. For example, at 298.15 K the value of ΔG° (marcasite → pyrite) is (-0.95 ± 0.05) kcal$_{th}$ mol^{-1}.

Our results together with the critically evaluated values of ΔH_f°(pyrite) from Mills' [3] and from Robie and Waldbaum's [12] reviews together with entropies for iron [16] and sulphur [17] yield the following standard enthalpies, entropies, and Gibbs energies of formation of FeS_2 at 298.15 K:

		Pyrite	Marcasite
$\Delta_f H^\circ$,	kcal$_{th}$ mol^{-1}	-41.5 ± 0.5	-40.5 ± 0.5
$\Delta_f S^\circ$,	cal$_{th}$ K^{-1} mol^{-1}	-9.07 ± 0.10	-8.84 ± 0.10
$\Delta_f G^\circ$,	kcal$_{th}$ mol^{-1}	-38.8 ± 0.5	-37.9 ± 0.5

The geological occurrence of pyrite pseudomorphs after marcasite is consistent with above interpretation, since

† Throughout this paper, cal$_{th}$ = 4.184 J.

marcasite presumably occurs in low-temperature hydrothermal deposits and apparently occasionally transforms into pyrite at temperatures well below 700 K.

V. COBALT DITELLURIDE AND COBALT DISELENIDE

We have determined the heat capacity of another compound of marcasite-type structure—orthorhombic cobalt ditelluride—from 5 to 1030 K by adiabatic-shield calorimetry with intermittent energy inputs and equilibration. It shows interesting behaviour [18].

Its paramagnetism indicates the presence of unpaired 3*d*-electrons. The effective magnetic moment (2.2 μ_B at 720 K) [19] is much smaller than the moment (3.87 μ_B) expected for Co^{2+} in the high-spin state and somewhat higher than the value 1.73 μ_B for the low-spin state in the configuration spin-only approximation. The intermediate moment observed is possibly due to orbital contributions of the kind commonly observed in the case of Co(II) complexes. Hence, the effect of orbital ordering might be observable in the heat capacity of $CoTe_2(m)$ just as predicted [20] for the related ferromagnetic case and observed for $CoS_2(p)$‡.

According to Goodenough [21], $CoTe_2(m)$ contains one itinerant 3*d*-electron in a σ^*-band sufficiently wide to preclude cooperative magnetic ordering. Overlap of this band with a σ^*-band of the anions was suggested as an explanation of the non-stoichiometry of the $CoTe_{2+x}$-phase. The Vandenbempt alternative view [22] presupposes antiferromagnetic ordering in $CoTe_2(m)$, by analogy with the assumption made for $CoSe_2(p)$ by Adachi et al. [23] However, neither the present heat-capacity measurements, nor the Mössbauer experiments by Kjekshus and Nicholson [24] indicate the presence of cooperative ordering or magnetic exchange interactions due to localization of 3*d*-electrons into sub-bands.

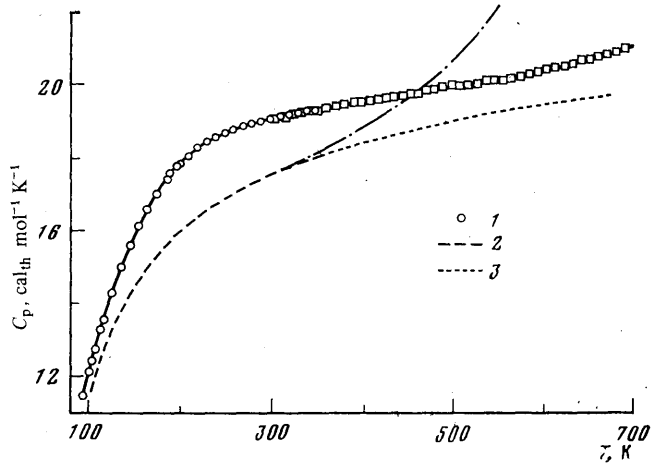

Figure 2. Molar heat capacity of $FeSb_2$ from 100 to 700 K compared with that of $FeTe_2$. ○, Results for $FeSb_2$ from low-temperature calorimetry; □, results for $FeSb_2$ from high-temperature calorimetry; ---, results for $FeTe_2$ by Westrum et al. [25], –·–·–, results for $FeTe_2$ by Mikler et al. [26], ----, extrapolated lattice heat capacity of $FeTe_2$.

‡ *m* = magnetic; *p* = paramagnetic.

No lattice-dynamical analysis has yet been carried out. In analysing the thermophysical properties of $CoTe_2$, we therefore used the experimental heat capacity of $FeTe_2$ [25]—a rate isostructural analogue of $CoTe_2$. This compound is non-magnetic, has semiconducting properties and its atomic masses, interatomic distances, and angles are almost identical with those of $CoTe_2$. Thus, the excess heat capacity of $CoTe_2(m)$ relative to $FeTe_2$ might be related to differences in the outer electronic structure rather than to differences in the lattice contributions. The excess heat capacity rises to a rather pronounced maximum of 1.7 cal_{th} mol^{-1} K^{-1} at 80 K and then falls gradually with increasing temperature. It may reflect a large increase in density of states just above the Fermi level, and thus the presence of levels or bands with high-density regions which presumably derive from the broader bands assumed by Goodenough [21] and by Vandenbempt et al. [22] In the absence of further details about the level and band structure of $CoTe_2(m)$, it remains to be investigated whether the lowest excited level or band is primarily an antibonding σ^*-metal state, an overlapping-anion, *p*-band state, or of other origin.

The resemblance of the excess heat capacity to a Schottky-type transition is illustrated in Fig. 2 on the assumption of two excited levels 65 and 175 cm^{-1} above the ground level with degeneracies $g_0 : g_1 : g_2 = 1 : 1 : 3$. The rather good fit in the region up to 100 K cannot be taken as a proof of the uniqueness of the explanation, but even so, the model might approximate the variation in the density of states. Because of uncertainty in the assumptions, the introduction of further levels to account for the deviation above 100 K has not been attempted.

Since it is well known that Schottky-like heat capacity contributions occur also as differences between Debye and/or Einstein functions with different characteristic temperature, the metallic nature of $CoTe_2(m)$ might give rise to a lower characteristic temperature than that for $FeTe_2$ and a more rapid heat capacity rise will then be expected at intermediate temperatures. This alternative interpretation of the excess heat capacity is also illustrated in Fig. 2, assuming (constant) Debye temperature of 300 K for $FeTe_2$ and 250 K for $CoTe_2(m)$.

Interestingly, the estimated value for the entropy calculated through the cationic and anionic entropy contributions [1] for solid transition-metal chalcogenides is 24.0 cal_{th} mol^{-1} K^{-1} at 298.15 K, or about 3.4 cal_{th} mol^{-1} K^{-1} lower than that observed. This result is analogous to those for other cobalt and nickel chalcogenides as a consequence of the neglect of the contributions from population of low-lying electronic states or bands, which we thus far had been unable to evaluate properly.

The heat capacity increase for $CoTe_2$ above 300 K follows a different pattern from that observed for $FeTe_2$. [26,27] An unusual increase is observed of a temperature as low as 400 K in the latter, probably occasioned by defect formation as in $FeSe_2$, [28] while for $CoTe_2(m)$ only a gradual increase in heat capacity, primarily due to the dilational term is observed up to 900 K. Above this temperature a sigmoid increase is noted from about 23 cal_{th} mol^{-1} K^{-1} at 930 K to about 33 cal_{th} mol^{-1} K^{-1} at 1030 K. This reflects the precipitation of the $Co_{1-x}Te$-phase from stoichiometric $CoTe_2$ as the peritectic decomposition temperature for the $CoTe_2(m)$-phase is approached.

The entropy of $CoTe_2(m)$, the entropies of the elements [29], and the enthalpy of formation of $CoTe_2(m)$ (found by solution calorimetry) [30], have been determined and their

values for $CoTe_2(m)$ at 298.15 K are:

$\Delta_f H^0$, $kcal_{th}\ mol^{-1}$	-17.44 ± 0.7
$\Delta_f S^0$, $cal_{th}\ mol^{-1}\ K^{-1}$	-4.37 ± 0.3
$\Delta_f G^0$, $kcal_{th}\ mol^{-1}$	-16.1 ± 0.8

The latter two values are at variance with those determined by Komarek et al.[30] from decomposition pressures.

Measurements on $CoSe_2$ have thus far revealed only a simple approximately sigmoid heat capacity over both low- and high-temperature regions[31].

VI. THERMOPHYSICAL PROPERTIES OF $FeSb_2$

Let us consider $FeSb_2$ as one example—not necessarily totally typical—of the problems encountered in this endeavour. Electrical and magnetic measurements on well-characterized samples of $FeSb_2$ by Fan et al.[32] led them to conclude that $FeSb_2$ is a semiconductor or a semimetal with an extremely narrow band gap. Further support was provided by the study of the Mössbauer effect from 6.4 to 560 K by Steger and Kostiner[33] who fitted their data to a function indicating that the temperature dependence of the quadrupole splitting is the result of an electrical process which involves the thermal population of an empty conduction band. Hence, the study of the heat capacity of $FeSb_2$ would offer conclusive evidence for the absence of cooperative phenomena in the compound, and also show the effect of band population.

The heat capacity of $FeSb_2$ increases quite monotonically over the entire temperature region and with little evidence of preperitectic decomposition[34]. This contrasts with the X-ray diffraction results by Fan et al.[32] that $FeSb_2$ decomposes into FeSb and Sb under vacuum at 573 K. The decomposition found here (1021.2 ± 0.2) K is in complete agreement with that found by Geiderikh et al.[35] (1021 K) while the results of Kurnakov and Konstantinov[36] (1001 ± 2 K) and Holseth[37] (1004.6 ± 0.5) K are considerably in error.

No trace of the antiferromagnetic transition claimed to exist around 800 K to 1000 K by Rosenqvist[38] and by Holseth and Kjekshus[39] was detected, which accords with the observation by the latter authors that no purely magnetic reflections were obtained in their neutron-diffraction study of $FeSb_2$ around 300 K. Thus, iron is accordingly in a non-magnetic ground state, which presumably arises from the $3d^4$ configuration. The ΔH_d for the peritectic decomposition at 1021.2 K is ($12\,910 \pm 30$) $cal_{th}\ mol^{-1}$.

However, the heat capacity of $FeSb_2$ does not show the pronounced increase at higher temperatures characteristic of $FeTe_2$[26,27] (see Fig. 2). Similar behaviour in $FeSe_2$ has been attributed to defect formation[28], while neither isostructural FeS_2[10] nor isoelectronic $NiSb_2$[40] show comparable excess heat capacities in the higher-temperature region. A comparison of $FeSb_2$ and $FeTe_2$[41] has already been made.

In the Goodenough[42] and the Fan et al.[32] model the $3d$-electron b-band is filled with four electrons, while the next doubly degenerate $a_\parallel$-band is empty. Steger and Kostiner[33] concluded from the unusual temperature dependence of the Mössbauer quadrupole splitting that electrons were promoted across an energy gap of only (33 ± 1) meV (or 265 cm^{-1}), that is, having approximately the same value as that derived by Fan et al.[32] from electrical conductivity measurements ($\sim$210 cm^{-1}). If the band is assumed to be narrow and its population approximated by a Boltzmann distribution, we find that excitation from a fourfold-degenerate b-band does not produce the observed increase in heat capacity. Thus, either the b-band might be split, or further levels or bands in addition to $a_\parallel$ and σ^* are also being populated. We are not at this time able to make a decision between the various alternatives, but should like to remark that a surprisingly good agreement is obtained (see Fig. 3) if a split $(2)b$-band is succeeded by $(2)a_\parallel$ and $(4)\sigma^*$ (in Goodenough's model) with $E_1/hc = 200\ cm^{-1}$ and $E_2/hc = 500\ cm^{-1}$.

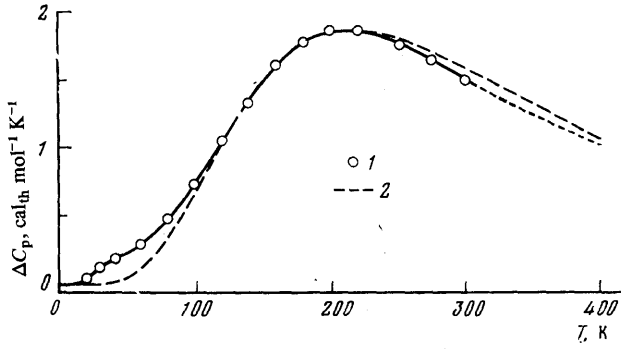

Figure 3. o, Excess molar heat capacity of $FeSb_2$ relative to that of $FeTe_2$. – – –, Calculated Schottky heat capacity for $E_1/hc = 300\ cm^{-1}$, $E_2/hc = 500\ cm^{-1}$, and $g_0, g_1, g_2 = 1, 1, 2$.

VII. CHROMIUM DIANTIMONIDE

The magnetic properties of chromium diantimonide with orthorhombic marcasite-type structure[43] show a maximum in susceptibility of $CrSb_2$ around 600 K and indicate the presence of two unpaired spins per chromium atom at high temperatures, and hence of formally quadrivalent chromium in $CrSb_2$. It was mentioned already by Foex and Graff[44] that $CrSb_2$ showed antiferromagnetic behaviour just as does CrSb, but no evidence was presented. In a later susceptibility study by Holseth and Kjekshus[39] the unusual susceptibility behaviour was confirmed and it was suggested that $CrSb_2$ might be antiferromagnetic with a Néel temperature close to the decomposition temperature. But Adachi et al.[45] interpreted their susceptibility measurements over the range 77 to 900 K in terms of the excitation of electrons from a singlet-to a triplet-spin state with an energy separation of 0.07 eV. The same value of the energy gap was derived from low-temperature resistivity measurements. Accordingly, a broad, Schottky-type heat-capacity maximum of 2.03 $cal_{th}\ mol^{-1}\ K^{-1}$ at 288 K was expected. Adachi et al.[45] carried out heat capacity measurements only above 330 K and the results failed to confirm the correctness of their model.

In view of possible antiferromagnetic spin ordering, Adachi et al.[45] carried out neutron diffraction experiments near 300 K, but did not observe any magnetic reflections. Similar experiments by Holseth et al.[46] showed antiferromagnetic ordering at 4.2 K with doubled cell dimensions in the b- and c-directions. The magnetic spin quantum number is 0.97 per chromium atom and the magnetic moments are coupled parallel in each 011 plane of the magnetic unit cell, but in opposite directions in adjacent planes and with

orientation approximately normal to the 101 plane. Interestingly—of all the compounds with marcasite-type structure—$CrSb_2$ is the only one which shows clear evidence of magnetic ordering. In view of the observed cooperative ordering, a study of the heat capacity behaviour of $CrSb_2$ in the critical region seemed especially interesting. In addition, the increase in magnetic susceptibility to a maximum value around 600 K should also be reflected in the heat capacity and not result in a linear temperature relationship of the kind reported by Adachi et al.[45]

From the randomization of the spins of the two unpaired electrons revealed by magnetic susceptibility and neutron diffraction (neglecting further contributions from orbital states), a magnetic entropy $S_m = R \ln 3 = 2.17$ cal_{th} mol^{-1} K^{-1} is obtained, since the heat capacity of $CrSb_2$ (shown in Fig. 4) shows a small, sharp λ-type transition with a maximum at 274.1 K, where the change from the antiferromagnetic to the paramagnetic state occurs on heating[47].

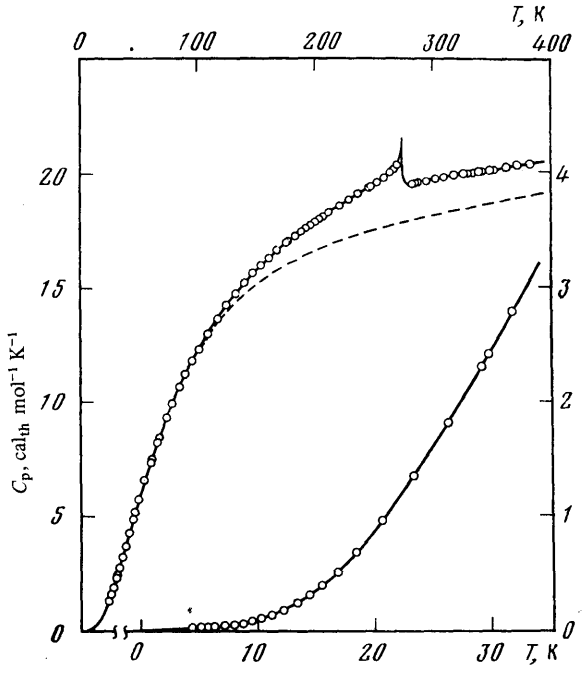

Figure 4. Heat capacity and antiferroelectric anomaly in $CrSb_2$; – – –, the estimated lattice contribution[47].

Obviously, only a fraction of this entropy (0.12 cal_{th} mol^{-1} K^{-1}) is generated in the clearly cooperative part of the transition. The heat capacity of $CrSb_2$ is, however, seen to be unusually high over a wide range in temperature above the transition at 274.1 K. This is evident by comparing it with those of the isostructural analogues $FeTe_2$,[41] $CoTe_2$,[48] and $FeSb_2$;[34] none of these are especially suited as "lattice heat-capacity models"—as they apparently differ substantially in vibrational properties, and the last two are also influenced by conduction-electron contributions. We, therefore, derive the lattice heat capacity of $CrSb_2$ from an estimate of its effective Debye temperature and by the application of a dilational heat-capacity term according to Nernst and Lindemann[49].

The constant Debye temperature used for calculating C_V(lattice) in the higher-temperature region was taken as the maximum of Θ_D in the lower-temperature region, $\Theta_D = 298$ K being obtained at 90 K. The dilational heat capacity is

$$C(d) = C_p - C_v = AC_p^2(T/T_m)$$

where the constant $A = 0.00713$ K mol cal_{th}^{-1} according to Nernst and Lindemann and $T_m = 991.3$ K is the peritectic decomposition temperature found here. Accordingly, the excess magnetic heat capacities are 1.7, 1.6, and 1.1 cal_{th} K^{-1} mol^{-1} at 300, 500, and 700 K respectively. Although this excess heat capacity was not observed by Adachi et al.[45], they nevertheless associated the magnetic behaviour with a transition from a singlet spin ground state to a split triplet state. Accordingly, a Schottky heat-capacity contribution with a maximum 2.03 cal_{th} K^{-1} mol^{-1} at 288 K should be observed.

Even though this model appears to fit the magnetic susceptibility data (disregarding the rather arbitrary subtraction of a temperature independent susceptibility term), it is not in agreement with the neutron-diffraction results, which point to the existence of two unpaired electrons per chromium atom in the ground state. According to our estimate, the total magnetic entropy up to 900 K is about 2.6 cal_{th} mol^{-1} K^{-1} or, well above this temperature, $R \ln 3 = 2.17$ cal_{th} mol^{-1} K^{-1}. In the search for further magnetic contributions the orbital components ought to be considered; according to ligand field theory the ground term of the d^2-configuration in an octahedral field is $^3T_{1g}$ with a total degeneracy $3 \times 3 = 9$. The exact splittings of the ground term are not known and in the zeroth approximation we assume that the first excited state (connected with the disappearance of cooperative magnetism) is a doublet, and that this state is followed by the remaining states, which might roughly correspond to a 3 : 6 Schottky heat-capacity contribution. Further consideration of this resolution is clearly a desideratum. Another point of interest concerns the composition of the $CrSb_2$ phase, but the original paper[47] will need to be consulted for that information.

VIII. CHROMIUM MONOARSENIDE

The heat capacity of chromium arsenide provides an interesting example of these AB compounds[48]. Here the heat capacity shows a distinct bell-shaped transition with a peak at 259.9 K related to the disappearance of antiferromagnetic helical ordering on heating. The entropy of this transition is 0.69 cal_{th} mol^{-1} K^{-1}. At 1170 K another transition is observed related to the phase change from the (300 K, stable) MnP-type to the NiAs-type structure. The entropy of the latter (gradual) transition is 0.077 cal_{th} mol^{-1} K^{-1}.

Chromium monoarsenide has been extensively studied by X-ray and neutron-diffraction, magnetic-susceptibility, and magnetization techniques, and two solid-state transitions have been described. The thermodynamic properties of CrAs are largely unknown, however, except for the heat capacity measurements by Kazama and Watanabe[50] in the region from 180 to 280 K. Our investigation was undertaken to improve and extend the earlier heat capacity data, thereby providing thermodynamic data for CrAs over the stability ranges of the solid phases, and, in particular,

to explore the detailed trends in the regions of both the low-temperature transformation and higher-temperature transition.

According to Haraldsen and Nygaard[51], the magnetic susceptibility of CrAs increases steadily over the region from 80 to 600 K, indicating an enhanced population of higher magnetic states. Yuzuri[52] found a peak in the susceptibility at 820 K which was taken to imply an antiferromagnetic to paramagnetic transition in this region, while Selte and Kjekshus[53] observed a further small increase in susceptibility in the region from 800 to 970 K. Above 300 K, one might then expect to encounter an excess heat capacity due to the population of excited electronic states in chromium and also a thermal effect accompanying the transformation of the MnP-type into the NiAs-type structure.

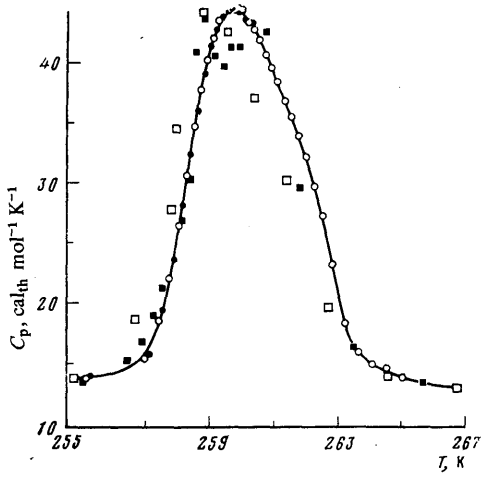

Figure 5. Heat capacity anomaly associated with double helical-spin ordering in $CrAs_2$.[48]

Below 300 K, a sudden structural change occurs in CrAs, which is related to a double helical-spin ordering with spiral propagation in the AB-plane. Watanabe et al.[54,55] reported that this occurred at about 280 K, while discontinuities in the lattice constants and anomalies in electrical resistivity and thermoelectric power occurred at 265 K. Selte et al.[56,57] observed the transition to go to completion at 272 K on heating, while the spiral structure reappeared at 261 K on cooling. According to Boller and Kallel[58], the transformation takes place in the range from 190 to 240 K and shows hysteresis and supercooling effects. The volume contraction on heating is accompanied by a shortening of the distance of one additional Cr-Cr contact considerably below the value r_C = 318 pm, which, according to Mott[59,60] and Goodenough[42], is the critical intermetallic distance for the localized-collective electron behaviour.

The heat capacity at the low-temperature transition is shown in Fig. 5. It rises to a rounded peak and then drops gradually with a shoulder on the high-temperature side. A cooling curve recorded at a rate of about 0.09 K min^{-1} shows that the sample does supercool by at least 6 K, as might be expected for a first-order transition.

In attempting to ascertain the thermodynamics of the magnetic ordering transition, we note that apparently none of the MnP-type pnictides is diamagnetic[61]. This makes it difficult to find an adequate lattice heat-capacity model among the isostructural analogues of CrAs, such as FeAs, CoAs, MnAs, and FeP. A further complication is that Schottky-type contributions to the heat capacity are anticipated above the transition. In order to estimate the lattice contribution, the heat capacity curve far below T_{tr} was connected smoothly to the C_p curve above the transition. The estimated lattice heat capacity is represented in Fig. 5 by a dashed line. With this lattice estimate, we find ΔS_{tr} = 0.69 cal_{th} mol^{-1} K^{-1} and ΔH_{tr} = 177 cal_{th} mol^{-1}. Watanabe et al.[54] report T_{tr} = 265 K and ΔH_{tr} = 124 cal_{th} mol^{-1} for this transition, determined by continuous heating adiabatic calorimeter. Despite the large differences in T_{tr} and ΔH_{tr} compared with our study, they report a shape of the transition curve that is quite similar to ours. The discrepancies in T_{tr} and ΔH_{tr} might be partly explained by the different methods used: dynamic versus equilibrium measurements—and differences in the lattice heat capacity, but probably differences in the nature nature of the samples are more important.

The value of the Néel temperature, T_{tr} = (259.86 ± 0.05) K, is not within the broad temperature range from 240 to 190 K assigned to the occurrence of the transition by Boller and Kallel[58] and is also much lower than the approximate value of 280 K reported by Watanabe et al.[54] from neutron diffraction studies.

Crystallographic and magnetization studies[58] have shown that the transition is of first order. The shape of the curve suggests that the order is higher but the hysteresis and long equilibrium times support the hypotheses of a first-order transition. Bean and Rodbell[62] presented a model for first-order magnetic transitions, in which the transition is shifted to higher temperatures as a consequence of the dependence of exchange interactions on interatomic distances and the volume change on transition.

IX. ACTINIDE PNICTIDES

U_3Pn_4 compositions. Attention has been drawn increasingly to the magnetic and thermophysical properties of uranium pnictides (U_3Pn_4) (in which Pn = P, As, Sb, or Bi), all of which have cubic Th_3P_4 structures. Magnetic susceptibility and magnetization measurements show that all of them are ordered to a ferromagnetic state below 300 K and that the Curie-Weiss law is obeyed above the Curie temperature (T_C) up to at least 400 K. The paramagnetic moment increases with increasing pnigogen size, but lack of such a correlation for the ordering temperature might indicate that the magnetic coupling is anomalously weak in U_3Pn_4.

For U_3X_4, the U^{4+} site has S_4-symmetry, which splits the ninefold degenerate $^3H_4$ ground term into five singlets and two doublets. Troc et al.[63] calculated the energy levels of the ground term using a point charge model and obtained a good correlation with their high-temperature magnetic susceptibility data. The lowest excited level, a singlet, is 9 cm^{-1} above the singlet ground level, and is followed by seven higher levels (the lowest of which is at 700 cm^{-1}).

So far we have only examined uranium arsenide and antimonide[64]; for the bismuthide and for the resolution of the problem of the low-temperature heat-capacity data for U_3P_4 reported by two authors—who disagree by a factor of two (!) as regards the entropy of transition—more work

is contemplated. Moreover, we need to study the heat capacities of the isostructural diamagnetic thorium analogues to be assured to a good resolution of the magnetic heat capacity.

Single crystals of U_3As_4 [64] are semimetallic with a resistivity of 290 pohm cm^{-1} at 300 K, while U_3Sb_4 is reported to be metallic [65]. Our electronic contributions are consistent with these interpretations.

It is well known that the magnetic contribution to the heat capacity cannot be easily separated from the total heat capacity [66]. Lacking heat-capacity data for diamagnetic Th_3As_4 and Th_3Sb_4, our estimate of ΔS_{tr} is somewhat arbitrary. Stalinski et al. [67] used the Heisenberg theory of spin-wave interactions [68] to estimate the magnetic heat capacity below $T_C/2$ for U_3P_4. We also used this method to establish the Debye-temperature curve at low temperatures, but, as pointed out by de Jongh and Miedema [69], this method can only be expected to be rigorous for insulating ferromagnets. Neutron-diffraction measurements [70,71] favour a non-collinear alignment of the spins and electrical resistivity measurements for U_3P_4 and U_3As_4 show a strong magnon conduction electron scattering [72].

From the adjusted heat capacities below $T_C/2$ and above T_C, the effective Θ_D's for U_3Sb_4 were evaluated and plotted against temperature. The gap in the curve caused by the transition was bridged and converted into a non-cooperative heat capacity. That for U_3As_4 was then calculated by the method of corresponding states [73]. The excess (cooperative) heat capacities were obtained by the subtraction of the respective integrated curves. Cooperative entropy values of 4.15 cal_{th} mol^{-1} K^{-1} for U_3As_4 and 6.60 cal_{th} mol^{-1} K^{-1} for U_3Sb_4 were thus obtained.

Since at the transition temperature essentially only the two lowest singlets are populated, an effective spin (s) equal to 1/2 results. This gives a $\Delta S_{tr} = R \ln(2s + 1) = R \ln 2 = 1.38\,cal_{th}$ (mol U)$^{-1}$ K^{-1}, [74] in good agreement with the experimental value for U_3As_4: ΔS_{tr} = 1.4 cal_{th} (mol U)$^{-1}$ K^{-1}. The ΔS_{tr} for U_3Sb_4 (2.2 cal_{th} mol^{-1} K^{-1}) cannot be explained thus unless the higher excited levels are lower in energy than those for U_3P_4. [63] The reputed presence of conduction electrons in U_3Sb_4, however, has been neglected in the above model.

Since these ΔS_{tr}'s are so much smaller than theoretical values of $\Delta S_{tr} = R \ln(2J + 1) = R \ln 9$ for the $^3H_4$ ground term and since the observed heat capacities at high temperatures are seen to be much larger than would be expected from lattice dilational contributions, additional electronic contributions are to be anticipated.

The lattice heat capacities of U_3As_4 and U_3Sb_4 at constant volume were generated from effective Θ_D values equal to 240 and 190 K, obtained as the maximum values of the adjusted heat capacities below the transition. A dilational contribution $C(d) = C_p - C_v$ was calculated from the Nernst-Lindemann expression $C(d) = AC_p^2(\frac{T}{T_m})$, in which A = 0.0212 K mol cal^{-1} and T_m, the melting point of the compounds, is taken to be 1700 K. The quantity $[C_v + C(d)]$ is then subtracted from the observed heat capacity to give the total electronic heat capacity, as shown in Fig. 6. This arises from the cooperative (magnetic) contribution already discussed and the excitation of additional electronic levels. Assuming the energy levels of U_3Sb_4 to be approximately the same as those for U_3P_4, the Schottky heat capacity contribution in the region above T_C can be calculated from the levels and degeneracies given by Troc et al. [63], assuming that the two low levels represent a doubly degenerate level responsible for the cooperative phenomenon. The resulting neat capacity, shown in Fig. 6, is essentially compatible with the high-temperature data, but a better fit may be obtained by lowering some energy values slightly.

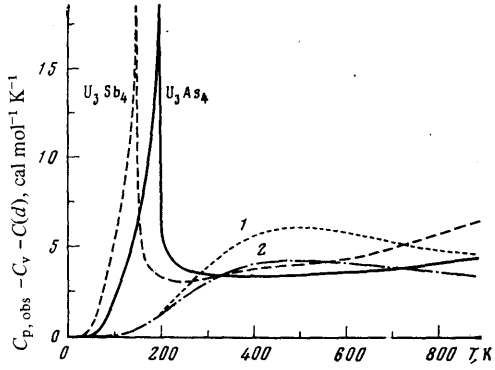

Figure 6. Excess heat capacities $[C_{p,obs} - C_v - C(d)]$ for ferromagnetic transitions in U_3As_4 and U_3Sb_4. The higher-temperature data are fit by a two level Schottky heat capacity contribution using the energies of Troc et al. (– – – – –) [63] and those of the authors (cf. text) (–·–·–). [64]

Entropies of transition significantly below the value expected for the ground-term degeneracy are observed for several uranium compounds [66]. As pointed out by Counsell et al. [75], such low ΔS_{tr} values are evidence of crystal-field effects.

A model that does not require assumptions about a definite ionic state and allows for the essential interdependence of magnetic and conduction phenomena has been proposed by Robinson and Erdös [76]. The model takes into account the closeness of the 5f- and the 6s-levels of uranium. This model has been successful in explaining the electronic and magnetic transition in UP. The larger ΔS_{tr} for U_3Sb_4 can be explained qualitatively by the fact that U_3Sb_4 is more metallic and has a lower ordering temperature than U_3As_4. This model cannot be applied to U_3As_4, since its resistivity behaviour is very different from that of uranium monopnictides.

UPn$_2$ compositions. The UPn$_2$ compositions we have studied are again the arsenide and the antimonide only. These results [77] already published in a concise form will be but briefly mentioned here.

In the dipnictide series UN_2 is an exception; it is stable only under high N_2 pressure and has the fluorite structure [78]. The remaining members UP_2, UAs_2, USb_2, and UBi_2—are isostructural with the tetragonal Cu_2Sb structure. Magnetic susceptibility and neutron diffraction measurements have been made on the four dipnictides from UP_2 to UBi_2. The dependence of the inverse magnetic susceptibility on temperature indicates that all the compounds are ordered antiferromagnetically and that Curie-Weiss behaviour obtains above the ordering (Néel) temperature. The paramagnetic moment increases monotonically with increasing pnigogen size, but Néel temperatures do not. Hence the magnetic coupling may either be anomalously weak, as in UP_2 or anomalously strong, as in UAs_2.

The antiferromagnetic structures of UP_2, UAs_2, and USb_2 determined by neutron diffraction (in the ordered state) consist of ferromagnetic sheets of uranium ions stacked perpendicularly to the c-axis and in the sequence $+ - +$. The magnetic unit cell is twice as large as the chemical one due to its doubled c-axis. In contrast to this, the UBi_2 chemical and magnetic unit cells are identical and the ferromagnetic sheets have the order $+ - + -$. The compounds display metallic conduction with $\rho(298\,K) = 1.83 \times 10^{-4}$ and 1.95×10^{-4} ohm cm for single-crystal samples of UP_2 and UAs_2 respectively [79].

The heat capacity of UP_2 (22.5 to 350 K) has been reported by Stalinski et al. [80] Here a prominent lambda anomaly at 203.2 K accords well with the transition to the antiferromagnetic state, as observed in magnetic susceptibility measurements. In our measurements on UAs_2 and USb_2, [81] we found that both substances show λ-type transitions in the heat capacity with maxima at 272.2 and 202.5 K respectively. Heat capacities below 5 K were extrapolated with a term proportional to T^3 (Debye lattice contribution) and one proportional to T (conduction electron contribution γ). The respective parameters, the Θ_D and γ, were taken from C_p/T versus T^2 plots of the heat capacity below about 20 K. The values of γ were found to be 1.36×10^{-3} cal_{th} mol^{-1} K^{-2} for UAs_2 and USb_2.

Difficulties associated with determination of magnetic heat capacity contributions have been alluded to already and are encountered with uranium compounds involving Group IV, V, and VI elements [66,75]. In the absence of heat-capacity data for the isostructural diamagnetic compounds (i.e. the corresponding thorium compounds) such resolutions must be regarded as tentative and probably too low. It is interesting to note, however, that the heat capacity of USe_2 [82] (with nearly the same molecular weight as UAs_2 although its crystal structure differs) agrees rather well with the heat capacity of the latter compound for some ranges both above and below the transition and with our lattice contribution described below.

The magnetic ordering contributions were determined by plotting the effective Θ_D's for the total heat capacities as a function of T and by interpolating over the gap caused by the enhanced heat capacity in the transition region. The Θ_D's thus obtained over this interval were used to generate "lattice" heat capacities, which were then integrated.

The amount of entropy to be expected is relevant to the interpretation of the ΔS_m, despite reservations about well defined oxidation states for conducting compounds involving the pnigogens. Naively, one may—at least initially—adopt a model with a specified oxidation state for uranium (U^{4+}) and proceed from the free-ion, ground term ($^3H_4$), on the assumption of Russell-Saunders coupling, to the expected magnetic entropy $R \ln(2J + 1) = 4.37$ cal_{th} mol^{-1} K^{-1}. The failure of the experimental results to account for this amount of entropy is usually attributed to the crystal-field quenching of the orbital moment. Occasionally the paramagnetic moment and the excess entropy in such systems can be identified more closely with spin-only values, which in the present case would be $R \ln(2S + 1) = R \ln 3 = 2.18$ cal_{th} mol^{-1} K^{-1}. The paramagnetic moments are all less than the free-ion values (3.58 μ_B) and vary from below the spin-only value (2.83 μ_B) for UP_2 to near the free-ion value for UBi_2. However, $\Delta S_m(UAs_2) = 0.99$ cal_{th} mol^{-1} K^{-1} and $\Delta S_m(USb_2) = 1.70$ cal_{th} mol^{-1} K^{-1} are both well below even the spin-only values.

The UP_2 heat capacity near 350 K is already well above the Dulong and Petit limit and the trend of these data contrasts markedly with that for UAs_2 and USb_2. Magnetic susceptibility [83], electrical conductivity [84], and more recently X-ray crystallographic [85,86] studies have shown the presence of a phase transition in UP_2 near 356 K, where the tetragonal superstructure disappears on heating.

X. THE COPPER–SULPHUR SYSTEM

Although early investigations indicated that the copper–sulphur system is relatively uncomplicated and consists, in fact, of only three binary phases, covellite (CuS), digenite ($Cu_{1.80}S$), and chalcocite (Cu_2S), recent studies have produced a veritable population explosion of distinct new phases in the system, which have not as yet yielded an unambiguous phase diagram, particularly in the region below 400 K. The marked ambiguity is produced by a multiplicity of phases, a strong tendency of the copper–sulphur system to exhibit metastability, and confusion—partly because of the similarity—of the X-ray diffraction patterns and optical properties. Moreover, extensive solid solutions, unquenchable phases, and phase transformations produced by grinding and handling have created considerable confusion since the comprehensive study of the phase equilibria in this system by Roseboom [87]. Since this almost classical study, numerous additional papers have appeared reporting the application of a great variety of techniques. Perhaps one of the most interesting, from the point of view of a thermodynamicist, is one as yet not in print, by R. W. Potter [88], in which he has been able to resolve much of the contradictory nature of the other data by means of galvanic cell measurements to delineate the metastable equilibria, the stable phase diagram, and the thermochemical properties of both phases.

We may note that, like the first system mentioned in this paper, the present one, the last to be discussed, is mineralogical. However, marcasite is already known in the literature, whereas our data on the copper–sulphur system are the least complete of any that I have discussed today and work is still, therefore, in very active progress. We are eager to obtain thermophysical data to test the correctness of Potter's galvanic cell studies [88].

To date, we have studied the high- and low-temperature heat capacities of the three copper compositions which I mentioned as those originally identified with the system. We are undertaking measurements at the present time on anilite and djurleite.

One of the remarkable aspects of the behaviour of these materials is in the fact that, under some temperature conditions, many of them show "superionic conductivity" to an interesting degree.

Turning our attention to digenite, we note first of all that at about 350 K high-temperature digenite transforms on cooling into low-temperature digenite. Rather more amazing is the fact that at 310.8 K—just above room temperature—a transition occurs which we are obliged to describe as a disproportionation transition. Apparently, on cooling to about this temperature, one departs from the solid-solution range of the low-temperature digenite phase and crosses the boundary into the low-temperature digenite–djurleite field. In other words, the low-temperature digenite disproportionates to some extent into djurleite. Although one is inclined to think of disproportionation equilibria as relatively slow phenomena even at elevated temperatures, there is nothing very slow about this transition. It should be noted, of course, by examining the

phase diagram[87,89], that the boundary mentioned above apparently continues to be a function of temperature well below 300 K.

It appears that the transformation takes place gradually as one goes down in temperature and our measurements indicate that it is insufficient to supercool 10 or 20 K below the above transition; one has to go to very low temperatures indeed if a reproducible enthalpy of disproportionation is sought. As a matter of fact, we found it routinely most convenient to cool a full 100 K below the transition in order to ensure a complete transformation. The exact trend of the boundary between the fields is apparently not yet well delineated, but we find that we can reproduce to within approximately 0.01 per cent the enthalpy increment associated with this transition. The overall shape of the transition is presented in Fig. 7. The dashed lines represent an interim estimate of the lattice contribution, which will probably ultimately need revision[90].

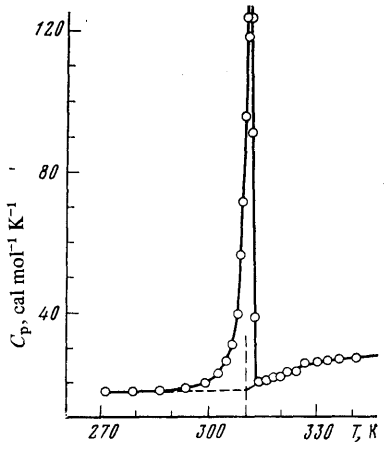

Figure 7. The heat capacity and disproportionation anomaly in lowdigenite $Cu_{1.80}S$.[90]

The enthalpy increment of this transition (ΔH_{tr}) is 477 cal$_{th}$ K^{-1} and the corresponding entropy is 1.50 cal$_{th}$ mol^{-1} K^{-1} or just slightly larger than $R \ln 2 = 1.38$ cal$_{th}$ mol^{-1} K^{-1}. In all respects this has proven to be one of the most striking disproportionation transitions ever encountered in that the rapidity with which equilibrium is reached is unusual. A detailed analysis of the heat-capacity curve below the transition has not yet been completed but it will presumably show excess heat capacity for a gradual transformation of the sample with temperature.

It has been my pleasure to summarize for you some of the recent types of phenomena we have been encountering in the heat-capacity studies in recent months in both the chalcogenides and the pnictides. Were greater time available, more examples could have been discussed and presented and would have shown an even greater diversity. We have not yet reached the point where we recognize anything which can be described as "typical behaviour" and find rather a very interesting variety of phenomena.

There still remains a great deal more of "systematic" work to be done. Table 2 does summarize the thermophysical functions which have become available as a result of our studies on the compounds mentioned in this presentation.

Table 2. Thermodynamic functions for chalcogenides and pnictides at 298.15 K recently determined by Grønvold and Westrum et al.

Substance	S°, cal mol^{-1} K^{-1}	$H^\circ - H^\circ_0$, cal mol^{-1}	$-[(G^\circ - H^\circ_0)/T]$ cal mol^{-1} K^{-1}

ACKNOWLEDGEMENT

In addition to Dosent F. Grønvold, whose able cooperation has already been mentioned, the low-temperature measurements at the University of Michigan have been greatly aided by the participation of Professors J. A. R. Cheda (Chemistry), University Complutense, Madrid, David B. Downie (Metallurgy), University of Strathclyde, Scotland, and D. Gonzalez (Physics), University of Zaragoza, Spain, as well as Bengt Falk (Thermochemistry), University of Lund, Sweden, C. G. Galeas (Chemistry), University of Michigan, and Albert Highe (Chemistry), California Institute of Technology.

Infrared Spectroscopy of the Hydrogen Bond as a Method for the Investigation of Intramolecular Interactions

A.N.Egorochkin and S.E.Skobeleva

Infrared spectroscopic data on hydrogen-bonded complexes incorporating the main classes of organic and organoelemental electron donors and electron acceptors are examined and surveyed. The dependence of the parameter $\Delta\nu$ (the frequency shift of the stretching vibration of the A-H bond in the infrared spectrum of the electron acceptor on formation of the hydrogen-bonded complex) on intramolecular interactions in the molecules of the species involved in the hydrogen bond is analysed. The use of this parameter in the investigation of weak electronic effects of substituents in the molecules of electron donors and electron acceptors involved in the formation of the hydrogen bond is considered.
The bibliography includes 191 references.

III. Intramolecular interactions in electron acceptors involved in hydrogen-bonded complexes 1206

INTRODUCTION

There has been a continuous increase in the number of reports surveying the extensive experimental data on complexes with an intermolecular hydrogen bond; these surveys help to create a modern theory of the hydrogen bond (see, for example, Refs. 1–6). At present the state of the theory is such that it permits a semiempirical (for example, on the basis of spectroscopic manifestations of the hydrogen bond) investigation of the fine details of the molecular structure of the electron acceptor A–H and the electron donor B, forming a hydrogen-bonded complex of the type A–H...B. One of the main criteria of the existence of the hydrogen bond is the shift $\Delta\nu$ of the stretching vibration frequency ν(A–H) of the electron acceptor on formation of the hydrogen bond, which can be readily measured experimentally in the infrared spectrum. The shifts $\Delta\nu$ yields important information about the structure of the electron donor and electron acceptor and particularly about the intramolecular interactions in these molecules; however, so far this information has been inadequately surveyed and analysed.

The influence of intramolecular interactions in electron donor and electron acceptor molecules on their ability to form hydrogen-bonded complexes is analysed in the present review. Among the extensive literature data, we discuss almost exclusively those obtained in the analysis of $\Delta\nu$ in infrared spectra, since these quantities are known for the majority of the hydrogen-bonded complexes investigated. Mainly studies undertaken to obtain information on the basis of the $\Delta\nu$ about the electronic structure of the species involved in the hydrogen bond (i.e. the electron donor and electron acceptor) are considered.

We shall consider briefly the validity of using the parameter $\Delta\nu$ for the solution of the problem formulated. The hypothesis[7,8] of a linear relation between $\Delta\nu$ and the enthalpy of formation of the hydrogen bond ΔH has been confirmed[9–12] only for short series of compounds. For a large number of hydrogen-bonded complexes of the type phenol (and probably any other electron acceptor) – electron donor, a quadratic relation $\Delta\nu \propto (\Delta H)^2$ is observed[3]. A relation of the type $(\Delta H)^2 = 0.11\,(\Delta\nu - 40)$ describes satisfactorily the variation of ΔH with $\Delta\nu$ over the entire known range of the energies of phenol hydrogen bonds[3], i.e. it is valid for both strong and weak hydrogen bonds. However, this relation must be used with a certain amount of caution, because it is empirical and will therefore be inevitably revised in the future as more accurate values of ΔH become available for weak hydrogen bonds. However, for the weakest hydrogen bonds $\Delta\nu$ values not only characterise the hydrogen bond but also reflect the influence of non-specific interactions in solution (for example, van der Waals interactions). However, within the limits of each of the narrow series of compounds (derivatives of benzene, ethylene, etc.) and under standard experimental conditions (constant electron acceptor, solvent, experimental temperature, and concentration, which is the case in virtually all the studies considered in this review), the influence of non-specific interactions on $\Delta\nu$ can be assumed constant to a first approximation for all the representatives of the given narrow series. The main task of the present review is a survey of the studies of intramolecular interactions in the above narrow series of electron donors on the basis of the analysis of the changes in the parameter $\Delta\nu$ in these series.

An important generalisation described in the literature is the "rule of the product of factors"[4,5], which characterises quantitatively the contributions of the electron donor and electron acceptor to the enthalpy of the hydrogen bond and, in the absence of strong steric hindrance, also in general to the capacity of the electron donor and electron acceptor for the formation of any intermolecular hydrogen-bonded complexes. This rule is characteristic of both the donor–acceptor interaction as a whole and of its special case — hydrogen bonding. It is known (see, for example, Gur'yanova et al.[13]) that the enthalpy of complex formation depends significantly on the electron densities at the donor and acceptor centres, which are in their turn determined by the intramolecular interactions (the inductive and mesomeric effects) in the donor and acceptor molecules. The influence of these effects is characterised quantitatively by the substituent constants of the Taft–Hammett type[14].

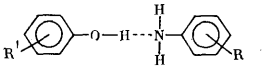
It follows that for hydrogen-bonded complexes there should be a relation between the $\Delta\nu$ and the Taft–Hammett constants of the substituents in the electron donor and electron acceptor molecules. For narrow series of electron donors, this relation should be linear. The influence of steric factors on the formation of the hydrogen bond can be estimated by methods of correlation analysis.

The great sensitivity of the parameters $\Delta\nu$ to molecular structure factors makes it possible to investigate fine details in their changes (particularly in series of compounds with related structures).

II. INTRAMOLECULAR INTERACTIONS IN ELECTRON DONORS INVOLVED IN HYDROGEN-BONDED COMPLEXES

Data for the influence of substituents linked to the donor centre, which is responsible to the greatest extent for the electron-donating capacity of the entire molecule in the formation of the hydrogen bond, were arranged systematically in the present review on the basis of the type of donor centre (an element of Group V, VI, or VII, a multiple carbon–carbon bond). Particular attention has been devoted to the consideration of intramolecular interactions in compounds containing elements of the silicon subgroup as substituents in view of the importance of this problem for the chemistry of organoelemental compounds.

1. Electron Donors containing Group V Elements

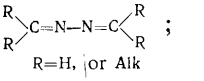


The electron-donating capacity of nitrogen derivatives R_3N varies over a wide range, and together with the inductive effect of R, is determined also by the conjugation effects in the R–N fragments and by the steric factors which control the possibility of the mutual approach of the donor and acceptor centres on formation of the hydrogen bond[10,15–22].

Table 1. The parameters $\Delta\nu$(O–H) (cm^{-1}) for the infrared spectra of certain hydrogen-bonded complexes.

Electron donor	Electron acceptor			References
	C_6H_5OH	p-ClC_6H_4OH	p-FC_6H_4OH	
H_3N	462	—	—	20
C_5H_5N	465	491	489	16
$(C_2H_5)_3N$	556	586	576	16

Table 1 shows that the frequency shift $\Delta\nu$(OH) in the hydrogen-bonded complexes of aliphatic amines and pyridine derivatives depends on the type of electron acceptor employed[16,20,23,24]. The study of hydrogen bonds between methanol and pyridine derivatives[25] showed that the presence of bulky substituents in the 2- and 6-positions in the electron donor molecule hinders the formation of the hydrogen bond. Steric factors have a similar influence both on the electron-donating capacity of pyridine derivatives in the formation of a hydrogen bond and on their basicity. This is indicated by the correlation between the parameter $\Delta\nu$(O–H) for methanol and the pK_a of pyridine derivatives. In the study of hydrogen bonds in cyclic azoles[26,27] it was established that imidazoles have a greater electron-donating capacity than pyrazoles. The electron-donating properties of the "pyridine" nitrogen atoms increase after the introduction of electron-donating substituents into the heterocycle and decrease in the presence of electron-accepting substituents.



The influence of substituents in the electron donor molecule (substituted aniline) has been estimated quantitatively in relation to the hydrogen-bonded complexes between aniline and phenol derivatives[28]. The values of $\Delta\nu$(O–H) for phenol involved in the formation of a hydrogen-bonded complex of the type

are correlated with the enthalpy of complex formation and with the Hammett σ constants of the substituents R.

Elements of the nitrogen subgroup exhibit different electron-donating capacities in the formation of the hydrogen bond, decreasing in the sequence N ≫ P > As,[29,30] Such variation of the electron-donating capacities is observed also for their aliphatic derivatives. In aromatic compounds the phosphorus atom forms stronger hydrogen bonds than nitrogen[31]. Thus the values of $\Delta\nu$(O–H) for phenol are 800 and 240 cm^{-1} in the presence of $(C_2H_5)_3N$ and $(C_4H_9)_3P$ respectively and at 150 and 240 cm^{-1} in the presence of $(C_6H_5)_3N$ and $(C_6H_5)_3P$ respectively. According to the authors[31], the electron-accepting properties of tervalent phosphorus cannot be explained by the involvement of the d orbitals of the phosphorus atom in the bonding. However, we may note the appreciable discrepancy between $\Delta\nu$(O–H) obtained for triethylamine by the above workers[31] (800 cm^{-1}) and the value measured by Drago and Epley[16] (556 cm^{-1}).

The formation of multiple bonds by the nitrogen atom or its involvement in conjugation alter appreciably the electron-donating properties of compounds containing this atom as a donor centre. Thus in the azines

there may be p,π conjugation of the lone electron pairs of the nitrogen atoms with the π electrons of the neighbouring azomethine linkages[32]. The electron density at the nitrogen atoms, which determines their electron-donating properties, should therefore be determined by the degree of p,π conjugation in addition to the inductive effect of the substituents. The infrared spectra of the hydrogen-bonded complexes of azines with deuterochloroform, potentiometric data, and quantum-mechanical calculations confirmed the existence of p,π conjugation in azines[32].

The study of the electron-donating capacity of the nitriles R–C≡N and isonitriles R–N≡C established that the parameter $\Delta\nu$(OH) for phenol is correlated with the Taft inductive constant σ^* of the substituents R.[33–35] Isonitriles have a greater electron donating capacity compared with nitriles (Table 2). Thus the lone electron pair of the carbon atom in isonitriles $R-\overset{\cdot\cdot}{N}\equiv\overset{\cdot}{C}$ forms a stronger hydrogen bond than the electron pair of the nitrogen atom in nitriles. The deviations of the points corresponding to BrCN and ICN from the correlation straight line for RCN, i.e. $\Delta\nu$(O–H) = 162.7–38.56 σ^*_R, can be accounted for, according to a number of workers[33–35], by the contribution of the resonance structures $X-C\equiv N \leftrightarrow X^+ = C = N^-$. The electron-donating capacity of dimethyl aminobenzonitriles has been investigated[36]. Analysis of the correlations between $\sqrt{\Delta\nu(O-H)}$ (with phenol and methanol as electron acceptors) and the σ constants of the substituents in benzonitriles and between $\sqrt{\Delta\nu(O-H)}$ and the σ^- constants of the substituents in dimethylanilines as well as enthalpy data have shown that the nitrile group is the reaction centre in dimethylaminobenzonitriles.

Alkyl thiocyanates have a smaller electron donating capacity than nitriles[37,38] (Table 2). The values of $\Delta\nu$(O–H) for phenol involved in the formation of hydrogen bonds with alkyl thiocyanates are linearly related to the Taft σ^* constants for the alkyl substituents. On the basis of the decrease of the electron-donating capacity in the sequence nitriles > thiocyanates > isothiocyanates, it has been suggested that the hydrogen bond formed by thiocyanates involves the nitrogen atom, while that formed by isothiocyanates involves the sulphur atom[39]. The reduced electron donating capacity of the thio-derivatives compared with nitriles is associated with the conjugation within the NCS group[39]. The authors of a later study[40] of intermolecular interactions of alkyl isothiocyanates with phenol also concluded that alkyl isothiocyanates have a lower electron-donating capacity than alkyl thiocyanates and nitriles but, in contrast to Barakat et al.[39], they postulate that the hydrogen bonds of isothiocyanates are formed with the participation of the nitrogen atom and not sulphur.

A spectroscopic study of the electron-donating capacity of organosilicon amines showed[41,42] that the $\Delta\nu$(C–D) shift of the stretching frequency of the bond in deuterochloroform in mixtures with silylamines amounts to 50–60 cm^{-1} for compounds of the type $(CH_3)_3SiNHR$, 60–80 cm^{-1} for $(CH_3)_3SiNR_2$, and 30–35 cm^{-1} for the cyclic derivatives $[(CH_3)_3SiNR]_3$. In view of the greater electron-donating capacity of the isostructural carbon derivatives, the authors[41,42] concluded that there is a strong d_π–p_π interaction in the Si–N group (Table 3; compounds 1 and 2, 5 and 6, and 8 and 9). Here and henceforth in the review the d_π–p_π interaction is understood as the manifestation of the π-acceptor properties of the silicon and phosphorus subgroup elements (when these elements are linked to atoms having lone electron pairs or to α,β-unsaturated carbon substituents). Together with the hypothesis of the involvement of the vacant *nd* orbitals of these elements, there exists an alternative view concerning the explanation of the π-acceptor properties[43,44], based on an examination of hypervalent bonds[45]. The electron-donating capacities of two series of compounds, $(CH_3)_3En(CH_3)_2$ and $E[N(CH_3)_2]_4$ (E = C, Si, or Ge), have been estimated for the formation of hydrogen bonds by these derivatives with deuterochloroform[46]. The weakest hydrogen bonds are formed by silicon derivatives owing to the delocalisation of the *p* electrons of the nitrogen atom over the vacant *d* orbitals of the silicon atom (the effect of the d_π–p_π interaction). On passing to germanium derivatives the effect of the d_π–p_π interaction is appreciably weakened (Table 3; compounds 2 and 3, 6 and 7, and 9 and 10, and 11 and 12).

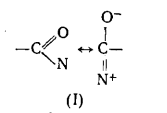
The influence of molecular structure factors on the electron-donating capacity of disilazanes[47], cyclosilazanes and cyclogermazanes[48], ethyl(dimethylamino)germanes[50], and dialkylaminochlorogermanes[52] has been investigated. The electron donating capacity diminishes in the sequence C–N–C > Ge–N–Ge ≃ Ge–N–C > Si–N–C > Si–N–Si. The results were interpreted on the basis of a smaller contribution of the effect of the $d_\pi - p_\pi$ interaction in the case of the Ge–N bond compared with the Si–N bond. Infrared spectroscopic data for silylamines[51] and trimethylsilyldiazomethane[53] also indicates the occurrence of d_π–p_π interaction in the Si–N bond.

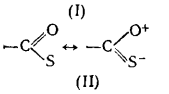
The electron-donating capacity of organosilicon amines depends significantly on the distance between the silicon and nitrogen atoms[54]. The lower electron-donating capacity of methylsilylamines compared with that of the remaining alkylsilylamines (Table 4, compounds 2–4 and 5–8) is due to the intramolecular interaction of the nitrogen atom and silicon[55]. Similarly the reduced electron-donating capacity of $[(CH_3)_3SiCH_2]_2NH$ [$\Delta\nu$(C–D) = 49 cm^{-1}] compared with $(CH_3)_3SiCH_2N(Alk)H$ [$\Delta\nu$(C–D) ≃ 60 cm^{-1}] is caused, according to the authors[56], by the ($p \rightarrow d$) σ interaction.

2. Electron Donors containing Group VI Elements



The electron-donating capacity of the oxygen atom in a wide variety of organic compounds has been studied by infrared spectroscopy[9,10,12,15,16,18,54–59,74]. It was established that the electron-donating capacity of the oxygen atom depends significantly on the nature of the substituents linked to it. In the majority of studies[12,60–62] the characteristic features of the variation in electron-donating capacity are considered solely on the basis of qualitative ideas concerning the donor-acceptor properties of substituents (see, for example, Table 7; compounds 1–6).

The formation of hydrogen bonds by a large series of ethers with different electron acceptors has been investigated[12,15]. Correlations were established between the association constant K_{ass} and $\Delta\nu$(O–H) for phenol and also between the shifts of the stretching vibration frequencies ν(X–H) of various electron acceptors for constant electron donors. The electron-donating capacity of dialkoxymethanes R′OCH$_2$OR″ has been characterised in terms of the stretching vibration frequency shift $\Delta\nu$(O–D) for deuteromethanol on formation of hydrogen bonds with the given compounds[63]. $\Delta\nu$(O–D) = 102 cm^{-1} for $(CH_3)_3COCH_2$.$OC(CH_3)_3$. When the t-butyl groups are replaced by the electron-accepting F_3CCH_2 groups, $\Delta\nu$(O–D) decreases to 32 cm^{-1}. The electron-donating capacity of di(β-chlorovinyl)ethers CCl_2 = CH–O–R depends both on the inductive effect of the substituents R and on the p,π conjugation effect. The latter leads to a decrease of $\Delta\nu$ for the given ethers compared with saturated ethers[64].



The electron-donating capacity of the carbonyl oxygen atom in the compounds RR_iC = O (for constant R) decreases when R_i changes in the sequence $N(CH_3)_2$ > CH_3 > OCH_3.[65] The relation between $\Delta\nu$(O–H) and the enthalpy of formation of the hydrogen bonds between phenol and diaryl ketones $RC_6H_4COC_6H_4R'$ (where R and R′ = Cl, CH_3, H, or OCH_3) has been investigated; an increase of $\Delta\nu$(OH) for phenol following the enhancement of the electron-donating properties of the substituents R and R′ was noted[67]. The hydrogen bond involving triphenylalkylidenephosphoranes has been investigated[68,69]. As for ketones, the replacement of the methyl group in $(C_6H_5)_3P$ = CH–C(O)CH_3 by the methoxy-group reduces $\Delta\nu$(O–H) for phenol; this is caused by the predominance of the *-I* effect of the methoxy-group over the mesomeric effect[69]. The very strong hydrogen bonds with phenol [$\Delta\nu$(O–H) ≃ 400 cm^{-1}] formed by these compounds have been explained[68] by the delocalisation of the charge:

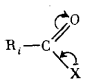
$$(C_6H_5)_3\overset{+}{P}-\overset{-}{C}H-\underset{\underset{O}{\|}}{C}-R \leftrightarrow (C_6H_5)_3\overset{+}{P}-CH=\underset{\underset{O}{\|}}{C}-R \leftrightarrow (C_6H_5)_3\overset{+}{P}-CH=\underset{\underset{O^-}{|}}{C}-R \quad .$$

The electron-donating capacity of thioesters in the formation of hydrogen bonds with phenylacetylene has also been estimated[66]. Comparison of the results with data for esters and amides showed that the electron-donating capacity of the carbonyl oxygen atom decreases in the sequence amides > esters > thioesters. This can be associated with the fact that structure (I) makes an appreciable contribution to the structure of amides, while structure (II) is significant in thioesters[66]:

(I)

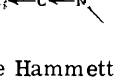
(II)

The electron-donating capacities of cyclic ethers[70], ketones[71], lactones [72], and lactams[73,74] have been studied in a number of investigations. The influence of ring size is reflected in different ways in the electron-donating capacity of the oxygen atom incorporated in the ring or outside the ring. The difference has been explained[70] by the preferential formation of a hydrogen bond with the carbonyl oxygen atom and not with the oxygen atom of the alkoxy-group. However, a spectroscopic study of the hydrogen bonds between esters and trifluoroacetic acid led to the conclusion[75] that both carbonyl and alkoxy-oxygen atoms behave as electron donors.



In the above investigations the principal characteristics of the changes in the electron-donating capacity of the oxygen atom in different compounds were interpreted on the basis of qualitative ideas concerning the donor–acceptor properties of the substituents. The details of the changes in the electron-donating capacity, caused by varying the substituents, frequently remained uninvestigated. Studies were therefore undertaken[76,77] to investigate the influence of the inductive and mesomeric effect of the substituents R_i on the electron-donating capacity in relation to compounds of the type R_i–O–R_i and $(R_i)_2C$ = O. The influence of substituents on the electron-donating capacity of the compounds can be characterised quantitatively by the Hammett–Taft σ constants, which are known for the majority of organic substituents†.

For the compounds $(R_i)_2C$ = O, where the substituents R_i exert only an inductive influence on the electron-donating capacity, the following equation was fitted by the method of least squares:



$$\Delta\nu_{ind}(cm^{-1}) = -33\Sigma\sigma^* + 190, \qquad (1)$$

which relates the values of $\Delta\nu$(O–H) for phenol to the sums of the Taft inductive constants σ^* for two substituents R_i.[76] If the substituents R_i are involved in conjugation with the oxygen atom, then the experimental values ($\Delta\nu_{exp}$) differ from those calculated on the assumption of a purely inductive influence of the substituents ($\Delta\nu_{ind}$). The difference $\Delta(\Delta\nu) = \Delta\nu_{exp} - \Delta\nu_{ind}$ characterises the conjugation with the oxygen atom.

Table 5 shows that the experimental values ($\Delta\nu_{exp}$) for the majority of compounds exceed appreciably the values calculated from Eqn. (1) ($\Delta\nu_{ind}$). The reason for the difference $\Delta(\Delta\nu)$ is the p,π conjugation effect:

as a result of which the electron density at the oxygen atom increases. The contribution of this effect rises as X is varied in the series C_6H_5 < OAlk ≃ CH = CHC_6H_5 < $NAlk_2$. On the other hand, the electron-donating capacity of the amides R_i–C(O)–NR_2 decreases as R_i is varied in the series CH_3 > $CH_3CH_2CH_2$ > CH_3CH_2 > C_6H_5 > CH_2Cl > p-$NO_2C_6H_4$.[9] It has been shown[76] that, apart from the p,π conjugation effect, in amides there is yet another mesomeric effect — p,σ conjugation:

† The application of the Hammett–Taft system makes it possible to resolve the influence of electronic effects into components associated with the inductive and mesomeric effects.

Its contribution increases with the $-I$ effect of the substituents R_i.

Table 5. The values of $\Delta(\Delta\nu)$ for the infrared spectra of compounds of the type $(R_i)_2C = O$.

$C_6H_5OCH_3$	−38	$CH_2=CHOC_2H_5$	−63
n-$BrC_6H_4OCH_3$	−39	$CH_2=CHOCH_2CH_2Cl$	−55
CH_2-$CHOC_6H_5$	−35	$(C_2H_5)_3SiOCH_3$	−83
$C_6H_5OC_6H_5$	−32	$(CH_3)_3SiOSi(CH_3)_3$	−255
$CH_2=CHOC(CH_3)_3$	−52	$(C_2H_5)_3SiOSi(C_2H_5)_3$	−261

The influences of the inductive and mesomeric effects on the electron-donating capacity of the oxygen atom have been separated by correlation analysis, which was also carried out for the R_i–O–R_i derivatives[76,77]. For compounds with substituents R_i which are not conjugated with the oxygen atom, the values of $\Delta\nu$(O–H) are related to the sum of the Taft inductive constants σ^* for two substituents by the linear equation

$$\Delta\nu_{ind}\,(cm^{-1}) = -90\Sigma\sigma^* + 263. \qquad (2)$$

Table 6 shows that, in compounds with O–C_6H_5 and O–CH=CH_2 fragments, the values of $\Delta\nu_{exp}$ are smaller than those of $\Delta\nu_{ind}$ calculated by Eqn. (2). This is caused by the p,π conjugation effect:

which acts in the same direction as the $-I$ effect of aryl and vinyl substituents. The electron-accepting properties of these substituents therefore become more pronounced and the electron-donating capacity of the oxygen atom in compounds containing the given substituents is weakened. Trialkylsilyl groups have an appreciable $+I$ effect. However, the values of $\Delta\nu_{exp}$ for alkoxysilanes and siloxanes are comparatively small and the differences $\Delta(\Delta\nu)$ are large. The differences are caused by the effect of the d_π–p_π interaction in the Si–O fragments which consist in the delocalisation of the lone electron pairs of the oxygen atom over the vacant $3d$ orbitals of the silicon atom.

Infrared spectroscopic study of the hydrogen bond makes it possible to investigate different aspects of the conjugation effects in organoelemental compounds[78]. Thus studies of the electron-donating capacities of a number of ethers, alkoxysilanes, siloxanes[10,60,62,79–82], alkoxygermanes[61,83,89], and germoxanes[84] showed convincingly that the variation of the electron-donating capacity of the above compounds cannot be accounted for solely by the inductive effects of the substituents and the difference between the electronegativities of the central atoms. A sharp reduction of the electron-donating capacity of the oxygen atom in alkoxysilanes and siloxanes compared with carbon derivatives is a consequence of the shift of the p electrons of the oxygen atom to the vacant $3d$ orbitals of the silicon atom (Table 7; compounds 2 and 7 and 3 and 8). The electron-donating capacity of monoethoxygermanes is greater than that of monoethoxysilanes, which is consistent with the greater d_π–p_π interaction in the Si–O bond compared with Ge–O (Table 7; compounds 7 and 13 and 12 and 17). On the other hand, the values of $\Delta\nu$(N–H) for tetraethoxygermane are only slightly greater than for tetraethoxysilane (Table 7; compounds 11 and 16), which is a consequence, according to the authors[61], of the weaker π bonding to each oxygen atom compared with that in monoethoxysilane. It has been shown[84–86] that the relative electron-donating capacities of silicon, germanium, and tin derivatives vary in the following sequences:

$$SiOC > Si(OC)_2 > Si(OC)_3 > SiOSi;$$
$$GeOGe > GeOC > Ge(OC)_2 > Ge(OC)_3;$$
$$SnOSn > SnOC > Sn(OC)_2.$$

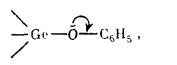
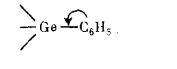
The electron-donating capacities of cyclic organosilicon compounds with Si–O bonds have also been investigated[87]. The greater values of $\Delta\nu$ for cyclotrisiloxanes compared with cyclotetrasiloxanes can apparently be explained by the more favourable conditions for the d_π–p_π interaction of the lone electron pairs of the oxygen atoms with the d orbitals of silicon in trimers compared with tetramers. The values of $\Delta\nu$(C–D) for alkoxy- and aminoalkoxy-silanes (with deuterochloroform as the electron acceptor) diminish with increase of the number of alkoxy-groups, i.e. with the increase of the $-I$ effect of the latter[88]. The study of the electron-donating capacities of trialkoxysilanes $RSi(OR')_3$ ($R' = CH_3$ or C_2H_5; R is an organic substituent) established a linear correlation between $\Delta\nu$(A–H) for phenol or pyrrole and the Taft inductive constants for the substituents R.[90] This apparently indicates a predominantly inductive mechanism of the influence of the substituents R.

The values of $\Delta\nu$(O–H) for phenol involved in the formation of a hydrogen bond with oxygen-containing organoalkynes $(CH_3)_2(CH_2=CHC\equiv C)COSi(CH_3)_3$ and $(CH_3)_2.(CH_2=CHC\equiv C)SiOSi(CH_3)_3$ indicate a decrease of the electron-donating capacity of the oxygen atom in the sequence C–O–C > C–O–Si > SiOSi.[96,97] The low electron donating capacity of the oxygen atoms in the Si–O and Si–O–Si fragments can be explained by the delocalisation of the electrons of the oxygen atom over the 3*d* orbitals of the silicon atom.



The experimental value of $\Delta\nu$(A–H) for the infrared spectrum of the electron acceptor in many instances characterises an effective electron-donating capacity of the donor in the hydrogen bond and not its true value. The difference between the true and effective values is associated with the steric hindrance of the approach of the electron acceptor molecule to the electron donor centre shielded by bulky substituents. Indeed it has been shown for alkoxy-derivatives of Group IV elements[98,99] that the t-butyl and trimethylsilyl groups give rise to steric shielding of the oxygen atom linked to them, which reduces the experimental $\Delta\nu$(A–H). Allowance for steric factors made it possible to reach a better-founded conclusion concerning the lower extent of the d_π–p_π interaction in the Ge–O bond compared with the Si–O bond.

The application of correlation analysis makes it possible to investigate fairly weak conjugation effects in alkoxy-derivatives of germanium[99]. If the substituents R in $(CH_3)_2Ge(OR)_2$ and $RGe(OC_2H_5)_3$ have only an inductive effect, then the values of $\Delta\nu$(N–H) for pyrrole and the Taft σ^* constants for these substituents are linked by the linear relations (3) and (4) respectively:



$$\Delta\nu_{N-H}(cm^{-1}) = -47\sigma_R^* + 181, \quad (3)$$

$$\Delta\nu_{N-H}(cm^{-1}) = -44\sigma_R^* + 154. \quad (4)$$

For R = C_6H_5, the corresponding points on the plots deviate from the correlation lines defined by Eqns. (3) and (4). The low values of $\Delta\nu$(N–H) for dimethyldiphenoxygermane are caused by the *p*, π conjugation effect:

and the enhanced electron-donating capacity of triethoxyphenylgermane is due to the effect of the d_π–p_π interaction in the bond, which weakens the electron-accepting properties of the phenyl group[99].

The electron-donating capacities of the organoelemental peroxides $(R_i)_3E–O–O–E'(R_i)_3$ (where E and E′ = C, Si, or Ge and R_i are alkyl or aryl substituents) depend significantly on the inductive effects of the substituents R_i linked to the E and E′ atoms[100]. If E and E′ = Si or Ge, the electron-donating capacity is also determined by the contributions of the effect of the $d_\pi - p_\pi$ interaction, which is more significant for organosilicon compounds and varies non-additively as the number of aryl substituents at the E and E′ atoms is varied.

The influence of the structure on the donor–acceptor properties of certain trialkylsilyl- and germyl-substituted alcohols has been studied[91,92] and it has been established that the electron density at the oxygen atoms in compounds with *n* > 2 in the $(CH_3)_3Si(CH_2)_nOH$ series is independent of the inductive effect of the organosilicon substituent. Evidence for the occurrence of the (*p* → *d*) σ interaction between the oxygen and silicon atoms has not been obtained. According to the values of $\Delta\nu$(O–H) found for phenol, intramolecular coordination takes place in the compounds $(CH_3)_3Si(CH_2)_nOSi(CH_3)_3$ (*n* = 1–4) when *n* = 1; for *n* ≥ 2, the effect is greatly reduced[93]. Among all the compounds investigated, the maximum value of $\Delta\nu$(O–H) was observed for $(CH_3)_3SiCH_2OSi(CH_3)_3$; nevertheless, according to the authors[93], this quantity is unduly low owing to intramolecular coordination, which partially compensates for the +*I* effect of the $(CH_3)_3SiCH_2$ group. The interpretation of the electron-donating capacities of the esters $(C_6H_5)_3ECH_2COOC_2H_5$ does not require the hypothesis of intramolecular coordination between the oxygen atom and the E atom[95]. The low value of the coordination effect and the resulting complications in its study make it at present impossible to regard the above data[91–95] as entirely correct.

The formation of hydrogen bonds by sulphur-containing compounds has been studied by a number of workers. The variation of the frequency and intensity of the ν(S–H) stretching vibration band in the infrared spectra of aliphatic mercaptans demonstrated the presence of a hydrogen bond of the type S–H... S.[101] The formation of hydrogen bonds of the type S–H... Y and X–H... S (X, Y = O, N, or S) in different classes of organic compounds has been examined in a review[102].

The electron-donating capacities of Group VI elements decrease in the sequence O > S > Se > Te. This conclusion was reached in the study of the hydrogen bonds between phenol and the compounds Alk_2X (X = O, S, Se, or Te)[59,103–106]. At the same time there is evidence for a greater electron-donating capacity of the sulphur atom compared with the oxygen atom[105]. In analysing the causes of the discrepancies between the results of these studies, one must take into account the fact that the electron-donating capacity of Group VI atoms depends significantly on the nature of the substituents linked to them[106,107]. Table 8 shows that the shift of the stretching vibration frequency ν(O–H) for phenol on formation of hydrogen bonds by the latter with the derivatives $(n\text{-}C_4H_9)_2X$ diminishes as X varies in the sequence O > S > Se > Te. The values of $\Delta\nu$(O–H) for phenol involved in hydrogen bonding with the $(C_6H_5)_2X$ derivatives diminish for different X in the opposite sequence: Se > S > O.

Table 8. The parameters $\Delta\nu$(O–H) for the infrared spectra of hydrogen-bonded complexes (with phenol as the electron acceptor).

X	$(n\text{-}C_4H_9)_2X$		$(C_6H_5)_2X$	
	$\Delta\nu$(O–H), cm^{-1}	References	$\Delta\nu$(O–H), cm^{-1}	Refs.
O	278	103	119	106
S	254	103	151	106
Se	240	103	161	106
Te	220	103	–	–

Apart from the electronegativities of the X atoms, the electron-donating capacity of $(C_6H_5)_2X$ is appreciably influenced by the *p*, π conjugation effect. The effect is a maximum for X = O, which results in a sharp decrease of the electron density at the oxygen atom in diphenyl ether and leads to the inversion of the electron capacity series

for the derivatives $(C_6H_5)_2X$ compared with $(n\text{-}C_4H_9)_2X$. Comparison of the spectroscopic and thermodynamic parameters of the hydrogen bonds between a number of electron acceptors and organic sulphides and selenides showed that the electron-donating capacity depends on the electronegativities of sulphur and selenium atoms and also on the steric and inductive effects of the substitutents[39]. The virtually identical electron-donating capacities of isostructural selenides and sulphides is a consequence of the similar electronegativities of sulphur and selenium atoms[39].

The electron-donating capacity of Group VI elements (X) changes sharply on passing from compounds with the C–X–C fragment to derivatives with the E–X–E group (where E is an element in the silicon sub-group)[42,108,109]. This is associated with the differences between the steric effects of the substituents — mainly with the sharp differences between the inductive effects and with the partial double bond character of the E–X fragments (the effect of the d_π–p_π interaction). The electron-donating capacity of Group VI elements with E = Si diminishes as X varies in the sequence Te > Se > S > O, which is exactly the opposite of the sequence of the electron-donating capacities of X in the Alk_2X derivatives[59,103,104] (see Tables 8 and 9). In series with E = Ge or Sn the maximum electron-donating capacity is shown by oxygen derivatives, but the overall sequence based on the variation of $\Delta\nu$ as a function of the nature of X also differs from the sequence of the given quantities for carbon compounds. These experiments indicate a decrease of the amount of double bond character in the E–X fragments with increase of the atomic number of the elements E and X.

Table 9. The parameters $\Delta\nu$(C–D) (cm^{-1}) for the infrared spectra of the hydrogen-bonded complexes of $[(C_2H_5)_3E]_2X$ (with deuterochloroform as the electron acceptor).[109]

X	E = Si	E = Ge	E = Sn
O	10	47	85
S	29	37	43
Se	31	42	45
Te	42	45	46

In the study of the formation of hydrogen-bonded complexes of the $R_3EXE'R_3$ and R_3EXR' derivatives (E, E' = C, Si, Ge, or Sn; X = O or S) using phenol and indole as electron acceptors the following series based on decreasing electron-donating capacities of the oxygen and sulphur atoms were obtained[110]: SnOSn > GeOGe > SnOSi > COC > SiOSi; SnSSn > GeSGe > SnSSi > CSC > SiSSi; SnOC > GeOC > SiOC; SiSC > SnSC > GeSC. It is noteworthy that the series based on the variation of the electron-donating capacity of the sulphur atom in the compounds R_3ESR' (E = Si, Ge, or Sn), found by Shevchenko et al.[110], differs from the series obtained using deuterochloroform as the electron acceptor[42]. It is known[23,24,98] that the parameter $\Delta\nu$(A–H) can depend on the type of electron acceptor employed, since the steric hindrance in the formation of the hydrogen bond is determined not only by the steric accessibility of the electron-donating centre, which depends on the structure of the electron donor molecule, but also by the dimensions of the electron acceptor molecule.

A correlation between the logarithms of the association constants and the parameter $\Delta\nu$ (A–H) for each electron acceptor was established in the systematic infrared spectroscopic study of the formation of hydrogen-bonded complexes of phosphorus-containing compounds using different electron acceptors[11,111–113]. The electron density in the P = O fragment depends on the inductive and mesomeric effects of the substituents linked to the phosphorus atom. Thus the electron-donating capacity of the oxygen atom in the vinyl-substituted organophosphorus compounds $R_2P(O).CH=CH_2$ decreases in the following sequence for different R: $N(CH_3)_2 \geqslant C_2H_5 > C_6H_5 \geqslant p\text{-}CH_3C_6H_4 > OC_2H_5 > OC_6H_5 > Cl$.[114]

The electron-donating capacities of the arsenic-containing compounds $R_3As=O$ were estimated in the study of their hydrogen bonds with phenol[115,116]. Their electron-donating capacities are much greater than those of the organophosphorus analogues. This is related particularly to the shift of electron density in the P = O fragment towards the phosphorus atom via the d_π–p_π interaction mechanism. In arsenic compounds this effect plays a smaller role.

The study of the electron-donating capacities of the derivatives $R_2S=O$ (R = Alk, AlkO, C_6H_5, or $C_6H_5CH_2$) and nitroso-compounds using phenol as the electron acceptor established a correlation between the parameter $\Delta\nu$(O–H) and the logarithms of the constants for association via hydrogen bonding[117].

It has been shown[118,119] that compounds with the fragments P = S and As = S form hydrogen bonds of the type Ph–O–H...S = X< on association with phenol. The derivatives $R_3As=S$ form stronger hydrogen bonds than the compounds $R_3P=S$, as in the case of the related oxygen-containing compounds[115,116].

3. Electron Donors containing Group VII Elements

The formation of intermolecular hydrogen bonds of the type O–H...Hal has been studied by a number of investigators[20,29,103,106,120,121]. Certain data[103,121] are presented in Table 10. With increase of the atomic number of the halogens, their electron donating capacity increases and

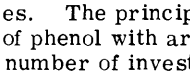
the ionisation potentials of the alkyl halides diminish[106]. The stronger hydrogen bonds formed by cyclohexyl halides compared with n-heptyl and n-butyl halides can be explained by the greater $+I$ effect of the cyclohexyl group[121], which entails an increase of the electron-donating capacity of the halogen atom.

The electron-donating capacity of the chlorine atom in $(CH_3)_3ECl$, $(CH_3)_2ECl_2$, and $(CH_3)_3ECH_2Cl$, where E = C, Si, Ge, or Sn, has been measured[122]. For the first two compounds, the electron-donating capacity of the chlorine atom increases in the sequence Si < C < Ge < Sn, which is inconsistent with the variation of the electronegativities of these elements. The anomalously low values of $\Delta\nu$(O–H) for $(CH_3)_3SiCl$ and $(CH_3)_2SiCl_2$ are related to the π-acceptor properties of the silicon atom, i.e. to the effect of the d_π–p_π interaction in the Si–Cl bond. The electron-donating capacity of the Cl atom in the compounds $(CH_3)_3$. ECH_2Cl is almost independent of the nature of the element E and can be accounted for purely by the inductive effect of the $(CH_3)_3ECH_2$ fragments. Thus the possible intramolecular coordination (σ-effect) between the chlorine atoms and E atoms (for E = Si, Ge, or Sn) was not shown under the conditions of the given experiment. Phenol used as the proton donor in the study of the hydrogen bond is fairly nucleophilic and, by solvating the organoelemental compounds at the E atom, it apparently prevents intramolecular coordination between the Cl and E atoms.

4. π-Type Electron Donors

Aromatic compounds having molecular π-orbitals form hydrogen bonds of the type O–H... π on interaction with phenols, alcohols, and other electron acceptors[123,124]. A correlation has been observed[125–127] between $\Delta\nu$(O–H) for the electron acceptor and the ionisation potentials of aromatic π-bases. The principal characteristics of the association of phenol with aromatic compounds have been studied in a number of investigations and the influence of substituents on the stability of the resulting hydrogen bonds has been examined[39,106,120,128–131,142]. The electron-donating properties of the aromatic ring are weakened as the substituents R are varied in the sequence $N(C_2H_5)_2 > OCH_3 >$ Alk $> C_6H_5 > CH_2Cl \sim H \sim C \equiv CH > I \sim Br > Cl > F > CF_3$. The electron-accepting properties of the substituents become more pronounced in the same sequence and can be characterised by the Hammett σ_n constants. The parameter $\Delta\nu$(O–H) of phenol is virtually the same in interaction with naphthalene derivatives as in interaction with the corresponding benzene derivatives[132–134].

The possibility of an increase of the multiplicity of the E–C_6H_5, E–C = C, and E–C $\equiv$ C (E = Si, Ge, or Sn) bonds as a result of the d_π–p_π interaction has been partly considered[43,140]. Comparison of the electron-donating capacities of silicon-containing derivatives of benzene and their carbon analogues (Table 11, compounds 3 and 15 and 4 and 16) shows that the $\Delta\nu$(O–H) of phenol in interaction with arylsilanes are lower, which indicates the operation of the effect of the d_π–p_π interaction in the Si–C_6H_5 fragment.



In unsaturated hydrocarbons the most weakly bound electrons are in the molecular π orbitals. Olefins are therefore classified as π-bases. The principal characteristics of the intermolecular association of olefins with phenol and p-fluorophenol have been investigated[131,133,134,135]. The electron-donating capacity of olefins increases with increase of the number of alkyl substituents attached to the sp^2-hybridised carbon atom (Table 12, compounds 1–5).

The nature of the variation of the parameter $\Delta\nu$(O–H) is in general the same as that of the ionisation potentials of the unsaturated hydrocarbons. Indeed, as alkyl substituents at a double bond accumulate, the ionisation potentials of olefins diminish; those of cyclic olefins are much lower than the ionisation potentials of their linear analogues[136,137].

* R=Alk.

The above features of the influence of substituents on the electron density at a double bond also obtain for vinyl derivatives of the elements in the silicon sub-group. The increase of the number of methyl groups attached to the sp^2-hybridised carbon atom is accompanied by the additive increase of $\Delta\nu$(O–H) (Table 12, compounds 7–9). The introduction of electron-accepting substituents (the phenyl group, a hydrogen atom, and halogens; Table 12, compounds 7, 10, and 11) leads to a decrease of the π-electron density at the double bond. The electron-donating capacities of derivatives with the E–C = C fragments, where E = Si, Ge, or Sn, increase in the sequence Si < Ge < Sn (Table 12, compounds 7, 12, and 13). This sequence differs from that of the electronegativities of the elements, E, which indicates the operation of mesomeric effects in the organometallic derivatives of ethylene (d_π–p_π interaction). The effect of the d_π–p_π interaction is a maximum in silicon-containing derivatives. This also follows

from a comparison of the values of $\Delta\nu$(O–H) for vinylsilanes and related carbon compounds (see, for example, Table 12, compounds 1 and 7 and 2 and 8).

Phenol also forms hydrogen bonds with cyclopropane derivatives, which behave in many respects like compounds with a double bond[138]. For cyclopropane derivatives, the parameter $\Delta\nu$ is smaller than for alkylbenzenes and monoolefins (~40 cm^{-1}). The low electron-donating capacity of cyclopropane derivatives can probably be accounted for by the comparatively high ionisation potentials (10–9.7 eV) of these compounds[138]. On the other hand, acetylene derivatives exhibit stronger electron-donating properties compared with substituted olefins and alkylbenzenes[131,135,139]. Thus $\Delta\nu$(OH) for phenol hydrogen-bonded to butylacetylene is 90 cm^{-1}, according to West and Kraihanzel[139], and increases to 137 cm^{-1} when the second hydrogen atom is replaced by the ethyl group.

Furan and thiophen derivatives also behave as π-bases in the formation of hydrogen bonds[133,141,143]. Evidently the electron density in the furan and thiophen rings depends significantly on the nature of the substituents. The data presented in Table 13 confirm this convincingly. The introduction of methyl groups greatly increases the electron-donating capacity of furan and thiophen (Table 13; compounds 1–3 and 4–6). The substitution of hydrogen atoms by chlorine leads to a decrease of $\Delta\nu$(O–H) (Table 13; compounds 4 and 7–9). Comparison of the values of $\Delta\nu$(O–H) for organosilicon derivatives and their carbon analogues shows that the electronic effects of the silyl substituents are made up of the inductive effect and effect of the d_π–p_π interaction in the Si–thienyl bond (Table 13; compounds 5 and 10, 6 and 11, and 6 and 12).

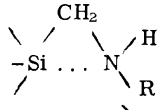
III. INTRAMOLECULAR INTERACTIONS IN ELECTRON ACCEPTORS INVOLVED IN HYDROGEN-BONDED COMPLEXES



The ability of the hydrogen atom in the AH fragment to form a hydrogen bond of the type AH...X depends both on the type of electron donor X and on the nature of the atom A. If A is a carbon atom, the formation of a hydrogen bond is accompanied by only a slight change in the stretching vibration frequency $\Delta\nu$(C–H)[145–151]. Alkyne derivatives are self-associated via hydrogen bonds with participation of the ≡CH group and the π-electron cloud of the triple bond; self-association leads to a shift of ν(≡CH) by ~10–15 cm^{-1} for alkylacetylenes and ~22 cm^{-1} for phenylacetylene. The change in the stretching vibration frequency of phenylacetylene $\Delta\nu$(≡CH) can be conveniently used as a measure of the electron-donating capacity of carbonyl compounds[66,152]. The electron-accepting capacity of acetylene derivatives has also been studied using *N*,*N*-dimethylacetamide, *N*,*N*-dimethylformamide, and ether as bases[139,153]. The introduction of electronegative substituents leads to an enhancement of the electron-accepting capacity of the carbon atom of the ≡CH group. Thus, when the n-butyl group is replaced by the phenyl group, $\Delta\nu$(≡CH) in dimethylacetamide increases from 74 to 91 cm^{-1}.[139] The study of the infrared spectra of alkyne derivatives of the type $R_3EC\equiv CH$ (E is a Group IVB element) in electron-donating solvents showed that silicon and tin compounds form more stable hydrogen-bonded complexes than carbon derivatives[154,155,157]. This is caused by the intramolecular interaction between the π electrons of the triple bond and the vacant *d* orbitals of the elements of the silicon subgroup. Data for the electron-accepting capacity show that the above interaction diminishes with increase of the atomic number of the element of the silicon subgroup. It has been shown for organosilicon derivatives[156] that the electron-accepting properties of the $\equiv CH$ fragment in $R_3Si-C\equiv CH$ depend on the nature of the substituents R. Electron-accepting substituents at the silicon atom increase and electron-donating substituents decrease the mobility of the hydrogen atom and hence the shift $\Delta\nu$(≡CH).

We shall now examine data for the electron-accepting capacities of compounds with the NH fragment. Primary amines exhibit a weak electron-accepting capacity. Therefore, in the study of the stretching vibration frequencies of the NH group (ν^s and ν^{as}) in aniline derivatives in electron-donating solvents (acetone, ether, and pyridine), the infrared spectra revealed comparatively small values of the parameter $\Delta\nu$(N–H).[158–161] Thus the ν^{as}(N–H) stretching vibration band in the spectrum of *p*-chloroaniline in acetone undergoes a bathochromic shift by 25 cm^{-1}. If the nitrogen atom forms part of a heterocyclic system, the parameter $\Delta\nu$(N–H) increases (Table 14; compounds 1–3). Therefore pyrrole has been used particularly widely as an electron acceptor in the study of the electron-donating capacities of organic compounds[15,57,61,85].

Table 14 shows that the electron-accepting capacity of the hydrogen atom in the NH fragment depends very significantly on the nature of the two substituents linked to the nitrogen atom. Following the enhancement of the electron-accepting properties of the substituents (Table 14; compounds 1–6), the values of $\Delta\nu$(N–H) increase. The parameter $\Delta\nu$(N–H) is therefore a sensitive indicator of the electronic effects of substituents and can be used in the study of fine details of the changes in these effects, for example, on passing from carbon derivatives to derivatives of silicon subgroup elements[47,48,51,162]. The electron-accepting capacity of silazanes, like that of amines, depends on the nature of the groups at the silicon atom, i.e. on the inductive effect of the silyl groups (Table 14; compounds 7–10). In contrast to alkyl groups, the electronic effects of organosilicon substituents are made up not only of the inductive effect but also of the effect of the d_π–p_π interaction in the Si–N bond. The R_3Si groups therefore become electron acceptors and the mobility of the hydrogen atom in the derivatives $(R_3Si)_2NH$ is appreciably higher than in secondary amines (Table 14; compounds 1, 7, and 10).

The values of $\Delta\nu$(N–H) are also a source of information about other weak intermolecular interactions in organoelemental compounds, for example about the α-effect.[163] The latter obtains in compounds with an $E-CH_2-X$ fragment (E is an element of the silicon subgroup or another atom having vacant orbitals and X is an atom having lone electron pairs) and represents intramolecular coordination, for example,  . In amides and amines containing groups of the type  , the electron-accepting capacity of the hydrogen atom in the NH group depends on the electronic effects of the substituent R linked to the nitrogen atom (the I effect, p,π conjugation, and the α-effect)[163]. The α-effect depends on the nature of the substituents R. When R = Alk, the α-effect is a maximum; it decreases for R = C_6H_5 owing to competition with the effect of p,π conjugation; when R = $C(O)OCH_3$, there is no α-effect.

A large number of spectroscopic studies of the formation of hydrogen bonds with participation of OH groups and various electron donors have been made[12,15,67,96,106,164–178]. The electron-accepting capacity increases after the introduction of electron-accepting substituents into the molecule. Thus the O–H stretching vibration frequency shift $\Delta\nu$(O–H) in the infrared spectrum of tetrafluoropropanol dissolved in acetone is 165 cm^{-1}, while the corresponding shift for propanol is only 110 cm^{-1}.[67] The electron-accepting capacity of chloroalcohols increases as chlorine atoms accumulate in the molecule[168,169]. However, the electron-donating capacity of alcohols then diminishes, which induces a decrease of the degree of self-association of chloroalcohols. Thus the ν(O–H) stretching vibration band of $(CCl_3)_2CHOH$, corresponding to an associated species formed via an intermolecular hydrogen bond, is not observed even at an alcohol concentration of ~2 M.

The electron-accepting properties of phenol derivatives can be regulated over a wide range by varying the nature of the substituents in the aromatic ring[171–173]. The introduction of electron-accepting substituents in the p-position in phenol increases the mobility of the hydrogen atom of the OH group. $\Delta\nu$(O–H) for phenol in diethyl sulphide is 256 cm^{-1}, increasing to 280 cm^{-1} for p-chlorophenol[105].

The stretching vibration frequency of the S–H bond changes little on formation of a hydrogen bond. It was therefore believed for a long time that the self-association of the corresponding compounds via the formation of hydrogen bonds of the type S–H. . . S does not occur. However, subsequently the presence of hydrogen bonds of this type was demonstrated and certain characteristics of the formation of such hydrogen-bond complexes were investigated: the dependence of the electron-accepting capacity of the S–H group in p-substituted thiophenols on the nature of substituents[179]; the presence of a hydrogen bond of the type S–H. . . S in aliphatic thiols and of the type S–H. . . S and S–H. . . π in benzenethiols and α-toluenethiols[180]; the formation of a hydrogen bond between mercaptans RSH and amines, ethers, and thioethers[101]. Comparison of the electron-accepting capacities of the OH and SH groups in the formation of an intermolecular hydrogen bond showed that the hydrogen in thioacids is less mobile[181,182]. The greater shielding at the proton in the SH group is normally due to the more diffuse nature of the orbitals of the outer electrons of the sulphur atom compared with the outer orbitals of the oxygen atom[182].

The formation of hydrogen-bonded complexes by organoelemental compounds of Group IVB elements was first studied[140,183–185] in relation to alcohols of the type R_3EOH and $(C_6H_5)_3EOH$, where E is an element of the silicon subgroup. Diethyl ether, mesitylene, and tetrahydrofuran were studied as electron donors. Compared with the corresponding carbinols, silanols exhibit much greater shifts $\Delta\nu$(O–H) (Table 15, compounds 1–3). The series corresponding to the diminution of the electron accepting properties of alcohols as a function of the element E(Si > Ge ≃ C > Pb ≃ Sn) does not agree with the electronegativity series of these elements. Taking into account only the inductive effect, it was to be expected that the greatest electron-accepting capacity would be shown by carbinols and germanols. On the basis of these data, it was concluded[140,183–185] that the d_π–p_π interaction takes place in the E–O fragments, its intensity diminishing as E is varied in the sequence Si > Ge > Sn > Pb. The greater electron-accepting capacity of vinylacetylenic silanols compared with their carbon analogues can also be explained by the d_π–p_π interaction between the oxygen and silicon atoms[96]. The greater electron-accepting capacity

of silanethiols compared with the corresponding thiols is due to the delocalisation of the lone electron pair of the sulphur atom over the 3*d* orbitals of the silicon atom, which increases the mobility of the hydrogen atom in the Si–S–H fragment[186].

The electron-accepting capacity of the hydrogen atom in the test compounds decreases in the sequence $(C_6H_5)_3$. .SiSH ≫ C_6H_5SH > $(CH_3)_3SiSH$ > $(C_6H_5)_3CSH$ > $(CH_3)_3CSH$, which is analogous to the sequence based on the decrease of the mobility of the hydrogen atom of the given group in oxygen-containing compounds: $(C_6H_5)_3SiOH$ ≫ C_6H_5OH > $(CH_3)_3SiOH$ > $(C_6H_5)_3COH$.[184] In the series of alcohols $(C_6H_5)_3ECH_2OH$ the electronegativities of the Group IVB elements E suggested that the carbinol should have the greatest electron-accepting capacity. However, the experimental electron-accepting capacity series for the alcohols is different: $(C_6H_5)_3GeCH_2OH$ > $(C_6H_5)_3SiCH_2OH$ > $(C_6H_5)_3CCH_2OH$ (Table 15, compounds 4–6). This fact can probably be accounted for by an intramolecular coordination of the type $(p \rightarrow d)\sigma$ between the oxygen and germanium atoms as a result of the existence of the vacant 4*d* orbitals in the latter. In the silicon derivative this effect is less pronounced and in the carbon derivative it is altogether absent. The nature of the element E has almost no influence on the mobility of the hydrogen atom in the alcohols $(C_6H_5)_3ECH_2CH_2OH$,[187] because the inductive effect of groups $(C_6H_5)_3ECH_2CH_2$ changes only slightly as E is varied (Table 15, compounds 7–9). There is apparently no intramolecular coordination in these compounds.

In the study of the electron-accepting properties of the silicon containing alcohols $(CH_3)_3Si(CH_2)_nOH$ and $R(CH_3)_2$. .$SiCH_2OH$ (n = 1–4, R = C_2H_5 or C_6H_5) the authors[91,188] concluded that there is no intramolecular interaction in these compounds between the oxygen and silicon atoms. However, intramolecular interaction does take place in the compounds $C_6H_5(CH_3)_2Si(CH_2)nOH$ (n = 1, 2) and $(C_6H_5)_3$. .$SiCH_2OH$.[188] This interaction apparently involves the formation of an intramolecular hydrogen bond, since in the carbon analogues the effect is more marked.

When the electron-accepting capacities of organosilicon hydroperoxides, carbinols and silanols and organic hydroperoxides were compared, the following series were obtained[189]: R_3COH < R_3SiOH, R_3COH < R_3COOH, $(CH_3)_3$. .EOH < $(C_6H_5)_3EOH$ (E = C or Si); R_3SiOH < R_3SiOOH, $(CH_3)_3SiOOH$ < $(C_6H_5)_3SiOOH$, R_3COOH < R_3SiOOH (R = CH_3 or C_6H_5). The results indicate the operation of the effect of the d_π–p_π interaction in the Si–O bond.

The electron-accepting capacity of the hydroperoxides $(C_6H_5)_3EOOH$ (E = C, Si, Ge, or Sn) decreases in the sequence $(C_6H_5)_3SiOOH$ > $(C_6H_5)_3GeOOH$ > $(C_6H_5)_3COOH$ > $(C_6H_5)_3SnOOH$ (Table 15, compounds 10–13). This leads to an electronegativity series of Group IV elements, Si > Ge > C > Sn, which differs from the corresponding series in the absence of conjugation effects: C > Ge > Si ≈ Sn.[191] This discrepancy between the electronegativity series can be accounted for by the effect of the d_π–p_π interaction, which diminishes in the sequence Si > Ge > Sn.

* * *

Thus the parameter $\Delta\nu$, which can be most readily determined experimentally from the infrared spectrum, serves at the same time as a source of fairly extensive information both in a qualitative assessment of the weak effects of substituents in the molecules involved in the hydrogen bond and in a semiempirical study of the effects using the Taft–Hammett system. This method for the investigation of intramolecular interactions has been by no means exhausted in the study of organic compounds; a quantitative theory relating the parameter $\Delta\nu$ to molecular structure factors will probably be created in the future. The simplicity and clarity of the method makes it promising for the study of organoelemental compounds, where the inadequate development of the theory of chemical bonding frequently restricts the employment of complex research techniques.

The Formation of Coatings in the Anodic Electrodeposition of Water-Miscible Lacquer Systems

P.I.Zubov and I.A.Krylova

The physicochemical principles of the formation of polymeric coatings in the electrodeposition of water-miscible compositions based on carboxyl-containing oligomeric electrolytes are described. The mechanism of the formation of the deposit on the anode and the film formation processes on various metallic supports are considered.
The influence of the composition of the system and the deposition conditions on the electrodeposition mechanism and the properties of the coatings are discussed. It is shown that electrodeposition is one of the ways of creating an ordered structure in the formation of polymeric coatings, which ensures a higher rate of relaxation processes.
The bibliography includes 104 references.

I. INTRODUCTION

Lacquer coatings are thin polymeric films bound to the support by adhesion forces. The mechanism of their formation includes the formation of local bonds between the active groups of the polymer molecules and the surface of the support. This results in a retardation of the relaxation processes and the occurrence of internal stresses which lower the lifetime of the coatings. The rate of relaxation processes and the cause of the stresses depend on the conformations of the molecules in solution, on the nature of the supermolecular structures arising in the coating at a particular stage in the formation of macromolecules, and also on the number and nature of the bonds between them.

This review deals with the formation of coatings from water-miscible lacquer materials based on water-soluble oligomeric electrolytes when they are electrodeposited on a support[1,2]. This is a new method of colouring, which appeared at the beginning of the 1960's as a special procedure for the deposition on a metal of aqueous lacquer systems[3-9], whose application has been extremely limited hitherto owing to the difficulty of their conversion into a coating in view of the specific features of water as a solvent. A characteristic of this method of colouring, in contrast to traditional methods based on the evaporation of solvents, is that the coatings are formed in two stages. Initially a water-insoluble deposit is formed on the anode in the field of a direct current, the anode consisting of the article to be coloured, and subsequently, in the course of thermal hardening, a three-dimensional network is formed from the virtually dehydrated oligomeric system. The review deals with the mechanisms of the processes occurring in this system.

II. CHARACTERISTIC FEATURES OF THE FORMATION OF COATINGS IN THE ELECTRODE POSITION OF WATER-SOLUBLE FILM-FORMING AGENTS

1. The Formation of a Deposit on the Anode

The film-forming agents used as binders in lacquers for electrodeposition consist of water-soluble carboxyl-containing oligomeric electrolytes. Their acid form is weakly dissociated; after the neutralisation of the carboxy-groups by organic amines (ammonia), they become water-soluble and capable of dissociation via the mechanism[7]

$$RCOONH_4 \rightleftarrows COO^- + NH_4^+ \quad ,$$

where $RCOO^-$ is the film-forming component converted into the anionic form. The diphilic structure of the molecules of the film-forming agents makes it possible to compare them with a set of low-molecular-weight surfactants whose hydrophobic component consist of a polymer (oligomer) chain and the hydrophilic component consists of COOH groups.

It has been established, on the basis of the surface tensions, electrical conductivities, and light scattering in aqueous solutions of a number of film-forming agents as a function of concentration[10], that aqueous solutions of neutralised film-forming agents at the concentrations used for electrodeposition (6–10%) are either micellar solutions containing ionised micelles (together with individual ions) or polyelectrolytes, in which neutral molecules (or their associated species) and ions are involved in an equilibrium controlled by the dissociation constant. In the first stage

of the development of the method of colouring by electrodeposition the mechanism of the formation of the deposits on the anode from such systems was obscure.

Numerous studies were carried out during this period and general hypotheses were put forward concerning the process mechanism, by analogy with galvanic processes as well as the electrophoretic process for the formation of coatings[11-19]. It was to be expected that the segregation on the anode of a polymer phase from the solution of a carboxyl-containing polyelectrolyte is associated with electrochemical processes in the region near the electrode under the influence of the electric current.

Anodic processes in an aqueous medium have been thoroughly investigated in relation to a number of metals[20-22]; in the case of metals incapable of being passivated these involve anodic dissolution:

$$M \rightarrow M^{n+} + ne \quad , \qquad (1)$$

while in the case of metals which can be passivated as well as certain inert electrodes such as platinum and graphite the relevant process involves the electrolytic dissociation of water:

$$H_2O \rightarrow 2H^+ + 1/2O_2 + 2e \qquad (2)$$

At high pH values reaction (2), which can occur in solutions at pH $\leq$ 11.5, is replaced by the discharge of hydroxide ions:

$$2OH^- \rightarrow 1/2O_2 + H_2O + 2e \quad . \qquad (3)$$

Apart from reactions (1)–(3), other electrochemical processes can occur on the anode in the electrodeposition of water-soluble film-forming agents—anodic oxidation of the metal (for example in the colouring of aluminium) as well as the decarboxylation and oxidation reactions of the organic molecules:

$$2RCOO^- \rightarrow R{-}R - + 2CO_2 + 2e \quad , \qquad (4)$$

$$RCOO^- + H_2O \rightarrow ROH^- + CO_2 + 2e \quad , \qquad (5)$$

$$\overset{|}{-}CH_2 + \cdot H_2O \rightarrow HCOH + 2H^+ + 2e \quad . \qquad (6)$$

It is believed[23] that the formation of a deposit on the anode under the electrodeposition conditions takes place as a result of the electrochemical discharge of the anions of the film-forming agent associated with decarboxylation as in the Kolbe synthesis in accordance with reaction (4).

Beck[24,25] calculated the change in the concentration of hydrogen ions in the anodic compartment during the electrodeposition of water-soluble oligomers. In the electrodeposition from solution at pH 8 and a current density of 2.5 mA cm^{-2} the pH in the anodic compartment falls to 2, which corresponds to (or is lower than) the pH at which deposits are formed in the electrodeposition of anionic water-soluble film-forming agents.

In order to elucidate the mechanism of the formation of the deposit on the anode in the electrodeposition of water-soluble film-forming agents (in relation to VBFS-4 resin, VML oil, rezidrol and water-soluble acrylic carboxyl-containing film-forming agents), the chemical composition of the films electrodeposited on anodes made of different metals was analysed by infrared spectroscopy (before thermal hardening).[29-30,44] It was established that, in the electrodeposition of the film-forming agents on anodes made of metals such as copper, cadmium, and zinc, the products are predominantly the salts of the binders, while in the electrodeposition on insoluble anodes and on steel mainly their acid form is produced. The acid form of the film-forming agents is produced as a result of their interaction with the H^+ ions generated in the anodic compartment by reaction (2), while the formation of the salt form is associated with reaction (1). It was observed that a steel anode dissolves at the rate of 0.25 and 0.18 g m^{-2} min^{-1} in the electrodeposition of the FL-149E enamel and the FL-093 primers respectively. Chemical analysis established the presence of iron in the electrodeposited film. X-Ray diffraction analysis showed that the thermally hardened coating contains iron in the form of the oxides Fe_2O_3 and Fe_3O_4 and not as products of the interaction with the film-forming agents. The oxides were probably formed during drying from the iron hydroxides deposited on the anode.

It has been suggested[27] that the difference between the mechanisms of electrodeposition on anodes of different types can be accounted for by the different solubilities of the salt and acid forms of the film-forming agents, on the one hand, and the hydroxides of the metal of the support, on the other. According to the solubility products (SP) of the hydroxides, iron(III) hydroxide is deposited most readily ($SP_{Fe(OH)_3} = 3.8 \times 10^{-38}$), while zinc hydroxide is deposited with the greatest difficulty ($SP_{Zn(OH)_2} = 5 \times 10^{-7}$). The concentration of the metal ions at the copper, cadmium, zinc, and other metal anodes is sufficient for the deposition of the binders in the salt form. It is noteworthy that the electrodeposition of the VML oil and rezidrol is accompanied by the partial oxidation of the double bonds, as shown by the decrease (up to complete disappearance) of the bands at 3020 and 997 cm^{-1} in the spectra of the resulting electrodeposited films.

In the electrodeposition of acrylic film-forming agents[28-30] the deposit is produced on the steel anode as a result of the interaction of the film-forming agent with both hydrogen and metal ions produced in the anodic dissolution of the electrode. If the electrodeposition is carried out on a steel anode over a long period (>3 min), then in the case of rezidrol the deposit is found to contain a certain amount of the salt form owing to the secondary interaction between the acid form of the film forming-agent produced and the metal hydroxides present in the film.

Thus the mechanism of the formation of a deposit on the anode (as the acid or salt form of the film-forming agent) depends on the nature of the metal on the surface being coloured, the chemical composition of the film-forming agent, and the conditions of the electrodeposition process (i.e. is determined by the solubility of the acid or salt form of the film-forming agent under the given electrodeposition conditions). The mechanism of the electrodeposition consists in the loss of solubility by the film-forming agent in the anodic compartment on interaction with the hydrogen or metal ions formed as a result of the primary electrochemical reactions in the electrolysis of water and the anodic dissolution of the metal. Reactions (4) can take place only on insoluble anodes at a rigorously defined temperature and pressure[31]. Oxidation of the film-forming agent plays an insignificant role. Furthermore, the discharge of ions on the surface of the anode should have ceased immediately after the segregation of a monomolecular organic layer, lacking in electronic conductivity, which was not confirmed by observations on the growth of the thickness of the coating.

Analysis of the composition of the gas involved on the anode[32-34] and the determination of the range of electrode potentials[35-38] at which electrodeposition takes place established that the current is mainly consumed in reactions (1)–(3). The partial oxidation at the anode of the

amines used as neutralisers of the film forming agents can also be included among secondary reactions[32,38]. This mechanism of the formation of a deposit on the anode agrees satisfactorily with the fundamental electrochemical studies of the electrodeposition of carboxyl-containing polyelectrolytes carried out in recent years[35-38]. These data established that, in the electrodeposition of polyelectrolytes on steel and also on phosphated steel, the main electrode reaction in the absence of activators of anodic dissolution is evolution of oxygen as a result of the oxidation of water molecules; at the same time the binder may be oxidised, which also leads to the formation of H^+ ions in the region near the anode.

Since the solution is stirred in the course of the electrochemical decomposition, the bath with the working solution may be regarded as a volume with a constant concentration[36]. A difference between concentrations is observed only at the interface where a diffuse double layer (Nernst layer) is "stuck" to the electrode. In this quasi-stationary layer species are transported via diffusion, which arises owing to the concentration gradient due to the discharge of the ions on the electrode and the migration of protons to the cathode as well as the migration of ions under the influence of electrical forces. Calculations have shown[36] that the thickness of the anodic layer of hydrogen ions is 10^{-2} cm. The film-forming agent loses its solubility in water on interaction with the precipitant ions in the layer near the anode. The deposits formed on the anode are highly concentrated two-phase systems. These are colloidal structures consisting of globular particles, whose size varies from 0.1 μm to several hundred μm, depending on the type of the film-forming agent and the process conditions[39,40].

The electrodeposition process takes place in a relatively dilute medium (6–15%), but the electrodeposits consist of highly concentrated systems. The dry residue of the electrodeposited films amounts to 94–98% and the electrodeposition conditions have only an insignificant influence on this proportion[36,39,40]. The hypothesis of the decisive role of electroosmosis in the mechanism of the dehydration of anodic deposits, which remained current for a long time, was not confirmed when the degree of electroosmotic dehydration was calculated from electrochemical equations[36] although electroosmosis undoubtedly takes place. Since the system passes through a metastable state on formation of a deposit, water is evidently removed also as a result of syneresis. The deposit is dehydrated also in consequence of the decomposition of water in the diffuse layer near the anode[36]; the protons evolved are transported through the film via diffusion and migration. According to Beck's view[36], the negative ions of the film-forming agent still fixed in the deposit can be regarded as bound to mobile protons, as happens in weakly acidic ion-exchange resins; the protons are expelled to the surface of the film, which ensures an increase of its thickness.

When the process is carried out under the conditions of a constant current density (galvanostatic conditions), the rate of electrodeposition can be expressed by adding the weight of the deposit on the anode per unit time. The overall form of the experimental time variation of the increment in the weight of the deposit is illustrated in Fig. 1*a* for a number of film-forming agents[36,38,39]. The relation along section *1* (Fig. 1*a*) is linear, but the corresponding straight line does not pass through the origin of coordinates. The induction period at the beginning of the process, where the coating is not formed, is necessary to create in the anodic compartment a concentration of H^+ of M^+ ions sufficient to precipitate the film-forming agent. The induction period and the slope $\tan\alpha$ depend on the nature of the film-forming agent and on the process conditions. For the same film-forming agent in a bath without stirring, there is a qualitative relation between the duration of the induction period and the reciprocal of the square of the current density. Theoretically one gram-equivalent of the precipitant ions evolved in the electrochemical reaction should neutralise one gram-equivalent of the macroanions. Thus

$$q = 5.6 \times 10^6/\text{A.N.} \times aF, \qquad (7)$$

where A.N. is the acid number of the film-forming agent (mg KOH/g resin), a the degree of neutralisation, and F the Faraday. Hence it follows that the quantity q, called the "conventional current yield", should be a constant characterising the given carboxyl-containing polyelectrolyte. However, experimental tests showed[36-39] that q and $\tan\alpha$ (for the given current density) depend on the concentration of the film-forming agent, the stirring conditions in the bath, the pH, temperature, the conversion of the film-forming agent into an insoluble state on partial neutralisation of the ionised carboxy-groups, the polydispersity with respect to the molecular weight and composition, etc. It has been established for acrylic film-forming agents[41,42] that, with increase in the number of carboxy-groups in the copolymer per unit molecular weight, in the degree of neutralisation of the binder, in the pH of the system, in the rate of stirring, and, when the temperature is reduced, also with increased current density[40], the induction period increases and $\tan\alpha$ falls.

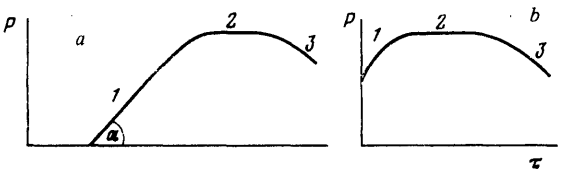

Figure 1. Schematic illustration of the dependence of the increment in the weight of the deposit on the anode P as a function of the process time τ [7,29,41] under different conditions: *a*) i = const.; *b*) u = const.

When the process is carried out under constant-potential conditions (potentiostatic conditions; Fig. 1*b*), there is a high initial current density, so that the induction period does not play an important role along section *1*. The thickness of the coating increases with time. Along section *2*, the thickness of the film does not increase for a long time (up to 5–10 min, depending on the type of film-forming agent and current density) and then begins to decrease (section *3*). The retardation of film growth is attributed[36] to the hindrance of ion transport through the film, which is regarded as the rate-limiting process. The presence of maxima and minima on the $i(\tau)$ and $u(\tau)$ curves has been observed by a number of workers[35,36,43] and some of them believe that this is caused by dielectric breakdown[44]; other studies established a relation between the heat evolution in the film and the existence of the extrema[43,45]. It has been observed[40,46] that the presence of section *3* on the curves in Figs. 1*a* and 1*b* is associated

with the stripping of the deposit from the anode owing to the increase of the amount of heat evolved during the electrodeposition. This was established in a study of the structural-mechanical properties of the films formed on the anode under different electrodeposition conditions.

2. The Influence of Structural-Mechanical Properties of the Film-Forming Agents on Their Electrodeposition

The formation of polymeric coatings proceeds via a structure formation stage[1-5]. The structure formation in the solution from which the coating is produced influences the rate of inhibition of relaxation processes. During electrodeposition, a structure is produced on formation of the deposit on the anode before the onset of thermal hardening. The ability of the system to give rise to relaxation processes, on which the formation of monolithic defect-free films depends, can be inferred from structural-mechanical properties.

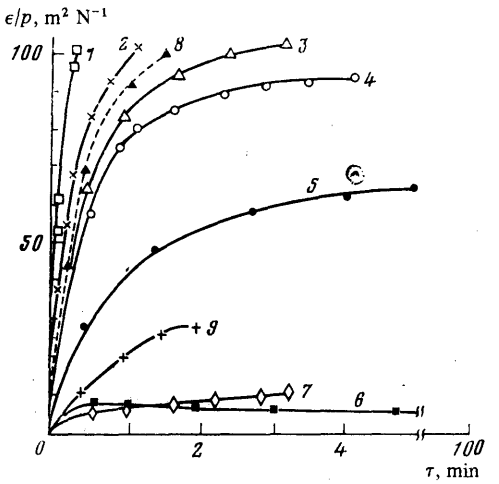

Figure 2. The development of the shear deformation (ϵ/p) of the electrodeposits with time (t) ($p = 2$ N m^{-2}):[46] 1) VML oil; 2) VA-105 rezidrol; 3) VA-133 rezidrol; 4) polyacrylate + 3% butanol; 5) polyacrylate + 2% butanol; 6) polyacrylate without butanol ($p = 20 \times 10^3$ N m^{-2}); 7) VBFS-4 resin + 3% of 2:1 mixture of butyl and isopropyl alcohols; 8) VBFS-4 resin + VML oil + 3% of 2:1 mixture of butyl and isopropyl alcohols; 9) VBFS-4 resin + VML oil with a reduced content of solvents.

In the formation of coatings by the electrodeposition method the structural-mechanical properties of the deposits on the anode play a special role associated with their influence on the mechanism of the electrical insulation of the anode. The rheological characteristics of the electrodeposits obtained from systems of water-soluble film-forming agents, differing in their chemical nature and in the presence of added organic solvents, have been investigated[45-47]. The form of the deformation curves (Fig. 2) leads to the conclusion that the electrodeposits exhibit different rheological properties. Thus deformation curves for rezidrol and acrylic film forming-agents containing added organic solvents have sections with conventional instantaneous elastic and plastic deformation, while the VML oil flows and the VBFS-4 resin is not deformed at all owing to its brittleness. The capacity for deformation of acrylic film-forming agents without added organic solvents is weak. There is a corresponding difference in the behaviour of the above systems in electrodeposition. Monolithic defect-free films are formed from rezidrol and the VML oil. The electrodeposition of the VBFS-4 resin and acrylic film-forming agents from systems without organic solvents leads to the formation of thin porous coatings. When organic solvents are added to these systems, the nature of the porosity changes. With increase in the amount of solvent in the system, the pores ("craters") in the coating become smaller and then disappear altogether. Under these conditions, the electrical resistance of the anode diminishes and there is a corresponding increase in the thickness of the coating. The introduction of organic additives into the system based on the VML oil (the deposit exhibits an appreciable irreversible deformation) leads to the formation of bulges on the coating and to a decrease of the electrical potential during deposition.

The increased hindrance to the coalescence of the electrodeposited species with increasing rigidity of the film-forming agent leads to the retardation of the removal of oxygen bubbles from the surface of the anode, to an increase in the resistivity of the latter, and to the consequent formation of thin porous coatings (the pores are sites where oxygen bubbles are located)[47-51]. Conversely factors promoting the coalescence of particles (for example, the introduction of organic solvents plasticising the electrodeposits) causes an increase of the capacity of the system for undergoing relaxation processes, which leads to the "healing" of the pores, to a decrease of the resistivity of the anode, and to an increase of the thickness of the coatings. However, a high plasticity of the system is also undesirable from the standpoint of the electrodeposition process. This has been shown[46] by comparing the VML oil, the VA-105 rezidrol, and the VA-133 rezidrol, which differ in the rheological characteristics of their electrodeposits and the deposition parameters (Fig. 3).

Direct measurement of the temperature of the anode during the electrodeposition process with the aid of a Chromel–Copel thermocouple welded into the anode established[43] that during electrodeposition the temperature of the anode rises up to 70–80°C depending on the electrical parameters. Such heating in the case of the highly plastic VML oil (Fig. 3) leads to the formation of bulges on the surface of the coating and, on further increase of the potential, the coating flows off the surface of the anode. The optimum potential in the electrodeposition of the VML oil is 30–40 V. The high viscosity of the rezidrol deposit (Figs. 3*b* and 3*c*) makes it possible to increase the potential considerably during electrodeposition (up to 300 V) for the VA-133 rezidrol.

Thus a significant factor in the formation of coatings by electrodeposition is the viscosity of the deposit formed for low shear stresses. From this it also follows that one of the causes of the differences between films electrodeposited from high-resistance lacquer materials at high potentials (hundreds of volts) and low-resistance materials (deposition potential of tens of volts) consists in the difference between the structural-mechanical properties of their deposits, which play an important role in the mechanism

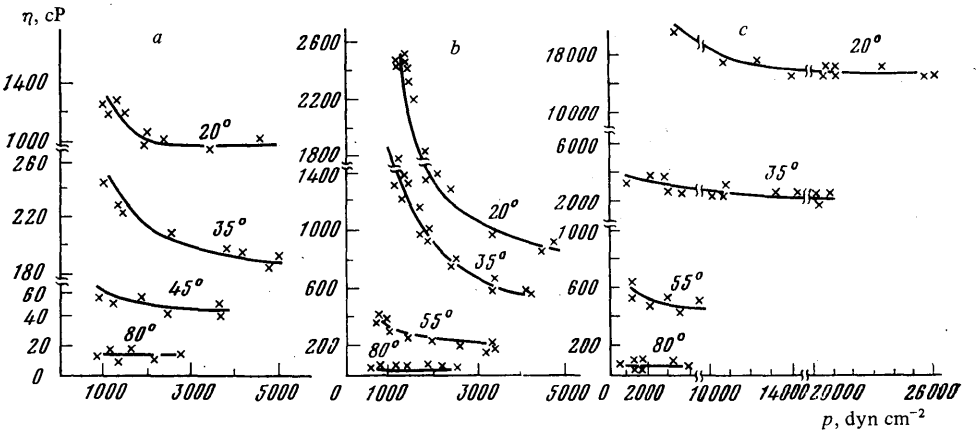

Figure 3. Dependence of the viscosity η of electrodeposits based on different materials as a function of the stress p corresponding to the slipping of the deposits[46]: *a*) VML oil; *b*) VA-105 rezidrol; *c*) VA-133 rezidrol.

of the electrical insulation of the anode during electrodeposition[45].

3. The Mechanism of Film Formation in the Electrodeposition of Water-Soluble Film-Forming Agents

(a) The influence of the method of deposition of water-soluble film-forming agents on the support. It has been established by infrared spectroscopy that the mechanism of film formation in the production of coatings by methods based on the evaporation of solvents (pouring, spraying) and on electrodeposition is in principle the same at the molecular level and is associated mainly with oxidative polymerisation (VML oil[27], rezidrol[52]), with formation of ester linkages via carboxy- and hydroxy-groups (VML oil, VBFS-4 resin, and partly rezidrol), and also (in the case of acrylic film-forming agents) the interaction of hydroxymethyl groups with carboxy- and amide groups[53]. However, in electrodeposition the formation of a three-dimensional network takes place to a greater extent than in the formation of coatings by pouring and the difference is greater the lower the hardening temperature (Table 1).

Electron microscope study of coatings has shown that electrodeposited coatings are structurally more homogeneous and that the size of the structural elements and the distance between them is smaller than in the formation of coatings by pouring or spraying (Fig. 4). With increase of the hardening temperature, the size of the structural elements of the coating and the distance between them diminish, but in electrodeposition there is a greater number of structural elements per unit surface than in the pouring method over the entire experimental temperature range (from 20° to 250°C). Owing to the smaller dimensions of the structural aggregates, better conditions are probably established in electrodeposition for a more complete interaction between the structural elements on the surface via the reactive groups than in the pouring method. Apart from the smaller size of the structural elements of the coating, the acceleration of the film formation process in electrodeposition is associated with the regeneration of the reactive carboxy-groups on formation of a deposit on the anode (in the pouring method this occurs only during thermal hardening) and also, in the case of oily binders, with the preliminary oxidation of the film-forming agent on the anode.

Table 1.* Dependence of the molecular weight of the section of the chain between the effective nodes of the three-dimensional network (M_C) in the formation of rezidrol coatings on the hardening temperature[52].

Method of colouring	Hardening temperature			
	130°	180°	200°	220°
Pouring method	3792	975	371	308
Electrodeposition method	371	280	241	238

The presence of a homogeneous fine globular structure of the electrodeposited coating creates conditions better than in other deposition methods for the acceleration of relaxation processes. This is confirmed by data obtained in the study of the thermal conductivities of coatings. It has been established[27] that the thermal conductivities of electrodeposited coatings are greater than those of the coatings formed by spraying or pouring. As a result, the electrodeposited coatings have smaller internal stresses and hence better physicomechanical properties. Indeed, the resistance to wear and adhesion are superior in electrodeposited coatings to those of coatings obtained by the pouring and spraying methods[52]. The available literature data[54], suggesting that the properties of coatings obtained by electrodeposition and spraying do not differ, are based on a comparison of properties of coatings which, although obtained from water-soluble systems, were produced in different media (a comparison was made of coatings obtained by electrodeposition from an aqueous medium and deposited by spraying from an acid paste diluted with organic solvents). Tests on the protective properties of the coating showed that electrodeposited

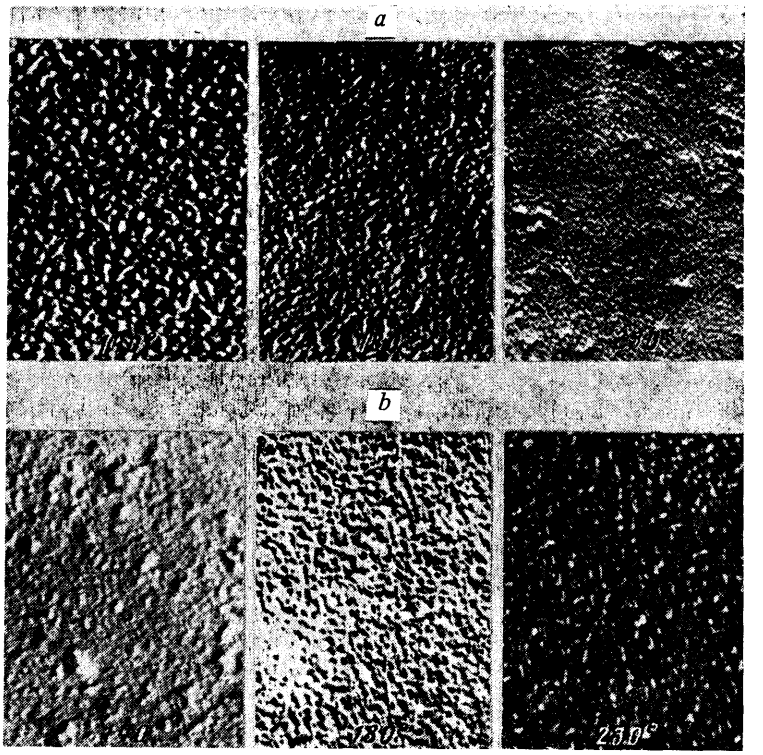

Figure 4. Electromicroscope structure of coatings based on rezidrol[52]: *a*) formation by electrodeposition; *b*) formation by the pouring method. Magnification 1 × 32 000

coatings exhibit a more satisfactory resistance to water and salts than films produced by other deposition methods[52].

All these factors suggested a longer lifetime of the electrodeposited coatings compared with those produced from the same lacquer systems by other deposition procedures.

It has been established in a number of studies[55,56] that the lifetime of polymer coatings obeys the relation

$$t = A e^{-\beta x},$$

where t is the time before the breakdown of the coating, x a characteristic of the state of the coatings which may be a number which represents the estimated state of the coating, the disruptive or internal stresses, the change in the content of functional groups, etc., A = the logarithm of the time required for the attainment by the coating of the state estimated in terms of a specified number, and β is the rate of change of the state of the coating. Thus, in terms of logarithmic coordinates, there is a linear relation between $\lg t$ and x.

It follows from the data in Fig. 5 that the protective properties of the electrodeposited coating persist appreciably longer than those of the coating produced by spraying when tests are made for water resistance (Fig. 5*a*); in tests carried out in a salt mist chamber (Fig. 5*b*) the change in the properties of the coatings obtained by both electrodeposition and spraying begins simultaneously but the electrodeposited coatings lose their protective properties one and a half times more slowly than those produced by spraying[57].

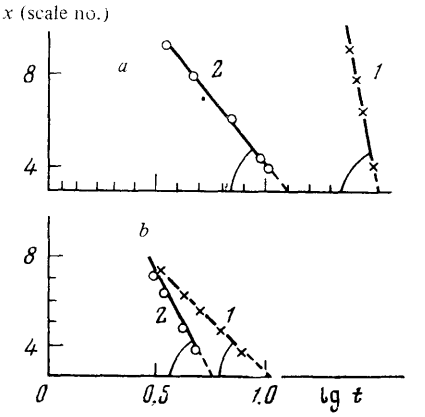

Figure 5. Variation in the state of the coatings based on the FL-093 primer deposited by electrodeposition (line *1*) and spraying (line *2*) in the course of ageing in a hydrostat (*a*) and in a salt mist chamber (*b*).[57]

(b) The influence of the nature of the metallic support. A characteristic feature of the coatings, which distinguishes them from other polymeric materials, is that they are formed on a support. The influence of the nature of the support on the structure and

properties of coatings produced by the methods based on solvent evaporation is determined both by the overall area of contact and by the shape of the surface, the number and nature of bonds at the boundary, and the nature of their distribution.

In oligomeric systems the formation of a structure inhomogeneous with respect to thickness and area takes place in consequence of the adsorption interaction of the oligomers with the support before the start of polymerisation. Furthermore, as shown above, in electrodeposition the nature of the support influences the chemical composition of the deposit formed on the anode.

It has been shown[58] that electrodeposition on steel and aluminium proceeds via a mechanism involving the formation of the acid form of the film-forming agent. The electrodeposition on aluminium is characterised by a lower degree of oxidation of the film-forming agent on the anode, as a result of which the oxygen evolved in the electrolysis of water is consumed to a greater extent on aluminium anodisation processes. Electrodeposition on copper involved the formation of the salt form of the film-forming agent. The above specific features of the formation of the electrodeposit on anodes of different kinds are responsible for the differences between their structural-mechanical properties (Table 2).

Table 2. The influence of the nature of the support on the conventional viscosity η of rezidrol electrodeposits and on the M_c for coatings formed on different metals[58].

Metal	$10^{-5}\eta$, Pa s	M_c at the hardening temperature			
		130°	180°	200°	225°
Copper	2.000	157	76	49	25
Steel	0.480	184	98	87	69
Aluminium	0.324	374	280	241	225

The conventional viscosity of the deposit, calculated from the rate of development of the shear deformation between two plane-parallel plates, is a maximum for a copper support. The greater conventional viscosity of films on steel compared with aluminium can be accounted for by the greater degree of oxidation of the film-forming agent. During thermal hardening on steel and aluminium, the formation of a three-dimensional network in oils is associated with oxidative polymerisation.

In a coating on copper double bonds are retained even at 275°C. The cause of this is the blocking of the double bond by copper ions, which can form a coordinate bond with the latter. Nevertheless data obtained by the direct determination of the molecular weight of the section of the chain between the effective nodes of the three-dimensional network (M_c) showed that the greatest density of cross-links obtains in the coating electrodeposited on copper. These phenomena are associated with the fact that the mechanism of film formation in electrodeposition on copper is in principle different from that of film formation on steel and aluminium and consists in the formation of ionic and coordinate bonds with copper ions.

The results of the determination of the mechanical properties of the coatings during hardening agree satisfactorily with the film formation mechanism examined above[58]. Coatings obtained on steel and aluminium supports exhibit the greatest and smallest resistance to wear. The formation of a three-dimensional network on a copper support via ionic bonds is responsible for the higher resistance to wear of the coatings at a low hardening temperature and the smaller influence of the hardening temperature on the mechanical properties as compared with steel. The lower resistance to wear of the coatings on copper, compared with steel, at temperatures above 150°C is associated with their greater rigidity and their coarsely globular structure, which retard the relaxation processes.

III. THE MECHANISM OF THE ELECTRODEPOSITION OF THE PIGMENT COMPONENT OF WATER-MISCIBLE LACQUER MATERIALS

Apart from film-forming materials, the most important components of the lacquer system are pigments and fillers. However, the problem of the mechanism of the electrodeposition of filled systems containing water-soluble film-forming agents has been very little studied. Previously it was assumed that the electrodeposition of pigments obeys the rules governing the electrophoretic deposition of dispersions, although this was not confirmed experimentally. The existing ideas about the mechanism of the electrophoretic deposition of dispersions are applicable to lyophobic colloids stabilised by an ionic mechanism. They are based on Deryagin and Landau's theory of the stability and coagulation of lyophobic colloids, which at its present stage of development takes into account not only pair but also collective interactions of the species, the possibility of their fixation at long distances from one another, as well as the influence of homogeneous and inhomogeneous electric fields[59-68].

The systems of water-soluble lacquer materials considered here differ from the systems of lyophobic colloids stabilised by an ionic mechanism primarily by the fact that the concentration of the third component, constituting, together with the aqueous dispersion medium, a single phase, is very high compared with the concentration of the disperse phase. In fact, one is dealing with dispersions of pigments in a concentrated aqueous solution of a polyelectrolyte. The problems of the stability, electrokinetic properties, and electrodeposition of such systems have already been examined[69-72].

1. Interaction of Water-Soluble Film-Forming Agents with Pigments

Since in the absence of a film-forming agent there is no electrodeposition of the majority of pigments from a pigment–water system on electrodes[73,74], it was concluded that the pigment particles in an aqueous medium are surrounded by particles of the binder, which impart to them a negative charge[74-76] and are responsible for their electrodeposition[74-77].

The interaction of water-soluble film-forming agents with pigments was studied in relation to the Printex U carbon black and R-820 titanium dioxide, which are used in electrodeposition systems[69]. The determination of the ξ-potential of the particles and of the sedimentation potential on a Figurovskii balance demonstrated the stabilising influence of film-forming agents in relation to pigments. It has been established on the basis of the surface tension isotherm of an aqueous solution of rezidrol in the presence of pigments that a considerable degree of

adsorption is characteristic of the test systems. In order to determine its nature, a study was made by a gravimetric method of the adsorption of rezidrol on the test pigments from aqueous solutions at different concentrations with subsequent removal by washing; the results were used to calculate the adsorption parameters. It was established that part of the adsorbed film-forming agent is bound to the surface of the pigment by irreversible linkages. Thus in real electrodeposition systems the pigment is stabilised by a binder adsorbed on its surface. This condition is necessary for the electrodeposition of the pigment on the anode, which has been demonstrated by the absence of the electrodeposition of oxidised carbon black from an aqueous medium. In this case the carbon black–water system has a high kinetic stability and a high ξ-potential of the particles (62 mV); nevertheless in an electric field the carbon black particles are not deposited on the anode.

Thus the deposition of pigments on the anode is determined by the film-forming agent linked to their surface by adsorption interaction.

2. The Nature of the Stability of Dispersion of Pigments in Solutions of Water-Soluble Film-Forming Agents

In order to elucidate the nature of the stability of the systems under consideration, a study was made of their aggregative and kinetic stability as a function of the ξ-potential of their particles[69]; the ξ-potential was varied by introducing into the system a 20% NaCl solution, which influences the thickness of the electrical double layer but does not lead to the loss of solubility of the film-forming agent, and also by changing the pH of the medium within the limits where the film-forming agent is soluble. Despite the fact that the ξ-potential was changed almost by a factor of two, neither the optical density of the systems nor the volume and weight of the sedimentation deposit were changed. Consequently the aggregative and kinetic stabilities of the dispersions are not affected by a change in the ξ-potential.

The data quoted show that, apart from the ionic-electrostatic factor, the non-electrostatic stability factor plays an important role in the mechanism of the stabilisation of the particles. This is demonstrated by the finding that, when the concentration of the film-forming agent in solution diminishes appreciable (to a value less than that required for the complete adsorption saturation, calculated as 15 mg of rezidrol per gram of TiO_2), the ionic-electrostatic stability factor becomes of decisive importance in the stabilisation mechanism[67,71]. An analogous conclusion was also reached in a study[78] devoted to colloidal chemical interaction of titanium dioxide with water-soluble acrylic copolymers.

3. The Study of the Electrodeposition of Pigments on the Anode

The electrodeposition of pigments on the anode has been examined[71] in relation to the rezidrol–titanium dioxide system. The influence of the electrodeposition parameters on the variation of the amount of the electrodeposited pigment on the anode is analogous to the influence of the deposition parameters on the yield of the deposit on the anode for a non-pigmented solution of a film-forming agent, which indicates the decisive role of the latter in the pigment electrodeposition mechanism. The coagulation thresholds for the test systems of filled carboxyl-containing polyelectrolytes virtually correspond to the concentration of the precipitant causing the precipitation of a deposit from a solution of an unfilled film-forming agent.

However, there is also a weak variation of the yield of the pigment deposit on the anode with the ξ-potential of the particles. One may therefore conclude that electrophoresis may be important in the mechanism of the concentration of pigment particles in the layer near the anode. This factor explains the enrichment of the electrodeposited film in the pigment compared with the pigment concentration in the bath. An electrid field does not influence the optical densities of the systems; consequently, there is no structure formation in the test systems in an electric field. The dimensions of the pigment aggregates in the coatings obtained by the pouring and electrodeposition methods are the same. The attempt to apply quantitative electrophoretic relations to the calculation of the amount of electrodeposited pigment on the anode gave rise to more than an order of magnitude discrepancy between the experimental and calculated results.

Evidently the phenomena under consideration are caused by the fact that the non-electrostatic stability factor plays an appreciable role in the mechanism of the particle stabilisation in the test systems; consequently, the theory of the electrophoretic formation of deposits on the anode, developed for systems stabilised by an ionic mechanism, cannot be applied to the case under consideration[79]. The deposition of pigments on the anode is due to the loss of solubility in the anodic compartment by the water-soluble film forming-agent adsorbed on the surface of the pigments. On the other hand, if the stability of the dispersions is caused mainly by the electrostatic factor (the TiO_2–0.02% rezidrol solution system), structure formation does take place in an electric field. In this case the determination of the yield of the pigment on the anode as a function of the duration of the electrodeposition gives results closer to data calculated in accordance with the electrophoretic mechanism[71,72].

4. The Influence of Pigments on the Parameters of the Electrodeposition Process

There are data, albeit contradictory, showing that pigments can influence the thickness and the electrical resistance of the anodic deposit and hence also the electrodeposition parameters[74,80]. The influence of the Printex U carbon black and titanium dioxide (R-820) on the electrodeposition process has been studied at constant currents and potentials in relation to rezidrol[72]. The results were compared with the structural-mechanical properties of non-hardened coatings obtained from the rate of development of the shear deformation between two plane-parallel plates, and also with the viscosities and electrical conductivities of the systems used for electrodeposition. It was established that the influence of the pigments on the electrodeposition parameters depends on their influence on the rheological properties of the electrodeposited system and the resulting coatings and also on the ability of the pigments to form conducting structures in a system with a film-forming agent. Thus the data presented confirm the validity of the hypothesis that the electrodeposition of pigments on the anode takes place as a result of the loss of solubility, in the layer near

the anode, by the film-forming agent linked to the surface of the pigments by adsorption interaction.

IV. THE INFLUENCE OF ELECTRODEPOSITION CONDITIONS ON THE FORMATION OF A DEPOSIT ON THE ANODE AND THE PROPERTIES OF THE COATINGS

Apart from the composition of the lacquer system, the electrodeposition of water-soluble lacquer materials and the properties of the resulting coatings are known to be greatly influenced by the concentration and pH of the lacquer material in the bath, the electrical parameters, the process time, temperature, and rate of stirring[7,13,14,73,81]. The form of the rectified current has been found to have an influence in a number of investigations[82-84]. Coatings with optimum properties are produced in a specific range of values of the parameters enumerated. The causes of the influence of the deposition parameters on the electrodeposition process and the properties of the coatings have been investigated[85-87].

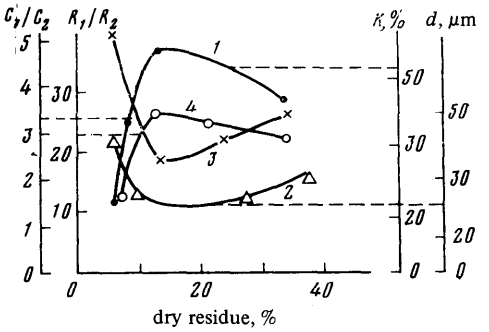

Figure 6. Dependence of the scattering capacity of the bath K (curve *1*), the thickness of the coatings d (curve *2*), and the ratios of the capacitative (C) (curve *3*) and ohmic (R) (curve *4*) components of the impedance obtained at frequencies of 500 Hz (R_1, C_1) and 20 000 Hz (R_2, C_2) on the rezidrol concentration in the bath[85].

1. The Influence of the Concentration of the Lacquer Material in the Bath

The dependence of the protective properties of coatings and of the scattering capacity of the bath on concentration is illustrated in Fig. 6. The maximum scattering capacity of the bath corresponds to the most effective corrosion-protective properties of the coatings characterised by the capacitative–ohmic method[88].

Electron microscope studies of the structure of the coatings showed that structural elements of smallest size are then close-packed to the maximum extent. At a rezidrol concentration smaller or greater than the optimum value, the coatings have a structure with loose packing.

It has been shown[85] that the influence of the concentration of the aqueous solution on the electrodeposition process and the structure and properties of the resulting coatings is associated with the difference between the supermolecular structures of the solutions of the film-forming agents. The study of the viscosities and conductivities of these solutions showed that at elevated concentrations, where the resistance of the anode diminishes, the protective properties of the coatings become less effective, and defects such as bulges arise, structure formation processes begin in the test solutions. This results in an increase of the mass of each structural element of the solution involved in the interaction with hydrogen ions, which leads to the formation of thickened coatings with bulges. Under these conditions, the number of carboxylate ions on the surface of each structural element involved in the neutralisation processes diminishes, as shown by the shift of the inflections on the conductimetric titration curves towards lower pH values. Under the conditions of a structured solution, the deposition of the same mass of polymer as at lower concentrations therefore requires a smaller number of hydrogen ions. This results in an increased acidity in the anodic compartment, which leads to an increase of the solubility of the anode, the expansion of the diffusion layer in the anodic compartment where deposition takes place, and the formation of thickened coatings with a loose packing of the structural elements.

If the electrodeposition is carried out in a structured solution with reduced electrical parameters (i.e. the concentration of hydrogen ions formed in the anodic compartment during the electrolysis of water is diminished), then it is possible to avoid the above defects to a large extent. In electrodeposition in the region of reduced concentrations of the film-forming agent in the anodic compartment there is apparently also an excess of free hydrogen ions owing to the low concentration of the ions of the film-forming agent. The reaction zone therefore expands, which results in the formation of loose bulky deposits and the solubility of the anode increases owing to the increased acidity of the solution in the anodic compartment.

The electrodeposition of low-resistance film-forming agents has characteristic features due to the poor structural-mechanical properties of their deposits. In the region of concentrations where structure formation takes place in the solution, a decrease and not an increase in the weight of the coating is observed during delectrodeposition. This is apparently caused by the slipping of the deposit from the anode under the influence of its own weight owing to its poor structural-mechanical properties. Such slipping can be observed visually. It entails the formation of bulges and runs on the coating.

2. The Influence of the Electrical Parameters and Process Time

With increase of the potential and current and also process time, an increase in the weight of the coating is initially observed in accordance with a virtually linear law, the growth of the thickness of the coating then slows down, and, on further increase of the electrical parameters and process time beyond certain limiting values, "superdeposition" defects are observed on the coatings, manifested by bulges and a "shagreen" effect; for low-resistance lacquer materials, a decrease in the weight increment of the coatings is observed.

The maximum packing density and the most effective protective properties of the coatings correspond to the optimum electrical parameters and process time. With increase of time, potential, and current above the optimum values, coatings are formed which consist of

aggregates of indefinite form and with a loose packing. Direct measurement of the temperature of the anode established[86] that the above phenomena are caused by the increased evolution of heat with increase of the above parameters. The decrease of the quality of the rezidrol coatings described above is observed when the temperature of the anode exceeds 60°C, the reaction time is 2 min, and the potential is 200 V. The impairment of the quality of the coatings is altogether absent in electrodeposition on a cooled anode whose temperature does not exceed 30°C, at a potential up to 300 V, and for a process time up to 5 min. It has been shown that, with increase of the temperature of the anode, there is an appreciable increase of the rate of formation of a deposit on the latter, which impairs the structure and protective properties of the coatings.

In the electrodeposition of low-resistance lacquer materials an increase of the electrical parameters and process time entails an increase of the rate of electrodeposition and of the thickness of the coatings, which is followed by their decrease owing to the poor structural-mechanical properties of the deposits, the latter becoming still more inferior when the temperature increases.

3. The Degree of Neutralisation of the Binder and the Type of Neutraliser

The solubility in water of film-forming agents used for electrodeposition is ensured by the neutralisation of carboxy-groups by bases. Electrodeposition takes place in an alkaline medium. The pH of the lacquer material has a significant influence on the stability of the lacquer system, the rate of electrodeposition, and the quality of the coatings in electrodeposition. As a rule, for each lacquer material there is an optimum pH range. The existence of a lower pH limit is due to the stability of the water-soluble film forming-agents whose acid form is insoluble in water. An increase of pH entails an increased degree of neutralisation of the carboxy-groups of the film-forming agent and an increase in the charge per unit molecular weight (owing to the increase of the degree of dissociation). This is accompanied by an increased repulsion of like charges and an increased solubility of the film-forming agent in water. In a highly alkaline medium an aqueous system is so stable that the formation of coatings by electrodeposition is hindered[73,77,81].

The thickness of the electrodeposition coatings therefore increases with increasing pH of the system and the curve relating the scattering capacity of the solution in the bath and the protective properties of the coatings to the pH passes through a maximum. The presence of the latter is caused, on the one hand, by the decrease of the size of the structural elements of the solution with increasing pH and by the increase of the packing density in the structure of the coatings and, on the other hand, by a significant decrease of the thickness of the coatings.

There is information showing that not only the pH but also the type of neutraliser used to convert the film-forming agent into a water-soluble state can influence the electrodeposition process[89-92]. In order to render the film-forming agent water-soluble, different neutralisers are employed: ammonia, primary, secondary, and tertiary alkylamines, hydroxyalkylamines (aminoalcohols), and morpholine; inorganic alkalies (KOH, NaOH) are sometimes used. The influence of the type of neutraliser on the electrodeposition process has been investigated[93] in relation to rezidrol. The following neutralisers were used: ammonia, triethylamine (TEA), triethanolamine (TEOLA), and diethylenetriamine (DETA). It was established that, in the neutralisation of polyacids by diethylenetriamine, conformational transformations take place in the system, associated with the partial "twisting" of the macromolecules and with processes involving partial conversion into a globular form. The reason is that the composition of DETA includes two primary amino-groups and one secondary amino-group. As a result, the film-forming agent forms amide linkages with two primary DETA amino-groups and the remaining free carboxy-groups interact with the secondary amino-groups of the neutraliser. The coatings formed in electrodeposition from globular solutions exhibit a reduced capacity for relaxation processes. Consequently, owing to the increase in the polarisation component, there is an appreciable increase of the resistance of the anode, which permits electrodeposition at higher potentials. As a result, DETA can be recommended as an additive to the electrodeposition bath in order to increase the potential, which makes it possible to increase the scattering capacity of the bath[94].

4. The Influence of Deposition Parameters on the Physicomechanical Properties of the Coatings and the Molecular Weight of the Section of the Chain between the Effective Nodes of the Three-Dimensional Network

The influence of the above electrodeposition parameters on the physicomechanical properties of coatings and the quantity M_c has been studied[95] in relation to rezidrol. In order to estimate the physicomechanical properties of the coatings as a function of the deposition conditions, a generalised parameter, namely the resistance to wear, was adopted as a criterion. The rupturing force for coatings electrodeposited on aluminium foil was also determined as a function of the deposition parameters—from the difference between the strength of the coating—foil system and the strength of the foil without the coating. It was established that coatings with the optimum mechanical properties are formed for the same electrodeposition parameters as in the formation of coatings with the optimum protective properties and with the maximum scattering capacity of the system, i.e. under conditions where the formation of a coating whose structure consists of elements of the smallest size is most uniform and is most close-packed. At the same time, M_c (according to equilibrium swelling data) for coatings formed for different electrodeposition parameters changes only slightly, but the minimum value of M_c corresponds to the coating produced for the optimum parameters. All these findings suggest that, as the electrodeposition parameters are changed, the chemical bonds within and between structural elements of the coating are redistributed.

5. The Influence of Hydrodynamic Conditions in the Bath on the Electrodeposition Process

The electrodeposition of water-miscible lacquer materials takes place with constant stirring whose optimum rate depends primarily on the lacquer material employed; usually the optimum rate of stirring is chosen empirically. There are data[24-26,96,97] showing that the hydrodynamic conditions in the bath (i.e. the rate of stirring) influence the thickness of the electrodeposited coating. It has been shown[24] in relation to the electrodeposition of acrylic

lacquer on a rotating disc electrode that there is a definite (limiting) rate of rotation of the disc electrode above which a deposit is not formed. The authors explain this phenomenon by the decreased thickness of the diffuse component of the electrical double layer and hence by the decreased number of hydrogen ions required for the formation of a deposit.

The influence of the rate of stirring of the lacquer material on the rate of electrodeposition, the thickness and protective properties of coatings, and the relation between the rate of stirring and the electrodeposition parameters has been investigated[7] for the FL-093 primer and the FL-149E enamel. For both lacquer materials, there is a sharp decrease of the rate of electrodeposition with increasing rate of stirring and its extent is the same. This is because, with increase of the rate of stirring, there is the same decrease in the thickness of the diffuse layer of hydrogen ions produced in the electrolysis of water and responsible for the formation of the deposit. However, the maximum rate of stirring at which the coating is not formed is higher for the FL-093 primer, which is probably associated with the higher conventional current yield, i.e. with the higher rate of the electrodeposition in the absence of stirring compared with the FL-149E enamel. The increase of the optimum range of electrical parameters and of the deposition time with increasing rate of stirring has been established by the capacitative-optical method. Direct measurement of the temperature of the anode by means of a Chromel–Copel thermocouple showed that this is caused by the decreased temperature of the anode with increasing rate of stirring, which is related to the influence of the rate of stirring on the heat transfer in the system.

Since the scattering capacity of the bath in colouring by electrodeposition is proportional to electrical parameters, it can be increased by creating a special stirring system in the bath.

6. The Influence of the Pulsation of the Rectified Current on the Electrodeposition Process

The electrodeposition of water-miscible lacquer materials requires the use of a rectified current. The coloured layers obtained at a constant potential and at a constant current density are distinguished in terms of the mode of supply of the electric current. There have been a number of studies and patents[82–84, 98, 99] devoted to the problems of the selection of schemes for the supply of the electric current in electrodeposition. In particular, there is information showing that with a pulsed supply of the current an increase in the thickness of the electrodeposited coatings is observed in some cases[98]. The influence of the form of the rectified current on the electrodeposition process under the conditions of a constant potential has been investigated[86]. It has been established that the influence is associated with the differences in the thermal phenomena on the anode when different schemes for the rectification of the current are used. An increase of the amplitude of the pulsations for the same effective rectified current leads to greater heating of the anode largely owing to the change of the maximum rectified current. In the single-phase half-wave rectification, a current passes through the bath during one half-period, its amplitude exceeding almost by a factor of three the effective value. This probably leads to an increase of the amount of heat evolved during a time shorter than one half-period. Owing to the low thermal conductivity of the film, the heat evolved gradually accumulates in the deposited layer and the temperature of the anode continues to increase. The increase of the temperature of the anode increases the rate of electrodeposition. This results in the formation of thicker coatings (or, in the case of low-resistance lacquer materials, thinner coatings owing to the slipping of the film from the anode because of its poor structural-mechanical properties), but the scattering capacity of the bath decreases and the protective properties of the coatings become less effective. Hence the pulsed supply of the current is desirable only in the electrodeposition of film-forming agents with a high rigidity.

Thus the mechanism of the process involving the formation of polymer coatings, developed in the last 10–15 years[100–104], operates also in the formation of films from water-miscible lacquer materials by electrodeposition. Under these conditions, the polymer coating is produced from the structure arising in the anodic compartment before the start of the thermal hardening process when the oligomer loses its solubility in water; the deposit is formed on the anode owing to the interaction with the hydrogen or metal ions formed as a result of the accompanying electrochemical reactions in the aqueous medium at the anode.

Transformations in Refractory Compounds, Brought about by High Pressures and Temperatures

Yu.G.Zainulin, S.I.Alyamovskii, and G.P.Shveikin

The influence of high pressures and temperatures on the structural characteristics of the refractory carbides, nitrides, and monoxides of the transition metals have been examined. The results have been discussed in the light of one of the components of Kurnakov's theory of daltonides and berthollides—the concept of imaginary compounds, developed by Bokii. A number of new ideas following from this examination have been formulated. It has been shown that at high pressures and temperatures it is possible to obtain new electronic modifications of compounds and to extend considerably the range of existence of phases of variable composition. It has been shown that the concept of imaginary compounds is correct, and it has been suggested that a large number of imaginary compounds are realised at high pressures and temperatures. Other methods of obtaining imaginary compounds have been recommended. The bibliography contains 109 references.

I. INTRODUCTION

In recent years there has been considerable interest in the study of processes taking place in a solid under the simultaneous influence of high pressures (p) and temperatures (t). This is due because it is thus possible to bring about various transformations (polymorphic transformations, decomposition and reduction of a substance, perfection and ordering of a crystal structure, transitions from the crystalline state to the amorphous and vitreous states, production of the metallic state, changes in the electronic structure of compounds and the valency state of atoms, the synthesis of periodic and "imaginary" compounds, the production of new electronic modifications of known compounds, etc.); see for example Refs. 1–34.

In the present work an attempt is made to examine systematically the influence of high p and t chiefly on refractory carbides and nitrides and partly on oxides of the transition metals and their reciprocal solid solutions.

The compounds discussed, which are formed chiefly from metals of sub-groups IVa–Va, belong to the class of so-called interstitial phases and are distinguished by a number of characteristic features, which it is appropriate to discuss briefly. Firstly, most of these compounds (which exhibit the properties of metals or covalent crystals) have wide homogeneity ranges, and their unit cells sometimes contain a large number of structural vacancies in one part (for example the monocarbides of the transition metals of groups IV and V, and Fe monoxide) or both parts (for example the cubic NaCl-type monoxides of Ti and V, and the oxide carbides and oxide nitrides of Ti, Zr, Hf, V, and Nb). The metal atoms of these compounds often exhibit cubic or hexagonal close packing, with the non-metal atoms arranged in the octahedral sites. Under certain conditions, some interstitial phase compositions exhibit ordering ($NbC_{0.75}$, $TaC_{0.75}$, $TiO_{1.00}$, $TiC_{0.5}O_{0.5}$, $VC_{0.5}O_{0.5}$, etc.). More detailed data on interstitial phases are given in a number of monographs (see for example Refs. 35–38).

II. CARBIDES

The first report of the influence of high pressures† on carbides, including those of refractory metals, is found in papers dealing with the synthesis of artificial diamonds. In these papers (reviewed, for example, in Refs. 2, 23, and 40), carbides are used as the carbon-containing material, which liberates carbon at high p and t as a result of chemical reactions.

The first special study of the influence of high pressures on the refractory carbide (and nitride) of titanium TiC (and TiN), of unknown composition, was carried out by Bridgman[40], who determined the compressibility and electrical resistance at a pressure $p = 1.2 \times 10^4$ kg cm^{-2} and found that the electrical resistance decreased with increase in pressure; no structural transformations were recorded. Semerchan and coworkers[41] studied the influence of pressure (up to 10^5 kg cm^{-2}) and temperature (1400°) on the hard alloy T15K6 (composition, wt.%: Ti 12.5, C 7.5, Co 6.0, Fe 0.1, remainder W). The specimens in the form of cylinders of diameter 6 mm and height 8 mm were kept under these conditions for 5 min in the apparatus previously developed[42]. The heating was then stopped, and when the temperature had decreased to ambient the pressure was also removed. The alloy treated in this way consisted of three phases—the carbide WC, a solid solution of tungsten carbide in titanium carbide TiC–WC, and a solid solution of tungsten (up to 3%), titanium (up to 0.5%), and carbon (up to 0.5%) in cobalt, Co(W, Ti, C). (Semerchan and coworkers[41] report that the loss of carbon by the specimens during this treatment was prevented, but they do not describe how this was achieved.) The experimental data are given in Table 1.[41] The decrease in the specific gravity of the treated specimens compared with the original specimens

† In accordance with the published classification[39], high pressures correspond to $p \geq 10^4$ kg cm^{-2}.

was attributed[41] to the filling of the cracks by katlinite—the medium in direct contact with the specimen, used to transmit the pressure. The decrease in the lattice spacing of the phase TiC–WC is related to the additional solution (up to 5 wt.%) of WC in TiC. In the X-ray diffraction patterns of the treated alloy, the diffraction maxima were broader, and their point character, observed for the original specimen, had disappeared. All this was attributed[41] to the production of distortions in the crystal structure of the carbide phases.

Table 1. Influence of high pressure and temperature on the characteristics of the alloy T15K6.[41]

Characteristics of the specimens	Original alloy	Treated alloy
Specific gravity, g cm^{-3}	11.25	11.0–11.48
Average particle size of the phase WC, μm	3.46	3.65
Average particle size of the phase TiC–WC, μm	3.60	3.56
Concentration of graphite inclusions in the field of view, %	up to 0.5	up to 0.5
Porosity, %	up to 0.2	up to 0.2
Vickers hardness, kg cm^{-2}	1480	1480–1100
Lattice period of the phase TiC–WC, A	4.3119	4.3105
Width of the 420 diffraction line of the phase TiC, min	63	92
Width of the 202 diffraction line of the phase WC, min	80	153

Pivovarov and coworkers[43] subjected specimens of the hexagonal carbide $WC_{0.99}$ to all-round compression (up to ~100 kbar) with simultaneous heating (up to 2130°C). Under these conditions, the diffraction maxima became appreciably broader (the width of the 211 line increased from 6 mradian to 26 mradian). Moreover, this treatment led to a significant increase in the micro-hardness (from 1800 kg mm^{-2} to 2800–3200 kg mm^{-2}). These results were attributed to an increase in the density of dislocations and other defects in the crystal lattice, leading to plastic deformation of the carbide $WC_{0.99}$.[43] When the specimen was annealed to 1800° for 1.5 h, the micro-hardness decreased to 1870 kg mm^{-2}; at the same time, the width of the diffraction line decreased to 14 mradian. The same effects were observed by Koval'skii and coworkers[44], when the carbides WC, TaC, TiC, NbC, ZrC, and Cr_3C_2 were treated for 3 min under conditions of quasi-hydrostatic pressure (p = 100 kbar) with simultaneous heating to 1400°; part of the carbides contained up to 3 wt.% cobalt. These data[44] are given in Table 2. Koval'skii and coworkers[44] also drew attention to the marked increase in the micro-hardness and the broadening of the X-ray lines after treatment. In this case, in contrast to the earlier data[43], annealing did not lead to a significant change in the micro-hardness of pure tungsten carbide (the conditions of annealing, however, were slightly different from those described in Ref. 43, see Table 2). The addition of cobalt leads to a marked increase in the rate at which the hardness decreases, as a consequence of the participation of the liquid phase in the recrystallisation (see Table 2), including that in WC.

Unlike Koval'skii and coworkers[44], Samsonov and coworkers[45] were able to achieve a significant increase in the micro-hardness of specimens of titanium carbide TiC treated under conditions of quasi-hydrostatic pressure in the range 25–80 kbar and temperatures in the range 1000–2000°. The specimens were first heated in cells to the required temperature, kept at this temperature for 3 min, and then compressed for 1 min. The maximum micro-hardness achieved in the compressed titanium carbide[45] was 3300 kg mm^{-2}.

Table 2. Characteristics of the alloys studied by Koval'skii and coworkers[44].

Parameters	Original specimens								
	TiC+Co	ZrC	NbC+Co	NbC	TiC+Co	WC+Co	VC	Cr_3C_2+Co	Cr_3C_2
Micro-hardness, kg mm^{-2}:									
original specimen	2400	2900	1800	1800	1600	1800	1800	1350	1350
treated specimen	2500	2900	2600	2600	2200	3100	3100	2600	2600
after annealing*	2400	3000	1800	2100	1700	1900	3000	1700	2200
Broadening of the lines, radian	8.75×10^{-4}	1.75×10^{-3}	1.31×10^{-2}	1.16×10^{-2}	1.05×10^{-2}	1.13×10^{-2}	2.33×10^{-3}	9.35×10^{-3}	8.20×10^{-3}

* Annealed at 1400° for 3 h.

Samsonov and coworkers[46] applied static and dynamic pressures to specimens of hexagonal tungsten carbide WC_X (x = 0.85, 0.90, 0.95) and mixtures of the metal and carbon black with the same compositions. Shock compression was applied in retaining ampoules; the pressure at the front of the leading wave was $(1.45–1.65)\times10^6$ kg cm^{-2}. The quasi-hydrostatic pressure treatment was carried out at 1200° and 90 kbar for 30 min. X-Ray phase analysis and measurement of the micro-hardness of the specimens treated in this way revealed individual granules and conglomerates of granules of the cubic modification of WC.[46] The formation of the cubic carbide WC was observed on compression of both the original carbides ($WC_{0.90}$ and $WC_{0.95}$) and the mixtures of tungsten and carbon black having the same compositions. Explosive shocks[46] also led to decomposition of the original hexagonal carbide $WC_{0.95}$ to metallic tungsten, hexagonal W_2C and cubic WC. An interesting feature is that it has been reported[47] that high-temperature cubic WC, synthesised under ordinary conditions, has a restricted range of existence with respect to both composition ($WC_{0.61-0.67}$) and temperature (2530–2747°).

Sevast'yanova and coworkers[48] synthesised cubic tungsten carbide under conditions slightly different from those used by Samsonov and coworkers[46]. Hexagonal tungsten carbide and a mixture of finely divided metallic tungsten and carbon black in equi-atomic proportions were subjected to high pressures (35–70 kbar) and temperatures (1400–2000°). The duration of treatment was varied from 1 min to 3 min. In addition, the original specimens contained 0.1–2 at.% of stabilisers—metals of groups IV and V and their cubic carbides TiC, ZrC, and VC. When hexagonal tungsten carbide was used as starting material, the cubic carbide could not be obtained, even when stabilisers were added. It was formed, however, by compressing a mixture of the metal and carbon black containing TiC. The lattice period of the cubic phase, determined from the 220 line for one of the heterophase specimens, was 4.336 Å. This large value of the lattice period was attributed to the formation of a solid solution WC–TiC.

Clougherty and coworkers[49] treated an equi-atomic mixture of metallic molybdenum and carbon, and also Mo_2C and carbon, at high temperatures (1800–2500°) and pressures (40–70 kbar). X-Ray phase analysis of the resulting specimens showed the presence of ten additional lines, in addition to those of the phases existing under ordinary conditions. All were indexed in a cubic face-centred lattice with period $a = 4.27$ Å. This carbide was assigned the stoichiometric composition MoC, with four metal atoms in the unit cell[49]. Cubic molybdenum carbide synthesised under ordinary conditions exists in a different composition range ($MoC_{0.66-0.76}$) at temperatures of 1960–2600°.[50,51]

Table 3. Characteristics of MoC_x specimens[52].

Compn. of original specimen	Phase compn. of original specimen	Phase compn. after treatment* (lattice periods of individual components)
$MoC_{0.567}$	$Mo_2C + \eta$-MoC_x (hexagonal)	$Mo_2C + \eta$-MoC_x ($a = 3.02$ Å; $c = 14.41$ Å)
$MoC_{0.661}$	$Mo_2C + C$	η-$MoC_x + Mo_2C$
$MoC_{0.661}$	$Mo + C$	η-$MoC_x + Mo_2C$
$MoC_{0.733}$	α-MoC_x (cubic)	η-MoC_x ($a = 3.011$ Å; $c = 14.63$ Å)
	η-MoC_x (hexagonal)	α-MoC_x

* Treatment at 25 kbar and 1500° for 14 min.

Table 4. Characteristics of specimens obtained by Dubrovskaya and Nazarova[53].

Original specimens				Treated specimens ($p = 120$ kbar, $t = 1500°$, $\tau = 30$ min)			
compn. of mixture	concentration of carbon, wt.%		a, Å	concentration of carbon, wt.%		a, Å	concn. of nitrogen, wt.%
	combined	free		combined	free		
$Nb_{0.95}Mo_{0.05}C$	11.0	0.28	4.4646	—	нет	4.4674	0.1
$Nb_{0.85}Mo_{0.15}C$	10.73	0.60	4.4528	10.38	0.17	4.4420	—
$Nb_{0.71}Mo_{0.29}C$	10.62	0.95	4.430	9.59	0.02 0.63	4.4341 4.4344	—
$Nb_{0.51}Mo_{0.49}C$	9.63	1.57	4.3926	9.68 8.88	1.02 1.22	4.3926 4.3897	—
$Nb_{0.30}Mo_{0.70}C$	8.90	1.64	4.3417	—	0.88	4.3629	—
$Nb_{0.15}Mo_{0.85}C$	7.94	2.42	4.295	—	1.01	4.319 4.3273	—

The behaviour of the carbide phases in the Mo–C system at high pressures was also studied by Shinyaev and coworkers[52]; heterophase alloys of molybdenum and carbon, and their mixtures having the composition $MoC_{0.661}$, were treated for 40 min at 25 kbar and 1500° in an apparatus of the "anvil with indentation" type (see Table 3). X-Ray diffraction study after treatment showed that all the specimens contained the hexagonal η-carbide. Its lattice periods in the specimen having the composition $MoC_{0.567}$ differed considerably from those of the carbide synthesised under ordinary conditions ($a = 3.006–3.011$ Å; $c = 14.61–14.64$ Å).[50,51] It was concluded[52] that the homogeneity range of η-MoC_x is extended towards lower concentrations of carbon at high p and t. In addition, a thermodynamic calculation[52] showed that a pressure of 25 kbar lowers the decomposition temperature of the hexagonal η-carbide from 1650° to 1380°.

Dubrovskaya and Nazarova[53] tried to achieve additional introduction of carbon into the lattice of the solid solutions $NbC_{1.0}$–$MoC_{0.67}$ to obtain specimens having compositions close to the stoichiometric. Mixtures of the solid solutions and free carbon were treated at a pressure of 120 kbar and 1500° for 30 min. Chemical analysis of these specimens showed a decrease in the concentrations of both free and combined carbon. An interesting feature is that the lattice period, compared with the original value, remained unchanged for one of the specimens, decreased for another, and increased for the remainder (see Table 4).

The all-round compression of a substance can also be brought about under dynamic conditions. Compression by explosion leads to various transformation in a solid[10,11,13,15,17,20,24,27,54]. The influence of pressure pulses on refractory compounds has been studied by a number of workers[55–60,62]. Appreciable micro-porosity has been reported[55] in various specimens subjected to compression by explosion, including TiC, ZrC, NbC, and WC. The X-ray diffraction patterns (particularly those of the ZrC, NbC and WC specimens show diffuse broadening of the lines, indicating that the crystal structure is imperfect. In addition to the lines due to the original phases the X-ray diffraction patterns of the carbides ZrC, NbC, and WC, recorded after compression by explosion[55], contained extra reflections (in the case of WC these lines belong to hexagonal α-W_2C), the intensity of which increased with increased strength of the shock wave. It was concluded[55] that partial decomposition of the carbides NbC, ZrC, and WC takes place. The X-ray density of the compressed specimens remained unchanged[55].

The increase in the strength of the hard alloy WC–Co (15 wt.% Co) under the influence of an explosion (pressure 105–230 kbar) has been studied[56]. The micro-hardness of the original alloy (1200–1365 kg mm^{-2}) and the carbide (1824–1994 kg mm^{-2}) increased sharply after compression: to 2173–2311 kg mm^{-2} for the alloy, and to 2954–3200 kg mm^{-2} for tungsten carbide. These results show satisfactory agreement with results obtained by other workers[44]. The density of the alloy increased[56] from 13.6 g cm^{-3} to 14.5 g cm^{-3}, and the tungsten carbide particle size decreased. A phase transformation in metallic cobalt from the hexagonal to the cubic modification was also observed[56].

The influence of dynamic compression (67–190 kbar) on the structure of the carbides of titanium (TiC_x; $x = 0.62$, 0.75, 0.83, 0.98), zirconium (ZrC_x; $x = 0.62$, 0.72, 0.80, 0.96), and niobium (NbC_x; $x = 0.72$, 0.82, 0.90, 0.99) in their ranges of existence has been studied[57]. The compression was carried out in cylindrical and annular retention ampoules. Hexagen, pentaerythritol tetranitrate, and fused trinitrotoluene were used as explosives. The X-ray diffraction patterns of the carbides, recorded after shock compression, showed broadening of the diffraction maxima[57]. In addition, some of the specimens showed an increase in micro-hardness (by 6.8% for $TiC_{0.62}$, 20% for $NbC_{0.72}$, 14.3% for $NbC_{0.82}$, 11.1% for $NbC_{0.9}$, and 11.6% for $NbC_{0.90}$) after the effect of the explosion. This indicated[57] the passage of plastic deformation in local volumes, which was also related to the increased density of dislocations in the compressed specimens.

The influence of shock waves (160–350 kbar) on the physicochemical characteristics of technical zirconium carbide (Zr 87.75%, $C_{combined}$ 10.15%, C_{free} 0.1%, Fe 0.35%, Mg 0.01%) has been studied[58]. The dimensions of the regions of coherent scattering, the degree of distortion of the crystal lattice, the pyknometric density, and other characteristics of both the original and the compressed specimens were determined. The pyknometric density remained unchanged (6.45 g cm^{-3}) up to a pressure of 160 kbar, then increased to a maximum (6.51 g cm^{-3}) at 160 kbar, and finally decreased up to a pressure in the shock front equal to 350 kabr, reaching a minimum value (6.37 g cm^{-3}). The lattice period of the phase remained unchanged at $a = 4.688 \pm 0.002$ Å. The increase in the pyknometric density was attributed[58] to a decrease in the concentration of defects as a result of the "collapse" of micro-cracks and micro-cavities.

The influence of pressure pulses on the carbides of chromium (850 kbar) and molybdenum (1.05 Mbar) has been studied[59]. In one of the original heterophase specimens containing Cr_7C_3 and Cr_3C_2, the explosion led to rupture of the ampoule. X-Ray phase analysis of the products showed the presence of the higher carbide $Cr_{23}C_6$ in addition to the original phases. The carbide Mo_2C, however, decomposed to Mo and α-MoC_x on compression. These results were attributed to a change in the electronic structure of the original phases under the influence of high pressures.

III. NITRIDES

There is very little published information on the influence of all-round compression on refractory nitrides. The effect of shock waves on the nitrides of niobium, zirconium, silicon, chromium, and gallium has been studied[60]. Cylindrical steel retention ampoules were used, and the explosive was hexagen. The nitrides of Zr and Si did not show structural transformations[60], but the crystal structure of chromium nitride became less perfect; gallium nitride decomposed. Under the influence of the shock wave, the original hexagonal nitride $NbN_{0.98\pm0.03}$ was converted into the cubic nitride δ-$NbN_{0.83\pm0.10}$ with lattice period 4.39 ± 0.01 Å and density 7.20 ± 0.01 g cm^{-3} (density of the original niobium nitride 7.932 ± 0.006 g cm^{-3}). This change in density was attributed to latent micro-porosity in the $NbN_{0.83}$ subjected to shock compression[60].

Cubic (NaCl type) tantalum nitride with lattice period $a = 4.358 \pm 0.001$ Å has been synthesised[61] at $p = 30$–100 kbar and $t = 1800°$. This nitride is fairly stable: the polymorphic transformation to a phase having the WC structure, stable under ordinary experimental conditions, took place only after heating for 4 h in a vacuum (10^{-5} mmHg) at 1200°. It was assumed[61] that the composition of the nitride obtained differs from the stoichiometric composition, since the temperature of its conversion into the superconducting state ($T_c = 6.5$ K) is lower than that for tantalum carbide, whereas in the isomorphous niobium carbide and nitride the opposite T_c ratio is observed: 17.3K for NbN and 11.0 K for NbC.[61]

Samsonov and coworkers[62] applied dynamic pressure (~ 3 Mbar) to powdered hexagonal stoichiometric tantalum nitride ($TaN_{1.0}$) and detected a cubic (NaCl type) phase with $a = 4.33$ Å in addition to the hexagonal phase. Samsonov and coworkers assigned to it the composition $Ta_{0.8}N(TaN_{1.25})$ and reported the presence of vacant sites in the metallic sublattice ($\rho_{expt} = 15.652$ g cm^{-3}) although this does not follow from the original data (calculation gives the values of 3.85 and 4.81 for the numbers of tantalum and nitrogen atoms respectively).

The action of high pressures (up to 80 kbar) and temperatures (up to 2000°) does not lead to structural changes in the nitride VN or in mixtures of the nitrides TaN and Ta_2N.[63]

IV. MONOXIDES

Before examining published data on the influence of high p and t on the monoxides TiO_x and VO_x, titanium oxide carbides and oxide nitrides, and iron monoxide, it should be noted that all these phases exhibit appreciable homogeneity ranges and have structural vacancies in both sublattices (only FeO_x has vacancies confined to the metal sublattice); see for example Refs. 35–38.

Table 5. Change in the lattice periods, density, and percentage of vacancies in $TiO_{1.0}$ with change in pressure and temperature[67].

The decomposition of iron(II) oxide under the influence of hydrostatic pressure (10^4 kg cm^{-2}) has been studied[64]. The original FeO specimen with $a = 4.294$ Å was subjected to pressure and isothermal heating at 400, 450, 480, 500, 550, and 590°C. The products of the decomposition of wüstite ($aFeO \xrightarrow{p,t} bFe + cFe_3O_4 + dFeO$), obtained under pressure, contain much larger quantities of the metallic phase than specimens prepared without using high pressure (other conditions being the same).[64] The explanation given for this difference[64] is that in the first case the iron ions may partly fill the vacancies in the metal sublattice of FeO (since pressure generally decreases the rate of diffusion processes), forming chiefly the metallic phase. This was proved[64] by X-ray diffraction, magnetic measurements, metallography, and chemical analysis. The synthesis of stoichiometric wüstite $FeO_{1.00}$ by the reaction between $Fe_{0.95}O$ and Fe at high pressures (> 36 kbar) and temperature (770°) has been reported[65].

The simultaneous influence of high pressure (up to 78.1 kbar) and temperature (from 880° to 1650°) on the monoxide $TiO_{1.00}$ (a_{init} = 4.1784 Å and 4.1796 Å) has been studied[66,67]. At a pressure of 77.4 kbar and temperatures of 1550° and 1650°, the unit cell of this phase became complete (that is contained no structural vacancies). The gradual decrease in the concentration of vacancies with change in p and t [67] is shown in Table 5. The number of atoms in the unit cell was determined[67] from data on the composition and lattice periods, and from the density of the specimens, measured by flotation, hydrostatic weighing, and powder pyknometry. Table 5 shows that increase in pressure leads to a regular increase in the lattice period and density, and to a decrease in the number of vacancies.

With increase in pressure to ~60 kbar at room temperature[68], the lattice periods of specimens of non-stoichiometric $Ti_{0.82}$ and $TiO_{1.25}$ decrease. The same results were obtained for wüstite[69]. The authors cited[69], however, were not convinced that the vacancies were filled under the conditions of their experiment. In fact, calculations[69] showed that the disappearance of the vacancies, as observed in Ref. 67, should lead to an increase in a after treatment of the specimens, whereas the values of a for the monoxide specimens, including FeO, acquired practically their original value after the high pressure was removed.

The equilibrium concentration of structural vacancies in TiO at high pressures and temperatures has been calculated[70] by the methods of statistical thermodynamics. The calculations indicate that the concentration of vacancies decreases from 14.5% at a pressure of 1 bar to ~10–14% at 100 kbar.

Subsequent experiments[71,72] confirmed the chief results of the previous studies on the filling of the vacancies in titanium monoxide, and also gave new data. Specimens of TiO_x in the homogeneity range (x = 0.86–1.24) were subjected to all-round compression at p = 50–60 kbar and t = 1100–1300°.[71] This led to a considerable decrease in the number of vacancies in both sublattices of TiO_x (see Table 6). The same result was obtained[72] by treating specimens of $TiO_{0.88}$ and $TiO_{1.27}$ at p = 90 kbar and t = 500–1300°. The lattice periods of these specimens increased sharply compared with the original specimens (Table 7), and this was attributed to filling of the structural vacancies in the metal sublattice ($TiO_{0.88}$) and oxygen sublattice ($TiO_{1.27}$) to give complete lattices.

An interesting result was obtained by Zainulin and coworkers[72] who found that a specimen of $TiO_{1.27}$, synthesised at $t > 1300°$, consisted of three phases, unlike other specimens. Its X-ray diffraction pattern, in addition to the lines of the cubic monoxide with a = 4.230 Å, showed a phase with interplanar spacings close to those for orthorhombic TiO_2(II),[73] and tetragonal TiO_2. The latter was readily indexed in a structure of the rutile type with lattice periods a = 4.575 Å, c = 3.080 Å, c/a = 0.673. These values differ considerably from the values corresponding to rutile stable under ordinary conditions: a = 4.59373 Å, c = 2.95812 Å, c/a = 0.64395.[75] In the opinion of the authors cited[72], this indicates that at p = 90 kbar and $t > 1300°$, the $TiO_{1.27}$ specimen decomposes to TiO_2 and a Ti_2O phase having a lower oxygen content than $TiO_{0.88}$. In fact, according to Ehrlich[74], the lattice period (and the intensity ratio I_{111}/I_{200}) of the monoxide TiO_x obtained under ordinary conditions increases with decrease in the oxygen concentration over its homogeneity range. According to the data obtained by Zainulin and coworkers[72], $a(TiO_{0.88})$ (for p = 90 kbar and t = 1020° and 1200°) is smaller than the period of the cubic lattice in the two-phase specimen of $TiO_{1.27}$; the same applies to the ratio I_{111}/I_{200}.

** Face-centred cubic.

Indirect evidence of the decomposition of the $TiO_{1.27}$ specimen was also obtained by Banus and coworkers[71], who obtained a very large cubic lattice period for a single-phase specimen of $TiO_{1.27}$ (see Table 6); this diverged considerably from the general $a = f(x)$ relationship. This value of a can probably be attributed to the decomposition of $TiO_{1.24}$ to TiO_x ($x \ll 1.24$) and TiO_2; because of the small quantities present, however, the presence of TiO_2 could not be detected by X-ray diffraction.

The influence of dynamic pressure on titanium monoxide has also been studied[76,77]. The following mixtures were subjected to shock compression[76] (p ~ 800 kbar,

$t \sim 1730°C$): $Ti + TiO_2 = 2TiO_{1.0}$; $2Ti + 3TiO2 = 5TiO_{1.2}$ $3Ti + 2TiO_2 = 5TiO_{0.8}$. The reaction products in all cases contained a cubic (NaCl type) phase with lattice periods equal to 4.177–4.179 Å, 4.169 Å, and 4.188 Å respectively. The subsequent action of shock waves on the monoxide synthesised in this way did not alter the lattice periods[76]. Similarly, no significant change in the concentration of structural vacancies was observed when $TiO_{0.84}$, $TiO_{1.06}$, and $TiO_{1.28}$ were subjected to shock compression at pressures up to 600 kbar.[77]

Specimens of vanadium monoxide (a_{init} = 4.0738 Å) have been subjected to the simultaneous influence of high pressures (56.4 kbar) and temperatures (1650°).[67] An increase in the lattice period (due to the filling of vacancies) to 4.1004 Å and even 4.1295 Å was observed[67]. A similar result was obtained by other workers[78] who subjected specimens of cubic vanadium monoxide VO_x (x = 0.86–1.23) to a pressure of 60 kbar and T = 1300° under static conditions. The results of these experiments[78] are given in Table 8; the lattice period increases considerably, and the degree of defect character of the phase decreases. An interesting feature is that, in spite of the high pressure and temperature of treatment (p = 56.4 kbar, t = 1650°), the lattice period of the monoxide NbO (which can be regarded as crystallising in a NaCl structure with 25% ordered vacancies) remains unchanged[67].

Stable zirconium and tantalum monoxides cannot be synthesised under ordinary conditions (vacuum or inert medium, high temperatures).[79] Zainulin and coworkers[80] attempted to prepare ZrO and TaO. The experiments were carried out at p = 77 kbar and t = 800–1250° for 10 min under static conditions in a standard compartment[81]. Specimens of the corresponding oxides were first heated at a reduced pressure of 1.3×10^{-7} mmHg and t = 1400° for 10 h, after which the resuling powders were placed in cylinders of Ta (for the TaO specimen) or zirconium (for the ZrO specimen). The products of the reaction of the mixture of Ta and Ta_2O_5 contained an unknown phase, which crystallised in the orthorhombic system (a = 11.35 Å, b = 8.199 Å, c = 8.396 Å). The mixture of Zr and ZrO_2 treated at 950° contained small quantities of a cubic phase isostructural with NbO. Comparison of the volumes (V) of the starting materials and final products of the reaction $Zr + ZrO = 2ZrO$ ($-\Delta V/V$ = 4.9%) and $3Ta + Ta_2O_5 = 5TaO$ ($-\Delta V/V$ = 12.2%) showed that these reactions should take place with a decrease in V. It was therefore suggested[80] that it is possible in principle to obtain the monoxides TaO and ZrO at high p and t.

V. OXIDE CARBIDES AND OXIDE NITRIDES

Specimens of the cubic oxide carbide $TiC_{0.44}O_{0.57}$ and oxide nitride $TiN_{0.37}O_{0.51}$ have been subjected to all-round compression under quasi-hydrostatic conditions at p = 90 kbar and t = 620–1400° (Table 9).[82] The lattice periods of the specimens of the oxide carbide and oxide nitride treated at p = 90 kbar and t = 1200–1400° are significantly greater than the original values (Table 9). This result, together with the results of the pyknometric determination of the densities, led to the conclusion[82] that the structural vacancies in the unit cell of these phases are filled. An interesting feature is that in the oxide carbide $TiC_{0.44}O_{0.57}$, both sublattices are complete, whereas in the oxide nitride only the metal sublattice is completely filled. There are no other published data on the influence of high p and t on the characteristics of phases of this kind.

Table 9. Change in the structural characteristics of titanium oxdie carbide and oxide nitride under the influence of pressure p = 90 kbar and different temperatures[82].

VI. SUMMARY

Before discussing the above results, it is appropriate to mention briefly one of the component parts of Kurnakov's theory of daltonides and berthollides—the concept of "imaginary" compounds[83]. Kurnakov, in an examination of the chemical character of berthollides, postulated the following possible treatments:

a) berthollides are definite compounds in a state of dissociation;

b) berthollides are solid solutions of definite compounds, unstable in the free state;

c) berthollides are solutions of polymorphic modifications of the components, unstable in the free state.

The term definite compounds is here understood to mean chemical compounds of constant composition, which obey the law of simple and multiple proportions. In accordance with this, Kurnakov proposed three types of equilibrium diagram (Fig. 1). The compounds AB_n, AB_{n_1}, AB_{n_2} which are unstable in the free state and which obey

the laws of stoichiometry, and the modification of the component B_1, were later, at Ageev's suggestion[83,85], called "imaginary". Kurnakov, referring to the method of finding imaginary compounds and modifications, warned that considerable difficulties are encountered in attempts to distinguish these cases experimentally; this can be done only tentatively, by comparing with analogous systems in which the singular ordinate AB_n (Fig. 1*b*) or the second modification (B_1) of the component B (Fig. 1*c*) can be observed directly. In other words, it is necessary to assume the existence, in a given system A–B, of an imaginary compound AB_n, AB_{n_1}, AN_{n_2} or an imaginary modification B_1 if these phases are present in an analogous system.

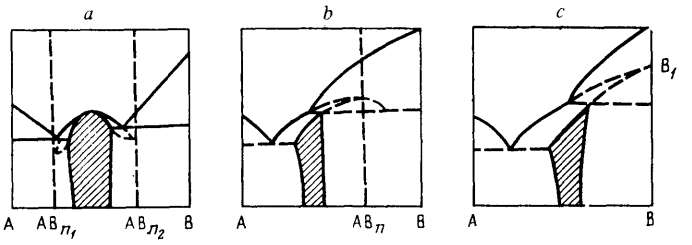

Figure 1. Types of equilibrium diagram with imaginary compounds and an imaginary modification of a component according to Kurnakov, formed: *a*) by isomorphous mixing of non-existent compounds or definite compounds unstable in the free state, AB_{n_1} and AB_{n_2}; b) from a compound AB_n which is unstable or non-existent in pure form; *c*) from a second (B_1) modification of component B, unstable in the free state.

Subsequently, these ideas of Kurnakov were developed in detail by many workers (see for example Refs. 83–97). The nature of imaginary compounds not realised under ordinary conditions was first developed from the structural viewpoint by Bokii[91]. Bokii regarded berthollides as phases of variable composition, in which the limiting degree of filling of the regular system of points (RSP) of the structure is not achieved. In other words, if the processes of substitution, introduction, and removal of atoms under given experimental conditions do not reach the limits characteristic of a given structure, the limiting rational composition is not realised in these phases. In Bokii's opinion, this composition, corresponding to the imaginary compound, can readily be determined by extrapolating the curve characterising the change in the RSP to the composition at which the RSP is completely filled (although this composition will lie beyond the limits of the homogeneity range). It should be noted that in Kurnakov's work[83], for berthollides with and without a maximum on the "composition–property" diagram, two (Fig. 1*a*) and one (Fig. 1*b*) limits respectively were noted, corresponding to the imaginary compound. According to Bokii[91], however, any curve (on the "composition–property" diagram) which does not end at a component or at a compound can be continued in both directions as far as the corresponding compound. In Kurnakov's opinion, the determination of the composition of imaginary compounds on the "composition–property" curve requires the availability of the maximum number of points (in order to carry out the extrapolation over the shortest possible distance), whereas according to Bokii[91], the composition of the imaginary compound can readily be determined from only one point, and the position on the curve, characterising the change in the RSP, at which this extremal point is situated is not important. It is only in the case of a berthollide with a maximum that it is necessary to use two points, since the change takes place in two RSP.

From the foregoing, and with allowance for the ideas put forward by Zainulin and coworkers[82], it is possible to explain various results obtained using high pressures and temperatures, in particular data[49,52,53,65–67,71–73,82] which indicate broadening of the homogeneity range of various phases. Thus stoichiometric cubic (NaCl type) molybdenum carbide, synthesised at high p and t and unstable under ordinary conditions, is the limiting compound at which the RSP is completely filled. In this connection, from data obtained[49] at high p and t, the upper limit of the range of existence of the phase MoC_x must be assigned the composition $MoC_{1.0}$ (under ordinary conditions, the carbide $MoC_{0.76}$ is obtained[50,51]).

A composition close to the limiting composition is observed[98,99] for cubic rhenium carbide ReC (a = 4.005 Å), synthesised at p = 160–180 kbar and t = 1000° (τ = 2–5 min), which cannot be obtained under ordinary conditions. For various monocarbides of metals of sub-groups IVa–VIa, the compositions with the maximum saturation by carbon correspond to the formula $MC_{<1.00}$. The composition $MC_{1.00}$ for these compounds can also be realised at high p and t. It may be noted that the specific values of p and t required to achieve the limiting composition with respect to non-metals cannot always be chosen immediately. Thus in the opinion of Boiko and Popova[61], the composition of cubic tantalum nitride, obtained for the first time, is not stoichiometric; this is also indicated by other data[62].

This in the case of carbides and nitrides with the NaCl structure, the maximum concentration of the non-metal is characteristic of the compositions $MC_{1.0}$ and $MN_{1.0}$ (or, with allowance for complete filling of the RSP, M_4C_4 and M_4N_4). The question of the lower boundary of the homogeneity range of these phases is of interest. From structural considerations[91], for the NaCl structure it should correspond to the compositions $M_2X(M_4X_2)$ or, less probably, M_4X. (The carbide Nb_4C has been obtained[100], but its formation is apparently due to impurities). It should be noted that the carbide $TiC_{0.5}$ [101] and the nitrides $TiN_{0.42}$ [102] and $ZrN_{0.5}$ [103] can be obtained even under ordinary experimental conditions. However, there are as yet no data on carbides and nitrides of analogous composition for other transition metals, synthesised at high p and t. As noted by Bokii[91], the width of the homogeneity range of a phase naturally is not always determined by purely structural factors; it is also influenced by the valency state of the atoms.

Mention must also be made of the oxides of various refractory metals. As already noted, at high temperatures and pressures, increase in these parameters leads to an increase in both the lattice period of the phases TiO_x and VO_x and their densities (for a given composition), due to the filling of the vacancies in the unit cell of the monoxides. Here, however, there is also a change in the charge state of the atoms. In fact for example, the complete monoxide $TiO_{1.00}$, in

contrast to the defect structure apparently contains no M–M bonds, since the M atoms are completely shielded by oxygen atoms[104]. The X-ray emission spectra of compressed specimens of $TiO_{0.88}$ (90 kbar, 1200°, 3 min) and $TiO_{1.27}$ (90 kbar, 1240°, 1 min) also indicate a change in the charges on the atoms[105].

In Batsanov's opinion[54], a change in the charge is also responsible for the increase in the lattice periods of NdF_3 after shock compression (a_{init} = 7.035 Å, c_{init} = 7.211 Å, a_{compr} = 7.066 Å, c_{compr} = 7.230 Å). Batsanov also gave the same explanation for the observed increase[105] in the lattice periods of Co and Ni subjected to dynamic compression.

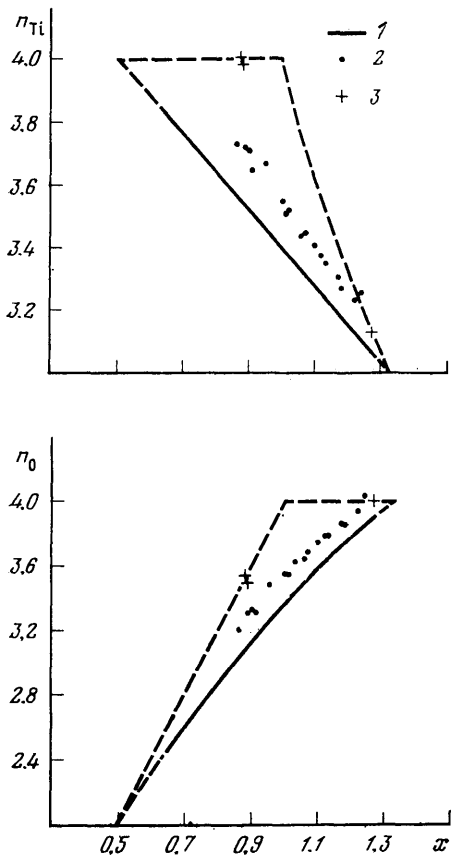

Figure 2. Limits of the change in the degree of filling of the unit cell of the phase TiO_x (range of existence of electronic modifications of titanium monoxide); *1*) data from Ref. 79 for the phase TiO_x synthesised under ordinary conditions; *2*) and *3*) data from Refs. 67 and 72 for the phase TiO_x obtained at high *p* and *t*.

In the homogeneity range of titanium monoxide[82,97], it is possible to distinguish three imaginary compounds: $Ti_2O(Ti_4O_2)$, Ti_3O_4, and $TiO_{1.0}(Ti_4O_4)$ with filled metal, non-metal, and both sublattices respectively. The compounds Ti_3O_4 and Ti_4O_4 can be regarded as already realised[67,71]. As far as the compound $Ti_2O(Ti_4O_2)$ is concerned, it has been noted[82] that it may correspond to the cubic phase detected in the decomposition of $TiO_{1.27}$ (90 kbar, 1300°, 2 min). The same imaginary compounds are revealed in the homogeneity range of VO_x. Up to the present, however, it has been possible to synthesise only the monoxide having an almost completely filled non-metal sublattice, with the composition $VO_{1.23}$ [78] (instead of $VO_{1.33}$).

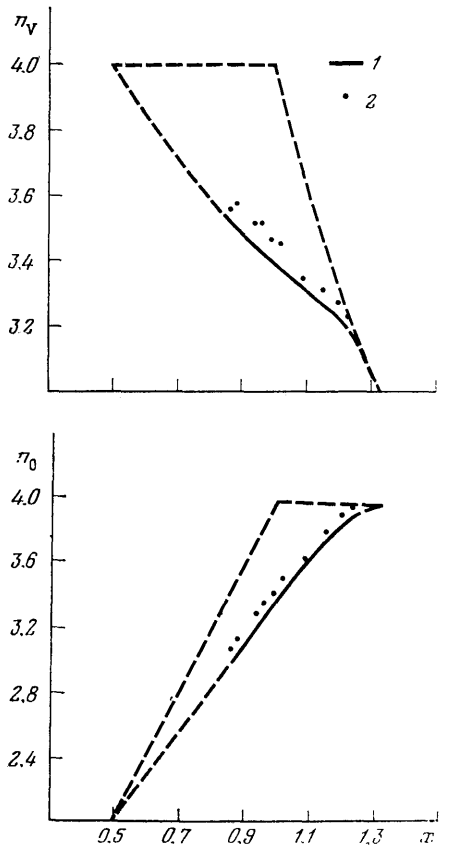

Figure 3. Limits of the change in the degree of filling of the unit cell of the phase VO_x (range of existence of electronic modifications of vanadium monoxide); *1*) data from Ref. 79 for the phase VO_x synthesised under ordinary conditions; *2*) data from Ref. 78 for the phase VO_x obtained at high *p* and *t*.

Thus in the case of phases having dual defect character, it is possible, by filling the structural vacancies in one or both sublattices (by the action of high temperatures and pressures), without changing the composition, to obtain compounds with different concentrations of electrons in the unit cell, that is new electronic modifications.

This feature is illustrated in Figs. 2 and 3. It can be seen that in addition to the imaginary (limiting) compounds (M_4O_2, M_3O_4, M_4O_4), it is possible in the Ti–O and V–O systems to obtain a large number of phases in which the number of particles in the unit cell varies within the ranges indicated in Figs. 2 and 3. If the degree of

completeness changes under the influence of p and t along a straight line parallel to the ordinate (x = const), it follows that in the general case, as far as the limiting degree of filling of one of the sublattices, corresponding electronic modifications of the phase MO_x, which exists under ordinary experimental conditions, are realised successively. This may be followed by decomposition with the liberation of metal (for $x < 1.0$) or oxygen (for $x > 1.0$) or filling by the atoms of the "other" sublattice. In the case of compounds with vacancies in only one of the sublattices, however, filling of the unoccupied positions can take place only with a simultaneous change in composition. In other words, in order to obtain, for example, defect-free FeO it is necessary to introduce a sufficient additional quantity of iron atoms into the lattice of wüstite Fe_xO. This was demonstrated by Katsura and coworkers[65], who synthesised stoichiometric wüstite at p = 36 kbar and t = 770°.

In conclusion, other methods of realising imaginary compounds may be mentioned, for example the use of low temperatures ($t < 0$°C) and high pressures[91] and also the use of super-fast quenching from high temperatures[107]. In addition, cubic tantalum nitride has been obtained[108] by treating the metal in an atmosphere of nitrogen, ionised by a glow discharge, at $t > 1600$°. Finally, Bokii[91], following Kurnakov[83], considers that imaginary compounds can be obtained using chemical additives. This possibly applies to the cubic (NaCl type) carbide Nb_4C, synthesised by Umanskii[100]. Finally, the possibility of obtaining chemical compounds of this type by ion implantation is not excluded (see for example Ref. 109). A large number of imaginary compounds, including those predicted by Ageev[84,85], may also be realised by the methods described above, in addition to the use of high temperatures and pressures.
